Abstract

The existence of singularities often affects the learning dynamics in feedforward neural networks. In this paper, based on theoretical analysis results, we numerically analyze the learning dynamics of radial basis function (RBF) networks near singularities to understand to what extent singularities influence the learning dynamics. First, we show the explicit expression of the Fisher information matrix for RBF networks. Second, we demonstrate through numerical simulations that the singularities have a significant impact on the learning dynamics of RBF networks. Our results show that overlap singularities mainly have influence on the low dimensional RBF networks and elimination singularities have a more significant impact to the learning processes than overlap singularities in both low and high dimensional RBF networks, whereas the plateau phenomena are mainly caused by the elimination singularities. The results can also be the foundation to investigate the singular learning dynamics in deep feedforward neural networks.

Keywords: RBF networks, Singularity, Learning dynamics, Numerical analysis, Deep learning

1. Introduction

The results in (Watanabe, 2007) indicate that the parameter spaces of almost all types of learning machines have singular regions where the Fisher information matrices degenerate, including layered neural networks, normal mixtures, binomial mixtures, Bayes networks, hidden Markov models, Boltzmann machines, stochastic context-free grammars, and reduced rank regressions. For the widely used feedforward neural networks, researchers have found that the learning dynamics are affected by the existing singularities. Some strange behaviors occur in the learning process, such as learning dynamics often become very slow and the learning process is trapped in plateaus.

Researchers have realized that such plateau phenomena arise from the singular structure of the parameter space and the Fisher information matrix degenerates at singularities (Fukumizu, 1996; Fukumizu and Amari, 2000; Amari and Ozeki, 2001; Amari et al., 2009). The geometrical structure of such statistical models has been studied by information geometry (Amari and Nagaoka, 2000). The standard statistical paradigm of the Cramer-Rao theorem does not hold at singularities and the model selection criteria, such as Akaike information criterion (AIC), Bayes information criterion (BIC) and minimum description length (MDL), may fail due to the existence of singularities (Amari et al., 2006). The effect of singularity in Bayesian inference was studied in (Watanabe, 2001a,b, 2010; Aoyagi, 2010), and a widely applicable Bayesian information criterion (WBIC) was proposed which remains efficient for the singular model (Watanabe, 2013). Mononen (2015) applied the WBIC to the analytically solvable Gaussian process regression case.

The error function was used instead of traditional log-sigmoid function to investigate online learning dynamics of the multilayer perceptrons (MLPs)(Biehl and Schwarze, 1995; Saad and A.Solla, 1995; Park et al., 2003). Cousseau et al. (2008) used the error function to discuss the learning dynamics of a toy model of MLPs near singularities. Guo et al. (2014, 2015) obtained the analytical expression of averaged learning equations and took the theoretical analysis of learning dynamics near overlap singularities of MLPs. For the Gaussian mixtures, Park and Ozeki (2009) analyzed the dynamics of the EM algorithm around singularities. Radial basis function (RBF) networks are typical feedforward neural networks which have been applied in many fields. Wei et al. (2008) gave a general mathematical analysis of the learning dynamics near singularities in layered networks, and obtained universal trajectories of learning near the overlap singularities. By using the methods in (Wei et al., 2008), Wei and Amari (2008) obtained the averaged learning equations of RBF networks, analyzed the learning dynamics near overlap singularities, and revealed the mechanism of plateau phenomena near the singularities. Nitta (2013, 2015) discussed the singular learning dynamics of complex-valued neural networks. Due to the existence of singularities, the standard gradient method is not Fisher efficient and the gradient descent direction is no longer the steepest descent direction. In order to overcome this problem, natural gradient method was proposed to accelerate the learning dynamics (Rattray et al., 1998; Amari, 1998; Amari et al., 2000; Park et al., 2000; Heskes, 2000; Pascanu and Bengio, 2014; Zhao et al., 2015a).

In recent years, deep learning has become a very hot topic in the machine learning community. Deep neural networks are designed based on traditional neural networks; however, it is very difficult to train deep neural networks by using the Backpropagation (BP)

algorithm. The training is computationally expensive and often presents vanishing gradient problems (Bengio et al., 1994). Till Hinton et al. (2006) proposed deep belief networks to overcome the difficulties by constructing multilayer restricted Boltzmann machines and training them layer-by-layer in a greedy fashion, many types of deep neural networks, including deep Boltzmann machine, deep convolutional neural networks, deep recurrent neural networks etc, have been applied to various fields successively, such as computer vision, pattern classification, natural language processing, nonlinear system identification, etc (Schmidhuber, 2015; Goodfellow et al., 2016).

Due to the much larger number of hidden layers and architecture size, training deep neural networks also faces many challenges (van Hasselt et al., 2016; Gulcehre et al., 2017). On the other hand, the robustness of the training effect cannot be guaranteed, even with a pre-training process (Erhan et al., 2009). Researchers are very interested in what causes the difficulties in training the deep neural networks and various analytical tools are used to study this problem. Goodfellow et al. (2014) provided some empirical evidence that the learning processes did not seem to encounter significant obstacles on a straight path from initialization to solution (obtained via gradient descent method). However, they also puzzled why the training of large models remained slow despite the scarcity of obstacles. Dauphin et al. (2014) came to the conclusion that the training difficulties were originated from the proliferation of saddle points and local minima with high error are exponentially rare in high dimensions. The saddle points caused the long plateaus in the training process. Choromanska et al. (2015) obtained the results that the gradient descent converge to the band of low critical points, and that all critical points found there are local minima of high quality. Lipton (2016) thought that large flat basins in the parameter space were the barrier to training the networks.

From the point of view of singularities in the parameter space, the above results have a certain rationality. From the theoretical results in previous literature and simulation results in this paper, we can find that the points in the elimination singularity are saddles, the points in the overlap singularity are local minima (in the batch mode learning) and the generalization error surface near the overlap singularity is very flat. It would be much clearer if the analytical form of Fisher information matrix of such deep neural networks is obtained.

Besides, Saxe et al. (2014) investigated the deep linear neural networks and found that the error did not change under a scaling transformation. This would cause the training difficulty which was called scaling symmetries in (Dauphin et al., 2014). The scaling symmetries are very similar to elimination singularities which will be discussed in Section 3. These results can be applied to a more general case. For instance, deep belief nets are based on the restricted Boltzmann machine. However, the restricted Boltzmann machine is singular, which implies the learning dynamics of deep belief nets may be seriously affected by the singularities. The learning processes of deep convolutional neural networks and deep multilayer perceptrons also face this problem. The analytical results of learning dynamics near singularities in shallow neural networks can be generalized to the deep neural networks and improve the learning efficiency. Due to overfitting issues in deep learning and the singular structure of the learning machine, it is worthy to analyze the influence of singularities in the deep neural networks in the future.

Currently, the effects of singularities to the learning dynamics of neural networks are still unknown and, therefore, it is important to examine the learning dynamics near singularities. As there are only two types of singularities (i.e. overlap and elimination singularities) in the parameter space of RBF networks and Wei and Amari (2008) has obtained the analytical form of averaged learning equations, we choose the RBF networks as the research objective in this paper. Based on the theoretical analysis results, we numerically analyze the learning dynamics near singularities through a large number of simulation experiments. From the results in (Wei and Amari, 2008; Park and Ozeki, 2009; Guo et al., 2015), it can be seen that the learning dynamics near singularities are similar in RBF networks, multilayer perceptrons and Gaussian mixtures. Thus, though the analysis is taken based on RBF networks in this paper, the statistical results can also reflect other feedforward neural networks.

For typical RBF networks with k hidden units:

$$f(\boldsymbol{x}, \boldsymbol{\theta}) = \sum_{i=1}^{k} w_i \phi(\boldsymbol{x}, \boldsymbol{J}_i), \tag{1}$$

where $\boldsymbol{x} \in \mathcal{R}^n$ denotes the input vector, $\boldsymbol{J}_i \in \mathcal{R}^n$ is the center vector for neuron i, and w_i is the weight of neuron i in the linear output neuron. $\phi(\cdot)$ denotes the Gaussian function and $\phi(\boldsymbol{x}, \boldsymbol{J}_i) = \exp(-\frac{\|\boldsymbol{x}-\boldsymbol{J}_i\|^2}{2\sigma^2})$, $\boldsymbol{\theta} = \{\boldsymbol{J}_1, \cdots, \boldsymbol{J}_k, w_1, \cdots, w_k\}$ represents all the parameters of the model.

Next we introduce two types of singularities. If two hidden units i and j overlap, i.e. $\boldsymbol{J}_i = \boldsymbol{J}_j$, then $w_i\phi(\boldsymbol{x}, \boldsymbol{J}_i) + w_j\phi(\boldsymbol{x}, \boldsymbol{J}_j) = (w_i + w_j)\phi(\boldsymbol{x}, \boldsymbol{J}_i)$ remains the same value when $w_i + w_j$ takes a fixed value, regardless of particular values of w_i and w_j. Therefore, we can identify their sum $w = w_i + w_j$, nevertheless, each of w_i and w_j remains unidentifiable. When one output weight $w_i = 0$, $w_i\phi(\boldsymbol{x}, \boldsymbol{J}_i) = 0$, whatever value $\boldsymbol{J}_i$ takes. These are the only two types of singularities existed in the parameter space of RBF networks (Fukumizu, 1996; Wei and Amari, 2008):
(1) Overlap singularity:

$$\mathcal{R}_1 = \{\boldsymbol{\theta} | \boldsymbol{J}_i = \boldsymbol{J}_j\},$$

(2) Elimination singularity:

$$\mathcal{R}_2 = \{\boldsymbol{\theta} | w_i = 0\}.$$

In this paper, we first derive the explicit expression of the Fisher information matrix for RBF networks. Secondly, we use the average learning equations (ALEs) to investigate the batch mode learning dynamics of RBF networks. A large number of numerical simulations are conducted. By judging whether the Fisher information matrix degenerates and tracing important variables of numerical simulations, we evaluate the learning processes which are seriously affected by the two types of singularities. We also examine the effects of the existence of singularities to RBF networks.

The rest of the paper is organized as follows. Section 2 shows the analytical expression of Fisher information matrix of RBF networks. Section 3 contains the numerical analysis near singularities for various specific cases. Finally, Section 4 presents our conclusions.

2. Analytical Expression of Fisher Information Matrix in RBF Networks

As the singularities are the regions where the Fisher information matrix of system parameters degenerates, the Fisher information matrix can be seen as an important indicator to judge whether the learning process has arrived to the singularities. We show the explicit expression of the Fisher information matrix in this section.

In the case of regression, we have a number of observed data $(\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_t, y_t)$, which are generated by an unknown teacher function:

$$y = f_0(\boldsymbol{x}) + \varepsilon, \tag{2}$$

where ε is an additive noise, usually subject to Gaussian distribution with zero mean.

We also assume that the training input is subject to a Gaussian distribution with zero mean and a covariance matrix $\boldsymbol{\Sigma}$:

$$q(\boldsymbol{x}) = (\sqrt{2\pi})^{-n} |\boldsymbol{\Sigma}|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}\boldsymbol{x}^T \boldsymbol{\Sigma}^{-1} \boldsymbol{x}\right). \tag{3}$$

As the covariance matrix plays a constant term role in the numerical analysis process and does not essentially influence the analytical results, without loss of generality, we choose the covariance to be the identity matrix, namely $\boldsymbol{\Sigma} = \mathbf{I}$. $q(\boldsymbol{x})$ can be generalized as an uniform distribution (Wei and Amari, 2008).

For the RBF networks (1), the Fisher information matrix is defined as follows (Amari and Nagaoka, 2000):

$$F(\boldsymbol{\theta}) = \left\langle \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{\theta}} \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{\theta}^T} \right\rangle, \tag{4}$$

where $\langle \cdot \rangle$ denotes the expectation with respect to the teacher distribution. The teacher distribution is given by:

$$p_0(y, \boldsymbol{x}) = q(\boldsymbol{x}) \frac{1}{\sqrt{2\pi}\sigma_0} \exp\left(-\frac{(y - f_0(\boldsymbol{x}))^2}{2\sigma_0^2}\right). \tag{5}$$

Then by using the results obtained in (Wei and Amari, 2008) and taking further calculations, we can obtain the following theorem:

Theorem 1 *The explicit expression of Fisher information matrix for RBF networks is:*

$$\begin{aligned} F(\boldsymbol{\theta}) &= \left\langle \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{\theta}} \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{\theta}^T} \right\rangle \\ &= \begin{bmatrix} F_{11} & \cdots & F_{1k} & F_{1(k+1)} & \cdots & F_{1(2k)} \\ \vdots & & \vdots & \vdots & & \vdots \\ F_{k1} & \cdots & F_{kk} & F_{k(k+1)} & \cdots & F_{k(2k)} \\ F_{(k+1)1} & \cdots & F_{(k+1)k} & F_{(k+1)(k+1)} & \cdots & F_{(k+1)(2k)} \\ \vdots & & \vdots & \vdots & & \vdots \\ F_{(2k)1} & \cdots & F_{(2k)k} & F_{(2k)(k+1)} & \cdots & F_{(2k)(2k)} \end{bmatrix}, \end{aligned} \tag{6}$$

where:

$$C(\boldsymbol{J}_i, \boldsymbol{J}_j) = \left(\frac{\sigma^2}{\sigma^2 + 2}\right)^{\frac{N}{2}} \exp\left(-\frac{\sigma^2(\|\boldsymbol{J}_i\|^2 + \|\boldsymbol{J}_j\|^2) + \|\boldsymbol{J}_i - \boldsymbol{J}_j\|^2}{2\sigma^2(\sigma^2 + 2)}\right), \tag{7}$$

$$B(\boldsymbol{J}_i, \boldsymbol{J}_j) = -\frac{\sigma^2 \boldsymbol{J}_j - (\boldsymbol{J}_i - \boldsymbol{J}_j)}{\sigma^2(\sigma^2 + 2)}, \tag{8}$$

$$\left\langle \frac{\partial \phi(\boldsymbol{x}, \boldsymbol{J}_i)}{\partial \boldsymbol{J}_i} \frac{\partial \phi(\boldsymbol{x}, \boldsymbol{J}_j)}{\partial \boldsymbol{J}_j^T} \right\rangle = \frac{C(\boldsymbol{J}_i, \boldsymbol{J}_j)}{\sigma^2(\sigma^2 + 2)} \left(\mathbf{I}_n + (\boldsymbol{J}_j - (\sigma^2 + 1)\boldsymbol{J}_i) B^T(\boldsymbol{J}_i, \boldsymbol{J}_j)\right), \tag{9}$$

$$\mathbf{I}_n \text{ is the compatable identity matrix.} \tag{10}$$

For $1 \le i \le k, \quad 1 \le j \le k,$

$$\begin{aligned} F_{ij} &= \left\langle \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{J}_i} \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{J}_j^T} \right\rangle = w_i w_j \left\langle \frac{\partial \phi(\boldsymbol{x}, \boldsymbol{J}_i)}{\partial \boldsymbol{J}_i} \frac{\partial \phi(\boldsymbol{x}, \boldsymbol{J}_j)}{\partial \boldsymbol{J}_j^T} \right\rangle \\ &= w_i w_j \frac{C(\boldsymbol{J}_i, \boldsymbol{J}_j)}{\sigma^2(\sigma^2 + 2)} \left(I_n + (\boldsymbol{J}_j - (\sigma^2 + 1)\boldsymbol{J}_i) B^T(\boldsymbol{J}_i, \boldsymbol{J}_j)\right). \end{aligned} \tag{11}$$

For $1 \le i \le k, \quad k+1 \le j \le 2k,$

$$\begin{aligned} F_{ij} &= \left\langle \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{J}_i} \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial w_{j-k}} \right\rangle = w_i \left\langle \frac{\partial \phi(\boldsymbol{x}, \boldsymbol{J}_i)}{\partial \boldsymbol{J}_i} \phi(\boldsymbol{x}, \boldsymbol{J}_{j-k}) \right\rangle \\ &= w_i C(\boldsymbol{J}_i, \boldsymbol{J}_{j-k}) B(\boldsymbol{J}_i, \boldsymbol{J}_{j-k}). \end{aligned} \tag{12}$$

For $k+1 \le i \le 2k, \quad 1 \le j \le k,$

$$F_{ij} = \left\langle \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial w_{i-k}} \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial \boldsymbol{J}_j^T} \right\rangle = F_{ji}^T. \tag{13}$$

For $k+1 \le i \le 2k, \quad k+1 \le j \le 2k,$

$$\begin{aligned} F_{ij} &= \left\langle \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial w_{i-k}} \frac{\partial f(\boldsymbol{x}, \boldsymbol{\theta})}{\partial w_{j-k}} \right\rangle = \langle \phi(\boldsymbol{x}, \boldsymbol{J}_{i-k}) \phi(\boldsymbol{x}, \boldsymbol{J}_{j-k}) \rangle \\ &= C(\boldsymbol{J}_{i-k}, \boldsymbol{J}_{j-k}). \end{aligned} \tag{14}$$

■

Remark 1: When the Fisher information matrix is near singular, the condition value of the matrix becomes very large, namely, the inverse of the condition value is near to 0. Thus the inverse of the condition value can be used to measure how close the system parameters are to the singularities. In the following numerical analysis, we record the inverse of condition value of the Fisher information matrix to show the influence of singularities on the learning process more clearly.

Remark 2: By adding the inverse of Fisher information matrix as an coefficient to the weights update in the standard gradient descent algorithm, researchers proposed the natural gradient descent method to overcome or decrease the serious influence of the singularities. Thus the Fisher information matrix plays a key role in natural gradient descent method. This means that besides being the fundamental in the following numerical analysis, obtaining the analytical form of Fisher information matrix can greatly help us in designing the modified natural gradient descent algorithms with better performance in the future.

3. Numerical Analysis near Singularities

After having obtained the analytical form of Fisher information matrix in Theorem 1, we numerically analyzed the learning dynamics of RBF networks by taking four experiments in this section, where the specific learning dynamics influenced by different types of singularities are shown and the experiment results are statistically analyzed. In Section 3.1 and Section 3.2, we conduct artificial experiments for low and medium dimensional cases, where the input distribution is known. For these cases, the Fisher information matrix can be obtained by using Theorem 1, and the relation between the stage where the singular learning dynamics occur and the stage where the Fisher information matrix degenerates can be clearly observed. In Section 3.3, the experiment for high dimensional case is carried out by a real data set to investigate the effects of the singularities.

3.1 Two-hidden-unit RBF Networks

The results obtained in (Wei and Amari, 2008) indicate that the batch mode learning dynamics are very similar to the averaged learning dynamics and we can use the averaged learning equations (ALEs) to investigate the dynamics in batch mode learning. Moreover, the ALEs do not depend on any specific sample data set which can overcome the disturbance caused by randomness of the model noise. Besides, as the ALEs are ordinary differential equations (ODEs), and for the given teacher parameters and initial values of student parameters, the learning processes of the student parameters can be obtained by solving ODEs. Thus, in this section, we use the ALEs to perform the experiments, where the analytical form of ALEs in RBF networks has been obtained in (Wei and Amari, 2008).

The student RBF network is defined in Eq.(1). We also assume that the teacher function is described by a RBF network with s hidden units:

$$f_0(\boldsymbol{x}) = f(\boldsymbol{x}, \boldsymbol{\theta_0}) + \varepsilon = \sum_{i=1}^{s} v_i \phi(\boldsymbol{x}, \boldsymbol{t}_i) + \varepsilon, \tag{15}$$

where ε denotes zero mean Gaussian additive noise that is uncorrelated with training input $\boldsymbol{x}$. When the true teacher function $f_0(\boldsymbol{x})$ cannot be represented by a RBF network, $f(\boldsymbol{x}, \boldsymbol{\theta}_0)$ is assumed to be its best approximation by the RBF network.

The analytical form of ALEs is as follows (Wei and Amari, 2008):

$$\dot{\boldsymbol{J}}_i = \eta w_i \left(\sum_{j=1}^{s} v_j C(\boldsymbol{t}_j, \boldsymbol{J}_i) B(\boldsymbol{t}_j, \boldsymbol{J}_i) - \sum_{j=1}^{k} w_j C(\boldsymbol{J}_j, \boldsymbol{J}_i) B(\boldsymbol{J}_j, \boldsymbol{J}_i) \right), \tag{16}$$

$$\dot{w}_i = \eta \left(\sum_{j=1}^{s} v_j C(\boldsymbol{t}_j, \boldsymbol{J}_i) - \sum_{j=1}^{k} w_j C(\boldsymbol{J}_j, \boldsymbol{J}_i) \right), \tag{17}$$

where $i = 1, 2, \cdots, k$. $C(\boldsymbol{t}, \boldsymbol{J})$ and $B(\boldsymbol{t}, \boldsymbol{J})$ have the same meanings with Eq.(7) and Eq.(8), respectively.

The generalization error is:

$$\begin{aligned} L(\boldsymbol{\theta}) &= \left\langle \frac{1}{2} \left(f(\boldsymbol{x}, \boldsymbol{\theta}_0) - f(\boldsymbol{x}, \boldsymbol{\theta}) \right)^2 \right\rangle \\ &= \frac{1}{2} \sum_{i,j} v_i v_j C(\boldsymbol{t}_i, \boldsymbol{t}_j) - \sum_{i,j} v_i w_j C(\boldsymbol{t}_i, \boldsymbol{J}_j) + \frac{1}{2} \sum_{i,j} w_i w_j C(\boldsymbol{J}_i, \boldsymbol{J}_j). \end{aligned} \tag{18}$$

Results in (Wei and Amari, 2008) indicate that investigating the model with two hidden units is enough to capture the essence of the learning dynamics near singularities. Therefore, we first perform the numerical analysis of the RBF networks with two hidden units, and we then analyze the RBF networks in a more general case in the following sections. The learning dynamics of RBF networks are all obtained by solving ALEs for the given teacher parameters and initial student parameters.

In this subsection we analyze the case where the teacher and student models both have two hidden units.

The student model has the following form:

$$f(\boldsymbol{x}, \boldsymbol{\theta}) = w_1 \phi(\boldsymbol{x}, \boldsymbol{J}_1) + w_2 \phi(\boldsymbol{x}, \boldsymbol{J}_2). \tag{19}$$

The teacher model is also described by a RBF network with two hidden units:

$$f(\boldsymbol{x}, \boldsymbol{\theta_0}) = v_1 \phi(\boldsymbol{x}, \boldsymbol{t}_1) + v_2 \phi(\boldsymbol{x}, \boldsymbol{t}_2) + \varepsilon. \tag{20}$$

We choose the spread constant $\sigma = 0.5$.

In order to investigate the influence of the singularities in the learning process of RBF networks more accurately, we mainly focus on input $\boldsymbol{x}$ with dimension 1. For this type of RBF networks, the global minimum is the point where the generalization error is 0, which makes easier to analyze the simulation results.

3.1.1 Toy Model of RBF Networks

In order to visually represent the learning trajectories of parameters in the loss error surface and given that a 3D figure can only show three parameters, we initially focus on a special case of RBF networks, where part of the student parameters will remain invariable in the training process.

In the case of overlap singularity, we choose the teacher model parameters v_1 and v_2 to be the initial state of w_1 and w_2, and only J_1 and J_2 will be modified in the learning process. In all the other cases, the weights J_2 and w_2 are fixed to be the same as the teacher parameters t_2 and v_2, and therefore, only J_1 and w_1 will be modified in the learning process. Thus, for all cases, there are only two variable parameters: J_1-J_2 or J_1-w_1. When the learning process has been completed, we can plot the learning trajectories of parameters through the generalization error surface in a 3D figure. Although the student model is a toy model, the simulation results can show the influence of singularities during the learning process in a direct and visual manner.

In what follows, the teacher model is chosen as: $t_1 = -1.95$, $t_2 = -0.90$, $v_1 = 1.35$, $v_2 = 1.72$, the width spread $\sigma = 0.5$. The main reason behind only choosing one teacher function is to illustrate that the learning process of a RBF network can be affected by all

the types of singularities under different initial states. For a given initial state of student parameters, the learning trajectories of J_i and w_i can be obtained by solving Eqs.(16) and (17). The generalization error trajectory and error surface can also be obtained from Eq.(18) after J_i and w_i have been calculated.

By analyzing the simulation results, we list all the cases of learning processes as follows. In the following figures, '$\circ$' and '$\times$' represent the initial state and final state, respectively.

Case 1 (**Fast convergence**) : The learning process converges to the global minimum fast.

In this case, the singularities do not affect the learning process and the learning dynamics quickly converge to the global minimum after the beginning of learning process. An example is provided in Figure 1, which represents the trajectories in a log scale of the inverse of the condition number, generalization error and learning trajectory in the generalization error surface, respectively. In the training process, J_2 and w_2 remain invariable. As shown in Figure 1, the parameters J_1 and w_1 directly converge to the global minimum (Figure 1(c)) and the Fisher information matrix remains regular (Figure 1(a)).

Case 2 (**Overlap singularity**) :The learning process is significantly affected by overlap singularity.

In this case, the learning trajectories of parameters J_1 and J_2 arrive at the overlap singularity, namely $J_1 = J_2$. An example is given in Figure 2, which shows the trajectories of log scale of inverse of condition number, generalization error, weights J_i and learning trajectory in the generalization error surface, respectively. In the training process, w_1 and w_2 remain invariable.

From Figure 2(a), we can see that the inverse of the condition number of Fisher information matrix gets closer and closer to 0 as the training process runs, and finally smaller than $10e-15$ which means that the Fisher information matrix nearly degenerates. Meanwhile, J_1 and J_2 nearly equal to each other (Figure 2(c)), namely the parameters arrive at the overlap singularity. The generalization error descents fast at the beginning of the learning process, and after J_1 and J_2 nearly overlap, the generalization error changes slightly. As shown in Figure 2(d), the generalization error surface is very flat near the final state of J_1 and J_2, which indicates that the parameters present difficulties escaping from the overlap singularity. In order to explore what causes the difficulties in training large-scale networks, (Lipton, 2016) revealed the high degree of nonlinearity in the learning path by analyzing the learning trajectories using the 2D PCA and thought that the large flat regions of the weight space hinder the learning process. From Figure 2(d), we can see that the error surface near the overlap singularity is very flat. Due to the so flat error surface around the overlap singularity, the learning may become very slow even if the two hidden units do not equal to each other exactly.

Remark 3: It can be seen that the log scale of the inverse of the condition number obviously fluctuates at the end of the learning process (Figure 2(a)). We think this is mainly because the value is too small (smaller than $10e-15$), and even a slight change of the parameters would cause the obvious fluctuation of the condition number of the Fisher information matrix due to the limit to the degree of accuracy of computer.

Case 3 (**Cross elimination singularity**): The learning process crosses the elimination and reaches the global optimum after training.

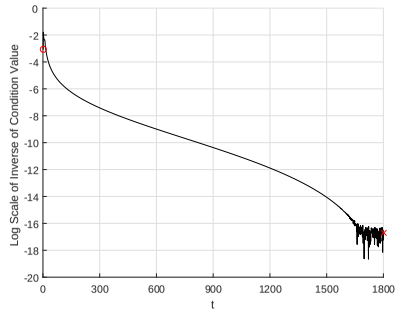
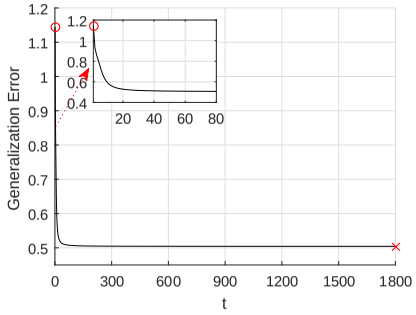
(c) Learning trajectory in generalization error surface

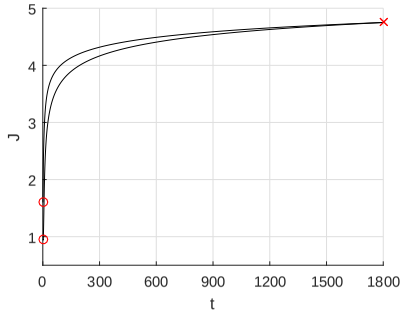
Figure 1: Case 1 (Fast convergence) in toy model of RBF networks
The initial student parameters are $J_1^{(0)} = 0.30$, $w_1^{(0)} = 0.57$, $J_2^{(0)} = t_2$, $w_2^{(0)} = v_2$. In the training process J_2 and w_2 remain invariable. The final student parameters are $J_1 = -1.95$ and $w_1 = 1.35$.



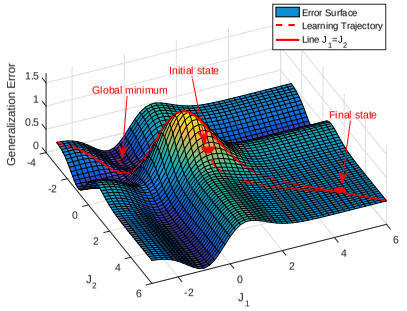
(a) Trajectory of log scale of inverse of condition value



(b) Time evolution of generalization error



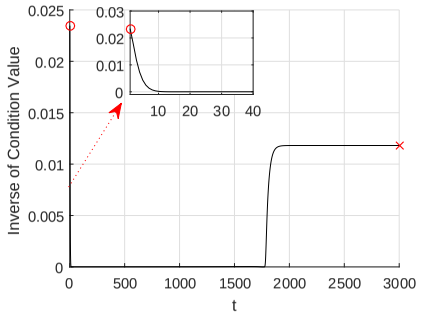
(c) Time evolution of J_1 and J_2



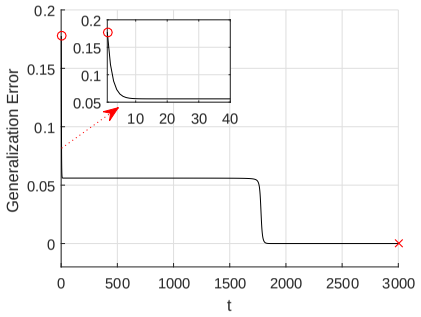
(d) Learning trajectory in generalization error surface

Figure 2: Case 2 (Overlap singularity) in toy model of RBF networks
The initial student parameters are $J_1^{(0)} = 1.60$, $J_2^{(0)} = 0.95$, $w_1^{(0)} = v_1$, $w_2^{(0)} = v_2$. In the training process w_1 and w_2 remain invariable. The final student parameters are $J_1 = 4.7504$ and $J_2 = 4.7504$.

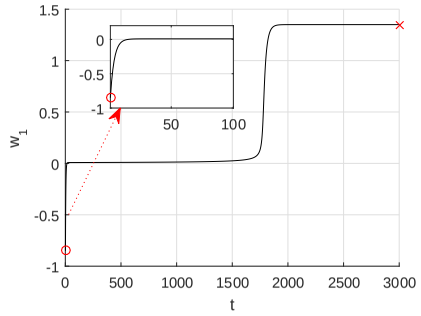
When the learning process arrives at the elimination singularity, e.g. $w_1 = 0$, the term $w_1\phi(x, J_1)$ vanishes. Hence J_1 does not affect the behavior of $f(x, \boldsymbol{\theta})$ and is not identifiable on the subspace $w_1 = 0$. An example is shown in Figure 3, where the learning process arrived at the elimination singularity and finally reached the global optimum after crossing it. Figure 3 shows the trajectories of the inverse of the condition number, generalization error, weight w_1 and learning trajectory in the generalization error surface, respectively.



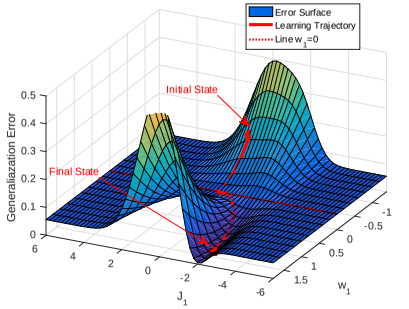
(a) Trajectory of inverse of condition value



(b) Time evolution of generalization error



(c) Time evolution of w_1



(d) Learning trajectory in generalization error surface

Figure 3: Case 3 (Cross elimination singularity) in toy model of RBF networks
The initial student parameters are $J_1^{(0)} = 0.18$, $w_1^{(0)} = -0.85$, $J_2^{(0)} = t_2$, $w_2^{(0)} = v_2$. In the training process J_2 and w_2 remain invariable. The final student parameters are $J_1 = -1.95$ and $w_1 = 1.35$.

From the trajectory of the inverse of the condition value of Fisher information matrix in Figure 3(a), the Fisher information became nearly singular at the early stage of training and remain so for some time. w_1 nearly equaled 0 at this stage (Figure 3(c)) which means

that the learning process has arrived at the elimination singularity. It can be clearly seen from Figure 3(d) that the points on the line $w_1 = 0$ are all saddle points. Then the student parameters randomly walked around $w_1 = 0$ and finally the learning process skipped the elimination singularity and the student model exactly learned the teacher model. An obvious plateau phenomenon can be observed during the learning process as shown in Figure 3(b).

Case 4 (**Near elimination singularity**): When the student parameters are near the elimination singularity in the training, the learning process is significantly affected by the elimination singularity.

In our simulation experiments, we observed another case in which, when w_1 is close to 0 but not equal to 0, the learning process is also significantly affected by elimination singularity. Then the parameters do not skip the elimination singularity and reach the global optimal points. Figure 4 shows the trajectories of the inverse of the condition number, generalization error, weight w_1 and learning trajectory in the generalization error surface, respectively.

The two learning processes are similar to each other by comparing Figure 4(a) with Figure 3(a) and Figure 4(b) with Figure 3(b), respectively. However, the trajectory of w_1 in Figure 4(c) shows that w_1 is close to 0 during the training process but does not equal 0. During the stage where w_1 approaches 0 and departs from it, the learning process is significantly affected and a plateau phenomenon can clearly be observed. This means that the elimination singularity will significantly affect the learning process even if the parameters are only near to it.

By investigating the deep linear neural networks, (Saxe et al., 2014) obtained a case similar to the elimination singularity that slows down the learning process. The equation of error E is derived as $E(a,b) = \frac{1}{2\tau}(s-ab)^2$, where τ represents the inverse of the learning rate, s represents the input-output correlation information, a represents the weight from the input node to the hidden layer and b represents the weight from the hidden layer to the output node. Obviously $b = 0$ represents the elimination singularity. It can be seen that the error did not change under the scaling transformations $a \to \lambda a$, $b \to \frac{b}{\lambda}$. $a = 0$, $b = 0$ is also a fixed point. As shown in Figure 2 in (Saxe et al., 2014), we can see that certain directions of the learning point to $a = 0$, $b = 0$ which implies the parameters will converge to the point at first under an appropriate initial state. As the point $a = 0$, $b = 0$ is not stable, the parameters will escape from it and finally converge to the global minimum. During this process, long plateau can be observed. This is basically the same as with the learning trajectories in Figure 3(d) and Figure 4(d). The results illustrate the importance of investigating the singularities in deep neural networks.

Case 5 (**Output weight 0**) : After training, output weight w_1 becomes nearly equal to 0.

In the simulation experiments, we also observe that sometimes the output weight w_1 becomes nearly equal to 0 after training. Even if the training process lasts longer, the weight also remains nearly 0. We give an example of this case in Figure 5. Figure 5 shows the trajectories of log scale of the inverse of the condition number, generalization error, weight w_1 and learning trajectory in the generalization error surface, respectively.

From Figure 5(d), it can be seen that w_1 quickly drops to 0 at the beginning of the training, and does not escape from it till the end. Even if we continue the training process for a longer time, the student parameters remain almost unchanged. This is mainly because

(d) Learning trajectory in generalization error surface

Figure 5: Case 5 (Output weight 0) in toy model of RBF networks
The initial student parameters are $J_1^{(0)} = 0.95$, $w_1^{(0)} = 1.55$, $J_2^{(0)} = t_2$, $w_2^{(0)} = v_2$. In the training process J_2 and w_2 remain invariable. The final student parameters are $J_1 = 1.6192$ and $w_1 = 0$.

the radial basis function has little effect on a region that far from the center. When the centers of the teacher and the student are very far from each other, the student cannot exactly approximate the teacher and the output weight w_1 will become zero in order to avoid a bigger error. In this example, the initial student center J_1 is far away from the teacher center t_1, and w_1 is close to 0 after training. In this case, the student model is trapped in local optimum after the training process.

Hitherto, four cases of interesting learning processes in RBF networks have been visually introduced. In addition to the overlap singularity case, the other cases are actually one-hidden-unit RBF network to approximate one-hidden-unit RBF network. Even under only one hidden unit situation, the learning dynamics of RBF networks are still seriously affected by singularities.

In summary, 1) in the overlap singularity case, as the generalization error surface is very flat around the overlap singularity, the parameters cannot escape from it once they have been affected by overlap singularity. 2) For the elimination singularity case, it can be seen that the points in the elimination singularity are saddles, where part of the region is in a local minimum direction and another part of the region is in a local maximum direction. When the learning process arrives near the elimination singularity by local minimum direction, the parameters walk randomly on the singularity till they arrive at the local maximum direction, then the parameters converge to the global minimum. During the random walk stage, a plateau phenomenon can be obviously observed. If the parameters can not walk to the local maximum direction (mainly because the student center is far from the teacher center), the output weight finally nearly equals 0.

In the following subsection, we investigate the case of two-hidden-unit RBF networks approximated by normal two-hidden-unit RBF networks.

3.1.2 RBF Networks with Two Hidden Units

In this subsection, we consider three cases of v_1 and v_2: (1) v_1 and v_2 are both positive; (2) v_1 and v_2 are both negative; and (3) v_1 and v_2 have opposite sign, respectively. For each case of v_1 and v_2, we consider three cases of w_1 and w_2: (1) w_1 and w_2 are both positive; (2) w_1 and w_2 are both negative and (3) w_1 and w_2 have opposite sign. Therefore, there are 9 cases of the teacher parameters.

The procedure followed for the numerical analysis is given as:
Step 1: The teacher parameters are generated uniformly in the interval $[-2,\ 2]$. There are 9 cases. For each case, we generate 500 groups of teacher parameters.
Step 2: After each group of teacher parameters is generated, 20 groups of initial student parameters are generated uniformly in the interval $[-2,\ 2]$.
Step 3: For each group of teacher parameters and initial student parameters, we use the ALEs to accomplish the learning process. Some important variables, such as the generalization error, or the student parameters J_i and w_i, are traced and recorded.
Step 4: For each learning process, as the student parameters have been traced, the Fisher information matrix can be obtained. Then we record the inverse of the condition number of the Fisher information matrix.
Step 5: After the inverse of the condition value of the Fisher information value is recorded, a primary screening can be taken to judge whether the inverse of the condition number of

the Fisher information matrix of the learning processes has been close to 0.

Step 6: After this primary screening, we make a further analysis. If weight w_i was nearly equal to 0 in the process, then the process was affected by elimination singularity. If the two weights J_1 and J_2 nearly overlapped after training, the learning process was affected by overlap singularity. We count the numbers of the learning processes which were affected by elimination singularities and overlap singularities, respectively.

In this experiment, we totally accomplish the learning processes 90000 ($3\times3\times500\times20$) times. Given that the cases which are affected by the singularities in this subsection are exactly the same with those in Section 3.1.1, in order to keep the paper more concise, we do not show the learning trajectories belong to these cases in this subsection. Next, we count the number of learning processes which contain one of the cases above and focus on the ratio of learning processes influenced by different singularities. As the learning processes are both affected by elimination singularities in case 3 and case 4, we view case 3 and case 4 as one case in the counting process. The statistical results are shown in Table 1.

Number of total experiments	90000
Number of case 1 (Fast convergence)	61299
Number of case 2 (Overlap singularity)	6786
Number of case 3 and case 4 (Elimination singularity)	11288
Number of case 5 (Output weight 0)	10627

Table 1: Statistical results of two-hidden-unit RBF networks

From the 4 cases of observed behaviors and the statistical results shown in Table 1, we can obtain some conclusions as follows:

1) Many researchers have noticed the plateau phenomenon in the learning dynamics of feedforward neural networks (Amari et al., 2006; Saad and A.Solla, 1995; Biehl and Schwarze, 1995; Fukumizu and Amari, 2000). However, the reason why the plateau phenomenon occurs remains controversial. From the experimental results in Figure 3 and Figure 4, we found that the existence of singularities in the student parameter space results in the plateaus.

2) As shown in Table 1, nearly 68 percent of all the experiments did not get affected by the singularities and the learning dynamics converged to the global minimum fast. Almost 7.5 percent of experiments have been affected by overlap singularities and 12.5 percent of experiments have been affected by the elimination singularities. The data indicates that the singularities have a great impact on the learning processes of RBF networks. In light of the wide application of the RBF networks in practice, the influence of singularities ought to attract more attention of researchers. For the two-hidden-unit RBF networks, the initial center of the student model may be often relatively too far from the center of the teacher model, which causes the output weight of the student model to be nearly 0 after training. This case has been observed and mentioned in (Wei et al., 2007). From the results in Table 1, nearly 12 percent of experiments belong to this case.

3) From the statistical results shown in Table 1, it can be seen that the elimination singularities have much more influence in the learning dynamics than the overlap singularities. However, by now, few results in analyzing the elimination singularities have been obtained, which forms a sharp contrast to the overlap singularities. Due to the serious influence of

elimination singularities on the learning dynamics, it is worthy to take a theoretical analysis of elimination singularities.

3.2 RBF Networks in a General Case

In the previous subsection, we showed the results for the RBF networks with two hidden units. In this subsection, we generalize these results for the general RBF networks.

Without loss of generality, we introduce the student as a ten-hidden-unit model, namely:

$$f(\boldsymbol{x},\boldsymbol{\theta}) = \sum_{i=1}^{k} w_i \phi(\boldsymbol{x},\boldsymbol{J}_i), \tag{21}$$

where $k = 10$.

We also assume that the teacher model is represented by a RBF network with 10 units, namely:

$$f(\boldsymbol{x},\boldsymbol{\theta_0}) = \sum_{i=1}^{s} v_i \phi(\boldsymbol{x},\boldsymbol{t}_i) + \varepsilon, \tag{22}$$

where $s = 10$.

We choose the spread constant $\sigma = 0.5$ and the input dimension $n = 2$.

When the number of hidden units in the student model is larger than that of the teacher, the redundant case exists. This implies that the teacher parameter might be on the singularity and the learning processes are basically affected by the singularity. In order to overcome this problem and avoid the overlap of the teacher units, we choose the minimal distance between the teacher units $\boldsymbol{t}_i$ and $\boldsymbol{t}_j$ to be bigger than $2\sigma^2$. The main reason behind this choice are based on the results obtained in (Wei and Amari, 2008). (Wei and Amari, 2008) obtained that the two teacher units are well separated when the distance between two hidden units is bigger than $2\sigma^2$.

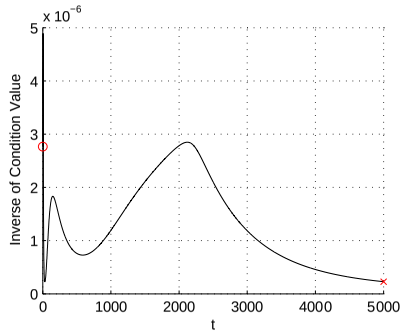
In our experiments, the teacher parameters $\boldsymbol{t}_i$, v_i, are uniformly generated in the interval $[-4,\ 4]$ and we generate 50 groups of teacher parameters. After each group of teacher parameters is generated, 20 groups of initial student parameters $\boldsymbol{J}_i^{(0)}$, $w_i^{(0)}$ are generated uniformly in the interval $[-4,\ 4]$. We use the ALEs to accomplish the learning processes. The experiment procedure is similar to that in Section 3.1.2.

By analyzing the simulation results, the cases where the learning processes present the undesirable behaviors are similar to those of RBF networks with two hidden units. To make the paper concise, the teacher parameters, the initial student parameters and the final student parameters of the following cases are listed in Appendix A. In the following figures, 'o' and '×' represent the initial state and final state, respectively.

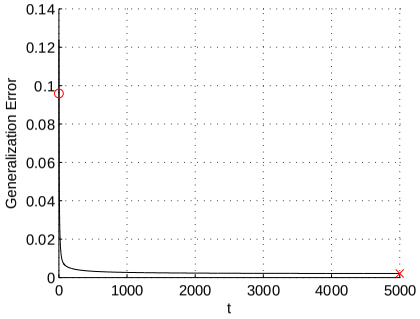
Case 1 (**Fast convergence**): The learning process quickly converges to the global minimum and the singularities do not affect the learning process.

We provide an example of this case. Figure 6 shows the trajectories of the inverse of the condition number, generalization error, and weights w_i, respectively.

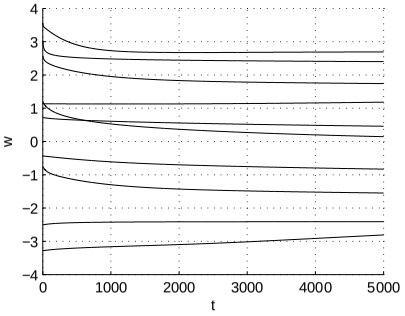
From Figure 6(a), the Fisher information matrix did not become singular during the learning process. Meanwhile, the generalization error dropped fast after the beginning of the learning process, and the singularity did not obviously affect the learning process. After the training process, the student model has converged to the global minimum.



(a) Trajectory of inverse of condition value



(b) Time evolution of generalization error



(c) Time evolution of w

Figure 6: Case 1 (Fast convergence) in RBF networks of general case

Case 2 (**Overlap singularity**): The learning process is affected by overlap singularity.

In this case, the learning processes are trapped in overlap singularities after training. An example belonging to this case is shown in Figure 7.

By analyzing the simulation results, it can be seen that, apart from the case where two student hidden units overlapped exactly after training, the phenomenon that two hidden units did not exactly overlap sometimes occurs. For the multidimensional parameters, we adopt the variable $h(i,j) = \frac{1}{2}\|\boldsymbol{J}_i - \boldsymbol{J}_j\|^2$ to indicate the distance between $\boldsymbol{J}_i$ and $\boldsymbol{J}_j$. When $\boldsymbol{J}_i$ and $\boldsymbol{J}_j$ nearly overlap, $h(i,j)$ nearly equals 0. Figure 7 shows the trajectories of the inverse of the condition number, generalization error, $h(4,8)$, weights w_i, respectively.

From Figure 7(a), the inverse of the condition value reduced to nearly 0 at the early stage of training process which implies that the Fisher information matrix nearly degenerated, and therefore this state remains till the end. Meanwhile, $h(4,8)$ (shown in Figure 7(c)) dropped to a very small value which implied $\boldsymbol{J}_4$ and $\boldsymbol{J}_8$ nearly overlapped, and the learning process is trapped in overlap singularities. From the final state of $\boldsymbol{J}$, it can be seen that $\boldsymbol{J}_4$ and $\boldsymbol{J}_8$ are close to each other, but do not exactly overlap. However, the gradient of the generalization error $L(\boldsymbol{\theta})$ respect to the final student parameters is nearly 0, which is too small to influence the learning process, and the student parameters will remain almost unchanged even though the learning process lasts longer. This is mainly because the error surface of RBF networks in a general case near overlap singularities is very flat. When the learning process arrives at the neighborhood of overlap singularities, although the student units have not overlapped completely, the student units will slightly change as the result of the relatively unchanged error in the remaining stage. The trajectories in Figure 7(a) and Figure 7(b) are similar to the corresponding trajectories in Figure 2(a) and Figure 2(b), respectively.

Case 3 (**Elimination singularity**): The learning process is affected by the elimination singularity and a plateau phenomenon can be observed.

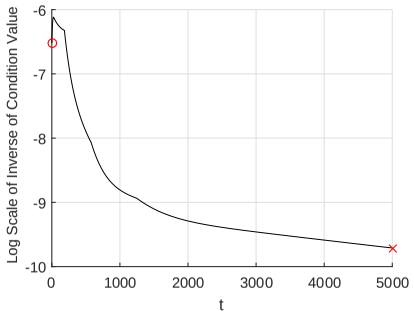
In this case, the learning process is significantly affected by the elimination singularity. This case is similar to cases 3 or 4 in Section 3.1.2. A plateau phenomenon can be observed during the learning process. We give an example of this case in Figure 8, which shows the trajectories of the inverse of the condition number, generalization error, and weights w_i.

As shown in Figure 8(a), the Fisher information matrix became nearly singular at an early stage of the learning process, and then became regular again. From the trajectories in Figure 8(b), it can be observed that w_5 (the wider line) skipped 0 when the Fisher information matrix became singular and then regular. This means that the learning process was affected by the elimination singularity. A plateau phenomenon can be observed in the trajectory of the generalization error as shown in Figure 8(b).

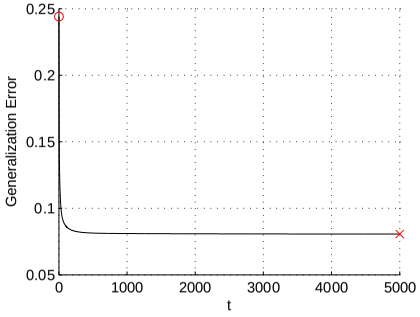
Case 4 (**Output weight 0**): After training, one of output weights w_i becomes nearly equal to 0.

This case is similar to case 5 in Section 3.1.2. When the initial student center is too far from the center of the teacher model, the output weight w_i of the student model usually becomes nearly 0 after the training process. An example is shown in Figure 9.

Figure 9 shows the trajectories of the inverse of the condition number, generalization error, and weights w_i, respectively. From Figure 9(c), w_5 (the wider line) has become nearly 0 after training.



(a) Trajectory of inverse of condition value



(b) Time evolution of generalization error

(c) Time evolution of w

Figure 9: Case 4 (Output weight 0) in RBF networks of general case

Case 5 (**Overlap and elimination singularity**): The learning process is affected by not only the overlap singularity but also the elimination singularity.

Different from the case of RBF with two hidden units, we find that sometimes the learning process in a more general case is simultaneously affected by the elimination singularity and the overlap singularities. We give an example of this case in Figure 10, which shows the trajectories of log scale of the inverse of the condition number, generalization error, $h(1,9)$, and weights w_i, respectively.

From Figure 10(a), the Fisher information matrix became singular at the early stage of the learning process, and as a result the learning process arrived in singularities. As shown in Figure 10(b), a plateau phenomenon can be obviously observed. From Figure 10(d), it can be seen that w_3 (the wider line) crossed 0 when the plateau phenomenon occurred, namely the learning process crossed the elimination singularity. From Figure 10(c), $h(1,9)$ became very small along the training process. After training, $\boldsymbol{J}_1 = [2.4494, \ -2.1973]^T$ and $\boldsymbol{J}_9 = [2.4020, \ -2.2118]^T$, i.e. $\boldsymbol{J}_1$ and $\boldsymbol{J}_9$ nearly equaled to each other, so the learning process was trapped in an overlap singularity.

Case 6 (**Elimination singularity and output weight 0**): The learning process is affected by elimination singularity and one of the output weights w_i becomes nearly 0 after the learning process.

In addition to the case above, we also find a case where the learning dynamics are affected by the elimination singularities during the learning process, one of the weights w_i becomes nearly 0 after training and the student parameters are trapped in an local minimum. We give an example that belongs to this case in Figure 11.

Figure 11 shows the trajectories of the inverse of the condition number, generalization error, and weights w_i, respectively. From Figure 11(b) and Figure 11(c), at the stage where w_3 crossed 0, a plateau phenomenon occurred and the learning process was affected by the elimination singularity. After training, $w_5 = -0.0004$, which is nearly equal to 0.

In comparison with the analysis results in Section 3.1.2, the RBF networks in a more general case have similar singular behaviors as those in RBF networks with two hidden units. The statistical results are summarized in Table 2.

Number of total experiments	1000
Number of case 1 (Fast convergence)	675
Number of case 2 (Overlap singularity)	109
Number of case 3 (Elimination singularity)	56
Number of case 4 (Output weight 0)	123
Number of case 5 (Overlap and elimination singularity)	16
Number of case 6 (Elimination singularity and output weight 0)	21

Table 2: Statistical results of RBF networks in a general case

From the results shown in Table 2, 67.5 percent of experiments did not get affected by the singularities and the learning dynamics converged to the global minimum fast. On the other hand, 20.2 percent of the learning processes are affected by the singularities. This ratio is close to the one for RBF networks with two hidden units, which implies that the existence of singularities indeed significantly affects the learning process of RBF networks. 12.3 percent of the experiments belong to case 4, which implies that the case should attract

more attention. In case 5 and case 6, plateau phenomenons can be obviously observed where the learning dynamics are affected by the elimination singularities.

3.3 Extended Complex Scene Saliency Data set (ECSSD)

In the above experiments, we use artificial examples. We now perform an experiment by using a factual data set. Salient object detection plays a key role in many image analysis tasks that identifies important locations and structure in the visual field (Borji and Itti, 2013; Zhang et al., 2017). In recent years researchers utilize deep learning to improve the performance of saliency detection (Zhao et al., 2015b; Lee et al., 2016). As a benchmark data set in saliency detection community, extended complex scene saliency data set (ECSSD) has been widely used since its release in 2013 (Yan et al., 2013). In this experiment, we use the method proposed in (Zhang et al., 2014) to extract the features of the images in ECSSD data set as the input of the RBF networks. We get three conspicuity maps in both the rarity and the distinctiveness factors, and one conspicuity map in central bias factor. Thus the number of the nodes in the input layer is 7. The output of the training samples is '1' or '0', where '1' represents this part of the image is salient and '0' represents this part of the image is not salient.

As the distribution of input data is unknown in this experiment, we cannot obtain the analytical form of both ALEs of the training process and the Fisher information matrix. Thus we use batch mode learning to accomplish the experiment. By using a trial-and-error method, we choose the number of hidden unit in the student model to be $k = 90$ and the spread constant $\sigma = 0.5$, such that the student RBF network for the input $\boldsymbol{x}$ is given by:

$$f(\boldsymbol{x}, \boldsymbol{\theta}) = \sum_{i=1}^{90} w_i \phi(\boldsymbol{x}, \boldsymbol{J}_i). \tag{23}$$

We use 200 samples to train the RBF network. For the learning rate $\eta = 0.002$, the model is trained by the gradient algorithm for 15000 times and the sum squared training error $E = \frac{1}{2}\sum_{i=1}^{200}(y_i - \sum_{j=1}^{90} w_j \phi(\boldsymbol{x}_i, \boldsymbol{J}_j))^2$ is used to replace the generalization error. Then we clone it 200 times. Each clone is trained with different random initial weights. The initial student parameters $\boldsymbol{J}_i^{(0)}$ and $w_i^{(0)}$ are uniformly generated in the interval $[-2,\ 2]$.

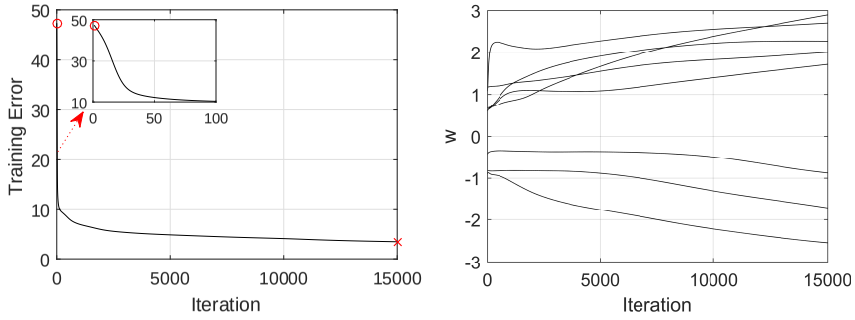
By analyzing the simulation results, the different types of learning processes are listed as follows. In the following figures, '$\circ$' and '$\times$' represent the initial state and final state, respectively.

Case 1 (**Fast convergence**): The learning process is not affected by singularities.

We give an example of this case in Figure 12, which shows the trajectories of the training error and part of output weights $\boldsymbol{w}$. From Figure 12(a), we can see that the training error comes down to a small number after the training starts and remains small till the learning stops. We do not observe that the singularities have affected the training process.

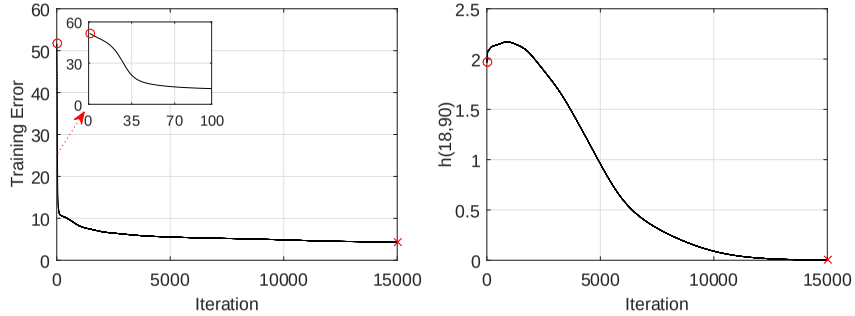
Case 2 (**Overlap singularity**): The learning process is affected by overlap singularity.

We give an example of this case in Figure 13, which shows the trajectories of the training error and $h(18, 90)$. From Figure 13(b), the Euclid distance between $\boldsymbol{J}_{18}$ and $\boldsymbol{J}_{90}$ became nearly 0, which means $\boldsymbol{J}_{18}$ and $\boldsymbol{J}_{90}$ nearly overlapped after learning.



(a) Trajectory of training error (b) Trajectory of w

Figure 12: Case 1 (Fast convergence) in approximating ECSSD data set



(a) Trajectory of training error (b) Trajectory of $h(18, 90)$

Figure 13: Case 2 (Overlap singularity) in approximating ECSSD data set

The initial state is:

$\boldsymbol{J}_{18}^{(0)} = [-0.4159,\ -1.0079,\ -0.3436,\ 0.1162,\ 0.6212,\ 0.3521,\ 0.9892]^T$,

$\boldsymbol{J}_{90}^{(0)} = [-0.1619,\ 0.0519,\ 0.1225,\ 0.6200,\ -0.8639,\ -0.0874,\ 0.8953]^T$.

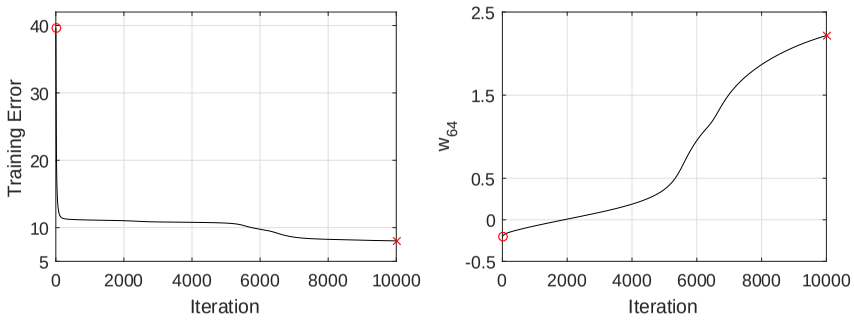
The final state is:

$\boldsymbol{J}_{18} = [-0.2480,\ 0.0515,\ -0.1948,\ 0.2474,\ 0.0130,\ 0.0531,\ 1.2120]^T$,

$\boldsymbol{J}_{90} = [-0.2353,\ 0.0871,\ -0.1995,\ 0.2585,\ -0.0267,\ 0.0538,\ 1.1964]^T$.

Case 3 (**Elimination singularity**): The learning process is affected by elimination singularity.

We give an example of this case. Figure 14 shows the trajectories of the training error and output weight w_{64}. We can see that during the stage where w_{64} crosses 0 (Figure 14(b)), a plateau phenomenon can be observed (Figure 14(a)). The learning process is, thus, significantly affected by the elimination singularity.



(a) Trajectory of training error (b) Trajectory of w_{64}

Figure 14: Case 3 (Elimination singularity) in approximating ECSSD data set

Case 4 (**Output weight 0**): After training, one of the output weights w_i nearly equals to 0.

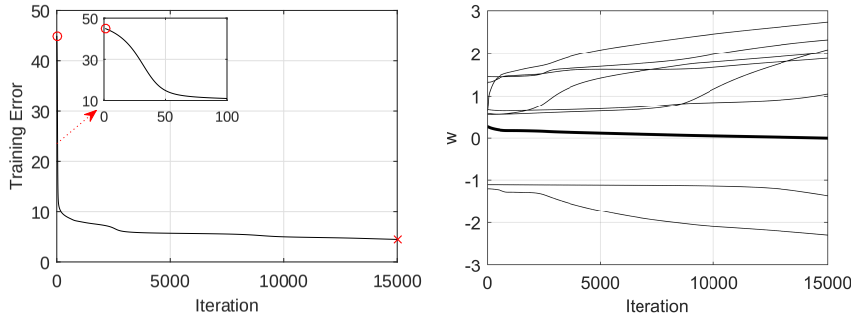
We give an example of this case. Figure 15 shows the trajectories of the training error and part of output weights $\boldsymbol{w}$. From the trajectory in Figure 15(b), it can be seen that w_{80} (the wider line) became nearly 0 after the training process.

Next, we count the learning processes which belong to each of the three cases and show them in Table 3.

Number of total experiments	200
Number of case 1 (Fast convergence)	153
Number of case 2 (Overlap singularity)	3
Number of case 3 (Elimination singularity)	42
Number of case 4 (Output weight 0)	2

Table 3: Statistical results of RBF networks in approximating ECSSD data set

It can be seen from the statistical results in Table 3 that as many as 22.5 percent of the experiments were seriously affected by the different types of singularity. There are only three experiments affected by the overlap singularity. On the other hand, we can see that 21 percent of the experiments were affected by elimination singularities. The results indicate that, in a high dimensional data scenario, the learning process is more likely affected by the elimination singularity. Therefore, it is worthy to pay more attention to investigating



(a) Trajectory of training error (b) Trajectory of w

Figure 15: Case 4 (Output weight 0) in approximating ECSSD data set

the elimination singularity. Moreover, different from our other earlier simulation results, only 1 percent of the experiments belong to case 4. The ratio is much less than those of the former experiments. The main reason is that a factual function can be represented by different suboptimal RBF networks which are equivalent to each other and the case where the initial center of the student model is far away from the center of teacher model becomes infrequent.

The statistical results confirm the previous results investigating the training difficulties in large networks from another view of point. (Dauphin et al., 2014) concluded that the local minima with high error were rare in high dimensions and the training difficulties were mainly caused by saddle points. From Table 3, we can see that the experiments affected by the overlap singularities (local minimum case) are much less than those in low dimensional networks. However, nearly all of the singular learning dynamics are affected by the elimination singularities (saddle point case). The results are in accordance with those obtained in (Dauphin et al., 2014).

4. Conclusion

Many previous works have demonstrated that the learning dynamics of feedforward neural networks are affected by the existence of singularities, but which type of singularity has more influence on the learning dynamics remains unclear. RBF networks are typical feedforward neural networks, and the learning dynamics near overlap singularities have been theoretically analyzed. Based on the obtained results, we have focused on the relationship between the existence of singularities and the learning dynamics of RBF networks in this paper. We have presented the analytical expression of the Fisher information matrix for RBF networks, as the singularities are the subspaces of the parameter space where the Fisher information matrix degenerates.

From the learning trajectories of the parameters in the generalization error surface, it can be clearly seen that the learning dynamics of RBF networks are affected by the singularities. Through a large number of numerical simulation experiments for RBF networks with two hidden units, we have identified 4 cases presenting strange learning behaviors. Nearly 7.5 percent and 12.5 percent of our experiments have shown significant effects of the overlap singularities and the elimination singularities, respectively. The points in the overlap singularity are local minima and the points in the elimination singularity are saddle points. The elimination singularities have a more significant impact to the learning processes than the overlap singularities. Our experimental results have also indicated that the plateau phenomena are mainly caused by the elimination singularities. Moreover, about 12 percent of our experiments have shown that one of the output weights of RBF networks could be close to zero after training and the student parameters are trapped into local minimum.

Through numerical simulation experiments for large scale RBF networks using a practice data set, we have found that the results are some different. Nearly all singular cases belong to the elimination singularity case and the overlap singularity case rarely occurred. This means that the large scale networks are more likely affected by the saddle points. The cases that converge to a local minimum with high error rarely appeared and the networks mainly converge to the global minimum or local minimum with good performance. The results are in accordance with the previous findings in large scale neural networks (Dauphin et al., 2014; Saxe et al., 2014; Choromanska et al., 2015).

In summary, we conclude that:

1) Overlap singularities lead to genuine local minima and elimination singularities lead to saddle points. The plateau phenomena are mainly caused by the elimination singularities.

2) The elimination singularities have a more significant impact to the learning processes than the overlap singularities. The overlap singularities mainly influence the learning dynamics of neural networks with low dimension. The large scale networks predominantly suffer from elimination singularities (saddle point case) and local minima with high error have rare influence.

Future research should pay more attention to the elimination singularities, and special treatments should be designed both for the traditional feedforward neural networks and deep neural networks to deal with the existence of singularities.

Acknowledgments

The authors would like to thank Professor S. Amari for his very constructive comments and suggestions. Appendix A. Proof of Theorem 1

By substituting $f(\boldsymbol{x},\boldsymbol{\theta}) = \sum_{i=1}^{k} w_i \phi(\boldsymbol{x},\boldsymbol{J}_i)$ into Eq.(4), we have

$$F(\boldsymbol{\theta}) = (F_{ij})_{(2k)\times(2k)}. \tag{A-1}$$

From Eq.(5), we have:

$$y - f_0(\boldsymbol{x}) = \varepsilon \sim \mathcal{N}(0,\sigma_0^2), \tag{A-2}$$

then

$$\frac{1}{\sqrt{2\pi}\sigma_0}\int_{-\infty}^{+\infty}\exp\left(-\frac{(y-f_0(\boldsymbol{x}))^2}{2\sigma_0^2}\right)\mathrm{d}y = \frac{1}{\sqrt{2\pi\sigma_0}}\int_{-\infty}^{+\infty}\exp(-\frac{\varepsilon^2}{2\sigma_0^2})\mathrm{d}\varepsilon = 1. \tag{A-3}$$

Thus,

$$\begin{aligned}\langle\phi(\boldsymbol{x},\boldsymbol{J}_i)\phi(\boldsymbol{x},\boldsymbol{J}_j)\rangle &= \left(\sqrt{2\pi}\right)^{-n}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\phi(\boldsymbol{x},\boldsymbol{J}_i)\phi(\boldsymbol{x},\boldsymbol{J}_j)\exp\left(-\frac{1}{2}\boldsymbol{x}^T\boldsymbol{x}\right)\\ &\quad\times\frac{1}{\sqrt{2\pi}\sigma_0}\exp\left(-\frac{(y-f_0(\boldsymbol{x}))^2}{2\sigma_0^2}\right)\mathrm{d}y\mathrm{d}\boldsymbol{x}\\ &= \left(\sqrt{2\pi}\right)^{-n}\int_{-\infty}^{+\infty}\phi(\boldsymbol{x},\boldsymbol{J}_i)\phi(\boldsymbol{x},\boldsymbol{J}_j)\exp\left(-\frac{1}{2}\boldsymbol{x}^T\boldsymbol{x}\right)\mathrm{d}\boldsymbol{x}.\end{aligned} \tag{A-4}$$

From results in Eq.(B.6)(Wei and Amari, 2008), we have:

$$\langle\phi(\boldsymbol{x},\boldsymbol{J}_i)\phi(\boldsymbol{x},\boldsymbol{J}_j)\rangle = C(\boldsymbol{J}_i,\boldsymbol{J}_j). \tag{A-5}$$

Then we calculate $\left\langle\phi(\boldsymbol{x},\boldsymbol{J}_j)\frac{\partial\phi(\boldsymbol{x},\boldsymbol{J}_i)}{\partial\boldsymbol{J}_i}\right\rangle$ and $\left\langle\frac{\partial\phi(\boldsymbol{x},\boldsymbol{J}_i)}{\partial\boldsymbol{J}_i}\frac{\partial\phi(\boldsymbol{x},\boldsymbol{J}_j)}{\partial\boldsymbol{J}_j^T}\right\rangle$:

$$\left\langle\phi(\boldsymbol{x},\boldsymbol{J}_j)\frac{\partial\phi(\boldsymbol{x},\boldsymbol{J}_i)}{\partial\boldsymbol{J}_i}\right\rangle = \frac{\partial}{\partial\boldsymbol{J}_i}\langle\phi(\boldsymbol{x},\boldsymbol{J}_i)\phi(\boldsymbol{x},\boldsymbol{J}_j)\rangle = C(\boldsymbol{J}_i,\boldsymbol{J}_j)B(\boldsymbol{J}_i,\boldsymbol{J}_j). \tag{A-6}$$

$$\begin{aligned}\left\langle\frac{\partial\phi(\boldsymbol{x},\boldsymbol{J}_i)}{\partial\boldsymbol{J}_i}\frac{\partial\phi(\boldsymbol{x},\boldsymbol{J}_j)}{\partial\boldsymbol{J}_j^T}\right\rangle &= \frac{\partial}{\partial\boldsymbol{J}_j^T}\left\langle\frac{\partial\phi(\boldsymbol{x},\boldsymbol{J}_i)}{\partial\boldsymbol{J}_i}\phi(\boldsymbol{x},\boldsymbol{J}_j)\right\rangle\\ &= \frac{C(\boldsymbol{J}_i,\boldsymbol{J}_j)}{\sigma^2(\sigma^2+2)}\left(\mathbf{I}_n + (\boldsymbol{J}_j - (\sigma^2+1)\boldsymbol{J}_i)B^T(\boldsymbol{J}_i,\boldsymbol{J}_j)\right).\end{aligned} \tag{A-7}$$

From Eq.(A-1) and Eqs.(A-5)-(A-7), we can obtain the results in Theorem 1. ■

Appendix B. Teacher and Student Parameters of RBF Networks of General Case

Case 1 (Fast convergence):
The teacher parameters are:

$$\boldsymbol{t} = \begin{bmatrix} 2.4872 & -1.8617 & -3.8418 & 3.2283 & -3.4445 & 2.4688 & -1.7230 & -3.8000 & 2.5460 & 3.6434 \\ -0.8149 & 3.4688 & 1.3114 & 3.8362 & -1.5388 & -2.2370 & -3.9184 & 0.1137 & 0.6776 & 0.0255 \end{bmatrix},$$

$\boldsymbol{v} = [2.5148, -2.6292, -2.9227, 0.3614, -0.1168, -1.1332, -2.4091, 1.4182, 0.6103, 1.9928]$.

The initial student parameters are:

$$\boldsymbol{J}^{(0)} = \begin{bmatrix} 0.9014 & 2.1329 & -1.6206 & -2.9885 & 3.7966 & -2.5606 & 2.6824 & -0.3329 & 2.2608 & -3.8733 \\ 2.0291 & -3.2296 & -3.3590 & 1.2210 & -2.8917 & 0.7866 & 2.7598 & 2.7933 & 0.0625 & 1.7027 \end{bmatrix},$$

$\boldsymbol{w}^{(0)} = [3.0312, -3.2829, -2.5060, -0.7531, 1.1339, 2.5729, 0.7212, 1.2064, 3.5641, -0.4348]$.

The final student parameters are:

$$\boldsymbol{J} = \begin{bmatrix} 2.0234 & 2.8324 & -1.7438 & -3.6897 & 3.5900 & -3.7365 & 2.9589 & -0.2505 & 2.5353 & -3.7203 \\ 4.3690 & -2.6481 & -3.9085 & 0.9678 & -2.8629 & 0.2693 & 2.8289 & 3.8682 & -0.7019 & 1.4435 \end{bmatrix},$$

$\boldsymbol{w} = [2.4010, -2.8088, -2.4106, -1.5482, 1.1832, 1.7415, 0.4593, 0.1452, 2.6930, -0.8301]$.

Case 2 (**Overlap singularity**):
The teacher parameters are:

$$\boldsymbol{t} = \begin{bmatrix} 2.6147 & -1.9288 & -2.0314 & -1.6500 & 3.6916 & 0.0861 & -3.9215 & 1.8375 & 0.4179 & -2.8322 \\ 2.3125 & -1.8576 & 0.4307 & -3.5281 & -3.3686 & 2.5186 & 3.0892 & 0.5955 & -1.7836 & -1.3025 \end{bmatrix},$$

$\boldsymbol{v} = [3.6158, -0.3521, 1.9219, 1.9590, -3.3921, -3.9902, 2.8331, -0.5973, 1.8690, -1.9287]$.

The initial student parameters are:

$$\boldsymbol{J}^{(0)} = \begin{bmatrix} -2.5084 & 3.9684 & 0.3200 & 3.9631 & -0.8001 & -1.1329 & -0.4638 & 2.5393 & -2.0853 & -2.8973 \\ 3.3105 & 3.4805 & -3.9175 & -0.2992 & 2.0027 & -3.3396 & 2.6410 & -0.7964 & -1.1499 & -1.0947 \end{bmatrix},$$

$\boldsymbol{w}^{(0)} = [-1.4711, 1.7100, -3.1748, -2.3028, 3.0340, -1.9053, -1.8244, 3.8838, -1.0591, -3.4191]$.

The final student parameters are:

$$\boldsymbol{J} = \begin{bmatrix} -2.2057 & 3.7966 & 0.4940 & 3.9223 & -2.3099 & -1.3950 & 0.0860 & 4.0588 & -2.2064 & -3.0322 \\ 3.3668 & 3.3314 & -4.9285 & -0.7460 & 3.4631 & -4.7794 & 2.5181 & -0.7819 & -1.7263 & -1.4229 \end{bmatrix},$$

$\boldsymbol{w} = [-1.6246, 1.7315, -3.0298, -2.4627, 2.4273, -1.5311, -3.9856, 3.4951, -0.5322, -2.2387]$.

Case 3 (**Elimination singularity**):
The teacher parameters are:

$$\boldsymbol{t} = \begin{bmatrix} -3.8655 & -1.9977 & -0.9693 & -0.6684 & 0.8680 & 1.0865 & 1.1128 & 2.2843 & 3.0604 & 3.7053 \\ -0.2720 & -3.6433 & 0.3606 & -1.3656 & -1.6714 & 3.0623 & -0.1191 & 1.5496 & 0.5356 & -0.5962 \end{bmatrix},$$

$\boldsymbol{v} = [-0.3246, 1.3070, 2.5382, 1.4447, 1.8875, -1.5562, 3.3401, 2.5875, -1.1534, 0.8754]$.

The initial student parameters are:

$$\boldsymbol{J}^{(0)} = \begin{bmatrix} 2.5721 & -2.0317 & -3.0520 & 2.2606 & -3.7871 & -3.4318 & -3.4161 & -3.3289 & -2.9387 & 2.9206 \\ -0.9149 & 2.3647 & 1.9332 & 0.3286 & 2.6422 & -2.5984 & 2.3670 & -3.9398 & -2.0198 & -0.9915 \end{bmatrix},$$

$\boldsymbol{w}^{(0)} = [0.7242, 2.1926, -2.5681, -2.1687, -0.5425, 1.2113, -0.1622, -3.9397, -2.9404, -2.3096]$.

The final student parameters are:

Abstract

We propose a two-stage penalized least squares method to build large systems of structural equations based on the instrumental variables view of the classical two-stage least squares method. We show that, with large numbers of endogenous and exogenous variables, the system can be constructed via consistent estimation of a set of conditional expectations at the first stage, and consistent selection of regulatory effects at the second stage. While the consistent estimation at the first stage can be obtained via the ridge regression, the adaptive lasso is employed at the second stage to achieve the consistent selection. This method is computationally fast and allows for parallel implementation. We demonstrate its effectiveness via simulation studies and real data analysis.

Keywords: graphical model, high-dimensional data, reciprocal graphical model, simultaneous equation model, structural equation model

1. Introduction

We consider a linear system with p endogenous and q exogenous variables. With a sample of n observations from this system, we denote the observed values of endogenous and exogenous variables by $\mathbf{Y}_{n\times p} = (\mathbf{Y}_1, \cdots, \mathbf{Y}_p)$ and $\mathbf{X}_{n\times q} = (\mathbf{X}_1, \cdots, \mathbf{X}_q)$, respectively. The interactions among endogenous variables and the direct causal effects by exogenous variables can be described by a system of structural equations,

$$\mathbf{Y} = \mathbf{Y}\boldsymbol{\Gamma} + \mathbf{X}\boldsymbol{\Psi} + \boldsymbol{\epsilon}, \tag{1}$$

where the $p \times p$ matrix $\boldsymbol{\Gamma}$ has zero diagonal elements and contains regulatory effects, the $q \times p$ matrix $\boldsymbol{\Psi}$ contains causal effects, and $\boldsymbol{\epsilon}$ is an $n \times p$ matrix of error terms. We assume that $\mathbf{X}$ and $\boldsymbol{\epsilon}$ are independent of each other, and each component of $\boldsymbol{\epsilon}$ is independently distributed as normal with zero mean while rows of $\boldsymbol{\epsilon}$ are identically distributed.

With gene expression levels and genotypic values as endogenous and exogenous variables, respectively, the model (1) has been used to represent a gene regulatory network with each equation modeling the regulatory genetic effects as well as the causal genomic effects from cis-eQTL (i.e., expression quantitative trait loci located within the regions of their target genes) on a given gene, see Xiong *et al.* (2004), and Liu *et al.* (2008), among others. Genetical genomics experiments, which collect genome-wide gene expressions and genotypic values, have been widely undertaken to construct gene regulatory networks (Jansen and Nap, 2001; Schadt *et al.*, 2003). However, fitting a system of structural equations in (1) to genetical genomics data for the purpose of revealing a whole-genome gene regulatory network is still hindered by lack of an effective statistical method which addresses issues brought by large numbers of endogenous and exogenous variables.

Several efforts have been made to construct the system (1) with genetical genomics data. Xiong *et al.* (2004) proposed to use a genetic algorithm to search for genetic networks which minimize the Akaike Information Criterion (AIC; Akaike, 1974), and Liu *et al.* (2008) instead proposed to minimize the Bayesian Information Criterion (BIC; Schwartz, 1978) and its modification (Broman and Speed, 2002) for the optimal genetic networks. Both AIC and BIC are applicable to inferring networks for only a small number of endogenous variables. For a large system with many endogenous and exogenous variables, Cai *et al.* (2013) proposed to maximize a penalized likelihood to construct a sparse system. However, it is computationally formidable to fit a large system based on the likelihood function of the complete model. Logsdon and Mezey (2010) instead proposed to apply the adaptive lasso (Zou, 2006) to fitting each structural equation separately, and then recover the network relying on additional assumption on unique exogenous variables. However, Cai *et al.* (2013) demonstrated its inferior performance via simulation studies, which is consistent with our conclusion.

Instead of the full information model specified in (1), we seek to establish the large system via constructing a large number of limited information models, each for one endogenous variable (Schmidt, 1976). For example, when the k-th endogenous variable is concerned, we focus on the k-th structural equation in (1) which models the regulatory effects of other endogenous variables and direct causal effects of exogenous variables, and ignore the system structures contained in other structural equations, leading to the following limited-information model,

$$\begin{cases} \mathbf{Y}_k = \mathbf{Y}_{-k}\boldsymbol{\gamma}_k + \mathbf{X}\boldsymbol{\psi}_k + \boldsymbol{\epsilon}_k, \\ \mathbf{Y}_{-k} = \mathbf{X}\boldsymbol{\pi}_{-k} + \boldsymbol{\xi}_{-k}. \end{cases} \tag{2}$$

Here $\mathbf{Y}_{-k}$ refers to $\mathbf{Y}$ excluding the k-th column, $\boldsymbol{\gamma}_k$ refers to the k-th column of $\boldsymbol{\Gamma}$ excluding the diagonal zero, and $\boldsymbol{\psi}_k$ and $\boldsymbol{\epsilon}_k$ refer to the k-th columns of $\boldsymbol{\Psi}$ and $\boldsymbol{\epsilon}$ respectively. The second part of the model (2) is from the following reduced model by excluding the k-th reduced-form equation, with $\boldsymbol{\pi} = \boldsymbol{\Psi}(\mathbf{I} - \boldsymbol{\Gamma})^{-1}$ and $\boldsymbol{\xi} = \boldsymbol{\epsilon}(\mathbf{I} - \boldsymbol{\Gamma})^{-1}$,

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\pi} + \boldsymbol{\xi}. \tag{3}$$

In a classical low-dimensional setting, applying the ordinary least squares method to the first equation in (2) leads to underestimated $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_k$ due to correlated $\mathbf{Y}_{-k}$ and $\boldsymbol{\epsilon}_k$. Instead, the reduced-form equations in (2) are fitted to obtain least squares estimator $\hat{\boldsymbol{\pi}}_{-k}$ of $\boldsymbol{\pi}_{-k}$, and least squares estimators of $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_k$ are further obtained by regressing $\mathbf{Y}_k$ against $\hat{\mathbf{Y}}_{-k} = \mathbf{X}\hat{\boldsymbol{\pi}}_{-k}$ and $\mathbf{X}$. This procedure is widely known as the two-stage least squares

*. The first two authors contribute equally.

(2SLS) method which can produce consistent estimates of the parameters when the system is identifiable. The 2SLS estimator was originally proposed by Theil (1953a,b, 1961) and, independently, Basmann (1957), and can be restated as the instrumental variables estimator (Reiersøl, 1941, 1945).

As in a typical genetical genomics experiment, we are interested in constructing a large system with the number of endogenous variables p possibly larger than the sample size n. Such a high-dimensional and small sample size data set makes it infeasible to directly apply the 2SLS method. Indeed, $p \geq n$ may result in perfect fits of reduced-form equations at the first stage, which implies that we regress against the observed values of endogenous variables at the second stage and therefore obtain ordinary least squares estimates of the parameters. It is well known that such ordinary least squares estimates are inconsistent. Furthermore, constructing a large system demands, at the second stage, selecting regulatory endogenous variables among massive candidates, i.e., variable selection in fitting high-dimensional linear models.

In the setting of selecting instrumental variables (IVs) among a large number of candidates, L_1 regularized least squares estimators have been recently proposed to replace the ordinary least squares estimator at the first stage of 2SLS (Belloni *et al.*, 2012; Lin *et al.*, 2015; Zhu, 2015). Belloni *et al.* (2012) applied lasso-based methods to select IVs and obtain consistent estimations at the first stage when the first stage is approximately sparse. For sparse instrumental variables models, Zhu (2015) proposed to replace with lasso-based methods at both stages of 2SLS and Lin *et al.* (2015) considered the representative L_1 regularization methods and a class of concave regularization methods for both stages. All of these methods assume that each endogenous variable is only associated to a relatively small set of exogenous variables, i.e., each row of $\boldsymbol{\pi}$ in (3) only has a small set of nonzero components.

Here we consider to construct a general system of structural equations, which allows us to model nonrecursive or even cyclic relationships between endogenous variables. With the instrumental variables view of the two-stage approach, we observed that successful identification and consistent estimation of model parameters rely on consistent estimation of a set of conditional expectations which are optimal instruments. Therefore, establishing the system (1) in a high-dimensional setting is contingent on obtaining consistent estimation of these conditional expectations at the first stage, and effectively selecting and estimating of regulatory effects out of a large number of candidates at the second stage. Accordingly, we propose a two-stage penalized least squares (2SPLS) method to fit regularized linear models at each stage, with L_2 regularized linear models at the first stage and L_1 regularized linear models at the second stage.

The proposed method addresses three challenging issues in constructing a large system of structural equations, i.e., memory capacity, computational time, and statistical power. First, the limited information models are considered to develop the algorithm. In this way, we avoid working with full information models which may consist of many subnetworks and involve a massive number of endogenous variables. Second, allowing us to fit one linear model for each endogenous variable at each stage makes the algorithm computationally fast. It also makes it feasible to parallelize the large number of model fittings at each stage. Finally, the oracle properties of the resultant estimates show that the proposed method can achieve optimal power in identifying and estimating regulatory effects. Furthermore,

the efficient computation makes it feasible to use the bootstrap method to evaluate the significance of regulatory effects.

The rest of this paper is organized as follows. First, we state an identifiable model in Section 2. Section 3 revisits the instrumental variables view on the classical 2SLS method, which motivates our development of the 2SPLS method in Section 4. We show in Section 5 the theoretical properties of the estimates from 2SPLS, with the proof included in the Appendix. Simulation studies are carried out in Section 6 to evaluate the performance of 2SPLS. An application to a real data set to infer a yeast gene regulatory network is presented in Section 7. We conclude this paper with a discussion in Section 8.

2. The Identifiable Model

We follow the practice of constructing system (1) in analyzing genetical genomics data (Logsdon and Mezey, 2010; Cai *et al.*, 2013), and assume that each endogenous variable is affected by a unique set of exogenous variables, that is, the structural equation in (2) has known zero elements of $\boldsymbol{\psi}_k$. Explicitly, we use $\mathcal{S}_k$ to denote the set of row indices of known nonzero elements in $\boldsymbol{\psi}_k$. Then we have known sets $\mathcal{S}_k, k = 1, 2, \cdots, p$, which dissect the set $\{1, 2, \cdots, q\}$. We explicitly state this assumption in the below.

Assumption A. $\mathcal{S}_k \neq \emptyset$ for $k = 1, \cdots, p$, but $\mathcal{S}_j \cap \mathcal{S}_k = \emptyset$ as long as $j \neq k$.

The above assumption satisfies the rank condition (Schmidt, 1976), which is a sufficient condition for model identification. Since each $\boldsymbol{\psi}_k$ has a set of known zero components, from this point forward we ignore them and rewrite the structural equation in the model (2) as,

$$\mathbf{Y}_k = \mathbf{Y}_{-k}\boldsymbol{\gamma}_k + \mathbf{X}_{\mathcal{S}_k}\boldsymbol{\psi}_{\mathcal{S}_k} + \boldsymbol{\epsilon}_k, \qquad \boldsymbol{\epsilon}_k \sim N(\mathbf{0}, \sigma_k^2 \mathbf{I}_n), \tag{4}$$

where $\mathbf{X}_{\mathcal{S}_k}$ refers to $\mathbf{X}$ including only columns indicated by $\mathcal{S}_k$, and $\boldsymbol{\psi}_{\mathcal{S}_k}$ refers to $\boldsymbol{\psi}_k$ including only elements indicated by $\mathcal{S}_k$.

3. The Instrumental Variables View of the Two-Stage Least Squares Method

Because $\mathbf{Y}_{-k}$ and $\boldsymbol{\epsilon}_k$ are correlated, fitting merely the model (4) results in biased estimates of $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_{\mathcal{S}_k}$. However, the following two sets of variables are independent,

$$\begin{cases} \mathbf{Z}_{-k} = E[\mathbf{Y}_{-k}|\mathbf{X}] = \mathbf{X}\boldsymbol{\pi}_{-k}, \\ \boldsymbol{\varepsilon}_k = \boldsymbol{\epsilon}_k + \boldsymbol{\xi}_{-k}\boldsymbol{\gamma}_k. \end{cases}$$

Consequently, consistent estimates of $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_{\mathcal{S}_k}$ can be obtained by applying least squares method to the following model,

$$\mathbf{Y}_k = \mathbf{Z}_{-k}\boldsymbol{\gamma}_k + \mathbf{X}_{\mathcal{S}_k}\boldsymbol{\psi}_{\mathcal{S}_k} + \boldsymbol{\varepsilon}_k. \tag{5}$$

Observing $\mathbf{Y}_{-k}$ instead of $\mathbf{Z}_{-k} = E[\mathbf{Y}_{-k}|\mathbf{X}]$ naturally leads to application of the instrumental variables method (Reiersøl, 1941, 1945), that is, replacing $\mathbf{Z}_{-k} = \mathbf{X}\boldsymbol{\pi}_{-k}$ with its estimate $\hat{\mathbf{Z}}_{-k} = \mathbf{X}\hat{\boldsymbol{\pi}}_{-k}$ in fitting the linear model (5). When a $\sqrt{n}$-consistent least squares

estimator of $\boldsymbol{\pi}_j$ is obtained by fitting each equation in (3) for $j = 1, \cdots, p$, the resultant estimators of $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_{\mathcal{S}_k}$ are exactly the 2SLS estimators by Theil (1953a,b, 1961) and Basmann (1957).

Suppose that the matrix $\mathbf{X}$ satisfies the assumption in the below. It is easy to prove that, in a low-dimensional setting, we can obtain consistent estimators for the model (5) with any consistent estimate of $\boldsymbol{\pi}_{-k}$.

Assumption B. $n^{-1}\mathbf{X}^T\mathbf{X} \to \mathbf{C}$, where $\mathbf{C}$ is a positive definite matrix.

Proposition 3.1 *Suppose Assumptions A and B are satisfied for the system (1) with fixed $p \ll n$ and $q \ll n$. When there exists a consistent estimator $\hat{\boldsymbol{\pi}}_{-k}$ of $\boldsymbol{\pi}_{-k}$, the ordinary least squares estimators of $(\boldsymbol{\gamma}_k, \boldsymbol{\psi}_{\mathcal{S}_k})$ obtained by regressing $\mathbf{Y}_k$ against $(\mathbf{X}\hat{\boldsymbol{\pi}}_{-k}, \mathbf{X}_{\mathcal{S}_k})$ are also consistent.*

The above instrumental variables view implies that the conditional expectation $\mathbf{Z}_{-k} = E[\mathbf{Y}_{-k}|\mathbf{X}]$ serves as the optimal instrument for $\mathbf{Y}_{-k}$. Although, in a low-dimensional setting, any consistent estimator $\hat{\boldsymbol{\pi}}_{-k}$ leads to the instrument $\hat{\mathbf{Z}}_{-k} = \mathbf{X}\hat{\boldsymbol{\pi}}_{-k}$, an efficient estimate of $\boldsymbol{\pi}_{-k}$ should be used to produce efficient estimates of $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_{\mathcal{S}_k}$. In the following section, we build up on this view and construct the high-dimensional system (1) by first fitting high-dimensional linear models to consistently estimate the conditional expectations of endogenous variables given exogenous variables.

4. The Two-Stage Penalized Least Squares Method

To construct the limited-information model (2), we can obtain consistent estimates of the conditional expectations of endogenous variables given exogenous variables by fitting high-dimensional linear models, and then conduct a high-dimensional variable selection following our view on the model (5). Accordingly, we propose a two-stage penalized least squares (2SPLS) procedure to construct each model in (2) so as to establish the large system (1).

4.1 The Method

At the first stage, we use the ridge regression to fit each reduced-form equation in (3) to obtain consistent estimates of the conditional expectations of endogenous variables given exogenous variables, that is, for each $j = 1, 2, \cdots, p$, we obtain the ridge regression estimator of $\boldsymbol{\pi}_j$ by minimizing the following penalized sum of squares,

$$\|\mathbf{Y}_j - \mathbf{X}\boldsymbol{\pi}_j\|_2^2 + \tau_j\|\boldsymbol{\pi}_j\|_2^2, \tag{6}$$

where $\|\cdot\|_2$ is the L_2 norm, and $\tau_j > 0$ is a tuning parameter that controls the strength of the penalty. The solution to the minimization problem is $\hat{\boldsymbol{\pi}}_j = (\mathbf{X}^T\mathbf{X} + \tau_j\mathbf{I})^{-1}\mathbf{X}^T\mathbf{Y}_j$, which leads to a consistent estimate of $\mathbf{Z}_j$,

$$\hat{\mathbf{Z}}_j = \mathbf{P}_{\tau_j}\mathbf{Y}_j,$$

where $\mathbf{P}_{\tau_j} = \mathbf{X}(\mathbf{X}^T\mathbf{X} + \tau_j\mathbf{I})^{-1}\mathbf{X}^T$. With a proper choice of τ_j, the ridge regression has a good estimation performance as shown in the next section.

At the second stage, we replace $\mathbf{Z}_{-k}$ with $\hat{\mathbf{Z}}_{-k}$ in model (5) to derive estimates of $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_{\mathcal{S}_k}$, specifically, we minimize the following penalized error squares to obtain estimates of $\boldsymbol{\gamma}_k$ and $\boldsymbol{\psi}_{\mathcal{S}_k}$,

$$\frac{1}{2}\|\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k - \mathbf{X}_{\mathcal{S}_k}\boldsymbol{\psi}_{\mathcal{S}_k}\|_2^2 + \lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k|, \tag{7}$$

where $|\boldsymbol{\gamma}_k|$ denotes componentwise absolute value of $\boldsymbol{\gamma}_k$, $\boldsymbol{\omega}_k$ is a known weight vector, and $\lambda_k > 0$ is a tuning parameter.

Minimizing for $\boldsymbol{\psi}_{\mathcal{S}_k}$ in (7) leads to

$$\hat{\boldsymbol{\psi}}_{\mathcal{S}_k} = (\mathbf{X}_{\mathcal{S}_k}^T\mathbf{X}_{\mathcal{S}_k})^{-1}\mathbf{X}_{\mathcal{S}_k}^T(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k),$$

where $\mathbf{X}_{\mathcal{S}_k}$ is usually of low dimension, and the above least squares estimator of $\boldsymbol{\psi}_{\mathcal{S}_k}$ is easy to obtain.

Plugging $\hat{\boldsymbol{\psi}}_{\mathcal{S}_k}$ into (7), we can solve the following minimization problem to obtain an estimate of $\boldsymbol{\gamma}_k$,

$$\hat{\boldsymbol{\gamma}}_k = \arg\min_{\boldsymbol{\gamma}_k}\left\{\frac{1}{2}(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k)^T\mathbf{H}_k(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k) + \lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k|\right\}, \tag{8}$$

where $\mathbf{H}_k = \mathbf{I} - \mathbf{X}_{\mathcal{S}_k}(\mathbf{X}_{\mathcal{S}_k}^T\mathbf{X}_{\mathcal{S}_k})^{-1}\mathbf{X}_{\mathcal{S}_k}^T$, this is equivalent to a variable selection problem in regressing $\mathbf{H}_k\mathbf{Y}_k$ against high-dimensional $\mathbf{H}_k\hat{\mathbf{Z}}_{-k}$. We will resort to adaptive lasso to select nonzero components of $\boldsymbol{\gamma}_k$ and estimate them. Specifically, picking up a $\delta > 0$ and obtaining $\tilde{\boldsymbol{\gamma}}_k$ as a $\sqrt{n}$-consistent estimate of $\boldsymbol{\gamma}_k$, we calculate the weight vector $\boldsymbol{\omega}_k$ with components inversely proportional to components of $|\tilde{\boldsymbol{\gamma}}_k|^\delta$. The above minimization problem (8) is a convex optimization problem which is computationally efficient.

4.2 Tuning Parameter Selection

In this method, we need to select tuning parameters at each stage. At the first stage, we propose to choose each τ_j in (6) by the method of generalized cross-validation (GCV; Golub *et al.*, 1979), that is,

$$\tau_j = \arg\min_{\tau>0} G_j(\tau) = \arg\min_{\tau>0}\frac{(\mathbf{Y}_j - \mathbf{P}_\tau\mathbf{Y}_j)^T(\mathbf{Y}_j - \mathbf{P}_\tau\mathbf{Y}_j)}{(n - \mathrm{tr}\{\mathbf{P}_\tau\})^2}.$$

It is a rotation-invariant version of ordinary cross-validation, and leads to an approximately optimal estimate of the conditional expectation $\mathbf{Z}_j$. At the second stage, the tuning parameter λ_k in (8) is obtained via K-fold cross validation.

5. Theoretical Properties

5.1 The Number of Endogenous Variables is Fixed

As an extension of the classical 2SLS method to high dimensions, the proposed 2SPLS method also has some good theoretical properties. In this section, we will show that the 2SPLS estimates enjoy the oracle properties. As the second-stage estimation relies on the

ridge estimates $\hat{\mathbf{Z}}_{-k}$ obtained from the first stage, we start with the theoretical properties of $\hat{\mathbf{Z}}_{-k}$.

As mentioned previously, each τ_j in (6) is obtained by GCV. Interestingly, as stated by Golub *et al.* (1979), such a τ_j is closely related to the one minimizing

$$T_j(\tau) = (\mathbf{Z}_j - \mathbf{P}_\tau \mathbf{Y}_j)^T (\mathbf{Z}_j - \mathbf{P}_\tau \mathbf{Y}_j).$$

We have the following result similar to Theorem 2 of Golub *et al.* (1979).

Theorem 5.1 *Suppose that all components of $\boldsymbol{\pi}_j$ are i.i.d. with mean zero and variance $\sigma^2_{\boldsymbol{\pi}}$, then*

$$\arg\min_{\tau>0} E\left[E[G_j(\tau)|\boldsymbol{\pi}_j]\right] = \arg\min_{\tau>0} E\left[E[T_j(\tau)|\boldsymbol{\pi}_j]\right] = \sigma^2_{\boldsymbol{\xi}_j}/\sigma^2_{\boldsymbol{\pi}},$$

where $\sigma^2_{\boldsymbol{\xi}_j}$ is the variance component of $\boldsymbol{\xi}_j$ in model (2).

This theorem implies that the GCV estimate $\hat{\mathbf{Z}}_j = \mathbf{P}_{\tau_j}\mathbf{Y}_j$ is approximately the optimal estimate of the conditional expectation $\mathbf{Z}_j$; furthermore, as the optimal tuning parameter approximates a constant determined by the variance components ratio, we make the following assumption on τ_j.

Assumption C. $\tau_j/\sqrt{n} \to 0$ as $n \to \infty$, for $j = 1, \cdots, p$.

We then have the following properties on $\hat{\mathbf{Z}}_{-k}$.

Theorem 5.2 *For $k = 1, \ldots, p$, let $\mathbf{M}_k = \boldsymbol{\pi}^T_{-k}(\mathbf{C} - \mathbf{C}_{\bullet\mathcal{S}_k}\mathbf{C}^{-1}_{\mathcal{S}_k,\mathcal{S}_k}\mathbf{C}_{\mathcal{S}_k\bullet})\boldsymbol{\pi}_{-k}$ where each $\mathbf{C}_{\mathcal{S}_r\mathcal{S}_c}$ is a submatrix of $\mathbf{C}$ identified with row indices in $\mathcal{S}_r$ and column indices in $\mathcal{S}_c$ (the dot implies all rows or columns). Then, under Assumptions A, B, and C,*

a. $n^{-1}\hat{\mathbf{Z}}^T_{-k}\mathbf{H}_k\hat{\mathbf{Z}}_{-k} \to_p \mathbf{M}_k$, *as* $n \to \infty$;

b. $n^{-1/2}(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k)^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k} \to_d N(\mathbf{0}, \sigma^2_k\mathbf{M}_k)$, *as* $n \to \infty$.

Since $n^{-1}\mathbf{Z}^T_{-k}\mathbf{H}_k\mathbf{Z}_{-k} \to \mathbf{M}_k$, Theorem 5.2.a states that $\hat{\mathbf{Z}}^T_{-k}\mathbf{H}_k\hat{\mathbf{Z}}_{-k}$ is a good approximation to $\mathbf{Z}^T_{-k}\mathbf{H}_k\mathbf{Z}_{-k}$. On the other hand, $\mathbf{H}_k(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k)$ is the error term in regressing $\mathbf{H}_k\mathbf{Y}_k$ against $\mathbf{H}_k\hat{\mathbf{Z}}_{-k}$, and Theorem 5.2.b implies that $n^{-1}(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k)^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k} \to_d 0$. Thus $\hat{\mathbf{Z}}_{-k}$ results in regression errors with good properties, i.e., the error effects on the 2SPLS estimators will vanish when the sample size gets sufficiently large.

In summary, the above theorem indicates that $\hat{\mathbf{Z}}_{-k}$ behaves the same way as $\mathbf{Z}_{-k}$ asymptotically, which makes it reasonable to replace $\mathbf{Z}_{-k}$ with $\hat{\mathbf{Z}}_{-k}$ at the second stage. Denote the j-th elements of $\boldsymbol{\gamma}_k$ and $\hat{\boldsymbol{\gamma}}_k$ as γ_{kj} and $\hat{\gamma}_{kj}$, respectively. Then, the properties of $\hat{\mathbf{Z}}_{-k}$ in Theorem 5.2, together with the oracle properties of the adaptive lasso, will lead to the following oracle properties of our proposed estimates.

Theorem 5.3 *(Oracle Properties) Let $\mathcal{A}_k = \{j : \gamma_{kj} \neq 0, j \neq k\}$ and $\hat{\mathcal{A}}_k = \{j : \hat{\gamma}_{kj} \neq 0, j \neq k\}$. Further index both rows and columns of $\mathbf{M}_k$ with $1, \cdots, k-1, k+1, \cdots, p$, and let $\mathbf{M}_{k,\mathcal{A}_k}$ be the submatrix of $\mathbf{M}_k$ identified with both row and column indices in $\mathcal{A}_k$. Suppose that $\lambda_k/\sqrt{n} \to 0$ and $\lambda_k n^{(\delta-1)/2} \to \infty$. Then, under Assumptions A, B, and C, the estimates from the proposed 2SPLS method satisfy the following properties,*

a. Consistency in variable selection: $\lim_{n\to\infty} P(\hat{\mathcal{A}}_k = \mathcal{A}_k) = 1$;

b. Asymptotic normality: $\sqrt{n}(\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k} - \boldsymbol{\gamma}_{k,\mathcal{A}_k}) \to_d N(\mathbf{0}, \sigma^2_k\mathbf{M}^{-1}_{k,\mathcal{A}_k})$, *as* $n \to \infty$.

It is worth mentioning that Theorem 5.2 plays an essential role in establishing the oracle properties of 2SPLS. In fact, as long as the properties in Theorem 5.2 hold true for the first-stage estimates of $\mathbf{Z}_{-k}$, the oracle properties can be expected from the adaptive lasso (Zou, 2006) at the second stage. On the other hand, we can also generalize the second-stage regularization to a wide class of regularization methods (Fan and Li, 2001; Huang *et al.*, 2011; Zhang, 2010), the theoretical properties, of which, can still be inherited due to the results in Theorem 5.2.

5.2 The Number of Endogenous Variables is Divergent

In this section, we investigate the theoretical properties of 2SPLS with a divergent p. That is, per Assumption A, both p and q may grow with sample size n at the the same order. The theoretical properties will be described by a prespecified sequence $f_n = o(n)$ but $f_n \to \infty$.

We first update Assumptions B and C for the divergent p and q.

Assumption B′. Both p and q grow at the same order of $o(n)$, i.e., $p \asymp q = o(n)$. Furthermore, the singular values of $\mathbf{I} - \boldsymbol{\Gamma}$ are positively bounded from below, and there exist positive constants c_1 and c_2 such that, for any vector δ with $\|\delta\|_2 = 1$, $c_1 \geq n^{-1/2}\|\mathbf{X}\delta\|_2 \geq c_2$.

Assumption C′. $r_{nk} \triangleq \tau^2_k \|\pi_k\|^2_2/n = o(n)$.

We have the following properties on the ridge regression estimator of $\boldsymbol{\pi}_k$ from the first stage.

Theorem 5.4 *Under Assumptions A, B′, and C′, for each ridge regression estimator $\hat{\boldsymbol{\pi}}_k$, there exist constants C_1 and C_2 such that, with probability at least $1 - e^{-f_n}$,*

(a) $\|\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k\|^2_2 \leq C_1(r_{nk} \vee q \vee f_n)/n$;

(b) $n^{-1}\|\mathbf{X}(\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k)\|^2_2 \leq C_2(r_{nk} \vee q \vee f_n)/n$.

Denote $r_{\max} = \max_{1\leq k\leq p} r_{nk}$. Then the system-wise losses in both $\|\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k\|^2_2$ and $n^{-1}\|\mathbf{X}(\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k)\|^2_2$ have upper bounds in the same order as $(r_{\max} \vee q \vee f_n)/n$, with probability at least $1 - e^{-(f_n - \log(p))}$. With $p = o(n)$, we henceforth select f_n to dominate $log(p)$, i.e. $f_n - \log(p) \to \infty$, to guarantee the well-controlled losses over the whole system.

Denote $\mathcal{A}_k = \{j : \gamma_{kj} \neq 0, j \neq k\}$. Indexing all rows and columns with only $j = 1, \cdots, k-1, k+1, \cdots, p$, we define the restricted eigenvalue for a $(p-1)\times(p-1)$ matrix $\mathbf{M}$ as

$$\phi_k(\mathbf{M}) = \min\left\{n^{-1/2}\|\mathbf{M}\gamma\|_2\|\gamma_{\mathcal{A}_k}\|^{-1}_2 : \|\gamma_{\mathcal{A}^c_k}\|_1 \leq 3\|\gamma_{\mathcal{A}_k}\|_1\right\}.$$

We further define $\|\cdot\|_\infty$ and $\|\cdot\|_{-\infty}$ to be the maximum and minimum absolute values of the components of a vector, respectively. For a matrix, $\|\cdot\|_\infty$ is defined to be the maximum absolute row sum of the matrix.

We further make the following assumption on the tuning parameter λ_k of the adaptive lasso at the second stage.

Assumption D. The adaptive tuning parameter λ_k is at the same order as $\|\omega_k\|_{-\infty}^{-1}\|\mathbf{\Gamma}\|_1 \|\boldsymbol{\pi}\|_1 \sqrt{n(r_{\max} \vee q \vee f_n)\log p}$.

We then have the consistency property of estimator $\hat{\boldsymbol{\gamma}}_k$.

Theorem 5.5 *(Estimation Consistency) Suppose that, for each node k, both inequalities $\|\omega_{k,\mathcal{A}_k}\|_\infty \|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}^{-1} \leq 1$ and $\sqrt{(r_{max} \vee q \vee f_n)/n} + c_1\|\boldsymbol{\pi}\|_1 \leq \sqrt{c_1^2\|\boldsymbol{\pi}\|_1^2 + \phi_0^2/64C_2|\mathcal{A}_k|}$ hold, and there exists a positive constant ϕ_0 such that $\phi_k(\mathbf{H}_k\mathbf{X}\boldsymbol{\pi}_{-k}) \geq \phi_0$. Denote $h_n = (\|\mathbf{\Gamma}\|_1^2 \wedge 1)\left[(\frac{n}{q}\|\boldsymbol{\pi}\|_1^2) \wedge (r_{max} \vee q \vee f_n)\right]\log p$. Under Assumptions A, B′, C′, and D, there exist constants $C_3 > 0$ and $C_4 > 0$ such that, with probability at least $1 - e^{-C_3 h_n + \log(4pq)} - e^{-f_n + \log(p)}$, each 2SPLS estimator $\hat{\boldsymbol{\gamma}}_k$ satisfies that*

1. $\|\hat{\boldsymbol{\gamma}}_k - \boldsymbol{\gamma}_k\|_1 \leq 8C_4 \frac{\|\omega_{k,\mathcal{A}_k}\|_\infty \|\boldsymbol{\pi}\|_1 \|\mathbf{\Gamma}\|_1}{\phi_0^2 \|\omega_k\|_{-\infty}} |\mathcal{A}_k| \sqrt{\frac{(r_{max} \vee q \vee f_n)\log p}{n}}$;
2. $n^{-1}\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k - \boldsymbol{\gamma}_k)\right\|_2^2 \leq \frac{C_4^2\|\omega_{k,\mathcal{A}_k}\|_\infty^2 \|\boldsymbol{\pi}\|_1^2 \|\mathbf{\Gamma}\|_1^2}{\phi_0^2\|\omega_k\|_{-\infty}^2} |\mathcal{A}_k| \frac{(r_{max} \vee q \vee f_n)\log p}{n}$.

Note that the system-wide upper bounds, defined by replacing $|\mathcal{A}_k|$ with $\max_k |\mathcal{A}_k|$, can also be achieved with probability at least $1 - e^{-C_3 h_n + \log(4q) + 2\log(p)} - e^{-f_n + 2\log(p)}$.

Let $W_k = diag\{\boldsymbol{\omega}_k\}$ and $V_k = (v_{ij})_{(p-1)\times(p-1)} \triangleq \frac{1}{n}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{H}_k\mathbf{X}\boldsymbol{\pi}_{-k}$. Further denote $W_{k,\mathcal{A}_k} = diag\{\boldsymbol{\omega}_{k,\mathcal{A}_k}\}$, $W_{k,\mathcal{A}_k^c} = diag\{\boldsymbol{\omega}_{k,\mathcal{A}_k^c}\}$, $V_{k,21} = (v_{ij})_{i\in\mathcal{A}_k^c, j\in\mathcal{A}_k}$, $V_{k,11} = (v_{ij})_{i\in\mathcal{A}_k, j\in\mathcal{A}_k}$, and $\theta_k = \left\|V_{k,11}^{-1}W_{k,\mathcal{A}_k}\right\|_\infty$. We then have the following selection property.

Theorem 5.6 *(Selection Consistency) Suppose that, for each node k, $V_{k,11}$ is invertible, and $\sqrt{(r_{max} \vee q \vee f_n)/n} + c_1\|\boldsymbol{\pi}\|_1 \leq \sqrt{c_1^2\|\boldsymbol{\pi}\|_1^2 + \min(\phi_0^2/64, \zeta(4-\zeta)^{-1}\|\boldsymbol{\omega}_k\|_{-\infty}/\theta_k)/(C_2|\mathcal{A}_k|)}$. Further assume that there exists a positive constant $\zeta \in (0,1)$ such that $\min_{j\in\mathcal{A}_k}|\gamma_{kj}| > \frac{2\lambda_k\theta_k}{n(2-\zeta)}$ and $\left\|W_{k,\mathcal{A}_k^c}^{-1}V_{k,21}V_{k,11}^{-1}W_{k,\mathcal{A}_k}\right\|_\infty < 1-\zeta$. Under Assumptions A, B′, C′, and D, there exists a 2SPLS estimator $\hat{\gamma}_k$ satisfying that, with probability at least $1 - e^{-C_5 h_n + \log(4pq)} - e^{-f_n + \log(p)}$ for some constant $C_5 > 0$, $\hat{\mathcal{A}}_k = \mathcal{A}_k$ with $\hat{\mathcal{A}}_k = \{j : \hat{\gamma}_{kj} \neq 0, j \neq k\}$.*

6. Simulation Studies

We conducted simulation studies to compare 2SPLS with the adaptive lasso based algorithm (AL) by Logsdon and Mezey (2010), and the sparsity-aware maximum likelihood algorithm (SML) by Cai *et al.* (2013). To investigate whether it is necessary to select instrumental variables at the first stage as proposed in Belloni *et al.* (2012), Lin *et al.* (2015), and Zhu (2015), we also consider a method which replaces the ridge regression at the first stage of 2SPLS with the adaptive lasso, that is, the two-stage adaptive lasso (2SAL) method. Both acyclic networks and cyclic networks were simulated, each involving 300 endogenous variables. Each endogenous variable was simulated to have, on average, one regulatory effect for sparse networks, or three regulatory effects for dense networks. The regulatory effects were independently simulated from a uniform distribution over $(-1,-0.5)\cup(0.5,1)$. To allow the use of AL and SML, every endogenous variable in the same network was

simulated to have the same number (either one or three) of nonzero exogenous effects (EEs) by the exogenous variables, with all effects equal to one. Each exogenous variable was simulated to take values 0, 1 and 2 with probabilities 0.25, 0.5 and 0.25, respectively, emulating genotypes of an F2 cross in a genetical genomics experiment. All error terms were independently simulated from $N(0, 0.1^2)$, and the sample size n varied from 100 to 1,000. For each network setup, we simulated 100 data sets and applied all four algorithms to calculate the power and false discovery rate (FDR).

For inferring acyclic networks, the power and FDR of the four different algorithms are plotted in Figure 1. 2SPLS has greater power than the other three algorithms to infer both sparse and dense acyclic networks when the sample size is small or moderate. When the sample size is large, 2SPLS, SML, and 2SAL are comparable for constructing both sparse and dense acyclic networks. In any case, AL has much lower power than other methods. Specifically, AL provides power as low as under 10% when the sample size is small, and its power is still under 50% even when the sample size increases to 1,000. On the other hand, 2SPLS provides power over 80% for small sample sizes, and over 90% for moderate to large sample sizes.

As shown in Figure 1, 2SPLS controls the FDR under 20% except for the case which has three available EEs with small sample sizes ($n = 100$). Although SML controls the FDR as low as under 5% for sparse acyclic networks when the sample sizes are large, it reports large FDRs when the sample sizes are small. For example, when the sample sizes are under 200, SML reports FDR over 40% for dense acyclic networks. In general, both 2SPLS and SML outperform AL and 2SAL in terms of FDR. Only in the case when inferring sparse acyclic networks with one available EE from data sets of moderate or large sample sizes, AL and 2SAL report FDR lower than 2SPLS.

Plotted in Figure 2 are the power and FDR of the four different algorithms when inferring cyclic networks. Similar to the results on acyclic networks, 2SPLS has greater power than SML and AL across all sample sizes and has lower FDR when the sample size is small. 2SPLS has greater power than 2SAL in most scenarios and has much lower FDR than 2SAL except for the case when inferring sparse cyclic networks from data sets of large sample sizes. SML provides power competitive to 2SPLS for sparse cyclic networks, but its power is much lower than that of 2SPLS for dense cyclic networks. Similar to the case of acyclic networks, SML reports much higher FDR for inferring dense networks from data sets with small sample sizes though it reports small FDR when the sample sizes are large. 2SAL reports the highest FDR, especially for networks with three available EEs.

Although not performing as well as 2SPLS, 2SAL reports competitive power to SML when inferring either acyclic or cyclic networks. For the acyclic sparse network with one EE, 2SAL can control FDR at a similar level to 2SPLS because each endogenous variable may be associated to a very small set of exogenous variables in (3). However, we observed high FDR of 2SAL in Figure 1.b for the acyclic sparse network with three EEs which triples the average number of exogenous variables associated to each endogenous variable. The similar phenomenon of 2SAL appears in Figure 2.b for the cyclic sparse networks. The dense networks also triple the average number of regulatory effects for each endogenous variable, which implies an increased number of exogenous variables associated to each endogenous variable in (3). Therefore, we unsurprisingly observed even higher FDR of 2SAL in Figure 1.d and Figure 2.d, where the FDR is over 0.8. In summary, variable selection at

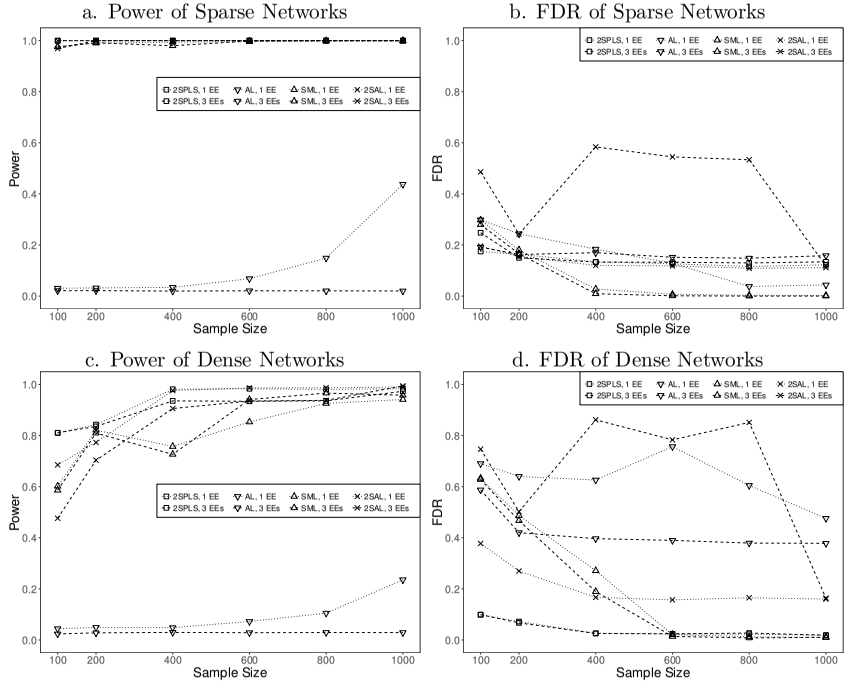

Figure 1: Performance of 2SPLS, AL, SML, and 2SAL when identifying regulatory effects in acyclic networks with one EE or three EEs.

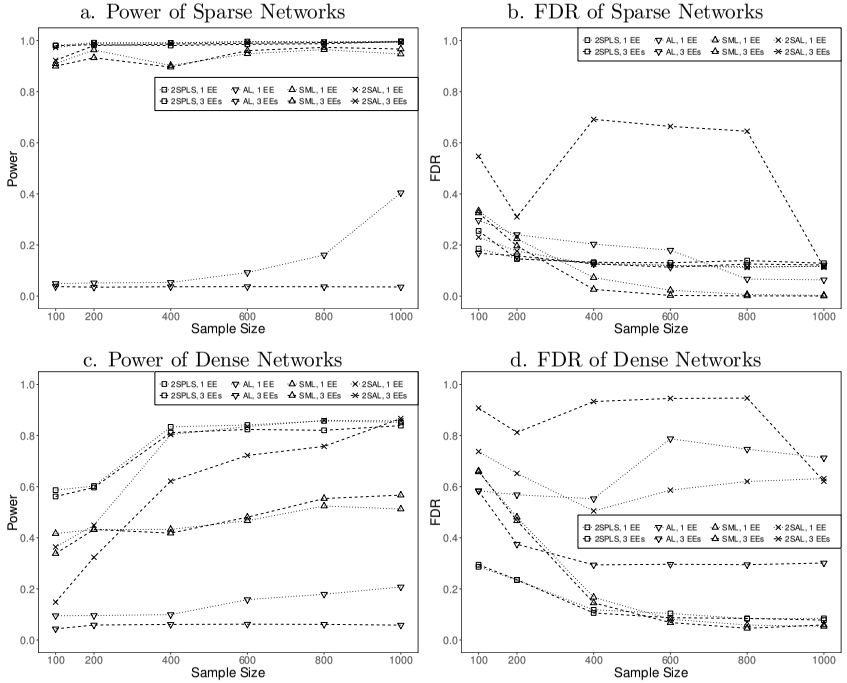

Figure 2: Performance of 2SPLS, AL, SML, and 2SAL when identifying regulatory effects in cyclic networks with one EE or three EEs.

the first stage seems work well when each endogenous variable is associated to a small set of exogenous variables in (3), but may compromise the identification of regulatory effects at the second stage when the number of exogenous variables associated to an endogenous variable increases.

Both 2SPLS and 2SAL are two-stage methods developed based on the limited-information model (2), instead of the full-information model used by SML, leading to fast computation and potential implementation of parallel computing. To demonstrate the computational advantage of 2SPLS and 2SAL, we recorded the computing time of all algorithms when inferring the same networks from small data sets ($n = 100$). Each algorithm analyzed the same data set using only one CPU in a server with Quad-Core AMD Opteron^{TM} Processor 8380. Reported in Table 1 are the running times of all four algorithms for inferring different networks. AL is the fastest although it performs with the least power. The running time of 2SPLS usually doubles or triples that of AL, but the computation time of 2SAL generally triples that of 2SPLS because 2SAL employed K-fold cross-validation to choose the tuning

parameter at the first stage. SML is the slowest algorithm which generally takes more than 40 times longer than 2SPLS to infer different networks. In particular, SML is almost 200 times slower than 2SPLS when inferring acyclic sparse networks.

	Acyclic				Cyclic			
	Sparse		Dense		Sparse		Dense	
	1 EE	3 EEs	1 EE	3 EEs	1 EE	3 EEs	1 EE	3 EEs
2SPLS	1303	1332	1127	1112	1297	1337	1125	1165
AL	405	652	404	637	443	659	430	781
SML	258875	195739	58509	43118	49393	58716	67949	68081
2SAL	3239	4726	3398	5357	3135	4681	3686	5651

Table 1: The running time (in seconds) of inferring networks from a data set with $n = 100$.

The robustness of 2SPLS was also evaluated from different aspects: (i) its robustness to different noise levels by doubling or even quadrupling the error variance; (ii) its robustness to non-normality of error terms by simulating errors sampled from a t-distribution, i.e., $t(3)$; (iii) its robustness to uncertainty in the connections between exogenous and endogenous variables by simulating three exogenous effects for each endogenous variable (to emulate the genetical genomics experiment, the three exogenous variables are correlated with correlation coefficients at 0.8, and have effects at 1, 0.5, and -0.3, respectively) but including only one exogenous variable with the strongest estimated effects for each endogenous variable; (iv) its robustness to existence of hub nodes by simulating networks with six hub nodes having five regulatory effects on average while other endogenous variables having on average one regulatory effect for sparse networks, or three regulatory effects for dense networks. All networks include 300 endogenous variables, and the networks with errors following $N(0, 0.01)$ are the same as those shown in Figure 1. As shown in Figure 3, the 2SPLS method demonstrated robust power while the FDR was slightly affected when the error variance doubled. When the error variance quadrupled, a higher FDR was reported as expected. With errors from $t(3)$, we observed similar power and slightly increased FDR of 2SPLS, which confirms the robustness of 2SPLS to non-normality. The uncertainty in the connections between exogenous and endogenous variables had almost no effect on the power of 2SPLS, and only slightly increased the FDR in constructing sparse networks. The existence of hub nodes rarely affected construction of dense networks, but decreased the FDR in constructing sparse networks. Overall, the performance of 2SPLS is remarkable in demonstrating robustness under a variety of realistic data structures.

7. Real Data Analysis

We analyzed a yeast data set with 112 segregants from a cross between two strains BY4716 and RM11-la (Brem and Kruglyak, 2005). A total of 5,727 genes were measured for their expression values, and 2,956 markers were genotyped. Each marker within a genetic region (including 1kb upstream and downstream regions) was evaluated for its association with the corresponding gene expression, yielding 722 genes with marginally significant cis-eQTL (p-value < 0.05). The set of cis-eQTL for each gene was filtered to control a pairwise correlation under 0.90, and then further filtered to keep up to three cis-eQTL which have the strongest association with the corresponding gene expression.

With 112 observations of 722 endogenous variables and 732 exogenous variables, we applied 2SPLS to infer the gene regulatory network in yeast. The constructed network includes 7,300 regulatory effects in total. To evaluate the reliability of constructed gene regulations, we generated 10,000 bootstrap data sets (each with $n = 112$) by randomly sampling the original data with replacement, and applied 2SPLS to each data set to infer the gene regulatory network. Among the 7,300 regulatory effects, 323 effects were repeatedly identified in more than 80% of the 10,000 data sets, and Figure 4 shows the three largest subnetworks formed by these 323 effects. Specifically, the largest subnetwork consists of 22 endogenous variables and 26 regulatory effects, the second largest one includes 14 endogenous variables and 18 regulatory effects, and the third largest one has 11 endogenous variables and 16 regulatory effects.

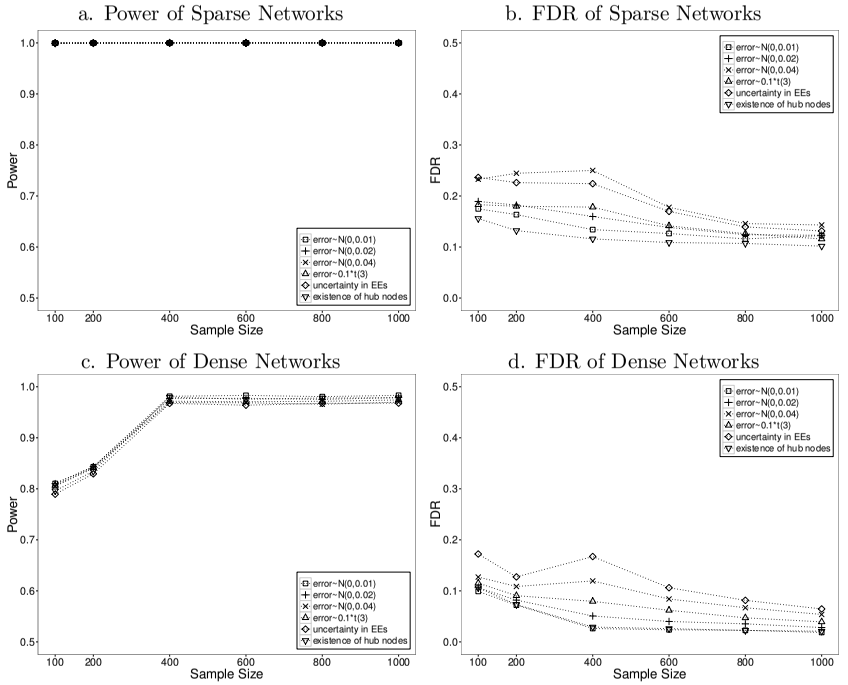

Figure 3: Performance of 2SPLS in robustness tests when identifying regulatory effects in acyclic networks with one EE.

A gene-enrichment analysis with DAVID (Huang *et al.*, 2009) showed that the three subnetworks are enriched in different gene clusters (controlling p-values from Fisher's exact tests under 0.01). A total of six gene clusters are enriched with genes from the first subnetwork, and four of them are related to either methylation or methyltransferase. Six of 22 genes in the first subnetwork are found in a gene cluster which is related to none-coding RNA processing. The second subnetwork is enriched in nine gene clusters. While three of the clusters are related to electron, one cluster includes half of the genes from the second subnetwork and is related to oxidation reduction. The third subnetwork is also enriched in nine different gene clusters, with seven clusters related to proteasome.

A total of 18 regulations were constructed from each of the 10,000 bootstrap data sets, and are shown in Figure 5. There are seven pairs of genes which regulate each other. It is interesting to observe that all regulatory genes up-regulate the target genes except two genes, namely, YCL018W and YEL021W.

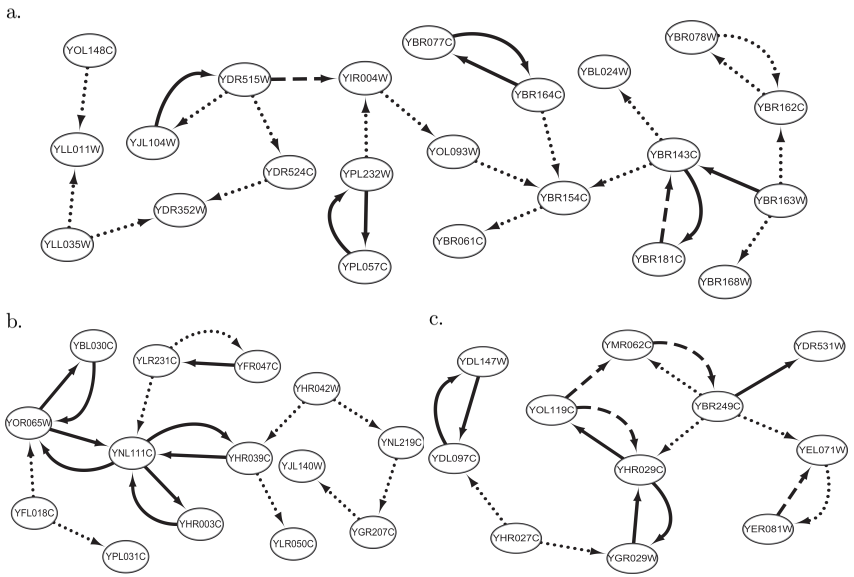

Figure 4: Three gene regulatory subnetworks in yeast (the dotted, dashed, and solid arrows implied that the corresponding regulations were constructed respectively from over 80%, 90%, and 95% of the bootstrap data sets).

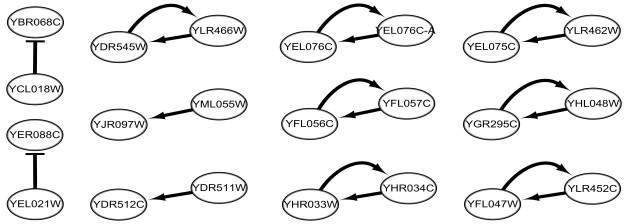

Figure 5: The yeast gene regulatory subnetworks constructed in each of 10,000 bootstrap data sets (with arrow- and bar-headed lines implying up and down regulations, respectively).

8. Discussion

In a classical setting with small numbers of endogenous/exogenous variables, constructing a system of structural equations has been well studied since Haavelmo (1943, 1944). Anderson and Rubin (1949) first proposed to estimate the parameters of a single structural equation with the limited information maximum likelihood estimator. Later, Theil (1953a,b, 1961) and Basmann (1957) independently developed the 2SLS estimator, which is the simplest and most common estimation method for fitting a system of structural equations. However, genetical genomics experiments usually collect data in which both the number of endogenous variables and the number of exogenous variables can be very large, invalidating the classical methods for building gene regulatory networks. It is noteworthy that, although each structural equation modeling gene regulation has few exogenous variables, the genome-wide gene regulatory network consists of a large number of structural equations and therefore has a large number of exogenous variables.

The instrumental variables view of 2SLS sheds light on the consistency of 2SLS estimators which is guaranteed by good estimation of the conditional expectations of endogenous variables given exogenous variables. For large systems, we proposed to estimate these conditional expectations via ridge regression coupled with GCV so as to address possible overfitting issues brought by a large number of exogenous variables. We obtained approximately optimal estimation of these conditional expectations at the first stage. At the second stage, we could adopt results from high-dimensional variable selection, e.g., Fan and Li (2001), Zou (2006), Zhang (2010), and Huang *et al.* (2011), to consistently identify and further estimate the regulatory effects of the endogenous variables. As a high-dimensional extension of the classical 2SLS method, the 2SPLS method is also computationally fast and easy to implement. As shown in constructing a genome-wide gene regulatory network of yeast, the high computational efficiency of 2SPLS allows us to employ the bootstrap method to calculate the p-values of the regulatory effects.

Our simulation studies show a seemingly counterintuitive result that our moment-based method 2SPLS provides higher power than the likelihood-based method SML, because the maximum likelihood method is usually the most efficient method, and dominates moment methods. However, as evidenced in Bollen (1996) and Kennedy (1985) (p.134), 2SLS can perform better than the maximum likelihood method in small samples. Furthermore, SML is not a pure likelihood method but rather a penalized likelihood method, and 2SPLS is not a pure moment method but rather a penalized moment method. Therefore, the theoretical advantage of likelihood methods over moment methods may not carry over to comparing penalized likelihood methods versus penalized moment methods. In fact, SML uses an L_1 penalty to penalize nonzero regulatory effects, but 2SPLS employs an L_2 penalty on the regression coefficients of the reduced models at the first stage and an L_1 penalty on the regulatory effects at the second stage. We conjecture that the different choice of penalty terms may also distinguish the two different methods as shown in the advantage of the elastic net (Zou and Hastie, 2005) over lasso (Tibshirani, 1996).

Although applicable to diverse fields, our development of 2SPLS is motivated by constructing gene regulatory networks using genetical genomics data. The algorithm is applicable to any population-based studies with either experimental crosses or natural populations. Assumption A means that each gene under investigation has at least one unique polymor-

phism from its cis-eQTL, which can be detected with classical eQTL mapping methods, e.g., Kendziorski *et al.* (2006), Gelfond *et al.* (2007), and Jia and Xu (2007). Trans-eQTL (i.e., eQTL outside the regions of their target genes) hold the key to our understanding of gene regulation because their indirect regulations are likely caused by interactions among genes. When the gene regulatory network is modeled with a system of structural equations, classical eQTL mapping methods essentially identify both cis-eQTL and trans-eQTL involved in each reduced-form equation in the reduced model (3). Nonetheless, it is challenging, if not impossible, to recover a large system from the reduced model.

An alternative strategy to construct the whole system is to build undirected graphs first (Spirtes *et al.*, 2001; Shipley, 2002; de la Fuente *et al.*, 2004) and then locally orient the edges in the graphs (Aten *et al.*, 2008; Neto *et al.*, 2008). While constructing a small network is much easier and more robust than constructing a large system, we here intend to construct large networks, such as whole-genome gene regulatory networks from genetical genomics data. Furthermore, application of the alternative strategy is contingent on whether the underlying system is composed of unconnected subsystems, because ignoring the regulatory effects from other genes outside a subset of genes may lead to false regulatory interaction (Neto *et al.*, 2008; de la Fuente *et al.*, 2004). Instead, 2SPLS allows to construct a subset of structural equations inside the whole system, ignoring many other structural equations. Therefore, we can apply 2SPLS to investigate the interactive regulation among a subset of genes as well as how these genes are regulated by others.

It is evidenced in different species that effects of trans-eQTL are weaker than those of cis-eQTL and trans-eQTL are more difficult to identify than cis-eQTL (Schadt *et al.*, 2003; Dixon *et al.*, 2007). On the other hand, a system of structural equations modeling genome-wide gene regulation may induce a large number of trans-eQTL to each reduced-form equation in (3). While constructing the system is contingent on the accuracy of predicting each endogenous variable on the basis of the corresponding reduced-form equation in (3), the weak effects of a large number of trans-eQTL privilege the use of ridge regression at the first stage of 2SPLS for constructing gene regulatory networks (Frank and Friedman, 1993). By comparing 2SPLS with 2SAL, our simulation studies demonstrated the superiority of using ridge regression over the adaptive lasso at the first stage. In fact, when some genes have a relatively large number of trans-eQTL, selecting variables at the first stage may compromise the identification of regulatory effects at the second stage.

Appendix A: Proof of Theorem 5.2

a. Since $\tau_j/\sqrt{n} \to 0$ for any $1 \le j \le p$, the different choice of τ_j for each j does not affect the following asymptotic property involving τ_j,

$$n(\mathbf{X}^T\mathbf{X} + \tau_j\mathbf{I})^{-1} \to \mathbf{C}. \tag{9}$$

Without loss of generality, we assume $\tau_1 = \tau_2 = \cdots = \tau_p = \tau$. Then $\hat{\mathbf{Z}}_{-k} = \mathbf{P}_\tau \mathbf{Y}_{-k}$.

$$\begin{aligned} n^{-1}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k} &= n^{-1}(\mathbf{X}\boldsymbol{\pi}_{-k} + \boldsymbol{\xi}_{-k})^T\mathbf{P}_\tau^T\mathbf{H}_k\mathbf{P}_\tau(\mathbf{X}\boldsymbol{\pi}_{-k} + \boldsymbol{\xi}_{-k}) \\ &= n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} + n^{-1}\boldsymbol{\xi}_{-k}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} \\ &\quad + n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k} + n^{-1}\boldsymbol{\xi}_{-k}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k} \end{aligned}$$

We will consider the asymptotic property of each of the above four terms.

First, $n^{-1}\mathbf{X}^T\mathbf{X} \to \mathbf{C}$ implies that

$$n^{-1}\mathbf{X}^T\mathbf{H}_k\mathbf{X} = n^{-1}\mathbf{X}^T\{\mathbf{I} - \mathbf{X}_{\mathcal{S}_k}(\mathbf{X}_{\mathcal{S}_k}^T\mathbf{X}_{\mathcal{S}_k})^{-1}\mathbf{X}_{\mathcal{S}_k}^T\}\mathbf{X} \to \mathbf{C} - \mathbf{C}_{\bullet\mathcal{S}_k}\mathbf{C}_{\mathcal{S}_k,\mathcal{S}_k}^{-1}\mathbf{C}_{\mathcal{S}_k\bullet}. \tag{10}$$

The above result and (9) easily lead to the following result,

$$\begin{aligned} & n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} \\ &= n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{X}(\mathbf{X}^T\mathbf{X} + \tau\mathbf{I})^{-1}\mathbf{X}^T\mathbf{H}_k\mathbf{X}(\mathbf{X}^T\mathbf{X} + \tau\mathbf{I})^{-1}\mathbf{X}^T\mathbf{X}\boldsymbol{\pi}_{-k} \\ &\to \boldsymbol{\pi}_{-k}^T(\mathbf{C} - \mathbf{C}_{\bullet\mathcal{S}_k}\mathbf{C}_{\mathcal{S}_k,\mathcal{S}_k}^{-1}\mathbf{C}_{\mathcal{S}_k\bullet})\boldsymbol{\pi}_{-k} = \mathbf{M}_k. \end{aligned} \tag{11}$$

The other three terms approaching to zero directly follows that $n^{-1}\boldsymbol{\xi}_{-k}^T\mathbf{X} \to_p \mathbf{0}$. Thus, $\frac{1}{n}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k} \to_p \mathbf{M}_k$.

b. Since $\mathbf{H}_k(\mathbf{Y}_k - \mathbf{Y}_{-k}\boldsymbol{\gamma}_k) = \mathbf{H}_k\boldsymbol{\epsilon}_k$, we have

$$\begin{aligned} & n^{-1/2}(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k)^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k} \\ &= n^{-1/2}\{(\mathbf{Y}_k - \mathbf{Y}_{-k}\boldsymbol{\gamma}_k) + (\mathbf{I} - \mathbf{P}_\tau)\mathbf{Y}_{-k}\boldsymbol{\gamma}_k\}^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k} \\ &= n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{P}_\tau\mathbf{Y}_{-k} + n^{-1/2}\boldsymbol{\gamma}_k^T\{(\mathbf{I} - \mathbf{P}_\tau)\mathbf{Y}_{-k}\}^T\mathbf{H}_k\mathbf{P}_\tau\mathbf{Y}_{-k}. \end{aligned}$$

In the following, we will prove that the second term approaches to zero, and the first term asymptotically approaches to the required distribution, i.e.,

$$n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{P}_\tau\mathbf{Y}_{-k} \to_d N(\mathbf{0}, \sigma_k^2\mathbf{M}_k). \tag{12}$$

We notice that

$$n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} \sim N(\mathbf{0}, n^{-1}\sigma_k^2\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k}).$$

Following (11), we have

$$n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} \to_d N(\mathbf{0}, \sigma_k^2\mathbf{M}_k). \tag{13}$$

Because of (10) and

$$n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{X} \sim N(\mathbf{0}, n^{-1}\sigma_k^2\mathbf{X}^T\mathbf{H}_k\mathbf{X}),$$

we have

$$n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{X} \to_d N(\mathbf{0}, \sigma_k^2(\mathbf{C} - \mathbf{C}_{\bullet\mathcal{S}_k}\mathbf{C}_{\mathcal{S}_k,\mathcal{S}_k}^{-1}\mathbf{C}_{\mathcal{S}_k\bullet})).$$

Since $n^{-1}\boldsymbol{\xi}_{-k}^T\mathbf{X} \to_p \mathbf{0}$, we can apply Slutsky's theorem and obtain that

$$n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k} = n^{-1/2}\boldsymbol{\epsilon}_k^T\mathbf{H}_k\mathbf{X}(\mathbf{X}^T\mathbf{X} + \tau\mathbf{I})^{-1}\mathbf{X}^T\boldsymbol{\xi}_{-k} \to_p \mathbf{0}.$$

Pooling the above result and (13) leads to the asymptotic distribution in (12).

To prove that the second term asymptotically approaches to zero, we further partition it as follows,

$$\begin{aligned} & n^{-1/2}\boldsymbol{\gamma}_k^T\{(\mathbf{I}-\mathbf{P}_\tau)\mathbf{Y}_{-k}\}^T\mathbf{H}_k\mathbf{P}_\tau\mathbf{Y}_{-k} \\ = \;& n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\pi}_{-k}^T\mathbf{X}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} + n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} \\ & + n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\pi}_{-k}^T\mathbf{X}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k} + n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k}. \end{aligned}$$

It suffices to prove each of these four parts asymptotically approaches to zero.

First, notice that

$$\mathbf{X}^T(\mathbf{I}-\mathbf{P}_\tau) = \tau(\mathbf{X}^T\mathbf{X}+\tau\mathbf{I})^{-1}\mathbf{X}^T,$$

we have

$$\begin{aligned} & n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\pi}_{-k}^T\mathbf{X}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k} \\ = \;& n^{-1/2}\tau\boldsymbol{\gamma}_k^T\boldsymbol{\pi}_{-k}^T(\mathbf{X}^T\mathbf{X}+\tau\mathbf{I})^{-1}\mathbf{X}^T\mathbf{H}_k\mathbf{X}(\mathbf{X}^T\mathbf{X}+\tau\mathbf{I})^{-1}\mathbf{X}^T\mathbf{X}\boldsymbol{\pi}_{-k} \to \mathbf{0}, \end{aligned} \tag{14}$$

which follows (10) and that $\tau/\sqrt{n}\to 0$ as $n\to\infty$.

Because $\mathbf{C}_{\mathcal{S}_k\bullet}\mathbf{C}^{-1}\mathbf{C}_{\bullet\mathcal{S}_k} = \mathbf{C}_{\mathcal{S}_k\mathcal{S}_k}$, we have

$$(\mathbf{C}-\mathbf{C}_{\bullet\mathcal{S}_k}\mathbf{C}_{\mathcal{S}_k,\mathcal{S}_k}^{-1}\mathbf{C}_{\mathcal{S}_k\bullet})\mathbf{C}^{-1}(\mathbf{C}-\mathbf{C}_{\bullet\mathcal{S}_k}\mathbf{C}_{\mathcal{S}_k,\mathcal{S}_k}^{-1}\mathbf{C}_{\mathcal{S}_k\bullet}) = \mathbf{C}-\mathbf{C}_{\bullet\mathcal{S}_k}\mathbf{C}_{\mathcal{S}_k,\mathcal{S}_k}^{-1}\mathbf{C}_{\mathcal{S}_k\bullet},$$

which implies that

$$\begin{aligned} & n^{-1/2}\mathbf{X}^T\mathbf{P}_\tau^T\mathbf{H}_k^T(\mathbf{I}-\mathbf{P}_\tau)^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\mathbf{X} \\ = \;& n^{-1}\mathbf{X}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\mathbf{X} - 2n^{-1}\mathbf{X}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau\mathbf{X} + n^{-1}\mathbf{X}^T\mathbf{P}_\tau\mathbf{H}_k\mathbf{P}_\tau^2\mathbf{H}_k\mathbf{P}_\tau\mathbf{X} \to \mathbf{0}. \end{aligned}$$

Since $\mathrm{Var}(\boldsymbol{\xi}_{-k}\boldsymbol{\gamma}_k)$ is proportional to an identity matrix, the above result leads to that

$$\mathrm{Var}\left(n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k}\right)\to\mathbf{0},$$

which implies that

$$n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\mathbf{X}\boldsymbol{\pi}_{-k}\to_p\mathbf{0}. \tag{15}$$

Similarly, we can prove that, for each $\boldsymbol{\xi}_j$,

$$\mathrm{Var}\left(n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\pi}_{-k}^T\mathbf{X}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_j\right)\to\mathbf{0},$$

which implies that

$$n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\pi}_{-k}^T\mathbf{X}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k}\to_p\mathbf{0}. \tag{16}$$

Note that

$$n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k} = \left\{n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{X}\right\}\left\{(\mathbf{X}^T\mathbf{X}+\tau\mathbf{I})^{-1}\mathbf{X}^T\boldsymbol{\xi}_{-k}\right\}.$$

Since

$$n^{-1}\mathbf{X}^T\mathbf{H}_k(\mathbf{I}-\mathbf{P}_\tau)(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{X}\to\mathbf{0},$$

we have

$$\mathrm{Var}\left(n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{X}\right)\to\mathbf{0}.$$

Therefore,

$$n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{X}\to_p\mathbf{0},$$

which, together with $(\mathbf{X}^T\mathbf{X}+\tau\mathbf{I})^{-1}\mathbf{X}^T\boldsymbol{\xi}_{-k}\to_p\mathbf{0}$, leads to that

$$n^{-1/2}\boldsymbol{\gamma}_k^T\boldsymbol{\xi}_{-k}^T(\mathbf{I}-\mathbf{P}_\tau)\mathbf{H}_k\mathbf{P}_\tau\boldsymbol{\xi}_{-k}\to_p\mathbf{0}. \tag{17}$$

Pooling (14), (15), (16) and (17), we have proved that $n^{-1/2}\boldsymbol{\gamma}_k^T\{(\mathbf{I}-\mathbf{P}_\tau)\mathbf{Y}_{-k}\}^T\mathbf{H}_k\mathbf{P}_\tau\mathbf{Y}_{-k}\to_p\mathbf{0}$, which concludes the proof.

Appendix B: Proof of Theorem 5.3

Let $\psi_n(\boldsymbol{\mu}) = \|\mathbf{H}_k\mathbf{Y}_k-\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\boldsymbol{\gamma}_k+\boldsymbol{\mu}/\sqrt{n})\|_2^2+\lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k+\boldsymbol{\mu}/\sqrt{n}|$. Let $\hat{\boldsymbol{\mu}} = \arg\min_{\boldsymbol{\mu}}\psi_n(\boldsymbol{\mu})$, then $\hat{\boldsymbol{\gamma}}_k = \boldsymbol{\gamma}_k+\hat{\boldsymbol{\mu}}/\sqrt{n}$ or $\hat{\boldsymbol{\mu}} = \sqrt{n}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k)$. Note that $\psi_n(\boldsymbol{\mu})-\psi_n(\mathbf{0}) = V_n(\boldsymbol{\mu})$, where

$$\begin{aligned} V_n(\boldsymbol{\mu}) \;=\; & \boldsymbol{\mu}^T(n^{-1}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k})\boldsymbol{\mu} - 2n^{-1/2}(\mathbf{Y}_k-\hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k)^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\boldsymbol{\mu} \\ & + n^{-1/2}\lambda_k\boldsymbol{\omega}_k^T\times\sqrt{n}(|\boldsymbol{\gamma}_k+n^{-1/2}\boldsymbol{\mu}|-|\boldsymbol{\gamma}_k|). \end{aligned}$$

Denote the j-th elements of $\boldsymbol{\omega}_k$ and $\boldsymbol{\mu}$ as ω_{kj} and μ_j, respectively.

If $\gamma_{kj}\neq 0$, then $\omega_{kj}\to_p|\gamma_{kj}|^{-\delta}$ and $\sqrt{n}(|\gamma_{kj}+\mu_j/\sqrt{n}|-|\gamma_{kj}|)\to_p\mu_j\mathrm{sign}(\gamma_{kj})$. By Slutsky's theorem, we have $(\lambda_k/\sqrt{n})\omega_{kj}\sqrt{n}(|\gamma_{kj}+\mu_j/\sqrt{n}|-|\gamma_{kj}|)\to_p 0$. If $\gamma_{kj}=0$, then $\sqrt{n}(|\gamma_{kj}+\mu_j/\sqrt{n}|-|\gamma_{kj}|) = |\mu_j|$ and $(\lambda_k/\sqrt{n})\omega_{kj} = (\lambda_k/\sqrt{n})n^{\delta/2}(|\sqrt{n}\tilde{\gamma}_{kj}|)^{-\delta}$, where $\sqrt{n}\tilde{\gamma}_{kj} = O_p(1)$. Thus,

$$n^{-1/2}\lambda_k\boldsymbol{\omega}_k^T\times n^{1/2}(|\boldsymbol{\gamma}_k+n^{-1/2}\boldsymbol{\mu}|-|\boldsymbol{\gamma}_k|)\to_p\begin{cases}0, & \text{if } \|\boldsymbol{\mu}_{\mathcal{A}_k^c}\|_2=0;\\ \infty, & \text{otherwise.}\end{cases}$$

Hence, following Theorem 5.2 and Slutsky's theorem, we see that $V_n(\boldsymbol{\mu})\to_d V(\boldsymbol{\mu})$ for every $\boldsymbol{\mu}$, where

$$V(\boldsymbol{\mu}) = \begin{cases}\boldsymbol{\mu}_{\mathcal{A}_k}^T\mathbf{M}_{k,\mathcal{A}_k}\boldsymbol{\mu}_{\mathcal{A}_k}-2\boldsymbol{\mu}_{\mathcal{A}_k}^T\mathbf{W}_{k,\mathcal{A}_k}, & \text{if } \|\boldsymbol{\mu}_{\mathcal{A}_k^c}\|_2=0;\\ \infty, & \text{otherwise.}\end{cases}$$

$V_n(\boldsymbol{\mu})$ is convex, and the unique minimizer of $V(\boldsymbol{\mu})$ is $(\mathbf{M}_{k,\mathcal{A}_k}^{-1}\mathbf{W}_{k,\mathcal{A}_k},\mathbf{0})^T$. Following the epi-convergence results of Geyer (1994) and Fu and Knight (2000), we have

$$\begin{cases}\hat{\boldsymbol{\mu}}_{\mathcal{A}_k}\to_d\mathbf{M}_{k,\mathcal{A}_k}^{-1}\mathbf{W}_{k,\mathcal{A}_k},\\ \hat{\boldsymbol{\mu}}_{\mathcal{A}_k^c}\to_d\mathbf{0}.\end{cases}$$

Since $\mathbf{W}_{k,\mathcal{A}_k}\sim N(\mathbf{0},\sigma_k^2\mathbf{M}_{k,\mathcal{A}_k})$, we indeed have proved the asymptotic normality.

Now we show the consistency in variable selection. $\forall j\in\mathcal{A}_k$, the asymptotic normality indicates that $\hat{\gamma}_{kj}\to_p\gamma_{kj}$, thus $P(j\in\hat{\mathcal{A}}_k)\to 1$. Then it suffices to show that $\forall j\notin\mathcal{A}_k$, $P(j\in\hat{\mathcal{A}}_k)\to 0$.

When $j \in \hat{\mathcal{A}}_k$, by the KKT normality conditions, we know that $\hat{\mathbf{Z}}_j^T \mathbf{H}_k(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\hat{\gamma}_k) = \lambda_k \omega_{kj}$. Note that $\lambda_k \omega_{kj}/\sqrt{n} \to_p \infty$, whereas $\hat{\mathbf{Z}}_j^T \mathbf{H}_k(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\hat{\gamma}_k)/\sqrt{n} = (\hat{\mathbf{Z}}_j^T \mathbf{H}_k \hat{\mathbf{Z}}_{-k}/n) \times \sqrt{n}(\gamma_k - \hat{\gamma}_k) + \hat{\mathbf{Z}}_j^T \mathbf{H}_k(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\gamma_k)/\sqrt{n}$. Following Theorem 5.2 and the asymptotic normality, $\hat{\mathbf{Z}}_j^T \mathbf{H}_k(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\hat{\gamma}_k)/\sqrt{n}$ asymptotically follows a normal distribution. Thus, $P(j \in \hat{\mathcal{A}}_k) \le P(\hat{\mathbf{Z}}_j^T \mathbf{H}_k(\mathbf{Y}_k - \hat{\mathbf{Z}}_{-k}\hat{\gamma}_k) = \lambda_k \omega_{kj}) \to 0$. Then we have proved the consistency in variable selection.

Appendix C: Proof of Theorem 5.4

Denote $\lambda_{min}(\mathbf{M})$ and $\lambda_{max}(\mathbf{M})$ the minimum and maximum eigenvalues of matrix $\mathbf{M}$, respectively. Follow Assumption B′ to assume that the singular values of matrix $\mathbf{I} - \mathbf{\Gamma}$ are positively bounded from below by a constant c. Further denote $\tilde{\sigma}_k^2 = \mathrm{var}(\boldsymbol{\xi}_k)$, and $\sigma_{p\max}^2 = \max_{1 \le k \le p}(\sigma_k^2)$. Noting that $\boldsymbol{\xi} = \boldsymbol{\epsilon}(\mathbf{I} - \mathbf{\Gamma})^{-1}$, we have $\tilde{\sigma}_k^2 \le \sigma_{p\max}^2/c$.

(a) From the ridge regression, we have the following closed form solution,

$$\hat{\boldsymbol{\pi}}_k = (\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-1}\mathbf{X}^T\mathbf{Y}_k = (\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-1}\mathbf{X}^T\mathbf{X}\boldsymbol{\pi}_k + (\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-1}\mathbf{X}^T\boldsymbol{\xi}_k.$$

Note that

$$\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k = -\tau_k(\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-1}\boldsymbol{\pi}_k + (\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-1}\mathbf{X}^T\boldsymbol{\xi}_k = \boldsymbol{\mu} + A_k^T\boldsymbol{\xi}_k,$$

where $\boldsymbol{\mu} = -\tau_k(\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-1}$ and $A_k = \mathbf{X}(\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-1}$. Then we have

$$\|\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k\|_2^2 = \underbrace{\boldsymbol{\mu}^T\boldsymbol{\mu}}_{T_1} + \underbrace{2\boldsymbol{\mu}^T A_k^T\boldsymbol{\xi}_k}_{T_2} + \underbrace{\boldsymbol{\xi}_k^T A_k A_k^T\boldsymbol{\xi}_k}_{T_3}. \tag{18}$$

Via the singular value decomposition of $\mathbf{X}$, we can have the decomposition $\mathbf{X}^T\mathbf{X} = \mathbf{P}^T\mathbf{U}\mathbf{P}$, where $\mathbf{P}$ is a unitary matrix and matrix $\mathbf{U}$ is a diagonal matrix with non-negative diagonal elements u_i. Therefore,

$$(\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-2} = \mathbf{P}^T(\mathbf{U} + \tau_k I_q)^{-2}\mathbf{P}.$$

Following Assumption B′, we have $\lambda_{min}(\mathbf{X}^T\mathbf{X}) > c_2^2 n$ and $\lambda_{max}(\mathbf{X}^T\mathbf{X}) < c_1^2 n$, which implies that $u_i \asymp n$ for all i. Therefore,

$$T_1 = \tau_k^2\boldsymbol{\pi}_k^T\mathbf{P}^T(\mathbf{U} + \tau_k I_q)^{-2}\mathbf{P}\boldsymbol{\pi}_k = \sum_{i=1}^{q}\frac{\tau_k^2 a_{ik}^2}{(u_i + \tau_k)^2} = \mathcal{O}(\tau_k^2\|\boldsymbol{\pi}_k\|_2^2/n^2) = \mathcal{O}(r_{nk}/n), \tag{19}$$

where a_{ik} is the i-th element of $\mathbf{a}_k = \mathbf{P}\boldsymbol{\pi}_k$ with $\|\mathbf{a}_k\|_2 = \|\boldsymbol{\pi}_k\|_2$.

For the term T_2, we have that

$$E[T_2] = 0, \qquad \mathrm{Var}(T_2) = 4\tilde{\sigma}_k^2\boldsymbol{\mu}^T A_k^T A_k\boldsymbol{\mu}.$$

By the classical Gaussian tail probability, we have

$$\mathbb{P}(T_2 \le t) \ge 1 - \exp\left\{-t^2/\left(8\tilde{\sigma}_k^2\boldsymbol{\mu}^T A_k^T A_k\boldsymbol{\mu}\right)\right\}.$$

Note that,

$$\boldsymbol{\mu}^T A_k^T A_k\boldsymbol{\mu} = \tau_k^2\boldsymbol{\pi}_k^T\mathbf{P}^T(\mathbf{U} + \tau_k I_q)^{-2}\mathbf{U}(\mathbf{U} + \tau_k I_q)^{-2}\mathbf{P}\boldsymbol{\pi}_k = \sum_{i=1}^{q}\frac{\tau_k^2 u_i a_{ik}^2}{(u_i + \tau_k)^4} = \mathcal{O}(\tau_k^2\|\boldsymbol{\pi}_k\|_2^2/n^3).$$

Letting $t = \sqrt{8\tilde{\sigma}_k^2\boldsymbol{\mu}^T A_k^T A_k\boldsymbol{\mu}(f_n + \log 2)}$, we have, with probability at least $1 - e^{-f_n}/2$,

$$T_2 = \mathcal{O}(\sqrt{r_{nk} f_n}/n). \tag{20}$$

For the term T_3, we can invoke the Hanson-Wright inequality (Rudelson and Vershynin, 2013) to have, for some constant $t_1 > 0$,

$$P(T_3 \le E[T_3] + t) \ge 1 - \exp\left\{-t_1\min\left(\frac{t^2}{\tilde{\sigma}_k^4\left\|A_k A_k^T\right\|_F^2}, \frac{t}{\tilde{\sigma}_k^2\left\|A_k A_k^T\right\|_{op}}\right)\right\},$$

where $\|\cdot\|_{op} = \max_{x \ne 0}\|\cdot x\|_2/\|x\|_2$ is the operator norm and $\|\cdot\|_F$ is the Frobenius norm.

Since

$$A_k A_k^T = \mathbf{X}(\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-2}\mathbf{X}^T = \mathbf{X}\mathbf{P}^T(\mathbf{U} + \tau_k I_q)^{-2}\mathbf{P}\mathbf{X}^T,$$

we have

$$\begin{aligned}
E[T_3] &= \tilde{\sigma}_k^2\mathrm{trace}(A_k A_k^T) = \tilde{\sigma}_k^2\mathrm{trace}(\mathbf{X}^T\mathbf{X}(\mathbf{X}^T\mathbf{X} + \tau_k I_q)^{-2}) \\
&= \tilde{\sigma}_k^2\mathrm{trace}(\mathbf{U}(\mathbf{U} + \tau_k I_q)^{-2}) = \sum_{i=1}^{q}\frac{\tilde{\sigma}_k^2 u_i}{(u_i + \tau_k)^2} = \mathcal{O}(\tilde{\sigma}_k^2 q/n), \\
\left\|A_k A_k^T\right\|_F^2 &= \mathrm{trace}(A_k A_k^T A_k A_k^T) = \mathrm{trace}(A_k^T A_k A_k^T A_k) \\
&= \mathrm{trace}(P^T\mathbf{U}(\mathbf{U} + \tau_k I_q)^{-2}U(U + \tau_k I_q)^{-2}) = \sum_{i=1}^{q}\frac{u_i^2}{(u_i + \tau_k)^4} = \mathcal{O}(q/n^2), \\
\left\|A_k A_k^T\right\|_{op} &= \mathcal{O}(\lambda_{max}\left(\mathbf{X}\mathbf{X}^T\right)/n^2) = \mathcal{O}(n^{-1}).
\end{aligned}$$

Letting $t = \max\left(\sqrt{\tilde{\sigma}_k^4\left\|A_k A_k^T\right\|_F^2(f_n + \log 2)/t_1}, \tilde{\sigma}_k^2\left\|A_k A_k^T\right\|_{op}(f_n + \log 2)/t_1\right)$, we obtain that, with probablity at least $1 - e^{-f_n}/2$,

$$T_3 = \mathcal{O}(q/n) + \mathcal{O}(\sqrt{f_n q}/n) + \mathcal{O}(f_n/n). \tag{21}$$

Collecting the bounds in (19), (20), and (21), we conclude that there exist a positive constant C_1 such that, with probability at least $1 - e^{-f_n}$,

$$\|\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k\|_2^2 \le C_1(r_{nk} \vee q \vee f_n)/n.$$

(b) Similar to (18), we have

$$\|\mathbf{X}(\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k)\|_2^2 = \underbrace{\boldsymbol{\mu}^T\mathbf{X}^T\mathbf{X}\boldsymbol{\mu}}_{T_4} + \underbrace{2\boldsymbol{\mu}^T\mathbf{X}^T\mathbf{X}A_k^T\boldsymbol{\xi}_k}_{T_5} + \underbrace{\boldsymbol{\xi}_k^T A_k\mathbf{X}^T\mathbf{X}A_k^T\boldsymbol{\xi}_k}_{T_6}.$$

For the term T_4, we have

$$\begin{aligned} T_4 &= \tau_k^2 \mathbf{a}_k^T \mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{a}_k \\ &= \tau_k^2 \sum_{i=1}^{q} \frac{u_i a_{ik}^2}{(u_i+\tau_k)^2} = \mathcal{O}(\tau_k^2 \left\|\boldsymbol{\pi}_k\right\|_2^2/n) = \mathcal{O}(r_{nk}). \end{aligned} \tag{22}$$

For the term T_5, by the classical Gaussian tail inequality, we have

$$P\left(T_5 \le t\right) \ge 1 - \exp\left\{-t^2/(2\mathrm{Var}(T_5))\right\},$$

where

$$\begin{aligned} \mathrm{Var}(T_5) &= 4\tilde{\sigma}_k^2 \boldsymbol{\mu}^T \mathbf{X}^T \mathbf{X} A_k^T A_k \mathbf{X}^T \mathbf{X}\boldsymbol{\mu} \\ &= 4\tilde{\sigma}_k^2 \tau_k^2 \mathbf{a}_k^T (\mathbf{U}+\tau_k I_q)^{-1}\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{a}_k \\ &= 4\tilde{\sigma}_k^2 \tau_k^2 \sum_{i=1}^{q} \frac{u_i^3 a_{ik}^2}{(u_i+\tau_k)^4} = \mathcal{O}(\tilde{\sigma}_k^2 \tau_k^2 \left\|\boldsymbol{\pi}_k\right\|_2^2/n). \end{aligned}$$

Taking $t = \sqrt{2\mathrm{Var}(T_5)(f_n + \log 2)}$, we can obtain that, with probability at least $1 - e^{-f_n}/2$,

$$T_5 = \mathcal{O}(\sqrt{r_{nk} f_n}). \tag{23}$$

For the term T_6, by the Hanson-Wright inequality, we have, for some constant $t_2 > 0$,

$$P(T_6 \le \mathbb{E}(T_6) + t) \ge 1 - \exp\left\{-t_2 \min\left(\frac{t^2}{\tilde{\sigma}_k^4 \left\|A_k \mathbf{X}^T \mathbf{X} A_k^T\right\|_F^2}, \frac{t}{\tilde{\sigma}_k^2 \left\|A_k \mathbf{X}^T \mathbf{X} A_k^T\right\|_{op}}\right)\right\}.$$

Similar to managing the term T_3 in (a), we have

$$\begin{aligned} E[T_6] &= \tilde{\sigma}_k^2 \mathrm{trace}(A_k \mathbf{X}^T \mathbf{X} A_k^T) = \tilde{\sigma}_k^2 \mathrm{trace}(U(U+\tau_k I_q)^{-1} U (U+\tau_k I_q)^{-1}) \\ &= \tilde{\sigma}_k^2 \sum_{i=1}^{q} \frac{u_i^2}{(u_i+\tau_k)^2} = \mathcal{O}(\tilde{\sigma}_k^2 q), \\ \left\|A_k \mathbf{X}^T \mathbf{X} A_k^T\right\|_F^2 &= \mathrm{trace}(A_k \mathbf{X}^T \mathbf{X} A_k^T A_k \mathbf{X}^T \mathbf{X} A_k^T) = \mathrm{trace}(\mathbf{X}^T \mathbf{X} A_k^T A_k \mathbf{X}^T \mathbf{X} A_k^T A_k) \\ &= \mathrm{trace}(\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}\mathbf{U}(\mathbf{U}+\tau_k I_q)^{-1}) \\ &= \sum_{i=1}^{q} \frac{u_i^4}{(u_i+\tau_k)^4} = \mathcal{O}(q), \\ \left\|A_k \mathbf{X}^T \mathbf{X} A_k^T\right\|_{op} &= \left\|\mathbf{X}(\mathbf{X}^T\mathbf{X}+\tau_k I_q)^{-1}\mathbf{X}^T\mathbf{X}(\mathbf{X}^T\mathbf{X}+\tau_k I_q)^{-1}\mathbf{X}^T\right\|_{op} \\ &= \mathcal{O}(\lambda_{\max}\left(\mathbf{X}\mathbf{X}^T\mathbf{X}\mathbf{X}^T\right)/n^2) = \mathcal{O}(1). \end{aligned}$$

Letting $t = \max\left(\sqrt{\tilde{\sigma}_k^4 \left\|A_k \mathbf{X}^T \mathbf{X} A_k^T\right\|_F^2 (f_n + \log 2)/t_2}, \tilde{\sigma}_k^2 \left\|A_k \mathbf{X}^T \mathbf{X} A_k^T\right\|_{op} (f_n + \log 2)/t_2\right)$, we have that, with probability at least $1 - e^{-f_n}/2$,

$$T_6 = \mathcal{O}(q) + \mathcal{O}(\sqrt{q f_n}) + \mathcal{O}(f_n). \tag{24}$$

Collecting the bounds in (22), (23), and (24), we conclude that there exists a positive constant C_2 such that, with probability at least $1 - e^{-f_n}$,

$$n^{-1} \left\|\mathbf{X}(\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k)\right\|_2^2 \le C_2(r_{nk} \vee q \vee f_n)/n.$$

Appendix D: Proof of Theorem 5.5

Let

$$g_n = C_2\left(r_{\max} \vee q \vee f_n\right)/n + 2c_1 C_2 \left\|\boldsymbol{\pi}\right\|_1 \sqrt{\left(r_{\max} \vee q \vee f_n\right)/n}.$$

We will first prove some lemmas, and then proceed to prove Theorem 5.5.

Lemma 1 *Suppose that there exists a positive constant ϕ_0 such that $\phi_k(\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_{-k}) \ge \phi_0$ for all k. If*

$$\sqrt{(r_{max} \vee q \vee f_n)/n} + c_1 \left\|\boldsymbol{\pi}\right\|_1 \le \sqrt{c_1^2 \left\|\boldsymbol{\pi}\right\|_1^2 + \phi_0^2/(64 C_2 |\mathcal{A}_k|)} \tag{25}$$

then, with probability at least $1 - e^{-(f_n - \log p)}$, we have $\phi_k(\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_{-k}) \ge \phi_0/2$.

Proof Note that the inequality (25) implies that $g_n \le \frac{\phi_0^2}{64|\mathcal{A}_k|}$. Then, for any index i and j, we first investigate the bound of

$$\begin{aligned} &(\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_i)^T (\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_j) - (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_i)^T (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_j) \\ &= \underbrace{(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)^T \mathbf{X}^T \mathbf{H}_k \mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)}_{T_7} + \underbrace{(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)^T \mathbf{X}^T \mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_j}_{T_8} + \underbrace{(\mathbf{X}\boldsymbol{\pi}_i)^T \mathbf{H}_k \mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)}_{T_9}. \end{aligned}$$

Note that $\lambda_{max}(\mathbf{H}_k) = 1$. By Theorem 5.4, we have, with probability at least $1 - e^{-f_n}$,

$$\begin{aligned} |T_7| &\le \left\|\mathbf{H}_k \mathbf{X}(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)\right\|_2 \times \left\|\mathbf{H}_k \mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)\right\|_2 \\ &\le \lambda_{max}(\mathbf{H}_k) \times \left\|\mathbf{X}(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)\right\|_2 \times \left\|\mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)\right\|_2 \le C_2\left(r_{\max} \vee q \vee f_n\right). \end{aligned} \tag{26}$$

Following that $\left\|\mathbf{X}\boldsymbol{\pi}_j\right\|_2 \le c_1\sqrt{n}\left\|\boldsymbol{\pi}_j\right\|_2$, we have,

$$\begin{aligned} |T_8| &\le \left\|\mathbf{X}\boldsymbol{\pi}_j\right\|_2 \times \left\|\mathbf{H}_k \mathbf{X}(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)\right\|_2 \le c_1\sqrt{n}\left\|\boldsymbol{\pi}_j\right\|_2 \times \left\|\mathbf{X}(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)\right\|_2 \\ &\le c_1 C_2 \left\|\boldsymbol{\pi}\right\|_1 \sqrt{n\left(r_{\max} \vee q \vee f_n\right)}. \end{aligned} \tag{27}$$

Similarly, we have,

$$|T_9| \le c_1\sqrt{n}\left\|\boldsymbol{\pi}_i\right\|_2 \left\|\mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)\right\|_2 \le c_1 C_2 \left\|\boldsymbol{\pi}\right\|_1 \sqrt{n\left(r_{\max} \vee q \vee f_n\right)}. \tag{28}$$

Putting together the bounds in (26), (27), and (28), we have, with probability at least $1 - e^{-f_n}$,

$$|(\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_i)^T (\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_j) - (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_i)^T (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_j)| \le n g_n. \tag{29}$$

By definition, for any set $\mathcal{A}_k$ and any β, we have

$$\left\|\beta\right\|_1^2 \le \left(\left\|\beta_{\mathcal{A}_k^c}\right\|_1 + \left\|\beta_{\mathcal{A}_k}\right\|_1\right)^2 \le \left(3\sqrt{|\mathcal{A}_k|}\left\|\beta_{\mathcal{A}_k}\right\|_2 + \sqrt{|\mathcal{A}_k|}\left\|\beta_{\mathcal{A}_k}\right\|_2\right)^2 = 16|\mathcal{A}_k|\left\|\beta_{\mathcal{A}_k}\right\|_2^2.$$

We then have, with probability at least $1 - pe^{-f_n}$,

$$\begin{aligned} &|\beta^T((\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_{-k})^T (\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_{-k}) - (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_{-k})^T (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_{-k}))\beta| / (n\left\|\beta_{\mathcal{A}_k}\right\|_2^2) \\ &\le \left\|\beta\right\|_1^2 \left\|\beta_{\mathcal{A}_k}\right\|_2^{-2} \max_{i,j} |(\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_i)^T (\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_j) - (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_i)^T (\mathbf{H}_k \mathbf{X}\boldsymbol{\pi}_j)|/n \\ &\le 16|\mathcal{A}_k| \times g_n \le 16|\mathcal{A}_k| \times \phi_0^2/\left(64|\mathcal{A}_k|\right) = \phi_0^2/4, \end{aligned}$$

which implies that $\phi_k(\mathbf{H}_k \mathbf{X}\hat{\boldsymbol{\pi}}_{-k}) \ge \phi_0/2$. ■

Lemma 2 *(Basic Inequality) Let random vector* $\boldsymbol{J}_k = 2n^{-1}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k\boldsymbol{\epsilon}_k - 2n^{-1}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k(\hat{\mathbf{Z}}_{-k} - \mathbf{Y}_{-k})\boldsymbol{\gamma}_k$ *and* $W_k^{-1} = diag(\boldsymbol{w}_k^{-1})$*, then, for the event*

$$\mathcal{J}_k(\lambda_k) = \left\{ \left\| W_k^{-1}\boldsymbol{J}_k \right\|_\infty \le \lambda_k/n \right\},$$

there exists a constant $C_3 > 0$ *such that*

$$P(\mathcal{J}_k(\lambda_k)) \ge 1 - e^{-C_3 h_n + \log(4pq)} - e^{-f_n + \log(p)}.$$

Furthermore, concurring with the random vector $\boldsymbol{J}_k$*, we have the following basic inequality,*

$$n^{-1}\left\| \mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k - \boldsymbol{\gamma}_k) \right\|_2^2 + 2n^{-1}\lambda_k\boldsymbol{\omega}_k^T|\hat{\boldsymbol{\gamma}}_k| \le 2n^{-1}\lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k| + \boldsymbol{J}_k^T|\hat{\boldsymbol{\gamma}}_k - \boldsymbol{\gamma}_k|. \tag{30}$$

Proof With $\mathbf{Y}_{-k} = \mathbf{X}\boldsymbol{\pi}_{-k} + \boldsymbol{\xi}_{-k}$ and $\hat{\mathbf{Z}}_{-k} = \mathbf{X}\hat{\boldsymbol{\pi}}_{-k}$, we have

$$\begin{aligned}
\boldsymbol{J}_k &= 2n^{-1}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k\boldsymbol{\epsilon}_k - 2n^{-1}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k(\hat{\mathbf{Z}}_{-k} - \mathbf{Y}_{-k})\boldsymbol{\gamma}_k \\
&= 2n^{-1}\hat{\boldsymbol{\pi}}_{-k}^T\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k - \frac{2}{n}\hat{\boldsymbol{\pi}}_{-k}^T\mathbf{X}^T\mathbf{H}_k(\mathbf{X}\hat{\boldsymbol{\pi}}_{-k} - \mathbf{X}\boldsymbol{\pi}_{-k} - \boldsymbol{\xi}_{-k})\boldsymbol{\gamma}_k \\
&= \underbrace{2n^{-1}(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})^T\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k}_{T_{10}} + \underbrace{2n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k}_{T_{11}} + \underbrace{2n^{-1}(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})^T\mathbf{X}^T\mathbf{H}_k\boldsymbol{\xi}_{-k}\boldsymbol{\gamma}_k}_{T_{12}} \\
&\quad + \underbrace{2n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{H}_k\boldsymbol{\xi}_{-k}\boldsymbol{\gamma}_k}_{T_{13}} \underbrace{-2n^{-1}(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})^T\mathbf{X}^T\mathbf{H}_k\mathbf{X}(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})\boldsymbol{\gamma}_k}_{T_{14}} \\
&\quad \underbrace{-2n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{H}_k\mathbf{X}(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})\boldsymbol{\gamma}_k}_{T_{15}}.
\end{aligned}$$

Denote $\mathbf{X} = (X_{\cdot 1}, X_{\cdot 2}, \ldots, X_{\cdot q})$, then $X_{\cdot j}^T X_{\cdot j} = n$ due to standardization. With $\sigma_{pmax}^2 = \max_{1\le k\le p}\sigma_k^2$, we have $\mathrm{Var}(X_{\cdot j}^T\mathbf{H}_k\boldsymbol{\epsilon}_k) = X_{\cdot j}^T\mathbf{H}_k X_{\cdot j}\sigma_k^2 \le n\sigma_k^2 \le n\sigma_{pmax}^2$. Further let, for some constant $t_\lambda > 0$,

$$\lambda_k = t_\lambda\|\omega_k\|_{-\infty}^{-1}\|\boldsymbol{\Gamma}\|_1\|\boldsymbol{\pi}\|_1\sqrt{n(r_{\max}\vee q\vee f_n)\log p}.$$

By the Gaussian tail inequality, we have

$$\begin{aligned}
P\left(\left\|W_k^{-1}T_{10}\right\|_\infty \ge \lambda_k/(6n)\right) &\le P\left(\|T_{10}\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&= P\left(\left\|2n^{-1}(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})^T\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k\right\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&\le P\left(\left\|(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})^T\right\|_\infty \times \left\|2n^{-1}\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k\right\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&\le P\left(\left\|2n^{-1}\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k\right\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n\delta_\pi)\right) \\
&\le q\exp\left\{-\lambda_k^2\|\omega_k\|_{-\infty}^2/(288n\sigma_{pmax}^2\delta_\pi^2)\right\} = q\cdot p^{-\frac{n}{q}t_3\|\Gamma\|_1^2\|\pi\|_1^2},
\end{aligned}$$

where $t_3 = t_\lambda^2/\left(288C_1\sigma_{pmax}^2\right)$ and

$$\delta_\pi = \max_k\|\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k\|_1 \le \max_k\sqrt{q}\,\|\hat{\boldsymbol{\pi}}_k - \boldsymbol{\pi}_k\|_2 = \sqrt{C_1 q(r_{\max}\vee q\vee f_n)/n}.$$

Similarly, letting $t_4 = t_\lambda/\left(288\sigma_{pmax}^2\right)$, we have

$$\begin{aligned}
P\left(\left\|W_k^{-1}T_{11}\right\|_\infty \ge \lambda_k/(6n)\right) &\le P\left(\|T_{11}\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&= P\left(\left\|2n^{-1}\boldsymbol{\pi}_{-k}^T\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k\right\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&\le \mathbb{P}\left(\left\|\boldsymbol{\pi}_{-k}^T\right\|_\infty\left\|2n^{-1}\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k\right\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&\le P\left(\left\|2n^{-1}\mathbf{X}^T\mathbf{H}_k\boldsymbol{\epsilon}_k\right\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}\left\|\boldsymbol{\pi}_{-k}^T\right\|_\infty^{-1}/(6n)\right) \\
&\le q\exp\left\{-\lambda_k^2\|\omega_k\|_{-\infty}^2\left\|\boldsymbol{\pi}_{-k}^T\right\|_\infty^{-2}/(288n\sigma_{pmax}^2)\right\} \\
&= q\cdot p^{-t_4\|\Gamma\|_1^2(r_{\max}\vee q\vee f_n)}.
\end{aligned}$$

Let $\tilde{\sigma}_{pmax}^2 = \max_k\mathrm{Var}(\boldsymbol{\xi}_k)$ and $t_5 = t_\lambda/\left(288C_1\tilde{\sigma}_{pmax}^2\right)$. For the term T_{12}, we have

$$\begin{aligned}
P\left(\left\|W_k^{-1}T_{12}\right\|_\infty \ge \lambda_k/(6n)\right) &\le P\left(\|T_{12}\|_\infty \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&\le P\left(\left\|(\hat{\boldsymbol{\pi}}_{-k} - \boldsymbol{\pi}_{-k})^T\right\|_\infty\left\|2n^{-1}\mathbf{X}^T\mathbf{H}_k\boldsymbol{\xi}_{-k}\boldsymbol{\gamma}_k\right\|_1 \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&\le P\left(\delta_\pi\max_{i,j}\left|2n^{-1}\mathbf{x}_i^T\mathbf{H}_k\boldsymbol{\xi}_j\right|\|\boldsymbol{\gamma}_k\|_1 \ge \lambda_k\|\omega_k\|_{-\infty}/(6n)\right) \\
&\le P\left(\max_{i,j}\left|2n^{-1}\mathbf{x}_i^T\mathbf{H}_k\boldsymbol{\xi}_j\right| \ge \lambda_k\|\omega_k\|_{-\infty}\|\boldsymbol{\gamma}_k\|_1^{-1}/(6n\delta_\pi)\right) \\
&\le qp\exp\left\{-\lambda_k^2\|\omega_k\|_{-\infty}^2\tilde{\sigma}_{pmax}^{-2}\delta_\pi^{-2}\|\boldsymbol{\gamma}_k\|_1^{-2}/(288n)\right\} = qp^{1-t_5\|\pi\|_1^2 n/q}.
\end{aligned}$$

Letting $t_6 = t_\lambda/\left(288\tilde{\sigma}_{pmax}^2\right)$, we similarly have

$$\begin{aligned}
&P\left(\left\|W_k^{-1}T_{13}\right\|_\infty \ge \lambda_k/(6n)\right) \\
&\le qp\exp\left\{-\lambda_k^2\tilde{\sigma}_{pmax}^{-2}\left\|\boldsymbol{\pi}_{-k}^T\right\|_\infty^{-2}\|\boldsymbol{\gamma}_k\|_1^{-2}/(288n)\right\} = qp^{1-t_6(r_{max}\vee q\vee f_n)}.
\end{aligned}$$

When t_λ is sufficiently large, say $t_\lambda \ge 6C_2\|\boldsymbol{\pi}\|_1^{-1}\sqrt{(r_{max}\vee q\vee f_n)/(n\log p)}$, we have

$$\begin{aligned}
\left\|W_k^{-1}T_{14}\right\|_\infty &\le n^{-1}\|\omega_k\|_{-\infty}^{-1}\|\boldsymbol{\gamma}_k\|_1\max_{i,j}|(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)^T\mathbf{X}^T\mathbf{H}_k\mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)| \\
&\le n^{-1}\|\omega_k\|_{-\infty}^{-1}\|\boldsymbol{\gamma}_k\|_1\max_{i,j}\|\mathbf{H}_k\mathbf{X}(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)\|_2\|\mathbf{H}_k\mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)\|_2 \\
&\le n^{-1}\|\omega_k\|_{-\infty}^{-1}\|\boldsymbol{\gamma}_k\|_1\max_{i,j}\lambda_{\max}(\mathbf{H}_k)\|\mathbf{X}(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)\|_2\|\mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)\|_2 \\
&\le n^{-1}\|\omega_k\|_{-\infty}^{-1}\|\boldsymbol{\gamma}_k\|_1\max_{i,j}\|\mathbf{X}(\hat{\boldsymbol{\pi}}_i - \boldsymbol{\pi}_i)\|_2\|\mathbf{X}(\hat{\boldsymbol{\pi}}_j - \boldsymbol{\pi}_j)\|_2 \\
&\le C_2\|\omega_k\|_{-\infty}^{-1}\|\boldsymbol{\gamma}_k\|_1 n^{-1}(r_{\max}\vee q\vee f_n) \\
&\le \left\{\lambda_k/(6n)\right\}\times\left\{6C_2 t_\lambda^{-1}\|\boldsymbol{\pi}\|_1^{-1}\sqrt{n^{-1}(\log p)^{-1}(r_{max}\vee q\vee f_n)}\right\} \le \lambda_k/(6n).
\end{aligned}$$

Similarly, when $t_\lambda \geq 12\sqrt{C_2/\log p}$,

$$\begin{aligned}
\left\|W_k^{-1}T_{15}\right\|_\infty &\leq 2n^{-1}\left\|\gamma_k\right\|_1\left\|\boldsymbol{\pi}_{-k}^T\right\|_\infty\left\|\omega_k\right\|_{-\infty}^{-1}\max_{i,j}|X_{\cdot i}^T\mathbf{H}_k\mathbf{X}(\hat{\boldsymbol{\pi}}_j-\boldsymbol{\pi}_j)| \\
&\leq 2n^{-1/2}\left\|\gamma_k\right\|_1\left\|\boldsymbol{\pi}_{-k}^T\right\|_\infty\left\|\omega_k\right\|_{-\infty}^{-1}\max_j\left\|\mathbf{H}_k\mathbf{X}(\hat{\boldsymbol{\pi}}_j-\boldsymbol{\pi}_j)\right\|_2 \\
&\leq 2n^{-1/2}\left\|\gamma_k\right\|_1\left\|\boldsymbol{\pi}_{-k}^T\right\|_\infty\left\|\omega_k\right\|_{-\infty}^{-1}\max_j\left\|\mathbf{X}(\hat{\boldsymbol{\pi}}_j-\boldsymbol{\pi}_j)\right\|_2 \\
&\leq \left\{\lambda_k/(6n)\right\}\times\left\{12t_\lambda^{-1}\sqrt{C_2/\log p}\right\}\leq\lambda_k/(6n).
\end{aligned}$$

Putting together all the above results, we have, for some constant $C_3>0$,

$$P(\mathcal{J}_k(\lambda_k))\geq 1-e^{-C_3h_n+\log(4pq)}-e^{-f_n+\log(p)}.$$

Concurring with the random vector $\boldsymbol{J}_k$, we have the following inequality based on the optimality of $\hat{\boldsymbol{\gamma}}_k$,

$$\left\|\mathbf{H}_k\mathbf{Y}_k-\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\hat{\boldsymbol{\gamma}}_k\right\|_2+2\lambda_k\boldsymbol{\omega}_k^T|\hat{\boldsymbol{\gamma}}_k|\leq\left\|\mathbf{H}_k\mathbf{Y}_k-\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k\right\|_2+2\lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k|. \tag{31}$$

With $\mathbf{H}_k\mathbf{Y}_k=\mathbf{H}_k\mathbf{Y}_{-k}\boldsymbol{\gamma}_k+\mathbf{H}_k\boldsymbol{\epsilon}_k$, we also have

$$\begin{aligned}
&\left\|\mathbf{H}_k\mathbf{Y}_k-\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\hat{\boldsymbol{\gamma}}_k\right\|_2^2 \\
&= \left\|\mathbf{H}_k\mathbf{Y}_{-k}\boldsymbol{\gamma}_k+\mathbf{H}_k\boldsymbol{\epsilon}_k-\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\hat{\boldsymbol{\gamma}}_k\right\|_2^2 \\
&= \|\mathbf{H}_k\boldsymbol{\epsilon}_k\|_2^2-2\boldsymbol{\epsilon}_k^T\mathbf{H}_k(\hat{\mathbf{Z}}_{-k}\hat{\boldsymbol{\gamma}}_k-\mathbf{Y}_{-k}\boldsymbol{\gamma}_k)+\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\hat{\boldsymbol{\gamma}}_k-\mathbf{H}_k\mathbf{Y}_{-k}\boldsymbol{\gamma}_k\right\|_2^2 \\
&= \|\mathbf{H}_k\boldsymbol{\epsilon}_k\|_2^2-2\boldsymbol{\epsilon}_k^T\mathbf{H}_k(\hat{\mathbf{Z}}_{-k}\hat{\boldsymbol{\gamma}}_k-\mathbf{Y}_{-k}\boldsymbol{\gamma}_k)+\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k)\right\|_2^2 \\
&\quad+\left\|\mathbf{H}_k(\hat{\mathbf{Z}}_{-k}-\mathbf{Y}_{-k})\boldsymbol{\gamma}_k\right\|_2^2+2\boldsymbol{\gamma}_k^T(\hat{\mathbf{Z}}_{-k}-\mathbf{Y}_{-k})^T\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k), \qquad (32)
\end{aligned}$$

$$\begin{aligned}
&\left\|\mathbf{H}_k\mathbf{Y}_k-\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k\right\|_2^2 \\
&= \left\|\mathbf{H}_k\mathbf{Y}_{-k}\boldsymbol{\gamma}_k+\mathbf{H}_k\boldsymbol{\epsilon}_k-\mathbf{H}_k\hat{\mathbf{Z}}_{-k}\boldsymbol{\gamma}_k\right\|_2^2 \\
&= \|\mathbf{H}_k\boldsymbol{\epsilon}_k\|_2^2+\left\|\mathbf{H}_k(\hat{\mathbf{Z}}_{-k}-\mathbf{Y}_{-k})\boldsymbol{\gamma}_k\right\|_2^2-2\boldsymbol{\epsilon}_k^T\mathbf{H}_k(\hat{\mathbf{Z}}_{-k}-\mathbf{Y}_{-k})\boldsymbol{\gamma}_k. \qquad (33)
\end{aligned}$$

Combining the equations (31), (32), and (33), we obtain that

$$\begin{aligned}
&n^{-1}\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k)\right\|_2^2+2n^{-1}\lambda_k\boldsymbol{\omega}_k^T|\hat{\boldsymbol{\gamma}}_k| \\
&\leq 2n^{-1}\lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k|+\left(\frac{2}{n}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k\boldsymbol{\epsilon}_k-2n^{-1}\hat{\mathbf{Z}}_{-k}^T\mathbf{H}_k(\hat{\mathbf{Z}}_{-k}-\mathbf{Y}_{-k})\boldsymbol{\gamma}_k\right)^T(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k) \\
&= 2n^{-1}\lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k|+\boldsymbol{J}_k^T(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k),
\end{aligned}$$

which concludes the proof. ■

By the basic inequality we just proved above and condition on the event $\mathcal{J}_k(\lambda_k)$, we have that

$$\begin{aligned}
n^{-1}\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k)\right\|_2^2 &\leq 2n^{-1}\lambda_k\boldsymbol{\omega}_k^T|\boldsymbol{\gamma}_k|-2n^{-1}\lambda_k\boldsymbol{\omega}_k^T|\hat{\boldsymbol{\gamma}}_k|+\boldsymbol{J}_k^T(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k) \\
&\leq 2n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k}^T|\boldsymbol{\gamma}_{k,\mathcal{A}_k}|-2n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}|-2n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k^c}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c}| \\
&\quad+\boldsymbol{J}_{k,\mathcal{A}_k^c}^T(\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c})+\boldsymbol{J}_{k,\mathcal{A}_k}^T(\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}) \\
&\leq 2n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}|-2n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k^c}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c}| \\
&\quad+n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k^c}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c}|+n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}| \\
&\leq 3n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}|-n^{-1}\lambda_k\boldsymbol{\omega}_{k,\mathcal{A}_k^c}^T|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c}| \\
&\leq 3n^{-1}\lambda_k\|\omega_{k,\mathcal{A}_k}\|_\infty\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}\right\|_1-n^{-1}\lambda_k\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c}\right\|_1,
\end{aligned}$$

which implies that

$$n^{-1}\lambda_k\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c}\right\|_1\leq 3n^{-1}\lambda_k\|\omega_{k,\mathcal{A}_k}\|_\infty\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}\right\|_1. \tag{34}$$

Note that $\|\omega_{k,\mathcal{A}_k}\|_\infty\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}^{-1}\leq 1$, we have that

$$\begin{aligned}
&\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k^c}-\boldsymbol{\gamma}_{k,\mathcal{A}_k^c}\right\|_1 \\
&\leq 3\|\omega_{k,\mathcal{A}_k}\|_\infty\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}^{-1}\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}\right\|_1\leq 3\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}\right\|_1. \qquad (35)
\end{aligned}$$

On the other hand, following Lemma 1, we have, with $C_4=6t_\lambda$,

$$\begin{aligned}
n^{-1}\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k)\right\|_2^2 &\leq 3n^{-1}\lambda_k\|\omega_{k,\mathcal{A}_k}\|_\infty\sqrt{|\mathcal{A}_k|}\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}\right\|_2 \\
&\leq 3n^{-1}\lambda_k\|\omega_{k,\mathcal{A}_k}\|_\infty\sqrt{|\mathcal{A}_k|}\times 2n^{-1/2}\phi_0^{-1}\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k)\right\|_2 \\
&\leq 36n^{-2}\phi_0^{-2}\|\omega_{k,\mathcal{A}_k}\|_\infty^2|\mathcal{A}_k|\lambda_k^2 \\
&= C_4^2\phi_0^{-2}\|\omega_k\|_{-\infty}^{-2}\|\omega_{k,\mathcal{A}_k}\|_\infty^2\left\|\boldsymbol{\pi}\right\|_1^2\left\|\boldsymbol{\Gamma}\right\|_1^2|\mathcal{A}_k|(r_{\max}\vee q\vee f_n)\log p/n.
\end{aligned}$$

Employing the inequality (34), along with $\|\omega_{k,\mathcal{A}_k}\|_\infty\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}^{-1}\leq 1$, we have

$$\begin{aligned}
\|\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k\|_1 &\leq \left(3\|\omega_{k,\mathcal{A}_k}\|_\infty\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}^{-1}+1\right)\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}\right\|_1 \\
&\leq \left(3\|\omega_{k,\mathcal{A}_k}\|_\infty\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}^{-1}+1\right)\sqrt{|\mathcal{A}_k|}\left\|\hat{\boldsymbol{\gamma}}_{k,\mathcal{A}_k}-\boldsymbol{\gamma}_{k,\mathcal{A}_k}\right\|_2 \\
&\leq \left(6\|\omega_{k,\mathcal{A}_k}\|_\infty\|\omega_{k,\mathcal{A}_k^c}\|_{-\infty}^{-1}+2\right)\sqrt{|\mathcal{A}_k|}\times n^{-1/2}\left\|\mathbf{H}_k\hat{\mathbf{Z}}_{-k}(\hat{\boldsymbol{\gamma}}_k-\boldsymbol{\gamma}_k)\right\|_2\phi_0^{-1} \\
&\leq 8C_4\times\|\omega_{k,\mathcal{A}_k}\|_\infty\left\|\boldsymbol{\pi}\right\|_1\left\|\boldsymbol{\Gamma}\right\|_1\phi_0^{-2}\|\omega_k\|_{-\infty}^{-1} \\
&\quad\times|\mathcal{A}_k|\sqrt{(r_{\max}\vee q\vee f_n)\log p/n}.
\end{aligned}$$

Since we condition on event $\mathcal{J}_k(\lambda_k)$, the above prediction and estimation bounds hold with probability at least $1-e^{-C_3h_n+\log(4pq)}-e^{-f_n+\log(p)}$.

Appendix E: Proof of Theorem 5.6

Denote $\hat{V}_k = (\hat{v}_{ij})_{(p-1)\times(p-1)} \triangleq n^{-1}\hat{\boldsymbol{\pi}}_{-k}^T \mathbf{X}^T \mathbf{H}_k \mathbf{X} \hat{\boldsymbol{\pi}}_{-k}$, $\hat{V}_{k,21} = (\hat{v}_{ij})_{i\in\mathcal{A}_k^c, j\in\mathcal{A}_k}$, and $\hat{V}_{k,11} = (\hat{v}_{ij})_{i\in\mathcal{A}_k, j\in\mathcal{A}_k}$. The proof of Theorem 5.6 will be presented after the following lemma.

Lemma 3 *Assume that, for each node i, the following inequality holds.*

$$\begin{aligned}&\sqrt{(r_{max} \vee q \vee f_n)/n} + c_1 \|\boldsymbol{\pi}\|_1 \\ \leq\ & \sqrt{c_1^2 \|\boldsymbol{\pi}\|_1^2 + \min(\phi_0^2/64, \zeta(4-\zeta)^{-1}\|\boldsymbol{\omega}_k\|_{-\infty}/\theta_i)/(C_2|\mathcal{A}_k|)}. \end{aligned} \tag{36}$$

Under the assumptions and conditions of Theorem 5.6, we have that, with probability at least $1 - pe^{-f_n}$,

$$\left\| W_{k,\mathcal{A}_k^c}^{-1} \left(\hat{V}_{k,21} \hat{V}_{k,11}^{-1} \right) W_{k,\mathcal{A}_k} \right\|_\infty \leq 1 - \zeta/2.$$

Proof Following Theorem 5.4, we have, with probability at least $1 - pe^{-f_n}$,

$$n^{-1} \max_{i,j} \left| (\mathbf{H}_k \mathbf{X} \hat{\boldsymbol{\pi}}_i)^T (\mathbf{H}_k \mathbf{X} \hat{\boldsymbol{\pi}}_j) - (\mathbf{H}_k \mathbf{X} \boldsymbol{\pi}_i)^T (\mathbf{H}_k \mathbf{X} \boldsymbol{\pi}_j) \right| \leq g_n.$$

The inequality (36) implies that $\theta_k \|\omega_{k,\mathcal{A}_k}\|_{-\infty}^{-1} |\mathcal{A}_k| g_n \leq \zeta/(4-\zeta)$, we have

$$\left\| W_{k,\mathcal{A}_k}^{-1} (\hat{V}_{k,11} - V_{k,11}) \right\|_\infty \leq \|\omega_{k,\mathcal{A}_k}\|_{-\infty}^{-1} |\mathcal{A}_k| g_n \leq \zeta / \{(4-\zeta)\theta_k\}.$$

Similarly we have that

$$\left\| W_{k,\mathcal{A}_k^c}^{-1} (\hat{V}_{k,21} - V_{k,21}) \right\|_\infty \leq \zeta / \{(4-\zeta)\theta_k\}.$$

Applying the matrix inversion error bound in Horn and Johnson (2012), we obtain

$$\begin{aligned} &\left\| \hat{V}_{k,11}^{-1} W_{k,\mathcal{A}_k} \right\|_\infty \leq \left\| V_{k,11}^{-1} W_{k,\mathcal{A}_k} \right\|_\infty + \left\| \hat{V}_{k,11}^{-1} W_{k,\mathcal{A}_k} - V_{k,11}^{-1} W_{k,\mathcal{A}_k} \right\|_\infty \\ \leq\ & \theta_k + \theta_k \left\| W_{k,\mathcal{A}_k}^{-1} (\hat{V}_{k,11} - V_{k,11}) \right\|_\infty \left(1 - \theta_k \left\| W_{k,\mathcal{A}_k}^{-1} (\hat{V}_{k,11} - V_{k,11}) \right\|_\infty \right)^{-1} \theta_k \\ \leq\ & \theta_k (4-\zeta)/(4-2\zeta). \end{aligned}$$

Therefore,

$$\begin{aligned} &\left\| W_{k,\mathcal{A}_k^c}^{-1} \left(\hat{V}_{k,21} \hat{V}_{k,11}^{-1} - V_{k,21} V_{k,11}^{-1} \right) W_{k,\mathcal{A}_k} \right\|_\infty \\ \leq\ & \left\| W_{k,\mathcal{A}_k^c}^{-1} \left(\hat{V}_{k,21} - V_{k,21} \right) (\hat{V}_{k,11}^{-1}) W_{k,\mathcal{A}_k} \right\|_\infty \\ & + \left\| W_{k,\mathcal{A}_k^c}^{-1} V_{k,21} V_{k,11}^{-1} W_{k,\mathcal{A}_k} W_{k,\mathcal{A}_k}^{-1} \left(\hat{V}_{k,11} - V_{k,11} \right) (\hat{V}_{k,11}^{-1}) W_{k,\mathcal{A}_k} \right\|_\infty \\ \leq\ & \left\| W_{k,\mathcal{A}_k^c}^{-1} \left(\hat{V}_{k,21} - V_{k,21} \right) \right\|_\infty \left\| (\hat{V}_{k,11}^{-1}) W_{k,\mathcal{A}_k} \right\|_\infty \\ & + \left\| W_{k,\mathcal{A}_k^c}^{-1} V_{k,21} V_{k,11}^{-1} W_{k,\mathcal{A}_k} \right\|_\infty \left\| W_{k,\mathcal{A}_k}^{-1} \left(\hat{V}_{k,11} - V_{k,11} \right) \right\|_\infty \left\| (\hat{V}_{k,11}^{-1}) W_{k,\mathcal{A}_k} \right\|_\infty \\ \leq\ & \zeta/2, \end{aligned}$$

which implies that $\left\| W_{k,\mathcal{A}_k^c}^{-1} (\hat{V}_{k,21} \hat{V}_{k,11}^{-1}) W_{k,\mathcal{A}_k} \right\|_\infty \leq 1 - \zeta/2.$ ■

By the optimality of $\hat{\gamma}_k$, it must satisfy the KKT condition as follows,

$$-2n^{-1}(\mathbf{H}_k \hat{\mathbf{Z}}_{-k})^T (\mathbf{H}_k \mathbf{Y}_k - \mathbf{H}_k \hat{\mathbf{Z}}_{-k} \hat{\gamma}_k) + 2n^{-1} \lambda_k W_k \alpha_k = 0, \tag{37}$$

where $\|\alpha_k\|_\infty \leq 1$ and $\alpha_{kj} I[\hat{\gamma}_{kj} \neq 0] = sign(\hat{\gamma}_{kj})$. Plug in the equation $\mathbf{H}_k \mathbf{Y}_k = \mathbf{H}_k \mathbf{Y}_{-k} \boldsymbol{\gamma}_k + \mathbf{H}_k \epsilon_k$, we can have that

$$\begin{aligned} \mathbf{H}_k \mathbf{Y}_k - \mathbf{H}_k \hat{\mathbf{Z}}_{-k} \hat{\gamma}_k &= \mathbf{H} \mathbf{Y}_{-k} \gamma_k + \mathbf{H}_k \epsilon_k - \mathbf{H}_k \hat{\mathbf{Z}}_{-k} \hat{\gamma}_k \\ &= \mathbf{H}_k \epsilon_k + \mathbf{H}_k \mathbf{Y}_{-k} \gamma_k - -\mathbf{H}_k \hat{\mathbf{Z}}_{-k} \gamma_k + \mathbf{H}_k \hat{\mathbf{Z}}_{-k} \gamma_k - \mathbf{H}_k \hat{\mathbf{Z}}_{-k} \hat{\gamma}_k \\ &= \mathbf{H}_k \epsilon_k - \mathbf{H}_k (\hat{\mathbf{Z}}_{-k} - \mathbf{Y}_{-k}) \gamma_k - \mathbf{H}_k \hat{\mathbf{Z}}_{-k} (\hat{\gamma}_k - \gamma_k). \end{aligned} \tag{38}$$

Combining (37) and (38), we can get that

$$2\hat{V}_k (\hat{\gamma}_k - \gamma_k) - \boldsymbol{J}_k = -2\lambda_k W_k \alpha_k / n, \tag{39}$$

where $\boldsymbol{J}_k = 2n^{-1} \hat{\mathbf{Z}}_{-k}^T \mathbf{H}_k \boldsymbol{\epsilon}_k - 2n^{-1} \hat{\mathbf{Z}}_{-k}^T \mathbf{H}_k (\hat{\mathbf{Z}}_{-k} - \mathbf{Y}_{-k}) \boldsymbol{\gamma}_k$. For an estimator satisfying $\hat{\gamma}_{k,\mathcal{A}_k^c} = \gamma_{k,\mathcal{A}_k^c} = 0$, the above equation implies that

$$\begin{cases} 2\hat{V}_{k,11} (\hat{\gamma}_{k,\mathcal{A}_k} - \gamma_{k,\mathcal{A}_k}) - \boldsymbol{J}_{k,\mathcal{A}_k} = -\lambda_k W_{k,\mathcal{A}_k} \alpha_{k,\mathcal{A}_k} / n, \\ 2\hat{V}_{k,21} (\hat{\gamma}_{k,\mathcal{A}_k} - \gamma_{k,\mathcal{A}_k}) - \boldsymbol{J}_{k,\mathcal{A}_k^c} = -\lambda_k W_{k,\mathcal{A}_k^c} \alpha_{k,\mathcal{A}_k^c} / n. \end{cases} \tag{40}$$

Manipulating the above equations, we have that

$$\begin{aligned} \hat{\gamma}_{k,\mathcal{A}_k} - \gamma_{k,\mathcal{A}_k} &= 2^{-1} \hat{V}_{k,11}^{-1} (\boldsymbol{J}_{k,\mathcal{A}_k} - \lambda_k W_{k,\mathcal{A}_k}^T \alpha_{k,\mathcal{A}_k}) \\ &= 2^{-1} \hat{V}_{k,11}^{-1} W_{k,\mathcal{A}_k} (W_{k,\mathcal{A}_k}^{-1} \boldsymbol{J}_{k,\mathcal{A}_k} - \lambda_k \alpha_{k,\mathcal{A}_k}). \end{aligned} \tag{41}$$

Following the similar strategy in proving Lemma 2, we can prove that there exists a constant $C_5 > 0$ such that $\left\| W_k^{-1} \boldsymbol{J}_k \right\|_\infty \leq 2\lambda_k \zeta / \{n(4-\zeta)\}$ with probability at least $1 - e^{-C_5 h_n + \log(4pq)} - e^{-f_n + \log(p)}$. Therefore, with $\|\alpha_{k,\mathcal{A}_k}\|_\infty \leq 1$, we have that

$$\begin{aligned} &\|\hat{\gamma}_{k,\mathcal{A}_k} - \gamma_{k,\mathcal{A}_k}\|_\infty \leq 2^{-1} \left\| \hat{V}_{k,11}^{-1} W_{k,\mathcal{A}_k} \right\|_\infty \left(\left\| W_{k,\mathcal{A}_k}^{-1} \boldsymbol{J}_{k,\mathcal{A}_k} \right\|_\infty + 2n^{-1}\lambda_k \right) \\ \leq\ & \{\theta_k (4-\zeta)/(2-\zeta)\} \times \{4/(4-\zeta)\} \times \{2\lambda_k/n\} = 2\lambda_k \theta_k / \{n(2-\zeta)\} \leq \min_{j\in\mathcal{A}_k} |\gamma_{kj}|. \end{aligned}$$

The above inequality implies that $sign(\hat{\gamma}_{k,\mathcal{A}_k}) = sign(\gamma_{k,\mathcal{A}_k})$.

Combining (40) and (41), we can also verify that

$$\begin{aligned} &\left\| W_{k,\mathcal{A}_k^c}^{-1} \hat{V}_{k,21} (\hat{V}_{k,11})^{-1} (\boldsymbol{J}_{k,\mathcal{A}_k} - 2\lambda_k W_{k,\mathcal{A}_k} \alpha_{k,\mathcal{A}_k} / n) - W_{k,\mathcal{A}_k^c}^{-1} J_{k,\mathcal{A}_k^c} \right\|_\infty \\ \leq\ & \left\| W_{k,\mathcal{A}_k^c}^{-1} \hat{V}_{k,21} (\hat{V}_{k,11})^{-1} W_{k,\mathcal{A}_k} \right\|_\infty \left(\left\| W_{k,\mathcal{A}_k}^{-1} \boldsymbol{J}_k \right\|_\infty + 2\lambda_k / n \right) + \left\| W_{k,\mathcal{A}_k^c}^{-1} J_{k,\mathcal{A}_k^c} \right\|_\infty \\ \leq\ & (1 - \zeta/2)(4/(4-\zeta)) 2\lambda_k/n + \zeta/(4-\zeta) 2\lambda_k/n = 2\lambda_k/n. \end{aligned}$$

Therefore, there exists an estimator $\hat{\gamma}_k$ satisfying the KKT condition (39) as well as $sign(\hat{\gamma}_k) = sign(\gamma_k)$ which implies $\hat{\mathcal{A}}_k = \mathcal{A}_k$.

Abstract

We introduce the *submodularity ratio* as a measure of how "close" to submodular a set function f is. We show that when f has submodularity ratio γ, the greedy algorithm for maximizing f provides a $(1 - e^{-\gamma})$-approximation. Furthermore, when γ is bounded away from 0, the greedy algorithm for minimum submodular cover also provides essentially an $O(\log n)$ approximation for a universe of n elements.

As a main application of this framework, we study the problem of selecting a subset of k random variables from a large set, in order to obtain the best linear prediction of another variable of interest. We analyze the performance of widely used greedy heuristics; in particular, by showing that the submodularity ratio is lower-bounded by the smallest $2k$-sparse eigenvalue of the covariance matrix, we obtain the strongest known approximation guarantees for the Forward Regression and Orthogonal Matching Pursuit algorithms.

As a second application, we analyze greedy algorithms for the dictionary selection problem, and significantly improve the previously known guarantees. Our theoretical analysis is complemented by experiments on real-world and synthetic data sets; in particular, we focus on an analysis of how tight various spectral parameters and the submodularity ratio are in terms of predicting the performance of the greedy algorithms.

1. Introduction

Over the past 10–15 years, submodularity has established itself as one of the workhorses of the Machine Learning community. A function f mapping sets to real numbers is called *submodular* if $f(S \cup \{v\}) - f(S) \geq f(T \cup \{v\}) - f(T)$ whenever $S \subseteq T$. One of the most popular consequences of submodularity is that greedy algorithms perform quite well for maximizing the function subject to a cardinality constraint. Specifically, suppose that f is non-negative, monotone, and submodular, and consider the algorithm that, for k iterations, adds the element x_{i+1} that has largest marginal gain $f(S_i \cup \{x_{i+1}\}) - f(S_i)$ with respect to the current set S_i. By a classic result of Nemhauser et al. (1978), this algorithm guarantees that the final set achieves a function value within a factor $1 - 1/e$ of the optimum set S^* of cardinality k.

This approximation guarantee has been applied in a large number of settings; see, e.g., a survey in (Krause and Golovin, 2014). Of course, greedy algorithms are also popular when the objective function is not submodular. Typically, when f is not submodular, the greedy algorithm, though perhaps still useful in practice, will not provide theoretical performance guarantees. However, one might suspect that when f is "close to" submodular, then the performance of the greedy algorithm should degrade gracefully.

In the present article (Section 2), we formalize this intuition by defining a measure of "approximate submodularity" which we term *submodularity ratio*, and denote by γ. We prove that when a function f has submodularity ratio γ, the greedy algorithm gives a $(1 - e^{-\gamma})$-approximation; in particular, whenever γ is bounded away from 0, the greedy algorithm guarantees a solution within a constant factor of optimal. We also show that for the complementary *Minimum Submodular Cover* problem, where the goal is to find the smallest set S with $f(S) \geq C$ for a given value C, the greedy algorithm gives essentially an $O(\log n)$ approximation when γ is bounded away from 0.

Subset Selection for Regression. To illustrate the usefulness of the approximate submodularity framework, we analyze greedy algorithms for the problem of *Subset Selection for Regression*: select a subset of k variables from a given set of n observation variables which, taken together, "best" predict another variable of interest. This problem has many applications ranging from feature selection, sparse learning and dictionary selection in machine learning, to sparse approximation and compressed sensing in signal processing. From a machine learning perspective, the variables are typically features or observable attributes of a phenomenon, and we wish to predict the phenomenon using only a small subset from the high-dimensional feature space. In signal processing, the variables usually correspond to a collection of dictionary vectors, and the goal is to parsimoniously represent another (output) vector. For many practitioners, the prediction model of choice is linear regression, and the goal is to obtain a linear model using a small subset of variables, to minimize the mean square prediction error or, equivalently, maximize the squared multiple correlation R^2 (Johnson and Wichern, 2002; Miller, 2002).

Thus, we formulate the Subset Selection problem for Regression as follows: Given the (normalized) covariances between n variables X_i (which can in principle be observed) and a variable Z (which is to be predicted), select a subset of $k \ll n$ of the variables X_i and a linear prediction function of Z from the selected X_i that maximizes the R^2 fit. (A formal definition is given in Section 3.) The covariances are usually obtained empirically from detailed past observations of the variable values.

The above formulation is known (see, e.g., (Das and Kempe, 2008)) to be equivalent to the problem of *sparse approximation* over dictionary vectors: the input consists of a dictionary of n feature vectors $\mathbf{x_i} \in \mathbb{R}^m$, along with a target vector $\mathbf{z} \in \mathbb{R}^m$, and the goal is to select at most k vectors whose linear combination best approximates $\mathbf{z}$. The pairwise

covariances of the previous formulation are then exactly the inner products of the dictionary vectors.[1]

This problem is **NP**-hard (Natarajan, 1995), so no polynomial-time algorithms are known to solve it optimally for all inputs. Two approaches are frequently used for approximating such problems: greedy algorithms (Miller, 2002; Tropp, 2004; Gilbert et al., 2003; Zhang, 2008) and convex relaxation schemes (Tibshirani, 1996; Candès et al., 2005; Tropp, 2006; Donoho, 2005). For our formulation, a disadvantage of convex relaxation techniques is that they do not provide explicit control over the target sparsity level k of the solution; additional effort is needed to tune the regularization parameter.

Greedy algorithms are widely used in practice for subset selection problems; for example, they are implemented in all commercial statistics packages. They iteratively add or remove variables based on simple measures of fit with Z. Two of the most well-known and widely used greedy algorithms are the subject of our analysis: Forward Regression (Miller, 2002) and Orthogonal Matching Pursuit (Tropp, 2004). (These algorithms are defined formally in Section 3).

Our main result is that using the approximate submodularity framework, approximation guarantees much stronger than all previously known bounds can be obtained quite immediately. Specifically, we show that the relevant submodularity ratio for the R^2 objective is lower-bounded by the smallest $(2k)$-sparse eigenvalue $\lambda_{\min}(C, 2k)$ of the covariance matrix C of the observation variables. Combined with our general bounds for approximately submodular functions, this immediately implies a $(1 - \mathrm{e}^{-\lambda_{\min}(C,2k)})$-approximation guarantee for Forward Regression. For Orthogonal Matching Pursuit, a similar analysis leads to a somewhat weaker guarantee of essentially $(1 - \mathrm{e}^{-\lambda_{\min}(C,2k)^2})$. In a precise sense, our analysis thus shows that the less singular C (or its small principal submatrices) are, the "closer to" submodular the R^2 objective. Previously, Das and Kempe (2008) had shown that R^2 is truly submodular when there are no "conditional suppressor" variables; however, the latter is a much stronger condition.

Most previous results for greedy subset selection algorithms (e.g., (Gilbert et al., 2003; Tropp, 2004; Das and Kempe, 2008)) had been based on coherence of the input data, i.e., the maximum correlation μ between any pair of variables. Small coherence is an extremely strong condition, and the bounds usually break down when the coherence is $\omega(1/k)$. On the other hand, most bounds for greedy and convex relaxation algorithms for sparse recovery are based on a weaker sparse-eigenvalue or Restricted Isometry Property (RIP) condition (Zhang, 2009, 2008; Lozano et al., 2009; Zhou, 2009; Candès et al., 2005). However, these results apply to a different objective: minimizing the difference between the actual and estimated coefficients of a sparse vector. Simply extending these results to the subset selection problem adds a dependence on the largest k-sparse eigenvalue and only leads to weak additive bounds.

Dictionary Selection. As a second illustration of the approximate submodularity framework, we obtain much tighter theoretical performance guarantees for greedy algorithms for dictionary selection (Krause and Cevher, 2010). In the *Dictionary Selection problem*, we are given s target vectors, and a candidate set V of feature vectors. The goal is to select a set

1. For this reason, the dimension m of the feature vectors only affects the problem indirectly, via the accuracy of the estimated covariance matrix.

$D \subset V$ of at most d feature vectors, which will serve as a *dictionary* in the following sense. For each of the target vectors, the best $k < d$ vectors from D will be selected and used to achieve a good R^2 fit; the goal is to maximize the average R^2 fit for all of these vectors. (A formal definition is given in Section 4.) The problem of finding a dictionary of basis functions for sparse representation of signals has several applications in machine learning and signal processing. Krause and Cevher (2010) showed that greedy algorithms for dictionary selection can perform well in many instances, and proved additive approximation bounds for two specific algorithms, $\mathrm{SDS}_{\mathrm{MA}}$ and $\mathrm{SDS}_{\mathrm{OMP}}$ (defined in Section 4). Our approximate submodularity framework directly yields stronger multiplicative approximation guarantees.

Our theoretical analysis is complemented by experiments comparing the performance of the greedy algorithms and a baseline convex-relaxation algorithm for subset selection on two real-world data sets and a synthetic data set. We also evaluate the submodularity ratio of these data sets and compare it with other spectral parameters: while the input covariance matrices are close to singular, the submodularity ratio actually turns out to be significantly larger.

While the submodularity ratio is always *lower-bounded* by the smallest (sparse) eigenvalue, our experiments reveal that this lower bound can be loose. This happens when there are small (sparse) eigenvalues, but the predictor variable is not badly aligned with their eigenspace. Hence, computing the submodularity ratio explicitly (although it appears computationally intensive to do so) can lead to stronger post hoc approximation guarantees. In this context, we also discuss ways in which a more careful analysis of the greedy algorithms allows significantly stronger post hoc approximation guarantees.

Our main contributions can be summarized as follows:

1. We introduce (in Section 2) the notion of the submodularity ratio as a predictor of the performance of greedy algorithms. We show that a submodularity ratio of γ leads to a $(1-\mathrm{e}^{-\gamma})$-approximation guarantee for the greedy algorithm for maximum coverage. For the minimum cover probem, we show essentially a $\frac{\log n}{\gamma}$ approximation guarantee for the greedy algorithm.

2. Using the approximate submodularity framework, in Section 3, we obtain the strongest known theoretical performance guarantees for greedy algorithms for subset selection. In particular, we show that the Forward Regression and OMP algorithms are within a $1-\mathrm{e}^{-\gamma}$ factor and $1-\mathrm{e}^{-(\gamma\cdot\lambda_{\min})}$ factor of the optimal solution, respectively (where the γ and λ terms are appropriate submodularity and sparse-eigenvalue parameters).

3. Again using the approximate submodularity framework, in Section 4, we obtain the strongest known theoretical guarantees for algorithms for dictionary selection, improving on the results of Krause and Cevher (2010). In particular, we show that the $\mathrm{SDS}_{\mathrm{MA}}$ algorithm is within a factor $\frac{\gamma}{\lambda_{\max}}(1-\frac{1}{\mathrm{e}})$ of optimal.

4. We evaluate our theoretical bounds for subset selection by running greedy and L1-relaxation algorithms on real-world and synthetic data, and show how the various submodular and spectral parameters correlate with the performance of the algorithms in practice.

1.1 Related and Subsequent Work

We provide an overview of related work both in the context of subset selection (and its variants) and in submodular optimization, as well as a discussion of work that appeared subsequent to the conference version of the present article.

1.1.1 Subset Selection and Sparse Recovery

There has been a lot of related work in the statistics, machine learning and signal processing communities on problems with sparsity constraints (such as sparse recovery, compressed sensing, sparse approximation and feature selection).

In sparse recovery, one is given an $n \times m$ dictionary ϕ of m vectors in $\mathbb{R}^n$ (where $n < m$), along with another vector $y \in \mathbb{R}^n$. It is known that y has some sparse representation in terms of k vectors of ϕ, up to a small noise term ϵ, and the goal is to recover the coefficients α given y, ϕ and ϵ. There has been a lot of recent interest in greedy and convex relaxation techniques for the sparse recovery problems, both in the noiseless and noisy setting. For L1 relaxation techniques, Tropp (2006) showed conditions based on the coherence (i.e., the maximum correlation between any pair of variables) of the dictionary that guaranteed near-optimal recovery of a sparse signal. In (Candès et al., 2005; Donoho, 2005), it was shown that if the target signal is truly sparse, and the dictionary obeys a Restricted Isometry Property (RIP), then L1 relaxation can almost exactly recover the true sparse signal. Other results (Zhao and Yu, 2006; Zhou, 2009) also prove conditions under which L1 relaxation can recover a sparse signal. Though related, the above results are not directly applicable to our subset selection formulation, since the goal in sparse recovery is to recover the true coefficients of the sparse signal, as opposed to our problem of minimizing the prediction error of an arbitrary signal subject to a specified sparsity level.

For greedy sparse recovery, Zhang (2008, 2009) and Lozano et al. (2009) provided conditions based on sparse eigenvalues under which Forward Regression and Forward-Backward Regression can recover a sparse signal. As with the L1 results for sparse recovery, the objective function analyzed in these papers is somewhat different from that in our subset selection formulation; furthermore, these results are intended mainly for the case when the predictor variable is truly sparse. Simply extending these results to our problem formulation gives weaker, additive bounds and requires stronger conditions than our results.

The papers by Das and Kempe (2008), Gilbert et al. (2003) and Tropp et al. (2003); Tropp (2004) analyzed greedy algorithms for sparse approximation, which as mentioned previously is equivalent to our subset selection formulation presented in this work. In particular, they obtained a $1 + \Theta(\mu^2 k)$ multiplicative approximation guarantee for the mean square error objective and a $1 - \Theta(\mu k)$ guarantee for the R^2 objective, whenever the coherence μ of the dictionary is $O(1/k)$. These results are thus weaker than those presented here, since they do not apply to instances with even moderate correlations of $\omega(1/k)$.

Other analysis of greedy methods includes the work of Natarajan (1995), which proved a bicriteria approximation bound for minimizing the number of vectors needed to achieve a given prediction error.

As mentioned earlier, the paper by Krause and Cevher (2010) analyzed greedy algorithms for the dictionary selection problem, which generalizes subset selection to prediction of multiple variables. They too use a notion of approximate submodularity to provide additive approximation guarantees. Since their analysis is for a more general problem than subset selection, applying their results directly to the subset selection problem predictably gives much weaker bounds than those presented in this paper for subset selection. Furthermore, even for the general dictionary selection problem, our techniques can be used to significantly improve their analysis of greedy algorithms and obtain tighter multiplicative approximation bounds (as shown in Section 4).

In general, we note that the performance bounds for greedy algorithms derived using the coherence parameter are usually the weakest, followed by those using the Restricted Isometry Property, then those using sparse eigenvalues, and finally those using the submodularity ratio. (We show an empirical comparison of these parameters in Section 5.)

1.1.2 Submodular Maximization and Curvature

In the context of submodular maximization, the celebrated result of Nemhauser et al. (1978) proved that the greedy algorithm obtained a $(1 - 1/e)$-approximation for maximizing any monotone, submodular set function subject to a uniform matroid. The same guarantee was obtained by Calinescu et al. (2011) for an arbitrary matroid constraint, using a continuous variant of the greedy algorithm.

While we are not aware of prior work on defining a notion of how far a function is from being submodular (or analyzing greedy algorithms for such functions), there is a well-known notion of curvature (Conforti and Cornuéjols, 1984; Vondrák, 2010) that captures how far a submodular function is from being *modular*. In particular, the *total curvature* of a submodular set function is defined as $c = 1 - \min_{S, j \notin S} \frac{f_S(j)}{f_\emptyset(j)}$, where $f_S(j) = f(S \cup j) - f(S)$. (Additional related notions include average curvature and monotonicity ratio; see (Iyer, 2015) for a discussion.) Intuitively c measures how far away f is from being modular, and is equal to 0 if f is modular. Conforti and Cornuéjols (1984) analyzed the greedy algorithm for submodular maximization in terms of the c parameter, and showed a $\frac{1}{c}(1 - e^{-c})$ approximation for a uniform matroid. The result was extended to an arbitrary matroid by Vondrák (2010), and an improved guarantee of $(1 - c/e)$ was obtained recently by Sviridenko et al. (2015). Curvature was also used by Iyer et al. (2013) to obtain improved bounds for submodular function approximation, PMAC-learning and submodular minimization.

Another notion of approximate modularity was recently proposed by Chierichetti et al. (2015), who defined a function to be ϵ-approximately modular if it satisfies all the modularity requirements to within an ϵ additive error. Chierichetti et al. (2015) analyzed how close (in the l_∞ distance) any approximately modular function can be to a modular function.

Note that both the notions of total curvature and approximate modularity are different from the submodularity ratio proposed in this paper, which measures how far a set function is from being submodular.

1.1.3 Subsequent Work

Subsequent to our work introducing the submodularity ratio, several papers have used this notion for analyzing greedy algorithms for machine learning applications. Das et al. (2012) proposed diversity-promoting spectral regularizers for feature selection, and used the submodularity ratio to analyze a hybrid greedy and local search algorithm for the diverse feature selection problem. Grubb and Bagnell (2012) analyzed greedy algorithms for learning an

ensemble of *anytime predictors* that automatically trade computation time with predictive accuracy. Using the submodularity ratio, the authors provide an approximation guarantee for the performance of their ensemble algorithm. Kusner et al. (2014) analyzed greedy methods for training a tree of classifiers for feature-cost sensitive learning, and show that the objective function for obtaining a cost-sensitive tree of classifiers is approximately submodular. Qian et al. (2015) proposed a Pareto optimization approach for subset selection in sparse regression and analyzed the performance of their algorithm using the submodularity ratio.

Most directly following up on our initial work is a recent result of Elenberg et al. (2018) that extends our analysis of greedy algorithms for subset selection from the linear regression setting to arbitrary Generalized Linear Models. The main result is a lower bound on any function's submodularity ratio in terms of its restricted strong convexity and smoothness parameters, which can then be used to obtain approximation guarantees for greedy feature selection algorithms.

2. Approximate Submodularity

We begin by defining our notion of approximate submodularity, and explaining its relationship with the traditional notion of submodularity. Then, we show that approximation results for greedy algorithms degrade gracefully as the function becomes less and less submodular.

2.1 Submodularity Ratio

We introduce the notion of submodularity ratio for a general set function, which captures "how close" to submodular the function is. Let $\mathcal{X}$ be a universe of elements, and Let $f : 2^{\mathcal{X}} \to \mathbb{R}^+$ be a non-negative set function.

Definition 1 (Monotonicity, Submodularity) *1. f is* monotone *iff $f(S) \leq f(T)$ whenever $S \subseteq T$.*

2. f is submodular *iff $f(S \cup \{x\}) - f(S) \geq f(T \cup \{x\}) - f(T)$ whenever $S \subseteq T$.*

Our definition of the submodularity ratio smoothly interpolates between functions that are submodular and those that are far from so.

Definition 2 (Submodularity Ratio) *The* submodularity ratio *of a monotone function f with respect to a set U and a parameter $k \geq 1$ is*

$$\gamma_{U,k}(f) = \min_{L \subseteq U, S:|S| \leq k, S \cap L = \emptyset} \frac{\sum_{x \in S} f(L \cup \{x\}) - f(L)}{f(L \cup S) - f(L)}, \tag{1}$$

where we define $0/0 := 1$. Thus, the submodularity ratio captures how much more f can increase by adding any subset S of size k to L, compared to the combined benefits of adding its individual elements to L. That Definition 2 generalizes submodularity is captured by the following proposition.

Proposition 3 *f is submodular if and only if $\gamma_{U,k} \geq 1$ for all U and k.*

Proof. First, assume that $\gamma_{U,k} \geq 1$ for all U and k. By choosing $k = 2$ and $S = \{x, y\}$ in Equation (1), we obtain that $f(L \cup \{x\}) + f(L \cup \{y\}) \geq f(L \cup \{x, y\}) + f(L)$, or, rearranged, $f(L \cup \{x\}) - f(L) \geq f(L \cup \{x, y\}) - f(L \cup \{y\})$. Now, when we have two sets S and $T = S \cup \{x_1, x_2, \ldots, x_k\}$, define $S_i := S \cup \{x_1, \ldots, x_i\}$ for $0 \leq i \leq k$. Setting $L = S_i$ now gives us that $f(S_i \cup \{x\}) - f(S_i) \geq f(S_{i+1} \cup \{x\}) - f(S_{i+1})$. Induction on i now completes the proof.

Conversely, assume that f is submodular. In Equation (1), let $S = \{x_1, \ldots, x_k\}$ and $S_i = \{x_1, \ldots, x_i\}$, and write a telescoping series $f(L \cup S) - f(L) = \sum_{i=0}^{k-1} f(L \cup S_{i+1}) - f(L \cup S_i)$. By submodularity of f, we can bound

$$f(L \cup S_{i+1}) - f(L \cup S_i) \;=\; f(L \cup S_i \cup \{x_{i+1}\}) - f(L \cup S_i) \;\leq\; f(L \cup \{x_{i+1}\}) - f(L),$$

which gives us a lower bound of 1 on the ratio. ■

Remark 4 *The submodularity ratio is defined as a minimum over exponentially many values, and in general, it is* **NP***-hard to compute exactly (more recently, Bai and Bilmes (2018) showed that it cannot be computed in polynomial time in the value oracle model). This is a property it shares with the well-known Restricted Isometry Property (RIP) (Candès and Tao, 2005): computing the RIP of a matrix is essentially equivalent to computing the expansion of a graph, yet the guarantees for sparse approximation algorithms are frequently expressed in terms of the RIP.*

Whether one can efficiently approximate the submodularity ratio to within non-trivial factors is an interesting open question. Approximating it would allow one to at least derive post hoc approximation guarantees, i.e., to give the user guarantees on the approximation quality for the specific instance that was solved. In the appendix, we discuss some (fairly strong) assumptions under which one can derive non-trivial lower bounds on the submodularity ratio.

Typically, rather than computing the submodularity ratio on a given instance, one would use problem-specific insights to derive a priori lower bounds on the submodularity ratio in terms of quantities that are easier to compute exactly or approximately. For example, in the primary application studied here (linear regression), the submodularity ratio is lower-bounded by the (easy to compute) smallest eigenvalue of the covariance matrix, and more tightly bounded by the (not so easy to compute) smallest $2k$-sparse eigenvalue of the covariance matrix. Recently, Elenberg et al. (2018) showed how to derive similar lower bounds for a more general class of linear objective functions. We anticipate that similar types of bounds can be obtained for other classes of objectives.

2.2 The Greedy Algorithm for Maximum Coverage

Probably the most widely used fact about (monotone) submodular functions is that a simple greedy algorithm approximately optimizes the function subject to a cardinality constraint.[2] This is a celebrated result by Nemhauser et al. (1978). Specifically, Nemhauser et al. (1978) analyzed the following algorithm.

Let S^{NG} be the final set S_k returned by the algorithm. The following theorem of Nemhauser et al. (1978) is widely used in the Machine Learning and related communities:

2. Many other algorithmic optimization problems are easier for submodular function. Some of them are discussed in Section 6.

Algorithm 1 The Nemhauser Greedy Algorithm for a non-negative, monotone, and submodular set function f on a universe $\mathcal{X}$.

1: Initialize $S_0 = \emptyset$.
2: **for** each iteration $i+1 = 1, 2, \ldots$ **do**
3: Let $x_{i+1} \in \mathcal{X}$ be an element maximizing $f(S_i \cup \{x_{i+1}\})$, and set $S_{i+1} = S_i \cup \{x_{i+1}\}$.
4: Output S_k.

Theorem 5 (Nemhauser et al. (1978)) *The set S^{NG} returned by the Nemhauser Greedy Algorithm guarantees that $f(S^{NG}) \geq (1 - \frac{1}{e}) \cdot f(S_k^*)$, where S_k^* is the set maximizing $f(S)$ among all size-k sets S.*

The centerpiece of our algorithmic analysis is a generalization of Theorem 5 to approximately submodular functions.

Theorem 6 *Let f be a nonnegative, monotone set function, and OPT be the maximum value of f obtained by any set of size k. Then, the set S^{NG} selected by the Nemhauser Greedy Algorithm has the following approximation guarantee:*

$$f(S^{NG}) \geq \left(1 - \mathrm{e}^{-\gamma_{S^{NG},k}(f)}\right) \cdot OPT.$$

Notice that for submodular functions, because $\gamma_{S^{\mathrm{NG}},k}(f) \geq 1$, our theorem recovers the result of Nemhauser et al. (1978) as a special case.

Proof. We carry out the analysis in somewhat more generality than needed here, since most of it will be useful in Section 2.3. Let k be the number of iterations that Algorithm 1 was run, and S_i^{NG} the set of elements greedily chosen in the first i iterations. Let S_i^{NG} be the set of variables chosen by the Nemhauser Greedy Algorithm (Algorithm 1) in the first i iterations. Define $A(i) = f(S_i^{\mathrm{NG}}) - f(S_{i-1}^{\mathrm{NG}})$ to be the gain obtained from the variable chosen by the algorithm in iteration i. Then $f(S^{\mathrm{NG}}) = \sum_{i=1}^{k} A(j)$.

For simplicity of notation, we write $f(x/S)$ to denote $f(\{x\} \cup S) - f(S)$, and $f(T/S)$ to denote $f(T \cup S) - f(S)$, for any element $x \in \mathcal{X}$ and sets S and T. We will also write $\gamma_{S^{\mathrm{NG}},k}$ to denote $\gamma_{S^{\mathrm{NG}},k}(f)$.

Let S^* be some (optimum) set of k^* variables, achieving a value of (at least) C. Let $S_i = S^* \setminus S_i^{\mathrm{NG}}$. By monotonicity of f and the fact that $S_i \cup S_i^{\mathrm{NG}} \supseteq S^*$, we have that $f(S_i \cup S_i^{\mathrm{NG}}) \geq C$. We will show that at least one of the $x \in S_i$ is a good candidate in iteration $i+1$ of the algorithm. First, the joint contribution of S_i, conditioned on the set S_i^{NG}, must be fairly large: $f(S_i/S_i^{\mathrm{NG}}) = f(S_i \cup S_i^{\mathrm{NG}}) - f(S_i^{\mathrm{NG}}) \geq C - f(S_i^{\mathrm{NG}})$. Using Definition 2, as well as $S_i^{\mathrm{NG}} \subseteq S^{\mathrm{NG}}$ and $|S_i| \leq k^*$,

$$\sum_{x \in S_i} f(x/S_i^{\mathrm{NG}}) \geq \gamma_{S_i^{\mathrm{NG}},|S_i|} \cdot f(S_i/S_i^{\mathrm{NG}}) \;\geq\; \gamma_{S^{\mathrm{NG}},k^*} \cdot f(S_i/S_i^{\mathrm{NG}}).$$

Let $\hat{x} \in \mathrm{argmax}_{x \in S_i} f(x/S_i^{\mathrm{NG}})$ maximize $f(\hat{x}/S_i^{\mathrm{NG}})$. Then we get that

$$f(\hat{x}/S_i^{\mathrm{NG}}) \geq \frac{\gamma_{S^{\mathrm{NG}},k^*}}{|S_i|} \cdot f(S_i/S_i^{\mathrm{NG}}) \;\geq\; \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*} \cdot f(S_i/S_i^{\mathrm{NG}}).$$

Since the $\hat{x}$ above was a candidate to be chosen in iteration $i+1$, and the algorithm chose a variable x_{i+1} such that $f(x_{i+1}/S_i^{\mathrm{NG}}) \geq f(x/S_i^{\mathrm{NG}})$ for all $x \notin S_i^{\mathrm{NG}}$, we obtain that

$$A(i+1) \geq \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*} \cdot f(S_i/S_i^{\mathrm{NG}}) \;\geq\; \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*} \cdot (C - f(S_i^{\mathrm{NG}})) \;\geq\; \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*} \cdot (C - \sum_{j=1}^{i} A(j)).$$

We will use the above inequality to prove by induction on t that

$$C - \sum_{i=1}^{t} A(i) \leq C \cdot (1 - \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*})^t \;\leq\; C \cdot \mathrm{e}^{-\gamma_{S^{\mathrm{NG}},k^*} \cdot \frac{t}{k^*}}. \tag{2}$$

The base case is clearly true for $t = 0$. Suppose that the inequality is true after t iterations. Then, at iteration $t+1$, we have

$$\begin{aligned} C - \sum_{i=1}^{t+1} A(i) &= C - \sum_{i=1}^{t} A(i) - A(t+1) \\ &\leq C - \sum_{i=1}^{t} A(i) - \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*} \cdot (C - \sum_{i=1}^{t} A(i)) \\ &= (C - \sum_{i=1}^{t+1} A(i)) \cdot \left(1 - \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*}\right) \\ &\leq C \cdot \left(1 - \frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*}\right)^{t+1}, \end{aligned}$$

thus completing the inductive proof. Using Inequality(2) with $k = k^*, t = k-1$ and $C = \mathrm{OPT}$, we obtain that

$$f(S^{\mathrm{NG}}) = \sum_{i=1}^{k} A(i) \;\geq\; \mathrm{OPT} \cdot \left(1 - \mathrm{e}^{-\gamma_{S^{\mathrm{NG}},k}}\right).$$

This completes the proof of the approximation guarantee. ∎

Remark 7 *As the submodularity ratio goes to 0, the approximation guarantee of Theorem 6 deteriorates and becomes 0 in the limit. This is not surprising: in the limit, the definition does not place any restrictions on the function f. Without any restrictions on f, not only can the greedy algorithm perform arbitrarily poorly, but the same may be true for* any *efficient algorithm, since f might be a function that is provably hard to approximate to within any non-trivial factor.*

Indeed, the goal of Theorem 6 is not to provide a universal approximation guarantee, but rather to outline conditions under which running the greedy algorithm comes with provable approximation guarantees. Practitioners run greedy algorithms routinely without any guarantees, and the submodularity ratio may provide guidance under what conditions doing so has theoretical justification, even when the objective function f is not submodular.

2.3 The Greedy Algorithm for Minimum Submodular Cover

The "complementary" problem to submodular function maximization is minimum submodular cover, where the goal is to find a smallest set S with $f(S) \geq C$, a given target value. The name derives from one of the most common instance of submodular functions: coverage functions.[3] Here, the elements x correspond to sets, and the function value f is the size of the union of the selected sets. In the Maximum Coverage Problem, the goal is to maximize the size of the union by selecting k sets, and in the Minimum Set Cover Problem, the goal is to cover all elements selecting as few sets as possible.

For both problems, the greedy algorithm (Algorithm 1) provides essentially best possible guarantees. The only difference is the termination condition: for maximum coverage, the algorithm is terminated when k sets are selected, while for minimum cover, the algorithm is terminated when all elements (or a given number) have been covered. For the Minimum Set Cover Problem, the greedy algorithm achieves a $\ln n$ approximation, which is best possible unless $\mathbf{P} = \mathbf{NP}$. For more general monotone submodular functions, the results are somewhat less clean to express, but are summarized by the following theorem of Wolsey (1982).

Theorem 8 (Theorem 1 of Wolsey (1982)) *Let f be nonnegative, monotone and submodular, and let $n = |\mathcal{X}|$. For any given C, let $k^*(C)$ be the size of the smallest set $S \subseteq V$ such that $f(S) \geq C$. Let k be the size of the set S^{NG} selected by Algorithm 1 when run until $f(S) \geq C$. Then,*

$$k \leq \left(1 + \log\left(\frac{C}{C - f(S^{NG}_{k-1})}\right)\right) \cdot k^*(C),$$

where S^{NG}_{k-1} is the set selected by Algorithm 1 after $k-1$ iterations.

If f is integer valued, then

$$k \leq (1 + \log(\theta)) \cdot k^*,$$

where $\theta = \max_{x \in \mathcal{X}} f(x)$ is the maximum value of the set function obtained by a single element.

We show that Theorem 8, too, extends gracefully to approximately submodular functions f.

Theorem 9 *Let f be a nonnegative and monotone function, and let $n = |\mathcal{X}|$. For any given C, let $k^*(C)$ be the size of the smallest set $S \subseteq V$ such that $f(S) \geq C$. Let k be the size of the set S^{NG} selected by Algorithm 1 when run until $f(S) \geq C$. Then,*

$$k \leq 1 + \frac{1}{\gamma_{S^{NG},k^*(C)}(f)} \cdot \log\left(\frac{C}{C - f(S^{NG}_{k-1})}\right) \cdot k^*(C),$$

where S^{NG}_{k-1} is the set selected by Algorithm 1 after $k-1$ iterations.

3. A characterization of coverage functions in terms of functional properties akin to submodularity is given by Salek et al. (2010).

Proof. We use the same notation as in the proof of Theorem 6. For notational convenience, write $k^* = k^*(C)$. Let k be the number of iterations taken by Algorithm 1, so that $f(S^{\mathrm{NG}}_k) \geq C$ and $f(S^{\mathrm{NG}}_{k-1}) < C$. Thus $f(S^{\mathrm{NG}}) = \sum_{j=1}^{k} A(j)$.

Let S^* be a smallest set (i.e., $|S^*| = k^*$) with $f(S^*) \geq C$. Substituting $t = k-1$ into Equation (2) and solving for k, we obtain that

$$k \leq 1 + \frac{1}{\gamma_{S^{\mathrm{NG}},k^*}(f)} \cdot \log\left(\frac{C}{C - f(S^{\mathrm{NG}}_{k-1})}\right) \cdot k^*,$$

as claimed. ∎

As with Wolsey's result for submodular functions, the bounds can be improved when f is integer-valued.

Theorem 10 *Assume that f is integer-valued, in addition to all conditions (and notation) of Theorem 9. Let $\theta = \max_{x \in \mathcal{X}} f(x)$ is the maximum value of the set function obtained by any single element. Then, the number k of elements selected by Algorithm 1 satisfies*

$$k \leq 1 + \frac{1}{\gamma_{S^{NG},k^*(C)}(f)} \cdot \log(C) \cdot k^*(C),$$
$$k \leq \left(1 + \frac{1}{\gamma_{S^{NG},k^*(C)}(f)} \log\left(\frac{\theta}{\gamma_{\emptyset,k^*}(f)}\right)\right) \cdot k^*(C).$$

Proof. The first result follow directly from Theorem 9, because $C - f(S^{\mathrm{NG}}_{k-1}) \geq 1$ for integer-valued functions.

For the second result, substitute $t = \frac{k^*}{\gamma_{S^{\mathrm{NG}},k^*}(f)} \cdot \log\left(\frac{f(S^*)}{k^*}\right)$ into Inequality (2) to obtain that

$$C - f(S^{\mathrm{NG}}_t) \leq C \cdot \mathrm{e}^{-\frac{\gamma_{S^{\mathrm{NG}},k^*}}{k^*} \cdot t} \;\leq\; k^*.$$

Because f is a monotone and integer-valued, $f(S^{\mathrm{NG}}_i) - f(S^{\mathrm{NG}}_{i-1}) \geq 1$ for all remaining iterations i, and it takes at most k^* additional iterations to reach a value of C. Hence,

$$k \leq t + k^* \;=\; \left(1 + \frac{1}{\gamma_{S^{\mathrm{NG}},k^*}(f)} \cdot \log(C/k^*)\right) \cdot k^* \;\leq\; \left(1 + \frac{1}{\gamma_{S^{\mathrm{NG}},k^*}(f)} \cdot \log\left(\frac{\theta}{\gamma_{\emptyset,k^*}(f)}\right)\right) \cdot k^*.$$

The inequality $C/k^* \leq \theta/\gamma_{\emptyset,k^*}(f)$ is directly from Definition 2. ∎

The same techniques can be used to obtain the following bicriteria approximation guarantee below. The bicriteria guarantees are similar in spirit to, for instance, (Krause and Golovin, 2014, Theorem 1.5). We believe that similar results for submodular functions are folklore among researchers, though we are unaware of a reference stating precisely the form we give here.

Theorem 11 *For any $\epsilon \in (0,1)$, if Algorithm 1 is run until $f(S^{NG}) \geq (1-\epsilon) \cdot C$, the size of the set S^{NG} that is returned is at most $\frac{1}{\gamma_{S^{NG},k^*}(f)} \log(\frac{1}{\epsilon}) \cdot k^*(C)$.*

Proof. For the proof, simply substitute $t = \frac{1}{\gamma_{S^{\mathrm{NG}},k^*}(f)} \log(\frac{1}{\epsilon}) \cdot k^*(C)$ into Inequality (2). ■

A particularly clean corollary of this theorem is obtained when $\epsilon = 1/\mathrm{e}$. In that case, we obtain a $(1 - 1/\mathrm{e})$ approximation by increasing the set size by a factor $\frac{1}{\gamma_{S^{\mathrm{NG}},k^*}(f)}$. Thus, instead of a smooth degradation of the customary $(1 - 1/\mathrm{e})$ approximation guarantee, we can choose a smooth increase in the size of the set that the greedy algorithm is allowed to select, and thus retain the customary $(1 - 1/\mathrm{e})$ approximation, even for functions that are only approximately submodular.

3. Subset Selection for Regression

As our first and main application of the approximate submodularity framework, we analyze greedy algorithms for subset selection in regression. The goal in subset selection is to estimate a *predictor variable* Z using linear regression on a small subset from the set of *observation variables* $\mathcal{X} = \{X_1, \ldots, X_n\}$. We use $\mathrm{Var}[X_i]$, $\mathrm{Cov}[X_i, X_j]$ and $\rho(X_i, X_j)$ to denote the variance, covariance and correlation of random variables, respectively. By appropriate normalization, we can assume that all the random variables have expectation 0 and variance 1. The matrix of covariances between the X_i and X_j is denoted by C, with entries $c_{i,j} = \mathrm{Cov}[X_i, X_j]$. Similarly, we use $\mathbf{b}$ to denote the covariances between Z and the X_i, with entries $b_i = \mathrm{Cov}[Z, X_i]$. Formally, the *Subset Selection* problem can now be stated as follows:

Definition 12 (Subset Selection) *Given pairwise covariances among all variables, as well as a parameter k, find a set $S \subset \mathcal{X}$ of at most k variables X_i and a linear predictor $Z' = \sum_{i \in S} \alpha_i X_i$ of Z, maximizing the* squared multiple correlation *(Diekhoff, 2002; Johnson and Wichern, 2002)*

$$R^2_{Z,S} = \frac{\mathrm{Var}[Z] - \mathbb{E}\left[(Z - Z')^2\right]}{\mathrm{Var}[Z]}.$$

R^2 is a widely used measure for the goodness of a statistical fit; it captures the fraction of the variance of Z explained by variables in S. Because we assumed Z to be normalized to have variance 1, it simplifies to $R^2_{Z,S} = 1 - \mathbb{E}\left[(Z - Z')^2\right]$.

For a set S, we use C_S to denote the submatrix of C with row and column set S, and $\mathbf{b}_S$ to denote the vector with only entries b_i for $i \in S$. For notational convenience, we frequently do not distinguish between the index set S and the variables $\{X_i \mid i \in S\}$. Given the subset S of variables used for prediction, the optimal regression coefficients α_i are well known to be $\mathbf{a}_S = (\alpha_i)_{i \in S} = C_S^{-1} \cdot \mathbf{b}_S$ (see, e.g., (Johnson and Wichern, 2002)), and hence $R^2_{Z,S} = \mathbf{b}_S^\intercal C_S^{-1} \mathbf{b}_S$. Thus, the subset selection problem can be phrased as follows: Given C, $\mathbf{b}$, and k, select a set S of at most k variables to maximize $R^2_{Z,S} = \mathbf{b}_S^\intercal (C_S^{-1}) \mathbf{b}_S$.[4]

Many of our results are phrased in terms of eigenvalues of the covariance matrix C and its submatrices. Covariance matrices are positive semidefinite, so their eigenvalues are real

4. We assume throughout that C_S is non-singular. For some of our results, an extension to singular matrices is possible using the Moore-Penrose generalized inverse.

and non-negative (Johnson and Wichern, 2002). We denote the eigenvalues of a positive semidefinite matrix A by $\lambda_{\min}(A) = \lambda_1(A) \leq \lambda_2(A) \leq \cdots \leq \lambda_n(A) = \lambda_{\max}(A)$. We use $\lambda_{\min}(C, k) = \min_{S:|S|=k} \lambda_{\min}(C_S)$ to refer to the smallest eigenvalue of any $k \times k$ submatrix of C (i.e., the smallest k-sparse eigenvalue), and similarly $\lambda_{\max}(C, k) = \max_{S:|S|=k} \lambda_{\max}(C_S)$.[5] We also use $\kappa(C, k)$ to denote the largest condition number (the ratio of the largest and smallest eigenvalue) of any $k \times k$ submatrix of C. This quantity is strongly related to the Restricted Isometry Property in (Candès et al., 2005). We also use $\mu(C) = \max_{i \neq j} |c_{i,j}|$ to denote the *coherence*, i.e., the maximum absolute pairwise correlation between the X_i variables. Recall the L_2 vector and matrix norms: $\|\mathbf{x}\|_2 = \sqrt{\sum_i |x_i|^2}$, and $\|A\|_2 = \lambda_{\max}(A) = \max_{\|\mathbf{x}\|_2=1} \|A\mathbf{x}\|_2$. We also use $\|\mathbf{x}\|_0 = |\{i \mid x_i \neq 0\}|$ to denote the sparsity of a vector $\mathbf{x}$.

The Rayleigh-Ritz representation for $\|A\|_2$ is useful in bounding $\lambda_{\min}(A)$, as for any vector $\mathbf{x}$, we have $\lambda_{\min}(A) \leq \frac{\|A\mathbf{x}\|_2}{\|\mathbf{x}\|_2}$.

The part of a variable Z that is not correlated with the X_i for all $i \in S$, i.e., the part that cannot be explained by the X_i, is called the *residual* (see (Diekhoff, 2002)), and defined as $\mathrm{Res}(Z, S) = Z - \sum_{i \in S} \alpha_i X_i$.

3.1 Approximate Submodularity of R^2

The key insight enabling our analysis is a bound on the submodularity ratio of the R^2 function. To avoid notational clutter, when we are specifically concerned with the R^2 objective defined on the variables X_i, we omit the function name in the definition of the submodularity ratio, and simply write

$$\gamma_{U,k} = \min_{L \subseteq U, S: |S| \leq k, S \cap L = \emptyset} \frac{\sum_{i \in S} (R^2_{Z,L \cup \{X_i\}} - R^2_{Z,L})}{R^2_{Z,S \cup L} - R^2_{Z,L}} = \min_{L \subseteq U, S: |S| \leq k, S \cap L = \emptyset} \frac{(\mathbf{b}_S^L)^\intercal \mathbf{b}_S^L}{(\mathbf{b}_S^L)^\intercal (C_S^L)^{-1} \mathbf{b}_S^L},$$

where C^L and $\mathbf{b}^L$ are the normalized covariance matrix and normalized covariance vector corresponding to the set $\{\mathrm{Res}(X_1, L), \mathrm{Res}(X_2, L), \ldots, \mathrm{Res}(X_n, L)\}$.

Our key lemma can now be stated as follows:

Lemma 13 $\gamma_{U,k} \geq \lambda_{\min}(C, k + |U|) \geq \lambda_{\min}(C)$.

For all our analysis in this paper, we will use $|U| = k$, and hence $\gamma_{U,k} \geq \lambda_{\min}(C, 2k)$. Thus, the smallest $2k$-sparse eigenvalue is a lower bound on this submodularity ratio; as we show later, it is often a weak lower bound.

Before proving Lemma 13, we first introduce two lemmas that relate the eigenvalues of a normalized covariance matrix with those of its submatrices.

Lemma 14 *Let C be the covariance matrix of n zero-mean random variables $X_1, X_2, \ldots, X_n$, each of which has variance at most 1. Let C_ρ be the corresponding correlation matrix of the n random variables, that is, C_ρ is the covariance matrix of the variables after they are normalized to have unit variance. Then $\lambda_{\min}(C) \leq \lambda_{\min}(C_\rho)$.*

5. Computing $\lambda_{\min}(C, k)$ is NP-hard. In Appendix A we describe how to efficiently approximate the values for some scenarios.

Proof. Since C_ρ is obtained by normalizing the variables such that they have unit variance, we get $C_\rho = D^\intercal C D$, where D is a diagonal matrix with diagonal entries $d_i = \frac{1}{\sqrt{\mathrm{Var}[X_i]}}$.

Since both C_ρ and C are positive semidefinite, we can perform Cholesky factorization to get lower-triangular matrices A_ρ and A such that $C = AA^\intercal$ and $C_\rho = A_\rho A_\rho^\intercal$. Hence $A_\rho = D^\intercal A$.

Let $\sigma_{\min}(A)$ and $\sigma_{\min}(A_\rho)$ denote the smallest singular values of A and A_ρ, respectively. Also, let $\mathbf{v}$ be the singular vector corresponding to $\sigma_{\min}(A_\rho)$. Then,

$$\|A\mathbf{v}\|_2 = \|D^{-1}A_\rho\mathbf{v}\|_2 \;\le\; \|D^{-1}\|_2\|A_\rho\mathbf{v}\|_2 \;=\; \sigma_{\min}(A_\rho)\|D^{-1}\|_2 \;\le\; \sigma_{\min}(A_\rho),$$

where the last inequality follows since

$$\|D^{-1}\|_2 \;=\; \max_i \frac{1}{d_i} \;=\; \max_i \sqrt{\mathrm{Var}[X_i]} \;\le\; 1.$$

Hence, by the Courant-Fischer theorem, $\sigma_{\min}(A) \le \sigma_{\min}(A_\rho)$, and consequently, $\lambda_{\min}(C) \le \lambda_{\min}(C_\rho)$. ∎

Lemma 15 *Let $\lambda_{\min}(C)$ be the smallest eigenvalue of the covariance matrix C of n random variables $X_1, X_2, \ldots, X_n$, and $\lambda_{\min}(C')$ be the smallest eigenvalue of the $(n-1)\times(n-1)$ covariance matrix C' corresponding to the $n-1$ random variables $\mathrm{Res}(X_1, X_n), \ldots, \mathrm{Res}(X_{n-1}, X_n)$. Then $\lambda_{\min}(C) \le \lambda_{\min}(C')$.*

Proof. Let λ_i and λ'_i denote the eigenvalues of C and C', respectively. Also, let $c'_{i,j}$ denote the entries of C'. Using the definition of the residual, we get that

$$c'_{i,j} = \mathrm{Cov}[\mathrm{Res}(X_i, X_n), \mathrm{Res}(X_j, X_n)] \;=\; c_{i,j} - \frac{c_{i,n}c_{j,n}}{c_{n,n}},$$

$$c'_{i,i} = \mathrm{Var}[\mathrm{Res}(X_i, X_n)] \;=\; c_{i,i} - \frac{c_{i,n}^2}{c_{n,n}}.$$

Defining $D = \frac{1}{c_{n,n}} \cdot [c_{1,n}, c_{2,n}, \ldots, c_{n-1,n}]^\intercal \cdot [c_{1,n}, c_{2,n}, \ldots, c_{n-1,n}]$, we can write $C_{\{1,\ldots,n-1\}} = C' + D$. To prove $\lambda_1 \le \lambda'_1$, let $\mathbf{e}' = [e'_1, \ldots, e'_{n-1}]^\intercal$ be the eigenvector of C' corresponding to the eigenvalue λ'_1, and consider the vector $\mathbf{e} = [e'_1, e'_2, \ldots, e'_{n-1}, -\frac{1}{c_{n,n}}\sum_{i=1}^{n-1} e'_i c_{i,n}]^\intercal$. Then, $C \cdot \mathbf{e} = [\begin{smallmatrix}\mathbf{y}\\ 0\end{smallmatrix}]$, where

$$\begin{aligned}\mathbf{y} &= -\frac{1}{c_{n,n}}\sum_{i=1}^{n-1} e'_i c_{i,n}[c_{1,n}, c_{2,n}, \ldots, c_{n-1,n}]^\intercal + C_{\{1,\ldots,n-1\}} \cdot \mathbf{e}' \\ &= -\frac{1}{c_{n,n}}\sum_{i=1}^{n-1} e'_i c_{i,n}[c_{1,n}, c_{2,n}, \ldots, c_{n-1,n}]^\intercal + D \cdot \mathbf{e}' + C' \cdot \mathbf{e}' \\ &= C' \cdot \mathbf{e}'.\end{aligned}$$

Thus, $C \cdot \mathbf{e} = [\lambda'_1 e'_1, \lambda'_1 e'_2, \ldots, \lambda'_1 e'_{n-1}, 0]^\intercal = \lambda'_1[e'_1, e'_2, \ldots, e'_{n-1}, 0]^\intercal \le \lambda'_1 \|\mathbf{e}\|_2$, which by Rayleigh-Ritz bounds implies that $\lambda_1 \le \lambda'_1$. ∎

Using the above two lemmas, we now prove Lemma 13.

Proof of Lemma 13. Since

$$\frac{(\mathbf{b}_S^L)^\intercal (C_S^L)^{-1}\mathbf{b}_S^L}{(\mathbf{b}_S^L)^\intercal \mathbf{b}_S^L} \le \max_{\mathbf{x}} \frac{\mathbf{x}^\intercal (C_S^L)^{-1}\mathbf{x}}{\mathbf{x}^\intercal\mathbf{x}} \;=\; \lambda_{\max}((C_S^L)^{-1}) \;=\; \frac{1}{\lambda_{\min}(C_S^L)},$$

we can use Definition 2 to obtain that

$$\gamma_{U,k} \ge \min_{(L\subseteq U, S: |S|\le k, S\cap L=\emptyset)} \lambda_{\min}(C_S^L).$$

Next, we relate $\lambda_{\min}(C_S^L)$ with $\lambda_{\min}(C_{L\cup S})$, using repeated applications of Lemmas 14 and 15. Let $L = \{X_1, \ldots, X_\ell\}$; for each i, define $L_i = \{X_1, \ldots, X_i\}$, and let $C^{(i)}$ be the covariance matrix of the random variables $\{\mathrm{Res}(X, L \setminus L_i) \mid X \in S \cup L_i\}$, and $C_\rho^{(i)}$ the covariance matrix after normalizing all its variables to unit variance. Then, Lemma 14 implies that for each i, $\lambda_{\min}(C^{(i)}) \le \lambda_{\min}(C_\rho^{(i)})$, and Lemma 15 shows that $\lambda_{\min}(C_\rho^{(i)}) \le \lambda_{\min}(C^{(i-1)})$ for each $i > 0$. Combining these inequalities inductively for all i, we obtain that

$$\lambda_{\min}(C_S^L) = \lambda_{\min}(C_\rho^{(0)}) \;\ge\; \lambda_{\min}(C^{(\ell)}) \;=\; \lambda_{\min}(C_{L\cup S}) \;\ge\; \lambda_{\min}(C, |L\cup S|).$$

Finally, since $|S| \le k$ and $L \subseteq U$, we obtain $\gamma_{U,k} \ge \lambda_{\min}(C, k + |U|)$. ∎

3.2 Forward Regression

We now use our approximate submodularity framework along with the result of Lemma 13 to achieve theoretical performance bounds for Forward Regression and Orthogonal Matching Pursuit, which are widely used in practice. We also analyze the Oblivious algorithm, one of the simplest greedy algorithms for subset selection. Throughout the remainder of this section, we use $\mathrm{OPT} = \max_{S:|S|=k} R^2_{Z,S}$ to denote the optimum R^2 value achievable by any set of size k.

We begin with an analysis of Forward Regression, which is the standard algorithm used by many researchers in medical, social, and economic domains.[6]

Algorithm 2 The Forward Regression (also called Forward Selection) algorithm.

1: Initialize $S_0 = \emptyset$.
2: **for** each iteration $i + 1 = 1, 2, \ldots$ **do**
3: Let X_{i+1} be a variable maximizing $R^2_{Z,S_i\cup\{X_{i+1}\}}$, and set $S_{i+1} = S_i \cup \{X_{i+1}\}$.
4: Output S_k.

Notice that Forward Regression is exactly the special case of the general Nemhauser Greedy Algorithm (Algorithm 1) applied to the R^2 objective.

Our main result is the following theorem.

6. There is some inconsistency in the literature about naming of greedy algorithms. Forward Regression is sometimes also referred to as Orthogonal Matching Pursuit (OMP). We choose the nomenclature consistent with Miller (2002) and Tropp (2004).

Theorem 16 *The set S^{FR} selected by Forward Regression has the following approximation guarantees:*

$$\begin{aligned} R^2_{Z,S^{FR}} &\geq (1-\mathrm{e}^{-\gamma_{S^{FR},k}})\cdot OPT \\ &\geq (1-\mathrm{e}^{-\lambda_{\min}(C,2k)})\cdot OPT \\ &\geq (1-\mathrm{e}^{-\lambda_{\min}(C,k)})\cdot \Theta((\frac{1}{2})^{1/\lambda_{\min}(C,k)})\cdot OPT. \end{aligned}$$

The first inequality is just an application of Theorem 6 to the R^2 objective, and the second inequality follows directly from Lemma 13 by noticing that $|S^{\mathrm{FR}}| = k$. Thus, our proof will focus on the third inequality, which relates the performance measured with respect to the smallest k-sparse eigenvalue to that measured with respect to the smallest $2k$-sparse eigenvalue. We begin with a general lemma that bounds the amount by which the R^2 value of a set and the sum of R^2 values of its elements can differ.

Lemma 17 *Let C and $\mathbf{b}$ be the covariance matrix and covariance vector corresponding to a predictor variable Z and a set S of random variables $X_1, X_2, \ldots, X_n$ that are normalized to have zero mean and unit variance. Then,*

$$\frac{1}{\lambda_{\max}(C)}\sum_{i=1}^{n} R^2_{Z,X_i} \leq R^2_{Z,\{X_1,\ldots,X_n\}} \leq \frac{1}{\gamma_{\emptyset,n}}\sum_{i=1}^{n} R^2_{Z,X_i} \leq \frac{1}{\lambda_{\min}(C)}\sum_{i=1}^{n} R^2_{Z,X_i}.$$

Proof. Let the eigenvalues of C^{-1} be $\lambda'_1 \leq \lambda'_2 \leq \ldots \leq \lambda'_n$, with corresponding orthonormal eigenvectors $\mathbf{e_1}, \mathbf{e_2}, \ldots, \mathbf{e_n}$. We write $\mathbf{b}$ in the basis $\{\mathbf{e_1}, \mathbf{e_2}, \ldots, \mathbf{e_n}\}$ as $\mathbf{b} = \sum_i \beta_i \mathbf{e_i}$. Then,

$$R^2_{Z,\{X_1,\ldots,X_n\}} = \mathbf{b}^\intercal C^{-1}\mathbf{b} = \sum_i \beta_i^2 \lambda'_i.$$

Because $\lambda'_1 \leq \lambda'_i$ for all i, we get $\lambda'_1 \sum_i \beta_i^2 \leq R^2_{Z,\{X_1,\ldots,X_n\}}$, and $\sum_i \beta_i^2 = \mathbf{b}^\intercal\mathbf{b} = \sum_i R^2_{Z,X_i}$, because the length of the vector $\mathbf{b}$ is independent of the basis it is written in. Also, by definition of the submodularity ratio, $R^2_{Z,\{X_1,\ldots,X_n\}} \leq \frac{\sum_i \beta_i^2}{\gamma_{\emptyset,n}}$. Finally, because $\lambda'_1 = \frac{1}{\lambda_{\max}(C)}$, and using Lemma 13, we obtain the result. ∎

The next lemma relates the optimal R^2 value using k elements to the optimal R^2 using $k' < k$ elements.

Lemma 18 *For each k, let $S^*_k \in \mathrm{argmax}_{|S|\leq k} R^2_{Z,S}$ be an optimal subset of at most k variables. Then, for any $k' = \Theta(k)$ such that $\frac{1}{\lambda_{\min}(C,k)} < k' < k$, we have that $R^2_{Z,S^*_{k'}} \geq R^2_{Z,S^*_k} \cdot \Theta((\frac{k'}{k})^{1/\lambda_{\min}(C,k)})$, for large enough k. In particular, $R^2_{Z,S^*_{k/2}} \geq R^2_{Z,S^*_k} \cdot \Theta((\frac{1}{2})^{1/\lambda_{\min}(C,k)})$, for large enough k.*

Proof. We first prove that $R^2_{Z,S^*_{k-1}} \geq (1-\frac{1}{k\lambda_{\min}(C,k)})R^2_{Z,S^*_k}$. Let $T = \mathrm{Res}(Z, S^*_k)$; then, $\mathrm{Cov}[X_i, T] = 0$ for all $X_i \in S^*_k$, and $Z = T + \sum_{X_i\in S^*_k} \alpha_i X_i$, where $\alpha = (\alpha_i) = C^{-1}_{S^*_k} \cdot \mathbf{b}_{S^*_k}$ are

the optimal regression coefficients. We write $Z' = Z - T$. For any $X_j \in S^*_k$, by definition of R^2, we have that

$$R^2_{Z',S^*_k\setminus\{X_j\}} = 1 - \frac{\alpha_j^2 \mathrm{Var}[X_j]}{\mathrm{Var}[Z']} = 1 - \frac{\alpha_j^2}{\mathrm{Var}[Z']};$$

in particular, this implies that $R^2_{Z',S^*_{k-1}} \geq 1 - \frac{\alpha_j^2}{\mathrm{Var}[Z']}$ for all $X_j \in S^*_k$.

Focus now on j minimizing α_j^2, so that $\alpha_j^2 \leq \frac{\|\alpha\|_2^2}{k}$. As in the proof of Lemma 17, by writing α in terms of an orthonormal eigenbasis of $C_{S^*_k}$, one can show that $|\alpha^\intercal C_{S^*_k}\alpha| \geq \|\alpha\|_2^2 \lambda_{\min}(C_{S^*_k})$, or $\|\alpha\|_2^2 \leq \frac{|\alpha^\intercal C_{S^*_k}\alpha|}{\lambda_{\min}(C_{S^*_k})}$. Furthermore, $\alpha^\intercal C_{S^*_k}\alpha = \mathrm{Var}[\sum_{X_i\in S^*_k} \alpha_i X_i] = \mathrm{Var}[Z']$, so $R^2_{Z',S^*_{k-1}} \geq 1 - \frac{1}{k\lambda_{\min}(C_{S^*_k})}$. Finally, by definition, $R^2_{Z',S^*_k} = 1$, so

$$\frac{R^2_{Z,S^*_{k-1}}}{R^2_{Z,S^*_k}} \geq \frac{R^2_{Z',S^*_{k-1}}}{R^2_{Z',S^*_k}} \geq 1 - \frac{1}{k\lambda_{\min}(C_{S^*_k})} \geq 1 - \frac{1}{k\lambda_{\min}(C,k)}.$$

Now, applying this inequality repeatedly, we get

$$R^2_{Z,S^*_{k'}} \geq R^2_{Z,S^*_k} \cdot \prod_{i=k'+1}^{k} (1 - \frac{1}{i\lambda_{\min}(C,i)}).$$

Let $t = \lceil 1/\lambda_{\min}(C,k)\rceil$, so that the previous bound implies $R^2_{Z,S^*_{k'}} \geq R^2_{Z,S^*_k} \cdot \prod_{i=k'+1}^{k} \frac{i-t}{i}$. Most of the terms in the product telescope, giving us a bound of $R^2_{Z,S^*_k} \cdot \prod_{i=1}^{t} \frac{k'-t+i}{k-t+i}$. Since $\prod_{i=1}^{t} \frac{k'-t+i}{k-t+i}$ converges to $(\frac{k'}{k})^t$ with increasing k (keeping t constant), we get that for large k,

$$R^2_{Z,S^*_{k'}} \geq R^2_{Z,S^*_k} \cdot \Theta((\frac{k'}{k})^t) \geq R^2_{Z,S^*_k} \cdot \Theta((\frac{k'}{k})^{1/\lambda_{\min}(C,k)}).$$

This completes the proof. ∎

Using the above lemmas, we now prove the main theorem.

Proof of Theorem 16. As mentioned earlier, the first inequality is a direct corollary of Theorem 6, obtained by replacing f with the R^2 function. The second inequality follows directly from Lemma 13 and the fact that $|S^{\mathrm{FR}}| = k$.

By applying the above result after $k/2$ iterations, we obtain $R^2_{Z,S^{\mathrm{NG}}_{k/2}} \geq (1-\mathrm{e}^{-\lambda_{\min}(C,k)})\cdot R^2_{Z,S^*_{k/2}}$. Now, using Lemma 18 and monotonicity of R^2, we get

$$R^2_{Z,S^{\mathrm{NG}}_k} \geq R^2_{Z,S^{\mathrm{NG}}_{k/2}} \geq (1-\mathrm{e}^{-\lambda_{\min}(C,k)})\cdot\Theta((\frac{1}{2})^{1/\lambda_{\min}(C,k)})\cdot R^2_{Z,S^*_k},$$

proving the third inequality. ∎

Algorithm 3 The Orthogonal Matching Pursuit algorithm.

1: Initialize $S_0 = \emptyset$.
2: **for** each iteration $i+1 = 1, 2, \ldots$ **do**
3: Let X_{i+1} be a variable maximizing $|\mathrm{Cov}[\mathrm{Res}(Z, S_i), X_{i+1}]|$, and set $S_{i+1} = S_i \cup \{X_{i+1}\}$.
4: Output S_k.

3.3 Orthogonal Matching Pursuit

The second greedy algorithm we analyze is Orthogonal Matching Pursuit (OMP), frequently used in signal processing domains.

By applying similar techniques as in the previous section, we can also obtain approximation bounds for OMP. We start by proving the following lemma that lower-bounds the variance of the residual of a variable.

Lemma 19 *Let A be the $(n+1) \times (n+1)$ covariance matrix of the normalized variables $Z, X_1, X_2, \ldots, X_n$. Then* $\mathrm{Var}[\mathrm{Res}(Z, \{X_1, \ldots, X_n\})] \geq \lambda_{\min}(A)$.

Proof. The matrix A is of the form $A = \begin{pmatrix} 1 & \mathbf{b}^\intercal \\ \mathbf{b} & C \end{pmatrix}$. We use $A[i,j]$ to denote the matrix obtained by removing the i^{th} row and j^{th} column of A, and similarly for C. Recalling that the (i,j) entry of C^{-1} is $\frac{(-1)^{i+j}\det(C[i,j])}{\det(C)}$, and developing the determinant of A by the first row and column, we can write

$$\begin{aligned}
\det(A) &= \sum_{j=1}^{n+1} (-1)^{1+j} a_{1,j} \det(A[1,j]) \\
&= \det(C) + \sum_{j=1}^{n} (-1)^j b_j \det(A[1, j+1]) \\
&= \det(C) + \sum_{j=1}^{n} (-1)^j b_j \sum_{i=1}^{n} (-1)^{i+1} b_i \det(C[i,j]) \\
&= \det(C) - \sum_{j=1}^{n} \sum_{i=1}^{n} (-1)^{i+j} b_i b_j \det(C[i,j]) \\
&= \det(C)(1 - \mathbf{b}^\intercal C^{-1} \mathbf{b}).
\end{aligned}$$

Therefore, using that $\mathrm{Var}[Z] = 1$,

$$\mathrm{Var}[\mathrm{Res}(Z, \{X_1, \ldots, X_n\})] \;=\; \mathrm{Var}[Z] - \mathbf{b}^\intercal C^{-1} \mathbf{b} \;=\; \frac{\det(A)}{\det(C)}.$$

Because $\det(A) = \prod_{i=1}^{n+1} \lambda_i^A$ and $\det(C) = \prod_{i=1}^{n} \lambda_i^C$, and $\lambda_1^A \leq \lambda_1^C \leq \lambda_2^A \leq \lambda_2^C \leq \ldots \leq \lambda_{n+1}^A$ by the eigenvalue interlacing theorem, we get that $\frac{\det(A)}{\det(C)} \geq \lambda_1^A$, proving the lemma. ∎

The above lemma, along with an analysis similar to the proof of Theorem 16, can be used to prove the following approximation bounds for OMP:

Theorem 20 *The set S^{OMP} selected by orthogonal matching pursuit has the following approximation guarantees:*

$$\begin{aligned}
R^2_{Z,S^{OMP}} &\geq (1 - \mathrm{e}^{-(\gamma_{S^{OMP},k} \cdot \lambda_{\min}(C,2k))}) \cdot OPT \\
&\geq (1 - \mathrm{e}^{-\lambda_{\min}(C,2k)^2}) \cdot OPT \\
&\geq (1 - \mathrm{e}^{-\lambda_{\min}(C,k)^2}) \cdot \Theta((\frac{1}{2})^{1/\lambda_{\min}(C,k)}) \cdot OPT.
\end{aligned}$$

Proof. We begin by proving the first inequality. Using notation similar to that in the proof of Theorem 16, we let S_k^* be the optimum set of k variables, S_i^{OMP} the set of variables chosen by OMP in the first i iterations, and $S_i = S_k^* \setminus S_i^{\mathrm{OMP}}$. For each $X_j \in S_i$, let $X'_j = \mathrm{Res}(X_j, S_i^{\mathrm{OMP}})$ be the residual of X_j conditioned on S_i^{OMP}, and write $S'_i = \{X'_j \mid X_j \in S_i\}$.

Consider some iteration $i+1$ of OMP. We will show that at least one of the X'_i is a good candidate in this iteration. Let ℓ maximize R^2_{Z,X'_ℓ}, i.e., $\ell \in \mathrm{argmax}_{(j:X'_j \in S'_i)} R^2_{Z,X'_j}$. By Lemma 19,

$$\mathrm{Var}[X'_\ell] \geq \lambda_{\min}(C_{S_G^i \cup \{X'_\ell\}}) \;\geq\; \lambda_{\min}(C, 2k).$$

The OMP algorithm chooses a variable X_m to add which maximizes $|\mathrm{Cov}[\mathrm{Res}(Z, S_G^i), X_m]|$. Thus, X_m maximizes

$$\mathrm{Cov}[\mathrm{Res}(Z, S_G^i), X_m]^2 = \mathrm{Cov}[Z, \mathrm{Res}(X_m, S_G^i)]^2 \;=\; R^2_{Z,\mathrm{Res}(X_m,S_G^i)} \cdot \mathrm{Var}[\mathrm{Res}(X_m, S_G^i)].$$

In particular, this implies

$$\begin{aligned}
R^2_{Z,\mathrm{Res}(X_m,S_G^i)} &\geq R^2_{Z,X'_\ell} \cdot \frac{\mathrm{Var}[X'_\ell]}{\mathrm{Var}[\mathrm{Res}(X_m, S_G^i)]} \\
&\geq R^2_{Z,X'_\ell} \cdot \frac{\lambda_{\min}(C,2k)}{\mathrm{Var}[\mathrm{Res}(X_m, S_G^i)]} \;\geq\; R^2_{Z,X'_\ell} \cdot \lambda_{\min}(C,2k),
\end{aligned}$$

because $\mathrm{Var}[\mathrm{Res}(X_m, S_G^i)] \leq 1$. As in the proof of Theorem 6, $R^2_{Z,X'_\ell} \geq \frac{\gamma_{S^{\mathrm{OMP}},k}}{k} \cdot R^2_{Z,S'_i}$, so $R^2_{Z,\mathrm{Res}(X_m,S_G^i)} \geq R^2_{Z,S'_i} \cdot \frac{\lambda_{\min}(C,2k) \cdot \gamma_{S^{\mathrm{OMP}},k}}{k}$. With the same definition of $A(i)$ as in the proof of Theorem 6, we get that $A(i+1) \geq \frac{\lambda_{\min}(C,2k)\gamma_{S^{\mathrm{OMP}},k}}{k} \cdot (\mathrm{OPT} - \sum_{j=1}^{i} A(j))$. An inductive proof now shows that

$$R^2_{Z,S_G} \;=\; \sum_{i=1}^{k} A(i) \;\geq\; (1 - \mathrm{e}^{-\lambda_{\min}(C,2k) \cdot \gamma_{S^{\mathrm{OMP}},k}}) \cdot R^2_{Z,S_k^*}.$$

The proofs of the other two inequalities follow the same pattern as the proof for Forward Regression. ∎

3.4 Oblivious Algorithm

As a baseline, we also consider a greedy algorithm which completely ignores C and simply selects the k variables individually most correlated with Z.

Lemma 17 immediately implies a simple bound for the oblivious algorithm:

Algorithm 4 The oblivious algorithm.

1: Sort the X_i by non-increasing b_i values.
2: Return $\{X_1, X_2, \ldots, X_K\}$.

Theorem 21 *The set S^{OBL} selected by the oblivious algorithm has the following approximation guarantees:*

$$R^2_{Z,S^{OBL}} \;\geq\; \frac{\gamma_{\emptyset,k}}{\lambda_{\max}(C,k)} \cdot OPT \;\geq\; \frac{\lambda_{\min}(C,k)}{\lambda_{\max}(C,k)} \cdot OPT.$$

Proof. Let S be the set chosen by the oblivious algorithm, and S^*_k the optimum set of k variables. By definition of the oblivious algorithm, $\sum_{i\in S} R^2_{Z,X_i} \geq \sum_{i\in S^*_k} R^2_{Z,X_i}$, so using Lemma 17, we obtain that

$$R^2_{Z,S} \geq \frac{\sum_{i\in S} R^2_{Z,X_i}}{\lambda_{\max}(C,k)} \;\geq\; \frac{\sum_{i\in S^*_k} R^2_{Z,X_i}}{\lambda_{\max}(C,k)} \;\geq\; \frac{\gamma_{\emptyset,k}}{\lambda_{\max}(C,k)} R^2_{Z,S^*_k}.$$

The second inequality of the theorem follows directly from Lemma 13. ■

4. Dictionary Selection Bounds

To demonstrate the wider applicability of the approximate submodularity framework, we next obtain a tighter analysis for two greedy algorithms for the dictionary selection problem, introduced by Krause and Cevher (2010).

The Dictionary Selection problem generalizes the Subset Selection problem by considering s predictor variables $Z_1, Z_2, \ldots, Z_s$. The goal is to select a dictionary D of d observation variables, to optimize the average R^2 fit for the Z_i using at most k vectors from D for each. Formally, the Dictionary Selection problem is defined as follows:

Definition 22 (Dictionary Selection) *Given all pairwise covariances among the Z_j and X_i variables, as well as parameters d and k, find a set D of at most d variables from $\{X_1, \ldots, X_n\}$ maximizing*

$$F(D) = \sum_{j=1}^{s} \max_{S\subset D, |S|=k} R^2_{Z_j,S}.$$

4.1 The Algorithm $\mathrm{SDS_{MA}}$

The $\mathrm{SDS_{MA}}$ algorithm generalizes the oblivious greedy algorithm to the problem of Dictionary Selection. It replaces the $R^2_{Z_j,S}$ term in Definition 22 with its modular approximation $f(Z_j, S) = \sum_{i\in S} R^2_{Z_j,X_i}$. Thus, it greedily tries to maximize the function $\hat{F}(D) = \sum_{j=1}^{s} \max_{S\subset D,|S|=k} f(Z_j, S)$, over sets D of size at most d; the inner maximum can be computed efficiently using the oblivious algorithm.

Using Lemma 17, we obtain the following multiplicative approximation guarantee for $\mathrm{SDS_{MA}}$:

Algorithm 5 The SDS_{MA} algorithm for dictionary selection.

1: Initialize $D_0 = \emptyset$.
2: **for** each iteration $i + 1 = 1, 2, \ldots$ **do**
3: Let X_{i+1} be a variable maximizing $\hat{F}(D \cup \{X_m\})$, and set $S_{i+1} = S_i \cup \{X_{i+1}\}$.
4: Output D_d.

Theorem 23 *Let D^{MA} be the dictionary selected by the SDS_{MA} algorithm, and D^* the optimum dictionary of size $|D| \leq d$, with respect to the objective $F(D)$ from Definition 22. Then,*

$$F(D^{MA}) \geq \frac{\gamma_{\emptyset,k}}{\lambda_{\max}(C,k)}(1-\frac{1}{\mathrm{e}}) \cdot F(D^*) \;\geq\; \frac{\lambda_{\min}(C,k)}{\lambda_{\max}(C,k)}(1-\frac{1}{\mathrm{e}}) \cdot F(D^*).$$

Proof. Let $\hat{D}$ be a dictionary of size d maximizing $\hat{F}(D)$. Because $f(Z_j, S)$ is monotone and modular in S, $\hat{F}$ is a monotone, submodular function. Hence, using the submodularity results of Nemhauser et al. (1978) and the optimality of $\hat{D}$ for $\hat{F}$,

$$\hat{F}(D^{\mathrm{MA}}) \geq \hat{F}(\hat{D}) \cdot (1-\frac{1}{\mathrm{e}}) \;\geq\; \hat{F}(D^*) \cdot (1-\frac{1}{\mathrm{e}}).$$

Now, by applying Lemma 17 for each Z_j, it is easy to show that $\hat{F}(D^*) \geq \gamma_{\emptyset,k} \cdot F(D^*)$, and similarly $\hat{F}(D^{\mathrm{MA}}) \leq \lambda_{\max}(C,k) \cdot F(D^{\mathrm{MA}})$. Thus we get $F(D^{\mathrm{MA}}) \geq \frac{\gamma_{\emptyset,k}}{\lambda_{\max}(C,k)}(1-\frac{1}{\mathrm{e}})F(D^*)$.

The second part now follows from Lemma 13. ■

Note that these bounds significantly improve the previous additive approximation guarantee obtained by Krause and Cevher (2010): $F(D^{\mathrm{MA}}) \geq (1-\frac{1}{\mathrm{e}}) \cdot F(D^*) - (2-\frac{1}{\mathrm{e}}) \cdot k \cdot \mu(C)$. In particular, when $\mu(C) > \Theta(1/k)$, i.e., even just one pair of variables has moderate correlation, the approximation guarantee of Krause and Cevher becomes trivial.

4.2 The Algorithm $\mathrm{SDS_{OMP}}$

We also obtain a multiplicative approximation guarantee for the greedy $\mathrm{SDS_{OMP}}$ algorithm, introduced by Krause and Cevher for dictionary selection. Our bounds for $\mathrm{SDS_{OMP}}$ are much stronger than the additive bounds obtained by Krause and Cevher. However, for both our results and theirs, the performance guarantees for $\mathrm{SDS_{OMP}}$ are much weaker than those for $\mathrm{SDS_{MA}}$.

The $\mathrm{SDS_{OMP}}$ algorithm generalizes the Orthogonal Matching Pursuit algorithm for subset selection to the problem of dictionary selection. In each iteration, it adds a new element to the currently selected dictionary by using Orthogonal Matching Pursuit to approximate the estimation of $\max_{|S|=k} R^2_{Z_j,S}$.

We now show how to obtain a multiplicative approximation guarantee for $\mathrm{SDS_{OMP}}$. The following definitions are key to our analysis; the first two are from Definition 22 and

Algorithm 6 The *SDS$_{OMP}$* algorithm for dictionary selection.

1: Initialize $D_0 = \emptyset$.
2: **for** each iteration $i+1 = 1, 2, \ldots$ **do**
3: Let X_{i+1} be a variable maximizing $\sum_{j=1}^{s} R^2_{Z_j, S_{\mathrm{OMP}}(D_i \cup \{X_{i+1}\}, Z_j, k)}$ where $S_{\mathrm{OMP}}(D, Z, k)$ denotes the set selected by Orthogonal Matching Pursuit for predicting Z using k variables from D.
4: Set $S_{i+1} = S_i \cup \{X_{i+1}\}$.
5: Output D_d.

Theorem 23.

$$F(D) = \sum_{j=1}^{s} \max_{S \subset D, |S|=k} R^2_{Z_j,S},$$

$$\hat{F}(D) = \sum_{j=1}^{s} \max_{S \subset D, |S|=k} f(Z_j, S),$$

$$\tilde{F}(D) = \sum_{j=1}^{s} R^2_{Z_j, S_{\mathrm{OMP}}(D, Z_j, k)}.$$

We first prove the following lemma about approximating the function $\hat{F}(D)$ by $\tilde{F}(D)$:

Lemma 24 *For any set D, we have that*

$$\frac{(1 - \mathrm{e}^{-\lambda_{\min}(C,2k)^2})}{\lambda_{\max}(C,k)} \cdot \hat{F}(D) \leq \tilde{F}(D) \ \leq \ \frac{\hat{F}(D)}{\gamma_{\emptyset,k}}.$$

Proof. Using Theorem 20 and Lemma 17 and summing up over all the Z_j terms, we obtain that

$$\tilde{F}(D) \geq (1 - \mathrm{e}^{-\lambda_{\min}(C,2k)^2}) \cdot F(D) \ \geq \ (1 - \mathrm{e}^{-\lambda_{\min}(C,2k)^2}) \frac{\hat{F}(D)}{\lambda_{\max}(C,k)}.$$

Similarly, using Lemma 17 and the fact that $\max_{S \subset D, |S|=k} R^2_{Z_j,S} \geq R^2_{Z_j, S_{OMP}(D, Z_j, k)}$, we have

$$\hat{F}(D) \geq \gamma_{\emptyset,k} \cdot F(D) \ \geq \ \gamma_{\emptyset,k} \cdot \tilde{F}(D). \ \blacksquare$$

Using the above lemma, we now prove the following bound for $\mathrm{SDS}_{\mathrm{OMP}}$:

Theorem 25 *Let D^{OMP} be the dictionary selected by the SDS$_{OMP}$ algorithm, and D^* the optimum dictionary of size $|D| \leq d$, with respect to the objective $F(D)$ from Definition 22. Then,*

$$F(D^{OMP}) \geq F(D^*) \cdot \frac{\gamma_{\emptyset,k}}{\lambda_{\max}(C,k)} \cdot \frac{(1 - \mathrm{e}^{-(p \cdot \gamma_{\emptyset,k})})}{d - d \cdot p \cdot \gamma_{\emptyset,k} + 1} \ \geq \ F(D^*) \cdot \frac{\lambda_{\min}(C,k)}{\lambda_{\max}(C,k)} \cdot \frac{(1 - \mathrm{e}^{-(p \cdot \gamma_{\emptyset,k})})}{d - d \cdot p \cdot \gamma_{\emptyset,k} + 1},$$

where $p = \frac{1}{\lambda_{\max}(C,k)} \cdot (1 - \mathrm{e}^{-\lambda_{\min}(C,2k)^2})$.

Proof. Let $\hat{D}$ be the dictionary of size d that maximizes $\hat{F}(D)$. We first prove that $\hat{F}(D^{\mathrm{OMP}})$ is a good approximation to $\hat{F}(\hat{D})$.

Let S_i^{NG} be the variables chosen by $\mathrm{SDS}_{\mathrm{OMP}}$ after i iterations. Define $S_i = \hat{D} \setminus S_i^{\mathrm{NG}}$. By monotonicity of $\hat{F}$, we have that $\hat{F}(S_i \cup S_i^{\mathrm{NG}}) \geq \hat{F}(\hat{D})$.

Let $\hat{X} \in S_i$ be the variable maximizing $\hat{F}(S_i^{\mathrm{NG}} \cup \{\hat{X}\})$, and similarly $\tilde{X} \in S_i$ be the variable maximizing $\tilde{F}(S_i^{\mathrm{NG}} \cup \{\tilde{X}\})$.

Since $\hat{F}$ is a submodular function, it is easy to show (using an argument similar to the proof of Theorem 16) that $\hat{F}(S_i^{\mathrm{NG}} \cup \{\hat{X}\}) - \hat{F}(S_i^{\mathrm{NG}}) \geq \frac{\hat{F}(\hat{D}) - \hat{F}(S_i^{\mathrm{NG}})}{d}$.

Now, using Lemma 24 above, and the optimality of $\tilde{X}$ for $\tilde{F}(S_i^{\mathrm{NG}} \cup \{\tilde{X}\})$, we obtain that

$$\frac{1}{\gamma_{\emptyset,k}} \cdot \hat{F}(S_i^{\mathrm{NG}} \cup \{\tilde{X}\}) \geq \tilde{F}(S_i^{\mathrm{NG}} \cup \{\tilde{X}\}) \ \geq \ \tilde{F}(S_i^{\mathrm{NG}} \cup \{\hat{X}\}) \ \geq \ p \cdot \hat{F}(S_i^{\mathrm{NG}} \cup \{\hat{X}\}).$$

Thus, $\hat{F}(S_i^{\mathrm{NG}} \cup \{\tilde{X}\}) \geq p \cdot \gamma_{\emptyset,k} \cdot \hat{F}(S_i^{\mathrm{NG}} \cup \{\hat{X}\})$, or

$$\hat{F}(S_i^{\mathrm{NG}} \cup \{\tilde{X}\}) - \hat{F}(S_i^{\mathrm{NG}}) \geq p \cdot \gamma_{\emptyset,k} \cdot (\hat{F}(S_i^{\mathrm{NG}} \cup \{\hat{X}\}) - \hat{F}(S_i^{\mathrm{NG}})) - (1 - p \cdot \gamma_{\emptyset,k}) \hat{F}(S_i^{\mathrm{NG}}).$$

Define $A(i) = \hat{F}(S_i^{\mathrm{NG}}) - \hat{F}(S_{i-1}^{\mathrm{NG}})$ to be the gain, with respect to $\hat{F}$, obtained from the variable chosen by $\mathrm{SDS}_{\mathrm{OMP}}$ in iteration i. Then $\hat{F}(D^{\mathrm{OMP}}) = \sum_{i=1}^{d} A(i)$. From the preceding paragraphs, we obtain

$$A(i+1) \geq \frac{p \cdot \gamma_{\emptyset,k}}{d} \cdot (\hat{F}(\hat{D}) - (1 + \frac{d}{p \cdot \gamma_{\emptyset,k}} - d) \sum_{j=1}^{i} A(j)).$$

Since the above inequality holds for each iteration $i = 1, 2, \ldots, d$, a simple inductive proof shows that

$$\hat{F}(\hat{D}) - \sum_{i=1}^{d} A(i) \leq \hat{F}(\hat{D}) \cdot (1 - \frac{p\gamma_{\emptyset,k}}{d})^d + (d - dp\gamma_{\emptyset,k}) \cdot \sum_{i=1}^{d} A(i).$$

Rearranging the terms and simplifying, we get that

$$\hat{F}(D^{\mathrm{OMP}}) = \sum_{i=1}^{d} A(i) \ \geq \ \hat{F}(\hat{D}) \cdot \frac{(1 - \mathrm{e}^{-(p \cdot \gamma_{\emptyset,k})})}{d - dp\gamma_{\emptyset,k} + 1} \ \geq \ \hat{F}(D^*) \cdot \frac{(1 - \mathrm{e}^{-(p \cdot \gamma_{\emptyset,k})})}{d - dp\gamma_{\emptyset,k} + 1},$$

where the last inequality is due to the optimality of $\hat{D}$ for $\hat{F}$.

Now, using Lemma 17 for each Z_j term, it can be easily seen that $\hat{F}(D^*) \geq \gamma_{\emptyset,k} \cdot F(D^*)$. Similarly, using Lemma 3.3 on the set D^{OMP}, we have $F(D^{\mathrm{OMP}}) \geq \frac{1}{\lambda_{\max}(C,k)} \cdot \hat{F}(D^{\mathrm{OMP}})$.

Using the above inequalities, we therefore get the desired bound

$$F(D^{\mathrm{OMP}}) \geq F(D^*) \cdot \frac{\gamma_{\emptyset,k}}{\lambda_{\max}(C,k)} \cdot \frac{(1 - \mathrm{e}^{-(p \cdot \gamma_{\emptyset,k})})}{d - d \cdot p \cdot \gamma_{\emptyset,k} + 1}.$$

The second inequality of the Theorem now follows directly from Lemma 13. $\blacksquare$

5. Experiments

In this section, we evaluate Forward Regression (FR) and OMP empirically, on two real-world and one synthetic data set. We compare the two algorithms against an optimal solution (OPT), computed using exhaustive search, the oblivious greedy algorithm (OBL), and the L1-regularization/Lasso (L1) algorithm (in the implementation of Koh et al. (2008)). Beyond the algorithms' performance, we also compute the various spectral parameters from which we can derive lower bounds. Specifically, these are

1. the submodularity ratio: $\gamma_{S^{\mathrm{FR}},k}$, where S^{FR} is the subset selected by forward regression.
2. the smallest sparse eigenvalues $\lambda_{\min}(C,k)$ and $\lambda_{\min}(C,2k)$. (In some cases, computing $\lambda_{\min}(C,2k)$ was not computationally feasible due to the problem size.)
3. the sparse inverse condition number $\kappa(C,k)^{-1}$. As mentioned earlier, the sparse inverse condition number $\kappa(C,k)$ is strongly related to the Restricted Isometry Property in (Candès et al., 2005).
4. the smallest eigenvalue $\lambda_{\min}(C) = \lambda_{\min}(C,n)$ of the entire covariance matrix.

The aim of our experiments is twofold: First, we wish to evaluate which among the submodular and spectral parameters are good predictors of the performance of greedy algorithms in practice. Second, we wish to highlight how the theoretical bounds for subset selection algorithms reflect on their actual performance. Our analytical results predict that Forward Regression should outperform OMP, which in turn outperforms Oblivious. For Lasso, it is not known whether strong multiplicative bounds, like the ones we proved for Forward Regression or OMP, can be obtained.

5.1 Data Sets

Because several of the spectral parameters (as well as the optimum solution) are **NP**-hard to compute, we restrict our experiments to data sets with $n \leq 30$ features, from which $k \leq 8$ are to be selected. We stress that the greedy algorithms themselves are very efficient, and the restriction on data set sizes is only intended to allow for an adequate evaluation of the results.

Each data set contains $m > n$ samples, from which we compute the empirical covariance matrix (analogous to the Gram matrix in sparse approximation) between all observation variables and the predictor variable; we then normalize it to obtain C and $\mathbf{b}$. We evaluate the performance of all algorithms in terms of their R^2 fit; thus, we implicitly treat C and $\mathbf{b}$ as the ground truth, and also do not separate the data sets into training and test cases.

Our data sets are the *Boston Housing Data*, a data set of *World Bank Development Indicators*, and a synthetic data set generated from a distribution similar to the one used by Zhang (2008). The *Boston Housing Data* (available from the UCI Machine Learning Repository) is a small data set frequently used to evaluate ML algorithms. It comprises $n = 15$ features (such as crime rate, property tax rates, etc.) and $m = 516$ observations. Our goal is to predict housing prices from these features. The *World Bank Data* (available from `http://databank.worldbank.org`) contains an extensive list of socio-economic and

health indicators of development, for many countries and over several years. We choose a subset of $n = 29$ indicators for the years 2005 and 2006, such that the values for all of the $m = 65$ countries are known for each indicator. (The data set does not contain all indicators for each country.) We choose to predict the average life expectancy for those countries.

To perform tests in a controlled fashion, we also generate random instances from a known distribution similar to one used by Zhang (2008): There are $n = 29$ features, and $m = 100$ data points are generated from a joint Gaussian distribution with moderately high correlations of 0.6. The target vector is obtained by generating coefficients uniformly from 0 to 10 along each dimension, and adding noise with variance $\sigma^2 = 0.1$. Notice that the target vector is not truly sparse. As for the other two data sets, the covariances are then taken to be the empirical ones of the generated data. The plots we show are the average R^2 values for 20 independent runs of the experiment.

5.2 Results

We run the different subset selection algorithms for values of k from 2 through 8, and plot the R^2 values for the selected sets. When including all of the features, the R^2 value is close to 1 in all data sets, implying that nearly all of the variance in the function to be predicted can be explained by the features.

Figures 1, 3 and 5 show the results for the three data sets. The main insight is that on all data sets, Forward Regression performs optimally or near-optimally, and OMP is only slightly worse. This is despite the fact that (as we discuss shortly) the spectral properties would not necessarily predict such near-optimal performance. Lasso performs somewhat worse on all data sets, and, not surprisingly, the baseline oblivious algorithm performs even worse. The last fact implies that the optimal solution is non-trivial in that it must account for correlation between the observation variables. The order of performance of the greedy algorithms match the order of the strength of the theoretical bounds we derived for them.

On the World Bank data (Figure 3), all algorithms perform quite well with just 2–3 features already. The main reason is that adolescent birth rate is by itself highly predictive of life expectancy, so the first feature selected by all algorithms already contributes high R^2 value.

Figures 2, 4 and 6 show the different spectral quantities for the data sets, for varying values of k. Both of the real-world data sets are nearly singular, as evidenced by the small $\lambda_{\min}(C)$ values. In fact, the near-singularities manifest themselves for small values of k already; in particular, since $\lambda_{\min}(C,2)$ is already small, we observe that there are pairs of highly correlated observations variables in the data sets. Thus, the bounds on approximation we would obtain by considering merely $\lambda_{\min}(C,k)$ or $\lambda_{\min}(C,2k)$ would be quite weak. Notice, however, that they are still quite a bit stronger than the inverse condition number $\kappa(C,k)^{-1}$: this bound — which is closely related to the RIP property frequently at the center of sparse approximation analysis — takes on much smaller values, and thus would be an even looser bound than the eigenvalues.

On the other hand, the submodularity ratios $\gamma_{S^{\mathrm{FR}},k}$ for all the data sets are much larger than the other spectral quantities (almost 5 times larger, on average, than the corresponding $\lambda_{\min}(C)$ values). Notice that unlike the other quantities, the submodularity ratios are not

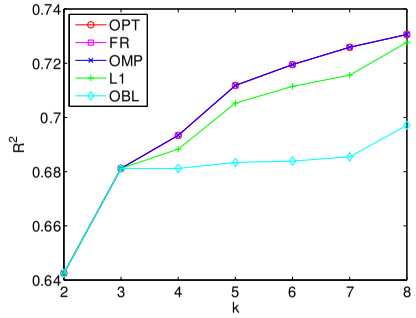

Figure 1: Boston Housing R^2

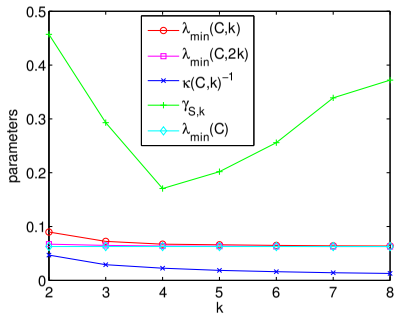

Figure 2: Boston Housing parameters

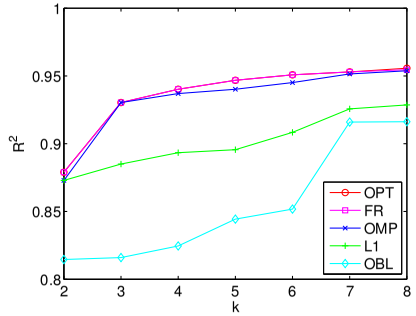

Figure 3: World Bank R^2

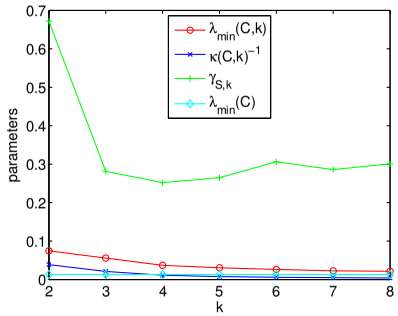

Figure 4: World Bank parameters

monotonically decreasing in k — this is due to the dependency of $\gamma_{S^{\mathrm{FR}},k}$ on the set S^{FR}, which is different for every k.

The discrepancy between the small values of the eigenvalues and the good performance of all algorithms shows that bounds based solely on eigenvalues can sometimes be loose. Significantly better bounds are obtained from the submodularity ratio $\gamma_{S^{\mathrm{FR}},k}$, which takes on values above 0.2, and significantly larger in many cases. While not entirely sufficient to explain the performance of the greedy algorithms, it shows that the near-singularities of C do not align unfavorably with $\mathbf{b}$, and thus do not provide an opportunity for strong supermodular behavior that adversely affects greedy algorithms.

The synthetic data set we generated is somewhat further from singular, with $\lambda_{\min}(C) \approx 0.11$. However, the same patterns persist: the simple eigenvalue based bounds, while somewhat larger for small k, still do not fully predict the performance of greedy algorithms, whereas the submodularity ratio here is close to 1 for all values of k. This shows that the near-singularities do not at all provide the possibility of strongly supermodular benefits of sets of variables. Indeed, the plot of R^2 values on the synthetic data is concave, an indicator of submodular behavior of the function.

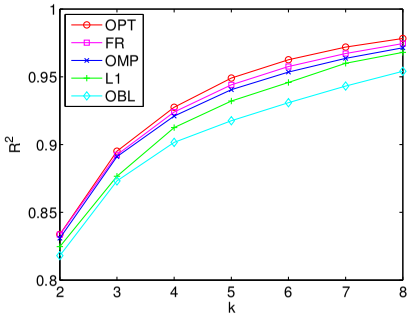

Figure 5: Synthetic Data R^2

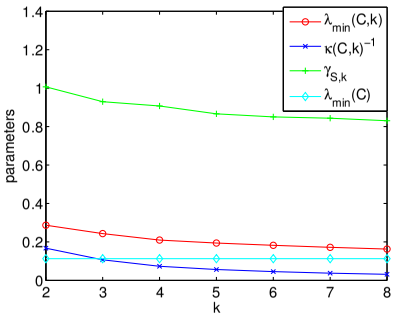

Figure 6: Synthetic Data parameters

The above observations suggest that bounds based on the submodularity ratio are better predictors of the performance of greedy algorithms, followed by bounds based on the sparse eigenvalues, and finally those based on the condition number or RIP property.

5.3 Narrowing the gap between theory and practice

Our theoretical bounds, though much stronger than previous results, still do not fully predict the observed near-optimal performance of Forward Regression and OMP on the real-world datasets. In particular, for Forward Regression, even though the submodularity ratio is less than 0.4 for most cases, implying a theoretical guarantee of roughly $1 - e^{-0.4} \approx 33\%$, the algorithm still achieves near-optimal performance. While gaps between worst-case bounds and practical performance are commonplace in algorithmic analysis, they also suggest that there is scope for further improving the analysis, by looking at more fine-grained parameters.

Indeed, a slightly more careful analysis of the proof of Theorem 16 and our definition of the submodularity ratio reveals that we do not really need to calculate the submodularity ratio over all sets S of size k while analyzing the greedy steps of Forward Regression. We can ignore sets S whose submodularity ratio is low, but whose marginal contribution to the current R^2 is only a small fraction (say, at most ϵ). This is because the proof of Theorem 16 shows that for each iteration $i+1$, we only need to consider the submodularity ratio for the set $S_i = S_k^* \setminus S_i^{\mathrm{NG}}$, where S_i^{NG} is the set selected by the greedy algorithm after i iterations, and S_k^* is the optimal k-subset. Thus, if $R^2_{Z,S_i \cup S_i^{\mathrm{NG}}} \leq (1+\epsilon) \cdot R^2_{Z,S_i^{\mathrm{NG}}}$, then the currently selected set must already be within a factor $\frac{1}{1+\epsilon}$ of optimal.

By carefully pruning such sets (using $\epsilon = 0.2$) while calculating the submodularity ratio, we see that the resulting values of $\gamma_{S^{\mathrm{FR}},k}$ are much higher (more than 0.8), thus significantly reducing the gap between the theoretical bounds and experimental results. Table 1 shows the values of $\gamma_{S^{\mathrm{FR}},k}$ obtained using this method.

The results suggest an interesting direction for future work: namely, to characterize for which sets the submodular behavior of R^2 really matters.

Data Set	$k=2$	$k=3$	$k=4$	$k=5$	$k=6$	$k=7$	$k=8$
Boston	0.9	0.91	1.02	1.21	1.36	1.54	1.74
World Bank	0.8	0.81	0.81	0.81	0.94	1.19	1.40

Table 1: Improved estimates for submodularity ratio

6. Discussion and Concluding Remarks

In this paper, we defined a notion of approximate submodularity. We showed that it naturally captures the performance degradation of the greedy algorithm. As a concrete application of the framework, we connected the submodularity ratio with spectral parameters of the covariance matrix to obtain the strongest known approximation guarantees for the Forward Selection and Orthogonal Matching Pursuit algorithms for regression. As a second example, we gave improved approximation guarantees for known greedy algorithms for dictionary selection.

We believe that our techniques for analyzing greedy algorithms using a notion of "approximate submodularity" are not specific to subset selection and dictionary selection, and could also be used to analyze other problems in compressed sensing and sparse recovery. A natural further direction is hence to identify other applications of the approximate submodularity technique.

While approximation guarantees for the greedy algorithm are perhaps the most widely used consequence of submodularity, they are far from the only one. Some other useful consequences include the following:

1. In *valid utility games* (Vetta, 2002), where utility functions are essentially submodular and interact with each other in certain ways, equilibria always achieve high social welfare.

2. A monotone submodular function can be approximately maximized subject to a Knapsack constraint (Sviridenko, 2004), Matroid constraint (Vondrák, 2008) or combinations thereof (e.g., (Chekuri et al., 2011)).

3. If the function f is submodular, but not necessarily monotone, it can be approximately maximized, with or without a cardinality constraint. Without a cardinality constraint, it can also be exactly minimized.

It would be desirable to verify whether some of these results gracefully degrade when the submodularity ratio is bounded away from 0. The third property (optimization of non-monotone submodular functions) seems unlikely to carry over, as our definition was targeted

at monotone submodular functions. This raises the natural question of whether there is a more general definition of approximate submodularity that retains the positive results of the present work while also yielding an analogue to some or all of the above properties.

Our bicriteria approximation guarantees, trading off a maximization of coverage against a minimization of cost, could be generalized to more general constraints. For instance, Iyer and Bilmes (Iyer and Bilmes, 2013) give bicriteria approximation guarantees for maximizing a submodular function subject to a submodular cost constraint, or minimizing a submodular function subject to a submodular coverage constraint. It is natural to ask whether similar guarantees can be obtained for approximately submodular functions.

As discussed in Remark 4, it is open how well one can approximate the submodularity ratio of a given function f in general; being able to do so would allow one to obtain approximation guarantees at least for specific instances. Alternatively, it may be possible to establish approximation hardness results for computing the submodularity ratio.

The approximation guarantees of the greedy algorithm are worst when the covariance matrix is singular, or close to singular. When the covariance matrix is estimated from data (rather than explicitly given), the natural variance in data generated from joint distributions may keep it from being too close to singular. A detailed investigation would constitute an interesting direction for future work, though to be useful, it would have to provide a lower bound of $\omega(1/\log n)$ on the smallest (sparse) eigenvalue.

Appendix A. Estimating $\lambda_{\min}(C,k)$

Several of our approximation guarantees are phrased in terms of $\lambda_{\min}(C,k)$. Finding the exact value of $\lambda_{\min}(C,k)$ is **NP**-hard in general; here, we show how to estimate lower and upper bounds. Let $\lambda_1 \leq \lambda_2 \leq \ldots \leq \lambda_n$ be the eigenvalues of C, and $\mathbf{e_1}, \mathbf{e_2}, \ldots, \mathbf{e_n}$ the corresponding eigenvectors. A first simple bound can be obtained directly from the eigenvalue interlacing theorem: $\lambda_1 \leq \lambda_{\min}(C,k) \leq \lambda_{n-k+1}$.

One case in which good lower bounds on $\lambda_{\min}(C,k)$ can possibly be obtained is when only a small (constant) number of the λ_i are small. The following lemma allows a bound in terms of any λ_j; however, since the running time by the implied algorithm is exponential in j, and the quality of the bound depends on λ_j, it is useful only in the special case when $\lambda_j \gg 0$ for a small constant j.

Lemma 26 *Let V_j be the vector space spanned by the eigenvectors $\mathbf{e_1}, \mathbf{e_2}, \ldots, \mathbf{e_j}$, and define*

$$\beta_j = \max_{\mathbf{y} \in V_j, \mathbf{x} \in \mathbb{R}^n, \|\mathbf{y}\|_2 = \|\mathbf{x}\|_2 = 1, \|\mathbf{x}\|_0 \leq k} |\mathbf{x} \cdot \mathbf{y}|.$$

Then, $\lambda_{\min}(C,k) \geq \lambda_{j+1} \cdot (1 - \beta_j)$.

Proof. Let $\mathbf{x}' \in \mathbb{R}^n, \|\mathbf{x}'\|_2 = 1, \|\mathbf{x}\|_0 \leq k$ be an eigenvector corresponding to $\lambda_{\min}(C,k)$. Let α_i be the coefficients of the representation of $\mathbf{x}'$ in terms of the $\mathbf{e_i}$: $\mathbf{x}' = \sum_{i=1}^n \alpha_i \mathbf{e_i}$. Thus, $\sum_{i=1}^n \alpha_i^2 = 1$, and we can write

$$\lambda_{\min}(C,k) \;=\; \mathbf{x'^T} C \mathbf{x}' \;=\; \sum_{i=1}^{n} \alpha_i^2 \lambda_i \;\geq\; \lambda_{j+1}(1 - \sum_{i=1}^{j} \alpha_i^2).$$

Since $\sum_{i=1}^j \alpha_i^2$ is the length of the projection of $\mathbf{x}$ onto V_j, we have

$$\sum_{i=1}^{j} \alpha_i^2 \;=\; \max_{\mathbf{y} \in V_j, \|\mathbf{y}\|_2 = 1} |\mathbf{x}' \cdot \mathbf{y}| \;\leq\; \max_{\mathbf{y} \in V_j, \mathbf{x} \in \mathbb{R}^n, \|\mathbf{x}\|_2 = \|\mathbf{y}\|_2 = 1, \|\mathbf{x}\|_0 \leq k} |\mathbf{y} \cdot \mathbf{x}|,$$

completing the proof. ■

Since all the λ_j can be computed easily, the crux in using this bound is finding a good bound on β_j. Next, we show a PTAS (Polynomial-Time Approximation Scheme) for approximating β_j, for any constant j.

Lemma 27 *For every $\epsilon > 0$, there is a $1 - \epsilon$ approximation for calculating β_j, running in time $O((\frac{n}{\epsilon})^j)$.*

Proof. Any vector $\mathbf{y} \in V_j$ with $\|\mathbf{y}\|_2 = 1$ can be written as $\mathbf{y} = \sum_{i=1}^j \eta_i \mathbf{e_i}$ with $\eta_i \in [-1, 1]$ for all i. The idea of our algorithm is to exhaustively search over all $\mathbf{y}$, as parametrized by their η_i entries. To make the search finite, the entries are discretized to multiples of $\delta = \epsilon \cdot \sqrt{k/(nj)}$. The total number of such vectors to search over is $(2/\delta)^j \leq (n/\epsilon)^j$.

Let $\hat{\mathbf{x}}, \hat{\mathbf{y}}$ attain the maximum in the definition of β_j, and write $\hat{\mathbf{y}} = \sum_{i=1}^j \hat{\eta}_i \mathbf{e_i}$. For each i, let η_i be $\hat{\eta}_i$, rounded to the nearest multiple of δ, and $\mathbf{y} = \sum_{i=1}^j \eta_i \mathbf{e_i}$. Then, $\|\hat{\mathbf{y}} - \mathbf{y}\|_2 \leq \|\delta \sum_{i=1}^j \mathbf{e_j}\|_2 = \delta\sqrt{j}$.

The vector $\mathbf{x}' = \text{argmax}_{\mathbf{x} \in \mathbb{R}^n, \|\mathbf{x}\|_2 = 1, \|\mathbf{x}\|_0 \leq k} |\mathbf{y} \cdot \mathbf{x}|$ is of the following form: Let I be the set of k indices i such that $|y_i|$ is largest, and $\gamma = \sqrt{\sum_{i \in I} y_i^2}$. Then, $x'_i = 0$ for $i \notin I$ and $x'_i = y_i/\gamma$ for $i \in I$. Notice that given $\mathbf{y}$, we can easily find $\mathbf{x}'$, and because $|\hat{\mathbf{x}} \cdot \mathbf{y}| \leq |\mathbf{x}' \cdot \mathbf{y}| \leq |\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}|$, we have

$$\frac{||\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}| - |\mathbf{x}' \cdot \mathbf{y}||}{|\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}|} \;\leq\; \frac{||\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}| - |\hat{\mathbf{x}} \cdot \mathbf{y}||}{|\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}|} \;\leq\; \frac{\|\hat{\mathbf{x}}\|_2 \|\hat{\mathbf{y}} - \mathbf{y}\|_2}{|\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}|} \;\leq\; \frac{\delta\sqrt{j}}{|\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}|} \;\leq\; \delta\sqrt{jn/k}.$$

The last inequality follows since the sum of the k largest entries of $\hat{\mathbf{y}}$ is at least $k/\sqrt{n}$, so by setting $x_i = 1/\sqrt{k}$ for each of those coordinates, we can attain at least an inner product of $\sqrt{k/n}$, and the inner product with $\hat{\mathbf{x}}$ cannot be smaller.

The value output by the exhaustive search over all discretized values is at least $|\mathbf{x}' \cdot \mathbf{y}|$, and thus within a factor of $1 - \frac{\delta\sqrt{j}n}{k} = 1 - \epsilon$ of the maximum value, attained by $\hat{\mathbf{x}}, \hat{\mathbf{y}}$. ■

Abstract

Modeling continuous-time physiological processes that manifest a patient's evolving clinical states is a key step in approaching many problems in healthcare. In this paper, we develop the *Hidden Absorbing Semi-Markov Model* (HASMM): a versatile probabilistic model that is capable of capturing the modern electronic health record (EHR) data. Unlike existing models, the HASMM accommodates irregularly sampled, temporally correlated, and informatively censored physiological data, and can describe non-stationary clinical state transitions. Learning the HASMM parameters from the EHR data is achieved via a novel *forward-filtering backward-sampling* Monte-Carlo EM algorithm that exploits the knowledge of the end-point clinical outcomes (informative censoring) in the EHR data, and implements the E-step by sequentially sampling the patients' clinical states in the reverse-time direction while conditioning on the future states. Real-time inferences are drawn via a forward-filtering algorithm that operates on a virtually constructed discrete-time *embedded Markov chain* that mirrors the patient's continuous-time state trajectory. We demonstrate the prognostic utility of the HASMM in a critical care prognosis setting using a real-world dataset for patients admitted to the Ronald Reagan UCLA Medical Center. In particular, we show that using HASMMs, a patient's clinical deterioration can be predicted 8-9 hours prior to intensive care unit admission, with a 22% AUC gain compared to the Rothman index, which is the state-of-the-art critical care risk scoring technology.

Keywords: Hidden Semi-Markov Models, Medical Informatics, Monte Carlo methods.

1. Introduction

Modeling the clinical conditions of a patient using evidential physiological data is a ubiquitous problem that arises in many healthcare settings, including disease progression modeling (Schulam and Saria (2015); Mould (2012); Wang et al. (2014); Jackson et al. (2003); Sweeting et al. (2010); Liu et al. (2015)) and critical care prognosis (Moreno et al. (2005); Matos et al. (2006); Yoon et al. (2016); Hoiles and van der Schaar (2016); Alaa et al. (2016)). Accurate physiological modeling in these settings confers an *instrumental value* that manifests in the ability to provide early diagnosis, individualized treatments and timely interventions (e.g. early warning systems in hospital wards (Yoon et al. (2016)), early diagnosis for Scleroderma patients (Varga et al. (2012); Alaa and van der Schaar (2016)), early detection of a progressing breast cancer (Bartkova et al. (2005)), etc). Physiological modeling also confers an *epistemic value* that manifests in the knowledge extracted from data about the progression and severity phases of a disease (Stelfox et al. (2012))), or the short-term dynamics of the physiological behavior of critically ill patients (Li-wei et al. (2013)).

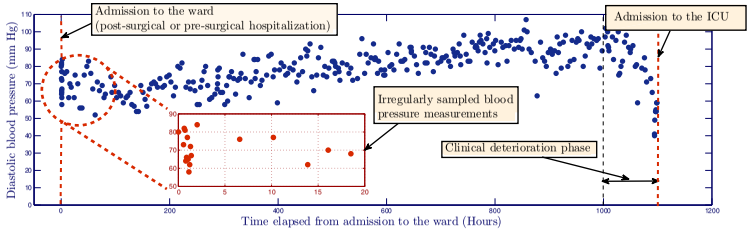

Figure 1: An episode of the diastolic blood pressure measurements (as recorded in the EHR) for a patient hospitalized in a regular ward for 50 days and then admitted to the ICU after the ward staff realized she is clinically deteriorating.

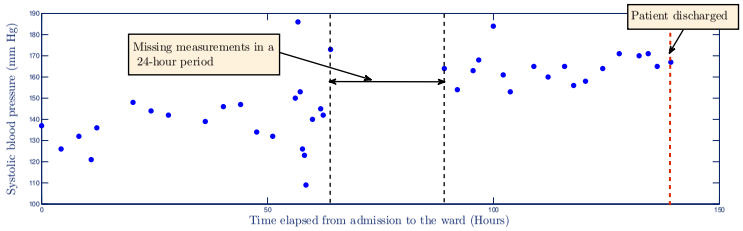

Figure 2: An episode of the systolic blood pressure measurements for a patient hospitalized in a regular ward for 6 days and then discharged home by the ward staff. Measurements are missing in a 24-hour period during the patient's stay in the ward.

The recent availability of data in the electronic health records (EHR)[1] creates a promising horizon for establishing rich and complex physiological models (Gunter and Terry (2005)). Modern EHRs comprise *episodic* data records for individual (anonymized) patients; every patient's episode is a temporal sequence of clinical findings (e.g. visual field index for Glaucoma patients (Liu et al. (2015)), CD4 cell counts for HIV-infected patients (Guihenneuc-Jouyaux et al. (2000)), etc), lab test results (e.g. white cell blood count for

1. A recent data brief from the Office for National Coordinator (ONC) for healthcare technology shows that the adoption of EHR in US hospitals exhibited a spectacular increase from 9.4% in 2008, 27.6% in 2011, to 75.5% in 2014 (Charles et al. (2015)).

post-operative patients under immunosuppressive drugs (Cholette et al. (2012)), etc), or vital signs (e.g. blood pressure and O_2 saturation (Yoon et al. (2016))). The time span of these episodes may be as short as few days in short-term hospitalization episodes (e.g. patients with solid tumors, hematological malignancies or neutropenia who are hospitalized in regular wards before or after a surgery (Kause et al. (2004); Hogan et al. (2012); Kirkland et al. (2013))), or as long as few years in longitudinal episodes (e.g. chronic obstructive pulmonary disease may evolve from a mild Stage I to a very severe Stage IV over a time span of 10 years (Pedersen et al. (2011); Wang et al. (2014))). **In this paper, we develop a versatile time-series model that provides means for accurate real-time risk prognostication of adverse clinical outcomes.** Other applications of the model include but are not limited to modeling default data in quantitative finance (Giampieri et al. (2005)), and fault detection in general dynamic systems (Smyth (1994)). In the next Subsection, we expose our modeling rationale and challenges posed by the structure of modern EHR data. We conclude this Section by summarizing our contributions in Subsection 1.2.

1.1 Modeling Rationale and Challenges

1.1.1 Rationale

Previous physiological models have branched into two different modeling paths with respect to the way a patient's clinical states are defined. One strand of literature adopts *fully observable models*; these models assume that clinical states are quantifiable via *observable* clinical markers or disease severity measures (e.g. PFVC in Scleroderma (Schulam and Saria (2015)), GFR in kidney disease (Eddy and Neilson (2006)), etc). Another strand of literature adopts *latent variable models*, which assume that clinical states are latent and manifest only through proximal, noisy physiological measurements. Table 1 lists some notable previous works that fall under each modeling category[2].

Table 1: Modeling methodologies in previous works.

Methodology	Previous Works
Fully observable models	• HIV (Dessie (2014); Foucher et al. (2005)) • Chronic kidney diseases (Eddy and Neilson (2006)) • Scleroderma (Schulam and Saria (2015)) • ICU (Ghassemi et al. (2015)).
Latent variable models	• Alzheimer (Chen and Zhou (2011)) • HIV (Guihenneuc-Jouyaux et al. (2000)) • Glaucoma (Liu et al. (2015)) • Comorbidities (Wang et al. (2014)).

2. While the models in (Schulam and Saria (2015)) and (Ghassemi et al. (2015)) involve latent variables that designate patient subtypes, the clinical states in both works are considered to be captured via observable bio-markers (PFVC in the former and the Cerebrovascular Autoregulation index in the latter).

Our modeling choice is to go with a latent variable model for the following reasons:

- In a wide range of problems, a concrete clinical marker that can be directly used as a surrogate for the patient's true clinical condition is **not** available. This is especially true in critical care settings where no solid definition or measure of a "clinical state" exists (Li-wei et al. (2013)). Previous works that adopted a clinical risk score as a surrogate for the clinical state in critical care settings have found that other physiological features, when augmented with the clinical risk score, still hold a significant predictive power with respect to end-point clinical outcomes (Ghassemi et al. (2015)). This implies that a clinical risk score or a severity of illness measure (such as APACHE II, SAPS and SOFA (Knaus et al. (1991); Subbe et al. (2001))) is not a sufficient measure of a patient's true clinical condition, and hence cannot be reliably modeled as an observable clinical state.

- The same line of argument extends to disease progression models: (Jackson et al. (2003)) has shown that significant modeling gain can be attained by treating clinical markers and diagnostic assessments as noisy manifest variables for the patient's true clinical state rather than defining a clinical state in terms of those markers.

- For various chronic disease, such as HIV, Scleroderma, and kidney disease, progression stages are well defined in terms of observable clinical markers (CD4 cell count, PFVC and GFR). However, a latent variable model can help validate and assess the current domain knowledge-based clinical practice guidelines by learning alternative, data-driven guidelines. Other diseases, such as COPD, have their progression stages manifesting only through symptoms (e.g. chronic bronchitis, emphysema and chronic airway obstruction (Wang et al. (2014))), which may or may not accurately reflect the disease's true state, and hence a latent variable model is necessary.

- Conclusive clinical markers that reveal a patient's true state may be available only occasionally in a patient's longitudinal episode. For instance, in a breast cancer progression setting, most of the data points associated with a patient's longitudinal episode would be imaging test results (e.g. BI-RADS scores of a mammogram or an MRI (Gail and Mai (2010); Taghipour et al. (2013))), which are noisy markers for the existence of a tumor, whereas a conclusive biopsy result that truly reveals whether the patient is in a preclinical or clinical breast cancer state may not be available because the patient did not undergo a biopsy test.

- A fully observable model does not provide diagnostic utility since it assumes that an already observable clinical marker provides an immediate, domain-knowledge-based diagnosis for the patient. Contrarily, a latent variable model leaves room for diagnoses to be learned from evidential data by learning the association between physiological evidence and clinical states, which may help inform and improve clinical practice.

1.1.2 Challenges

Hidden Markov Models (HMMs) and their variants have been widely deployed as temporal latent variable models for dynamical systems (Smyth (1994); Zhang et al. (2001); Giampieri et al. (2005); Genon-Catalot et al. (2000); Ghahramani and Jordan (1997)). Such models

have achieved considerable success in various applications, such as topic modeling (Gruber et al. (2007)), speaker diarization (Fox et al. (2011b)), and speech recognition (Rabiner (1989)). However, the nature of the clinical setting, together with the format of the modern EHR data pose the following set of serious challenges that confound classical HMM models:

(A) Non-stationarity: Recently developed disease progression models, such those in (Wang et al. (2014)) and (Liu et al. (2015)), use conventional stationary Markov chain models. In particular, they assume that state transition probabilities are independent of time. However, this assumption is seriously at odds with even casual observational studies which show that the probability of transiting from the current state to another state depends on the time spent in the current state (Lagakos et al. (1978); Huzurbazar (2004); Gillaizeau et al. (2015)). This effect, which violates the memorylessness assumptions adopted by continuous-time Markovian models, was verified in patients who underwent renal transplantation (Foucher et al. (2007, 2008)), patients who are HIV infected (Joly and Commenges (1999); Dessie (2014); Foucher et al. (2005)), and patients with chronic obstructive pulmonary disease (Bakal et al. (2014)).

(B) Irregularly spaced observations: The times at which the clinical findings of a patient (vital signs or lab tests) are observed is controlled either by clinicians (in the case of hospitalized inpatients), or by the patient's visit times (in the case of a chronic disease follow up). The time interval between every two measurements may vary from one patient to another, and may also vary for the same patient within her episode. This is reflected in the structure of the episodes in the EHR records, as shown in Figure 1 and 2. Figure 1 depicts an actual diastolic blood pressure episode for a patient hospitalized in a regular ward for 1200 hours (50 days)[3]. The patient's stay in the ward was concluded with an admission to the ICU after the ward staff realized she was clinically deteriorating. As we can see, the blood pressure measurements in the first 20 hours were initially taken with a rate of 1 sample per hour, and then later the rate changed to 1 sample every 5 hours[4]. While some recent works have argued for the parametrization of time in longitudinal data via the natural event sequence (Hripcsak et al. (2015)), it is often the case that the sampling times are themselves informative of the patients' clinical well-being (Alaa et al. (2017)). Thus, a direct application of a regular, discrete-time HMM (e.g. the models in (Murphy (2002); Fox et al. (2011b,a); Rabiner (1989); Yu (2010); Matos et al. (2006); Guihenneuc-Jouyaux et al. (2000))) will not suffice for jointly describing the latent states and observations, and hence ensuring accurate inferences.

(C) Discrete observations of a continuous-time phenomena: A patient's physiological signals and latent states evolve in continuous time; however, the observed physiological measurements are gathered at discrete time steps that can differ from one physiological signal to another. (One alternative view of such a structure is to think of a time series with irregularly sampled multidimensional measurements and with missing data in every measurement (Lipton et al. (2016)). We do not address data that is missing **not** at random

3. A detailed description for the data involved in this paper is provided in Section 5.
4. While Figure 1 illustrates a short-term episode for a critical care patient, similar effects are experienced in longitudinal episodes for patients with chronic disease (see Figure 4 in (Wang et al. (2014))).

in this paper.) The intervals between observed measurements can vary quite significantly; as we can see in Figure 2, the systolic blood pressure for a patient who stayed in a ward for 140 hours exhibits an entire day without measurements [5]. This means that the patient may encounter multiple hidden state transitions without any associated observed data. These effects make learning and inference problems more complicated since the inference algorithms need to consider potential unobserved trajectories of state evolution between every two timestamps. This challenge has been recently addressed in (Nodelman et al. (2012); Wang et al. (2014); Liu et al. (2015)), but only on the basis of memoryless Markov chain models for the hidden states, for which tractable inferences that rely on the solutions to Chapman-Kolmogorov equations can be executed. However, incorporating non-stationarity in state transitions (i.e. addressing challenge (A)) would make the problem of reasoning about a continuous-time process through discrete observations much more complicated.

(D) Lack of supervision: The episodes in the EHR may be labeled with the aid of domain knowledge (e.g. the stages and symptoms of some chronic diseases, such as chronic kidney disease (Eddy and Neilson (2006)), are known to clinicians and may be provided in the EHR). However, in many cases, including the case of (post or pre-operative) critical care, we do not have access to any labels for the patients' states. Hence, unsupervised learning approaches need to be used for learning model parameters from EHR episodes. While unsupervised learning of discrete-time HMMs has been extensively studied and is well understood (e.g. the Baum-Welch EM algorithm is predominant in such settings (Zhang et al. (2001); Yu (2010); Rabiner (1989))), the problem of unsupervised learning of continuous-time models for which both the patient's states and state transition times are hidden is far less understood, and indeed far more complicated.

(E) Censored observations: Episodes in the EHR are usually terminated by an informative intervention or event, such as death, ICU admission, discharge, etc. This is known as *informative censoring* (Scharfstein and Robins (2002); Huang and Wolfe (2002); Link (1989)). Unlike classical HMM settings where training sets comprise fixed length, or arbitrarily-censored, HMM sequence instances, a typical EHR dataset would comprise a set of episodes with different durations, and the duration of each episodes is itself informative of the state trajectory. Learning in such settings requires algorithms that can efficiently compute the likelihood of observing a set of episodes conditioned on their durations and terminating states.

1.2 Summary of Contributions

In order to address the challenges above, we develop a new model –which we call the *Hidden Absorbing Semi-Markov Model* (HASMM)– as a versatile generative model for a patient's (physiological) episode as recorded in the EHR. The HASMM captures non-stationary transitions for a patient's clinical state via a continuous-time semi-Markov model with explicitly specified state sojourn time distributions. Informative censoring is captured via absorbing states that designate clinical endpoint outcomes (e.g. cardiac arrest, mortality, recovery,

5. This may have resulted due to the patient undergoing a surgery or an intervention, or because the EHR recording system accidentally did not receive the data from the clinicians during that day.

etc); entering an absorbing state of an HASMM stimulates censoring events (e.g. clinical deterioration leads to an ICU admission which terminates the physiological observations for a monitored patient in a ward, etc). Observable variables are modeled via a multi-task Gaussian process (Bonilla et al. (2007)), for which the observation times (i.e. follow up visits, vital sign gathering, lab tests, etc) are modeled as a point process. Using multi-task Gaussian process with state-dependent hyper-parameters, an HASMM accounts for both correlations among different physiological variables, in addition to the temporal correlations among the observation variables that are generated by the same hidden state during its sojourn period. In that sense, an HASMM is a segment model (Ostendorf et al. (1996)) and also a *state-switching* model (Fox et al. (2011a))).

To allow for real-time inference of a patient's state, we develop a forward-filtering HASMM inference algorithm that can estimate a patient's latent state using her history of irregularly sampled physiological measurements. The inference algorithm operates by constructing a virtual, discrete-time *embedded Markov chain* that fully describes the patient's state transitions at observation times. The embedded Markov chain is constructed in an offline stage by solving a system of *Volterra integral equations of the second kind* using the *successive approximation* method; the solution to this system of equations, which parallels the Chapman-Kolmogorov equations in ordinary Markov chains, describe the HASMM's semi-Markovian state transitions as observed at arbitrarily selected discrete timestamps.

Offline learning of the HASMM model parameters from patients' episodes in an EHR is a daunting task. Since the HASMM is a continuous-time model, we cannot directly use the classical Baum-Welch EM algorithms for learning its parameters (Rabiner (1989)). Moreover, the semi-Markovianity of an HASMM yields an intractable integral in the E-step of the Expectation-Maximization (EM) formulation. Since the HASMM's state transitions are not captured by the conventional continuous-time Markov chain transition rate matrices, we cannot make use of the *Expm* and *Unif* methods that were used in (Hobolth and Jensen (2011)), and more recently in (Liu et al. (2015)) for evaluating the integrals involved in the E-step of learning continuous-time HMMs. To address this challenge, we develop a novel *forward-filtering backward-sampling Monte Carlo EM* (FFBS-MCEM) algorithm that approximates the integral involved in the E-step by efficiently sampling the latent clinical trajectories conditioned on observations in the EHR by exploiting the informative censoring of the patients' episodes. The FFBS-MCEM algorithm samples the latent clinical states of every (offline) patient episode in the EHR as follows: it starts from the known clinical endpoints, and sequentially samples the patient's states by traversing in the reverse-time direction while conditioning on the future states, and then uses the sampled state trajectories to evaluate a Monte Carlo approximation for the E-step.

2. The Hidden Absorbing Semi-Markov Model (HASMM)

2.1 Abstract Model

We start by describing the HASMM's hidden state evolution process, and then we describe the structure of its observable variables.

2.1.1 Hidden States

We consider a filtered probability space $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}_{t\in\mathbb{R}_+}, \mathbb{P})$, over which a continuous-time stochastic process $X(t)$ is defined on $t \in \mathbb{R}_+$. The process $X(t)$ corresponds to a temporal trajectory of the patient's hidden clinical states, which take on values from a finite *state-space* $\mathcal{X} = \{1, 2, \ldots, N\}$. Because the process $X(t)$ takes on only finitely many values, it can be decomposed in the form[6]

$$X(t) = \sum_n X_n \cdot \mathbf{1}_{\{\tau_n \leq t < \tau_{n+1}\}}, \tag{1}$$

where $(X(t))_{t\in\mathbb{R}_+}$ is a càdlàg path, $X_n \in \mathcal{X}$, and the interval $[\tau_n, \tau_{n+1})$ is the time interval accommodating the n^{th} hidden state. Every path $(X(t))_{t\in\mathbb{R}_+}$ on the stochastic basis $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}_{t\in\mathbb{R}_+}, \mathbb{P})$ is a *semi-Markov path* (Janssen and De Dominicis (1984); Durrett (2010)), where the *sojourn time* of state n, which we denote as $S_n = \tau_{n+1} - \tau_n$, is drawn from a *state-specific* distribution $v_j(S_n = s\,|\lambda_j) = d\mathbb{P}(S_n = s\,|X_n = j)$, with λ_j being a state-specific *duration parameter* associated with state $j \in \mathcal{X}$. Unlike ordinary time-homogeneous semi-Markov transitions, in which the transition probabilities among states are assumed to be constant conditioned on there being a transition from the current state (Gillaizeau et al. (2015); Murphy (2002); Johnson and Willsky (2013); Yu (2010); Dewar et al. (2012); Guédon (2007)), our model accounts for *duration-dependent* semi-Markov transitions, i.e. we have that

$$\mathbb{P}(X_{n+1} = j | X_n = i, S_n = s) = g_{ij}(s), \tag{2}$$

where $g_{ij} : \mathbb{R}_+ \to [0, 1], \forall i, j \in \mathcal{X}$ is a *transition function* for which $\frac{\partial g_{ij}(s)}{\partial s}$ is well defined, and $\sum_{j=1}^{N} g_{ij}(s) = 1, \forall s \in \mathbb{R}_+, i \in \mathcal{X}$.

Now consider the bi-variate (renewal) process $(X_n, S_n)_{n\in\mathbb{N}_+}$, which comprises the sequence of states and sojourn times. Semi-Markovianity of $X(t)$ implies that $(X_n, S_n)_{n\in\mathbb{N}_+}$ satisfies the following condition on its transition probabilities

$$\begin{aligned}\mathbb{P}(X_{n+1} = j, S_n \leq s\,|\,\mathcal{F}_{\tau_n}) &= \mathbb{P}(X_{n+1} = j, S_n \leq s\,|\,X_n = i)\\ &= \mathbb{P}(X_{n+1} = j\,|\,X_n = i, S_n \leq s) \cdot \mathbb{P}(S_n \leq s\,|\,X_n = i)\\ &= \mathbb{E}_{S_n}\left[g_{ij}(S_n)\,|\,S_n \leq s\right] \cdot V_i(s\,|\,\lambda_i) = \bar{g}_{ij}(s) \cdot V_i(s\,|\,\lambda_i),\end{aligned} \tag{3}$$

where $\{X_n = i\} \in \mathcal{F}_{\tau_n}$, $V_i(.)$ is the cumulative distribution function of state i's sojourn time, and $\bar{g}_{ij}(s)$ is the probability mass function that reflects the probability that a patient's next state being j given that she was at state i and her sojourn time in i is less than (or equal to) s. Based on (3), we define the *semi-Markov transition kernel* as a matrix-valued function $\mathbf{Q} : \mathbb{R}_+ \to [0, 1]^{N\times N}$ that describes the dynamics of $X(t)$ in continuous time, with entries $\mathbf{Q}(s) = (Q_{ij}(s))_{i,j\in\mathcal{X}}$ that are given by

$$Q_{ij}(s) = \bar{g}_{ij}(s) \cdot V_i(s\,|\,\lambda_i). \tag{4}$$

The initial state X_1 is random[7], and the initial state distribution is given by $\mathbf{p}^o = [p_1^o, \ldots, p_N^o]^T$, where $p_j^o = \mathbb{P}(X(0) = j)$, and $\sum_{j=1}^{N} p_j^o = 1$.

6. By convention, we set $\tau_1 = 0$.
7. We do not consider left-censored observations in this model.

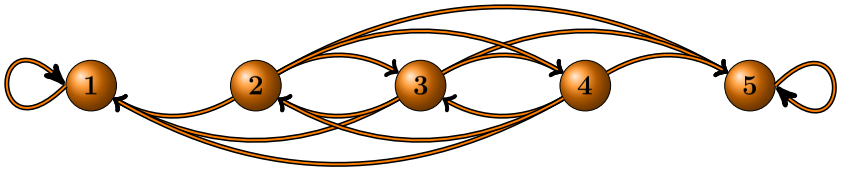

Figure 3: The Markov chain model for a 5-state HASMM.

We assume that whenever the patient enters either state 1 or state N, she remains there forever[8]. Therefore, we model states $\{1, N\}$ as *absorbing states*, whereas we model the remaining states in $\mathcal{X} \setminus \{1, N\}$ as *transient states* that represent intermediate levels of risk. We define and interpret states 1 and N as follows:

- **State** 1 is denoted as the *safe state*, and represents the state at which the patient is at minimum (or no) risk (e.g. clinically stable post-operative patient, etc).
- **State** N is denoted as the *catastrophic state*, and represents the state at which the patient is at severe risk or encounters an adverse event (e.g. a very severe stage of a chronic disease (Bakal et al. (2014)), a cardiac or respiratory arrest (Subbe et al. (2001)), mortality (Knaus et al. (1991)), etc).

We do not assume that the transient states are ordered linearly in terms of clinical risk. Following the assumptions in (Murphy (2002); Johnson and Willsky (2013)), we eliminate the self-transitions for all transient states by setting $g_{ii}(s) = 0, Q_{ii}(s) = 0, \forall s \in \mathbb{R}_+, i \in \mathcal{X} \setminus \{1, N\}$, whereas we restrict the transitions from states 1 and N to self-transitions only, i.e. $g_{ii}(s) = 1, i \in \{1, N\}$. Figure 3 depict the Markov chain for the sequence $\{X_n\}_{n\in\mathbb{N}_+}$.

We define $\mathcal{A}_1$ as the event that the path $(X(t))_{t\in\mathbb{R}_+}$ is absorbed in the safe state 1, i.e. $\mathcal{A}_1 = \{\lim_{t\to\infty} X(t) = 1\}$, and $\mathcal{A}_N$ as the event that $(X(t))_{t\in\mathbb{R}_+}$ is absorbed in the catastrophic state N, i.e. $\mathcal{A}_N = \{\lim_{t\to\infty} X(t) = N\}$. Since $(X(t))_{t\in\mathbb{R}_+}$ is an absorbing semi-Markov chain[9], we know that $\mathbb{P}(\mathcal{A}_1 \vee \mathcal{A}_N) = 1$, and since the events $\mathcal{A}_1$ and $\mathcal{A}_N$ are mutually exclusive, it follows that $\mathbb{P}(\mathcal{A}_N) = 1 - \mathbb{P}(\mathcal{A}_1)$. The quantity $\mathbb{P}(\mathcal{A}_N)$ describes a patient's prior risk of ending in the catastrophic state, whereas $\mathbb{P}(\mathcal{A}_N \,|\mathcal{F}_t\,)$ describes the patient's posterior risk of ending in the catastrophic state having observed its evolution history up to time t[10]. Define T_s as an $\mathcal{F}$-stopping time representing the absorption time

8. The model can be easily extended to accommodate an arbitrary number of competing absorbing states.
9. We assume that the transition functions $g_{i1}(s)$ and $g_{iN}(s)$ for any transient state i is non-zero for every s. Hence, it follows that $(X(t))_{t\in\mathbb{R}_+}$ is an absorbing semi-Markov chain since it has 2 absorbing states, each of which can be visited starting from any other state (Durrett (2010)).
10. In the clinical applications under consideration, transient states can be ordered by their respective relative risks of encountering event $\mathcal{A}_N$ in the subsequent transitions, i.e. in a 5-state chain, it is more likely for the patient to be absorbed in state 5 in the future when it is in state 4 than when it is in state 3. For instance, it is more likely for a patient's chronic obstructive pulmonary disease that is currently assessed to have a severity degree of GOLD1 (mild severity as defined in the GOLD standard Pedersen et al. (2011)) to progress (in the near future) to a severity degree of GOLD2 (moderate) rather than GOLD3 (severe).
11. This means that the sampling times are uninformative of the latent states; which simplifies the inference problem. The HASMM model can be extended to incorporate a state-dependent sampling process using a Cox process (Lando (1998)) or a Hawkes process (Hawkes and Oakes (1974)) to modulate the point-process intensity;however, such an extension would result in a significantly harder inference problem. A good discussion on conditional intensity models can be found in (Qin and Shelton (2015)).
12. Note that what is observed is a sequence of sampling times $\mathcal{T}$, the elements of which are not labeled by the corresponding state indexes, for that the states are latent, i.e. the sets $\mathcal{T}_n$ are unobserved partitions of $\mathcal{T}$.

of the path $(X(t))_{t\in\mathbb{R}_+}$ in either state 1 or state N, i.e.

$$T_s = \inf\{t \in \mathbb{R}_+ : X(t) \in \{1, N\}\}.$$

Finally, we define K as the (random) number of state realizations in the sequence $\{X_n\}_{n=1}^K$ up to the stopping time T_s, which has to be concluded by either state 1 or N, e.g. when $|\mathcal{X}| = 4$, the sequences $\{1\}, \{4\}, \{2, 3, 2, 3, 4\}$, and $\{3, 2, 1\}$ are valid, random-length realizations of $\{X_n\}_{n=1}^K$, and each represents a certain state evolution trajectory for the patient.

2.1.2 Observations and Censoring

The path $(X(t))_{t\in\mathbb{R}_+}$ is unobservable; what is observable is a corresponding process $(Y(t))_{t\in\mathbb{R}_+}$ on $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}_{t\in\mathbb{R}_+}, \mathbb{P})$, the values of which are drawn from an *observation-space* $\mathcal{Y}$, and whose distributional properties are dependent on the latent states' path $(X(t))_{t\in\mathbb{R}_+}$. The observable process $(Y(t))_{t\in\mathbb{R}_+}$ can be put in the form

$$Y(t) = \sum_n Y_n(t) \cdot \mathbf{1}_{\{\tau_n \le t < \tau_{n+1}\}}, \tag{5}$$

where $(Y(t))_{t\in\mathbb{R}_+}$ is a càdlàg path, comprising a sequence of function-valued variables $\{Y_n(t)\}_{n=1}^K$, with $Y_n : [\tau_n, \tau_{n+1}) \to \mathcal{Y}$. Even though the path $(Y(t))_{t\in\mathbb{R}_+}$ is accessible, only a sequence of irregularly spaced samples of it is observed over time, and is denoted by $\{Y(t_m)\}_{t_m\in\mathcal{T}}$, where $\mathcal{T} = \{t_1, t_2, \ldots, t_M\}$ is the set of observed measurements, and M is the total number of such measurements. We say that the process is censored if $M < \infty$; typical episodes in an EHR are censored: observations stop at some point of time due to a release from care, an ICU admission, mortality, etc.

The sampling times in $\mathcal{T}$ represent the times at which a patient with a chronic disease took clinical tests (i.e. time intervals in $\mathcal{T}$ spans years), or the times at which clinicians have gathered vital signs for a monitored critically ill patient in a hospital ward (i.e. time intervals in $\mathcal{T}$ span days or hours). We assume that the sampling times in $\mathcal{T}$ are drawn from a *point-process* $\Phi = \sum_{m\in\mathbb{N}_+} \delta_{t_m}$, with δ_t being the Dirac measure. The point-process Φ is assumed to be independent of the latent states path[11]. Define $\mathcal{T}_n$ as the set of M_n samples that are gathered during the interval[12] $[\tau_n, \tau_{n+1})$, i.e. $\mathcal{T}_n = \{t_m : t_m \in \mathcal{T}, t_m \in [\tau_n, \tau_{n+1})\}$, $M_n = |\mathcal{T}_n|$, and $\sum_n M_n = M$. Since $\mathcal{T}_n$ could possibly be empty ($\mathcal{T}_n = \emptyset$), some states can have no corresponding observations (i.e. an inpatient may exhibit a transition to a deteriorating state during the night, even though her blood pressure were not measured during the night.

Recall the illustration in Figure 2).

The paths $\{Y_n(t)\}_{n=1}^K$ are assumed to be conditionally independent given the hidden sequence of states $\{X_n\}_{n=1}^K$, and hence we have that

$$\{Y(t_m)\}_{t_m\in\mathcal{T}_n} \perp\!\!\!\perp \{Y(t_m)\}_{t_m\in\mathcal{T}_{n+1}} \,|\, X_n, X_{n+1}\,, \forall n \in \{1,2,\ldots,K-1\}.$$

The observed samples generated under every state X_n and sampled at the times in $\mathcal{T}_n$ are drawn from $\mathcal{Y}$ according to a distribution $\mathbb{P}(\{Y(t_m)\}_{t_m\in\mathcal{T}_n}|X_n = j, \Theta_j)$, where Θ_j is an *emission parameter* that controls the distributional properties of the observations generated under state j.

The number of observation samples is finite: the observed sequence is *censored* at some point of time, which we call the censoring time T_c, after which no more observation samples are available. Censoring reflects an external intervention/event that terminated the observation sequence, i.e. death, intensive care unit (ICU) admission, etc. Censoring is *informative* (Scharfstein and Robins (2002);Huang and Wolfe (2002);Link (1989)), because the censoring time is correlated with the absorption time T_s, and T_s strictly precedes T_c (in an almost sure sense). That is, T_c is an $\mathcal{F}$-stopping time that is given by $T_c = T_s + S_K$, i.e. once the patient enters state 1 or state N, the observations stop after the patient's sojourn time in that state (i.e. observations stop after a time S_K from the entrance in the absorbing state). Therefore, the duration distributions $v_1(s|\lambda_1)$ and $v_N(s|\lambda_N)$ of states 1 and N are used to determine the censoring times conditioned on the chain $\{X_n\}_{n=1}^K$ being absorbed at time T_s.

Every sample from the HASMM is an episode comprising a random-length sequence of hidden states $\{X_n\}_{n=1}^K$, and a random-length sequence of observations $\{Y(t_m)\}_{m=1}^M$ together with the associated observation times. We only observe $\{Y(t_m)\}_{m=1}^M$; the path of latent states $X(t)$, the number of realized states K, the association between observations and states (i.e. the sets $\mathcal{T}_n$) are all unobserved, which makes the inference problem very challenging, but captures the realistic EHR data format and the associated inferential hurdles. In the next subsection, we specify the model's generative process and present an algorithm to generate episodic samples from an HASMM.

2.2 Model Specification and Generative Process

As have been discussed in Subsection 2.1, the hidden and observables variables of an HASMM can be listed as follows:

- **Hidden variables:** The hidden states sequence $\{X_n\}_{n=1}^K$ and the states' sojourn times $\{S_n\}_{n=1}^K$ (or equivalently, the transition times $\{\tau_n\}_{n=1}^K$).

- **Observable variables:** The observed episode $\{Y(t_m)\}_{m=1}^M$ and the associated sampling times $\mathcal{T} = \{t_m\}_{m=1}^M$.

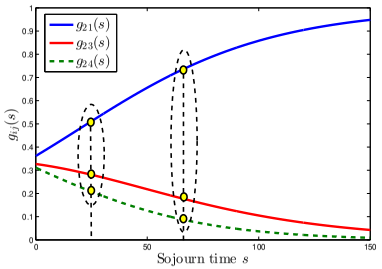

Figure 4: Exemplary transition functions $(g_{2j})_{j=1}^4$ for a 4-state HASMM.

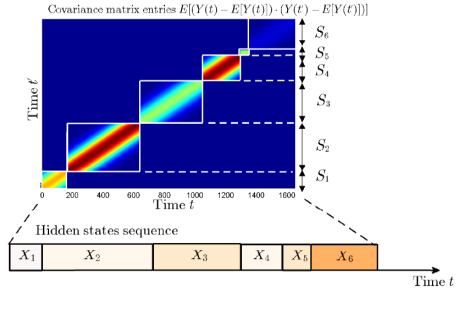

Figure 5: Depiction for the correlation structure of the observable variables for an underlying state sequence $\{X_n\}_{n=1}^6$.

The HASMM model parameters that generate both the hidden and observable variables are encompassed in the parameter set Γ, i.e.

$$\Gamma = \left(\underbrace{N}_{\text{State cardinality}}, \underbrace{\lambda = \{\lambda_j\}_{j=1}^N}_{\text{State duration}}, \underbrace{\mathbf{p}^o}_{\text{Initial states}}, \underbrace{\mathbf{Q} = \{Q_{ij}(s)\}_{i,j=1}^N}_{\text{Transitions}}, \underbrace{\mathbf{\Theta} = \{\Theta_j\}_{j=1}^N}_{\text{Emission}} \right).$$

The total number of parameters in an HASMM is $N^2 + 3N(E+1)$.

2.2.1 Distributional specifications for the hidden variables

We model the state sojourn time of each state $i \in \mathcal{X}$ via a Gamma distribution. The selection of a Gamma distribution ensures that the generative process encompasses ordinary continuous-time Markov models for the path $(X(t))_{t\in\mathbb{R}_+}$, since the exponential distribution[13] is a special case of the Gamma distribution (Durrett (2010)). Thus, if the underlying physiology of the patient is naturally characterized by memoryless state transitions, this will be automatically learned from the data via the parameters of the Gamma distribution. The sojourn time distribution for state i is given by

$$v_i(s|\lambda_i = \{\lambda_{i,s}, \lambda_{i,r}\}) = \frac{1}{\Gamma(\lambda_{i,s})} \cdot \lambda_{i,r}^{\lambda_{i,s}} \cdot s^{\lambda_{i,s}-1} \cdot e^{-s\cdot\lambda_{i,r}}, s \geq 0,$$

where $\lambda_{i,s} > 0$ and $\lambda_{i,r} > 0$ are the shape and rate parameters of the Gamma distribution respectively.

Now we specify the structure of the transition kernel $\mathbf{Q}(s) = (Q_{ij}(s))_{i,j}, i,j \in \mathcal{X}$. Recall from (4) that the each element in the transition kernel matrix can be written as $\mathbb{E}_S[g_{ij}(S)|S \leq s] \cdot V_i(s|\lambda_i)$. Having specified the distribution $v_i(s|\lambda_i)$ as a Gamma distribution, it remains to specify the function $g_{ij}(s)$ in order to construct the elements of $\mathbf{Q}(s)$.

13. Note that a semi-Markov chain reduces to a Markov chain if the sojourn times are exponentially distributed.

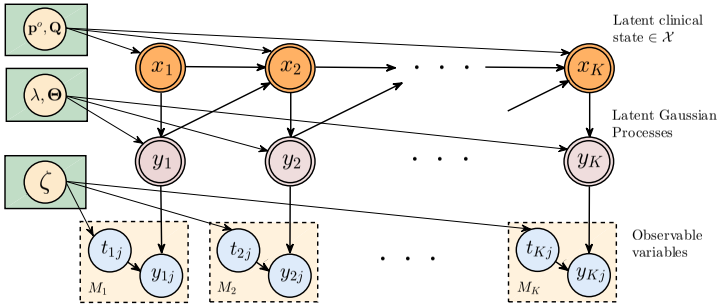

Figure 6: A basic graphical model for the HASMM. The arrow between the (function-valued) variable y_n and the latent state X_{n+1} designates the dependence of state transitions on the sojourn time of the previous state (duration-dependence).

The transition functions $(g_{ij}(s))_{i,j}$ are given by *multinomial logistic* functions as follows

$$\begin{aligned} g_{ij}(s) &= \frac{e^{(\eta_{ij}+\beta_{ij}\cdot s)}}{\sum_{k=1}^{N} e^{(\eta_{ik}+\beta_{ik}\cdot s)}}, \forall i \neq j, i \notin \{1, N\} \\ g_{ii}(s) &= 0, \forall i \in \{2, \ldots, N-1\}, \\ g_{ii}(s) &= 1, \forall i \in \{1, N\}, \end{aligned} \tag{6}$$

where $\eta_{ij}, \beta_{ij} \in \mathbb{R}_+$. The parameters $(\eta_{ij})_{j=1}^{N}$ determine the baseline values for the transition probability mass from state i to state j, i.e. $g_{ij}(0)$, whereas the parameters β_{ij} controls the dependence of the transition probability mass on the sojourn time[14]. If $\beta_{ij} = 0$, then we have that $g_{ij}(s) = g_{ij}(0) = \frac{e^{\eta_{ij}}}{\sum_{k=1}^{N} e^{\eta_{ik}}}, \forall s \in \mathbb{R}_+$, i.e. the transition probability out of state i remains constant irrespective of the sojourn time in that state. In the limit when s goes to infinity, β_{ij} dominates the functional form in (6), and we have that $g_{ij}(\infty) = \arg\max_j \beta_{ij}$. Figure 4 depicts exemplary transition functions for a 4-state HASMM.

14. Similar effects for the sojourn time on the transition probabilities has been demonstrated in the progression of breast cancer from healthy to preclinical states in (Taghipour et al. (2013)), where age (the main risk factor for breast cancer) was shown to affect the probability of progressing across the states of healthy to preclinical, clinical and death. These effects may be also prevailing in other diseases, or in critical care settings where the length of time during which a patient stays clinically stable may imply that the patient is more likely to transit to a more healthy state in the future. Through the HASMM model, we can recognize whether or not this effect is evident in the EHR data, i.e. whether the transition function reflects an underlying homogeneous (if $g_{ij}(s)$ is independent of s) or duration-dependent transitions by learning the parameter β_{ij}. Moreover, the parameter β_{ij} is defined per state; the HASMM model can capture scenarios where transitions are duration-independent from some states, but are duration-dependent from others.

2.2.2 Distributional specifications for the observable variables

As explained in Subsection 2.1, the observable process $Y(t)$ can be decomposed as $Y(t) = \sum_{n=1}^{K} Y_n(t) \cdot \mathbf{1}_{\{\tau_n \leq t < \tau_{n+1}\}}$, where the paths $(Y_n(t))_{n=1}^{K}$ are conditionally independent given the state sequence $\{X_n\}_{n=1}^{K}$. Since observations are drawn from $Y(t)$ at arbitrarily, and irregularly spaced time instances $\mathcal{T}$, we have to model the distributional properties of $Y(t)$ in continuous time. We model every path $Y_n(t)$ defined over $[\tau_n, \tau_{n+1})$ as a segment drawn from a multi-task Gaussian Process (GP), with a hyper-parameter set Θ_i that depends on the corresponding latent state $X_n = i$ (Rasmussen (2006); Bonilla et al. (2007)). The input to the multi-task GP is the time variable and the output is the set of physiological variables at a certain point of time. The GP associated with every state $X_n = i$ is parametrized by a constant mean function $m_i(t) = m_i$, a *squared-exponential* covariance kernel $k_i(t, t') = \sigma_i^2 e^{-\frac{1}{2\ell_i^2}||t-t'||^2}$, and a "free-form" covariance matrix Σ_i between the different physiological measurements (Bonilla et al. (2007)). Thus, for a E-dimensional physiological stream $Y(t) = (Y^1(t), \ldots, Y^E(t))$, the observations for state i are generated as follows

$$\left\langle Y_i^l(t) \cdot Y_i^v(t') \right\rangle = \Sigma_i(l, v) \cdot k_i(t, t'), \qquad \{Y_i^l(t)\}_{t \in \mathcal{T}, 1 \leq l \leq E} \sim \mathcal{N}(m_i(t), \mathbf{\Sigma}_i),$$

where $\mathbf{\Sigma}_i(l, v, t, t') = \left\langle Y_i^l(t) \cdot Y_i^v(t') \right\rangle$. The GP hyper-parameters associated with state i are given by $\Theta_i = (m_i, \sigma_i, \Sigma_i, \ell_i)$, i.e. $Y_n(t)|X_n = i \sim \mathcal{GP}(\Theta_i)$.
We note that the HASMM model is a *segment model* (Ostendorf et al. (1996); Murphy (2002); Yu (2010); Guédon (2007)), i.e. observation samples that are defined within the sojourn time of the same state are correlated, but observation samples in different states are independent. **The segmental nature of the model allows for easily handling irregular sampling of temporally correlated observation at the cost of introducing discontinuities of the observed data at the state transition times; in all clinical settings of interest, capturing temporal correlations of irregular observations is crucial whereas the continuity of observations is of less relevance.** The model can also be viewed as a state-switching model, but for which the transition dynamics do not need to be linear as in (Georgatzis et al. (2016); Fox et al. (2011a)), but rather depend on the covariance kernel $k_i(t, t')$. Figure 5 depicts the correlation structure of the observable variables in terms of the covariance matrix of a discrete version of $Y(t)$ generated under a specific hidden state sequence. We can see that conditioned on the hidden state sequence, the covariance matrix is a block diagonal matrix, where the sizes of the blocks are random and are determined by the states' sojourn times.

Figure. 6 depicts the graphical model for an HASMM. In Figure. 6, the variables y_n are function-valued and correspond to the finite-duration, continuous-time functions $\{Y_n(t)\}_{t \in \mathcal{T}_n}$. **The arrow between the (function-valued) y_n and the latent state x_{n+1} designates the dependence of the transition probabilities on the state sojourn time (i.e. the domain over which y_n is non-zero).** In Appendix A, we present an algorithm (`GenerateHASMM(`Γ`)`) for sampling episodes from an HASMM with a hyper-parameter set Γ; Figure 7 depicts an exemplary episode sampled via Algorithm 7.

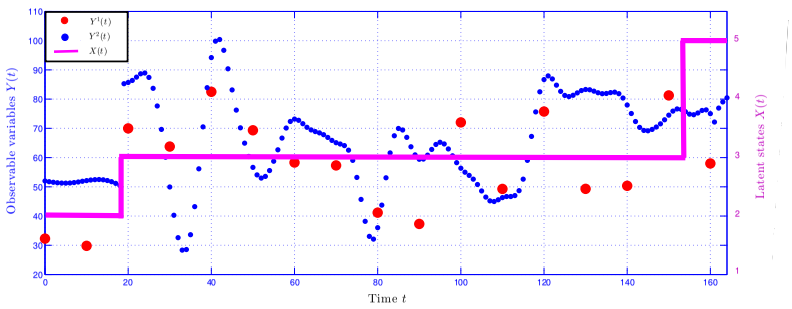

Figure 7: An episode generated by `GenerateHASMM(Γ)` with $N = 5$. The realized hidden state sequence (upper) is $\{2, 3, 5\}$, and is absorbed in state 5. The physiological stream $(Y^1(t), Y^2(t))$ is 2-dimensional and stream $Y^2(t)$ is sampled more intensely than $Y^1(t)$.

3. Inference in Hidden Absorbing Semi-Markov Models

In this Section, we develop an online algorithm that carries out diagnostic and prognostic inferences for a monitored patient's episode in real-time. Given an ongoing realization of an episode $\{y(t_1), y(t_2), \ldots, y(t_m)\}$ at time t_m (before the censoring time T_c), and the HASMM model parameter Γ that has generated this realization, we aim at carrying out the following inference tasks:

- **Diagnosis:** Infer the patient's current clinical state, i.e. compute

$$\mathbb{P}(X(t_m) = j \,|\, Y(t_1) = y(t_1), \ldots, Y(t_m) = y(t_m), \Gamma), \forall j \in \mathcal{X}.$$

- **Prognostic Risk Scoring:** Compute the patient's risk of absorption in the catastrophic state, i.e.

$$\mathbb{P}(\mathcal{A}_N \,|\, Y(t_1) = y(t_1), \ldots, Y(t_m) = y(t_m), \Gamma).$$

In the rest of this Section, we drop the conditioning on Γ for notational brevity. The first inference task corresponds to disease severity estimation for patients with chronic disease, or clinical acuity assessment for critical care patients. The second task corresponds to risk scoring for future adverse events for patients who have been monitored for some period of time, i.e. the risk of developing a future preclinical or clinical breast cancer state (Gail and Mai (2010)), the risk of clinical deterioration for post-operative patients in wards (Rothman et al. (2013)), the risk of mortality for ICU patients (Knaus et al. (1985)), etc.

3.1 Challenges facing the HASMM Inference Tasks

The inference tasks discussed in the previous Subsection are confronted with 3 main challenges –listed hereunder– that hinder the direct deployment of classical forward-backward message-passing routines.

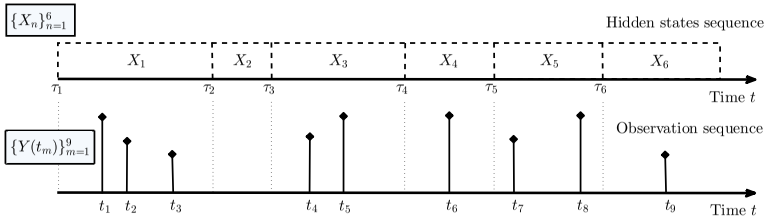

Figure 8: An exemplary HASMM episode with 6 hidden state realizations and 9 observed samples.

1. In addition to the clinical states $\{X_n\}_{n=1}^K$ being unobserved, the transition times among the states, $\{\tau_n\}_{n=1}^K$, are also unobserved (i.e. we do not know the time at which the patient's state changed). Thus, unlike the discrete-time models in (Murphy (2002); Johnson and Willsky (2013); Yu (2010); Dewar et al. (2012); Guédon (2007)), in which we know that the underlying states switch sequentially in a (known) one-to-one correspondence with the observations, in an HASMM the association between states and observations is unknown. Figure 8 depicts an exemplary HASMM episode with 6 realized states and 9 observations samples; in this realization, the association between the observations $\{Y(t_1), Y(t_2), Y(t_3)\}$ and state X_1 is hidden. The importance of reasoning about the hidden transition times is magnified by the duration-dependence of the transition probabilities that govern the sequence $\{X_n\}_{n=1}^K$.

2. Since observations are made at random and arbitrary time instances, some transitions may not be associated with any evidential data. That is, as it is the case for state X_2 in Figure 8, there is no guarantee that for every state X_n, an observation is drawn during its occupancy, i.e. $[\tau_n, \tau_{n+1})$. In a practical setting, the inference algorithm should be able to reason about the state trajectories even in silence periods that come with no observations (recall the example in Figure 2 where observations of a critical care patient's systolic blood pressure stop for an entire day). Hence, one cannot directly discretize the time variable and use the discrete-time HMM inference algorithms (e.g. the algorithms in (Rabiner (1989))) since in that case we would exhibit time steps that come with no associated observations, and with potential state transitions.

3. The HASMM model assumes that observations that belong to the same state are correlated (e.g. in Figure 8, each of the subset of observations $\{Y(t_1), Y(t_2), Y(t_3)\}$, $\{Y(t_4), Y(t_5)\}$ and $\{Y(t_7), Y(t_8)\}$ are not drawn independently conditioned on the latent state since they are sampled from a GP), thus we cannot use the variable-duration and explicit-duration HSMM inference algorithms in (Murphy (2002); Johnson and Willsky (2013); Yu (2010); Guédon (2007)), as those assume that all observations are conditionally independent given the latent states. Our model is closer to a segment-HSMM model (Yu (2010); Guédon (2007)), but with irregularly spaced observations and an underlying duration-dependent state evolution process, which requires a different construction of the forward messages.

In the following Subsection, we develop a forward filtering algorithm that deals with episodes generated from an HASMM and addresses the above challenges.

3.2 The HASMM Forward Filtering Algorithm

Given a realization of an episode $\{y(t_1), y(t_2), \ldots, y(t_m)\}$ at time t_m, the posterior probability of the patient's current clinical state $X(t_m)$ is given by[15]

$$\mathbb{P}(X(t_m) = j \,|\, y(t_1), \ldots, y(t_m), \mathcal{T}) = \frac{d\mathbb{P}(X(t_m) = j, y(t_1), \ldots, y(t_m) \,|\, \mathcal{T})}{d\mathbb{P}(y(t_1), \ldots, y(t_m)|\mathcal{T})} = \frac{d\mathbb{P}(X(t_m) = j, y(t_1), \ldots, y(t_m) \,|\, \mathcal{T})}{\sum_{j'=1}^{N} d\mathbb{P}(X(t_m) = j', y(t_1), \ldots, y(t_m) \,|\, \mathcal{T})}. \quad (7)$$

The above application of Bayes' rule implies that, given the observation times $\mathcal{T}$, computing the joint probability density $d\mathbb{P}(X(t_m) = j, y(t_1), \ldots, y(t_m) \,|\, \mathcal{T})$ suffices for computing the posterior probability of the patient's clinical states. As it is the case for the conventional HMM setting, we denote these joint probabilities as the *forward messages* $\alpha_m(j \,|\, \mathcal{T}) = d\mathbb{P}(X(t_m) = j, y(t_1), \ldots, y(t_m) \,|\, \mathcal{T})$.

Since the HASMM is a segment model, the conventional notion of the forward messages $\alpha_m(j \,|\, \mathcal{T})$ does not suffice for constructing the forward filtering algorithm since we need to account for the latent correlation structures between the (conditionally-dependent) observations (Murphy (2002)). To that end, we define $\alpha_m(j, w \,|\, \mathcal{T})$ as the forward message for the j^{th} state at the m^{th} observation time (i.e. t_m) *with a lag* w as follows

$$\alpha_m(j, w \,|\, \mathcal{T}) = d\mathbb{P}(X(t_m) = j, \{t_u\}_{u=m-w+1}^{m} \in \mathcal{T}_n, t_{m-w} \in \mathcal{T}_{n'}, \{y(t_u)\}_{u=1}^{m} \,|\, \mathcal{T}), \quad (8)$$

for some $n, n^{'} \in \mathbb{N}_+$, and $n \neq n^{'}$. That is, the forward message $\alpha_m(j, w \,|\, \mathcal{T})$ is simply the joint probability that the current state is j, that the associated observations are $(y(t_1), \ldots, y(t_m))$, and that the current state has lasted for the last w measurements. For notational brevity, denote the event $\left\{\{t_u\}_{u=m-w+1}^{m} \in \mathcal{T}_n, t_{m-w} \in \mathcal{T}_{n'}\right\}$ as $\psi(m, w)$. Thus, $\alpha_m(j, w \,|\, \mathcal{T})$ can be written as

$$\alpha_m(j, w \,|\, \mathcal{T}) = \sum_{i=1}^{N} \sum_{w'=1}^{m-w} d\mathbb{P}(X(t_m) = j, \psi(m, w), X(t_{m-w}) = i, \psi(m - w, w^{'}), \{y(t_u)\}_{u=1}^{m} \,|\, \mathcal{T}),$$

which can be decomposed using the conditional independence properties of the states, observable variables and sojourn times as follows

$$d\mathbb{P}(X(t_m) = j, \psi(m, w), X(t_{m-w}) = i, \psi(m - w, w^{'}), \{y(t_u)\}_{u=1}^{m}) =$$

$$d\mathbb{P}(\{y(t_u)\}_{u=m-w+1}^{m} \,|\, X(t_m) = j, \psi(m, w)) \times \underbrace{\mathbb{P}(X(t_m) = j \,|\, X(t_{m-w}) = i, \psi(m - w, w^{'}))}_{p_{ij}(t_m - t_{m-w}, \psi(m-w, w'))} \times$$

$$\underbrace{\mathbb{P}(\psi(m, w) \,|\, X(t_m) = j)}_{V_j(t_m - t_{m-w}|\lambda_j) - V_j(t_m - t_{m-w+1}|\lambda_j)} \times \underbrace{d\mathbb{P}(X(t_{m-w}) = i, \psi(m - w, w^{'}), \{y(t_u)\}_{u=1}^{m-w})}_{\alpha_{m-w}(i, w')}, \quad (9)$$

15. We use the notation $d\mathbb{P}$ to denote a probability density defined with respect to $(\Omega, \mathcal{F}, \mathbb{P})$.

where we have dropped the conditioning on $\mathcal{T}$ for notational brevity. The first term, $d\mathbb{P}(\{y(t_u)\}_{u=m-w+1}^{m} \,|\, X(t_m) = j, \psi(m, w))$, is the probability density of the observable variables in $\{y(t_u)\}_{u=m-w+1}^{m}$ conditioned on the hidden state being $X(t_m) = j$ and that the time instances $\{t_u\}_{u=m-w+1}^{m}$ reside in the sojourn time of $X(t_m) = j$. The second term, $p_{ij}(t_m - t_{m-w}, \psi(m - w, w^{'}))$, is the *interval transition probability*, i.e. the probability that the state sequence transits to state j after a period $t_m - t_{m-w}$, given that its sojourn time in state $X(t_{m-w}) = i$ at t_m is at least $t_m - t_{m-w+1}$, and at most $t_m - t_{m-w-w'}$. The third term is the probability that the sojourn time in state $X(t_m) = j$ is between $t_m - t_{m-w+1}$ and $t_m - t_{m-w}$, whereas the fourth term, $\alpha_{m-w}(i, w^{'})$, is the $(m-w)^{th}$ forward message with a lag of $w^{'}$. Thus, we can write the m^{th} forward message with a lag w as follows

$$\alpha_m(j, w) = d\mathbb{P}(\{y(t_u)\}_{u=m-w+1}^{m} \,|\, X(t_m) = j) \times$$

$$\sum_{i=1}^{N} \sum_{w'=1}^{m-w} p_{ij}(t_m - t_{m-w}, \psi(m - w, w^{'})) \cdot (V_j(t_m - t_{m-w}|\lambda_j) - V_j(t_m - t_{m-w+1}|\lambda_j)) \cdot \alpha_{m-w}(i, w^{'}). \quad (10)$$

As we can see in (10), one can express $\alpha_m(j, w)$ using a recursive formula that makes use of the older forward messages $\{\alpha_{m-w}(i, w^{'})\}_{w=1}^{m}$, where $\alpha_o(i, w^{'}) = 0$, which allows for an efficient dynamic programming algorithm to infer the patient's clinical state in real-time.

The construction of the forward messages in (10) parallels the structure of forward message-passing in segment-HSMM (See Section 1.2 in (Murphy (2002)) and Section 4.2.2 in (Yu (2010))), but with the following differences. In (10), the time interval between every two observation samples is irregular, which reflects in the correlation between the observations in $\{y(t_u)\}_{u=m-w+1}^{m}$ (depends on the covariance kernel of the GP, and the probability of the current latent state's sojourn time being encompassing the most recent w samples, i.e. $(V_j(t_m - t_{m-w}|\lambda_j) - V_j(t_m - t_{m-w+1}|\lambda_j))$. However, the most challenging ingredient of the forward message is the interval transition probability $p_{ij}(t_m - t_{m-w}, \psi(m - w, w^{'}))$. This is because unlike the discrete-time HSMM models in (Murphy (2002); Yu (2010)), which exhibit transitions only at discrete time steps that are always accompanied with evidential observations, i.e. no hidden transitions can occur between observation samples, and the transitions among hidden states are duration-independent, in an HASMM, transitions can occur at arbitrary time instances, multiple transitions can occur between two observation samples, and transitions are duration-dependent.

In order to evaluate the term $p_{ij}(t_m - t_{m-w}, \psi(m - w, w^{'}))$, we construct a virtual (discrete-time) trivariate *embedded Markov chain* $\{X(t_m), t_{m-w}, t_{m-w+1}\}$, the transition probabilities of which are equal to the interval transition probabilities. In the recent work in (Liu et al. (2015)), a similar embedded Markov chain analysis was conducted for a CT-HMM (Continuous-time HMM), but for which the underlying state evolution process was assumed to be a duration-independent ordinary Markov chain for which the expressions for the interval transition probabilities are readily available by virtue of the exponential distributions of the memoryless state sojourn times.

Recall from Subsection 2.1.1 that the semi-Markov kernel of the hidden state sequence $\{X_n\}_{n=1}^K$ is defined as $Q_{ij}(\tau) = \mathbb{P}(X_{n+1} = j, S_n \leq \tau | X_n = i)$, i.e. the probability that the sequence transits from state i to state j given that the sojourn time in i is less than or equal to τ. Theorem 1 establishes the methodology for computing the interval transition probabilities $p_{ij}(t_m - t_{m-w}, \psi(m-w, w'))$ using the parameters of an HASMM. In Theorem 1, we define $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})$ as a matrix-valued function $\tilde{\mathbf{P}} : \mathcal{S} \rightarrow [0,1]^{N \times N}$, $\mathcal{S} = \{(\tau, \underline{s}, \bar{s}) : \tau \in \mathbb{R}_+, \bar{s} \in \mathbb{R}_+, \underline{s} \leq \bar{s}\}$, the entries of which are given by

$$\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s}) = \underbrace{\left[\begin{array}{c|c|c|c} \tilde{p}_{11}(\tau, \underline{s}, \bar{s}) & \tilde{p}_{21}(\tau, \underline{s}, \bar{s}) & \cdots & \tilde{p}_{N1}(\tau, \underline{s}, \bar{s}) \\ \tilde{p}_{12}(\tau, \underline{s}, \bar{s}) & \tilde{p}_{22}(\tau, \underline{s}, \bar{s}) & \cdots & \tilde{p}_{N2}(\tau, \underline{s}, \bar{s}) \\ \vdots & \vdots & & \vdots \\ \tilde{p}_{1N}(\tau, \underline{s}, \bar{s}) & \tilde{p}_{2N}(\tau, \underline{s}, \bar{s}) & \cdots & \tilde{p}_{NN}(\tau, \underline{s}, \bar{s}) \end{array}\right]}_{\text{Size } N \times N \text{ matrix}}.$$

In addition, we define a *truncated semi-Markov kernel* as

$$\bar{Q}_{ij}(\tau, \underline{s}, \bar{s}) = \int_{s=\underline{s}}^{\bar{s}} (\bar{g}_{ij}(\tau + s) - \bar{g}_{ij}(s)) \cdot \frac{V_i(\tau + s|\lambda_i) - V_i(s|\lambda_i)}{1 - V_i(s|\lambda_i)} \cdot dV_i(s|\lambda_i),$$

a scalar-valued function $\bar{Q}_i(\tau, \underline{s}, \bar{s}) = \sum_{j \in \mathcal{X} \setminus \{i\}} \bar{Q}_{ij}(\tau, \underline{s}, \bar{s})$, and a matrix-valued function

$$\bar{\mathbf{Q}}(\tau, \underline{s}, \bar{s}) = \underbrace{\left[\begin{array}{c|c|c|c} 0 & \bar{Q}_{21}(\tau, \underline{s}, \bar{s}) & \cdots & \bar{Q}_{N1}(\tau, \underline{s}, \bar{s}) \\ \bar{Q}_{12}(\tau, \underline{s}, \bar{s}) & 0 & \cdots & \bar{Q}_{N2}(\tau, \underline{s}, \bar{s}) \\ \vdots & \vdots & & \vdots \\ \bar{Q}_{1N}(\tau, \underline{s}, \bar{s}) & \bar{Q}_{2N}(\tau, \underline{s}, \bar{s}) & \cdots & 0 \end{array}\right]}_{\text{Size } N \times N \text{ matrix}}.$$

Theorem 1 (Interval transition probabilities) *Let $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})$ be the solution to the following integral equation*

$$\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s}) = \mathbf{I}_{N \times N} - \text{diag}\left(\bar{Q}_1(\tau, \underline{s}, \bar{s}), \ldots, \bar{Q}_N(\tau, \underline{s}, \bar{s})\right) + \int_{u=0}^{\tau} \frac{\partial \bar{\mathbf{Q}}(u, \underline{s}, \bar{s})}{\partial u} \times \tilde{\mathbf{P}}(\tau - u, 0, 0)\, du, \tag{11}$$

for the three independent variables $(\tau, \underline{s}, \bar{s}) \in \mathcal{S}$. Then, the interval transition probability p_{ij} is given by $p_{ij}(t_m - t_{m-w}, \psi(m-w, w')) = \tilde{p}_{ij}(\tau, \underline{s}, \bar{s}), \forall i, j \in \mathcal{X}$, at $\tau = t_m - t_{m-w}$, $\underline{s} = t_m - t_{m-w+1}$, and $\bar{s} = t_m - t_{m-w+w'}$.

Proof *See Appendix B.* ■

Theorem 1 follows from a *first-step analysis* that is akin to the derivation of the conventional Chapman-Kolmogorov equations in ordinary Markov chains (Kulkarni (1996)). The integral equation in (11) is a (matrix-valued) non-homogeneous *Volterra integral equation of the second kind* (Polyanin and Manzhirov (2008)). It can be easily demonstrated that a closed-form solution that hinges on conventional kernel methods cannot be obtained. Hence, we

resort to a numerical method in order to solve (11) for $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})$, $\forall (\tau, \underline{s}, \bar{s}) \in \mathcal{S}$. Before presenting the numerical method, we reformulate (11) as follows

$$\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s}) = \mathbf{I}_{N \times N} - \text{diag}\left(\bar{Q}_1(\tau, \underline{s}, \bar{s}), \ldots, \bar{Q}_N(\tau, \underline{s}, \bar{s})\right) + \left(\frac{\partial \bar{\mathbf{Q}}(., \underline{s}, \bar{s})}{\partial u} \star \tilde{\mathbf{P}}(., 0, 0)\right)(\tau), \tag{12}$$

where $\star$ is an element-wise convolution operator. (12) follows from (11) by the fact that the integral in (11) is a convolution integral; (12) can be expressed as follows

$$\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s}) = \mathcal{B}\{\bar{\mathbf{Q}}(\tau, \underline{s}, \bar{s})\}(\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})), \tag{13}$$

where the (functional) operator $\mathcal{B}\{\mathbf{Q}\}(\tilde{\mathbf{P}})$ is given by

$$\begin{aligned} &\mathcal{B}\{\bar{\mathbf{Q}}(\tau, \underline{s}, \bar{s})\}(\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})) = \\ &\mathbf{I}_{N \times N} - \text{diag}\left(\bar{Q}_1(\tau, \underline{s}, \bar{s}), \ldots, \bar{Q}_N(\tau, \underline{s}, \bar{s})\right) + \mathscr{F}^{-1}\left\{\mathscr{F}\left\{\frac{\partial \bar{\mathbf{Q}}(\tau, \underline{s}, \bar{s})}{\partial \tau}\right\} \cdot \mathscr{F}\left\{\tilde{\mathbf{P}}(\tau, 0, 0)\right\}\right\}, \end{aligned} \tag{14}$$

where $\mathscr{F}$ is the Fourier transform operator, and the transforms in (14) are all taken with respect to τ.

The solution to (13) can be obtained via the *successive approximation* method (Opial (1967)) as follows. We initialize the function $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})$ with the truncated semi-Markov kernel[16] $\bar{\mathbf{Q}}(\tau, \underline{s}, \bar{s})$, and then iteratively apply the operator $\mathcal{B}(.)$ to obtain a new value for $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})$ until convergence. That is, the successive approximation procedure goes as follows

$$\begin{aligned} &\tilde{\mathbf{P}}^o(\tau, \underline{s}, \bar{s}) = \bar{\mathbf{Q}}(\tau, \underline{s}, \bar{s}) \\ &\text{While } \left\| \tilde{\mathbf{P}}^z(\tau, \underline{s}, \bar{s}) - \tilde{\mathbf{P}}^{z-1}(\tau, \underline{s}, \bar{s}) \right\|_\infty > \epsilon \\ &\tilde{\mathbf{P}}^z(\tau, \underline{s}, \bar{s}) = \mathcal{B}\{\bar{\mathbf{Q}}(\tau, \underline{s}, \bar{s})\}(\tilde{\mathbf{P}}^{z-1}(\tau, \underline{s}, \bar{s})). \end{aligned} \tag{15}$$

The following Theorem establishes the validity of the procedure in (15) as a solver for (13). Before presenting the statement of Theorem 2, we define the function space $\mathcal{P}$ as follows

$$\mathcal{P} = \left\{ \tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s}) : \ \tilde{p}_{ij}(\tau, \underline{s}, \bar{s}) \in [0,1], \sum_j \tilde{p}_{ij}(\tau, \underline{s}, \bar{s}) = 1, \tilde{p}_{ij}(0, \underline{s}, \bar{s}) = \delta_{ij}, (\tau, \underline{s}, \bar{s}) \in \mathcal{S} \right\},$$

where δ_{ij} is the Kronecker delta function.

Theorem 2 (Convergence of successive approximations) *The functional $\mathcal{B}\{\bar{\mathbf{Q}}\}(\tilde{\mathbf{P}})$ has a unique fixed-point $\tilde{\mathbf{P}}^*$ in $\mathcal{P}$, and the successive approximation procedure in (15) always converges to the fixed point, i.e. $\tilde{\mathbf{P}}^\infty(\tau, \underline{s}, \bar{s}) = \tilde{\mathbf{P}}^*(\tau, \underline{s}, \bar{s})$, starting from any initial value $\tilde{\mathbf{P}}^o(\tau, \underline{s}, \bar{s}) \in \mathcal{P}$.*

Proof *See Appendix C.* ■

16. This is a reasonable initialization since the entries of the semi-Markov kernel correspond to interval transition probabilities conditioned on there being no intermediate transitions on the way from state i to state j.

Algorithm 1 Constructing a look-up table of interval transition probabilities

procedure TransitionLookUp(Γ, ϵ)
  Input: HASMM parameters Γ and precision ϵ
  Output: A look-up table $[\tilde{p}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s})]_{i,j,a,b,c}$
  Set the values of A, B and C (number of steps), $\Delta\tau$ (step sizes)
  for $a = 1$ to A, $b = 1$ to B, $c = 1$ to C **do**
    $g^{\tau}_{ij}(a\Delta\tau) \leftarrow \sum_{x=1}^{a} \frac{e^{(\eta_{ij}+\beta_{ij}x\Delta\tau)}}{\sum_{k=1}^{N} e^{(\eta_{ik}+\beta_{ik}x\Delta\tau)}} \left(\frac{1}{\Gamma(\lambda_{i,s})\,\lambda_{i,r}^{\lambda_{i,s}}} (x\Delta\tau)^{\lambda_{i,s}-1} e^{-\frac{x\Delta\tau}{\lambda_{i,r}}} \right) \Delta\tau$
    $g^{s}_{ij}(a\Delta s) \leftarrow \sum_{x=1}^{a} \frac{e^{(\eta_{ij}+\beta_{ij}x\Delta s)}}{\sum_{k=1}^{N} e^{(\eta_{ik}+\beta_{ik}x\Delta s)}} \left(\frac{1}{\Gamma(\lambda_{i,s})\,\lambda_{i,r}^{\lambda_{i,s}}} (x\Delta s)^{\lambda_{i,s}-1} e^{-\frac{x\Delta s}{\lambda_{i,r}}} \right) \Delta s$
    $\bar{Q}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) \leftarrow \sum_{x=b}^{c} \frac{(g^{\tau}_{ij}(a\Delta\tau) - g^{s}_{ij}(x\Delta s))\,(V_i(a\Delta\tau|\lambda_i) - V_i(x\Delta s|\lambda_i))}{1 - V_i(x\Delta s|\lambda_i)}\, v_i(x\Delta s|\lambda_i)$
  end for
  $e = \epsilon + 1$
  $z \leftarrow 1$
  $\tilde{p}^{(o)}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) \leftarrow \bar{Q}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s})$, $\forall a, b, c, i, j$.
  while $e > \epsilon$ **do**
    $CQ_{i,j,k}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) \leftarrow$
      $\text{IFFT}\left(\text{FFT}\left(\text{diff}\left(\bar{Q}_{ik}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s})\right)\right), \text{FFT}\left(\tilde{p}^{(z-1)}_{jk}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s})\right)\right),$
    $\tilde{p}^{(z)}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) \leftarrow \delta_{ij}\,\bar{Q}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) + \sum_{k=1}^{N} CQ_{i,j,k}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s})$
    $\tilde{\mathbf{P}}^{(z)}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) = \left[\tilde{p}^{(z)}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}))\right]_{i,j,a,b,c}$
    $e \leftarrow \left\| \tilde{\mathbf{P}}^{(z)}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) - \tilde{\mathbf{P}}^{(z-1)}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) \right\|_{\infty}$
    $z \leftarrow z + 1$
  end while
  return $\tilde{\mathbf{P}}^{(z)}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s})$
end procedure

It is important to note that we do not need to solve for $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})$ during real-time inference. Instead, we create a look-up table comprising a discretized version of $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s}) = [\tilde{p}_{ij}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}))]_{i,j,a,b,c}$, and then we query this table when performing real-time inference for monitored patients. Hence, efficient and fast inferences can be provided for critical care patients for whom prompt diagnoses are necessary for the efficacy of clinical interventions. Algorithm 1 shows a pseudocode for constructing a look-up table of interval transition probabilities, `TransitionLookUp`(Γ, ϵ), which takes as an input the parameter set Γ and a precision level ϵ (to control the termination of the successive approximation iterations), and outputs the interval transitions look-up table $\tilde{\mathbf{P}}(\tau, \underline{s}, \bar{s})$. In Algorithm 1, FFT and IFFT refer to the fast Fourier transform operation and its inverse, respectively, and "diff(.)" refers to a numerical differentiation operation.

Now that we have constructed the algorithm `TransitionLookUp` to compute the interval transition probabilities in the look-up table $\tilde{\mathbf{P}}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s})$, we can implement a forward-filtering inference algorithm using dynamic programming (by virtue of the recursive formula in (10)). In particular, the posterior probability of the patient's current clinical state in

Algorithm 2 Forward filtering inference

procedure ForwardFilter(Γ, $\{y(t_w)\}_{w=1}^{m}$, ϵ)
  Input: Observed samples $\{y(t_w)\}_{w=1}^{m}$, HASMM parameters Γ, and precision ϵ
  Output: The posterior state distribution $\{\mathbb{P}(X(t_m) = j \,|\, \{y(t_w)\}_{w=1}^{m})\}_{j=1}^{N}$
  $\tilde{\mathbf{P}}(a\Delta\tau, b\Delta\underline{s}, c\Delta\bar{s}) \leftarrow$ `TransitionLookUp`(Γ, ϵ)
  $\alpha_1(j,1) = d\mathbb{P}(y(t_1) \,|\, X(t_1) = j)\, \sum_{i=1}^{N} \tilde{p}_{ij}(t_1, 0, 0) \cdot p_i^{o},\ \forall j \in \mathcal{X}$
  for $j = 1$ **to** N
  for $z = 2$ to m **do**
    for $w = 1$ to z **do**
      $a^*(z,w) = \arg\min_a |t_z - t_{z-w} - a\Delta\tau|$
      $b^*(z,w) = \arg\min_b |t_z - t_{z-w+1} - b\Delta\underline{s}|$
      $c^*(z,w,w') = \arg\min_c \left|t_z - t_{z-w-w'} - c\Delta\bar{s}\right|$
      $\alpha_z(j,w) = d\mathbb{P}(\{y(t_u)\}_{u=z-w+1}^{z} \,|\, X(t_z) = j)\, \sum_{i=1}^{N} \sum_{w'=1}^{z-w} \alpha_{z-w}(i,w') \times$

$$\tilde{p}_{ij}(a^*(z,w)\Delta\tau, b^*(z,w)\Delta\underline{s}, c^*(z,w,w')\Delta\bar{s}) \times (V_j(t_z - t_{z-w}|\lambda_j) - V_j(t_z - t_{z-w+1}|\lambda_j))$$

    end for
  end for
  $\mathbb{P}(X(t_m) = j \,|\, \{y(t_u)\}_{u=1}^{m}) = \frac{\sum_{w=1}^{m} \alpha_m(j,w)}{\sum_{k=1}^{N} \sum_{w=1}^{m} \alpha_m(k,w)}$
  return $\{\mathbb{P}(X(t_m) = j \,|\, \{y(t_w)\}_{w=1}^{m})\}_{j=1}^{N}$
end procedure

terms of the forward messages can be written as

$$\mathbb{P}(X(t_m) = j \,|\, y(t_1), \ldots, y(t_m)) = \frac{\sum_{w=1}^{m} \alpha_m(j,w)}{\sum_{k=1}^{N} \sum_{w=1}^{m} \alpha_m(k,w)}. \tag{16}$$

Algorithm 2, `ForwardFilter`, implements real-time inference of a patient's clinical state given a sequence of measurements $\{y(t_1), \ldots, y(t_m)\}$. In Algorithm 2, we invoke `TransitionLookUp` initially to construct the look-up table of transition probabilities, but in practice, the look-up table can be constructed in an offline stage once the HASMM parameter set Γ is known.

The number of computations can be reduced by limiting the lags w for every forward message $\alpha_m(j,w)$ to a maximum of W lags. Ignoring the computations involved in evaluating the GP likelihoods, the complexity of `ForwardFilter` is $\mathcal{O}(mWN + mN^2)$. Since evaluating the GP likelihoods is cubic in the number of observations, the worst caset complexity of `ForwardFilter` is $\mathcal{O}((mWN + mN^2)W^3)$. (In most practical clinical settings of interest, the number of observations W can be restricted to include the most recent few samples.)

3.3 Prognostic risk scoring using an HASMM

Diagnostic inference, e.g. estimating the patient's current state after a screening test, can be conducted by a direct application of the forward filtering algorithm presented in the previous Subsection. Prognostic risk scoring plays an important role in designing screening guidelines

(Gail and Mai (2010)), acute care interventions (Knaus et al. (1985)) and surgical decisions (Foucher et al. (2007)). A risk score is a measure for the patient's risk of encountering an adverse event (abstracted as state N in our model) at any future time step starting from time t_m. That is, the patient's risk score at time t_m can be formulated as

$$\begin{aligned} R(t_m) &= \mathbb{P}(\mathcal{A}_N \,|\, \{y(t_u)\}_{u=1}^{m}, \Gamma) \\ &= 1 - \mathbb{P}(X(\infty) = N \,|\, \{y(t_u)\}_{u=1}^{m}, \Gamma), \end{aligned} \tag{17}$$

which can be computed using the outputs of `TransitionLookUp` and `ForwardFilter` as follows

$$R(t_m) = \sum_{j=1}^{N} \tilde{p}_{jN}(A, 0, 0) \cdot \frac{\sum_{w=1}^{m} \alpha_m(j, w)}{\sum_{k=1}^{N} \sum_{w=1}^{m} \alpha_m(k, w)}. \tag{18}$$

Therefore, the procedures `TransitionLookUp` and `ForwardFilter` suffice for executing both the diagnostic and prognostic inference tasks.

4. Learning Hidden Absorbing Semi-Markov Models

In Section 3.1, we developed an inference algorithm that can handle diagnostic and prognostic tasks for patients in real-time assuming that the true HASMM parameter set Γ is known. In practice, the parameter set Γ is not known, and has to be learned from an offline EHR dataset $\mathcal{D}$ that comprises D episodes for previously hospitalized or monitored patients, i.e.

$$\mathcal{D} = \left\{ \{y_m^d, t_m^d\}_{m=1}^{M^d}, T_c^d, l^d \right\}_{d=1}^{D},$$

where $\{y_m^d, t_m^d\}_{m=1}^{M^d}$ are the observable variables and sampling times for the d^{th} episode, T_c^d is the episode's censoring time, and $l^d \in \{1, N\}$ is a label for the realized absorbing state.

We note that unlike the conventional HMM learning setting (Rabiner (1989); Zhang et al. (2001); Nodelman et al. (2012)), the episodes are not of equal-length as the observations for every episode stop at a random, but informative, censoring time. Thus, the patient's state trajectory does not manifest only in the observable time series, i.e. $\{y_m^d, t_m^d\}_{m=1}^{M^d}$, but also in the episode's censoring variables $\{T_c^d, l^d\}$. In this Section, we develop an efficient algorithm, which we call the *forward-filtering backward-sampling Monte Carlo EM* (FFBS-MCEM) algorithm, that computes the Maximum Likelihood (ML) estimate of Γ given an informatively censored dataset $\mathcal{D}$, i.e. $\Gamma^* = \arg\max_\Gamma \Lambda(\mathcal{D} \,|\, \Gamma)$, where $\Lambda(\mathcal{D} \,|\, \Gamma) = d\mathbb{P}(\mathcal{D} \,|\, \Gamma)$ is the likelihood of the dataset $\mathcal{D}$ given the parameter set Γ. We start by presenting the learning setup in Section 4.1, and then we present the FFBS-MCEM algorithm Section 4.3.

4.1 The Learning Setup

We focus on the challenging scenario when no domain knowledge or diagnostic assessments for the patients' latent states are provided in the dataset [17] $\mathcal{D}$ (with the exception of the absorbing state which is declared by the variable l^d), i.e. the learning setup is an *unsupervised* one. For such a scenario, the main challenge in constructing the ML estimator Γ^* resides in the hiddenness of the patients' state trajectories in the training dataset $\mathcal{D}$; the dataset $\mathcal{D}$ contains only the sequence of observable variables, their respective observation times, the episode's censoring time and the state in which the trajectory was absorbed. If the patients' latent state trajectories $(X(t))_{t\in\mathbb{R}_+}$ were observed in $\mathcal{D}$, the ML estimation problem $\Gamma^* = \arg\max_\Gamma \mathbb{P}(\mathcal{D} \,|\, \Gamma)$ would have been straightforward; the hiddenness of $(X(t))_{t\in\mathbb{R}_+}$ entails the need for marginalizing over the space of all possible latent trajectories conditioned on the observed variables, which is a hard task even for conventional CT-HMM models (Liu et al. (2015); Nodelman et al. (2012); Leiva-Murillo et al. (2011); Metzner et al. (2007)).

We start by writing the complete likelihood, i.e. the likelihood of an HASMM with a parameter set Γ to generate both the hidden states trajectory $\{x_n^d, s_n^d\}_{n=1}^{k^d}$ and the observable variables $\{y_m^d, t_m^d\}_{m=1}^{M^d}$ for the d^{th} episode in the dataset $\mathcal{D}$ as follows

$$\begin{aligned} &d\mathbb{P}\left(\{x_n^d, s_n^d\}_{n=1}^{k^d}, \{y_m^d, t_m^d\}_{m=1}^{M^d} \,\middle|\, \Gamma \right) = \mathbb{P}(x_1^d|\Gamma) \cdot d\mathbb{P}(s_1^d|x_1^d, \Gamma) \cdot d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_1^d}|x_1^d, \Gamma) \times \\ &\prod_{n=2}^{k^d} \mathbb{P}(x_n^d \,|\, x_{n-1}^d, s_{n-1}^d, \Gamma) \cdot d\mathbb{P}(s_n^d \,|\, x_n^d, \Gamma) \cdot d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_n^d} \,|\, x_n^d, \Gamma), \end{aligned} \tag{19}$$

where k^d is the number of states that realized in episode d from $t = 0$ until absorption. The factorization in (19) follows from the conditional independence properties of the HASMM variables (see Figure 6). Since we cannot observe the latent states trajectory $\{x_n^d, s_n^d\}_{n=1}^{k^d}$, the ML estimator deals with the expected likelihood $\Lambda(\mathcal{D} \,|\, \Gamma)$, which is evaluated by marginalizing the complete likelihood over the latent states trajectories, i.e.

$$\begin{aligned} \Lambda(\mathcal{D} \,|\, \Gamma) &= \mathbb{E}_{x(t)|\mathcal{D},\Gamma} \left[\prod_{d=1}^{D} d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}, \{y_m^d, t_m^d\}_{m=1}^{M^d} \,|\, \Gamma) \right] \\ &= \prod_{d=1}^{D} \mathbb{E}_{x^d(t)|\mathcal{D},\Gamma} \left[d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}, \{y_m^d, t_m^d\}_{m=1}^{M^d} \,|\, \Gamma) \right] \\ &= \prod_{d=1}^{D} \int d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}, \{y_m^d, t_m^d\}_{m=1}^{M^d} \,|\, \Gamma) \cdot d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d} \,|\, \mathcal{D}, \Gamma), \end{aligned} \tag{20}$$

where the expectation is taken with respect to the latent trajectory conditioned on the observed dataset $\mathcal{D}$, **which contains the information on every episode's censoring time T_c^d and terminating state l^d**. The integral in (20) can be further decomposed as follows

$$\begin{aligned} \Lambda(\mathcal{D} \,|\, \Gamma) = \prod_{d=1}^{D} \int & \mathbb{P}(x_1^d|\Gamma) \cdot d\mathbb{P}(s_1^d|x_1^d, \Gamma) \cdot d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_1^d}|x_1^d, \Gamma) \cdot d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d} \,|\, \mathcal{D}, \Gamma) \\ & \times \prod_{n=2}^{k^d} \mathbb{P}(x_n^d \,|\, x_{n-1}^d, s_{n-1}^d, \Gamma) \cdot d\mathbb{P}(s_n^d \,|\, x_n^d, \Gamma) \cdot d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_n^d} \,|\, x_n^d, \Gamma). \end{aligned} \tag{21}$$

17. For some settings, such as chronic kidney disease progression estimation (Eddy and Neilson (2006)), the EHR records may include some anchors or assessments to the latent states over time. A simpler version of the learning algorithm proposed in this Section can be used to deal with such datasets. In critical care settings, it is more common that the EHR records are not labeled with any clinical state assessments over time (Yoon et al. (2016)).

4.2 Challenges Facing the HASMM Learning Task

The problem of learning the HASMM parameters by maximizing the likelihood function in (21) is obstructed by various obstacles that hinder the deployment of off-the-shelf learning algorithms; we list these challenges hereunder.

1. Finding the ML estimate Γ^* by direct maximization of $\Lambda(\mathcal{D}\,|\,\Gamma)$ is not viable due to the intractability of the integral in (21), i.e. $\Lambda(\mathcal{D}\,|\,\Gamma)$ has no analytic maximizer. The difficulty of evaluating the expected likelihood $\Lambda(\mathcal{D}\,|\,\Gamma)$ follows from the need to average the complete likelihood over a complicated posterior density function for the latent state trajectory.

2. Direct adoption of the conventional Baum-Welch implementation of the EM algorithm as a solution to the intractable problem of maximizing the expected likelihood in (21) –as has been applied in HMMs (Rabiner (1989)), HSMMs (Murphy (2002)), EDHMMs and VDHMMs (Yu (2010)– is not possible for the HASMM setting. This is due to the intractability of the integral involved in the E-step; a problem that is also faced by other continuous-time models (Liu et al. (2015); Nodelman et al. (2012)). However, these models assumed Markovian state trajectories, in which case the implementation of the E-step boils down to computing the expected state durations and transition counts as sufficient statistics for estimating the latent trajectories[18] (e.g. see Equations (12) and (13) in (Liu et al. (2015))). This simplification, which follows from the plausible properties of the Markov chain's transition rate matrix, does not materialize for semi-Markovian transitions. Further complications are introduced by the duration-dependence of the state-transitions and the segmental nature of the observables.

3. Learning an informatively censored dataset would naturally benefit from the information conveyed in the censoring variables $\{T_c^d, l^d\}$. However, the availability of censoring information leads to more complicated posterior density expressions for the latent state trajectories, which complicates the job of any analytic, variational or Monte Carlo based inference method one would use to infer the latent state trajectories[19].

In the following Section, we present a learning algorithm that addresses the above challenges, and provides insights into general settings in which informatively censored time series data are to be dealt with.

18. Different approaches have been developed in the literature for computing these quantities: (Wang et al. (2014)) assumes that the transition rate matrix is diagonalizable, and hence utilize a closed-form estimator for the transition rates, whereas (Liu et al. (2015)) uses the *Expm* and *Unif* methods (originally developed in (Hobolth and Jensen (2011))) to evaluate the integrals of the transition matrix exponential. Unfortunately, none of these methods could be utilized for computing the proximal log-likelihood of an HASMM due to the semi-Markovianity of the state trajectory (i.e. state-durations are not exponentially distributed as it is the case in (Liu et al. (2015); Nodelman et al. (2012); Hobolth and Jensen (2011); Wang et al. (2014))).

19. Note that the censoring information are only available in the model training (learning) phase since we deal with an offline batch of data through which we can see the full patients' episodes, whereas real-time inference, discussed in the previous Section, does not take advantage of any external censoring information.

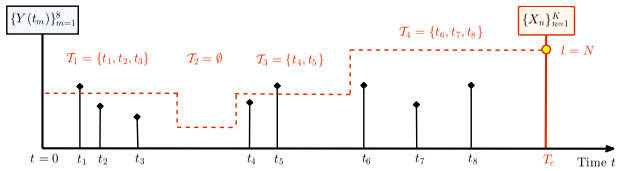

Figure 9: An episode that comprised 8 observable samples, censored at time T_c, and absorbed in state N (catastrophic state). The dashed state trajectory is a trajectory that could have generated the observables with a positive probability. Computing the proximal log-likelihood requires averaging over infinitely many paths that could have generated the observables with a positive probability.

4.3 The Forward-filtering Backward-sampling Monte Carlo EM Algorithm

4.3.1 Expectation-Maximization

As in the case of classical discrete and continuous-time HMMs, we address the first challenge stated in Section 4.2 by using the EM algorithm (Liu et al. (2015); Nodelman et al. (2012)). The iterative EM algorithm starts with an initial guess $\hat{\Gamma}^o$ for the parameter set, and maximizes a proxy for the log-likelihood in the z^{th} iteration as follows:

- **E-step:** $U(\Gamma;\hat{\Gamma}^{z-1}) = \sum_{d=1}^{D} \mathbb{E}\left[\log(\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}, \{y_m^d, t_m^d\}_{m=1}^{M^d}\,|\,\Gamma))\middle|\ \mathcal{D}, \hat{\Gamma}^{z-1}\right]$.
- **M-step:** $\hat{\Gamma}^z = \arg\max_\Gamma U(\Gamma;\hat{\Gamma}^{z-1})$.

The E-step computes the *proximal expected log-likelihood* $U(\Gamma;\hat{\Gamma}^{z-1})$, which entails evaluating the following integral

$$U(\Gamma;\hat{\Gamma}^{z-1}) = \sum_{d=1}^{D} \int \log(d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}, \{y_m^d, t_m^d\}_{m=1}^{M^d}\,|\,\Gamma)) \cdot d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}\,|\,\mathcal{D}, \hat{\Gamma}^{z-1}),$$

where $d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}\,|\,\mathcal{D}, \hat{\Gamma}^{z-1}) = d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d}\,|\,\{y_m^d, t_m^d\}_{m=1}^{M^d}, x^d(T_c^d) = l^d, \hat{\Gamma}^{z-1})$. That is, the proximal expected log-likelihood $U(\Gamma;\hat{\Gamma}^{z-1})$ is computed by marginalizing the likelihood of the observed samples of the d^{th} episodes $\{y_m^d, t_m^d\}_{m=1}^{M^d}$ over all potential latent paths $(x^d(t))_{t\in\mathbb{R}_+}$ that are censored at time T_c^d and absorbed in state l^d. Figure 9 depicts a set of observables $(\{y_m^d, t_m^d\}_{m=1}^{M^d}, x^d(T_c^d) = l^d)$ for one episode, and a potential latent path $\{x_n^d, s_n^d\}_{n=1}^{k^d}$ that could have generated such observables. Computing $U(\Gamma;\hat{\Gamma}^{z-1})$ requires averaging over the posterior density of the latent paths conditional on an observable episode.

4.3.2 "The Only Good Monte Carlo is a Dead Monte Carlo"

Since computing $U(\Gamma;\hat{\Gamma}^{z-1})$ does not admit a closed-form solution, as mentioned earlier in the second challenge stated in Section 4.2, we resort to a Monte Carlo approach for approximating the integral involved in the E-step (Caffo et al. (2005)). That is, in the z^{th} iteration of the EM algorithm, we draw G random trajectories $(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}})_{g=1}^{G}$ for every episode

d, and use those trajectories to construct a Monte Carlo approximation $\hat{U}_G(\Gamma;\hat{\Gamma}^{z-1})$ for the proximal log-likelihood function $U(\Gamma;\hat{\Gamma}^{z-1})$. Sample trajectories are drawn from the posterior density of the latent states' trajectory conditional on the the observable variables (including the censoring information). That is to say, the g^{th} sample trajectory $\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}}$ is drawn as follows

$$\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}} \sim d\mathbb{P}(\{x_n^d, s_n^d\}_{n=1}^{k^d} \,|\, \{y_m^d, t_m^d\}_{m=1}^{M^d}, x^d(T_c^d) = l^d, \hat{\Gamma}^{z-1}), \tag{22}$$

for $g \in \{1,\ldots,G\}$. Hence, the proximal log-likelihood $U(\Gamma;\hat{\Gamma}^{z-1})$ can be approximated via a Monte Carlo estimate $\hat{U}_G(\Gamma;\hat{\Gamma}^{z-1})$ as follows

$$\hat{U}_G(\Gamma;\hat{\Gamma}^{z-1}) \triangleq \sum_{d=1}^{D}\frac{1}{G}\sum_{g=1}^{G}\log(d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}}, \{y_m^d, t_m^d\}_{m=1}^{M^d} \,|\, \Gamma)). \tag{23}$$

It follows from the *Glivenko-Cantelli* Theorem (Durrett (2010)) that

$$||\, U(\Gamma;\hat{\Gamma}^{z-1}) - \hat{U}_G(\Gamma;\hat{\Gamma}^{z-1})\,||_\infty = \sup_{\Gamma} |\, U(\Gamma;\hat{\Gamma}^{z-1}) - \hat{U}_G(\Gamma;\hat{\Gamma}^{z-1})\,| \to 0 \;\text{ a.s.},$$

and hence the Monte Carlo implementation of the E-step becomes more accurate as the sample size G increases. Sampling trajectories from the posterior distribution specified in (22) in order to obtain a Monte Carlo estimate for $U(\Gamma;\hat{\Gamma}^{z-1})$ is not a straight forward task; the sampler needs to jointly sample the states and their sojourn times taking into account the duration-dependent transitions among states, and that the number of variables sampled (number of states) $k^{d,g}$ in each trajectory is itself random.

Since there is no straightforward method that can generate samples for the random state trajectory $\{x_n^d, s_n^d\}_{n=1}^{k^d}$ from the joint posterior density in (22), the normative solution for such a problem is to resort to a Markov Chain Monte Carlo (MCMC) method such as Metropolis-Hastings or Gibbs sampling (Carter and Kohn (1994)). Since the number of state and sojourn time variables, k^d, is itself random, one can even resort to a reversible jump MCMC method (Green and Hastie (2009)) in order to generate the samples for $\{x_n^d, s_n^d\}_{n=1}^{k^d}$. At this point of our analysis, we invoke the classical aphorism with which we titled this Subsection: *"The Only Good Monte Carlo is a Dead Monte Carlo"* (Trotter and Tukey (1956)). By this quote, Trotter meant to advocate the view that sophisticated Monte Carlo methods should be avoided whenever possible; whenever an integral is analytically tractable, or whenever some analytic insights can be exploited to built simpler samplers, doing so should be preferred to an expensive Monte Carlo method. MCMCs are indeed expensive: they mix very slowly and they generate correlated samples. Adopting an MCMC to generate random state trajectories in every iteration of the EM algorithm and for every episode in $\mathcal{D}$ is beyond affordable. Fortunately, in the rest of this Section we show that an efficient sampler that generates independent samples of $\{x_n^d, s_n^d\}_{n=1}^{k^d}$ and for which the run-time is geometrically distributed can be constructed by capitalizing on the censoring information and utilizing some insights from the literature on sequential Monte Carlo smoothing (Godsill et al. (2004)).

4.3.3 The Forward-filtering Backward-sampling Recipe

The availability of the censoring information for every episode d in $\mathcal{D}$, together with the inherent non-linearity of the semi-Markovian transition dynamics encourage the development of a *forward-filtering backward-sampling* (FFBS) Monte Carlo algorithm[20] that goes in the reverse-time direction of every episode by starting from the censoring instance, and sequentially sampling the latent states conditioned on the (sampled) future trajectory (Godsill et al. (2004)). That is, unlike the *generative process* (described by the routine `GenerateHASMM`(Γ)) which uses the knowledge of Γ to generate sample trajectories by drawing an initial state and then sequentially going forward in time and sampling future states until absorption, the *inferential process* naturally goes the other way around: it exploits informative censoring by starting from the (known) final absorbing state (and censoring time), and sequentially samples a trajectory by traversing backwards in time and conditioning on the future.

We start constructing our forward-filter backward-sampler by first formulating the posterior density of the latent trajectory $\{x_n, s_n\}_{n=1}^{k}$ (from which we sample the G trajectories in the z^{th} iteration of the FFBS-MCEM algorithm as shown in (22)) as follows

$$\begin{aligned} &d\mathbb{P}(\{x_n, s_n\}_{n=1}^{k} \,|\, \{y_m, t_m\}_{m=1}^{M},\, x(T_c) = l,\, \hat{\Gamma}^{z-1}) = \\ &d\mathbb{P}(s_k \,|\, \{y_m, t_m\}_{m=1}^{M},\, x(T_c) = l) \cdot \prod_{n=1}^{k-1} d\mathbb{P}(x_n, s_n \,|\, \underbrace{\{x_{n'}, s_{n'}\}_{n'=n+1}^{k}}_{\text{Future trajectory}},\, \{y_m, t_m\}_{m=1}^{M},\, T_c), \end{aligned} \tag{24}$$

where the conditioning on the $(z-1)^{th}$ guess of the parameter set, $\hat{\Gamma}^{z-1}$ and the episode index d are suppressed for notational convenience. The formulation in (24) decomposes the posterior density of the latent trajectory $\{x_n, s_n\}_{n=1}^{k}$ into factors in which the likelihood of every state n is conditioned on the future trajectory starting from n (i.e. the states x_{n+1} up to the absorbing states, together with their corresponding sojourn times). The posterior density in (24) can be further decomposed as follows

$$\begin{aligned} &d\mathbb{P}(\{x_n, s_n\}_{n=1}^{k} \,|\, \{y_m, t_m\}_{m=1}^{M},\, x(T_c) = l) = d\mathbb{P}(s_k \,|\, x_k = l, s_k < T_c) \times \\ &\prod_{n=1}^{k-1} d\mathbb{P}(x_n, s_n \,|\, \{x_{n'}, s_{n'}\}_{n'=n+1}^{k}, s_n < \underbrace{T_c - (s_{n+1} + \ldots + s_k)}_{\text{Elapsed time in the episode}},\, \{y_m, t_m\}_{m=1}^{M}), \end{aligned} \tag{25}$$

which, using the conditional independence properties of the HASMM (see Figure 6), can be simplified as follows

$$\begin{aligned} &d\mathbb{P}(\{x_n, s_n\}_{n=1}^{k} \,|\, \{y_m, t_m\}_{m=1}^{M},\, x(T_c) = l) = \\ &d\mathbb{P}(s_k \,|\, x_k = l,\, s_k < T_c) \cdot \mathbb{P}(x_1 \,|\, x_2,\, s_1 = T_c - (s_2 + \ldots + s_k),\, \{(y_m, t_m) : t_m \in \mathcal{T}_1\}) \times \\ &\prod_{n=2}^{k-1} d\mathbb{P}(x_n,\, s_n \,|\, x_{n+1},\, s_n < \underbrace{T_c - (s_{n+1} + \ldots + s_k)}_{\text{Elapsed time in the episode}},\, \underbrace{\{(y_m, t_m) : t_m \in \mathcal{T} / \cup_{n'=n+1}^{k} \mathcal{T}_{n'}\}}_{\text{Observable variables up to state } n}). \end{aligned} \tag{26}$$

20. The methods used in this Section are also known in the literature as *sequential Monte Carlo* or *particle filtering* methods (Godsill et al. (2004)).

From (26), we can see that for the last state in every episode, i.e. state k, we already know that $x_k = l$, and hence the randomness is only in the last state's sojourn time $s_k = l$. Contrarily, for the first state, we know that conditioned on the sojourn times of the "future states" $(s_2, \ldots, s_k)$, the sojourn time of state x_1 is equal to $T_c - \sum_{n'=2}^{k} s_{n'}$ almost surely, and hence the randomness is only in the initial state realization x_1. Generally, (26) says that a sufficient statistic for the n^{th} state and sojourn time is the future trajectory (starting from state $n+1$) summarized by: the next state, i.e. x_{n+1}, the observable variables up to state n, and the time elapsed in the episode up to state n, i.e. the duration of state n cannot exceed the difference between the censoring time T_c and the sojourn time of the future trajectory that stems from state $n+1$. This is captured by the last factor in (26), which explicitly specifies the likelihood of a joint realization for a state and its sojourn time conditioned on the future trajectory. Using Bayes' rule, we can further represent the last factor in (26) in terms of familiar quantities that are directly derived from the HASMM model parameters as follows

$$\begin{aligned} &d\mathbb{P}(x_n, s_n \,|\, x_{n+1}, s_n < T_c - (s_{n+1} + \ldots + s_K), \{(y_m, t_m) : t_m \in \mathcal{T} / \cup_{n'=n+1}^{k} \mathcal{T}_{n'}\}) \\ &\propto \underbrace{\mathbb{P}(x_n \,|\, \{(y_m, t_m) : t_m \in \mathcal{T} / \cup_{n'=n+1}^{k} \mathcal{T}_{n'}\})}_{\text{Forward message}} \times \underbrace{d\mathbb{P}(s_n \,|\, x_n, s_n < T_c - (s_{n+1} + \ldots + s_k))}_{\text{Truncated sojourn time distribution}} \\ &\quad \times \underbrace{\mathbb{P}(x_{n+1} \,|\, x_n, s_n)}_{\text{Transition function}} . \end{aligned} \tag{27}$$

Thus, a sampler for the latent states trajectories can be constructed using the forward messages, the HASMM's transition functions $(g_{ij}(s))_{i,j}$, and the sojourn time distributions. A compact representation for the factors in (27) is given by

(Forward messages) $\mathbb{P}(X_n = j \,|\, \{y_{m'}, t_{m'}\}_{m'=1}^{m}, \hat{\Gamma}^{z-1}) = \alpha_m^{z-1}(j)$, $\forall 1 \le m \le M$, $j \in \mathcal{X}$.

(Transition functions) $\mathbb{P}(X_{n+1} = j \,|\, X_n = i, S_n = s, \hat{\Gamma}^{z-1}) = g_{ij}^{z-1}(s), i, j \in \mathcal{X}$,

(Truncated sojourn times) $d\mathbb{P}(S_n = s \,|\, X_n = j, S_n < \bar{s}) = \dfrac{v_j(s|\hat{\lambda}_j^{z-1}) \cdot \mathbf{1}_{\{s<\bar{s}\}}}{V_j(\bar{s}|\hat{\lambda}_j^{z-1})}, j \in \mathcal{X}$.

Given the representations above, we can write the last factor in (26) in the z^{th} iteration of the EM algorithm as follows

$$d\mathbb{P}(x_n, s_n \,|\, x_{n+1}, s_n < \bar{s}, \{y_m, t_m\}, \hat{\Gamma}^{z-1}) \propto \alpha_m^{z-1}(x_n) \cdot g_{x_n, x_{n+1}}^{z-1}(s_n) \cdot \frac{v_{x_n}(s_n|\hat{\lambda}_{x_n}^{z-1}) \cdot \mathbf{1}_{\{s_n \le \bar{s}\}}}{V_{x_n}(\bar{s}|\hat{\lambda}_{x_n}^{z-1})}. \tag{28}$$

From the factor decomposition in (27), we can see that informative censoring allows us to construct a sampler for the latent state trajectories that operates sequentially in the reverse time direction by sampling from the posterior probability of every state n given the future trajectory of states that starts from state $n+1$. From (28), we note that the posterior density of the latent states conditioned on the future trajectory, from which sequential sampling is conducted, can be explicitly decomposed in terms of the HASMM parameters.

A complete recipe for the forward-filtering backward-sampling procedure for sampling trajectories from the posterior density $d\mathbb{P}(\{x_n, s_n\}_{n=1}^{k} \,|\, \{y_m, t_m\}_{m=1}^{M}, x(T_c) = l, \hat{\Gamma}^{z-1})$ using the decomposition in (27) and the posterior density in (28) is provided as follows:

- **Forward filtering pass:**
  For every episode in $\mathcal{D}$, compute the forward messages $\{\alpha_m^{z-1}(j)\}$ for all time instances $t_m \in \mathcal{T}$ using the current estimate for the parameter set $\hat{\Gamma}^{z-1}$, i.e. invoke the routine `ForwardFilter`$(\hat{\Gamma}^{z-1}, \{y_m, t_m\}_{m=1}^{M}, \epsilon)$.

- **Backward sampling pass:**
  For every episode in $\mathcal{D}$, carry out the following steps:

  1. Set a dummy *placeholder index* as $k^{\#} = 1$ and set $u_{k^{\#}} = l$.
  2. Sample a Bernoulli random variable $B_{k^{\#}} \sim \text{Bernoulli}(\mathbb{P}(k = k^{\#} \,|\, \{u_k, w_k\}_{k=1}^{k^{\#}-1}, l))$.
  3. If $B_{k^{\#}} = 0$ and $k^{\#} > 1$, sample a bi-variate random variable $(u_{k^{\#}}, w_{k^{\#}})$ using the routines `TRSampler` and `BARSampler` as follows

     $$(u_{k^{\#}}, w_{k^{\#}}) \sim \frac{1}{\mathcal{U}} \cdot \alpha_m^{z-1}(u_{k^{\#}}) \cdot g_{u_{k^{\#}}, u_{k^{\#}-1}}^{z-1}(w_{k^{\#}}) \cdot \frac{v_{u_{k^{\#}}}(w_{k^{\#}}|\hat{\lambda}_{u_{k^{\#}}}^{z-1}) \cdot \mathbf{1}_{\{w_{k^{\#}} \le \bar{s}\}}}{V_{u_{k^{\#}}}(\bar{s}|\hat{\lambda}_{u_{k^{\#}}}^{z-1})},$$

     where $\mathcal{U} = \sum_u \int_w \alpha_m^{z-1}(u) \cdot g_{u, u_{k^{\#}-1}}^{z-1}(w) \cdot \frac{v_u(w|\hat{\lambda}_u^{z-1}) \cdot \mathbf{1}_{\{w \le \bar{s}\}}}{V_u(\bar{s}|\hat{\lambda}_u^{z-1})}$, $\bar{s} = T_c - \sum_{n'=1}^{k^{\#}-1} w_{n'}$, and $m = \arg\max_{m'} \{\mathcal{T} : t_{m'} \le \bar{s}\}$.

     If $B_{k^{\#}} = 0$ and $k^{\#} = 1$, then sample $w_{k^{\#}}$ as follows

     $$w_{k^{\#}} \sim \frac{v_{u_{k^{\#}}}(w_{k^{\#}}|\hat{\lambda}_{u_{k^{\#}}}^{z-1}) \cdot \mathbf{1}_{\{w_{k^{\#}} \le T_c\}}}{V_{u_{k^{\#}}}(T_c|\hat{\lambda}_{u_{k^{\#}}}^{z-1})}.$$

  4. If $B_{k^{\#}} = 1$, then set $w_{k^{\#}} = \bar{s}$. If $k^{\#} > 1$, then sample $u_{k^{\#}}$ as follows

     $$u_{k^{\#}} \sim \frac{d\mathbb{P}(\{y_{m'}, t_{m'}\}_{m'=1}^{m} \,|\, u_{k^{\#}}) \cdot g_{u_{k^{\#}}, u_{k^{\#}-1}}(\bar{s}) \cdot v_{u_{k^{\#}}}(\bar{s}|\hat{\lambda}_{u_{k^{\#}}}^{z-1}) \cdot \hat{p}_{u_{k^{\#}}}^{o,z-1}}{\sum_u d\mathbb{P}(\{y_{m'}, t_{m'}\}_{m'=1}^{m} \,|\, u) \cdot g_{u, u_{k^{\#}-1}}(\bar{s}) \cdot v_u(\bar{s}|\hat{\lambda}_u^{z-1}) \cdot \hat{p}_u^{o,z-1}}.$$

  5. If $B_{k^{\#}} = 0$, then increment the placeholder index $k^{\#}$ and go to step 2 and repeat the consequent steps.
  6. If $B_{k^{\#}} = 1$, then set $k = k^{\#}$ and terminate the sampling process. Set the sampled trajectory by swapping the bi-variate sequence $(u_{k^{\#}}, w_{k^{\#}})$ as follows: $(x_n, s_n) = (u_{k^{\#}-n+1}, w_{k^{\#}-n+1}), \forall n \in \{1, \ldots, k^{\#}\}$.

The forward-filtering backward-sampling procedure constitutes of a forward pass in which we compute the forward messages for all the data points in $\mathcal{D}$ using the dynamic programming algorithms presented in Section 3, and a backward pass in which these forward messages are used to sample latent state trajectories. The backward sampling procedure for every episode goes as follows. We start from the censoring time at which we know what

Algorithm 3 Truncated Rejection Sampler

procedure TRSAMPLER(Γ, u, $\bar{s}$)
  Input: A parameter set Γ, a state u and a truncation threshold $\bar{s}$
  Output: A random variable s
  $k \leftarrow 0$
  while $k = 0$ **do**
    $s \sim v_u(s|\lambda_u)$
    Accept s and set $k \leftarrow 1$ if $s < \bar{s}$. Reject s otherwise.
  end while
  return s
end procedure

Algorithm 4 Bivariate Adaptive Rejection Sampler

procedure BARSAMPLER($\{\alpha(j)\}_{j=1}^{N}$, Γ, $u^{'}$, $\bar{w}$)
  Input: A set of N forward messages $\{\alpha(j)\}_{j=1}^{N}$, parameter set Γ, and a state $u^{'}$
  Output: A bivariate conditional random variable $(u, w)|u^{'}$
  $k \leftarrow 0$
  while $k = 0$ **do**
    $u \sim$ Multinomial$(\alpha(1), \ldots, \alpha(N))$
    $w =$ `TRSampler`$(\Gamma, u, \bar{w})$
    $\tilde{u} \sim$ Multinomial$(g_{u1}(w), \ldots, g_{uN}(w))$
    Accept (u, w) and set $k \leftarrow 1$ if $\tilde{u} = u^{'}$. Reject (u, w) otherwise.
  end while
  return (u, w)
end procedure

state has actually materialized, i.e. the absorbing state. Since we do not know the number of states in the state trajectory, we initialize a placeholder index $k^{\#} = 1$ as an index for the absorbing state, and increment it whenever a new state is sampled. We start the sampling procedure as follows. Given the the censoring variables and the observable time series, we sample the sojourn time of the last state (the absorbing state): this is sampled from a truncated sojourn time distribution, with a truncation threshold at T_c, and a point mass at T_c with an assigned measure that is equal to the posterior probability of the absorbing state being the initial state as depicted in Figure 10. This is implemented by first sampling a Bernoulli random variable $B_{k^{\#}}$ with a success probability equal to the posterior probability of the absorbing state being the initial state, and then sampling the truncated sojourn time if $B_{k^{\#}} = 0$ using the simple rejection sample executed by the routine `TRSampler` which is provided in Algorithm 3. Having sampled the last state's sojourn time, we sample the penultimate state and its sojourn time jointly using the routine `BARSampler` (Algorithm 4) as depicted in Figure 11. The routine `BARSampler` uses a sampling algorithm, that we call the *bi-variate adaptive rejection sampler*, which jointly samples the current state and its sojourn time given the next state as follows. First, a state is sampled from a Multinomial distribution with probability masses equal to the forward messages. Next, given the sam-

Algorithm 5 A sampler for latent state trajectories

procedure BACKWARDSAMPLING($\Gamma, \{\{\alpha_m^o(j)\}_{m,j}\}, \{y_m, t_m\}_{m=1}^{M}, x(T_c) = l$)
  Input: Parameter Γ, forward messages, observables, and censoring information
  Output: A sampled latent state trajectory $\{x_n, s_n\}_{n=1}^{k}$
  $k^{\#} \leftarrow 1$, $u_{k^{\#}} \leftarrow l$, $B_{k^{\#}} \sim$ Bernoulli$(\mathbb{P}(k = k^{\#}|\{y_m, t_m\}_{m=1}^{M}, x(T_c) = l))$
  if $B_{k^{\#}} = 0$ **then**
    $w_{k^{\#}} =$ `TRSampler`$(\Gamma, u_{k^{\#}}, T_c)$
    $k^{\#} \leftarrow k^{\#} + 1$
  else
    $w_{k^{\#}} = T_c$, $k = 1$, $\{x_1, s_1\} \leftarrow \{u_{k^{\#}}, w_{k^{\#}}\}$
    Terminate `BackwardSampling`.
  end if
  while $k^{\#} > 0$ **do**
    $B_{k^{\#}} \sim$ Bernoulli$(\mathbb{P}(k = k^{\#}|\{u_k, w_k\}_{k=1}^{k^{\#}-1}, \{y_m, t_m\}_{m=1}^{M}))$
    $\bar{s} = T_c - \sum_{n'=1}^{k^{\#}-1} w_{k^{\#}}$
    if $B_{k^{\#}} = 0$ **then**
      $(u_{k^{\#}}, w_{k^{\#}}) \leftarrow$ `BARSampler`$(\{\alpha_m^o(j)\}_j, \Gamma, u_{k^{\#}-1}, \bar{s})$
      $k^{\#} \leftarrow k^{\#} + 1$
    else
      Sample the initial state $u_{k^{\#}}$, set $w_{k^{\#}} \leftarrow \bar{s}$
      $\{x_n, s_n\} = \{u_{k^{\#}-n+1}, w_{k^{\#}-n+1}\}$, $\forall n \in \{1, \ldots, k^{\#}\}$
      $k^{\#} \leftarrow -1$
    end if
  end while
  return $\{x_n, s_n\}_{n=1}^{k}$
end procedure

pled state, we sample a sojourn time from the truncated sojourn time distribution. Finally, given the sampled state and the sampled sojourn time, we sample a dummy state from a Multinomial whose masses are equal to the transition functions, and we accept the sample only if the sampled dummy state is equal to the next state. It can be easily proven that `BARSampler` generates samples that are equal in distribution to the true state trajectory.

The backward-sampling procedure operates sequentially by invoking the `BARSampler` to generate new state and sojourn times samples conditional on the previously sampled (future) states. The process terminates whenever $B_{k^{\#}} = 1$, i.e. a state is sampled as an "initial state". The routine `BackwardSampling` (Algorithm 5) implements the overall backward-sampling procedure for every episode in $\mathcal{D}$. **The computational complexity of the `BackwardSampling` routine is dominated by the computation of the GP likelihood (Step 4 in the sampling procedure described above), which is cubic in the number of observations ($\mathcal{O}(W^3)$). The computations in the `BackwardSampling` procedure scales only linearly with the number of states N.**

Note that, unlike the slowly mixing MCMC methods, the backward-sampling algorithm can generate the latent state trajectory in an efficient manner, i.e. the run-time of the

Algorithm 6 Forward-filtering Backward-sampling Monte Carlo EM Algorithm

procedure `FFBS-MCEM`($\mathcal{D}$, G, ϵ)
  Input: A dataset $\mathcal{D}$, number of Monte Carlo samples G, and a precision level ϵ
  Output: An estimate $\hat{\Gamma}$ for the HASMM parameters
  Set an initial value $\hat{\Gamma}^o$ for the HASMM parameters
  $\{\alpha_m^{d,o}\}_{m=1}^{M_d} = \texttt{ForwardFilter}(\hat{\Gamma}^o, \{y_m^d, t_m^d\}_{m=1}^{M_d}, \epsilon), \forall 1 \leq d \leq D$ ▷ Forward pass
  for $d = 1$ to D **do** ▷ Backward pass: sample G latent state trajectories
    for $g = 1$ to G **do**
      $\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}} = \texttt{BackwardSampling}(\hat{\Gamma}^o, \{y_m^d, t_m^d\}_{m=1}^{M_d}, x^d(T_c^d) = l^d)$
    end for
  end for
  $z \leftarrow 1$
  $E \leftarrow \epsilon + 1$
  while $E > \epsilon$ **do**
    $I_{d,g}^{z-1} \leftarrow d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}} | \hat{\Gamma}^{z-1}) / d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}} | \hat{\Gamma}^o)$ ▷ Importance weights
    $\hat{U}_G(\Gamma; \hat{\Gamma}^{z-1}) = \sum_{d,g} \log(d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}}, \{y_m^d, t_m^d\}_{m=1}^{M^d} | \Gamma)) \cdot \frac{I_{d,g}^{z-1}}{G}$ ▷ E-step
    $\hat{\Gamma}^z = \arg\max_\Gamma \hat{U}_G(\Gamma; \hat{\Gamma}^{z-1})$ ▷ M-step
    $z \leftarrow z + 1$
  end while
  return $\hat{\Gamma} = \hat{\Gamma}^z$
end procedure

backward-sampling algorithm is stochastically dominated by a geometrically-distributed random variable with a success probability that, other than in a pathological HASMM parameter settings, would not be close to zero. Moreover, since `BackwardSampling` generates independent samples, no wasteful burn-in sampling iterations are involved in the FFBS-MCEM operation. We provide a pseudocode for the overall operation of the `FFBS-MCEM` algorithm in Algorithm 6. We omit the standard EM operations for the sake of brevity. The details of the M-step is provided in Appendix D.

In Algorithm 6, we avoid the need for running the routine `BackwardSampling` in every iteration of the EM algorithm by re-using the sampled trajectories based on the initial parameter guess $\hat{\Gamma}^o$ through the usage of importance weights in the E-step. That is, in the z^{th} iteration of the EM algorithm, we implement the E-step as follows (Booth and Hobert (1999))

$$\hat{U}_G(\Gamma; \hat{\Gamma}^{z-1}) = \sum_{d,g} \log(d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}}, \{y_m^d, t_m^d\}_{m=1}^{M^d} | \Gamma)) \cdot \underbrace{\frac{d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}} | \hat{\Gamma}^{z-1})}{d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}} | \hat{\Gamma}^o)}}_{\text{Importance weights}}.$$

This implementation for the E-step offers a tremendous advantage in the computational cost of `FFBS-MCEM`. By using importance weights, we need to compute the forward messages and sample the latent state trajectories only once, and then reuse the sampled trajectories in all the subsequent EM iterations.

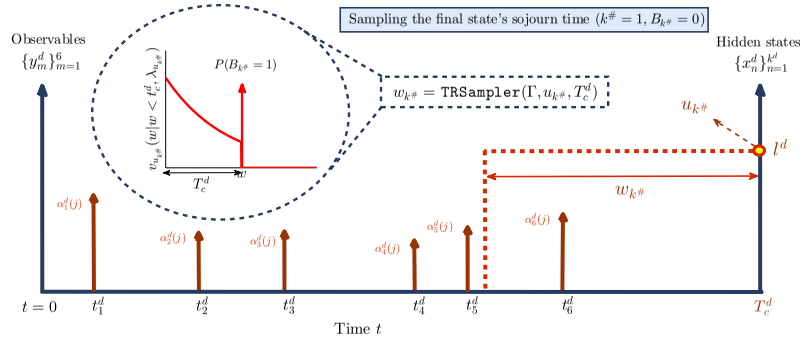

Figure 10: Depiction of the backward sampling pass for the last state of an episode d.

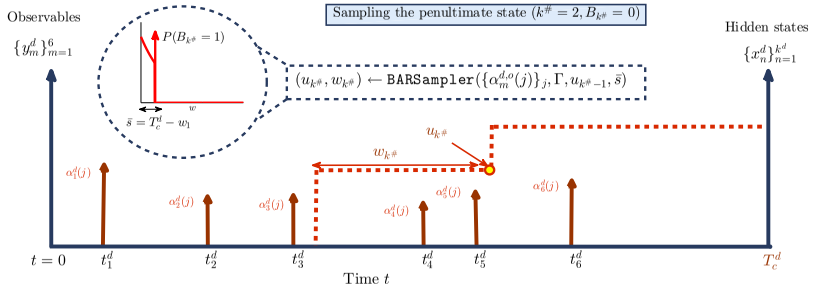

Figure 11: Depiction of the backward sampling pass for the penultimate state after having sampled the last state as depicted in the Figure above.

5. Experiments: Intensive Care Unit Prognostication

We investigate the utility of the HASMM in the setting of ICU prognostication; we use the HASMM as a model for the physiology of critically ill patients in regular hospital wards who are monitored for various vital signs and lab tests. Through the HASMM, we construct a risk score (based on the analysis in Section 3.3) that assesses the risk of clinical deterioration for the monitored patients, which allows for timely ICU admission whenever clinical decompensation is detected. Risk scoring in hospital wards and ICU admission management is a pressing problem with a huge social and clinical impact: qualitative medical studies have suggested that up to 50% of cardiac arrests on general wards could be prevented by earlier transfer to the ICU (Hershey and Fisher (1982)). Since over 200,000 in-hospital cardiac arrests occur in the U.S. each year with a mortality rate of 75% (Merchant et al. (2011)), improved patient monitoring and vigilant care in wards enabled by the HASMM would translate to a large number of lives saved yearly.

5.1 Evidence of the Clinical Utility of Early ICU Admission

Throughout this Section, we will evaluate the clinical utility of our model by investigating both the *accuracy* and *timeliness* of the real-time risk scores that the model computes. This approach has been the standard approach for evaluating the clinical utility of risk scores in retrospective clinical cohort studies that deal with critical care data (Pirracchio et al. (2015); Rothman et al. (2013). More accuracy and timeliness translates to a necessarily improved clinical outcomes; this fact has been confirmed by a large number of medical studies (Cardoso et al. (2011); Johnson et al. (2013); Hershey and Fisher (1982)). For instance, in (Cardoso et al. (2011)), it was shown that each hour of waiting in the ward was independently associated with a 1.5% increased risk of mortality in the ICU.

We stress that knowing the exact magnitude of the improvement in clinical utility (in terms of the reduction in the incidence rates of adverse outcomes) upon using our model is not possible since all available datasets are observational in nature. That is, it is impossible to answer the question of "what would have happened to the patient in the ICU had she been admitted earlier?". Estimation of such counterfactual outcomes is also not viable due to the highly imbalanced nature of the data and the wide variety of possible adverse outcomes in the ICU, some of which are not available in our dataset. Evaluating the clinical utility in terms of the reduction in the incidence rates of adverse outcomes is only possible through an actual clinical trial. Hence, after consulting with our medical collaborators and following the clinical literature on observational studies, we rely on the accuracy and timeliness metrics as proxies for the clinical utility.

5.2 Data

5.2.1 The Patients' Cohort

Experiments were conducted on a heterogeneous cohort of 6,094 episodes for patients who were hospitalized in Ronald Reagan UCLA medical center during the period between March 3^{rd}, 2013 to March 29^{th}, 2016. The patients' population is heterogeneous: we considered admissions to all the floors and units in the medical center, those include the acute care pediatrics unit, cardiac observation unit, cardiothoracic unit, hematology and stem cell transplant unit and the liver transplant service. Patients admitted to those floors (or wards) are post-operative or pre-operative critically ill patients who are vulnerable to adverse clinical outcomes that may require an impending ICU transfer. The cohort comprised patients with a wide variety of ICD-9 codes and medical conditions, including leukemia, hypertension, septicemia, sepsis, abdomen and pelvis, pneumonia, and renal failure. Table 2 shows the distribution of the most common ICD-9 codes in the patient cohort together with the corresponding medical conditions . The notable heterogeneity of the cohort suggests that the results presented in this Section are generalizable to different cohorts extracted from different hospitals. Every patient in the cohort is associated with a set of 21 (temporal) physiological streams comprising a set of vital signs and lab tests that are listed in Table 2. The physiological measurements are gathered over time during the patient's stay in the ward, and they manifest -in a subtle fashion- the patient's clinical state. The physiological measurements are collected over irregularly spaced time intervals (usually ranging from 1

5.2.2 Inclusion and Exclusion Criteria

In all the experiments hereafter, we split the patient cohort into a training set and a testing set. In the training set, we included a total of 4,939 patients admitted to the medical center in the period between March 3^{rd}, 2013 to November 1^{st}, 2015; the testing set comprises 1,155 patients admitted in the period between November 1^{st}, 2015 to March 29^{th}, 2016. This split of the data allows us to assess the performance under the realistic scenario when a certain algorithm learns from the data available up to a certain date, and then is used to assess the risk for patients admitted in future dates. In Table 2, we show statistics for the patients' baseline static features (e.g. gender, age, etc) in both the training and testing sets; as we can see, the characteristics of the patients admitted in the period (March 2013 - November 2015) has not significantly changed from those admitted in the period (November 2015 - March 2016). We have verified this fact using a two-sample t-test through which we compared the expected values of the baseline co-variates in both the training and testing sets. This means that the hospital's management policy with respect to the patients' acceptance and triaging has not significantly changed across the two time periods, and hence whatever is learned from the training data can be sensibly applied to the testing data. **We have excluded all patients who underwent a preplanned ICU admission from the dataset since those patients did not actually experience clinical deterioration, but were transferred routinely to the ICU after a surgery.**

5.2.3 Informative Censoring

All the patient episodes in the cohort were informatively censored. That is, for every patient in the cohort, we know the following information:

• **The censoring time (T_c):** the length of stay of each patient in the ward is recorded in the dataset, and hence we have access to the HASMM's censoring time variable T_c. The average hospitalization time (or censoring time) in the cohort is 157 hours and 34 minutes (6.5 days). The patient episodes' censoring times ranged from 4 hours to 2,672 hours.

• **The absorbing clinical state (l):** with the help of experts from the division of pulmonary and critical care medicine at Ronald Reagan UCLA medical center, we set the value of the variable l (absorbing state) for every patient's episode based on the clinicians' interventions as reported in the dataset. That is, as advised by our medical collaborators, we assigned the label $l = 1$ to every patient who was admitted to the ICU and underwent an intervention in the ICU (e.g. ventilator, drug, etc), or was reported to exhibit a cardiac or respiratory arrest (before or after the ICU transfer). According to the medical experts, those patients have experienced "clinical deterioration" as their absorbing state, and would have benefited from an earlier admission to the ICU. We assigned the label $l = 0$ to all patients who were discharged home after the clinician's in charge realized they were clinically stable. Since the readmission rate at the UCLA medical center is quite low, our medical collaborators believe that the labels $l = 1$ and $l = 0$ represent an accurate representation for the patients' true absorbing clinical states upon censoring.

Patient episodes with the absorbing state $l = 0$ had an average censoring time of 155 hours, whereas those with $l = 1$ had an average censoring time of 204 hours. The percentage of episodes with an absorbing state $l = 1$ was $4.98\% \pm 0.64\%$ in the training period (March 2013 - November 2015), and was $5.19\% \pm 1.44\%$ in the testing period (November 2015 - March 2016). A two-sample t-test reveals that the censoring information (distributions of T_c and l) has not significantly changed from the training to testing periods, which suggests that the HASMM learned from the training data can be sensibly applied to the testing data. Figure 12 visualizes the informative censoring information over the time period between March 2013 and March 2016. Every patient episode, starting at a certain admission date, is represented by its censoring time (hospitalization time); light colored episodes are ones that were absorbed in the clinical stability state ($l = 0$), whereas dark colored ones were absorbed in the clinical deterioration state ($l = 1$).

5.3 Baseline Algorithms

We compare our model with other baseline early warning methods. The comparisons involve both state-of-the-art clinical risk scores that are currently used in various healthcare facilities around the world, in addition to benchmark machine learning algorithms. The details of the baselines are provided in the following subsections.

5.3.1 State-of-the-art Clinical Risk Scores

We have conducted comparisons with the most prominent clinical risk scores currently deployed in major healthcare facilities. We list the clinical risk scores involved in our comparisons hereunder.

(i) **Modified Early Warning System (MEWS)**: a risk scoring scheme used currently by many healthcare facilities and rapid response teams to quickly assess the severity of illness of a hospitalized patient (Morgan et al. (1997)). The score ranges from 0 to 3 and is based on the following cardinal vital signs: systolic blood pressure, respiratory rate, SaO_2, temperature, and heart rate.

(ii) **Sequential Organ Failure Assessment (SOFA)**: a risk score (ranging from 1 to 4) that is used to determine the extent of a hospitalized patient's respiratory, cardiovascular, hepatic, coagulation, renal and neurological organ function in the ICU (Vincent et al. (1996)).

(iii) **Acute Physiology and Chronic Health Evaluation (APACHE II)**: a risk scoring system (an integer score from 0 to 71) for predicting mortality of patients in the ICU (Knaus et al. (1991)). The score is based on 12 physiological measurements, including creatinine, white blood cell count, and glasgow coma scale.

(iv) **Rothman Index**: a regression-based data-driven risk score that utilizes physiological data to predict mortality, 30-days readmission, and ICU admissions for patients in regular wards (Rothman et al. (2013)). The Rothman index is the state-of-the-art risk score for regular ward patients and is currently used in more than 70 hospitals in the US, including the Houston Methodist hospital in Texas and the Yale-New Haven hospital in Connecticut (Landro (2015)). At the time of conducting these experiments, the Rothman index was also deployed in the Ronald Reagan UCLA medical center.

We implemented the MEWS, SOFA, APACHE II and Rothman scores according to the specifications in (Vincent et al. (1996); Knaus et al. (1991); Rothman et al. (2013)). Note that while the SOFA and APACHE II scores are usually deployed for patients in the ICU, both scores have been recently shown to provide a prognostic utility for predicting clinical deterioration for patients in regular wards (Yu et al. (2014)), and hence we consider both scores in our comparisons. All the features used by these scores were also fed to the machine learning baselines.

5.3.2 Machine Learning Algorithms

In order to demonstrate the modeling gain of HASMMs, we make comparisons with 12 competing machine learning algorithms. We list all the baseline models hereunder.

- **Random forest.**
- **Logistic regression.**
- **XGBoost.**
- **AdaBoost.**
- **Bagging.**
- **Least absolute shrinkage and selection operator (LASSO).**
- **Deep Neural Networks (DNN) trained with BFGS.**
- **DNN trained with ADAM.**
- **Recurrent Neural Networks (RNN) trained with BFGS.**
- **RNN trained with ADAM.**

- **Hidden Markov Models (HMM) with Gaussian emissions.**
- **Multi-task Gaussian process (MTGP).**

Recently, notable works have built on ideas from deep learning and deep hierarchical models to construct survival predictors that learn from time-to-event data: examples of such models are those in (Katzman et al. (2016)) and (Ranganath et al. (2016)). Unfortunately, these models do not apply directly to our setting for two reasons. First, the models therein are not well-suited for handling irregularly sampled follow-ups and computing survival curves in a dynamic fashion. Second, and more importantly, our main focus is to predict whether or not a patient will exhibit clinical deterioration in the future, and not estimating survival curves with respect to a single endpoint event. Hence, our problem is technically equivalent to survival analysis with two "competing risks" (Prentice et al. (1978)), with the competing risks being *ICU admission* and *hospital discharge*, and thus the problem cannot be directly cast to the standard survival analysis setting tackled in (Katzman et al. (2016)) and (Ranganath et al. (2016)).

In order to ensure that the censoring information is properly utilized by all the discriminative predictors (Random forest, Logistic regression, XGBoost, AdaBoost, Bagging, LASSO, MTGP, and DNN), we train every predictor by constructing a training dataset that comprises the physiological data gathered within a temporal window before the censoring event (ICU admission or patient discharge), and using the censoring information (i.e. the variable l) as the labels. The size of this window is a hyper-parameter that is tuned separately for every predictor. For the testing data, the predictors are applied sequentially to a sliding window of every patient's episode, and the predictor's output is considered as the patient's real-time risk score. We used Python's `Sklearn` library (Pedregosa et al. (2011)) for training the Random forest, Logistic regression, XGBoost, AdaBoost, Bagging, LASSO and DNN predictors, and the `GPy library` (group (2012)) for training the MTGP predictor. The RNN models were implemented in `TensorFlow` (Abadi et al. (2016)).

Although RNNs are not clinically interpretable, they have been frequently applied to the problem of clinical time series prediction, and the recent work in (Che et al. (2016)) have considered RNNs to predict mortality in the ICU using the MIMIC dataset (Saeed et al. (2002)). We have trained an RNN with 5 hidden layers, and 10 neurons with each layer, using both the *Broyden-Fletcher-Goldfarb-Shanno* (BFGS) algorithm[21], where gradients are computed using the *Backpropagation Through Time* algorithm (Werbos (1990)). We have also trained an RNN model using the ADAM optimizer (Kingma and Ba (2014)). All the training time series were temporally aligned via the endpoint censoring information, and training was accomplished via 1000 iterations of the gradient descent algorithm. A top layer with a squashing sigmoid function was used to map the RNN hidden states to a risk score between 0 and 1 at each point in time. The DNNs are implemented as multi-layer perceptrons, the hyper-parameters of which (number of layers and hidden units) are optimized using grid search.

21. We have also tried the Levenberg-Marquardt algorithm, but the network learned by BFGS offered a significantly better performance.

We used the Baum-Welch algorithm for learning the HMM (Murphy et al. (2001)); the informative censoring information was incorporated by including two absorbing states for clinical stability ($l = 0$) and deterioration ($l = 1$), and informing the forward-backward algorithm with the labeled states at the end of every episode. We tried many initializations for the HMM parameters and picked the initialization that led to the maximum likelihood for the training dataset. The complete data log likelihood after 100 EM iterations was -1.25$\times$ 10^7. In real-time, a patient's risk score at every point of time is computed by first applying forward filtering to obtain the posterior probability of the patient's states, and then averaging over the distribution of the absorbing states. Using the Bayesian Information Criterion, we selected an HMM model with 4 latent states.

For the multi-task Gaussian process, we used the free-form parametrization (intrinsic coregionalization model) in (Bonilla et al. (2007)), and used the gradient method to learn the parameters of two Gaussian process models: one for patients with $l = 0$, and one for patients with $l = 1$. The risk score for a patient's risk score is computed as the test statistic of a sequential hypothesis test that is based on the two learned Gaussian process models. This differs from the static simulation setting in (Ghassemi et al. (2015)) were predictions are issued in a one-shot fashion using only the data obtained within 24 hours after a patient's admission.

We used the correlated feature selection algorithm to select the physiological stream for every predictor (Yu and Liu (2003)). **To ensure a fair comparison, we did not include the static (background) co-variates in any predictor, including the HASMM, since they are not used by the clinical risk scores.**

5.4 Results

5.4.1 Performance metrics

In order to assess the performance of every algorithm, we compute each algorithm's risk score $R(t)$ at every point of time in every patient's episode. We only use the patient episodes in the testing set for performance evaluation. The risk score that is based on an HASMM is evaluated as discussed in Section 3.3. We emulate the ICU admission decisions by setting a threshold on the risk score $R(t)$ above which a patient is identified as "clinically deteriorating". The accuracy of such decisions are assessed via the following performance metrics: true positive rate (TPR), positive predictive value (PPV) and timeliness. These performance metrics are formally defined as follows:

$$\text{TPR} = \frac{\#\,\text{patients with } l = 1 \text{ and } R(t) \text{ exceeding threshold for some } t < Tc}{\#\,\text{patients with } l = 1},$$

$$\text{PPV} = \frac{\#\,\text{patients with } l = 1 \text{ and } R(t) \text{ exceeding threshold for some } t < Tc}{\#\,\text{patients with } R(t) \text{ exceeding threshold for some } t < Tc},$$

and

$$\text{Timeliness} = \mathbb{E}\left[\text{Time at which } R(t) \text{ exceeds threshold} - T_c \mid R(t) \text{ exceeds threshold}, l = 1\right].$$

The three performance metrics described above evaluate the different risk scoring algorithms in terms of their detection power, false alarm rate, and timeliness in detecting clinical deterioration. We sweep the threshold value of every risk scoring algorithm and report the AUC of the TPR vs. PPV ROC curve. All results reported hereafter are statistically significant (p-value < 0.001).

The usage of precision and recall (TPR and PPV) instead of the conventional (TPR and FPR) metrics is driven by the following motives. Since we are using our model as an alarm system, our algorithm only picks patients who are believed to be deterioration (patients with label 1), and we are not identifying stable patients (i.e. there is no well-defined "true negative" count). The performance of an algorithm in this particular "information retrieval" setting is more sensibly assessed via precision and recall. That is, we are trying to identify as many deteriorating patients as possible (TPR) and avoid overwhelming the ward staff with many false alarms (PPV). The "true negative" count does not play an important role in our setting. We also note that the ward's patient cohort has a significant class imbalance (the ICU admission rate is around 5%). Hence, we are typically trying to identify a small number of deteriorating patients in a large pool of stable patients. In such an unbalanced cohort, it is significantly more difficult to achieve a good PPV (PPV = TP/(TP + FP)) than a low false positive rate (FPR = FP/(FP + TN)) for a fixed TPR, since most patients are already clinically stable and therefore the false positive and true negative counts (which are counted in the stable population) will naturally be significantly larger than the true positive counts. Hence, the FPR rates (and consequently the AUC values) may look deceptively high, but they are not truly reflective of the "usefulness" of the algorithm. This is because one can still have numerous false alarms, the quantification of which is distorted by the large true negative rates that results mainly because of the fact most patients are stable. Due to reasons above, the area under the TPR vs. PPV curve has been recently identified by the critical care community as being a more sensible measure of accuracy (Romero-Brufau et al. (2015)).

While the traditional AUCROC metric can be interpreted as the probability of miss-ranking two instances with positive and negative classes, the area under the TPR vs. PPV curve can be interpreted as a measure of how well an algorithm can identify the positive classes in a pool of instances with a negative class (Davis and Goadrich (2006)). **Note that random guessing yields an area under TPR vs. FPR curve of 0.5; in the case of the TPR vs. PPV curve, and given the definitions above, random guessing yields and AUC that is equal to the fraction of instances with a positive class. That is, in our dataset, the area under the TPR vs. PPV curve for random guessing is as small as 0.05.**

5.4.2 Learning the HASMM

We applied the FFBS-MCEM algorithm to the training episodes in order to estimate the parameter set Γ. Based on the Bayesian information criterion, we have selected a model with 4 clinical states, i.e. $\mathcal{X} = \{1, 2, 3, 4\}$. State 1 is the clinical stability state, whereas state 4 is the clinical deterioration state. We ran 100 MCEM iterations and used $\hat{\Gamma}^{100}$ as the

estimate for Γ. The parameter set Γ was initialized randomly using uniform distributions that cover each parameter's admissible bounds.

We discretized the time domain into steps of 1 hour while computing the elements of the look-up table holding the values of the tensor $\tilde{\mathbf{P}}$. With a granular 1-hour discretization of the time horizon, the Gaussian covariance matrix was found to be ill-conditioned for many patient episodes. To ensure the numerical stability of the computations involving the Gaussian process likelihood functions, we used the Moore-Penrose pseudo-inverse for the covariance matrix instead of direct matrix inversion. The function `TransitionLookUp` was invoked once before running the MCEM iterations, and its run time was 2 minutes and 15 seconds on a dual-core 3 GHz machine. The function `ForwardFilter` was invoked 150,852 times (all data points in all patients' episodes in both the training and testing sets), and its overall run time was 3 hours and 50 minutes (on a dual-core 3 GHz machine). The run time for every risk score update for a single patient is less than 1 second, which implies that the algorithm can efficiently prompt quick risk assessments if implemented on a machine with a reasonable computational power.

From the learned HASMM, we were able to extract the following "medical concept" out of the training data. The patients' clinical state space $\mathcal{X} = \{1, 2, 3, 4\}$ comprises the following 4 states:

- **State 1: clinical stability.**
- **State 2: type-1 critical state.**
- **State 3: type-2 critical state.**
- **State 4: clinical deterioration.**

As implied by the model, states 1 and 4 are absorbing states: once the patient is believed to be in state 1, the clinicians should release her from care, whereas exhibiting clinical state 4 should be treated with an admission to the ICU. States 2 and 3 are critical states that require the patient to stay under vigilant care in the ward. The two states are different ways to manifest "criticality". We characterize the properties of the four clinical states in the rest of this subsection.

Figures 13-16 depict the different characteristics of the four clinical states. In Figure 13, we plot a bipartite correlation graph that shows the correlations among the relevant physiological streams in the different clinical states. These graphs were constructed by computing the *Pearson correlation coefficient* $\sigma_{Y^l Y^v} = \frac{\text{COV}(Y^l, Y^v)}{\sigma_{Y^l} \cdot \sigma_{Y^v}}$ using the entries of the multi-task Gaussian process covariance matrix $\mathbf{\Sigma}$. An edge is connected between every two features for whom the Pearson correlation coefficient exceeds 0.1, i.e. $\sigma_{Y^l Y^v} > 0.1$. As we can see, different physiological variables become less or more correlated in the different clinical states. For instance, only the clinically stable patients experience significant correlations between their urea Nitrogen and the diastolic blood pressure; the Pearson coefficient between those variables becomes insignificant in the other states. Clinicians can use this piece of information, extracted solely from the data, to construct simple tests for clinical stability by computing

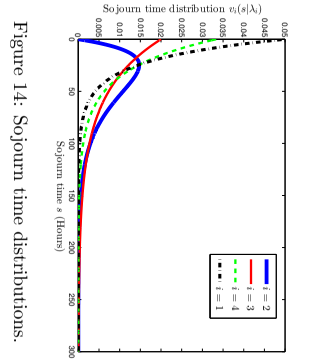

Figure 14: Sojourn time distributions.

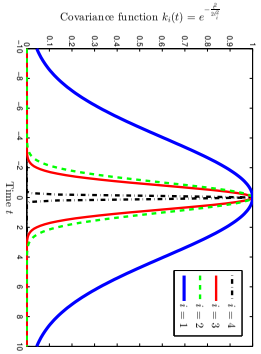

Figure 15: Covariance functions.

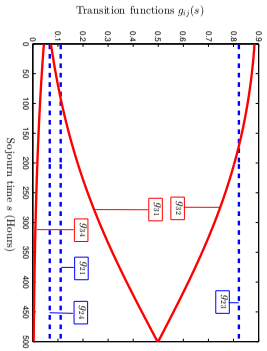

Figure 16: Transition functions.

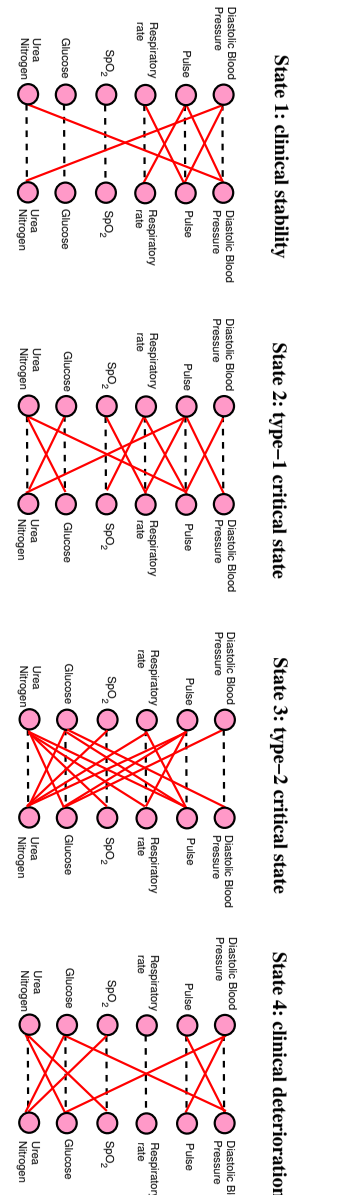

Figure 13: Correlations between the patients' physiological streams in the different clinical states.

the correlations between blood pressure and urea Nitrogen for a hospitalized patient before deciding to discharge her. Generally speaking, we observe that the critical, transient states display more correlations among the physiological streams than the clinical stability and deterioration states. In particular, the type-2 critical state has most of the physiological streams being strongly correlated. We speculate that the reason behind these strong correlations is that some kinds of interventions (e.g. drugs, mechanical pumps, ventilators, etc) applied to hospitalized patients affect all the physiological streams simultaneously; and hence we believe that type-1 and type-2 critical state patients are hospitalized patients with and without clinical interventions. We will examine this claim when we retrieve information about interventions and the time they were applied from the Ronald Reagan medical center; such information was not available at the time of conducting these experiments.

Figure 14 shows the sojourn time distributions for the four states. Recall that the "sojourn time" of an absorbing state (state 1 or 4) is defined as the time between entering the state and the censoring time; such a time interval corresponds to the clinicians' policy with respect to patient discharge and ICU admission. That is, the sojourn time of an absorbing state is not a natural physiological quantity, but it rather reflects the speed with which patients are released from care or receive leveraged level of care. The sojourn time distribution for state i is an exponential distribution if the shape parameter $\lambda_{i,s} = 1$. The sojourn time distributions for states 2 and 3 significantly deviate from an exponential distribution of an ordinary, memoryless Markov model, which supports our assumption of semi-Markovianity. As we can see in Figure 14, the sojourn time distribution is not concentrated around 0 and hence is radically different from an exponential distribution (the estimated shape parameter is $\lambda_{2,s} = 2.25$). State 2 is the state with the largest first moment for the sojourn time distribution: this means that most patients in the ward exhibit this state and hence it is the most relevant for predictions. Figure 14 clearly shows that this state is not memoryless. State 3 exhibits a sojourn time distribution that is concentrated around 0; however, its shape parameter is $\lambda_{2,s} = 0.55$, and hence cannot be adequately modeled by a memoryless process.

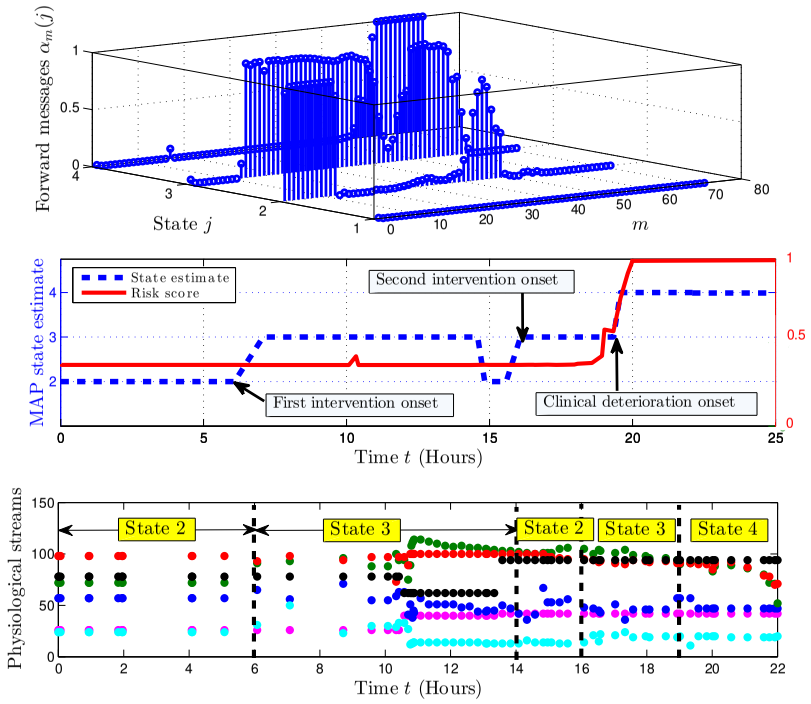

Figure 17: Depiction for the episode of a clinically deteriorating patient. (The physiological streams are color coded as follows: Diastolic blood pressure is in green, systolic blood pressure is in red, blood urea nitrogen is in cyan, and heart rate is in black, respiratory rate is in purple.)

Figure 15 displays the covariance function $k_i(t, t')$ for the 4 clinical states; the state-specific covariance function quantifies the physiological streams' temporal correlations in a particular clinical conditions. Knowing such correlation patterns are useful for deciding the frequency with which nurses and clinicians should collect physiological measurements over time for different patients in different clinical conditions (Alaa and van der Schaar (2016)). We observed that, as one would expect, the temporal correlations increase when the patient becomes more stable; the temporal correlation is greatest in state 1 and smallest in state 4. This means that one would expect deteriorating patients to experience more physiological fluctuations over time. We also note that physiological stream for which the constant mean function differed significant among the clinical state was the urea Nitrogen. The level of urea Nitrogen increases significantly when the patient is in a more risky state; the average blood urea nitrogen is 11.7 milligrams per deciliter (mg/dL) in state 1, 23.8 mg/dL in state 2, 41.1 mg/dL in state 3 and 64.9 mg/dL in state 4. This is consistent with medical domain knowledge and recent discoveries in the area of critical care medicine; in (Beier et al. (2011)), it was shown that there is a substantial evidence that that elevated urea Nitrogen can be associated with all cause mortality in a heterogeneous critically ill population.

Figure 16 depicts the transition functions g_{ij} out of the transient states 2 and 3 as a function of the sojourn time in those states. We note that the transition probabilities are almost a constant function of sojourn time for patients in state 2 ($\beta_{2j} \approx 0$), whereas the duration-dependence is more significant ($\beta_{3j} > 0$); as the sojourn time in state 3 increases, the transition probabilities become more biased towards state 1. This reinforces our hypothesis that state 3 corresponds to patients for whom interventions were applied. That is, as time passes for a patient in state 3 after receiving an intervention, her chances for recovery (transiting to state 1) increases.

Now we illustrate the real-time operation of the inference algorithm as it computes risk score over time by focusing on an episode of a particular patient who was hospitalized for 1 day and then admitted to the ICU. As shown in Figure 17 (top), the inference algorithm

computes the forward messages whenever new physiological measurements become available. Using the forward messages, the algorithm can display the maximum a posteriori (MAP) state estimates to the clinicians over time. As we can see in Figure 17 (middle), the patient under consideration was in clinical state 2 (type-1 critical state) at the time of admission to the ward. After 6 hours, the patient switched to state 3 (type-2 critical state), probably due to a clinical intervention. After around 9 hours, the patient switched back to the type-1 critical state for a brief 2-hour period, before switching to the type-2 critical state (probably due to a second intervention). Our algorithm was able to detect clinical deterioration (state 4) conclusively (through both the MAP state estimate and the risk score) more than 6 hours before the clinicians actually sent the patient to the ICU. Had the clinicians used the algorithm for monitoring that patient, they would have been able to send the patient to the ICU 6 hours early, allowing for a potentially much more efficient therapeutic intervention in intensive care. In Figure 17 (bottom), we plot the patient's physiological stream and tag the different time intervals with the corresponding clinical state estimates. The clinicians can rely on these clinically interpretable tags to describe the patient's states at each point of time rather than using a high-dimensional, and potentially inexpressive set of physiological measurements.

5.4.3 Performance comparisons

Since we focus on the AUC for the TPR vs. PPV performance, the AUC values are nominally less than that for the TPR vs. FPR curves. The AUC values in the TPR vs. PPV analyses are usually less than 0.5, whereas in the TPR vs. FPR analysis they can reach 0.8 (Rothman et al. (2013)). As mentioned earlier, random guessing yields an area under the TPR vs. PPV curve that is as small as 0.05. Table 3 reports the AUC and timeliness (in hours) for: ♡ HASMM, ♣ sequential (sliding-window) classification benchmarks, ♠ deep learning algorithms, ★ HMMs and ♢ clinical risk scores. As we can see, all the machine learning algorithms significantly outperform the state-of-the-art clinical risk scores (Rothman, MEWS, APACHE and SOFA). The reason behind the significant performance gain of the HASMM as compared to the clinical risk scores is that it incorporates the patients' history when updating the forward messages (as shown in Figure 17), and reasons about the future trajectory when computing the risk score (as discussed in Section 3.3). Clinical risk scores are instantaneous in that they map the current physiological measurements to a risk score without considering the previously measured physiological variables, and hence they are vulnerable to high false alarm rates (low PPV). Moreover, the clinical risk scores do not reason about the future trajectory given the current physiological measurements, and hence they display a sluggish risk signal that fail to quickly cope with subtle clinical deterioration.

With the exception of MTGPs, all the competing machine learning baselines are incapable of handling irregularly sampled data. Hence, for the baselines, we discretized the time domain into steps of 1 hour and interpolated the missing samples using zero-order-hold filtering. (We have tried cubic spline interpolation as well but this yield worse accuracies for the baselines.) The timeliness values reported in Table 3 are evaluated for the operating point for which the TPR is 50% and the PPV is 35%; this operating point was decided by

Table 3: Performance comparisons for various algorithms.

		AUC	Timeliness (hours)

	SOFA	0.131	—
	APACHE	0.143	—

our medical collaborators as an acceptable balance between predictive accuracy and alarm fatigue. Non of the clinical risk scores were able to achieve the desired operating point at any timeliness level.

We can see from Table 3 that HASMMs outperforms conventional HMMs; this is a consequence of incorporating temporal correlations and semi-Markovian state transitions, which more accurately describe the patient's physiology. This manifests in the sojourn time distributions in Figure 14, which largely deviate from the exponential distribution adopted by an HMM, and also manifests in the temporal correlation patterns in Figure 15, which largely deviate from the Dirac-delta function and are clearly discriminative of the different states. RNNs trained via BFGS and ADAM did not display high predictive power, probably due to the relatively limited sample size of the patient cohort under study. DNNs operating on a sliding window provided a competitive predictive accuracy: the most competitive was a DNN trained with BFGS and had its hyper-parameters (number of layers and hidden units) optimized using grid search, outperforming the different ensemble methods involved in the comparisons (XGBoost, Random Forest, AdaBoost, and Bagging).

As expected, algorithms that involved a principled time series models provided the most timely predictions as they not only evaluate the current measurements but also forecast the future. Conventional HMMs, due to their memoryless nature, provided the most timely pre-

dictions, slightly exceeding the timeliness of our model with a tight margin of 4.8 minutes. This comes at a huge false alarms' cost, manifesting in a relatively poor AUC of 0.32. This means that using a conventional HMM for risk scoring can provide decent timeliness for the patients who are identified as deteriorating, but would miss a large number of patients who will go unidentified. Contrarily, our model provides excellent timeliness together with high accuracy.

We stress that not only the proposed model outperforms the competing models in terms of accuracy, but also unlike these models, it provides a clinically interpretable model that can be used for understanding the nuances of the complex critical care setting and guiding clinical practice and ward management policies (see Figure 17). This epistemic value cannot be obtained from any of the black-box predictors, including RNNs and DNNs.

5.4.4 Controlled Analysis of the HASMM Performance

Table 3 demonstrates the performance gains achieved by our model, but it does not show the individual contributions of the different elements of the model in achieving these gains. In Table 4, we report the results of a controlled analysis of our model by investigating the impact of removing individual modeling aspects and assessing the resulting performance. To this end, we create three versions of our model, listed below, where each version lacks one of the modeling aspects:

- HASMM*: this version of the model does not capture the temporal correlations in the observations. We implement this model by forcing the length-scale parameter ℓ for all the observations to be infinite in all the iterations of the FFBS-EM algorithm. The resulting observation model corresponds to a model with independent Gaussian emissions at each time step.
- HASMM**: this version of the model adopts an exponential distribution for the sojourn times of all states. We implement this model by forcing the shape parameter $\lambda_{i,s}$ for every state i to be equal to 1.
- HASMM***: this version of the model adopts duration-independent transitions for all states. We implement this model by forcing the parameters β_{ij} to be equal to 0 for all i and j.

Table 4: A controlled analysis of the HASMM modeling aspects.

	AUC
HASMM	0.489
HASMM*	0.425
HASMM**	0.445
HASMM***	0.462

As we can see in Table 4, every aspect of the HASMM model contributes to its predictive capacity. Removing temporal correlations from our model (HASMM*) caused the biggest

drop in the AUC. This shows the importance of capturing temporal correlations (i.e. physiological trends) in predicting the endpoint outcomes. The model HASMM* still significantly outperforms a standard HMM, mainly because it captures semi-Markovianity, whereas an HMM exhibits memoryless transitions, which significantly increases the false alarms. As we can see from the performance of the HASMM**, semi-Markovian transitions are instrumental in improving the AUC performance, mainly because of their role in reducing the false alarms by mitigating rapid transitions in the state process. The HASMM***, which removes duration dependence, is also inferior to the full HASMM in terms of accuracy. It is important to note that the model HASMM*** captures temporal trends in irregularly sampled data, which cannot be achieved via simpler auto-regressive HMM models that operate in discrete time.

It is important to note that our model is not developed with the exclusive goal of predicting clinical outcomes; the epistemic value of interpreting the model parameters are of great importance for managing the complex (and rather poorly understood) critical care environment. Hence, while Table 4 shows that all modeling aspects contribute to the predictive accuracy, it is worth mentioning that all of these aspects contribute to the extracted clinical knowledge as well. (This clinical knowledge is summarized in Figures 13-17.) For instance, modeling the duration dependence is not just aimed at improving the model's accuracy, but is also crucial for understating how should a clinician schedule the therapeutic interventions for a certain patient over time even during the same clinical state. A concrete example for clinical knowledge extracted from our model is the knowledge that the HASMM learned about state 3. Having learned from the model that blood urea nitrogen is predictive of clinical deterioration (see Subsection 5.4.2) and is relatively high in clinical state 3, the clinician can use the information on duration dependence in 16 to manage the administration and timing of drugs, such as Allopurinol and Aminoglycoside antibiotics, that may increase the urea nitrogen.

6. Conclusions

We developed a versatile model, which we call the Hidden Absorbing Semi-Markov Model (HASMM), for clinical time series data which accurately represents physiological data in modern EHRs. The HASMM can deal with irregularly sampled, temporally correlated, and informatively censored physiological data with non-stationary clinical state transitions. We also proposed an efficient Monte Carlo EM learning algorithms that is based on particle filtering, and developed an inference algorithm that can effectively carry out real-time inferences. We have shown, using a real-world dataset for patients admitted to the Ronald Reagan UCLA Medical Center, that HASMMs provide a significant gain in critical care prognosis when utilized for constructing an early warning and risk scoring system.

. Acknowledgments

We would like to thank Dr. Scott Hu (Division of Pulmonary and Critical Care Medicine, Department of Medicine, David Geffen School of Medicine, UCLA) for providing us with the clinical data and the appropriate medical background and insights used in Section 5. We also thank Mr. Jinsung Yoon for his valuable help with the simulations in Section 5.

This research was funded by grants from the Office of Naval Research (ONR) and NSF ECCS 1462245.

Appendix A. An Algorithm for Sampling episodes from an HASMM

Algorithm 7 Sampling episodes from an HASMM

procedure GENERATEHASMM(Γ)
  Input: HASMM model parameters $\Gamma = (N, \lambda, \mathbf{p}^o, \mathbf{Q}(s), \mathbf{\Theta}, \zeta)$
  Output: An episode $(\{X_n\}_{n=1}^K, \{\tau_n\}_{n=1}^K, \{Y(t_m)\}_{m=1}^M, \{t_m\}_{m=1}^M)$
  $\tau_1 \leftarrow 0$, $k \leftarrow 1$, $\mathcal{T} \sim$ Poisson(ζ) ▷ Initializations
  $x_1 \sim$ Multinomial($p_1^o, p_2^o, \ldots, p_N^o$) ▷ Sample an initial latent state
  $s_1 \sim$ Gamma($\lambda_{x_1,s}, \lambda_{x_1,r}$), $\tau_2 \leftarrow \tau_1 + s_1$
  $\mathcal{T}_1 = \{t \in \mathcal{T} : \tau_1 \leq t \leq \tau_2\}$
  while $x_k \notin \{1, N\}$ **do** ▷ Sample latent states until absorption
    $x_{k+1} \sim$ Multinomial($g_{x_k 1}(s_k), g_{x_k 2}(s_k), \ldots, g_{x_k N}(s_k)$)
    $s_{k+1} \sim$ Gamma $\left(\lambda_{x_{k+1},s}, \lambda_{x_{k+1},r}\right)$, $\tau_{k+2} \leftarrow \tau_{k+1} + s_{k+1}$
    $\mathcal{T}_{k+1} = \{t \in \mathcal{T} : \tau_{k+1} \leq t \leq \tau_{k+2}\}$
    $\{y(t_m)\}_{t_m \in \mathcal{T}_{k+1}} \sim \mathcal{GP}(\Theta_{x_{k+1}})$ ▷ Sample observations from a Gaussian Process
    $k \leftarrow k + 1$
  end while
  return $(\{x_n\}_{n=1}^K, \{\tau_n\}_{n=1}^K, \{y(t_m)\}_{m=1}^M, \{t_m\}_{m=1}^M)$
end procedure

Appendix B. Proof of Theorem 1

We start by rewriting (11) as follows:

$$\begin{bmatrix} \tilde{p}_{11}(\tau,\underline{s},\bar{s}) & \ldots & \tilde{p}_{1N}(\tau,\underline{s},\bar{s}) \\ \vdots & \ddots & \vdots \\ \tilde{p}_{N1}(\tau,\underline{s},\bar{s}) & \ldots & \tilde{p}_{NN}(\tau,\underline{s},\bar{s}) \end{bmatrix} = \begin{bmatrix} 1-\bar{Q}_1(\tau,\underline{s},\bar{s}) & \ldots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \ldots & 1-\bar{Q}_N(\tau,\underline{s},\bar{s}) \end{bmatrix} + \int_{u=0}^{\tau} \left(\frac{\partial}{\partial u} \begin{bmatrix} \bar{Q}_{11}(u,\underline{s},\bar{s}) & \ldots & \bar{Q}_{1N}(u,\underline{s},\bar{s}) \\ \vdots & \ddots & \vdots \\ \bar{Q}_{N1}(u,\underline{s},\bar{s}) & \ldots & \bar{Q}_{NN}(u,\underline{s},\bar{s}) \end{bmatrix} \right) \times \begin{bmatrix} \tilde{p}_{11}(\tau-u,0,0) & \ldots & \tilde{p}_{1N}(\tau-u,0,0) \\ \vdots & \ddots & \vdots \\ \tilde{p}_{N1}(\tau-u,0,0) & \ldots & \tilde{p}_{NN}(\tau-u,0,0) \end{bmatrix} du. \tag{29}$$

Starting with the left hand side, we can use a first-step analysis to write every term $\tilde{p}_{ij}(\tau,\underline{s},\bar{s})$ as follows

$$\begin{aligned} \tilde{p}_{ij}(\tau,\underline{s},\bar{s}) &= \mathbb{P}(X(t+\tau)=j|X(t)=i, \underline{s} \leq S(t) \leq \bar{s}) \\ &= \delta_{ij}\left(\mathbb{P}(S_i<\tau|X(t)=i,\underline{s}\leq S(t)\leq\bar{s})\right)+ \\ &\int_{u=0}^{\tau} \mathbb{P}(X(t+u)=k|X(t)=i,\underline{s}\leq S(t)\leq\bar{s}) \cdot \mathbb{P}(X(t+\tau)=j|X(t+u)=k)\,du \\ &= \delta_{ij}\left(1-\bar{Q}_i(\tau,\underline{s},\bar{s})\right)+ \\ &\int_{u=0}^{\tau} \mathbb{P}(X(t+u)=k|X(t)=i,\underline{s}\leq S(t)\leq\bar{s}) \cdot \mathbb{P}(X(t+\tau-u)=j|X(t)=k)\,du \\ &= \delta_{ij}\left(1-\bar{Q}_i(\tau,\underline{s},\bar{s})\right) + \int_{u=0}^{\tau} \frac{\partial}{\partial u} \sum_{k\neq i} \bar{Q}_{ik}(u,\underline{s},\bar{s}) \cdot \tilde{p}_{kj}(\tau-u,0,0)\,du, \end{aligned} \tag{30}$$

$\forall i,j \in \mathcal{X}$, where $S(t)$ is the time elapsed in state $X(t)$, and S_i is the sojourn time of state i. The integral equation in (30) can be written in a matrix form as in the right hand side of (29), and hence the Theorem follows.

Appendix C. Proof of Theorem 2

Recall that the operation

$$\tilde{\mathbf{P}}(\tau,\underline{s},\bar{s}) = \mathcal{B}\{\bar{\mathbf{Q}}(\tau,\underline{s},\bar{s})\}(\tilde{\mathbf{P}}(\tau,\underline{s},\bar{s}))$$

can be written as

$$\tilde{\mathbf{P}}(\tau,\underline{s},\bar{s}) = \mathbf{I}_{N\times N} - \text{diag}\left(\bar{Q}_1(\tau,\underline{s},\bar{s}),\ldots,\bar{Q}_N(\tau,\underline{s},\bar{s})\right) + \left(\frac{\partial\bar{\mathbf{Q}}(.,\underline{s},\bar{s})}{\partial u} \star \tilde{\mathbf{P}}(.,0,0)\right)(\tau).$$

Now consider n applications of the operator $\mathcal{B}(.)$, we have that

$$\begin{aligned} \left(\frac{\partial\bar{\mathbf{Q}}(.,\underline{s},\bar{s})}{\partial u_1} \star \ldots \star \frac{\partial\bar{\mathbf{Q}}(.,\underline{s},\bar{s})}{\partial u_n} \star \tilde{\mathbf{P}}(.,0,0)\right)(\tau) &\leq N^n \cdot \int_0^{\tau}\int_0^{\tau-u_{n-1}} \ldots \int_0^{\tau-u_1} du_1\,du_2\ldots,du_n \\ &= N^n \cdot \frac{\tau^n}{n!}. \end{aligned} \tag{31}$$

Thus, for every $\tilde{\mathbf{P}}(\tau,\underline{s},\bar{s}) \in \mathcal{P}$ and every $\bar{\mathbf{Q}}(\tau,\underline{s},\bar{s}) < 1$, there exists n such that $\mathcal{B}^n\{.\}(.)$ is a contraction mapping. Therefore, the operation $\tilde{\mathbf{P}}(\tau,\underline{s},\bar{s}) = \mathcal{B}\{\bar{\mathbf{Q}}(\tau,\underline{s},\bar{s})\}(\tilde{\mathbf{P}}(\tau,\underline{s},\bar{s}))$ has a unique fixed point that can be reached via $n \in \mathbb{N}$ successive approximations.

Appendix D. The M-step of the FFBS-MCEM Algorithm

The proximal likelihood function at the z^{th} iteration is given by

$$\hat{U}_G(\Gamma;\hat{\Gamma}^{z-1}) = \sum_{d,g} \log(d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}}, \{y_m^d, t_m^d\}_{m=1}^{M^d}|\,\Gamma)) \cdot \frac{I_{d,g}^{z-1}}{G},$$

where the likelihood inside the logarithm can be factorized as follows

$$d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}}, \{y_m^d, t_m^d\}_{m=1}^{M^d} \,|\, \Gamma) = \mathbb{P}(x_1^{d,g}|\Gamma) \cdot d\mathbb{P}(s_1^{d,g}|x_1^{d,g}, \Gamma) \cdot d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_1^d} | x_1^{d,g}, \Gamma) \times$$
$$\prod_{n=2}^{k^{d,g}} \mathbb{P}(x_n^{d,g} \,|\, x_{n-1}^{d,g}, s_{n-1}^{d,g}, \Gamma) \cdot d\mathbb{P}(s_n^{d,g} \,|\, x_n^{d,g}, \Gamma) \cdot d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_n^d} \,|\, x_n^{d,g}, \Gamma),$$

and hence the log-likelihood is given by

$$\log(d\mathbb{P}(\{x_n^{d,g}, s_n^{d,g}\}_{n=1}^{k^{d,g}}, \{y_m^d, t_m^d\}_{m=1}^{M^d} \,|\, \Gamma)) = \log(\mathbb{P}(x_1^{d,g}|\Gamma)) + \sum_{n=2}^{k^{d,g}} \log(\mathbb{P}(x_n^{d,g} \,|\, x_{n-1}^{d,g}, s_{n-1}^{d,g}, \Gamma))$$
$$+ \sum_{n=1}^{k^{d,g}} \log(d\mathbb{P}(s_n^{d,g} \,|\, x_n^{d,g}, \Gamma)) + \sum_{n=1}^{k^{d,g}} \log(d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_n^d} \,|\, x_n^{d,g}, \Gamma)).$$

The updated parameter set $\hat{\Gamma}^z$ is obtained by maximizing:

$$\hat{\Gamma}^z = \arg\max_{\Gamma} \hat{U}_G(\Gamma; \hat{\Gamma}^{z-1}).$$

Updating the initial state distribution is straightforwardly conducted as follows

$$\hat{p}_k^{o,z} = \frac{1}{G \cdot D} \sum_{d,g} \mathbf{1}_{\{x_1^{d,g}=k\}} \cdot \frac{I_{d,g}^{z-1}}{G}.$$

For the k^{th} state sojourn time distribution parameters (shape and rate parameters for the Gamma distribution), we solve the optimization problem by computing the Maximum Likelihood Estimate (MLE) based on the observed sojourn times in the sampled trajectories as follows

$$\mathcal{N}_k = \{(d, g, n) : x_n^{d,g} = k\},$$
$$\Xi_k = \log\left(\frac{1}{|\mathcal{N}_k|} \sum_{(d,g,n)\in\mathcal{N}_k} s_n^{d,g}\right) - \frac{1}{|\mathcal{N}_k|} \sum_{(d,g,n)\in\mathcal{N}_k} \log\left(s_n^{d,g}\right),$$
$$\hat{\lambda}_{k,s}^z = \frac{3 - \Xi_k + \sqrt{(\Xi_k - 3)^2 - 24\Xi_k}}{12\Xi_k},$$
$$\hat{\lambda}_{k,r}^z = \frac{\hat{\lambda}_{k,s}^z |\mathcal{N}_k|}{\sum_{(d,g,n)\in\mathcal{N}_k} s_n^{d,g}}.$$

The optimization problem is intractable for the rest of the parameters, and hence we resort to approximate solutions. For the transition parameters, we maximize the term $\sum_{n=2}^{k^{d,g}} \log(\mathbb{P}(x_n^{d,g} \,|\, x_{n-1}^{d,g}, s_{n-1}^{d,g}, \Gamma))$ using the successive approximations, whereas for the GP parameters, we maximize the term $\sum_{n=1}^{k^{d,g}} \log(d\mathbb{P}(\{y_m^d, t_m^d\}_{t_m^d \in \mathcal{T}_n^d} \,|\, x_n^{d,g}, \Gamma))$ via conjugate gradient descent.

Abstract

We consider the performance of the bootstrap in high-dimensions for the setting of linear regression, where $p < n$ but p/n is not close to zero. We consider ordinary least-squares as well as robust regression methods and adopt a minimalist performance requirement: can the bootstrap give us good confidence intervals for a single coordinate of β (where β is the true regression vector)?

We show through a mix of numerical and theoretical work that the bootstrap is fraught with problems. Both of the most commonly used methods of bootstrapping for regression—residual bootstrap and pairs bootstrap—give very poor inference on β as the ratio p/n grows. We find that the residual bootstrap tend to give anti-conservative estimates (inflated Type I error), while the pairs bootstrap gives very conservative estimates (severe loss of power) as the ratio p/n grows. We also show that the jackknife resampling technique for estimating the variance of $\hat{\beta}$ severely overestimates the variance in high dimensions.

We contribute alternative procedures based on our theoretical results that result in dimensionality adaptive and robust bootstrap methods.

Keywords: Bootstrap, high-dimensional inference, random matrices, resampling

1. Introduction

The bootstrap (Efron, 1979) is a ubiquitous tool in applied statistics, allowing for inference when very little is known about the properties of the data-generating distribution. The bootstrap is a powerful tool in applied settings because it does not make the strong assumptions common to classical statistical theory regarding this data-generating distribution. Instead, the bootstrap resamples the observed data to create an estimate, $\hat{F}$, of the unknown data-generating distribution, F. The distribution $\hat{F}$ then forms the basis of further inference.

Since its introduction, a large amount of research has explored the theoretical properties of the bootstrap, improvements for estimating F under different scenarios, and how to most effectively estimate different quantities from $\hat{F}$ (see the pioneering Bickel and Freedman, 1981 for instance and many many more references in the book-length review of Davison and Hinkley, 1997, as well as van der Vaart, 1998 for a short summary of the modern point of view on these questions). Other resampling techniques exist of course, such as subsampling, m-out-of-n bootstrap, and jackknifing, all of which have been studied and much discussed (see Efron, 1982; Hall, 1992; Politis et al., 1999; Bickel et al., 1997; and Efron and Tibshirani, 1993 for a practical introduction).

An important limitation for the bootstrap is the quality of $\hat{F}$. The standard bootstrap estimate of F based on the empirical distribution of the data may be a poor estimate when the data has a non-trivial dependency structure, when the quantity being estimated, such as a quantile, is sensitive to the discreteness of $\hat{F}$, or when the functionals of interest are not smooth (see e.g., Bickel and Freedman, 1981 for a classic reference, as well as Beran and Srivastava, 1985 or Eaton and Tyler, 1991 in the context of multivariate statistics).

An area that has received less attention is the performance of the bootstrap in high dimensions and this is the focus of our work. In particular, we consider the setting of standard linear models where data y_i are drawn from the linear model

$$\forall i, y_i = \beta' X_i + \epsilon_i \ , 1 \leq i \leq n \ , \quad \text{where } X_i \in \mathbb{R}^p \ .$$

We are interested in the bootstrap or resampling properties of the estimator defined as

$$\widehat{\beta}_\rho = \text{argmin}_{b \in \mathbb{R}^p} \sum_{i=1}^{n} \rho(y_i - X_i' b) \ , \text{ where } \rho \text{ is a convex function.}$$

We consider the two standard methods for resampling to create a bootstrap distribution in this setting. The first is *pairs resampling*, where bootstrap samples are drawn from the empirical distribution of the pairs (y_i, X_i). The second resampling method is *residual resampling*, where the bootstrapped data consists of $y_i^* = \widehat{\beta}_\rho' X_i + \hat{\epsilon}_i^*$, where $\hat{\epsilon}_i^*$ is drawn from the empirical distribution of the estimated residuals, e_i. We also consider the jackknife, a resampling method focused specifically on estimating the variance of functionals of $\widehat{\beta}_\rho$. These three methods are extremely flexible for linear models regardless of the method of fitting β or the error distribution of the ϵ_i.

The high dimensional setting: $\boldsymbol{p/n \to \kappa \in (0,1)}$ In this work we call a high-dimensional setting one where the number of predictors, p, is of the same order of magnitude as the number of observations, n, formalized mathematically by assuming that $p/n \to \kappa \in (0,1)$. Several reasons motivate our theoretical study in this regime. The asymptotic behavior of the estimate $\widehat{\beta}_\rho$ is known to depend heavily on whether one makes the classical theoretical assumption that $p/n \to 0$ or instead assumes $p/n \to \kappa \in (0,1)$ (see Section 1.2 and AppendixA and references therein). But from the standpoint of practical usage on moderate-sized data sets (i.e., n and p both moderately sized with $p < n$), it is not always obvious which assumption is justified. Working in the high-dimensional regime of $p/n \to \kappa \in (0,1)$ captures better the complexity encountered even in reasonably low-dimensional practice than using the classical assumption $p/n \to 0$. In fact, asymptotic predictions based on the

high-dimensional assumption can work surprisingly well in very low-dimension (see Johnstone, 2001). Furthermore, in these high-dimensional settings, where much is still unknown theoretically, the bootstrap is a natural and compelling alternative to asymptotic analysis.

Another motivation for our investigation is that of very large scale applications (Chapelle et al., 2014; Criteo, 2017; Langford et al., 2007), where one might resort to subsampling methods or recent variants like the bag-of-little-bootstraps (Kleiner et al., 2014) for uncertainty assessment. Subsampling is also very commonly used in this setting for simple computational speed-up. In such cases, even if one had started with a data set where $p \ll n$, after subsampling one often ends up with p comparable to n on the subsamples where bootstrap-like computations are performed. It is therefore important to know if the bootstrap and other resampling plans perform well when p is comparable to n.

Defining success: accurate inference on β_1 The common theoretical definition of whether the bootstrap "works" is that the bootstrap distribution of the entire bootstrap estimate $\widehat{\beta}^*_\rho$ converges conditionally almost surely to the sampling distribution of the estimator $\widehat{\beta}_\rho$ (see e.g., van der Vaart, 1998). The work of Bickel and Freedman (1983) on the residual bootstrap for least squares regression, which we discuss in the background section 1.2, shows that this theoretical requirement is not fulfilled even for the simple problem of least squares regression.

In this paper, we choose to focus only on accurate inference for the projection of our parameter on a pre-specified direction v. More specifically, we concentrate only on whether the bootstrap gives accurate confidence intervals for $v'\beta$. We think that this is the absolute minimal requirement we can ask of a bootstrap inferential method, as well as one that is meaningful from the standpoint of applied statistics. This is of course a much less stringent requirement than performing well on complicated functionals of the whole parameter vector, which is the implicit demand of standard definitions of bootstrap success. For this reason, we focus throughout the exposition on inference for β_1 (the first element of β) as an example of a pre-defined direction of interest (where β_1 corresponds to choosing $v = e_1$, the first canonical basis vector).

We note that considering the asymptotic behavior of $v'\beta$ as $p/n \to \kappa \in (0, 1)$ implies that $v = v(p)$ changes with p. By "pre-defined" we will mean simply a deterministic sequence of directions $v(p)$. We will continue to suppress the dependence on p in writing v in what follows for the sake of clarity.

1.1 Organization and Main Results of the Paper

In Section 2 we demonstrate that in high dimensions residual-bootstrap resampling results in extremely poor inference on the coordinates of β_ρ with error rates much higher than the reported Type I error. We show that the error in inference based on residual bootstrap resampling is due to the fact that the distribution of the residuals e_i are a poor estimate of the distribution of ϵ_i; we further illustrate that common methods of standardizing the e_i do not solve the problem for general ρ. We propose two new dimension-adaptive methods of residual resampling that appear promising for use in bootstrapping linear models. We also provide some theoretical results for the behavior of this method as $p/n \to 1$.

In Section 3 we examine *pairs-bootstrap resampling* and show that confidence intervals based on bootstrapping the pairs also perform very poorly. Unlike in the residual-bootstrap

case discussed in Section 2, the confidence intervals obtained from the pairs-bootstrap are instead conservative to the point of being non-informative. This results in a dramatic loss of power. We prove in the case of L_2 loss, i.e., $\rho(x) = x^2$, that the variance of the bootstrapped $v'\widehat{\beta}^*$ is greater than that of $v'\widehat{\beta}$, leading to the overly conservative performance we see in simulations. We demonstrate that a different resampling scheme we propose can provide accurate confidence intervals in moderately high dimensions.

In Section 4, we discuss another resampling scheme, the jackknife. We focus on the jackknife estimate of variance and show that it has similarly poor behavior in high dimensions. In the case of L_2 loss with Gaussian design matrices, we further prove that the jackknife estimator over estimates the variance of our estimator by a factor of $1/(1-p/n)$; we also provide corrections for other losses that improve the jackknife estimate of variance in moderately high dimensions.

We rely on simulation results to demonstrate the practical impact of the failure of the bootstrap. The settings for our simulations and corresponding theoretical analyses are idealized, without many of the common settings of heteroskedasticity, dependency, outliers and so forth that are known to be a problem for bootstrapping. This is intentional, since even these idealized settings are sufficient to demonstrate that the standard bootstrap methods have poor performance. For brevity, we give only brief descriptions of the simulations in what follows; detailed descriptions can be found in AppendixD.1.

Similarly, we focus on the basic implementations of the bootstrap for linear models. While there are many proposed alternatives (often for specific loss functions or types of data), the standard methods we study are most commonly used and recommended in practice. Furthermore, to our knowledge none of the alternative bootstrap methods we have seen specifically address the underlying theoretical problems that appear in high dimensions without making low-dimensional assumptions about either the design matrix or the sparsity of β, and therefore are likely to suffer from the same fate as standard methods. We note that in truly large scale applications, sparsity assumptions are not always made by practitioners (Chapelle et al., 2014; Langford et al., 2007; Criteo, 2017) and it is hence natural to study the performance of estimators outside of sparse settings. We have also experimented with more complicated ways to build confidence intervals (e.g., bias correction methods), but have found their performance to be erratic in high-dimension and offer no improvement.

We first give some background regarding the bootstrap and estimation of linear models in high dimensions before presenting our new results.

1.2 Background: Inference Using the Bootstrap

We consider the setting $y_i = \beta' X_i + \epsilon_i$, where $E(\epsilon_i) = 0$ and $\mathrm{var}(\epsilon_i) = \sigma^2_\epsilon$. The vector β is estimated as minimizing the average loss,

$$\widehat{\beta}_\rho = \mathrm{argmin}_{b\in\mathbb{R}^p} \sum_{i=1}^{n} \rho(y_i - X_i' b), \tag{1}$$

where ρ defines the loss function for a single observation. The function ρ is assumed to be convex in all the paper. Common choices are $\rho(x) = x^2$, i.e., least-squares, $\rho(x) = |x|$, which defines L_1 regression, or Huber$_k$ loss where $\rho(x) = (x^2/2)1_{|x|<k} + (k|x| - k^2/2)1_{|x|\geq k}$.

Bootstrap methods are used in order to estimate the distribution of the estimate $\widehat{\beta}_\rho$ under the true data-generating distribution, F. The bootstrap estimates this distribution with the distribution obtained when the data is drawn from an estimate $\hat{F}$ of F. Following standard convention, we designate this bootstrapped estimator $\widehat{\beta}^*_\rho$ to note that this is an estimate of β using loss function ρ when the data-generating distribution is known to be exactly equal to $\hat{F}$. Since $\hat{F}$ is completely specified, we can in principle exactly calculate the distribution of $\widehat{\beta}^*_\rho$ and use it as an approximation of the distribution of $\widehat{\beta}_\rho$ under F. In practice, we simulate B independent draws of size n from the distribution $\hat{F}$ and perform inference based on the empirical distribution of $\widehat{\beta}^{*b}_\rho$, $b = 1, \ldots, B$.

In bootstrap inference for the linear model, there are two common methods for re-sampling, which results in different estimates $\hat{F}$. In the first method, called the residual bootstrap, $\hat{F}$ is an estimate of the conditional distribution of y_i given β and X_i. In this case, the corresponding resampling method consists of resampling ϵ^*_i from an estimate of the distribution of ϵ and forming data $y^*_i = X_i'\widehat{\beta}_\rho + \epsilon^*_i$, from which $\widehat{\beta}^*_\rho$ is computed. This method of bootstrapping assumes that the linear model is correct for the mean of y (i.e., that $\mathbf{E}\,(y_i) = X_i'\beta$); it also assumes fixed X_i design vectors because the sampling is conditional on the X_i. In the second method, called pairs bootstrap, $\hat{F}$ is an estimate of the joint distribution of the vector $(y_i, X_i) \in R^{p+1}$ given by the empirical joint distribution of $\{(y_i, X_i)\}_{i=1}^n$; the corresponding resampling method resamples the pairs (y_i, X_i). This method makes no assumption about the mean structure of y and, by resampling the X_i, also does not condition on the values of X_i. For this reason, pairs resampling is often considered to be more generally applicable than residuals resampling (see e.g., Davison and Hinkley, 1997).

1.3 Background: High-dimensional Inference of Linear Models

Recent research shows that $\widehat{\beta}_\rho$ has very different asymptotic properties when p/n has a limit κ that is bounded away from zero than it does in the classical setting where $p/n \to 0$ (see e.g., Huber, 1973; Huber and Ronchetti, 2009; Portnoy, 1984, 1985, 1986, 1987; Mammen, 1989 for $\kappa = 0$; El Karoui et al., 2013 for $\kappa \in (0, 1)$). A simple example is that the vector $\widehat{\beta}_\rho$ is no longer consistent in Euclidean norm when $\kappa > 0$. We should be clear, however, that projections on fixed non-random directions such as we consider, i.e., $v'\widehat{\beta}_\rho$, are $\sqrt{n}$ consistent for $v'\beta$, even when $\kappa > 0$. In particular, the coordinates of $\widehat{\beta}_\rho$ are $\sqrt{n}-$consistent for the coordinates of β (El Karoui et al., 2013, Lemma 1). Hence, in practice the estimator $\widehat{\beta}_\rho$ is still a reasonable quantity to consider.

Bootstrap in high-dimensional linear models Very interesting work exists already in the literature about bootstrapping regression estimators when p is allowed to grow with n (Shorack, 1982; Wu, 1986; Mammen, 1989, 1992, 1993; Parzen et al., 1994; Koenker, 2005, Section 3.9). With a few exceptions, this work has been in the classical, low-dimensional setting where either p is held fixed or p grows slowly relative to n (i.e., $\kappa = 0$ in our notation). For instance, in Mammen (1993), it is shown that under mild technical conditions and assuming that $p^{1+\delta}/n \to 0$, $\delta > 0$, the pairs bootstrap distribution of linear contrasts $v'(\widehat{\beta}^*_\rho - \widehat{\beta}_\rho)$ is in fact very close to the sampling distribution of $v'(\widehat{\beta}_\rho - \beta)$ with high-probability, when using least-squares. Other results, such as Shorack (1982) and Mammen (1989),

also allow for increasing dimensions, for example in the case of linear contrasts in robust regression, by making assumptions on the diagonal entries of the hat matrix. In our context, these assumptions would be satisfied only if $p/n \to 0$. Hence those interesting results do not apply to the present study. We also note that Hall (1992, p. 167) contains cautionary notes about using the bootstrap in high-dimension.

While there has not been much theoretical work on the bootstrap in the setting where $p/n \to \kappa \in (0, 1)$, one early work of Bickel and Freedman (1983) considered bootstrapping scaled residuals for least-squares regression when $\kappa > 0$. They show that when $p/n \to \kappa \in (0, 1)$, there exists a data-dependent direction c, such that $c'\widehat{\beta}^*_{LS}$ does not have the correct asymptotic distribution (Bickel and Freedman, 1983, Theorem 3.1, p.39), i.e., its distribution is not conditionally in probability close to the sampling distribution of $c'\widehat{\beta}_{LS}$. Furthermore, they show that when the errors in the model are Gaussian, under the assumption that the diagonal entries of the hat matrix are not all close to a constant, the empirical distribution of the residuals is a scaled-mixture of Gaussian, which is not close to the original error distribution.

As we previously explained, in this work we instead only consider inference for *predefined* contrasts $v'\beta$. The important and interesting problems pointed out in Bickel and Freedman (1983) disappear if we focus on fixed, non-data-dependent projection directions. Hence, our work complements the work of Bickel and Freedman (1983) and is not redundant with it.

There has been some recent interest in residual bootstrap methods for penalized likelihood methods in high-dimensions (often proposed for the case when $p >> n$), for example lasso estimates (Chatterjee and Lahiri, 2010, 2011), adaptive lasso estimates (Chatterjee and Lahiri, 2013), de-biased lasso estimates (Belloni et al., 2015; Dezeure et al., 2017), and ridge regression (Lopes, 2014). These bootstrap results make the assumption of sparsity of some form, generally in terms of the number of non-zero components of β, but in the case of Lopes (2014) by the assumption that the design matrix X is nearly low-rank. As explained previously, our work is focused on a very different line of inquiry: the case of a comparatively diffuse signal in β, where there is no reduction of the high-dimensional problem to a low-dimensional approximation.

The role of the distribution of X An important consideration in interpreting theoretical work on linear models in high dimensions is the role of the design matrix X. In classical asymptotic theory, the results can be stated conditionally on X so that the assumptions can be stated in terms of conditions that can be evaluated on any observed design matrix X. In the high dimensional setting, the available theoretical tools do not yet allow for an asymptotic analysis conditional on X; instead the results make assumptions about the distribution of the entries of X. Theoretical work in the nascent literature for the high dimensional setting usually allows for a fairly general class of distributions for the individual elements of X_i and can handle covariance between the predictor variables. However, the X_i's are generally considered i.i.d., which limits the ability of any X_i to be too influential in the fit of the model (see AppendixA for more detail). For discussion of limitations of the corresponding models for statistical purposes, see Diaconis and Freedman (1984); Hall et al. (2005); El Karoui (2009).

1.4 Notations and Default Conventions

When referring to the Huber loss in a numerical context, we refer (unless otherwise noted) to the default implementation in the `rlm` package in R, where the transition from quadratic to linear behavior is at $k = 1.345$. We call X the design matrix and $\{X_i\}_{i=1}^n$ its rows. We have $X_i \in \mathbb{R}^p$. β denotes the true regression vector, i.e., the population parameter. $\widehat{\beta}_\rho$ refers to the estimate of β using loss ρ; from this point on, however, we will often drop the ρ and refer to simply $\widehat{\beta}$. The i-th residual is denoted as e_i, i.e., $e_i = y_i - X_i'\widehat{\beta}$. Throughout the paper, we assume that the linear model holds, i.e., $y_i = X_i'\beta + \epsilon_i$ for some fixed $\beta \in \mathbb{R}^p$ and that ϵ_i's are i.i.d. with mean 0 and $\text{var}(\epsilon_i) = \sigma_\epsilon^2$. We call G the distribution of ϵ. When we need to stress the impact of the error distribution on the distribution of $\widehat{\beta}_\rho$, we will write $\widehat{\beta}_\rho(G)$ or $\widehat{\beta}_\rho(\epsilon)$ to denote our estimate of β obtained assuming that ϵ_i's are i.i.d. G.

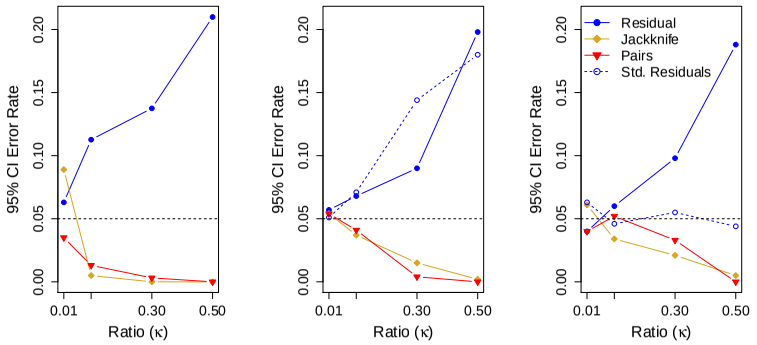
We denote generically by $\kappa = \lim_{n\to\infty} p/n$. We restrict ourselves to $\kappa \in (0,1)$. The standard notation $\widehat{\beta}_{(i)}$ refers to the leave-one-out estimate of $\widehat{\beta}$ where the i-th pair (y_i, X_i) is excluded from the regression, and $\tilde{e}_{i(i)} \triangleq y_i - X_i'\widehat{\beta}_{(i)}$ is the i-th predicted error (based on the leave-one-out estimate of $\widehat{\beta}$). We also use the notation $\tilde{e}_{j(i)} \triangleq y_j - X_j'\widehat{\beta}_{(i)}$. The hat matrix is of course $H = X(X'X)^{-1}X'$. o_P denotes a "little-oh" in probability, a standard notation (see van der Vaart, 1998). When we say that we work with a Gaussian design with covariance Σ, we mean that $X_i \overset{iid}{\backsim} \mathcal{N}(0,\Sigma)$. Throughout the paper, the loss function ρ is assumed to be convex, $\mathbb{R} \mapsto \mathbb{R}^+$. We use the standard notation $\psi = \rho'$. We finally assume that ρ is such that there is a unique solution to the robust regression problem—an assumption that applies to all classical losses in the context of our paper.

2. Residual Bootstrap

We first focus on the method of bootstrap resampling where $\hat{F}$ is the conditional distribution $y|\widehat{\beta}, X$. In this case the distribution of $\widehat{\beta}^*$ under $\hat{F}$ is formed by independent resampling of ϵ_i^* from an estimate $\hat{G}$ of the distribution G that generated ϵ_i. Then new data y_i^* are formed as $y_i^* = X_i'\widehat{\beta} + \epsilon_i^*$ and the model is fitted to this new data to get $\widehat{\beta}^*$. Generally the estimate of the error distribution, $\hat{G}$, is taken to be empirical distribution of the observed residuals, so that the ϵ_i^* are found by sampling with replacement from the e_i.

Yet, even a cursory evaluation of e_i in the simple case of least-squares regression ($\rho(x) = x^2$) reveals that the empirical distribution of the e_i may be a poor approximation to the error distribution of ϵ_i. In particular, it is well known that e_i has variance equal to $\sigma_\epsilon^2(1-h_i)$ where h_i is the ith diagonal element of the hat matrix. This problem becomes particularly pronounced in high dimensions. For instance, if $X_i \overset{iid}{\backsim} \mathcal{N}(0,\Sigma)$, $h_i = p/n + o_P(1)$ so that e_i has variance approximately $\sigma_\epsilon^2(1-p/n)$, i.e., generally much smaller than the true variance of ϵ for $\lim p/n > 0$. This fact is also true when assuming more general distributions for the design matrix X (see e.g.,Wachter, 1978; Haff, 1979; Silverstein, 1995; Pajor and Pastur, 2009; El Karoui and Koesters, 2011, where the main results of some of these papers require minor adjustments to get the approximation of h_i we just mentioned).

In Figure 1, we plot the error rate of 95% bootstrap confidence intervals based on resampling from the residuals for different loss functions, based on a simulation when the entries of X are i.i.d. $\mathcal{N}(0,1)$ and $\epsilon \sim N(0,1)$. Even in this idealized situation, as the ratio of



(a) L_1 loss (b) Huber loss (c) L_2 loss

Figure 1: **Performance of 95% confidence intervals of β_1 :** Here we show the coverage error rates for 95% confidence intervals for $n = 500$ based on applying common resampling-based methods to simulated data: pairs bootstrap (red), residual bootstrap (blue), and jackknife estimates of variance (yellow). These bootstrap methods are applied with three different loss functions shown in the three plots above: (a) L_1, (b) Huber, and (c) L_2. For L_2 and Huber loss, we also show the performance of methods for standardizing the residuals before bootstrapping described in the text (blue, dashed line). If accurate, all of these methods should have an error rate of 0.05 (shown as a horizontal black line). Error rates above 5% correspond to anti-conservative methods. Error rates below 5% correspond to conservative methods. The error rates are based on 1,000 simulations, with $N(0,1)$ error, and entries of the design matrix i.i.d $N(0,1)$; see the description in Appendix D.1 for more details. The exact values plotted here are given in Table A-1 in Appendix I.

p/n increases the error rate of the confidence intervals in least squares regression increases well beyond the expected 5%: we observe error rates of 10-15% for $p/n = 0.3$ and approximately 20% for $p/n = 0.5$. We see similar error rates for other robust-regression methods, such as L_1 and Huber loss, and also for different error distributions and distributions of X (Supplementary Figures A-1 and A-2). We explain some of the reasons for these problems in Subsection 2.2 below.

2.1 Bootstrapping from Corrected Residuals

While resampling directly from the uncorrected residuals is widespread and often given as a standard bootstrap procedure (e.g., Koenker, 2005; Chernick, 1999), the discrepancy between the distribution of ϵ_i and e_i has spurred more refined recommendations in the

case of least-squares: form corrected residuals $r_i = e_i/\sqrt{1-h_i}$ and sample the ϵ_i^* from the empirical distribution of the $r_i - \bar{r}$ (see e.g., Davison and Hinkley, 1997).

This correction is known to exactly align the variance of r_i with that of ϵ_i regardless of the design vectors X_i or the true error distribution, using simply the fact that the hat matrix is a rank $min(n,p)$ orthogonal projection matrix. We see that for L_2 loss it corrects the error in bootstrap inference in our simulations (Figure 1). This is not so surprising, given that with L_2 loss, the error distribution G impacts the inference on β only through σ_ϵ^2, in the case of homoskedastic errors (see Section 2.4 for much more detail).

However, this adjustment of the residuals is a correction specific to the least-squares problem. Similar corrections for robust estimation procedures using a loss function ρ are given by McKean et al. (1993) with standardized residuals r_i given by,

$$r_i = \frac{e_i}{\sqrt{1-dh_i}}, \text{ where } d = \frac{2\sum e_j'\psi(e_j')}{\sum \psi(e_j')} - \frac{\sum \psi(e_j')^2}{(\sum \psi(e_j'))^2}, \tag{2}$$

where h_i is the i-th diagonal entry of the hat matrix, $e_j' = e_j/s$, s is a estimate of σ, and ψ is the derivative of ρ, assuming ψ is a bounded and odd function (see Davison and Hinkley, 1997 for a complete description of its implementation for the bootstrap and McKean et al., 1993 for a full description of the regularity conditions).

Unlike the correction for L_2 loss mentioned earlier, however, the scaling described in Equation (2) for the residuals is an approximate variance correction, and the approximation depends on assumptions that do not hold true in higher dimensions. The error rate of confidence intervals in our simulations based on this rescaling show no improvement in high dimensions over that of simple bootstrapping of the residuals. This could be explained by the fact that standard perturbation analytic methods used for the analysis of M-estimators in low-dimension, which are at the heart of the correction in Equation (2), fail in high-dimensions.

2.2 Understanding the Behavior of the Residual Bootstrap

This misbehavior of the residual bootstrap can be explained by the fact that in high-dimension, the residuals tend to have a very different distribution from that of the true errors. Their distributions differ not only in simple properties, such as their variances, but in more general aspects, such as their marginal distributions. To make these statements precise, we make use of the previous work of El Karoui et al. (2013) and El Karoui (2013). These papers do not discuss bootstrap or resampling issues, but rather are entirely focused on providing asymptotic theory for the behavior of $\widehat{\beta}_\rho$ as $p/n \to \kappa \in (0,1)$; in the course of doing so, they characterize the asymptotic relationship of e_i to ϵ_i in high-dimensions. We make use of this relationship to characterize the behavior of the residual bootstrap and to suggest an alternative estimates of $\hat{G}$ for bootstrap resampling.

Behavior of residuals in high-dimensional regression We now summarize the asymptotic relationship between e_i and ϵ_i in high-dimensions given in the above cited work (see AppendixA for a more detailed and technical summary). Let $\widehat{\beta}_{(i)}$ be the estimate of β based on fitting the linear model of Equation (1) without using observation i, and $\tilde{e}_{j(i)}$ be the error of observation j from this model (the leave-one-out or predicted error), i.e., $\tilde{e}_{j(i)} = y_j - X_j'\widehat{\beta}_{(i)}$

For simplicity of exposition, X_i is assumed to have an elliptical distribution, i.e., $X_i = \lambda_i\Gamma_i$, where $\Gamma_i \sim N(0,\Sigma)$, and λ_i is a scalar random variable independent of Γ_i with $\mathbf{E}\left(\lambda_i^2\right) = 1$. For simplicity in restating their results, we will assume $\Sigma = \mathrm{Id}_p$, but equivalent statements can be made for arbitrary Σ; similar results also apply when $\Gamma_i = \Sigma^{1/2}\xi_i$, with ξ_i having i.i.d. non-Gaussian entries, satisfying a few technical requirements (see AppendixA).

With this assumption on X_i, for any sufficiently smooth loss function ρ and any size dimension where $p/n \to \kappa < 1$, the relationship between the i-th residual e_i and the true error ϵ_i can be summarized as,

$$\tilde{e}_{i(i)} = \epsilon_i + |\lambda_i|\|\widehat{\beta}_{\rho(i)} - \beta\|_2 Z_i + \mathrm{o}_P(u_n) \tag{3}$$

$$e_i + c_i\lambda_i^2\psi(e_i) = \tilde{e}_{i(i)} + \mathrm{o}_P(u_n) \tag{4}$$

where Z_i is a random variable distributed $N(0,1)$ and independent of ϵ_i. The variable u_n refers to a sequence of numbers tending to 0. The quantities c_i, λ_i and $\|\widehat{\beta}_{\rho(i)} - \beta\|_2$ are all of order 1, i.e., they are not close to 0 in general in the high-dimensional setting. The scalar c_i is given as $\frac{1}{n}\mathrm{trace}\left(S_i^{-1}\right)$, where $S_i = \frac{1}{n}\sum_{j\neq i}\psi'(\tilde{e}_{j(i)})X_jX_j'$. For p,n large the c_i's are approximately equal and $\|\widehat{\beta}_{\rho(i)} - \beta\|_2 \simeq \|\widehat{\beta}_\rho - \beta\|_2 \simeq \mathbf{E}\left(\|\widehat{\beta}_\rho - \beta\|_2\right)$; furthermore $c_i\lambda_i^2$ can be approximated by $X_i'S_i^{-1}X_i/n$. Note that when ρ is either non-differentiable at all points (L_1) or not twice differentiable (Huber), arguments can be made that make these expressions valid, using for instance the notion of sub-differential for ψ (Hiriart-Urruty and Lemaréchal, 2001).

Interpretation of Equations (3) *and* (4) Equation (3) means that the marginal distribution of the leave-i-th-out predicted error, $\tilde{e}_{i(i)}$, is asymptotically a convolution of the true error, ϵ_i, and an independent scale mixture of Normals. Furthermore, Equation (4) means that the i-th residual e_i can be understood as a non-linear transformation of $\tilde{e}_{i(i)}$. As we discuss below, these relationships are qualitatively very different from the classical case $p/n \to 0$.

2.2.1 Consequence for the Residual Bootstrap

We apply these results to the question of the residual bootstrap to give an understanding of why bootstrap resampling of the residuals can perform so badly in high-dimension. The distribution of the e_i is far removed from that of the ϵ_i, and hence bootstrapping from the residuals effectively amounts to sampling errors from a distribution that is very different from the original error distribution, ϵ.

The impact of these discrepancies for bootstrapping is not equivalent for all dimensions, error distributions, or loss functions. It depends on the constant c_i and the risk, $\|\widehat{\beta}_{\rho(i)} - \beta\|_2$, both of which are highly dependent on the dimensions of the problem, the distribution of the errors and the choice of loss function. We now discuss some of these issues.

Least Squares regression In the case of least squares regression, the relationships given in Equation (3) are exact, i.e., $u_n = 0$. Further, $\psi(x) = x$, and $c_i = h_i/(1-h_i)$, giving the well known linear relationship $e_i = (1-h_i)\tilde{e}_{i(i)}$ (see, e.g., the standard reference Weisberg, 2014). This linear relationship is exact regardless of dimension, though the dimensionality aspects are captured by h_i. This expression can be used to show that asymptotically $\mathbf{E}\left(\sum_{i=1}^n e_i^2\right) = \sigma_\epsilon^2(n-p)$, when ϵ_i's have the same variance. Hence, sampling at random

from the residuals results in a distribution that underestimates the variance of the errors by a factor $1 - p/n$. The corresponding bootstrap confidence intervals are then naturally too small, and hence the error rate increases far from the nominal 5% - as we observed in Figure 1c.

More general robust regression The situation is much more complicated for general robust regression estimators. One clear implication of Equations (3) and (4) is that simply rescaling the residuals e_i should not in general result in an estimated error distribution $\hat{G}$ that will have similar properties to those of G. The relationship between the residuals and the errors is very non-linear in high-dimensions. This is why in what follows we will propose to work with leave-one-out predicted errors $\tilde{e}_{i(i)}$ instead of the residuals e_i.

The classical case of $\boldsymbol{p/n \to 0}$*:* In this setting, $c_i \to 0$ and therefore Equation (3) shows that the residuals e_i are approximately equal in distribution to the predicted errors, $\tilde{e}_{i(i)}$. Similarly, $\widehat{\beta}_\rho$ is L_2 consistent when $p/n \to 0$, so $\|\widehat{\beta}_{\rho(i)} - \beta\|_2^2 \to 0$ and Equation (4) gives $\tilde{e}_{i(i)} \simeq \epsilon_i$. Hence, the residuals should be fairly close to the true errors in the model when p/n is small. This dimensionality assumption is key to many theoretical analyses of robust regression, and underlies the derivation of corrected residuals r_i of McKean et al. (1993) given in Equation (2) above for losses other than L_2.

2.3 Alternative Residual Bootstrap Procedures

We propose two methods for improving the performance of confidence intervals obtained through the residual bootstrap. Both do so by providing alternative estimates of $\hat{G}$ from which bootstrap errors ϵ_i^* can be drawn. They estimate a $\hat{G}$ appropriate for the setting of high-dimensional data by accounting for relationship of the distribution of ϵ and $\tilde{e}_{i(i)}$.

Method 1: Deconvolution The relationship in Equation (3) says that the distribution of $\tilde{e}_{i(i)}$ is a convolution of the correct G distribution and a normal distribution. This suggests applying techniques for deconvolving a signal from Gaussian noise. Specifically, we propose the following bootstrap procedure: **1)** calculate the predicted errors, $\tilde{e}_{i(i)}$; **2)** estimate the variance of the normal (i.e., $|\lambda_i|\|\widehat{\beta}_{\rho(i)} - \beta\|_2^2$); **3)** deconvolve in $\tilde{e}_{i(i)}$ the error term ϵ_i from the normal term; **4)** Use the resulting estimate $\hat{G}$ to draw errors ϵ_i^* for residual bootstrapping.

Deconvolution problems are known to be very difficult (see Fan, 1991, Theorem 1 p. 1260, that gives $1/\log(n)^\alpha$ rates of convergence when convolving with a Gaussian distribution). The resulting deconvolved errors are likely to be quite noisy estimates of ϵ_i. However, it is possible that while individual estimates are poor, the distribution of the deconvolved errors is estimated well-enough to form a reasonable $\hat{G}$ for the bootstrap procedure.

We used the deconvolution algorithm in the `decon` package in R (Wang and Wang, 2011) to estimate the distribution of ϵ_i. The deconvolution algorithm requires knowledge of the variance of the Gaussian that is convolved with the ϵ_i, i.e., estimation of $|\lambda_i|\|\widehat{\beta}_{\rho(i)} - \beta\|_2$ term. In what follows, we assume a Gaussian design, i.e., $\lambda_i = 1$, so that we need to estimate only the term $\|\widehat{\beta}_{\rho(i)} - \beta\|_2^2$. An estimation strategy for the more general setting of $|\lambda_i| \neq 1$ is presented in AppendixB.5. We use the fact that $\|\widehat{\beta}_{\rho(i)} - \beta\|_2^2 \simeq \|\widehat{\beta}_\rho - \beta\|_2^2$ for all i and estimate $\|\widehat{\beta}_{\rho(i)} - \beta\|_2$ as $\widehat{var}(\tilde{e}_{i(i)}) - \hat{\sigma}_\epsilon^2$, where $\widehat{var}(\tilde{e}_{i(i)})$ is the empirical variance of the $\tilde{e}_{i(i)}$ and $\hat{\sigma}_\epsilon^2$ is an estimate of the variance of G, which we discuss below. We note

that the deconvolution strategy we employ makes assumptions of homoskedastic errors ϵ_i's, which is true in our simulations but may not be true in practice. See AppendixB for details regarding the implementation of Method 1.

Method 2: Bootstrapping from standardized $\tilde{e}_{i(i)}$ A simpler alternative is bootstrapping from the predicted error terms, $\tilde{e}_{i(i)}$, without deconvolution. Specifically, we propose to bootstrap from a scaled version of $\tilde{e}_{i(i)}$,

$$\tilde{r}_{i(i)} = \frac{\hat{\sigma}_\epsilon}{\sqrt{\widehat{var}(\tilde{e}_{i(i)})}}\tilde{e}_{i(i)},$$

where $\widehat{var}(\tilde{e}_{i(i)})$ is the standard estimate of the variance of $\tilde{e}_{i(i)}$ and $\hat{\sigma}_\epsilon$ is an estimate of σ_ϵ. This scaling aligns the first two moments of $\tilde{e}_{i(i)}$ with those of ϵ_i. On the face of it, resampling from $\tilde{r}_{i(i)}$ seems problematic, since Equation (3) demonstrates that $\tilde{e}_{i(i)}$ does not have the same distribution as ϵ_i, even if the first two moments are the same. However, as we demonstrate in simulations, this distributional mismatch appears to have limited practical effect on our bootstrap confidence intervals.

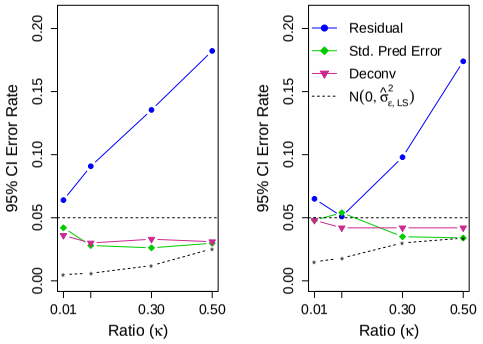
Estimation of σ_ϵ^2 Both methods described above require an estimator of σ_ϵ that is consistent regardless of dimension and error distribution. As we have explained earlier, for general ρ we cannot rely on the observed residuals e_i nor on $\tilde{e}_{i(i)}$ for estimating σ_ϵ (see Equations (3) and (4)). The exception is the standard estimate of σ_ϵ^2 from least-squares regression, i.e., $\rho(x) = x^2$,

$$\widehat{\sigma}_{\epsilon,LS}^2 = \frac{1}{n-p}\sum_i e_{i,L_2}^2.$$

$\widehat{\sigma}_{\epsilon,LS}^2$ is a consistent estimator of σ^2 for any error distribution G, assuming i.i.d. errors and mild moment requirements. In implementing the two alternative residual-bootstrap methods described above, we use $\widehat{\sigma}_{\epsilon,LS}$ as our estimate of σ_ϵ, including for bootstrapping robust regression where $\rho(x) \neq x^2$.

Performance in bootstrap inference In Figure 2 we show the error rate of confidence intervals based on the two residual-bootstrap methods we proposed above. We see that both methods control the Type I error, unlike bootstrapping directly from the residuals, and that both methods are conservative. There is little difference between the two methods with this sample size ($n = 500$), though with $n = 100$, we observe the deconvolution performance to be worse in L_1 (data not shown).

The deconvolution strategy, however, depends on the distribution of the design matrix, which in these simulations we assumed was Gaussian (so we did not have to estimate λ_i's). For elliptical designs ($\lambda_i \neq 1$), the error rate of the deconvolution method described above, with no adaptation for the design, was similar to that of uncorrected residuals in high dimensions (i.e., > 0.25 for $p/n = 0.5$). Individual estimates of λ_i might improve the deconvolution strategy, but this problem points to the general reliance of the deconvolution method on precise knowledge about the design matrix. The bootstrap using standardized predicted errors, on the other hand, had a Type I error for an elliptical design only slightly higher than the target 0.05 (around 0.07, data not shown), suggesting that it might be less sensitive to the properties of the design matrix.



(a) L_1 loss (b) Huber loss

Figure 2: **Bootstrap based on predicted errors:** We plotted the error rate of 95% confidence intervals for the alternative bootstrap methods described in Section 2.3: bootstrapping from standardized predicted errors (green) and from deconvolution of predicted error (magenta). We demonstrate its improvement over the standard residual bootstrap (blue) for (a) L_1 loss and (b) Huber loss. The error distribution is double exponential, but otherwise the simulations parameters are as in Figure 1. The error rates on confidence intervals based on bootstrapping from a $N(0, \hat{\sigma}^2_{\epsilon,LS})$ (dashed curve) are as a lower bound on the problem. For the precise error rates see Appendix, Table A-3.

Given our previous discussion of the behavior of $\tilde{e}_{i(i)}$, it is somewhat surprising that resampling from the distribution of $\tilde{r}_{i(i)}$ performed well in our simulations. Clearly a few cases exist where $\tilde{r}_{i(i)}$ should work well as an approximation of ϵ_i. We have already noted that as $p/n \to 0$, the effect of the convolution with the Gaussian disappears since $\|\widehat{\beta}_\rho - \beta\| \to 0$; in this case both e_i and $\tilde{r}_{i(i)}$ should be good estimates of ϵ_i. Similarly, in the case $\epsilon_i \sim N(0, \sigma^2)$, Equation (3) tells us that $\tilde{e}_{i(i)}$ are also asymptotically marginally normally distributed, so that correcting the variance should result in $\tilde{r}_{i(i)}$ having the same distribution as ϵ_i, at least when $X_{i,j}$ are i.i.d.

Surprisingly, for larger p/n we do not see a deterioration of the performance of bootstrapping from $\tilde{r}_{i(i)}$. This is unexpected, since as $p/n \to 1$ the risk $\|\widehat{\beta}_\rho - \beta\|_2^2$ grows to be much larger than σ_ϵ^2 (a claim we will make more precise in the next section); together with Equation (3), this implies that $\tilde{r}_{i(i)}$ is essentially distributed $N(0, \widehat{\sigma}^2_{\epsilon,LS})$ as $p/n \to 1$ regardless of the original distribution of ϵ_i. This is confirmed in Figure 2 where we superimpose the results of bootstrap confidence intervals from when we simply estimate $\hat{G}$ with $N(0, \hat{\sigma}^2_{\epsilon,LS})$; we see the Type I error rate of the confidence intervals based on bootstrapping from $\tilde{r}_{i(i)}$ do indeed approach that of $N(0, \hat{\sigma}^2_{\epsilon,LS})$. Putting these two pieces of information

together leads to the conclusion that as $p/n \to 1$ we can estimate $\hat{G}$ simply as $N(0, \hat{\sigma}_{\epsilon,LS})$ regardless of the actual distribution of ϵ.

In the next section we give some theoretical results that seek to understand this phenomenon.

2.4 Behavior of the Risk of $\widehat{\beta}$ When $\kappa \to 1$

In the previous section we saw even if the distribution of the bootstrap errors ϵ_i^*, given by $\hat{G}$, is not close to that of G, we can sometime get accurate bootstrap confidence intervals. For example, in least squares Equation (3) makes clear that even the standardized residuals, r_i, do not have the same marginal distribution as ϵ_i, yet they still provide accurate bootstrap confidence intervals in our simulations. We would like to understand for what choice of distributions $\hat{G}$ will we see the same performance in our bootstrap confidence intervals of $\widehat{\beta}_1$?

When working conditional on X as in residual resampling, the statistical properties of $(\widehat{\beta}^* - \widehat{\beta})$ differ from that of $(\widehat{\beta} - \beta)$ only because the errors are drawn from a different distribution: $\hat{G}$ rather than G. Then to understand whether the distribution of $\widehat{\beta}_1^*$ matches that of $\widehat{\beta}_1$ we can ask, what are the distributions of errors, G, that yield the same distribution for the resulting $\widehat{\beta}_1(G)$? In this section, we narrow our focus on understanding not the entire distribution of $\widehat{\beta}_1$, but only its variance. We do so because under assumptions on the design matrix X, it is known that $\widehat{\beta}_1$ is asymptotically normally distributed. This is true for both the classical setting of $\kappa = 0$ and the high-dimensional setting of $\kappa \in (0, 1)$ (see AppendixA for a review of these results and a more technical discussion). Our previous question is then reduced to understanding which distributions G give the same var $\left(\widehat{\beta}_1(G)\right)$.

In the setting of least squares, it is clear that the only property of $\epsilon_i \overset{iid}{\sim} G$ that matters for the variance of $\widehat{\beta}_{1,L_2}$ is σ_ϵ^2, since var $\left(\widehat{\beta}_{1,L_2}\right) = (X'X)^{-1}(1,1)\sigma_\epsilon^2$. For general ρ, if we assume $p/n \to 0$, then var $\left(\widehat{\beta}_{1,\rho}\right)$ will depend on features of G beyond the first two moments (specifically through $\mathbf{E}\left(\psi^2(\epsilon)\right)/[\mathbf{E}\left(\psi'(\epsilon)\right)]^2$, (Huber, 1973)). If we assume instead $p/n \to \kappa \in (0,1)$, then it has been shown (El Karoui et al., 2013) that var $\left(\widehat{\beta}_{1,\rho}(G)\right)$ depends on G only by the effect of G on the squared risk of the vector $\widehat{\beta}_\rho(G)$, i.e., through $\mathbf{E}\left(\|\widehat{\beta}_\rho(G) - \beta\|_2^2\right)$ (for the convenience of the reader we give a review of these results, which are a bit scattered in the literature, in AppendixA).

For this reason, in the setting of $p/n \to \kappa \in (0,1)$, we need to characterize the risk of $\widehat{\beta}_\rho$ to understand when different distributions of ϵ result in the same variance of $\widehat{\beta}_{1,\rho}$. In what follows, we denote by $r_\rho^2(\kappa; G)$ the asymptotic squared risk of $\widehat{\beta}_\rho(G)$ as p and n tend to ∞,

$$r_\rho^2(\kappa; G) = \lim_{n,p\to\infty, \frac{p}{n}\to\kappa} E||\widehat{\beta}_\rho(G) - \beta||^2 \, .$$

The dependence of $r_\rho^2(\kappa; G)$ on ϵ is characterized, under appropriate technical conditions on X, ρ and ϵ_i's, by a system of two non-linear equations (El Karoui et al., 2013). Specifically, if we define $\hat{z}_\epsilon = \epsilon + r_\rho(\kappa; G)Z$, where $Z \sim \mathcal{N}(0,1)$ is independent of ϵ, and ϵ has the same distribution G as the ϵ_i's, then there exists a constant c such that the pair of positive,

finite, and deterministic scalars $(c, r_\rho(\kappa;G))$ satisfy the following system of equations:

$$\begin{aligned} \mathbf{E}\left((\mathrm{prox}(c\rho))'(\hat{z}_\epsilon)\right) &= 1-\kappa\ , \\ \kappa r_\rho^2(\kappa;G) &= \mathbf{E}\left([\hat{z}_\epsilon - \mathrm{prox}(c\rho)(\hat{z}_\epsilon)]^2\right)\ . \end{aligned} \tag{5}$$

In this system, $\mathrm{prox}(c\rho)$ refers to Moreau's proximal mapping of the convex function $c\rho$ (see Moreau, 1965; Hiriart-Urruty and Lemaréchal, 2001).

It is therefore not entirely trivial to characterize those distributions Γ for which $r_\rho^2(\kappa;G) = r_\rho^2(\kappa;\Gamma)$. In the following theorem, however, we show that as $\kappa \to 1$, $r_\rho^2(\kappa;G)$ converges to a constant that depends only on σ_ϵ^2. This implies that when $\kappa \to 1$, two different error distributions that have the same variances will result in estimators $\widehat{\beta}_{1,\rho}$ with the same variance. Before stating our theorem formally, however, we will review the necessary assumptions for the system of equations in (5) to hold. For a precise statement of the assumptions, see El Karoui (2017)

Assumptions for Equation 5: The proof of (5) provided in El Karoui (2013) assumes that the X_i's have mean 0, $\mathrm{cov}\,(X_i) = \mathrm{Id}_p$, and they satisfy sub-Gaussian concentration assumptions (with constants dependent on n). El Karoui (2013) further assumes that the ϵ_i have a unimodal density, are independent from the X_{ij}, $\sup_{1\leq i\leq n}|\epsilon_i| = \mathrm{O}_P(\mathrm{polyLog}(n))$, and that similiar bounds also hold for a few moments of ϵ_i (the number of such moments depends on the loss function ρ). Log-concave densities such as those corresponding to double exponential or Gaussian errors used in the current paper fall within the scope of this theorem. The reader interested in generalizations and truly heavy-tailed situation is referred to El Karoui (2017) and references therein.

The loss function ρ is assumed by El Karoui (2013) (in the unpenalized case) to be non-negative, twice differentiable, strongly convex, non-linear, taking value 0 at 0, and with a derivative that grows at most polynomially at infinity and a second derivative that is locally Lipschitz, with local Lipschitz constant that grow at most polynomially at infinity. It should be noted that distributions with sufficiently many moments, the condition of strong convexity of ρ can be obtained by adding $\delta x^2/2$ to the initial ρ, with δ "small", e.g., $\delta = 10^{-10}$, and that modification will change very little or anything to the estimator. Furthermore, the requirement of strong convexity of ρ, though superficially limiting, is likely an artifact of the proof, where the main motivation was log-concave distributions with an eye towards optimality (Bean et al., 2013). In fact, the theoretical predictions of (5) were verified numerically in El Karoui et al. (2011) outside of the assumptions stated above, and the predictions of Equation (5) were found to be very accurate in simulations even for non-smoothed ℓ_1 and Huber losses with certain error distributions.

We now state the theorem formally; see AppendixE for the proof of this statement.

Theorem 1 *Suppose we are working with robust regression estimators with loss ρ, and $p/n \to \kappa$. Suppose that $r_\rho^2(\kappa;G)$ is characterized by the system of equations in* (5)*. Then,*

$$\lim_{\kappa\to 1}\frac{1-\kappa}{\sigma_\epsilon^2}r_\rho^2(\kappa;G) = 1\ ,$$

provided ρ is additionally differentiable near 0 and $\rho'(x) \sim x$ near 0.

Implications for the Bootstrap For the purposes of the residual-bootstrap, Theorem 1 implies that different methods of estimating the residual distribution $\hat{G}$ will result in similar residual-bootstrap confidence intervals as $p/n \to 1$, if $\hat{G}$ has the same variance. This agrees with our simulations, where both of our proposed bootstrap strategies set the variance of $\hat{G}$ equal to $\widehat{\sigma}^2_{\epsilon,LS}$ and both had similar performance in our simulations for large p/n. Furthermore, as we noted, for p/n closer to 1, they both had similar performance to a bootstrap procedure that simply sets $\hat{G} = \mathcal{N}(0, \widehat{\sigma}^2_{\epsilon,LS})$ (Figure 2) (see also AppendixA.3 for further discussion of residual bootstrap methods which draw from the "wrong" distribution, i.e., forms of wild bootstraps (Wu, 1986)).

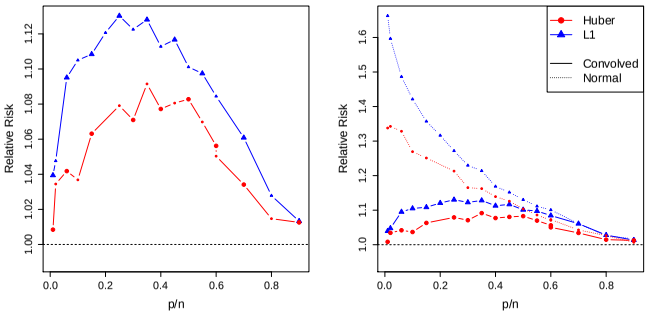
We return specifically to the bootstrap based on $\tilde{r}_{i(i)}$, the standardized predicted errors. Equation (3) tells us that the marginal distribution of $\tilde{e}_{i(i)}$ is a convolution of the distribution of ϵ_i and a normal, with the variance of the normal governed by the term $\|\widehat{\beta}_\rho - \beta\|_2$. Theorem 1 makes rigorous our previous assertion that as $p/n \to 1$, the normal term will dominate and the marginal distribution of $\tilde{e}_{i(i)}$ will approach normality, regardless of the distribution of ϵ. However, Theorem 1 also implies that as $p/n \to 1$, inference for the coordinates of β will be increasingly less reliant on features of the error distribution beyond the variance, implying that our standardized predited errors, $\tilde{r}_{i(i)}$, will still result in an estimate $\hat{G}$ that will give accurate confidence intervals. Conversely, as $p/n \to 0$ classical theory tells us that the inference of β relies heavily on the distribution G beyond the first two moments, but in that case the distribution of $\tilde{r}_{i(i)}$ approaches the correct distribution as we explained earlier. So bootstrapping from the marginal distribution of $\tilde{r}_{i(i)}$ also makes sense when p/n is small.

For κ between these two extremes it is difficult to theoretically predict the risk of $\widehat{\beta}_\rho(\hat{G})$ when the distribution $\hat{G}$ is given by resampling from the $\tilde{r}_{i(i)}$. We turn to numerical simulations to evaluate this risk. Specifically, for $\epsilon_i \sim G$, we simulated data that is a convolution of G and a normal with variance equal to $r_\rho^2(\kappa;G)$; we then scale this simulated data to have variance σ_ϵ^2. The scaled data are the ϵ_i^* and we refer to the distribution of ϵ_i^* as the convolution distribution, denoted G_{conv}. Then, G_{conv} is the asymptotic version of the marginal distribution of the standardized predicted errors, $\tilde{r}_{i(i)}$, used in our bootstrap method proposed above.

In Figure 3 we plot for both Huber loss and L_1 loss the average risk $r_\rho(\kappa;G_{conv})$ (i.e., errors given by G_{conv}) relative to the average risk $r_\rho(\kappa;G)$ (i.e., errors distributed according to G), where G has a double exponential distribution. We also plot the relative average risk $r_\rho(\kappa;G_{norm})$, where $G_{norm} = N(0,\sigma_\epsilon^2)$. As predicted by Theorem 1, for κ close to 1, $r_\rho(\kappa;G_{conv})/r_\rho(\kappa;G)$ and $r_\rho(\kappa;G_{norm})/r_\rho(\kappa;G)$ converge to 1. Conversely, as $\kappa \to 0$, $r_\rho(\kappa;G_{norm})/r_\rho(\kappa;G)$ diverges dramatically from 1, while $r_\rho(\kappa;G_{conv})/r_\rho(\kappa;G)$ approaches 1, as expected. For Huber, the divergence of $r_\rho(\kappa;G_{conv})/r_\rho(\kappa;G)$ from 1 is at most 8%, but the difference is larger for L_1 (12%), probably due to the fact that the convolution with a normal error has a larger effect on the risk for L_1.

3. Pairs Bootstrap

As described above, estimating the distribution $\hat{F}$ from the empirical distribution of (y_i, X_i) (*pairs bootstrapping*) is generally considered the most general and widely applicable method of bootstrapping, allowing for the linear model to be incorrectly specified (i.e., $\mathbf{E}\,(y_i)$ is not a linear function of X_i). It is also considered to be slightly more conservative compared



(a) Relative risk of G_{conv} to G (b) Relative risk of G_{conv} and G_{norm} to G

Figure 3: **Relative Risk of $\widehat{\beta}$ for scaled predicted errors vs original errors - population version:** (a) Plotted with a solid lines are the ratios of the average risk of $\widehat{\beta}(G_{conv})$ to the average risk of $\widehat{\beta}(G)$ for Huber and L_1 loss. (b) shows the same plot, but added to the plot (dotted lines) is the relative risk of $\widehat{\beta}(G)$ when the errors are distributed $G_{norm} = \mathcal{N}(0, \sigma_\epsilon^2)$. For both figures, the y-axis gives the relative risk, and the x-axis is the ratio p/n, with n fixed at 500. Blue/triangle plotting symbols indicate L_1 loss; red/circle plotting symbols indicate Huber loss. The average risk is calculated over 500 simulations, where the design matrix X has Gaussian entries. The "true" error distribution G is the standard Laplacian distribution with $\sigma_\epsilon^2 = 2$. Each simulation uses the standard estimate of σ_ϵ^2 from the generated ϵ_i's. $r_\rho(\kappa; G)$ was computed using a first run of simulations with $\epsilon_i \overset{iid}{\backsim} G$. The Huber loss in this plot is Huber_1 and not the default $\text{Huber}_{1.345}$ of the `rlm` function.

to bootstrapping from the residuals. In the case of random design, it makes also a lot of intuitive sense to use the pairs bootstrap, since resampling the predictors might be interpreted as mimicking the data generating process.

However, as in residual bootstrap, it is clear that the pairs bootstrap will have problems, at least in quite high dimensions. In fact, when resampling the X_i's from $\hat{F}$, the number of times a certain vector X_{i_0} is picked has asymptotically Poisson(1) distribution. So the expected number of different vectors appearing in the bootstrapped design matrix X^* is $n(1 - 1/e)$. When p/n is large, with increasingly high probability the bootstrapped design matrix X^* will no longer be of full rank. For example, if $p/n > (1 - 1/e) \approx 0.63$ then with probability tending to one as $n \to \infty$, the bootstrapped design matrix X^* is singular, even when the original design matrix X is of rank $p < n$. Bootstrapping the pairs in that situation makes little statistical sense (El Karoui, 2010, Subsection 4.4; Zheng et al., 2014).

For smaller ratios of p/n, we evaluate the performance of pairs bootstrapping on simulated data. We see that the performance of the bootstrap for inference also declines

dramatically as the dimension increases, becoming increasingly conservative (Figure 1). In pairs bootstrapping, the error rates of 95%-confidence-intervals drop far below the nominal 5%, and are essentially zero for the ratio of $p/n = 0.5$. Like residual bootstrap, this overall trend is seen for all the settings we simulated under (Supplemental Figures A-1, A-2). For L_1 loss, even ratios as small as 0.1 yield incredibly conservative bootstrap confidence intervals for $\widehat{\beta}_1$, with the error rate dropping to less than 0.01. For Huber and L_2 losses, the severe loss of power in our simulations starts for ratios of 0.3.

A minimal requirement for the distribution of the bootstrapped data to give reasonable inferences is that the variance of the bootstrap estimator $\widehat{\beta}_1^*$ needs to be a good estimate of the variance of $\widehat{\beta}_1$. This is not the case in high-dimensions. In Figure 5 we plot the ratio of the variance of $\widehat{\beta}_1^*$ to the variance of $\widehat{\beta}_1$ evaluated over simulations. We see that for $p/n = 0.3$ and design matrices X with i.i.d. $\mathcal{N}(0, 1)$ entries, the average variance of $\widehat{\beta}_1^*$ roughly overestimates the true variance of $\widehat{\beta}_1$ by a factor 1.3 in the case of least-squares; for Huber and L_1 the bootstrap estimate of variance is roughly twice as large as it should be.

In the case of least-squares, we can further quantify this loss in power by comparing the size of the bootstrap confidence intervals to the size of the correct confidence interval based on theoretical results (Figure 4). We see that even for ratios κ as small as 0.1, the confidence intervals for some design matrices X were 15% larger for pairs bootstrap than the correct size (e.g., the case of elliptical distributions where λ_i is exponential). For much higher dimensions of $\kappa = 0.5$, the simple case of i.i.d. normal entries for the design matrix gives intervals that are 80% larger than needed; for the elliptical distributions we simulated, the width of the bootstrap confidence interval was as much as 3.5 times larger than that of the correct confidence interval. Furthermore, as we can see in Figure 1, least-squares regression represents the best case scenario; L_1 and Huber will have even worse loss of power and at smaller values of κ.

3.1 Theoretical Analysis for Least-Squares

In the setting of least-squares, we can for some distributions of the design matrix X theoretically determine the asymptotic expectation of the variance of $v'\widehat{\beta}^*$ and show that it is a severe over-estimate of the true variance of $v'\widehat{\beta}$.

We first setup some notation for the theorem that follows. Define $\widehat{\beta}_w$ as the result of regressing y on X with random weight w_i for each observation (y_i, X_i). In other words,

$$\widehat{\beta}_w = \text{argmin}_{u \in \mathbb{R}^p} \sum_{i=1}^{n} w_i (y_i - X_i' u)^2 \, .$$

We assume that the weights are independent of $\{y_i, X_i\}_{i=1}^n$ and define $\widehat{\beta}_w^*$ to be the random variable with distribution equal to that of $\widehat{\beta}_w$ conditional on the data $\{y_i, X_i\}_{i=1}^n$, i.e., $\widehat{\beta}_w^* \overset{\mathcal{L}}{=} \widehat{\beta}_w | \{y_i, X_i\}_{i=1}^n$. For the standard pairs bootstrap, the distribution of $\widehat{\beta}^*$ from resampling from the pairs (y_i, X_i) is equivalent to the distribution of $\widehat{\beta}_w^*$, where w is drawn from a multinomial distribution with expectation $1/n$ for each entry. In which case, the variance of $v'\widehat{\beta}_w^*$ refers to the standard bootstrap estimate of variance given by the distribution of $v'\widehat{\beta}^*$ over repeated resampling from the pairs (y_i, X_i).

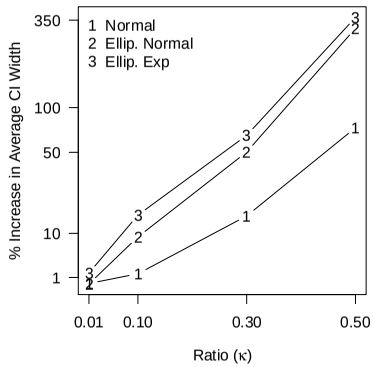


Figure 4: **Comparison of width of 95% confidence intervals of β_1 for L_2 loss:** Here we demonstrate the increase in the width of the confidence interval due to pairs bootstrapping. Shown on the y-axis is the percent increase of the average confidence interval width based on simulation ($n = 500$), as compared to the average for the standard confidence interval based on normal theory in L_2; the percent increase is plotted against the ratio $\kappa = p/n$ (x-axis). Shown are three different choices in simulating the entries of the design matrix X: (1) $X_{ij} \sim N(0,1)$ (2) elliptical X_{ij} with $\lambda_i \sim N(0,1)$ and (3) elliptical X_{ij} with $\lambda_i \sim Exp(\sqrt{2})$. The methods of simulation are the same as described in Figure 1; exact values are given in Table A-2 in AppendixI.

We have the following result for the expected value of the bootstrap variance of any contrast $v'\widehat{\beta}^*_w$ where v is deterministic, assuming independent weights with a Gaussian design matrix X and some mild conditions on the distribution of the w's.

Theorem 2 *Let the weights $(w_i)_{i=1}^n$ be i.i.d. and without loss of generality that $\mathbf{E}(w_i) = 1$; we suppose that the w_i's have 8 moments and for all i, $w_i > \eta > 0$. Suppose X_i's are i.i.d. $\mathcal{N}(0,\Sigma)$, Σ is positive definite and the vector v is deterministic with $\|v\|_2 = 1$.*

Suppose $\widehat{\beta}$ is obtained by solving a least-squares problem and $y_i = X_i'\beta + \epsilon_i$, ϵ_i's being i.i.d. mean 0, with $\mathrm{var}(\epsilon_i) = \sigma_\epsilon^2$.

If $\lim p/n = \kappa < 1$ then the expected variance of the bootstrap estimator, asymptotically as $n \to \infty$, is given by

$$p\frac{\mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}^*_w\right)\right)}{v'\Sigma^{-1}v} = p\frac{\mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}_w|\{y_i,X_i\}_{i=1}^n\right)\right)}{v'\Sigma^{-1}v} \to \sigma_\epsilon^2\left[\frac{\kappa}{1-\kappa-f(\kappa)} - \frac{1}{1-\kappa}\right],$$

where $f(\kappa) = \mathbf{E}\left(\frac{1}{(1+cw_i)^2}\right)$ and c is the unique solution of $\mathbf{E}\left(\frac{1}{1+cw_i}\right) = 1-\kappa$.

We note that $\mathbf{E}\left(\frac{1}{(1+cw_i)^2}\right) \geq \left[\mathbf{E}\left(\frac{1}{1+cw_i}\right)\right]^2 = (1-\kappa)^2$ - where the first inequality comes from Jensen's inequality, and therefore the expression we give for the asymptotic limit of the expected bootstrap variance is non-negative. For a proof of this theorem and a consistent estimator of this limit, see AppendixF.

In light of previous work on model robustness issues in high-dimensional statistics (see e.g., (Diaconis and Freedman, 1984; Hall et al., 2005; El Karoui, 2009, 2010)), it is natural to ask whether the central results of Theorem 2 still apply when X_i is not Gaussian but has an elliptical distribution. The formula in Theorem 2 does not apply directly to this latter case. However, the proof given in AppendixF extends to that setting, and we refer the interested reader to the AppendixF.1 where we give the necessary details of how to change the formulas and proof to encompass the elliptical case (we do not provide them in rigorous mathematical detail in this work as they are substantially more cumbersome than those in Theorem 2 and do not give enough additional insights to justify inclusion). On the other hand, a number of the quantities appearing in the proof of Theorem 2 will converge to the same limit as that given in Theorem 2 when i.i.d. Gaussian predictors are replaced by i.i.d. predictors with mean 0 and variance 1 and sufficiently many moments (an example being bounded random variables). Thus the results we present here should be fairly robust to changing i.i.d. normality assumptions for the entries of the design matrix X, but again the technical work necessary for making this rigorous is beyond the scope of this paper.

Implications for Pairs Bootstrap In the standard pairs bootstrap, the weights are chosen according to a Multinomial$(n, 1/n)$ distribution. This violates two conditions in the previous theorem: independence of w_i's and the condition $w_i > 0$. In AppendixF.2, we give the technical details for how to extend the proof of Theorem 2 to multinomial weights. In what follows, however, we use i.i.d. Poisson(1) weights, which asymptotically and marginally correspond to the Multinomial$(n, 1/n)$ weights, to develop intuition about the bootstrap. In this case, we can apply the formula in Theorem 2 to explain why pairs bootstrap confidence intervals perform poorly in high-dimensions, at least for least squares regression with Gaussian design matrix.

When $X_i \overset{iid}{\backsim} \mathcal{N}(0,\Sigma)$, it is well known in the least-squares case that the quantity $p \text{ var}\left(v'\widehat{\beta}\right)/v'\Sigma^{-1}v$ converges asymptotically to $\kappa/(1-\kappa)\sigma_\epsilon^2$ (this can be shown through simple Wishart computations Haff, 1979; Mardia et al., 1979). If the variance of $v'\widehat{\beta}_w^*$ converged to the variance of $v'\widehat{\beta}$, we should be able to equate this latter quantity to the limit given in Theorem 2, i.e.,

$$\left[\frac{\kappa}{1-\kappa-f(\kappa)}-\frac{1}{1-\kappa}\right]=\frac{\kappa}{1-\kappa}\,,$$

and hence should have

$$f(\kappa)=\mathbf{E}\left(\frac{1}{(1+cw_i)^2}\right)=\frac{1-\kappa}{1+\kappa}\,.$$

However, this relationship does not hold for most weight distributions, and in particular does not hold for weights following a Poisson(1) distribution (which asymptotically corresponds to the standard pairs bootstrap, as explained above). Thus the pairs bootstrap does not correctly estimate the variance of $v'\widehat{\beta}$. In Figure 5a we calculate the theoretical predictions of $\mathbf{E}\left(\text{var}\left(\widehat{\beta}_w^*\right)\right)$ given by Theorem 2 (using Poisson(1) weights and $\Sigma=\text{Id}_p$), and we compare them to the asymptotic variance of $\widehat{\beta}_1$ given by $\kappa/(1-\kappa)\sigma_\epsilon^2/p$. We see that Theorem 2 predicts that the pairs bootstrap overestimates the variance of the estimator by a factor that ranges from 1.2 to 3 as κ varies between 0.3 and 0.5. These theoretical predictions correspond to the level of overestimation of the variance seen in our bootstrap simulations (Figure 5b).

3.2 Alternative Weight Distributions for Resampling

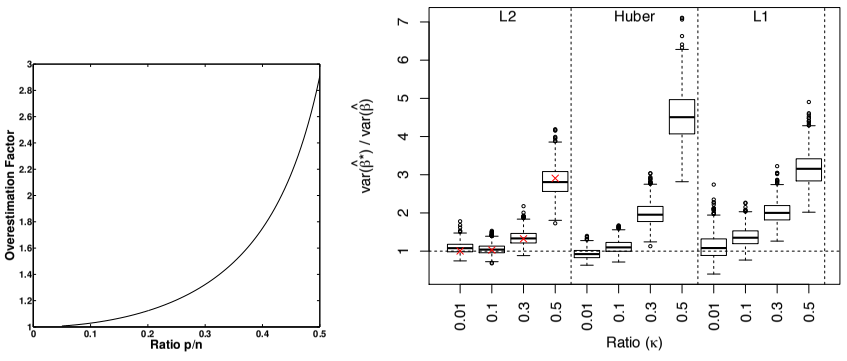
The formula given in Theorem 2 suggests that resampling from a distribution $\hat{F}$ defined using weights other than i.i.d. Poisson(1) (or, equivalently for our asymptotics, Multinominal(n,1/n)) should give us better bootstrap estimators than using the standard pairs bootstrap. In fact, we should require, at least, that the bootstrap expected variance of these estimators match the correct variance $\text{var}\left(v'\widehat{\beta}\right)=\kappa/(1-\kappa)\sigma_\epsilon^2/p$ (for the Gaussian design, when $\Sigma=\text{Id}_p$). We focus our discussion on the case $\Sigma=\text{Id}_p$; see AppendixC for the case $\Sigma\neq\text{Id}_p$.

We note that if we use $w_i=1,\ \forall i$, the bootstrap variance will be 0, since with such a resampling scheme the resampled data set is always the original data set. On the other hand, we have seen that with $w_i\sim\text{Poisson}(1)$, the expected bootstrap variance was too large compared to $\kappa/(1-\kappa)\sigma_\epsilon^2/p$. Hence, we tried to find alternative weights via calculating a parameter α such that if

$$w_i \overset{iid}{\backsim} 1-\alpha+\alpha\text{Poisson}(1)\,, \tag{6}$$

the expected bootstrap variance would match the theoretical value of $\kappa/(1-\kappa)\sigma_\epsilon^2/p$.

We numerically solved this problem to find $\alpha(\kappa)$ (for details of computation see AppendixC). We then used these values and performed bootstrap resampling using the weights defined in Equation (6). We evaluated bootstrap estimate of $\text{var}\left(\widehat{\beta}_1\right)$ as well as the confidence interval coverage of the true β_1. We find that this adjustment of the weights in



(a) L_2 (Theoretical) (b) All (Simulated)

Figure 5: **Factor by which standard pairs bootstrap over-estimates the variance:** (a) plotted is the ratio of the value of the expected bootstrap variance computed from Theorem 2 using Poisson(1) weights to the asymptotic variance $\kappa/(1-\kappa)\sigma_\epsilon^2$. (b) boxplots of the ratio of the bootstrap variance of $\widehat{\beta}_1^*$ to the variance $\widehat{\beta}_1$, as calculated over 1000 simulations (i.e., $\text{var}\left(\widehat{\beta}\right)$ is estimated across simulated design matrices X, and not conditional on X). The theoretical prediction for the mean of the distribution from Theorem 2 is marked with a 'X' for L_2 regression. Simulations were performed with normal design matrix X and normal error ϵ_i with values of $n=500$. For the median values of each boxplot, see Table A-6 in AppendixI.

estimating $\hat{F}$ results in accurate bootstrap estimates of variance and appropriate levels of confidence interval coverage (Table 1).

However, small changes in the choice of α can result in fairly large changes in $\mathbf{E}\left(\text{var}\left(v'\widehat{\beta}_w|X,\epsilon\right)\right)$. For instance, for $\kappa=0.5$, using the value of $\alpha=0.95$ which is close to the correct value of $\alpha(0.5)=0.92$ results in an expected bootstrap variance roughly 30% larger than it should be.

Moreover, this strategy for finding a good weight distribution requires knowing a great deal about the distribution of the design matrix. Hence the work we just presented on finding new weight distributions for bootstrapping is a proof of principle that alternative weighting schemes could be used for pairs bootstrapping in high-dimension, but important practical details would depend strongly on the statistical model that is assumed. This is in sharp contrast with the low-dimensional situation, where a unique and model-free bootstrap resampling technique works in a broad variety of situations.

	κ			
	.1	.2	.3	.5
α	.9875	.9688	.9426	.9203
Error Rate of 95% CIs	0.051	0.06	0.061	0.057
Ratio of Variances	1.0119	1.0236	0.9931	0.9992

Table 1: **Summary of weight-adjusted bootstrap simulations for L_2 :** Given are the results of performing bootstrap resampling for $n = 500$ according to the estimate of $\hat{F}$ given by the weights in Equation (6). "Error Rate of 95% CIs" denotes the percent of bootstrap confidence intervals that did not contain the correct value of the parameter β_1. "Ratio of Variances" gives the ratio of the empirical expected bootstrap variance over our simulations divided by the theoretical value $\sigma_\epsilon^2\kappa/(1-\kappa)$. Results are based on 1000 simulations, with a Gaussian random design and errors distributed as double exponential.

4. The Jackknife

In the context we are investigating, where we know that the distribution of $\widehat{\beta}_1$ is asymptotically normal, it is natural to ask whether we could simply use the jackknife to estimate the variance of $\widehat{\beta}_1$. The jackknife relies on leave-one-out procedures to estimate var $\left(\widehat{\beta}_1\right)$. More specifically, for a fixed vector v, the jackknife estimate of var $\left(v'\widehat{\beta}\right)$ is given by:

$$\widehat{var}_{JACK}(v'\widehat{\beta}) = \frac{n-1}{n}\sum_{i=1}^{n}(v'[\widehat{\beta}_{(i)} - \tilde{\beta}])^2 \tag{7}$$

where $\tilde{\beta} = \frac{1}{n}\sum_{i=1}^{n}\widehat{\beta}_{(i)}$. The case of $\widehat{\beta}_1$ corresponds to picking $v = e_1$, i.e., the first canonical basis vector. The Efron-Stein inequality guarantees in general that the expectation of the jackknife estimate of variance gives an upper-bound on the variance of the statistic under consideration (Efron and Stein, 1981).

Given the problems we just documented with the pairs bootstrap, it is natural to ask whether confidence intervals based on the jackknife estimate of variance perform better than pairs bootstrap intervals in high-dimensions. The jackknife is known to have problems (Efron, 1982 or Koenker, 2005, p.105), but the reliance of the jackknife on leave-one-out estimates $\widehat{\beta}_{(i)}$ might suggest it could be more robust to dimensionality issues than other methods.

Empirical findings As in the pairs bootstrap case, simulations show that confidence intervals based on the jackknife estimate of variance lead to extremely poor inference for β_1 (Figure 1) and that the jackknife dramatically overestimates the variance of $\widehat{\beta}_1$ (Figure 6). For L_2 and Huber loss, the jackknife estimate of variance is 10-15% too large for $p/n = 0.1$, and for $p/n = 0.5$ the jackknife estimate of variance is 2-2.5 times larger than it should be. In the case of L_1 loss, the jackknife variance is completely erratic, even in low dimensions; this is not completely surprising given the known problems with the jackknife for the median (Koenker,

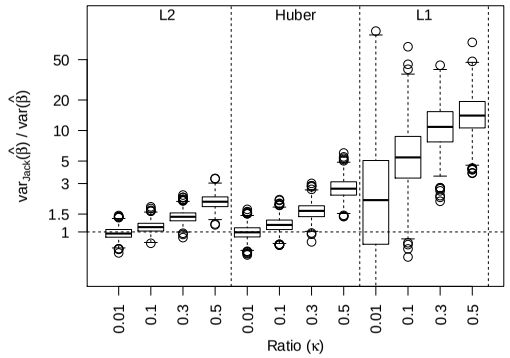


Figure 6: **Factor by which jackknife over-estimates the variance:** boxplots of the ratio of the jackknife estimate of the variance $\widehat{\beta}_1$ to the variance of $\widehat{\beta}_1$ as calculated over 1000 simulations. Simulations were with normal design matrix X and normal error ϵ_i with values of $n = 500$. Note that because the L_1 jackknife estimates so wildly overestimate the variance, in order to put all the methods on the same plot the boxplot of ratio is on log-scale; y-axis labels give the corresponding ratio to which the log values correspond. For the median values of each boxplot, see Table A-6 in AppendixI.

2005). Even for $p/n = 0.01$, the estimate is not unbiased for L_1, with median estimates twice as large as they should be and enormous variance in the estimates of variance. Higher dimensions only worsen the behavior with jackknife estimates being 15 times larger than they should.

4.1 Theoretical Results

Again, in the case of least-squares regression with a Gaussian design matrix, we can theoretically evaluate the behavior of the jackknife. The proof of the following theorem is given in AppendixG (when the observations have covariance Id) and in AppendixH (to show how to extend the results to general covariance).

Theorem 3 *Let us call var_{JACK} the jackknife estimate of variance of $v'\widehat{\beta}$ given in* (7)*, where v is any deterministic vector with $\|v\|_2 = 1$. Suppose the design matrix X is such that $X_i \overset{iid}{\backsim} \mathcal{N}(0,\Sigma)$, $\widehat{\beta}$ is computed using least-squares, and the errors ϵ have a variance. Then we have, as $n, p \to \infty$ and $p/n \to \kappa < 1$,*

$$\frac{\mathbf{E}\left(var_{JACK}\right)}{\text{var}\left(v'\widehat{\beta}\right)} \to \frac{1}{1-\kappa}\,.$$

As in Theorem 2, the proof of Theorem 3 is based on random matrix techniques where further technical work should allow an extension for the entries of $X_{i,j}$ to be i.i.d. from a distribution other than Gaussian, provided $X_{i,j}$'s have sufficiently many moments. This is also beyond the scope of our work, but interested readers can see AppendixG.3 for more details.

Correcting the Jackknife in Least Squares Theorem 3 implies that scaling the jackknife estimate of variance by multiplying it by $1-p/n$ will result in an estimate of var $\left(\widehat{\beta}_1\right)$ with the correct expectation; simulations shown in Figure 7 confirm that confidence intervals based on this corrected estimate of variance yield correct confidence intervals for least-squares estimates of $\widehat{\beta}$ when the design matrix X is Gaussian. However this scaling factor is not robust to violations of these assumptions. In particular when the X matrix follows an elliptical distribution the correction of $1-p/n$ from Theorem 3 gives little improvement even when the loss is still L_2 (Figure 7).

Corrections for more general settings For the more general setting of an elliptical design matrix X and loss function ρ, preliminary computations suggest an alternative result. Let $\mathcal{S}$ be the random matrix defined by

$$\mathcal{S} = \frac{1}{n}\sum_{i=1}^{n} \psi'(e_i) X_i X_i'.$$

Then in our asymptotic regime, and when $\Sigma = \mathrm{Id}_p$, preliminary heuristic calculations suggest that we can estimate the amount by which $\mathbf{E}\left(var_{JACK}\right)$ overestimates the variance of $\widehat{\beta}_1$ by $\mathbf{E}\left(\hat{\gamma}\right)$, where

$$\hat{\gamma} \triangleq \frac{\mathrm{trace}\left(\mathcal{S}^{-2}\right)/p}{\left[\mathrm{trace}\left(\mathcal{S}^{-1}\right)/p\right]^2}\,. \tag{8}$$

Note that when applied to least-squares regression with $X \sim \mathcal{N}(0, Id_p)$ this conforms to our result in Theorem 3. Theoretical considerations suggest that in our asymptotics, for smooth ρ, $\hat{\gamma} \simeq \mathbf{E}\left(\hat{\gamma}\right)$, which suggests a data-driven correction to the jackknife estimate of variance; however that correction depends having information about the distribution of the design matrix.

Equation (8) assumes that the loss function can be twice differentiated, which is not the case for either Huber or L_1 loss. In the case of non-differentiable ρ and ψ, we can use appropriate regularizations to make sense of those functions. For $\rho = \mathrm{Huber}_k$, i.e., a Huber function that transitions from quadratic to linear at $|x| = k$, ψ' should be understood as $\psi'(x) = 1_{|x|\leq k}$. For L_1 loss, ψ' should be understood as $\psi'(x) = 1_{x=0}$.

In Figure 7 we show simulation results for confidence intervals created based on rescaling the jackknife estimate of variance by $\mathbf{E}\left(\hat{\gamma}\right)$ defined in Equation (8). In the case of least-squares with an elliptical design matrix, this correction—which directly uses the distribution of the observed X matrix—leads to a definite improvement in our jackknife confidence intervals. Similarly, for the Huber loss we see a definite improvement as compared to the standard jackknife estimate, as well as an improvement over the simpler correction of $1-p/n$ that would be appropriate for squared error loss.

It should be noted that the quality of this proposed correction seems to depend on how smooth is the function ψ. In particular, even using the previous interpretations, the

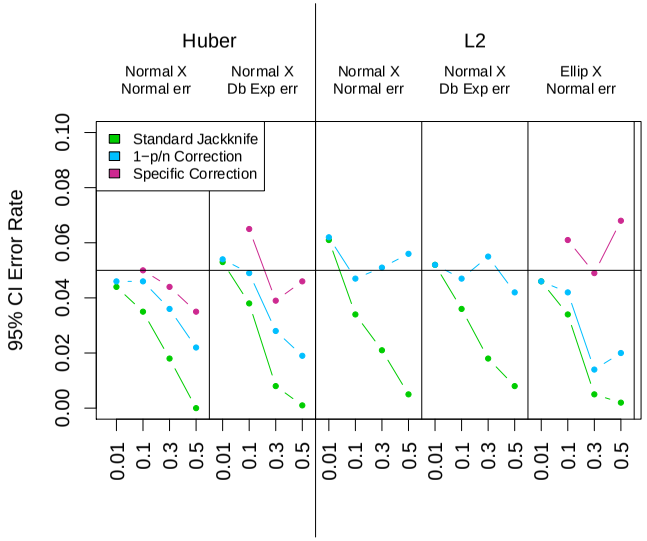

Figure 7: **Rescaling jackknife estimate of variance:** Shown are the error rates for confidence intervals for different re-scalings of the jackknife estimate of variance: the standard jackknife estimate (green); re-scaling using $1-p/n$ as given in Theorem 3 for the L_2 case with normal design matrix X (blue); and re-scaling based on the heuristic in Equation (8) for those settings not covered by the assumptions of Theorem 3 (magenta). The Huber loss in this plot is Huber_1 rather than the default $\mathrm{Huber}_{1.345}$; Huber_1 is further from L_2 than $\mathrm{Huber}_{1.345}$ and therefore better shows the improvement gained by using the heuristic in Equation (8).

correction does not perform well for L_1 (at least for $n = 1000$ and $\kappa = 0.1, 0.3, 0.5$, data not shown) - though as we mentioned Figure 6 shows that jackknifing in L_1-regression is probably not a good idea; see also Koenker (2005, Section 3.9).

We also note that the assumption of cov $(X_i) = \mathrm{Id}_p$ is essential to the jackknife correction proposed in Equation (8). Let $\widehat{\beta}_\rho(\Sigma)$ denotes our estimator of β when cov $(X_i) = \Sigma$. $\hat{\gamma}$ in equation (8) is an estimate of

$$R(\widehat{\beta}_\rho) = \frac{\mathbf{E}\left(var_{JACK}(v'\widehat{\beta}_\rho(\mathrm{Id}_p))\right)}{\mathrm{var}\left(v'\widehat{\beta}_\rho(\mathrm{Id}_p)\right)}.$$

Invariance arguments applied to cov (X_i) can be used to show that when X_i has an elliptical distribution, then $R(\widehat{\beta}_\rho(\mathrm{Id}_p)) = R(\widehat{\beta}_\rho(\Sigma))$ for all convex loss functions ρ (see AppendixH).

However, even though this population quantity is unchanged when $\mathrm{cov}\,(X_i) = \Sigma$ changes, the estimate $\hat{\gamma}$ we give above depends crucially on knowing that $\mathrm{cov}\,(X_i) = \mathrm{Id}_p$ and cannot be used as-is when $\Sigma \neq \mathrm{Id}_p$.

5. Conclusion

In this paper, we have studied various resampling plans in the high-dimensional setting where p/n is not close to zero. One of our main findings is that the two most widely-used and advocated bootstraps will yield either highly conservative or highly anti-conservative confidence intervals. This is in sharp contrast to the low-dimensional setting where p is fixed and $n \to \infty$ or $p/n \to 0$. Under various assumptions underlying our simulations, we explained theoretically the phenomena we were observing in our numerical work.

Beside our theoretical contributions, we propose improved and dimension-adaptive bootstrap methods for both pairs and residual bootstraps, as well as jackknife corrections, that give confidence intervals with approximately correct coverage probability. These methods are novel dimensionality-robust resampling techniques for linear models. The resulting modified pairs bootstrap gives a principled method for pairs bootstrapping regardless of the value of $p/n < 1$, and avoids the problem of non-invertible bootstrapped design matrices X^* that commonly result from the standard pairs bootstrap. The most promising of our proposed resampling schemes is our proposed residual bootstrapping method that resamples from appropriately scaled predicted errors. This bootstrap routine performed well without distribution-specific corrections that some of our other methods require. It has the greatest potential to be a general-purpose bootstrap method for linear models in high dimensions.

This work has focused on estimation of the linear model, where there are theoretical benchmarks. The real practical power of the bootstrap lays in giving the ability to perform inference in complicated settings involving sophisticated statistical procedures for which we do not even begin to have theoretical results for the behavior of our estimators. Yet our work shows that even for the simple case of inference in the linear model and for the simplest inferential question, the two most common and natural resampling techniques perform very poorly in only moderately high-dimensions. More importantly, these two equally intuitive methods have completely divergent statistical behavior with one being extremely conservative and the other anti-conservative. This casts serious doubts about the reliability, interpretability and accuracy of inferential statements made through generic resampling methods in moderate and high dimensions. This is troubling for more complicated problems where resampling techniques are the only inference tools currently available. Our findings also suggest that appropriate resampling methods for high-dimensional problems may not be able to rely on generic resampling procedures but rather need to be tailored to the statistical problem of interest. This raises many interesting new theoretical and methodological questions for the future.

Acknowledgments

Appendices

Notations : in these appendices, we use e_i to denote the i-th residual, i.e., $e_i = y_i - X_i'\widehat{\beta}$. We use $\tilde{e}_{i(i)}$ to denote the i-th prediction error, i.e., $\tilde{e}_{i(i)} = y_i - X_i'\widehat{\beta}_{(i)}$, where $\widehat{\beta}_{(i)}$ is the estimate of $\widehat{\beta}$ with the i-th pair (y_i, X_i) left out. We assume that the linear model holds so that $y_i = X_i'\beta + \epsilon_i$. We assume that the errors ϵ_i are i.i.d with mean 0.

Appendix A. Technical Background on Existing Literature on Robust Regression

Recall that we consider

$$\widehat{\beta}_\rho = \mathrm{argmin}_{u\in\mathbb{R}^p} \sum_{i=1}^n \rho(y_i - X_i'u) \ , \ \text{where } y_i = \epsilon_i + X_i'\beta \ .$$

The ϵ_i's are assumed to be i.i.d with mean 0 here.

A.1 Classical Results and Asymptotic Normality

Least-squares In this case $\rho(x) = x^2/2$ and we have of course

$$\widehat{\beta}_{LS} - \beta = (X'X)^{-1}X'\epsilon \ .$$

Hence,

$$\mathrm{cov}\left(\widehat{\beta}_{LS}\right) = (X'X)^{-1}\mathrm{var}\left(\epsilon\right) \ .$$

Robust regression We recall the classic result of Huber (Huber, 1973) and (Huber and Ronchetti, 2009), Chapter 7: when p is fixed and $n \to \infty$, the limiting covariance of $\widehat{\beta}_\rho$ is, with a slight abuse of notation,

$$\mathrm{cov}\left(\widehat{\beta}_\rho\right) = \frac{1}{n}\left(\frac{X'X}{n}\right)^{-1}\frac{\mathbf{E}\left(\psi^2(\epsilon)\right)}{\left[\mathbf{E}\left(\psi'(\epsilon)\right)\right]^2} \ .$$

See also the papers Portnoy (1984, 1985, 1987); Mammen (1989) for the situation where $p \to \infty$ and $p/n \to 0$ at various rates.

Asymptotic normality questions and impact on confidence intervals: $\boldsymbol{p/n \to 0}$ In the case of least-squares, the Lindeberg-Feller theorem (Stroock, 1993) guarantees that under mild conditions on the $p \times n$ matrix X, the coordinates of $\widehat{\beta}_{LS}$ are asymptotically Normal. Similarly if the $1 \times n$ vector $v'(X'X)^{-1}X'$ satisfy the conditions of the the Lindeberg-Feller theorem, then $v'(\widehat{\beta}_{LS} - \beta)$ is asymptotically normal. Similarly, under mild conditions on X, the classic papers mentioned above guarantee asymptotic normality of the coordinates of $\widehat{\beta}_\rho$ when $p/n \to 0$. In these cases, the width of confidence intervals for the coordinates of β are hence only dependent asymptotically on the variance of the coordinates of $\widehat{\beta}_\rho$.

A.2 Summary of recent results on high-dimensional robust regression

We summarize in this section the key results we use from the recent papers El Karoui et al. (2011); El Karoui et al. (2013); El Karoui (2013, 2017). The third paper is a mathematically rigorous version of the heuristic arguments of the first two; the first paper is the long-form version of the second one. Those papers are concerned with the asymptotic properties of $\widehat{\beta}_\rho$ when $p/n \to \kappa \in (0,1)$. The predictor vectors X_i's are assumed to be random and independent, with $X_i = \lambda_i\Sigma^{1/2}\tilde{X}_i$, where $\tilde{X}_i$ has i.i.d (not necessarily Gaussian) entries with mean 0 and variance 1. λ_i's are independent random variables with $\mathbf{E}\left(\lambda_i^2\right) = 1$. (The

$n \times p$ design matrix X is full rank with probability 1. Σ has only positive eigenvalues.) X_i's are independent of ϵ_i's.

Role of $\mathrm{cov}\,(X_i) = \Sigma$ It is shown in these papers that, if $\widehat{\beta}(\beta;\Sigma)$ is the regression vector corresponding to the situation where $y_i = X_i'\beta + \epsilon_i$ and $\mathrm{cov}\,(X_i) = \Sigma$ for all i,

$$\widehat{\beta}_\rho(\beta;\Sigma) = \beta + \Sigma^{-1/2}\widehat{\beta}(0;\mathrm{Id}_p)\ .$$

This follows from a simple change of variable. It also means that to understand the properties of $\widehat{\beta}_\rho(\beta;\Sigma)$, it is enough to understand the "null case" $\beta = 0$ and $\Sigma = \mathrm{Id}_p$.

Consequence for leave-one-out-predicted errors The result we just mentioned has an important consequence for our leave-one-out predicted error, i.e $\tilde{e}_{i(i)} = y_i - X_i'\widehat{\beta}_{(i)}$: $\tilde{e}_{i(i)}(\beta;\Sigma) = \tilde{e}_{i(i)}(0;\mathrm{Id}_p)$. In other words, we can assume without loss of generality that $\beta = 0$ and $\Sigma = \mathrm{Id}_p$ when working with leave-one-out-predicted errors.

A non-asymptotic and exact stochastic representation in the elliptical case When $X_i \overset{iid}{\backsim} \lambda_i \upsilon_i$, where $\upsilon_i \sim \mathcal{N}(0,\Sigma)$ and λ_i is a random variable independent of υ_i, it is shown that

$$\widehat{\beta}_\rho(\beta;\Sigma) \overset{\mathcal{L}}{=} \beta + \|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2 \Sigma^{-1/2} u\ ,$$

where u is uniformly distributed on the unit sphere in $\mathbb{R}^p$ and $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$ is independent of u. $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$ is simply the norm of $\widehat{\beta}_\rho$ when $\beta = 0$ and $\mathrm{cov}\,(X_i) = \mathrm{Id}_p$. Note that u has the stochastic representation $u \overset{\mathcal{L}}{=} Z_p/\|Z_p\|_2$, where $Z_p \sim \mathcal{N}(0,\mathrm{Id}_p)$.

Consequence of the previous representation for large p Since $\|Z_p\|_2$ has χ_p distribution, it is clear that as $p \to \infty$, if v is a deterministic vector,

$$\sqrt{p}\frac{v'(\widehat{\beta}_\rho(\beta;\Sigma) - \beta)}{\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2} \Longrightarrow \mathcal{N}(0, v'\Sigma^{-1}v)\ ,$$

where $\Longrightarrow$ denotes weak convergence of distributions. Hence, provided $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$ and $v'\Sigma^{-1}v$ remain bounded, $v'\widehat{\beta}_\rho(\beta;\Sigma)$ is $\sqrt{p}$-consistent for $v'\beta$.

Properties of $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$ It is shown, under various technical assumptions, that as p and n tend to infinity with $p/n \to \kappa$, the variance of the random variable $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$ goes to zero. Hence, for practical matters, $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$ can be considered non-random. In particular, that implies that

$$\sqrt{p}v'(\widehat{\beta}_\rho(\beta;\Sigma) - \beta) \text{ is approximately Normal as } p/n \to \kappa\ .$$

Of great importance is the characterization of $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$, since it will affect the width of confidence intervals. It can be characterized, in the case where $\lambda_i = 1$ (see the papers for the case $\lambda_i \neq 1$) in the following way: $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2 \to r_\rho(\kappa)$. The non-random scalar $r_\rho(\kappa)$ can be characterized through a system of two non-linear equations, involving another constant, c. The pair of positive and deterministic scalars $(c, r_\rho(\kappa))$ satisfy: if $\hat{z}_\epsilon = \epsilon + r_\rho(\kappa)Z$, where $Z \sim \mathcal{N}(0,1)$ is independent of ϵ, and ϵ has the same distribution as ϵ_i's:

$$\left\{ \begin{array}{rl} \mathbf{E}\left((\mathrm{prox}(c\rho))'(\hat{z}_\epsilon)\right) & = 1-\kappa\ , \\ \kappa r_\rho^2(\kappa) & = \mathbf{E}\left([\hat{z}_\epsilon - \mathrm{prox}(c\rho)(\hat{z}_\epsilon)]^2\right)\ . \end{array} \right. \tag{9}$$

In this system, $\mathrm{prox}(c\rho)$ refers to Moreau's proximal mapping of the convex function $c\rho$ - see Moreau (1965) or Hiriart-Urruty and Lemaréchal (2001). (The system is rigorously shown in El Karoui (2013) under the assumption that the X_i's have i.i.d entries with mean 0 and variance 1, as well as a few other minor requirements; these assumptions are satisfied when $X_{i,j}$ have a Gaussian distribution, or are bounded, or do not have heavy tails, the latter requiring appeal to various truncation arguments. Another proof of the validity of this system, which first appeared in El Karoui et al. (2011), can be found in Donoho and Montanari (2013). That proof is limited to the case of X_i's having i.i.d Gaussian entries.) The assumptions on ϵ_i's and ρ are relatively mild. See El Karoui (2017) for the latest, handling the situation where ϵ_i's have for instance a Cauchy distribution. We note that some of the results in El Karoui (2013) are stated with ρ strongly convex (and ϵ_i's having many moments). While the proof in that paper suggests several ways of removing this assumption, it is also possible to change ρ in to $\rho + \eta x^2/2$ with η very small (e.g $\eta = 10^{-100}$) to satisfy this technical assumption and change essentially nothing to the statistical problem at hand.

Consequences for the distribution of $\widehat{\beta}_1$ *or other contrasts of interest* In our simulation setup, the previous results imply that the distribution of $\widehat{\beta}_1$ (or any other coordinates or contrasts $v'\widehat{\beta}$ for v deterministic) is asymptotically normal. In the case where $\Sigma = \mathrm{Id}_p$, the variance of $\sqrt{p}(\widehat{\beta}_1 - \beta_1)$ is roughly $\mathcal{N}(0, r_\rho^2(\kappa))$. See Bean et al. (2013) and its supplementary material for a longer discussion and questions related to building confidence intervals.

Asymptotic normality questions and impact on confidence intervals: $\boldsymbol{p/n \to \kappa \in (0,1)}$ Because we know that, in the Gaussian design case, the coordinates of $\widehat{\beta}_\rho$ are asymptotically normal, the width of these intervals is completely determined by the variance of the coordinates of $\widehat{\beta}_\rho$. We explain above how these variances depend on the distribution of ϵ and the loss function ρ: basically through $\|\widehat{\beta}(\rho;\mathrm{Id})\|_2$ and hence $r_\rho(\kappa)$. Therefore, as was the case in the low-dimensional situation, the variance of the coordinates of $\widehat{\beta}_\rho$ can be used as a proxy for the width of the confidence interval in the high-dimensional case where $p/n \to \kappa$, $0 < \kappa < 1$.

In (Bean et al., 2013), these asymptotic normality results are used to create confidence intervals for $v'\beta$ in the Gaussian design case: if $z_{1-\alpha/2}$ is the $(1-\alpha/2)$-quantile of the Gaussian distribution a $100(1-\alpha)\%$ confidence interval for $v'\beta$ is

$$v'\widehat{\beta} \pm \frac{z_{1-\alpha/2}}{\sqrt{p}}\hat{r}\sqrt{(1-p/n)v'\widehat{\Sigma}^{-1}v}\ ,$$

where $\hat{r}$ is a consistent estimator of $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$. In (Bean et al., 2013), it is said without more precision that leave-one-techniques can be used to come up with $\hat{r}$; we propose in the current paper estimates $\hat{r}$ based on leave-one-out predicted errors that can therefore be used for the purpose of building those confidence intervals. (See Section 2.3 in the main paper)

Leave-one-out approximations for $\widehat{\beta}$ It is shown in the aforementioned papers that

$$\widehat{\beta} \simeq \widehat{\beta}_{(i)} + \frac{1}{n}S_i^{-1}X_i\psi(e_i)\ ,$$

where $\simeq$ means that we are neglecting a quantity that is negligible for all our mathematical and statistical purposes (see the papers for very precise bounds on the quantity we are

neglecting). This approximation is the key to the approximations in Equations (3) and (4) which we use in the main paper. Recall that $S_i = \frac{1}{n}\sum_{j\neq i}\psi'(\tilde{e}_{j(i)})X_jX_j'$.

A.3 Consequences for the residual bootstrap

We call $\{\epsilon_i^*\}_{i=1}^n$ the estimated errors used in the residual bootstrap. When doing a residual bootstrap, we are effectively sampling from a model with fixed design X, "true β" taken to be equal to $\widehat{\beta}_\rho$ and i.i.d errors sampled according to the empirical distribution of the $\{\epsilon_i^*\}_{i=1}^n$. As a shortcut, we call this distribution ϵ^* in what follows. We call $\widehat{\beta}_\rho^*$ the bootstrapped version of $\widehat{\beta}$.

Case $\boldsymbol{p/n \to 0}$ Naturally, the classic results mentioned above imply that the distribution of $v'(\widehat{\beta}_\rho^* - \widehat{\beta}_\rho)$ is going to be asymptotically normal (under mild conditions on X that are satisfied in our simulations); the variance of the coordinates of $\widehat{\beta}_\rho^*$, on the other hand depends on $\frac{\mathbf{E}\left(\psi^2(\epsilon^*)\right)}{[\mathbf{E}(\psi'(\epsilon^*))]^2}$. Hence, even if the distribution of the estimated errors ϵ^* is very different from that of the "true" errors, ϵ, the residual bootstrap may work very well: indeed, if ϵ and ϵ^* have two very different distribution but

$$\frac{\mathbf{E}\left(\psi^2(\epsilon^*)\right)}{[\mathbf{E}\left(\psi'(\epsilon^*)\right)]^2} = \frac{\mathbf{E}\left(\psi^2(\epsilon)\right)}{[\mathbf{E}\left(\psi'(\epsilon)\right)]^2},$$

using a residual bootstrap with "the wrong error distribution", ϵ^*, will give us bootstrap confidence intervals of the right width. An important question then becomes, when p/n is small: what class of distributions ϵ^* is such that $\frac{\mathbf{E}\left(\psi^2(\epsilon^*)\right)}{[\mathbf{E}(\psi'(\epsilon^*))]^2} = \frac{\mathbf{E}\left(\psi^2(\epsilon)\right)}{[\mathbf{E}(\psi'(\epsilon))]^2}$, as this class defines all acceptable error distributions from the point of view of our residual bootstrap.

Case $\boldsymbol{p/n \to \kappa \in (0,1)}$ We note that at this point in the case $p/n \to \kappa \in (0,1)$ we are not aware of central limit theorems for the coordinates of $\widehat{\beta}$ that are valid conditional on the design matrix X. However, it is expected that such theorems will hold if the design matrix results from a draw of a random design matrix similar to the ones we consider (with very high-probability with respect to the sampling of the design matrix). The discussions above make then clear that the key quantity to describe the width of the residual bootstrap confidence intervals becomes the risk $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p;\epsilon^*)\|_2$, i.e the risk $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p)\|_2$ when the error distribution is ϵ^*. A "good" error distribution is therefore one for which $r_\rho(\kappa;\epsilon^*) \simeq r_\rho(\kappa;\epsilon)$. (We used the notation $r_\rho(\kappa;\epsilon) = \lim_{n\to\infty}\|\widehat{\beta}_\rho(0;\mathrm{Id}_p;\epsilon)\|$, when $p/n \to \kappa$.)

The case of least squares Let us call $\hat{G}_{n,p}$ the distribution of the errors we use in our residual bootstrap. We assume that $\hat{G}_{n,p}$ has mean 0. Let us call $w' = v'(X'X)^{-1}X'$ - where we choose to not index v and w by p for the sake of clarity. v is a deterministic sequence of p-dimensional vectors. Assume that w and $\hat{G}_{n,p}$ satisfy the conditions of the Linderberg-Feller theorem for triangular arrays, and that $\lim_{n\to\infty}\mathrm{var}\left(\hat{G}_{n,p}\right) = \sigma_\epsilon^2$. Then the Lindeberg-Feller theorem guarantees that

$$\frac{v'(\widehat{\beta}^* - \widehat{\beta})}{\|w\|} \Longrightarrow \mathcal{N}(0,\sigma_\epsilon^2)\ .$$

Note that it also guarantees, under the same assumptions on w that

$$\frac{v'(\widehat{\beta} - \beta)}{\|w\|} \Longrightarrow \mathcal{N}(0,\sigma_\epsilon^2)\ .$$

These results do not depend on the size of κ, the limit of the ratio p/n.

Informally, what this means is that provided that the entries of w are all relatively small, that $\hat{G}_{n,p}$ has mean 0 and var $\left(\hat{G}_{n,p}\right)$ is close to σ_ϵ^2, then bootstrapping from the residuals in least-squares works for approximating the distribution $v'(\widehat{\beta} - \beta)$.

Conclusion for the purposes of the main paper In our discussions we use $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p;\epsilon^*)\|$ and its closeness to its value under the correct error distribution, $\|\widehat{\beta}_\rho(0;\mathrm{Id}_p;\epsilon)\|$, as a proxy to understand a priori the quality of residual bootstrap confidence intervals when using ϵ^* to sample the errors instead of ϵ. The previous discussion explains why we do so. Our numerical work in Section 2.3 of the main text shows numerically that this yields valuable insights. This is why our discussion in Section 2.4 is focused on understanding $\|\widehat{\beta}(0;\mathrm{Id}_p;\epsilon)\|_2$ for various error distributions. In particular, Theorem 1 shows that when p/n is close to 1, if ϵ^* has approximately the same two first moments as ϵ, $\|\widehat{\beta}(0;\mathrm{Id}_p;\epsilon^*)\|/\|\widehat{\beta}(0;\mathrm{Id}_p;\epsilon)\| \simeq 1$. This explains why the scaled $\tilde{r}_{i(i)}$ is probably a good error distribution ϵ^* to use in the residual bootstrap when κ is close to 0 or 1. We note that when κ is close to 1, $\tilde{r}_{i(i)}$ gives an error distribution that is in general very different from the distribution of ϵ. Our numerical work of Section 2.3 shows that it is nonetheless a good error distribution from the point of view of the residual bootstraps we consider.

Appendix B. Deconvolution Bootstrap

In the main text, we considered situations where our predictors X_i are i.i.d with an elliptical distribution and assume for instance that $X_i = \lambda_i\xi_i$, where $\xi_i \sim \mathcal{N}(0,\Sigma)$ and λ_i are i.i.d scalar random variables with $\mathbf{E}\left(\lambda_i^2\right) = 1$. As described in the main text, if X is elliptical, $\tilde{e}_{i(i)}$ is a convolution of the correct G distribution and a Normal distribution,

$$\tilde{e}_{i(i)} \simeq \epsilon_i + \tilde{Z}_i,$$

where

$$\tilde{Z}_i \overset{iid}{\backsim} \mathcal{N}(0,\lambda_i^2\|\widehat{\beta}_{\rho(i)} - \beta\|_2^2)$$

and are independent of ϵ_i.

We proposed in Section 2.3 of the main text an alternative bootstrap method based on using deconvolution techniques to estimate G (Method 1). Specifically, we proposed the following bootstrap procedure:

1. Calculate the predicted errors, $\tilde{e}_{i(i)}$
2. Estimate $|\lambda_i|\|\widehat{\beta}_{\rho(i)} - \beta\|_2$ (the standard deviation of the $\tilde{Z}_i$)
3. Deconvolve in $\tilde{e}_{i(i)}$ the error term ϵ_i from the $\tilde{Z}_i$ term ;
4. Use the resulting estimates of G as the estimate of $\hat{G}$ in residual bootstrapping.

B.1 Estimating $\|\widehat{\beta}_\rho - \beta\|$ and the Variance of the Z_i

Deconvolution methods that deconvolve ϵ from the $\tilde{Z}_i$ require an estimate of the variance of the $\tilde{Z}_i$. Equation (3) gives the variance as $\lambda_i^2\|\widehat{\beta}_{\rho(i)} - \beta\|_2^2$, and we need to estimate this quantity from the data. We use the approximation

$$\|\widehat{\beta}_{\rho(i)} - \beta\|_2 \simeq \|\widehat{\beta}_\rho - \beta\|_2.$$

See AppendixA and references therein for justification of this approximation.

Furthermore, as we note in the main text, in our implementation of this deconvolution in simulations we assume $X \sim \mathcal{N}(0, Id_p)$ so that $\lambda_i = 1$ (see Section B.5 below for estimating λ_i in the elliptical case). This means we are estimating the variance of $\tilde{Z}_i$ as $\|\widehat{\beta} - \beta\|_2^2$ for all i. We estimate this as

$$\widehat{var}(\tilde{Z}_i) = \widehat{var}(\tilde{e}_{i(i)}) - \hat{\sigma}_\epsilon^2,$$

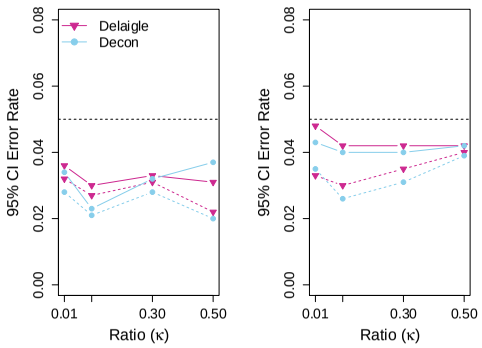
where $\widehat{var}(\tilde{e}_{i(i)})$ is the standard estimate of variance and $\hat{\sigma}_\epsilon^2$ is the estimate of variance from the least squares fit, $\widehat{\sigma}_{\epsilon,LS}^2$, defined in the main text.

In the case where $\widehat{var}(\tilde{e}_{i(i)}) \leq \hat{\sigma}_\epsilon^2$, we do not do a deconvolution, but simply bootstrap from the $\tilde{e}_{i(i)}$. This is generally only the case when p/n is quite small.

B.2 Estimating $\hat{G}$

We used the deconvolution algorithm in the `decon` package in R (Wang and Wang, 2011) to estimate the distribution of ϵ_i. Deconvolution algorithms require selection of a bandwidth in the kernels that make up the functional basis of the estimate. The appropriate bandwidth parameter in deconvolution problems is tied intrinsically to the use of the estimate, with optimal bandwidths depending on what functional of the distribution is wanted (e.g. the pdf versus the cdf). Moreover, the optimal bandwidth depends on the distribution of $\tilde{Z}_i$ with which the signal is being convolved. Ultimately, our procedure resamples from the distribution $\hat{G}$, requiring estimates of $G^{-1}(y)$, and the distribution of $\tilde{Z}_i$ is Gaussian. There is no specific theory for the optimal bandwidth in this setting (though see the work of Hall and Lahiri (2008) for optimal bandwidth selection for estimations of the quantiles of $\hat{G}$ if the $\tilde{Z}_i$ are distributed according to a distribution whose characteristic function decays polynomially at infinity - see Assumption (A.11) on p.2133; this is clearly violated in our case where $\tilde{Z}_i$ are normally distributed.)

We used the bandwidth estimation procedure `bw.dboot2` provided in the package `decon`. Delaigle (2014) outlines problems in the estimation of bandwidth parameter in `decon`; specifically that the implementation in `decon` of existing bandwidth estimation procedures does not match their published descriptions. `bw.dboot2` was not one of the bandwidth procedures with these discrepancies. However, we also compared our results with a bandwidth selected via the bandwidth selection method of Delaigle and Gijbels (2002, 2004) and used the R code implementation provided by the authors on `http://www.ms.unimelb.edu.au/~aurored/links.html#Code`. The two different choices in bandwidth, however, had little effect on the coverage of the bootstrap confidence intervals (Supplemental Figure 8). The results in Figure 2 in the main text make use of the bandwidth parameter of Delaigle and Gijbels (2002, 2004).



(a) L_1 loss (b) Huber loss

Figure 8: **Different bandwidths for Method 1:** We plotted the error rate of 95% confidence intervals for the deconvolution bootstrap (Method 1) using two different choices of bandwith: the bw.dboot2 in `decon` (light blue) or that of Delaigle and Gijbels (2002, 2004) (maroon). The solid lines refer to bootstrapping by drawing $\{\epsilon_i^*\}_{i=1}^n$ as i.i.d draws from $\hat{G}$; the dashed lines refer to $\{\epsilon_i^*\}_{i=1}^n$ drawn from repeated resampling of a single draw $(\{\hat{\epsilon}_i\}_{i=1}^n)$ from $\hat{G}$. See section B.4 below. Note that the y-axis for these plots is different than that shown in the main text.

For both bandwidth selections, we estimated the cdf using the function `DeconCdf` provided in the `decon` package and provided the bandwidth parameters described above. We specified the error distribution as 'Normal' and set the variance of $\tilde{Z}_i$ as described above in Section B.1. The number of grid points for evaluating the cdf (the 'ngrid' argument) was set to be the number needed to get a space of 0.01 across the range of observed $\tilde{e}_{i(i)}$, with a lower bound of 512 grid points (the default of 'ngrid' given by the `DeconCdf` function). Other options were set to the default of `DeconCdf`.

B.3 Random Draws from $\hat{G}$

The end result of the `DeconCdf` function was values of the $\hat{G}$ evaluated at specific grid points x. The resulting $\hat{G}(x)$ was not always guaranteed to be ≤ 1 nor monotonically decreasing; this is likely due to the fact that use of higher-order kernels estimates (which is standard practice in deconvolution literature) does not constrain the estimate be a proper density. Furthermore, the tail ends of the cdf are based on little data and unlikely to be reliable, as well as having problems either non-monotonicity or extending beyond the boundaries of $(0, 1)$. We truncated the left tail of $\hat{G}(x)$ to be within 0.001 by finding the largest such x_0 such that $\hat{G}(x_0) \leq 0.001$ and setting $\hat{G}(x) = 0.001$ for $x \leq x_0$; and we similarly trimmed the right tail based on $1 - 0.001$. We then calculated the differences $d_i = \hat{G}(x_i) - \hat{G}(x_{i-1})$

and for $d_i < 0$ set $d_i = 0$. We then defined a monotone cdf based on the cumulative sum of the d_i,

$$C(x_j) = \sum_{i=1}^{j} d_i.$$

We then renormalized the values $C(x_j)$ so that they extend from 0 to 1, giving the final monotone estimate of $\hat{G}(x_j)$ as

$$\hat{G}(x_j) = \frac{C(x_j) - \min_i C(x_i)}{\max_i C(x_i) - \min_i C(x_i)}$$

To randomly sample from $\hat{G}$, we needed to be able to evaluate $\hat{G}$ for all x. We did this by linearly interpolating between the $\hat{G}(x_j)$ values. In what follows, we consider the values $\hat{G}(x)$ based on this smoothed and monotone version of the original output of the `DeconCdf` function.

We create random draws from $\hat{G}$ by drawing random variables U_i from a $Unif(0,1)$ and calculating $E_i = \hat{G}(U_i)$. We further centered and standardized the draws E_j from $\hat{G}$ to get

$$\epsilon_j^* = (E_j - mean_i(E_j)) \frac{\widehat{\sigma}_{\epsilon,LS}}{\sqrt{\text{var}\,(E_i)}}$$

so that the resulting ϵ_j^* have mean zero and variance $\widehat{\sigma}^2_{\epsilon,LS}$. This was done because the variance of $\hat{G}$ was not guaranteed to have the correct variance, despite the fact we had to pre-specify the variance in the deconvolution call. Ensuring the correct moments of ϵ_j^* was a critical component for reasonable coverage of the bootstrap confidence intervals. When we did not standardize the results and just took the draws from E_j, the resulting bootstrap confidence intervals became more and more conservative as p/n grew. This again highlights the results of Theorem 1 – the variance of $\hat{G}$ is the most important feature of the distribution in order to have accurate confidence intervals.

B.4 Bootstrap Estimates $\widehat{\beta}^*$ from $\hat{G}$

We used $\hat{G}$ to create bootstrap errors, $\{\epsilon_i^*\}_{i=1}^n$ in two ways. For the first method we estimated $\{\epsilon_i^*\}_{i=1}^n$ as i.i.d draws from $\hat{G}$, and repeatedly drew such samples from $\hat{G}$, B times. In the second method, we drew one single estimate $\{\hat{\epsilon}_i\}_{i=1}^n$ as i.i.d draws from $\hat{G}$ and then created $\{\epsilon_i^*\}_{i=1}^n$ from resampling from the empirical distribution of the $\{\hat{\epsilon}_i\}_{i=1}^n$, and repeated this resampling from the empirical distribution of $\{\hat{\epsilon}_i\}_{i=1}^n$ B times. For both methods, we then calculated $\widehat{\beta}^*$ from the data (X_i, y_i^*) where $y_i^* = X_i'\widehat{\beta} + \epsilon_i^*$, as in the standard residual bootstrap. The first method seems to do slightly better in simulations, see Figure 8.

B.5 Estimation of λ_i^2

To extend the deconvolution bootstrapping method to the elliptical case when $p/n \to \kappa \in (0,1)$, one needs to be able to estimate λ_i, at least up to sign. In which case, one could estimate individually the variance of $\tilde{Z}_i$ and feed these individual estimates into the deconvolution method described above.

We recall a simple proposal from the paper (El Karoui, 2010) to solve this problem. Specifically, the author proposes to use

$$\widehat{\lambda_i}^2 = \frac{\|X_i^2\|_2/p}{\frac{1}{p}\text{trace}\left(\widehat{\Sigma}\right)} = \frac{\|X_i\|_2^2}{\frac{1}{n}\sum_{i=1}^n \|X_i\|_2^2},$$

where $\widehat{\Sigma} = \frac{1}{n}\sum_{i=1}^n X_i X_i'$. Under mild conditions on Σ and λ_i, it can be shown that when $n \to \infty$ and $p/n \to \kappa \in (0,\infty)$

$$\sup_{1 \le i \le n} |\lambda_i^2 - \widehat{\lambda_i^2}| \to 0 \text{ in probability.}$$

The intuition and proof are as follows. Concentration of measure arguments (Ledoux, 2001) show that if $\xi_i \sim \mathcal{N}(0,\Sigma)$, $\|\xi_i\|^2/p \simeq \text{trace}\,(\Sigma)/p$ and hence $\|X_i\|^2/p \simeq \lambda_i^2 \text{trace}\,(\Sigma)/p$. The law of large numbers and a little bit of further technical work then imply that $\frac{1}{n}\sum_{i=1}^n \|X_i\|^2/p \simeq \mathbf{E}\left(\lambda_i^2\right)\text{trace}\,(\Sigma)/p = \text{trace}\,(\Sigma)/p$.

Appendix C. Alternative Weight Distributions for Pairs Bootstrap

The formula given in Theorem 2 suggests resampling from a distribution $\hat{F}$ defined using weights other than i.i.d. Poisson(1). An acceptable weight distribution is such that the variance of the resampled estimator is equal to the variance of the sampling distribution of the original estimator. In Section 3.2 we consider the least-squares estimator where the variance, in the case where $\Sigma = \text{Id}_p$ is asymptotically $\kappa/(1-\kappa)\sigma_\epsilon^2/p$.

In the main text, we proposed to use

$$w_i \overset{iid}{\backsim} 1 - \alpha + \alpha\text{Poisson}(1)$$

We determined α numerically so that

$$\left[\kappa \frac{1}{1-\kappa-\mathbf{E}_{w_i}\left[\frac{1}{(1+cw_i)^2}\right]} - \frac{1}{1-\kappa}\right] = \frac{\kappa}{1-\kappa}. \tag{10}$$

This was done via a simple dichotomous search for α over the interval $[0,1]$. Our initial α was .95. We specified a tolerance of 10^{-2} for the results reported in the paper in Table 1. This means that we stopped the algorithm when the ratio of the two terms in Equation (10) was within 1% of 1. We used a sample size of 10^6 to estimate all the expectations. Table 2 gives the values of $\alpha(\kappa)$ found.

C.1 Case $\Sigma \neq \text{Id}_p$

In the case where $\Sigma \neq \text{Id}$, both $\mathbf{E}\left(\text{var}\left(v'\widehat{\beta}^*\right)\right)$ and $\text{var}\left(v'\widehat{\beta}\right)$ depend on $v'\Sigma^{-1}v$. It is therefore natural to ask how we could estimate this quantity. If we are able to do so, it is clear that we could follow the same strategy as above to find α from the data. Standard Wishart results (Mardia et al. (1979), Theorem 3.4.7) give that

$$\frac{v'\Sigma^{-1}v}{v'\widehat{\Sigma}^{-1}v} \sim \frac{\chi^2_{n-p}}{n-1} \to (1-\kappa) \text{in probability.}$$

κ	0.05	0.10	0.15	0.20	0.25
$\alpha(\kappa)$	0.9938	0.9875	0.9812	0.9688	0.9562
κ	0.30	0.35	0.40	0.45	0.50
$\alpha(\kappa)$	0.9426	0.9352	0.9277	0.9222	0.9203

Table 2: Values of $\alpha(\kappa)$ to use to fix the variance estimation issue in high-dimensional pairs-bootstrap

This of course suggests using $(1-p/n)v'\widehat{\Sigma}^{-1}v$ as an estimator of $v'\Sigma^{-1}v$ and solves the question we were discussing above.

However, we note that since

$$\frac{\mathbf{E}\left(\text{var}\left(v'\widehat{\beta}^*\right)\right)}{\text{var}\left(v'\widehat{\beta}\right)}$$

does not depend on Σ when the design is Gaussian or Elliptical, the same α should work regardless of Σ, provided it is positive definite. In particular, an acceptable weight distribution for resampling as defined above could be computed by assuming $\Sigma = \text{Id}_p$ and would work for any positive definite Σ.

Appendix D. Description of Numerics

Here we describe the implementation of various computational numerics used in the paper.

D.1 Simulation Description

In the simulations described in the paper, we explored variations in the distribution of the design matrix X, the error distribution, the loss function, the sample size (n), and the ratio of $\kappa = p/n$, detailed below.

All results in the paper were based upon $1,000$ replications of our simulation routine for each combination of these values. Each simulation consisted of

1. Simulation of data matrix X, $\{\epsilon_i\}_{i=1}^n$ and construction of data $y_i = X'\beta + \epsilon_i$. However, for our simulations, $\beta = 0$ (without loss of generality for the results, which are shift equivariant), so $y_i = \epsilon_i$.

2. Estimate $\hat{\beta}$ using the corresponding loss function. For L_2 this was via the `lm` command in R, for Huber via the `rlm` command in the `MASS` package with default settings ($k = 1.345$) (Venables and Ripley, 2002), and for L_1 via an internal program making use of MOSEK optimization package and accessed in R using the `Rmosek` package (MOSEK, 2014). The internal L_1 program was checked to give the same results as the `rq` function that is part of the R package `quantreg` (Koenker, 2013), but was much faster for simulations.

3. Bootstrapping according to the relevant bootstrap procedure (using the `boot` package) and estimating $\hat{\beta}^*$ for each bootstrap sample. Each bootstrap resampling consisted of $R = 1,000$ bootstrap samples, the minimum generally suggested for 95% confidence intervals (Davison and Hinkley, 1997). For jackknife resampling and for calculating leave-one-out prediction errors $\tilde{e}_{i(i)}$, we wrote an internal function that left out each observation in turn and recalculated $\hat{\beta}_{(i)}$.

4. Construction of confidence intervals for $\hat{\beta}_1$. For bootstrap resampling, we used the function `boot.ci` in the `boot` package to calculate confidence intervals. We calculated "basic", "percentile", "normal", and "BCA" confidence intervals (see help of `boot.ci` and Davison and Hinkley (1997) for details about each of these), but all results shown in the manuscript rely on only the percentile method. The percentile method calculates the boundaries of the confidence intervals as the estimates of 2.5% and 97.5% percentiles of $\hat{\beta}_1^*$ (note that the estimate is not exactly the *observed* 2.5% and 97.5% of $\hat{\beta}_1^*$, since there is a correction term for estimating the percentile, again see Davison and Hinkley (1997)). For the jackknife confidence intervals, the confidence interval calculated was a standard normal confidence interval ($\pm 1.96\sqrt{\widehat{var}_{Jack}(\hat{\beta}_1)}$)

D.2 Values of Simulation Parameters

Design Matrix For the design matrix X, we considered the following designs for the distribution of an element X_{ij} of the matrix X, ensuring that the vectors X_i had covariance Id_p in all cases :

- Normal: X_{ij} are i.i.d $N(0,1)$
- Double Exp: X_{ij} are i.i.d. double exponential with variance 1.
- Elliptical: $X_{ij} \sim \lambda_i Z_{ij}$ where the Z_{ij} are i.i.d $N(0,1)$ and the λ_i are i.i.d according to
  - $\lambda_i \sim Exp(\sqrt{2})$ (i.e. mean $1/\sqrt{2}$), so $\mathbf{E}\left(\lambda_i^2\right) = 1$
  - $\lambda_i \sim N(0,1)$
  - $\lambda_i \sim Unif(\sqrt{\frac{12}{13}}0.5, \sqrt{\frac{12}{13}}1.5)$ so that $\mathbf{E}\left(\lambda_i^2\right) = 1$

Error Distribution We used two different distributions for the i.i.d errors ϵ_i: $N(0,1)$ and standard double exponential (with variance 2).

Dimensions We simulated from $n = 100$, 500, and $1,000$ though we showed only $n = 500$ in our results for simplicity. Except where noted, no significant difference in the results was seen for varying sample size. The ratio κ was simulated at $0.01, 0.1, 0.3, 0.5$.

D.3 Details of Additional Numerics

In Tables A-1 to A-5 in AppendixI we give the precise numerical results from our simulations that are plotted in both the main text and supplementary figures.

Calculating Correction Factors for Jackknife We computed these quantities using the formula we mentioned in the text and Matlab. We solve the associated regression problems with `cvx` (Grant and Boyd, 2014, 2008), running `Mosek` (ApS, 2015) as our optimization

engine. We used $n = 500$ and $1,000$ simulations to compute the mean of the quantities we were interested in.

Relative Risk (Figure 3) In Figure 3 we plot for both Huber loss and L_1 loss the average risk $r_\rho(\kappa; G_{conv})$ (i.e. errors given by G_{conv}) relative to the average risk $r_\rho(\kappa; G)$ (i.e. errors distributed according to G), where G has a double exponential distribution. We also plot the relative average risk $r_\rho(\kappa; G_{norm})$, where $G_{norm} = N(0, \sigma_\epsilon^2)$. The values for Figure 3 were generated with Matlab, using cvx and Mosek, as described above. We picked $n = 500$ and did 500 simulations. p was taken in (5, 10, 30, 50, 75, 100, 125, 150, 175, 200, 225, 250, 275, 300, 350, 400, 450). We used our simulations for the case of the original errors to estimate $\mathbf{E}\left(\|\widehat{\beta} - \beta\|_2\right)$. We used this estimate in our simulation under the convolved error distribution. The Gaussian error simulations were made with $\mathcal{N}(0, 2)$ to match the variance of the double exponential distribution.

Calculation of amount of variance overestimated in pairs bootstrap (Figure 5a)

In Figure 5a, we plot the theoretical factor by which the pairs bootstrap overestimates the actual variance of $\beta_{1\rho}$. This figure was generated by assuming Poisson(1) weights and computing deterministically the expectations of interest. This was easy since if $W \sim$ Poisson(1), $P(W = k) = \frac{\exp(-1)}{k!}$.

We truncated the expansion of the expectation at $K = 100$, so we neglected terms of order 1/100! or lower only. The constant c was found by dichotomous search, with tolerance 10^{-6} for matching the equation $\mathbf{E}\left(1/(1 + Wc)\right) = 1 - p/n$. Once c was found, we approximated the expectation in Theorem 2 in the same fashion as we just described.

Once we had computed the quantity appearing in Theorem 2, we divided it by $\kappa/(1-\kappa)$. We repeated these computations for $\kappa = .05$ to $\kappa = .5$ by increments of 10^{-3} to produce our figure.

Appendix E. Proof of Theorem 1 (Residual bootstrap, p/n close to 1)

Proof

Recall the system describing the asymptotic limit of $\|\widehat{\beta}_\rho - \beta\|$ when $p/n \to \kappa$ and the design matrix has i.i.d mean 0, variance 1 entries, is, under some conditions on ϵ_i's and some mild further conditions on the design (see Section A above): $\|\widehat{\beta}_\rho - \beta\| \to r_\rho(\kappa)$ and the pair of positive and deterministic scalars $(c, r_\rho(\kappa))$ satisfy: if $\hat{z}_\epsilon = \epsilon + r_\rho(\kappa)Z$, where $Z \sim \mathcal{N}(0, 1)$ is independent of ϵ, and ϵ has the same distribution as ϵ_i's:

$$\begin{cases} \mathbf{E}\left((\text{prox}(c\rho))'(\hat{z}_\epsilon)\right) &= 1 - \kappa \ , \\ \kappa r_\rho^2(\kappa) &= \mathbf{E}\left([\hat{z}_\epsilon - \text{prox}(c\rho)(\hat{z}_\epsilon)]^2\right) \ . \end{cases}$$

In this system, prox$(c\rho)$ refers to Moreau's proximal mapping of the convex function $c\rho$ - see Moreau (1965) or Hiriart-Urruty and Lemaréchal (2001).

We first give an informal argument to "guess" the correct values of various quantities of interest, namely c and of course, $r_\rho(\kappa)$.

Note that when $|x| \ll c$, and when $\psi(x) \sim x$ at 0, prox$(c\rho)(x) \simeq \frac{x}{1+c}$. Hence, $x -$ prox$(c\rho)(x) \simeq xc/(1 + c)$. (Note that as long as $\psi(x)$ is linear near 0, we can assume that $\psi(x) \sim x$, since the scaling of ρ by a constant does not affect the performance of the estimators.)

We see that $1 - \kappa \simeq 1/(1 + c)$, so that $c \simeq \kappa/(1 - \kappa)$ - assuming for a moment that we can apply the previous approximations in the system. Hence, we have

$$\kappa r_\rho(\kappa)^2 \simeq (c/(1 + c))^2[r_\rho(\kappa)^2 + \sigma_\epsilon^2] \simeq \kappa^2[r_\rho(\kappa)^2 + \sigma_\epsilon^2] \ .$$

We can therefore conclude (informally at this point) that

$$r_\rho(\kappa)^2 \sim \frac{\sigma_\epsilon^2 \kappa}{1 - \kappa} \sim \frac{\sigma_\epsilon^2}{1 - \kappa} \ .$$

Once these values are guessed, it is easy to verify that $r_\rho(\kappa) \ll c$ and hence all the manipulations above are valid if we plug these two expressions in the system driving the performance of robust regression estimators described above. We note that our argument is not circular: we just described a way to guess the correct result. Once this has been done, we have to make a verification argument to show that our guess was correct.

In this particular case, the verification is done as follows: we can rewrite the expectations as integrals and split the domain of integration into $(-\infty, -s_\kappa)$, $(-s_\kappa, s_\kappa)$, (s_κ, ∞), with $s_\kappa = (1 - \kappa)^{-3/4}$. Using our candidate values for c and $r_\rho(\kappa)$, we see that the corresponding $\widehat{z}_\epsilon$ has extremely low probability of falling outside the interval $(-s_\kappa, s_\kappa)$ - recall that $1 - \kappa \to 0$. Coarse bounding of the integrands outside this interval shows the corresponding contributions to the expectations are negligible at the scales we consider. On the interval $(-s_\kappa, s_\kappa)$, we can on the other hand make the approximations for prox$(c\rho)(x)$ we discussed above and integrate them. That gives us the verification argument we need, after somewhat tedious but simple technical arguments. (Note that the method of propagation of errors in analysis described in (Miller, 2006) works essentially in a similar a-posteriori-verification fashion. Also, s_κ could be picked as $(1 - \kappa)^{-(1/2+\delta)}$ for any $\delta \in (0, 1/2)$ and the arguments would still go through.) ■

Appendix F. Proof of Theorem 2 (Expected Variance of the Pairs Bootstrap Estimator)

In this section, we compute the expected variance of the bootstrap estimator.

We recall that for random variables T, Γ, we have

$$\text{var}\left(T\right) = \text{var}\left(\mathbf{E}\left(T|\Gamma\right)\right) + \mathbf{E}\left(\text{var}\left(T|\Gamma\right)\right) \ .$$

In our case, $T = v'\widehat{\beta}_w$, the projection of the regression estimator $\widehat{\beta}_w$ obtained using the random weights w on the contrast vector v. Γ represents both the design matrix and the errors. We assume without loss of generality that $\|v\|_2 = 1$.

Hence,

$$\text{var}\left(v'\widehat{\beta}_w\right) = \text{var}\left(v'\mathbf{E}\left(\widehat{\beta}_w|\Gamma\right)\right) + \mathbf{E}\left(\text{var}\left(v'\widehat{\beta}_w|\Gamma\right)\right) \ .$$

In plain English, the variance of $v'\widehat{\beta}_w$ is equal to the variance of the bagged estimator plus the expectation of the variance of the bootstrap estimator (where we randomly weight observation (y_i, X_i) with weight w_i).

As explained in Section H, we can study without loss of generality the case where $\Sigma = \mathrm{Id}_p$ and $\beta = 0$. This is what we do in this proof. Further the rotational invariance arguments we give in Section H mean that we can focus on the case $v = e_p$,the p-th canonical basis vector, without loss of generality.

We consider the case where $X_i \overset{iid}{\backsim} \mathcal{N}(0, \mathrm{Id}_p)$. This allows us to work with results in El Karoui et al. (2011); El Karoui et al. (2013), El Karoui (2013).

Notational simplification To make the notation lighter, in what follows in this proof we use the notation $\widehat{\beta}$ for $\widehat{\beta}_w$. There are no ambiguities as we are always using a weighted version of the estimator and hence this simplification should not create any confusion.

In particular, we have, using the derivation of Equation (9) in El Karoui et al. (2013) and noting that in the least-squares case all approximations in that paper are actually exact equalities,

$$\widehat{\beta}_p = \hat{c}\frac{\sum_{i=1}^n w_i X_i(p) e_{i,[p]}}{p} \ .$$

$e_{i,[p]}$ here are the residuals based on the first $p-1$ predictors, when $\beta = 0$. We note that, under our assumptions on X_i's and w_i's, $\hat{c} = \frac{1}{n}\mathrm{trace}\left(S_w^{-1}\right) + \mathrm{o}_{L_2}(1)$, where $S_w = \frac{1}{n}\sum_{i=1}^n w_i X_i X_i'$. It is known from work in random matrix theory (see e.g El Karoui (2009)) that $\frac{1}{n}\mathrm{trace}\left(S_w^{-1}\right)$ is asymptotically deterministic in the situation under investigation with our assumptions on w and X, i.e $\frac{1}{n}\mathrm{trace}\left(S_w^{-1}\right) = c + \mathrm{o}_{L_2}(1)$, where $c = \mathbf{E}\left(\frac{1}{n}\mathrm{trace}\left(S_w^{-1}\right)\right)$.

We also recall the residuals representation from El Karoui et al. (2013), which are exact in the case of least-squares : namely here,

$$\widehat{\beta} - \widehat{\beta}_{(i)} = \frac{w_i}{n} S_i^{-1} X_i \psi(e_i) \ ,$$

which implies that, with $S_i = \frac{1}{n}\sum_{j\neq i} w_j X_j X_j'$,

$$\tilde{e}_{i(i)} = e_i + w_i \frac{X_i' S_i^{-1} X_i}{n}\psi(e_i) \ .$$

In the case of least-squares, $\psi(x) = x$, so that

$$e_i = \frac{\tilde{e}_{i(i)}}{1 + w_i c_i} \ ,$$

where

$$c_i = \frac{X_i' S_i^{-1} X_i}{n} \ .$$

These equalities also follow from simple linear algebra since we are in the least-squares case. We note that $c_i = c + \mathrm{o}_P(1)$, where c is deterministic, as explained in e.g El Karoui (2010), El Karoui (2013). Furthermore, here the approximation holds in L_2 because of our assumptions on w's and existence of moments for the inverse Wishart distribution - see e.g Haff (1979). As explained in El Karoui (2013), the same is true for $c_{i,[p]}$ which is the same quantity computed using the first $(p-1)$ coordinates of X_i, vectors we denote generically by V_i. We can rewrite

$$\widehat{\beta}_p = \hat{c}\frac{\sum_{i=1}^n w_i X_i(p)\frac{\tilde{e}_{i(i),[p]}}{1+w_i c_{i,[p]}}}{p} \ .$$

Let us call $\widehat{b}$ the bagged estimate. We note that $\tilde{e}_{i(i),[p]}$ is independent of w_i and so is $c_{i,[p]}$. We have already seen that $\hat{c}$ is close to a constant, c. So taking expectation with respect to the weights, we have, if $w_{(i)}$ denotes $\{w_j\}_{j\neq i}$, and using independence of the weights,

$$\widehat{b}_p = \frac{1}{p}\sum_{i=1}^n \mathbf{E}_{w_i}\left(\frac{cw_i}{1+cw_i}\right) X_i(p)\mathbf{E}_{w_{(i)}}\left(\tilde{e}_{i(i),[p]}\right)\left[1 + \mathrm{o}_{L_2}(1)\right] \ .$$

Now the last term is of course the prediction error for the bagged problem, i.e

$$\mathbf{E}_{w_{(i)}}\left(\tilde{e}_{i(i),[p]}\right) = \epsilon_i - V_i'(\widehat{g}_{(i)} - \gamma)$$

where $\widehat{g}_{(i)}$ is the bagged estimate of $\hat{\gamma}$ and $\hat{\gamma}$ is the regression vector obtained by regressing y_i on the first $p-1$ coordinates of X_i. (Recall that in these theoretical considerations we are assuming that $\beta = 0$, without loss of generality.)

So we have, since we can work in the null case where $\gamma = 0$ (without loss of generality),

$$\widehat{b}_p = \frac{1}{p}\sum_{i=1}^n \mathbf{E}_{w_i}\left(\frac{cw_i}{1+cw_i}\right) X_i(p)\left[\epsilon_i - V_i'\widehat{g}_{(i)}\right](1 + \mathrm{o}_{L_2}(1)) \ .$$

Hence,

$$\mathbf{E}\left(p\widehat{b}_p^2\right) = \frac{1}{p}\sum_{i=1}^n \left[\mathbf{E}_{w_i}\left(\frac{cw_i}{1+cw_i}\right)\right]^2 (\sigma_\epsilon^2 + \mathbf{E}\left(\|\widehat{g}_{(i)}\|_2^2\right))(1 + \mathrm{o}(1)) \ .$$

Now, in expectation, using e.g El Karoui (2013), $\mathbf{E}\left(\|\widehat{g}_{(i)}\|_2^2\right)(1 + \mathrm{o}(1)) = \mathbf{E}\left(\|\widehat{b}\|_2^2\right) = p\mathbf{E}\left(\widehat{b}_p^2\right)$. The last equality comes from the fact that all coordinates play a symmetric role in this problem, so they are all equal in law.

Now, recall that according to e.g El Karoui et al. (2013), top-right equation on p. 14562, or El Karoui (2010)

$$\frac{1}{n}\sum_{i=1}^n \frac{1}{1+cw_i} = 1 - \frac{p}{n} + \mathrm{o}_{L_2}(1) \ ,$$

since the previous expression effectively relates $\mathrm{trace}\left(D_w X(X' D_w X)^{-1} X'\right)$ to $n-p$, the rank of the corresponding "hat matrix".

Since $\frac{cw_i}{1+cw_i} = 1 - \frac{1}{1+cw_i}$, we see that

$$\mathbf{E}_{w_i}\left(\frac{cw_i}{1+cw_i}\right) = \frac{p}{n} + \mathrm{o}(1) \ .$$

Hence, for the bagged estimate, we have the equation

$$\mathbf{E}\left(\|\widehat{b}\|_2^2\right) = \frac{p}{n}\left(\sigma^2 + \mathbf{E}\left(\|\widehat{b}\|_2^2\right)\right)(1 + \mathrm{o}(1)) \ .$$

We conclude that

$$\mathbf{E}\left(\|\widehat{b}\|_2^2\right) = (1 + \mathrm{o}(1))\frac{\kappa}{1-\kappa}\sigma^2 \ .$$

Note that $\frac{\kappa}{1-\kappa}\sigma^2 = \mathbf{E}\left(\|\widehat{\beta}_{sLS}\|_2^2\right)$, where the latter is the standard (i.e non-weighted) least squares estimator.

We note that the rotational invariance argument given in El Karoui et al. (2011); El Karoui et al. (2013) still apply here, so that we have the

$$\widehat{b} - \beta \stackrel{\mathcal{L}}{=} \|\widehat{b} - \beta\| u \ ,$$

where u is uniform on the sphere and independent of $\|\widehat{b} - \beta\|$ (recall that this simply comes from the fact that if X_i is changed into OX_i, where O is orthogonal, $\widehat{b}$ is changed into $O\widehat{b}$ - and we then apply invariance arguments coming from rotational invariance of the distribution of X_i). Therefore,

$$\mathrm{var}\left(v'(\widehat{b} - \beta)\right) = \frac{\|v\|^2}{p}\mathbf{E}\left(\|\widehat{b} - \beta\|_2^2\right) \ .$$

So we conclude that

$$p\mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}_w|\Gamma\right)\right) = p\mathrm{var}\left(v'\widehat{\beta}_w\right) - \frac{\kappa}{1-\kappa}\sigma^2\|v\|_2^2 + \mathrm{o}(1) \ .$$

Now, the quantity $\mathrm{var}\left(v'\widehat{\beta}_w\right)$ is well understood. The rotational invariance arguments we mentioned before give that

$$\mathrm{var}\left(v'\widehat{\beta}_w\right) = \frac{\|v\|_2^2}{p}\mathbf{E}\left(\|\widehat{\beta}_w - \beta\|_2^2\right) \ .$$

In fact, using the notation D_w for the diagonal matrix with $D_w(i,i) = w_i$, since

$$\widehat{\beta}_w - \beta = (X'D_wX)^{-1}X'D_w\epsilon \ ,$$

we see that

$$\mathbf{E}\left(\|\widehat{\beta}_w - \beta\|_2^2\right) = \sigma_\epsilon^2\mathbf{E}\left(\mathrm{trace}\left((X'D_wX)^{-2}X'D_{w^2}X\right)\right) \ .$$

(Note that under mild conditions on ϵ, X and w, we also have $\|\widehat{\beta}_w - \beta\|_2^2 = \mathbf{E}\left(\|\widehat{\beta}_w - \beta\|_2^2\right) + \mathrm{o}_{L_2}(1)$ - owing to concentration results for quadratic forms of vectors with independent entries; see Ledoux (2001).)

We now need to simplify this quantity.

Analytical simplification of trace $\left((X'D_wX)^{-2}X'D_{w^2}X\right)$ Of course,

$$\mathrm{trace}\left((X'D_wX)^{-2}X'D_{w^2}X\right) = \mathrm{trace}\left(D_wX(X'D_wX)^{-2}X'D_w\right) = \sum_{i=1}^n w_i^2X_i'(X'D_wX)^{-2}X_i \ .$$

Hence, if $\widehat{\Sigma}_w = \frac{1}{n}\sum_{i=1}^n w_iX_iX_i' \triangleq \frac{w_i}{n}X_iX_i' + \widehat{\Sigma}_{(i)}$, we have

$$\mathrm{trace}\left((X'D_wX)^{-2}X'D_{w^2}X\right) = \frac{1}{n}\sum_{i=1}^n w_i^2\frac{X_i'\widehat{\Sigma}^{-2}X_i}{n} \ .$$

Call $\widehat{\Sigma}(z) = \widehat{\Sigma} - z\mathrm{Id}_p$. Using the identity

$$(\widehat{\Sigma} - z\mathrm{Id}_p)(\widehat{\Sigma} - z\mathrm{Id}_p)^{-1} = \mathrm{Id}_p \ ,$$

we see, after taking traces, that (Silverstein (1995))

$$\frac{1}{n}\sum_{i=1}^n w_iX_i'(\widehat{\Sigma} - z\mathrm{Id}_p)^{-1}X_i - z\mathrm{trace}\left((\widehat{\Sigma} - z\mathrm{Id}_p)^{-1}\right) = p \ .$$

We call, for $z \in \mathbb{C}$, $c(z) = \frac{1}{n}\mathrm{trace}\left((\widehat{\Sigma} - z\mathrm{Id}_p)^{-1}\right)$ and $c_i(z) = X_i'(\widehat{\Sigma}_{(i)} - z\mathrm{Id}_p)^{-1}X_i$, provided z is not an eigenvalue of $\widehat{\Sigma}$.

Differentiating with respect to z and taking $z = 0$ (we know here that $\widehat{\Sigma}$ is non-singular with probability 1, so this does not create a problem), we have

$$\frac{1}{n}\sum_{i=1}^n w_iX_i'\widehat{\Sigma}^{-2}X_i - \mathrm{trace}\left(\widehat{\Sigma}^{-1}\right) = 0 \ .$$

Also, since, by the Sherman-Morrison-Woodbury formula (Horn and Johnson (1990)),

$$X_i'\widehat{\Sigma}(z)^{-1}X_i = \frac{X_i'\widehat{\Sigma}_{(i)}(z)^{-1}X_i}{1 + w_i\frac{1}{n}X_i'\widehat{\Sigma}_{(i)}(z)^{-1}X_i} \ ,$$

we have, after differentiating,

$$\frac{1}{n}X_i'\widehat{\Sigma}^{-2}X_i = \frac{c_i'(0)}{[1 + w_ic_i(0)]^2} \ ,$$

where of course $c_i'(0) = X_i'\widehat{\Sigma}_{(i)}^{-2}X_i$. Hence,

$$\frac{1}{n}\sum_{i=1}^n w_i^2\frac{1}{n}X_i'\widehat{\Sigma}^{-2}X_i = \frac{1}{n}\sum_{i=1}^n w_i^2\frac{c_i'(0)}{[1 + w_ic_i(0)]^2} = c'(0)\frac{1}{n}\sum_{i=1}^n\frac{w_i^2}{[1 + w_ic(0)]^2} \ .$$

(Note that the arguments given in e.g El Karoui (2010) or El Karoui and Koesters (2011) for why $c_i(z) = c(z)(1 + \mathrm{o}_P(1))$ extend easily to c_i' and c' given our assumptions on w's and the fact that these functions have simple interpretations in terms of traces of powers of inverses of certain well-behaved - under our assumptions - matrices.)

Going back to

$$\frac{1}{n}\sum_{i=1}^n w_iX_i'(\widehat{\Sigma} - z\mathrm{Id}_p)^{-1}X_i - z\mathrm{trace}\left((\widehat{\Sigma} - z\mathrm{Id}_p)^{-1}\right) = p \ ,$$

and using the previously discussed identity

$$\frac{w_i}{n}X_i'(\widehat{\Sigma} - z\mathrm{Id}_p)^{-1}X_i = 1 - \frac{1}{1 + w_ic_i(z)} \ ,$$

we have

$$n - \sum_{i=1}^n\frac{1}{1 + w_ic_i(z)} - znc(z) = p \ .$$

In other words,

$$1-\kappa=\frac{1}{n}\sum_{i=1}^{n}\frac{1}{1+w_ic_i(z)}+zc(z)\ .$$

Now,

$$\begin{aligned}c(z)\frac{1}{n}\sum_{i=1}^{n}\frac{w_i}{1+w_ic(z)}&=\frac{1}{n}\sum_{i=1}^{n}(1-\frac{1}{1+w_ic(z)})\\&=\frac{1}{n}\sum_{i=1}^{n}(1-\frac{1}{1+w_ic_i(z)})+\eta(z)\\&=\kappa+zc(z)+\eta(z)\ ,\end{aligned}$$

where $\eta(z)$ is such that $\eta(z)=\mathrm{o}_P(1)$ and $\eta'(z)=\mathrm{o}_P(1)$ (η has an explicit expression which allows us to verify these claims). Therefore, by differentiation, and after simplifications,

$$\frac{1}{n}\sum\left[\frac{w_i}{1+w_ic(0)}\right]^2c'(0)=\kappa\frac{c'(0)}{[c(0)]^2}-1+\mathrm{o}_P(1)\ .$$

Hence,

$$\mathrm{trace}\left((X'D_wX)^{-2}X'D_{w^2}X\right)=\left[\kappa\frac{\mathrm{trace}\left(\widehat{\Sigma}_w^{-2}\right)/n}{[\mathrm{trace}\left(\widehat{\Sigma}_w^{-1}\right)/n]^2}-1\right]+\mathrm{o}_P(1)\ .$$

The fact that we can take expectations on both sides of this equation and that $\mathrm{o}_P(1)$ is in fact $\mathrm{o}_{L_2}(1)$ come from our assumptions about w_i's - especially the fact that they are independent and bounded away from 0 - and properties of the inverse Wishart distribution.

Conclusion We can now conclude that a consistent estimator of the expected variance of the bootstrap estimator is

$$\frac{\|v\|_2^2}{p}\sigma_\epsilon^2\left[\kappa\frac{\mathrm{trace}\left(\widehat{\Sigma}_w^{-2}\right)/n}{[\mathrm{trace}\left(\widehat{\Sigma}_w^{-1}\right)/n]^2}-\frac{1}{1-\kappa}\right]\ .$$

Using the fact that

$$1-\kappa=\frac{1}{n}\sum_{i=1}^{n}\frac{1}{1+w_ic(z)}+zc(z)\ ,$$

we see that, since $\frac{1}{n}\mathrm{trace}\left(\widehat{\Sigma}_w^{-2}\right)=c'(0)$,

$$\frac{1}{n}\mathrm{trace}\left(\widehat{\Sigma}_w^{-2}\right)=\frac{c(0)}{\frac{1}{n}\sum_{i=1}^{n}w_i/(1+w_ic(0))^2}\ .$$

We further note that asymptotically, when w_i are i.i.d and satisfy our assumptions, $c(0)\to c$, which solves:

$$\mathbf{E}_{w_i}\left[\frac{1}{1+w_ic}\right]=1-\kappa\ .$$

Hence, asymptotically, when w_i's are i.i.d and satisfy our assumptions, we have

$$\frac{\mathrm{trace}\left(\widehat{\Sigma}_w^{-2}\right)/n}{[\mathrm{trace}\left(\widehat{\Sigma}_w^{-1}\right)/n]^2}\to\frac{1}{c\mathbf{E}_{w_i}[w_i/(1+w_ic)^2]}\ .$$

Since $cw_i/(1+cw_i^2)=1/(1+cw_i)-1/(1+cw_i)^2$, we finally see that

$$\begin{aligned}c\mathbf{E}_{w_i}\left[\frac{w_i}{(1+w_ic)^2}\right]&=\mathbf{E}_{w_i}\left[\frac{1}{1+cw_i}\right]-\mathbf{E}_{w_i}\left[\frac{1}{(1+cw_i)^2}\right]\ ,\\&=1-\kappa-\mathbf{E}_{w_i}\left[\frac{1}{(1+cw_i)^2}\right]\ .\end{aligned}$$

So asymptotically, the expected bootstrap variance is equivalent to, when $\|v\|_2=1$,

$$\frac{\sigma_\epsilon^2}{p}\left[\kappa\frac{1}{1-\kappa-\mathbf{E}\left(\frac{1}{(1+cw_i)^2}\right)}-\frac{1}{1-\kappa}\right]\ ,$$

where $\mathbf{E}\left(\frac{1}{1+cw_i}\right)=1-\kappa$.

In particular, when $w_i=1$, we see, unsurprisingly, that the above quantity is 0, as it should, given that the bootstrapped estimate does not change when resampling.

We finally make note of a technical point, that is addressed in papers such as El Karoui (2010, 2013) and on which we rely here by using those papers. Essentially, theoretical considerations regarding quantities such as $\frac{1}{p}\mathrm{trace}\left(\widehat{\Sigma}_w^{-k}\right)$ are easier to handle by working rather with $\frac{1}{p}\mathrm{trace}\left((\widehat{\Sigma}_w+\tau\mathrm{Id}_p)^{-k}\right)$, for some $\tau>0$. In the present context, it is easy to show (and done in those papers) that this approximation allows us to take the limit - even in expectation - for $\tau\to 0$ in all the expressions we get for $\tau>0$ and that that limit is indeed $\mathbf{E}\left(\frac{1}{p}\mathrm{trace}\left(\widehat{\Sigma}_w^{-k}\right)\right)$. Technical details rely on using the first resolvent identity (Kato, 1995), using moment properties of inverse Wishart distributions and using the fact that w_i's are bounded below.

F.1 Extension: Elliptical Design

In this case, we have $\tilde{X}_i=\lambda_iX_i$, where $X_i\sim\mathcal{N}(0,\mathrm{Id}_p)$ and $y_i=\epsilon_i+\tilde{X}_i'\beta$. We assume $\lambda_i\neq 0$ for all i, $\mathbf{E}\left(\lambda_i^2\right)=1$, λ_i's are i.i.d and bounded away from 0.

We can go through the proof of Theorem 2 and make necessary adjustments.

Of course, we have

$$\mathbf{E}\left(\|\widehat{\beta}_w-\beta\|_2^2\right)=\sigma_\epsilon^2\mathbf{E}\left(\mathrm{trace}\left((\tilde{X}'D_w\tilde{X})^{-2}\tilde{X}'D_{w^2}\tilde{X}\right)\right)\ .$$

If we reformulate this expression in terms of X we get

$$\mathbf{E}\left(\|\widehat{\beta}_w-\beta\|_2^2\right)=\sigma_\epsilon^2\mathbf{E}\left(\mathrm{trace}\left((X'D_{\lambda^2w}X)^{-2}X'D_{\lambda^2w^2}X\right)\right)\ .$$

So this quantity is affected by the distribution of λ_i's; hence the risk of $\widehat{\beta}_w$ is different in the Gaussian and elliptical design case.

The other important part of the proof is the computation of the risk of the bagged estimator. In this case, earlier work in random matrix theory (e.g El Karoui (2009); El Karoui and Koesters (2011)) shows that we can use the approximations

$$c_i \simeq \lambda_i^2 c \, ,$$

where $c = \lim_{n,p\to\infty} \mathbf{E}\left(\frac{1}{n}\text{trace}\left(S^{-1}\right)\right)$, where $S = \frac{1}{n}\sum_{i=1}^n \lambda_i^2 w_i X_i X_i'$, i.e $S = \frac{1}{n}X' D_{\lambda^2 w} X$.

If we call

$$g(\lambda_i^2) = \mathbf{E}_{w_i}\left(\frac{c\lambda_i^2}{1+c\lambda_i^2 w_i}\right) \, ,$$

we see by keeping track of changes in the earlier proof that we have asymptotically

$$\mathbf{E}\left(\|\hat{b}\|_2^2\right) = \frac{\mathbf{E}_{\lambda_i}(\lambda_i^2 g^2(\lambda_i^2))}{\kappa - \mathbf{E}_{\lambda_i}(\lambda_i^4 g^2(\lambda_i^2))}\sigma_\epsilon^2 \, .$$

The same arguments we used before give that

$$\mathbf{E}\left(g(\lambda_i^2)\right) = \kappa \, .$$

Based on this information, we can compute $\mathbf{E}\left(\text{var}\left(v'\widehat{\beta}_w^*\right)\right)$ as we had in the proof of Theorem 2 and compare it to var $\left(v'\widehat{\beta}\right)$. The expressions do not seem to simplify much further however in this case, by contrast to the Gaussian design case where $\lambda_i = 1$ for all i. (For instance, when λ_i=1 for all i's, $g(\lambda_i) = g(1) = \kappa$ and we recover the results of Theorem 2.)

Importantly, the characteristics of the distribution of λ_i that affect $\mathbf{E}\left(\text{var}\left(v'\widehat{\beta}_w^*\right)\right)$ go beyond $\mathbf{E}\left(\lambda_i^2\right)$. And hence the expression we gave in Theorem 2 won't apply directly to the elliptical case.

F.2 Extension: Multinomial$(n, 1/n)$ weights

A natural question is whether the computations we have made can be extended to w_i's that are i.i.d *Poisson*(1) and/or Multinomial$(n, 1/n)$, as in the standard bootstrap.

In both cases, technical issues arise because with asymptotically negligible but non-zero probability, the matrix $X' D_w X$ may be of rank less than p. This can handled in several ways. A simple one is to replace the weights w_i by $w_i(\tau) = \tau + (1-\tau)w_i$ and study the problem when $\tau \to 0$.

Beyond that technicality, an important question is whether one can handle the fact that the weights are dependent in the multinomial case. For quantities of the type $\frac{1}{n}\text{trace}\left((X' D_w X)^{-1}\right)$, it was argued in El Karoui (2010) that one could ignore the dependency issue and treat the problem as if the weights where i.i.d Po(1). This type of arguments would be easy to extend where we need them here, for instance in quantities that arise in the computation of $\mathbf{E}\left(\|\widehat{\beta}_w - \beta\|_2^2\right)$ or to show that we can write $c_i = c + \text{o}_P(1)$, where c is deterministic.

The remaining question is therefore the characterization of the risk of the bagged estimator. We have, with a slight modification with respect to the case of independent weights,

$$\hat{b}_p = \frac{1}{p}\sum_{i=1}^n X_i(p)\left[\mathbf{E}_{w_i}\left(\frac{cw_i}{1+cw_i}\right)\epsilon_i - V_i'\mathbf{E}_w\left(\hat{\gamma}_{(i)}\frac{cw_i}{1+cw_i}\right)\right](1+\text{o}_P(1)) \, .$$

As before, $\mathbf{E}_{w_i}\left(\frac{cw_i}{1+cw_i}\right) = p/n + \text{o}(1)$. The problem is the dependence between $\hat{\gamma}_{(i)}$ and w_i. The rotational invariance arguments we invoked before still hold, so that $\hat{\gamma}_i = \|\hat{\gamma}_{(i)}\|_2 u$, where u is uniform on the unit sphere and independent of $\|\hat{\gamma}_i\|_2$. It is also independent of V_i, since $\hat{\gamma}_{(i)}$ is the leave-one-out estimate of γ. The same rotational invariance arguments hold for the bagged estimate $\mathbf{E}_w \hat{\gamma}_{(i)}\frac{cw_i}{1+cw_i}$. Hence, after a little bit of work we see that

$$\mathbf{E}\left([V_i'\mathbf{E}_w\left(\hat{\gamma}_{(i)}\frac{cw_i}{1+cw_i}\right)]^2\right) = \mathbf{E}\left(\|\mathbf{E}_w\left(\hat{\gamma}_{(i)}\frac{cw_i}{1+cw_i}\right)\|_2^2\right) \, .$$

Using the fact that $w_{(i)}|w_i \sim \text{Multinomial}(n-w_i, 1/(n-1))$, the only real technical hurdle is to show that $\mathbf{E}_{w_i}\hat{\gamma}_{(i)}$ is asymptotically deterministic and independent of w_i. A strategy for this is to create a coupling: one can compare $\hat{\gamma}_{(i)}$ to $\hat{\mathfrak{g}}_{(i)}$, where $\hat{\mathfrak{g}}_{(i)}$ is computed using a $n-1$ dimensional vector of weights with distribution Multinomial$(n-1, 1/(n-1))$ - i.e running $w_i - 1$ multinomial trials after having obtained $w_{(i)}$ (the case $w_i = 0$ is easy to handle separately). Clearly, the distribution of $\hat{\mathfrak{g}}_{(i)}$ is independent of w_i, by construction. On the other hand, a bit of work on top of the leave-one-observation-out expansions shows that $\|\hat{\mathfrak{g}}_{(i)} - \hat{\gamma}_{(i)}\|_2^2$ is roughly of size at most $w_i^2/n \to 0$. Furthermore, $\|\mathbf{E}_w(\hat{\mathfrak{g}}_{(i)}) - \mathbf{E}_w(\hat{\gamma}_{(i)})\|_2 \to 0$ for the same reason. This suggests that further technical work along those lines will give that

$$\mathbf{E}_w\left(\hat{\gamma}_{(i)}\frac{cw_i}{1+cw_i}\right) \simeq \mathbf{E}_w\left(\hat{\gamma}_{(i)}\right)\mathbf{E}_w\left(\frac{cw_i}{1+cw_i}\right) \, ,$$

where $\simeq$ means that the approximation is valid in Euclidean norm. The same coupling arguments will give that

$$\|\mathbf{E}_w\left(\hat{\gamma}_{(i)}\right)\| \simeq \|\hat{b}\| \, ,$$

where $\hat{b}$ is the bagged estimator. This will yield the same results as in the i.i.d Po(1) case.

Numerical results We verified that our theoretical results (i.e Theorem 2) hold for Poisson(1) weights in limited simulations (note that in this case $w_i = 0$ is possible). For Gaussian design matrix, double exponential errors, and ratios $\kappa = .1, .3, .5$ we found that the ratio of the observed bootstrap expected variance of $\widehat{\beta}_1^*$ to our theoretical prediction using Poisson(1) weights was 1.0027, 1.0148, and 1.0252, respectively (here $n = 500$, and there were $R = 1000$ bootstrap resamples for each of 1000 simulations).

Appendix G. Proof of Theorem 3 (Jackknife Variance)

As explained in Section H, we can study without loss of generality the case where $\Sigma = \text{Id}_p$ and $\beta = 0$. This is what we do in this proof.

We study it in details in the least-squares case, and postpone a detailed analysis of the robust regression case to future studies.

According to the approximations in El Karoui et al. (2013), which are exact for least squares, or classic results Weisberg (2014) we have:

$$\widehat{\beta} - \widehat{\beta}_{(i)} = \frac{1}{n}\widehat{\Sigma}_{(i)}^{-1} X_i e_i \ .$$

Recall also that

$$e_i = \frac{\tilde{e}_{i(i)}}{1 + \frac{1}{n} X_i' \widehat{\Sigma}_{(i)}^{-1} X_i} \ .$$

Hence,

$$v'(\widehat{\beta} - \widehat{\beta}_{(i)}) = \frac{1}{n} v' \widehat{\Sigma}_{(i)}^{-1} X_i \frac{\tilde{e}_{i(i)}}{1 + \frac{1}{n} X_i' \widehat{\Sigma}_{(i)}^{-1} X_i} \ .$$

Hence,

$$n \sum_{i=1}^{n} [v'(\widehat{\beta} - \widehat{\beta}_{(i)})]^2 = \frac{1}{n} \sum_{i=1}^{n} \frac{[v' \widehat{\Sigma}_{(i)}^{-1} X_i \tilde{e}_{i(i)}]^2}{[1 + \frac{1}{n} X_i' \widehat{\Sigma}_{(i)}^{-1} X_i]^2} \ .$$

Note that at the denominator, we have

$$\begin{aligned} 1 + \frac{1}{n} X_i' \widehat{\Sigma}_{(i)}^{-1} X_i &= 1 + \frac{1}{n} \text{trace}\left(\widehat{\Sigma}^{-1}\right) + \text{o}_P(1) \ , \\ &= 1 + \frac{p}{n} \frac{1}{1 - p/n} + \text{o}_P(1) = \frac{1}{1 - p/n} + \text{o}_P(1) \ . \end{aligned}$$

by appealing to standard results about concentration of high-dimensional Gaussian random variables, and standard results in random matrix theory and classical multivariate statistics (see Mardia et al. (1979); Haff (1979)). By the same arguments, this approximation works not only for each i but for all $1 \leq i \leq n$ at once. The approximation is also valid in expectation, using results concerning Wishart matrices found for instance in Mardia et al. (1979).

For the numerator, we see that

$$T_i = v' \widehat{\Sigma}_{(i)}^{-1} X_i \tilde{e}_{i(i)} = v' \widehat{\Sigma}_{(i)}^{-1} X_i (\epsilon_i - X_i'(\widehat{\beta}_{(i)} - \beta)) \ .$$

Since ϵ_i is independent of X_i and $\widehat{\Sigma}_{(i)}$, we see that

$$\mathbf{E}\left(T_i^2\right) = \mathbf{E}\left(\epsilon_i^2\right) \mathbf{E}\left((v' \widehat{\Sigma}_{(i)}^{-1} X_i)^2\right) + \mathbf{E}\left([X_i'(\widehat{\beta}_{(i)} - \beta)]^2 [v' \widehat{\Sigma}_{(i)}^{-1} X_i]^2\right) \ .$$

If α and β are fixed vectors, $\alpha' X_i$ and $\beta' X_i$ are Gaussian random variables with covariance $\alpha'\beta$, since we are working under the assumption that $X_i \sim \mathcal{N}(0, \text{Id}_p)$. It is easy to check that if Z_1 and Z_2 are two Gaussian random variables with covariance γ and respective variances σ_1^2 and σ_2^2, we have

$$\mathbf{E}\left((Z_1 Z_2)^2\right) = \sigma_1^2 \sigma_2^2 + 2\gamma^2 \ .$$

We conclude that

$$\mathbf{E}\left((a' X_i)^2 (b' X_i)^2\right) = \|a\|_2^2 \|b\|_2^2 + 2(a'b)^2 \ .$$

We note that

$$\mathbf{E}\left([v' \widehat{\Sigma}_{(i)}^{-1} X_i]^2\right) = \mathbf{E}\left(v' \widehat{\Sigma}_{(i)}^{-2} v\right) \ .$$

Classic Wishart computations give (Haff (1979), p.536 (iii)) that as $n, p \to \infty$,

$$\mathbf{E}\left(\widehat{\Sigma}_{(i)}^{-2}\right) = \left[\frac{1}{(1 - p/n)^3} + \text{o}(1)\right] \text{Id}_p \ .$$

Hence, in our asymptotics,

$$\mathbf{E}\left((v' \widehat{\Sigma}_{(i)}^{-1} X_i)^2\right) \to \frac{1}{(1 - p/n)^3} \|v\|_2^2 \ .$$

We also note that

$$\mathbf{E}_\epsilon\left[(v' \widehat{\Sigma}_{(i)}^{-1} \widehat{\beta}_{(i)})^2\right] = \frac{1}{n} v' \widehat{\Sigma}_{(i)}^{-3} v \ .$$

Hence,

$$\mathbf{E}\left((v' \widehat{\Sigma}_{(i)}^{-1} \widehat{\beta}_{(i)})^2\right) = \text{o}(1) \text{in our asymptotics} \ .$$

Therefore,

$$\mathbf{E}\left(T_1^2\right) = \frac{1}{(1 - p/n)^3} \|v\|_2^2 \sigma_\epsilon^2 (1 + \frac{p/n}{1 - p/n}) + \text{o}(1)$$

since $\mathbf{E}\left(\|\widehat{\beta}_{(i)} - \beta\|_2^2\right) = \sigma_\epsilon^2 \frac{p/n}{1 - p/n} + \text{o}(1)$.

When $v = e_1$, we therefore have

$$\mathbf{E}\left(T_1^2\right) = \sigma_\epsilon^2 \frac{1}{(1 - p/n)^4} + \text{o}(1) \ .$$

Therefore, in that situation,

$$\mathbf{E}\left(n \sum_{i=1}^{n} (v'(\widehat{\beta}_{(i)} - \widehat{\beta})^2)\right) = \sigma_\epsilon^2 \frac{1}{(1 - p/n)^2} + \text{o}(1) \ .$$

In other words,

$$\mathbf{E}\left(\sum_{i=1}^{n} (v'(\widehat{\beta}_{(i)} - \widehat{\beta})^2)\right) = \left[\frac{1}{1 - p/n} + \text{o}(1)\right] \text{var}\left(\widehat{\beta}_1\right)$$

G.1 Dealing with Centering

Let us call $\widehat{\beta}_{(\cdot)} = \frac{1}{n} \sum_{i=1}^{n} \widehat{\beta}_{(i)}$. We have previously studied the properties of $\sum_{i=1}^{n} ([v'(\widehat{\beta} - \widehat{\beta}_{(i)})]^2)$ and now need to show that the same results apply to $\sum_{i=1}^{n} ([v'(\widehat{\beta}_{(\cdot)} - \widehat{\beta}_{(i)})]^2)$.

To show that replacing $\widehat{\beta}$ by $\widehat{\beta}_{(\cdot)}$ does not affect the result, we consider the quantity

$$n^2 [v'(\widehat{\beta} - \widehat{\beta}_{(\cdot)})]^2 \ .$$

Since $\widehat{\beta} - \widehat{\beta}_{(i)} = \frac{1}{n} \widehat{\Sigma}_{(i)}^{-1} X_i e_i$, we have

$$\widehat{\beta} - \widehat{\beta}_{(\cdot)} = \frac{1}{n^2} \sum_{i=1}^{n} \widehat{\Sigma}_{(i)}^{-1} X_i e_i \ .$$

Hence,

$$n^2[v'(\widehat{\beta}-\widehat{\beta}_{(\cdot)})]^2 = \left[\frac{1}{n}\sum_{i=1}^n v'\widehat{\Sigma}_{(i)}^{-1}X_i(\epsilon_i - X_i'(\widehat{\beta}-\beta))\right]^2 .$$

A simple variance computation gives that $\frac{1}{n}\sum_{i=1}^n v'\widehat{\Sigma}_{(i)}^{-1}X_i\epsilon_i \to 0$ in L^2, since each term has mean 0 and the variance of the sum goes to 0.

Recall now that

$$\widehat{\Sigma}^{-1}X_i = \frac{\widehat{\Sigma}_{(i)}^{-1}X_i}{1+c_i} ,$$

where all c_i's are equal to $p/n/(1-p/n)+\mathrm{o}_P(1)$. Let us call $\mathsf{c} = p/n/(1-p/n)$.

We conclude that

$$\frac{1}{n}\sum_{i=1}^n v'\widehat{\Sigma}_{(i)}^{-1}X_iX_i'(\widehat{\beta}-\beta) = v'(\widehat{\beta}-\beta)(1+\mathsf{c}+\mathrm{o}(1)) .$$

When v is given, we clearly have $v'(\widehat{\beta}-\beta) = \mathrm{o}_P(p^{-1/2})$, given the distribution of $\widehat{\beta}-\beta$ under our assumptions on X_i's and ϵ_i's. So we conclude that

$$n^2[v'(\widehat{\beta}-\widehat{\beta}_{(\cdot)})]^2 \to 0 \text{ in probability} .$$

Because we have enough moments, the previous result is also true in expectation.

G.2 Putting Everything Together

The jackknife estimate of variance of $v'\widehat{\beta}$ is up to a factor going to 1

$$\begin{aligned}\frac{n}{n-1}\mathrm{JACK}(\mathrm{var}\left(v'\widehat{\beta}\right)) &= \sum_{i=1}^n [(v'\widehat{\beta}_{(i)}-\widehat{\beta}_{(\cdot)})]^2 \\ &= \sum_{i=1}^n [(v'\widehat{\beta}_{(i)}-\widehat{\beta})]^2 + n[v'(\widehat{\beta}-\widehat{\beta}_{(\cdot)})]^2 .\end{aligned}$$

Our previous analyses therefore imply (using $v=e_1$) that

$$\frac{n}{n-1}\mathbf{E}\left(\mathrm{JACK}(\mathrm{var}\left(\widehat{\beta}_1\right))\right) = \left[\frac{1}{1-p/n}+\mathrm{o}(1)\right]\mathrm{var}\left(\widehat{\beta}_1\right) .$$

This completes the proof of Theorem 3

G.3 Extension: More Involved Designs and Different Loss Functions

Our approach could be used to analyze similar problems in the case of elliptical designs. However, in that case, it seems that the factor that will appear in quantifying the amount by which the variance is mis-estimated will depend in general on the ellipticity parameters. We refer to El Karoui (2013) for computations of quantities such as $v'\widehat{\Sigma}^{-2}v$ in that case, which are of course essential to measuring mis-estimation.

We obtained the possible correction we mentioned in the paper for these more general settings following the ideas used in the rigorous proof we just gave, as well as approximation

arguments given in El Karoui et al. (2013) and justified rigorously in El Karoui (2013). Checking fully rigorously all the approximations we made in this Jackknife computation would require a very large amount of technical work, and since this is tangential to our main interests in this paper, we postpone that to a future work of a more technical nature.

It is also clear, since all these results and the proof we just gave rely on random matrix techniques, that a similar analysis could be carried out in the case where $X_{i,j}$ are i.i.d with a non-Gaussian distribution, provided that distribution has enough moments (see e.g Pajor and Pastur (2009) or El Karoui and Koesters (2011) for examples of such techniques, actually going beyond the case of i.i.d entries for the design matrix). The main issues in carrying out this program seem to be technical and not conceptual at this point, so we leave this problem to possible future work.

Appendix H. Going from $\Sigma = \mathrm{Id}_p$ to $\Sigma \neq \mathrm{Id}_p$

As discussed in Section A, we have

$$\widehat{\beta}_\rho(y_i;X_i;\epsilon_i) - \beta = \Sigma^{-1/2}\widehat{\beta}_\rho(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i) ,$$

In other words, $\widehat{\beta}_\rho(\tilde{y}_i;\Sigma^{-1/2}X_i;\epsilon_i)$ is the robust regression estimator in the null case where $\beta=0$ and X_i is replaced by $\tilde{X}_i = \Sigma^{-1/2}X_i$. Of course, if $\mathrm{cov}\,(X_i)=\Sigma$, $\mathrm{cov}\left(\tilde{X}_i\right) = \mathrm{Id}_p$.

H.1 Consequences for the Jackknife

Naturally the same equality applies to leave-one-out estimators. So, with the notations of Equation (7) in the main text, we have, when $\mathrm{span}(\{X_i\}_{i=1}^n) = \mathbb{R}^p$ and Σ is positive definite,

$$(v'[\widehat{\beta}_{(i)}-\tilde{\beta}])^2 = (v'\Sigma^{-1/2}[\widehat{\beta}_{(i)}(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i) - \tilde{\beta}(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i)])^2 .$$

Let us call $\widehat{\beta}_\rho(\Sigma;\beta)$ our robust regression estimator when $\mathrm{cov}\,(X_i)=\Sigma$ and $\mathbf{E}\,(y_i|X_i) = X_i'\beta$. It is clear from the previous display that the properties of $var_{JACK}(v'\widehat{\beta}_\rho(\Sigma;\beta))$ are the same as those of $var_{JACK}(v'\Sigma^{-1/2}\widehat{\beta}_\rho(\mathrm{Id}_p;0))$. So understanding the null case is enough to understand the general case, which is why we focus on the null case in our computations.

Furthermore, by the same arguments, we have

$$\mathrm{var}\left(v'\widehat{\beta}_\rho(y_i;X_i;\epsilon_i)\right) = \mathrm{var}\left(v'\Sigma^{-1/2}\widehat{\beta}_\rho(\mathrm{Id}_p;0)\right) .$$

So we have

$$\frac{var_{JACK}(v'\widehat{\beta}_\rho(\Sigma;\beta))}{\mathrm{var}\left(v'\widehat{\beta}_\rho(\Sigma;\beta)\right)} = \frac{var_{JACK}(v'\Sigma^{-1/2}\widehat{\beta}_\rho(\mathrm{Id}_p;0))}{\mathrm{var}\left(v'\Sigma^{-1/2}\widehat{\beta}_\rho(\mathrm{Id}_p;0)\right)} .$$

Calling $u_1 = \Sigma^{-1/2}v/\|\Sigma^{-1/2}v\|$, we see that u_1 is a unit vector. And we finally see that

$$\frac{var_{JACK}(v'\widehat{\beta}_\rho(\Sigma;\beta))}{\mathrm{var}\left(v'\widehat{\beta}_\rho(\Sigma;\beta)\right)} = \frac{var_{JACK}(u_1'\widehat{\beta}_\rho(\mathrm{Id}_p;0))}{\mathrm{var}\left(u_1'\widehat{\beta}_\rho(\mathrm{Id}_p;0)\right)} .$$

Hence, characterizing $\frac{var_{JACK}(v'\widehat{\beta}_\rho(\mathrm{Id}_p;0))}{\mathrm{var}(v'\widehat{\beta}_\rho(\mathrm{Id}_p;0))}$ for all fixed unit vectors v characterizes

$$\frac{var_{JACK}(v'\widehat{\beta}_\rho(\Sigma;\beta))}{\mathrm{var}\left(v'\widehat{\beta}_\rho(\Sigma;\beta)\right)}$$

for all β and invertible Σ. This is why our proof is focused on the null case $\Sigma = \mathrm{Id}_p$ and $\beta = 0$.

H.2 Consequences for the Pairs Bootstrap

Let us call D_w the diagonal matrix with (i,i)-entry $D(i,i) = w_i$. We consider only the case where $w_i > 0$, so we do not have to consider the case where fewer than p X_i's are assigned positive weights - which would result in $\widehat{\beta}_\rho$ being ill-defined (since infinitely many solutions would then be feasible).

In particular, for least squares, we have in our setting

$$\widehat{\beta}_w = (X'D_wX)^{-1}X'D_wY = \beta + (X'D_wX)^{-1}X'D_w\epsilon \ .$$

More generally, by a simple change of variables, since $w_i > 0$ and $\mathrm{span}(\{X_i\}_{i=1}^n) = \mathbb{R}^p$, when Σ is invertible,

$$\widehat{\beta}_{w,\rho}(y_i;\{X_i\}_{i=1}^n;\epsilon_i) - \beta = \Sigma^{-1/2}\widehat{\beta}_{w,\rho}(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i) \ .$$

If b_ρ is the corresponding bagged estimate, obtained by averaging $\widehat{\beta}_{w,\rho}$ over w's, we also have

$$b_\rho(y_i;\{X_i\}_{i=1}^n;\epsilon_i) - \beta = \Sigma^{-1/2}b_\rho(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i) \ .$$

Hence, we also have

$$\widehat{\beta}_{w,\rho}(y_i;\{X_i\}_{i=1}^n;\epsilon_i) - b_\rho(y_i;\{X_i\}_{i=1}^n;\epsilon_i) = \Sigma^{-1/2}\left[\widehat{\beta}_{w,\rho}(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i) - b_\rho(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i)\right]$$

We further note that since $y_i = \epsilon_i + X_i'\beta$, $y_i = \epsilon_i + (\Sigma^{-1/2}X_i)'\Sigma^{1/2}\beta$ and hence

$$\widehat{\beta}_{w,\rho}(y_i;\Sigma^{-1/2}X_i;\epsilon_i) = \Sigma^{1/2}\beta + \widehat{\beta}_{w,\rho}(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i) \ .$$

The previous equation clearly implies that, if v is a fixed vector and $u_1 = \Sigma^{-1/2}v$

$$\begin{aligned} &v'(\widehat{\beta}^*_\rho(y_i;\{X_i\}_{i=1}^n;\beta) - b_\rho(y_i;\{X_i\}_{i=1}^n;\beta)) \\ &= u_1'\left[\widehat{\beta}^*_\rho(y_i;\Sigma^{-1/2}X_i;\epsilon_i) - b_\rho(y_i;\Sigma^{-1/2}X_i;\epsilon_i)\right] \ , \\ &= u_1'\left[\widehat{\beta}^*_\rho(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i) - b_\rho(\epsilon_i;\Sigma^{-1/2}X_i;\epsilon_i)\right] \ . \end{aligned}$$

We note that if $\mathrm{cov}\,(X_i) = \Sigma$, the last line in the previous display corresponds to the bootstrap distribution of our estimator in the null case where $\beta = 0$ and $\Sigma = \mathrm{Id}_p$, but v has been replaced by $u_1 = \Sigma^{-1/2}v$. This shows that understanding the bootstrap properties of $v'(\widehat{\beta}^*_\rho - b_\rho)$ in the null case $\mathrm{cov}\,(X_i) = \Sigma$ and $\beta = 0$ gives the result we seek in the general case of $\Sigma \neq \mathrm{Id}_p$ and $\beta \neq 0$. (Here we centered our estimator around the bagged estimator, because it is natural when computing bootstrap variances. The arguments above show that many other centering choices are possible, however.)

The last small issue that one needs to handle is the fact that our computations are done for v with unit norm and u_1 may not have unit norm. This is easily handled by simply scaling by the deterministic $\|u_1\|$. In particular, it is easy to see through simple scaling arguments that

$$\frac{\mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}^*_\rho(\Sigma;\beta)\right)\right)}{\mathrm{var}\left(v'\widehat{\beta}_\rho(\Sigma;\beta)\right)} = \frac{\mathbf{E}\left(\mathrm{var}\left(\tilde{u_1}'\widehat{\beta}^*_\rho(\mathrm{Id}_p;0)\right)\right)}{\mathrm{var}\left(\tilde{u}_1'\widehat{\beta}_\rho(\mathrm{Id}_p;0)\right)} \ ,$$

where $\tilde{u}_1 = u_1/\|u_1\|$ has unit norm.

H.3 Rotational Invariance Arguments and Consequences

Motivated by the arguments in the previous two subsections, we now consider the null case where $\beta = 0$ and $\mathrm{cov}\,(X_i) = \mathrm{Id}_p$. Note that then $y_i = \epsilon_i$. Also, if X_i is replaced by OX_i, where O is an orthogonal matrix, and $\widehat{\beta}$ is replaced by $O\widehat{\beta}$. In other words,

$$\widehat{\beta}_\rho(\epsilon_i;\{OX_i\}_{i=1}^n;\epsilon_i) = O\widehat{\beta}_\rho(\epsilon_i;\{X_i\}_{i=1}^n;\epsilon_i) \ ,.$$

Note that when the design matrix is such that $OX_i \overset{\mathcal{L}}{=} X_i$ for all i (i.e the distribution of X_i's is invariant by rotation),

$$\widehat{\beta}_\rho(\epsilon_i;\{OX_i\}_{i=1}^n;\epsilon_i) \overset{\mathcal{L}}{=} \widehat{\beta}_\rho(\epsilon_i;\{X_i\}_{i=1}^n;\epsilon_i) \ .$$

When $w_i > 0$ for all i, we see that exactly the same arguments apply to $\widehat{\beta}_{w,\rho}(\epsilon_i;\{X_i\}_{i=1}^n;\epsilon_i)$ and hence $\widehat{\beta}^*_\rho(\epsilon_i;\{X_i\}_{i=1}^n;\epsilon_i)$. In particular, for any orthogonal matrix O, since $X_i \overset{\mathcal{L}}{=} OX_i$,

$$\begin{aligned} \mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}^*_\rho(\epsilon_i;\{X_i\}_{i=1}^n;\epsilon_i)\right)\right) &= \mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}^*_\rho(\epsilon_i;\{OX_i\}_{i=1}^n;\epsilon_i)\right)\right) \\ &= \mathbf{E}\left(\mathrm{var}\left(v'O\widehat{\beta}^*_\rho(\epsilon_i;\{X_i\}_{i=1}^n;\epsilon_i)\right)\right) \ . \end{aligned}$$

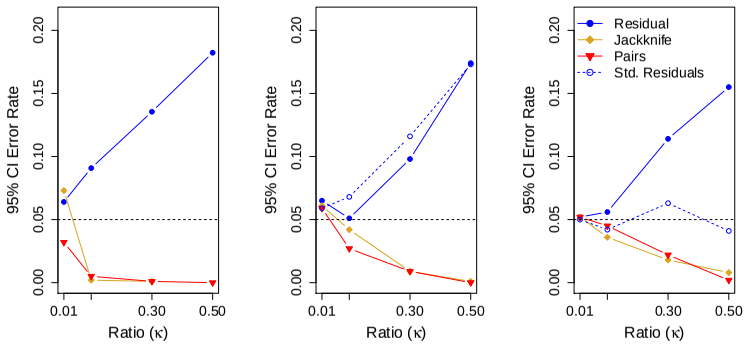
This implies that for any unit vector v, we have, if e_1 is the first canonical basis vector,

$$\mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}^*_\rho(\epsilon_i;X_i;\epsilon_i)\right)\right) = \mathbf{E}\left(\mathrm{var}\left(e_1'\widehat{\beta}^*_\rho(\epsilon_i;X_i;\epsilon_i)\right)\right) \ .$$

Indeed, we just need to take O to be such that $O'v = e_1$ to prove the above result.

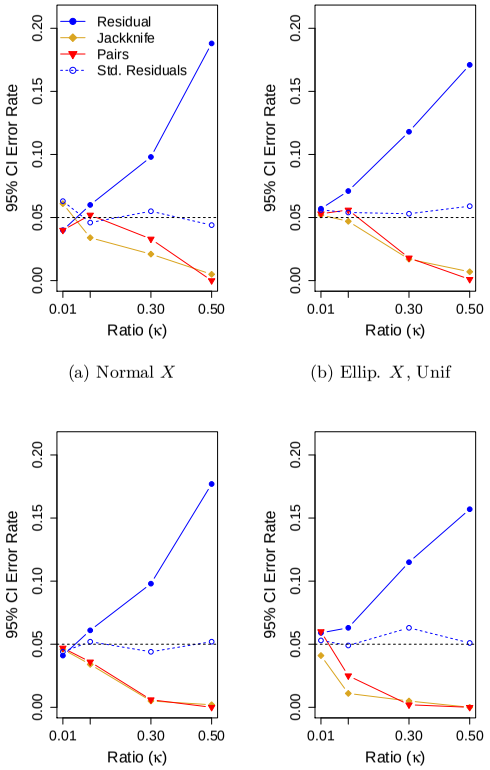
In the case where X_i's are i.i.d $\mathcal{N}(0,\mathrm{Id}_p)$, we do have $X_i \overset{\mathcal{L}}{=} OX_i$, so the arguments above apply. Therefore, to understand $\mathbf{E}\left(\mathrm{var}\left(v'\widehat{\beta}^*_\rho\right)\right)$ in this case it is sufficient to understand $\mathbf{E}\left(\mathrm{var}\left(e_1'\widehat{\beta}^*_\rho\right)\right)$. This latter case is the case tackled in the proof of Theorem 2. (These rotational invariance arguments are closely related to those in El Karoui et al. (2013).)

Appendix I. Supplementary Tables & Figures



(a) L_1 loss (b) Huber loss (c) L_2 loss

Figure A-1: **Performance of 95% confidence intervals of β_1 (double exponential error):** Here we show the coverage error rates for 95% confidence intervals for $n = 500$ with the error distribution being double exponential (with $\sigma^2 = 2$) and i.i.d. normal entries of X. See the caption of Figure 1 for more details.



(a) Normal X (b) Ellip. X, Unif

(c) Ellip. X, $N(0,1)$ (d) Ellip. X, Exp

Figure A-2: **Performance of 95% confidence intervals of β_1 for L_2 loss (elliptical design X):** Here we show the coverage error rates for 95% confidence intervals for $n = 500$ with different distributions of the design matrix X using ordinary least squares regression: (a) $N(0,1)$, (b) elliptical with $\lambda_i \sim U(\sqrt{\frac{12}{13}}0.5, \sqrt{\frac{12}{13}}1.5)$, (c) elliptical with $\lambda_i \sim N(0,1)$, and (d) elliptical with $\lambda_i \sim Exp(\sqrt{2})$. In all of these plots, the error is distributed $N(0,1)$ and the loss is L_2. See the caption of Figure 1 for additional details.

Abstract

In this paper, we study the efficiency of a **R**estarted **S**ub**G**radient (RSG) method that periodically restarts the standard subgradient method (SG). We show that, when applied to a broad class of convex optimization problems, RSG method can find an ϵ-optimal solution with a lower complexity than the SG method. In particular, we first show that RSG can reduce the dependence of SG's iteration complexity on the distance between the initial solution and the optimal set to that between the ϵ-level set and the optimal set multiplied by a logarithmic factor. Moreover, we show the advantages of RSG over SG in solving a broad family of problems that satisfy a local error bound condition, and also demonstrate its advantages for three specific families of convex optimization problems with different power constants in the local error bound condition. (a) For the problems whose epigraph is a polyhedron, RSG is shown to converge linearly. (b) For the problems with local quadratic growth property in the ϵ-sublevel set, RSG has an $O(\frac{1}{\epsilon}\log(\frac{1}{\epsilon}))$ iteration complexity. (c) For the problems that admit a local Kurdyka-Łojasiewicz property with a power constant of $\beta \in [0,1)$, RSG has an $O(\frac{1}{\epsilon^{2\beta}}\log(\frac{1}{\epsilon}))$ iteration complexity. The novelty of our analysis lies at exploiting the lower bound of the first-order optimality residual at the ϵ-level set. It is this novelty that allows us to explore the local properties of functions (e.g., local quadratic growth property, local Kurdyka-Łojasiewicz property, more generally local error bound conditions) to develop the improved convergence of RSG. We also develop a practical variant of RSG enjoying faster convergence than the SG method, which can be run without knowing the involved parameters in the local error bound condition. We demonstrate the effectiveness of the proposed algorithms on several machine learning tasks including regression, classification and matrix completion.

Keywords: subgradient method, improved convergence, local error bound, machine learning

1. Introduction

We consider the following generic optimization problem

$$f_* := \min_{\mathbf{w}\in\Omega} f(\mathbf{w}), \tag{1}$$

where $f : \mathbb{R}^d \to (-\infty, +\infty]$ is an extended-valued, lower semicontinuous and convex function, and $\Omega \subseteq \mathbb{R}^d$ is a closed convex set such that $\Omega \subseteq \mathrm{dom}(f)$. Here, we do not assume the smoothness of f on $\mathrm{dom}(f)$. During the past several decades, many fast (especially linearly convergent) optimization algorithms have been developed for (1) when f is smooth and/or strongly convex. On the contrary, there are relatively fewer techniques for solving generic non-smooth and non-strongly convex optimization problems, which have many applications in machine learning, statistics, computer vision, and etc. To solve (1) with f being potentially non-smooth and non-strongly convex, one of the simplest algorithms to use is the subgradient (SG) [1] method. When f is Lipschitz-continuous, it is known that SG method requires $O(1/\epsilon^2)$ iterations for obtaining an ϵ-optimal solution (Rockafellar, 1970; Nesterov, 2004). It has been shown that this iteration complexity is unimprovable for general non-smooth and non-strongly convex problems in a black-box first-order oracle model of computation (Nemirovsky A.S. and Yudin, 1983). However, better iteration complexity can be achieved by other first-order algorithms for certain classes of f where additional structural information is available (Nesterov, 2005; Gilpin et al., 2012; Freund and Lu, 2017; Renegar, 2014, 2015, 2016).

In this paper, we present a generic restarted subgradient (RSG) method for solving (1) which runs in multiple stages with each stage warm-started by the solution from the previous stage. Within each stage, the standard projected subgradient update is performed for a fixed number of iterations with a constant step size. This step size is reduced geometrically from stage to stage. With these schemes, we show that RSG can achieve a lower iteration complexity than the classical SG method when f belongs to some classes of functions. In particular, we summarize the main results and properties of RSG below:

- For the general problem (1), under mild assumptions (see Assumption 1 and 2), RSG has an iteration complexity of $O(\frac{1}{\epsilon^2}\log(\frac{\epsilon_0}{\epsilon}))$ which has an additional $\log(\frac{\epsilon_0}{\epsilon})$ [2] term but has significantly smaller constant in $O(\cdot)$ compared to SG. In particular, compared with SG whose iteration complexity quadratically depends on the distance from the initial solution to the optimal set, RSG's iteration complexity has a quadratic dependence on the distance from the ϵ-level set to the optimal set, which is much smaller than the distance from the initial solution to the optimal set. Its dependence on the initial solution is through ϵ_0 - a known upper bound of the initial optimality gap, which only scales logarithmically.
- When the epigraph of f over Ω is a polyhedron, RSG can achieve linear convergence, i.e., an $O(\log(\frac{1}{\epsilon}))$ iteration complexity.
- When f is locally quadratically growing (see Definition 10), which is a weaker condition than strong convexity, RSG can achieve an $O(\frac{1}{\epsilon}\log(\frac{1}{\epsilon}))$ iteration complexity.
- When f admits a local Kurdyka-Łojasiewicz property (see Definition 13) with a power desingularizing function of degree $1-\beta$ where $\beta \in [0,1)$, RSG can achieve an $O(\frac{1}{\epsilon^{2\beta}}\log(\frac{1}{\epsilon}))$ complexity.

∗. Correspondence

1. In this paper, we use SG to refer deterministic subgradient method, though it is used in literature for stochastic gradient methods.
2. ϵ_0 is a known upper bound of the initial optimality gap in terms of the objective value.

These results, except for the first one, are derived from a generic complexity of RSG for the problem satisfying a *local error condition* (15), which has a close connection to the existing error bound conditions and growth conditions in the literature (Pang, 1997, 1987; Luo and Tseng, 1993; Necoara et al., 2015; Bolte et al., 2006). In spite of its simplicity, the analysis of RSG provides additional insight on improving first-order methods' iteration complexity via restarting. It is known that restarting can improve the theoretical complexity of (stochastic) SG method for non-smooth problems when strongly convexity is assumed (Ghadimi and Lan, 2013; Chen et al., 2012; Hazan and Kale, 2011) but we show that restarting can be still helpful for SG methods under other (weaker) assumptions. We would like to remark that the key lemma (Lemma 4) developed in this work can be leveraged to develop faster algorithms in different contexts. For example, built on the groundwork laid in this paper, Xu et al. (2016) have developed new smoothing algorithms to improve the convergence of Nesterov's smoothing algorithm (Nesterov, 2005) for non-smooth optimization with a special structure, and Xu et al. (2017) have developed new stochastic subgradient methods to improve the convergence of standard stochastic subgradient method.

We organize the reminder of the paper as follows. Section 2 reviews some related work. Section 3 presents some preliminaries and notations. Section 4 presents the algorithm of RSG and the general theory of convergence. Section 5 considers several classes of non-smooth and non-strongly convex problems and shows the improved iteration complexities of RSG. Section 6 presents parameter-free variants of RSG. Section 8 presents some experimental results. Finally, we conclude in Section 9.

2. Related Work

Smoothness and strong convexity are two key properties of a convex optimization problem that affect the iteration complexity of finding an ϵ-optimal solution by first-order methods. In general, a lower iteration complexity is expected when the problem is either smooth or strongly convex. Recently there has emerged a surge of interest in further accelerating first-order methods for non-strongly convex or non-smooth problems that satisfy some particular conditions (Bach and Moulines, 2013; Wang and Lin, 2014; So and Zhou, 2017; Hou et al., 2013; Zhou et al., 2015; Gong and Ye, 2014; Gilpin et al., 2012; Freund and Lu, 2017). The key condition for us to develop an improved complexity is a local error bound condition (15) which is closely related to the error bound conditions in the literature (Pang, 1987, 1997; Luo and Tseng, 1993; Necoara et al., 2015; Bolte et al., 2006; Zhang, 2016).

Various error bound conditions have been exploited in many studies to analyze the convergence of optimization algorithms. For example, Luo and Tseng (1992a,b, 1993) established the asymptotic linear convergence of a class of feasible descent algorithms for smooth optimization, including coordinate descent method and projected gradient method, based on a local error bound condition. Their results on coordinate descent method were further extended to a more general class of objective functions and constraints by Tseng and Yun (2009a,b). Wang and Lin (2014) showed that a global error bound holds for a family of non-strongly convex and smooth objective functions for which feasible descent methods can achieve a global linear convergence rate. Recently, these error bounds have been generalized and leveraged to show faster convergence for structured convex optimization that consists of a smooth function and a simple non-smooth function (Hou et al., 2013; Zhou and So, 2017; Zhou et al., 2015). Recently, Necoara and Clipici (2016) considered a generalized error bound condition, and established linear convergence of a parallel version of a randomized (block) coordinate descent method for minimizing the sum of a partially separable smooth convex function and a fully separable non-smooth convex function.

We would like to emphasize that the aforementioned error bounds are different from the local error bound explored in this paper. In particular, they bound the distance of a point to the optimal set by using the norm of the projected gradient or proximal gradient at the point, thus requiring the (partial) smoothness of the objective function. In contrast, we bound the distance of a point to the optimal set by its objective residual with respect to the optimal value, covering a much broader family of functions. More recently, there have appeared many studies that consider smooth optimization or composite smooth optimization problems whose objective functions satisfy different error bound conditions, growth conditions or other non-degeneracy conditions and established the linear convergence rates of several first-order methods including proximal-gradient method, accelerated gradient method, prox-linear method and so on (Gong and Ye, 2014; Necoara et al., 2015; Zhang and Cheng, 2015; Zhang, 2016; Karimi et al., 2016; Drusvyatskiy and Lewis, 2018; Drusvyatskiy and Kempton, 2016; Hou et al., 2013; Zhou et al., 2015). The relative strength and relationships between some of those conditions are studied by Necoara et al. (2015) and Zhang (2016). For example, Necoara et al. (2015) showed that under the smoothness assumption the second-order growth condition (i.e., the considered error bound condition in the present work with $\theta = 1/2$) is equivalent to the error bound condition considered by Wang and Lin (2014). It was brought to our attention that the local error bound condition in the present paper is closely related to metric subregularity of subdifferentials (Artacho and Geoffroy, 2008; Kruger, 2015; Drusvyatskiy et al., 2014; Mordukhovich and Ouyang, 2015).

Gilpin et al. (2012) established a polyhedral error bound condition for problems whose epigraph is polyhedral and domain is a bounded polytope. Using this polyhedral error bound condition, they studied a two-person zero-sum game and proposed a restarted first-order method based on Nesterov's smoothing technique (Nesterov, 2005) that can find the Nash equilibrium and has linear convergence rate. The differences between Gilpin et al. (2012)'s work and this work are: (i) we study subgradient methods instead of Nesterov's smoothing technique, where the former have broader applicability than Nesterov's smoothing technique; (ii) our linear convergence can be derived for a slightly general problem where the domain is allowed to be an unbounded polyhedron as long as the polyhedral error bound condition in Lemma 8 holds, which is the case for many important applications; (iii) we consider a general condition that subsumes the polyhedral error bound condition as a special case and we try to solve the general problem (1) rather than the bilinear saddle-point problem considered by Gilpin et al. (2012).

The error bound condition that allows us to derive a linear convergence of RSG is the same to the weak sharp minimum condition, which was first coined in 1970s (Polyak, 1979). However, it was used even earlier for studying the convergence of subgradient method (Eremin, 1965; Polyak, 1969). Later, it was studied in many subsequent works (Polyak, 1987; Burke and Ferris., 1993; Studniarski and Ward, 1999; Ferris, 1991; Burke and Deng, 2002, 2005, 2009). Finite or linear convergence of several algorithms has been established under the weak sharp minimum condition, including gradient projection method (Polyak, 1987), the proximal point algorithm (PPA) (Ferris, 1991), and subgradient method with a

particular choice of step size (see below) (Polyak, 1969). We would like to emphasize the differences between the results in these works and the results in the present work that make our results novel: (i) the gradient projection method and its finite convergence established in (Polyak, 1987) requires the gradient of the objective function to be Lipschitz continuous, i.e., the objective function is smooth (see Polyak, 1987, Chap. 7, pp 207, Theorem 1), in contrast we do not assume smoothness of the objective function; (ii) the PPA studied in (Ferris, 1991) requires solving a proximal sub-problem consisting of the original objective function and a strongly convex function at every iteration, and therefore its finite convergence does not mean that only a finite number of subgradient evaluations is needed. In contrast, the linear convergence in this paper was in terms of the number of subgradient evaluations; (iii) linear convergence of a subgradient method studied by Polyak (1969) requires knowing the optimal objective value for setting its step size, and its convergence is in terms of the distance of the iterates to the optimal set, which is weaker than our linear convergence in terms of objective gap. In addition, our method does not require knowing the optimal objective value. Instead the basic variant of RSG that has a linear convergence only needs to know the value of the multiplicative constant parameter in the local error bound condition. For problems without knowing this parameter, we also develop a practical variant of RSG that can achieve a convergence rate close to linear convergence.

In his recent work (Renegar, 2014, 2015, 2016), Renegar presented a framework of applying first-order methods to general conic optimization problems by transforming the original problem into an equivalent convex optimization problem with only linear equality constraints and a Lipschitz-continuous objective function. This framework greatly extends the applicability of first-order methods to the problems with general linear inequality constraints and leads to new algorithms and new iteration complexity. One of his results related to this work implies (Renegar, 2015, Corollary 3.4), if the objective function has a polyhedral epigraph and the optimal objective value is known beforehand, a subgradient method can have a linear convergence rate. Compared to this result of his, our method does not need to know the optimal objective value. Note that Renegar's method can be applied in a general setting where the objective function is not necessarily polyhedral while our method obtains improved iteration complexities under the local error bound conditions.

More recently, Freund and Lu (2017) proposed a new SG method by assuming that a strict lower bound of f_*, denoted by f_{slb}, is known and f satisfies a growth condition, $\|\mathbf{w} - \mathbf{w}^*\|_2 \leq \mathcal{G} \cdot (f(\mathbf{w}) - f_{slb})$, where $\mathbf{w}^*$ is the optimal solution closest to $\mathbf{w}$ and $\mathcal{G}$ is a growth rate constant depending on f_{slb}. Using a novel step size that incorporates f_{slb}, for non-smooth optimization, their SG method achieves an iteration complexity of $O(\mathcal{G}^2(\frac{\log H}{\epsilon'} + \frac{1}{\epsilon'^2}))$ for finding a solution $\hat{\mathbf{w}}$ such that $f(\hat{\mathbf{w}}) - f_* \leq \epsilon'(f_* - f_{slb})$, where $H = \frac{f(\mathbf{w}_0) - f_{slb}}{f_* - f_{slb}}$ and $\mathbf{w}_0$ is the initial solution. We note that there are several key differences in the theoretical properties and implementations between our work and that by Freund and Lu (2017): (i) Their growth condition has a similar form to the inequality (7) proved for a general function but there are still noticeable differences in the both sides and the growth constants. (ii) The convergence results established by Freund and Lu (2017) are based on finding an solution $\hat{\mathbf{w}}$ with a relative error of ϵ' while we consider absolute error. (iii) By rewriting the convergence results of Freund and Lu (2017) in terms of absolute accuracy ϵ with $\epsilon = \epsilon'(f_* - f_{slb})$, their algorithm's complexity depends on $f_* - f_{slb}$ and may be higher than ours if $f_* - f_{slb}$ is large. However, Freund and Lu's new SG method is still attractive due to that it is a parameter free algorithm without requiring the value of the growth constant $\mathcal{G}$. We will compared our RSG method with the method of Freund and Lu (2017) with more details in Section 7.

Restarting and multi-stage strategies have been employed to achieve the (uniformly) optimal theoretical complexity of (stochastic) SG methods when f is strongly convex (Ghadimi and Lan, 2013; Chen et al., 2012; Hazan and Kale, 2011) or uniformly convex (Juditsky and Nesterov, 2014). Here, we show that restarting can be still helpful even without uniform or strong convexity. Furthermore, in all the algorithms proposed in existing works (Ghadimi and Lan, 2013; Chen et al., 2012; Hazan and Kale, 2011; Juditsky and Nesterov, 2014), the number of iterations per stage increases between stages while our algorithm uses the same number of iterations in all stages. This provides a different possibility of designing restarted algorithms for a better complexity only under a local error bound condition.

3. Preliminaries

In this section, we define some notations used in this paper and present the main assumptions needed to establish our results. We use $\partial f(\mathbf{w})$ to denote the set of subgradients (the subdifferential) of f at $\mathbf{w}$. Since the objective function is not necessarily strongly convex, the optimal solution is not necessarily unique. We denote by Ω_* the optimal solution set and by f_* the unique optimal objective value. We denote by $\|\cdot\|_2$ the Euclidean norm in $\mathbb{R}^d$.

Throughout the paper, we make the following assumption.

Assumption 1 *For the convex minimization problem (1), we assume*

- **a.** *For any $\mathbf{w}_0 \in \Omega$, we know a constant $\epsilon_0 \geq 0$ such that $f(\mathbf{w}_0) - f_* \leq \epsilon_0$.*
- **b.** *There exists a constant G such that $\max_{\mathbf{v} \in \partial f(\mathbf{w})} \|\mathbf{v}\|_2 \leq G$ for any $\mathbf{w} \in \Omega$.*

We make several remarks about the above assumptions: (i) Assumption 1.a is equivalent to assuming we know a lower bound of f_* which is one of the assumptions made by Freund and Lu (2017). In machine learning applications, f_* is usually bounded below by zero, i.e., $f_* \geq 0$, so that $\epsilon_0 = f(\mathbf{w}_0)$ for any $\mathbf{w}_0 \in \mathbb{R}^d$ will satisfy the condition; (ii) Assumption 1.b is a standard assumption also made in many previous subgradient-based methods.

Let $\mathbf{w}^*$ denote the closest optimal solution in Ω_* to $\mathbf{w}$ measured in terms of norm $\|\cdot\|_2$, i.e.,

$$\mathbf{w}^* := \arg\min_{\mathbf{u} \in \Omega_*} \|\mathbf{u} - \mathbf{w}\|_2^2.$$

Note that $\mathbf{w}^*$ is uniquely defined for any $\mathbf{w}$ due to the convexity of Ω_* and that $\|\cdot\|_2^2$ is strongly convex. We denote by $\mathcal{L}_\epsilon$ the ϵ-level set of $f(\mathbf{w})$ and by $\mathcal{S}_\epsilon$ the ϵ-sublevel set of $f(\mathbf{w})$, respectively, i.e.,

$$\mathcal{L}_\epsilon := \{\mathbf{w} \in \Omega : f(\mathbf{w}) = f_* + \epsilon\} \quad \text{and} \quad \mathcal{S}_\epsilon := \{\mathbf{w} \in \Omega : f(\mathbf{w}) \leq f_* + \epsilon\}. \tag{2}$$

Let B_ϵ be the maximum distance between the points in the ϵ-level set $\mathcal{L}_\epsilon$ and the optimal set Ω_*, i.e.,

$$B_\epsilon := \max_{\mathbf{w} \in \mathcal{L}_\epsilon} \min_{\mathbf{u} \in \Omega_*} \|\mathbf{w} - \mathbf{u}\|_2 = \max_{\mathbf{w} \in \mathcal{L}_\epsilon} \|\mathbf{w} - \mathbf{w}^*\|_2. \tag{3}$$

In the sequel, we also make the following assumption.

Assumption 2 *For the convex minimization problem (1), we assume that B_ϵ is finite.*

Remark: B_ϵ is finite when the optimal set Ω_* is bounded (e.g., when the objective function is a proper lower-semicontinuous convex and coercive function). This is because that the sublevel set $\mathcal{S}_\epsilon$ must be bounded for any $\epsilon \geq 0$ (Rockafellar, 1970, Corollary 8.7.1). Nevertheless, the bounded optimal set is not a necessary condition for a finite B_ϵ. For example, $f(x) = \max(0, x)$. Although its optimal set is not bounded, $B_\epsilon = \epsilon$. In Section 5, we will consider a broad family of problems with a local error bound condition, which will satisfy the above assumption.

Let $\mathbf{w}_\epsilon^\dagger$ denote the closest point in the ϵ-sublevel set to $\mathbf{w}$, i.e.,

$$\mathbf{w}_\epsilon^\dagger := \arg\min_{\mathbf{u}\in\mathcal{S}_\epsilon} \|\mathbf{u} - \mathbf{w}\|_2^2. \tag{4}$$

Denote by $\Omega\backslash\mathcal{S} = \{\mathbf{w} \in \Omega : \mathbf{w} \notin \mathcal{S}\}$. It is easy to show that $\mathbf{w}_\epsilon^\dagger \in \mathcal{L}_\epsilon$ when $\mathbf{w} \in \Omega\backslash\mathcal{S}_\epsilon$ (using the optimality condition of 4).

Given $\mathbf{w} \in \Omega$, we denote the normal cone of Ω at $\mathbf{w}$ by $\mathcal{N}_\Omega(\mathbf{w})$. Formally, $\mathcal{N}_\Omega(\mathbf{w}) = \{\mathbf{v} \in \mathbb{R}^d : \mathbf{v}^\top(\mathbf{u} - \mathbf{w}) \leq 0, \forall \mathbf{u} \in \Omega\}$. Define $\text{dist}(0, f(\mathbf{w}) + \mathcal{N}_\Omega(\mathbf{w}))$ as

$$\text{dist}(0, f(\mathbf{w}) + \mathcal{N}_\Omega(\mathbf{w})) := \min_{\mathbf{g}\in\partial f(\mathbf{w}), \mathbf{v}\in\mathcal{N}_\Omega(\mathbf{w})} \|\mathbf{g} + \mathbf{v}\|_2. \tag{5}$$

Note that $\mathbf{w} \in \Omega_*$ if and only if $\text{dist}(0, f(\mathbf{w}) + \mathcal{N}_\Omega(\mathbf{w})) = 0$. Therefore, we call $\text{dist}(0, f(\mathbf{w}) + \mathcal{N}_\Omega(\mathbf{w}))$ the *first-order optimality residual* of (1) at $\mathbf{w} \in \Omega$. Given any $\epsilon > 0$ such that $\mathcal{L}_\epsilon \neq \emptyset$, we define a constant ρ_ϵ as

$$\rho_\epsilon := \min_{\mathbf{w}\in\mathcal{L}_\epsilon} \text{dist}(0, f(\mathbf{w}) + \mathcal{N}_\Omega(\mathbf{w})). \tag{6}$$

Given the notations above, we provide the following lemma which is the key to our analysis.

Lemma 1 *For any $\epsilon > 0$ such that $\mathcal{L}_\epsilon \neq \emptyset$ and any $\mathbf{w} \in \Omega$, we have*

$$\|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2 \leq \frac{1}{\rho_\epsilon}(f(\mathbf{w}) - f(\mathbf{w}_\epsilon^\dagger)). \tag{7}$$

Proof Since the conclusion holds trivially if $\mathbf{w} \in \mathcal{S}_\epsilon$ (so that $\mathbf{w}_\epsilon^\dagger = \mathbf{w}$), we assume $\mathbf{w} \in \Omega\backslash\mathcal{S}_\epsilon$. According to the first-order optimality conditions of (4), there exist a scalar $\zeta \geq 0$ (the Lagrangian multiplier of the constraint $f(\mathbf{u}) \leq f_* + \epsilon$ in 4), a subgradient $\mathbf{g} \in \partial f(\mathbf{w}_\epsilon^\dagger)$ and a vector $\mathbf{v} \in \mathcal{N}_\Omega(\mathbf{w}_\epsilon^\dagger)$ such that

$$\mathbf{w}_\epsilon^\dagger - \mathbf{w} + \zeta\mathbf{g} + \mathbf{v} = 0. \tag{8}$$

The definition of normal cone leads to $(\mathbf{w}_\epsilon^\dagger - \mathbf{w})^\top\mathbf{v} \geq 0$. This inequality and the convexity of $f(\cdot)$ imply

$$\zeta\left(f(\mathbf{w}) - f(\mathbf{w}_\epsilon^\dagger)\right) \geq \zeta(\mathbf{w} - \mathbf{w}_\epsilon^\dagger)^\top\mathbf{g} \geq (\mathbf{w} - \mathbf{w}_\epsilon^\dagger)^\top(\zeta\mathbf{g} + \mathbf{v}) = \|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2^2,$$

where the equality is due to (8). Since $\mathbf{w} \in \Omega\backslash\mathcal{S}_\epsilon$, we must have $\|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2 > 0$ so that $\zeta > 0$. Therefore, $\mathbf{w}_\epsilon^\dagger \in \mathcal{L}_\epsilon$ by complementary slackness. Dividing the inequality above by ζ gives

$$f(\mathbf{w}) - f(\mathbf{w}_\epsilon^\dagger) \geq \frac{\|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2^2}{\zeta} = \|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2\|\mathbf{g} + \mathbf{v}/\zeta\|_2 \geq \rho_\epsilon\|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2, \tag{9}$$

where the equality is due to (8) and the last inequality is due to the definition of ρ_ϵ in (6). The lemma is then proved. ■

The inequality in (7) is the key to achieve improved convergence by RSG, which hinges on the condition that the first-order optimality residual on the ϵ-level set is lower bounded. It is important to note that (i) the above result depends on f rather than the optimization algorithm applied; and (ii) the above result can be generalized to using other norms such as the p-norm $\|\mathbf{w}\|_p$ ($p \in (1, 2]$) to measure the distance between $\mathbf{w}$ and $\mathbf{w}_\epsilon^\dagger$ and using the corresponding dual norm to define the lower bound of the residual in (5) and (6). This generalization allows one to design mirror decent (Nemirovski et al., 2009) variant of RSG. To our best knowledge, this is the first work that leverages the lower bound of the optimal residual to improve the convergence for non-smooth convex optimization.

In the next several sections, we will exhibit the value of ρ_ϵ for different classes of problems and discuss its impact on the convergence. In the sequel, we abuse the Big O notation $T = O(h(\epsilon))$ to mean that there exists a constant $C > 0$ independent of ϵ such that $T \leq Ch(\epsilon)$.

4. Restarted SubGradient (RSG) Method and Its Generic Complexity for General Problem

In this section, we present a framework of restarted subgradient (RSG) method and prove its general convergence result using Lemma 1. It will be noticed that the algorithmic results developed in this section is less interesting from the viewpoint of practice. However, it will exhibit the insights for the improvements and provide the template for the developments in next several sections, where we will present improved convergence of RSG for problems of different classes.

The steps of RSG are presented in Algorithm 2 where SG is a subroutine of projected subgradient method given in Algorithm 1 and $\Pi_\Omega[\mathbf{w}]$ is defined as

$$\Pi_\Omega[\mathbf{w}] = \arg\min_{\mathbf{u}\in\Omega} \|\mathbf{u} - \mathbf{w}\|_2^2.$$

The values of K and t in RSG will be revealed later for proving the convergence of RSG to an 2ϵ-optimal solution. The number of iterations t is the only varying parameter in RSG that depends on the classes of problems. The parameter α could be any value larger than 1 (e.g., 2) and it only has a small influence on the iteration complexity.

We emphasize that (i) RSG is a generic algorithm that is applicable to a broad family of non-smooth and/or non-strongly convex problems without changing updating schemes except for one tuning parameter, the number of iterations per stage, whose best value varies with problems; (ii) RSG has different variants with different subroutines in stages. In

Algorithm 1 SG: $\widehat{\mathbf{w}}_T = \mathrm{SG}(\mathbf{w}_1, \eta, T)$

1: **Input**: a step size η, the number of iterations T, and the initial solution $\mathbf{w}_1 \in \Omega$
2: **for** $\tau = 1, \ldots, T$ **do**
3: Query the subgradient oracle to obtain $\mathcal{G}(\mathbf{w}_\tau) \in \partial f(\mathbf{w}_\tau)$
4: Update $\mathbf{w}_{\tau+1} = \Pi_\Omega[\mathbf{w}_\tau - \eta \mathcal{G}(\mathbf{w}_\tau)]$
5: **end for**
6: **Output**: $\widehat{\mathbf{w}}_T = \sum_{\tau=1}^T \frac{\mathbf{w}_\tau}{T}$

Algorithm 2 RSG: $\mathbf{w}_K = \mathrm{RSG}(\mathbf{w}_0, K, t, \alpha)$

1: **Input**: the number of stages K and the number of iterations t per-stage, $\mathbf{w}_0 \in \Omega$, and $\alpha > 1$.
2: Set $\eta_1 = \epsilon_0/(\alpha G^2)$, where ϵ_0 is from Assumption 1.a
3: **for** $k = 1, \ldots, K$ **do**
4: Call subroutine SG to obtain $\mathbf{w}_k = \mathrm{SG}(\mathbf{w}_{k-1}, \eta_k, t)$
5: Set $\eta_{k+1} = \eta_k/\alpha$
6: **end for**
7: **Output**: $\mathbf{w}_K$

fact, we can use other optimization algorithms than SG as the subroutine in Algorithm 2, as long as a similar convergence result to Lemma 2 is guaranteed. Examples include dual averaging (Nesterov, 2009) and the regularized dual averaging (Chen et al., 2012) in the non-Euclidean space. In the following discussions, we will focus on using SG as the subroutine.

Next, we establish the convergence of RSG. It relies on the convergence result of the SG subroutine which is given in the lemma below.

Lemma 2 *(Zinkevich, 2003; Nesterov, 2004) If Algorithm 1 runs for T iterations, we have, for any $\mathbf{w} \in \Omega$,*

$$f(\widehat{\mathbf{w}}_T) - f(\mathbf{w}) \leq \frac{G^2\eta}{2} + \frac{\|\mathbf{w}_1 - \mathbf{w}\|_2^2}{2\eta T}.$$

We omit the proof because it follows a standard analysis and can be found in cited papers. With the above lemma, we can prove the following convergence of RSG.

Theorem 3 *Suppose Assumption 1 and 2 holds. If $t \geq \frac{\alpha^2 G^2}{\rho_\epsilon^2}$ and $K = \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil$ in Algorithm 2, with at most K stages, Algorithm 2 returns a solution $\mathbf{w}_K$ such that $f(\mathbf{w}_K) - f_* \leq 2\epsilon$. The total number of iterations for Algorithm 2 to find an 2ϵ-optimal solution is at most $T = t\lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil$ where $t \geq \frac{\alpha^2 G^2}{\rho_\epsilon^2}$.*

Remark: If t also satisfies $t = O\left(\frac{\alpha^2 G^2}{\rho_\epsilon^2}\right)$, then the iteration complexity of Algorithm 2 for finding an ϵ-optimal solution is $O\left(\frac{\alpha^2 G^2}{\rho_\epsilon^2} \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil\right)$.

Proof

Let $\mathbf{w}_{k,\epsilon}^\dagger$ denote the closest point to $\mathbf{w}_k$ in the ϵ-sublevel set. Let $\epsilon_k := \frac{\epsilon_0}{\alpha^k}$ so that $\eta_k = \epsilon_k/G^2$ because $\eta_1 = \epsilon_0/(\alpha G^2)$ and $\eta_{k+1} = \eta_k/\alpha$. We will show by induction that

$$f(\mathbf{w}_k) - f_* \leq \epsilon_k + \epsilon, \tag{10}$$

for $k = 0, 1, \ldots, K$ which leads to our conclusion if we let $k = K$.

Note that (10) holds obviously for $k = 0$. Suppose it holds for $k-1$, namely, $f(\mathbf{w}_{k-1}) - f_* \leq \epsilon_{k-1} + \epsilon$. We want to prove (10) for k. We apply Lemma 2 to the k-th stage of Algorithm 2 and get

$$f(\mathbf{w}_k) - f(\mathbf{w}_{k-1,\epsilon}^\dagger) \leq \frac{G^2\eta_k}{2} + \frac{\|\mathbf{w}_{k-1} - \mathbf{w}_{k-1,\epsilon}^\dagger\|_2^2}{2\eta_k t}. \tag{11}$$

We now consider two cases for $\mathbf{w}_{k-1}$. First, assume $f(\mathbf{w}_{k-1}) - f_* \leq \epsilon$, i.e., $\mathbf{w}_{k-1} \in \mathcal{S}_\epsilon$. Then $\mathbf{w}_{k-1,\epsilon}^\dagger = \mathbf{w}_{k-1}$ and $f(\mathbf{w}_k) - f(\mathbf{w}_{k-1,\epsilon}^\dagger) \leq \frac{G^2\eta_k}{2} = \frac{\epsilon_k}{2}$. As a result,

$$f(\mathbf{w}_k) - f_* \leq f(\mathbf{w}_{k-1,\epsilon}^\dagger) - f_* + \frac{\epsilon_k}{2} \leq \epsilon + \epsilon_k.$$

Next, we consider the case that $f(\mathbf{w}_{k-1}) - f_* > \epsilon$, i.e., $\mathbf{w}_{k-1} \notin \mathcal{S}_\epsilon$. Then we have $f(\mathbf{w}_{k-1,\epsilon}^\dagger) = f_* + \epsilon$. By Lemma 1, we have

$$\begin{aligned} \|\mathbf{w}_{k-1} - \mathbf{w}_{k-1,\epsilon}^\dagger\|_2 &\leq \frac{1}{\rho_\epsilon}(f(\mathbf{w}_{k-1}) - f(\mathbf{w}_{k-1,\epsilon}^\dagger)) = \frac{f(\mathbf{w}_{k-1}) - f_* + (f_* - f(\mathbf{w}_{k-1,\epsilon}^\dagger))}{\rho_\epsilon} \\ &\leq \frac{\epsilon_{k-1} + \epsilon - \epsilon}{\rho_\epsilon}. \end{aligned} \tag{12}$$

Combining (11) and (12) and using the facts that $\eta_k = \frac{\epsilon_k}{G^2}$ and $t \geq \frac{\alpha^2 G^2}{\rho_\epsilon^2}$, we have

$$f(\mathbf{w}_k) - f(\mathbf{w}_{k-1,\epsilon}^\dagger) \leq \frac{\epsilon_k}{2} + \frac{\epsilon_{k-1}^2}{2\epsilon_k \alpha^2} = \epsilon_k,$$

which, together with the fact that $f(\mathbf{w}_{k-1,\epsilon}^\dagger) = f_* + \epsilon$, implies (10) for k. Therefore, by induction, we have (10) holds for $k = 1, 2, \ldots, K$ so that

$$f(\mathbf{w}_K) - f_* \leq \epsilon_K + \epsilon = \frac{\epsilon_0}{\alpha^K} + \epsilon \leq 2\epsilon,$$

where the last inequality is due to the definition of K. ■

In Theorem 3, the iteration complexity of RSG for the general problem (1) is given in terms of ρ_ϵ. Next, we show that $\rho_\epsilon \geq \frac{\epsilon}{B_\epsilon}$, which allows us to leverage the local error bound condition in next sections to upper bound B_ϵ to obtain specialized and more practical algorithms for different classes of problems.

Lemma 4 *For any $\epsilon > 0$ such that $\mathcal{L}_\epsilon \neq \emptyset$, we have $\rho_\epsilon \geq \frac{\epsilon}{B_\epsilon}$, where B_ϵ is defined in (3), and for any $\mathbf{w} \in \Omega$*

$$\|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2 \leq \frac{\|\mathbf{w}_\epsilon^\dagger - \mathbf{w}_\epsilon^*\|_2}{\epsilon}(f(\mathbf{w}) - f(\mathbf{w}_\epsilon^\dagger)) \leq \frac{B_\epsilon}{\epsilon}(f(\mathbf{w}) - f(\mathbf{w}_\epsilon^\dagger)), \tag{13}$$

where $\mathbf{w}_\epsilon^*$ is the closest point in Ω_* to $\mathbf{w}_\epsilon^\dagger$.

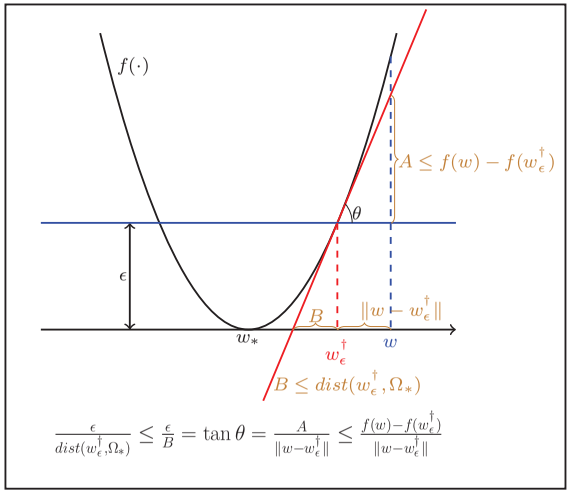

Figure 1: A geometric illustration of the inequality (13), where $dist(w_\epsilon^\dagger, \Omega_*) = |w_\epsilon^\dagger - w_\epsilon^*|$.

Proof Given any $\mathbf{u} \in \mathcal{L}_\epsilon$, let $\mathbf{g}_\mathbf{u}$ be any subgradient in $\partial f(\mathbf{u})$ and $\mathbf{v}_\mathbf{u}$ be any vector in $\mathcal{N}_\Omega(\mathbf{u})$. By the convexity of $f(\cdot)$ and the definition of normal cone, we have

$$f(\mathbf{u}^*) - f(\mathbf{u}) \ge (\mathbf{u}^* - \mathbf{u})^\top \mathbf{g}_\mathbf{u} \ge (\mathbf{u}^* - \mathbf{u})^\top (\mathbf{g}_\mathbf{u} + \mathbf{v}_\mathbf{u}),$$

where $\mathbf{u}^*$ is the closest point in Ω_* to $\mathbf{u}$. This inequality further implies

$$\|\mathbf{u}^* - \mathbf{u}\|_2 \|\mathbf{g}_\mathbf{u} + \mathbf{v}_\mathbf{u}\|_2 \ge f(\mathbf{u}) - f(\mathbf{u}^*) = \epsilon, \quad \forall \mathbf{g}_\mathbf{u} \in \partial f(\mathbf{u}) \text{ and } \mathbf{v}_\mathbf{u} \in \mathcal{N}_\Omega(\mathbf{u}), \tag{14}$$

where the equality is because $\mathbf{u} \in \mathcal{L}_\epsilon$. By (14) and the definition of B_ϵ, we obtain

$$B_\epsilon \|\mathbf{g}_\mathbf{u} + \mathbf{v}_\mathbf{u}\|_2 \ge \epsilon \Longrightarrow \|\mathbf{g}_\mathbf{u} + \mathbf{v}_\mathbf{u}\|_2 \ge \epsilon / B_\epsilon.$$

Since $\mathbf{g}_\mathbf{u} + \mathbf{v}_\mathbf{u}$ can be any element in $\partial f(\mathbf{u}) + \mathcal{N}_\Omega(\mathbf{u})$, we have $\rho_\epsilon \ge \frac{\epsilon}{B_\epsilon}$ by the definition (6).

To prove (13), we assume $\mathbf{w} \in \Omega \backslash \mathcal{S}_\epsilon$ and thus $\mathbf{w}_\epsilon^\dagger \in \mathcal{L}_\epsilon$; otherwise it is trivial. In the proof of Lemma 1, we have shown that (see (9)) there exists $\mathbf{g} \in \partial f(\mathbf{w}_\epsilon^\dagger)$ and $\mathbf{v} \in \mathcal{N}_\Omega(\mathbf{w}_\epsilon^\dagger)$ such that $f(\mathbf{w}) - f(\mathbf{w}_\epsilon^\dagger) \ge \|\mathbf{w} - \mathbf{w}_\epsilon^\dagger\|_2 \|\mathbf{g} + \mathbf{v}/\zeta\|_2$, which, according to (14) with $\mathbf{u} = \mathbf{w}_\epsilon^\dagger$, $\mathbf{g}_\mathbf{u} = \mathbf{g}$ and $\mathbf{v}_\mathbf{u} = \mathbf{v}/\zeta$, leads to (13). ■

A geometric explanation of the inequality (13) in one dimension is shown in Figure 1. With Lemma 4, the iteration complexity of RSG can be stated in terms of B_ϵ in the following corollary of Theorem 3.

Corollary 5 *Suppose Assumption 1 holds. The iteration complexity of RSG for obtaining an 2ϵ-optimal solution is $O(\frac{\alpha^2 G^2 B_\epsilon^2}{\epsilon^2} \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil)$ provided $t = \frac{\alpha^2 G^2 B_\epsilon^2}{\epsilon^2}$ and $K = \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil$.*

We will compare this result with SG in Section 7. Compared to the standard SG, the above improved result of RSG does require knowing strong knolwedge about f. In particular, one issue is that the above improved complexity is obtained by choosing $t = \frac{\alpha^2 G^2 B_\epsilon^2}{\epsilon^2}$, which requires knowing the order of magnitude of B_ϵ, if not its exact value. To address the issue of unknown B_ϵ for general problems, in the next section, we consider different families of problems that admit a local error bound condition and show that the requirement of knowing B_ϵ is relaxed to knowing some particular parameters related to the local error bound.

5. RSG for Some Classes of Non-smooth Non-strongly Convex Optimization

In this section, we consider a particular family of problems that admit local error bounds and show the improved iteration complexities of RSG compared to standard SG method.

5.1 Complexity for the Problems with Local Error Bounds

We first define a local error bound condition of the objective function.

Definition 6 *We say $f(\cdot)$ admits a **local error bound** on the ϵ-sublevel set $\mathcal{S}_\epsilon$ if*

$$\|\mathbf{w} - \mathbf{w}^*\|_2 \le c(f(\mathbf{w}) - f_*)^\theta, \quad \forall \mathbf{w} \in \mathcal{S}_\epsilon, \tag{15}$$

where $\mathbf{w}^*$ is the closet point in Ω_* to $\mathbf{w}$, $\theta \in (0, 1]$ and $0 < c < \infty$ are constants.

Because $\mathcal{S}_{\epsilon_2} \subset \mathcal{S}_{\epsilon_1}$ for $\epsilon_2 \le \epsilon_1$, if (15) holds for some ϵ, it will always hold when ϵ decreases to zero with the same θ and c. Indeed, a smaller ϵ may induce a smaller value of c. It is notable that the local error bound condition has been extensively studied in the community of optimization, mathematical programming and variational analysis (Yang, 2009; Li, 2010, 2013; Artacho and Geoffroy, 2008; Kruger, 2015; Drusvyatskiy et al., 2014; Li and Mordukhovich, 2012; Hou et al., 2013; Zhou and So, 2017; Zhou et al., 2015), to name just a few of them. The value of θ has been exhibited for many problems. For certain problems, the value of c is also computable (see Bolte et al., 2017).

If the problem admits a local error bound like (15), RSG can achieve a better iteration complexity than $O(1/\epsilon^2)$. In particular, the property (15) implies

$$B_\epsilon \le c\epsilon^\theta. \tag{16}$$

Replacing B_ϵ in Corollary 5 by this upper bound and choosing $t = \frac{\alpha^2 G^2 c^2}{\epsilon^{2(1-\theta)}}$ in RSG if c and θ are known, we obtain the following complexity of RSG.

Corollary 7 *Suppose Assumption 1 holds and $f(\cdot)$ admits a local error bound on $\mathcal{S}_\epsilon$. The iteration complexity of RSG for obtaining an 2ϵ-optimal solution is $O\left(\frac{\alpha^2 G^2 c^2}{\epsilon^{2(1-\theta)}} \log_\alpha\left(\frac{\epsilon_0}{\epsilon}\right)\right)$ provided $t = \frac{\alpha^2 G^2 c^2}{\epsilon^{2(1-\theta)}}$ and $K = \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil$.*

Remark: If $t = \Theta(\frac{\alpha^2 G^2}{\epsilon^{2(1-\theta)}}) > \frac{\alpha^2 G^2 c^2}{\epsilon^{2(1-\theta)}}$, then the same order of iteration complexity remains. If one aims to find a point $\mathbf{w}$ such that $\|\mathbf{w} - \mathbf{w}^*\|_2 \le \epsilon$, we can apply RSG to find a solution $\mathbf{w}$

such that $f(\mathbf{w}) - f_* \leq (\epsilon/c)^{1/\theta} \leq \epsilon$ (where the last inequality is due to $\theta \leq 1$ and assuming $c \geq 1$ without loss of generality). Then under the local error bound condition, we have $\|\mathbf{w}-\mathbf{w}^*\|_2 \leq c(f(\mathbf{w})-f_*)^\theta \leq \epsilon$. For finding a solution $\mathbf{w}$ such that $f(\mathbf{w})-f_* \leq (\epsilon/c)^{1/\theta} \leq \epsilon$, RSG requires an iteration complexity of $\widetilde{O}(\frac{1}{\epsilon^{2(1-\theta)/\theta}})$. Therefore, in order to find a solution $\mathbf{w}$ such that $\|\mathbf{w} - \mathbf{w}^*\|_2 \leq \epsilon$, the iteration complexity of RSG is $\widetilde{O}(\frac{1}{\epsilon^{2(1-\theta)/\theta}})$.

Next, we will consider different convex optimization problems that admit a local error bound on $\mathcal{S}_\epsilon$ with different θ and show the faster convergence of RSG when applied to these problems.

5.2 Linear Convergence for Polyhedral Convex Optimization

In this subsection, we consider a special family of non-smooth and non-strongly convex problems where the epigraph of $f(\cdot)$ over Ω is a polyhedron. In this case, we call (1) a **polyhedral convex minimization** problem. We show that, in polyhedral convex minimization problem, $f(\cdot)$ has a linear growth property and admits a local error bound with $\theta = 1$ so that $B_\epsilon \leq c\epsilon$ for a constant $c < \infty$.

Lemma 8 (Polyhedral Error Bound Condition) *Suppose Ω is a polyhedron and the epigraph of $f(\cdot)$ is also polyhedron. There exists a constant $\kappa > 0$ such that*

$$\|\mathbf{w} - \mathbf{w}^*\|_2 \leq \frac{f(\mathbf{w}) - f_*}{\kappa}, \quad \forall \mathbf{w} \in \Omega.$$

Thus, $f(\cdot)$ admits a local error bound on $\mathcal{S}_\epsilon$ with $\theta = 1$ and $c = \frac{1}{\kappa}$ [3] (so $B_\epsilon \leq \frac{\epsilon}{\kappa}$) for any $\epsilon > 0$.

Remark: The above inequality is also known as weak sharp minimum condition in literature (Burke and Ferris., 1993; Studniarski and Ward, 1999; Ferris, 1991; Burke and Deng, 2002, 2005, 2009). A proof of Lemma 8 is given by Burke and Ferris. (1993). We also provide a proof (see Yang and Lin, 2016). We remark that the above result can be extended to any valid norm to measure the distance between $\mathbf{w}$ and $\mathbf{w}_*$. Lemma 8 generalizes Lemma 4 of Gilpin et al. (2012), which requires Ω to be a bounded polyhedron, to a similar result where Ω can be an unbounded polyhedron. This generalization is simple but useful because it helps the development of efficient algorithms based on this error bound for unconstrained problems without artificially including a box constraint.

Lemma 8 provides the basis for RSG to achieve a linear convergence for the polyhedral convex minimization problems. In fact, the following linear convergence of RSG can be obtained if we plugin the values of $\theta = 1$ and $c = \frac{1}{\kappa}$ into Corollary 7.

Corollary 9 *Suppose Assumption 1 holds and (1) is a polyhedral convex minimization problem. The iteration complexity of RSG for obtaining an ϵ-optimal solution is $O(\frac{\alpha^2 G^2}{\kappa^2}\lceil\log_\alpha(\frac{\epsilon_0}{\epsilon})\rceil)$ provided $t = \frac{\alpha^2 G^2}{\kappa^2}$ and $K = \lceil\log_\alpha(\frac{\epsilon_0}{\epsilon})\rceil$.*

We want to point out that Corollary 9 can be proved directly by replacing $\mathbf{w}^\dagger_{k-1,\epsilon}$ by $\mathbf{w}^*_{k-1}$ and replacing ρ_ϵ by κ in the proof of Theorem 3. Here, we derive it as a corollary of a more general result. We also want to mention that, as shown by Renegar (2015), the linear convergence rate in Corollary 9 can be also obtained by a SG method for the historically best solution, provided f_* is known.

3. In fact, this property of $f(\cdot)$ is a global error bound on Ω.

5.2.1 Examples

Many non-smooth and non-strongly convex machine learning problems satisfy the assumptions of Corollary 9, for example, ℓ_1 **or** ℓ_∞ **constrained or regularized piecewise linear loss minimization**. In many machine learning tasks (e.g., classification and regression), there exists a set of data $\{(\mathbf{x}_i, y_i)\}_{i=1,2,\ldots,n}$ and one often needs to solve the following empirical risk minimization problem

$$\min_{\mathbf{w}\in\mathbb{R}^d} f(\mathbf{w}) \triangleq \frac{1}{n}\sum_{i=1}^n \ell(\mathbf{w}^\top\mathbf{x}_i, y_i) + R(\mathbf{w}),$$

where $R(\mathbf{w})$ is a regularization term and $\ell(z, y)$ denotes a loss function. We consider a special case where (a) $R(\mathbf{w})$ is a ℓ_1 regularizer, ℓ_∞ regularizer or an indicator function of a ℓ_1/ℓ_∞ ball centered at zero; and (b) $\ell(z, y)$ is any piecewise linear loss function, including hinge loss $\ell(z, y) = \max(0, 1 - yz)$, absolute loss $\ell(z, y) = |z - y|$, ϵ-insensitive loss $\ell(z, y) = \max(|z - y| - \epsilon, 0)$, and etc (Yang et al., 2014). It is easy to show that the epigraph of $f(\mathbf{w})$ is a polyhedron if $f(\mathbf{w})$ is defined as a sum of any of these regularization terms and any of these loss functions. In fact, a piecewise linear loss functions can be generally written as

$$\ell(\mathbf{w}^\top\mathbf{x}, y) = \max_{1\leq j\leq m} a_j\mathbf{w}^\top\mathbf{x} + b_j, \tag{17}$$

where (a_j, b_j) for $j = 1, 2, \ldots, m$ are finitely many pairs of scalars. The formulation (17) indicates that $\ell(\mathbf{w}^\top\mathbf{x}, y)$ is a piecewise affine function so that its epigraph is a polyhedron. In addition, the ℓ_1 or ℓ_∞ norm is also a polyhedral function because we can represent them as

$$\|\mathbf{w}\|_1 = \sum_{i=1}^d \max(w_i, -w_i), \quad \|\mathbf{w}\|_\infty = \max_{1\leq i\leq d}|w_i| = \max_{1\leq i\leq d}\max(w_i, -w_i).$$

Since the sum of finitely many polyhedral functions is also a polyhedral function, the epigraph of $f(\mathbf{w})$ is a polyhedron.

Another important family of problems whose objective function has a polyhedral epigraph is **submodular function minimization**. Let $V = \{1, \ldots, d\}$ be a set and 2^V denote its power set. A submodular function $F(A) : 2^V \to \mathbb{R}$ is a set function such that $F(A)+F(B) \geq F(A\cup B)+F(A\cap B)$ for all subsets $A, B \subseteq V$ and $F(\emptyset) = 0$. A submodular function minimization can be cast into a non-smooth convex optimization using the Lovász extension (Bach, 2013). In particular, let the base polyhedron $B(F)$ be defined as

$$B(F) = \{\mathbf{s} \in \mathbb{R}^d, \mathbf{s}(V) = F(V), \forall A \subseteq V, \mathbf{s}(A) \leq F(A)\},$$

where $\mathbf{s}(A) = \sum_{i\in A} s_i$. Then the Lovász extension of $F(A)$ is $f(\mathbf{w}) = \max_{\mathbf{s}\in B(F)} \mathbf{w}^\top\mathbf{s}$, and $\min_{A\subseteq V} F(A) = \min_{\mathbf{w}\in[0,1]^d} f(\mathbf{w})$. As a result, a submodular function minimization is essentially a non-smooth and non-strongly convex optimization with a polyhedral epigraph.

5.3 Improved Convergence for Locally Semi-Strongly Convex Problems

First, we give a definition of local semi-strong convexity.

Definition 10 *A function $f(\mathbf{w})$ is semi-strongly convex on the ϵ-sublevel set $\mathcal{S}_\epsilon$ if there exists $\lambda > 0$ such that*

$$\frac{\lambda}{2}\|\mathbf{w} - \mathbf{w}^*\|_2^2 \leq f(\mathbf{w}) - f(\mathbf{w}^*), \quad \forall \mathbf{w} \in \mathcal{S}_\epsilon, \tag{18}$$

where $\mathbf{w}^*$ is the closest point to $\mathbf{w}$ in the optimal set.

We refer to the property (18) as *local* semi-strong convexity when $\mathcal{S}_\epsilon \neq \Omega$. The two papers (Gong and Ye, 2014; Necoara et al., 2015) have explored the semi-strong convexity on the whole domain Ω to prove linear convergence of smooth optimization problems. In some literature (Necoara et al., 2015), the inequality (18) is also called **second-order growth property**. Necoara et al. (2015) have also shown that a class of problems satisfy (18) (see examples given below). The inequality (18) indicates that $f(\cdot)$ admits a local error bound on $\mathcal{S}_\epsilon$ with $\theta = \frac{1}{2}$ and $c = \sqrt{\frac{2}{\lambda}}$, which leads to the following the corollary about the iteration complexity of RSG for locally semi-strongly convex problems.

Corollary 11 *Suppose Assumption 1 holds and $f(\mathbf{w})$ is semi-strongly convex on $\mathcal{S}_\epsilon$. Then $B_\epsilon \leq \sqrt{\frac{2\epsilon}{\lambda}}$ [4] and the iteration complexity of RSG for obtaining an 2ϵ-optimal solution is $O(\frac{2\alpha^2G^2}{\lambda\epsilon}\lceil\log_\alpha(\frac{\epsilon_0}{\epsilon})\rceil)$ provided $t = \frac{2\alpha^2G^2}{\lambda\epsilon}$ and $K = \lceil\log_\alpha(\frac{\epsilon_0}{\epsilon})\rceil$.*

Remark: Here, we obtain an $\widetilde{O}(1/\epsilon)$ iteration complexity ($\widetilde{O}(\cdot)$ suppresses constants and logarithmic terms) only with local semi-strong convexity. It is obvious that strong convexity implies local semi-strong convexity (Hazan and Kale, 2011) but not vice versa.

For examples, let us consider a family of functions in the form of $f(\mathbf{w}) = h(X\mathbf{w}) + r(\mathbf{w})$, where $X \in \mathbb{R}^{n\times d}$, $h(\cdot)$ is *strongly convex* on any *compact set* and $r(\cdot)$ has a polyhedral epigraph. According to (Gong and Ye, 2014; Necoara et al., 2015), such a function $f(\mathbf{w})$ satisfies (18) for any $\epsilon \leq \epsilon_0$ with a constant value for λ. Although smoothness is assumed for $h(\cdot)$ in (Gong and Ye, 2014; Necoara et al., 2015), we find that it is not necessary for proving (18). We state this result as the lemma below.

Lemma 12 *Suppose Assumption 1 holds, $\Omega = \{\mathbf{w} \in \mathbb{R}^d | C\mathbf{w} \leq \mathbf{b}\}$ with $C \in \mathbb{R}^{k\times d}$ and $\mathbf{b} \in \mathbb{R}^k$, and $f(\mathbf{w}) = h(X\mathbf{w}) + r(\mathbf{w})$ where $h : \mathbb{R}^n \to \mathbb{R}$ satisfies $dom(h) = \mathbb{R}^k$ and is a strongly convex function on any compact set in $\mathbb{R}^n$, and $r(\mathbf{w})$ has a polyhedral epigraph. Then, $f(\mathbf{w})$ satisfies (18) for any $\epsilon \leq \epsilon_0$.*

The proof of this lemma can be duplicated following analysis in some existing works (Gong and Ye, 2014; Necoara et al., 2015; Necoara and Clipici, 2016). For example, it is almost identical to the proof of Lemma 1 by Gong and Ye (2014) which assumes $h(\cdot)$ is smooth. However, a similar result holds without the smoothness of $h(\cdot)$.

4. Recall (16).

The function of this type covers some commonly used loss functions and regularization terms in machine learning and statistics. For example, we can consider **robust regression with/without ℓ_1 regularizer** (Xu et al., 2010; Bertsimas and Copenhaver, 2014):

$$\min_{\mathbf{w}\in\Omega} \frac{1}{n}\sum_{i=1}^n |\mathbf{x}_i^\top\mathbf{w} - y_i|^p + \lambda\|\mathbf{w}\|_1, \tag{19}$$

where $p \in (1, 2)$, $\mathbf{x}_i \in \mathbb{R}^d$ denotes the feature vector and y_i is the target output. The objective function is in the form of $h(X\mathbf{w}) + r(\mathbf{w})$ where X is a $n \times d$ matrix with $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ being its rows and $h(\mathbf{u}) := \sum_{i=1}^n |u_i - y_i|^p$. According to Goebel and Rockafellar (2007), $h(\mathbf{u})$ is a strongly convex function on any compact set so that the objective function above is semi-strongly convex on $\mathcal{S}_\epsilon$ for any $\epsilon \leq \epsilon_0$.

5.4 Improved Convergence for Convex Problems with KL property

Lastly, we consider a family of non-smooth functions with a local Kurdyka-Łojasiewicz (KL) property. The definition of KL property is given below.

Definition 13 *The function $f(\mathbf{w})$ has the Kurdyka - Łojasiewicz (KL) property at $\bar{\mathbf{w}}$ if there exist $\eta \in (0, \infty]$, a neighborhood $U_{\bar{\mathbf{w}}}$ of $\bar{\mathbf{w}}$ and a continuous concave function $\varphi : [0, \eta) \to \mathbb{R}_+$ such that (i) $\varphi(0) = 0$; (ii) φ is continuous on $(0, \eta)$; (iii) for all $s \in (0, \eta)$, $\varphi'(s) > 0$; (iv) and for all $\mathbf{w} \in U_{\bar{\mathbf{w}}} \cap \{\mathbf{w} : f(\bar{\mathbf{w}}) < f(\mathbf{w}) < f(\bar{\mathbf{w}}) + \eta\}$, the Kurdyka - Łojasiewicz (KL) inequality holds*

$$\varphi'(f(\mathbf{w}) - f(\bar{\mathbf{w}}))\|\partial f(\mathbf{w})\|_2 \geq 1, \tag{20}$$

where $\|\partial f(\mathbf{w})\|_2 := \min_{\mathbf{g}\in\partial f(\mathbf{w})} \|\mathbf{g}\|_2$.

The function φ is called the **desingularizing function** of f at $\bar{\mathbf{w}}$, which sharpens the function $f(\mathbf{w})$ by reparameterization. An important desingularizing function is in the form of $\varphi(s) = cs^{1-\beta}$ for some $c > 0$ and $\beta \in [0, 1)$, by which, (20) gives the KL inequality

$$\|\partial f(\mathbf{w})\|_2 \geq \frac{1}{c(1-\beta)}(f(\mathbf{w}) - f(\bar{\mathbf{w}}))^\beta.$$

Note that all semi-algebraic functions satisfy the KL property at any point (Bolte et al., 2014). Indeed, all the concrete examples given before satisfy the Kurdyka - Łojasiewicz property. For more discussions about the KL property, we refer readers to some previous works (Bolte et al., 2014, 2007; Schneider and Uschmajew, 2015; Attouch et al., 2013; Bolte et al., 2006). The following corollary states the iteration complexity of RSG for unconstrained problems that have the KL property at each $\bar{\mathbf{w}} \in \Omega_*$.

Corollary 14 *Suppose Assumption 1 holds, $f(\mathbf{w})$ satisfies a (uniform) Kurdyka - Łojasiewicz property at any $\bar{\mathbf{w}} \in \Omega_*$ with the same desingularizing function φ and constant η, and*

$$\mathcal{S}_\epsilon \subset \cup_{\bar{\mathbf{w}}\in\Omega_*} \left[U_{\bar{\mathbf{w}}} \cap \{\mathbf{w} : f(\bar{\mathbf{w}}) < f(\mathbf{w}) < f(\bar{\mathbf{w}}) + \eta\}\right]. \tag{21}$$

RSG has an iteration complexity of $O\left(\alpha^2G^2(\frac{\varphi(\epsilon)}{\epsilon})^2\lceil\log_\alpha(\frac{\epsilon_0}{\epsilon})\rceil\right)$ for obtaining an 2ϵ-optimal solution provided $t = \alpha^2G^2(\varphi(\epsilon)/\epsilon)^2$. In addition, if $\varphi(s) = cs^{1-\beta}$ for some $c > 0$ and $\beta \in [0, 1)$, the iteration complexity of RSG is $O(\frac{\alpha^2G^2c^2(1-\beta)^2}{\epsilon^{2\beta}}\lceil\log_\alpha(\frac{\epsilon_0}{\epsilon})\rceil)$ provided $t = \frac{\alpha^2G^2c^2}{\epsilon^{2\beta}}$ and $K = \lceil\log_\alpha(\frac{\epsilon_0}{\epsilon})\rceil$.

Proof We can prove the above corollary following a result by Bolte et al. (2017) as presented in Proposition 1 in the Appendix. According to Proposition 1, if $f(\cdot)$ satisfies the KL property at $\bar{\mathbf{w}}$, then for all $\mathbf{w} \in U_{\bar{\mathbf{w}}} \cap \{\mathbf{w} : f(\bar{\mathbf{w}}) < f(\mathbf{w}) < f(\bar{\mathbf{w}}) + \eta\}$ it holds that $\|\mathbf{w} - \mathbf{w}^*\|_2 \leq \varphi(f(\mathbf{w}) - f(\bar{\mathbf{w}}))$. It then, under the uniform condition in (21), implies that, for any $\mathbf{w} \in \mathcal{S}_\epsilon$

$$\|\mathbf{w} - \mathbf{w}^*\|_2 \leq \varphi(f(\mathbf{w}) - f_*) \leq \varphi(\epsilon),$$

where we use the monotonic property of φ. Then the first conclusion follows similarly as Corollary 5 by noting $B_\epsilon \leq \varphi(\epsilon)$. The second conclusion immediately follows by setting $\varphi(s) = cs^{1-\beta}$ in the first conclusion. Please note that the above inequality implies the local error bound condition with $\theta = 1 - \beta$ for $\varphi(s) = cs^{1-\beta}$. ■

While the conclusion in Corollary 14 hinges on a condition in (21) for certain $U_{\bar{\mathbf{w}}}$ and η, in practice many convex functions (e.g., continuous semi-algebraic or subanalytic functions) satisfy the KL property with $U = \mathbb{R}^d$ and any finite $\eta < \infty$ (Attouch et al., 2010; Bolte et al., 2017; Li, 2010).

It is worth mentioning that to our best knowledge, the present work is the first to leverage the KL property for developing improved subgradient methods, though it has been explored in non-convex and convex optimization for deterministic descent methods for smooth optimization (Bolte et al., 2017, 2014; Attouch et al., 2010; Karimi et al., 2016). For example, Bolte et al. (2017) studied the convergence of **subgradient descent sequence** for minimizing a convex function under an error bound condition. A sequence $\{\mathbf{x}_k\}$ is called a subgradient descent sequence if there exist $a > 0, b > 0$ it satisfies two conditions, namely sufficient decrease condition $f(\mathbf{x}_k) + a\|\mathbf{x}_k - \mathbf{x}_{k-1}\|_2^2 \leq f(\mathbf{x}_{k-1})$, and relative error condition, i.e., there exists $\omega_k \in \partial f(\mathbf{x}_k)$ such that $\|\omega_k\|_2 \leq b\|\mathbf{x}_k - \mathbf{x}_{k-1}\|_2$. However, for a general non-smooth function $f(\mathbf{x})$, the sequence generated by subgradient method, i.e., $\mathbf{x}_k = \mathbf{x}_{k-1} - \eta_k \partial \nabla f(\mathbf{x}_{k-1})$ do not necessarily satisfy the above two conditions. Instead, Bolte et al. (2017) considered proximal gradient method that only applies to a smaller family of functions consisting of a smooth component and a non-smooth component by assuming the proximal mapping for the non-smooth component can be efficiently computed. In contrast, our algorithm and analysis are developed for much general non-smooth functions.

6. Variants of RSG without knowing the constant c and the exponent θ in the local error bound

In Section 5, we have discussed the local error bound and presented several classes of problems to reveal the magnitude of B_ϵ, i.e., $B_\epsilon = c\epsilon^\theta$. For some problems, the value of θ is exhibited. However, the value of the constant c could be still difficult to estimate, which renders it challenging to set the appropriate value $t = \frac{\alpha^2 c^2 G^2}{\epsilon^{2(1-\theta)}}$ for inner iterations of RSG. In practice, one might use a sufficiently large c to set up the value of t. However, such an approach might be vulnerable to both over-estimation and under-estimation of t. Over-estimating the value of t leads to a waste of iterations while under-estimation leads to an less accurate solution that might not reach to the target accuracy level. In addition, for some problems the value of θ is still an open problem. One interesting family of objective functions in machine learning is the sum of piecewise linear loss over training data and a nuclear norm regularizer or an overlapped or non-overlapped group lasso regularizer. In this section, we present variants of RSG that can be implemented without knowing the value of c in the local error bound condition and even the value of exponent θ, and prove their improved convergence over the SG method.

6.1 RSG without knowing c

The key idea is to use an increasing sequence of t and another level of restarting for RSG. The detailed steps are presented in Algorithm 3, to which we refer as R^{2}SG. With large enough t_1 in R^{2}SG, the complexity of R^{2}SG for finding an ϵ solution is given by the theorem below.

Theorem 15 *Suppose $\epsilon \leq \epsilon_0/4$ and $K = \lceil \log_\alpha(\epsilon_0/\epsilon) \rceil$. Let t_1 in Algorithm 3 be large enough so that there exists $\hat{\epsilon}_1 \in (\epsilon, \epsilon_0/2)$, with which $f(\cdot)$ satisfies a local error bound condition on $\mathcal{S}_{\hat{\epsilon}_1}$ with $\theta \in (0,1)$ and the constant $\hat{c}$, and $t_1 = \frac{\alpha^2 \hat{c}^2 G^2}{\hat{\epsilon}_1^{2(1-\theta)}}$. Then, with at most $S = \lceil \log_2(\hat{\epsilon}_1/\epsilon) \rceil + 1$ calls of RSG in Algorithm 3, we find a solution $\mathbf{w}^S$ such that $f(\mathbf{w}^S) - f_* \leq 2\epsilon$. The total number of iterations of R^{2}SG for obtaining 2ϵ-optimal solution is upper bounded by $T_S = O\left(\frac{\hat{c}^2 G^2}{\epsilon^{2(1-\theta)}} \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil\right)$.*

Proof Since $K = \lceil \log_\alpha(\epsilon_0/\epsilon) \rceil \geq \lceil \log_\alpha(\epsilon_0/\hat{\epsilon}_1) \rceil$ and $t_1 = \frac{\alpha^2 \hat{c}^2 G^2}{\hat{\epsilon}_1^{2(1-\theta)}}$, we can apply Corollary 7 with $\epsilon = \hat{\epsilon}_1$ to the first call of RSG in Algorithm 3 so that the output $\mathbf{w}^1$ satisfies

$$f(\mathbf{w}^1) - f_* \leq 2\hat{\epsilon}_1. \tag{22}$$

Then, we consider the second call of RSG with the initial solution $\mathbf{w}^1$ satisfying (22). By the setup $K = \lceil \log_\alpha(\epsilon_0/\epsilon) \rceil \geq \lceil \log_\alpha(2\hat{\epsilon}_1/(\hat{\epsilon}_1/2)) \rceil$ and $t_2 = t_1 2^{2(1-\theta)} = \frac{\hat{c}^2 G^2}{(\hat{\epsilon}_1/2)^{2(1-\theta)}}$, we can apply Corollary 7 with $\epsilon = \hat{\epsilon}_1/2$ and $\epsilon_0 = 2\hat{\epsilon}_1$ so that the output $\mathbf{w}^2$ of the second call satisfies $f(\mathbf{w}^2) - f_* \leq \hat{\epsilon}_1$. By repeating this argument for all the subsequent calls of RSG, with at most $S = \lceil \log_2(\hat{\epsilon}_1/\epsilon) \rceil + 1$ calls, Algorithm 3 ensures that

$$f(\mathbf{w}^S) - f_* \leq 2\hat{\epsilon}_1 / 2^{S-1} \leq 2\epsilon.$$

The total number of iterations during the S calls of RSG is bounded by

$$\begin{aligned} T_S &= K \sum_{s=1}^{S} t_s = K \sum_{s=1}^{S} t_1 2^{2(s-1)(1-\theta)} = K t_1 2^{2(S-1)(1-\theta)} \sum_{s=1}^{S} \left(\frac{1}{2^{2(1-\theta)}}\right)^{S-s} \\ &\leq \frac{K t_1 2^{2(S-1)(1-\theta)}}{1 - 1/2^{2(1-\theta)}} \leq O\left(K t_1 \left(\frac{\hat{\epsilon}_1}{\epsilon}\right)^{2(1-\theta)}\right) = O\left(\frac{\hat{c}^2 G^2}{\epsilon^{2(1-\theta)}} \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil\right). \end{aligned}$$

■

Remark: We make several remarks about Algorithm 3 and Theorem 15: (i) Theorem 15 applies only when $\theta \in (0,1)$. If $\theta = 1$, in order to have an increasing sequence of t_s, we can set θ in Algorithm 3 to a little smaller value than 1 in practical implementation, and the

Algorithm 3 RSG with restarting: R^{2}SG

1: **Input**: the number of iterations t_1 in each stage of the first call of RSG and the number of stages K in each call of RSG
2: **Initialization:** $\mathbf{w}^0 \in \Omega$;
3: **for** $s = 1, 2 \ldots, S$ **do**
4: Let $\mathbf{w}^s = \text{RSG}(\mathbf{w}^{s-1}, K, t_s, \alpha)$
5: Let $t_{s+1} = t_s 2^{2(1-\theta)}$
6: **end for**

iteration complexity in Theorem 15 implies that R^{2}SG can enjoy a convergence rate close to linear convergence for problems satisfying the weak sharp minimum condition. (ii) the ϵ_0 in the implementation of RSG (Algorithm 2) can be re-calibrated for $s \geq 2$ to improve the performance (e.g., one can use the relationship $f(\mathbf{w}_{s-1}) - f_* = f(\mathbf{w}_{s-2}) - f_* + f(\mathbf{w}_{s-1}) - f(\mathbf{w}_{s-2})$ to do re-calibration); (iii) as a tradeoff, the exiting criterion of R^{2}SG is not as automatic as RSG. In fact, the total number of calls S of RSG for obtaining an 2ϵ-optimal solution depends on an unknown parameter (namely $\hat{\epsilon}_1$). In practice, one could use other stopping criteria to terminate the algorithm. For example, in machine learning applications one can monitor the performance on the validation data set to terminate the algorithm. (vi) The quantities $\hat{\epsilon}_1$, S in the proof above are implicitly determined by t_1 and one does not need to compute $\hat{\epsilon}_1$ and S in order to apply Algorithm 3. Finally, we note that when a local strong convexity condition holds on $\mathcal{S}_{\hat{\epsilon}_1}$ with $\hat{\epsilon}_1 \geq \epsilon$ one might derive an iteration complexity of $O(1/\epsilon)$ for SG by first showing that SG converges to $\mathcal{S}_{\hat{\epsilon}_1}$ with a number of iterations independent of ϵ, then showing that the iterates stay within $\mathcal{S}_{\hat{\epsilon}_1}$ and converge to an ϵ-level set with an iteration complexity of $O(1/\epsilon)$ following existing analysis of SG for strongly convex functions, e.g., (Lacoste-Julien et al., 2012). However, it still needs to know the value of the local strong convexity parameter unlike our result in Theorem 15 that does not need to known the local strong convexity parameter.

6.2 RSG for unknown θ and c

Without knowing $\theta \in (0, 1]$ and c to get a sharper local error bound, we can simply let $\theta = 0$ and $c = B_{\epsilon'}$ with $\epsilon' \geq \epsilon$, which still render the inequaity (15) hold (c.f. Definition 6). Then we can employ the same trick to increase the values of t. In particular, we start with a sufficiently large value of t and run RSG with $K = \lceil \log_\alpha(\epsilon_0/\epsilon) \rceil$ stages, and then increase the value of t by a factor of 4 and repeat the process.

Theorem 16 *Let $\theta = 0$ in Algorithm 3 and suppose $\epsilon \leq \epsilon_0/4$ and $K = \lceil \log_\alpha(\epsilon_0/\epsilon) \rceil$. Assume t_1 in Algorithm 3 is large enough so that there exists $\hat{\epsilon}_1 \in (\epsilon, \epsilon_0/2]$ giving $t_1 = \frac{\alpha^2 B^2_{\hat{\epsilon}_1} G^2}{\hat{\epsilon}_1^2}$. Then, with at most $S = \lceil \log_2(\hat{\epsilon}_1/\epsilon) \rceil + 1$ calls of RSG in Algorithm 3, we find a solution $\mathbf{w}^S$ such that $f(\mathbf{w}^S) - f_* \leq 2\epsilon$. The total number of iterations of R^{2}SG for obtaining 2ϵ-optimal solution is upper bounded by $T_S = O\left(\frac{B^2_{\hat{\epsilon}_1} G^2}{\epsilon^2} \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil\right)$.*

Remark: Since B_ϵ/ϵ is a monotonically decreasing function in ϵ (Xu et al., 2017, Lemma 7), such a t_1 in Theorem 16 exists. Note that if the problem satisfies a KL property as in Corollary 14 and the value of β is unknown, the above theorem still holds.

Proof The proof is similar to that of Theorem 15 except that we let $c = B_{\hat{\epsilon}_1}$ and $\theta = 0$. Since $K = \lceil \log_\alpha(\epsilon_0/\epsilon) \rceil \geq \lceil \log_\alpha(\epsilon_0/\hat{\epsilon}_1) \rceil$ and $t_1 = \frac{\alpha^2 B^2_{\hat{\epsilon}_1} G^2}{\hat{\epsilon}_1^2}$, we can apply Corollary 5 with $\epsilon = \hat{\epsilon}_1$ to the first call of RSG in Algorithm 3 so that the output $\mathbf{w}^1$ satisfies

$$f(\mathbf{w}^1) - f_* \leq 2\hat{\epsilon}_1. \tag{23}$$

Then, we consider the second call of RSG with the initial solution $\mathbf{w}^1$ satisfying (23). By the setup $K = \lceil \log_\alpha(\epsilon_0/\epsilon) \rceil \geq \lceil \log_\alpha(2\hat{\epsilon}_1/(\hat{\epsilon}_1/2)) \rceil$ and $t_2 = t_1 2^2 = \frac{B^2_{\hat{\epsilon}_1} G^2}{(\hat{\epsilon}_1/2)^2}$, we can apply Corollary 5 with $\epsilon = \hat{\epsilon}_1/2$ and $\epsilon_0 = 2\hat{\epsilon}_1$ (noting that $B_{\hat{\epsilon}_1} > B_{\hat{\epsilon}_1/2}$) so that the output $\mathbf{w}^2$ of the second call satisfies $f(\mathbf{w}^2) - f_* \leq \hat{\epsilon}_1$. By repeating this argument for all the subsequent calls of RSG, with at most $S = \lceil \log_2(\hat{\epsilon}_1/\epsilon) \rceil + 1$ calls, Algorithm 3 ensures that

$$f(\mathbf{w}^S) - f_* \leq 2\hat{\epsilon}_1/2^{S-1} \leq 2\epsilon.$$

The total number of iterations during the S calls of RSG is bounded by

$$\begin{aligned} T_S = K\sum_{s=1}^{S} t_s = K\sum_{s=1}^{S} t_1 2^{2(s-1)} = K t_1 2^{2(S-1)} \sum_{s=1}^{S} \left(\frac{1}{2^2}\right)^{S-s} \\ \leq \frac{K t_1 2^{2(S-1)}}{1 - 1/2^2} \leq O\left(K t_1 \left(\frac{\hat{\epsilon}_1}{\epsilon}\right)^2\right) = O\left(\frac{B^2_{\hat{\epsilon}_1} G^2}{\epsilon^2} \lceil \log_\alpha(\frac{\epsilon_0}{\epsilon}) \rceil\right). \end{aligned}$$

■

7. Discussions and Comparisons

In this section, we further discuss the obtained results and compare them with existing results.

7.1 Comparison with the standard SG

The standard SG's iteration complexity is known as $O(\frac{G^2 \|\mathbf{w}_0 - \mathbf{w}_0^*\|_2^2}{\epsilon^2})$ for achieving an 2ϵ-optimal solution. By assuming t is appropriately set in RSG according to Corollary 5, its iteration complexity is $O(\frac{G^2 B_\epsilon^2}{\epsilon^2} \log(\epsilon_0/\epsilon))$, which depends on B_ϵ^2 instead of $\|\mathbf{w}_0 - \mathbf{w}_0^*\|_2^2$ and only has a logarithmic dependence on ϵ_0, the upper bound of $f(\mathbf{w}_0) - f_*$. When the initial solution is far from the optimal set so that $B_\epsilon^2 \ll \|\mathbf{w}_0 - \mathbf{w}_0^*\|_2^2$, RSG could have a lower worst-case complexity. Even if t is not appropriately set up to be larger than $\alpha^2 G^2 B_\epsilon^2/\epsilon^2$, Theorem 16 guarantees that the proposed R^{2}SG could still has a lower iteration complexity than that of SG as long as t_1 is sufficiently large. In some special cases, e.g., when f satisfies the local error bound condition (15) with $\theta \in (0, 1]$, RSG only needs $O\left(\frac{1}{\epsilon^{2(1-\theta)}} \log\left(\frac{1}{\epsilon}\right)\right)$ iterations (see Corollary 7 and Theorem 15), which has a better dependency on ϵ than the complexity of standard SG method.

7.2 Comparison with the SG method by Freund and Lu (2017)

Freund and Lu (2017) introduced a similar but different growth condition:

$$\|\mathbf{w} - \mathbf{w}^*\|_2 \leq \mathcal{G} \cdot (f(\mathbf{w}) - f_{slb}), \quad \forall \mathbf{w} \in \Omega, \tag{24}$$

where f_{slb} is a strict lower bound of f_*. The main differences from our key condition (7) are: the left-hand side is the distance of $\mathbf{w}$ to the optimal set in (24) while it is the distance of $\mathbf{w}$ to the ϵ-sublevel set in (7); the right-hand side is the objective gap with respect to f_{slb} in (24) and it is the objective gap with respect to f_* in (7); the growth constant $\mathcal{G}$ in (24) varies with f_{slb} and ρ_ϵ in (7) may depend on ϵ in general.

Freund and Lu's SG method has an iteration complexity of $O(G^2\mathcal{G}^2(\frac{\log H}{\epsilon'} + \frac{1}{\epsilon'^2}))$ for finding a solution $\hat{\mathbf{w}}$ such that $f(\hat{\mathbf{w}}) - f_* \leq \epsilon'(f_* - f_{slb})$, where f_{slb} and $\mathcal{G}$ are defined in (24) and $H = \frac{f(\mathbf{w}_0) - f_{slb}}{f_* - f_{slb}}$. In comparison, our RSG can be better if $f_* - f_{slb}$ is large. To see this, we represent the complexity of the method by Freund and Lu (2017) in terms of the absolute error ϵ with $\epsilon = \epsilon'(f_* - f_{slb})$ and obtain $O(G^2\mathcal{G}^2(\frac{(f_* - f_{slb})\log H}{\epsilon} + \frac{(f_* - f_{slb})^2}{\epsilon^2}))$. If the gap $f_* - f_{slb}$ is large, e.g., $O(f(\mathbf{w}_0) - f_{slb})$, the second term is dominating, which is at least $\Omega(\frac{G^2\|\mathbf{w}_0 - \mathbf{w}_0^*\|_2^2}{\epsilon^2})$ due to the definition of $\mathcal{G}$ in (24). This complexity has the same order of magnitude as the standard SG method so that RSG can be better due to the reasoning in last paragraph. More generally, the iteration complexity of Freund and Lu's SG method can be reduced to $O(\frac{G^2 B_{f_* - f_{slb}}^2}{\epsilon^2})$ by choosing the best $\mathcal{G}$ in the proof of Theorem 1.1 in Freund and Lu (2017)'s paper, which depends on $f_* - f_{slb}$. In comparison, RSG could have a lower complexity if $f_* - f_{slb}$ is larger than ϵ as in Corollary 5 or $\hat{\epsilon}_1$ as in Theorem 15. Our experiments in subsection 8.4 also corroborate this point. In addition, RSG can leverage the local error bound condition to enjoy a lower iteration complexity than $O(1/\epsilon^2)$.

7.3 Comparison with the method by Juditsky and Nesterov (2014)

Juditsky and Nesterov (2014) considered primal-dual subgradient methods for solving the problem (1) with f being *uniformly convex*, namely,

$$f(\alpha\mathbf{w} + (1-\alpha)\mathbf{v}) \leq \alpha f(\mathbf{w}) + (1-\alpha)f(\mathbf{v}) - \frac{1}{2}\mu\alpha(1-\alpha)[\alpha^{\rho-1} + (1-\alpha)^{\rho-1}]\|\mathbf{w} - \mathbf{v}\|_2^\rho,$$

for any $\mathbf{w}$ and $\mathbf{v}$ in Ω and any $\alpha \in [0,1]$ [5], where $\rho \in [2, +\infty]$ and $\mu \geq 0$. In this case, the method by (Juditsky and Nesterov, 2014) has an iteration complexity of $O\left(\frac{G^2}{\mu^{2/\rho}\epsilon^{2(\rho-1)/\rho}}\right)$. The uniform convexity of f further implies $f(\mathbf{w}) - f_* \geq \frac{1}{2}\mu\|\mathbf{w} - \mathbf{w}^*\|_2^\rho$ for any $\mathbf{w} \in \Omega$ so that $f(\cdot)$ admits a local error bound on the ϵ-sublevel set $\mathcal{S}_\epsilon$ with $c = \left(\frac{2}{\mu}\right)^{\frac{1}{\rho}}$ and $\theta = \frac{1}{\rho}$. Therefore, our RSG has a complexity of $O\left(\frac{G^2}{\mu^{2/\rho}\epsilon^{2(\rho-1)/\rho}}\log(\frac{\epsilon_0}{\epsilon})\right)$ according to Corollary 7. Compared to the result of Juditsky and Nesterov (2014), our complexity is higher by a logarithmic factor. However, we only require the local error bound property of f that is weaker than uniform convexity and also covers much broader family of functions. Note that the above comparison is fair, since for achieving a target ϵ-optimal solution the algorithms

5. The Euclidean norm in the definition here can be replaced by a general norm as in (Juditsky and Nesterov, 2014).

proposed by Juditsky and Nesterov (2014) do need the knowledge of uniform convexity parameter ρ and the parameter μ. It is worth mentioning that Juditsky and Nesterov (2014) also presented algorithms with a fixed number of iterations T as input that achieve adaptive rates without knowledge of ρ and μ. However, they only considered the case when $\rho >= 2$, which corresponds to $\theta \leq 1/2$ in our notations, while our methods can be applied also when $\theta > 1/2$.

8. Experiments

In this section, we present some experiments to demonstrate the effectiveness of RSG. We first consider several applications in machine learning, in particular regression, classification and matrix completion, and focus on the comparison between RSG and SG. Then we make comparison between RSG with Freund & Lu's SG variant for solving regression problems. In experiments, all compared algorithms use the same initial solution unless otherwise specified.

8.1 Robust Regression

The regression problem is to predict an output y based on a feature vector $\mathbf{x} \in \mathbb{R}^d$. Given a set of training examples $(\mathbf{x}_i, y_i), i = 1, \ldots, n$, a linear regression model can be found by solving the optimization problem in (19).

We solve two instances of the problem with $p = 1$ and $p = 1.5$ and $\lambda = 0$. We conduct experiments on two data sets from libsvm website [6], namely housing ($n = 506$ and $d = 13$) and space-ga ($n = 3107$ and $d = 6$). We first examine the convergence behavior of RSG with different values for the number of iterations per-stage $t = 10^2$, 10^3, and 10^4. The value of α is set to 2 in all experiments. The initial step size of RSG is set to be proportional to $\epsilon_0/2$ with the same scaling parameter for different variants. We plot the results on housing data in Figure 2 (a,b) and on space-ga data in Figure 3 (a,b). In each figure, we plot the objective value vs number of stages and the log difference between the objective value and the converged value (to which we refer as level gap). We can clearly see that with different values of t RSG converges to an ϵ-level set and the convergence rate is linear in terms of the number of stages, which is consistent with our theory.

Secondly, we compare with SG to verify the effectiveness of RSG. The baseline SG is implemented with a decreasing step size proportional to $1/\sqrt{\tau}$, where τ is the iteration

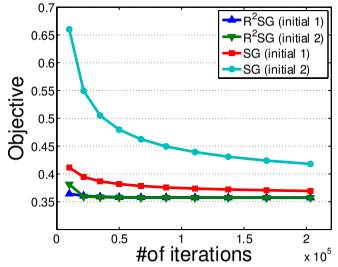
(a) comparison between different algorithms



(b) sensitivity to initial solutions

Figure 4: Results for solving SVM classification with GFlassso regularizer. In (b), the objective values of the two initial solutions are 1 and 70.35. One iteration means one subgradient update in all algorithms.

index. The initial step size of SG is tuned in a wide range to give the fastest convergence. The initial step size of RSG is also tuned around the best initial step size of SG. The results are shown in Figure 2(c,d) and Figure 3(c,d), where we show RSG with two different values of t and also R^{2}SG with an increasing sequence of t. In implementing R^{2}SG, we restart RSG for every 5 stages, and increase the number of iterations by a certain factor. In particular,we increase t by a factor of 1.15 and 1.5 respectively for $p = 1$ and $p = 1.5$. From the results, we can see that (i) RSG with a smaller value of $t = 10^3$ can quickly converge to an ϵ-level, which is less accurate than SG after running a sufficiently large number of iterations; (ii) RSG with a relatively large value $t = 10^4$ can converge to a much more accurate solution; (iv) R^{2}SG converges much faster than SG and can bridge the gap between RSG-$t = 10^3$ and RSG-$t = 10^4$.

8.2 SVM Classification with a graph-guided fused lasso

The classification problem is to predict a binary class label $y \in \{1, -1\}$ based on a feature vector $\mathbf{x} \in \mathbb{R}^d$. Given a set of training examples $(\mathbf{x}_i, y_i), i = 1, \ldots, n$, the problem of training a linear classification model can be cast into

$$\min_{\mathbf{w} \in \mathbb{R}^d} F(\mathbf{w}) := \frac{1}{n} \sum_{i=1}^{n} \ell(\mathbf{w}^\top \mathbf{x}_i, y_i) + R(\mathbf{w}).$$

Here we consider the hinge loss $\ell(z, y) = \max(0, 1 - yz)$ as in support vector machine (SVM) and a graph-guided fused lasso (GFlasso) regularizer $R(\mathbf{w}) = \lambda \|F\mathbf{w}\|_1$ (Kim et al., 2009), where $F = [F_{ij}]_{m \times d} \in \mathbb{R}^{m \times d}$ encodes the edge information between variables. Suppose there is a graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$ where nodes $\mathcal{V}$ are the attributes and each edge is assigned a weight s_{ij} that represents some kind of similarity between attribute i and attribute j. Let $\mathcal{E} = \{e_1, \ldots, e_m\}$ denote a set of m edges, where an edge $e_\tau = (i_\tau, j_\tau)$ consists of a tuple of two attributes. Then the τ-th row of F matrix can be formed by setting $F_{\tau, i_\tau} = s_{i_\tau, j_\tau}$ and $F_{\tau, j_\tau} = -s_{i_\tau, j_\tau}$ for $(i_\tau, j_\tau) \in \mathcal{E}$, and zeros for other entries. Then the GFlasso becomes

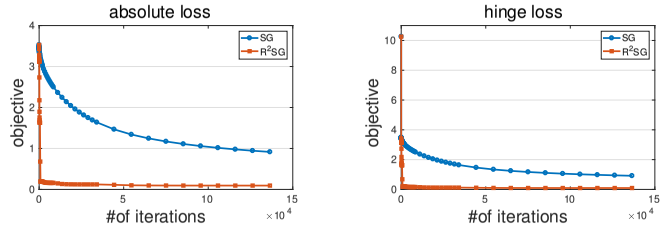


Figure 5: Results for solving low rank matrix completion with different loss functions.

$R(\mathbf{w}) = \lambda \sum_{(i,j)\in\mathcal{E}} s_{ij}|w_i - w_j|$. Previous studies have found that a carefully designed GFlasso regularization helps in reducing the risk of over-fitting. In this experiment, we follow (Ouyang et al., 2013) to generate a dependency graph by sparse inverse covariance selection (Friedman et al., 2008). To this end, we first generate a sparse inverse covariance matrix using the method in (Friedman et al., 2008) and then assign an equal weight $s_{ij} = 1$ to all edges that have non-zero entries in the resulting inverse covariance matrix. We conduct the experiment on the dna data ($n = 2000$ and $d = 180$) from the libsvm website, which has three class labels. We solve the above problem to classify class 3 versus the rest. The comparison between different algorithms starting from an initial solution with all zero entries for solving the above problem with $\lambda = 0.1$ is presented in Figure 4(a). For R^{2}SG, we start from $t_1 = 10^3$ and restart it every 10 stages with t increased by a factor of 1.15. The initial step sizes for all algorithms are tuned.

We also compare the dependence of R^{2}SG's convergence on the initial solution with that of SG. We use two different initial solutions (the first initial solution $\mathbf{w}_0 = 0$ and the second initial solution $\mathbf{w}_0$ is generated once from a normal Gaussian distribution). The convergence curves of the two algorithms from the two different initial solutions are plotted in Figure 4(b). Note that the initial step sizes of SG and R^{2}SG are separately tuned for each initial solution. We can see that R^{2}SG is much less sensitive to a bad initial solution than SG consistent with our theory.

8.3 Matrix Completion for Collaborative Filtering

In this subsection, we consider low rank matrix completion problems to demonstrate the effectiveness of R^{2}SG without having the knowledge of c and θ in the local error bound condition. We consider a movie recommendation data set, namely MovieLens 100k data [7], which contains 100,000 ratings from $m = 943$ users on $n = 1682$ movies. We formulate the problem as a task of recovering a full user-movie rating matrix X from the partially observed matrix Y. The objective is composed of a loss function measuring the difference between X and Y on the observed entries and a nuclear norm regularizer on X for enforcing

7. https://grouplens.org/datasets/movielens/

a low rank, i.e.,

$$\min_{X\in\mathbb{R}^{m\times n}} \frac{1}{N}\sum_{(i,j)\in\Sigma} \ell(X_{ij}, Y_{ij}) + \lambda\|X\|_*, \tag{25}$$

where Σ is a set of user-movie pairs that denote the observed entries, $\ell(\cdot,\cdot)$ denote a loss function, $\|X\|_*$ denotes the nuclear norm, $N = |\Sigma|$ and $\lambda > 0$ is a regularization parameter. We consider two loss functions, i.e, the hinge loss and the absolute loss. For absolute loss, we set $\ell(a, b) = |a - b|$. For hinge loss, we follow Rennie and Srebro (2005) by introducing four thresholds $\theta_{1,2,3,4}$ due to there are five distinct ratings in $\{1, 2, 3, 4, 5\}$ that can be assigned to each movie, and defining $\ell(a, b) = \sum_{r=1}^{4} \max(0, 1 - T^r_{i,j}(\theta_r - X_{ij}))$, where $T^r_{ij} = \begin{cases} 1 & \text{if } r \geq Y_{ij} \\ 0 & \text{otherwise} \end{cases}$. In our experiment, we set $\theta_{1,2,3,4} = (0, 3, 6, 9)$ and $\lambda = 10^{-5}$ following (Yang et al., 2014). Since the loss function and the nuclear norm are both semi-algebraic functions (Yang et al., 2016; Bolte et al., 2014), then the problem (25) satisfies an error bound condition on any compact set (Bolte et al., 2017). However, it remains an open problem what are the proper values of c and θ to make local error bound condition hold. Hence, we run R^{2}SG by setting $\theta = 0$. To compare with SG, we simply set $t_1 = 10$ - the number of iterations of each stage of the first call of RSG. The baseline SG is implemented in the same way as before. The results of the objective values vs the number of iterations are plotted in Figure 5. We can see that R^{2}SG converges much faster than SG, verifying the effectiveness of R^{2}SG predicted by Theorem 16.

8.4 Comparison with Freund & Lu's SG

In this subsection, we compare the proposed RSG with Freund & Lu' SG algorithm empirically. The later algorithm is designed with a fixed relative accuracy ϵ' such that $\frac{f(\mathbf{x}_t)-f_*}{f_*-f_{slb}} \leq \epsilon'$, where f_{slb} is a strict lower bound of f_*, and requires to maintain the best solution in terms of the objective value during the optimization. For fair comparison, we run RSG with a fixed t and then vary ϵ' for Freund & Lu's SG algorithm that is an input parameter, and then plot the objective values versus the running time and the number of iterations for both algorithms. The experiments are conducted on the two classification data sets as used in subsection 8.1, namely the housing data and the space-ga data, for solving robust regression problems (19) with $p = 1$ and $p = 1.5$. The strict lower bound f_{slb} in Freund & Lu's algorithm is set to 0. The results are shown in Figure 6 and Figure 7, where SGR refers to Freund & Lu's SG algorithm with a specified relative accuracy. For each problem instance (a data set and a particular value of p), we report two results comparing the objective values vs. running time and the number of iterations. We can see that RSG is very competitive in performance in terms of running time and converge faster than Freund & Lu's algorithm with a small $\epsilon' = 10^{-4}$ for achieving the same accurate solution (e.g., with objective gap less than 10^{-10}).

9. Conclusion

In this work, we have proposed a novel restarted subgradient method for non-smooth and/or non-strongly convex optimization for obtaining an ϵ-optimal solution. By leveraging the

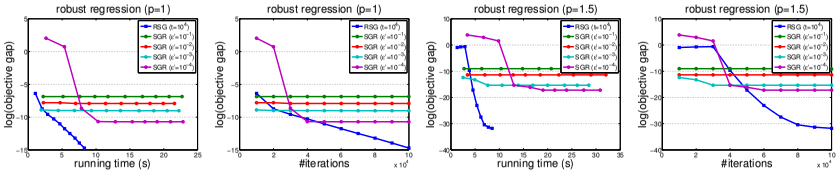

Figure 6: Comparison of RSG with Freund & Lu's SG algorithm (SGR) on the housing data.

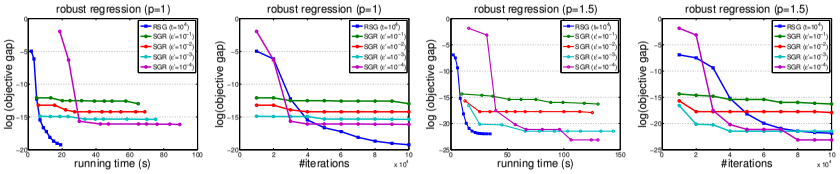

Figure 7: Comparison of RSG with Freund & Lu's SG algorithm (SGR) on the space-ga data.

lower bound of the first-order optimality residual, we establish a generic complexity of RSG that improves over standard subgradient method. We have also considered several classes of non-smooth and non-strongly convex problems that admit a local error bound condition and derived the improved order of iteration complexities for RSG. Several extensions have been made to design a parameter-free variant of RSG without requiring the knowledge of the constants in the local error bound condition. Experimental results on several machine learning tasks have demonstrated the effectiveness of the proposed algorithms in comparison to the subgradient method.

Acknowledgments

We would like to sincerely thank anonymous reviewers for their very helpful comments. We thank James Renegar for pointing out the connection to his work and for his valuable comments on the difference between the two work. We also thank to Nghia T.A. Tran for pointing out the connection between the local error bound and metric subregularity of subdifferentials. Thanks to Mingrui Liu for spotting an error in the formulation of the F matrix for GFlasso in earlier versions. T. Yang was supported by NSF (1463988, 1545995).

Appendix A. A proposition needed to prove Corollary 14

The proof of Corollary 14 leverages the following result (Bolte et al., 2017).

Proposition 1 *(Bolte et al., 2017, Theorem 5) Let $f(x)$ be an extended-valued, proper, convex and lower semicontinuous function that satisfies the KL inequality* (20) *at $x_* \in \arg\min f(\cdot)$ for all $x \in U \cap \{x : f(x_*) < f(x) < f(x_*)+\eta\}$, where U is a neighborhood of x_*, then $dist(x, \arg\min f(\cdot)) \leq \varphi(f(x) - f(x_*))$ for all $x \in U \cap \{x : f(x_*) < f(x) < f(x_*)+\eta\}$.*

Abstract

This paper presents a new approach for Gaussian process (GP) regression for large datasets. The approach involves partitioning the regression input domain into multiple local regions with a different local GP model fitted in each region. Unlike existing local partitioned GP approaches, we introduce a technique for patching together the local GP models nearly seamlessly to ensure that the local GP models for two neighboring regions produce nearly the same response prediction and prediction error variance on the boundary between the two regions. This largely mitigates the well-known discontinuity problem that degrades the prediction accuracy of existing local partitioned GP methods over regional boundaries. Our main innovation is to represent the continuity conditions as additional pseudo-observations that the differences between neighboring GP responses are identically zero at an appropriately chosen set of boundary input locations. To predict the response at any input location, we simply augment the actual response observations with the pseudo-observations and apply standard GP prediction methods to the augmented data. In contrast to heuristic continuity adjustments, this has an advantage of working within a formal GP framework, so that the GP-based predictive uncertainty quantification remains valid. Our approach also inherits a sparse block-like structure for the sample covariance matrix, which results in computationally efficient closed-form expressions for the predictive mean and variance. In addition, we provide a new spatial partitioning scheme based on a recursive space partitioning along local principal component directions, which makes the proposed approach applicable for regression domains having more than two dimensions. Using three spatial datasets and three higher dimensional datasets, we investigate the numerical performance of the approach and compare it to several state-of-the-art approaches.

Keywords: Local Kriging, Model Split and Merge, Pseudo Observations, Spatial Partition

1. Introduction

Gaussian process (GP) regression is a popular Bayesian nonparametric approach for nonlinear regression (Rasmussen and Williams, 2006). A GP prior is assumed for the unknown regression function, and the posterior estimate of the function is from this prior, combined with noisy (or noiseless, for deterministic simulation response surfaces) response observations. The posterior estimate can be easily derived in a simple closed form using the properties induced by the GP prior, and the estimator has several desirable properties, e.g., it is the best linear unbiased estimator under the assumed model and offers convenient quantification of the prediction error uncertainty. Its conceptual simplicity and attractive properties are major reasons for its popularity. On the other hand, the computational expense for evaluating the closed form solution is proportional to N^3, where N denotes the number of observations, which can be prohibitively expensive for large N. Broadly speaking, this paper concerns fast computation of the GP regression estimate for large N.

The major computational bottleneck for GP regression is the inversion of a $N \times N$ sample covariance matrix, which is also often poorly numerically conditioned. Different approaches for representing or approximating the sample covariance matrix with a more efficiently invertible form have been proposed. The approaches can be roughly categorized as sparse approximations, low-rank approximations, or local approximations. Sparse methods represent the sample covariance with a sparse version, e.g. by applying a covariance tapering technique (Furrer et al., 2006; Kaufman et al., 2008), using a compactly supported covariance function (Gneiting, 2002), or using a Gaussian Markov approximation of a GP (Lindgren et al., 2011). The inversion of a sparse positive definite matrix is less computationally expensive than the inversion of a non-sparse matrix of the same size, because its Cholesky decomposition is sparse and can be achieved more quickly.

Low-rank approximations of the sample covariance matrix can be performed in multiple ways. The most popular approach for the low-rank approximation introduces latent variables and assume a certain independence conditioned on the latent variables (Seeger et al., 2003; Snelson and Ghahramani, 2006), so that the resulting sample covariance matrix has reduced rank. The (pseudo)inversion of a $N \times N$ matrix of rank M can be computed with reduced $O(NM^2)$ expense. Titsias (2009) introduced a variational formulation to infer the latent variables along with covariance parameters, and a variant of the idea was proposed using the stochastic variational inference technique (Hensman et al., 2013). The latent variable model approaches are exploited to develop parallel computing algorithms for GP regression (Chen et al., 2013). Another way for low rank approximation is to approximate the sample covariance matrix with a product of a block diagonal matrix and multiple blocked low-rank matrices (Ambikasaran et al., 2016).

Local approximation approaches partition the input domain into a set of local regions and assume an independent GP regression model within each region (Das and Srivastava, 2010). The resulting sample covariance matrix is a block diagonal matrix of local sample covariance matrices, and inverting the block diagonal matrix is much cheaper computationally. Such local approximation approaches have many advantages. By their local nature, they adapt better to local and nonstationary data features, and independent local approximation models can be computed in parallel to reduce total computation time. Their major weakness is that two local models for two neighboring local regions produce different predictions at the boundary between the regions, creating discontinuity of the regression function over the boundary. This boundary discontinuity is not just an aesthetic problem, as it was empirically shown that greater discontinuity implies greater degradation in prediction accuracy, particularly around the boundaries of the local regions (Park and Huang, 2016). This discontinuity issue has been addressed in different ways. Perhaps the most popular

approach is to smooth out some of the discontinuity by using some weighted average across the local models or across multiple sets of local models via a Dirichlet mixture (Rasmussen and Ghahramani, 2002), a treed mixture (Gramacy and Lee, 2008), Bayesian model averaging (Tresp, 2000; Chen and Ren, 2009; Deisenroth and Ng, 2015), or locally weighted projections (Nguyen-Tuong et al., 2009). Other, related approaches use additive covariance functions consisting of a global covariance and a local covariance (Snelson and Ghahramani, 2007; Vanhatalo and Vehtari, 2008), construct a local model for each testing point (Gramacy and Apley, 2015), or use a local partition but constrain the local models for continuity (Park et al., 2011; Park and Huang, 2016).

In this work we use a partitioned input domain like Park et al. (2011) and Park and Huang (2016), but we introduce a different form of continuity constraints that are more easily and more naturally integrated into the GP modeling framework. Both Park et al. (2011) and Park and Huang (2016) basically reformulated local GP regression as an optimization problem, and the local GP models for neighboring regions were constrained to have the same predictive means on the boundaries of the local regions by adding some linear constraints to the optimization problems that infer the local GP models. Park et al. (2011) used a constrained quadratic optimization that constrains the predictive means for a finite number of boundary locations, and Park and Huang (2016) introduced a functional optimization formulation to enforce the same constraints for all boundary locations. The optimization-based formulations make it infeasible to derive the marginal likelihood and the predictive variances in closed forms, which were roughly approximated. In contrast, this paper presents a simple and natural way to enforce continuity. We consider a set of GPs that are defined as the differences between the responses for the local GPs in neighboring regions. Continuity implies that these differenced GPs are identically zero along the boundary between neighboring regions. Hence, we impose continuity constraints by treating the values of the differenced GPs at a specified set of boundary points as all having been "observed to be zero", and we refer to these zero-valued differences as pseudo-observations. We can then conveniently incorporate continuity constraints by simply augmenting the actual set of response observations with the set of pseudo-observations, and then using standard GP modeling to calculate the posterior predictive distribution given the augmented set of observations. We note that *observing* the differenced GPs to be zero at a set of boundary points is essentially equivalent to *assuming* continuity at these points without imposing any further assumptions on the nature of the GPs.

The new modeling approach creates several major benefits over the previous domain partitioning approaches. The new modeling is simpler than the previous approaches, so the marginal likelihood function can be explicitly derived for tuning hyperparameters, which was not possible for the previous approaches. In the previous approaches, the values of the predictive means on the boundaries of local regions must be explicitly specified, which involves solving a large linear system of equations. Unlike the previous approaches, observing the pseudo-observations of the differenced GPs to be zero does not require specifying the actual values of the predictive means and variances on the boundaries. Furthermore, the proposed approach enforces that the local models for neighboring regions produce the same values for both the predictive means and variances at the boundary points between the local regions, while both of the previous approaches are only able to enforce the same predictive means but not the same predictive variances. Last, the previous approaches are

only applicable for one- or two-dimensional problems, while our new approach is applicable for higher dimensional regression problems. We view our approach as "patching" together a collection of local GP regression models using the boundary points as "stitches", and, hence, we refer to it as *patchwork kriging*.

The remainder of the paper is organized as follows. Section 2 briefly reviews the general GP regression problem and notational convention. Section 3 presents the core methodology of the patchwork kriging approach, including the prior model assumptions, the pseudo-observation definition, the resulting posterior predictive mean and variance equations, and the detailed computation steps along with choice of tuning parameters. Section 4 shows how the patchwork kriging performs with a toy example for illustrative purpose. Section 5 investigates the numerical performance of the proposed method for different simulated cases and compares it with the exact GP regression (i.e., the GP regression without partitions, using the entire dataset to predict each point) and a global GP approximation method. Section 6 presents the numerical performance of the proposed approach for five real datasets and compares it with Park and Huang (2016) and other state-of-the-art methods. Finally, Section 7 concludes the paper with a discussion.

2. Gaussian Process Regression

Consider the general regression problem of estimating an unknown predictive function f that relates a d dimensional predictor $x \in \mathbb{R}^d$ to a real response y, using noisy observations $\mathcal{D} = \{(x_i, y_i), i = 1, \ldots, N\}$,

$$y_i = \mu + f(x_i) + \epsilon_i, \qquad i = 1, \ldots, N,$$

where $\epsilon_i \sim \mathcal{N}(0, \sigma^2)$ is white noise, independent of $f(x_i)$. We assume that $\mu = 0$. Otherwise, one can normalize y_i by subtracting the sample mean of the y_i's from y_i. Notice that we do not use bold font for the multivariate predictor x_i and reserve bold font for the collection of observed predictor locations, $\mathbf{x} = [x_1, x_2, \ldots, x_N]^T$.

In a GP regression for this problem, one assumes that f is a realization of a zero-mean Gaussian process having covariance function $c(\cdot, \cdot)$ and then uses the observations $\mathcal{D}$ to obtain the posterior predictive distribution of f at an arbitrary x_*, denoted by $f_* = f(x_*)$. Denote $\boldsymbol{y} = [y_1, y_2, \ldots, y_N]^T$. The joint distribution of $(f_*, \boldsymbol{y})$ is

$$P(f_*, \boldsymbol{y}) = \mathcal{N}\left(\mathbf{0}, \begin{bmatrix} c_{**} & \boldsymbol{c}_{\mathbf{x}*}^T \\ \boldsymbol{c}_{\mathbf{x}*} & \sigma^2 \boldsymbol{I} + \boldsymbol{C}_{\mathbf{xx}} \end{bmatrix}\right),$$

where $c_{**} = c(x_*, x_*)$, $\boldsymbol{c}_{\mathbf{x}*} = (c(x_1, x_*), \ldots, c(x_N, x_*))^T$ and $\boldsymbol{C}_{\mathbf{xx}}$ is an $N \times N$ matrix with $(i, j)^{th}$ entry $c(x_i, x_j)$. The subscripts on c_{**}, $\boldsymbol{c}_{\mathbf{x}*}$, and $\boldsymbol{C}_{\mathbf{xx}}$ indicate the two sets of locations between which the covariance is computed, and we have abbreviated the subscript x_* as $*$. Applying the Gaussian conditioning formula to the joint distribution gives the predictive distribution of f_* given $\boldsymbol{y}$ (Rasmussen and Williams, 2006),

$$P(f_*|\boldsymbol{y}) = \mathcal{N}(\boldsymbol{c}_{\mathbf{x}*}^T(\sigma^2 \boldsymbol{I} + \boldsymbol{C}_{\mathbf{xx}})^{-1}\boldsymbol{y}, c_{**} - \boldsymbol{c}_{\mathbf{x}*}^T(\sigma^2 \boldsymbol{I} + \boldsymbol{C}_{\mathbf{xx}})^{-1}\boldsymbol{c}_{\mathbf{x}*}). \tag{1}$$

The predictive mean $\boldsymbol{c}_{\mathbf{x}*}^T(\sigma^2 \boldsymbol{I} + \boldsymbol{C}_{\mathbf{xx}})^{-1}\boldsymbol{y}$ is taken to be the point prediction of $f(x)$ at location x_*, and its uncertainty is measured by the predictive variance $c_{**} - \boldsymbol{c}_{\mathbf{x}*}^T(\sigma^2 \boldsymbol{I} + \boldsymbol{C}_{\mathbf{xx}})^{-1}\boldsymbol{c}_{\mathbf{x}*}$. Efficient calculation of the predictive mean and variance for large datasets has been the focus of much research.

3. Patchwork Kriging

As mentioned in the introduction, for efficient computation we replace the GP regression by a set of local GP models on some partition of the input domain, in a manner that enforces a level of continuity in the local GP model responses over the boundaries separating their respective regions. Section 3.1 conveys the main idea of the proposed approach,

3.1 Inference with Boundary Continuity Constraints

To specify the idea more precisely, consider a spatial partition of the input domain of $f(x)$ into K local regions $\{\Omega_k : k = 1, 2, ..., K\}$, and define $f_k(x)$ as the local GP approximation of $f(x)$ at $x \in \overline{\Omega}_k$, where $\overline{\Omega}_k$ is the closure of Ω_k. Temporarily ignoring the continuity requirements, the local models are assumed to follow independent GP priors:

Assumption 1 *Each $f_k(x)$ follows a GP prior distribution with zero mean and covariance function $c_k(\cdot,\cdot)$, and the $f_k(x)$'s are mutually independent a priori (prior to enforcing the continuity conditions). The choice of the local covariance function(s) can differ depending on the specifics of the problem. If $f(x)$ is expected to be a stationary process, then one could use the same $c_k(\cdot,\cdot) = c(\cdot,\cdot)$ for all k. In this case, the purpose of this local GP approximation would be to approximate $f(x)$ computationally efficiently. On the other hand, if one expects non-stationary behavior of the data, then different covariance functions should be used for each region.*

It is important to note that the independence of the GPs in Assumption 1 is prior to enforcing the continuity conditions via the pseudo-observations, as described below. After enforcing the continuity conditions, the GPs will no longer be independent *a priori*, since the assumed continuity at the boundaries imposes a very strong prior dependence of the surfaces. Since the pseudo-observations should also be viewed as additional prior information, the independence condition in Assumption 1 might be more appropriately viewed as a *hyperprior* condition. In fact, we view the incorporation of the boundary pseudo-observations as an extremely tractable and straightforward way of imposing some reasonable form of dependency of the $f_k(x)$ across regions (which is the ultimate goal), while still allowing us to begin with an independent GP *hyperprior* (which results in the tractability of the analyses).

Now partition the training set $\mathcal{D}$ into $\mathcal{D}_k = \{(x_i, y_i) : x_i \in \Omega_k\}$ $(k = 1, 2, ..., K)$, and denote $\mathbf{x}_k = \{x_i : x_i \in \Omega_k\}$ and $\boldsymbol{y}_k = \{y_i : x_i \in \Omega_k\}$. By the independence part of Assumption 1, the predictive distribution of $f_k(x)$ given $\mathcal{D}$ is equivalent to the predictive distribution of $f_k(x)$ given $\mathcal{D}_k$, which gives the standard local GP solution with no continuity requirements. The primary problem with this formulation is that the predictive distributions of $f_k(x)$ and $f_l(x)$ are not equal on the boundary of their neighboring regions Ω_k and Ω_l.

Our objective is to improve the local kriging prediction by enforcing $f_k(x) = f_l(x)$ on their shared boundary. The key idea is illustrated in Figure 1 and described as follows. For two neighboring regions Ω_k and Ω_l, let $\Gamma_{k,l} = \overline{\Omega}_k \cap \overline{\Omega}_l$ denote their shared boundary. For each pair of neighboring regions Ω_k and Ω_l, we define the auxiliary process $\delta_{k,l}(x)$ to be the difference between the two local GP models,

$$\delta_{k,l}(x) = f_k(x) - f_l(x) \text{ for } x \in \Gamma_{k,l}, \tag{2}$$

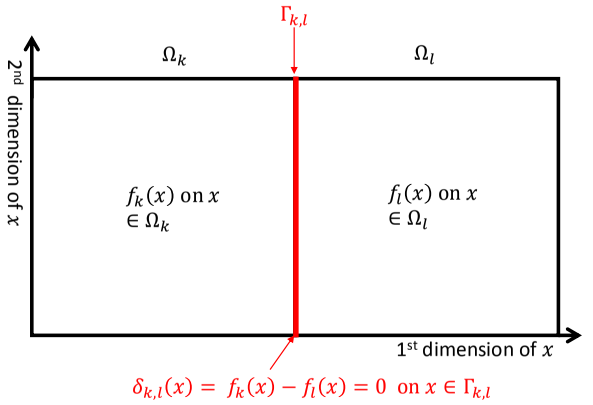

Figure 1: Illustration of the notation and concepts for defining the local models $f_k(x)$ and $f_l(x)$. Ω_k and Ω_l represent two local regions resulting from some appropriate spatial partition (discussed later) of the regression input domain. The (posterior distributions for the) GP functions $f_k(x)$ and $f_l(x)$ represent the local approximations of the regression function on Ω_k and Ω_l, respectively. The subset $\Gamma_{k,l}$ represents the interfacial boundary between the two regions Ω_k and Ω_l, and $\delta_{k,l}(x)$ is defined as the difference between $f_k(x)$ and $f_l(x)$, which is identically zero on $\Gamma_{k,l}$ by the continuity assumption.

and it is only defined for $k < l$ to avoid any duplicated definition of the auxiliary process. By the definition and under Assumption 1, $\delta_{k,l}(x)$ is a Gaussian process with zero mean and covariance function $c_k(\cdot,\cdot) + c_l(\cdot,\cdot)$, and its covariance with $f_j(x)$ is

$$\begin{aligned}\mathbb{C}\text{ov}(\delta_{k,l}(x_1), f_j(x_2)) &= \mathbb{C}\text{ov}(f_k(x_1) - f_l(x_1), f_j(x_2)) \\ &= \mathbb{C}\text{ov}(f_k(x_1), f_j(x_2)) - \mathbb{C}\text{ov}(f_l(x_1), f_j(x_2)).\end{aligned}$$

Since $\mathbb{C}\text{ov}(f_k(x_1), f_l(x_2)) = c_k(x_1, x_2)$ for $k = l$ and zero otherwise under Assumption 1,

$$\mathbb{C}\text{ov}(\delta_{k,l}(x_1), f_j(x_2)) = \begin{cases} c_k(x_1, x_2) & \text{if } k = j \\ -c_l(x_1, x_2) & \text{if } l = j \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

Likewise, $\delta_{k,l}(x)$ and $\delta_{u,v}(x)$ are correlated with covariance

$$\mathbb{C}\text{ov}(\delta_{k,l}(x_1), \delta_{u,v}(x_2)) = \begin{cases} c_k(x_1, x_2) & \text{if } k = u, l \neq v \\ c_l(x_1, x_2) & \text{if } l = v, k \neq u \\ -c_k(x_1, x_2) & \text{if } k = v, l \neq u \\ -c_l(x_1, x_2) & \text{if } l = u, k \neq v \\ c_k(x_1, x_2) + c_l(x_1, x_2) & \text{if } k = u, l = v \\ 0 & \text{otherwise.} \end{cases} \tag{4}$$

Boundary continuity between $f_k(x)$ and $f_l(x)$ can be achieved by enforcing the condition $\delta_{k,l}(x) = 0$ at $\Gamma_{j,k}$. We reiterate that $f_k(x)$ and $f_l(x)$ are no longer independent after conditioning on the additional information $\delta_{k,l}(x) = 0$. In fact, they are strongly dependent, as they must be in order to achieve continuity *a priori*. Hence, the independence condition in Assumption 1 is really a *hyperprior* independence.

Deriving the exact prior distribution of the surface conditioned on $\delta_{k,l}(x) = 0$ everywhere on the boundaries appears to be computationally intractable, because there are uncountably infinitely many x's in $\Gamma_{j,k}$. Instead, we propose a much simpler continuity correction that begins with the Assumption 1 prior (including the independence *hyperprior*) and augments the observed data $\mathcal{D}$ with the pseudo observations $\delta_{k,l}(x) = 0$ for a finite number of input locations $x \in \Gamma_{k,l}$. As the number of boundary pseudo-observations grows, we can better approximate the theoretical ideal condition that $\delta_{k,l}(x) = 0$ everywhere on the boundary. The choice of the boundary input locations will be discussed later.

Notice that observing "$\delta_{k,l}(x) = 0$" is equivalent to observing that $f_k(x) = f_l(x)$ without observing the actual values of $f_k(x)$ and $f_l(x)$. Thus, if we augment $\mathcal{D}$ to include these pseudo observations when calculating the posterior predictive distributions of $f_k(x)$ and $f_l(x)$, it will force the posterior distributions of $f_k(x)$ and $f_l(x)$ to be the same at each boundary input location x, because observing $\delta_{k,l}(x) = 0$ means that we have observed $f_k(x)$ and $f_l(x)$ to be the same (see (19) and (20), for a formal proof). This implies that their posterior means (which are the GP regression predictive functions) and their posterior variances (which quantify the uncertainty in the predictions) will both be equal.

Suppose that we place B pseudo observations on each $\Gamma_{k,l}$. Let $\boldsymbol{x}_{k,l}$ denote the set of B input boundary locations chosen in $\Gamma_{k,l}$, let $\boldsymbol{\delta}_{k,l}$ denote a collection of the noiseless observations of $\delta_{k,l}(x)$ at the selected boundary locations, and let $\boldsymbol{\delta}$ denote the collection of all $\boldsymbol{\delta}_{k,l}$'s in the following order,

$$\boldsymbol{\delta}^T = (\boldsymbol{\delta}_{1,1}^T, \boldsymbol{\delta}_{1,2}^T, \ldots, \boldsymbol{\delta}_{1,K}^T, \boldsymbol{\delta}_{2,1}^T, \ldots, \boldsymbol{\delta}_{2,K}^T, \ldots, \boldsymbol{\delta}_{KK}^T).$$

Note that the observed pseudo value of $\boldsymbol{\delta}$ will be a vector of zeros, but its prior distribution (prior to observing the pseudo values or any response observations) is represented by the above covariance expressions. Additionally, let $f_*^{(k)} = f_k(x_*)$ denote the value of the response $f_k(x)$ at any $x_* \in \Omega_k$, and let $\boldsymbol{y}^T = (\boldsymbol{y}_1^T, \boldsymbol{y}_2^T, \ldots, \boldsymbol{y}_K^T)$. The prior joint distribution of $f_*^{(k)}$, $\boldsymbol{y}$ and $\boldsymbol{\delta}$ is

$$\begin{bmatrix} f_*^{(k)} \\ \boldsymbol{y} \\ \boldsymbol{\delta} \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} 0 \\ \boldsymbol{0} \\ \boldsymbol{0} \end{bmatrix}, \begin{bmatrix} c_{**} & \boldsymbol{c}_{*\mathcal{D}}^{(k)} & \boldsymbol{c}_{*,\delta}^{(k)} \\ \boldsymbol{c}_{\mathcal{D}*}^{(k)} & \boldsymbol{C}_{\mathcal{D}\mathcal{D}} & \boldsymbol{C}_{\mathcal{D},\delta} \\ \boldsymbol{c}_{\delta,*}^{(k)} & \boldsymbol{C}_{\delta,\mathcal{D}} & \boldsymbol{C}_{\delta,\delta} \end{bmatrix} \right), \tag{5}$$

where the expressions of the covariance blocks are given by $c_{**} = \mathbb{C}\mathrm{ov}(f_*^{(k)}, f_*^{(k)})$,

$$\boldsymbol{c}_{*\mathcal{D}}^{(k)} = (\mathbb{C}\mathrm{ov}(f_*^{(k)}, \boldsymbol{y}_1), \mathbb{C}\mathrm{ov}(f_*^{(k)}, \boldsymbol{y}_2), \ldots, \mathbb{C}\mathrm{ov}(f_*^{(k)}, \boldsymbol{y}_K)),$$

$$\boldsymbol{c}_{*\delta}^{(k)} = (\mathbb{C}\mathrm{ov}(f_*^{(k)}, \boldsymbol{\delta}_{1,1}), \mathbb{C}\mathrm{ov}(f_*^{(k)}, \boldsymbol{\delta}_{1,2}), \ldots, \mathbb{C}\mathrm{ov}(f_*^{(k)}, \boldsymbol{\delta}_{K,K})),$$

$$\boldsymbol{c}_{\mathcal{D}\mathcal{D}} = \begin{bmatrix} \mathbb{C}\mathrm{ov}(\boldsymbol{y}_1, \boldsymbol{y}_1) & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_1, \boldsymbol{y}_2) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_1, \boldsymbol{y}_K) \\ \mathbb{C}\mathrm{ov}(\boldsymbol{y}_2, \boldsymbol{y}_1) & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_2, \boldsymbol{y}_2) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_2, \boldsymbol{y}_K) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbb{C}\mathrm{ov}(\boldsymbol{y}_K, \boldsymbol{y}_1) & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_K, \boldsymbol{y}_2) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_K, \boldsymbol{y}_K) \end{bmatrix},$$

$$\boldsymbol{C}_{\mathcal{D},\delta} = \begin{bmatrix} \mathbb{C}\mathrm{ov}(\boldsymbol{y}_1, \boldsymbol{\delta}_{1,1}) & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_1, \boldsymbol{\delta}_{1,2}) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_1, \boldsymbol{\delta}_{K,K}) \\ \mathbb{C}\mathrm{ov}(\boldsymbol{y}_2, \boldsymbol{\delta}_{1,1}) & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_2, \boldsymbol{\delta}_{1,1}) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_2, \boldsymbol{\delta}_{K,K}) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbb{C}\mathrm{ov}(\boldsymbol{y}_K, \boldsymbol{\delta}_{1,1}) & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_K, \boldsymbol{\delta}_{1,2}) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{y}_K, \boldsymbol{\delta}_{K,K}) \end{bmatrix}, \text{ and}$$

$$\boldsymbol{C}_{\delta,\delta} = \begin{bmatrix} \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{1,1}, \boldsymbol{\delta}_{1,1}) & \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{1,1}, \boldsymbol{\delta}_{1,2}) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{1,1}, \boldsymbol{\delta}_{K,K}) \\ \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{1,2}, \boldsymbol{\delta}_{1,1}) & \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{1,2}, \boldsymbol{\delta}_{1,1}) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{1,2}, \boldsymbol{\delta}_{K,K}) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{K,K}, \boldsymbol{\delta}_{1,1}) & \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{K,K}, \boldsymbol{\delta}_{1,2}) & \ldots & \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{K,K}, \boldsymbol{\delta}_{K,K}) \end{bmatrix}.$$

Note that joint covariance matrix is very sparse, because of the many zero values in (3) and (4).

From the standard GP modeling results applied to the augmented data, the posterior predictive distribution of $f_*^{(k)}$ given $\boldsymbol{y}$ and the pseudo observations $\boldsymbol{\delta} = \boldsymbol{0}$ is Gaussian with mean

$$\mathbb{E}[f_*^{(k)} | \boldsymbol{y}, \boldsymbol{\delta} = \boldsymbol{0}] = (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{c}_{*\delta}^{(k)} \boldsymbol{C}_{\delta,\delta}^{-1} \boldsymbol{C}_{\mathcal{D}\delta}^T)(\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta} \boldsymbol{C}_{\delta,\delta}^{-1} \boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1} \boldsymbol{y}. \tag{6}$$

and variance

$$\begin{aligned} \mathbb{V}\mathrm{ar}[f_*^{(k)} | \boldsymbol{y}, \boldsymbol{\delta}] = {} & c_{**} - \boldsymbol{c}_{*,\delta}^{(k)} \boldsymbol{C}_{\delta,\delta}^{-1} \boldsymbol{c}_{\delta*}^{(k)} \\ & - (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{c}_{*\delta}^{(k)} \boldsymbol{C}_{\delta,\delta}^{-1} \boldsymbol{C}_{\mathcal{D}\delta}^T)(\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta} \boldsymbol{C}_{\delta,\delta}^{-1} \boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1} (\boldsymbol{c}_{\mathcal{D}*}^{(k)} - \boldsymbol{C}_{\mathcal{D}\delta} \boldsymbol{C}_{\delta,\delta}^{-1} \boldsymbol{c}_{\delta*}^{(k)}). \end{aligned} \tag{7}$$

The derivation of the predictive mean and variance can be found in Appendix A.

One implication of the continuity imposed by including the pseudo observations $\boldsymbol{\delta} = \boldsymbol{0}$ is that the posterior predictive means and variances of $f_*^{(k)}$ and $f_*^{(l)}$ for two neighboring regions Ω_k and Ω_l are equal at the specified input boundary locations $\mathbf{x}_{k,l}$; see Appendix B for details. The continuity imposed certainly does not guarantee that the posterior means and variances of $f_*^{(k)}$ and $f_*^{(l)}$ are equal for every $x^* \in \Gamma_{k,l}$, including those not in the locations of pseudo observations $\mathbf{x}_{k,l}$. Our numerical experiments in Section 5 demonstrate that as we place more pseudo inputs, the posterior means and variances of $f_*^{(k)}$ and $f_*^{(l)}$ converge to each other.

From the preceding, our proposed approach enforces that the two local GP models for two neighboring local regions have the same posterior predictive means and variances (and they satisfy an even stronger condition, that the responses themselves are identical) at the chosen set of boundary points corresponding to the pseudo observations. We view this as patching together the independent local models in a nearly continuous way. The chosen sets of boundary points serve as the stitches when patching together the pieces, and the more boundary points are chosen, the closer the models are to being continuous over the entire boundary. In light of this, we refer to the approach as *patchwork kriging*.

3.2 Hyperparameter Learning and Prediction

The hyperparameters of the covariance function(s) $c_k(\cdot, \cdot)$ determine the correlation among the values of $f(x)$, which has significant effect on the accuracy of a Gaussian process regression. We jointly estimate all correlation parameters (multiple sets of parameters if

different $c_k(\cdot,\cdot)$ are assumed for each region) using maximum likelihood estimation (MLE) by minimizing the negative log marginal likelihood,

$$\begin{aligned} NL(\theta) =& -\log p(\boldsymbol{y}, \boldsymbol{\delta}=\mathbf{0}|\theta) \\ =& \frac{N}{2}\log(2\pi) + \frac{1}{2}\log\left|\begin{array}{cc} \boldsymbol{C}_{\mathcal{D}\mathcal{D}} & \boldsymbol{C}_{\mathcal{D},\delta} \\ \boldsymbol{C}_{\delta,\mathcal{D}} & \boldsymbol{C}_{\delta,\delta}\end{array}\right| + \frac{1}{2}[\boldsymbol{y}^T \mathbf{0}^T]\left[\begin{array}{cc} \boldsymbol{C}_{\mathcal{D}\mathcal{D}} & \boldsymbol{C}_{\mathcal{D},\delta} \\ \boldsymbol{C}_{\delta,\mathcal{D}} & \boldsymbol{C}_{\delta,\delta}\end{array}\right]^{-1}\left[\begin{array}{c}\boldsymbol{y}\\ \mathbf{0}\end{array}\right] \end{aligned} \tag{8}$$

Note that we have augmented the data to included the pseudo observations $\boldsymbol{\delta}=\mathbf{0}$ in the likelihood expression, which results in a better behaved likelihood by imposing some continuity across regions. This essentially allows data to be shared across regions when estimating the covariance parameters. Using the properties of a determinant for a partitioned matrix, the determinant part in the marginal likelihood becomes

$$\left|\begin{array}{cc} \boldsymbol{C}_{\mathcal{D}\mathcal{D}} & \boldsymbol{C}_{\mathcal{D},\delta} \\ \boldsymbol{C}_{\delta,\mathcal{D}} & \boldsymbol{C}_{\delta,\delta}\end{array}\right| = |\boldsymbol{C}_{\mathcal{D}\mathcal{D}}||\boldsymbol{C}_{\delta,\delta} - \boldsymbol{C}_{\delta,\mathcal{D}}\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D},\delta}|,$$

which can be used to compute the log determinant term in $NL(\theta)$ as follows,

$$\log\left|\begin{array}{cc} \boldsymbol{C}_{\mathcal{D}\mathcal{D}} & \boldsymbol{C}_{\mathcal{D},\delta} \\ \boldsymbol{C}_{\delta,\mathcal{D}} & \boldsymbol{C}_{\delta,\delta}\end{array}\right| = \log|\boldsymbol{C}_{\mathcal{D}\mathcal{D}}| + \log\left|\boldsymbol{C}_{\delta,\delta} - \boldsymbol{C}_{\delta,\mathcal{D}}\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D},\delta}\right|.$$

Note that the log determinant of the block diagonal matrix $\boldsymbol{C}_{\mathcal{D}\mathcal{D}}$ is equal to the sum of the log determinants of its diagonal blocks, and $\boldsymbol{C}_{\delta,\delta} - \boldsymbol{C}_{\delta,\mathcal{D}}\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D},\delta}$ is very sparse, so the cholesky decomposition of the sparse matrix can be taken to evaluate their determinants; we will detail the sparsity discussion in the next section. Evaluating the quadratic term of the negative log marginal likelihood function involves the inversion of $(\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)$. The inversion can be effectively evaluated using

$$(\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1} = \boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1} + \boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}(\boldsymbol{C}_{\delta,\delta} - \boldsymbol{C}_{\mathcal{D}\delta}^T\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D}\delta})^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}. \tag{9}$$

After the hyperparameters were chosen by the MLE criterion, evaluating the predictive mean and variance for the patchwork kriging model can be performed as follows. Let $\boldsymbol{Q}$ denote the inversion result of (9), and let $\boldsymbol{L}$ denote the cholesky decomposition of $\boldsymbol{C}_{\delta,\delta}$ such that $\boldsymbol{C}_{\delta,\delta} = \boldsymbol{L}\boldsymbol{L}^T$. After the pre-computation of the two matrices and $\boldsymbol{v} = \boldsymbol{L}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T$, the predictive mean (6) and the predictive variance (7) can be evaluated for each $x_* \in \Omega_k$,

$$\begin{aligned} \mathbb{E}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}=\mathbf{0}] &= (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{w}_*^T\boldsymbol{v})\boldsymbol{Q}\boldsymbol{y} \\ \mathbb{V}\mathrm{ar}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}=\mathbf{0}] &= c_{**} - \boldsymbol{w}_*^T\boldsymbol{w}_* - (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{w}_*^T\boldsymbol{v})\boldsymbol{Q}(\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{w}_*^T\boldsymbol{v})^T, \end{aligned} \tag{10}$$

where $\boldsymbol{w}_* = \boldsymbol{L}^{-1}(\boldsymbol{c}_{*\delta}^{(k)})^T$. The computation steps of patchwork kriging were described in Algorithm 1.

3.3 Sparsity and Complexity Analysis

The computational expense of patchwork kriging is much less than that of the global GP regression. The computational expense of the patchwork kriging model is dominated by evaluating the inversion (9). The inversion comes in two parts. The first part is to invert

Algorithm 1 Computation Steps for Patchwork Kriging

Require:
1: Decomposition of domain $\{\Omega_k; k = 1, \ldots, K\}$; see Section 3.4 for a choice.
2: Locations of pseudo data $\{\mathbf{x}_{k,l}; k, l = 1, \ldots, K\}$; see Section 3.4 for a choice.
3: Hyperparameters of covariance function $c_k(\cdot,\cdot)$; use the MLE criterion (8) for a choice.
Input: Data $\mathcal{D}$ and test location x_*
Output: $\mathbb{E}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}=\mathbf{0}]$ and $\mathbb{V}\mathrm{ar}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}=\mathbf{0}]$
4: **Evaluate** $\mathbf{Q} = (\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}$ using (9).
5: **Take** the Cholesky Decomposition of $\boldsymbol{C}_{\delta,\delta} = \boldsymbol{L}\boldsymbol{L}^T$.
6: **Evaluate** $\boldsymbol{v} = \boldsymbol{L}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T$.
7: **for** $x_* \in \Omega_k$ **do**
8: **Evaluate** $\boldsymbol{w}_* = \boldsymbol{L}^{-1}(\boldsymbol{c}_{*\delta}^{(k)})^T$.
9: $\mathbb{E}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}=\mathbf{0}] = (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{w}_*^T\boldsymbol{v})\boldsymbol{Q}\boldsymbol{y}$.
10: $\mathbb{V}\mathrm{ar}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}=\mathbf{0}] = c_{**} - \boldsymbol{w}_*^T\boldsymbol{w}_* - (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{w}_*^T\boldsymbol{v})\boldsymbol{Q}(\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{w}_*^T\boldsymbol{v})^T$.
11: **end for**

$\boldsymbol{C}_{\mathcal{D}\mathcal{D}}$. Note that $\boldsymbol{C}_{\mathcal{D}\mathcal{D}}$ is a block diagonal matrix with the kth block size equal to the size of $\mathcal{D}_k$. If the size of each $\mathcal{D}_k$ is M, evaluating $\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}$ requires only inverting K matrices of size $M \times M$, and its expense is $O(KM^3)$. Given $\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}$, evaluating $\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}$ adds $O(KBM^2)$ to the computational expense.

The second part of the inversion (9) is to invert $\boldsymbol{C}_{\delta,\delta} - \boldsymbol{C}_{\mathcal{D}\delta}^T\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}$. The matrix is very sparse, because $\mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{k,l}, \boldsymbol{\delta}_{u,v}) - \sum_{m=1}^K \mathbb{C}\mathrm{ov}(\boldsymbol{\delta}_{k,l}, \boldsymbol{y}_m)\,\mathbb{C}\mathrm{ov}(\boldsymbol{y}_m, \boldsymbol{y}_m)^{-1}\,\mathbb{C}\mathrm{ov}(\boldsymbol{y}_m, \boldsymbol{\delta}_{u,v})$ is a zero matrix unless the tuple (k, l, u, v) satisfies the non-zero conditions listed in (4). The symmetric sparse matrix can be converted into a symmetric sparse banded matrix by the reverse Cuthill-McKee algorithm (Chan and George, 1980), and the computational complexity of the conversion algorithm is linearly proportional to the number of non-zero elements in the original sparse matrix. Let d_f denote the number of neighboring local regions of each local region, and B denote the number of pseudo observations placed per boundary. The number of non-zero elements in the sparse matrix is $O(d_f BK)$, so the time complexity of the reverse Cuthill-McKee algorithm is $O(d_f BK)$. The bandwidth of the resulting sparse matrix is linearly proportional to $d_f B$, and the size of the matrix is proportional to $d_f BK$. The complexity of taking the inverse of a symmetric banded matrix with size r and bandwidth p through Cholesky decomposition is $O(rp^2)$ (Golub and Van Loan, 2012, pp. 154). Therefore, the complexity of inverting $\boldsymbol{C}_{\delta,\delta} - \boldsymbol{C}_{\mathcal{D}\delta}^T\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}$ is $O(d_f^3 B^3 K)$. Note that $d_f \propto d$ if data are more densely distributed over the entire input dimensions, and $d_f \propto d'$ if data are a d'-dimensional embedding in d dimensional space. The complexity becomes $O(d^3 B^3 K)$ for the worst case scenario.

Therefore, the total computational expense of the inversion (9) is $O(KM^3 + KBM^2 + d_f^3 B^3 K)$. Typically, $B \ll M$, in which case the complexity is $O(KM^3 + d_f^3 B^3 K)$. Note that $M \approx N/K$, where the approximation error is due to rounding N/K to an integer value. Therefore, the complexity can be written as $O(N^3/K^2 + d_f^3 B^3 K)$. Given a fixed data size N, more splits of the regression domain will reduce the computation time due to the first term in the complexity, but too much increase would increase the second term, which will

be shown later in Section 6. When data are dense in the input space, $d_f \propto d$, for which the complexity would increase in d^3. For $d < 10$, the effect is pretty ignorable unless B is very large, but it becomes significant when $d > 10$. This computation issue related to data dimensions basically suggests to limit the practical use of this method to d less than 100. We will later discuss more on this issue and how to choose K and B to balance off the computation and prediction accuracy in Section 5.2.

In addition to the computational expense of the big inverse, additional incremental computations are needed per each test location x_*. The first part is to evaluate for the predictive mean and variances,

$$(\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{c}_{*\delta}^{(k)} \boldsymbol{C}_{\delta,\delta}^{-1} \boldsymbol{C}_{\mathcal{D}\delta}^{T}). \tag{11}$$

Note that the elements in $\boldsymbol{c}_{*\mathcal{D}}^{(k)}$ are mostly zero except for the columns that correspond to $\mathcal{D}_k$ (size M), and similarly most elements of $\boldsymbol{c}_{*\delta}^{(k)}$ are zero except for the columns that correspond to $\boldsymbol{\delta}_{k,l}$'s (size $d_f B$). The cost of evaluating (11) is $O(M + d_f B)$. Therefore, the cost of the predictive mean prediction per a test location is $O(M + d_f B)$, and the cost for the predictive variance is $O((M + d_f B)^2)$. When data are dense in the input dimensions, the costs become $O(M + dB)$ and $O((M + dB)^2)$.

3.4 Tuning Parameter Selection

The performance of the proposed patchwork kriging method depends on the choice of tuning parameters, including the number of partitions (K) and the number (B) and locations ($\mathbf{x}_{k,l}$) of the pseudo observations. This section presents guidelines for these choices. Choosing the locations of pseudo observations is related to the choice of domain partitioning. In this section, we discuss the choices of the locations and partitioning together.

There are many existing methods to partition a large set of data into smaller pieces. The simplest spatial partitioning is a uniform grid partitioning that divides a domain into uniform grids and splits data accordingly (Park et al., 2011; Park and Huang, 2016). This is simple and effective if the data are uniformly distributed over a low dimensional space. However, if the input dimension is high, it would either generate too many regions or it would produce many sparse regions that contain very few or no observations, and the latter also happens when the data are non-uniformly distributed; see examples in Figure 2-(c) and Figure 2-(e). Shen et al. (2006) used a kd-tree for spatial partitioning of unevenly distributed data points in a high dimensional space. A kd-tree is a recursive partitioning scheme that recursively bisects the subspaces along one chosen data dimension at a time. Later, McFee and Lanckriet (2011) generalized it to the spatial tree. Starting with a level 0 space $\Omega_1^{(0)}$ equal to the entire regression domain, the spatial tree recursively bisects each of level s spaces into two level $s+1$ spaces. Let $\Omega_j^{(s)} \in \mathbb{R}^d$ denote the jth region in the level s space. It is bisected into two level $s+1$ spaces as

$$\Omega_{2j-1}^{(s+1)} = \{\boldsymbol{x} \in \Omega_j^{(s)} : \boldsymbol{v}_{j,s}^T \boldsymbol{x} \le \nu\} \text{ and } \Omega_{2j}^{(s+1)} = \{\boldsymbol{x} \in \Omega_j^{(s)} : \boldsymbol{v}_{j,s}^T \boldsymbol{x} > \nu\}. \tag{12}$$

Each of $\Omega_{2j-1}^{(s+1)}$ and $\Omega_{2j}^{(s+1)}$ will be further partitioned in the next level using the same procedure. The choice of the linear projection vector $\boldsymbol{v}_{j,s}$ depends on the distribution of the

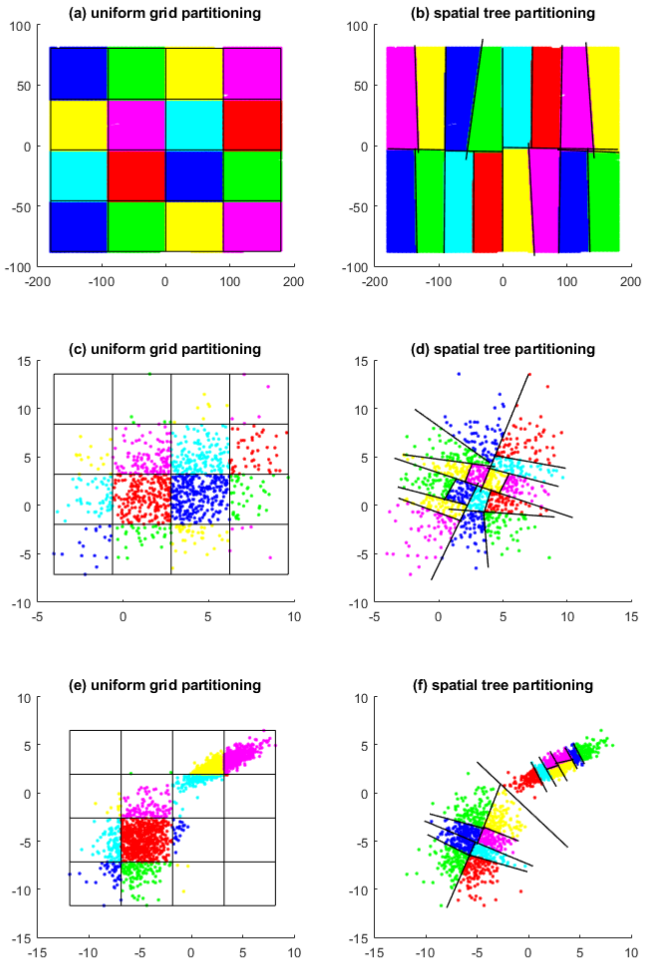

Figure 2: Comparison of two spatial partitioning schemes: a uniform grid (left panel) and a spatial tree (right panel). The spatial tree generates data partitioning of uniform sizes when data is unevenly distributed, but the uniform grid does not.

local data belonging to $\Omega_j^{(s)}$. For example, it can be the first principal component direction of the local data. The value for ν is chosen so that $\Omega_{2j-1}^{(s+1)}$ and $\Omega_{2j}^{(s+1)}$ have an equal number of observations. In this sense, the subregions at the same level are equally sized, which helps to level off the computation times of the local models. When the spatial tree is applied on data uniformly distributed over a rectangular domain, it produces a uniform grid partitioning; see examples in Figure 2-(b). The spatial tree is more effective than the grid partitioning when data is unevenly distributed; see examples in Figure 2-(d) and Figure 2-(f).

In this work, we use a spatial tree with the principal component (PC) direction for $\boldsymbol{v}_{j,s}$. Bisecting a space along the PC direction has effects of minimizing the area of the interfacial boundaries in between the two bisected regions, so the number of the pseudo observations necessary for connecting the two regions can be minimized. The maximum level of the recursive partitioning depends on the choice of K via $s_{max} = \lfloor \log_2 K \rfloor$. The choices of K and B will be discussed in the next section. Given B, the pseudo observations $\mathbf{x}_{k,l}$ are randomly generated from an uniform distribution over the intersection of the hyper-plane $\boldsymbol{v}_{j,s}^T \boldsymbol{x} = \nu$ and the level s region $\Omega_j^{(s)}$.

4. Illustrative Example

To illustrate how patchwork kriging changes the model predictions (relative to a set of independent GP models over each region, with no continuity conditions imposed), we designed the following simple simulation study; we will present more comprehensive simulation comparisons and analyses in Section 5. We generated a dataset of 6,000 noisy observations

$$y_i = f(x_i) + \epsilon_i \quad \text{for } i = 1, \ldots, 6000,$$

from a zero-mean Gaussian process with an exponential covariance function of $c(x_i, x_j) = 10 \exp(-||x_i - x_j||_2)$, where $x_i \sim \text{Uniform}(0, 10)$ and $\epsilon_i \sim \mathcal{N}(0, 1)$ are independently sampled, and $f(x_i)$ is simulated by the R package `RandomField`. Three hundred of the 6,000 observations were randomly selected as the training data $\mathcal{D}$, while the remaining 5,700 were reserved for test data. Figure 3 illustrates how the patchwork kriging predictor changes for different K, relative to the global GP predictor and the regular local GP predictor with no continuity conditions across regions. As the number of regions (K) increases, the regular local GP predictor deviates more from the global GP predictor. The test prediction mean square error (MSE) for the regular local GP predictor at the 5,700 test locations is 0.0137 for $K = 4$, 0.0269 for $K = 8$, 0.0594 for $K = 16$, and 0.1268 for $K = 32$. In comparison, patchwork kriging substantially improves the test MSE to 0.0072 for $K = 4$, 0.0123 for $K = 8$, 0.0141 for $K = 16$, and 0.0301 for $K = 32$.

We also generated a synthetic dataset in 2-d using the R package `RandomField`, and we denote this dataset by `synthetic-2d`. `synthetic-2d` consists of 8,000 noisy observations from a zero-mean Gaussian process with the exponential covariance function of $c(x_i, x_j) = 10 \exp(-||x_i - x_j||_2)$,

$$y_i = f(x_i) + \epsilon_i \quad \text{for } i = 1, \ldots, 8000,$$

where $x_i \sim \text{Uniform}([0, 6] \times [0, 6])$ and $\epsilon_i \sim \mathcal{N}(0, 1)$ were independently sampled. We used the dataset to illustrate how two local GP models for two neighboring local regions change

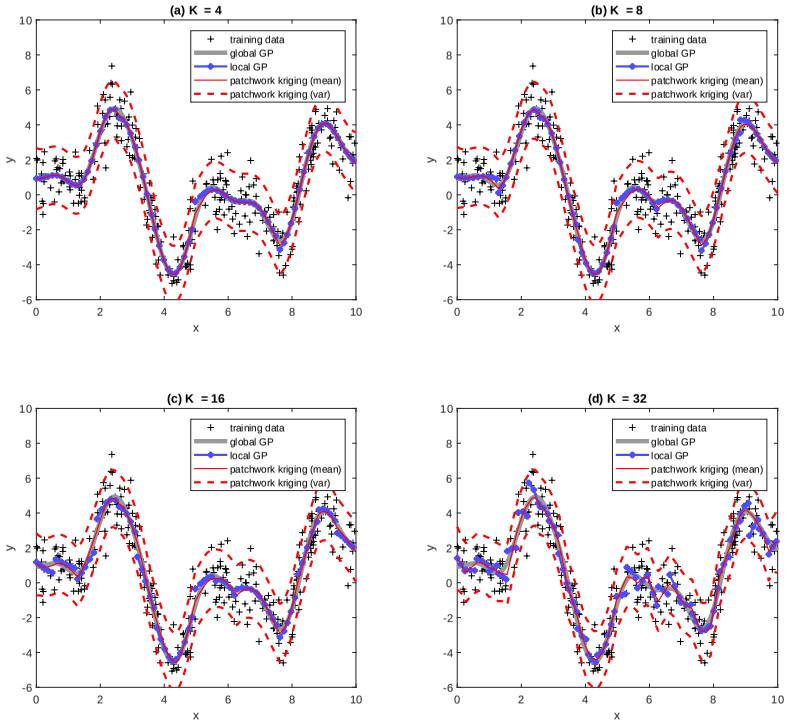

Figure 3: Example illustrating the patchwork kriging predictor, together with the global GP predictor and the regular local GP predictor with no continuity constraints. K is the number of local regions.

as B changes. We first partitioned the dataset into 128 local regions as shown in Figure 4-(a). For evaluation purposes, we considered test points that fell on the boundary cutting the entire regression domain into two (indicated by the black solid line in Figure 4-(a)), and sampled 201 test points uniformly over this boundary; the test locations do not coincide with the locations that pseudo observations placed. For each point, we get two mean predictions from the two local patchwork kriging models that straddle the boundary at that point. We compared the two mean predictions to each other for different choices of B and also compared them with the optimal global GP prediction, i.e., the prediction using the true GP covariance function and the entire dataset globally without spatial partitioning. Figure 4 shows the comparison. When $B = 0$, the two local models exhibited significant differences in their mean predictions. The differences decreased as B increased, and became negligible

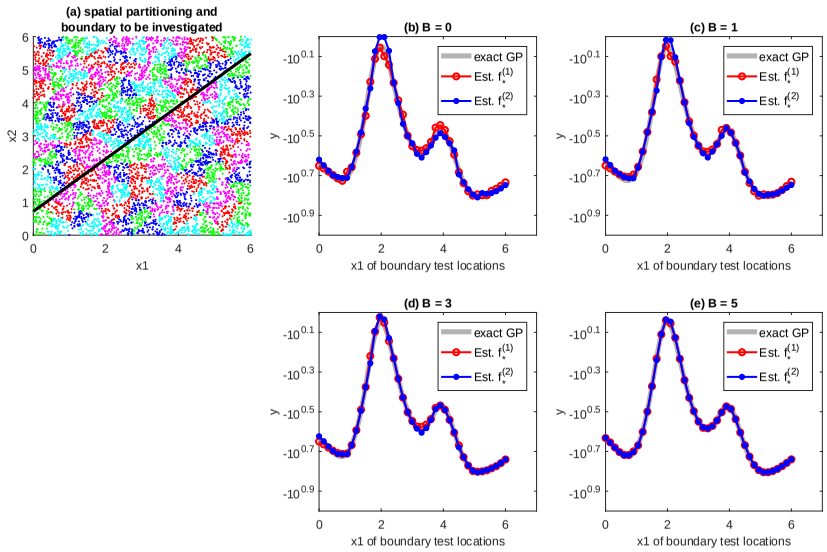

Figure 4: Comparison of the patchwork kriging mean predictions of two local models over interfacial boundaries. Panel (a) shows how the entire regression domain was spatially partitioned into 128 local regions, which are distinguished by their colors. The black solid line cutting through the entire space is the interfacial boundary that we selected to study the behavior of the patchwork kriging at interfacial boundaries. Panels (b), (c), (d) and (e) compare the patchwork kriging mean predictions of the neighboring local models when $B = 0$, 1, 3, and 5. In the panels, the horizontal axes represent the x1 coordinates of test locations on the solid interfacial boundary line shown in panel (a). $f_*^{(1)}$ and $f_*^{(2)}$ denote the mean predictions of the two local models on each side of the solid boundary line. As B increases, the two local predictions converge to each other, and the converged values are very close to the benchmark predictor achieved using the true GP model globally.

when $B \geq 5$. The mean predictions were also very close to the exact GP predictions. The similar results were observed in different simulated examples, which will be discussed in Section 5.

5. Evaluation with Simulated Examples

In this section, we use simulation datasets to understand how the patchwork kriging behaves under different input dimensions, covariance ranges and choices of K and B.

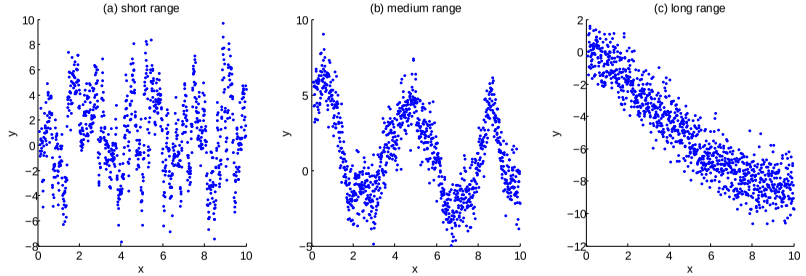

Figure 5: Illustrative Data with Short-range, Med-range and Long-range Covariances

5.1 Datasets and Evaluation Criteria

Simulation datasets are sampled from a Gaussian process with the squared exponential covariance function,

$$c(x_i, x_j) = \tau \exp\left(-\frac{(x_i - x_j)^T(x_i - x_j)}{2\rho^2}\right) \text{ for } x_i, x_j \in \mathbb{R}^d, \tag{13}$$

where $\tau > 0$ is the scale parameter, and $\rho > 0$ determines the range of covariance. We randomly sampled 10,000 pairs of x_i and y_i. Each x_i is uniformly from $[0, 10]^d$, and then evaluate the sample covariance matrix with τ and ρ for the 10,000 sampled inputs, $\boldsymbol{C}_{\tau,\rho}$. All y_i's are jointly sampled from $\mathcal{N}(\boldsymbol{0}, \sigma^2\boldsymbol{I} + \boldsymbol{C}_{\tau,\rho})$. We fixed $\tau = 10$ and $\sigma^2 = 1$, but chose ρ to 0.1 (short range), 1 (med range) or 10 (long range) to simulate datasets having different covariance ranges; see Figure 5 for illustrating simulated datasets for one dimensional input. In addition, the input dimension d was varied over $\{2, 5, 10, 100\}$. In total, we considered 12 different combinations of different ρ and d values. For each combination, we drew 50 datasets, so there are 600 datasets in total.

For each of the datasets, we ran the patchwork kriging with different choices of $K \in \{16, 32, 64, 128, 256\}$ and $B \in \{0, 1, 2, 3, 5, 7, 10, 15, 20, 25\}$. For each run, we evaluate the computation time and prediction accuracy of patchwork kriging. For the prediction accuracy, we first computed the predictive mean of the optimal GP predictor (i.e., using the true exponential covariance function) at test locations, and we used these optimal prediction values as a benchmark against which to judge the accuracy of the patchwork kriging predictions. One thousand test locations are uniformly sampled from the interior of local regions, denoted by $\{x_t; t = 1, ..., T_I\}$, and 200 additional test locations were uniformly sampled from the boundaries between local regions, which are denoted by $\{x_t; t = T_I + 1, ..., T_I + T_B\}$. Let μ_t denote the estimated posterior predictive mean at location x_t, and let $\tilde{\mu}_t$ denote the benchmark predictive mean at the same location. We measure three performance metrics for the mean predictions. The first two measures are the interior mean squared error (I-MSE) and the boundary mean squared error (B-MSE)

$$\text{I-MSE} = \frac{1}{T_I}\sum_{t=1}^{T_I}(\tilde{\mu}_t - \mu_t)^2, \text{ and B-MSE} = \frac{1}{T_B}\sum_{t=T_I+1}^{T_I+T_B}(\tilde{\mu}_t - \mu_t)^2, \tag{14}$$

which measure the average accuracy of the mean prediction inside local regions and on the boundary of local regions. For each boundary point in $\{x_t; t = T_I + 1, ..., T_I + T_B\}$, we get two mean predictions from the two local patchwork kriging models that straddle the boundary at that point. In the B-MSE calculation, we took one of the two predictions following the rule: when $x_* \in \Gamma_{kl}$, choose the prediction for $f_*^{(k)}$ if $k < l$. Please note that when a test location is at a corner where three or more local regions meet, we do have more than two predictions, which did not happen in all of our testing scenarios. We also evaluated the squared difference of the two mean predictions for each of 200 boundary points, and the mean squared mismatch (MSM) was defined as the average of the squared differences. We also measured the three performance metrics for the variance predictions, which were named 'I-MSE(σ^2)', 'B-MSE(σ^2)' and 'MSM(σ^2)' respectively.

5.2 Analysis of the Outcomes and Choices of K and B

Figure 6 shows the I-MSE, B-MSE and MSM performance of the patchwork kriging for different covariance ranges and different choices of K and B when $d = 100$, and Appendix C contains the plots of all six performance metrics for all simulation configurations. All of the performance metrics have shown the similar patterns:

- **Covariance Ranges:** All of the performance metrics became negligibly small for medium-range and long-range covariances with large B. This implies that the patchwork kriging approximates the full GP very well for medium-range and longer-range covariances; please see Appendix for detailed plots. This result is opposite to our initial expectation that local-based approaches would have some deviations from the full GP for long-range covariances. As long as the underlying covariance is stationary, the proposed approach works well for long-range covariance cases.

- **Effect of B:** All of the metrics decrease in B but does not change much for B above 8 for medium-range and long-range covariances. However, when the covariance range is short, the improvement of the three metrics goes slower. This implies larger B is required to achieve good accuracy for short-range covariances.

- **Effect of K:** All of the metrics increase in K when the other conditions are kept same. This is understandable, because the simulated data came from a stationary process. However, the effect of K on the three metrics was relatively small when $B > 7$ and covariance ranges are medium or long. Since the computational complexity of the proposed method decreases with increase of K, choosing a large K with $B > 7$ could be a computationally economic option with good prediction accuracy. See our computation time analysis below for an additional discussion on the choices of K and B.

- **Boundary Consistency:** Both of the MSM and MSM(σ^2) goes to zero as B increases for medium and long-range covariances. This implies that if data change smoothly, the patchwork idea does not only guarantee the same predictions on the locations pseudo data placed but also gives the same predictions over the entire inter-domain boundaries.

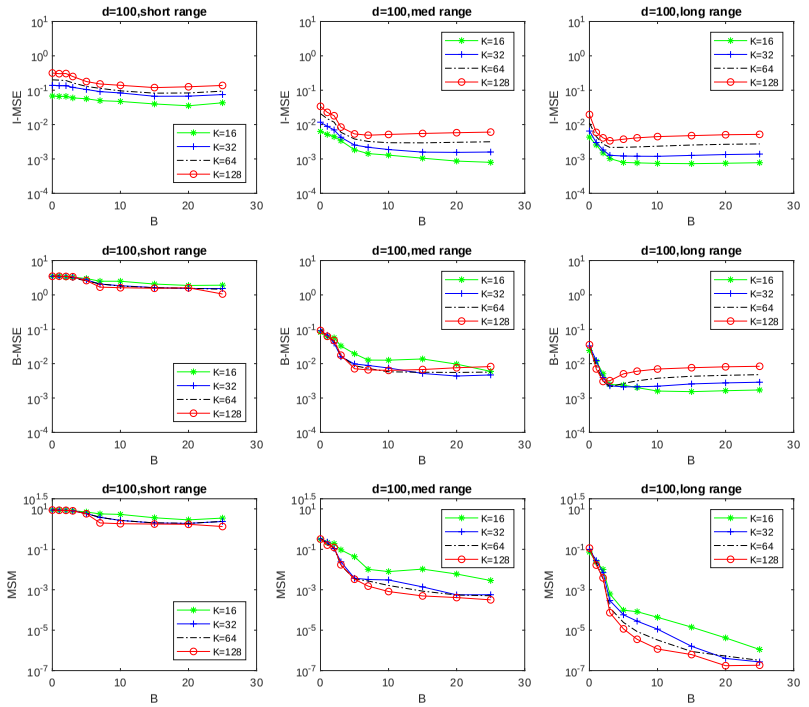

Figure 6: Performance of Patchwork Kriging for Simulated Cases with 100 Input Dimensions.

Figure 7 summarizes the total computation time of the patchwork kriging for different configuration.

- It appears that the input dimension is not a determining factor of the time if the input dimension $d \leq 10$, but for $d > 10$, it became a major factor to affect the time. As we discussed in Section 3.3, the computational complexity of the patchwork kriging is $O(N^3/K^2 + d_f^3 B^3 K)$. When data are uniformly located over the regression domain, $d_f \propto d$ and the computation of the patchwork kriging is scaling proportionally to d^3.

- When $d \leq 10$, the deciding factor for the computation time was K. In general, larger K gave shorter computation times.

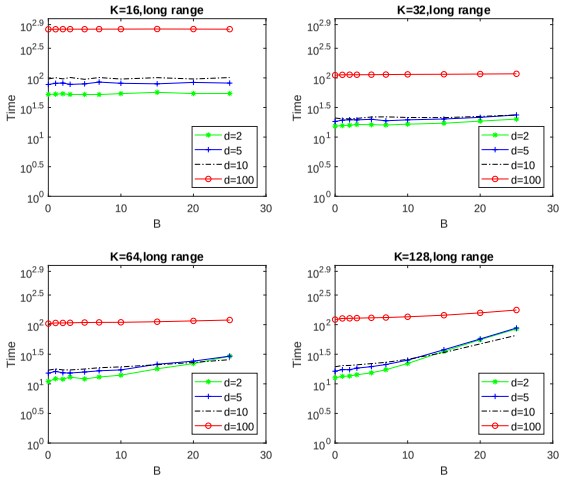

Figure 7: Summary of Total Computation Times for Simulated Cases.

- With larger K, B becomes more influential to the total computation time. This is due to the increase of the second term in the overall computational complexity, $O(N^3/K^2 + d_f^3 B^3 K)$.
- To keep the total computation time lower, both of N/K and $d_f B$ should be kept lower. On the other hand, N/K and $d_f B$ cannot be too small due to degradation of prediction accuracy with a large K and a small B.

Our numerical studies suggest to choose K so that N/K be in between 200 and 600 and then choose B so that $d_f B$ is in between 15 and 400 to balance off the computation and prediction accuracy; these were based on all of the simulation cases presented in this section as well as the six real data studies that will be presented in the next section. In order to keep $d_f B \leq 400$ for efficient computation and $B \geq 7$ for prediction accuracy, $d_f \leq 400/7$. Therefore, the proposed approach would benefit more for $d_f \leq 55$. However, the proposed approach still worked better than some existing approaches for the simulated cases with $d = 100$; see the numerical results in Sections 5.3 and 5.4.

5.3 Comparison to a Global Approximation Method

We also used the simulated cases to compare the patchwork kriging to a global GP approximation method, the Fully Independent Training Conditional (FITC) algorithm (Snelson and Ghahramani, 2006, FITC). We decided to compare ours with the global GP approximation method because we thought that the global GP approximation would work better when stationary covariances are used. For the patchwork kriging, we fixed $B = 7$ and varied $K \in \{32, 64, 128, 256\}$. For the FITC, the total number of pseudo inputs was varied over

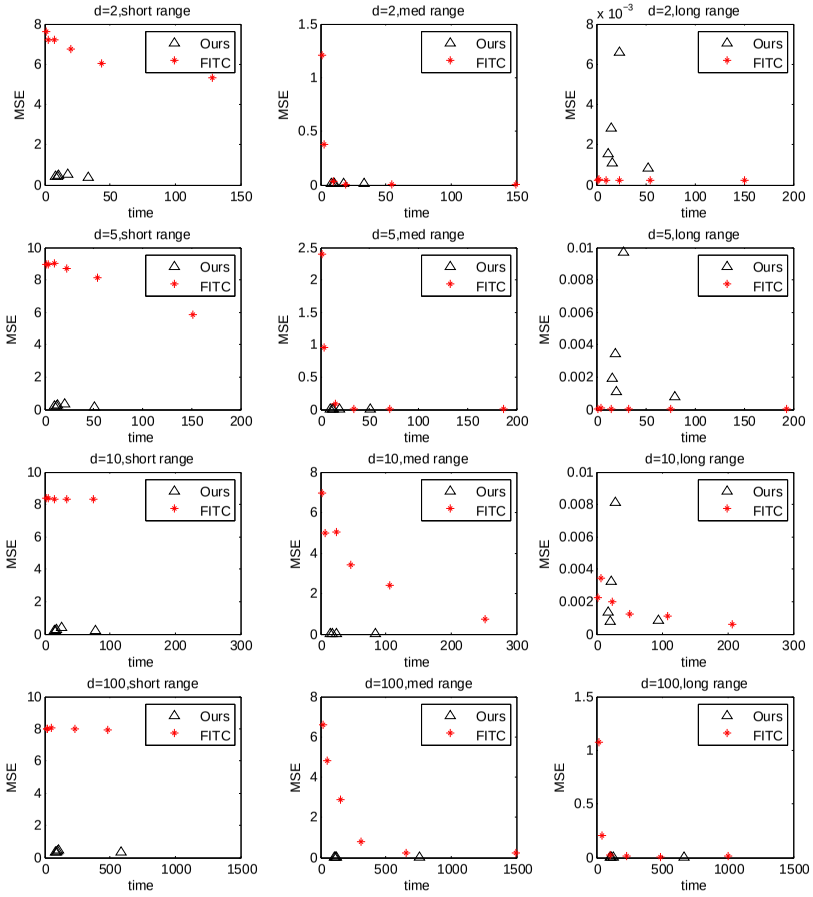

Figure 8: Comparison of Total Computation Times vs. MSE for Simulated Cases; triangles and stars represent the results of the patchwork kriging and FITC respectively.

$\{16, 32, 64, 128, 256, 512\}$. The computation times versus MSE of the mean prediction were compared for different input dimensions and covariance ranges. Figure 8 summarizes the outcome. The patchwork kriging outperformed the FITC with significant performance gaps for all short covariance and medium range covariance cases. For long range covariance cases,

the FITC performed better when $d < 10$, but the patchwork kriging performed comparably when $d \geq 10$.

The performance gap in between the FITC and the patchwork kriging can be explained by a more efficient computation of the patchwork kriging. Both of the FITC and patchwork kriging use pseudo inputs. Their accuracies depend on the total number of pseudo inputs used. When Q pseudo inputs were applied for both of FITC and the patchwork kriging, the computation of the FITC involves the inversion of a $Q \times Q$ dense matrix, while the computation of the patchwork kriging involves the inversion of the sparse matrix of the same size that corresponds to equation (9). Therefore, when comparable computation times were invested, the patchwork kriging could place more pseudo inputs than the FITC, so it can give better accuracy. In addition, the locations of the pseudo inputs in the FITC need to be learned together with covariance hyperparameters, and the increase in the number of pseudo inputs would increase the computation time for hyperparameter learning.

5.4 Comparison to Local Approximation Methods

We also used the simulated cases to compare the patchwork kriging to two local GP approximation methods, a robust Bayesian committee machine (Deisenroth and Ng, 2015, RBCM), and a partially independent conditional approach (Snelson and Ghahramani, 2007, PIC). For the patchwork kriging, we fixed $B = 7$ and varied $K \in \{32, 64, 128\}$. For RBCM, we used $K \in \{32, 64, 128\}$. For PIC, we used $K \in \{32, 64, 128\}$ with the total number of pseudo inputs fixed to 128. Figure 9 summarizes the comparison of MSE performance. The patchwork kriging performed very competitively for all simulated cases. The significant increase of computation time for the input dimension more than 10 was observed for all of the compared methods.

6. Evaluation with Real Data

In this section, we use five real datasets to evaluate the patchwork kriging and compare it with the state-of-the-art, including (Park and Huang, 2016, PGP), a Gaussian Markov random field approximation (Lindgren et al., 2011, GMRF), a robust Bayesian committee machine (Deisenroth and Ng, 2015, RBCM), and a partially independent conditional approach (Snelson and Ghahramani, 2007, PIC). The comparison with one additional dataset is presented in Appendix D.

6.1 Datasets and Evaluation Criteria

We considered five real datasets: two spatial datasets in 2-d with different spatial distributions of observations, one additional spatial dataset with a very large data size, and three higher dimensional datasets, one with 9-dimension, another with 21-dimension and the other with 8-dimension.

The first spatial dataset, `TCO.L2`, 182,591 observations collected by the NIMBUS-7/TOMS satellite, which measures the total column of ozone over the globe on Oct 1 1988. Two predictors represent the longitude and latitude of a measurement location, while the corresponding independent variable represents the measurement at the location. The observations are uniformly spread over the range of the two predictors. The main analysis objective with this dataset is to predict the total column of ozone at unobserved locations.

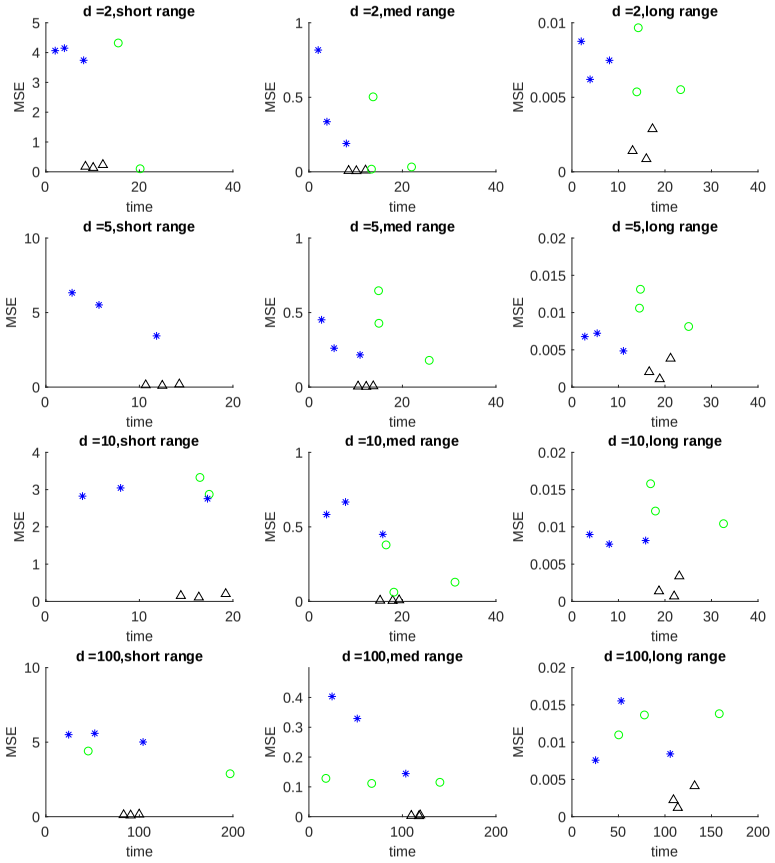

Figure 9: Comparison of Total Computation Times vs. MSE for Simulated Cases; triangles, stars and circles represent data for the patchwork kriging, PIC and RBCM respectively. The number of circles are not always same because PIC could not produce outcomes for some simulated cases due to singularity in numerical inversion.

The second dataset, `ICETHICK`, contains ice thickness measurements at 32,481 locations on the western Antarctic ice sheet and is available at `http://nsidc.org/`. It has two predictors that represent the longitude and latitude of a measurement location, and the

corresponding independent variable is the ice thickness measurement. The dataset has many sparse regions where there are very few observations. Regression analysis with this dataset would give the prediction of ice thickness at unobserved locations.

The third dataset, `PROTEIN`, has nine input variables that describe the tertiary structure of proteins and one independent variable that describes the physiochemical property of proteins. These data, which are available at `https://archive.ics.uci.edu/ml/datasets`, consist of 45,730 observations. Like typical high dimensional datasets, the measurements are embedded on a low dimensional subspace of the entire domain. This dataset can be studied to relate the structure of a protein with the physiochemical property of the protein for predicting the property from the structure.

The fourth dataset, `SARCOS`, contains measurements from a seven degrees-of-freedom SARCOS anthropomorphic robot arm. There are 21 predictors that describe the positions, moving velocities and accelerations of seven joints of the robot arm, and the seven response variables are the corresponding torques at the seven joints. We only use the first response variable for this numerical study. The dataset, which is available at `http://www.gaussianprocess.org/gpml/data/`, contains 44,484 training observations and 4,449 test observations. The main objective of the regression analysis is to predict one of the joint torques in a robot arm when the values of the predictors are available.

The last dataset, `FLIGHT`, consists of 800,000 flight records randomly selected from the database available at `http://stat-computing.org/dataexpo/2009/`. The same size subset of the database was used as a benchmark dataset in literature (Hensman et al., 2013). Following the use in the literature, we used 8 predictors that include the age of the aircraft, distance that needs to be covered, airtime, departure time, arrival time, day of the week, day of the month and month, and the response variable is the arrival time delay. This dataset was studied to predict the flight delay time when the predictors are given.

Using the five datasets, we compare the computation time and prediction accuracy of patchwork kriging with other methods. We randomly split each dataset into a training set containing 90% of the total observations and a test set containing the remaining 10% of the observations. To compare the computational efficiency of methods, we measure total computation times. For comparison of prediction accuracy, we measure two performance metrics on the test data, denoted by $\{(x_t, y_t) : t = 1, \ldots, T\}$, where T is the size of the test set. Let μ_t and σ_t^2 denote the estimated posterior predictive mean and variance at location x_t; when the testing location x_t is in the domain boundary Γ_{kl}, we may have two predictions, one for $f^{(k)}(x_t)$ and the other for $f^{(l)}(x_t)$, for which we choose one for $f^{(k)}(x_t)$ if $k < l$. Please note that when a test location is at a corner where three or more local regions meet, we do have more than two predictions, which did not happen in all of our testing scenarios. We also evaluated the squared The first measure is the mean squared error (MSE)

$$\text{MSE} = \frac{1}{T}\sum_{t=1}^{T}(y_t - \mu_t)^2, \tag{15}$$

which measures the accuracy of the mean prediction μ_t at location x_t. The second measure is the negative log predictive density (NLPD)

$$\text{NLPD} = \frac{1}{T}\sum_{t=1}^{T}\left[\frac{(y_t - \mu_t)^2}{2\sigma_t^2} + \frac{1}{2}\log(2\pi\sigma_t^2)\right]. \tag{16}$$

The NLPD quantifies the degree of fitness of the estimated predictive distribution $\mathcal{N}(\mu_t, \sigma_t^2)$ for the test data. These two criteria are used broadly in the GP regression literature. A smaller value of MSE or NLPD indicates better performance. All numerical experiments were performed on a desktop computer with Intel Xeon Processor W3520 and 6GB RAM.

The comparison was made in between our method and the state-of-the-art previously listed. Note that the PGP and the GMRF approaches cannot be applied for more than two input dimensions, and so were only compared for the three spatial datasets. We tried two covariance functions, a squared exponential covariance function and an exponential covariance function. Note that the PIC method does not work with an exponential covariance function because learning the pseudo inputs for the PIC method requires the derivative of a covariance function but an exponential covariance function is not differentiable. On the other hand, when an squared exponential covariance function is applied to the GMRF, the precision matrix construction is not straightforward. Therefore, we used a squared exponential covariance function for comparing the proposed approach with the PIC, RBCM, and PGP, while using an exponential covariance function for comparing it with the GMRF. For both of the cases, we assumed the same hyperparameters for local regions, and we used the entire training dataset to estimate the hyperparameters.

We chose and applied different partitioning methods for the compared methods. The choice of the partitioning schemes for the patchwork kriging and PGP is restrictive because every local region needs to be simply connected to minimize the area of the boundaries between local regions, so we used the spatial tree. The GMRF comes with a mesh generation scheme instead of a partitioning scheme, and following the suggestion by the GMRF's authors, we used the voronoi-tessellation of training points for the mesh generation. We tested the k-means clustering and the spatial tree for PIC and RBCM, but the choice did not make much difference in their performance. The results reported in this paper were the ones with the k-means clustering.

We tried different numbers of the local regions that partition an input domain, and the numbers of the local regions were ranged so that the numbers of observations per local region would be approximately in between 80 and 600 for the proposed approach. The numbers were similarly ranged for the other compared methods with some variations to have the computation times of all the compared methods comparable; note that we like to compare the prediction accuracies of the methods when the computation times spent are comparable. For patchwork kriging, the locations of pseudo observation were selected using the rule described in Section 3.4. For PIC, the locations were regarded as hyperparameters and were optimized using marginal likelihood maximization.

6.2 Example 1: `TCO.L2` Dataset

This dataset has two input dimensions, and the inputs of the data are densely distributed over a rectangular domain. For patchwork kriging, we varied $B \in \{3, 5\}$ and $K \in \{256, 512, 1024\}$.

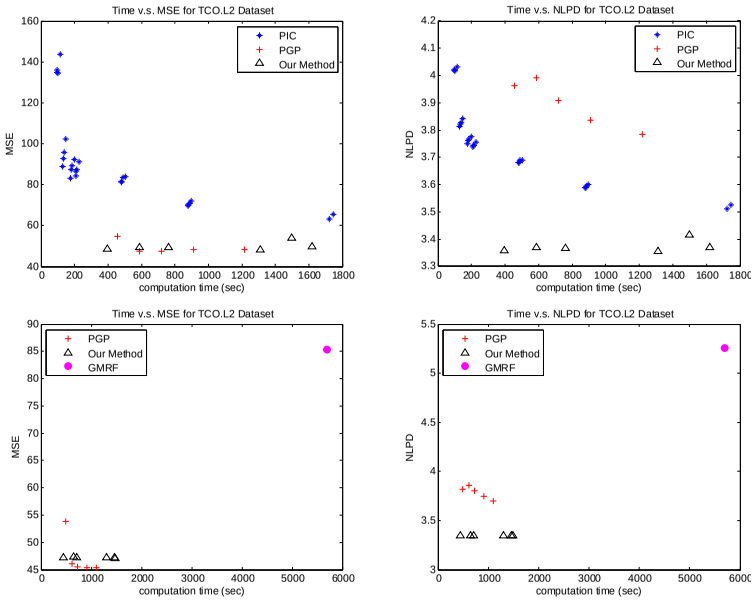

Figure 10: Prediction accuracy versus total computation time for the `TCO.L2` data.

The prediction accuracy of the PGP did not depend on the number of local regions K, so we fixed $K = 623$, while the number of finite element meshes per local region was varied from 5 to 25 with step size 5. For RBCM, we varied the number of local experts $K \in \{100, 150, 200, 250, 300, 600\}$. For PIC, K was varied over $\{100, 200, 300, 400, 600\}$, and the total number of pseudo inputs was also varied over $\{50, 70, 80, 100, 150, 200, 300\}$.

Figure 10 shows the main results. The shortest computation time of RBCM (2319 seconds) was much longer than the longest time of the other compared methods, while its MSE was not competitive as well. Therefore we did not plot its results in the figure. For both of the square exponential and the exponential covariance functions, our approach and the PGP approach had comparable MSE. However, our approach significantly outperformed the PGP and PIC approaches in terms of the NLPD. This implies that our approach provides more accurate variance estimations.

6.3 Example 2: `ICETHICK` Dataset

One characteristic of this dataset is the presence of many spatial voids where there are no or very little data points. For patchwork kriging, we varied $B \in \{3, 5, 7\}$ and $K \in \{64, 128, 256, 512, 1024\}$. For the PGP, we used $K = 47$, while the number of finite element meshes per local region was varied from 5 to 40 with step size 5. For RBCM, we

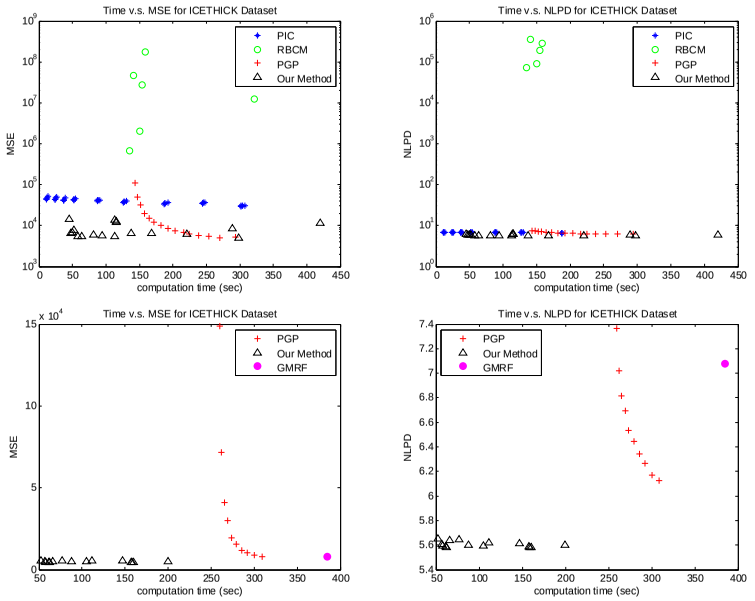

Figure 11: Prediction accuracy versus total computation time for the `ICETHICK` data. A squared exponential covariance function was used for the results in the top panel, while an exponential covariance function was used for the results in the bottom panel.

varied the number of local experts $K \in \{50, 100, 150, 200, 250, 300\}$. For PIC, M was varied over $\{50, 100, 150, 200\}$, and the total number of pseudo inputs was also varied over $\{50, 100, 150, 200, 300, 400, 500, 600, 700\}$.

Figure 11 compares the MSE and NLPD performance of the methods. Again, the PGP approach and the proposed approach outperformed the other methods, and the proposed approach achieved the best accuracy with much less computation time than the PGP approach. In addition, the proposed approach uniformly outperformed the other methods in terms of the NLPD. In other words, the proposed approach gives a predictive distribution that better fits the test data.

6.4 Example 3: `PROTEIN` Dataset

Different from the previous datasets, this dataset features nine input variables. We will use this dataset to see how the proposed approach works for input dimension more than two. For the patchwork kriging, we varied $B \in \{2, 3, 4\}$ and varied $K \in \{64, 128, 256\}$; we have not included the results for larger B because a larger B increased the computation times of the patchwork kriging to a range incomparable to those of the other algorithms. The

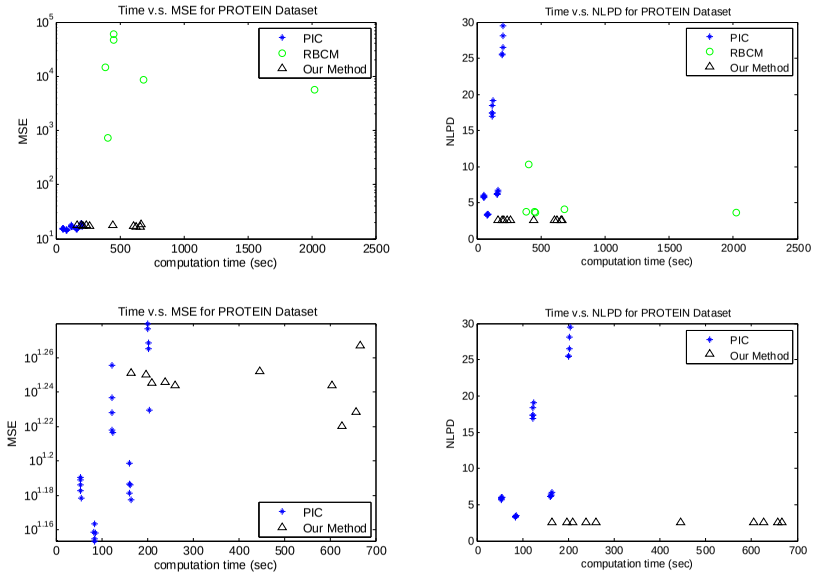

Figure 12: Prediction accuracy versus total computation time for the `PROTEIN` data. The upper panel compares all three methods. Since the performance of the PIC and our method was very close, the bottom panel provides a closer look of the PIC and our method.

PGP and GMRF approaches do not work with input dimensions more than two, and so were not included in this comparison. For RBCM, we varied the number of local experts $K \in \{100, 150, 200, 250, 300\}$. For PIC, K was varied over $\{100, 150, 200, 250, 300\}$, and the total number of pseudo inputs (M) was also varied over $\{100, 150, 200, 250, 300\}$. In this comparison, we used a squared exponential covariance function for all three methods.

Figure 12 shows the main results. For this dataset, the PIC approach outperformed our method in terms of the MSE performance, providing more accurate mean predictions. On the other hand, our method provided better NLPD performance, which implies that the predictive distribution estimated by our method was better fit to test data than that of the PIC. Figure 13 compares the predictive distributions estimated by the two methods. In the figure, the predicted mean ± 1.5 predicted standard deviations was plotted for 100 randomly chosen test observations. The interval for the PIC was overly narrow and excluded many of the test response observations, while the interval for our method more appropriately covered the majority of data, which is reflected in the better NLPD performance for our method. The percentages of the 4,573 test observations falling within the intervals was 50.47% for the PIC and 86.53% for our method. Note that the probability of a standard

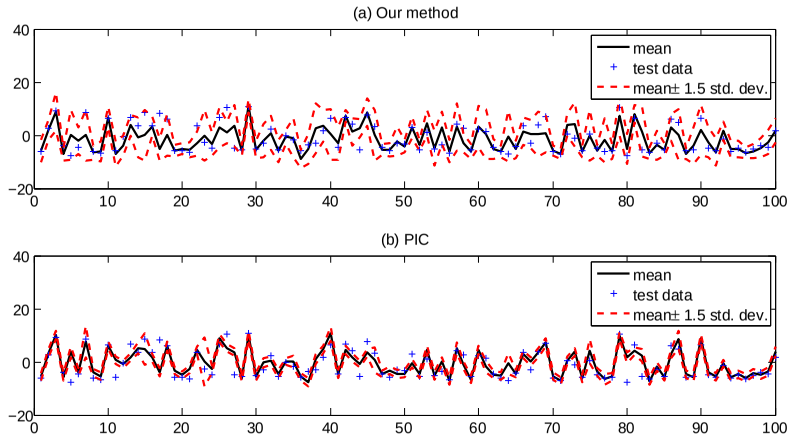

Figure 13: Comparison of the predictive distributions estimated by our method and by the PIC method for the `PROTEIN` data.

normal random variable within $\pm 1.5\sigma$ is 86.64%. Clearly, our method provides a better fit to the test data.

6.5 Example 4: `SARCOS` Dataset

This dataset has 21 input variables. For patchwork kriging, we varied $B \in \{3, 5, 7\}$, and we varied $K \in \{128, 256\}$. Again, the PGP and GMRF approaches do not work with high dimensional inputs, and so were not included in this comparison. For the RBCM approach, we varied the number of local experts $K \in \{100, 150, 200, 250, 300\}$. For PIC, K was varied over $\{100, 150, 200, 250, 300\}$, and the total number of pseudo inputs (M) was also varied over $\{100, 150, 200, 250, 300\}$. In this comparison, we used a squared exponential covariance function for all three methods.

Figure 14 summarizes the comparison of the MSEs and the NLPDs for the three methods. The MSE performances were comparable for all of the methods, while our approach provided a better fit to test data, which was evidenced by the smaller NLPD values of our approach. The PIC produced negative predictive variances for this dataset, so its NLPD values could not be calculated. In theory, the PIC approach should provide non-negative predictive variances with infinite precision. It evidently produced negative variances because of numerical errors. To be more specific, the numerical errors are mostly related to the inversion of covariance matrix of pseudo inputs. The condition number of the covariance matrix was very large, which incurred some round-off errors. Our patchwork kriging approach did not experience any such numerical issues in any of the examples, and it appears to be more numerically stable than the PIC approach.

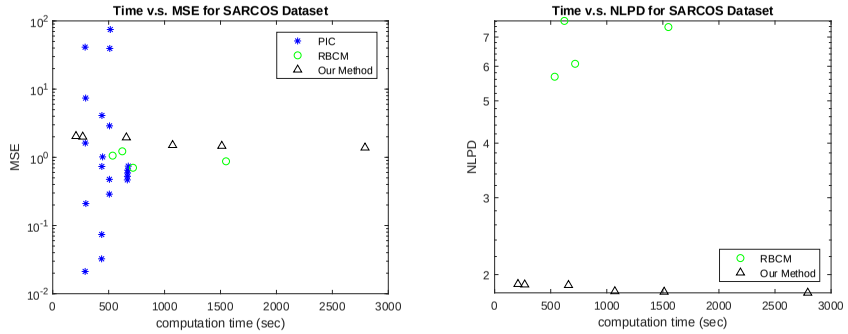

Figure 14: Prediction accuracy versus total computation time for the `SARCOS` data. A squared exponential covariance function was used. The PIC approach produced negative predictive variances, so its NLPD could not be computed. In the MSE plot, four triangles are supposed to show up. However, two of the four triangles are very closely located, so it looks like that there are only 3 triangles.

Methods	MSE	NLPD	Computation Time (seconds)
Ours	1188.4	4.8917	11729
RBCM	9790.2	10.5630	13218
PIC ($M = 1000$)	1494.8	5.0742	1624
PIC ($M = 1500$)	1492.7	5.0731	2094

Table 1: Comparison of MSE and NLPD performance for `Flight Delays` Dataset.

6.6 Example 5: `Flight Delays` Dataset

This dataset has 800,000 records and eight input variables. For this dataset, due to memory limitation of our testing environment, we could not try various cases with different choices of tuning parameters. For patchwork kriging, we fixed $K = 1024$ and $B = 5$. For the RBCM, we set the number of local experts $K = 1024$. For PIC, we set $K = 1024$, and the total number of pseudo inputs (M) was chosen to 1000 or 1500, and the further increase of M gave an out-of-memory error in our testing environment. Note that PIC requires to precompute K dense covariance matrices of size $N/K \times M$, which could be very large for this scale of N and M.

Table 1 summarizes the MSE and NLPD performance of our method, RBCM and PIC. The proposed approach gave a better MSE than the RBCM with less use of computation time. PIC showed very competitive computation performance, but its MSE was not as good as the MSE of our method. The increase of M could improve the PIC's MSE performance, but the improvement was not big in between $M = 1000$ and $M = 1500$.

6.7 Discussion

Based on the numerical comparison results for the two spatial datasets and the three higher dimensional datasets, we can summarize the benefits of the proposed approach as three-fold. First, it provides competitive or better mean prediction accuracy for both the spatial datasets and the higher dimensional datasets. As evidenced by the MSE comparisons, for the three spatial datasets, the mean predictions of the proposed approach were either more accurate than or at least comparable to those of the state-of-the-art approaches. For the first two higher dimensional datasets, its mean prediction accuracy was comparable to those of the state-of-the-art approaches. For the last dataset, it gave a better MSE performance than the state-of-the-art approaches.

Second, as evidenced by the NLPD comparisons, the predictive distribution estimated by the proposed approach provides a better fit to test data. This implies that the proposed approach provides better predictive mean and variance estimates when taken together. We designed a simple experiment to investigate this. We used the `TCO` dataset to compare the degrees of fitness of the predictive distributions from our approach and the PIC, RBCM, and PGP approaches when applied to the test data. In the comparison, the tuning parameters of each compared method were chosen so that the computation time was around 300 seconds, which resulted in approximately the best MSE value for each of the methods. Using these parameters, we calculated the predictive means $\hat{\mu}(x)$ and predictive standard deviations $\hat{\sigma}(x)$ for x in 4,833 test inputs, and we counted the fractions of 4,833 test observations that fell within $\hat{\mu}(x) \pm c\hat{\sigma}(x)$ for different c values, and the fractions were compared with ground truth $P(|X| \leq c)$ where $X \sim \mathcal{N}(0, 1)$. The fractional numbers closer to the ground truth are better. Table 2 shows the fractional numbers for different c values. The fractions for our method were very close to the ground truth for all choices c. The PGP method has much higher fractions than the ground truth, which implies that the PGP tends to overestimate the predictive standard deviation. Both the PIC and the RBCM methods have much lower fractional numbers than the ground truth, which implies that these two local methods significantly underestimate the predictive standard deviation.

Last but not least, the proposed patchwork kriging advances the PGP method by broadening the applicability to higher dimensional datasets, while the PGP method is practically limited to spatial regression with only two input dimensions.

c	0.5	1.0	1.5	2.0	2.5	3.0
$P(\|X\| \leq c)$, $X \sim \mathcal{N}(0,1)$	0.3829	0.6827	0.8664	0.9545	0.9876	0.9973
Our method	0.4471	0.7366	0.8814	0.9487	0.9766	0.9888
PGP	0.7118	0.8850	0.9549	0.9810	0.9905	0.9944
PIC	0.0126	0.0223	0.0362	0.0474	0.0604	0.0741
RBCM	0.1057	0.2090	0.3095	0.3987	0.4809	0.5535

Table 2: Percentages of test data ranging in between the estimated predictive mean $\pm c$ the estimated predictive standard deviation. The percentages were compared with $P(|X| \leq c)$ where X is a standard normal random variable. The percentage numbers closer to $P(|X| \leq c)$ are better.

7. Conclusion

We presented a new approach to efficiently solve the Gaussian process regression problem for large data. The approach first performs a spatial partitioning of a regression domain into multiple local regions and then assumes a local GP model for each local region. The local GP models are assumed *a priori* independent. However, *a posterior* dependence and related continuity constraints between the local GP models in neighboring regions are achieved by defining an auxiliary process that represents the difference between the local GP models on the boundary of the neighboring regions. By defining zero-valued pseudo observations of the auxiliary process and augmenting the actual data with the pseudo observations, we in essence force the two local GP models to have the same posterior predictive distributions at the collection of boundary points. The proposed idea of enforcing the local models to have the same boundary predictions via pseudo observations is entirely different from that of Park and Huang (2016), creating an entirely new framework for patching local GP models. The new approach provides significantly better prediction variance accuracy than the approach of Park and Huang (2016), while providing computation efficiency and mean prediction accuracy that are at least comparable and sometimes better. In addition, the spatial partitioning scheme proposed as a part of the new approach makes the new approach applicable for high dimensional regression settings, while the approach of Park and Huang (2016) is only applicable for one or two dimensional problems. Another advantage of the proposed approach is that its prediction accuracy does not depend strongly on the choice of tuning parameters, so one can simply fine-tune the tuning parameters to minimize the total computation time. Those advantages were numerically demonstrated with six well designed numerical experiments using six real datasets featuring different patterns and dimensions. The new approach has shown better trade-offs between total computation times and prediction accuracy than the approach of Park and Huang (2016) and other local-based approaches for GP regression. We believe that the proposed patchwork kriging approach is an attractive alternative for large-scale GP regression problems.

Appendix A. Derivation of the predictive mean and variance of the patchwork kriging

This appendix provides the detailed derivation of the predictive mean and variance in (6) and (7). From the standard GP modeling result (5), the posterior predictive distribution of $f_*^{(k)}$ given $\boldsymbol{y}$ and the pseudo observations $\boldsymbol{\delta}$ is Gaussian with mean

$$\mathbb{E}[f_*^{(k)}|\boldsymbol{y},\boldsymbol{\delta}] = [\boldsymbol{c}_{*\mathcal{D}}^{(k)}, \boldsymbol{c}_{*,\delta}^{(k)}] \begin{bmatrix} \boldsymbol{C}_{\mathcal{D}\mathcal{D}} & \boldsymbol{C}_{\mathcal{D},\delta} \\ \boldsymbol{C}_{\delta,\mathcal{D}} & \boldsymbol{C}_{\delta,\delta} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{y} \\ \boldsymbol{\delta} \end{bmatrix}$$

and variance given below. Using the partitioned matrix inversion formula

$$\begin{bmatrix} \boldsymbol{A} & \boldsymbol{B} \\ \boldsymbol{B}^T & \boldsymbol{D} \end{bmatrix}^{-1} = \begin{bmatrix} (\boldsymbol{A}-\boldsymbol{B}\boldsymbol{D}^{-1}\boldsymbol{B}^T)^{-1} & -(\boldsymbol{A}-\boldsymbol{B}\boldsymbol{D}^{-1}\boldsymbol{B}^T)^{-1}\boldsymbol{B}\boldsymbol{D}^{-1} \\ -\boldsymbol{D}^{-1}\boldsymbol{B}^T(\boldsymbol{A}-\boldsymbol{B}\boldsymbol{D}^{-1}\boldsymbol{B}^T)^{-1} & (\boldsymbol{D}-\boldsymbol{B}^T\boldsymbol{A}^{-1}\boldsymbol{B})^{-1} \end{bmatrix}, \quad (17)$$

we have

$$\begin{aligned}\mathbb{E}[f_*^{(k)}|\boldsymbol{y},\boldsymbol{\delta}] =& \boldsymbol{c}_{*\mathcal{D}}^{(k)}(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{y} - \boldsymbol{c}_{*,\delta}^{(k)}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{y} \\ & - \boldsymbol{c}_{*\mathcal{D}}^{(k)}(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{\delta} + \boldsymbol{c}_{*,\delta}^{(k)}(\boldsymbol{C}_{\delta,\delta}-\boldsymbol{C}_{\mathcal{D}\delta}^T\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D}\delta})^{-1}\boldsymbol{\delta}.\end{aligned}$$

In particular, for $\boldsymbol{\delta}=\boldsymbol{0}$, which is the only value for the pseudo observations that we need, we have

$$\mathbb{E}[f_*^{(k)}|\boldsymbol{y},\boldsymbol{\delta}=\boldsymbol{0}] = (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{c}_{*\delta}^{(k)}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{y}.$$

Similarly, the posterior predictive variance of $f_*^{(k)}$ given $\boldsymbol{y}$ and $\boldsymbol{\delta}$ is

$$\mathbb{V}\mathrm{ar}[f_*^{(k)}|\boldsymbol{y},\boldsymbol{\delta}] = c_{**} - [\boldsymbol{c}_{*\mathcal{D}}^{(k)}, \boldsymbol{c}_{*,\delta}^{(k)}] \begin{bmatrix} \boldsymbol{C}_{\mathcal{D}\mathcal{D}} & \boldsymbol{C}_{\mathcal{D},\delta} \\ \boldsymbol{C}_{\delta,\mathcal{D}} & \boldsymbol{C}_{\delta,\delta} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{c}_{\mathcal{D}*}^{(k)} \\ \boldsymbol{c}_{\delta*}^{(k)} \end{bmatrix}.$$

Applying the matrix inversion result (17) to this variance expression, we have

$$\begin{aligned}\mathbb{V}\mathrm{ar}[f_*^{(k)}|\boldsymbol{y},\boldsymbol{\delta}] =& c_{**} - \boldsymbol{c}_{*\mathcal{D}}^{(k)}(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{c}_{\mathcal{D}*}^{(k)} \\ & + \boldsymbol{c}_{*,\delta}^{(k)}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{c}_{\mathcal{D}*}^{(k)} \\ & + \boldsymbol{c}_{*\mathcal{D}}^{(k)}(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{c}_{\delta*}^{(k)} \\ & - \boldsymbol{c}_{*,\delta}^{(k)}(\boldsymbol{C}_{\delta,\delta}-\boldsymbol{C}_{\mathcal{D}\delta}^T\boldsymbol{C}_{\mathcal{D}\mathcal{D}}^{-1}\boldsymbol{C}_{\mathcal{D}\delta})^{-1}\boldsymbol{c}_{\delta*}^{(k)} \\ =& c_{**} - \boldsymbol{c}_{*,\delta}^{(k)}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{c}_{\delta*}^{(k)} \\ & - (\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{c}_{*\delta}^{(k)}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)(\boldsymbol{C}_{\mathcal{D}\mathcal{D}}-\boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}(\boldsymbol{c}_{\mathcal{D}*}^{(k)} - \boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{c}_{\delta*}^{(k)}).\end{aligned}$$

Appendix B. Equality of the posterior predictive means and variances of $f_*^{(k)}$ and $f_*^{(l)}$

Suppose that $\Gamma_{k,l} \neq \emptyset$, i.e., Ω_k and Ω_l are neighboring. This appendix shows

$$\begin{aligned} &\mathbb{E}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta} = \mathbf{0}] = \mathbb{E}[f_*^{(l)}|\boldsymbol{y}, \boldsymbol{\delta} = \mathbf{0}] \text{ for } x_* \in \mathbf{x}_{k,l}, \text{ and} \\ &\mathbb{V}\text{ar}[f_*^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}] = \mathbb{V}\text{ar}[f_*^{(l)}|\boldsymbol{y}, \boldsymbol{\delta}] \text{ for } x_* \in \mathbf{x}_{k,l}. \end{aligned} \tag{18}$$

Let $\boldsymbol{f}^{(k)}$ denote a column vector of the $f_*^{(k)}$ values for $x_* \in \mathbf{x}_{k,l}$ and $\boldsymbol{f}^{(l)}$ denote a column vector of the $f_*^{(l)}$ values for $x_* \in \mathbf{x}_{k,l}$.

$$\mathbb{E}[\boldsymbol{f}^{(k)} - \boldsymbol{f}^{(l)}|\boldsymbol{y}, \boldsymbol{\delta} = \mathbf{0}] = (\boldsymbol{V} - \boldsymbol{W}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)(\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{y}.$$

where $\boldsymbol{V}$ denote the matrix with its ith row $\boldsymbol{c}_{*\mathcal{D}}^{(k)} - \boldsymbol{c}_{*\mathcal{D}}^{(l)}$ evaluated for x_* equal to the ith entry of $\mathbf{x}_{k,l}$, and let $\boldsymbol{W}$ denote the matrix with its ith row $\boldsymbol{c}_{*\delta}^{(k)} - \boldsymbol{c}_{*\delta}^{(l)}$ evaluated for x_* equal to the ith entry of $\mathbf{x}_{k,l}$. Note that we can write $\boldsymbol{V} = \boldsymbol{\Theta}\boldsymbol{C}_{\mathcal{D}\delta}^T$ and $\boldsymbol{W} = \boldsymbol{\Theta}\boldsymbol{C}_{\delta,\delta}$ for some non-random matrix $\boldsymbol{\Theta}$. Therefore,

$$\begin{aligned} \mathbb{E}[\boldsymbol{f}^{(k)} - \boldsymbol{f}^{(l)}|\boldsymbol{y}, \boldsymbol{\delta} = \mathbf{0}] &= \boldsymbol{\Theta}(\boldsymbol{C}_{\mathcal{D}\delta}^T - \boldsymbol{C}_{\delta,\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)(\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{y} \\ &= \mathbf{0}. \end{aligned} \tag{19}$$

Similarly, we have

$$\begin{aligned} \mathbb{V}\text{ar}[\boldsymbol{f}^{(k)}|\boldsymbol{y}, \boldsymbol{\delta}] - \mathbb{V}\text{ar}[\boldsymbol{f}^{(l)}|\boldsymbol{y}, \boldsymbol{\delta}] &= \boldsymbol{\Theta}(\boldsymbol{C}_{\mathcal{D}\delta}^T - \boldsymbol{C}_{\delta,\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)(\boldsymbol{C}_{\mathcal{D}\mathcal{D}} - \boldsymbol{C}_{\mathcal{D}\delta}\boldsymbol{C}_{\delta,\delta}^{-1}\boldsymbol{C}_{\mathcal{D}\delta}^T)^{-1}\boldsymbol{Z} \\ &= \mathbf{0}, \end{aligned} \tag{20}$$

where $\boldsymbol{Z}$ denote the matrix with its jth column $\boldsymbol{c}_{\mathcal{D}*}^{(k)} + \boldsymbol{c}_{\mathcal{D}*}^{(l)}$ evaluated for x_* equal to the jth entry of $\mathbf{x}_{k,l}$.

Appendix C. Comparison of the patchwork kriging and the full GP for the simulated cases in Section 5

This appendix presents the full comparison data that are summarized in Section 5. Figures 15, 16 and 17 shows the comparison in a posterior mean prediction, and Figures 18, 19 and 20 shows the comparison in a posterior variance prediction

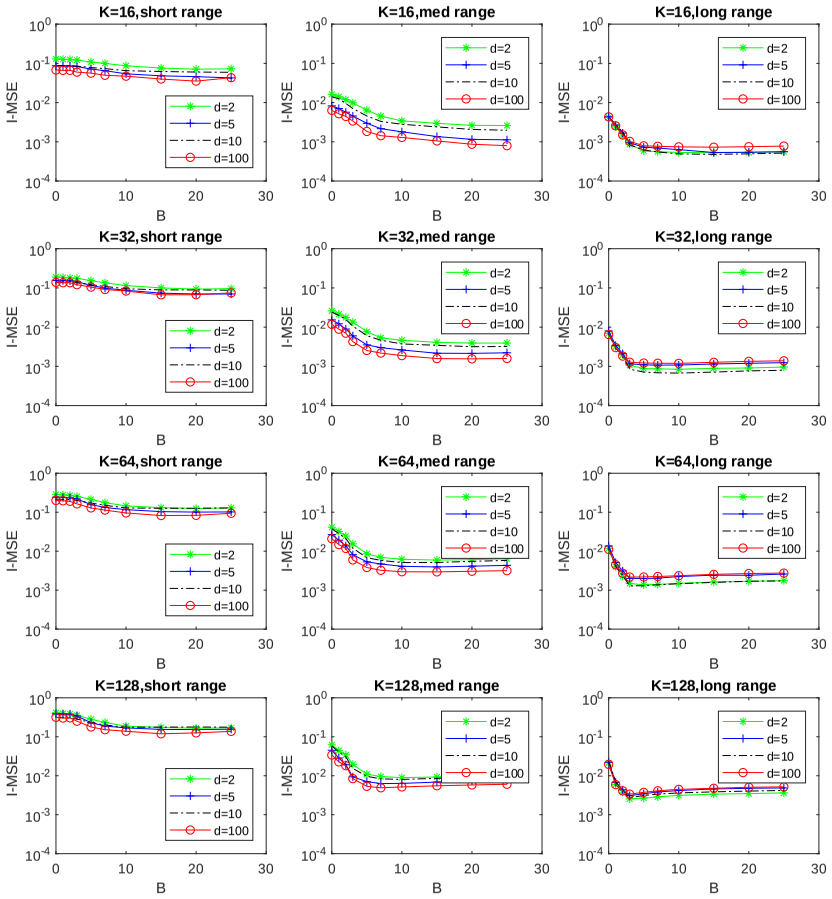

Figure 15: Summary of Interior Mean Squared Error for Predictive Mean (I-MSE)

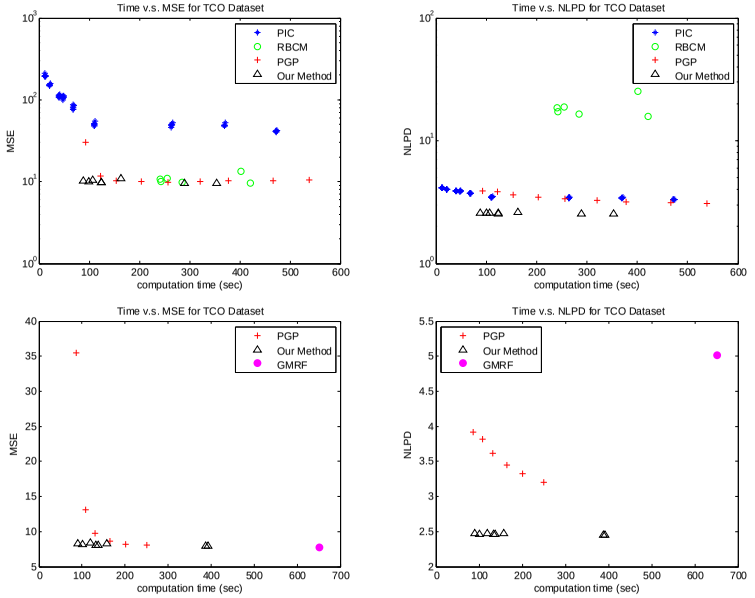

Figure 21: Prediction accuracy versus total computation time for the `TCO` data. Top panel: a squared exponential covariance function was used. Bottom panel: an exponential covariance function was used. In the top panel, eight triangles are supposed to show up. However, two of the eight triangles are very closely located, so it looks like that there are only 7 triangles.

Appendix D. Extra real data study

This appendix includes the numerical comparison with an extra real dataset, which were not in the main text. The dataset, `TCO`, contains 48,331 observations collected by the NIMBUS-7/TOMS satellite, which measures the total column of ozone over the globe on Oct 1 1988. This dataset has two input dimensions that represent a spatial location of the measurement, and the inputs of the data are densely distributed over a rectangular domain. For patchwork kriging, we varied $B \in \{5, 7\}$ and $K \in \{64, 128, 256, 512\}$. The prediction accuracy of the PGP did not depend on the number of local regions K, so we fixed $K = 145$, while the number of finite element meshes per local region was varied from 5 to 40 with step size 5. For RBCM, we varied the number of local experts $K \in \{100, 150, 200, 250, 300, 600\}$. For PIC, K was varied over $\{100, 150, 200, 250, 300, 400\}$, and the total number of pseudo inputs was also varied over $\{30, 50, 70, 80, 100, 150, 200, 250, 300\}$. For the GMRF, following the suggestion by the GMRF's authors, we used the voronoi-tessellation of training points for mesh generation.

Figure 21 summarizes the performance results. The two panels in the top row compare the proposed approach to the PGP, RBCM and PIC approaches when a square exponential covariance function is used. The MSE plot shows the mean square error of the mean predictions for the test data. The proposed approach and the PGP approach had better MSE than the RBCM and PIC approaches, and the proposed approach also had better MSE than the PGP approach at the 100 second computation time. The NLPD plot shows the degree of fitness of the estimated predictive distribution to the test data, which is affected by both of the mean prediction and the variance prediction. The proposed approach uniformly outperforms the other methods, including the PGP. The two panels in the bottom row compare the proposed approach to the PGP and the GMRF approaches when an exponential covariance function is used. The PGP and the proposed approaches had comparable MSEs at larger computation times, whereas the proposed approach had much smaller MSE at the lower computation times, and the proposed approach outperformed the PGP and the GMRF in terms of NLPD. The GMRF had longer computation time than the PGP and the proposed method.

Abstract

Divide-and-conquer based methods for Bayesian inference provide a general approach for tractable posterior inference when the sample size is large. These methods divide the data into smaller subsets, sample from the posterior distribution of parameters in parallel on all the subsets, and combine posterior samples from all the subsets to approximate the full data posterior distribution. The smaller size of any subset compared to the full data implies that posterior sampling on any subset is computationally more efficient than sampling from the true posterior distribution. Since the combination step takes negligible time relative to sampling, posterior computations can be scaled to massive data by dividing the full data into sufficiently large number of data subsets. One such approach relies on the geometry of posterior distributions estimated across different subsets and combines them through their barycenter in a Wasserstein space of probability measures. We provide theoretical guarantees on the accuracy of approximation that are valid in many applications. We show that the geometric method approximates the full data posterior distribution better than its competitors across diverse simulations and reproduces known results when applied to a movie ratings database.

Keywords: barycenter; big data; distributed Bayesian computations; empirical measures; linear programming; optimal transportation; Wasserstein distance; Wasserstein space.

1. Introduction

Developing efficient sampling algorithms is an active area of research motivated by tractable Bayesian inference in large sample settings. Sampling remains a primary tool for inference in Bayesian models, with Markov chain Monte Carlo (MCMC) and sequential Monte Carlo (SMC) providing two broad classes of algorithms that are routinely used. Most MCMC and SMC algorithms face problems in scaling up to massive data settings due to memory and computational bottlenecks that arise; this has motivated a rich literature in recent years proposing a variety of strategies to enable better performance in such settings. Our focus is on proposing a very general divide-and-conquer technique, which is designed to combine results from any posterior sampling algorithm applied in parallel using subsets of the data.

Massive data pose major problems for existing sampling algorithms. First, if full data require multiple machines for storage, then a sampler has access to only a small fraction of the full data stored on the machine where it runs. Posterior sampling given the full data is expensive due to network latency and extensive communication among machines. Second, with sample size n, sampling in hierarchical Bayesian models requires generation of $O(n)$ latent variables, which becomes inefficient as n increases. Finally, even if full data are available to the sampler, sampling can be infeasible in practice because computation of Hessians and acceptance ratios can scale as $O(n^3)$ in some nonparametric models based on Gaussian process priors (Rasmussen and Williams, 2006). A variety of methods exist to address these issues using optimization and sampling.

Optimization-based methods for Bayesian inference obtain an analytic approximation of the full data posterior distribution. The two most common techniques are polynomial approximation (Rue et al., 2009) and projection of the full data posterior distribution on a class of distributions with analytically tractable posterior densities, which includes variational Bayes and expectation propagation (Wainwright and Jordan, 2008; Gelman et al., 2014). Both techniques estimate parameters of the approximate distribution using a variety of optimization algorithms (Tan and Nott, 2013; Kucukelbir et al., 2015; Rezende and Mohamed, 2015; Ranganath et al., 2016). Stochastic approximation significantly improves the efficiency of estimation by accessing the data in small batches and updating the parameter estimates sequentially (Broderick et al., 2013; Hoffman et al., 2013); however, optimization can be nontrivial for complex likelihoods frequently used in hierarchical models. Furthermore, variational Bayes and expectation propagation often have excellent predictive performance but can be highly biased in estimation of posterior uncertainty and dependence (Giordano et al., 2017).

There is extensive work in sampling-based methods for Bayesian inference. The three main techniques used are as follows. First, subsampling-based methods obtain posterior samples conditioned on a small fraction of the data (Maclaurin and Adams, 2015). Coupling of subsampling with modified Hamiltonian or Langevin dynamics improves posterior exploration and convergence to the stationary distribution (Welling and Teh, 2011; Ahn et al., 2012; Chen et al., 2014; Korattikara et al., 2014; Lan et al., 2014; Shahbaba et al., 2014); see Bardenet et al. (2017) for a review. Second, the exact transition kernel in posterior sampling is replaced by an approximation that significantly reduces the time required to finish an iteration of the sampler (Johndrow et al., 2015; Alquier et al., 2016). Finally, divide-and-conquer approaches first divide the data into smaller subsets and sample in parallel across subsets, and then combine the posterior samples from all the subsets. Our focus is on scalable Bayesian methods based on the divide-and-conquer technique. These methods have two subgroups that differ mainly in their sampling scheme for every subset and their method for combining posterior samples obtained from all the subsets.

The first subgroup modifies the prior to sample from the posterior distribution of the parameter conditioned on a data subset. Let k be the number of subsets, $\pi(\theta)$ be the prior density of parameter θ, and $l_i(\theta)$ be the likelihood for subset i $(i = 1, \ldots, k)$. Samples from subset posterior distribution i are obtained using $l_i(\theta)$ and $\pi(\theta)^{1/k}$ as the likelihood

and prior. Consensus Monte Carlo combines subset posterior samples by averaging, which has been generalized in many ways (Rabinovich et al., 2015; Scott et al., 2016). This relies heavily on the normality assumption, which is relaxed using a combination based on kernel density estimation (Neiswanger et al., 2014). Both methods perform poorly if the supports of subset posteriors are different, which motivates the combination using the Weierstrass transform and random partition trees (Wang and Dunson, 2013; Wang et al., 2015). These methods offer simple approaches for combining samples from subset posterior distributions but have a major limitation that the sampling algorithm depends on the model parameterization.

The second subgroup modifies the subset likelihood to sample from a subset posterior distribution and combines samples from subset posterior distributions through their geometric center. These methods modify the likelihood to $l_i(\theta)^k$ and use prior $\pi(\theta)$ to sample from subset posterior distribution i ($i = 1, \ldots, k$). M-Posterior combines subset posterior distributions through their median in the Wasserstein space of order 1 (Minsker et al., 2014, 2017). The robustness of the median implies that it could ignore valuable information in some subset posterior distributions, which motivates combination through the mean in the Wasserstein space of order 2 called Wasserstein Posterior (WASP) (Srivastava et al., 2015). The WASP approach strikes a balance between the generality of sampling and the efficiency of optimization. While WASP can be applied to any data or Bayesian model, its computations are developed for independent identically distributed (*iid*) data and its theoretical properties are unknown.

Our main goal is to study the theoretical properties of WASP and apply WASP in a variety of practical problems. The *iid* assumption of WASP rules out many important practical problems, including regression and classification, where the data are independent and non-identically distributed (*inid*). We relax this assumption and our theoretical results are applicable to *inid* data. Second, we show that if the number of subsets are chosen appropriately, then the WASP achieves almost the same rate of convergence as that of the full data posterior distribution. For linear models with error distribution in the location-scale family, we strengthen this result and show that the WASP and the full data posterior distribution have the same asymptotic mean and asymptotic variance. This implies that WASP can be used as an efficient alternative to the full data posterior distribution in massive data settings. Third, we show that the method for estimating WASP is independent of the form of the model, which implies that WASP is very general and can be easily used for estimating posterior summaries for any function of the model parameters. We emphasize that WASP is not a new sampling algorithm but a general approach to easily extend any existing sampling algorithms for massive data applications.

2. Preliminaries

2.1 Wasserstein Space, Wasserstein Distance, and Wasserstein Barycenter

We recall elementary properties and definitions related to the Wasserstein space of probability measures. Let (Θ, ρ) be a complete separable metric space and $\mathcal{P}(\Theta)$ be the space of

all probability measures on Θ. The Wasserstein space of order 2 is defined as

$$\mathcal{P}_2(\Theta) := \left\{ \mu \in \mathcal{P}(\Theta) : \int_\Theta \rho^2(\theta_0, \theta)\mu(d\theta) < \infty \right\}, \tag{1}$$

where $\theta_0 \in \Theta$ is arbitrary and $\mathcal{P}_2(\Theta)$ does not depend on the choice of θ_0. The space $\mathcal{P}_2(\Theta)$ is equipped with a natural distance between its elements. Let $\mu, \nu \in \mathcal{P}_2(\Theta)$ and $\Pi(\mu, \nu)$ be the set of all probability measures on $\Theta \times \Theta$ with marginals μ and ν, then the Wasserstein distance of order 2 between μ and ν is defined as

$$W_2(\mu, \nu) = \left(\inf_{\pi \in \Pi(\mu,\nu)} \int_{\Theta\times\Theta} \rho^2(x, y)\, d\pi(x, y) \right)^{\frac{1}{2}}. \tag{2}$$

In our applications ρ is the Euclidean metric and we refer to $\mathcal{P}_2(\Theta)$ and W_2 as the Wasserstein space and the Wasserstein distance without explicitly mentioning their order. If $\Pi_1, \ldots, \Pi_k$ are a collection of probability measures in $\mathcal{P}_2(\Theta)$, then their barycenter in $\mathcal{P}_2(\Theta)$ is defined as

$$\overline{\Pi} = \operatorname*{argmin}_{\Pi \in \mathcal{P}_2(\Theta)} \sum_{j=1}^{k} \frac{1}{k} W_2^2(\Pi, \Pi_j). \tag{3}$$

This generalizes the Euclidean barycenter, which is the sample mean, to $\mathcal{P}_2(\Theta)$ (Agueh and Carlier, 2011). The barycenter $\overline{\Pi}$ is analytically intractable, except in few special cases. Let $\delta_a(x) = 1$ if $a = x$ and 0 otherwise. If $X_{j1}, \ldots, X_{jm}$ are samples from Π_j ($j = 1, \ldots, k$), then $\widehat{\Pi}_j(\cdot) = \sum_{i=1}^m \delta_{X_{ji}}(\cdot)/m$ is an empirical measure that approximates Π_j ($j = 1, \ldots, k$). If $\overline{\Pi}$ is assumed to be an empirical measure, then the optimization problem in (3) reduces to a linear program; see Cuturi and Doucet (2014), Carlier et al. (2015), and Srivastava et al. (2015) for different algorithms to solve this linear program.

2.2 Stochastic Approximation and Subset Posterior Density

Consider a general set-up for *inid* data. Let $Y^{(n)} = (Y_1, \ldots, Y_n)$ be n observations and the distribution of Y_i is $P_{\theta,i}$, $i = 1, \ldots, n$, where θ lies in the parameter space $\Theta \subset \mathbb{R}^p$. Assume that $P_{\theta,i}$ has density $p_i(\cdot|\theta)$ with respect to the Lebesgue measure, so $dP_{\theta,i}(y_i) = p_i(y_i|\theta)dy_i$ and the likelihood given $Y^{(n)}$ is $l(\theta) = \prod_{i=1}^n p_i(y_i|\theta)$. Given a prior distribution Π on Θ that has density π with respect to the Lebesgue measure, the posterior density of θ given $Y^{(n)}$ using Bayes theorem is

$$\pi(\theta \mid Y^{(n)}) = \frac{\prod_{i=1}^n p_i(y_i \mid \theta)\pi(\theta)}{\int_\Theta \prod_{i=1}^n p_i(y_i \mid \theta)\pi(\theta)d\theta} = \frac{l(\theta)\pi(\theta)}{\int_\Theta l(\theta)\pi(\theta)d\theta}. \tag{4}$$

In most cases $\pi(\theta \mid Y^{(n)})$ is analytically intractable, and accurate approximations of $\pi(\theta \mid Y^{(n)})$ are obtained using Monte Carlo methods, such as importance sampling and MCMC, and deterministic approximations, such as Laplace's method and variational Bayes. For example, in the context of logistic regression, $P_{\theta,i}$ is the Bernoulli distribution with mean $1/\left\{1 + \exp(-x_i^T\theta)\right\}$, where x_i^T is the ith row of the design matrix $X \in \mathbb{R}^{n\times p}$ and $\Theta = \mathbb{R}^p$. The posterior density of θ is analytically intractable, and it is typical to rely on Gibbs

samplers based on data augmentation (Bishop, 2006). These samplers introduce latent variables $\{z_i, i = 1, \ldots, n\}$ and alternately sample the latent variables and the parameters from their full conditional distributions. Related algorithms are very common and are computationally prohibitive for large n because they require repeated passes through the whole data.

Divide-and-conquer-type methods resolve this problem by partitioning the data into smaller subsets. Let k be the number of subsets. The default strategy is to randomly allocate samples to subsets. Let $Y_{[j]} \equiv Y_j^{(m_j)} = (Y_{j1}, \ldots, Y_{jm_j})$ denote data on the jth subset, where m_j is the size of the jth subset and $\sum_{j=1}^{k} m_j = n$. We assume that $m_j = m$ $(j = 1, \ldots, k)$ for ease of presentation, so $n = km$, the likelihood given $Y_{[j]}$ is $l_j(\theta) = \prod_{i=1}^{m} p_{ji}(y_{ji}|\theta)$, and $l(\theta)$ in (4) equals $\prod_{j=1}^{k} l_j(\theta)$. Define subset posterior density j given $Y_{[j]}$ as

$$\pi_m(\theta \mid Y_{[j]}) = \frac{\{\prod_{i=1}^{m} p_{ji}(y_{ji}|\theta)\}^{\gamma}\pi(\theta)}{\int_{\Theta}\{\prod_{i=1}^{m} p_{ji}(y_{ji}|\theta)\}^{\gamma}\pi(\theta)d\theta} = \frac{l_j(\theta)^{\gamma}\pi(\theta)}{\int_{\Theta} l_j(\theta)^{\gamma}\pi(\theta)d\theta}, \tag{5}$$

where γ is a positive real number such that $g_1\gamma m \leq n \leq g_2\gamma m$ for some $g_1, g_2 > 0$. In the present context, we assume that $\gamma = k$ with $g_1 = g_2 = 1$ following Minsker et al. (2014); more general conditions on γ are defined later in Section 3.2. This modified form of subset posterior compensates for the fact that jth subset has access to only (m/n)-fraction of the full data and ensures that $\pi_m(\theta \mid Y_{[j]})$ and $\pi_n(\theta \mid Y^{(n)})$ in (4) have variances of the same order. Minsker et al. (2014) refer to this as *stochastic approximation* because raising $l_j(\theta)$ $(j = 1, \ldots, k)$ to the power γ is equivalent to replicating every X_{ji} $(i = 1, \ldots, m)$ γ-times so that $\pi_m(\theta \mid Y_{[j]})$ $(j = 1, \ldots, k)$ are noisy approximations of $\pi(\theta \mid Y^{(n)})$.

One advantage of using stochastic approximation to define $\pi_m(\theta \mid Y_{[j]})$ in (5) is that off-the-shelf sampling algorithms can be used directly even when the prior density is the form of a discrete mixture. Consider a simple example of univariate density estimation using Dirichlet process (DP) mixtures of Gaussians. Let X_i $(i = 1, \ldots, n)$ be *iid* samples from a distribution P_0 with density p_0. The data are randomly split into k subsets of equal size m. The truncated stick-breaking representation of DP implies that the prior distribution Π on $\mathcal{P}$ has a finite mixture representation, where $\mathcal{P}$ is the set of probability distributions that have a density. We show in the Appendix that modification of the likelihood using stochastic approximation leads to nearly identical subset and full data posterior computations.

Stochastic approximation does not add any extra burden to the computations required for sampling from the subset posterior distribution of θ conditioned on m observations. We raise the likelihood in every subset to the power γ. This is equivalent to replicating observations γ-times, which seems to offset the benefits of partitioning. However, the replication of observation is not required in implementation of the sampler; we simply modify the likelihood in the full data sampler by raising it to the power γ. For example, stochastic approximation is easily implemented using the `increment_log_prob` function in Stan (Stan Development Team, 2014). We provide more examples for a variety of models in Section 4.

A simple logistic regression example demonstrates that $\pi_m(\theta \mid Y_{[j]})$ in (5) is a noisy approximation of $\pi(\theta \mid Y^{(n)})$ in (4). We simulated data for logistic regression with $n = 10^5$, $p = 2$, $\theta = (-1, 1)^T$, and entries of X randomly set to ± 1 (Figure 1). We set $\gamma = k = 40$ and obtained samples of θ from $\pi(\theta \mid Y^{(n)})$ and from $\pi_m(\theta \mid Y_{[j]})$ $(j = 1, \ldots, k)$ using the Stan's HMC sampling algorithm. The contours for the subset and full data posterior densities

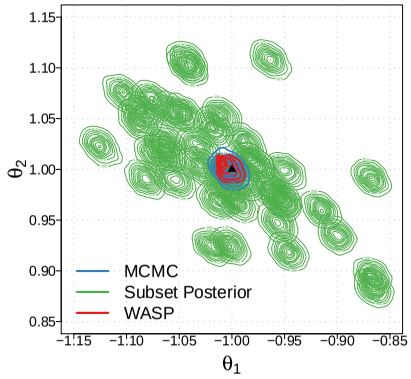

Figure 1: Binned kernel density estimates of full data posterior distribution, subset posterior distributions, and WASP for coefficients (θ_1, θ_2) in logistic regression. The x and y axes represent posterior samples for θ_1 and θ_2. The true values of θ_1 and θ_2 are -1 and 1 (black triangle).

are very similar, indicating all densities have similar spreads. We also notice that subset posteriors are noisy approximations of the full data posterior in that most of them have a bias and do not concentrate at the true θ.

3. Wasserstein Posterior (WASP): The General Framework

3.1 Definition and Estimation of the WASP

The WASP approach combines subset posterior distributions $\Pi_m(\cdot \mid Y_{[j]})$ $(j = 1, \ldots, k)$ through their barycenter in $\mathcal{P}_2(\Theta)$, where the density of $\Pi_m(\cdot \mid Y_{[j]})$ is $\pi_m(\cdot \mid Y_{[j]})$ in (5). The barycenter represents a geometric center of a collection of probability distributions that can be efficiently computed using a linear program. Motivated by this, Srivastava et al. (2015) proposed to combine a collection of subset posterior distributions through their barycenter in the Wasserstein space called *WASP*. Assuming that subset posterior distributions $\Pi_m(\cdot \mid Y_{[j]})$ $(j = 1, \ldots, k)$ have finite second moments, the WASP is defined using (3) as

$$\overline{\Pi}_n(\cdot \mid Y^{(n)}) = \underset{\Pi \in \mathcal{P}_2(\Theta)}{\operatorname{argmin}} \sum_{j=1}^{k} \frac{1}{k} W_2^2\{\Pi, \Pi_m(\cdot \mid Y_{[j]})\}. \tag{6}$$

Consider the following Gaussian example where the WASP is analytically tractable. Assume that the subset posterior distributions, $\Pi_1, \ldots, \Pi_k$, are Gaussian with means $\mu_1, \ldots, \mu_k$ and covariance matrices $\Sigma_1, \ldots, \Sigma_k$. If we fix ρ to be the Euclidean metric and $\Theta = \mathbb{R}^d$ in

Algorithm 1 Estimation of the WASP for $f(\theta)$ given samples of θ from k subset posteriors

Input: Samples from k subset posteriors, $\{\theta_{ji} : \theta_{ji} \sim \Pi_m(\cdot \mid Y_{[j]}),\ i = 1, \ldots, s_j,\ j = 1, \ldots, k\}$; mesh size $\epsilon > 0$.

Do:

1. Define $\phi_i^j = (\phi_{i1}^j, \ldots, \phi_{iq}^j) = f(\theta_{ji})$ $(i = 1, \ldots, s_j;\ j = 1, \ldots, k)$, the matrix of atoms of subset posterior j, $\Phi_j \in \mathbb{R}^{s_j \times q}$, with ϕ_i^j as row i $(i = 1, \ldots, s_j)$. For $r = 1, \ldots, q$, let $\phi_{\min} = (\phi_{\min\ 1}, \ldots, \phi_{\min\ q})$ with $\phi_{\min\ r} = \min_{j\ i} \phi_{ir}^j$, and $\phi_{\max} = (\phi_{\max\ 1}, \ldots, \phi_{\max\ q})$ with $\phi_{\max\ r} = \max_{j\ i} \phi_{ir}^j$.
2. Set the number of atoms in the empirical approximation for the WASP $g = g_1 \times \ldots \times g_q$, where $g_r = \left\lceil \frac{\phi_{\max\ r} - \phi_{\min\ r}}{\epsilon} \right\rceil$ $(r = 1, \ldots, q)$.
3. Define the matrix of WASP atoms $\overline{\Phi} \in \mathbb{R}^{g \times q}$ with rows formed by stacking vectors
$$\left\{ \phi_{\min\ 1} + \frac{i_1}{g_1} (\phi_{\max\ 1} - \phi_{\min\ 1}), \ldots, \phi_{\min\ q} + \frac{i_q}{g_q} (\phi_{\max\ q} - \phi_{\min\ q}) \right\}, \quad (i_r = 1, \ldots, g_r;\ r = 1, \ldots, q).$$
4. Set the distance matrix between the atoms of WASP and the jth subset posterior, $D_j \in \mathbb{R}_+^{g \times s_j}$, as
$$(D_j)_{uv} = \sum_{r=1}^{q} (\overline{\phi}_{ur} - \phi_{vr}^j)^2, \quad (u = 1, \ldots, g;\ v = 1, \ldots, s_j;\ j = 1, \ldots, k),$$
where $\overline{\phi}_{ur}$ is the (u, r)-entry of $\overline{\Phi}$.
5. Estimate $\hat{a}_1, \ldots, \hat{a}_g$ by solving the linear program (42) in Appendix C.

Return: $\widehat{f \sharp \overline{\Pi}}(\cdot \mid Y^{(n)}) = \sum_{i=1}^{g} \hat{a}_i \delta_{\overline{\phi}_i}(\cdot)$, the atomic approximation of $\overline{f \sharp \Pi}_n(\cdot \mid Y^{(n)})$.

(2), then (3) implies that $\overline{\Pi}_n$ is Gaussian with mean $\overline{\mu}$ and covariance matrix $\overline{\Sigma}$, where

$$\overline{\mu} = \frac{1}{k} \sum_{j=1}^{k} \mu_j \text{ and } \overline{\Sigma} \text{ is such that } \frac{1}{k} \sum_{j=1}^{k} \left(\overline{\Sigma}^{1/2} \Sigma_j \overline{\Sigma}^{1/2} \right)^{1/2} = \overline{\Sigma}, \tag{7}$$

where $A^{1/2}$ is the symmetric square root of A (Agueh and Carlier, 2011). If θ is one dimensional, then (7) says that the standard deviation of WASP is the average of standard deviations of subset posteriors; therefore, the variance of WASP is typically about the same order as that of any subset posterior distribution. A similar relation also holds in higher dimensions and for a large class of posterior distributions, including elliptical distributions (Álvarez-Esteban et al., 2016).

The WASP is analytically tractable only in special cases, but it can be estimated using a linear program if the subset posterior distributions have an atomic form. Let $\{\theta_{j1}, \ldots, \theta_{jS}\}$ be the θ samples obtained from subset posterior density j in (6) using a sampling algorithm, including HMC, MCMC, SMC, or importance sampling. Approximate jth subset posterior distribution $\Pi_m(\cdot \mid Y_{[j]})$ using the empirical measure

$$\hat{\Pi}_m(\cdot \mid Y_{[j]}) = \sum_{i=1}^{S} \frac{1}{S} \delta_{\theta_{ji}}(\cdot) \quad (j = 1, \ldots, k). \tag{8}$$

Srivastava et al. (2015) approximate the WASP as

$$\hat{\overline{\Pi}}_n(\cdot \mid Y^{(n)}) = \sum_{j=1}^{k} \sum_{i=1}^{S} a_{ji} \delta_{\theta_{ji}}(\cdot), \quad 0 \le a_{ji} \le 1, \quad \sum_{j=1}^{k} \sum_{i=1}^{S} a_{ji} = 1, \tag{9}$$

where a_{ji} $(j = 1, \ldots, k;\ i = 1, \ldots, S)$ are unknown weights of the atoms. There are many specialized algorithms to estimate the WASP that exploit the structure of the linear program in (6) when $\Pi_m(\cdot \mid Y_{[j]})$ and $\overline{\Pi}_n(\cdot \mid Y^{(n)})$ are restricted to have atomic forms in (8) and (9), respectively; for example, Cuturi and Doucet (2014) extend the Sinkhorn algorithm using entropy-smoothed sub-gradient methods, Carlier et al. (2015) develop a non-smooth optimization algorithm, and Srivastava et al. (2015) propose an efficient linear program that exploits the sparsity of constraints to solve (6). A simple and efficient algorithm to find the WASP of a given function of parameters is summarized in Algorithm 1.

3.2 Theoretical Properties of the WASP

The WASP, denoted as $\overline{\Pi}_n$, replaces the full data posterior distribution, denoted as Π_n, for inference and prediction in massive data applications where n is large. In motivating applications, computation of Π_n is inefficient, and dividing the data into smaller subsets and performing posterior computations in parallel leads to massive speed-ups. A formal asymptotic justification for using $\overline{\Pi}_n$ to approximate Π_n would ideally show that the distance between $\overline{\Pi}_n$ and Π_n tends to 0 as the full data size n increases to infinity. We will illustrate this using a linear model example in Section 3.2.1, where we show that $n^{1/2} W_2(\overline{\Pi}_n, \Pi_n) \to 0$ as $n \to \infty$. Since both $\overline{\Pi}_n$ and Π_n have variances of order n^{-1}, our result implies that the mean and the variance of WASP match those of the full data posterior distribution.

A general theoretical justification for using $\overline{\Pi}_n$ in the place of Π_n for a multivariate θ given *inid* data is technically much more challenging. If the data are *iid* and θ is one-dimensional, then Li et al. (2017) proves that $n^{1/2} W_2(\overline{\Pi}_n, \Pi_n) \to 0$ as $n \to \infty$ for regular parametric models. The proof in Li et al. (2017) relies heavily on the Bernstein-von Mises theorem (BvM) for *iid* data and the one-dimensional quantile representation of Wasserstein distance. Unlike the *iid* case, a BvM-type theorem is generally unavailable if the data are *inid* or the model is non-regular (Ibragimov and Has' Minskii, 2013). In Section 3.2.2, we show that the WASP $\overline{\Pi}_n$ converges to the true parameter value at almost the same rate as Π_n when the number of subset k increases slowly with n. The previous theoretical justification of WASP in Srivastava et al. (2015) only includes posterior consistency under the stronger *iid* assumption without characterizing the convergence rate. Relaxing these limitations, we provide the convergence rate for the WASP in the *inid* case, including the convergence rate for WASP of general functionals of the original parameters.

3.2.1 Approximation Error of WASP for inid Data: Weighted Linear Model Example

We use a weighted linear model example to illustrate the theoretical approximation accuracy of WASP to the true posterior under the *inid* setup. For $i = 1, \ldots, n$, let y_i be a scalar response, x_i be a $p \times 1$ vector of predictors, and ϵ_i be the idiosyncratic error in y_i. Let $\theta = (\theta_1, \ldots, \theta_p)^T$ be the $p \times 1$ regression coefficients vector. Let $y = (y_1, \ldots, y_n)^T$, $X = [x_1, \ldots, x_n]^T$, and $\epsilon = (\epsilon_1, \ldots, \epsilon_n)^T$ be the $n \times 1$ response vector, the $n \times p$ design matrix, and the $n \times 1$ error vector, respectively. If Σ is a known diagonal matrix with positive elements and $\text{cov}(\epsilon) = \Sigma$, then the weighted linear regression model of y on X with a flat prior on θ assumes that

$$y = X\theta + \epsilon, \quad \epsilon \sim N_n(0, \Sigma), \quad \Sigma = \text{diag}(\sigma_1^2, \ldots, \sigma_n^2), \quad \pi(\theta) \propto 1, \tag{10}$$

where $\pi(\theta)$ is the flat prior on θ and $N_n(0,\Sigma)$ is a n-variate Gaussian distribution with $n\times 1$ mean 0 and covariance Σ. In this case, the data are *inid* since the distribution of y_i depends on the value of x_i. Since Σ is assumed to be known, the posterior distribution of θ is normal with mean $\mu=(X^T\Sigma^{-1}X)^{-1}X^T\Sigma^{-1}y$ and covariance matrix $V=(X^T\Sigma^{-1}X)^{-1}$. Although the posterior of θ has a closed form in this example, the computational complexity of finding μ and V is $O(n^2)$, which becomes inefficient as the size of the data n increases.

The WASP of θ in (10) is analytically tractable. The computation of WASP has three steps. First, the training data are randomly split into k subsets. Let y_j, X_j, and Σ_j be the response vector, design matrix, and error covariance matrix specific to subset j ($j=1,\ldots,k$). Second, we compute the subset posterior distributions after stochastic approximation on the k subsets in parallel as in (5) with $\gamma=k$. The jth subset posterior distribution of θ is $N_p(\mu_j,V_j)$, where $\mu_j=(X_j^T\Sigma_j^{-1}X_j)^{-1}X_j^T\Sigma_j^{-1}y_j$ and $V_j=k^{-1}(X_j^T\Sigma_j^{-1}X_j)^{-1}$. Third, (7) implies that the WASP of θ is also Gaussian with mean vector $\overline{\mu}$ and covariance matrix $\overline{V}$, where $\overline{\mu}=k^{-1}\sum_{j=1}^k\mu_j$ and $\overline{V}$ satisfies $\overline{V}=k^{-1}\sum_{j=1}^k(\overline{V}^{1/2}V_j\overline{V}^{1/2})^{1/2}$.

The WASP and full data posterior distributions lead to the same posterior inference on θ up to $o(n^{-1})$ terms. Let $\overline{\Pi}_n=N_p(\overline{\mu},\overline{V})$ and $\Pi_n=N_p(\mu,V)$ be the WASP and full data posterior distributions for θ. Based on the divide-and-conquer technique, the computational complexity of $\overline{\Pi}_n$ is $O(km^2)$, which is smaller than that of Π_n by a factor of k. The true distribution of y, denoted as $P_{\theta_0}^{(n)}$, in (10) is $N_n(X\theta_0,\Sigma)$. If uncertainty quantification using $\overline{\Pi}_n$ and Π_n is the same, then it suffices to show that the difference in the second moments of $\overline{\Pi}_n$ and Π_n is $o(n^{-1})$ in $P_{\theta_0}^{(n)}$-probability because the variances $\overline{V}$ and V are both of order n^{-1}. This is equivalent to showing that the W_2 distance between $\overline{\Pi}_n$ and Π_n is $o(n^{-1})$ in $P_{\theta_0}^{(n)}$-probability, which is proved in the next theorem. In the statement of the theorem, we denote $A\prec B$ for positive definite matrices A and B if $B-A$ is also positive definite.

Theorem 1 *Assume that there exist $a_n=o(1)$, $b_m=o(1)$ such that $\Omega_0-a_nI_p\prec\frac{1}{n}X^T\Sigma^{-1}X\prec\Omega_0+a_nI_p$ and $\Omega_0-b_mI_p\prec\frac{1}{m}X_j^T\Sigma_j^{-1}X_j\prec\Omega_0+b_mI_p$ for all $j=1,\ldots,k$, where I_p, Ω_0 are $p\times p$ identity and constant positive definite matrices. Then,*

$$E_{P_{\theta_0}^{(n)}}\|\overline{\mu}-\mu\|_2^2=o\left(n^{-1}\right),\quad \mathrm{tr}\left(\overline{V}-V\right)=o\left(n^{-1}\right),\quad E_{P_{\theta_0}^{(n)}}W_2^2(\overline{\Pi}_n,\Pi_n)=o\left(n^{-1}\right).$$

The proof of this theorem is in the appendix along with other proofs.

Theorem 1 shows that the uncertainty quantification of Π_n and $\overline{\Pi}_n$ are the same in $P_{\theta_0}^{(n)}$-probability for the data following the model in (10). Essentially, the WASP and the true posterior have the same posterior mean and posterior variance, and their differences are only in high order of the full data size n. Furthermore, Theorem 1 is valid for any block diagonal Σ as long as the data that belong to a particular diagonal block of Σ also belong to the same partition. In other words, Theorem 1 even holds for dependent data in which the dependence can be expressed as a block diagonal Σ in (10). Finally, Theorem 1 is in fact true for any error distribution satisfying $E(\epsilon)=0$ and $\mathrm{cov}(\epsilon)=\Sigma$, which includes the Gaussian distribution; see Definition 2.1 and Theorem 2.3 in Álvarez-Esteban et al. (2016).

3.2.2 General Convergence Rates of the WASP for inid Data

For general non-iid data, the standard Bayesian asymptotic theory for posterior convergence rates has been established in Ghosal and van der Vaart (2007), which also includes our *inid* setup. We follow the theoretical framework of Ghosal and van der Vaart (2007) and develop the corresponding theory for divide-and-conquer Bayesian inference using the WASP.

We start with two definitions required to state the assumptions of our theoretical setup.

Definition 2 (Pseudo Hellinger distance) *The pseudo Hellinger distance between probability measures $P_{\theta_1}^{(m)},P_{\theta_2}^{(m)}\in\{\otimes_{i=1}^m P_{\theta,j,i}:\theta\in\Theta,\ dP_{\theta,j,i}(y)=p_{ji}(y\mid\theta)dy\}$ is $h_{mj}^2(\theta_1,\theta_2)=\frac{1}{m}\sum_{i=1}^m h^2\left\{p_{ji}(\cdot\mid\theta_1),p_{ji}(\cdot\mid\theta_2)\right\}$, where $h(p_1,p_2)=[\int\{\sqrt{p_1(y)}-\sqrt{p_2(y)}\}^2dy]^{1/2}$ is the Hellinger distance between two generic densities p_1,p_2.*

This definition generalizes the usual Hellinger distance to account for the *inid* data generating mechanism. The space $(\{\otimes_{i=1}^m P_{\theta,j,i}:\theta\in\Theta\},h_{mj})$ is a metric space.

Definition 3 (Generalized bracketing entropy) *Let Ξ be a fixed subset of Θ. For an m-dimensional random vector $Z=(Z_1,\ldots,Z_m)^T$, denote its L_q norm as $|Z|_q=\left[\frac{1}{m}\sum_{i=1}^m E\left(|Z_i|^q\right)\right]^{1/q}$ and use $\|Z\|$ to represent $|Z|_2$. For a fixed $j\in\{1,\ldots,k\}$, let*

$$\mathcal{P}_j(\Xi)=\left\{\boldsymbol{p}_j(\boldsymbol{y}|\theta)=(p_{j1}(y_1|\theta),\ldots,p_{jm}(y_m|\theta))^T:\boldsymbol{y}=(y_1,\ldots,y_m)^T\in\otimes_{i=1}^m\mathcal{Y}_{ji},\theta\in\Xi\right\}$$

be the class of m-dimensional functions indexed by θ. For a given $\delta>0$, let

$$\begin{aligned}\mathcal{B}\left(\delta,\mathcal{P}_j(\Xi)\right)=&\Big\{[\boldsymbol{l}_s,\boldsymbol{u}_s]:\boldsymbol{l}_s(\boldsymbol{y})=(l_{s1}(y_1),\ldots,l_{sm}(y_m))^T,\boldsymbol{u}_s(\boldsymbol{y})=(u_{s1}(y_1),\ldots,u_{sm}(y_m))^T,\\&\boldsymbol{y}=(y_1,\ldots,y_m)^T\in\otimes_{i=1}^m\mathcal{Y}_{ji},s=1,\ldots,N\Big\}\end{aligned}$$

be the generalized bracketing set of $\mathcal{P}_j(\Xi)$ with cardinality N, such that for any $\boldsymbol{p}_j(\boldsymbol{y}|\theta)\in\mathcal{P}_j(\Xi)$, there exists a pair of functions $[\boldsymbol{l}_s,\boldsymbol{u}_s]\in\mathcal{B}\left(\delta,\mathcal{P}_j(\Xi)\right)$, such that

$$\begin{aligned}&l_{si}(y_i)\le p_{ji}(y_i)\le u_{si}(y_i),\ \text{for all } \boldsymbol{y}\in\otimes_{i=1}^m\mathcal{Y}_{ji},\ \text{and all } i=1,\ldots,m\\&\text{and } \|\sqrt{\boldsymbol{u}_s}-\sqrt{\boldsymbol{l}_s}\|\le\delta.\end{aligned}$$

The h_{mj}-bracketing number of $\mathcal{P}_j(\Xi)$, $N_{[]}\left(\delta,\mathcal{P}_j(\Xi),h_{mj}\right)$, is defined as the smallest cardinality of the generalized bracketing set $\mathcal{B}\left(\delta,\mathcal{P}_j(\Xi)\right)$. The h_{mj}-bracketing entropy of $\mathcal{P}_j(\Xi)$ is defined as $H_{[]}\left(\delta,\mathcal{P}_j(\Xi),h_{mj}\right)=\log\left(1+N_{[]}\left(\delta,\mathcal{P}_j(\Xi),h_{mj}\right)\right)$.

Again, this definition generalizes the usual bracketing entropy to the *inid* cases. If the data are indeed *iid*, then Definition 3 coincides with that of the usual bracketing entropy.

Our theory for the convergence rate of WASP is built on the following assumptions.

(A1) Θ is a compact space in ρ metric, θ_0 is an interior point of Θ, and $g_1\gamma m\le n\le g_2\gamma m$ for some constants $g_1,g_2>0$.

(A2) For any $\theta,\theta'\in\Theta$ and $j=1,\ldots,m$, there exist positive constants α and C_L such that $h_{mj}^2(\theta,\theta')\ge C_L\rho^{2\alpha}(\theta,\theta')$, where h_{mj}^2 is the pseudo Hellinger distance in Definition 2.

(A3) (Entropy Condition) There exist constants $D_1 > 0$, $0 < D_2 < D_1^2/2^{12}$, a function $\Psi(u, r) \geq 0$ that is nonincreasing in $u \in \mathbb{R}^+$ and nondecreasing in $r \in \mathbb{R}^+$, such that for all $j = 1, \ldots, k$, for any $u, r > 0$ and for all sufficiently large m,

$$H_{[]}\left(u, \{\boldsymbol{p}_j(\boldsymbol{y}|\theta) : \theta \in \Theta, h_{mj}(\theta, \theta_0) \leq r\}, h_{mj}\right) \leq \Psi(u, r) \text{ for all } j = 1, \ldots, k;$$
$$\text{and } \int_{D_1 r^2/2^{12}}^{D_1 r} \sqrt{\Psi(u, r)} du < D_2 \sqrt{m} r^2,$$

where $\boldsymbol{p}_j(\boldsymbol{y}|\theta) = \{p_{j1}(y_{j1} \mid \theta), \ldots, p_{jm}(y_{jm} \mid \theta)\}^T$ and $H_{[]}$ is the h_{mj}-bracketing entropy of the set $\{\boldsymbol{p}_j(\boldsymbol{y}|\theta) : \theta \in \Theta, h_{mj}(\theta, \theta_0) \leq r\}$ in Definition 3.

(A4) (Prior Thickness) There exist positive constants κ and c_π, such that uniformly over all $j = 1, \ldots, k$,

$$\Pi\left(\theta \in \Theta : \frac{1}{m}\sum_{i=1}^{m} E_{P_{\theta_0}} \exp\left(\kappa \log_+ \frac{p_{ji}(Y_{ji}|\theta_0)}{p_{ji}(Y_{ji}|\theta)}\right) - 1 \leq \frac{\log^2 m}{m}\right) \geq \exp(-c_\pi k \log^2 m)$$

where $\log_+ x = \max(\log x, 0)$ for $x > 0$.

(A5) The metric ρ satisfies $\rho(\sum_{i=1}^N w_i \theta_i, \theta') \leq \sum_{i=1}^N w_i \rho(\theta_i, \theta')$ for any $N \in \{1, 2, \ldots\}$, $\theta_1, \ldots, \theta_N, \theta' \in \Theta$ and non-negative weights $\sum_{i=1}^N w_i = 1$.

Our assumptions above are based on the standard assumptions in Bayesian asymptotic theory. Similar to Theorem 10 in Ghosal and van der Vaart (2007), we have assumed a compact support in (A1) and lower bounded pseudo Hellinger distance in (A2). Typically, $\alpha = 1$ for most regular models, such as generalized linear models. If the model is non-regular, then α can be less than 1; for example, the densities may have discontinuities depending on the parameter (Ibragimov and Has' Minskii, 2013, Chapters V, VI). Assumption (A3) parallels the entropy condition used in Theorem 1 of Wong and Shen (1995), which has been adapted here for the *inid* setup using the generalized bracketing entropy, and will simplify to a similar entropy condition to that in Theorem 1 of Wong and Shen (1995) if the data are *iid*. Assumption (A4) is crucial in providing a stronger control over the tail probability as the posterior probability mass moves away from the true parameter θ_0, typically with an exponentially decaying rate. The convexity property of ρ in (A5) is mainly used to establish an averaging inequality under W_2 distance and is satisfied by, for example, the Euclidean metric and L_q metric with $q \geq 1$.

The posterior risks of Π_n and $\overline{\Pi}_n$ in the ρ metric is directly related to the W_2 distance based on the ρ metric. If θ_0 denotes the true parameter value from which the data are generated, then the posterior risk of Π_n in the estimation of θ_0 is

$$\int_{\mathcal{Y}^{(n)}} \int_\Theta \rho^2(\theta, \theta_0) d\Pi_n(\theta \mid Y^{(n)}) dP_{\theta_0}^{(n)}(y_1, \ldots, y_n) = E_{P_{\theta_0}^{(n)}}\left[W_2^2\left\{\Pi_n(\cdot \mid Y^{(n)}), \delta_{\theta_0}(\cdot)\right\}\right]. \quad (11)$$

The classical result says that the posterior risk (11) in regular parametric models converges to zero at the n^{-1} rate under assumptions similar to (A2)–(A4), with m replaced by n (van der Vaart, 2000). The next theorem shows that the same posterior risk of the WASP converges at a similar rate to that of the true posterior Π_n, which mainly depends on the size of subsets m, and can be made close to the standard n^{-1} rate up to some logarithmic factors for regular parametric models.

Theorem 4 *If Assumptions (A1)-(A4) hold for the jth subset posterior $\Pi_m(\cdot \mid Y_{[j]})$ $(j = 1, \ldots, k)$, then there exists a constants universal $C_1 > 0$ independent of j, such that as $m \to \infty$,*

$$E_{P_{\theta_0}^{(m)}}\left[W_2^2\left\{\Pi_m(\cdot \mid Y_{[j]}), \delta_{\theta_0}(\cdot)\right\}\right] \leq C_1 \left(\frac{\log^2 m}{m}\right)^{\frac{1}{\alpha}}, \quad j = 1, \ldots, k. \quad (12)$$

Additionally, if Assumption (A5) holds, then as $m \to \infty$,

$$E_{P_{\theta_0}^{(n)}}\left[W_2^2\left\{\overline{\Pi}_n(\cdot \mid Y^{(n)}), \delta_{\theta_0}(\cdot)\right\}\right] \leq C_1 \left(\frac{\log^2 m}{m}\right)^{\frac{1}{\alpha}}. \quad (13)$$

Theorem 4 proves posterior convergence in expectation, which is stronger than the commonly studied posterior convergence in probability. We present our results using the W_2 distance in order to account for the fact that the k subset posteriors sit on a common parameter space. Alternatively, from (11), the convergence rates in (12) and (13) are also the rates of posterior risks for the subset posterior distributions and the WASP. For regular models with $\alpha = 1$, if the number of subsets k increases slowly with n (e.g., $k = O(\log^c n)$ for some constant $c > 0$), then Theorem 4 implies that the WASP converges in W_2 distance at a near optimal convergence rate $O_p(n^{-1/2} \log^{c/2+1} n)$ to δ_{θ_0}. In this case, the standard parametric convergence rate of Π_n is $O_p(n^{-1/2})$, so the WASP attains the optimal convergence rate up to the $\log^{c/2+1} n$ factor. Equivalently, using (11), the posterior risk of the WASP converges to zero at the near optimal rate $O_p(n^{-1} \log^{c+2} n)$, compared to the $O_p(n^{-1})$ posterior risk of the true posterior Π_n.

In most applications, the interest also lies in functions of θ. Suppose $f : \Theta \mapsto \mathbb{R}^q$ is a function that maps θ to $\{f_1(\theta), \ldots, f_q(\theta)\}$, where $q \geq 1$ is a positive integer. A direct application of Lemma 8.5 in Bickel and Freedman (1981) gives the following corollary about the WASP of a function of θ. As long as the function is bounded almost linearly by the ρ metric in (1), its WASP possesses the same posterior convergence rate as in Theorem 4.

Corollary 5 *Suppose $f(\cdot) = \{f_1(\cdot), \ldots, f_q(\cdot)\}$ is a function that maps $\Theta \mapsto \mathbb{R}^q$ such that $|f(\theta)|^2 = \sum_{i=1}^q \{f_i(\theta)\}^2 \leq C_f\{1 + \rho^2(\theta, \theta_0)\}$, where $C_f > 0$ is a fixed constant. If the conditions in Theorem 4 hold and $\overline{f\sharp\Pi}_n(\cdot \mid Y^{(n)})$ represents the WASP of the subset posterior distributions for $f(\theta)$, then as $m \to \infty$,*

$$W_2\left\{\overline{f\sharp\Pi}_n(\cdot \mid Y^{(n)}), \delta_{f(\theta_0)}(\cdot)\right\} = O_{P_{\theta_0}^{(n)}}\left(\sqrt{\frac{\log^{2/\alpha} m}{m^{1/\alpha}}}\right).$$

Corollary 5 is very useful in applications because it says that the combination step in the WASP is independent of the model parametrization. Let $f\sharp\Pi_m(\cdot \mid Y_{[j]})$ be the jth subset posterior distribution for $f(\theta)$ $(j = 1, \ldots, k)$, then the WASP of k subset posterior distributions converges to $f(\theta_0)$ at the rate obtained in Theorem 4. In practice, we have S_j posterior samples of θ obtained from subset posterior j denoted as θ_{ji} $(i = 1, \ldots, s_j;$ $j = 1, \ldots, k)$. Algorithm 1 estimates an atomic approximation of $\overline{f\sharp\Pi}_n(\cdot \mid Y^{(n)})$, denoted as $\widehat{\overline{f\sharp\Pi}}_n(\cdot \mid Y^{(n)})$, based on the subset posterior samples $f(\theta_{ji})$ $(i = 1, \ldots, s_j;\ j = 1, \ldots, k)$.

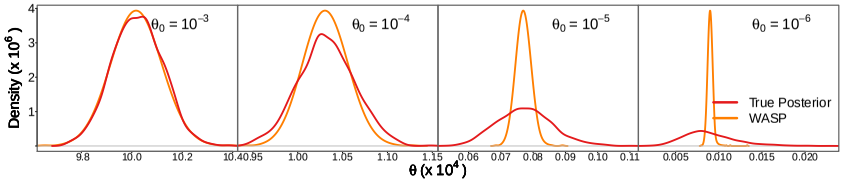

Figure 2: Kernel density estimates of the posterior densities of θ in the rare events example where assumption (A1) fails to hold for $\theta_0 = 10^{-5}, 10^{-6}$.

The atomic form of the WASP is supported on a grid with mesh-size ϵ estimated from the subset posterior samples of $f(\theta)$. Algorithm 1 estimates the weights of the atoms located on the grid by solving a discrete version of (6). The theoretical properties of discrete barycenters imply that $\widehat{f\sharp\Pi}_n(\cdot \mid Y^{(n)})$ is supported only on $O(k)$ elements of the grid; see Theorem 2 in Anderes et al. (2016). We exploit this sparsity by adapting the algorithm in Srivastava et al. (2015) and by using Gurobi (Gurobi Optimization Inc., 2014).

A key assumption in Theorem 4 and Corollary 5 is that the subset posterior distributions provide a noisy approximation of the full data posterior distribution. This is stated precisely in (12), which shows that the convergence rate of a subset posterior distribution in W_2 distance is obtained by using m as the sample size instead of n. If any of the assumptions (A1)–(A4) fail, then the subset posterior distributions may approximate the full data posterior distribution poorly, which could possibly lead to poor approximation quality for the WASP.

A simple example based on rare events demonstrates this phenomenon. Let $Y_1, \ldots, Y_n$ be *iid* Bernoulli random variables with unknown success probability $\theta \in (0, 1)$. The assumption (A1) is violated if the true parameter θ_0 is very close to 0; that is, observing 1 is a rare event. In our simulation example, we set $n = 10^7$ and $\theta_0 = 10^{-a}$ for $a = 3, 4, 5, 6$ so that as a increases, $s = \sum_{i=1}^{n} Y_i$ decreases and θ_0 gets closer and closer to the boundary of the parameter space. The standard Bayesian approach is to put Jefferys' prior Beta(0.5, 0.5) on θ and perform inference on θ using Beta($s + 0.5$, $n - s + 0.5$), which leads to a full data posterior that concentrates around the correct value of θ_0 even if θ_0 is small (Figure 2). However, if the data are randomly divided into $k = 100$ subsets, then a majority of the subsets contain only 0s as θ_0 decreases. As a result, a majority of the subset posterior distributions differ significantly in shape from the full data posterior distribution, leading to a failure of the WASP in approximating the full data posterior distribution because the assumption (A1) is severely violated for $\theta_0 = 10^{-5}, 10^{-6}$ (Figure 2).

4. Experiments

4.1 Setup

We compared WASP with consensus Monte Carlo (CMC) (Scott et al., 2016), semiparametric density product (SDP) (Neiswanger et al., 2014), and variational Bayes (VB). The sample sizes and the number of parameters in our experiments were chosen such that sampling from the full data posterior distribution was computationally feasible. Every sampling algorithm ran for 10,000 iterations. We discarded the first 5,000 samples as burn-in and thinned the chain by collecting every fifth sample. Convergence of the chains to their stationary distributions was confirmed using trace plots. All experiments ran on an Oracle Grid Engine cluster with 2.6GHz 16 core compute nodes. Full data posterior computations were allotted memory resources of 64GB, and all other methods were allotted memory resources of 16GB.

The sampling algorithm for the full data posterior was modified to obtain samples from the subset posteriors in CMC, SDP, and WASP. The sampling algorithms for subset posteriors in CMC and SDP were the same and were based on Equation (2) in Scott et al. (2016). The sampling algorithm for subset posteriors in WASP was based on (5). Samples from the approximate posterior distributions of θ in CMC, SDP, and WASP were obtained in two steps. First, samples from subset posteriors of θ were obtained in parallel across k subsets. Second, the samples of θ from all the subsets were combined using implementations of CMC and SDP in `parallelMCMC` package (Miroshnikov and Conlon, 2014) and using Algorithm 1 for the WASP.

The full data posterior distribution obtained using MCMC served as the benchmark in all our comparisons. Let $\pi(\theta \mid Y^{(n)})$ be the density of the full data posterior distribution for θ estimated using sampling and $\hat{\pi}(\theta \mid Y^{(n)})$ be the density of an approximate posterior distribution for θ estimated using the WASP or its competitors. We used the following metric based on the total variation distance to compare the accuracy $\hat{\pi}(\theta \mid Y^{(n)})$ in approximating $\pi(\theta \mid Y^{(n)})$

$$\text{accuracy}\left\{\hat{\pi}(\theta \mid Y^{(n)})\right\} = 1 - \frac{1}{2}\int_{\Theta} \left|\hat{\pi}(\theta \mid Y^{(n)}) - \pi(\theta \mid Y^{(n)})\right| \mathrm{d}\,\theta. \tag{14}$$

The accuracy metric lies in $[0, 1]$ (Faes et al., 2012). The approximation of full data posterior density by $\hat{\pi}$ is poor or excellent if the accuracy metric is close to 0 or 1, respectively. In our experiments, we computed the kernel density estimates of $\hat{\pi}$ and π from the posterior samples of θ using R package `KernSmooth` (Wand, 2015) and calculated the integral in (14) using numerical approximation.

4.2 Simulated Data: Finite Mixture of Gaussians

Finite mixture of Gaussians are widely used for model-based classification, clustering, and density estimation (Fraley and Raftery, 2002). Let n, p, and L be the sample size, the dimension of observations, and the number of mixture components. If $\mathbf{y}_i \in \mathbb{R}^p$ is the ith observation ($i = 1, \ldots, n$), then the mixture of L Gaussians assumes that any $\mathbf{y} \in \{\mathbf{y}_1, \ldots, \mathbf{y}_n\}$ is generated from the density

$$f_{\text{mix}}(\mathbf{y} \mid \theta) = \sum_{l=1}^{L} \pi_l \, \mathcal{N}_p(\mathbf{y} \mid \boldsymbol{\mu}_l, \Sigma_l), \tag{15}$$

where $\boldsymbol{\pi} = (\pi_1, \ldots, \pi_L)$ lies in a $(L-1)$-simplex, μ_l and Σ_l ($l = 1, \ldots, L$) are the mean and covariance parameters of a p-variate Gaussian distribution, and $\theta = \{\boldsymbol{\pi}, \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_L, \Sigma_1, \ldots, \Sigma_L\}$. We set $L = 2$ and $p = 2$ and simulated data from (15) using $\boldsymbol{\pi} = (0.3, 0.7)$, $\mu_1 = (1, 2)^T$, $\mu_2 = (7, 8)^T$, and $\Sigma_l = \Sigma$ ($l = 1, 2$), where $\Sigma_{12} = 0.5$, $\Sigma_{11} = 1$, and $\Sigma_{22} = 2$. We performed 10 simulation replications.

Table 1: Accuracies of the approximate posteriors for ρ_1, ρ_2, and $g_{0.05}(x)$ and $g_{0.95}(x)$ for $x \in \mathbb{R}$. The accuracies are averaged over 10 simulation replications. Monte Carlo errors are in parenthesis. CMC, consensus Monte Carlo; SDP, semiparametric density product; VB, variational Bayes; WASP, Wasserstein posterior

	ρ_1		ρ_2		$g_{0.05}$		$g_{0.95}$	
VB	0.77 (0.31)		0.76 (0.29)		0.99 (0.00)		0.99 (0.00)	
	$k = 5$	$k = 10$	$k = 5$	$k = 10$	$k = 5$	$k = 10$	$k = 5$	$k = 10$
CMC	0.97 (0.01)	0.96 (0.01)	0.96 (0.01)	0.96 (0.01)	0.99 (0.00)	0.99 (0.00)	0.99 (0.00)	0.99 (0.00)
SDP	0.97 (0.01)	0.96 (0.01)	0.95 (0.01)	0.96 (0.01)	-	-	-	-
WASP	0.97 (0.01)	0.95 (0.01)	0.97 (0.01)	0.96 (0.01)	0.99 (0.00)	0.99 (0.00)	0.99 (0.00)	0.99 (0.00)

This simple example demonstrated the generality of WASP in estimating the posterior distribution of functions of θ as described in Corollary 5. We defined two nonlinear functions of θ as

$$\rho_l = (\Sigma_l)_{12} / \{(\Sigma_l)_{11}(\Sigma_l)_{22}\}^{1/2} \quad l = 1, 2, \quad g(x) = f_{\text{mix}}\{(x, x)^T\} \quad x \in \mathbb{R}, \tag{16}$$

where ρ_l is the correlation of lth mixture component and $g(x)$ is the value of density f_{mix} in (15) when $\mathbf{y} = (x, x)^T$. Our simulation setup implied that $\rho_1 = \rho_2$ and $g(x)$ was bimodal for $x \in \mathbb{R}$. We completed the hierarchical model in (15) by specifying independent conjugate priors on $\boldsymbol{\pi}$ and (μ_l, Σ_l) $(l = 1, 2)$ as

$$\boldsymbol{\pi} \sim \text{Dirichlet}(1/2, 1/2), \quad \boldsymbol{\mu}_l \mid \Sigma_l \sim \mathcal{N}_2(\mathbf{0}, 100\Sigma_l), \quad \Sigma_l \sim \text{Inverse-Wishart}(2, 4I_2), \tag{17}$$

where 2 is the prior degrees of freedom and $4I_p$ is the scale matrix of the Inverse-Wishart distribution. The posterior samples of θ were obtained using Gibbs sampling (Bishop, 2006), which were used to obtain posterior samples for ρ_1, ρ_2, and g.

We compared WASP with the posterior distributions estimated using CMC, Gibbs sampling, SDP, and VB. We used the VB algorithm developed in Bishop (2006). Two values of $k \in \{5, 10\}$ were used for CMC, SDP, and WASP and full data were partitioned into k subsets such that the mixture proportions were preserved in every subset. The approximate posterior distributions of ρ_1, ρ_2, and $g(x), x \in \mathbb{R}$, under each method were estimated using the subset posterior samples obtained after modifying the original Gibbs sampler. The sampling algorithm for WASP is described in the Supplementary Material.

We compared the accuracy (14) of CMC, SDP, VB, and WASP in approximating the full data posterior distributions of ρ_1, ρ_2, and point-wise 90% credible bands of $g(x)$ for $x \in \mathbb{R}$, denoted as $g_{0.05}(x)$ and $g_{0.95}(x)$. CMC, SDP, and WASP accurately approximated the full data posterior distributions of ρ_1 and ρ_2 for both ks, but VB underestimated the posterior uncertainty in ρ_1 and ρ_2. CMC, VB, and WASP were very accurate in estimating $g_{0.05}(x)$ and $g_{0.95}(x)$ for $x \in \mathbb{R}$, whereas the application of SDP failed due to a numerical error in matrix inversion (Table 1). This provides an empirical verification of Corollary 5, showing that the accuracy of the WASP was unaffected by the form of the parameters in the combination step. Theoretical guarantees similar to Corollary 5 were unavailable for CMC or SDP, but our numerical results illustrated that a similar result might also hold for these methods in mixture models.

4.3 Simulated Data: Linear Mixed Effects Model

Linear mixed effects models are extensively used in extending linear regression to account for longitudinal and nested dependence structures. Let n, s, and s_i be the sample size, total number of observations, and total number of observations for sample i $(i = 1, \ldots, n)$ so that $s = \sum_{i=1}^{n} s_i$. Suppose $X_i \in \mathbb{R}^{s_i \times p}$ and $Z_i \in \mathbb{R}^{s_i \times r}$ include predictors in the fixed and random effects components, respectively. Letting $\mathbf{y}_i \in \mathbb{R}^{s_i}$ be the response for sample i, the linear mixed effects model assumes that

$$\mathbf{y}_i \mid \boldsymbol{\beta}, \mathbf{u}_i, \tau^2 \sim \mathcal{N}_{s_i}(X_i\boldsymbol{\beta} + Z_i\mathbf{u}_i, \tau^2 I_{n_i}), \quad \mathbf{u}_i \sim \mathcal{N}_r(\mathbf{0}, \Sigma), \quad (i = 1, \ldots, n), \tag{18}$$

where $\mathbf{u}_i \in \mathbb{R}^r$ is the random effect for sample i with mean $\mathbf{0}$ and $r \times r$ covariance Σ, $\boldsymbol{\beta} \in \mathbb{R}^p$ denotes the fixed effects, and τ^2 is the error variance. The model parameters are $\theta = \{\boldsymbol{\beta}, \Sigma, \tau^2\}$.

We simulated data for a fixed n and s and varying p and r. We chose two values of $(p, r) \in \{(4, 3), (80, 6)\}$, fixed n and s to be 6000 and 100,000, and randomly assigned the s observations to n samples. The two choices of (p, r) ensured that the number of unknown parameters in $\boldsymbol{\beta}$ and Σ was 10 and 100 in the former and latter cases. The entries of X_i and Z_i were set to 1 or -1 with equal probability for every i. We fixed $\boldsymbol{\beta}$ entries as -2 and 2 alternately and $\tau^2 = 1$. The random effects covariance matrix $\Sigma = \text{diag}(\sqrt{1}, \ldots, \sqrt{r})R\,\text{diag}(\sqrt{1}, \ldots, \sqrt{r})$, where diag($\mathbf{a}$) is a diagonal matrix with $\mathbf{a}$ along the diagonal and R is a correlation matrix with 1 along the diagonal. We set $R = R_1$ if $r = 3$ and $R = \text{bdiag}(R_1, R_1)$ if $r = 6$, where bdiag(A, B) is a block-diagonal matrix with A, B along the diagonal, $(R_1)_{ii} = 1$ $(i = 1, 2, 3)$, $R_{12} = -0.40$, $R_{13} = 0.30$, and $R_{23} = 0.001$. The matrix R_1 included negative, positive, and small to moderate strength correlations (Kim et al., 2013). We used this setup to simulate data from (18) and performed 10 replications.

We used the HMC algorithm in Stan for sampling from the full data and subset posterior distributions. The full data posterior computations were feasible for the chosen values of n and s and posterior samples were obtained after completing the hierarchical model in (18) by using the default weakly informative priors for $\boldsymbol{\beta}$, Σ, and τ^2 in Stan. Two values of $k \in \{10, 20\}$ were used for CMC, SDP, and WASP, and the n samples were randomly partitioned into k subsets. The sampling algorithms for subset posterior distributions for the three methods were implemented in Stan and posterior samples of θ were obtained in parallel across k subsets. This was followed by a combination step to estimate the approximate posterior distributions for the three methods. The sampling algorithm for WASP is described in the Supplementary Material. Stochastic gradient Langevin dynamics (SGLD; Welling and Teh 2011) has proven to be a successful stochastic version of MCMC in mixture and regression models but has not been extensively tested on linear mixed effects models in which multiple observations are available on a subject. We compared Stan's HMC and SGLD with batch sizes 2000, 4000, step sizes $10^{-4}, 10^{-5}$ and 10^4 iterations.

We compared the accuracy (14) of CMC, SDP, SGLD, VB, and WASP in approximating the marginal posterior distributions of fixed effects, variances and covariances of random effects, and the joint posterior distributions of three pairs of covariances of random effects. We used the streamlined algorithm (SA; Lee and Wand 2016) and automatic differentiation variational inference in Stan (ADVI; Kucukelbir et al. 2015) for estimating the VB posteriors for $\boldsymbol{\beta}$ and Σ . All methods except SGLD were significantly faster than the full data posterior

Table 2: Accuracies of the approximate posteriors for variances in (18). The accuracies are averaged over 10 simulation replications and across all diagonal elements of Σ. Monte Carlo errors are in parenthesis. 	$r=3$		$r=6$	
ADVI	0.48 (0.31)		0.09 (0.23)	
SA	0.26 (0.19)		0.34 (0.22)	
SGLD (2000)	0.68 (0.08)		0.73 (0.08)	
SGLD (4000)	0.69 (0.09)		0.72 (0.08)	
	$k=10$	$k=20$	$k=10$	$k=20$
CMC	0.93 (0.03)	0.91 (0.05)	0.89 (0.05)	0.80 (0.08)
SDP	0.92 (0.06)	0.86 (0.07)	0.84 (0.10)	0.77 (0.14)
WASP	0.97 (0.01)	0.97 (0.01)	0.97 (0.01)	0.97 (0.01)

distribution, with SA being the fastest. CMC, SA, SDP, and WASP provided accurate approximations of the marginal posterior distributions of fixed effects and covariances of random effects. Unlike Stan's HMC, SGLD's performance was sensitive to the choices of step size and batch size. SGLD failed to converge for all batch sizes when the step size was 10^{-4}, and its accuracy increased with batch size. The performance of ADVI and SGLD deteriorated quickly as r increased from 3 to 6. The accuracy of CMC and SDP in approximating the marginal posterior distributions of variances of random effects depended on k and r. ADVI and SA provided a poor approximation for the posterior variances of random effects. In all these cases, the accuracy of WASP was stable for every k and r (Tables 2 and 3). All methods except SGLD showed similar accuracies in approximating the true joint posterior distributions of three pairs of covariances of random effects. The differences in accuracies of CMC, SA, SDP, and WASP for different values of k and r were due to the differences in numerical approximation of (14) (Tables 4 and 5 and Figures 3 and 4); see Table 1 in the Supplementary Material.

The accuracy of CMC, SDP, and WASP decreased when k increased from 10 to 20 because subset posterior distributions conditioned on a smaller fraction of the data. This provided an empirical verification of Theorem 4 for the WASP. Our numerical results illustrated that a similar result might also hold for CMC and SDP. The stable performance of WASP compared to that of CMC and SDP in the approximation of the posterior distributions of variances of random effects showed that the validity of the normal approximation for subset posterior distributions was crucial in obtaining accurate approximations of full data posterior using CMC and SDP. On the other hand, WASP results were free of any such assumptions and were valid for any nonlinear function of μ and Σ; see Corollary 5.

4.4 Simulated Data: Probablistic Parafac Model

We use probabilistic parafac model as a representative example for nonparametric density estimation using WASP. Probabilistic parafac is an approach for nonparametric Bayes modeling of joint dependence in multivariate categorical data (Dunson and Xing, 2009). Let $\mathbf{x}_i = (x_{i1}, \ldots, x_{ij}, \ldots, x_{ip})$ be the data from sample i, where x_{ij} has d_j possible categorical values in $\{1, \ldots, d_j\}$ $(j = 1, \ldots, p)$. The hierarchical model for x_{ij} $(i = 1, \ldots, n;$

	$k=10$	$k=20$	$k=10$	$k=20$	$k=10$	$k=20$
CMC	0.88 (0.05)	0.79 (0.06)	0.88 (0.04)	0.82 (0.07)	0.91 (0.02)	0.85 (0.04)
SDP	0.90 (0.03)	0.89 (0.03)	0.90 (0.03)	0.87 (0.05)	0.92 (0.02)	0.89 (0.04)
WASP	0.93 (0.01)	0.94 (0.01)	0.93 (0.01)	0.94 (0.01)	0.94 (0.01)	0.94 (0.01)

$j = 1, \ldots, p)$ is

$$
\begin{aligned}
x_{ij} \mid \left(\psi_{h1}^{(j)}\right)_{h=1}^{\infty}, \ldots, \left(\psi_{hd_j}^{(j)}\right)_{h=1}^{\infty}, z_i &\sim \text{Multinomial}(\{1, \ldots, d_j\}, \psi_{z_i 1}^{(j)}, \ldots, \psi_{z_i d_j}^{(j)}), \\
z_i &\sim \sum_{h=1}^{\infty} V_h \prod_{l<h} (1 - V_l)\delta_h \equiv \sum_{h=1}^{\infty} \nu_h \delta_h, \quad V_h \sim \text{Beta}(1, \alpha), \\
\psi_h^{(j)} &\sim \text{Dirichlet}(a_{j1}, \ldots, a_{jd_j}), \quad \alpha \sim \text{Gamma}(a_\alpha, b_\alpha), \quad (19)
\end{aligned}
$$

where α has prior mean a_α / b_α. The hierarchical model for probabilistic parafac implies that

$$
\text{pr}(x_{i1} = c_1, \ldots, x_{ij} = c_j, \ldots, x_{ip} = c_p) = \pi_{c_1, \ldots, c_p} = \sum_{h=1}^{\infty} \nu_h \prod_{j=1}^{p} \psi_{hc_j}^{(j)}. \quad (20)
$$

The x_{ij}s are sampled independently given the latent class z_i and probability vectors $\boldsymbol{\psi}_h^{(j)}$ $(h = 1, \ldots, \infty)$. The latent class for every sample is generated using the stick breaking representation of Dirichlet processes. The Gibbs sampling algorithm developed in Dunson and Xing (2009) is very slow even for moderate sample sizes. This example demonstrates that WASP can easily scale existing sampling algorithms to massive data, even when efficient VB alternatives are unavailable.

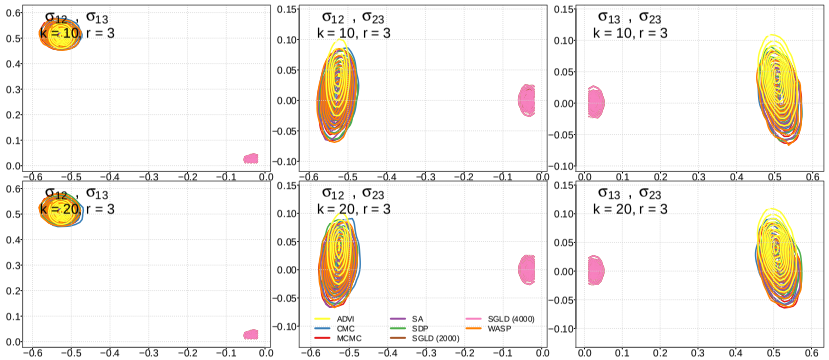

Figure 3: Kernel density estimates of the posterior densities of three covariance pairs when $r = 3$ in (18), where σ_{ab}, σ_{cd} on every panel represents the two-dimensional posterior density of $(\sigma_{ab}, \sigma_{cd})$. ADVI, automatic differentiation variational inference; SGLD, stochastic gradient Langevin dynamics with batch size in parenthesis; CMC, consensus Monte Carlo; MCMC, Markov chain Monte Carlo; SA, streamlined algorithm; SDP, semiparametric density product; WASP, Wasserstein posterior.

We followed the simulation setup in Dunson and Xing (2009), except with a much larger sample size. We fixed the sample size, number of dimensions, and number of categories in each dimension at $n = 10^5$, $p = 20$, and $d_j = 2$ $(j = 1, \ldots, p)$, respectively. These choices of n, p, and d_js ensured that computations for sampling from the full data posterior were tractable. Data were simulated as a mixture of two populations such that any sample belonged to the two populations with equal probability. The two categories in every dimension excluding $2, 4, 12$, and 14 were simulated from a discrete uniform in both populations. The dependence across dimensions $2, 4, 12$, and 14 was induced as follows. The probabilities π_2, π_4, π_{12}, and π_{14} were set to (0.20, 0.80), (0.25, 0.75), (0.80, 0.20), and (0.75, 0.25) in the first population and to (0.80, 0.20), (0.75, 0.25), (0.20, 0.80), and (0.25, 0.75) in the second population. The simulation setup was replicated 10 times.

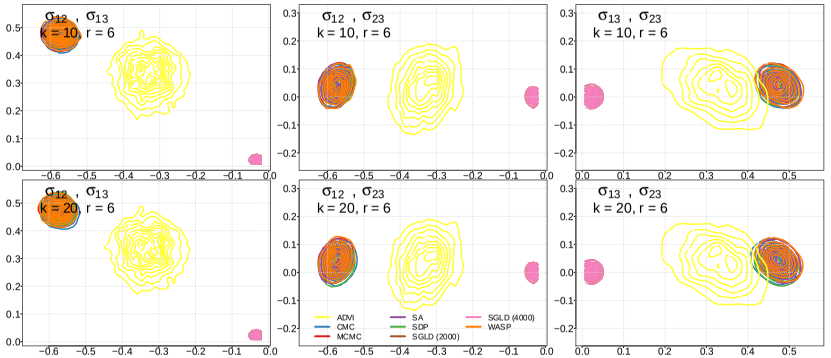

Figure 4: Kernel density estimates of the posterior densities of three covariance pairs when $r = 6$ in (18), where σ_{ab}, σ_{cd} on every panel represents the two-dimensional posterior density of $(\sigma_{ab}, \sigma_{cd})$. Figure 5: Kernel density estimates of the marginal posterior densities for dimensions 2, 4, 12, and 14. MCMC, Gibbs sampling algorithm of Dunson and Xing (2009); CMC, consensus Monte Carlo; SDP, semiparametric density product; VB, variational Bayes; WASP, Wasserstein posterior

We used CMC, SDP, and WASP to approximate the full data posterior distributions for $\text{pr}(x_i = 1)$, where $i \in \{2, 4, 12, 14\}$. Two values of $k \in \{5, 10\}$ were used for CMC, SDP, and WASP. The full data were randomly partitioned into k subsets and subset posterior samples for WASP were obtained after modifying the Gibbs sampling algorithm in Dunson and Xing (2009) using (5). Examples for the application of CMC and SDP were unavailable for Dirchlet process mixtures, and it was unclear how to raise the prior density to the power $1/k$ when the prior distribution has an atomic form similar to that in (19); therefore, we did not raise the prior to a power of $1/k$ for sampling from the subset posterior distributions

Table 6: Accuracies of the approximate marginal posterior distributions for dimensions 2, 4, 12, and 14 in (19). The accuracies are averaged over 10 simulation replications. Monte Carlo errors are in parenthesis. CMC, consensus Monte Carlo; SDP, semiparametric density product; WASP, Wasserstein posterior

	$k = 5$			$k = 10$		
	CMC	SDP	WASP	CMC	SDP	WASP
$\text{pr}(x_2 = 1)$	0.63 (0.02)	0.62 (0.02)	0.97 (0.01)	0.96 (0.02)	0.95 (0.01)	0.97 (0.01)
$\text{pr}(x_4 = 1)$	0.63 (0.02)	0.62 (0.02)	0.97 (0.01)	0.96 (0.01)	0.95 (0.02)	0.97 (0.01)
$\text{pr}(x_{12} = 1)$	0.62 (0.02)	0.62 (0.02)	0.97 (0.01)	0.95 (0.01)	0.96 (0.02)	0.97 (0.01)
$\text{pr}(x_{14} = 1)$	0.64 (0.01)	0.63 (0.01)	0.97 (0.01)	0.96 (0.02)	0.95 (0.02)	0.97 (0.01)

in CMC and SDP. The sampling algorithm for WASP based on stochastic approximation is summarized in the Supplementary Material. Subset posterior samples for $\text{pr}(x_2 = 1)$, $\text{pr}(x_4 = 1)$, $\text{pr}(x_{12} = 1)$, and $\text{pr}(x_{14} = 1)$ were combined to obtain their approximate posterior distributions using CMC, SDP, and WASP.

The accuracy (14) of CMC and SDP in approximating the full data marginal posterior distribution depended on k, with WASP outperforming CMC and SDP when $k = 5$ (Table 6). The approximate and full data posterior distributions were centered at the same value across all dimensions and replications, but the posterior densities for CMC and SDP were highly concentrated compared to the full data posterior density when $k = 5$ (Figure 5). The accuracy of WASP remained stable with varying k, providing an empirical verification of Theorem 4 in cases where our theory is not applicable. The time spent in combining subset posterior samples was negligible compared to the time spent in sampling; therefore, WASP could be used for data with much larger sample size by choosing k large enough such that sampling was efficient across all the data subsets.

4.5 Real Data: MovieLens Ratings Data

We used MovieLens data to illustrate the application of WASP to large-scale ratings data. MovieLens data are one of the largest publicly available ratings data with about 10 million ratings from about 72 thousand users of the MovieLens recommender system. Each observation in the database consists of a user, movie, rating of the movie from 0.5 to 5 in increments of 0.5, and the time of rating. Every movie is also classified into at least one of the 19 genres. We fit a linear mixed effects model (18) using movie- and user-specific information as predictors and the ratings as responses.

We generated three new predictors for accurate modeling of ratings following Perry (2017). First, movie genres were grouped into *movie categories* to reduce the number of genres from 19 to four: *Action* category included Action, Adventure, Fantasy, Horror, Sci-Fi, and Thriller genres; *Children* category included Animation and Children genres; *Comedy* category included Comedy genre; and *Drama* category included Crime, Documentary, Drama, Film-Noir, Musical, Mystery, Romance, War, and Western genres. If a movie belonged to multiple genres, then movie category scores were fractions proportional to the number of genres in the respective categories. Second, *popularity* predictor was defined as $\text{logit}\{(l+0.5)/(n+1.0)\}$, where l and n respectively were the number of users who liked and rated the movie in 30 most recent observations for the movie and $\text{logit}(x) = \log \frac{x}{1-x}$. Third, *previous* predictor was defined to be 1 if the user liked the previous movie and 0 otherwise.

WASP	0.92 (0.04)	0.93 (0.02)	0.87 (0.06)	0.85 (0.08)	0.92 (0.03)	0.93 (0.05)

We used *Action*, *Children* − *Action*, *Comedy* − *Action*, *Drama* − *Action*, *popularity*, and *previous* as the fixed and random effects in (18).

Following the setup in Section 4.3, we compared the performance of WASP with ADVI, CMC, SA, SGLD with batch sizes 2000, 4000, step size 10^{-5} and 10^4 iterations, and SDP using the full data posterior distribution as the benchmark. Sampling using the HMC algorithm in Stan was prohibitively slow for the full data posterior distribution, so we first randomly selected 5000 users and then randomly selected 20 ratings for every user. This resulted in a data set with 100,000 ratings. We randomly split the users into 10 training data sets such that ratings for any user belonged to the same training data set. To compute the approximate posteriors using CMC, SDP, and WASP, we set $k = 10$ and randomly partitioned the users into k subsets such that each subset contained all the ratings for a user. This setup was replicated for every training data.

WASP performed better than its competitors in approximating the full data posterior distributions for variances and covariances of the random effects. Similar to the simulation results in Section 4.3, ADVI, CMC, SA, SDP, and WASP were significantly faster than the full data posterior distribution, with SA being the fastest, and SGLD was the slowest. CMC, SDP, and WASP showed excellent performed in approximating the full data posterior distributions for the fixed effects. WASP outperformed its competitors in approximating the full data posterior distributions for variances, covariances, and pairs of covariances of the random effects (Tables 7, 8, and 9). ADVI, SA, and SGLD significantly under-performed in the estimation of the posterior distribution for the fixed effects and covariance matrix of the random effects. The accuracy of marginals in CMC and SDP depended on the magnitude of covariances, with both methods showing excellent accuracy for covariances with low magnitude. The accuracies of the two-dimensional joint distributions in CMC and SDP were poor because the full data posteriors concentrated at different locations (Figure 6). Except for the poor performance of CMC, SA, and SDP in approximating the posterior distribution of variances and covariances of the random effects, our real data results agreed with our simulation results. We concluded that WASP performed better than its competitors in MovieLens data analysis.

5. Discussion

We have presented WASP as an approach for computationally efficient approximation of the posterior distributions of parameters and their functions when the sample size is large. WASP allows extensions of existing samplers to massive data with minimal modifications and is easily implemented using probabilistic programming languages, such as Stan. Theoretically, we have showed that the rate of convergence of WASP to the Dirac measure centered at the true parameter value in W_2 distance matches the optimal parametric rate up to a logarithmic factor if the number of subsets increases slowly with the size of the full data set. Empirically, we demonstrated that results from WASP and MCMC agree closely in several widely different examples, while WASP enables massive speed-ups in computational time.

We plan to explore several extensions of WASP in the future. First, the combination of subset posterior distributions using WASP and the proof of the convergence rate for the WASP in Theorem 4 are valid even if the data in different subsets are dependent; however, independence assumption within each subset is required in the proof of (12) in Theorem 4 and in our justification of stochastic approximation. Currently, it is unclear how to extend stochastic approximation to cases where the likelihood is unavailable in a product form. This extension in crucial for proper uncertainty quantification outside of settings in which the observations are conditionally independent given latent variables. Second, it is unclear how to optimally choose k in practice; larger k improves computational time when abundant processors are available but choosing k too large may lead to increasing statistical errors (refer to Theorem 4). Our numerical experiments show that the accuracy of WASP is robust to the choice of k if all the subset sizes are moderately large relative to the number of parameters. In addition, it is of interest to study more deeply the impact of the partitioning schemes and attempt to develop approaches that deal with not only large sample sizes but also high-dimensional data. A possibility in this regard is to combine WASP with approximate MCMC (Johndrow et al., 2015).

Acknowledgments

Volkan Cevher and Quoc Tran-Dinh proposed and implemented the linear program for calculating Wasserstein barycenter described in Srivastava et al. (2015). All experiments were based on a modified version of Tran-Dinh's Matlab and Gurobi code for estimating Wasserstein barycenter. Jack Baker provided extensive help in implementing the SGLD algorithm. The code used in the experiments is available at `https://github.com/blayes/WASP`. We thank the Associate Editor and two anonymous referees for their helpful comments that improved our paper. Appendix A. Proofs of Theorems

A.1 Proof of Theorem 1

If $E_{P_{\theta_0}^{(n)}}$ represents the expectation with respect to $P_{\theta_0}^{(n)}$, then

$$E_{P_{\theta_0}^{(n)}}\left[W_2^2\{N_p(\mu,V),N_p(\overline{\mu},\overline{V})\}\right] = E_{P_{\theta_0}^{(n)}}\|\mu-\overline{\mu}\|_2^2 + \operatorname{tr}\left\{V+\overline{V}-2(\overline{V}^{1/2}V\overline{V}^{1/2})^{1/2}\right\}. \tag{21}$$

First, we find the asymptotic order of $E_{P_{\theta_0}^{(n)}}\|\mu_1-\mu_2\|_2^2$ in (21). Define

$$A=(X^T\Sigma^{-1}X)^{-1}X^T\Sigma^{-1}, \quad B=k^{-1}\left[(X_1^T\Sigma_1^{-1}X_1)^{-1}X_1^T\Sigma_1^{-1},\cdots,(X_k^T\Sigma_k^{-1}X_k)^{-1}X_k^T\Sigma_k^{-1}\right],$$

and $C=A-B$. After some algebra, we have that $AX=I_p$, $BX=I_p$, where I_p is a $p\times p$ identity matrix, and

$$\|\mu-\overline{\mu}\|_2^2=\|Cy\|_2^2, \quad E_{P_{\theta_0}^{(n)}}\|\mu-\overline{\mu}\|_2^2 = E_{P_{\theta_0}^{(n)}}(y^T)C^TCE_{P_{\theta_0}^{(n)}}(y)+\operatorname{tr}(C\Sigma C^T).$$

Since $E_{P_{\theta_0}^{(n)}}(y)=X\theta_0$ and $CX=AX-BX=I_p-I_p=0$, $E_{P_{\theta_0}^{(n)}}\|\mu-\overline{\mu}\|_2^2=\operatorname{tr}(C\Sigma C^T)$. Expanding $C\Sigma C^T$, we get

$$C=(X^T\Sigma^{-1}X)^{-1}X^T\Sigma^{-1}-k^{-1}\left[(X_1^T\Sigma_1^{-1}X_1)^{-1}X_1^T\Sigma_1^{-1},\cdots,(X_k^T\Sigma_k^{-1}X_k)^{-1}X_k^T\Sigma_k^{-1}\right],$$

$$C^T=\Sigma^{-1}X(X^T\Sigma^{-1}X)^{-1}-k^{-1}\begin{bmatrix}\Sigma_1^{-1}X_1(X_1^T\Sigma_1^{-1}X_1)^{-1}\\ \vdots \\ \Sigma_k^{-1}X_k(X_k^T\Sigma_k^{-1}X_k)^{-1}\end{bmatrix},$$

$$\operatorname{tr}(C\Sigma C^T)=\operatorname{tr}\{(X^T\Sigma X)^{-1}\}+k^{-2}\sum_{j=1}^k\operatorname{tr}\left\{(X_j^T\Sigma_jX_j)^{-1}\right\}-2\operatorname{tr}(D),$$

where

$$\begin{aligned}D&=k^{-1}\left[(X_1^T\Sigma_1X_1)^{-1}X_1^T,\cdots,(X_k^T\Sigma_kX_k)^{-1}X_k^T\right]\Sigma^{-1}X(X^T\Sigma^{-1}X)^{-1}\\&=\left\{k^{-1}\sum_{j=1}^k(X_j^T\Sigma_j^{-1}X_j)^{-1}X_j^T\Sigma_j^{-1}X_j\right\}(X^T\Sigma^{-1}X)^{-1}=(X^T\Sigma^{-1}X)^{-1}\end{aligned}$$

because Σ is diagonal. We use the above display to obtain that

$$\begin{aligned}E_{P_{\theta_0}^{(n)}}\|\mu-\overline{\mu}\|_2^2=\operatorname{tr}(C\Sigma C^T)&=\frac{1}{k^2}\sum_{j=1}^k\operatorname{tr}\left\{(X_j^T\Sigma_j^{-1}X_j)^{-1}\right\}-\operatorname{tr}\left\{(X^T\Sigma^{-1}X)^{-1}\right\},\\&=\frac{1}{km}\operatorname{tr}\left\{\tfrac{1}{k}\sum_{j=1}^k\left(\tfrac{1}{m}X_j^T\Sigma_j^{-1}X_j\right)^{-1}\right\}-\frac{1}{n}\operatorname{tr}\left\{\left(\tfrac{1}{n}X^T\Sigma^{-1}X\right)^{-1}\right\}.\end{aligned}$$

Our assumptions and continuity of the matrix inverse for positive definite matrices imply that there are exist positive $a_n'=o(1)$, $b_m'=o(1)$, such that

$$\begin{aligned}\Omega_0^{-1}-a_n'I_p\prec\left(\tfrac{1}{n}X^T\Sigma^{-1}X\right)^{-1}\prec\Omega_0^{-1}+a_n'I_p,\\ \Omega_0^{-1}-b_m'I_p\prec\left(\tfrac{1}{m}X_j^T\Sigma_j^{-1}X_j\right)^{-1}\prec\Omega_0^{-1}+b_m'I_p.\end{aligned}$$

This implies that the previous display reduces to

$$E_{P_{\theta_0}^{(n)}}\|\mu-\overline{\mu}\|_2^2\le p(b_m'+a_n')/n=o(n^{-1}), \tag{22}$$

where the equality follow because p is fixed.

We now find the asymptotic order of the traces of the covariance matrices in (21). Following the same arguments used to derive (22), the full data and jth subset posterior covariance matrices satisfy

$$\begin{aligned}\frac{1}{n}\left(\Omega_0^{-1}-a_n'I_p\right)\prec V=\frac{1}{n}\left(\frac{1}{n}X^T\Sigma^{-1}X\right)^{-1}\prec\frac{1}{n}\left(\Omega_0^{-1}+a_n'I_p\right),\\ \frac{1}{n}\left(\Omega_0^{-1}-b_m'I_p\right)\prec V_j=\frac{1}{km}\left(\frac{1}{m}X_j^T\Sigma_j^{-1}X_j\right)^{-1}\prec\frac{1}{n}\left(\Omega_0^{-1}+b_m'I_p\right).\end{aligned} \tag{23}$$

Let $M_j=\left\{\overline{V}^{1/2}\frac{1}{km}\left(\frac{1}{m}X_j^T\Sigma_j^{-1}X_j\right)^{-1}\overline{V}^{1/2}\right\}^{1/2}$. Then (23) implies that

$$-b_m'\overline{V}\prec nM_j^2-\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}=n\overline{V}^{1/2}\left(V_j-n^{-1}\Omega_0^{-1}\right)\overline{V}^{1/2}\prec b_m'\overline{V}. \tag{24}$$

From the first inequality in (24), we have

$$\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}\prec\left(nM_j^2+b_m'\overline{V}\right)^{1/2}\prec n^{1/2}M_j+b_m'^{1/2}\overline{V}^{1/2}.$$

And similarly the second inequality in (24) implies that

$$n^{1/2}M_j\prec\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}+b_m'\overline{V}\right)^{1/2}\prec\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}+b_m'^{1/2}\overline{V}^{1/2}.$$

Therefore

$$\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}-b_m'^{1/2}\overline{V}^{1/2}\prec n^{1/2}M_j\prec\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}+b_m'^{1/2}\overline{V}^{1/2}.$$

Using this relation and the definition of $\overline{V}$, we have that

$$\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}-b_m'^{1/2}\overline{V}^{1/2}\prec n^{1/2}\overline{V}=\frac{1}{k}\sum_{j=1}^k n^{1/2}M_j\prec\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}+b_m'^{1/2}\overline{V}^{1/2}. \tag{25}$$

In (25), we take the square of $n^{1/2}\overline{V}$, apply the inequality $(A_1+A_2)^2 \prec 2(A_1^2+A_2^2)$ for two generic positive definite matrices A_1, A_2, and obtain that

$$n\overline{V}^2 \prec 2\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2} + 2b'_m\overline{V},$$
$$n\overline{V}^2 \succ \frac{1}{2}\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2} - b'_m\overline{V}.$$

Multiplying by $\overline{V}^{-1/2}$ on the left and right hand sides yields,

$$n\overline{V} \prec 2\Omega_0^{-1} + 2b'_m I_p,$$
$$n\overline{V} \succ \frac{1}{2}\Omega_0^{-1} - b'_m I_p. \tag{26}$$

Notice that $b'_m = o(1)$, Ω_0 is a constant positive definite matrix, and $\overline{V}$ is a positive definite matrix. Clearly, (26) forces $n\overline{V}$ to be an order-1 matrix. Now we take the square of $n^{1/2}\overline{V}$ in (25) again and obtain that

$$n\overline{V}^2 \prec \overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2} + b'_m\overline{V} + b'^{1/2}_m\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}\overline{V}^{1/2} + b'^{1/2}_m\overline{V}^{1/2}\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2},$$
$$n\overline{V}^2 \succ \overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2} + b'_m\overline{V} - b'^{1/2}_m\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}\overline{V}^{1/2} - b'^{1/2}_m\overline{V}^{1/2}\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}.$$

Multiplying by $\overline{V}^{-1/2}$ on the left and right hand sides yields,

$$n\overline{V} \prec \Omega_0^{-1} + b'_m I_p + b'^{1/2}_m\overline{V}^{-1/2}\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2} + b'^{1/2}_m\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}\overline{V}^{-1/2},$$
$$n\overline{V} \succ \Omega_0^{-1} + b'_m I_p - b'^{1/2}_m\overline{V}^{-1/2}\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2} - b'^{1/2}_m\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}\overline{V}^{-1/2}. \tag{27}$$

Since $n\overline{V}$ is an order-1 matrix, we have that $b'_m\overline{V}^{-1/2}\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2} = o(1)$, $b'_m\left(\overline{V}^{1/2}\Omega_0^{-1}\overline{V}^{1/2}\right)^{1/2}\overline{V}^{-1/2} = o(1)$. Hence (23) and (27) reduce to

$$\frac{1}{n}\{\Omega_0^{-1} - o(1)I_p\} \prec V_j \prec \frac{1}{n}\{\Omega_0^{-1} + o(1)I_p\}, \quad \frac{1}{n}(\Omega_0^{-1} - o(1)I_p) \prec \overline{V} \prec \frac{1}{n}\{\Omega_0^{-1} + o(1)I_p\}.$$

This implies that

$$\mathrm{tr}(\overline{V} - V) = o(n^{-1}), \tag{28}$$

where the last equality follows because p is fixed.

Finally, we find the asymptotic order of the variance term in (21). The display before (28) implies that for some positive $c_n = o(1)$,

$$\overline{V}^{1/2}V\overline{V}^{1/2} \prec \frac{1}{n^2}\{\Omega_0^{-1/2} + o(1)I_p\}\{\Omega_0^{-1} + o(1)I_p\}\{\Omega_0^{-1/2} + o(1)I_p\}$$
$$\prec \frac{1}{n^2}[\Omega_0^{-2} + c_n I_p],$$
$$\overline{V}^{1/2}V\overline{V}^{1/2} \succ \frac{1}{n^2}\{\Omega_0^{-1/2} - o(1)I_p\}\{\Omega_0^{-1} - o(1)I_p\}\{\Omega_0^{-1/2} - o(1)I_p\}$$

$$\succ \frac{1}{n^2}[\Omega_0^{-2} - c_n I_p].$$

Therefore, $\mathrm{tr}\{(\overline{V}^{1/2}V\overline{V}^{1/2})^{1/2}\} = n^{-1}\,\mathrm{tr}(\Omega_0^{-1}) + o(n^{-1})$ since p is fixed. Using this and (23) for the variance term in (21) gives

$$\begin{aligned}&\mathrm{tr}\left\{V + \overline{V} - 2\left(\overline{V}^{1/2}V\overline{V}^{1/2}\right)^{1/2}\right\}\\ &= \{n^{-1}\,\mathrm{tr}(\Omega_0^{-1}) + o(n^{-1})\} + \{n^{-1}\,\mathrm{tr}(\Omega_0^{-1}) + o(n^{-1})\} - \{2n^{-1}\,\mathrm{tr}(\Omega_0^{-1}) + 2o(n^{-1})\}\\ &= o\left(n^{-1}\right).\end{aligned} \tag{29}$$

Combining the asymptotic expressions for the mean and variance terms in (22) and (29), (21) reduces to

$$E_{P_{\theta_0}^{(n)}}\left[W_2^2\left\{N(\overline{\mu},\overline{V}), N(\mu,V)\right\}\right] = o\left(n^{-1}\right),$$

which completes the proof. □

A.2 Proof of Theorem 4

Let $\epsilon_m = \left(\frac{m}{\log^2 m}\right)^{-1/(2\alpha)}$. For ease of notation, in all the following proofs, we will sometimes write $p(y_{ji} \mid \theta) \equiv p_{ji}(y_{ji} \mid \theta)$.

Due to the compactness of Θ in (A1), we assume that $\rho(\theta,\theta_0) \le M_0$ for a large finite constant M_0. We start with a decomposition of the W_2 distance from the jth subset posterior $\Pi_m(\cdot \mid Y_{[j]})$ to the Dirac measure at the true parameter θ_0:

$$\begin{aligned}&E_{P_{\theta_0}}W_2^2\left(\Pi_m(\cdot \mid Y_{[j]}), \delta_{\theta_0}(\cdot)\right) = E_{P_{\theta_0}}\int_\Theta \rho^2(\theta,\theta_0)\Pi_m(d\theta \mid Y_{[j]})\\ \le& E_{P_{\theta_0}}\int_{\{\theta:\rho(\theta,\theta_0)\le c_1\epsilon_m\}}\rho^2(\theta,\theta_0)\Pi_m(d\theta \mid Y_{[j]}) + E_{P_{\theta_0}}\int_{\{\theta:\rho(\theta,\theta_0)>c_1\epsilon_m\}}\rho^2(\theta,\theta_0)\Pi_m(d\theta \mid Y_{[j]})\\ \le&(c_1\epsilon_m)^2 + M_0^2 E_{P_{\theta_0}}\Pi_m\left(\rho(\theta,\theta_0) > c_1\epsilon_m \mid Y_{[j]}\right).\end{aligned} \tag{30}$$

We will choose the constant c_1 as $c_1 = \left(\frac{2r_1g_2}{q_1C_L}\right)^{1/(2\alpha)}$, where g_1, C_L, q_1, r_1 are the constants in (A1), (A2), and Lemma 5 and Lemma 6 in the Supplementary Material.

The following proofs are similar to the proofs of Theorem 1, 4, and 10 in Ghosal and van der Vaart (2007). The main difference is that our likelihood has been raised to the power γ. Using condition (A2), we can further replace the ρ metric by the pseudo Hellinger distance:

$$\begin{aligned}&\Pi_m\left(\theta\in\Theta : \rho(\theta,\theta_0) > c_1\epsilon_m \mid Y_{[j]}\right)\\ \le&\,\Pi_m\left(\theta\in\Theta : h_{mj}(P_{\theta,j}, P_{\theta_0,j}) > \sqrt{C_L}(c_1\epsilon_m)^\alpha \mid Y_{[j]}\right)\\ =&\int_{\left\{\theta\in\Theta:h_{mj}(\theta,\theta_0)>\sqrt{\frac{2r_1g_2}{q_1}}\epsilon_m^\alpha\right\}}\frac{\prod_{i=1}^m\left[\frac{p(Y_{ji}|\theta)}{p(Y_{ji}|\theta_0)}\right]^\gamma\Pi(d\theta)}{\int_\Theta\prod_{i=1}^m\left[\frac{p(Y_{ji}|\theta)}{p(Y_{ji}|\theta_0)}\right]^\gamma\Pi(d\theta)}.\end{aligned} \tag{31}$$

For the denominator in (31), by Condition (A4) and Lemma 6, for m sufficiently large, with probability at least $1-\exp(-r_2 m\epsilon_m^{2\alpha})$

$$\int_\Theta \prod_{i=1}^m \frac{p(Y_{ji}|\theta)^\gamma}{p(Y_{ji}|\theta_0)^\gamma}\Pi(d\theta) > \exp(-r_1 n\epsilon_m^{2\alpha}). \tag{32}$$

For the numerator in (31), by Condition (A3) and Lemma 5, we set $\delta = \sqrt{2r_1 g_2/q_1}\epsilon_m^\alpha$ and obtain that with probability at least $1-4\exp\left(-\frac{2r_1 g_2 q_2}{q_1} m\epsilon_m^{2\alpha}\right) \geq 1-4\exp\left(-\frac{2r_1 q_2}{q_1} n\epsilon_m^{2\alpha}\right)$,

$$\sup_{\left\{\theta\in\Theta: h_{mj}(\theta,\theta_0)\geq\sqrt{2r_1 g_2/q_1}\epsilon_m^\alpha\right\}} \prod_{i=1}^m \left[\frac{p(Y_{ji}|\theta)}{p(Y_{ji}|\theta_0)}\right]^\gamma \leq \exp\left(-2r_1 g_2 m\epsilon_m^{2\alpha}\right) \leq \exp\left(-2r_1 n\epsilon_m^{2\alpha}\right) \tag{33}$$

Therefore, based on (31), (32), and (33), we obtain that with probability at least $1-4\exp\left(-\frac{2r_1 q_2}{q_1} n\epsilon_m^{2\alpha}\right) - \exp(-r_2 m\epsilon_m^{2\alpha})$,

$$\Pi_m\left(\theta\in\Theta : \rho(\theta,\theta_0) > c_1\epsilon_m \;\middle|\; Y_{[j]}\right) \leq \exp\left(-2r_1 n\epsilon_m^{2\alpha} + r_1 n\epsilon_m^{2\alpha}\right) \leq \exp\left(-r_1 n\epsilon_m^{2\alpha}\right).$$

Let A_{ϵ_m} be the event $\left\{\theta\in\Theta : \Pi\left(\theta\in\Theta : \rho(\theta,\theta_0) > c_1\epsilon_m \;\middle|\; Y_{[j]}\right) \leq \exp\left(-r_1 n\epsilon_m^{2\alpha}\right)\right\}$. Then we can bound the second term in (30) as

$$\begin{aligned}
&E_{P_{\theta_0}}\Pi_m\left(\rho(\theta,\theta_0) > c_1\epsilon_m \;\middle|\; Y_{[j]}\right)\\
&\leq E_{P_{\theta_0}}\left[I(A_{\epsilon_m})\Pi_m\left(\rho(\theta,\theta_0) > c_1\epsilon_m \;\middle|\; Y_{[j]}\right)\right] + E_{P_{\theta_0}}\left[I(A_{\epsilon_m}^c)\Pi_m\left(\rho(\theta,\theta_0) > c_1\epsilon_m \;\middle|\; Y_{[j]}\right)\right]\\
&\leq \exp\left(-r_1 n\epsilon_m^{2\alpha}\right) + P_{\theta_0}^{(n)}(A_{\epsilon_m}^c)\cdot 1\\
&\leq \exp\left(-r_1 n\epsilon_m^{2\alpha}\right) + 4\exp\left(-\frac{2r_1 q_2}{q_1} n\epsilon_m^{2\alpha}\right) + \exp(-r_2 m\epsilon_m^{2\alpha})\\
&\leq 6\exp\left(-c_2 m\epsilon_m^{2\alpha}\right),
\end{aligned}$$

for $c_2 = \min(r_1, r_2, 2r_1 q_2/q_1)$, as clearly the second term is dominating the other two given $m \lesssim n$.

Therefore, for (30), since $\epsilon_m = (m/\log^2 m)^{-1/(2\alpha)}$, as $m\to\infty$, an explicit bound will be

$$\begin{aligned}
&E_{P_{\theta_0}} W_2^2\left(\Pi_m(\cdot \mid Y_{[j]}), \delta_{\theta_0}(\cdot)\right) \leq c_1^2\frac{\log^{2/\alpha} m}{m^{1/\alpha}} + 6M_0^2\exp\left(-c_2\log^2 m\right)\\
&\leq c_1^2\frac{\log^{2/\alpha} m}{m^{1/\alpha}} + \frac{1}{m^{1+\frac{1}{\alpha}}} \leq C_1\frac{\log^{2/\alpha} m}{m^{1/\alpha}}
\end{aligned}$$

as m becomes sufficiently large, where the constant C_1 depends on α, c_1, c_2, which further depends on $g_1, g_2, q_1, q_2, r_1, r_2, C_L$. Since q_1, q_2 in Lemma 5 and r_1, r_2 in Lemma 6 depend on $g_1, g_2, D_1, D_2, \kappa, c_\pi$, it follows that C_1 depends on $g_1, g_2, C_L, D_1, D_2, \kappa, c_\pi$. □

Based on Lemma 7 in the Supplementary Material, if the assumption (A5) holds, then we have

$$E_{P_{\theta_0}^{(n)}}\left[W_2^2\left\{\overline{\Pi}_n(\cdot \mid Y^{(n)}), \delta_{\theta_0}(\cdot)\right\}\right] \leq E_{P_{\theta_0}^{(n)}}\left[\frac{1}{k}\sum_{j=1}^k W_2\left\{\Pi_m(\cdot \mid Y_{[j]}), \delta_{\theta_0}(\cdot)\right\}\right]^2$$

$$\leq \frac{1}{k}\sum_{j=1}^k E_{P_{\theta_0}^{(n)}} W_2^2\left\{\Pi_m(\cdot \mid Y_{[j]}), \delta_{\theta_0}(\cdot)\right\} \leq C_1\frac{\log^{2/\alpha} m}{m^{1/\alpha}},$$

where the first inequality follows from Lemma 7 in the Supplementary Material, the second inequality follows from the Cauchy-Schwarz inequality, and the third inequality follows from the subset bound (12). □

Appendix B. Univariate Density Estimation

Let $X_1, \ldots, X_n$ be n copies of a scalar random variable X that follows probability distribution P_0 with density p_0. The full data are randomly split into k subsets and $X_{j1}, \ldots, X_{jm}$ represent the data on subset j ($j = 1, \ldots, k$). The hierarchical model for density estimation using the stick-breaking representation of Dirichlet process mixtures is

$$\begin{aligned}
&X_{ji} \mid z_{ji}, \{\mu_h\}_{h=1}^\infty, \{\sigma_h^2\}_{h=1}^\infty \sim \mathcal{N}(\mu_{z_{ji}}, \sigma_{z_{ji}}^2), \quad z_{ji} \sim \sum_{h=1}^\infty \nu_h\delta_h, \quad \nu_h = V_h\prod_{l<h}(1-V_l), \quad V_h \mid \alpha \sim \text{Beta}(1,\alpha),\\
&\alpha \sim \text{Gamma}(a_\alpha, b_\alpha), \quad \mu_h \mid \sigma_h^2 \sim \mathcal{N}(0, \sigma_h^2), \quad \sigma_h^2 \sim \text{Inverse-Gamma}(a_\sigma, b_\sigma),
\end{aligned} \tag{34}$$

where $a_\sigma > 2$ and Beta, Gamma, and Inverse-Gamma random variables have means $\frac{1}{1+\alpha}$, $\frac{a_\alpha}{b_\alpha}$, and $\frac{b_\sigma}{a_\sigma - 1}$ and variances $\frac{\alpha}{(1+\alpha)^2(2+\alpha)}$, $\frac{a_\alpha}{b_\alpha^2}$, and $\frac{b_\sigma^2}{(a_\sigma-1)^2(a_\sigma-2)}$. If l^* is the maximum number of atoms in the stick-breaking representation, then the prior density π is in the form a discrete mixture. We cannot use existing sampling algorithms directly if π is raised to a power of $1/k$, so it is unclear how to sample from the subset posterior density of competing approaches in Section 2.2.

We show that it is still possible to sample from the subset posterior density in (5) using data augmentation. Let L_j be the likelihood given $X_{j1}, \ldots, X_{jm}$ and latent variables $z_{j1}, \ldots, z_{jm}$ in (34), then

$$L_j(\{\mu_h\}_{h=1}^{l^*}, \{\sigma_h^2\}_{h=1}^{l^*}, \{\nu_h\}_{h=1}^{l^*}) = \prod_{h=1}^{l^*}(2\pi\sigma_h^2)^{-\frac{\sharp h_j}{2}} e^{-\frac{1}{2\sigma_h^2}\sum_{i=1}^m 1(z_{ji}=h)(x_{ji}-\mu_h)^2}\nu_h^{\sharp h_j}, \tag{35}$$

where $1(z_{ji}=h)$ is 1 if $z_{ji}=h$ and 0 otherwise and $\sharp h_j = \sum_{i=1}^m 1(z_{ji}=h)$. For stochastic approximation, we raise L_j in (35) to the power γ and obtain

$$L_j^\gamma(\{\mu_h\}_{h=1}^{l^*}, \{\sigma_h^2\}_{h=1}^{l^*}, \{\nu_h\}_{h=1}^{l^*}) = \prod_{h=1}^{l^*}(2\pi\sigma_h^2)^{-\frac{\gamma\sharp h_j}{2}} e^{-\frac{\gamma}{2\sigma_h^2}\sum_{i=1}^m 1(z_{ji}=h)(x_{ji}-\mu_h)^2}\nu_h^{\gamma\sharp h_j}. \tag{36}$$

Standard arguments imply that the analytic form of full conditional densities of parameters are

$$\begin{aligned}
\mu_h \mid \text{rest} &\propto e^{-\frac{\gamma\sharp h_j+1}{2\sigma_h^2}\left(\mu_h^2 - 2\mu_h\gamma\frac{\sum_{i=1}^m 1(z_{ji}=h)x_{ji}}{\gamma\sharp h_j+1}\right)},\\
\sigma_h^2 \mid \text{rest} &\propto \sigma_h^{2-\frac{\gamma\sharp h_j}{2}} e^{-\frac{\gamma}{2\sigma_h^2}\sum_{i=1}^m 1(z_{ji}=h)(x_{ji}-\mu_h)^2}\sigma_h^{2-\frac{1}{2}} e^{-\frac{\mu_h^2}{2\sigma_h^2}}\sigma_h^{2-a_\sigma-1} e^{-\frac{b_\sigma}{\sigma_h^2}},\\
V_h \mid \text{rest} &\propto V_h^{\gamma\sum_{i=1}^m 1(z_i=h)}(1-V_h)^{\gamma\sum_{i=1}^m 1(z_{ji}>h)}(1-V_h)^{\alpha-1},
\end{aligned}$$

$$\alpha \mid \text{rest} \propto \alpha^{a_\alpha - 1} e^{-b_\alpha \alpha} \alpha^{l^*} \prod_{h=1}^{l^*} (1 - V_d)^{\alpha - 1} \tag{37}$$

for $h = 1, \ldots, l^*$. Let

$$m_{jh} = \frac{\gamma \sum_{i=1}^m 1(z_{ji} = h) x_{ji}}{\gamma \sharp h_j + 1}, \quad v_{jh} = \frac{\sigma_h^2}{\gamma \sharp h_j + 1}, \tag{38}$$

$$a_{jh} = \frac{\gamma \sharp h_j + 1}{2} + a_\sigma, \quad b_{jh} = \frac{\gamma}{2} \sum_{i=1}^m 1(z_{ji} = h) \, (x_{ji} - \mu_h)^2 + \frac{\mu_h^2}{2} + b_\sigma \tag{39}$$

for $h = 1, \ldots, l^*$, then all full conditional densities are tractable in terms of standard distributions:

$$\begin{aligned}
&\mu_{jh} \mid \text{rest} \sim N(m_{jh}, v_{jh}), \quad \sigma_{jh}^2 \mid \text{rest} \sim \text{Inverse-Gamma}(a_{jh}, b_{jh}), \\
&V_{jh} \mid \text{rest} \sim \text{Beta}(1 + \gamma \sum_{i=1}^m 1(z_{ji} = h), \alpha + \gamma \sum_{i=1}^m 1(z_{ji} > h)), \\
&\alpha_{jh} \mid \text{rest} \sim \text{Gamma}(a_\alpha + l^*, b_\alpha - \sum_{h=1}^{l^*} \log(1 - V_{jh})).
\end{aligned} \tag{40}$$

Finally, posterior distribution of the latent variables is

$$z_{ji} \mid \text{rest} \sim \sum_{h=1}^{l^*} p_{jh} \delta_h, \quad p_{jh} = \frac{\nu_{jh} \mathcal{N}(\mu_{jh}, \sigma_{jh}^2)}{\sum_{\tilde{h}=1}^{l^*} \nu_{j\tilde{h}} \mathcal{N}(\mu_{j\tilde{h}}, \sigma_{j\tilde{h}}^2)}, \quad (i = 1, \ldots, m), \tag{41}$$

where $\nu_{jh} = V_{jh} \prod_{l<h} (1 - V_{jl})$ and $\mathcal{N}(m, v)$ is the Gaussian density with mean m and variance v.

Appendix C. Linear Program

$$\begin{aligned}
\underset{\mathbf{a}, T_1, \ldots, T_k}{\text{minimize}} \quad & \sum_{j=1}^k \text{trace}(T_j^T D_j) \\
\text{subject to} \quad & \\
& 0 \le a_i \le 1, \quad i = 1, \ldots, g, \\
& 0 \le (T_j)_{uv} \le 1, \quad u = 1, \ldots, g, \quad v = 1, \ldots, s_j, \quad j = 1, \ldots, k, \\
& \mathbf{1}^T \mathbf{a} = 1, \\
& T_j \, \mathbf{1}_{s_j} = \mathbf{a}, \quad j = 1, \ldots, k, \\
& T_j^T \, \mathbf{1}_s = \frac{\mathbf{1}_{s_j}}{s_j}, \quad j = 1, \ldots, k.
\end{aligned} \tag{42}$$

This linear program can be solved using a variety of linear programming solvers in `Matlab` or `R`, including the algorithms of Cuturi and Doucet (2014) and Srivastava et al. (2015).

Abstract

Experience replay is a technique that allows off-policy reinforcement-learning methods to reuse past experiences. The stability and speed of convergence of reinforcement learning, as well as the eventual performance of the learned policy, are strongly dependent on the experiences being replayed. Which experiences are replayed depends on two important choices. The first is which and how many experiences to retain in the experience replay buffer. The second choice is how to sample the experiences that are to be replayed from that buffer. We propose new methods for the combined problem of experience *retention* and experience *sampling*. We refer to the combination as experience *selection*. We focus our investigation specifically on the control of physical systems, such as robots, where exploration is costly. To determine which experiences to keep and which to replay, we investigate different proxies for their immediate and long-term utility. These proxies include age, temporal difference error and the strength of the applied exploration noise. Since no currently available method works in all situations, we propose guidelines for using prior knowledge about the characteristics of the control problem at hand to choose the appropriate experience replay strategy.

Keywords: reinforcement learning, deep learning, experience replay, control, robotics

1. Introduction

Reinforcement learning is a powerful framework that makes it possible to learn complex nonlinear policies for sequential decision making processes while requiring very little prior knowledge. Especially the subfield of deep reinforcement learning, where neural networks are used as function approximators, has recently yielded some impressive results. Among these results are learning to play Atari games (Mnih et al., 2015) and to control robots (Levine et al., 2016) straight from raw images, as well as beating the top human player in the game of Go (Silver et al., 2016).

Reinforcement learning methods can be divided into on-policy and off-policy methods. On-policy methods directly optimize the policy that is used to make decisions, while off-policy methods can learn about an optimal policy from data generated by another policy. Neither approach is without its problems, which has motivated work on methods that combine on and off-policy updates (Wang et al., 2017; Gu et al., 2017; O'Donoghue et al., 2017).

When a reinforcement learning method is either partially or entirely off-policy, past experiences can be stored in a buffer and reused for learning. Doing so not only reduces the sample complexity of the learning algorithm, but can also be crucial for the stability of reinforcement-learning algorithms that use deep neural networks as function approximators (Mnih et al., 2015; Lillicrap et al., 2016; Schaul et al., 2016; Wang et al., 2017).

If we have access to a buffer with past experiences, an interesting question arises: how should we *sample* the experiences to be replayed from this buffer? It has been shown by Schaul et al. (2016) that a good answer to this question can significantly improve the performance of the reinforcement-learning algorithm.

However, even if we know how to sample from the experience buffer, two additional questions arise: what should the buffer capacity be and, once it is full, how do we decide which experiences should be *retained* in the buffer and which ones can be overwritten with new experiences? These questions are especially relevant when learning on systems with a limited storage capacity, for instance when dealing with high-dimensional inputs such as images. Finding a good answer to the question of which experiences to retain in the buffer becomes even more important when exploration is costly. This can be the case for physical systems such as robots, where exploratory actions cause wear or damage and risks need to be minimized (Kober et al., 2013; Garcıa and Fernández, 2015; Tamar et al., 2016; Koryakovskiy et al., 2017). It is also the case for tasks where a minimum level of performance needs to be achieved at all times (Banerjee and Peng, 2004) or when the policy that generates the experiences is out of our control (Seo and Zhang, 2000; Schaal, 1999).

We will refer to the combined problem of experience *retention* and experience *sampling* as experience *selection*. The questions of which experiences to sample and which experiences to retain in the buffer are related, since they both require a judgment on the utility of the experiences. The difference between them is that determining which experiences to sample requires a judgment on the instantaneous utility: from which experiences can the agent learn the most at the moment of sampling? In contrast, a decision on experience retention should be based on the expected long term utility of experiences. Experiences need to be retained in a way that prevents insufficient coverage of the state action space in the future, as experiences cannot be recovered once they have been discarded.

To know the true utility of an experience, it would be necessary to foresee the effects of having the reinforcement-learning agent learn from the experience at any given time. Since this is not possible, we instead investigate *proxies* for the experience utility that are cheap to obtain.

In this work, we investigate age, surprise (in the form of the temporal difference error), and the amplitude of the exploration noise as proxies for the utility of experiences. To motivate the need for *multiple* proxies, we will start by showing the performance of different experience selection methods on control benchmarks that, at first sight, seem very closely related. As a motivating example we show how the current state-of-the-art experience selection method of Schaul et al. (2016), based on retaining a large number of experiences and sampling them according to their temporal difference error, compares on these benchmarks to sampling uniformly at random from the experiences of the most recent episodes. We show that the state-of-the-art method significantly outperforms the standard method on one benchmark while significantly *under*-performing on the other, seemingly similar benchmark.

The focus of this paper is on the control of physical systems such as robots. The hardware limitations of these systems can impose constraints on the exploration policy and the number of experiences that can be stored in the buffer. These factors make the correct choice of experience sampling strategy especially important. As we show on additional, more complex benchmarks, even when sustained exploration *is* possible, it can be beneficial to be selective about which and how many experiences to retain in the buffer. The costs involved in operating a robot mean that it is generally infeasible to rely on an extensive hyper-parameter search to determine which experience selection strategy to use. We therefore want to understand how this choice can be made based on prior knowledge of the control task.

With this in mind, the contributions of this work are twofold:

1. We investigate how the utility of different experiences is influenced by the aspects of the control problem. These aspects include properties of the system dynamics such as the sampling frequency and noise, as well as constraints on the exploration.

2. We describe how to perform experience retention and experience sampling based on experience utility proxies. We show how these two parts of experience selection work together under a range of conditions. Based on this we provide guidelines on how to use prior knowledge about the control problem at hand to choose an experience selection strategy.

Note that for many of the experiments in this work most of the hyper-parameters of the deep reinforcement-learning algorithms are kept fixed. While it would be possible to improve the performance through a more extensive hyper-parameter search, our focus is on showing the relationships between the performance of the different methods and the properties of the control problems. While we do introduce new methods to address specific problems, the intended outcome of this work is to be able to make more informed choices regarding experience selection, rather than to promote any single method.

The rest of this paper is organized as follows. Section 2 gives an overview of related work. In Section 3, the basics of reinforcement learning, as well as the deep reinforcement learning and experience replay methods used as a starting point are discussed. Section 4 gives a high-level overview of the simple benchmarks used in most of this work, with the mathematical details presented in Appendix 9.3. The notation we use to distinguish between different methods, as well as the performance criteria that we use, are discussed in Section 5. In

Section 6, we investigate what spread over the state-action the experiences ideally should have, based on the characteristics of the control problem to be solved. The proposed methods to select experiences are detailed in Section 7, with the results of applying these methods to the different scenarios in simple and more complex benchmarks are presented in Section 8. The conclusions, as well as our recommended guidelines for choosing the buffer size, retention proxy and sampling strategy are given in Section 9.

2. Related Work

When a learning system needs to learn a task from a set of examples, the order in which the examples are presented to the learner can be very important. One method to improve the learning performance on complex tasks is to gradually increase the difficulty of the examples that are presented. This concept is known as shaping (Skinner, 1958) in animal training and curriculum learning (Bengio et al., 2009) in machine learning. Sometimes it is possible to generate training examples of just the right difficulty on-line. Recent machine learning examples of this include generative adversarial networks (Goodfellow et al., 2014) and self play in reinforcement learning (see for example the work by Silver et al. 2017). When the training examples are fixed, learning can be sped up by repeating those examples that the learning system is struggling with more often than those that it finds easy, as was shown for supervised learning by, among others, Hinton (2007) and Loshchilov and Hutter (2015). Additionally, the eventual performance of supervised-learning methods can be improved by re-sampling the training data proportionally to the difficulty of the examples, as done in the boosting technique (Valiant, 1984; Freund et al., 1999)

In on-line reinforcement learning, a set of examples is generally not available to start with. Instead, an agent interacts with its environment and observes a stream of experiences as a result. The experience replay technique was introduced to save those experiences in a buffer and replay them from that buffer to the learning system (Lin, 1992). The introduction of an experience buffer makes it possible to choose which examples should be presented to the learning system again. As in supervised learning, we can replay those experiences that induced the largest error (Schaul et al., 2016). Another option that has been investigated in the literature is to replay more often those experiences that are associated with large immediate rewards (Narasimhan et al., 2015).

In off-policy reinforcement learning the question of which experiences to learn from extends beyond choosing how to sample from a buffer. It begins with determining which experiences should be in the buffer. Lipton et al. (2016) fill the buffer with successful experiences from a pre-existing policy before learning starts. Other authors have investigated criteria to determine which experiences should be retained in a buffer of limited capacity when new experiences are observed. In this context, Pieters and Wiering (2016) have investigated keeping only experiences with the highest immediate rewards in the buffer, while our previous work has focused on ensuring sufficient diversity in the state-action space (de Bruin et al., 2016a,b).

Experience replay techniques, including those in this work, often take the stream of experiences that the agent observes as given and attempt to learn from this stream in an optimal way. Other authors have investigated ways to instill the desire to seek out information that is useful for the learning process directly into the agent's behavior (Schmidhuber,

1991; Chentanez et al., 2004; Houthooft et al., 2016; Bellemare et al., 2016; Osband et al., 2016). Due to the classical exploration-exploitation dilemma, changing the agents behavior to obtain more informative experiences comes at the price of the agent acting less optimally according to the original reward function.

A safer alternative to actively seeking out *real* informative but potentially dangerous experiences is to learn, at least in part, from *synthetic* experiences. This can be done by using an a priori available environment model such as a physics simulator (Barrett et al., 2010; Rusu et al., 2016), or by learning a model from the stream of experiences itself and using that to generate experiences (Sutton, 1991; Kuvayev and Sutton, 1996; Gu et al., 2016; Caarls and Schuitema, 2016). The availability of a generative model still leaves the question of *which* experiences to generate. Prioritized sweeping bases updates again on surprise, as measured by the size of the change to the learned functions (Moore and Atkeson, 1993; Andre et al., 1997). Ciosek and Whiteson (2017) dynamically adjusted the distribution of experiences generated by a simulator to reduce the variance of learning updates.

Learning a model can reduce the sample complexity of a learning algorithm when learning the dynamics and reward functions is easy compared to learning the value function or policy. However, it is not straightforward to get improved performance in general. In contrast, the introduction of an experience replay buffer has shown to be both simple and very beneficial for many deep reinforcement learning techniques (Mnih et al., 2015; Lillicrap et al., 2016; Wang et al., 2017; Gu et al., 2017). When a buffer is used, we can decide which experiences to have in the buffer and which experiences to sample from the buffer. In contrast to previous work on this topic we investigate the combined problem of experience retention and sampling. We also look at several different proxies for the usefulness of experiences and how prior knowledge about the specific reinforcement learning problem at hand can be used to choose between them, rather than attempting to find a single universal experience-utility proxy.

3. Preliminaries

We consider a standard reinforcement learning setting (Section 3.1) in which an agent learns to act optimally in an environment, using the implementation by Lillicrap et al. (2016) of the off-policy actor-critic algorithm by Silver et al. (2014) (Section 3.2). Actor-critic algorithms make it possible to deal with the continuous action spaces that are often found in control applications. The off-policy nature of the algorithm enables the use of experience replay (Section 3.3), which helps to reduce the number of environment steps needed by the algorithm to learn a successful policy and improves the algorithms stability. Here, we summarize the deep reinforcement learning (Lillicrap et al., 2016) and experience replay (Schaul et al., 2016) methods that we use as a starting point.

3.1 Reinforcement Learning

In reinforcement learning, an agent interacts with an environment $\mathcal{E}$ with (normalized) state $s_\mathcal{E}$ by choosing (normalized) actions a according to its policy π: $a = \pi(s)$, where s is the agent's perception of the environment state.

To simplify the analysis in Section 6 and 7, and to aid learning, we normalize the state and action spaces in our benchmarks such that $s_\mathcal{E} \in [-1, 1]^n$ and $a_\mathcal{E} \in [-1, 1]^m$, where n

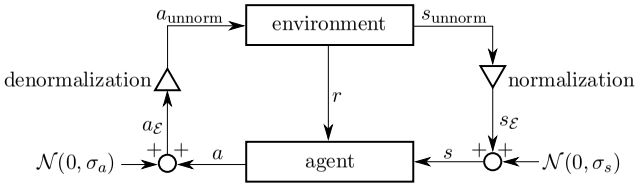

Figure 1: Reinforcement learning scheme and symbols used.

and m are the dimensions of the state and action spaces. We perform the (de)normalization on the connections between the agent and the environment, so the agent only deals with normalized states and actions.

We consider the dynamics of the environment to be deterministic: $s'_\mathcal{E} = f(s_\mathcal{E}, a_\mathcal{E})$. Here, $s'_\mathcal{E}$ is the state of the environment at the next time step after applying action $a_\mathcal{E}$ in state $s_\mathcal{E}$. Although the environment dynamics are deterministic, in some of our experiments we do consider sensor and actuator noise. In these cases, the state s that the agent perceives is perturbed from the actual environment state $s_\mathcal{E}$ by additive Gaussian noise

$$s = s_\mathcal{E} + \mathcal{N}(0, \sigma_s). \tag{1}$$

Similarly, actuator noise changes the actions sent to the environment according to:

$$a_\mathcal{E} = a + \mathcal{N}(0, \sigma_a). \tag{2}$$

A reward function ρ describes the desirability of being in an unnormalized state s_{unnorm} and taking an unnormalized action a_{unnorm}: $r_k = \rho(s^k_{\text{unnorm}}, a^k_{\text{unnorm}}, s^{k+1}_{\text{unnorm}})$, where k indicates the time step. An overview of the different reinforcement learning signals and symbols used is given in Figure 1.

The goal of the agent is to choose the actions that maximize the expected return from the current state, where the return is the discounted sum of future rewards: $\sum_{k=0}^{\infty} \gamma^k r_k$. The discount factor $0 \leq \gamma < 1$ keeps this sum finite and allows trading off short-term and long-term rewards.

Although we will come back to the effect of the sensor and actuator noise later on, in the remainder of this section we will look at the reinforcement learning problem from the perspective of the agent and consider the noise to be part of the environment. This makes the transition dynamics and reward functions stochastic: $\mathcal{F}(s'|s, a)$ and $\mathcal{P}(r|s, a, s')$.

3.2 Off-Policy Deep Actor-Critic Learning

In this paper we use the Deep Deterministic Policy Gradient (DDPG) reinforcement-learning method of Lillicrap et al. (2016), with the exception of Section 6.3, where we compare it to DQN (Mnih et al., 2015). In the DDPG method, based on the work of Silver et al. (2014), a neural network with parameters θ_π implements the policy: $a = \pi(s; \theta_\pi)$. A second neural network with parameters θ_Q, the critic, is used to approximate the Q function. The $Q^\pi(s, a)$ function gives the expected return when taking action a in state s and following

the policy π from next time-step onwards

$$Q^{\pi}(s,a) = \mathbb{E}_{\pi}\left[\sum_{k=0}^{\infty}\gamma^{k} r_k | s^0 = s, a^0 = a\right]. \tag{3}$$

The critic function $Q(s,a;\theta_Q)$ is trained to approximate the true $Q^{\pi}(s,a)$ function by minimizing the squared temporal difference error δ for experience $\langle s_i, a_i, s'_i, r_i\rangle$

$$\delta_i = \left[r_i + \gamma Q\left(s'_i, \pi(s'_i;\theta^-_{\pi});\theta^-_Q\right)\right] - Q\left(s_i, a_i;\theta_Q\right), \tag{4}$$

$$L_i(\theta_Q) = \delta_i^2,$$

$$\Delta_{i\theta_Q} \sim -\nabla_{\theta_Q} L_i(\theta_Q). \tag{5}$$

The index i is a generic index for experiences that we will in the following use to indicate the index of an experience in a buffer. The parameter vectors θ^-_{π} and θ^-_Q are copies of θ_{π} and θ_Q that are updated with a low-pass filter to slowly track θ_{π} and θ_Q

$$\theta^-_{\pi} \leftarrow (1-\tau)\theta^-_{\pi} + \tau\theta_{\pi},$$
$$\theta^-_Q \leftarrow (1-\tau)\theta^-_Q + \tau\theta_Q,$$

with $\tau \in (0,1), \tau \ll 1$. This was found to be important for ensuring stability when using deep neural networks as function approximators in reinforcement learning (Mnih et al., 2015; Lillicrap et al., 2016).

The parameters θ_{π} of the policy neural network $\pi(s;\theta_{\pi})$ are updated in the direction that changes the action $a = \pi(s;\theta_{\pi})$ in the direction for which the critic predicts the steepest ascent in the expected sum of discounted rewards

$$\Delta_{\theta_{\pi}} \sim \nabla_a Q\left(s_i, \pi(s_i;\theta_{\pi});\theta_Q\right) \nabla_{\theta_{\pi}} \pi(s_i;\theta_{\pi}). \tag{6}$$

3.3 Experience Replay

The actor and critic neural networks are trained by using sample-based estimates of the gradients ∇_{θ_Q} and $\nabla_{\theta_{\pi}}$ in a stochastic gradient optimization algorithm such as ADAM (Kingma and Ba, 2015). These algorithms are based on the assumption of independent and identically distributed (i.i.d.) data. This assumption is violated when the experiences $\langle s_i, a_i, s'_i, r_i\rangle$ in (5) and (6) are used in the same order during the optimization of the networks as they were observed by the agent. This is because the subsequent samples are strongly correlated, since the world only changes slowly over time. To solve this problem, an experience replay (Lin, 1992) buffer $\mathcal{B}$ with some finite capacity $\mathcal{C}$ can be introduced.

Most commonly, experiences are written to this buffer in a First In First Out (FIFO) manner. When experiences are needed to train the neural networks, they are sampled uniformly at random from the buffer. This breaks the temporal correlations of the updates and restores the i.i.d. assumption of the optimization algorithms, which improves their performance (Mnih et al., 2015; Montavon et al., 2012). The increased stability comes in addition to the main advantage of experience replay, which is that experiences can be used multiple times for updates, increasing the sample efficiency of the algorithm.

3.3.1 Prioritized Experience Replay

Although sampling experiences uniformly at random from the experience buffer is an easy default, the performance of reinforcement-learning algorithms can be improved by choosing the experience samples used for training in a smarter way. Here, we summarize one of the variants of Prioritized Experience Replay (PER) that was introduced by Schaul et al. (2016). Our enhancements to experience replay are given in Section 7.

The PER technique is based on the idea that the temporal difference error (4) provides a good proxy for the instantaneous utility of an experience. Schaul et al. (2016) argue that, when the critic made a large error on an experience the last time it was used in an update, there is more to be learned from the experience. Therefore, its probability of being sampled again should be higher than that of an experience associated with a low temporal difference error.

In this work we consider the rank-based stochastic PER variant. In this method, the probability of sampling an experience i from the buffer is approximately given by:

$$P(i) \approx \frac{\left(\frac{1}{\text{rank}(i)}\right)^{\alpha}}{\sum_j \left(\frac{1}{\text{rank}(j)}\right)^{\alpha}}. \tag{7}$$

Here, $\text{rank}(i)$ is the rank of sample i according to the absolute value of the temporal difference error $|\delta|$ according to (4), calculated when the experience was last used to train the critic. All experiences that have not yet been used for training have $\delta = \infty$, resulting in a large probability of being sampled. The parameter α determines how strongly the probability of sampling an experience depends on δ. We use $\alpha = 0.7$ as proposed by Schaul et al. (2016) and have included a sensitivity analysis for different buffer sizes in Appendix 9.3. Note that the relation is only approximate as sampling from this probability distribution directly is inefficient. For efficient sampling, (7) is used to divide the buffer $\mathcal{B}$ into S segments of equal cumulative probability, where S is taken as the number of experiences per training mini batch. During training, one experience is sampled uniformly at random from each of the segments.

3.3.2 Importance Sampling

The estimation of an expected value with stochastic updates relies on those updates corresponding to the same distribution as its expectation. Schaul et al. (2016) proposed to compensate for the fact that the changed sampling procedure can affect the value of the expectation in (3) by multiplying the gradients (5) with an Importance Sampling (IS) weight

$$\omega_i = \left(\frac{1}{\mathcal{C}}\frac{1}{P(i)}\right)^{\beta}. \tag{8}$$

Here, β allows scaling between not compensating at all ($\beta = 0$) to fully compensating for the changes in the sample distribution caused by the sampling strategy ($\beta = 1$). In our experiments, when IS is used, we follow Schaul et al. (2016) in scaling β linearly per episode from 0.5 at the start of a learning run to $\beta = 1$ at the end of the learning run. $\mathcal{C}$ indicates the capacity of the buffer.

Not all changes to the sampling distribution need to be compensated for. Since we use a deterministic policy gradient algorithm with a Q-learning critic, we do not need to compensate for the fact that the samples are obtained by a different policy than the one we are optimizing for (Silver et al., 2014). We can change the sampling distribution from the buffer, without compensating for the change, so long as these samples accurately represent the transition and reward functions.

Sampling based on the TD error can cause issues here, as infrequently occurring transitions or rewards will tend to be surprising. Replaying these samples more often will introduce a bias, which should be corrected through importance sampling.

However, the temporal difference error will also be partly caused by the function approximation error. These errors will be present even for a stationary sample distribution after learning has converged. The errors will vary over the state-action space and their magnitude will be related to the sample density. Sampling based on *this* part of the temporal difference error will make the function approximation accuracy more consistent over the state-space. This effect might be unwanted when the learned controller will be tested on the same initial state distribution as it was trained on. In that case, it is preferable to have the function approximation accuracy be highest where the sample density is highest. However, when the aim is to train a controller that generalizes to a larger part of the state space, we might *not* want to use importance sampling to correct this effect. Note that importance sampling based on the sample distribution over the state space is heuristically motivated and based on function approximation considerations. The motivation does not stem from the reinforcement learning theory, where most methods assume that the Markov decision process is ergodic and that the initial state distribution does not factor into the optimal policy (Aslanides et al., 2017). In practice however, deep reinforcement-learning methods can be rather sensitive to the initial state distribution (Rajeswaran et al., 2017).

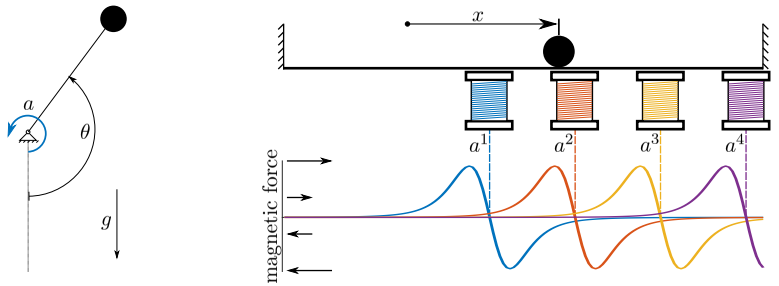
Unfortunately, we do not know to what extent the temporal difference error is caused by the stochasticity of the environment dynamics and to what extent it is caused by function approximation errors. We will empirically investigate the use of importance sampling in Section 8.4.

4. Experimental Benchmarks

In this section, we discuss two relatively simple control tasks that are considered in this paper, so that an understanding of their properties can be used in the following sections. The relative simplicity of these tasks enables a thorough analysis. We test our findings on more challenging benchmarks in Section 8.5.

We perform our tests on two simulated control benchmarks: a pendulum swing-up task and a magnetic manipulation problem. Both were previously discussed by Alibekov et al. (2018). Although both represent dynamical systems with a two dimensional state-space, it will be shown in Section 6 that they are quite different when it comes to the optimal experience selection strategy. Here, a high level description of these benchmarks is presented, with the full mathematical description given in Appendix 9.3.

The first task is the classic under-actuated pendulum swing-up problem, shown in Figure 2a. The pendulum starts out hanging down under gravity. The goal is to balance the pendulum in the upright position. The motor is torque limited such that a swing to one



(a) Pendulum task (b) Magnetic manipulation task

Figure 2: The two benchmark problems considered in this paper. In the pendulum task, an underactuated pendulum needs to be swung up and balanced in the upright position by controlling the torque applied by a motor. In the magnetic manipulation (magman) task, a steel ball (top) needs to be positioned by controlling the currents through four electromagnets. The magnetic forces exerted on the ball are shown at the bottom of the figure and can be seen to be a nonlinear function of the position. The forces scale linearly with the actions $a^1, ..., a^4$, which represent the squared currents through the magnets.

side is needed to build up momentum before swinging towards the upright position in the opposite direction. Once the pendulum is upright it needs to stabilize around this unstable equilibrium point. The state of the problem $s_\mathcal{E}$ consists of *normalized* versions of the angle θ and angular velocity $\dot{\theta}$ of the pendulum. The action space is a normalized version of the voltage applied to the motor that applies a torque to the pendulum. A reward is given at every time-step, based on the absolute distance of the state from the reference state of being upright with no rotational velocity.

The second benchmark is a magnetic manipulation (*magman*) task, in which the goal is to accurately position a steel ball on a 1-D track by dynamically changing a magnetic field. The relative magnitude and direction of the force that each magnet exerts on the ball is shown in Figure 2b. This force is linearly dependent on the actions, which represent the squared currents through the electromagnet coils. Normalized versions of the position x and velocity $\dot{x}$ form the state-space of the problem. A reward is given at every time-step, based on the absolute distance of the state from the reference state of having the ball at the fixed desired position.

In experiments where the buffer capacity $\mathcal{C}$ is limited, we take $\mathcal{C} = 10^4$ experiences, unless stated otherwise. All our experiments have episodes which last four seconds. Unless stated otherwise, a sampling frequency of 50 Hz is used, which means the buffer can store 50 episodes of experience tuples $\langle s_i, a_i, s'_i, r_i \rangle$.

Since we are especially interested in physical control problems where sustained exhaustive exploration is infeasible, the amount of exploration is reduced over time from its max-

imum at episode 1, to a minimum level from episode 500 onwards in all our experiments. At the minimum level, the amplitude of the exploration noise we add to the neural network policy is 10% of the amplitude at episode 1. Details of the exploration strategies used are given in Appendix 9.3.

5. Performance Measures and Experience Selection Notation

This section introduces the performance measures used and the notation used to distinguish between the experience selection strategies.

5.1 Performance Measures

When we investigate the performance of the learning methods in Sections 6 and 8, we are interested in the effect that these methods might have on *three* aspects of the learning performance: *the learning stability, the maximum controller performance* and *the learning speed*. We define performance metrics for these aspects, related to the normalized mean reward per episode μ_r. The normalization is performed such that $\mu_r = 0$ is the performance achieved by a random controller, while $\mu_r = 1$ is the performance of the off-line dynamic programming method described in Appendix 9.3. This baseline method is, at least for the noise-free tests, proven to be close to optimal.

The first learning performance aspect we consider is the *stability* of the learning process. As we have discussed in previous work (de Bruin et al., 2015, 2016a), even when a good policy has already been learned, the learning process can become unstable and the performance can drop significantly when the properties of the training data change. We investigate to what extent different experience replay methods can help prevent this instability. We use the mean of μ_r over the last 100 episodes of each learning run, where the learning runs should have converged to good behavior already, as a measure of learning stability. We denote this measure by μ_r^{final}.

Although changing the data distribution might help stability, it could at the same time prevent us from accurately approximating the true optimal policy. Therefore we also report the *maximum performance* achieved per learning trial $\mu_r^{\max}$.

Finally, we want to know the effects of the experience selection methods on the *learning speed*. We therefore report the number of episodes before the learning method achieves a normalized mean reward per episode of $\mu_r = 0.8$ and denote this by Rise-time 0.8.

For these performance metrics we report the means and the 95% confidence bounds of those means over 50 trials for each experiment. The confidence bounds are based on bootstrapping (Efron, 1992).

5.2 Experience Selection Strategy Notation

We consider the problem of *experience selection*, which we have defined as the combination of *experience retention* and *experience sampling*. The experience retention strategy determines which experiences are discarded when new experiences are available to a full buffer. The sampling strategy determines which experiences are used in the updates of the reinforcement-learning algorithm. We use the following notation for the complete experience selection strategy: *retention strategy[sampling strategy]*. Our abbreviations for the retention

Notation	Proxy	Explanation
FIFO	age	The oldest experiences are overwritten with new ones.
FULL DB	-	The buffer capacity $\mathcal{C}$ is chosen to be large enough to retain all experiences.

Table 1: Commonly used experience retention strategies for deep reinforcement learning.

Notation	Proxy	Explanation
Uniform	-	Experiences are sampled uniformly at random.
PER	surprise	Experiences are sampled using rank-based stochastic *prioritized experience replay* based on the temporal difference error. See Section 3.3.1.
PER+IS	surprise	Sampling as above, but with weighted *importance sampling* to compensate for the distribution changes caused by the sampling procedure. See Section 3.3.2.

Table 2: Experience sampling strategies from the literature.

and sampling strategies commonly used in deep RL that were introduced in Section 3.3 are given in Tables 1 and 2 respectively. The abbreviations used for the new or uncommonly used methods introduced in Section 7 are given there, in Tables 4 and 5.

6. Analysis of Experience Utility

As previously noted by Schaul et al. (2016); Narasimhan et al. (2015); Pieters and Wiering (2016) and de Bruin et al. (2016a, 2015), when using experience replay, the criterion that determines which experiences are used to train the reinforcement learning agent can have a large impact on the performance of the method. The aim of this section is to investigate what makes an experience useful and how this usefulness depends on several identifiable characteristics of the control problem at hand.

In the following sections, we mention only some relevant aspects of our implementation of the deep reinforcement-learning methods, with more details given in Appendix 9.3.

6.1 The Limitations of a Single Proxy

To motivate the need for understanding how the properties of a control problem influence the applicability of different experience selection strategies, and the need for multiple proxies for the utility of experiences rather than one universal proxy, we compare the performance of the two strategies from the literature that were presented in Section 3.3 on the benchmarks described in Section 4.

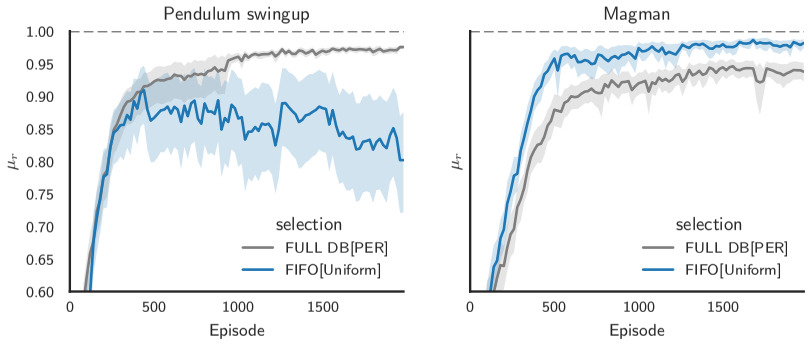


Figure 3: Comparison of the state-of-the-art (FULL DB[PER]) and the default method (FIFO[Uniform]) for experience selection on our two benchmark problems.

The first experience selection strategy tested is FIFO[Uniform]: overwriting the oldest experiences when the buffer is full and sampling uniformly at random from the buffer. We compare this strategy to the state-of-the-art prioritized experience replay method FULL DB[PER] by Schaul et al. (2016). Here, the buffer capacity $\mathcal{C}$ is chosen such that all experiences are retained during the entire learning run ($\mathcal{C} = N = 4 \times 10^5$ for this test).[1] The sampling strategy is the rank-based stochastic prioritized experience replay strategy as described in Section 3.3. The results of the experiments are shown in Figure 3.

Figure 3 shows that FULL DB[PER] method, which samples training batches based on the temporal difference error from a buffer that is large enough to contain all previous experiences, works well for the pendulum swing-up task. The method very reliably finds a near optimal policy. The FIFO[Uniform] method, which keeps only the experiences from the last 50 episodes in memory, performs much worse. As we reported previously (de Bruin et al., 2016a), the performance degrades over time as the amount of exploration is reduced and the experiences in the buffer fail to cover the state-action space sufficiently.

If we look at the result on the magman benchmark in Figure 3, the situation is reversed. Compared to simply sampling uniformly from the most recent experiences, sampling from all previous experiences according to their temporal difference error limits the final performance significantly. As shown in Appendix 9.3, this is not simply a matter of the function approximator capacity, as even much larger networks trained on all available data are outperformed by small networks trained on only recent data. When choosing an experience selection strategy for a reinforcement learning task, it seems therefore important to have some insights into how the characteristics of the task determine the need for specific kinds of experiences during training. We will investigate some of these characteristics below.

1. Schaul et al. (2016) use a FIFO database with a capacity of 10^6 experiences. We here denote this as FULL DB since all our experiments use a smaller number of time-steps in total.

6.2 Generalizability and Sample Diversity

One important aspect of the problem, which at least partly explains the differences in performance for the two methods on the two benchmarks in Figure 3, is the complexity of generalizing the value function and policy across the state and action spaces.

For the pendulum task, learning actor and critic functions that generalize across the entire state and action spaces will be relatively simple as a sufficiently deep neural network can efficiently exploit the symmetry in the value and policy functions (Montufar et al., 2014). Figure 4b shows the learned policy after 100 episodes for a learning run with FIFO[Uniform] experience selection. Due to the thorough initial exploration, the experiences in the buffer cover much of the state-action space. As a result, a policy has been learned that is capable of swinging the pendulum up and stabilizing it in both the clockwise and anticlockwise directions, although the current policy favors one direction over the other.

For the next 300 episodes this favored direction does not change and as the amount of exploration is decayed, the experiences in the buffer become less diverse and more centered around this favored trajectory through the state-action space. Even though the information on how to further improve the policy becomes increasingly local, the updates to the network parameters can cause the policy to be changed over the whole state space, as neural networks are global function approximators. This can be seen from Figure 4d, where the updates that further refine the policy for swinging up in the currently preferred direction have removed the previously obtained skill of swinging up in the opposite direction. The policy has suffered from *catastrophic forgetting* (Goodfellow et al., 2013) and has over-fitted to the currently preferred swing up direction.

For the pendulum swing up task, this over-fitting is particularly risky since the preferred swing up direction can and does change during learning, since both directions are equivalent with respect to the reward function. When this happens, the FIFO experience retention method can cause the data distribution in the buffer to change rapidly, which by itself can cause instability. In addition, the updates (4) and (6) now use the critic $Q(s, a; \theta_Q)$ function in regions of the state-action space that it has not been trained on in a while, resulting in potentially bad gradients. Both of these factors might destabilize the learning process. This can be seen in Figure 4f where, after the preferred swing up direction has rapidly changed a few times, the learning process is destabilized and the policy has deteriorated to the point that it no longer accomplishes the balancing task. By keeping all experiences in memory and ensuring the critic error δ stays low over the entire state-action space, the FULL DB[PER] method largely avoids these learning stability issues. We believe that this accounts for the much better performance for this benchmark shown in Figure 3.

For the magman task, a policy that generalizes over the whole state-space might be harder to find. This is because the effects of the actions, shown as the colored lines in Figure 2b, are strongly nonlinear functions of the (position)-state. The actor and critic functions must therefore be very accurate for the states that are visited under the policy. Requiring the critic to explain all of the experiences that have been collected so far might limit the ability of the function approximators to achieve sufficient accuracy for the relevant states.

Figure 4: The critic $Q(s, \pi(s;\theta_\pi);\theta_Q)$ and actor $\pi(s;\theta_\pi)$ functions trained on the pendulum swing up task using FIFO[Uniform] experience selection. The surfaces represent the functions. The black dots show the trajectories through the state-action space resulting from deterministically following the current policy. The red and blue lines show respectively the positive and negative 'forces' that shape the surfaces caused by the experiences in the buffer: for the critic these are $\delta(s,a)$ (note $a \neq \pi(s;\theta_\pi)$). For the actor these forces represent $\partial Q(s, \pi(s;\theta_\pi);\theta_Q)/\partial a$. Animations of these graphs for different experience selection strategies are available at `https://youtu.be/Hli1kyObgT4`. The episodes are chosen to illustrate the effect of reduced sample diversity described in Section 6.2.

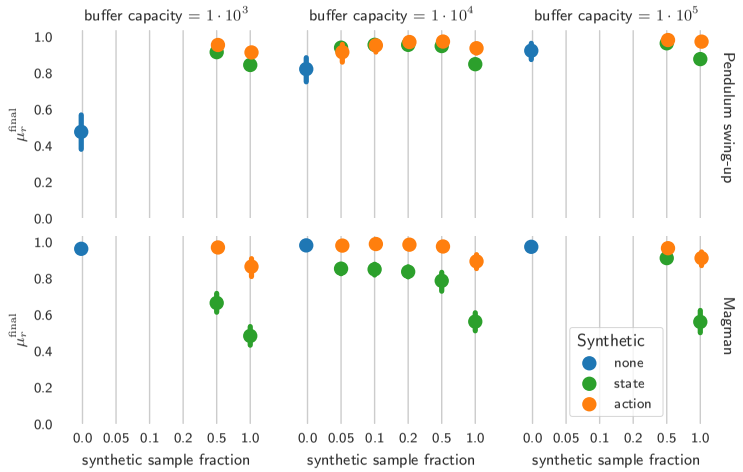

Figure 5: The effect on the mean performance during the last 100 episodes of the learning runs μ_r^{final} of the FIFO[Uniform] method when changing a fraction of the observed experiences with synthetic experiences, for different buffer sizes.

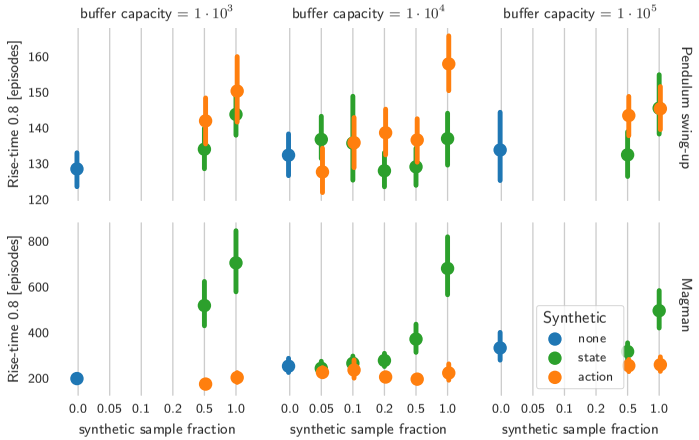
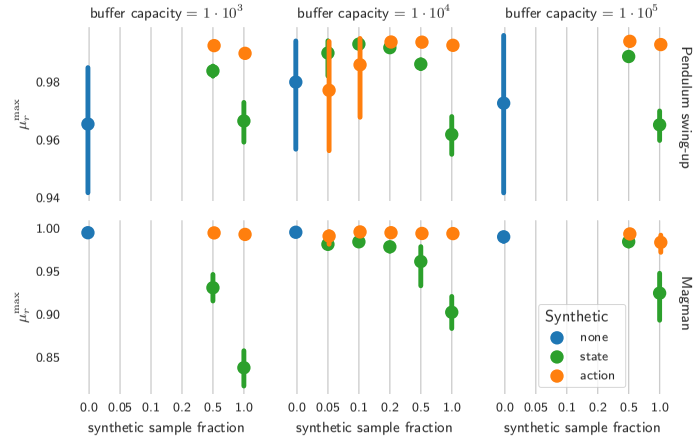
6.2.1 Buffer Size and Synthetic Sample Fraction

To test the hypothesis that the differences in performance observed in Figure 3 revolve around sample diversity, we will artificially alter the sample diversity and investigate how this affects the reinforcement learning performance. We will do so by performing the following experiment. We use the plain FIFO[Uniform] method as a baseline. However, with a certain probability we make a change to an experience $\langle s_i, a_i, s_i', r_i \rangle$ before it is written to the buffer. We change either the state s_i or the action a_i. The changed states and actions are sampled uniformly at random from the state and action spaces. When the state is re-sampled the action is recalculated as the policy action for the new state including exploration. In both cases, the next state and reward are recalculated to complete the altered experience. To calculate the next state and reward, we use the real system model. This is not possible for most practical problems; it serves here merely to gain a better understanding of the need for sample diversity.

The results of performing this experiment for different probabilities and buffer sizes are given in Figures 5 and 6. Interestingly, for the pendulum swing up task, changing some fraction of the experiences to be more diverse improves the stability of the learning method dramatically, regardless of whether the diversity is in the states or in the actions. The effect is especially noticeable for smaller experience buffers.



(a) Effect on the number of episodes needed to reach $\mu_r = 0.8$.



(b) Effect on the number of maximum controller performance obtained per learning run.

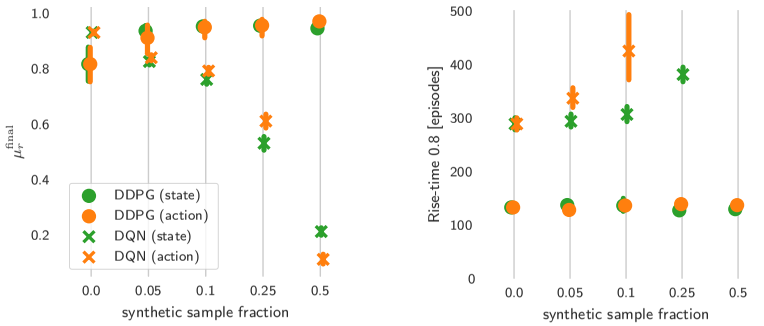
Figure 6: The effects on the learning performance of the FIFO[Uniform] method when replacing a fraction of the observed experiences with synthetic experiences, for different buffer sizes.

For the magman benchmark, as expected, having more diverse states reduces the performance significantly. Having a carefully chosen fraction of more diverse actions in the original states can however improve the stability and learning speed slightly. This can be explained from the fact that even though the effects of the actions are strongly nonlinear in the state-space, they are linear in the action space. Generalizing across the action space might thus be more straightforward and it is helped by having the training data spread out over this domain.

6.3 Reinforcement-Learning Algorithm

The need for experience diversity also depends on the algorithm that is used to learn from those experiences. In the rest of this work we exclusively consider the DDPG actor-critic algorithm, as the explicitly parameterized policy enables continuous actions, which makes it especially suitable for control. An alternative to using continuous actions is to discretize the action space. In this subsection, we compare the need for diverse data of the actor-critic DDPG algorithm (Lillicrap et al., 2016; Silver et al., 2014) to that of the closely related critic-only DQN algorithm (Mnih et al., 2015). The experiments are performed on the pendulum benchmark, where the one dimensional action is divided uniformly into 15 discrete actions. Results for the magman benchmark are omitted as the four dimensional action space makes discretization impractical.

For the actor-critic scheme to work, the critic needs to learn a general dependency of the Q-values on the states and actions. For the DQN critic, this is not the case as the Q-values for different actions are separate. Although the processing of the inputs is shared, the algorithm can learn at least partially independent value predictions for the different



(a) Effect on the mean performance during the last 100 episodes of the learning runs μ_r^{final}.

(b) Effect on the number of episodes needed to reach $\mu_r = 0.8$.

Figure 7: RL algorithm dependent effect of adding synthetic experiences to the FIFO[Uniform] method. Experiments on the pendulum benchmark. The effect on $\mu_r^{\max}$ is given in Figure 22 in Appendix 9.3.

actions. These functions additionally do not need to be correct, as long as the optimal action in a state has a higher value than the sub-optimal actions.

These effects can be seen in Figure 7. The DDPG algorithm can make more efficient use of the state-action space samples by learning a single value prediction, resulting in significantly faster learning than the DQN algorithm. The DDPG algorithm additionally benefits from more diverse samples, with the performance improving for higher fractions of randomly sampled states or actions. The DQN algorithm conversely seems to suffer from a more uniform sampling of the state-action space. This could be because it is now tasked with learning accurate mappings from the states to the state-action values for all actions. While doing so might not help to improve the predictions in the relevant parts of the state-action space, it could increase the time required to learn the function and limit the function approximation capacity available for those parts of the state-space where the values need to be accurate. Note again that learning precise Q-values for all actions over the whole state-space is not needed, as long as the optimal action has the largest Q-value.

Due to the better scalability of policy-gradient methods in continuous control settings, we exclusively consider the DDPG algorithm in the remainder of this work.

6.3.1 Sample Age

In the model-free setting it is not possible to add synthetic experiences to the buffer. Instead, in Section 7 we will introduce ways to select real experiences that have desirable properties and should be remembered for a longer time and replayed more often. This will inevitably mean that some experiences are used more often than others, which could have detrimental effects such as that the learning agent could over-fit to those particular experiences.

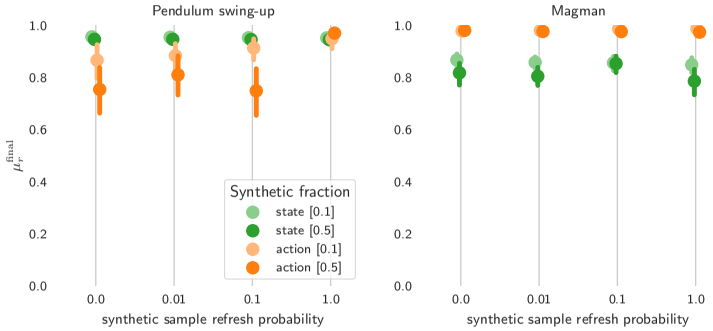


Figure 8: The effects on μ_r^{final} of the FIFO[Uniform] method when changing a fraction of the observed experiences with synthetic experiences, when the synthetic experiences are updated only with a certain probability each time they are overwritten. The effects on μ_r^{max} and the rise-time are given in Figure 24 in Appendix 9.3.

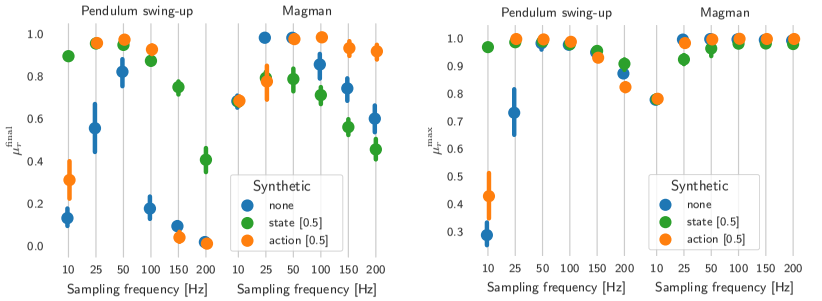
To investigate the effects of adding older experiences for diversity, we perform the following experiment. As before, a FIFO buffer is used with a certain fraction of synthetic experiences. However, when a synthetic experience is about to be over-written, we only sample a new synthetic experience with a certain probability. Otherwise, the experience is left unchanged. The result of this experiment is shown in Figure 8. For the pendulum benchmark, old experiences only hurt when they were added to provide diversity in the action space in states that were visited by an older policy. For the magman benchmark the age of the synthetic experiences is not seen to affect the learning performance.

6.4 Sampling Frequency

An important property of control problems that can influence the need for experience diversity is the frequency at which the agent needs to produce control decisions. The sampling frequency of a task is something that is often considered a given property of the environment in reinforcement learning. For control tasks however, a sufficiently high sampling frequency can be crucial for the performance of the controller and for disturbance rejection (Franklin et al., 1998). At the same time, higher sampling frequencies can make reinforcement learning more difficult as the effect of taking an action for a single time-step diminishes for increasing sampling frequencies (Baird, 1994). Since the sampling rate can be an important hyperparameter to choose, we investigate whether changing it changes the diversity demands for the experiences to be replayed.

In Figure 9, the performance of the FIFO[Uniform] method is shown for different sampling frequencies, with and without synthetic samples. The first thing to note is that, as expected, low sampling frequencies limit the controller performance. Interestingly, much of the performance loss on the pendulum at low frequencies can be prevented through in-



(a) Effect on the mean performance during the last 100 episodes of the learning runs μ_r^{final}.

(b) Effect on maximum controller performance per episode μ_r^{max}.

Figure 9: Sampling frequency dependent effect of adding synthetic experiences to the FIFO[Uniform] method. The effect on the rise time is given in Figure 23 in Appendix 9.3.

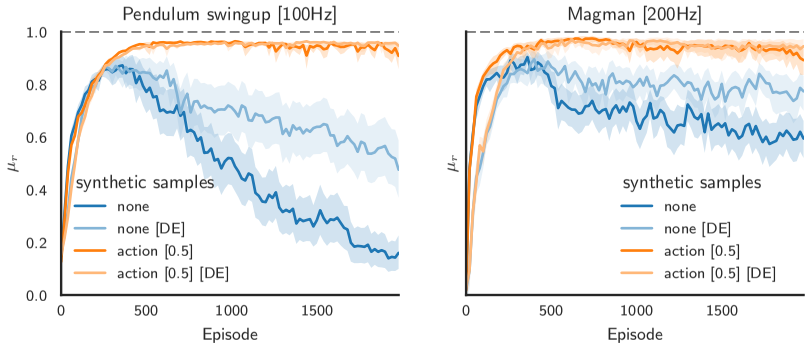


Figure 10: The effect of synthetic actions and stochastically preventing experiences from being written to the buffer [DE] for the FIFO[Uniform] method on the benchmarks with increased sampling frequencies.

creased sample diversity. This indicates that on this benchmark most of the performance loss at the tested control frequencies stems from the learning process rather than the fundamental control limitations. When increasing the sampling frequencies beyond our baseline frequency of 50Hz, sample diversity becomes more important for both stability and performance. For the pendulum swing-up it can be seen that as sampling frequency increases further, increased diversity in the *state-space* becomes more important. For the magman, adding synthetic *action* samples has clear benefits. This is very likely related to the idea that the effects of actions become harder to distinguish for higher sampling frequencies (Baird, 1994; de Bruin et al., 2016b).

There are several possible additional causes for the performance decrease at higher frequencies. The first is that by increasing the sampling frequency, we have increased the number of data points that are obtained and learned from per episode. Yet the amount of information that the data contains has not increased by the same amount. Since the buffer capacity is kept equal, the amount of information that the buffer contains has decreased and the learning rate has effectively increased. To compensate for these specific effects, experiments are performed in which samples are stochastically prevented from being written to the buffer with a probability proportional to the increase in sampling frequency. The results of these experiments are indicated with [DE] (dropped experiences) in Figure 10 and are indeed better, but still worse than the performance for lower sampling frequencies.

The second potential reason for the drop in performance is that we have changed the problem definition by changing the sampling frequency. This is because the forgetting factor γ determines how far into the future we consider the effects of our actions according to:

$$\gamma = e^{-\frac{T_s}{\tau_\gamma}},$$

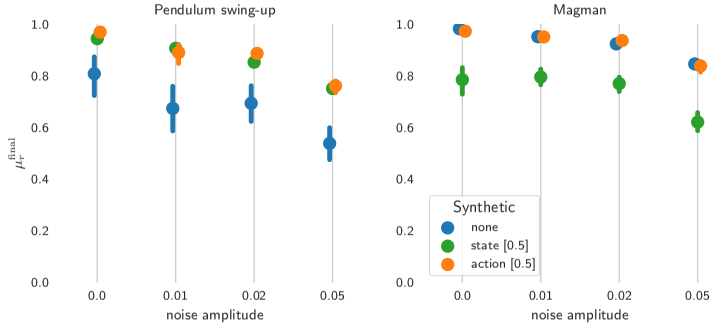

Figure 11: Experiments with altered experiences and sensor and actuator noise. Results are from the last 100 episodes of 50 learning runs. A description of the performance measures is given in Section 5.1.

where T_s is the sampling period in seconds and τ_γ is the lookahead horizon in seconds. To keep the same lookahead horizon, we recalculate γ, which is 0.95 in our other experiments ($T_s = 0.02$), to be $\gamma_{\text{pendulum}} = 0.9747$ ($T_s = 0.01$) and $\gamma_{\text{magman}} = 0.9873$ ($T_s = 0.005$). To keep the scale of the Q functions the same, which prevents larger gradients, the rewards are scaled down. Correcting the lookahead horizon was found to hurt performance on both benchmarks. The likely cause of this is that higher values of γ increase the dependence on the biased estimation of Q over the unbiased immediate reward signal (see Equation (4)). This can cause instability (François-Lavet et al., 2015).

6.5 Noise

The final environment property that we consider is the presence of sensor and actuator noise. So far, the agent has perceived the (normalized) environment state exactly and its (de-normalized) chosen actions have been implemented without change. Now we consider Equations (1) and (2) with $\sigma_s = \sigma_a \in \{0, 0.01, 0.02, 0.05\}$. The results of performing these experiments are shown in Figure 11. The results indicate that the need for data diversity is not dependent on the presence of noise. However, in Section 8.3 it will be shown that the methods used to determine which experiences are useful *can* be affected by noise.

6.6 Summary

This section has presented an investigation into how different aspects of the reinforcement learning problem at hand influence the need for experience diversity. In Table 3 a summary is given of the investigated aspects and the strength of their effect on the need for experience diversity. While this section has used the true environment model to examine the potential

Property	Effect	Explanation
Benchmark	Very high	The need for diverse states and actions largely depends on the ease and importance of generalizing across the state-actions space, which is benchmark dependent.
RL algorithm	Very high	Generalizing across the action space is fundamental to actor-critic algorithms, but not to critic-only algorithms with discrete action spaces.
Sampling frequency	High	The stability of RL algorithms depends heavily on the sampling frequency. Experience diversity can help learning stability. Having diverse actions at higher frequencies might be crucial as the size of their effect on the observed returns diminishes.
Buffer size	Medium	Small buffers can lead to rapidly changing data distributions, which causes unstable learning. Large buffers have more inherent diversity.
Sample age	Low	Although retaining old samples could theoretically be problematic, these problems were not clearly observable in practice.
Noise	None	The presence of noise was not observed to influence the need for experience diversity, although it can influence experience selection strategies, as will be shown in Section 8.3.

Table 3: The dependence of the need for diverse experiences on the investigated environment and reinforcement learning properties.

benefits of diversity, the next section will propose strategies to obtain diverse experiences in ways that are feasible on real problems.

7. New Experience-Selection Strategies

For the reasons discussed in Section 2, we do not consider changing the stream of experiences that an agent observes by either changing the exploration or by generating synthetic experiences. Instead, to be able to replay experiences with desired properties, valuable experiences need to be identified, so that they can be retained in the buffer and replayed from it. In this section we look at how several proxies for the utility of experiences can be used in experience selection methods.

7.1 Experience Retention

Although we showed in Section 6.4 that high sampling rates might warrant dropping experiences, in general we assume that each new experience has at least some utility. Therefore, unless stated otherwise, we will always write newly obtained experiences to the buffer. When the buffer is full, this means that we need some metric that can be used to decide which experiences should be overwritten.

7.1.1 Experience Utility Proxies

A criterion used to manage the contents of an experience replay buffer should be cheap enough to calculate,[2] should be a good proxy for the usefulness of the experiences and should not depend on the learning process in a way that would cause a feedback loop and possibly might destabilize that learning process. We consider three criteria for overwriting experiences.

Age: The default and simplest criterion is age. Since the policy is constantly changing and we are trying to learn its current effects, recent experiences might be more relevant than older ones. This (FIFO) criterion is computationally as cheap as it gets, since determining which experience to overwrite involves simply incrementing a buffer index. For smaller buffers, this does however make the buffer contents quite sensitive to the learning process, as a changing policy can quickly change the distribution of the experiences in the buffer. As seen in Figure 4, this can lead to instability.

Besides FIFO, we also consider reservoir sampling (Vitter, 1985). When the buffer is full, new experiences are added to it with a probability $\mathcal{C}/i$ where i is the index of the current experience. If the experience is written to the buffer, the experience it replaces is chosen uniformly at random. Note that this is the only retention strategy we consider that does not write all new experiences to the buffer. Reservoir sampling ensures that at every stage of learning, each experience observed so far has an equal probability of being in the buffer. As such, initial exploratory samples are kept in memory and the data distribution converges over time. These properties are shared with the FULL DB strategy, without needing the same amount of memory. The method might in some cases even improve the learning stability compared to using a full buffer, as the data distribution converges faster. However, when the buffer is too small this convergence can be premature, resulting in a buffer that does not adequately reflect the policy distribution. This can seriously compromise the learning performance.

Surprise: Another possible criterion is the unexpectedness of the experience, as measured by the temporal difference error δ from (4). The success of the Prioritized Experience Replay (PER) method of Schaul et al. (2016) shows that this can be a good proxy for the utility of experiences. Since the values have to be calculated to update the critic, the computational cost is very small if we accept that the utility values might not be

2. We have discussed the need for experience diversity in Section 6 and we have previously proposed overwriting a buffer in a way that directly optimized for diversity (de Bruin et al., 2016a). However, calculating the experience density in the state-action space is very expensive and therefore prohibits using the method on anything but small-scale problems.

current since they are only updated for experiences that are sampled. The criterion is however strongly linked with the learning process, as we are actively trying to minimize δ. This means that, when the critic is able to accurately predict the long term rewards of the policy in a certain region of the state-action space, these samples can be overwritten. If the predictions of the critic later become worse in this region, there is no way of getting these samples back. An additional problem might be that the error according to (4) will be caused partially by state and actuator noise. Keeping experiences for which the temporal difference error is high might therefore cause the samples saved in the buffer to be more noisy than necessary.

Exploration: We introduce a new criterion based on the observation that problems can occur when the amount of exploration is reduced. On physical systems that are susceptible to damage or wear, or for tasks where adequate performance is required even during training, exploration can be costly. This means that preventing the problems caused by insufficiently diverse experiences observed in Section 6 simply by sustained thorough exploration might not be an option. We therefore view the amount of exploration performed during an experience as a proxy for its usefulness. We take the 1-norm of the deviation from the policy action to be the usefulness metric. In our experiments on the small scale benchmarks we follow the original DDPG paper (Lillicrap et al., 2016) in using an Ornstein-Uhlenbeck noise process added to the output of the policy network. The details of the implementation are given in Appendix 9.3. In the experiments in Section 8.5 a copy of the policy network with noise added to the parameters is used to calculate the exploratory actions (Plappert et al., 2018).

For discrete actions, the cost of taking exploratory actions could be used as a measure of experience utility as well. The inverse of the probability of taking an action could be seen as a measure of the cost of the action. It could also be worth investigating the use of a low-pass filter, as a series of (semi)consecutive exploratory actions would be more likely to result in states that differ from the policy distribution in a meaningful way. These ideas are not tested here, as we only consider continuous actions in the remainder of this work.

Note that the size of the exploration signal is the deviation of the chosen action in a certain state from the policy action for that state. Since the policy evolves over time we could recalculate this measure of deviation from the policy actions per experience at a later time. Although we have investigated using this policy deviation proxy previously (de Bruin et al., 2016b), we found empirically that using the strength of the initial exploration yields better results. This can partly be explained by the fact that recalculating the policy deviation makes the proxy dependent on the learning process and partly by the fact that sequences with more exploration also result in different states being visited.

7.1.2 Stochastic Experience Retention Implementation

For the temporal difference error and exploration-based experience retention methods, keeping some experiences in the buffer indefinitely might lead to over-fitting to these samples.

Notation	Proxy	Explanation
Expl(α)	Exploration	Experiences with the least exploration are stochastically overwritten with new ones.
TDE(α)	Surprise	Experiences with the smallest temporal difference error are stochastically overwritten with new ones.
Resv	Age	The buffer is overwritten such that each experience observed so far has an equal probability of being in the buffer.

Table 4: New and uncommon experience retention strategies considered in this work.

Notation	Proxy	Explanation
Uniform + FIS	-	Experiences are sampled uniformly at random, FIS (Section 7.2) is used to account for the distribution changes caused by the *retention* policy.
PER+FIS	Surprise	Experiences are sampled using rank based stochastic prioritized experience replay based on the temporal difference error. Full importance sampling is used to account for the distribution changes caused by both the retention and sampling policies.

Table 5: New experience sampling strategies considered in this work.

Additionally, although the overwrite metric we choose might provide a decent proxy for the usefulness of experiences, we might still want to be able to scale the extent to which we base the contents of the buffer on this proxy. We therefore use the same stochastic rank-based selection criterion of (7) suggested by Schaul et al. (2016), but now to determine which experience in the buffer is overwritten by a new experience. We denote this as TDE(α) for the temporal difference-based retention strategy and Expl(α) for the exploration-based policy. Here, α is the parameter in (7) which determines how strongly the buffer contents will be based on the chosen utility proxy. A sensitivity analysis of α for both Expl and PER is given in Appendix 9.3. The notation used for the new experience retention strategies is given in Table 4.

7.2 Experience Sampling

For the choice of proxy when *sampling* experiences from the buffer, we consider the available methods from the literature: sampling either uniformly at random [Uniform], using stochastic rank-based prioritized experience replay [PER] and combining this with weighted importance sampling [PER+IS]. Given a buffer that contains useful experiences, these methods have shown to work well. We therefore focus on investigating how the experience reten-

tion and experience sampling strategies interact. In this context we introduce a weighted importance sampling method that accounts for the full experience selection strategy.

Importance sampling according to (8) can be used when performing prioritized experience replay from a buffer that contains samples with a distribution that is unbiased with respect to the environment dynamics. When this is not the case, we might need to compensate for the effects of changing the contents of the buffer, potentially in addition to the current change in the sampling probability. The contents of the buffer might be the result of many subsequent retention probability distributions. Instead of keeping track of all of these, we compensate for both the retention and sampling probabilities by using the number of times an experience in the buffer has actually been replayed. When replaying an experience i for the K-th time, we relate the importance-weight to the probability under uniform sampling from a FIFO buffer of sampling an experience X times, where X is at least K: $\Pr(X \geq K|_{\text{FIFO[Uniform]}})$. We refer to this method as Full Importance Sampling (FIS) and calculate the weights according to :

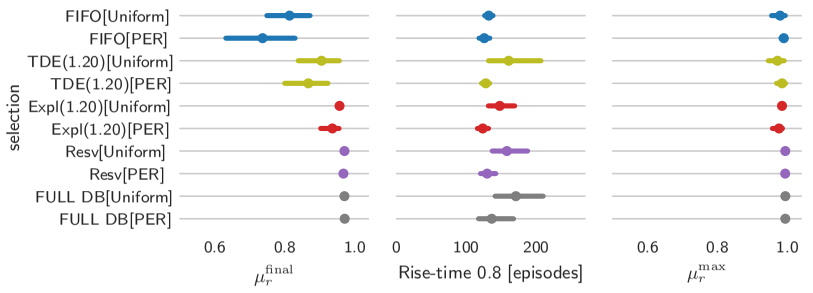
$$\omega_i^{\text{FIS}} = \left(\frac{\Pr(X \geq K|_{\text{FIFO[Uniform]}})}{\left[\sum_{j=1}^{\lceil np \rceil} \Pr(X \geq j|_{\text{FIFO[Uniform]}})\right]/np} \right)^{\beta}.$$

Here, n is the lifetime of an experience for a FIFO retention strategy in the number of batch updates, which is the number of batch updates performed so far when the buffer is not yet full. The probability of sampling an experience during a batch update when sampling uniformly at random is denoted by p. Note that np is the expected number of replays per experience, which following Schaul et al. (2016) we take as 8 by choosing the number of batch updates per episode accordingly. As in Section 3.3.2 we use β to scale between not correcting for the changes and correcting fully. Since the probability of being sampled at least K times is always smaller than one for $K > 0$, we scale the weights such that the sum of the importance weights for the expected np replays under FIFO[Uniform] sampling is the same as when not using the importance weights ($n \cdot p \cdot 1$). The probability of sampling an experience at least K times under FIFO[Uniform] sampling is calculated using the binomial distribution:

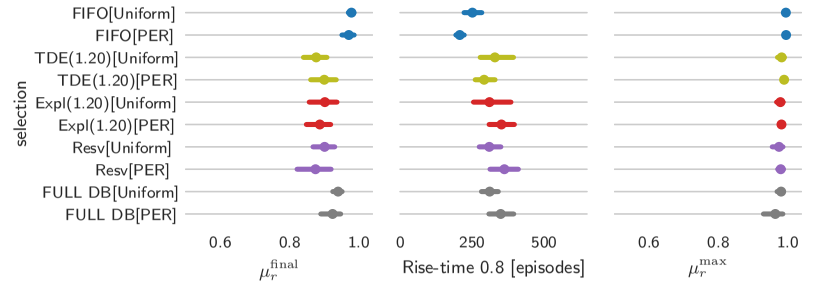
$$\Pr(X \geq K|_{\text{FIFO[Uniform]}}) = 1 - \sum_{k=0}^{K} \binom{n}{k} p^k (1-p)^{n-k}.$$

Correcting fully ($\beta = 1$) for the changed distributions would make the updates as unbiased as those from the unbiased FIFO uniform distribution (Needell et al., 2016). However, since the importance weights of experiences that are repeatedly sampled for stability will quickly go to zero, it might also undo the stabilizing effects that were the intended outcome of changing the distribution in the first place. Additionally, as discussed in Section 3.3.2, the FIFO Uniform distribution is not the only valid distribution. As demonstrated in Section 8.4, it is therefore important to determine whether compensating for the retention strategy is necessary before doing so.

The notation for the selection strategies with this form of importance sampling is given in Table 5.



(a) Swing-up



(b) Magman

Figure 12: Performance of the experience selection methods under the default conditions of moderate sampling frequencies and no state or actuator noise. A description of the performance measures is given in Section 5.1.

8. Experience Selection Results

Using the experience retention and sampling methods discussed in Section 7, we revisit the scenarios discussed in Section 6. We first focus on the methods without importance sampling, which we discuss separately in Section 8.4. Besides the tests on the benchmarks of Section 4, we also show results on six additional benchmarks in Section 8.5. There we also discuss how to choose the size of the experience buffer.

8.1 Basic Configuration

We start by investigating how these methods perform on the benchmarks in their basic configuration, with a sampling rate of 50 Hz and no sensor or actuator noise. The results are given in Figure 12 and show that it is primarily the combination of *retention* method

and buffer size that determines the performance. It is again clear that this choice here depends on the benchmark. On the pendulum benchmark, where storing all experiences works well, the Resv method works equally well while storing only 10^4 experiences, which equals 50 of the 3000 episodes. On the magman benchmark, using a small buffer with only recent experiences works better than any other method.

Sampling according to the temporal difference error can be seen to benefit primarily the learning speed on the pendulum. On the magman, PER only speeds up the learning process when sampling from recent experiences. When sampling from diverse experiences, PER will attempt to make the function approximation errors more even across the state-action space, which as discussed before, hurts performance on this benchmark.

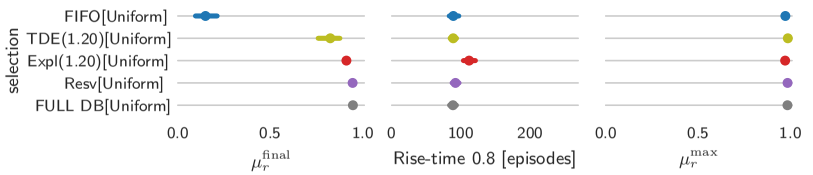
8.2 Effect of the Sampling Frequency

For higher sampling frequencies, the performance of the different experience selection methods is shown in Figure 13. We again see that higher sampling frequencies place different demands on the training data distribution. With the decreasing exploration, retaining the right experiences becomes important. This is most visible on the Magman benchmark where FIFO retention, which resulted in the best performance at the end of training for the base sampling frequency, now performs worst. Retaining all experiences works well on both benchmarks. When not all experiences can be retained, the reservoir retention method is still a good option here, with the exploration-based method a close second.

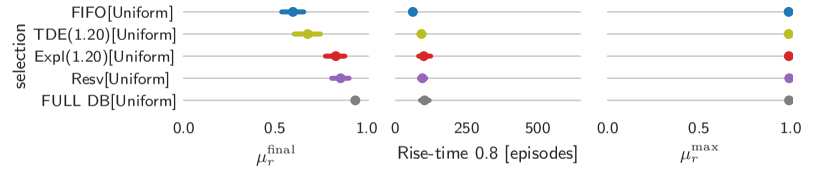
8.3 Sensor and Actuator Noise

We also test the performance of the methods in the presence of noise, similarly to Section 6.5. The main question here is how the noise might affect the methods that use the temporal difference error δ as the usefulness proxy. The concern is that these methods might favor noisy samples, since these samples might cause bigger errors. To test this we perform learning runs on the pendulum task while collecting statistics on all of the experiences in the mini-batches that are sampled for training. The mean absolute values of the noise in the experiences that are sampled are given in Table 6. It can be seen that the temporal difference error-based methods indeed promote noisy samples. The noise is highest for those dimensions that have the largest influence on the value of Q.

In Figure 14 the performance of the different methods on the two benchmarks with noise is given. The tendency to seek out noisy samples in the buffer is now clearly hurting the performance of PER sampling, as the performance with PER is consistently worse than with uniform sampling. For our chosen buffer size the retention strategy is still more influential and interestingly the TDE-based retention method does not seem to suffer as much here. The relative rankings of the retention strategies are similar to those without noise.



(a) Swing-up [100 Hz]



(b) Magman [200 Hz]

Figure 13: Performance of the experience selection methods with increased sampling frequencies. Results are from 50 learning runs. A description of the performance measures is given in Section 5.1.

	position	velocity	action

8.4 Importance Sampling

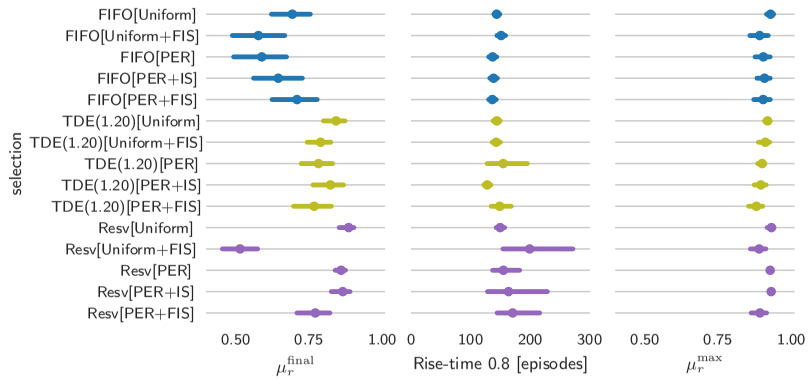
Finally, we investigate the different importance sampling strategies that were discussed in Sections 3.3.2 and 7.2. We do this by using the FIFO, TDE and Resv retention strategies as representative examples. We consider the benchmarks with noise, since as we discussed in Section 3.3.2, the stochasticity in the environment can make importance sampling more relevant. The results are shown in Figure 15. We discuss per retention strategy how the sample distribution is changed and whether the change introduces a bias that should be compensated for through importance sampling.

FIFO: This retention method results in an unbiased sample distribution. When combined with uniform sampling, there is no reason to compensate for the selection method. Doing so anyway (FIFO[Uniform + FIS]) results in downscaling the updates from experiences that happen to have been sampled more often than expected, effectively reducing the batch-size while not improving the distribution. The variance of the updates is therefore increased without reducing bias. This can be seen to hurt performance in Figure 15, especially on the swing-up task where sample diversity is most important. Using PER also hurts performance in the noisy setting as this sampling procedure *does* bias the sample distribution. Using importance sampling to compensate for just the sampling procedure (FIFO[PER+IS]) helps, but the resulting method is not clearly better than uniform sampling.

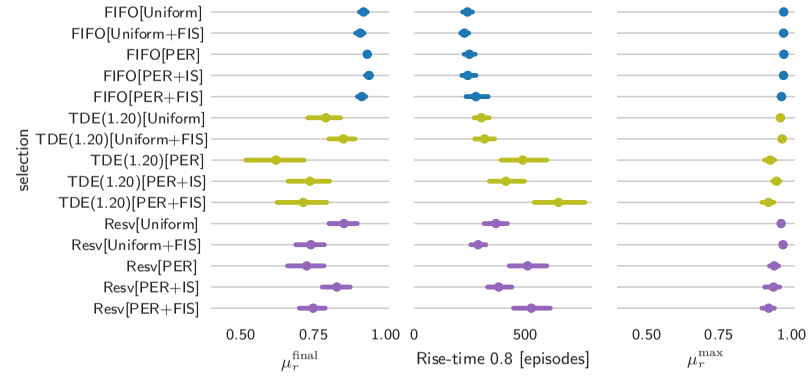
TDE: When the retention strategy is based on the temporal difference error, there is a reason to compensate for the bias in the sample distribution. It can be seen from Figure 15 however, that the full importance sampling scheme improves performance on the magman benchmark, but not on the swing-up task. The likely reason is again that importance sampling indiscriminately compensates for both the unwanted re-sampling of the environment dynamics and reward distributions as well as the beneficial re-sampling of the state-action space distribution. The detrimental effects of compensating for the latter seen to outweigh the beneficial effects of compensating for the former on this benchmark where state-action space diversity has been shown to be so crucial.

Resv: The reservoir retention method is not biased with respect to the reward function or the environment dynamics. Although the resulting distribution is strongly off-policy (assuming the policy has changed during learning), this does not present a problem for a deterministic policy gradient algorithm with Q-learning updates, other than that it might be harder to learn a function that generalizes to a larger part of the state space. When sampling uniformly, we do sample certain experiences, from early in the learning process, far more often than would be expected under a FIFO[Uniform] selection strategy. The FIS method compensates for this by weighing these experiences down, effectively reducing the size of both the buffer and the mini-batches. In Figure 15, this can be seen to severely hurt the performance on the swing-up problem, as well as the learning stability on the magman benchmark.

Interesting to note is that on these two benchmarks, for all three considered retention strategies, using importance sampling to compensate for the changes introduces by PER



(a) Swing-up [$\sigma_s = \sigma_a = 0.02$]



(b) Magman [$\sigma_s = \sigma_a = 0.02$]

Figure 15: Performance of representative experience selection methods with and without importance sampling on the benchmarks with sensor and actuator noise. A description of the performance measures is given in Section 5.1.

only improved the performance significantly when using PER resulted in poorer performance than not using PER. Similarly, using FIS to compensate for the changes introduced in the buffer distribution only improved the performance when those changes should not have been introduced to begin with.

8.5 Additional Benchmarks

The computational and conceptual simplicity of the two benchmarks used so far allowed for comprehensive tests and a good understanding of the characteristics of the benchmarks. However, we also saw that the right experience selection strategy is benchmark dependent. Furthermore, deep reinforcement learning yields most of its advantages over reinforcement learning without simpler function approximation on problems with higher dimensional state and action spaces. To obtain a more complete picture we therefore perform additional tests on 6 benchmarks of varying complexity.

8.5.1 Benchmarks

In the interest of reproducibility, we use the open source RoboSchool (Klimov, 2017) benchmarks together with the openAI baselines (Dhariwal et al., 2017) implementation of DDPG. We have adapted the baselines code to include the experience selection methods considered in this section. Our adapted code is available online.[3]

The baselines version of DDPG uses Gaussian noise added to the parameters of the policy network for exploration (Plappert et al., 2018). In contrast to the other experiments in this work, the strength of the exploration is kept constant during the entire learning run. For the Expl method we still consider the 1-norm of the distance between the exploration policy action and the unperturbed policy action as the utility of the sample.

For the benchmarks listed in Table 7, we compare the default FULL DB[Uniform] selection strategy in the baselines code to the alternative retention strategies considered in this work with uniform sampling. We show the maximum performance for these different retention strategies as a function of the buffer size in Figure 16.

8.5.2 Results

As shown in Figure 16, on these noise-free benchmarks with constant exploration and moderate sampling frequencies, the gains obtained by using the considered non-standard experience selection strategies are limited. However, in spite of the limited number of trials performed due to the computational complexity, trends do emerge on most of the bench-

3. The code is available at https://github.com/timdebruin/baselines-experience-selection.

Table 7: The RoboSchool benchmarks considered in this section with the dimensionalities of their state and action spaces.

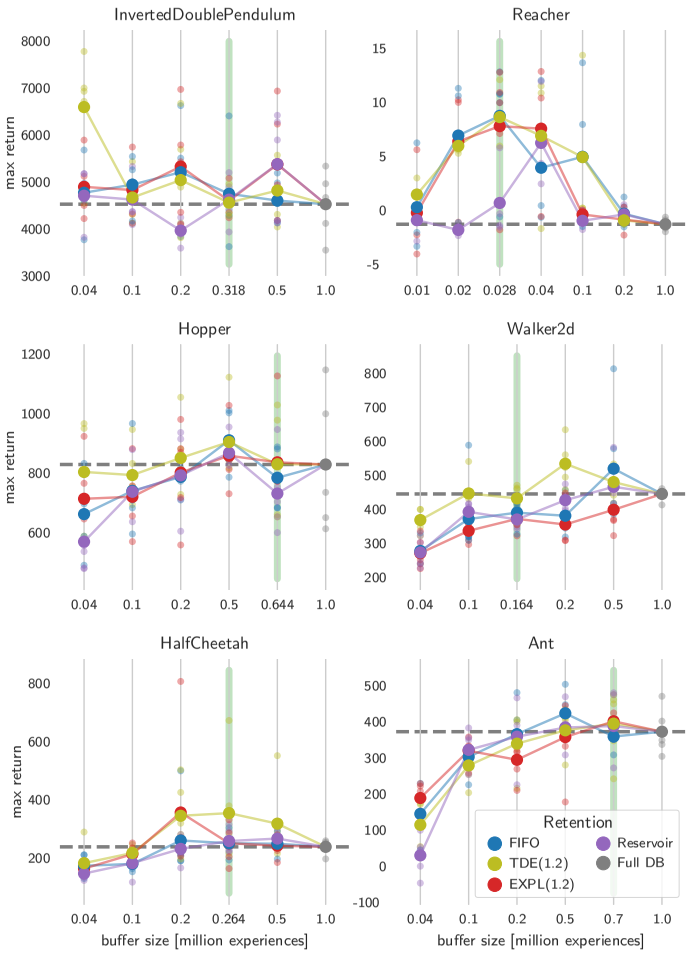

Figure 16: Maximum performance during a training run on the Roboschool benchmarks as a function of the retention strategy and buffer size. Results for the individual runs and their means are shown. In Appendix 9.3, we additionally show the mean (Figure 26) and final (Figure 25) performance. Green lines indicate the rule of thumb buffer sizes of Figure 17.

marks. On all benchmarks, the best performance is seen not when retaining all experiences, but rather when learning from a smaller number of experiences. This is most visible on the reacher task, which involves learning a policy for a 2-DOF arm to move from one random location in its workspace to another random location. For this task, the best performance for all retention strategies is observed when retaining less than a tenth of all experiences.

For these noise-free benchmarks, the temporal difference error is an effective proxy for the utility of the experiences, resulting in the highest or close to the highest maximum performance on all benchmarks.

The exploration-based retention strategy was introduced to prevent problems when reducing exploration and for high sampling frequencies. Since the exploration is not decayed and the sampling frequencies are modest, there is no real benefit when applying this strategy to these benchmarks. However, it also does not seem to hurt performance compared to the age-based retention strategies. The constant exploration on these benchmarks additionally means that the performance of FIFO and Reservoir retention are rather close, although due to premature convergence of the data distribution, reservoir retention does suffer the most when the buffer capacity is too low.

Figures 16, 25 and 26 show that when the right proxy for the utility of experiences is chosen, performance equal to and often exceeding that of retaining all experiences can be obtained while using only a fraction of the memory. This begs the question of how to choose the buffer size.

As it tends to result in more stable learning, retaining as many experiences as possible seems a sensible first choice for the buffer size. We therefore base our suggestion for subsequently tuning the buffer size on the learning curves of the FULL DB[Uniform] method. The complexity of the control task at hand determines the minimal number of environment steps required to learn a good policy, as well as the number of experiences that need to be retained in a buffer for decent learning performance. We propose to use the number of experiences needed to get to 90% of the final performance as a *rough* empirical estimate of the optimal buffer size. We show this rule of thumb in Figure 17 and have indicated the experiments with the proposed buffer sizes in Figure 16 with vertical green lines.

Instead of iteratively optimizing the buffer size over several reinforcement learning trials, extrapolation of the learning curve (Domhan et al., 2015) could also be used to limit the buffer capacity when the remaining learning performance increase is expected to be small. This would allow the method to work immediately for novel tasks.

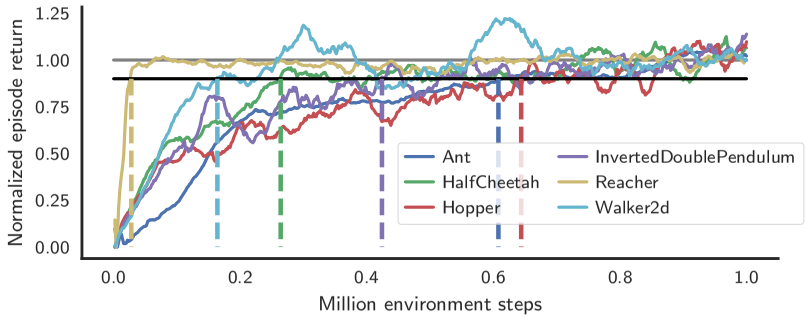

Figure 17: Learning curves of the FULL DB method on the different benchmarks, averaged over 5 trials. The curves are normalized by the final performance (the mean performance over the last $2 \cdot 10^5$ steps). Indicated are the number of steps needed to get to 90% of the final performance.

9. Conclusions and Recommendations

In this work, we have investigated how the characteristics of a control problem determine what experiences should be replayed when using experience replay in deep reinforcement learning.

We first investigated how factors such as the generalizability over the state-action space and the sampling frequency of the control problem influenced the balance between the need for on-policy experiences versus a broader coverage of the state-action space.

We then investigated a number of proxies for the utility of experiences which we used to both decide which experiences to retain in a buffer and how to sample from that buffer. We performed experiments that showed how these methods were affected by noise, increased sampling frequencies and how their performance varied across benchmarks and experience buffer sizes.

Based on these investigations we present a series of recommendations below for the three choices concerning experience selection: how to choose the capacity of the experience replay buffer, which experiences to retain in a buffer that has reached its capacity and how to sample from that buffer. These choices together should ensure that the experiences that are replayed to the reinforcement learning agent facilitate quick and stable learning of a policy with good performance. An example of applying the procedure outlined below on the Magman benchmark is given in Figure 18. Note the proposed methods are especially relevant when faced by issues that might occur in a physical-control setting, such as a need for constrained exploration, high or low sampling frequencies, the presence of noise and hardware limitations that limit the experience buffer size. Section 8.5 shows that the potential gains might be limited for processes where these problems do not occur.

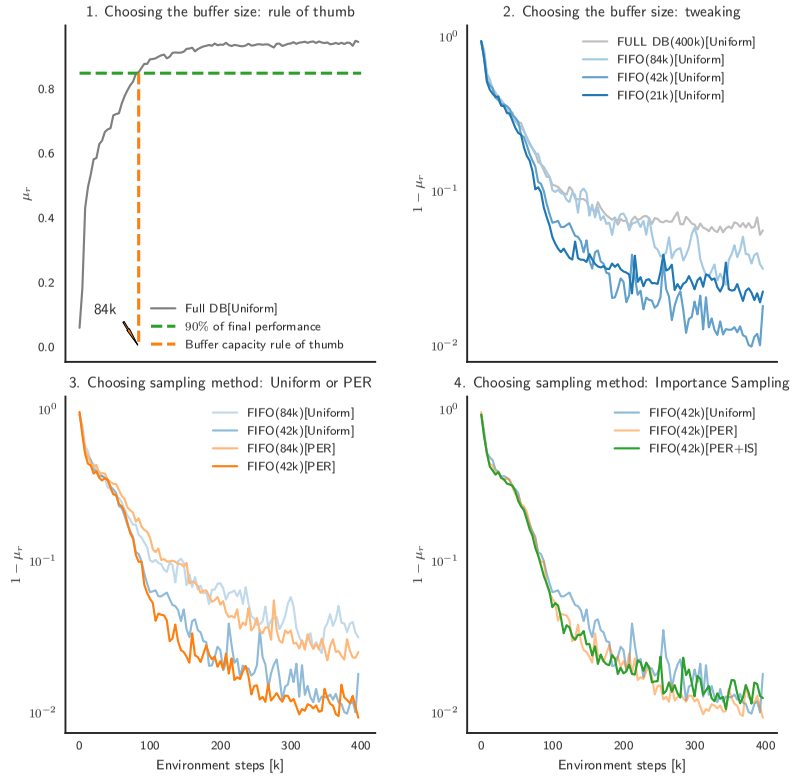

Figure 18: Demonstration of the proposed process for the magman benchmark. 1: Based on the performance of the Full DB[Uniform] method, the rule of thumb indicates a buffer capacity of 84×10^3 experiences. As there are no special circumstances such as high sampling frequencies and the magman requires a very precise policy that does not easily generalize due to the highly nonlinear behavior of the magnets, FIFO retention is used. 2: By exploring around the proposed buffer size, a buffer capacity of 42×10^3 experiences is chosen. 3: Sampling from the buffer based on the temporal difference error can help speed up and stabilize learning, but is very dependent on the experiences that are in the buffer to begin with. 4: Since the benchmark fully deterministic (noise free), importance sampling is not needed in this case and can be seen to undo some of the benefits of PER.

9.1 Choosing the Buffer Capacity

Although it is not the best retention strategy in most of the benchmarks we have considered, retaining as many experiences as possible is a good place to start. This tends to result in more stable learning, even if the eventual performance is not always optimal.

If the learning curve for the FULL DB experiments reaches a level of performance close to the performance after convergence in significantly fewer environment steps than there are experience samples in the buffer, it might be worthwhile reducing the size of the buffer. Our proposed rule of thumb is to to make the buffer size roughly equal to 90% the number of environment steps needed to reach the final performance level.

9.2 Choosing the Experience Utility Proxy

When not all experiences are retained in the buffer, a proxy for the utility of the individual experiences is needed to determine which experiences to retain and which to discard. In this work, we have discussed strategies based on several proxies and shown that the right strategy is problem dependent. Although finding the right one will likely require some experimentation, we discuss here what properties of the control problem at hand make certain strategies more likely or less likely to succeed.

FIFO: Although off-policy reinforcement-learning algorithms can learn from samples obtained by a different policy than the optimal policy that is being learned, the reality of deep reinforcement learning is that a finite amount of shared function approximation capacity is available to explain all of the training data. While simply using larger networks might help, we show in Appendix 9.3 that learning only from more recent data (which corresponds more closely to the policy being learned) can work better. A large potential downfall presents itself when the policy suddenly changes in a way that changes the distribution of the states that are visited. As shown in Section 6.2, this can quickly destabilize the learning process. Extra care should be taken when using FIFO retention in combination with decaying exploration. This is especially true for problems where multiple policies are possible that give similar returns but distinct state-space trajectories, such as swinging up a pendulum either clockwise or anti-clockwise.

TDE: The idea behind selecting certain experiences over others is that more can be learned from these samples. The temporal difference error is therefore an interesting proxy, especially during the early stages of the learning process when the error is mostly caused by the fact that the value function has not been accurately learned yet. In the experiments of Schaul et al. (2016) as well as in our own experiments, prioritizing experiences with larger TD errors was observed to improve both the speed of learning as well as the eventual performance in many cases. The downside of using the TD error as an experience utility proxy is that the error can also be caused by sensor and actuator noise, environment stochasticity or function approximation accuracy differences as a result of differences in the state space coverage. We have shown in Section 8.3 how noise can hurt the performance of the algorithm when using this proxy and argued in Section 3.3.2 how this proxy introduces a harmful bias in the presence of environment stochasticity.

Exploration: We introduced an additional proxy based on the observation that, on physical systems, exploration can be costly. By using the strength of the exploration signal as a proxy for the utility of the experience, some of the problems mentioned for the FIFO strategy when reducing exploration can be ameliorated. As shown in Section 6.4 and Section 8.2, sufficient diversity in the action space is most important when the dependency of the value function on the action is relatively small, such as for increased sampling frequencies. The downside of this strategy is that since it focuses on early experiences that are more off-policy, it can take longer for the true value function to be learned. Besides the impact on training speed, the focus on off-policy data can also limit the maximum controller performance.

Reservoir sampling: By using reservoir sampling as a retention strategy, the buffer contains, at all times, samples from all stages of learning. As with the exploration-based policy, this ensures that initial exploratory samples are retained which can significantly improve learning stability on domains where FIFO retention does not work. However, of the methods mentioned here, reservoir sampling is the one most severely impacted by a too small experience buffer, as the data distribution in the buffer will converge prematurely and will not cover the state-action space distribution of the optimal policy well enough.

9.3 Experience Sampling and Importance Sampling

The experiences that are used to learn from are not just determined by the buffer retention strategy, but also by the method of sampling experiences from the buffer. While the retention strategy needs to ensure that a good coverage of the state-action space is maintained in the buffer throughout learning, the sampling strategy can seek out those experiences that can result in the largest immediate improvement to the value function and policy. It can therefore be beneficial to *sample* based on the temporal difference error (as suggested by Schaul et al. 2016), which can improve learning speed and performance, while basing the *retention* strategy on a more stable criterion that either promotes stability or ensures that only samples from the relevant parts of the state-action space are considered by the sampling procedure.

As discussed in Sections 3.3.2 and 8.4, selecting experiences based on the temporal difference error in stochastic environments introduces a bias that should be compensated for through weighted importance sampling in order to make the learning updates valid. While the other experience selection methods in this work change the distribution of the samples, these changed distributions are still valid for an off-policy deterministic gradient algorithm.

Appendix A. Simple Benchmarks

Here, a more detailed mathematical description is given of the pendulum swing-up and magnetic manipulation benchmarks. A high level description of these benchmarks was given in Section 4.

The benchmarks will be described based on their true (unnormalized) physical environment states s_{unnorm} and actions a_{unnorm}. In the main body of this work the components of these states and actions are normalized: $s, s_{\mathcal{E}} \in [-1, 1]^n, a, a_{\mathcal{E}} \in [-1, 1]^m$. See Figure 1 for a description of the symbols used.

The dynamics of both problems are defined as differential equations, which we use to calculate the next environment state s'_{unnorm} as a function of the current state s_{unnorm} and action a_{unnorm} using the (fourth order) Runge-Kutta method. The reward is in both cases given by:

$$r = -(W_1|s'_{\text{unnorm}} - s_{\text{unnorm}_{\text{ref}}}| + W_2|a_{\text{unnorm}}|). \tag{9}$$

In both cases a fixed reference state $s_{\text{unnorm}_{\text{ref}}}$ is used.

A.1 Pendulum Swing-Up

For the pendulum swing-up task, the state s_{unnorm} is given by the angle $\theta \in [-\pi, \pi]$ and angular velocity $\dot{\theta}$ of a pendulum, which starts out hanging down under gravity $s^0_{\text{unnorm}} = [\theta\ \dot{\theta}]^T = [0\ 0]^T$. For the normalization of the velocities, $\theta_{\min} = -30\,\text{rad}\,\text{s}^{-1}$ and $\theta_{\max} = 30\,\text{rad}\,\text{s}^{-1}$ are used. The action space is one dimensional: it is the voltage applied to a motor that exerts torque on the pendulum $a_{\text{unnorm}} \in [-3, 3]$ V. The angular acceleration of the pendulum is given by:

$$\ddot{\theta} = \frac{-Mgl\sin(\theta) - (b + K^2/R)\dot{\theta} + (K/R)a_{\text{unnorm}}}{J}.$$

Where $J = 9.41 \times 10^{-4}\,\text{kg}\,\text{m}^2$, $M = 5.5 \times 10^{-2}\,\text{kg}$, $g = 9.81\,\text{m}\,\text{s}^{-2}$, $l = 4.2 \times 10^{-2}\,\text{m}$, $b = 3 \times 10^{-6}\,\text{kg}\,\text{m}^2\,\text{s}^{-1}$, $K = 5.36 \times 10^{-2}\,\text{kg}\,\text{m}^2\,\text{s}^{-2}\,\text{A}^{-1}$ and $R = 9.5\,\text{V}\,\text{A}^{-1}$ are respectively the pendulum inertia, the pendulum mass, the acceleration due to gravity, pendulum length, viscous damping coefficient, the torque constant and the rotor resistance (Alibekov et al., 2018). For this task $W_1 = [50\ 1]$ and $W_2 = 10$ and $s_{\text{unnorm}_{\text{ref}}} = [-\pi\ 0]^T = [\pi\ 0]^T$. The absolute value of the state is used in (9).

A.2 Magnetic Manipulation

In the magnetic manipulation problem, the action space represents the squared currents through four electromagnets under the track; $a^j_{\text{unnorm}} \in [0,\ 0.6]A^2$ for $j = 1, 2, 3, 4$. The state of the problem is defined as the position $x \in [-0.035,\ 0.105]$ m of the ball relative to the center of the first magnet and the velocity $\dot{x}$ $\text{m}\,\text{s}^{-1}$ of the ball: $s_{\text{unnorm}} = [x\ \dot{x}]^T$. For the normalization of the velocities, $\dot{x}_{\min} = -0.4\,\text{m}\,\text{s}^{-1}$ and $\dot{x}_{\max} = 0.4\,\text{m}\,\text{s}^{-1}$ are used. When the position of the ball exceeds the bounds, the position is set to the bound and the velocity is set to $0.01\,\text{m}\,\text{s}^{-1}$ away from the wall. An additional reward of -1 is given for the time-step at which the collision occurred. The acceleration of the ball is given by:

$$\ddot{x} = -\frac{b}{m}\dot{x} + \frac{1}{m}\sum_{j=1}^{4} g\,(x, j)\,a^j_{\text{unnorm}},$$

with

$$g(x, j) = \frac{-c_1\ (x - 0.025j)}{\left((x - 0.025j)^2 + c_2\right)^3}.$$

Here, $g(x, j)$ is the nonlinear magnetic force equation, $m = 3.200 \times 10^{-2}\,\text{kg}$ the ball mass, and $b = 1.613 \times 10^{-2}\,\text{N}\,\text{s}\,\text{m}^{-1}$ the viscous friction of the ball on the rail. The parameters c_1 and c_2 were empirically determined from experiments on a physical setup to be $c_1 = 5.520 \times 10^{-10}\,\text{N}\,\text{m}^5\,\text{A}^{-1}$ and $c_2 = 1.750 \times 10^{-4}\,\text{m}^2$ (Alibekov et al., 2018).

For the magnetic manipulation problem we take $W_1 = [100\ 5]$, $W_2 = [0\ 0\ 0\ 0]$, $s^0_{\text{unnorm}} = [0\ 0]^T$ and $s_{\text{unnorm}_{\text{ref}}} = [0.035\ 0]^T$ in (9).

Appendix B. Implementation Details

This appendix discusses the chosen hyperparameters of the methods discussed in Section 3, that were used to obtain the results in this paper. Only those hyperparameters that were not explicitly mentioned in the earlier sections of this work are mentioned here.

B.1 Neural Networks

This appendix describes the architecture and training procedure of the used neural networks.

Swing-up and Magman

To perform the experiments in this work, the DDPG method of Lillicrap et al. (2016) was reimplemented in Torch (Collobert et al., 2011). For all experiments except for the control experiment in Appendix 9.3, the actor and critic networks had the following configuration:

The actor is a fully connected network with two hidden layers, each with 50 units. The hidden layers have rectified linear activation functions. The output layer has hyperbolic tangent nonlinearities to map to the normalized action space.

The critic is a fully connected network with three hidden layers. The layers have rectified linear activation functions and 50, 50 and 20 units respectively. The state is the input to the first hidden layer, while the action is concatenated with the output of the first hidden layer and used as input to the second hidden layer. The output layer is linear.

To train the networks, the ADAM optimization algorithm is used (Kingma and Ba, 2015). We use a batch size of 16 to calculate the gradients. For all experiments we use 0.9 and 0.999 as the exponential decay rates of the first and second order moment estimates respectively. The step-sizes used are 10^{-4} for the actor and 10^{-3} for the critic. We additionally use $\mathcal{L}_2$ regularization on the critic weights of 5×10^{-3}.

For the DQN experiments, a critic network similar to the DDPG critic was used. The critic-only differs in the fact that instead of having actions as an input, the output size is increased to the number of discrete actions considered. The parameters θ^- of the target critic are updated to equal the online parameters θ every 200 batch updates.

Roboschool Benchmarks

For the experiments on the Roboschool benchmarks, we use a slightly modified version of the DDPG implementation in the openAI baselines (Dhariwal et al., 2017) repository. We have adapted the baselines code to include the experience selection methods considered in this section. Our adapted code is available online.[4] We here summarize the relevant differences from the implementation used on the simple benchmarks.

The actor and critic networks have two hidden layers with 64 units each. Layer normalization (Ba et al., 2016) is used in both networks after both hidden layers. The multiplier of the $\mathcal{L}_2$ regularization on the weights of the critic with is 1×10^{-2}. A batch size of 64 is used, with a sample reuse of 32. Training is performed every 100 environment steps, rather than after completed episodes.

B.2 Exploration

Swing-Up and Magman

We use an Ornstein-Uhlenbeck noise process (Uhlenbeck and Ornstein, 1930) as advocated by Lillicrap et al. (2016). The dynamics of the noise process are given by

$$u(k+1) = u(k) + \theta\mathcal{N}(0,1) - \sigma u(k).$$

The equation models the velocity of a Brownian particle with friction. We use $\theta = 5.14$, $\sigma = 0.3$. Using this temporally correlated noise allows for more effective exploration in domains such as the pendulum swing-up. It also reduces the amount of damage on physical systems relative to uncorrelated noise (Koryakovskiy et al., 2017). For high frequencies, uncorrelated noise is unlikely to result in more than some small oscillations around the downward equilibrium position.

The noise signal is clipped between -1 and 1 after which it is added to the policy action and clipped again to get the normalized version of the control action a.

For the DQN experiments, epsilon greedy exploration was used with the probability of taking an action uniformly at random decaying linearly from $\epsilon = 0.7$ to $\epsilon = 0.01$ over the first 500 episodes.

Roboschool Benchmarks

For easy comparison to other work, we use the exploration strategy included in the baselines code. This means that for the Roboschool benchmarks we do not decay the strength of the exploration signal over time. Compared to our other benchmarks, the second difference is that the noise is added in the parameter space of the policy rather than directly in the action space (Plappert et al., 2018). The amplitude of the noise on the parameters is scaled such that the standard deviation of the exploration signal in action-space is 0.2.

Appendix C. Baseline Controller

In this work we use the fuzzy Q-iteration algorithm of Buşoniu et al. (2010) as a baseline. This algorithm uses full knowledge of the system dynamics and reward function to compute a controller that has a proven bound on its sub-optimality for the deterministic (noise-free) case.

4. The code is available at https://github.com/timdebruin/baselines-experience-selection.

For the tests with sensor and actuator noise, the same controller as in the noise-free setting is used. To make the performance normalization (Section 5.1) fair, the performance of the controller is taken as the mean of 50 repetitions of taking the maximum obtained mean reward per episode over 1000 episodes with different realizations of the noise:

$$r_{\text{baseline with noise}} = \frac{1}{50}\sum_{i=1}^{50} \max(r^{\text{mean}}_{\text{episode i,1}}, \ldots, r^{\text{mean}}_{\text{episode i,1000}}).$$

Note that although this equalizes the chances of getting a favorable realization of the sensor and actuator noise sequences, it does not compensate for the fact that the fuzzy Q-iteration algorithm is unsuitable for noisy environments. Since the DDPG method used in this work can adjust the learned policy to the presence of noise in the environment, it outperforms the baseline in some situations. This is not an issue since we are interested in the relative performance of different experience selection strategies and only use the baseline as a reference point.

Appendix D. Additional Sensitivity Analyses and Figures

This section contains additional analyses and figures that were left out of the main body of the paper for brevity.

D.1 Performance on the Magman Benchmark as a Function of Network Size

In the main body of the paper, a number of experiments are shown in which the performance of the magman benchmark is better with a small FIFO experience buffer than it is when retaining all experiences. As we use relatively small neural networks on the magman benchmark, it could be expected that at least part of the reason that training on all experiences results in poorer performance is that the function approximator simply does not have enough capacity to accurately cover the state-action space. We therefore compare the performance of the networks used on the magman benchmark in the main body of this work to that of the original DDPG architecture, which has more than 40 times as many parameters. Table 8 compares the network architectures and the number of parameters of

Architecture	hidden layer units	parameters swing-up	parameters magman
Small-critic	[50, 50, 20]	3791	3941
Small-actor	[50, 50]	2751	2904
DDPG original-critic	[400, 300]	122101	123001
DDPG original-actor	[400, 300]	121801	122704

Table 8: The architectures of the networks compared in this section, with the number of parameters.

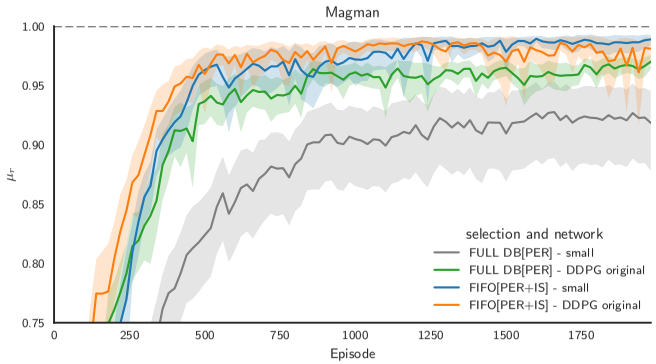

Figure 19: Influence of network size on the performance of the magman benchmark, when retaining all 4×10^5 experiences (FULL DB) versus retaining only the last 10^4 experiences (FIFO). The small policy network used for most of the experiments on the magman has 2904 parameters, while the original DDPG network has 122704 parameters on the magman benchmark. In both cases the critic networks had slightly more parameters.

these architectures. It can be seen from Figure 19 that, while the larger network is able to learn more successfully from the FULL DB buffer, it is outperformed by both the small and the large network using the FIFO buffer. The eventual performance is best for our smaller network trained on a small buffer, although learning is somewhat faster with the larger network.

D.2 Sensitivity Analysis α

In both the PER sampling as well as the TDE and Expl retention methods, the parameter α (7) determines how strongly the used experience utility proxy influences the selection method. Here, we show the sensitivity of both PER (Figure 21) and Expl (Figure 20) with respect to this parameter.

In Figure 20 it can be seen that on the Pendulum benchmark, where Expl retention has already been shown to aid stability, increasing α helps to improve the final performance more. This increased stability comes at the cost of somewhat reduced maximum performance. With PER sampling it does not seem to hurt the learning speed. On the Magman benchmark, where FIFO retention works better than Expl retention, increasing α (and thus relying more on the wrong proxy for the benchmark) hurts performance. Interesting to see is that compared to uniform sampling, PER speeds up the learning for low values of α, while it hurts for large values of α. This demonstrates again the need to choose both parts of experience selection with care.

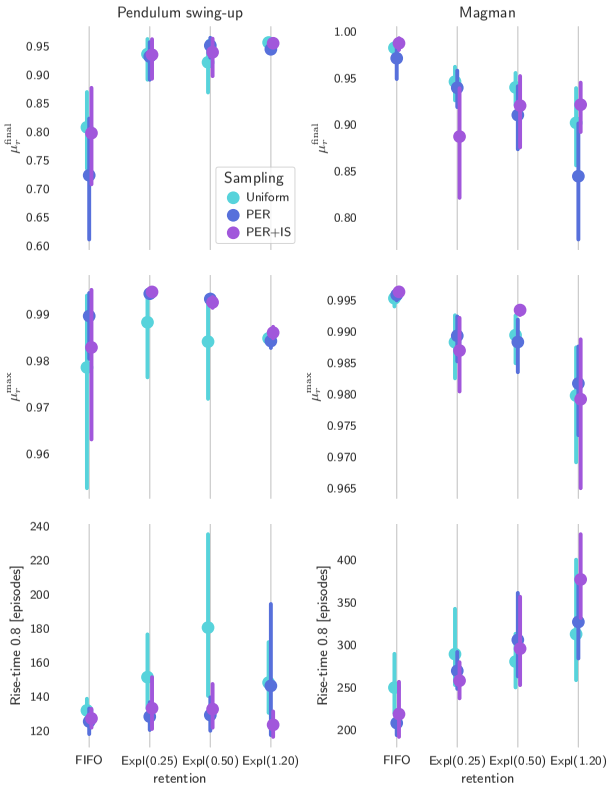

Figure 20: Influence of α in the Expl algorithm for different sampling strategies.

In Figure 21 it can again be seen that the benefits of PER are mostly to the speed of learning. Improvements to the maximum and final performance are possible when α is chosen correctly, but depend mostly on the contents of the buffer that PER is sampling from.

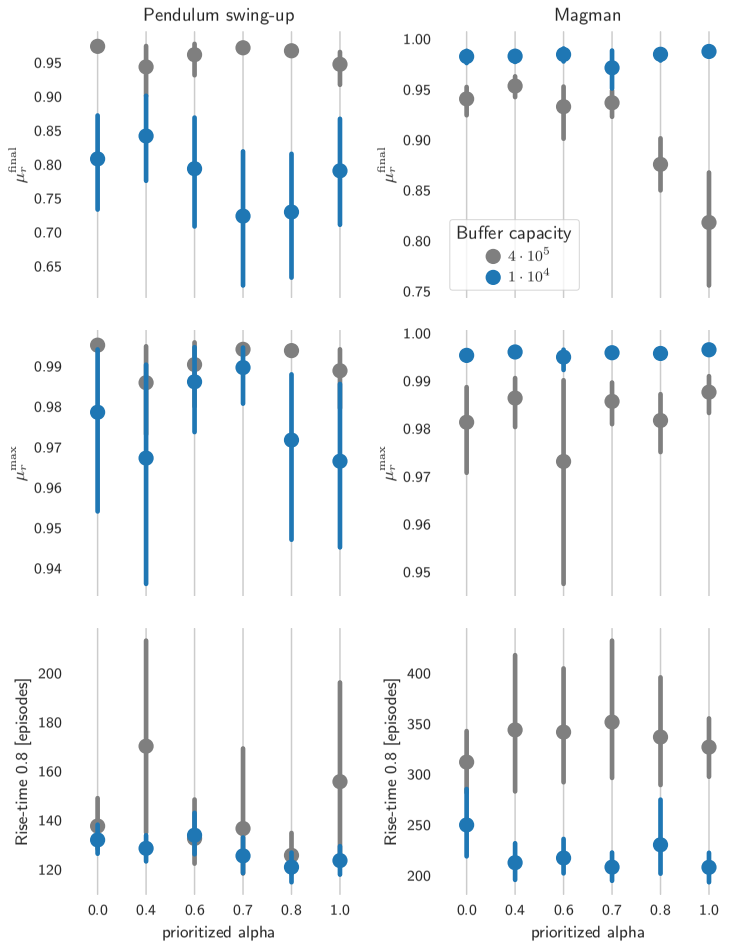

Figure 21: Influence of α in the PER algorithm for the Full DB strategy (buffer capacity $= 4 \times 10^5$) and FIFO retention (buffer capacity 1×10^{-4}).

D.3 Additional Figures Related to the Main Body

This subsection contains several figures that were left out of the main text of this work for brevity. They show the same experiments as Figures 6, 8, 16, according to the remaining performance criteria.

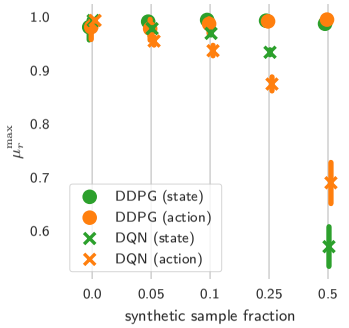

Figure 22: RL algorithm dependent effect of adding synthetic experiences to the FIFO[Uniform] method on the maximum performance per episode μ_r^{max} on the pendulum swing-up benchmark. The effect on the final performance and the rise-time is given in Figure 7.

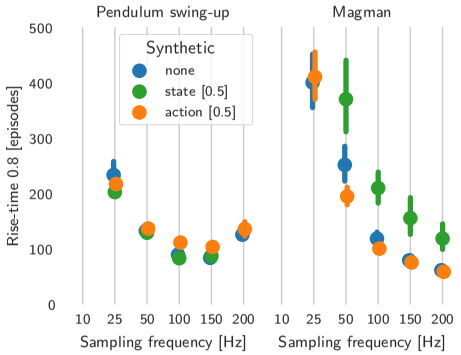

Figure 23: Sampling frequency dependent effect on the learning speed of adding synthetic experiences to the FIFO[Uniform] method. The effect on the final and maximum performance is given in Figure 9.

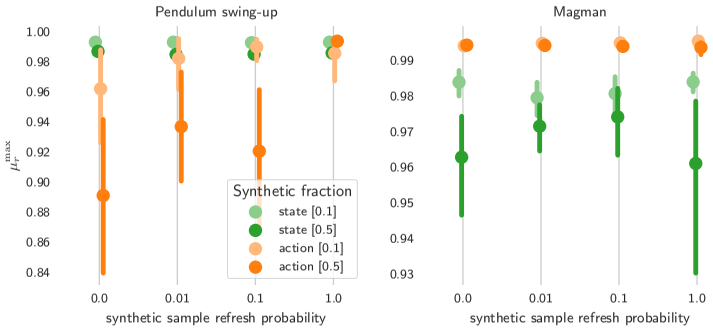
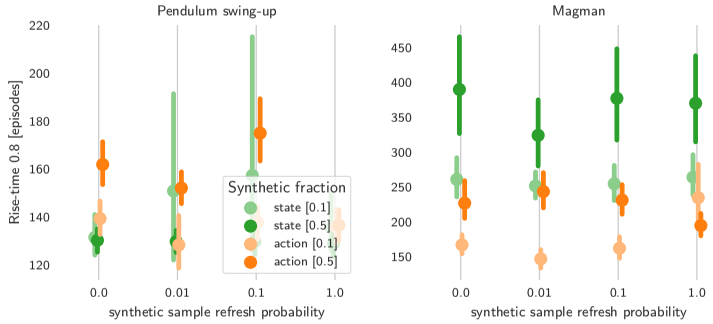


(a) Effect on $\mu_r^{\max}$.



(b) Effect on Rise − time0.8.

Figure 24: The effects on the performance of the FIFO[Uniform] method when changing a fraction of the observed experiences with synthetic experiences, when the synthetic experiences are updated only with a certain probability each time they are overwritten. The effects on μ_r^{final} is shown in Figure 8.

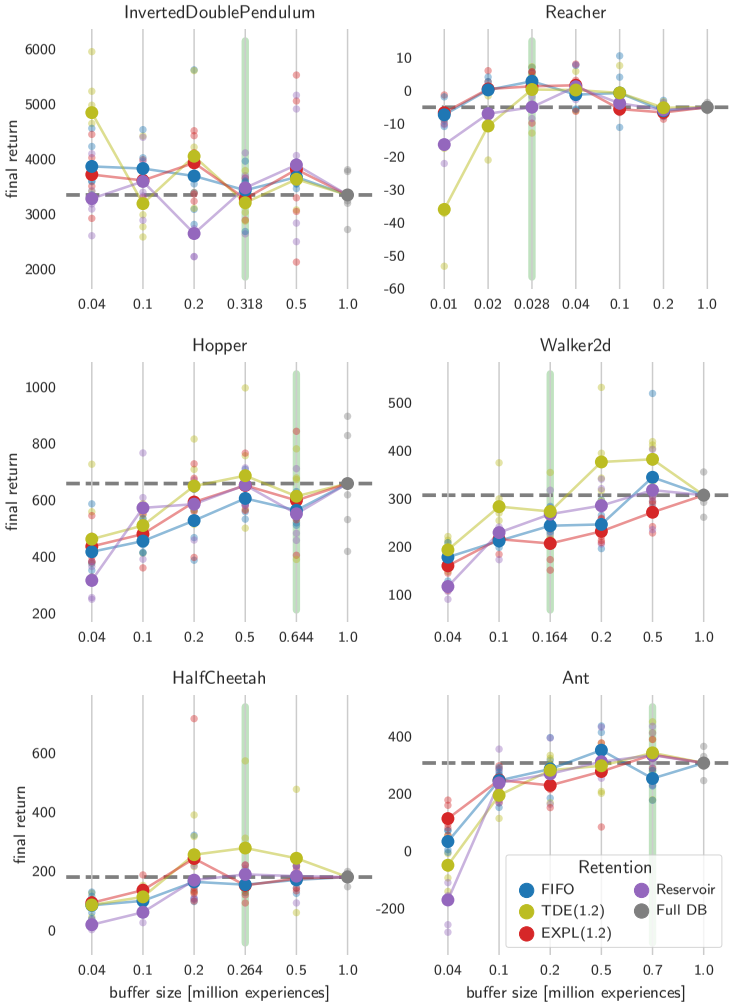


Figure 25: Mean performance during the last 2×10^5 training steps of a 1×10^6 step training run on the Roboschool benchmarks as a function of the retention strategy and buffer size. Results for the individual runs and their means are shown.

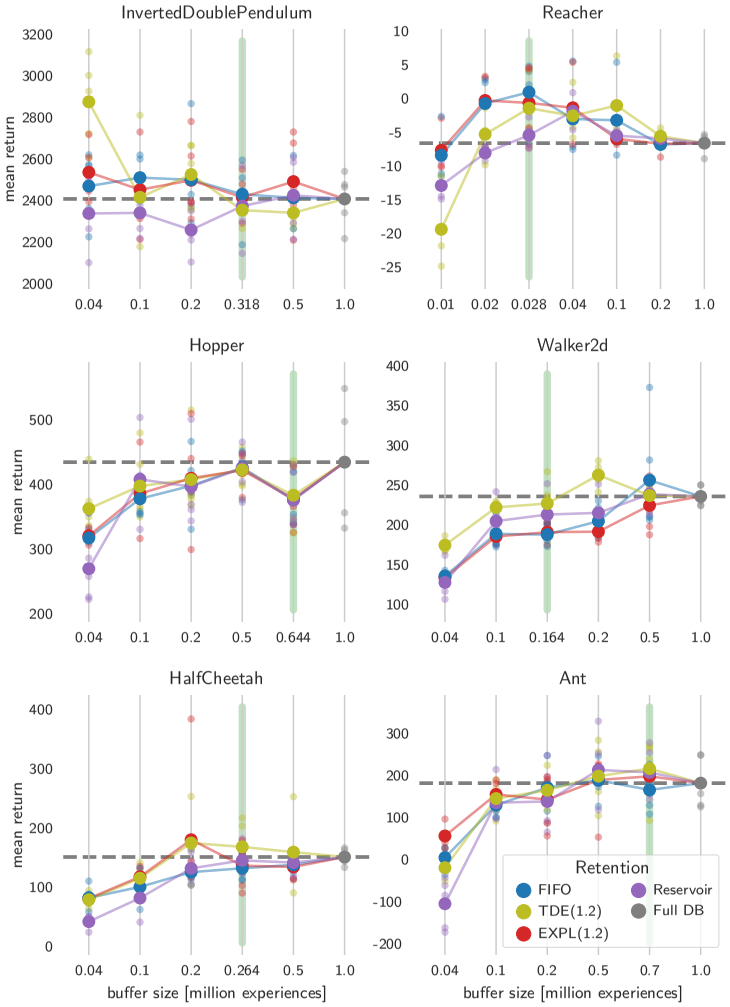

Figure 26: Mean performance during the whole training run on the Roboschool benchmarks as a function of the retention strategy and buffer size. Results for the individual runs and their means are shown.

Abstract

We propose a constructive approach to estimating sparse, high-dimensional linear regression models. The approach is a computational algorithm motivated from the KKT conditions for the ℓ_0-penalized least squares solutions. It generates a sequence of solutions iteratively, based on support detection using primal and dual information and root finding. We refer to the algorithm as SDAR for brevity. Under a sparse Riesz condition on the design matrix and certain other conditions, we show that with high probability, the ℓ_2 estimation error of the solution sequence decays exponentially to the minimax error bound in $O(\log(R\sqrt{J}))$ iterations, where J is the number of important predictors and R is the relative magnitude of the nonzero target coefficients; and under a mutual coherence condition and certain other conditions, the ℓ_∞ estimation error decays to the optimal error bound in $O(\log(R))$ iterations. Moreover the SDAR solution recovers the oracle least squares estimator within a finite number of iterations with high probability if the sparsity level is known. Computational complexity analysis shows that the cost of SDAR is $O(np)$ per iteration. We also consider an adaptive version of SDAR for use in practical applications where the true sparsity level is unknown. Simulation studies demonstrate that SDAR outperforms Lasso, MCP and two greedy methods in accuracy and efficiency.

1. Introduction

Consider the linear regression model

$$y = X\beta^* + \eta \tag{1}$$

where $y \in \mathbb{R}^n$ is a response vector, $X \in \mathbb{R}^{n\times p}$ is the design matrix with $\sqrt{n}$-normalized columns, $\beta^* = (\beta_1^*, \ldots, \beta_p^*)' \in \mathbb{R}^p$ is the vector of the underlying regression coefficients and $\eta \in \mathbb{R}^n$ is a vector of random noises. We focus on the case where $p \gg n$ and the model is sparse in the sense that only a relatively small number of predictors are important. Without any constraints on β^* there exist infinitely many least squares solutions for (1) since it is a highly undetermined linear system when $p \gg n$. These solutions usually over-fit the data. Under the assumption that β^* is sparse in the sense that the number of important nonzero elements of β^* is small relative to n, we can estimate β^* by the solution of the ℓ_0 minimization problem

$$\min_{\beta\in\mathbb{R}^p} \frac{1}{2n}\|X\beta - y\|_2^2, \quad \text{subject to} \quad \|\beta\|_0 \le s, \tag{2}$$

where $s > 0$ controls the sparsity level. However, (2) is generally NP hard (Natarajan, 1995; Chen et al., 2014), hence it is not tractable to design a stable and fast algorithm to solve it, especially in high-dimensional settings.

In this paper we propose a constructive approach to approximating the ℓ_0-penalized solution to (1). The approach is a computational algorithm motivated from the necessary KKT conditions for the Lagrangian form of (2). It finds an approximate sequence of solutions to the KKT equations iteratively based on support detection and root finding until convergence is achieved. For brevity, we refer to the proposed approach as SDAR.

1.1 Literature review

Several approaches have been proposed to approximate (2). Among them the Lasso (Tibshirani, 1996; Chen et al., 1998), which uses the ℓ_1 norm of β in the constraint instead of the ℓ_0 norm in (2), is a popular method. Under the irrepresentable condition on the design matrix X and a sparsity assumption on β^*, Lasso is model selection (and sign) consistent (Meinshausen and Bühlmann, 2006; Zhao and Yu, 2006; Wainwright, 2009). Lasso is a convex minimization problem. Several fast algorithms have been proposed, including LARS (Homotopy) (Osborne et al., 2000; Efron et al., 2004; Donoho and Tsaig, 2008), coordinate descent (Fu, 1998; Friedman et al., 2007; Wu and Lange, 2008), and proximal gradient descent (Agarwal et al., 2012; Xiao and Zhang, 2013; Nesterov, 2013).

However, Lasso tends to overshrink large coefficients, which leads to biased estimates (Fan and Li, 2001; Fan and Peng, 2004). The adaptive Lasso proposed by Zou (2006) and analyzed by Huang et al. (2008b) in high-dimensions can achieve the oracle property under certain conditions, but its requirements on the minimum value of the nonzero coefficients are not optimal. Nonconvex penalties such as the smoothly clipped absolute deviation (SCAD) penalty (Fan and Li, 2001), the minimax concave penalty (MCP) (Zhang, 2010a) and the capped ℓ_1 penalty (Zhang, 2010b) were proposed to remedy these problems (but these methods still require a minimum signal strength in order to achieve support recovery).

Although the global minimizers (also certain local minimizers) of these nonconvex regularized models can eliminate the estimation bias and enjoy the oracle property (Zhang and Zhang, 2012), computing the global or local minimizers with the desired statistical properties is challenging, since the optimization problem is nonconvex, nonsmooth and large scale in general.

There are several numerical algorithms for nonconvex regularized problems. The first kind of such methods can be considered a special case (or variant) of minimization maximization algorithm (Lange et al., 2000; Hunter and Li, 2005) or of multi-stage convex relaxation (Zhang, 2010b). Examples include local quadratic approximation (LQA) (Fan and Li, 2001), local linear approximation (LLA) (Zou and Li, 2008), decomposing the penalty into a difference of two convex terms (CCCP) (Kim et al., 2008; Gasso et al., 2009). The second type of methods is the coordinate descent algorithms, including coordinate descent of the Gauss-Seidel version (Breheny and Huang, 2011; Mazumder et al., 2011) and coordinate descent of the Jacobian version, i.e., the iterative thresholding method (Blumensath and Davies, 2008; She, 2009). These algorithms generate a sequence of solutions at which the objective functions are nonincreasing, but the convergence of the sequence itself is generally unknown. Moreover, if the sequence generated from multi-stage convex relaxation (starts from a Lasso solution) converges, it converges to some stationary point which may enjoy certain oracle statistical properties with the cost of a Lasso solver per iteration (Zhang, 2010b; Fan et al., 2014). Huang et al. (2018) proposed a globally convergent primal dual active set algorithm for a class of nonconvex regularized problems. Recently, there has been much effort to show that CCCP, LLA and the path following proximal-gradient method can track the local minimizers with the desired statistical properties (Wang et al., 2013; Fan et al., 2014; Wang et al., 2014; Loh and Wainwright, 2015).

Another line of research concerns the greedy methods such as the orthogonal matching pursuit (OMP) (Mallat and Zhang, 1993) for solving (2) approximately. The main idea is to iteratively select one variable with the strongest correlation with the current residual at a time. Roughly speaking, the performance of OMP can be guaranteed if the small submatrices of X are well conditioned like orthogonal matrices (Tropp, 2004; Donoho et al., 2006; Cai and Wang, 2011; Zhang, 2011b). Fan and Lv (2008) proposed a marginal correlation learning method called sure independence screening (SIS), see also Huang et al. (2008a) for an equivalent formulation that uses penalized univariate regression for screening. Fan and Lv (2008) recommended an iterative SIS to improve the finite-sample performance. As they discussed the iterative SIS also uses the core idea of OMP but it can select more features at each iteration. There are several more recently developed greedy methods aimed at selecting several variables a time or removing variables adaptively, such as iterative hard thresholding (IHT) (Blumensath and Davies, 2009; Jain et al., 2014) or hard thresholding gradient descent (GraDes) (Garg and Khandekar, 2009), adaptive forward-backward selection (FoBa) (Zhang, 2011a).

Liu and Wu (2007) proposed a Mixed Integer Optimization (MIO) approach for solving penalized classification and regression problems with a penalty that is a combination of ℓ_0 and ℓ_1 penalties. However, they only considered low-dimensional problems with p in the 10s and n in the 100s. Bertsimas et al. (2016) also considered an MIO approach for solving the best subset selection problem in linear regression with a possible side constraint. Their approach can solve problems with moderate sample sizes and moderate dimensions in minutes, for example, for $(n, p) \approx (100, 1000)$ or $(n, p) \approx (1000, 100)$. For the $p > n$ examples, the authors carried out all the computations on Columbia University's high performance computing facility using a commercial MIO solver GUROBI (Gurobi Optimization, 2015). In comparison, our proposed approach can deal with high-dimensional models. For the examples we consider in our simulation studies with $(n, p) = (5000, 50000)$, it can find the solution in seconds on a personal laptop computer.

1.2 Contributions

SDAR is a new approach for fitting sparse, high-dimensional regression models. Compared with the penalized methods, SDAR generates a sequence of solutions $\{\beta^k, k \geq 1\}$ to the KKT system of the ℓ_0 penalized criterion, which can be viewed as a primal-dual active set method for solving the ℓ_0 regularized least squares problem with a changing regularization parameter λ in each iteration (this will be explained in detail in Section 2).

We show that SDAR achieves sharp estimation error bounds within a finite number of iterations. Specifically, we show that: (a) under a sparse Riesz condition on X and a sparsity assumption on β^*, $\|\beta^k - \beta^*\|_2$ achieves the minimax error bound up to a constant factor with high probability in $O(\sqrt{J}\log(R))$ iterations, where J is the number of important predictors and R is the relative magnitude of the nonzero target coefficients (the exact definitions of J and R are given in Section 3); (b) under a mutual coherence condition on X and a sparsity assumption on β^*, the $\|\beta^k - \beta^*\|_\infty$ achieves the optimal error bound $O(\sigma\sqrt{\log(p)/n})$ in $O(\log(R))$ iterations; (c) under the conditions in (a) and (b), with high probability, β^k coincides with the oracle least squares estimator in $O(\sqrt{J}\log(R))$ and $O(\log(R))$ iterations, respectively, if J is available and the minimum magnitude of the nonzero elements of β^* is of the order $O(\sigma\sqrt{2\log(p)/n})$, which is the optimal magnitude of detectable signal.

An interesting aspect of the result in (b) is that the number of iterations for SDAR to achieve the optimal error bound is $O(\log(R))$, which does not depend on the underlying sparsity level. This is an appealing feature for the problems with a large triple (n, p, J). We also analyze the computational cost of SDAR and show that it is $O(np)$ per iteration, comparable to the existing penalized methods and the greedy methods.

In summary, the main contributions of this paper are as follows.

- We propose a new approach to fitting sparse, high-dimensional regression models. The approach seeks to directly approximate the solutions to the KKT equations for the ℓ_0 penalized problem.

- We show that the sequence of solutions $\{\beta^k, k \geq 1\}$ generated by the SDAR achieves sharp error bounds within a finite number of iterations.

- We also consider an adaptive version of SDAR, or simply ASDAR, by tuning the size of the fitted model based on a data driven procedure such as the BIC. Our simulation studies demonstrate that SDAR/ASDAR outperforms the Lasso, MCP and several greedy methods in terms of accuracy and efficiency in the generating models we considered.

1.3 Notation

For a column vector $\beta = (\beta_1, \ldots, \beta_p)' \in \mathbb{R}^p$, denote its q-norm by $\|\beta\|_q = (\sum_{i=1}^p |\beta_i|^q)^{1/q}, q \in [1, \infty]$, and its number of nonzero elements by $\|\beta\|_0$. Let $\mathbf{0}$ denote a column vector in $\mathbb{R}^p$ or a matrix whose elements are all 0. Let $S = \{1, 2, ..., p\}$. For any A and $B \subseteq S$ with length $|A|$ and $|B|$, let $\beta_A = (\beta_i, i \in A) \in \mathbb{R}^{|A|}$, $X_A = (X_i, i \in A) \in \mathbb{R}^{n\times|A|}$, and let $X_{AB} \in \mathbb{R}^{|A|\times|B|}$ be a submatrix of X whose rows and columns are listed in A and B, respectively. Let $\beta|_A \in \mathbb{R}^p$ be a vector with its i-th element $(\beta|_A)_i = \beta_i \mathbf{1}(i \in A)$, where $\mathbf{1}(\cdot)$ is the indicator function. Denote the support of β by $\text{supp}(\beta)$. Denote $A^* = \text{supp}(\beta^*)$ and $K = \|\beta^*\|_0$. Let $\|\beta\|_{k,\infty}$ and $|\beta|_{\min}$ be the kth largest elements (in absolute value) and the minimum absolute value of β, respectively. Denote the operator norm of X induced by the vector 2-norm by $\|X\|$. Let $\mathbb{I}$ be an identity matrix.

1.4 Organization

In Section 2 we develop the SDAR algorithm based on the necessary conditions for the ℓ_0 penalized solutions. In Section 3 we establish the nonasymptotic error bounds of the SDAR solutions. In Section 4 we describe the adaptive SDAR, or ASDAR. In Section 5 we analyze the computational complexity of SDAR and ASDAR. In Section 6 we compare SDAR with several greedy methods and a screening method. In Section 7 we conduct simulation studies to evaluate the performance of SDAR/ASDAR and compare it with Lasso, MCP, FoBa and DesGras. We conclude in Section 8 with some final remarks. The proofs are given in the Appendix.

2. Derivation of SDAR

Consider the Lagrangian form of the ℓ_0 regularized minimization problem (2),

$$\min_{\beta\in\mathbb{R}^p} \frac{1}{2n}\|X\beta - y\|_2^2 + \lambda\|\beta\|_0. \tag{3}$$

Lemma 1 *Let $\beta^\diamond$ be a coordinate-wise minimizer of (3). Then $\beta^\diamond$ satisfies:*

$$\begin{cases} d^\diamond = X'(y - X\beta^\diamond)/n, \\ \beta^\diamond = H_\lambda(\beta^\diamond + d^\diamond), \end{cases} \tag{4}$$

where $H_\lambda(\cdot)$ is the hard thresholding operator defined by

$$(H_\lambda(\beta))_i = \begin{cases} 0, & \text{if } |\beta_i| < \sqrt{2\lambda}, \\ \beta_i, & \text{if } |\beta_i| \geq \sqrt{2\lambda}. \end{cases} \tag{5}$$

Conversely, if $\beta^\diamond$ and $d^\diamond$ satisfy (4)*, then $\beta^\diamond$ is a local minimizer of* (3)*.*

Remark 2 *Lemma 1 gives the KKT condition of the ℓ_0 regularized minimization problem (3), which is also derived in Jiao et al. (2015). Similar results for SCAD, MCP and capped-ℓ_1 regularized least squares models can be derived by replacing the hard thresholding operator in* (4) *with their corresponding thresholding operators, see Huang et al. (2018) for details.*

Let $A^\diamond = \text{supp}(\beta^\diamond)$ and $I^\diamond = (A^\diamond)^c$. Suppose that the rank of $X_{A^\diamond}$ is $|A^\diamond|$. From the definition of $H_\lambda(\cdot)$ and (4) it follows that

$$A^\diamond = \left\{i \in S \middle| \, |\beta_i^\diamond + d_i^\diamond| \geq \sqrt{2\lambda}\right\}, \quad I^\diamond = \left\{i \in S \middle| \, |\beta_i^\diamond + d_i^\diamond| < \sqrt{2\lambda}\right\},$$

and

$$\begin{cases} \beta_{I^\diamond}^\diamond = \mathbf{0}, \\ d_{A^\diamond}^\diamond = \mathbf{0}, \\ \beta_{A^\diamond}^\diamond = (X'_{A^\diamond}X_{A^\diamond})^{-1}X'_{A^\diamond}y, \\ d_{I^\diamond}^\diamond = X'_{I^\diamond}(y - X_{A^\diamond}\beta_{A^\diamond}^\diamond)/n. \end{cases}$$

We solve this system of equations iteratively. Let $\{\beta^k, d^k\}$ be the solution at the kth iteration. We approximate $\{A^\diamond, I^\diamond\}$ by

$$A^k = \left\{i \in S \middle| |\beta_i^k + d_i^k| \geq \sqrt{2\lambda}\right\}, \quad I^k = (A^k)^c. \tag{6}$$

Then we can obtain an updated approximation pair $\{\beta^{k+1}, d^{k+1}\}$ by

$$\begin{cases} \beta_{I^k}^{k+1} = \mathbf{0}, \\ d_{A^k}^{k+1} = \mathbf{0}, \\ \beta_{A^k}^{k+1} = (X'_{A^k}X_{A^k})^{-1}X'_{A^k}y, \\ d_{I^k}^{k+1} = X'_{I^k}(y - X_{A^k}\beta_{A^k}^{k+1})/n. \end{cases} \tag{7}$$

Now suppose we want the support of the solutions to have the size T, where $T \geq 1$ is a given integer. We can choose

$$\sqrt{2\lambda^k} \triangleq \|\beta^k + d^k\|_{T,\infty} \tag{8}$$

in (6). With this choice of λ, we have $|A^k| = T, k \geq 1$. Then with an initial β^0 and using (6) and (7) with the λ^k in (8), we obtain a sequence of solutions $\{\beta^k, k \geq 1\}$.

There are two key aspects of SDAR. In (6) we detect the support of the solution based on the sum of the primal (β^k) and dual (d^k) approximations and, in (7) we calculate the least squares solution on the detected support. Therefore, SDAR can be considered an iterative method for solving the KKT equations (4) with an important modification: a different λ value given in (8) in each step of the iteration is used. Thus we can also view SDAR as a method that combines adaptive thresholding using primal and dual information and least-squares fitting. We summarize SDAR in Algorithm 1.

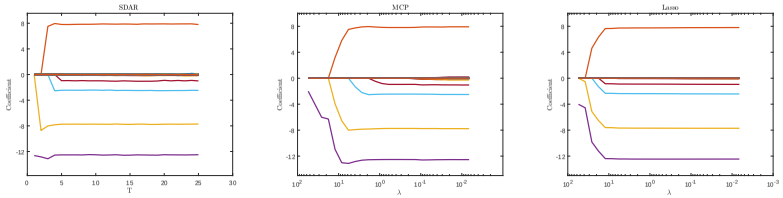

Figure 1: The solution paths of SDAR, MCP and Lasso. We see that large components were selected in by SDAR gradually when T increases. This is similar to Lasso and MCP as λ decreases.

As an example, Figure 1 shows the solution path of SDAR with $T = 1, 2, \ldots, 5K$ along with the MCP and the Lasso paths on $5K$ different λ values for a data set generated from a model with $(n = 50, p = 100, K = 5, \sigma = 0.3, \rho = 0.5, R = 10)$, which will be described in Section 7. The Lasso path is computed using LARS (Efron et al., 2004). Note that the SDAR path is a function of the fitted model size $T = 1, \ldots, L$, where L is the size of the largest fitted model. In comparison, the paths of MCP and Lasso are functions of the penalty parameter λ in a prespecified interval. In this example, when $T \leq K$, SDAR selects the first T largest components of β^* correctly. When $T > K$, there will be spurious elements included in the estimated support, the exact number of such elements is $T - K$. In Figure 1, the estimated coefficients of the spurious elements are close to zero.

Algorithm 1 Support detection and root finding (SDAR)

Require: β^0, $d^0 = X'(y - X\beta^0)/n$, T; set $k = 0$.
1: **for** $k = 0, 1, 2, \cdots$ **do**
2: $A^k = \{i \in S \big| |\beta_i^k + d_i^k| \geq \|\beta^k + d^k\|_{T,\infty}\}$, $I^k = (A^k)^c$
3: $\beta_{I^k}^{k+1} = \mathbf{0}$
4: $d_{A^k}^{k+1} = \mathbf{0}$
5: $\beta_{A^k}^{k+1} = (X'_{A^k} X_{A^k})^{-1} X'_{A^k} y$
6: $d_{I^k}^{k+1} = X'_{I^k}(y - X_{A^k}\beta_{A^k}^{k+1})/n$
7: **if** $A^{k+1} = A^k$, **then**
8: Stop and denote the last iteration by $\beta_{\hat{A}}, \beta_{\hat{I}}, d_{\hat{A}}, d_{\hat{I}}$
9: **else**
10: $k = k + 1$
11: **end if**
12: **end for**
Ensure: $\hat{\beta} = (\beta'_{\hat{A}}, \beta'_{\hat{I}})'$ as the estimate of β^*.

Remark 3 *If $A^{k+1} = A^k$ for some k we stop SDAR since the sequences generated by SDAR will not change. Under certain conditions, we will show that $A^{k+1} = A^k = supp(\beta^*)$ if k is large enough, i.e., the stop condition in SDAR will be active and the output is the oracle estimator when it stops.*

3. Nonasymptotic error bounds

In this section we present the nonasymptotic ℓ_2 and ℓ_∞ error bounds for the solution sequence generated by SDAR as given in Algorithm 1.

We say that X satisfies the sparse Rieze condition (SRC) (Zhang and Huang, 2008; Zhang, 2010a) with order s and spectrum bounds $\{c_-(s), c_+(s)\}$ if

$$0 < c_-(s) \leq \frac{\|X_A u\|_2^2}{n\|u\|_2^2} \leq c_+(s) < \infty, \forall\, 0 \neq u \in \mathbb{R}^{|A|} \text{ with } A \subset S \text{ and } |A| \leq s.$$

We denote this condition by $X \sim \text{SRC}\{s, c_-(s), c_+(s)\}$. The SRC gives the range of the spectrum of the diagonal sub-matrices of the Gram matrix $G = X'X/n$. The spectrum of the off diagonal sub-matrices of G can be bounded by the sparse orthogonality constant $\theta_{a,b}$ defined as the smallest number such that

$$\theta_{a,b} \geq \frac{\|X'_A X_B u\|_2}{n\|u\|_2}, \forall\, 0 \neq u \in \mathbb{R}^{|B|} \text{ with } A, B \subset S, |A| \leq a, |B| \leq b, \text{ and } A \cap B = \emptyset.$$

Another useful quantity is the mutual coherence μ defined as $\mu = \max_{i \neq j} |G_{i,j}|$, which characterizes the minimum angle between different columns of $X/\sqrt{n}$. Some useful properties of these quantities are summarized in Lemma 20 in the Appendix.

In addition to the regularity conditions on the design matrix, another key condition is the sparsity of the regression parameter β^*. The usual sparsity condition is to assume that the regression parameter β_i^* is either nonzero or zero and that the number of nonzero coefficients is relatively small. This strict sparsity condition is not realistic in many problems. Here we allow that β^* may not be strictly sparse but most of its elements are small. Let $A_J^* = \{i \in S : |\beta_i^*| \geq \|\beta^*\|_{J,\infty}\}$ be the set of the indices of the first J largest components of β^*. Typically, we have $J \ll n$. Let

$$R = \frac{\bar{M}}{\bar{m}}, \tag{9}$$

where $\bar{m} = \min\{|\beta_i^*|, i \in A_J^*\}$ and $\bar{M} = \max\{|\beta_i^*|, i \in A_J^*\}$. Since $\beta^* = \beta^*|_{A_J^*} + \beta^*|_{(A_J^*)^c}$, we can transform the non-exactly sparse model (1) to the following exactly sparse model by including the small components of β^* in the noise,

$$y = X\bar{\beta}^* + \bar{\eta}, \tag{10}$$

where

$$\bar{\beta}^* = \beta^*|_{A_J^*} \text{ and } \bar{\eta} = X\beta^*|_{(A_J^*)^c} + \eta. \tag{11}$$

Let $R_J = \|\beta^*|_{(A_J^*)^c}\|_2 + \|\beta^*|_{(A_J^*)^c}\|_1/\sqrt{J}$, which is a measure of the magnitude of the small components of β^* outside A_J^*. Of course, $R_J = 0$ if β^* is exactly K-sparse with $K \leq J$. Without loss of generality, we let $J = K$, $m = \bar{m}$ and $M = \bar{M}$ for simplicity if β^* is exactly K-sparse.

Let $\beta^{J,o}$ be the oracle estimator defined as $\beta^{J,o} = \arg\min_\beta\{\frac{1}{2n}\|y - X\beta\|_2^2, \beta_j = 0, j \notin A_J^*\}$, that is, $\beta_{A_J^*}^{J,o} = X_{A_J^*}^\dagger y$ and $\beta_{(A_J^*)^c}^{J,o} = \mathbf{0}$, where $X_{A_J^*}^\dagger$ is the generalized inverse of $X_{A_J^*}$ and equals to $(X'_{A_J^*} X_{A_J^*})^{-1} X'_{A_J^*}$ if $X_{A_J^*}$ is of full column rank. So $\beta^{J,o}$ is obtained by keeping the predictors corresponding to the J largest components of β^* in the model and dropping the other predictors. Obviously, $\beta^{J,o} = \beta^o$ if β^* is exactly K-sparse, where $\beta_{A^*}^o = X_{A^*}^\dagger y, \beta_{(A^*)^c}^o = \mathbf{0}$.

3.1 ℓ_2 error bounds

Let $1 \le T \le p$ be a given integer used in Algorithm 1. We require the following basic assumptions on the design matrix X and the error vector η.

(A1) The input integer T used in Algorithm 1 satisfies $T \ge J$.

(A2) For the input integer T used in Algorithm 1, $X \sim \mathrm{SRC}\{2T, c_-(2T), c_+(2T)\}$.

(A3) The random errors $\eta_1, \ldots, \eta_n$ are independent and identically distributed with mean zero and sub-Gaussian tails, that is, there exists a $\sigma \ge 0$ such that $E[\exp(t\eta_i)] \le \exp(\sigma^2 t^2/2)$ for $t \in \mathbb{R}^1$, $i = 1, \ldots, n$.

Let

$$\gamma = \frac{2\theta_{T,T} + (1+\sqrt{2})\theta_{T,T}^2}{c_-(T)^2} + \frac{(1+\sqrt{2})\theta_{T,T}}{c_-(T)}.$$

Define

$$h_2(T) = \max_{A \subseteq S: |A| \le T} \|X_A' \bar{\eta}\|_2 / n, \tag{12}$$

where $\bar{\eta}$ is defined in (11).

Theorem 4 *Let T be the input integer used in Algorithm 1, where $1 \le T \le p$. Suppose $\gamma < 1$.*

(i) Assume (A1) and (A2) hold. We have

$$\|\bar{\beta}^*|_{A_J^* \setminus A^{k+1}}\|_2 \le \gamma^{k+1}\|\bar{\beta}^*\|_2 + \frac{\gamma}{(1-\gamma)\theta_{T,T}} h_2(T), \tag{13}$$

$$\|\beta^{k+1} - \bar{\beta}^*\|_2 \le b_1 \gamma^k \|\bar{\beta}^*\|_2 + b_2 h_2(T), \tag{14}$$

where

$$b_1 = 1 + \frac{\theta_{T,T}}{c_-(T)} \quad \text{and} \quad b_2 = \frac{\gamma}{(1-\gamma)\theta_{T,T}} b_1 + \frac{1}{c_-(T)}. \tag{15}$$

(ii) Assume (A1)-(A3) hold. Then for any $\alpha \in (0, 1/2)$, with probability at least $1 - 2\alpha$,

$$\|\bar{\beta}^*|_{A_J^* \setminus A^{k+1}}\|_2 \le \gamma^{k+1}\|\bar{\beta}^*\|_2 + \frac{\gamma}{(1-\gamma)\theta_{T,T}} \varepsilon_1, \tag{16}$$

$$\|\beta^{k+1} - \bar{\beta}^*\|_2 \le b_1 \gamma^k \|\bar{\beta}^*\|_2 + b_2 \varepsilon_1, \tag{17}$$

where

$$\varepsilon_1 = c_+(J) R_J + \sigma\sqrt{T}\sqrt{2\log(p/\alpha)/n}. \tag{18}$$

Remark 5 *Part (i) of Theorem 4 establishes the ℓ_2 bounds for the approximation errors of the solution sequence generated by the SDAR algorithm at the $(k+1)$th iteration for a general noise vector η. In particular, (13) gives the ℓ_2 bound of the elements in A_J^* not included in the active set in the $(k+1)$th iteration, and (14) provides an upper bound for the ℓ_2 estimation error of β^{k+1}. These error bounds decay geometrically to the model error measured by $h_2(T)$ up to a constant factor. Part (ii) specializes these results to the case where the noise terms are sub-Gaussian.*

Remark 6 *Assumption (A1) is necessary for SDAR to select at least J nonzero features. The SRC in (A2) has been used in the analysis of the Lasso and MCP (Zhang and Huang, 2008; Zhang, 2010a). Sufficient conditions are provided for a design matrix to satisfy the SRC in Propositions 4.1 and 4.2 in Zhang and Huang (2008). For example, the SRC would follow from a mutual coherence condition. Let $c(T) = (1 - c_-(2T)) \vee (c_+(2T) - 1)$, which is closely related to the the RIP (restricted isometry property) constant δ_{2T} for X (Candes and Tao, 2005). By (43) in the Appendix, it can be verified that a sufficient condition for $\gamma < 1$ is $c(T) \le 0.1599$, i.e., $c_+(2T) \le 1.1599$, $c_-(2T) \ge 0.8401$. The sub-Gaussian condition (A3) is often assumed in the literature on sparse estimation and slightly weaker than the standard normality assumption. It is used to calculate the tail probabilities of certain maximal functions of the noise vector η.*

Remark 7 *Several greedy algorithms have also been studied under the assumptions related to the sparse Riesz condition. For example, Zhang (2011b) studied OMP under the condition $c_+(T)/c_-(31T) \le 2$. Zhang (2011a) analyzed the forward-backward greedy algorithm (FoBa) under the condition $8(T+1) \le (s-2)Tc_-^2(sT)$, where $s > 0$ is a properly chosen parameter. GraDes has been analyzed under the RIP condition $\delta_{2T} \le 1/3$ (Garg and Khandekar, 2009). These conditions and (A2) are related but do not imply each other. The order of ℓ_2-norm estimation error of SDAR is at least as good as that of the above mentioned greedy methods since it achieves the minimax error bound, see, Remark 10 below. A high level comparison between SDAR and the greedy algorithms will be given in Section 6.*

Corollary 8 *(i) Suppose (A1) and (A2) hold. Then*

$$\|\beta^k - \bar{\beta}^*\|_2 \le c h_2(T) \quad \text{if} \quad k \ge \log_{\frac{1}{\gamma}} \frac{\sqrt{J}\bar{M}}{h_2(T)}, \tag{19}$$

where $c = b_1 + b_2$ with b_1 and b_2 defined in (15).

Furthermore, assume $\bar{m} \ge \frac{\gamma h_2(T)}{(1-\gamma)\theta_{T,T}\xi}$ for some $0 < \xi < 1$, then we have

$$A^k \supseteq A_J^* \quad \text{if} \quad k \ge \log_{\frac{1}{\gamma}} \frac{\sqrt{J}R}{1-\xi}. \tag{20}$$

(ii) Suppose (A1)-(A3) hold. Then, for any $\alpha \in (0, 1/2)$, with probability at least $1 - 2\alpha$, we have

$$\|\beta^k - \bar{\beta}^*\|_2 \le c\varepsilon_1 \quad \text{if} \quad k \ge \log_{\frac{1}{\gamma}} \frac{\sqrt{J}\bar{M}}{\varepsilon_1}, \tag{21}$$

where ε_1 is defined in (18). Furthermore, assume $\bar{m} \ge \frac{\varepsilon_1 \gamma}{(1-\gamma)\theta_{T,T}\xi}$ for some $0 < \xi < 1$, then with probability at least $1 - 2\alpha$, we have

$$A^k \supseteq A_J^* \quad \text{if} \quad k \ge \log_{\frac{1}{\gamma}} \frac{\sqrt{J}R}{1-\xi}. \tag{22}$$

(iii) Suppose β^* is exactly K-sparse. Let $T = K$ in SDAR. Suppose (A1)-(A3) hold and $m \ge \frac{\gamma}{(1-\gamma)\theta_{T,T}\xi}\sigma\sqrt{K}\sqrt{2\log(p/\alpha)/n}$ for some $0 < \xi < 1$, we have with probability

at least $1-2\alpha$, $A^k = A^{k+1} = A^*$ *if* $k \geq \log_{\frac{1}{\gamma}}(\sqrt{K}R/(1-\xi))$, *i.e., with at most* $O(\log\sqrt{K}R)$ *iterations, SDAR stops and the output is the oracle least squares estimator* β^o.

Remark 9 *Parts (i) and (ii) in Corollary 8 show that the SDAR solution sequence achieves the minimax* ℓ_2 *error bound up to a constant factor and its support covers* A^*_J *within a finite number of iterations. In particular, the number of iterations required is* $O(\log(\sqrt{J}R))$, *depending on the sparsity level* J *and the relative magnitude* R *of the coefficients of the important predictors. In the case of exact sparsity with* K *nonzero coefficients in the model, part (iii) provides conditions under which the SDAR solution is the same as the oracle least squares estimator in* $O(\log(\sqrt{K}R))$ *iterations with high probability.*

Remark 10 *Suppose* β^* *is exactly* K*-sparse. In the event* $\|\eta\|_2 \leq \varepsilon$, *part (i) of Corollary 8 implies* $\|\beta^k - \beta^*\|_2 = O(\varepsilon/\sqrt{n})$ *if* k *is sufficiently large. Under certain conditions on the RIP constant of* X, *Candes et al. (2006) showed that* $\|\hat{\beta} - \beta^*\|_2 = O(\varepsilon/\sqrt{n})$, *where* $\hat{\beta}$ *solves*

$$\min_{\beta\in\mathbb{R}^p} \|\beta\|_1 \text{ subject to } \|X\beta - y\|_2 \leq \varepsilon. \tag{23}$$

So the result here is similar to that of Candes et al. (2006) (they assumed the columns of X *are unit-length normalized, here the result is stated for the case where the columns of* X *are* $\sqrt{n}$*-length normalized). However, it is a nontrivial task to solve* (23) *in high-dimensional settings. In comparison, SDAR only involves simple computational steps.*

Remark 11 *If* β^* *is exactly* K*-sparse and* $T = K$, *part (ii) of Corollary 8 implies that SDAR achieves the minimax error bound (Raskutti et al., 2011), that is,*

$$\|\beta^k - \beta^*\|_2 \leq c\sigma\sqrt{K}\sqrt{2\log(p/\alpha)/n}$$

with high probability if $k \geq \log_{\frac{1}{\gamma}} \frac{\sqrt{K}M}{\sigma\sqrt{T}\sqrt{2\log(p/\alpha)/n}}$.

3.2 ℓ_∞ error bounds

We now consider the ℓ_∞ error bounds of SDAR. We replace condition (A2) by

(A2*) The mutual coherence μ of X satisfies $T\mu \leq 1/4$.

Let

$$\gamma_\mu = \frac{(1+2T\mu)T\mu}{1-(T-1)\mu} + 2T\mu \text{ and } c_\mu = \frac{16}{3(1-\gamma_\mu)} + \frac{5}{3}.$$

Define

$$h_\infty(T) = \max_{A\subseteq S:|A|\leq T} \|X'_A\bar{\eta}\|_\infty/n, \tag{24}$$

where $\bar{\eta}$ is defined in (11).

Theorem 12 *Let* T *be the input integer used in Algorithm 1, where* $1 \leq T \leq p$.

(i) Assume (A1) and (A2) hold. We have*

$$\|\bar{\beta}^*|_{A^*_J\setminus A^{k+1}}\|_\infty < \gamma_\mu^{k+1}\|\bar{\beta}^*\|_\infty + \frac{4}{1-\gamma_\mu}h_\infty(T), \tag{25}$$

$$\|\beta^{k+1} - \bar{\beta}^*\|_\infty < \frac{4}{3}\gamma_\mu^k\|\bar{\beta}^*\|_\infty + \frac{4}{3}(\frac{4}{1-\gamma_\mu}+1)h_\infty(T), \tag{26}$$

(ii) Assume (A1), (A2) and (A3) hold. For any* $\alpha \in (0,1/2)$, *with probability at least* $1-2\alpha$,

$$\|\bar{\beta}^*|_{A^*_J\setminus A^{k+1}}\|_\infty < \gamma_\mu^{k+1}\|\bar{\beta}^*\|_\infty + \frac{4}{1-\gamma_\mu}\varepsilon_2, \tag{27}$$

$$\|\beta^{k+1} - \bar{\beta}^*\|_\infty < \frac{4}{3}\gamma_\mu^k\|\bar{\beta}^*\|_\infty + \frac{4}{3}(\frac{4}{1-\gamma_\mu}+1)\varepsilon_2, \tag{28}$$

where

$$\varepsilon_2 = (1+(T-1)\mu)R_J + \sigma\sqrt{2\log(p/\alpha)/n}. \tag{29}$$

Remark 13 *Part (i) of Theorem 12 establishes the* ℓ_∞ *bounds for the approximation errors of the solution sequence at the* $(k+1)$*th iteration for a general noise vector* η. *In particular, (25) gives the* ℓ_∞ *bound of the elements in* A^*_J *not selected at the* $(k+1)$*th iteration, and (26) provides an upper bound for the* ℓ_∞ *estimation error of* β^{k+1}. *These errors bounds decay geometrically to the model error measured by* $h_\infty(T)$ *up to a constant factor. Part (ii) specializes these to the case where the noise terms are sub-Gaussian.*

Corollary 14 *(i) Suppose (A1) and (A2*) hold. Then*

$$\|\beta^k - \bar{\beta}^*\|_\infty \leq c_\mu h_\infty(T) \quad \text{if} \quad k \geq \log_{\frac{1}{\gamma_\mu}} \frac{4\bar{M}}{h_\infty(T)}. \tag{30}$$

Furthermore, assume $\bar{m} \geq \frac{4h_\infty(T)}{(1-\gamma_\mu)\xi}$ *with* $\xi < 1$, *then we have*

$$A^k \supseteq A^*_J \quad \text{if} \quad k \geq \log_{\frac{1}{\gamma_\mu}} \frac{R}{1-\xi}. \tag{31}$$

(ii) Suppose (A1), (A2) and (A3) hold. Then for any* $\alpha \in (0,1/2)$, *with probability at least* $1-2\alpha$,

$$\|\beta^k - \bar{\beta}^*\|_\infty \leq c_\mu\varepsilon_2 \quad \text{if} \quad k \geq \log_{\frac{1}{\gamma_\mu}} \frac{4\bar{M}}{\varepsilon_2}, \tag{32}$$

where ε_2 *is given in (29).*

Furthermore, assume $\bar{m} \geq \frac{4\varepsilon_2}{\xi(1-\gamma_\mu)}$ *for some* $0 < \xi < 1$, *then*

$$A^k \supseteq A^*_J \quad \text{if} \quad k \geq \log_{\frac{1}{\gamma_\mu}} \frac{R}{1-\xi}. \tag{33}$$

(iii) Suppose β^* is exactly K-sparse. Let $T = K$ in SDAR. Suppose (A1), (A2) and (A3) hold and $m \geq \frac{4}{\xi(1-\gamma_\mu)}\sigma\sqrt{2\log(p/\alpha)/n}$ for some $0 < \xi < 1$. We have with probability at least $1-2\alpha$, $A^k = A^{k+1} = A^*$ if $k \geq \log_{\frac{1}{\gamma_\mu}} \frac{R}{1-\xi}$, i.e., with at most $O(\log R)$ iterations, SDAR stops and the output is the oracle least squares estimator β^o.*

Remark 15 *Theorem 4 and Corollary 8 can be derived from Theorem 12 and Corollary 14, respectively, by using the relationship between the ℓ_∞ norm and the ℓ_2 norm. Here we present them separately because (A2) is weaker than (A2*). The stronger assumption (A2*) brings us some new insights into the SDAR, i.e., the sharp ℓ_∞ error bound, based on which we can show that the worst case iteration complexity of SDAR does not depend on the underlying sparsity level, as stated in parts (ii) and (iii) of Corollary 14.*

Remark 16 *The mutual coherence condition $s\mu \leq 1$ with $s \geq 2K-1$ is used in the study of OMP and Lasso under the assumption that β^* is exactly K-sparse. In the noiseless case with $\eta = 0$, Tropp (2004); Donoho and Tsaig (2008) showed that under the condition $(2K-1)\mu < 1$, OMP can recover β^* exactly in K steps. In the noisy case with $\|\eta\|_2 \leq \varepsilon$, Donoho et al. (2006) proved that OMP can recover the true support if $(2K-1)\mu \leq 1-(2\varepsilon/m)$. Cai and Wang (2011) gave a sharp analysis of OMP under the condition $(2K-1)\mu < 1$. The mutual coherence condition $T\mu \leq 1/4$ in (A2*) is a little stronger than those used in the analysis of the OMP. However, under (A2*) we obtain a sharp ℓ_∞ error bound, which is not available for OMP in the literature. Furthermore, Corollary 14 implies that the number of iterations of SDAR does not depend on the sparsity level, which is a surprising result and does not appear in the literature on greedy methods, see Remark 18 below. Lounici (2008); Zhang (2009) derived an ℓ_∞ estimation error bound for the Lasso under the conditions $K\mu < 1/7$ and $K\mu \leq 1/4$, respectively. However, they needed a nontrivial Lasso solver for computing an approximate solution while SDAR only involves simple computational steps.*

Remark 17 *Suppose β^* is exactly K-sparse. Part (ii) of Corollary 14 implies that the sharp error bound*

$$\|\beta^k - \beta^*\|_\infty \leq c_\mu \sigma\sqrt{2\log(p/\alpha)/n} \tag{34}$$

is achieved with high probability if $k \geq \log_{\frac{1}{\gamma_\mu}} \frac{M}{\sigma\sqrt{2\log(p/\alpha)/n}}$.

Remark 18 *Suppose β^* is exactly K-sparse. Part (iii) of Corollary 14 implies that with high probability, the oracle estimator can be recovered in no more than $O(\log R)$ steps if we set $T = K$ in SDAR and the minimum magnitude of the nonzero elements of β^* is $O(\sigma\sqrt{2\log(p)/n})$, which is the optimal magnitude of detectable signals.*

Remark 19 *The number of iterations in Corollary 14 depends on the relative magnitude R, but not the sparsity level K, see Figure 2 for the numerical results supporting this. This improves the result in part (iii) of Corollary 8. This is a surprising result since as far as we know the number of iterations for the greedy methods to recover A^* depends on K, see for example, Garg and Khandekar (2009).*

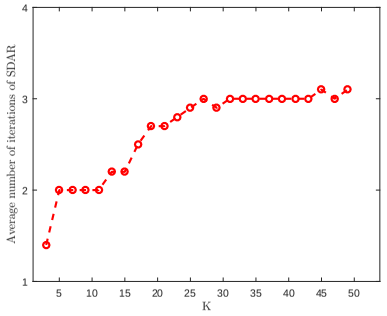

Figure 2: The average number of iterations of SDAR as K increases.

Figure 2 shows the average number of iterations of SDAR with $T = K$ based on 100 independent replications on data sets generated from a model with $(n = 500, p = 1000, K = 3:2:50, \sigma = 0.01, \rho = 0.1, R = 1)$, which will be described in Section 7.4. We can see that as the sparsity level increases from 3 to 50 the average number of iterations of SDAR remains stable, ranging from 1 to 3, which supports the assertion in Corollary 14. More numerical comparison on number of iterations with greedy methods are shown in Section 7.2.

3.3 A brief high-level description of the proofs

The detailed proofs of Theorems 4 and 12 and their corollaries are given in the Appendix. Here we describe the main ideas behind the proofs and point out the places where the SRC and the mutual coherence condition are used.

SDAR iteratively detects the support of the solution and then solves a least squares problem on the support. Therefore, to study the convergence properties of the sequence generated by SDAR, the key is to show that the sequence of active sets A^k can approximate A^*_J more and more accurately as k increases. Let

$$D(A^k) = \|\bar{\beta}^*|_{A^*_J \setminus A^k}\|, \tag{35}$$

where $\|\cdot\|$ can be either the ℓ_2 norm or the ℓ_∞ norm. This is a measure of the difference between A^*_J and A^k at the kth iteration in terms of the norm of the coefficients in A^*_J but not in A^k. A crucial step is to show that $D(A^k)$ decays geometrically to a value bounded by $h(T)$ up to a constant factor, where $h(T)$ is $h_2(T)$ defined in (12) or $h_\infty(T)$ in (24). Here $h(T)$ is a measure of the intrinsic error due to the noise η and the approximate error in (10). Specifically, much effort is spent on establishing the inequality (Lemma 27 in the Appendix)

$$D(A^{k+1}) \leq \gamma^* D(A^k) + c^* h(T), k = 0, 1, 2, \ldots, \tag{36}$$

where $\gamma^* = \gamma$ for the ℓ_2 results in Theorem 4 and $\gamma^* = \gamma_\mu$ for the ℓ_∞ results in Theorem 12, and $c^* > 0$ is a constant depending on the design matrix. The SRC (A2) and the

mutual coherence condition (A2*) play a critical role in establishing (36). Clearly, for this inequality to be useful, we need $0 < \gamma^* < 1$.

Another useful inequality is

$$\|\beta^{k+1} - \bar{\beta}^*\| \le c_1 D(A^k) + c_2 h(T), \tag{37}$$

where c_1 and c_2 are positive constants depending on the design matrix, see Lemma 23 in the Appendix. The SRC and the mutual coherence condition are needed to establish this inequality for the ℓ_2 norm and the ℓ_∞ norm, respectively. Then combining (36) and (37), we can show part (i) of Theorem 4 and part (i) of Theorem 12.

The inequalities (36) and (37) hold for any noise vector η. Under the sub-Gaussian assumption for η, $h(T)$ can be controlled by the sum of unrecoverable approximation error R_J and the universal noise level $O(\sigma\sqrt{2\log(p)/n})$ with high probability. This leads to the results in the remaining parts of Theorems 4 and 12, as well as Corollaries 8 and 14.

4. Adaptive SDAR

In practice, because the sparsity level of the model is usually unknown, we can use a data driven procedure to determine an upper bound, T, for the number of important variables, J, used in SDAR (Algorithm 1). The idea is to take T as a tuning parameter, so T plays a role similar to the penalty parameter λ in a penalized method. We can run SDAR from $T = 1$ to a large $T = L$. For example, we can take $L = O(n/\log(n))$ as suggested by Fan and Lv (2008), which is an upper bound of the largest possible model that can be consistently estimated with sample size n. By doing so we obtain a solution path $\{\hat{\beta}(T) : T = 0, 1, \ldots, L\}$, where $\hat{\beta}(0) = 0$, that is, $T = 0$ corresponds to the null model. Then we use a data driven criterion, such as HBIC (Wang et al., 2013), to select a $T = \hat{T}$ and use $\hat{\beta}(\hat{T})$ as the final estimate. The overall computational complexity of this process is $O(Lnp\log(R))$, see Section 5.

We can also compute the path by increasing T along a subsequence of the integers in $[1, L]$, for example, by taking a geometrically increasing subsequence. This will reduce the computational cost, but here we consider the worst-case scenario.

We note that tuning T is no more difficult than tuning a continuous penalty parameter λ in a penalized method. Indeed, we can simply increase T one by one from $T = 0$ to $T = L$ (or along a subsequence). In comparison, in tuning the value of λ based on a pathwise solution over an interval $[\lambda_{\min}, \lambda_{\max}]$, where $\lambda_{\max}$ corresponds to the null model and $\lambda_{\min} > 0$ is a small value, we need to determine the grid of λ values on $[\lambda_{\min}, \lambda_{\max}]$ as well as $\lambda_{\min}$. Here $\lambda_{\min}$ corresponds to the largest model on the solution path. In the numerical implementation of the coordinate descent algorithms for the Lasso (Friedman et al., 2007), MCP and SCAD (Breheny and Huang, 2011), $\lambda_{\min} = \alpha\lambda_{\max}$ for a small α, for example, $\alpha = 0.0001$. Determining the value of L is somewhat similar to determining $\lambda_{\min}$. However, L has the meaning of the model size, but the meaning of $\lambda_{\min}$ is less explicit.

We also have the option to stop the iteration early according to other criterions. For example, we can run SDAR by gradually increasing T until the change in the consecutive solutions is smaller than a given value. Candes et al. (2006) proposed to recover β^* based on (23) by finding the most sparse solution whose residual sum of squares is smaller than a

prespecified noise level ε. Inspired by this, we can also run SDAR by increasing T gradually until the residual sum of squares is smaller than a prespecified value ε.

We summarize these ideas in Algorithm 2 below.

Algorithm 2 Adaptive SDAR (ASDAR)

Require: Initial guess β^0, d^0, an integer τ, an integer L, and an early stopping criterion (optional). Set $k = 1$.

1: **for** $k = 1, 2, \cdots$ **do**
2: Run Algorithm 1 with $T = \tau k$ and with initial value (β^{k-1}, d^{k-1}). Denote the output by (β^k, d^k).
3: **if** the early stopping criterion is satisfied or $T > L$ **then**
4: stop
5: **else**
6: $k = k + 1$.
7: **end if**
8: **end for**

Ensure: $\hat{\beta}(\hat{T})$ as estimations of β^*.

5. Computational complexity

We look at the number of floating point operations line by line in Algorithm 1. Clearly it takes $O(p)$ flops to finish step 2-4. In step 5, we use conjugate gradient (CG) method (Golub and Van Loan, 2012) to solve the linear equation iteratively. During the CG iterations the main operation include two matrix-vector multiplications, which cost $2n|A_{k+1}|$ flops (the term $X'y$ on the right-hand side can be precomputed and stored). Therefore the number of CG iterations is smaller than $p/(2|A_{k+1}|)$, this ensures that the number of flops in step 5 is $O(np)$. In step 6, calculating the matrix-vector product costs np flops. In step 7, checking the stopping condition needs $O(p)$ flops. So the the overall cost per iteration of Algorithm 1 is $O(np)$. By Corollary 14 it needs no more than $O(\log(R))$ iterations to get a good solution for Algorithm 1 under the certain conditions. Therefore the overall cost of Algorithm 1 is $O(np\log(R))$ for exactly sparse and approximately sparse case under proper conditions.

Now we consider the cost of ASDAR (Algorithm 2). Assume ASDAR is stopped when $k = L$. Then the above discussion shows the the overall cost of Algorithm 2 is bounded by $O(Lnp\log(R))$ which is very efficient for large scale high dimension problem since the cost increases linearly in the ambient dimension p.

6. Comparison with greedy and screening methods

We give a high level comparison between SDAR and several greedy and screening methods, including OMP (Mallat and Zhang, 1993; Tropp, 2004; Donoho et al., 2006; Cai and Wang, 2011; Zhang, 2011b), FoBa (Zhang, 2011a), IHT (Blumensath and Davies, 2009; Jain et al., 2014) or GraDes (Garg and Khandekar, 2009), and SIS (Fan and Lv, 2008). These greedy methods iteratively select/remove one or more variables and project the response vector onto the linear subspace spanned by the variables that have already been selected. From

this point of view, they and SDAR share a similar characteristic. However, OMP and FoBa, select one variable per iteration based on the current correlation, i.e., the dual variable d^k in our notation, while SDAR selects T variables at a time based on the sum of primal (β^k) and dual (d^k) information. The following interpretation in a low-dimensional setting with a small noise term may clarify the differences between these two approaches. If $X'X/n \approx \mathbb{I}$ and $\eta \approx 0$, we have

$$d^k = X'(y - X\beta^k)/n = X'(X\beta^* + \eta - X\beta^k)/n \approx \beta^* - \beta^k + X'\eta/n \approx \beta^* - \beta^k,$$

and

$$\beta^k + d^k \approx \beta^*.$$

Hence, SDAR can approximate the underlying support A^* more accurately than OMP and Foba. This is supported by the simulation results given in Section 7.

IHT (Blumensath and Davies, 2009; Jain et al., 2014) or GraDes (Garg and Khandekar, 2009), can be formulated as

$$\beta^{k+1} = H_K(\beta^k + s_k d^k), \tag{38}$$

where $H_K(\cdot)$ is the hard thresholding operator by keeping the first K largest elements and setting others to 0. The step size s_k is chosen as $s_k = 1$ and $s_k = 1/(1 + \delta_{2K})$ (where δ_{2K} is the RIP constant) for IHT and GraDes, respectively. IHT and GraDes use both primal and dual information to detect the support of the solution, which is similar to SDAR. But when the approximate active set is given, SDAR uses least squares fitting, which is more accurate than just keeping the largest elements by hard thresholding. This is supported by the simulation results given in Section 7. Jain et al. (2014) proposed an iterative hard thresholding algorithm for general high-dimensional sparse regressions. In the linear regression setting, the algorithm proposed in Jain et al. (2014) is the same as GraDes. Jain et al. (2014) also considered a two-stage IHT, which involves a refit step on the detected support. Yuan et al. (2018) extended gradient hard thresholding for least squares loss to a general class of convex losses and analyzed the estimation and sparsity recovery performance of their proposed method. Under restricted strongly convexity (RSS) and restricted strongly smoothness conditions (RSC), Jain et al. (2014) derived an error estimate between the approximate solutions and the oracle solution in ℓ_2 norm, which has the same order as our result in Section 3.1. There are some differences between SDAR and the two-stage IHT proposed in Jain et al. (2014). First, SDAR solves an $n \times K$ least squares problem at each iteration while the two-stage IHT involves two least-squares problems with larger sizes. The regularity conditions on X for SDAR concerns $2K \times 2K$ submatrices of X, while the regularity conditions for the two-stage IHT involves larger submatries of X. Second, our results are applicable to approximately sparse models. Jain et al. (2014) only considered exact sparse case. Third, we showed in (iii) of Corollary 3.1 that the iteration complexity of SDAR is $\mathcal{O}(\log K)$. In comparison, the iteration complexity of the two-stage IHT is $\mathcal{O}(K)$. We also established an ℓ_∞ norm estimation result and showed that the number of iterations of SDAR is independent of the sparsity level, see (iii) of Corollary 3.2. Last, we showed that the stopping criterion for SDAR can be archived in finitely many steps (Corollary 3.1 (iii) and Corollary 3.2. (iii)). However, Jain et al. (2014) did not discuss this issue.

Fan and Lv (2008) proposed SIS for dimension reduction in ultrahigh dimensional liner regression problems. This method selects variables with the T largest absolute values of $X'y$. To improve the performance of SIS, Fan and Lv (2008) also considered an iterative SIS, which iteratively selects more than one feature at a time until a desired number of variables are selected. They reported that the iterative SIS outperforms SIS numerically. However, the iterative SIS lacks a theoretical analysis. Interestingly, the first step in SDAR initialized with $\mathbf{0}$ is exactly the same as the SIS. But again the process of SDAR is different from the iterative SIS in that the active set of SDAR is determined based on the sum of primal and dual approximations while the iterative SIS uses dual only.

7. Simulation Studies

7.1 Implementation

We implemented SDAR/ASDAR, FoBa, GraDes and MCP in MatLab. For FoBa, our MatLab implementation follows the R package developed by Zhang (2011a). We optimize it by keeping track of rank-one updates after each greedy step. Our implementation of MCP uses the iterative threshholding algorithm (She, 2009) with warm starts. Publicly available Matlab packages for LARS (included in the SparseLab package) are used. Since LARS and FoBa add one variable at a time, we stop them when K variables are selected in addition to their default stopping conditions. Of course, doing so will reduce the computation time for these algorithms as well as improve accuracy by preventing overfitting.

In GraDes, the optimal gradient step length s_k depends on the RIP constant of X, which is NP hard to compute (Tillmann and Pfetsch, 2014). Here, we set $s_k = 1/3$ following Garg and Khandekar (2009). We stop GraDes when the residual norm is smaller than $\varepsilon = \sqrt{n}\sigma$, or the maximum number of iterations is greater than $n/2$. We compute the MCP solution path and select an optimal solution using the HBIC (Wang et al., 2013). We stop the iteration when the residual norm is smaller than $\varepsilon = \|\eta\|_2$, or the estimated support size is greater than $L = n/\log(n)$. In ASDAR (Algorithm 2), we set $\tau = 50$ and we stop the iteration if the residual $\|y - X\beta^k\|$ is smaller than $\varepsilon = \sqrt{n}\sigma$ or $k \geq L = n/\log(n)$.

7.2 Accuracy and efficiency

We compare the accuracy and efficiency of SDAR/ASDAR with Lasso (LARS), MCP, GraDes and FoBa.

We consider a moderately large scale setting with $n = 5000$ and $p = 50000$. The number of nonzero coefficients is set to be $K = 400$. So the sample size n is about $O(K\log(p-K))$. The dimension of the model is nearly at the limit where β^* can be reasonably well estimated by the Lasso (Wainwright, 2009).

To generate the design matrix X, we first generate an $n \times p$ random Gaussian matrix $\bar{X}$ whose entries are i.i.d. $\mathcal{N}(0,1)$ and then normalize its columns to the $\sqrt{n}$ length. Then X is generated with $X_1 = \bar{X}_1$, $X_j = \bar{X}_j + \rho(\bar{X}_{j+1} + \bar{X}_{j-1})$, $j = 2, \ldots, p-1$ and $X_p = \bar{X}_p$. The underlying regression coefficient β^* is generated with the nonzero coefficients uniformly distributed in $[m, M]$, where $m = \sigma\sqrt{2\log(p)/n}$ and $M = 100m$. Then the observation vector $y = X\beta^* + \eta$ with $\eta_1, \ldots, \eta_n$ generated independently from $\mathcal{N}(0, \sigma^2)$. We set $R = 100, \sigma = 1$ and $\rho = 0.2, 0.4$ and 0.6.

Table 1 shows the results based on 100 independent replications. The first column gives the correlation value ρ and the second column shows the methods in the comparison. The third and the fourth columns give the averaged relative error, defined as ReErr $= \sum \|\hat{\beta} - \beta^*\|/\|\beta^*\|$, and the averaged CPU time (in seconds), The standard deviations of the CPU times and the relative errors are shown in the parentheses. In each column of Table 1, the numbers in boldface indicate the best performers.

Table 1: Numerical results (relative errors, CPU times) on data sets with $n = 5000, p = 50000, K = 400, R = 100, \sigma = 1, \rho = 0.2 : 0.2 : 0.6$.

ρ	Method	ReErr	time(s)
0.2	LARS	1.1e-1 (2.5e-2)	4.8e+1 (9.8e-1)
	MCP	**7.5e-4** (**3.6e-5**)	9.3e+2 (2.4e+3)
	GraDes	1.1e-3 (7.0e-5)	2.3e+1 (9.0e-1)
	FoBa	**7.5e-4** (7.0e-5)	4.9e+1 (3.9e-1)
	ASDAR	**7.5e-4** (4.0e-5)	8.4e+0 (4.5e-1)
	SDAR	**7.5e-4** (4.0e-5)	**1.4e+0** (**5.1e-2**)
0.4	LARS	1.8e-1 (1.2e-2)	4.8e+1 (1.8e-1)
	MCP	6.2e-4 (3.6e-5)	2.2e+2 (1.6e+1)
	GraDes	8.8e-4 (5.7e-5)	8.7e+2 (2.6e+3)
	FoBa	1.0e-2 (1.4e-2)	5.0e+1 (4.2e-1)
	ASDAR	**6.0e-4** (**2.6e-5**)	8.8e+0 (**3.2e-1**)
	SDAR	**6.0e-4** (**2.6e-5**)	**2.3e+0** (1.7e+0)
0.6	LARS	3.0e-1 (2.5e-2)	4.8e+1 (3.5e-1)
	MCP	4.5e-4 (**2.5e-5**)	4.6e+2 (5.1e+2)
	GraDes	7.8e-4 (1.1e-4)	1.5e+2 (2.3e+2)
	FoBa	8.3e-3 (1.3e-2)	5.1e+1 (1.1e+0)
	ASDAR	**4.3e-4** (3.0e-5)	1.1e+1 (5.1e-1)
	SDAR	**4.3e-4** (3.0e-5)	**2.1e+0** (**8.6e-2**)

We see that when the correlation ρ is low, i.e., $\rho = 0.2$, MCP, FoBa, SDAR and ASDAR are on the top of the list in average error (ReErr). In terms of speed, SDAR/ASDAR is about 3 to 100 times faster than the other methods. As the correlation ρ increases to $\rho = 0.4$ and $\rho = 0.6$, FoBa becomes less accurate than SDAR/ASDAR. MCP is similar to SDAR/ASDAR in terms of accuracy, but it is 20 to 100 times slower than SDAR/ASDAR. The standard deviations of the CPU times and the relative errors of MCP and SDAR/ASDAR are similar and smaller than those of the other methods in all the three settings.

7.3 Influence of the model parameters

We now consider the effects of each of the model parameters on the performance of ASDAR, LARS, MCP, GraDes and FoBa more closely.

In this set of simulations, the rows of the design matrix X are drawn independently from $\mathcal{N}(0, \Sigma)$ with $\Sigma_{jk} = \rho^{|j-k|}, 1 \le j, k \le p$. The elements of the error vector η are generated independently with $\eta_i \sim \mathcal{N}(0, \sigma^2)$, $i = 1, \ldots, n$. Let $R = M/m$, where, $M = \max\{|\beta^*_{A^*}|\}, m = \min\{|\beta^*_{A^*}|\} = 1$. The underlying regression coefficient vector $\beta^* \in \mathbb{R}^p$ is generated in such a way that A^* is a randomly chosen subset of $\{1, 2, ..., p\}$ with $|A^*| = K < n$ and $R \in [1, 10^3]$. Then the observation vector $y = X\beta^* + \eta$. We use $\{n, p, K, \sigma, \rho, R\}$ to indicate the parameters used in the data generating model described above. We run ASDAR with $\tau = 5, L = n/\log(n)$ (if not specified). We use the HBIC (Wang et al., 2013) to select the tuning parameter T. The simulation results given in Figure 3 are based on 100 independent replications.

7.3.1 Influence of the sparsity level K

The top left panel of Figure 3 shows the results of the influence of sparsity level K on the probability of exact recovery of A^* of ASDAR, LARS, MCP, GraDes and FoBa. Data are generated from the model with $(n = 500, p = 1000, K = 10 : 50 : 360, \sigma = 0.5, \rho = 0.1, R = 10^3)$. Here $K = 10 : 50 : 360$ means the sample size starts from 10 to 360 with an increment of 50. We use $L = 0.8n$ for both ASDAR and MCP to eliminate the effect of stopping rule since the maximum $K = 360$. When the sparsity level $K = 10$, all the solvers performed well in recovering the true support. As K increases, LARS was the first one that failed to recover the support and vanished when $K = 60$ (this phenomenon had also been observed in Garg and Khandekar (2009), MCP began to fail when $K > 110$, GraDes and FoBa began to fail when $K > 160$. In comparison, ASDAR was still able to do well even when $K = 260$.

7.3.2 Influence of the sample size n

The top right panel of Figure 3 shows the influence of the sample size n on the probability of correctly estimating A^*. Data are generated from the model with $(n = 30 : 20 : 200, p = 500, K = 10, \sigma = 0.1, \rho = 0.1, R = 10)$. We see that the performance of all the five methods becomes better as n increases. However, ASDAR performs better than the others when $n = 30$ and 50. These simulation results indicate that ASDAR is more capable of handling high-dimensional data when p/n is large in the generating models considered here

7.3.3 Influence of the ambient dimension p

The bottom left panel of Figure 3 shows the influence of ambient dimension p on the performance of ASDAR, LARS, MCP, GraDes and FoBa. Data are generated from the model with $(n = 100, p = 200 : 200 : 1000, K = 20, \sigma = 1, \rho = 0.3, R = 10)$. We see that the probabilities of exactly recovering the support of the underlying coefficients of ASDAR and MCP are higher than those of the other solvers as p increasing, which indicate that ASDAR and MCP are more robust to the ambient dimension.

7.3.4 Influence of correlation ρ

The bottom right panel of Figure 3 shows the influence of correlation ρ on the performance of ASDAR, LARS, MCP, GraDes and FoBa. Data are generated from the model with $(n = 150, p = 500, K = 25, \sigma = 0.1, \rho = 0.05 : 0.1 : 0.95, R = 10^2)$. The performance of

all the solvers becomes worse when the correlation ρ increases. However, ASDAR generally performed better than the other methods as ρ increases.

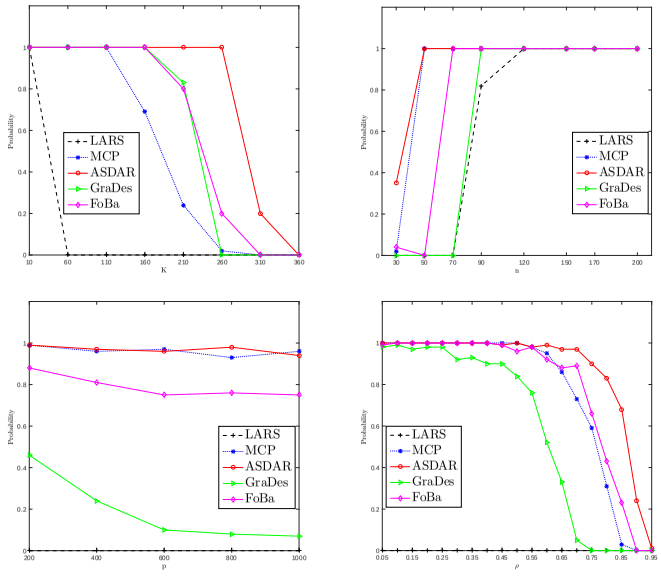

Figure 3: Numerical results of the influence of sparsity level K (top left panel), sample size n (top right panel), ambient dimension p (bottom left panel) and correlation ρ (bottom right panel) on the probability of exact recovery of the true support of all the solvers considered here.

In summary, our simulation studies demonstrate that SDAR/ASDAR is generally more accurate, more efficient and more stable than Lasso, MCP, FoBa and GraDes.

7.4 Number of iterations

In this subsection we compare SDAR with GraDes (IHT) in terms of the number of iterations. We run 100 independent replications on data sets generated from the models with $(n = 500, p = 1000, K = 5 : 5 : 55, \sigma = 0.05, \rho = 0, R = 1)$ and $(n = 2000, p = 5000, K = 10 : 20 : 250, \sigma = 0.05, \rho = 0, R = 1)$ described in Section 7.3. The average number of iteration (left column) and average absolute error in ℓ_∞ norm (right column) are displayed in Figure 4. We can see that the number of iterations of GraDes increases almost sublinearly as the sparsity level K increases while that of SDAR almost varies little. And in terms of the average error, SDAR is serval times more accurate than GraDes. This provides empirical support for our theoretical results in Corollary 30.

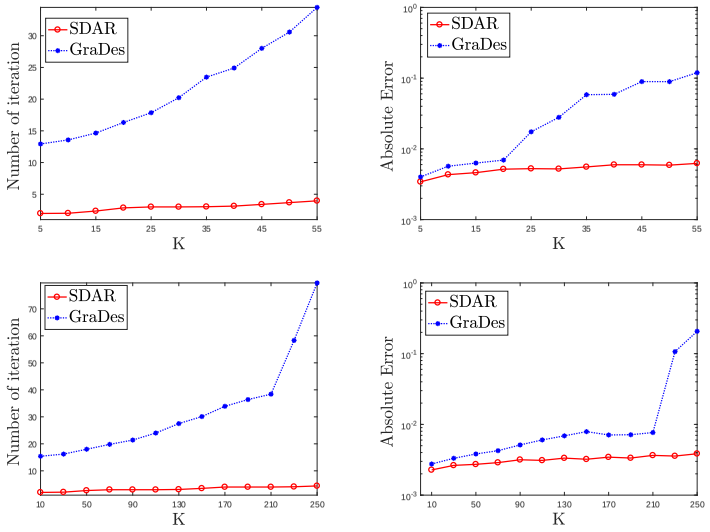

Figure 4: Comparisons the dependence of number of iterations (left panels) and accuracy (right panels) on sparsity level K with data set $(n = 500, p = 1000, K = 5 : 5 : 55, \sigma = 0.05, \rho = 0.3, R = 1)$ and $(n = 2000, p = 5000, K = 10 : 20 : 250, \sigma = 0.05, \rho = 0.3, R = 1)$.

8. Concluding remarks

SDAR is a constructive approach for fitting sparse, high-dimensional linear regression models. Under appropriate conditions, we established the nonasymptotic minimax ℓ_2 error bound and optimal ℓ_∞ error bound of the solution sequence generated by SDAR. We also calculated the number of iterations required to achieve these bounds. In particular, an interesting and surprising aspect of our results is that, under a mutual coherence condition on the design matrix, the number of iterations required for the SDAR to achieve the optimal ℓ_∞ bound does not depend on the underlying sparsity level. In addition, SDAR has the same computational complexity per iteration as LARS, coordinate descent and greedy methods. Our simulation studies demonstrate that SDAR/ASDAR is accurate, fast, stable and easy to implement, and it is competitive with or outperforms the Lasso, MCP and two greedy methods in efficiency and accuracy in the generating models we considered. These theoretical and numerical results suggest that SDAR/ASDAR is a useful addition to the literature on sparse modeling.

We have only considered the linear regression model. It would be interesting to generalize SDAR to models with more general loss functions or with other types of sparsity structures.

It would also be interesting to develop parallel or distributed versions of SDAR that can run on multiple cores for data sets with big n and large p or for data that are distributively stored.

We have implemented SDAR in a Matlab package *sdar*, which is available at `http://homepage.stat.uiowa.edu/~jian/`.

Acknowledgments

We are grateful to the action editor and the anonymous reviewers for their detailed and constructive comments which led to considerable improvements in the paper. We also thank Patrick Breheny for his critical reading of the paper and providing helpful comments. Appendix A

Proof of Lemma 1.

Proof Let $L_\lambda(\beta) = \frac{1}{2n}\|X\beta - y\|_2^2 + \lambda\|\beta\|_0$. Suppose $\beta^\diamond$ is a coordinate-wise minimizer of L_λ. Then

$$\begin{aligned}
& \beta_i^\diamond \in \operatorname*{argmin}_{t\in\mathbb{R}} L_\lambda(\beta_1^\diamond, ..., \beta_{i-1}^\diamond, t, \beta_{i+1}^\diamond, ..., \beta_p^\diamond) \\
\Rightarrow \quad & \beta_i^\diamond \in \operatorname*{argmin}_{t\in\mathbb{R}} \tfrac{1}{2n}\|X\beta^\diamond - y + (t-\beta_i^\diamond)X_i\|_2^2 + \lambda|t|_0 \\
\Rightarrow \quad & \beta_i^\diamond \in \operatorname*{argmin}_{t\in\mathbb{R}} \tfrac{1}{2}(t-\beta_i^\diamond)^2 + \tfrac{1}{n}(t-\beta_i^\diamond)X_i'(X\beta^\diamond - y) + \lambda|t|_0 \\
\Rightarrow \quad & \beta_i^\diamond \in \operatorname*{argmin}_{t\in\mathbb{R}} \tfrac{1}{2}(t-(\beta_i^\diamond + X_i'(y-X\beta^\diamond)/n))^2 + \lambda|t|_0.
\end{aligned}$$

Let $d^\diamond = X'(y - X\beta^\diamond)/n$. By the definition of the hard thresholding operator $H_\lambda(\cdot)$ in (5), we have

$$\beta_i^\diamond = H_\lambda(\beta_i^\diamond + d_i^\diamond) \quad \text{for } i = 1, ..., p,$$

which shows (4) holds.

Conversely, suppose (4) holds. Let

$$A^\diamond = \Big\{ i \in S \big| \, |\beta_i^\diamond + d_i^\diamond| \ge \sqrt{2\lambda} \Big\}.$$

By (4) and the definition of $H_\lambda(\cdot)$ in (5), we deduce that for $i \in A^\diamond$, $|\beta_i^\diamond| \ge \sqrt{2\lambda}$. Furthermore, $\mathbf{0} = d_{A^\diamond}^\diamond = X_{A^\diamond}'(y - X_{A^\diamond}\beta_{A^\diamond}^\diamond)/n$, which is equivalent to

$$\beta_{A^\diamond}^\diamond \in \operatorname{argmin} \tfrac{1}{2n}\|X_{A^\diamond}\beta_{A^\diamond} - y\|_2^2. \tag{39}$$

Next we show $L_\lambda(\beta^\diamond + h) \ge L_\lambda(\beta^\diamond)$ if h is small enough with $\|h\|_\infty < \sqrt{2\lambda}$. We consider two cases. If $h_{(A^\diamond)^c} \ne 0$, then

$$L_\lambda(\beta^\diamond + h) - L_\lambda(\beta^\diamond) \ge \tfrac{1}{2n}\|X\beta^\diamond - y + Xh\|_2^2 - \tfrac{1}{2n}\|X\beta^\diamond - y\|_2^2 + \lambda \ge \lambda - |\langle h, d^\diamond\rangle|,$$

which is positive for sufficiently small h. If $h_{(A^\diamond)^c} = 0$, by the minimizing property of $\beta_{A^\diamond}^\diamond$ in (39) we deduce that $L_\lambda(\beta^\diamond + h) \ge L_\lambda(\beta^\diamond)$. This completes the proof of Lemma 1. ■

Lemma 20 *Let A and B be disjoint subsets of S, with $|A| = a$ and $|B| = b$. Assume $X \sim SRC(a+b, c_-(a+b), c_+(a+b))$. Let $\theta_{a,b}$ be the sparse orthogonality constant and let μ be the mutual coherence of X. Then we have*

$$nc_-(a) \le \left\|X_A^T X_A\right\| \le nc_+(a), \tag{40}$$

$$\frac{1}{nc_+(a)} \le \left\|(X_A^T X_A)^{-1}\right\| \le \frac{1}{nc_-(a)}, \tag{41}$$

$$\left\|X_A'\right\| \le \sqrt{nc_+(a)} \tag{42}$$

$$\theta_{a,b} \le (c_+(a+b) - 1) \vee (1 - c_-(a+b)) \tag{43}$$

$$\|X_B' X_A u\|_\infty \le na\mu\|u\|_\infty, \quad \forall u \in \mathbb{R}^{|A|}, \tag{44}$$

$$\|X_A\| = \left\|X_A'\right\| \le \sqrt{n(1 + (a-1)\mu)}. \tag{45}$$

Furthermore, if $\mu < 1/(a-1)$, then

$$\|(X_A' X_A)^{-1} u\|_\infty \le \frac{\|u\|_\infty}{n(1-(a-1)\mu)}, \quad \forall u \in \mathbb{R}^{|A|}. \tag{46}$$

Moreover, $c_+(s)$ is an increasing function of s, $c_-(s)$ a decreasing function of s and $\theta_{a,b}$ an increasing function of a and b.

Proof The assumption $X \sim \mathrm{SRC}(a, c_-(a), c_+(a))$ implies the spectrum of $X_A'X_A/n$ is contained in $[c_-(a), c_+(a)]$. So (40) - (42) hold. Let $\mathbb{I}$ be an $(a+b)\times(a+b)$ identity matrix. (43) follows from the fact that $X_A'X_B/n$ is a submatrix of $X_{A\cup B}'X_{A\cup B}/n - \mathbb{I}$ whose spectrum norm is less than $(1 - c_-(a+b)) \vee (c_+(a+b) - 1)$. Let $G = X'X/n$. Then, $|\sum_{j=1}^a G_{i,j}u_j| \le \mu a\|u\|_\infty$, for all $i \in B$, which implies (44). By Gerschgorin's disk theorem,

$$|\,\|G_{A,A}\| - G_{i,i}| \le \sum_{i\ne j=1}^{a} |G_{i,j}| \le (a-1)\mu \quad \forall i \in A,$$

thus (45) holds. For (46), it suffices to show $\|G_{A,A}u\|_\infty \ge (1-(a-1)\mu)\|u\|_\infty$ if $\mu < 1/(a-1)$. In fact, let $i \in A$ such that $\|u\|_\infty = |u_i|$, then

$$\|G_{A,A}u\|_\infty \ge |\sum_{j=1}^{a} G_{i,j}u_j| \ge |u_i| - \sum_{i\ne j=1}^{a} |G_{i,j}|\,|u_j| \ge \|u\|_\infty - \mu(a-1)\|u\|_\infty.$$

The last assertion follows from their definitions. This completes the proof of Lemma 20. ■

Lemma 21 *Suppose (A3) holds. We have for any $\alpha \in (0, 1/2)$,*

$$\mathbf{P}\Big(\|X'\eta\|_\infty \le \sigma\sqrt{2\log(p/\alpha)n}\Big) \ge 1 - 2\alpha, \tag{47}$$

$$\mathbf{P}\Big(\max_{|A|\le T} \|X_A'\eta\|_2 \le \sigma\sqrt{T}\sqrt{2\log(p/\alpha)n}\Big) \ge 1 - 2\alpha. \tag{48}$$

Proof This lemma follows from the sub-Gaussian assumption (A3) and standard probability calculation, see Zhang and Huang (2008); Wainwright (2009) for details. ■

We now define some notation that will be useful in proving Theorems 4 and 12. For any given integers T and J with $T \geq J$ and $F \subseteq S$ with $|F| = T - J$, let $A^\circ = A^*_J \cup F$ and $I^\circ = (A^\circ)^c$. Let $\{A^k\}_k$ be the sequence of active sets generated by SDAR (Algorithm 1).

Define

$$D_2(A^k) = \|\bar{\beta}^*|_{A^*_J \setminus A^k}\|_2 \quad \text{and} \quad D_\infty(A^k) = \|\bar{\beta}^*|_{A^* \setminus A^k}\|_\infty.$$

These quantities measure the differences between A_k and A^*_J in terms of the ℓ_2 and ℓ_∞ norms of the coefficients in A^*_J but not in A^k. A crucial step in our proofs is to control the sizes of these measures.

Let

$$A^k_1 = A^k \cap A^\circ, A^k_2 = A^\circ \setminus A^k_1, I^k_3 = A^k \cap I^\circ, I^k_4 = I^\circ \setminus I^k_3.$$

Denote the cardinality of I^k_3 by $l_k = |I^k_3|$. Let

$$A^k_{11} = A^k_1 \setminus (A^{k+1} \cap A^k_1), A^k_{22} = A^k_2 \setminus (A^{k+1} \cap A^k_2), I^k_{33} = A^{k+1} \cap I^k_3, I^k_{44} = A^{k+1} \cap I^k_4,$$

and

$$\triangle^k = \beta^{k+1} - \bar{\beta}^*|_{A^k}.$$

These notation can be easily understood in the case $T = J$. For example, $D_2(A^k)$ and $D_\infty(A^k)$ are measures of the difference between the active set A^k and the target support A^*_J. A^k_1 and I^k_3 contain the correct indices and incorrect indices in A^k, respectively. A^k_{11} and A^k_{22} include the indices in A° that will be lost from the kth iteration to the $(k+1)$th iteration. I^k_{33} and I^k_{44} contain the indices included in I° that will be gained from the kth iteration to the $(k+1)$th iteration. By Algorithm 1, we have $|A^k| = |A^{k+1}| = T$, $A^k = A^k_1 \cup I^k_3$, $|A^k_2| = |A^\circ| - |A^k_1| = |A^\circ| - |I^k_3| = T - (T - l_k) = l_k \leq T$, and

$$|A^k_{11}| + |A^k_{22}| = |I^k_{33}| + |I^k_{44}|, \tag{49}$$

$$D_2(A^k) = \|\bar{\beta}^*|_{A^\circ \setminus A^k}\|_2 = \|\bar{\beta}^*|_{A^k_2}\|_2, \tag{50}$$

$$D_\infty(A^k) = \|\bar{\beta}^*|_{A^\circ \setminus A^k}\|_\infty = \|\bar{\beta}^*|_{A^k_2}\|_\infty. \tag{51}$$

In Subsection 3.3, we described the overall approach for proving Theorems 4 and 12. Before proceeding to the proofs, we break down the argument into the following steps.

1. In Lemma 22 we show that the effects of the noise and the approximation model (10) measured by $h_2(T)$ and $h_\infty(T)$ can be controlled by the sum of unrecoverable approximation error R_J and the universal noise level $O(\sigma\sqrt{2\log(p)/n})$ with high probability, provided that η is sub-Gaussian.

2. In Lemma 23 we show that the ℓ_2 norms (ℓ_∞ norms) of $\triangle^k$ and $\beta^k - \bar{\beta}^*$ are controlled in terms of $D_2(A^k)$ and $h_2(T)$ ($D_\infty(A^k)$ and $h_\infty(T)$).

3. In Lemma 24 we show that $D_2(A^{k+1})$ ($D_\infty(A^{k+1})$) can be bounded by the norm of $\bar{\beta}^*$ on the lost indices, which in turn can be controlled in terms of $D_2(A^k)$ and $h_2(T)$ ($D_\infty(A^k)$ and $h_\infty(T)$) and the norms of $\triangle^k$, β^{k+1} and d^{k+1} on the lost indices.

4. In Lemma 25 we make use of the orthogonality between β^k and d^k to show that the norms of β^{k+1} and d^{k+1} on the lost indices can be bounded by the norm on the gained indices. Lemma 26 gives the upper bound of the norms of β^{k+1} and d^{k+1} on the gained indices by the sum of $D_2(A^k)$, $h_2(T)$ ($D_\infty(A^k)$, $h_\infty(T)$), and the norm of $\triangle^k$.

5. We combine Lemmas 22-26 and get the desired relations between $D_2(A^{k+1})$ and $D_2(A^k)$ ($D_\infty(A^{k+1})$ and $D_\infty(A^k)$) in Lemma 27.

Then we prove Theorems 4 and 12 based on Lemma 27, (56) and (58).

Lemma 22 *Let $A \subset S$ with $|A| \leq T$. Suppose (A1) and (A3) holds. Then for $\alpha \in (0, 1/2)$ with probability at least $1 - 2\alpha$, we have*

(i) If $X \sim SRC(T, c_-(T), c_+(T))$, then

$$h_2(T) \leq \varepsilon_1, \tag{52}$$

where ε_1 is defined in (18).

(ii) We have

$$h_\infty(T) \leq \varepsilon_2, \tag{53}$$

where ε_2 is defined in (29).

Proof We first show

$$\|X\beta^*|_{(A^*_J)^c}\|_2 \leq \sqrt{nc_+(J)}R_J, \tag{54}$$

under the assumption of $X \sim SRC(c_-(T), c_+(T), T)$ and (A1). In fact, let β be an arbitrary vector in $\mathbb{R}^p$ and A_1 be the first J largest positions of β, A_2 be the next and so forth. Then

$$\begin{aligned}
\|X\beta\|_2 &\leq \|X\beta_{A_1}\|_2 + \sum_{i\geq 2}\|X\beta_{A_i}\|_2 \\
&\leq \sqrt{nc_+(J)}\|\beta_{A_1}\|_2 + \sqrt{nc_+(J)}\sum_{i\geq 2}\|\beta_{A_i}\|_2 \\
&\leq \sqrt{nc_+(J)}\|\beta\|_2 + \sqrt{nc_+(J)}\sum_{i\geq 1}\sqrt{\frac{1}{J}}\|\beta_{A_{i-1}}\|_1 \\
&\leq \sqrt{nc_+(J)}(\|\beta\|_2 + \sqrt{\frac{1}{J}}\|\beta\|_1),
\end{aligned}$$

where the first inequality follows from the triangle inequality, the second inequality follows from (42), and the third and fourth ones follows from simple algebra. This implies (54) holds by observing the definition of R_J. By the triangle inequality, (42), (54) and (48), we have with probability at least $1 - 2\alpha$,

$$\begin{aligned}
\|X'_A\bar{\eta}\|_2/n &\leq \|X'_A X\beta^*|_{(A^*_J)^c}\|_2/n + \|X'_A\eta\|_2/n \\
&\leq c_+(J)R_J + \sigma\sqrt{T}\sqrt{2\log(p/\alpha)/n}.
\end{aligned}$$

Therefore, (52) follows by noticing the monotone increasing property of $c_+(\cdot)$, the definition of ε_1 in (18) and the arbitrariness of A.

By a similar argument for (54) and replacing $\sqrt{nc_+(J)}$ with $\sqrt{n(1+(J-1)\mu)}$ based on (45), we get

$$\|X\beta^*|_{(A^*_J)^c}\|_2 \le \sqrt{n(1+(K-1)\mu)}R_J. \tag{55}$$

Therefore, by (45), (55) and (47), we have with probability at least $1-2\alpha$,

$$\begin{aligned}\|X'_A\bar{\eta}\|_\infty/n &\le \|X'_AX\beta^*|_{(A^*_J)^c}\|_\infty/n + \|X'_A\eta\|_2/n\\ &\le \|X'_AX\beta^*|_{(A^*_J)^c}\|_2/n + \|X'_A\eta\|_2/n\\ &\le (1+(J-1)\mu)R_J + \sigma\sqrt{2\log(p/\alpha)/n}.\end{aligned}$$

This implies part (ii) of Lemma 22 by noticing the definition of ε_2 in (29) and the arbitrariness of A. This completes the proof of Lemma 22. ■

Lemma 23 *Let $A \subset S$ with $|A| \le T$. Suppose (A1) holds.*

(i) If $X \sim SRC(T, c_-(T), c_+(T))$,

$$\|\beta^{k+1} - \bar{\beta}^*\|_2 \le \Big(1 + \frac{\theta_{T,T}}{c_-(T)}\Big)D_2(A^k) + \frac{h_2(T)}{c_-(T)}, \tag{56}$$

and

$$\|\triangle^k\|_2 \le \frac{\theta_{T,T}}{c_-(T)}\|\bar{\beta}^*|_{A^k_2}\|_2 + \frac{h_2(T)}{c_-(T)}. \tag{57}$$

(ii) If $(T-1)\mu < 1$, then

$$\|\beta^{k+1} - \bar{\beta}^*\|_\infty \le \frac{1+\mu}{1-(T-1)\mu}D_\infty(A^k) + \frac{h_\infty(T)}{1-(T-1)\mu}, \tag{58}$$

and

$$\|\triangle^k\|_\infty \le \frac{T\mu}{1-(T-1)\mu}\|\bar{\beta}^*|_{A^k_2}\|_\infty + \frac{h_\infty(T)}{(1-(T-1)\mu)}. \tag{59}$$

Proof We have

$$\begin{aligned}\beta^{k+1}_{A^k} &= (X'_{A^k}X_{A^k})^{-1}X'_{A^k}y\\ &= (X'_{A^k}X_{A^k})^{-1}X'_{A^k}(X_{A^k_1}\bar{\beta}^*_{A^k_1} + X_{A^k_2}\bar{\beta}^*_{A^k_2} + \bar{\eta}),\end{aligned} \tag{60}$$

$$\begin{aligned}(\bar{\beta}^*|_{A^k})_{A^k} &= (X'_{A^k}X_{A^k})^{-1}X'_{A^k}X_{A^k}(\bar{\beta}^*|_{A^k})_{A^k}\\ &= (X'_{A^k}X_{A^k})^{-1}X'_{A^k}(X_{A^k_1}\bar{\beta}^*_{A^k_1}),\end{aligned} \tag{61}$$

where the first equality uses the definition of β^{k+1} in Algorithm 1, the second equality follows from $y = X\bar{\beta}^* + \bar{\eta} = X_{A^k_1}\bar{\beta}^*_{A^k_1} + X_{A^k_2}\bar{\beta}^*_{A^k_2} + \bar{\eta}$, the third equality is simple algebra, and the last one uses the definition of A^k_1. Therefore,

$$\begin{aligned}\|\triangle^k\|_2 &= \|\beta^{k+1}_{A^k} - (\bar{\beta}^*|_{A^k})_{A^k}\|_2\\ &= \|(X'_{A^k}X_{A^k})^{-1}X'_{A^k}(X_{A^k_2}\bar{\beta}^*_{A^k_2} + \bar{\eta})\|_2\\ &\le \frac{1}{nc_-(T)}(\|X'_{A^k}X_{A^k_2}\bar{\beta}^*_{A^k_2}\|_2 + \|X'_{A^k}\bar{\eta}\|_2)\\ &\le \frac{\theta_{T,T}}{c_-(T)}\|\bar{\beta}^*|_{A^k_2}\|_2 + \frac{h_2(T)}{c_-(T)},\end{aligned}$$

where the first equality uses $\mathrm{supp}(\beta^{k+1}) = A^k$, the second equality follows from (61) and (60), the first inequality follows from (41) and the triangle inequality, and the second inequality follows from (50), the definition of $\theta_{a,b}$ and the definition of $h_2(T)$. This proves (57). Then the triangle inequality $\|\beta^{k+1} - \bar{\beta}^*\|_2 \le \|\beta^{k+1} - \bar{\beta}^*|_{A^k}\|_2 + \|\bar{\beta}^*|_{A^\circ\setminus A^k}\|_2$ and (57) imply (56).

Using an argument similar to the proof of (57) and by (46), (44) and (51), we can show (59). Thus (58) follows from the triangle inequality and (59). This completes the proof of Lemma 23. ■

Lemma 24

$$D_2(A^{k+1}) \le \|\bar{\beta}^*_{A^k_{11}}\|_2 + \|\bar{\beta}^*_{A^k_{22}}\|_2, \tag{62}$$

$$D_\infty(A^{k+1}) \le \|\bar{\beta}^*_{A^k_{11}}\|_\infty + \|\bar{\beta}^*_{A^k_{22}}\|_\infty. \tag{63}$$

$$\|\bar{\beta}^*_{A^k_{11}}\|_2 \le \|\triangle^k_{A^k_{11}}\|_2 + \|\beta^{k+1}_{A^k_{11}}\|_2, \tag{64}$$

$$\|\bar{\beta}^*_{A^k_{11}}\|_\infty \le \|\triangle^k_{A^k_{11}}\|_\infty + \|\beta^{k+1}_{A^k_{11}}\|_\infty. \tag{65}$$

Furthermore, assume (A1) holds. We have

$$\|\bar{\beta}^*_{A^k_{22}}\|_\infty \le \|d^{k+1}_{A^k_{22}}\|_\infty + T\mu\|\triangle^k_{A^k}\|_\infty + T\mu D_\infty(A^k) + h_\infty(T), \tag{66}$$

$$\|\bar{\beta}^*_{A^k_{22}}\|_2 \le \frac{\|d^{k+1}_{A^k_{22}}\|_2 + \theta_{T,T}\|\triangle^k_{A^k}\|_2 + \theta_{T,T}D_2(A^k) + h_2(T)}{c_-(T)} \text{ if } X \sim SRC(T, c_-(T), c_+(T)). \tag{67}$$

Proof By the definitions of $D_2(A^{k+1})$, A^k_{11}, A^k_{11} and A^k_{22}, we have

$$D_2(A^{k+1}) = \|\bar{\beta}^*|_{A^\circ\setminus A^{k+1}}\|_2 = \|\bar{\beta}^*|_{A^k_{11}\cup A^k_{22}}\|_2 \le \|\bar{\beta}^*_{A^k_{11}}\|_2 + \|\bar{\beta}^*_{A^k_{22}}\|_2.$$

This proves (62). (63) can be proved similarly. To show (64), we note that $\triangle^k = \beta^{k+1} - \bar{\beta}^*|_{A^k}$. Thus

$$\|\beta^{k+1}_{A^k_{11}}\|_2 = \|\Big(\bar{\beta}^*\big|_{A^k}\Big)_{A^k_{11}} + \triangle^k_{A^k_{11}}\|_2 \ge \|\bar{\beta}^*_{A^k_{11}}\|_2 - \|\triangle^k_{A^k_{11}}\|_2.$$

This proves (64). (65) can be proved similarly.

Now consider (67). We have

$$\begin{aligned}
\|d^{k+1}_{A^k_{22}}\|_2 &= \|X'_{A^k_{22}}\Big(X_{A^k}\beta^{k+1}_{A^k} - y\Big)/n\|_2 \\
&= \|X'_{A^k_{22}}\Big(X_{A^k}\triangle^k_{A^k} + X_{A^k}\bar\beta^*_{A^k} - X_{A^\circ}\bar\beta^*_{A^\circ} - \bar\eta\Big)/n\|_2 \\
&= \|X'_{A^k_{22}}\Big(X_{A^k}\triangle^k_{A^k} - X_{A^k_{22}}\bar\beta^*_{A^k_{22}} - X_{A^k_2\setminus A^k_{22}}\bar\beta^*_{A^k_2\setminus A^k_{22}} - \bar\eta\Big)/n\|_2 \\
&\geq c_-(|A^k_{22}|)\|\bar\beta^*_{A^k_{22}}\|_2 - \theta_{|A^k_{22}|,T}\|\triangle^k_{A^k}\|_2 - \theta_{l_k,l_k-|A^k_{22}|}\|\bar\beta^*_{A^k_2\setminus A^k_{22}}\|_2 - \|X_{A^k_{22}}\bar\eta/n\|_2 \\
&\geq c_-(T)\|\bar\beta^*_{A^k_{22}}\|_2 - \theta_{T,T}\|\triangle^k_{A^k}\|_2 - \theta_{T,T}D_2(A^k) - h_2(T),
\end{aligned}$$

where the first equality uses the definition of d^{k+1}, the second equality uses the the definition of $\triangle^k$ and y, the third equality is simple algebra, the first inequality uses the triangle inequality, (40) and the definition of $\theta_{a,b}$, and the last inequality follows from the monotonicity property of $c_-(\cdot)$, $\theta_{a,b}$ and the definition of $h_2(T)$. This proves (67).

Finally, we show (66). Let $i_k \in A^k_{22}$ be an index satisfying $\big|\bar\beta^*_{i_k}\big| = \|\bar\beta^*_{A^k_{22}}\|_\infty$. Then

$$\begin{aligned}
\Big|d^{k+1}_{i_k}\Big| &= \|X'_{i_k}(X_{A^k}\triangle^k_{A^k} - X_{i_k}\bar\beta^*_{i_k} - X_{A^k_2\setminus\, i_k}\bar\beta^*_{A^k_2\setminus\, i_k} - \bar\eta)/n\|_\infty \\
&\geq \big|\bar\beta^*_{i_k}\big| - T\mu\|\triangle^k_{A^k}\|_\infty - l_k\mu\|\bar\beta^*_{A^k_2\setminus\, i_k}\|_\infty - \|X'_{i_k}\bar\eta\|_\infty \\
&\geq \|\bar\beta^*_{A^k_{22}}\|_\infty - T\mu\|\triangle^k_{A^k}\|_\infty - T\mu D_\infty(A^k) - h_\infty(T),
\end{aligned}$$

where the first equality is derived from the first three equalities in the proof of (67) by replacing A^k_{22} with i_k, the first inequality follows from the triangle inequality and (44), and the last inequality follows from the definition of $h_\infty(T)$. Then (66) follows by rearranging the terms in the above inequality. This completes the proof of Lemma 24. ■

Lemma 25

$$\|\beta^k\|_\infty \vee \|d^k\|_\infty = \max\{|\beta^k_i| + |d^k_i| | i \in S\}, \forall k \geq 1. \tag{68}$$

$$\|\beta^{k+1}_{A^k_{11}}\|_\infty + \|d^{k+1}_{A^k_{22}}\|_\infty \leq \Big|\beta^{k+1}_{I^k_{33}}\Big|_{min} \wedge \Big|d^{k+1}_{I^k_{44}}\Big|_{min}. \tag{69}$$

$$\|\beta^{k+1}_{A^k_{11}}\|_2 + \|d^{k+1}_{A^k_{22}}\|_2 \leq \sqrt{2}\Big(\|\beta^{k+1}_{I^k_{33}}\|_2 + \|d^{k+1}_{I^k_{44}}\|_2\Big). \tag{70}$$

Proof By the definition of Algorithm 1 we have $\beta^k_i d^k_i = 0$, $\forall i \in S$, $\forall k \geq 1$, thus (68) holds. (69) follows from the definition of A^k_{11}, A^k_{22}, I^k_{33}, I^k_{44} and (68). Now

$$\begin{aligned}
\frac{1}{2}(\|\beta^{k+1}_{A^k_{11}}\|_2 + \|d^{k+1}_{A^k_{22}}\|_2)^2 &\leq \|\beta^{k+1}_{A^k_{11}}\|^2_2 + \|d^{k+1}_{A^k_{22}}\|^2_2 \\
&\leq (\|\beta^{k+1}_{I^k_{33}}\|_2 + \|d^{k+1}_{I^k_{44}}\|_2)^2,
\end{aligned}$$

where the first inequality follows from simple algebra, and the second inequality follows from (49) and (69). Thus (70) follows. This completes the proof of Lemma 25. ■

Lemma 26

$$\|\beta^{k+1}_{I^k_{33}}\|_2 \leq \|\triangle^k_{I^k_{33}}\|_2. \tag{71}$$

Furthermore, suppose (A1) holds. We have

$$\|d^{k+1}_{I^k_{44}}\|_\infty \leq T\mu\|\triangle^k_{A^k}\|_\infty + T\mu D_\infty(A^k) + h_\infty(T) \quad \textit{under the mutual coherence condition } (A^*), \tag{72}$$

$$\|d^{k+1}_{I^k_{44}}\|_2 \leq \theta_{T,T}\Big\|\triangle^k_{A^k}\Big\| + \theta_{T,T}D_2(A^k) + h_2(T) \quad \textit{if} \quad X \sim SRC(T, c_-(T), c_+(T)). \tag{73}$$

Proof By the definition of $\triangle^k$, the triangle inequality and the fact that $\bar\beta^*$ vanishes on $A^k \cap I^k_{33}$, we have

$$\|\beta^{k+1}_{I^k_{33}}\|_2 = \|\triangle^k_{I^k_{33}} + \bar\beta^*_{I^k_{33}}\|_2 \leq \|\triangle^k_{I^k_{33}}\|_2 + \|\bar\beta^*_{A^k\cap I^k_{33}}\|_2 = \|\triangle^k_{I^k_{33}}\|_2.$$

So (71) follows. Now

$$\begin{aligned}
\|d^{k+1}_{I^k_{44}}\|_2 &= \|X'_{I^k_{44}}\Big(X_{A^k}\triangle^k_{A^k} - X_{A^k_2}\bar\beta^*_{A^k_2} - \bar\eta\Big)/n\|_2 \\
&\leq \theta_{|I^k_{44}|,T}\|\triangle^k_{A^k}\|_2 + \theta_{|I^k_{44}|,l_k}\|\bar\beta^*_{A^k_2}\|_2 + \|X'_{I^k_{44}}\bar\eta\|_2 \\
&\leq \theta_{T,T}\|\triangle^k_{A^k}\|_2 + \theta_{T,T}D_2(A^k) + h_2(T),
\end{aligned}$$

where the first equality is derived from the first three equalities in the proof of (67) by replacing A^k_{22} with I^k_{44}, the first inequality follows from the triangle inequality and the definition of $\theta_{a,b}$, and the last inequality follows from the monotonicity property of $\theta_{a,b}$ and $h_2(T)$. This implies (73). Finally, (72) can be proved similarly by using (44) and (53). This completes the proof of Lemma 26. ■

Lemma 27 *Suppose (A1) holds.*

(i) If $X \sim SRC(T, c_-(T), c_+(T))$, then

$$D_2(A^{k+1}) \leq \gamma D_2(A^k) + \frac{\gamma}{\theta_{T,T}}h_2(T), \tag{74}$$

(ii) If $(T-1)\mu < 1$, then

$$D_\infty(A^{k+1}) \leq \gamma_\mu D_2(A^k) + \frac{3+2\mu}{1-(T-1)\mu}h_\infty(T). \tag{75}$$

Proof We have

$$\begin{aligned}
D_2(A^{k+1}) &\le \|\bar{\beta}^*_{A^k_{11}}\|_2 + \|\bar{\beta}^*_{A^k_{22}}\|_2 \\
&\le (\|\beta^{k+1}_{A^k_{11}}\|_2 + \|d^{k+1}_{A^k_{22}}\|_2 + \|\triangle^k_{A^k_{11}}\|_2 + \theta_{T,T}\|\triangle^k_{A^k}\|_2 + \theta_{T,T}D_2(A^k) + h_2(T))/c_-(T) \\
&\le (\sqrt{2}(\|\beta^{k+1}_{I^k_{33}}\|_2 + \|d^{k+1}_{I^k_{44}}\|_2) + \|\triangle^k_{A^k_{11}}\|_2 + \theta_{T,T}\left\|\triangle^k_{A^k}\right\| + \theta_{T,T}D_2(A^k) + h_2(T))/c_-(T) \\
&\le ((2+(1+\sqrt{2})\theta_{T,T})\|\triangle^k\|_2 + (1+\sqrt{2})\theta_{T,T}D_2(A^k) + (1+\sqrt{2})h_2(T))/c_-(T) \\
&\le (\frac{2\theta_{T,T}+(1+\sqrt{2})\theta^2_{T,T}}{c_-(T)^2} + \frac{(1+\sqrt{2})\theta_{T,T}}{c_-(T)})D_2(A^k) \\
&+ (\frac{2+(1+\sqrt{2})\theta_{T,T}}{c_-(T)^2} + \frac{1+\sqrt{2}}{c_-(T)})h_2(T),
\end{aligned}$$

where the first inequality is (62), the second inequality follows from (64) and (67), the third inequality follows from (70), the fourth inequality uses the sum of (71) and (73), and the last inequality follows from (57). This implies (74) by noticing the definitions of γ.

Now

$$\begin{aligned}
D_\infty(A^{k+1}) &\le \|\bar{\beta}^*_{A^k_{11}}\|_\infty + \|\bar{\beta}^*_{A^k_{22}}\|_2 \\
&\le \|\beta^{k+1}_{A^k_{11}}\|_\infty + \|d^{k+1}_{A^k_{22}}\|_\infty + \|\triangle^k_{A^k_{11}}\|_\infty + T\mu\|\triangle^k_{A^k}\|_\infty + T\mu D_\infty(A^k) + h_\infty(T). \\
&\le \|d^{k+1}_{I^k_{44}}\|_\infty + \|\triangle^k_{A^k_{11}}\|_\infty + T\mu\|\triangle^k_{A^k}\|_\infty + T\mu D_\infty(A^k) + h_\infty(T) \\
&\le \|\triangle^k_{A^k_{11}}\|_\infty + 2T\mu\|\triangle^k_{A^k}\|_\infty + 2T\mu D_\infty(A^k) + 2h_\infty(T) \\
&\le (\frac{(1+2T\mu)T\mu}{1-(T-1)\mu} + 2T\mu)D_\infty(A^k) + \frac{3+2\mu}{1-(T-1)\mu}h_\infty(T),
\end{aligned}$$

where the first inequality is (63), the second inequality follows from (65) and (66), the third inequality follows from (69), the fourth inequality follows from (72), and the last inequality follows from (59). Thus part (ii) of Lemma 27 follows by noticing the definition of γ_μ. This completes the proof of Lemma 27. ■

Proof of Theorem 4.

Proof Suppose $\gamma < 1$. By using (74) repeatedly,

$$\begin{aligned}
D_2(A^{k+1}) &\le \gamma D_2(A^k) + \frac{\gamma}{\theta_{T,T}}h_2(T) \\
&\le \gamma(\gamma D_2(A^{k-1}) + \frac{\gamma}{\theta_{T,T}}h_2(T)) + \gamma h_2(T) \\
&\le \cdots \\
&\le \gamma^{k+1}D_2(A^0) + \frac{\gamma}{\theta_{T,T}}(1+\gamma+\cdots+\gamma^k)h_2(T) \\
&< \gamma^{k+1}\|\bar{\beta}^*\|_2 + \frac{\gamma}{(1-\gamma)\theta_{T,T}}h_2(T),
\end{aligned}$$

i.e., (13) holds. Now

$$\begin{aligned}
\|\beta^{k+1} - \bar{\beta}^*\|_2 &\le (1+\frac{\theta_{T,T}}{c_-(T)})D_2(A^k) + \frac{h_2(T)}{c_-(T)} \\
&\le (1+\frac{\theta_{T,T}}{c_-(T)})\Big[\gamma^k\|\bar{\beta}^*\|_2 + \frac{\gamma\theta_{T,T}}{1-\gamma}h_2(T)\Big] \\
&= (1+\frac{\theta_{T,T}}{c_-(T)})\gamma^k\|\bar{\beta}^*\|_2 + \Big[\frac{\gamma\theta_{T,T}}{(1-\gamma)}(1+\frac{\theta_{T,T}}{c_-(T)}) + \frac{1}{c_-(T)}\Big]h_2(T),
\end{aligned}$$

where the first inequality follows from (56), the second inequality follows from (13), and the third line follows after some algebra. Thus (14) follows by noticing the definitions of b_1 and b_2. This completes the proof of part (i) of Theorem 4.

For part (ii), (16) follows from (13) and (52), (17) follows from (14) and (52). This completes the proof of Theorem 4. ■

Proof of Corollary 8.

Proof By (14),

$$\begin{aligned}
\|\beta^{k+1} - \bar{\beta}^*\|_2 &\le b_1\gamma_1^k\|\bar{\beta}^*\|_2 + b_2h_2(T) \\
&\le b_1h_2(T) + b_2h_2(T) \quad \text{if} \quad k \ge \log_{\frac{1}{\gamma}}\frac{\sqrt{J}\bar{M}}{h_2(T)}
\end{aligned}$$

where the second inequality follows after some algebra. By (13),

$$\begin{aligned}
\|\bar{\beta}^*|_{A^*_J\setminus A^k}\|_2 &\le \gamma^k\|\bar{\beta}^*\|_2 + \frac{\gamma\theta_{T,T}}{1-\gamma}h_2(T) \\
&\le \gamma^k\sqrt{J}\bar{M} + \xi\bar{m} \\
&< \bar{m} \quad \text{if} \quad k \ge \log_{\frac{1}{\gamma}}\frac{\sqrt{J}R}{1-\xi},
\end{aligned}$$

where the second inequality follows from the assumption $\bar{m} \ge \frac{\gamma h_2(T)}{(1-\gamma)\theta_{T,T}\xi}$ with $0 < \xi < 1$, and the last inequality follows after some simple algebra. This implies $A^*_J \subset A^k$ if $k \ge \log_{\frac{1}{\gamma}}\frac{\sqrt{J}R}{1-\xi}$. This proves part (i). The proof of part (ii) is similar to that of part (i) by using (52), we omit it here. For part (iii), suppose β^* is exactly K-sparse and $T = K$ in the SDAR algorithm (Algorithm 1). It follows from part (ii) that with probability at least $1-2\alpha$, $A^* = A^k$ if $k \ge \log_{\frac{1}{\gamma}}\frac{\sqrt{K}R}{1-\xi}$. Then part (iii) holds by showing that $A^{k+1} = A^*$. Indeed, by (74) and (52) we have

$$\begin{aligned}
\|\bar{\beta}^*|_{A^*\setminus A^{k+1}}\|_2 &\le \gamma\|\bar{\beta}^*|_{A^*\setminus A^k}\|_2 + \frac{\gamma}{\theta_{T,T}}\sigma\sqrt{K}\sqrt{2\log(p/\alpha)/n} \\
&= \frac{\gamma}{\theta_{T,T}}\sigma\sqrt{K}\sqrt{2\log(p/\alpha)/n}.
\end{aligned}$$

Then $A^{k+1} = A^*$ follows from the assumption that $m \ge \frac{\gamma}{(1-\gamma)\theta_{T,T}\xi}\sigma\sqrt{K}\sqrt{2\log(p/\alpha)/n} > \frac{\gamma}{\theta_{T,T}}\sigma\sqrt{K}\sqrt{2\log(p/\alpha)/n}$. This completes the proof of Corollary 8. ■

Proof of Theorem 12.

Proof For μ satisfying $T\mu \leq 1/4$, some algebra shows $\gamma_\mu < 1$ and $\frac{1+\mu}{1-(T-1)\mu} < \frac{3+2\mu}{1-(T-1)\mu} < 4$. Now Theorem 12 can be proved similarly to Theorem 4 by using (75), (53) and (58). We omit it here. This completes the proof of Theorem 12. ■

Proof of Corollary 14.

Proof The proofs of part (i) and part (ii) are similar to those of Corollary 8, we omit them here. Suppose β^* is exactly K-sparse and $T = K$ in SDAR. It follows from part (ii) that with probability at least $1-2\alpha$, $A^* = A^k$ if $k \geq \log_{\frac{1}{\gamma_\mu}} \frac{R}{1-\xi}$. Then part (iii) holds by showing that $A^{k+1} = A^*$. By (75), (53) and $\frac{3+2\mu}{1-(T-1)\mu} < 4$ we have

$$\begin{aligned}\|\bar{\beta}^*|_{A^*\setminus A^{k+1}}\|_\infty &\leq \gamma_\mu \|\bar{\beta}^*|_{A^*\setminus A^k}\|_\infty + 4\sigma\sqrt{2\log(p/\alpha)/n} \\ &= 4\sigma\sqrt{2\log(p/\alpha)/n}.\end{aligned}$$

Then $A^{k+1} = A^*$ by the assumption that

$$m \geq \frac{4}{\xi(1-\gamma_\mu)}\sigma\sqrt{2\log(p/\alpha)/n} > 4\sigma\sqrt{2\log(p/\alpha)/n}.$$

This completes the proof of Corollary 14. ■

Abstract

Graphical models with change-points are computationally challenging to fit, particularly in cases where the number of observation points and the number of nodes in the graph are large. Focusing on Gaussian graphical models, we introduce an approximate majorize-minimize (MM) algorithm that can be useful for computing change-points in large graphical models. The proposed algorithm is an order of magnitude faster than a brute force search. Under some regularity conditions on the data generating process, we show that with high probability, the algorithm converges to a value that is within statistical error of the true change-point. A fast implementation of the algorithm using Markov Chain Monte Carlo is also introduced. The performances of the proposed algorithms are evaluated on synthetic data sets and the algorithm is also used to analyze structural changes in the S&P 500 over the period 2000-2016.

Keywords: change-points, Gaussian graphical models, proximal gradient, simulated annealing, stochastic optimization

1. Introduction

Networks are fundamental structures that are commonly used to describe interactions between sets of actors or nodes. In many applications, the behaviors of the actors are observed over time and one is interested in recovering the underlying network connecting these actors. High-dimensional versions of this problem where the number of actors is large (compared to the number of time points) is of special interest. In the statistics and machine learning literature, this problem is typically framed as fitting large graphical models with sparse parameters, and significant progress has been made recently, both in terms of the statistical theory (Meinshausen and Buhlmann, 2006; Yuan and Lin, 2007; Banerjee et al., 2008; Ravikumar et al., 2011; Hastie et al., 2015), and practical algorithms (Friedman et al., 2007; Höfling and Tibshirani, 2009; Atchade et al., 2017).

In many problems arising in areas such as biology, finance, and political sciences, it is well-accepted that the underlying networks of interest are not static, but can undergo changes over time. Graphical models with change-points (or piecewise constant graphical models) are simple, yet powerful models that are particularly well-suited for such problems, and different versions have been explored in the literature. In this work, similarly to Zhou et al. (2009); Kolar et al. (2010); Roy et al. (2017), we focus on settings where the change occurring at a given change-point is global in the sense that it affects the joint distribution of all nodes. This differs from the approach of Kolar and Xing (2012) where at a given change-point only the conditional distribution of a single node sees a change. Which framework is more appropriate depends in general on the application. For instance in biological applications where interests are often on single biomolecules, nodewise change-point analysis might be preferred, whereas in many social science problems global structural changes in the network is often of interest. We also mention the alternative approach of Liu et al. (2013) which has an original parametrization that focuses directly on the occurring change. Although we work within the joint-change framework, we stress that our proposed algorithms can be easily adapted to work with other alternative models.

Despite their conceptual simplicity, graphical models with change-points are computationally challenging to fit. For instance a full grid search approach to locate a single change-point in a Gaussian graphical model with a lasso penalty (glasso) requires solving $O(T)$ glasso sub-problems, where T is the number of time points. Most algorithms for the glasso problem scale like $O(p^3)$ or worst[1], where p is the number of nodes. Hence when p and T are large, fitting a high-dimensional Gaussian graphical model with a single change-point has a taxing computational cost of $O(Tp^3)$ per iteration.

The literature addressing the computational aspects of model-based change-point models is rather sparse. A large portion of change-point detection procedures are based on cumulative sums (CUSUM) or similar statistic-monitoring approaches (Lévy-Leduc and Roueff, 2009; Aue et al., 2009; Fryzlewicz, 2014; Chen and Zhang, 2015; Cho and Fryzlewicz, 2015, and the references therein). By and large, these change-point detection procedures can be efficiently implemented, and the computational difficulty aforementioned can be avoided. However in problems where one wishes to detect structural changes in large networks, a CUSUM-based or a statistic-based approach can be difficult to employ, since it requires knowledge of the pertinent statistics to monitor. Furthermore the estimation of the parameters in a model-based change-point models can provide new insight in the underlying phenomenon driving the changes. Hence CUSUM-based approaches may not be appropriate in applications where the main driving forces of the network changes are poorly understood, and/or are of prime interest.

Specific works addressing computational issues in model-based change-point estimation include Roy et al. (2017); Leonardi and Bühlmann (2016). In Roy et al. (2017) the authors considered a discrete graphical model with change-point and proposed a two-steps algorithm for computation. However the success of their algorithm depends crucially on the choice of the coarse and refined grids, and there is limited insight on how to choose these. A related work is Leonardi and Bühlmann (2016) where the authors considered a high-dimensional linear regression model with change-points and proposed a dynamic programming approach to compute the change points. In the case of a single change-point their algorithm corresponds to the brute force (full-grid search) approach mentioned above.

In this work we propose an approximate majorize-minimize (MM) algorithm for fitting piecewise constant high-dimensional models. The algorithm can be applied more broadly. However to focus the idea we limit our discuss to Gaussian graphical models with an elastic net penalty. In this specific setting, the algorithm takes the form of a block update algorithm that alternates between a proximal gradient update of the graphical model parameters followed by a line search of the change-point. The proposed algorithm only solves for a single change-point. We extend it to multiple change-points by binary segmentation. We study the convergence of the algorithm and show under some regularity conditions on the data generating mechanism that the algorithm is stable, and produces values in the

1. Furthermore the constant in the big-O is typically problem dependent and can be large

vicinity of the true change-point (under the assumption that one such true change-point exists).

Each iteration of the proposed algorithm has a computational cost of $O(Tp^2 + p^3)$. Although this cost is one order of magnitude smaller than the $O(Tp^3)$ cost of the brute force approach, it can still be large when p and T are both large. As a solution we propose a stochastic version of the algorithm where the line search performed to update the change-point is replaced by a Markov Chain Monte Carlo (MCMC)-based simulated annealing. The simulated annealing update is cheap (its computational cost per iteration is $O(p^2)$) and is used as a stochastic approximation of the full line search. We show by simulation that the stochastic algorithm behaves remarkably well, and as expected outperforms the deterministic algorithm is terms of computing time.

The paper is organized as follows. Section 2 contains a presentation of the Gaussian graphical model with change-points, followed by a detailed presentation of the proposed algorithms. We performed extensive numerical experiments to investigate the behavior of the proposed algorithms. We also use the algorithm to analyze structural changes in the Standard & Poors (S&P) 500 over the period 2000-2016. The results are reported in Section 3. We gather some of the technical proofs in Section 4.

We end this introduction with some notation that we shall use throughout the paper. We denote $\mathcal{M}_p$ the set of all symmetric elements of $\mathbb{R}^{p\times p}$ equipped with its Frobenius norm $\|\cdot\|_{\mathsf{F}}$ and associated inner product

$$\langle A, B\rangle_{\mathsf{F}} \stackrel{\text{def}}{=} \sum_{1\le i\le j\le p} A_{ij}B_{ij}.$$

We denote $\mathcal{M}_p^+$ the subset of $\mathcal{M}_p$ of positive definite elements. For $0 < a < A \le +\infty$, let $\mathcal{M}_p^+(a, A)$ denote the subset of $\mathcal{M}_p^+$ of matrices θ such that $\lambda_{\mathsf{min}}(\theta) \ge a$, and $\lambda_{\mathsf{max}}(\theta) \le A$, where $\lambda_{\mathsf{min}}(M)$ (resp. $\lambda_{\mathsf{max}}(M)$) denotes the smallest eigenvalue (resp. the largest eigenvalue) of M.

If $u \in \mathbb{R}^p$, and $q \in [1,\infty]$, we define $\|u\|_q \stackrel{\text{def}}{=} (\sum_{j=1}^p |u_j|^q)^{1/q}$ ($\|u\|_\infty \stackrel{\text{def}}{=} \max_{1\le j\le p}|u_j|$). For a matrix $\theta \in \mathbb{R}^{p\times p}$ and $q \in [1,\infty]\setminus\{2\}$, we define $\|\theta\|_q$ similarly by viewing θ as a $\mathbb{R}^{p^2}$ vector. For $q = 2$, $\|\theta\|_2$ denotes the spectral norm (operator norm) of θ.

2. Fitting Gaussian Graphical Models with a Single Change-Point

Let $\{X^{(t)},\ 1 \le t \le T\}$ be a sequence of p-dimensional random vectors. The grid over which the change-points are searched is denoted $\mathcal{T} \stackrel{\text{def}}{=} \{n_0, \ldots, T - n_0\}$, for some integer $1 \le n_0 < T$. We define

$$S_1(\tau) \stackrel{\text{def}}{=} \frac{1}{\tau}\sum_{t=1}^{\tau} X^{(t)}X^{(t)'},\quad S_2(\tau) \stackrel{\text{def}}{=} \frac{1}{T-\tau}\sum_{t=\tau+1}^{T} X^{(t)}X^{(t)'},\ \ \tau \in \mathcal{T}.$$

We define the regularization function as

$$\wp(\theta) \stackrel{\text{def}}{=} \alpha\|\theta\|_1 + \frac{1-\alpha}{2}\|\theta\|_{\mathsf{F}}^2,\quad \theta \in \mathcal{M}_p, \tag{1}$$

where $\alpha \in [0, 1)$ is a given constant, and $\|\theta\|_1 \stackrel{\text{def}}{=} \sum_{i\le j}^p |\theta_{ij}|$. Then we define

$$g_{1,\tau}(\theta) = \begin{cases} \frac{1}{2}\frac{\tau}{T}\left[-\log\det(\theta) + \mathsf{Tr}(\theta S_1(\tau))\right] & \text{if } \theta \in \mathcal{M}_p^+, \\ +\infty & \text{otherwise,}\end{cases},\quad \tau \in \mathcal{T},$$

where $\mathsf{Tr}(A)$ (resp. $\det(A)$) denotes the trace (resp. the determinant) of A, and

$$g_{2,\tau}(\theta) = \begin{cases} \frac{1}{2}\left(1-\frac{\tau}{T}\right)\left[-\log\det(\theta) + \mathsf{Tr}(\theta S_2(\tau))\right] & \text{if } \theta \in \mathcal{M}_p^+, \\ +\infty & \text{otherwise,}\end{cases},\quad \tau \in \mathcal{T}.$$

For $j \in \{1, 2\}$, we set

$$\hat\theta_{j,\tau} \stackrel{\text{def}}{=} \mathsf{Argmin}_{\ \vartheta\in\mathcal{M}_p^+}\left[g_{j,\tau}(\vartheta) + \lambda_{j,\tau}\wp(\vartheta)\right], \tag{2}$$

for regularization parameters $\lambda_{1,\tau} > 0, \lambda_{2,\tau} > 0$, that we assume fixed throughout. Note that due to the quadratic term in the elastic-net regularization (1), each of these minimization problems (2) is strongly convex. Hence for each $\tau \in \mathcal{T}$, and $j \in \{1, 2\}$, $\hat\theta_{j,\tau}$ is well-defined. We consider the problem of computing the change point estimate $\hat\tau$ defined as

$$\hat\tau = \mathsf{Argmin}_{\ \tau\in\mathcal{T}}\left[g_{1,\tau}(\hat\theta_{1,\tau}) + \lambda_{1,\tau}\wp(\hat\theta_{1,\tau}) + g_{2,\tau}(\hat\theta_{2,\tau}) + \lambda_{2,\tau}\wp(\hat\theta_{2,\tau})\right]. \tag{3}$$

If the minimization problem in (3) has more than one solution, then $\hat\tau$ denotes any one of these solutions. The quantity $\hat\tau$ is the maximum likelihood estimate of a change point τ in the model which assumes that $X^{(1)}, \ldots, X^{(\tau)}$ are independent with common distribution $\mathbf{N}(0, \theta_1^{-1})$, and $X^{(\tau+1)}, \ldots, X^{(T)}$ are independent with common distribution $\mathbf{N}(0, \theta_2^{-1})$, for an unknown change-point τ, and unknown precision matrices $\theta_1 \ne \theta_2$.

The problem of computing the graphical lasso (glasso) estimators $\hat\theta_{j,\tau}$ in (2) has received a lot of attention in the literature, and several efficient algorithms have been developed for this purpose (see for instance Atchadé et al., 2015, and the references therein). Hence in principle, using any of these available glasso algorithms, the change-point problem in (3) can be solved by solving $T - 2n_0 + 1 = O(T)$ glasso sub-problems. A similar algorithm is advocated in Leonardi and Bühlmann (2016) for fitting a high-dimensional linear regression model with change-points. However this brute force approach can be very time-consuming in cases where p and T are large. For instance, one of the most cost-efficient algorithm for solving the glasso problem in high-dimensional cases is the standard proximal gradient algorithm (Rolfs et al., 2012; Atchadé et al., 2015), which has a computational cost of $O(p^3\mathsf{cond}(\hat\theta)^2\log(1/\delta))$ to deliver a δ-accurate solution (that is $\|\theta-\hat\theta\|_{\mathsf{F}} \le \delta$), where $\mathsf{cond}(A)$ denotes the condition number of A, that is the ratio of the largest eigenvalue over the smallest eigenvalue of A. Hence when p and T are large the computational cost of the brute force approach for computing (3) is of order $O\left(Tp^3\mathsf{cond}(\hat\theta_{j,\tau})^2\log(1/\delta)\right)$, which can become prohibitively large.

We propose an algorithm that we show has a better computational complexity. To motivate the algorithm we first introduce a majorize-minimize (MM) algorithm for solving (3). We refer the reader to Wu and Lange (2010) for a general introduction to MM algorithms. Let

$$G(t) \stackrel{\text{def}}{=} g_{1,t}(\hat\theta_{1,t}) + \lambda_{1,t}\wp(\hat\theta_{1,t}) + g_{2,t}(\hat\theta_{2,t}) + \lambda_{2,\tau}\wp(\hat\theta_{2,t}),\ \ t \in \mathcal{T}$$

denote the objective function of the minimization problem in (3). For $\theta_1, \theta_2 \in \mathcal{M}_p$, we also define

$$\mathcal{H}(\tau|\theta_1, \theta_2) \stackrel{\text{def}}{=} g_{1,\tau}(\theta_1) + \lambda_{1,\tau}\wp(\theta_1) + g_{2,\tau}(\theta_2) + \lambda_{2,\tau}\wp(\theta_2),\ \ \tau \in \mathcal{T}. \tag{4}$$

Instead of the brute force approach that requires solving (2) for each value $\tau \in \mathcal{T}$, consider the following algorithm.

Algorithm 1 (MM algorithm) *Pick $\tau^{(0)} \in \mathcal{T}$, and for $k = 1, \ldots, K$, repeat the following steps.*

1. *Given $\tau^{(k-1)} \in \mathcal{T}$, compute $\hat{\theta}_{1,\tau^{(k-1)}}$ and $\hat{\theta}_{2,\tau^{(k-1)}}$, and minimize the function $\mathcal{H}(t|\hat{\theta}_{1,\tau^{(k-1)}}, \hat{\theta}_{2,\tau^{(k-1)}})$ to get $\tau^{(k)}$:*

$$\tau^{(k)} = \mathsf{Argmin}_{t\in\mathcal{T}}\, \mathcal{H}(t|\hat{\theta}_{1,\tau^{(k-1)}}, \hat{\theta}_{2,\tau^{(k-1)}}).$$

□

By definition of $\hat{\theta}_{j,\tau}$ in (2), we have $G(t) \leq \mathcal{H}(t|\hat{\theta}_{1,\tau^{(k-1)}}, \hat{\theta}_{2,\tau^{(k-1)}})$ for all $t \in \mathcal{T}$. Furthermore $G(\tau^{(k-1)}) = \mathcal{H}(\tau^{(k-1)}|\hat{\theta}_{1,\tau^{(k-1)}}, \hat{\theta}_{2,\tau^{(k-1)}})$. Therefore, for all $k \geq 1$,

$$G(\tau^{(k)}) \leq \mathcal{H}(\tau^{(k)}|\hat{\theta}_{1,\tau^{(k-1)}}, \hat{\theta}_{2,\tau^{(k-1)}}) \leq \mathcal{H}(\tau^{(k-1)}|\hat{\theta}_{1,\tau^{(k-1)}}, \hat{\theta}_{2,\tau^{(k-1)}}) = G(\tau^{(k-1)}).$$

Hence the objective function G is non-increasing along the iterates of Algorithm 1. Note that this algorithm is already potentially faster than the brute force approach, particular when T is large, since we compute the graphical-lasso solutions $\hat{\theta}_{j,\tau^{(k)}}$ only for time points visited along the iterations. We propose to further reduce the computational cost by computing the solutions $\hat{\theta}_{j,\tau^{(k)}}$ only approximately, by simple gradient updates.

Given $\gamma > 0$, and a matrix $\theta \in \mathbb{R}^{p\times p}$, define $\mathrm{Prox}_\gamma(\theta)$ (the proximal map with respect to the penalty function $\wp(\theta) = \alpha\|\theta\|_1 + (1-\alpha)\,\|\theta\|_{\mathsf{F}}^2/2)$ as the symmetric $\mathbb{R}^{p\times p}$ matrix such that for $1 \leq i, j \leq p$,

$$(\mathrm{Prox}_\gamma(\theta))_{ij} = \begin{cases} 0 & \text{if } |\theta_{ij}| < \alpha\gamma \\ \frac{\theta_{ij}-\alpha\gamma}{1+(1-\alpha)\gamma} & \text{if } \theta_{ij} \geq \alpha\gamma \\ \frac{\theta_{ij}+\alpha\gamma}{1+(1-\alpha)\gamma} & \text{if } \theta_{ij} \leq -\alpha\gamma\,. \end{cases}$$

We consider the following algorithm.

Algorithm 2 *[Approximate MM algorithm] Fix a step-size $\gamma > 0$. Pick some initial value $\tau^{(0)} \in \mathcal{T}$, $\theta_1^{(0)}, \theta_2^{(0)} \in \mathcal{M}_p^+$. Repeat for $k = 1, \ldots, K$. Given ($\tau^{(k-1)}$, $\theta_1^{(k-1)}$, $\theta_2^{(k-1)}$), do the following:*

1. *Compute*

$$\theta_1^{(k)} = \mathrm{Prox}_{\gamma\lambda_{1,\tau^{(k-1)}}}\left(\theta_1^{(k-1)} - \gamma\left(S_1(\tau^{(k-1)}) - (\theta_1^{(k-1)})^{-1}\right)\right),$$

2. *compute*

$$\theta_2^{(k)} = \mathrm{Prox}_{\gamma\lambda_{2,\tau^{(k-1)}}}\left(\theta_2^{(k-1)} - \gamma\left(S_2(\tau^{(k-1)}) - (\theta_2^{(k-1)})^{-1}\right)\right),$$

3. *compute*

$$\tau^{(k)} \stackrel{\text{def}}{=} \mathsf{Argmin}_{t\in\mathcal{T}}\, \mathcal{H}\left(t|\theta_1^{(k)}, \theta_2^{(k)}\right).$$

□

Note that, if instead of a single proximal gradient update in Step (1)-(2), we do a large number proximal gradient updates (an infinite number for the sake of the argument), we recover exactly Algorithm 1. Hence Algorithm 2 is an approximate version of Algorithm 1.

Remark 1 *1. Notice that one can easily compute $\mathcal{H}(\tau+1|\theta_1, \theta_2)$ from $\mathcal{H}(\tau|\theta_1, \theta_2)$ by a rank-one update in $O(p^2)$ number of operations. Hence the computational cost of Step (3) is $O(Tp^2)$. And the total computational cost of one iteration of Algorithm 2 is $O(p^3 + Tp^2)$.*

2. *In practice, and as with any gradient descent algorithm, one needs to exercise some care in choosing the step-size γ. Clearly, too small values of γ lead to slow convergence. However, choosing γ too large might cause the algorithm to diverge. Another (related) issue is how to guarantee that the matrices $\theta_1^{(k)}$ and $\theta_2^{(k)}$ maintain positive definiteness throughout the iterations. What we show below is that positive definiteness is automatically guaranteed if the step-size γ is taken small enough. A nice trade-off that works well from the software engineering viewpoint is to start with a large value of γ and to re-initialize the algorithm with a smaller γ if at some point positive definiteness is lost. This issue is discussed more extensively in Atchadé et al. (2015).*

As suggested in the remark above, Algorithm 2 raises two basic questions. The first question is whether the algorithm is stable, where here by stability we mean whether the algorithm runs without $\theta_1^{(k-1)}$ or $\theta_2^{(k-1)}$ losing positive definiteness. Indeed we notice that Steps (1 and 2) involve taking the inverse of the matrices $\theta_1^{(k-1)}$, and $\theta_2^{(k-1)}$, but there is no guarantee a priori that these matrices are non-singular. Using results established in Atchadé et al. (2015), we answer this question by showing below that if the step-size γ is small enough then the algorithm is actually stable. The second basic question is whether the algorithm converges to the optimal value. We address this question below.

For $j \in \{1, 2\}$, we set

$$\underline{\lambda}_j \stackrel{\text{def}}{=} \min_{\tau\in\mathcal{T}} \lambda_{j,\tau},\quad \bar{\lambda}_j \stackrel{\text{def}}{=} \max_{\tau\in\mathcal{T}} \lambda_{j,\tau},\quad \mu_j \stackrel{\text{def}}{=} \max_{\tau\in\mathcal{T}} \left[\frac{1}{2}\|S_j(\tau)\|_2 + \alpha p\lambda_{j,\tau}\right],$$

$$\mathsf{b}_j \stackrel{\text{def}}{=} \frac{-\mu_j + \sqrt{\mu_j^2 + 2\bar{\lambda}_j(1-\alpha)\frac{n_0}{T}}}{2(1-\alpha)\bar{\lambda}_j},\quad \mathsf{B}_j \stackrel{\text{def}}{=} \frac{\mu_j + \sqrt{\mu_j^2 + 2\underline{\lambda}_j(1-\alpha)}}{2(1-\alpha)\underline{\lambda}_j}.$$

Lemma 2 *Fix $j \in \{1, 2\}$. For all $\tau \in \mathcal{T}$, $\hat{\theta}_{j,\tau} \in \mathcal{M}_p^+(\mathsf{b}_j, +\infty)$. Let $\{(\theta_1^{(k)}, \theta_2^{(k)}),\ k \geq 0\}$ be the output of Algorithm 2. If the step-size γ satisfies $\gamma \in (0, \mathsf{b}_j^2]$, and $\theta_j^{(0)} \in \mathcal{M}_p^+(\mathsf{b}_j, \mathsf{B}_j)$, then $\theta_j^{(k)} \in \mathcal{M}_p^+(\mathsf{b}_j, \mathsf{B}_j)$, for all $k \geq 0$.*

Proof We present the proof for $j = 1$, the case $j = 2$ being similar. Note that $\hat{\theta}_{1,\tau}$ is the graphical elastic-net estimate based on data $X^{(1)}, \ldots, X^{(\tau)}$. The fact that $\hat{\theta}_{1,\tau}$ exists (and is unique) and satisfies the spectral bound $\lambda_{\mathsf{min}}(\hat{\theta}_{1,\tau}) \geq \mathsf{b}_1$ then follows from known results on the graphical elastic-net (see for instance Lemma 1 of Atchadé et al., 2015).

The second part of the lemma is similar to Lemma 2 of Atchadé et al. (2015). The idea is to show that if $\theta_1^{(k)} \in \mathcal{M}_p^+(\mathsf{b}_1, \mathsf{B}_1)$ then $\theta_1^{(k+1)} \in \mathcal{M}_p^+(\mathsf{b}_1, \mathsf{B}_1)$. This is proved as follows. Suppose that $\theta_1^{(k)} \in \mathcal{M}_p^+(\mathsf{b}_1, \mathsf{B}_1)$. Hence $\theta_1^{(k)}$ is non-singular. It is well-known (see for instance Parikh and Boyd, 2013, Section 4.2) that we can write $\theta_1^{(k+1)}$ as

$$\theta_1^{(k+1)} \quad = \quad \mathsf{Argmin}_{u\in\mathcal{M}_p}\left[\left\langle \nabla g_{1,\tau^{(k)}}(\theta_1^{(k)}), u - \theta_1^{(k)}\right\rangle + \frac{1}{2\gamma}\left\|u - \theta_1^{(k)}\right\|_{\mathsf{F}}^2 + \lambda_{1,\tau^{(k)}}\wp(u)\right].$$

The optimality conditions of this problem implies that there exists $Z \in \mathbb{R}^{p\times p}$, where $Z_{ij} \in [-1, 1]$ for all i, j such that

$$\nabla g_{1,\tau^{(k)}}(\theta_1^{(k)}) + \frac{1}{\gamma}\left(\theta_1^{(k+1)} - \theta_1^{(k)}\right) + \lambda_{1,\tau^{(k)}}\left(\alpha Z + (1-\alpha)\theta_1^{(k+1)}\right) = 0.$$

Since $\nabla g_{1,\tau}(\theta) = \frac{\tau}{2T}(S_1(\tau) - \theta^{-1})$, we re-arrange this optimality condition into:

$$\left(1 + (1-\alpha)\lambda_{1,\tau^{(k)}}\gamma\right)\theta_1^{(k+1)} \quad = \quad \theta_1^{(k)} \; + \; \frac{\gamma\tau^{(k)}}{2T}\left(\theta_1^{(k)}\right)^{-1} \; - \; \gamma\left(\frac{\tau^{(k)}}{2T}S_1(\tau^{(k)}) + \alpha\lambda_{1,\tau^{(k)}}Z\right).$$

Hence, if $\lambda_{\mathsf{min}}(\theta_1^{(k)}) \geq \mathsf{b}_1$, and $\mathsf{b}_1^2 \geq \gamma\tau/(2T)$ (which holds true if $\gamma \leq 2\mathsf{b}_1^2$), and using the fact that $\lambda_{\mathsf{min}}(A+B) \geq \lambda_{\mathsf{min}}(A) + \lambda_{\mathsf{min}}(B)$, we get

$$\lambda_{\mathsf{min}}(\theta_1^{(k+1)}) \geq \frac{1}{1 + (1-\alpha)\bar{\lambda}_1\gamma}\left(\mathsf{b}_1 + \frac{\gamma n_0}{2T}\frac{1}{\mathsf{b}_1} - \gamma\mu_1\right), \tag{5}$$

where $\mu_1 = \max_{\tau\in\mathcal{T}}\left[\frac{1}{2}\|S_1(\tau)\|_2 + \alpha p\lambda_{1,\tau}\right]$, using the fact that $\|Z\|_2 \leq p$. We note that as chosen, b_1 satisfies

$$(1-\alpha)\bar{\lambda}_1\mathsf{b}_1^2 + \mu_1\mathsf{b}_1 - \frac{n_0}{2T} = 0,$$

and this (with some easy algebra) implies that the right hand side of (5) is equal to b_1. Hence $\lambda_{\mathsf{min}}(\theta_1^{(k+1)}) \geq \mathsf{b}_1$. Similarly, if $\lambda_{\mathsf{max}}(\theta_1^{(k)}) \leq \mathsf{B}_1$, then

$$\lambda_{\mathsf{max}}(\theta_1^{(k+1)}) \leq \frac{1}{1 + (1-\alpha)\underline{\lambda}_1\gamma}\left(\mathsf{B}_1 + \frac{\gamma}{2}\frac{1}{\mathsf{B}_1} + \gamma\mu_1\right) = \mathsf{B}_1,$$

where the last equality follows from the fact that we have chosen B_1 such that

$$(1-\alpha)\underline{\lambda}_1\mathsf{B}_1^2 - \mu_1\mathsf{B}_1 - \frac{1}{2} = 0.$$

This completes the proof. ■

Remark 3 *The first statement of Lemma 2 implies that the change-point problem (3) has at least one solution. The second part shows that when the step-size γ is small enough, all the iterates of the algorithm remains positive definite. We note that the fact that $\alpha < 1$ is crucial in the arguments. The result remains true where $\alpha = 1$, however the arguments is slightly more involved (see Atchadé et al., 2015, Lemma 2). For simplicity we focus in this paper on the case $\alpha \in [0,1)$.*

We now address the issue of convergence. Clearly the function $t \mapsto \mathcal{H}(t|\theta_1,\theta_2)$ is not smooth, nor convex. This implies that Algorithm 2 cannot be analyzed using standard optimization tools. And indeed, we will not be able to establish that the output of Algorithm 2 converges to the minimizer $\hat{\tau}$. Rather, we introduce a containment assumption (Assumption H1) and we show that when it holds, then the output of Algorithm 2 converges to some neighborhood of the true change-point (the existence of this true change-point is part of the assumption).

H1 *There exist $\epsilon > 0$, $c \geq 0$, $\kappa \in [0,1)$, and $\tau_\star \in \mathcal{T}$ such that the following holds. For any $\tau \in \mathcal{T}$, and for any $\theta_1, \theta_2 \in \mathcal{M}_p^+$ such that $\left\|\theta_1 - \hat{\theta}_{1,\tau}\right\|_F + \left\|\theta_2 - \hat{\theta}_{2,\tau}\right\|_F \leq \epsilon$ we have*

$$|\mathsf{Argmin}_{\,t\in\mathcal{T}}\mathcal{H}(t|\theta_1,\theta_2) - \tau_\star| \leq \kappa|\tau - \tau_\star| + c. \tag{6}$$

Remark 4 *Plainly, what is imposed in H1 is the existence of a time point $\tau_\star \in \mathcal{T}$ (that we can view as the true change-point), such that anytime we take $\tau \in \mathcal{T}$ that is far from $\tau_\star$ in the sense that $|\tau - \tau_\star| > c/(1-\kappa)$, if θ_1, θ_2 are sufficiently close to the solutions $\hat{\theta}_{1,\tau}$ and $\hat{\theta}_{2,\tau}$ respectively, then computing $\mathsf{Argmin}_{\,t\in\mathcal{T}}\mathcal{H}(t|\theta_1,\theta_2)$ brings us closer to $\tau_\star$:*

$$|\mathsf{Argmin}_{\,t\in\mathcal{T}}\mathcal{H}(t|\theta_1,\theta_2) - \tau_\star| \leq \kappa|\tau - \tau_\star| + c < |\tau - \tau_\star|.$$

This containment assumption is akin to a curvature assumption on the function $t \mapsto \mathcal{H}(t|\theta_1,\theta_2)$ when θ_1 and θ_2 are reasonably close to $\hat{\theta}_{1,\tau}$, $\hat{\theta}_{2,\tau}$, respectively. The assumption seems realistic in settings where the data $X^{(1:T)}$ is indeed drawn from a Gaussian graphical model with true change-point $\tau_\star$, and parameters $\theta_{\star,1}$, $\theta_{\star,2}$. Indeed in this case, and if T is large enough, for any τ that is not too close to the boundaries, one expects $\hat{\theta}_{1,\tau}$ and $\hat{\theta}_{2,\tau}$ to be good estimates of $\theta_{\star,1}$ and $\theta_{\star,2}$, respectively. Therefore if $\left\|\theta_1 - \hat{\theta}_{1,\tau}\right\|_F + \left\|\theta_2 - \hat{\theta}_{2,\tau}\right\|_F \leq \epsilon$ for ϵ small enough, one expect as well θ_1 and θ_2 to be close to $\theta_{\star,1}$ and $\theta_{\star,2}$ respectively. Hence $\mathsf{Argmin}_{\,t\in\mathcal{T}}\mathcal{H}(t|\theta_1,\theta_2)$ should be close to $\mathsf{Argmin}_{\,t\in\mathcal{T}}\mathcal{H}(t|\theta_{\star,1},\theta_{\star,2})$, which in turn should be close to $\tau_\star$. Theorem 9 below will make this intuition precise.

□

In the next result we will see that in fact the iterates $\theta_1^{(k)}$ and $\theta_2^{(k)}$ closely track $\theta_{1,\tau^{(k)}}$ and $\theta_{2,\tau^{(k)}}$ respectively. Hence, when H1 holds Equation (6) guarantees that the sequence $\tau^{(k)}$ remains close to $\tau_\star$.

Theorem 5 *Suppose that $\gamma \in (0, b_1^2 \wedge b_2^2]$, and $\theta_j^{(0)} \in \mathcal{M}_p^+(b_j, B_j)$, for $j = 1,2$. Then*

$$\lim_k \left\|\theta_1^{(k)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_F = 0, \quad \lim_k \left\|\theta_2^{(k)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_F = 0.$$

Furthermore, if H1 holds then

$$\limsup_{k\to\infty}\left|\tau^{(k)} - \tau_\star\right| \leq \frac{c}{1-\kappa}.$$

Proof See Section 4.1 ■

Remark 6 *Note that the theorem does not guarantee that $\tau^{(k)}$ converges to $\tau_\star$, but rather its conclusion is that for k large $\tau^{(k)}$ stays within $c/(1-\kappa)$ of $\tau_\star$.*

We now address the question whether H1 is a realistic assumption. More precisely we will show that the argument highlighted in Remark 4 holds true under some regularity conditions. Suppose that $X^{(1:T)} \stackrel{\text{def}}{=} (X^{(1)}, \ldots, X^{(T)})$ are p-dimensional independent random variables such that

$$X^{(1)}, \ldots, X^{(\tau_\star)} \overset{i.i.d.}{\sim} \mathbf{N}(0, \theta_{\star,1}^{-1}), \quad \text{and} \quad X^{(\tau_\star+1)}, \ldots, X^{(T)} \overset{i.i.d.}{\sim} \mathbf{N}(0, \theta_{\star,2}^{-1}), \tag{7}$$

for some unknown change-point $\tau_\star$, and unknown symmetric positive definite precision matrices $\theta_{\star,1} \neq \theta_{\star,2}$. We set $\Sigma_{\star,j} \stackrel{\text{def}}{=} \theta_{\star,j}^{-1}$, and we let s_j denote the number of non-zero entries of $\theta_{\star,j}$, $j = 1,2$. For an integer $\iota \in \{1, \ldots, p\}$, we define the ι-th restricted eigenvalues of $\Sigma_{\star,j}$ as

$$\underline{\kappa}_j(\iota) \stackrel{\text{def}}{=} \inf\left\{u'(\Sigma_{\star,j})u,\ \|u\|_2 = 1,\ \|u\|_0 \leq \iota\right\},$$

$$\bar{\kappa}_j(\iota) \stackrel{\text{def}}{=} \sup\left\{u'(\Sigma_{\star,j})u,\ \|u\|_2 = 1,\ \|u\|_0 \leq \iota\right\}.$$

We set $s \stackrel{\text{def}}{=} \max(s_1, s_2)$, $\bar{\kappa} \stackrel{\text{def}}{=} \max(\bar{\kappa}_1(2), \bar{\kappa}_2(2))$, $\underline{\kappa} \stackrel{\text{def}}{=} \min(\underline{\kappa}_1(2), \underline{\kappa}_2(2))$, and we set the regularization parameter $\lambda_{j,\tau}$ as

$$\lambda_{1,\tau} \stackrel{\text{def}}{=} \frac{\bar{\kappa}}{\alpha T}\sqrt{48\tau\log(pT)}, \quad \lambda_{2,\tau} \stackrel{\text{def}}{=} \frac{\bar{\kappa}}{\alpha T}\sqrt{48(T-\tau)\log(pT)}, \quad \tau \in \mathcal{T}. \tag{8}$$

We need to assume that the parameter $\alpha \in [0,1)$ in the regularization term is large enough to produce approximately sparse solutions in (2). To that end, we assume that

$$\frac{\alpha}{1-\alpha} \geq \max\left(\|\theta_{\star,1}\|_\infty, \|\theta_{\star,2}\|_\infty\right). \tag{9}$$

Finally, we assume that the search domain $\mathcal{T}$ is such that for all $\tau \in \mathcal{T}$,

$$\min(\tau, T-\tau) \geq A_1^2 \log(pT), \tag{10}$$

where

$$A_1 \stackrel{\text{def}}{=} \max\left(2\left(\frac{\bar{\kappa}}{\underline{\kappa}}\right)^2, (1280)s^{1/2}\bar{\kappa}(\|\theta_{\star,1}\|_2 \vee \|\theta_{\star,2}\|_2)\right),$$

and

$$\bar{\kappa}\sqrt{\tau\log(pT)} \geq \frac{1}{2\sqrt{3}}(\tau-\tau_\star)_+\|\theta_{\star,2}^{-1} - \theta_{\star,1}^{-1}\|_\infty,$$
$$\text{and} \quad \bar{\kappa}\sqrt{(T-\tau)\log(pT)} \geq \frac{1}{2\sqrt{3}}(\tau_\star-\tau)_+\|\theta_{\star,2}^{-1} - \theta_{\star,1}^{-1}\|_\infty, \tag{11}$$

where $x_+ \stackrel{\text{def}}{=} \max(x, 0)$.

Remark 7 *Assumption (10) is a minimum sample size requirement. See for instance Ravikumar et al. (2011) Theorem 1, and 2 for similar conditions in standard Gaussian graphical model estimation. Here we require to have $\mathcal{T}$ such that $\min(\tau, T-\tau) = O(s\log(pT))$ for all $\tau \in \mathcal{T}$. This obviously implies that we need T to be at least $O(s\log(p))$. It is unclear whether the large constant 1280 in (10) is tight or simply an artifact of our proof techniques.*

To understand Assumption (11), note that for $\tau > \tau_\star$, the estimator $\hat{\theta}_{1,\tau}$ in (2) is based on misspecified data $X^{(\tau_\star+1)}, \ldots, X^{(\tau)}$. Hence if $\tau > \tau_\star$ is too far away from $\tau_\star$, the estimators $\hat{\theta}_{1,\tau}$ may behave poorly, particularly if $\theta_{\star,1}$ are $\theta_{\star,2}$ are very different. Assumption (11) rules out such settings, by requiring the search domains $\mathcal{T}$ to be roughly a $\sqrt{T}$ neighborhood of $\tau_\star$. Indeed, suppose that $\tau_\star = \rho_\star T$, for some $\rho_\star \in (0,1)$. Then it can be easily checked that any search domain of the form $(\tau_\star - r_1 T^{1/2}, \tau_\star + r_2 T^{1/2})$, satisfies (10) and (11) for T large enough, provided that

$$0 < r_1 \leq \frac{2\sqrt{3}\bar{\kappa}\sqrt{\rho_\star\log(pT)}}{\|\theta_{\star,2}^{-1} - \theta_{\star,1}^{-1}\|_\infty}, \quad \textit{and} \quad 0 < r_2 \leq \frac{2\sqrt{3}\bar{\kappa}\sqrt{(1-\rho_\star)\log(pT)}}{\|\theta_{\star,2}^{-1} - \theta_{\star,1}^{-1}\|_\infty}.$$

Of course, this search domain is difficult to use in practice since it depends on $\tau_\star$. In practice, we have found that taking $\mathcal{T}$ of the form $(rT, (1-r)T)$ for $r \leq 0.1$ works well, even though it is much wider than what is prescribed by our theory.

□

For $\tau \in \mathcal{T}$, let

$$r_{1,\tau} \stackrel{\text{def}}{=} A_2\bar{\kappa}\|\theta_{\star,1}\|_2^2\sqrt{\frac{s_1\log(pT)}{\tau}}, \quad r_{2,\tau} \stackrel{\text{def}}{=} A_2\bar{\kappa}\|\theta_{\star,2}\|_2^2\sqrt{\frac{s_2\log(pT)}{T-\tau}},$$

where A_2 is an absolute constant that can be taken as $16 \times 20 \times \sqrt{48}$. We set $b \stackrel{\text{def}}{=} \min(\lambda_{\mathsf{min}}(\theta_{\star,1}), \lambda_{\mathsf{min}}(\theta_{\star,2}))$, and $B \stackrel{\text{def}}{=} \max(\lambda_{\mathsf{max}}(\theta_{\star,1}), \lambda_{\mathsf{max}}(\theta_{\star,2}))$. We assume that for $j = 1,2$, and for $\tau \in \mathcal{T}$,

$$r_{j,\tau} \leq \min\left(\frac{\lambda_{\mathsf{min}}(\theta_{\star,j})}{4}, \frac{\|\theta_{\star,j}\|_\infty}{2}, \frac{\|\theta_{\star,j}\|_1}{1+8s_j^{1/2}}\right), \quad r_{j,\tau} \leq \frac{\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}}{2(1+8s^{1/2})}$$
$$\text{and} \quad r_{j,\tau} \leq A_2\left(\frac{b}{B}\right)^4\frac{\|\theta_{\star,j}\|_1}{s_j^{1/2}}. \tag{12}$$

Remark 8 *Condition (12) is mostly technical. As we will see below in Lemma 16, the term $r_{j,\tau}$ is the convergence rate toward $\theta_{\star,j}$ of the estimator $\hat{\theta}_{j,\tau}$, and is expected to converge to 0 with p, T (which implies that the sample size T cannot be too small compared to $\|\theta_{\star,j}\|_2^4 s_j\log(pT)$). Hence according to (12) the matrices $\theta_{\star,1}$ and $\theta_{\star,2}$ need to be such that the terms on the right-hand sides do no vanish faster than the rate $r_{j,\tau}$. In particular $\theta_{\star,1}$ and $\theta_{\star,2}$ should be well-conditioned so that $\lambda_{min}(\theta_{\star,j})$ and the ratio b/B do not decay too fast.*

Theorem 9 *Consider the output $\{(\theta_1^{(k)}, \theta_2^{(k)}),\ k \geq 0\}$ of Algorithm 2. Suppose that $\gamma \in (0, \mathsf{b}_1^2 \wedge \mathsf{b}_2^2]$, and $\theta_j^{(0)} \in \mathcal{M}_p^+(\mathsf{b}_j, \mathsf{B}_j)$, for $j = 1,2$. Suppose that the statistical model underlying the data $X^{(1:T)}$ is as in (7), and that (8)-(12) hold. Suppose also that*

$$\|\theta_{\star,2} - \theta_{\star,1}\|_F \geq 8A_2\max\left[\left(\frac{\lambda_{min}(\theta_{\star,1})}{\lambda_{max}(\theta_{\star,1})}\right)^2\frac{\|\theta_{\star,1}\|_1}{s_1^{1/2}}, \left(\frac{\lambda_{min}(\theta_{\star,2})}{\lambda_{max}(\theta_{\star,2})}\right)^2\frac{\|\theta_{\star,2}\|_1}{s_2^{1/2}}\right]. \tag{13}$$

Then with probability at least $1 - \frac{8}{pT} - \frac{4}{p^2(1-e^{-C_0})}$, H1 holds with $\epsilon = (1/\sqrt{p})\min_{\tau\in\mathcal{T}}(r_{1,\tau} \wedge r_{2,\tau})$, $\kappa = 0$, and $c = 4\log(p)/C_0$, where

$$C_0 \stackrel{\text{def}}{=} \min\left[\frac{\|\theta_{\star,2}-\theta_{\star,1}\|_F^4}{128B^4\|\theta_{\star,2}-\theta_{\star,1}\|_1^2}, \left(\frac{\underline{\kappa}}{\bar{\kappa}}\right)^4\right].$$

In particular, with probability at least $1 - \frac{8}{pT} - \frac{4}{p^2(1-e^{-C_0})}$ we have

$$\limsup_{k\to\infty}\left|\tau^{(k)} - \tau_\star\right| \leq \frac{4}{C_0}\log(p), \tag{14}$$

Proof See Section 4.2. ■

Remark 10 *The main point of the theorem is that under the assumptions and data generation mechanism described above, the containment assumption H1 holds with probability as least $1 - \frac{8}{pT} - \frac{4}{p^2(1-e^{-C_0})}$, and where ϵ can be taken as $\min_\tau r_{1,\tau} \wedge r_{2,\tau}/\sqrt{p}$, $\kappa = 0$, and $c = 4\log(p)/C_0$. Conclusion (14) is then simply a consequence of Theorem 5. One should view (14) as saying that for k large, the output of Algorithm 2 fluctuates around $\tau_\star$, and the size of the fluctuation is $O(\log(p))$, under the assumed data generating mechanism. And we should stress that Algorithm 2 is not stochastic. Hence the randomness expressed in the theorem is with respect to the data generating mechanism.*

Remark 11 *We note that the bound in (14) grows with p. In classical change-point problems where p is fixed, and $T \to \infty$, it is known (see e.g. Bai, 1997) that with a fixed-magnitude change, the*

best one can achieve in estimating τ is $O(1)$. The rate in Theorem 9 suggests that in the high-dimensional setting where p grows the estimation rate for τ if of order $O(\log(p))$ (see also Roy et al., 2017). We believe that it is not possible to remove the additional $\log(p)$ factor, although to the best of our knowledge this question is still open. Note that it is customary in the change-point literature to take a re-scaled viewpoint and to define the change point as $a_\star \in (0,1)$ such that $\tau_\star = a_\star T$. In that setting the estimation rate for $a_\star$ is $O(1/T)$ in the classical fixed-dimensional fixed-magnitude change setting, and $O(\log(p)/T)$ in our setting.

2.1 A Stochastic Version

When T is much larger than p, Step 3 of Algorithm 2 becomes costly. In such cases, one can gain in efficiency by replacing Step 3 by a Monte Carlo approximation. We explore the use of simulated annealing to approximately solve Step 3 of Algorithm 2. Given $\theta_1, \theta_2 \in \mathcal{M}_p$, and $\beta > 0$, let $\pi_{\beta,\theta_1,\theta_2}$ denote the probability distribution on $\mathcal{T}$ defined as

$$\pi_{\beta,\theta_1,\theta_2}(\tau) = \frac{1}{Z_{\beta,\theta_1,\theta_2}} \exp\left(-\frac{\mathcal{H}(\tau|\theta_1,\theta_2)}{\beta}\right), \quad \tau \in \mathcal{T}.$$

Here, $Z_{\beta,\theta_1,\theta_2}$ is the normalizing constant, and $\beta > 0$ is the cooling parameter, that we shall drive down to zero with the iteration to increase the accuracy of the Monte Carlo approximation. Direct sampling from $\pi_{\beta,\theta_1,\theta_2}$ is typically possible, but this has the same computational cost as Step 3 of Algorithm 2. We will use a Markov Chain Monte Carlo approach which will allow us to make only a small number of calls of the function $\mathcal{H}$, per iteration. Let $\mathcal{K}_{\beta,\theta_1,\theta_2}$ denote a Markov kernel on $\mathcal{T}$ with invariant distribution $\pi_{\beta,\theta_1,\theta_2}$. Typically we will choose $\mathcal{K}_{\beta,\theta_1,\theta_2}$ as a Metropolis-Hastings Markov kernel (we give examples below).

We consider the following algorithm. As in Algorithm 2, γ is a given step-size. We choose a decrease sequence of temperature $\beta^{(k)}$ that we use along the iterations.

Algorithm 3 *Fix a step-size $\gamma > 0$, and a cooling sequence $\{\beta^{(k)}\}$. Pick some initial value $\tau^{(0)} \in \mathcal{T}$, $\theta_1^{(0)}, \theta_2^{(0)} \in \mathcal{M}_p^+$. Repeat for $k = 1, \ldots, K$. Given ($\tau^{(k-1)}$, $\theta_1^{(k-1)}$, $\theta_2^{(k-1)}$), do the following:*

1. *Compute*
$$\theta_1^{(k)} = \mathrm{Prox}_{\gamma\lambda_{1,\tau^{(k-1)}}}\left(\theta_1^{(k-1)} - \gamma\left(S_1(\tau^{(k-1)}) - (\theta_1^{(k-1)})^{-1}\right)\right),$$
2. *compute*
$$\theta_2^{(k)} = \mathrm{Prox}_{\gamma\lambda_{2,\tau^{(k-1)}}}\left(\theta_2^{(k-1)} - \gamma\left(S_2(\tau^{(k-1)}) - (\theta_2^{(k-1)})^{-1}\right)\right),$$
3. *draw*
$$\tau^{(k)} \sim \mathcal{K}_{\beta^{(k)},\theta_1^{(k)},\theta_2^{(k)}}(\tau^{(k-1)}, \cdot).$$

□

For most commonly used MCMC kernels, each iteration of Algorithm 3 has a computational cost of $O(p^3)$, which is better than $O(p^3 + Tp^2)$ needed by Algorithm 2, when $T \geq p$. However Algorithm 3 travels along the change-point space $\mathcal{T}$ more slowly. Hence overall, a larger number of iterations would typically be needed for Algorithm 3 to converge. Even after accounting for this slow convergence, Algorithm 3 is still substantially faster than Algorithm 2, as shown in Table 1 and 2. A rigorous analysis of the convergence of Algorithm 3 is beyond the scope of this work, and it left as a possible future research.

2.2 Extension to Multiple Change-Points

We extend the method to multiple change-points by binary segmentation. Binary segmentation is a standard method for detecting multiple change-points. The method proceeds by first searching for a single change-point. When a change-point is found the data is split into the two parts defined by the detected change-point. A similar search is then performed on each segment which can result in further splits. This recursive procedure continues until a certain stopping criterion is satisfied. Here we stop the recursion if

$$\ell_\tau + Cp \geq \ell_F,$$

where ℓ_τ is the penalized negative log-likelihood obtained with the additional change-point τ, and ℓ_F is the penalized negative log-likelihood without the change-point. The term Cp is a penalty term for model complexity, where C is a user-defined regularization parameter that controls the sparsity of the change-point model (the number of change-points). To the best of our knowledge there is no easy and principled approach for choosing C. We identify this as an important issue where more research is needed. Since C controls the number of change-points, in practice one ad-hoc approach is to set C such that the number of detected change-points is reasonable. This is the approach that we use in the real data analysis. Here we rely on simulation. We explore various scenarios by simulation and found that values of C between $(0, 4)$ produce the best results in our setting.

The binary segmentation algorithm can be defined more precisely as follows. Let us call $\mathcal{J}(X, t_0, t_1)$ the (single) change-point output either by Algorithm 3 or Algorithm 4 when applied to data set X using sample $X_{t_0}, \ldots, X_{t_1}$, for some $t_0, t_1 \in \mathcal{T}$, $t_0 < t_1$. Let $\mathcal{L}(X, t_0, t_1)$ denote the (penalized) minimum negative log-likelihood achieved on data $X_{t_0}, \ldots, X_{t_1}$. That is,

$$\mathcal{L}(X, t_0, t_1) = \min_{\theta \succ 0}\left[-\log\det(\theta) + \mathsf{Tr}\left(\theta\left(\frac{1}{t_1 - t_0 + 1}\sum_{t=t_0}^{t_1} X^{(t)}X^{(t)'}\right)\right) + \lambda\wp(\theta)\right].$$

Then the binary-segmentation algorithm $\mathcal{B}(X, t_0, t_1)$ can be written recursively as follows:

Algorithm 4 *Binary Segmentation*

1: ***function*** $\mathcal{B}(X, t_0, t_1)$
2: $\quad\tau = \mathcal{J}(X, t_0, t_1)$ *(apply either algorithm 3 or 4 to data $X_{t_0}, \ldots, X_{t_1}$)*
3: $\quad\ell_\tau = \mathcal{L}(X, t_0, \tau) + \mathcal{L}(X, \tau + 1, t_1)$
4: $\quad\ell_F = \mathcal{L}(X, t_0, t_1)$
5: $\quad$***if*** $\ell_\tau + Cp \geq \ell_F$ ***then***
6: $\quad\quad$***return*** *Null*
7: $\quad$***else***
8: $\quad\quad$***return*** $\{\tau, \mathcal{B}(X, t_0, \tau), \mathcal{B}(X, \tau + 1, t_1)\}$
9: $\quad$***end if***
10: ***end function***

We end this section with some words of caution. Binary segmentation is well-known to be a sub-optimal procedure and can perform poorly in some settings (see for instance Fryzlewicz, 2014). The issue is that at each step, binary segmentation is actually fitting a possibly misspecified model—one with a single change-point—to data with possibly multiple change-points. One approach is overcoming this limitation is to extend our proposed algorithms so as to handle directly multiple change-points. We leave this as an important future work.

3. Numerical Experiments

We investigate the different algorithms presented here in a variety of settings. For all the algorithms investigated the choice of the step-size γ and the regularizing parameter λ are important. For all experiments, and as suggested by (8), we found that setting $\lambda_{1,\tau} = \lambda\sqrt{\frac{\log\{p\}}{\tau}}$ and $\lambda_{2,\tau} = \lambda\sqrt{\frac{\log\{p\}}{T-\tau}}$ worked well. For the time-comparison in Section 3.1 we used $\lambda = 0.1$ and $\gamma = 3.5$ when $T = 1000$, and we used $\lambda = 0.01$ and $\gamma = 3.5$ when $T = 500$. For the remainder of the experiments we set $\lambda = 0.13$ and $\gamma = 0.25$. For all the experiments the search domain $\mathcal{T}$ is taken as $\{n_0, \ldots, T - n_0\}$, for a minimum sample size n_0 from $\{0.01T, 0.05T, 0.1T\}$.

We initialize $\tau^{(0)}$ to a randomly selected value in $\mathcal{T}$. The initial value $\theta_1^{(0)}$ and $\theta_2^{(0)}$ are taken as $\theta_j^{(0)} = (S_j(\tau^{(0)}) + \epsilon I)^{-1}$ where ϵ is a constant chosen to maintain positive definiteness. For cases where $p < \tau$ and $p < T - \tau$ we used $\epsilon = 0$, while for larger values of p we set $\epsilon = 0.2$.

For the data generation in the simulations, we typically choose $\tau_\star = T/2$ unless otherwise specified, and unless otherwise specified, we generate independently the matrices $\theta_{\star,1}$ and $\theta_{\star,2}$ as follows. First we generate a random symmetric sparse matrix M such that the proportion of non-zero entries is 0.25. We add 4 to all positive entries and subtract 4 from all negative entries. Then we set the actual precision matrix as $\theta_{\star,j} = M + (1 - \lambda_{\min}(M))I_p$ where $\lambda_{\min}(M)$ is the smallest eigenvalue of M. The resulting precision matrices contain roughly 25% non-zero off-diagonal elements. For each simulation a new pair of precision matrices was generated as well as the corresponding data set.

For Algorithm 3 we also experimented with a number of MCMC kernel $\mathcal{K}_{\beta,\theta_1,\theta_2}$. We experiment with the independence Metropolis sampler with proposal $\mathbf{U}(n_0, T - n_0)$. We also tried a Random Walk Metropolis with a truncated Gaussian proposal $\mathbf{N}(\tau^{(k-1)}, \sigma^2)$, for some scale parameter $\sigma > 0$. Finally, we also experimented with a mixture of these two Metropolis-Hastings kernels. We found that for our simulations the Independent Metropolis kernel works best, although the mixture kernel also performed well. For the cooling schedule of simulated annealing we use $\beta^{(0)} = 1$, and a geometric decay $\beta^{(n)} = \alpha\beta^{(n-1)}$ with $\alpha = \left(\frac{\beta^{(M)}}{\beta^{(0)}}\right)^{1/M}$ where $\beta^{(M)} = 0.001$, and M is the maximum number of iterations.

An implementation of the algorithms presented here for the Gaussian graphical model context is available in the changepointsHD package, Bybee (2017), available on the Comprehensive R Archive Network (CRAN).

3.1 Time Comparison

First we compare the running times of the proposed algorithms and the brute force approach. We consider two settings: $(p = 100, T = 1000)$ and $(p = 500, T = 500)$. In the setting $(p = 100, T = 1000)$, 100 independent runs of Algorithms 2 and 3 are performed and the average run-times are reported in Table 1. In the setting $(p = 500, T = 500)$ 10 independent runs of Algorithms 2 and 3 are used, and the results are presented in Table 2. We compare these times to results from one simulation run of the brute-force approach, the results of which are given in the description (caption) of Tables 1 and 2.

We consider two stopping criteria for Algorithm 2 or 3. The first criterion stops the iterations if

$$\frac{1}{T}|\tau^{(k)} - \tau_\star| < 0.005 \quad \text{and} \quad \frac{\|\theta_1^{(k)} - \hat{\theta}_1\|_F}{\|\hat{\theta}_1\|_F} + \frac{\|\theta_2^{(k)} - \hat{\theta}_2\|_F}{\|\hat{\theta}_2\|_F} < 0.05, \tag{V1}$$

where $\hat{\theta}_1$ and $\hat{\theta}_2$ are obtained by performing 1000 proximal-gradient steps at the true τ value. An interesting feature of the proposed approximate MM algorithms is that the

Variant		Approx. MM	Simulated Annealing
(V1)	Time (Seconds)	195.95 (48.94)	3.03 (0.40)
	Iterations	658.68 (82.93)	662.62 (88.51)
(V2)	Time (Seconds)	0.39 (0.10)	0.48 (0.46)
	Iterations	1.03 (0.17)	101.96 (100.29)

Table 1: Run-times of Algorithm 2 and 3 for $(p = 100, T = 1000)$. For comparison the run-time of the brute force algorithm for this problem is 2374.82.

Variant		Approx. MM	Simulated Annealing
(V1)	Time (Seconds)	3554.30 (404.24)	94.64 (5.50)
	Iterations	939.70 (11.03)	941.70 (16.23)
(V2)	Time (Seconds)	4.27 (1.10)	10.96 (8.26)
	Iterations	1.10 (0.32)	111.20 (90.71)

Table 2: Run-times of Algorithm 2 and 3 for $(p = 500, T = 500)$. For comparison the run-time of the brute force algorithm for this problem is 10854.44.

change-point sequence $\tau^{(k)}$ can converge well before $\theta_1^{(k)}$ and $\theta_2^{(k)}$. To illustrate this, we also explore the alternative approach of stopping the iterations only based on $\tau^{(k)}$, namely when

$$\frac{1}{T}|\tau^{(k)} - \tau_\star| < 0.005. \tag{V2}$$

Finally, we note that we implement the brute force approach by running 500 proximal-gradient steps for each possible value of τ. Note that 500 iterations is typically smaller than the number of iterations needed to satisfy (V1).

Tables 1 and 2 highlight the benefits of Algorithm 2 and Algorithm 3 as the run-time is several orders of magnitude lower than the brute force approach. Additionally, while Algorithm 3 requires more iterations than Algorithm 2 its run-time is typically smaller. The benefits of Algorithm 3 are particularly clear for large values of p and T (under stopping criterion (V1)). The stopping criteria (V2) highlights the fact that the $\tau^{(k)}$ sequence in the proposed algorithms can converge well before the θ-sequences.

3.2 Behavior of the Algorithm when the Change-Point is at the Edge

We investigate how the brute force algorithm, Algorithm 2, and Algorithm 3 perform when change-points are non-existent or close to the edges. The results for the brute force algorithm are presented in Figure 1, the results for Algorithm 2 are presented on Figure 2 and the results for Algorithm 3 are presented on Figure 3. For Algorithm 2 and Algorithm 3 the figure contains two subfigures, the first showing the sequences $\{\tau^{(k)}\}$ of solutions produced by the algorithm (trace plots) for all 200 replications, and the second showing a histogram of the final change-point estimate, based on 200 replications. Additionally, a line is included to show the location of the true τ. The trace plots show how quickly each algorithm converges under the various settings. For the brute force algorithm the trace plot is not relevant since the brute force algorithm is not an iterative algorithm. The results suggest that Algorithm 2 and Algorithm 3 have more trouble when the true τ is close to the edge of the sample. For $\tau = 0.1T$, Algorithm 3 performed slightly better, with 136 simulations ending within 5 units of the true τ compared to 90 for Algorithm 2.

3.3 Behavior of the Algorithms when θ_1 and θ_2 are Similar

As θ_1 and θ_2 get increasingly similar, the location of the change-point becomes increasingly more difficult to find. We investigate the behavior of the proposed algorithms in such settings. We generate the true precision matrices θ_1 and θ_2 as follows. We draw a random precision matrix θ with $q\%$ non-zero off-diagonal elements, and C_1 and C_2 two random precision matrix with $p\%$ non-zero off-diagonal elements. We choose C_1 and C_2 to have the same diagonal elements. Then we set $\theta_1 = \theta + C_1$ and $\theta_2 = \theta + C_2$, which are then used to generate the data set for the experiment. The ratio p/q is a rough indication of the signal. Figure 4-6 show the behavior of the three algorithms for different values of q and p. For Algorithms 2 and 3 we found that similar precision matrices sometimes leads the algorithm to converge to the edge of the search domain. This makes sense, since a strong similarity between the two precision matrices implies a weak signal-to-noise ratio, which makes the model with no change-point more attractive. Putting the estimated change-point at the boundary of the search domain is roughly equivalent to fitting a model with no change-point.

3.4 Sensitivity to the Stopping Criteria in Binary Segmentation

This section considers the stopping condition for the binary segmentation algorithm (see Section 2.2) and how it performs with different configurations. A condition is required for determining when the binary segmentation splitting should reject a change-point and stop running. The stopping condition that we use is the following, stop if

$$\ell_\tau + Cp \geq \ell_F,$$

where ℓ_τ is the penalized negative log-likelihood obtained with the additional change-point τ, and ℓ_F is the penalized negative log-likelihood without the change-point. The term C is a user-defined parameter.

As mentioned above, the proposed algorithms can diverge when the step-size γ is not appropriately selected. In particular the appropriate value of γ is highly dependent on the length of the data set, and the binary segmentation splittings of the data can result in data segments with very different lengths. We use this feature to our advantage. We have chosen not to tune γ to the data segment, and to stop the binary segmentation splitting if the sequence $\hat{\theta}_1^{(k)}$ or $\hat{\theta}_2^{(k)}$ appear to diverge. This has the effect of constraining the lengths of the change-point segments from being too small. We achieve this result without directly setting a minimum length constraint—which be hard to do in practice. We found that stopping the algorithm when $||\hat{\theta}_i^{(k)}||_2^2 > 2 \times 10^3$ was sufficient for our data.

In the binary segmentation, since the estimates of θ_1 and θ_2 may not have converged by the end of the search for τ it may be worth continuing the estimation procedure for θ_1 and θ_2 so that the resulting penalized log-likelihoods are comparable. Hence after each split from the binary segmentation search, we perform an additional 500 iterations to estimate θ_1 and θ_2 at the resulting τ.

See Figure 7 for a series of heatmaps showing how often the binary segmentation method finds a given number of change-points for different values of C. These results suggest that the choice of C in the interval $(0, 4)$ is reasonable. These results are produced using Algorithm 3 for speed, however, the results are identical for the other two algorithms considered. Note that since an additional change-point should always improve the log-likelihood, when $C \leq 0$ we only stop on the secondary stopping condition that $||\hat{\theta}_i^{(k)}||_2^2 > 2 \times 10^3$.

3.5 High Dimensional Experiments

We also investigate the behavior of the proposed algorithms for larger values of p. We performed several (100) runs of Algorithm 3 for $T = 1000$, and $p \in \{100, 500, 750, 1000\}$. From these 100 runs we estimate the distributions of the iterates (by boxplots) after $10, 100, 200, \ldots, 1000$ iterations. The results are presented in Figure 8. The results show again a very quick convergence toward $\tau_\star$ and this convergence persists even as p gets large.

3.6 A Real Data Analysis

In finance and econometrics there is considerable interest in regime-switching models in the context of volatility, particularly because these switches may correspond to real events in the economy (Banerjee and Urga, 2005; Beltratti and Morana, 2006; Günay, 2014; Choi et al., 2010). However, much of the literature is limited to the low dimensional case, due to the difficulty involved in estimating change-points for higher dimensions. We are able to use our method to estimate change-points in the covariance structure of the Standard & Poor's (S&P) 500—an American stock market index.

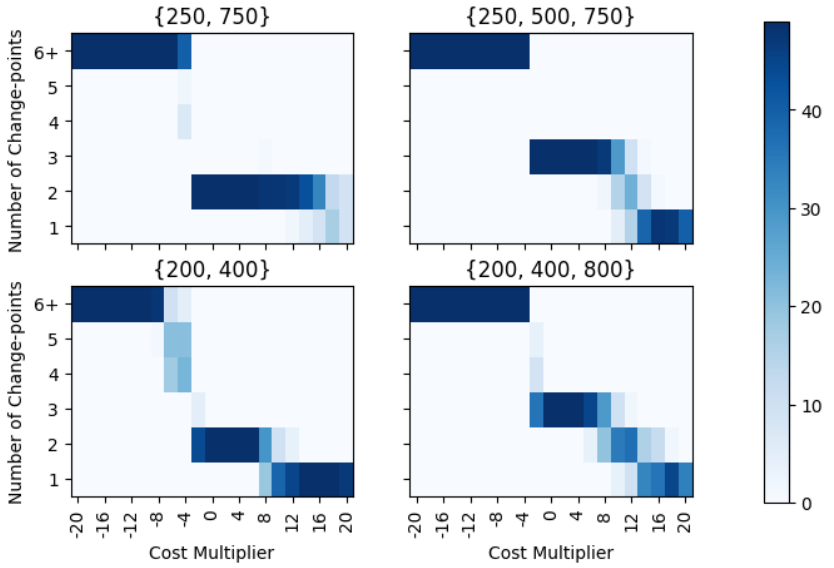

Figure 7: Number of change-points detected by binary segmentation as function of the cost multiplier C. The set of true change-points is indicated on top of the plots.

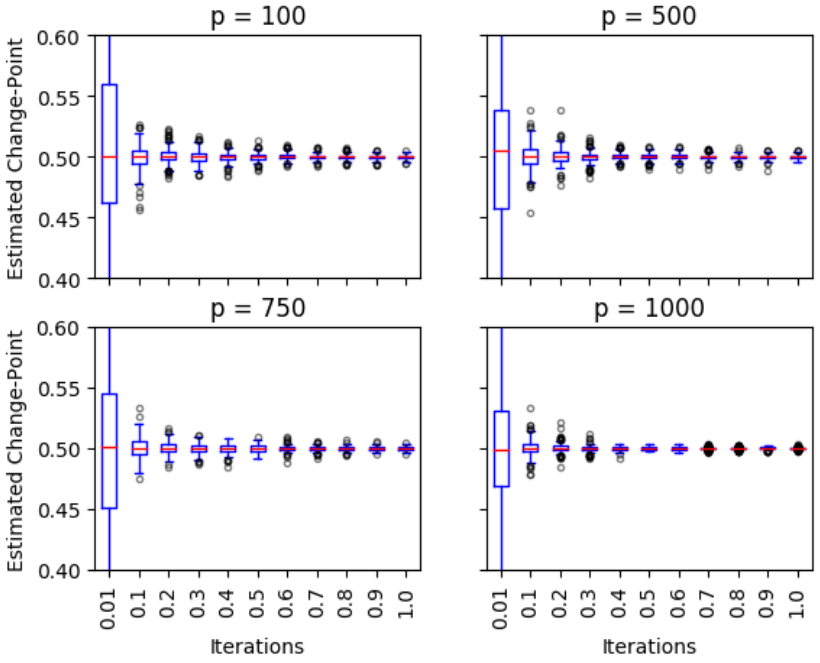

Figure 8: Boxplots of the iterates produced by Algorithm 4. Based on 100 replications.

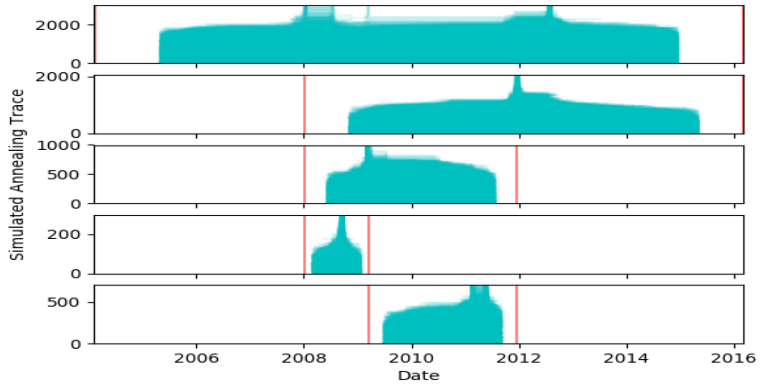
Data from the S&P 500 was collected for the period from 2000-01-01 to 2016-03-03. From this initial sample a subset of stocks (or tickers) was selected for which at least 3000 corresponding observations exist. This produced a sample extending from 2004-02-06 to 2016-03-03, consisting of 3039 observations and 436 stocks. We follow a similar data cleaning procedure to Lafferty et al. (2012), who investigate a comparable problem without change-points. For each stock we generate the log returns, $\log \frac{X_t}{X_{t-1}}$, and standarize the resulting returns. Following Lafferty et al. (2012), we then truncate (or clip) all observations beyond three standard deviations of the same mean, thereby limiting unwanted outliers in our sample. The reason for this cleaning procedure is that these outliers often correspond to stock splits instead of meaningful price changes.

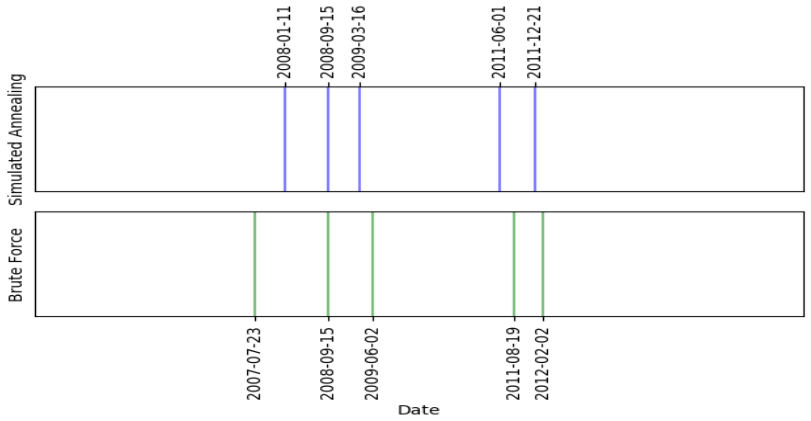
For our setting $\lambda = 0.002$ and $\gamma = 0.5$. We initialize $\hat{\theta}^{(0)} = (S(\tau^{(0)}) + I\epsilon)^{-1}$ where $\epsilon = 10^{-4}$ and $\tau^{(0)}$ is selected randomly. After the simulated annealing run the proximal gradient algorithm was run an additional 2000 steps, to produces estimates of θ_1 and θ_2. Here we increase the step-size to $\gamma = 350$ to accelerate the convergence. For the binary segmentation we found that selecting the threshold constant, $C = 0.005$, found a reasonable set of change-points. We found the choice of parameters important in this application, in particular, variation from the values used here can lead the algorithm to diverge. We use the same stopping criterion as with the prior binary-segmentation simulations. That is, a) stop when $\ell_\tau + Cp \geq \ell_F$ or b) stop when $||\hat{\theta}_i^{(k)}||_2^2 > 2 \times 10^3$.

Figure 9 presents the results of the change-point analysis using binary segmentation with Algorithm 4. As a reference we also present the results obtained using binary segmentation together with the brute force approach. For the brute force approach, we set $\gamma = 35$ and ran 10 iterations for each possible change-point, before running 2000 steps at $\gamma = 350$ to get the estimates for θ_1 and θ_2. The brute force approach took approximately an hour to run one layer of the search, while simulated annealing took approximately 15 minutes. Figure 9-(a) shows the trace plots from simulated annealing based on 100 replications. The red lines mark the detected time segments. Figure 9-(b) shows the resulting segmentation of the data. We note that simulated annealing and brute force produce slightly different sets of change-points. This brings up an important point: the resulting solution is a local optimum. Binary segmentation does introduce an element of path dependency to the results so there may be more than one viable set of change-points—in this particular case, the brute force approach starts with the first change-point on August 19th 2011 while simulated annealing starts with January 11th 2008.

We next look at how well the estimated change-points correspond to real world events. Our change-point set seems to do a good job of capturing both the Great Recession and a fall in stock prices during August of 2011 related to the European debt crisis and the downgrading of United State's credit-rating. The first change-point in our set is January 11th 2008. The National Bureau of Economic Research (NBER) identifies December of 2007 as the beginning of the Great Recession, which this change-point seems to capture. Additionally, 10 days after the change-point, the Financial Times Stock Exchange (FTSE) would experience its biggest fall since September 11th 2001. The brute force approach places this first change-point earlier in the series on July 23rd 2007, possibly capturing a relatively positive time in the economy before the downturn. The Second change-point occurred on September 15th 2008, the day on which Lehman Brothers filed for bankruptcy protection, one of the key events of the Great Recession (both methods agree on this change-point). The third change-point takes place on March 16th 2009, corresponding to the end of the bear market in the United States. For bthe brute force approach, this change-point is June 2nd 2009—June of 2009 was when the NBER officially declared the end of the recession. The fourth change-point, on June 1st 2011, and the fifth change-point, on December 21st 2011, likely capture a period of heightened concerns over the possible



(a) Simulated Annealing trace plots from 100 replications. The red lines represent the prior set of relevant change-points.



(b) Simulated annealing (top) and brute force segmentations of the data.

Figure 9: Change-points analysis of the S&P 500 data set over the period 2004-02-06 to 2016-03-03.

spread of the European debt crisis to Spain and Italy, during August of 2011. This period also saw the downgrading of the S&P's credit rating of the United States from AAA to

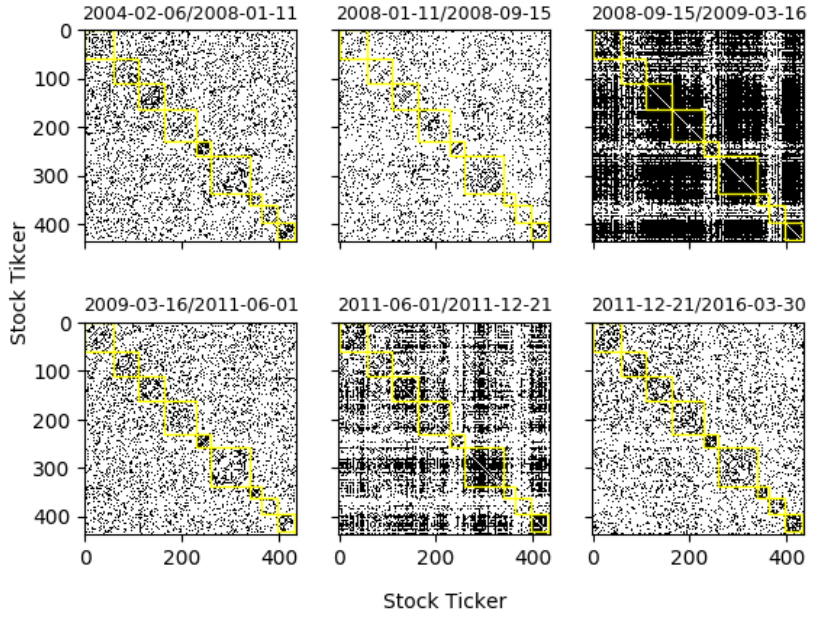


Figure 10: Adjacency matrices between stocks based on estimated precision matrices $\hat{\theta}$ for each time segment. A black dot represents an edge between two stocks.

AA+. The August 19th 2011 brute force change-point more precisely identifies this August downturn.

Given that the change-point set identified seems sensible, we then investigate what the corresponding $\hat{\theta}$ estimates look like, and whether any interesting conclusions can be drawn from our estimates. Here we focus only on the simulated annealing change-point set. See Figure 10 for a plot of the adjacency matrix for each $\hat{\theta}$ estimate. The black squares correspond to non-zero edges and he yellow boxes correspond to Global Industry Classification Standard (GICS) sectors. These results tell an intuitive story about how the economy behaves during financial crises. Following both the collapse of Lehamn Brother's and the events of August 2011, we see a dramatic increase in connectivity between returns even outside of GICS sectors. To get a better sense of this see Figure 11 for a similar series of plots where edges are summed over each sector. Figure 12 gives an expanded version of the summed edge plot for the first $\hat{\theta}$ estimate, as well as the corresponding sector labels for reference. Again, we can see that during periods of crisis, the off diagonal elements—corresponding to edges between different sectors—become more significant than during periods of general stability.

From these figures we can get a sense of which sectors are most affected during times of crisis. To expand upon this some, see Figure 12 for the edge count between each sector

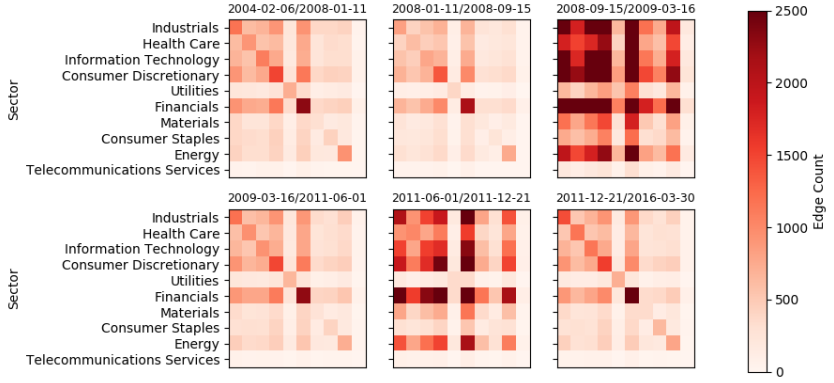

Figure 11: Adjacency matrices between sectors for each time segment. Based on the number of edges going from stocks of one sector to another as given by the estimated precision matrices $\hat{\theta}$.

and the Financial sector for each $\hat{\theta}$ estimate. We can see that during times of crisis, there is considerable connection between Industrials, Information Technology, Consumer Discretionary, and to a lesser extend Healthcare, and the Financial sector. Consumer Staples, Utilities, and Materials appear to be more stable during these periods and do not experience as much correlation with Financials. This might suggest that our method could be used as a tool to identify investment strategies that are likely to be resilient to periods of crisis in the market.

4. Proofs

4.1 Proof of Theorem 5

We will need the following lemma.

Lemma 12 *Set*

$$g(\theta) \stackrel{\text{def}}{=} -\log\det(\theta) + \mathit{Tr}(\theta S),$$

$$\textit{and} \quad \phi(\theta) \stackrel{\text{def}}{=} g(\theta) + \lambda\left[\alpha\|\theta\|_1 + \frac{1-\alpha}{2}\|\theta\|_F^2\right], \quad \theta \in \mathcal{M}_p^+,$$

for some symmetric matrix S, $\alpha \in (0,1)$, and $\lambda > 0$. Fix $0 < b < B \leq \infty$.

1. *For $\theta, \vartheta \in \mathcal{M}_p^+(b,B)$, we have*

$$g(\theta) + \langle \nabla g(\theta), \vartheta - \theta\rangle + \frac{1}{2B^2}\|\vartheta-\theta\|_F^2 \leq g(\vartheta) \leq g(\theta) + \langle \nabla g(\theta), \vartheta - \theta\rangle + \frac{1}{2b^2}\|\vartheta-\theta\|_F^2.$$

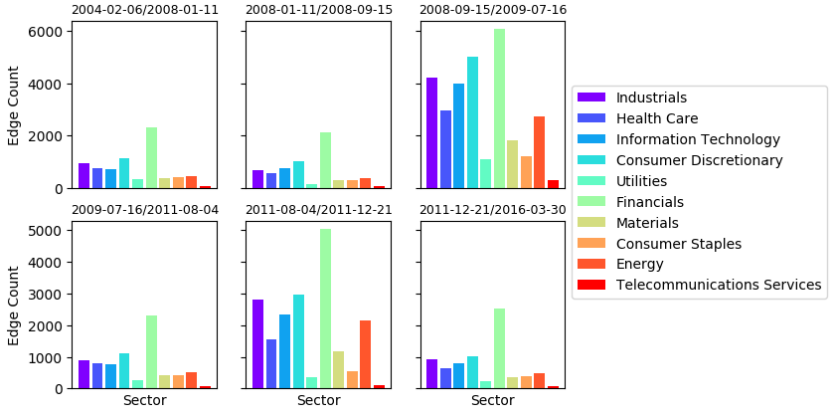

Figure 12: Number of edges between the financial sector and the remaining sectors, for each time segment. Based on the estimated precision matrices $\hat{\theta}$.

More generally, If $\theta, \vartheta \in \mathcal{M}_p^+$, then

$$g(\vartheta) - g(\theta) - \langle \nabla g(\theta), \vartheta - \theta\rangle \geq \frac{\|\vartheta-\theta\|_F^2}{4\|\theta\|_2\left(\|\theta\|_2 + \frac{1}{2}\|\vartheta-\theta\|_F\right)}.$$

2. *Let $\gamma \in (0, b^2]$, and $\theta, \bar{\theta}, \theta_0 \in \mathcal{M}_p^+(b,B)$. Suppose that*

$$\bar{\theta} = \mathrm{Prox}_{\gamma\lambda}\left(\theta - \gamma(S - \theta^{-1})\right),$$

then

$$2\gamma\left(\phi(\bar{\theta}) - \phi(\theta_0)\right) + \|\bar{\theta} - \theta_0\|_F^2 \leq \left(1 - \frac{\gamma}{B^2}\right)\|\theta - \theta_0\|_F^2.$$

Proof The first part of (1) is Lemma 12 of Atchadé et al. (2015), and Part (2) is Lemma 14 of Atchadé et al. (2015). The second part of (1) can be proved along similar lines. For completeness we give the details below.

Take $\theta_0, \theta_1 \in \mathcal{M}_p^+$. By Taylor expansion we have

$$g(\theta_1) - g(\theta_0) - \langle \nabla g(\theta_0), \theta_1 - \theta_0\rangle = -\int_0^1 \left\langle (\theta_0 + tH)^{-1} - \theta_0^{-1}, H\right\rangle \mathrm{d}t,$$

where $H \stackrel{\text{def}}{=} \theta_1 - \theta_0$. We have $(\theta_0 + tH)^{-1} - \theta_0^{-1} = -t\theta_0^{-1}H(\theta_0 + tH)^{-1}$, which leads to

$$g(\theta_1) - g(\theta_0) - \langle \nabla g(\theta_0), \theta_1 - \theta_0\rangle = \int_0^1 \mathrm{Tr}\left(\theta_0^{-1}H(\theta_0 + tH)^{-1}H\right) t\mathrm{d}t.$$

If $\theta_0 = \sum_{i=1}^p \rho_j u_j u_j'$ is the eigendecomposition of θ_0, we see that $\mathsf{Tr}\left(\theta_0^{-1} H(\theta_0+tH)^{-1}H\right) = \sum_{j=1}^p \frac{1}{\rho_j} u_j' H(\theta_0+tH)^{-1} H u_j$. Hence

$$g(\theta_1) - g(\theta_0) - \langle \nabla g(\theta_0), \theta_1 - \theta_0 \rangle \geq \sum_{j=1}^p \|Hu_j\|_2^2 \int_0^1 \frac{t\mathrm{d}t}{\|\theta_0\|_2 \left(\|\theta_0\|_2 + t\|H\|_{\mathsf{F}}\right)} \geq \frac{\sum_{j=1}^p \|Hu_j\|_2^2}{4\|\theta_0\|_2 \left(\|\theta_0\|_2 + \frac{1}{2}\|H\|_{\mathsf{F}}\right)},$$

and the result follows by noting that $\sum_{j=1}^p \|Hu_j\|_2^2 = \|H\|_{\mathsf{F}}^2$. ∎

Set

$$\mathcal{F}(\tau, \theta_1, \theta_2) = g_{1,\tau}(\theta_1) + \lambda_{1,\tau} p(\theta) + g_{2,\tau}(\theta_2) + \lambda_{2,\tau} p(\theta_2),$$

$\underline{\mathcal{F}} = \mathcal{F}(\hat{\tau}, \hat{\theta}_{1,\hat{\tau}}, \hat{\theta}_{1,\hat{\tau}})$ the value of Problem (3), and $\mathcal{F}_k = \mathcal{F}(\tau^{(k)}, \theta_1^{(k)}, \theta_2^{(k)}) - \underline{\mathcal{F}}$.

Lemma 13 *Suppose that $\gamma \in (0, b_1^2 \wedge b_2^2]$, and for $j = 1, 2$, $\theta_j^{(0)} \in \mathcal{M}_p^+(\mathsf{b}_j, \mathsf{B}_j)$. Then $\lim_k \left\|\theta_1^{(k)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}} = 0$, $\lim_k \left\|\theta_2^{(k)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}} = 0$. Furthermore the sequence $\{\mathcal{F}_k\}$ is non-increasing, and $\lim_k \mathcal{F}_k$ exists.*

Proof We know from Lemma 2 that for $\gamma \in (0, \mathsf{b}_1^2 \wedge \mathsf{b}_2^2]$, and $\theta_j^{(0)} \in \mathcal{M}_p^+(\mathsf{b}_j, \mathsf{B}_j)$, we have $\theta_j^{(k)} \in \mathcal{M}_p^+(\mathsf{b}_j, \mathsf{B}_j)$ for all $k \geq 0$, for $j = 1, 2$. We have,

$$\mathcal{F}_{k+1} - \mathcal{F}_k = \mathcal{F}(\tau^{(k+1)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) - \mathcal{F}(\tau^{(k)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) + \mathcal{F}(\tau^{(k)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) - \mathcal{F}(\tau^{(k)}, \theta_1^{(k)}, \theta_2^{(k)}).$$

By definition, $\mathcal{F}(\tau^{(k+1)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) - \mathcal{F}(\tau^{(k)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) \leq 0$, and by Lemma 12-Part(2),

$$\mathcal{F}(\tau^{(k)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) - \mathcal{F}(\tau^{(k)}, \theta_1^{(k)}, \theta_2^{(k)}) \leq -\frac{1}{2\gamma}\left\|\theta_1^{(k+1)} - \theta_1^{(k)}\right\|_{\mathsf{F}}^2 - \frac{1}{2\gamma}\left\|\theta_2^{(k+1)} - \theta_2^{(k)}\right\|_{\mathsf{F}}^2$$

It follows that

$$\mathcal{F}_{k+1} \leq \mathcal{F}_k - \frac{1}{2\gamma}\left\|\theta_1^{(k+1)} - \theta_1^{(k)}\right\|_{\mathsf{F}}^2 - \frac{1}{2\gamma}\left\|\theta_2^{(k+1)} - \theta_2^{(k)}\right\|_{\mathsf{F}}^2,$$

which implies that

$$\lim_k \left\|\theta_1^{(k+1)} - \theta_1^{(k)}\right\|_{\mathsf{F}} = 0, \quad \text{and} \quad \lim_k \left\|\theta_2^{(k+1)} - \theta_2^{(k)}\right\|_{\mathsf{F}} = 0. \tag{15}$$

It also implies that the sequence $\{\mathcal{F}_k\}$ is non-increasing and bounded from below by 0. Hence converges. Another application of Lemma 12 gives

$$2\gamma\left(\mathcal{F}(\tau^{(k)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) - \mathcal{F}(\tau^{(k)}, \hat{\theta}_{1,\tau^{(k)}}, \hat{\theta}_{2,\tau^{(k)}})\right) + \left\|\theta_1^{(k+1)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}}^2 + \left\|\theta_2^{(k+1)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}}^2 \leq \left(1 - \frac{\gamma}{\mathsf{B}_1^2}\right)\left\|\theta_1^{(k)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}}^2 + \left(1 - \frac{\gamma}{\mathsf{B}_2^2}\right)\left\|\theta_2^{(k)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}}^2.$$

And notice that $\mathcal{F}(\tau^{(k)}, \theta_1^{(k+1)}, \theta_2^{(k+1)}) - \mathcal{F}(\tau^{(k)}, \hat{\theta}_{1,\tau^{(k)}}, \hat{\theta}_{2,\tau^{(k)}}) \geq 0$. Hence

$$\left\|\theta_1^{(k+1)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}}^2 + \left\|\theta_2^{(k+1)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}}^2 \leq \left(1 - \frac{\gamma}{\mathsf{B}_1^2}\right)\left\|\theta_1^{(k)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}}^2 + \left(1 - \frac{\gamma}{\mathsf{B}_2^2}\right)\left\|\theta_2^{(k)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}}^2,$$

which can be written as

$$\frac{\gamma}{\mathsf{B}_1^2}\left\|\theta_1^{(k)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}}^2 + \frac{\gamma}{\mathsf{B}_2^2}\left\|\theta_2^{(k)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}}^2 \leq \left\|\theta_1^{(k+1)} - \theta_1^{(k)}\right\|_{\mathsf{F}}^2 + \left\|\theta_2^{(k+1)} - \theta_2^{(k)}\right\|_{\mathsf{F}}^2 - 2\left\langle\theta_1^{(k+1)} - \theta_1^{(k)}, \theta_1^{(k+1)} - \hat{\theta}_{1,\tau^{(k)}}\right\rangle - 2\left\langle\theta_2^{(k+1)} - \theta_2^{(k)}, \theta_2^{(k+1)} - \hat{\theta}_{2,\tau^{(k)}}\right\rangle.$$

Since $\{\theta_1^{(k)}\}$, $\{\theta_2^{(k)}\}$ $\{\hat{\theta}_{1,\tau^{(k)}}\}$, and $\{\hat{\theta}_{2,\tau^{(k)}}\}$ are bounded sequence, and given (15), letting $k \to \infty$, we conclude that

$$\lim_k \left\|\theta_1^{(k)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}} = 0, \quad \text{and} \quad \lim_k \left\|\theta_2^{(k)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}} = 0.$$

∎

Proof of Theorem 5 Let $\epsilon > 0$ as in H1. By Lemma 13, there exist $k_0 \geq 1$ such that for all $k \geq k_0$, $\left\|\theta_1^{(k+1)} - \hat{\theta}_{1,\tau^{(k)}}\right\|_{\mathsf{F}} \leq \epsilon$, and $\left\|\theta_2^{(k+1)} - \hat{\theta}_{2,\tau^{(k)}}\right\|_{\mathsf{F}} \leq \epsilon$. Since

$$\tau^{(k+1)} = \mathsf{Argmin}_{t \in \mathcal{T}} \mathcal{H}\left(t | \theta_1^{(k+1)}, \theta_2^{(k+1)}\right),$$

using H1 we conclude that for all $k \geq k_0$,

$$\left|\tau^{(k+1)} - \tau_\star\right| \leq \kappa\left|\tau^{(k)} - \tau_\star\right| + c \leq \kappa^{k-k_0+1}\left|\tau^{(k_0)} - \tau_\star\right| + \frac{c}{1-\kappa},$$

which implies the stated result. ∎

4.2 Proof of Theorem 9

We introduce some more notation. Given $M \in \mathbb{R}^{p\times p}$ the sparsity structure of M is the matrix $\delta \in \{0,1\}^{p\times p}$ such that $\delta_{jk} = \mathbf{1}_{\{|M_{jk}|>0\}}$. In particular we will write $\delta_{\star,j}$ $(j = 1, 2)$ to denote the sparsity structure of $\theta_{\star,j}$. Given matrices $A \in \mathbb{R}^{p\times p}$, and $\delta \in \{0,1\}^{p\times p}$, we will use the notation A_δ (resp. A_{δ^c}) to denote the component-wise product of A and δ (resp A and $1-\delta$). Given $j \in \{1, 2\}$, we define

$$\mathcal{C}_j \stackrel{\text{def}}{=} \left\{M \in \mathcal{M}_p : \ \|M_{\delta_{\star,j}^c}\|_1 \leq 7\|M_{\delta_{\star,j}}\|_1.\right\}. \tag{16}$$

We will need the following deviation bound.

Lemma 14 *Suppose that $X_i \overset{ind}{\sim} \boldsymbol{N}(0, \theta_i^{-1})$, $i = 1, \ldots, N$, where $\theta_i \in \mathcal{M}_p^+$. We set $\Sigma_i \stackrel{\text{def}}{=} \theta_i^{-1}$, and define*

$$\underline{\kappa}_i(2) \stackrel{\text{def}}{=} \inf\left\{u'\Sigma_i u, \ \|u\|_2 = 1, \ \|u\|_0 \leq 2\right\}, \quad \bar{\kappa}_i(2) \stackrel{\text{def}}{=} \sup\left\{u'\Sigma_i u, \ \|u\|_2 = 1, \ \|u\|_0 \leq 2\right\},$$

and suppose that $\underline{\kappa}_i(2) > 0$ *for* $i = 1, \ldots, N$. *Set* $G_N \stackrel{\text{def}}{=} N^{-1}\sum_{i=1}^N (X_i X_i' - \theta_i^{-1})$. *Then for* $0 < \delta \leq 2\left(\frac{\min_k \underline{\kappa}_k(2)}{\max_k \bar{\kappa}_k(2)}\right)^2$, *we have*

$$\mathbb{P}\left(\|G_N\|_\infty > \left(\max_k \bar{\kappa}_k(2)\right)\delta\right) \leq 4p^2 e^{-\frac{N\delta^2}{4}}.$$

Proof The proof is similar to the proof of Lemma 1 of Ravikumar et al. (2010), which itself builds on Bickel and Levina (2008). For $1 \leq i, j \leq p$, arbitrary, set $Z_{ij}^{(k)} = X_{k,i}X_{k,j}$, and $\sigma_{ij}^{(k)} = \Sigma_{k,ij}$, so that the (i,j)-th component of G_N is $N^{-1}\sum_{k=1}^N (Z_{ij}^{(k)} - \sigma_{ij}^{(k)})$. Suppose that $i \neq j$. The case $i = j$ is simpler. It is easy to check that

$$\sum_{k=1}^N \left[Z_{ij}^{(k)} - \sigma_{ij}^{(k)}\right] = \frac{1}{4}\sum_{k=1}^N \left[(X_{k,i} + X_{k,j})^2 - \sigma_{ii}^{(k)} - \sigma_{jj}^{(k)} - 2\sigma_{ij}^{(k)}\right] - \frac{1}{4}\sum_{k=1}^N \left[(X_{k,i} - X_{k,j})^2 - \sigma_{ii}^{(k)} - \sigma_{jj}^{(k)} + 2\sigma_{ij}^{(k)}\right].$$

Notice that $X_{k,i}+X_{k,j} \sim \mathbf{N}(0, \sigma_{ii}^{(k)}+\sigma_{jj}^{(k)}+2\sigma_{ij}^{(k)})$, and $X_{k,i}-X_{k,j} \sim \mathbf{N}(0, \sigma_{ii}^{(k)}+\sigma_{jj}^{(k)}-2\sigma_{ij}^{(k)})$. It follows that for all $x \geq 0$,

$$\mathbb{P}\left[\left|\sum_{k=1}^N \left[Z_{ij}^{(k)} - \sigma_{ij}^{(k)}\right]\right| > x\right] \leq \mathbb{P}\left[\left|\sum_{k=1}^N a_{ij}^{(k)}(W_k - 1)\right| > 2x\right] + \mathbb{P}\left[\left|\sum_{k=1}^N b_{ij}^{(k)}(W_k - 1)\right| > 2x\right],$$

where $W_{1:N} \stackrel{i.i.d.}{\sim} \chi_1^2$, $a_{ij}^{(k)} = \sigma_{ii}^{(k)} + \sigma_{jj}^{(k)} + 2\sigma_{ij}^{(k)}$, and $b_{ij}^{(k)} = \sigma_{ii}^{(k)} + \sigma_{jj}^{(k)} - 2\sigma_{ij}^{(k)}$. For any $x \geq 0$ and a sequence $a = (a_1, \ldots, a_N)$ of positive numbers, with $|a|_\infty = \max_i |a_i|$, $|a|_2 = \sqrt{\sum_i a_i^2}$, we write

$$2x = 2|a|_2\left(\frac{x}{2|a|_2}\right) + 2|a|_\infty\left(\frac{4|a|_2^2}{2x|a|_\infty}\right)\left(\frac{x}{2|a|_2}\right)^2.$$

Therefore if $2x|a|_\infty \leq 4|a|_2^2$, we can apply Lemma 1 of Laurent and Massart (2000) to conclude that

$$\mathbb{P}\left(\left|\sum_{k=1}^N a_k(W_k - 1)\right| \geq 2x\right) \leq 2e^{-\frac{x^2}{4|a|_2^2}}.$$

In particular, we can apply the above bound with $x = |a|_\infty N\delta$ for $\delta \in (0, \frac{2\min_j a_i^2}{\max_i a_i^2}]$ to get that

$$\mathbb{P}\left(\left|\sum_{k=1}^N a_k(W_k - 1)\right| \geq 2|a|_\infty N\delta\right) \leq 2e^{-\frac{N\delta^2}{4}}.$$

In the particular case above, $a_{ij}^{(k)} = \sigma_{ii}^{(k)} + \sigma_{jj}^{(k)} + 2\sigma_{ij}^{(k)} = u'\Sigma^{(k)}u$, where $u_i = u_j = 1$, and $u_r = 0$ for $r \notin \{i, j\}$. And

$$\frac{\min_k u'\Sigma^{(k)}u}{\max_k u'\Sigma^{(k)}u} \geq \frac{\min_k \underline{\kappa}_k(2)}{\max_k \bar{\kappa}(2)}.$$

A similar bound holds for $b_{ij}^{(k)}$. The lemma follows from a standard union-sum argument.

■

The following event plays an important role in the analysis.

$$\mathcal{E}_n \stackrel{\text{def}}{=} \bigcap_{\tau\in\mathcal{T}} \left\{\frac{1}{\lambda_{1,\tau}}\|\nabla g_{1,\tau}(\theta_{\star,1})\|_\infty \leq \frac{\alpha}{2}, \text{ and } \frac{1}{\lambda_{2,\tau}}\|\nabla g_{2,\tau}(\theta_{\star,2})\|_\infty \leq \frac{\alpha}{2}\right\}, \tag{17}$$

Lemma 15 *Under the assumptions of the theorem*

$$\mathbb{P}(\mathcal{E}_n) \geq 1 - \frac{8}{pT}.$$

Proof We have

$$\mathbb{P}(\mathcal{E}_n^c) \leq \mathbb{P}\left(\max_{\tau\in\mathcal{T}} \frac{1}{\lambda_{1,\tau}}\|\nabla g_{1,\tau}(\theta_{\star,1})\|_\infty > \frac{\alpha}{2}\right) + \mathbb{P}\left(\max_{\tau\in\mathcal{T}} \frac{1}{\lambda_{2,\tau}}\|\nabla g_{2,\tau}(\theta_{\star,2})\|_\infty > \frac{\alpha}{2}\right).$$

We show how to bound the first term. A similar bound follows for $g_{2,\tau}$ by working on the reversed sequence $X^{(T)}, \ldots, X^{(1)}$. We have $\nabla g_{1,\tau}(\theta) = \frac{\tau}{2T}(S_1(\tau) - \theta^{-1})$. Setting $U^{(t)} \stackrel{\text{def}}{=} X^{(t)}(X^{(t)})' - \mathbb{E}\left(X^{(t)}(X^{(t)})'\right)$, we can write

$$\nabla g_{1,\tau}(\theta_{\star,1}) = \frac{1}{2T}\sum_{t=1}^\tau U^{(t)} + \frac{(\tau - \tau_\star)_+}{2T}(\theta_{\star,2}^{-1} - \theta_{\star,1}^{-1}),$$

where $a_+ \stackrel{\text{def}}{=} \max(a, 0)$. Hence by a standard union-bound argument,

$$\mathbb{P}\left(\max_{\tau\in\mathcal{T}} \frac{1}{\lambda_{1,\tau}}\|\nabla g_{1,\tau}(\theta_{\star,1})\|_\infty > \frac{\alpha}{2}\right) \leq \sum_{\tau\in\mathcal{T}} \mathbb{P}\left(\left\|\sum_{t=1}^\tau U^{(t)}\right\|_\infty > \alpha\lambda_{1,\tau}T - (\tau - \tau_\star)_+\|\theta_{\star,2}^{-1} - \theta_{\star,1}^{-1}\|_\infty\right).$$

Given the choice of $\lambda_{1,\tau}$ in (8), $\alpha\lambda_{1,\tau}T/2 = 2\sqrt{3}\bar{\kappa}\sqrt{\tau\log(pT)} \geq (\tau - \tau_\star)_+\|\theta_{\star,2}^{-1} - \theta_{\star,1}^{-1}\|_\infty$, by assumption (11). In view of (10) we can apply Lemma 14 to deduce that

$$\begin{aligned}\mathbb{P}\left(\max_{\tau\in\mathcal{T}} \frac{1}{\lambda_{1,\tau}}\|\nabla g_{1,\tau}(\theta_{\star,1})\|_\infty > \frac{\alpha}{2}\right) &\leq \sum_{\tau\in\mathcal{T}} \mathbb{P}\left(\left\|\frac{1}{\tau}\sum_{t=1}^\tau U^{(t)}\right\|_\infty > \frac{\alpha\lambda_{1,\tau}T}{2\tau}\right)\\ &\leq 4Tp^2 e^{-\frac{\tau}{4}\left(\frac{\alpha\lambda_{1,\tau}T}{2\tau\bar{\kappa}}\right)^2}\\ &\leq 4\exp\left(2\log(pT) - 3\log(pT)\right) \leq \frac{4}{pT}.\end{aligned}$$

■

Lemma 16 *Under the assumptions of the theorem, and on the event* $\mathcal{E}_n$, *we have*

$$\left\|\hat{\theta}_{1,\tau} - \theta_{\star,1}\right\|_F \leq A\bar{\kappa}\|\theta_{\star,1}\|_2^2\sqrt{\frac{s_1\log(pT)}{\tau}},$$

and

$$\left\|\hat{\theta}_{2,\tau} - \theta_{\star,2}\right\|_F \leq A\bar{\kappa}\|\theta_{\star,2}\|_2^2\sqrt{\frac{s_2\log(pT)}{T - \tau}},$$

for all $\tau \in \mathcal{T}$, *where* A *is an absolute constant that can be taken as* $A = 16 \times 20 \times \sqrt{48}$.

Proof Fix $j \in \{1,2\}$, and $\tau \in \mathcal{T}$. Set $\bar{g}_{j,\tau}(\theta) \stackrel{\text{def}}{=} g_{j,\tau}(\theta) + (1-\alpha)\lambda_{j,\tau} \|\theta\|_{\mathsf{F}} /2$, and recall that $\phi_{j,\tau}(\theta) \stackrel{\text{def}}{=} g_{j,\tau}(\theta) + \lambda_{j,\tau}\wp(\theta)$. Hence $\phi_{j,\tau}(\theta) = \bar{g}_{j,\tau}(\theta) + \alpha\lambda_{j,\tau}\|\theta\|_1$. By a very standard argument that can be found for instance in Negahban et al. (2012), it is known that on the event $\mathcal{E}_n$, and if α satisfies (9) then we have $\hat{\theta}_{j,\tau} - \theta_{\star,j} \in \mathcal{C}_j$, where the cones $\mathcal{C}_j$ are as defined in (16). We write

$$\begin{aligned}\phi_{j,\tau}(\hat{\theta}_{j,\tau}) - \phi_{j,\tau}(\theta_{\star,j}) &= \left\langle \nabla g_{j,\tau}(\theta_{\star,j}) + (1-\alpha)\lambda_{j,\tau}\theta_{\star,j}, \hat{\theta}_{j,\tau} - \theta_{\star,j}\right\rangle \\ &\quad + \bar{g}_{j,\tau}(\hat{\theta}_{j,\tau}) - \bar{g}_{j,\tau}(\theta_{\star,j}) - \left\langle \nabla \bar{g}_{j,\tau}(\theta_{\star,j}), \hat{\theta}_{j,\tau} - \theta_{\star,j}\right\rangle \\ &\quad + \alpha\lambda_{j,\tau}\left(\|\hat{\theta}_{j,\tau}\|_1 - \|\theta_{\star,j}\|_1\right).\end{aligned}$$

On $\mathcal{E}_n$, $\hat{\theta}_{j,\tau} - \theta_{\star,j} \in \mathcal{C}_j$. Therefore

$$\alpha\lambda_{j,\tau}\left|\|\hat{\theta}_{j,\tau}\|_1 - \|\theta_{\star,j}\|_1\right| \le \alpha\lambda_{j,\tau}\left\|\hat{\theta}_{j,\tau} - \theta_{\star,j}\right\|_1 \le 8\alpha\lambda_{j,\tau}\sqrt{s_j}\left\|\hat{\theta}_{j,\tau} - \theta_{\star,j}\right\|_{\mathsf{F}},$$

and

$$\begin{aligned}&\left|\left\langle \nabla g_{j,\tau}(\theta_{\star,j}) + (1-\alpha)\lambda_{j,\tau}\theta_{\star,j}, \hat{\theta}_{j,\tau} - \theta_{\star,j}\right\rangle\right| \\ &\qquad \le \frac{\lambda_{j,\tau}}{2}\left(\alpha + 2(1-\alpha)\|\theta_{\star,j}\|_\infty\right)\left\|\hat{\theta}_{j,\tau} - \theta_{\star,j}\right\|_1 \\ &\qquad\qquad \le 4\lambda_{j,\tau}\left(\alpha + 2(1-\alpha)\|\theta_{\star,j}\|_\infty\right)\sqrt{s_j}\left\|\hat{\theta}_{j,\tau} - \theta_{\star,j}\right\|_{\mathsf{F}}.\end{aligned}$$

Suppose $j = 1$. The case $j = 2$ is similar. We then set $\Delta_{1,\tau} \stackrel{\text{def}}{=} \hat{\theta}_{1,\tau} - \theta_{\star,1}$, and use the second part of Lemma 12 (1) to deduce that

$$\begin{aligned}&\bar{g}_{1,\tau}(\hat{\theta}_{1,\tau}) - \bar{g}_{1,\tau}(\theta_{\star,1}) - \left\langle \nabla \bar{g}_{1,\tau}(\theta_{\star,1}), \hat{\theta}_{1,\tau} - \theta_{\star,1}\right\rangle \\ &\qquad \ge g_{1,\tau}(\hat{\theta}_{1,\tau}) - g_{1,\tau}(\theta_{\star,1}) - \left\langle \nabla g_{1,\tau}(\theta_{\star,1}), \hat{\theta}_{1,\tau} - \theta_{\star,1}\right\rangle \\ &\qquad\qquad \ge \frac{\tau}{2T}\frac{\|\Delta_{1,\tau}\|_{\mathsf{F}}^2}{2\|\theta_{\star,1}\|_2\left(2\|\theta_{\star,1}\|_2 + \|\Delta_{1,\tau}\|_{\mathsf{F}}\right)}.\end{aligned}$$

Set $c_1 = \frac{\tau}{4T\|\theta_{\star,1}\|_2^2}$, $c_2 = 4\lambda_{1,\tau}\sqrt{s_1}\left(3\alpha + 2(1-\alpha)\|\theta_{\star,1}\|_\infty\right)$. Since $\phi_{1,\tau}(\hat{\theta}_{1,\tau}) - \phi_{1,\tau}(\theta_{\star,1}) \le 0$, the above derivation shows that on the event $\mathcal{E}_n$,

$$\frac{c_1\|\Delta_{1,\tau}\|_{\mathsf{F}}^2}{2 + \frac{1}{\|\theta_{\star,1}\|_2}\|\Delta_{1,\tau}\|_{\mathsf{F}}} - c_2\|\Delta_{1,\tau}\|_{\mathsf{F}} \le 0,$$

Under the assumption that $c_1 \ge 2c_2/\|\theta_{\star,1}\|_2$ (which we impose in (10)), this implies that

$$\|\Delta_{1,\tau}\|_{\mathsf{F}} \le \frac{4c_2}{c_1} \le A\bar{\kappa}\|\theta_{\star,1}\|_2^2\sqrt{\frac{s_1\log(pT)}{\tau}},$$

where $A = 16 \times 20 \times \sqrt{48}$, as claimed. ∎

Proof of Theorem 9 For $\tau \in \mathcal{T}$, let

$$r_{1,\tau} \stackrel{\text{def}}{=} A\bar{\kappa}\|\theta_{\star,1}\|_2^2\sqrt{\frac{s_1\log(pT)}{\tau}}, \quad r_{2,\tau} \stackrel{\text{def}}{=} A\bar{\kappa}\|\theta_{\star,2}\|_2^2\sqrt{\frac{s_2\log(pT)}{T-\tau}},$$

be the convergence rates obtained in Lemma 16. Let $\epsilon > 0$ be given by

$$\epsilon \stackrel{\text{def}}{=} \min_{\tau\in\mathcal{T}}(r_{1,\tau} \wedge r_{1,\tau}).$$

For $j = 1, 2$, let $\theta_j \in \mathcal{M}_p^+$ be such that $\|\theta_j - \hat{\theta}_{\tau,j}\|_1 \le \epsilon$. Set $\check{\tau} = \mathsf{Argmin}_{t\in\mathcal{T}}\ \mathcal{H}(t|\theta_1,\theta_2)$, where $\mathcal{H}$ is as defined in (4). Set

$$C_0 = \min\left[\frac{\|\theta_{\star,2} - \theta_{\star,1}\|_{\mathsf{F}}^4}{128B^4\|\theta_{\star,2} - \theta_{\star,1}\|_1^2}, \left(\frac{\bar{\kappa}}{\bar{\kappa}}\right)^4\right].$$

We will show below that

$$\mathbb{P}\left(|\check{\tau} - \tau_\star| > \frac{4\log(p)}{C_0}\right) \le \frac{8}{pT} + \frac{4}{p^2\left(1 - e^{-C_0}\right)}. \tag{18}$$

This implies that with probability at least $1 - \frac{8}{pT} - \frac{4}{p^2(1-e^{-C_0})}$, Assumption H1 holds (with $\epsilon \leftarrow \epsilon/\sqrt{p}$, $\kappa = 0$, and $c = (4/C_0)\log(p)$). The theorem then follows by applying Theorem 5.

Given $\theta_j \in \mathcal{M}_p^+$ be such that $\|\theta_j - \hat{\theta}_{\tau,j}\|_1 \le \epsilon$, we will now show that (18) holds. We shall bound $\mathbb{P}(\check{\tau} > \tau_\star + \delta)$, $\delta = (4/C_0)\log(p)$. The bound on $\mathbb{P}(\check{\tau} < \tau_\star - \delta)$ follows similarly by working with the reversed sequence $X^{(T)}, \ldots, X^{(1)}$.

Note that θ_j can be written as

$$\theta_j = (\theta_j - \hat{\theta}_{\tau,j}) + (\hat{\theta}_{\tau,j} - \theta_{\star,j}) + \theta_{\star,j}. \tag{19}$$

This implies that on $\mathcal{E}_n$, for $\epsilon \le r_{j,\tau}$, and $r_{j,\tau} \le \min\left(\frac{\lambda_{\min}(\theta_{\star,j})}{4}, \frac{\|\theta_{\star,j}\|_\infty}{2}, \frac{\|\theta_{\star,j}\|_1}{1+8s_j^{1/2}}\right)$, we have

$$\begin{aligned}\lambda_{\min}(\theta_j) \ge \frac{1}{2}\lambda_{\min}(\theta_{\star,j}), \quad \lambda_{\max}(\theta_j) \le 2\lambda_{\max}(\theta_{\star,j}),& \\ \|\theta_j\|_\infty \le 2\|\theta_{\star,j}\|_\infty, \quad \text{and} \quad \|\theta_j\|_1 \le 2\|\theta_{\star,j}\|_1.&\end{aligned} \tag{20}$$

Using the event $\mathcal{E}_n$ introduced in (17), we have

$$\begin{aligned}\mathbb{P}\left(\check{\tau} > \tau_\star + \delta\right) &\le \mathbb{P}(\mathcal{E}_n^c) + \sum_{j\ge 0:\ \tau_\star+\delta+j\in\mathcal{T}} \mathbb{P}\left(\mathcal{E}_n,\ \check{\tau} = \tau_\star + \delta + j\right) \\ &\le \mathbb{P}(\mathcal{E}_n^c) + \sum_{j\ge 0:\ \tau_\star+\delta+j\in\mathcal{T}} \mathbb{P}\left(\mathcal{E}_n,\ \phi_{1,\tau_\star+\delta+j}(\theta_1) + \phi_{2,\tau_\star+\delta+j}(\theta_2) \le \phi_{1,\tau_\star}(\theta_1) + \phi_{2,\tau_\star}(\theta_2)\right),\end{aligned} \tag{21}$$

where $\phi_{j,\tau}(\theta) \stackrel{\text{def}}{=} g_{j,\tau}(\theta) + \lambda_{j,\tau}\wp(\theta)$. First we are going to bound the probability

$$\mathbb{P}\left(\mathcal{E}_n,\ \phi_{1,\tau}(\theta_1) + \phi_{2,\tau}(\theta_2) \le \phi_{1,\tau_\star}(\theta_1) + \phi_{2,\tau_\star}(\theta_2)\right),$$

for some arbitrary $\tau \in \mathcal{T}$, $\tau > \tau_\star$. A simple calculation shows that

$$\begin{aligned}\frac{2T}{\tau - \tau_\star}\left[\phi_{1,\tau}(\theta_1) + \phi_{2,,\tau}(\theta_2) - \phi_{1,\tau_\star}(\theta_1) - \phi_{2,\tau_\star}(\theta_2)\right] &= -\log\det(\theta_1) + \log\det(\theta_2) \\ &\quad + \langle\theta_1 - \theta_2, \theta_{\star,2}^{-1}\rangle + \left\langle \theta_1 - \theta_2, \frac{1}{\tau - \tau_\star}\sum_{t=\tau_\star+1}^{\tau}\left(X^{(t)}X^{(t)\prime} - \theta_{\star,2}^{-1}\right)\right\rangle \\ &\quad + 2T\left(\frac{\lambda_{1,\tau} - \lambda_{1,\tau_\star}}{\tau - \tau_\star}\right)\left(\frac{1-\alpha}{2}\|\theta_1\|_{\mathsf{F}}^2 + \alpha\|\theta_1\|_1\right) \\ &\quad + 2T\left(\frac{\lambda_{2,\tau} - \lambda_{2,\tau_\star}}{\tau - \tau_\star}\right)\left(\frac{1-\alpha}{2}\|\theta_2\|_{\mathsf{F}}^2 + \alpha\|\theta_2\|_1\right).\end{aligned}$$

We have $2T\left(\frac{\lambda_{1,\tau}-\lambda_{1,\tau_\star}}{\tau-\tau_\star}\right)\left(\frac{1-\alpha}{2}\|\theta_1\|_{\mathsf{F}}^2+\alpha\|\theta_1\|_1\right)\geq 0$, and

$$2T\left|\frac{\lambda_{2,\tau}-\lambda_{2,\tau_\star}}{\tau-\tau_\star}\right|\leq\frac{\bar{\kappa}}{\alpha}\sqrt{\frac{48\log(pT)}{T-\tau}}=\frac{c_0 r_{2,\tau}}{\alpha s_2^{1/2}\|\theta_{\star,2}\|_2^2},$$

for some absolute constant c_0. Using the infinity-norm and 1-norm bounds in (20) together with (9), we have

$$\frac{1-\alpha}{2}\|\theta_2\|_{\mathsf{F}}^2+\alpha\|\theta_2\|_1=\alpha\left[\frac{1-\alpha}{2\alpha}\|\theta_2\|_\infty+1\right]\|\theta_2\|_1\leq 4\alpha\|\theta_{\star,2}\|_1,$$

and it follows that

$$2T\left|\frac{\lambda_{2,\tau}-\lambda_{2,\tau_\star}}{\tau-\tau_\star}\right|\left(\frac{1-\alpha}{2}\|\theta_2\|_{\mathsf{F}}^2+\alpha\|\theta_2\|_1\right)\leq C_\tau\stackrel{\text{def}}{=}\left(\frac{4c_0\|\theta_{\star,2}\|_1}{s_2^{1/2}\|\theta_{\star,2}\|_2^2}\right)r_{2,\tau}.$$

Set

$$b\stackrel{\text{def}}{=}\min\left(\lambda_{\mathsf{min}}(\theta_{\star,1}),\lambda_{\mathsf{min}}(\theta_{\star,2})\right),\quad B\stackrel{\text{def}}{=}\max\left(\|\theta_{\star,1}\|_2,\|\theta_{\star,2}\|_2\right).$$

By the strong convexity of $\log\det$ (Lemma 12 Part(1)) we have:

$$-\log\det(\theta_1)+\log\det(\theta_2)+\left\langle\theta_1-\theta_2,\theta_{\star,2}^{-1}\right\rangle\geq\left\langle\theta_{\star,2}^{-1}-\theta_2^{-1},\theta_1-\theta_2\right\rangle+\frac{1}{2B^2}\|\theta_1-\theta_2\|_{\mathsf{F}}^2.$$

Since $\theta_{\star,2}^{-1}-\theta_2^{-1}=\theta_{\star,2}^{-1}(\theta_2-\theta_{\star,2})\theta_2^{-1}$, and using the fact that $\|AB\|_{\mathsf{F}}\leq\|A\|_2\|B\|_{\mathsf{F}}$, we have that on $\mathcal{E}_n$,

$$\left|\left\langle\theta_{\star,2}^{-1}-\theta_2^{-1},\theta_1-\theta_2\right\rangle\right|\leq 2r_{2,\tau}\|\theta_{\star,2}^{-1}\|_2\|\theta_2^{-1}\|_2\|\theta_2-\theta_1\|_{\mathsf{F}}\leq 4r_{2,\tau}\|\theta_{\star,2}^{-1}\|_2^2\|\theta_2-\theta_1\|_{\mathsf{F}}.$$

We conclude that on $\mathcal{E}_n$,

$$\frac{2T}{\tau-\tau_\star}\left[\phi_{1,\tau}(\theta_1)+\phi_{2,\tau}(\theta_2)-\phi_{1,\tau_\star}(\theta_1)-\phi_{2,\tau_\star}(\theta_2)\right]\geq\left\langle\theta_1-\theta_2,\frac{1}{\tau-\tau_\star}\sum_{t=\tau_\star+1}^{\tau}\left(X^{(t)}X^{(t)'}-\theta_{\star,2}^{-1}\right)\right\rangle-C_\tau-4r_{2,\tau}\|\theta_{\star,2}^{-1}\|_2^2\|\theta_2-\theta_1\|_{\mathsf{F}}+\frac{1}{2B^2}\|\theta_1-\theta_2\|_{\mathsf{F}}^2.$$

Under the assumption (12) imposed on $r_{j,\tau}$ and for $\epsilon\leq r_{1,\tau}\wedge r_{2,\tau}$, it can be shown that on $\mathcal{E}_n$, and for $\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}\geq\frac{8c_0\|\theta_{\star,2}\|_1}{s_2^{1/2}\|\theta_{\star,2}\|_2^2\|\theta_{\star,2}^{-1}\|_2^2}$, we have

$$-C_\tau-2\left(\epsilon+r_{2,\tau}\right)\|\theta_{\star,2}^{-1}\|_2^2\|\theta_2-\theta_1\|_{\mathsf{F}}+\frac{1}{4B^2}\|\theta_1-\theta_2\|_{\mathsf{F}}^2\geq 0.\tag{22}$$

To see this, note that (22) holds if $\|\theta_2-\theta_1\|_{\mathsf{F}}\geq 8B^2r_{2,\tau}\|\theta_{\star,2}^{-1}\|_2^2+2B\sqrt{C_\tau+16B^2\|\theta_{\star,2}^{-1}\|_2^4r_{2,\tau}^2}$. Then it can be checked that if $r_{2,\tau}\leq\frac{c_0\|\theta_{\star,2}\|_1}{16B^2s_2^{1/2}\|\theta_{\star,2}\|_2^2\|\theta_{\star,2}^{-1}\|_2^2}$, then

$$8B^2\|\theta_{\star,2}^{-1}\|_2^2r_{2,\tau}\leq\frac{C_\tau}{2\|\theta_{\star,2}^{-1}\|_2^2r_{2,\tau}},\quad\text{and}\quad 4B\sqrt{C_\tau}\leq\frac{C_\tau}{2\|\theta_{\star,2}^{-1}\|_2^2r_{2,\tau}}.$$

Therefore, (22) holds if

$$\|\theta_2-\theta_1\|_{\mathsf{F}}\geq\frac{C_\tau}{\|\theta_{\star,2}^{-1}\|_2^2r_{2,\tau}}=\frac{4c_0\|\theta_{\star,2}\|_1}{s_2^{1/2}\|\theta_{\star,2}\|_2^2\|\theta_{\star,2}^{-1}\|_2^2}.$$

Now we write

$$\theta_2-\theta_1=(\theta_2-\hat{\theta}_{\tau,2})+(\hat{\theta}_{\tau,2}-\theta_{\star,2})+(\theta_{\star,2}-\theta_{\star,1})+(\theta_{\star,1}-\hat{\theta}_{\tau,1})+(\hat{\theta}_{\tau,1}-\theta_1),$$

and use the fact that $\epsilon\leq r_{1,\tau}\wedge r_{2,\tau}$, and $r_{j,\tau}\leq\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}/8$ to deduce that on $\mathcal{E}_n$, $\|\theta_2-\theta_1\|_{\mathsf{F}}\geq\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}/2$, and this completes the proof of the claim.

It follows from the above that

$$\mathbb{P}\left(\mathcal{E}_n;\phi_{1,\tau}(\theta_1)+\phi_{2,\tau}(\theta_2)-\phi_{1,\tau_\star}(\theta_1)-\phi_{2,\tau_\star}(\theta_2)\leq 0\right)\leq\mathbb{P}\left(\left\|\frac{1}{\tau-\tau_\star}\sum_{t=\tau_\star+1}^{\tau}\left(X^{(t)}X^{(t)'}-\theta_{\star,2}^{-1}\right)\right\|_\infty>\frac{\|\theta_2-\theta_1\|_{\mathsf{F}}^2}{4B^2\|\theta_2-\theta_1\|_1}\right).\tag{23}$$

Proceeding as above, it is easy to see that if $\epsilon\leq r_{1,\tau}\wedge r_{2,\tau}$, and $r_{j,\tau}\leq\frac{\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}}{2(1+8s^{1/2})}$, then

$$\frac{\|\theta_2-\theta_1\|_{\mathsf{F}}^2}{4B^2\|\theta_2-\theta_1\|_1}\geq\frac{\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}^2}{32B^2\|\theta_{\star,2}-\theta_{\star,1}\|_1}.$$

Using this, and by Lemma 15, it follows that the probability on the right-hand side of (23) is upper-bounded by

$$4p^2\exp\left(-(\tau-\tau_\star)\min\left[\frac{\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}^4}{128B^4\|\theta_{\star,2}-\theta_{\star,1}\|_1^2},\left(\frac{\bar{\kappa}}{\bar{\kappa}}\right)^4\right]\right).$$

We apply this to (21) to get:

$$\mathbb{P}(\check{\tau}>\tau_\star+\delta)\leq\mathbb{P}(\mathcal{E}_n^c)+\sum_{j\geq 0}4p^2e^{-C_0(\delta+j)}\leq\frac{8}{pT}+\frac{4}{p^2(1-e^{-C_0})},$$

where $C_0=\min\left[\frac{\|\theta_{\star,2}-\theta_{\star,1}\|_{\mathsf{F}}^4}{128B^4\|\theta_{\star,2}-\theta_{\star,1}\|_1^2},\left(\frac{\kappa}{\bar{\kappa}}\right)^4\right]$, and by taking $\delta=4\log(p)/C_0$. This completes the proof. ■

Abstract

In this article, we study the question of the statistical convergence of the 1-dimensional Mapper to its continuous analogue, the Reeb graph. We show that the Mapper is an optimal estimator of the Reeb graph, which gives, as a byproduct, a method to automatically tune its parameters and compute confidence regions on its topological features, such as its loops and flares. This allows to circumvent the issue of testing a large grid of parameters and keeping the most stable ones in the brute-force setting, which is widely used in visualization, clustering and feature selection with the Mapper.

Keywords: Topological Data Analysis, Mapper, Parameter Selection, Confidence Regions, Extended Persistence

1. Introduction

In statistical learning, a large class of problems can be categorized into supervised or unsupervised problems. For supervised learning problems, an output quantity Y must be predicted or explained from the input measures X. On the contrary, for unsupervised problems there is no output quantity Y to predict and the aim is to explain and model the underlying structure or distribution in the data. In a sense, unsupervised learning can be thought of as extracting features from the data, assuming that the latter come with unstructured noise. Many methods in data sciences can be qualified as unsupervised methods, among the most popular examples are association methods, clustering methods, linear and non linear dimension reduction methods and matrix factorization to cite a few (see for instance Chapter 14 in Friedman et al. (2001)). Topological Data Analysis (TDA) has emerged in the recent years as a new field whose aim is to uncover, understand and exploit the topological and geometric structure underlying complex and possibly high-dimensional data. Most of TDA methods can thus be qualified as unsupervised. In this paper, we study a recent TDA algorithm called Mapper which was first introduced in Singh et al. (2007).

Starting from a point cloud $\mathbb{X}_n$ sampled from a metric space $\mathcal{X}$, the idea of the Mapper is to study the topology of the sublevel sets of a function $f : \mathbb{X}_n \to \mathbb{R}$ defined on the point cloud[1]. The function f is called a *filter function* and it has to be chosen by the user. The Mapper construction depends on the choice of a cover $\mathcal{I}$ of the image of f by open sets. Pulling back $\mathcal{I}$ through f gives an open cover of the domain $\mathbb{X}_n$. It is then refined into a connected cover by splitting each element into its various clusters using a clustering algorithm whose choice is left to the user. Then, the Mapper is defined as the nerve of the connected cover, having one vertex per element, one edge per pair of intersecting elements, and more generally, one k-simplex per non-empty $(k+1)$-fold intersection. It can also be seen as a discrete approximation of its continuous counterpart called the *Reeb graph*, which was originally introduced in Reeb (1946).

In practice, the Mapper has two major applications. The first one is data visualization and clustering. Indeed, when the cover $\mathcal{I}$ is minimal in terms of cardinality, i.e. no more than two cover elements can intersect at once, the Mapper provides a visualization of the data in the form of a graph whose topology reflects that of the data. As such, it brings additional information to the usual clustering algorithms by identifying *flares* and *loops* that outline potentially remarkable subpopulations in the various clusters. See e.g. Yao et al. (2009); Lum et al. (2013); Sarikonda et al. (2014); Hinks et al. (2015) for examples of applications. The second application of Mapper is about feature selection. Indeed, each feature of the data can be evaluated on its ability to discriminate the interesting subpopulations mentioned above (flares, loops) from the rest of the data, using for instance Kolmogorov-Smirnov tests. See e.g. Lum et al. (2013); Nielson et al. (2015); Rucco et al. (2015) for examples of applications.

Unsupervised methods generally depend on parameters that need to be chosen by the user, such as the number of selected dimensions for dimension reduction methods or the number of clusters for clustering methods. Contrarily to supervised problems, it can be very difficult to evaluate the output of unsupervised methods and thus to select parameters. Regarding Mapper, the only answer proposed in the literature consists in selecting parameters in a range of values for which the Mapper seems to be stable—see for instance Nielson et al. (2015). But with non trivial data sets, it is not easy to tune Mapper this way. The problem is illustrated for instance in Figure 1 on a data set that we study further in Section 5. More generally, we believe that such an approach is not satisfactory since it does not provide statistical guarantees on the inferred Mapper. This major drawback of Mapper is an important obstacle to its use in exploratory data analysis.

Contributions. Our main goal in this article is to provide a statistical method to tune the parameters of the Mapper automatically in various settings (Equations (8), (9) and (10)) by computing its rate of convergence (Propositions 11 and 13 and Corollary 14) to its continuous counterpart called the Reeb graph, avoiding the computational cost of testing millions of candidates and selecting the most stable ones in the brute-force setting of many practitioners. We also provide methods to assess stability, rates of convergence and confidence regions (Proposition 15) for the topological features of the Mapper. We believe that this set of methods open the way to an accessible and intuitive utilization of Mapper for non expert researchers in applied topology.

1. The Mapper was originally defined more generally for functions with values in $\mathbb{R}^d$, with arbitrary $d > 0$. In this work, we restrict the focus to scalar-valued functions, since the mathematical analysis is much easier in that case, and since it also corresponds to many use cases of the Mapper.

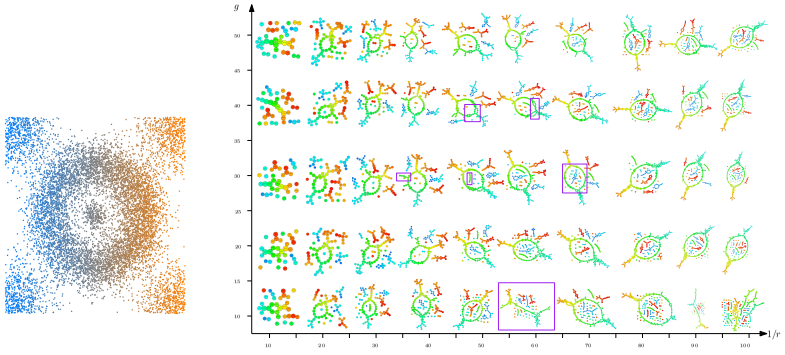

Figure 1: A collection of Mappers computed with various parameters. Left: crater data set. Right: outputs of Mapper with various parameters. One can see that for some Mappers (the ones with purple squares), topological features suddenly appear and disappear. These are discretization artifacts, that we overcome in this article by appropriately tuning the parameters.

Related work. Theoretical properties of Reeb graphs and Mappers have been the topic of several recent articles. Reeb graphs are now well understood and have been used in a wide range of applications. Algorithms for their computation have been proposed, as well as studies of their homology groups, like in Dey et al. (2017), and metrics for their comparison, such as the *functional distortion distance* of Bauer et al. (2014), the *interleaving distance* of de Silva et al. (2016) and the *edit distance* of di Fabio and Landi (2016). We refer the interested reader to the survey Biasotti et al. (2008) and to the introductions of Bauer et al. (2014) and Bauer et al. (2015) for a comprehensive list of references.

Concerning the Mapper, Babu (2013) characterized the Mapper with coarsened levelset zigzag persistence modules and showed that, as the lengths of the intervals in the cover $\mathcal{I}$ go to zero uniformly, the Mapper of a real-valued function converges to the Reeb graph in the bottleneck distance (defined in Section 2.2). Similarly, Munch and Wang (2016) recently characterized the Mapper with constructible cosheaves and showed the same type of convergence for the Mapper in the interleaving distance. Their result holds in the general case of vector-valued functions. However, in both approaches, the quantification of convergence is not precise enough to enable parameter selection.

Statistics in TDA have been so far focused on persistence diagrams, with the computation of rates of convergence, confidence regions and bootstrap—see e.g. Chazal et al. (2013); Fasy et al. (2014); Chazal et al. (2015a,b). In this article, we build on this line of work to provide results in the same vein for the Mapper. The integration of the Mapper in this framework is not straightforward since it encodes a different type of information than persistence diagrams. However, this is made possible by the recent work (in a deterministic setting) of Carrière and Oudot (2017b) about the structure and the stability of the Mapper. In this article, the authors provide a way to go from the input space to the Mapper using small perturbations. We build on this precise relation between the input space and its Mapper to show that the Mapper is itself a measurable construction. In Carrière and Oudot (2017b), the authors also show that the topological structure of the Mapper can actually be predicted from the cover $\mathcal{I}$ by looking at appropriate *signatures* that take the form of *extended persistence diagrams*. In this article, we use this observation, together with an approximation inequality, to show that the Mapper, computed with a specific set of parameters, is actually an optimal estimator of its continuous analogue, the so-called *Reeb graph*. Moreover, these specific parameters act as natural candidates to obtain a reliable Mapper with no artifacts.

Plan of the article. Section 2 presents the necessary background on the Reeb graph and the Mapper, and it also gives an approximation inequality—Theorem 7—for the Reeb graph with the Mapper. From this approximation result, we derive rates of convergences as well as candidate parameters in Section 3, and we show how to get confidence regions in Section 4. Section 5 illustrates the validity of our parameter tuning and confidence regions with numerical experiments on smooth and noisy data.

2. Approximation of a Reeb graph with the Mapper

2.1 Background on the Reeb graph and the Mapper

We start with some background on the Reeb graph and the Mapper. In particular, we present the specific Mapper algorithm that we study in this article.

Reeb graph. Let $\mathcal{X}$ be a topological space and let $f : \mathcal{X} \to \mathbb{R}$ be a continuous function. Such a function on $\mathcal{X}$ is called a *filter function* in the following. Then, we define the equivalence relation $\sim_f$ as follows: for all x and x' in $\mathcal{X}$, x and x' are in the same class ($x \sim_f x'$) if and only if x and x' belong to the same connected component of $f^{-1}(y)$, for some y in the image of f.

Definition 1 *The* Reeb graph $\mathrm{R}_f(\mathcal{X})$ *of* $\mathcal{X}$ *computed with the filter function* f *is the quotient space* $\mathcal{X}/\sim_f$ *endowed with the quotient topology.*

See Figure 2 for an illustration. Note that, since f is constant on equivalence classes, there is an induced map $f_{\mathrm{R}} : \mathrm{R}_f(\mathcal{X}) \to \mathbb{R}$ such that $f = f_{\mathrm{R}} \circ \pi$, where π is the quotient map $\mathcal{X} \to \mathrm{R}_f(\mathcal{X})$. The topological structure of a Reeb graph can be described if the pair $(\mathcal{X}, f)$ is regular enough. From now on, we will assume that the filter function $f : \mathcal{X} \to \mathbb{R}$ is *Morse-type*. Morse-type functions are generalizations of classical Morse functions that share some of their properties without having to be differentiable (nor even defined over a smooth manifold).

Definition 2 *Let* f *be a continuous real-valued function defined on a compact space* $\mathcal{X}$. *Then* f *is called* of Morse type *if:*

(i) *There is a finite set* $\mathrm{Crit}(f) = \{a_1 < ... < a_n\}$, *called the set of* critical values, *such that over every open interval* $(a_0 = -\infty, a_1), ..., (a_i, a_{i+1}), ..., (a_n, a_{n+1} = +\infty)$ *there is a compact and locally connected space* $\mathcal{Y}_i$ *and a homeomorphism* $\mu_i : \mathcal{Y}_i \times$

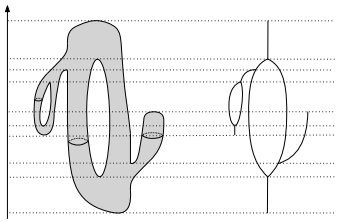

Figure 2: Example of Reeb graph computed on a double torus with the height function. Connected components of the level sets of the function (such as the three different ones drawn on the double torus) are contracted into single points.

$(a_i, a_{i+1}) \to f^{-1}((a_i, a_{i+1}))$ *such that* $\forall i = 0, ..., n, f|_{f^{-1}((a_i,a_{i+1}))} = \pi_2 \circ \mu_i^{-1}$, *where* π_2 *is the projection onto the second factor;*

(ii) $\forall i = 1, ..., n-1, \mu_i$ *extends to a continuous function* $\bar{\mu}_i : \mathcal{Y}_i \times [a_i, a_{i+1}] \to f^{-1}([a_i, a_{i+1}])$ *and similarly* μ_0 *extends to* $\bar{\mu}_0 : \mathcal{Y}_0 \times (-\infty, a_1] \to f^{-1}((-\infty, a_1])$ *and* μ_n *extends to* $\bar{\mu}_n : \mathcal{Y}_n \times [a_n, +\infty) \to f^{-1}([a_n, +\infty))$*;*

(iii) *Each levelset* $f^{-1}(t)$ *has a finitely-generated homology.*

Key fact 1a. (Proposition 2.10 in de Silva et al. (2016)) For $f : \mathcal{X} \to \mathbb{R}$ a Morse-type function, the Reeb graph $\mathrm{R}_f(\mathcal{X})$ is a multigraph.

For our purposes, in the following we further assume that $\mathcal{X}$ is a smooth and compact submanifold of $\mathbb{R}^D$. The set of Reeb graphs computed with Morse-type functions over such spaces is denoted $\mathcal{R}$ in this article. Whenever it is necessary, it will be equipped with extra structures in the following, such as pseudometrics or topologies.

Mapper. The Mapper is introduced in Singh et al. (2007) as a statistical version of the Reeb graph $\mathrm{R}_f(\mathcal{X})$ in the sense that it is a discrete and computable approximation of the Reeb graph computed with some filter function. Assume that we observe a point cloud $\mathbb{X}_n = \{X_1, \ldots, X_n\} \subset \mathcal{X}$ with known pairwise distances. A filter function is chosen and can be computed on each point of $\mathbb{X}_n$. The generic version of the Mapper algorithm on $\mathbb{X}_n$ computed with the filter function f can be summarized as follows:

1. Cover the range of values $\mathbb{Y}_n = f(\mathbb{X}_n)$ with a set of consecutive intervals $\{I_s\}_{1 \le s \le S}$ which overlap.

2. Apply a clustering algorithm to each pre-image $f^{-1}(I_s)$, $s \in \{1, ..., S\}$. This defines a *pullback cover* $\mathcal{C} = \{\mathcal{C}_{1,1}, \ldots, \mathcal{C}_{1,k_1}, \ldots, \mathcal{C}_{S,1}, \ldots, \mathcal{C}_{S,k_S}\}$ of the point cloud $\mathbb{X}_n$, where $\mathcal{C}_{s,k}$ denotes the kth cluster of $f^{-1}(I_s)$.

3. The Mapper is then the *nerve* of $\mathcal{C}$. Each vertex $v_{s,k}$ of the Mapper corresponds to one element $\mathcal{C}_{s,k}$ and two vertices $v_{s,k}$ and $v_{s',k'}$ are connected if and only if $\mathcal{C}_{s,k} \cap \mathcal{C}_{s',k'}$ is not empty, i.e. they have common points.

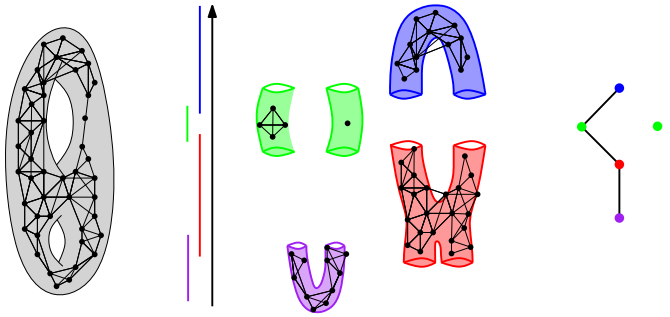

Figure 3: Example of Mapper computed on a sampling of the double torus with the height function f and a cover $\mathcal{I}$ of its range with four open intervals. Clusters are given by a neighborhood graph built on the sampling. Note that the rightmost green vertex is not connected to the other vertices of the Mapper since its corresponding cluster (which contains only one point) has no common points with the others.

See Figure 3 for an illustration. Even for one given filter function, many versions of the Mapper algorithm can be proposed depending on how one chooses the intervals that cover the image of f, and which method is used to cluster the pre-images. Moreover, note that the Mapper can be defined as well for continuous spaces. The definition is strictly the same except for the clustering step, which is replaced by taking the connected components of each pre-image $f^{-1}(I_s)$, $s \in \{1, ..., S\}$.

Our version of Mapper. In this article, we focus on a Mapper algorithm that uses neighborhood graphs. Of course, more sophisticated versions of Mapper can be used in practice but then the statistical analysis is more tricky. We assume that there exists a distance on $\mathbb{X}_n$ and that the matrix of pairwise distances is available. First, from the distance matrix we compute the δ-neighborhood graph built on top of $\mathbb{X}_n$, i.e. we draw an edge between two different points whenever their pairwise distance is less than δ. This object plays the role of an approximation of the underlying and unknown metric space $\mathcal{X}$ on which the data are sampled. Second, given $\mathbb{Y}_n = f(\mathbb{X}_n)$ the set of filter values, we choose a regular cover of $\mathbb{Y}_n$ with open intervals, where no more than two intervals can intersect at a time. More precisely, we use open intervals with same length r (apart from the first and the last one, which can have any positive length): $\forall s \in \{2, \ldots, S-1\}$,

$$r = \ell(I_s) \tag{1}$$

where ℓ is the Lebesgue measure on $\mathbb{R}$. The overlap g between two consecutive intervals is also a fixed constant: $\forall s \in \{1, \ldots, S-1\}$,

$$0 < g = \frac{\ell(I_s \cap I_{s+1})}{r} < \frac{1}{2}. \tag{2}$$

The parameters g and r are generally called the *gain* and the *resolution* in the literature on the Mapper algorithm. Finally, for the clustering step, we simply consider the connected components of the pre-images $f^{-1}(I_s)$ that are induced by the δ-neighborhood graph. The corresponding Mapper is denoted $\mathrm{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$ or M_n for short in the following. When dealing with a continuous space $\mathcal{X}$, there is no need to compute a neighborhood graph since the connected components are well-defined, so we let $\mathrm{M}_{r,g}(\mathcal{X}, f)$ denote our version of the Mapper in this case.

Key fact 1b. The Mapper $\mathrm{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$ is a combinatorial graph.

Moreover, following Carrière and Oudot (2017b), we can define a function on the nodes of M_n as follows.

Definition 3 *Let v be a node of M_n, i.e. v represents a connected component of $f^{-1}(I_s)$ for some $s \in \{1, \dots, S\}$. Then, we let*

$$f_{\mathcal{I}}(v) = \mathrm{mid}(\tilde{I}_s),$$

where $\tilde{I}_s = I_s \setminus (I_{s-1} \cup I_{s+1})$ and $\mathrm{mid}(\tilde{I}_s)$ denotes the midpoint of the interval $\tilde{I}_s$.

Filter functions. In practice, it is common to choose filter functions that are coordinate-independent, in order to avoid depending on solid transformations of the data like rotations or translations. The two most common filters that are used in the literature are:

- the *eccentricity*: $x \mapsto \sup_{y \in \mathcal{X}} d(x, y)$,
- the eigenfunctions of the covariance matrix as used in Principal Component Analysis.

2.2 Extended persistence signatures and the persistence metric

In this section, we introduce *extended persistence* and its associated metric, the *bottleneck distance*, which we will use later to compare Reeb graphs and Mappers. We merely provide a short introduction containing the necessary definitions since the statement of our results does not require a deep understanding of these notions. The understanding of the proofs of these results is more demanding, so we refer the reader willing to read proofs and already familiar with homology to Appendix C for more details, and to Edelsbrunner and Harer (2010); Oudot (2015) for a thorough treatment of extended persistence.

Extended persistence. Given any graph $G = (V, E)$ and a function defined on its nodes $f : V \to \mathbb{R}$, the so-called *extended persistence diagram* $\mathrm{Dg}(G, f)$, originally defined in Cohen-Steiner et al. (2009), is a multiset of points in the Euclidean plane $\mathbb{R}^2$ that can be computed with *extended persistence theory*. Each of the diagram points has a specific *type*, which is either Ord_0, Rel_1, Ext_0^+ or Ext_1^-. A rigorous connection between the Mapper and the Reeb graph was drawn recently by Carrière and Oudot (2017b), who show how extended persistence provides a relevant and efficient framework to compare a Reeb graph with a Mapper. We summarize below the main points of this work in the perspective of the present article.

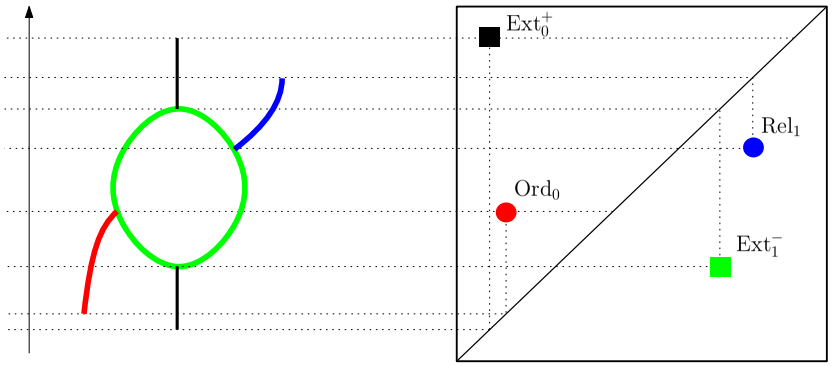

Figure 4: Example of correspondences between topological features of a graph and points in its corresponding extended persistence diagram. Note that ordinary persistence is unable to detect the blue upwards branch.

Topological dictionary. Given a topological space $\mathcal{X}$ and a Morse-type function $f : \mathcal{X} \to \mathbb{R}$, there is a nice interpretation of $\mathrm{Dg}(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}})$ in terms of the structure of $\mathrm{R}_f(\mathcal{X})$. Orienting the Reeb graph vertically so f_{R} is the height function, we can see each connected component of the graph as a trunk with multiple branches (some oriented upwards, others oriented downwards) and holes. Then, one has the following correspondences, where the *vertical span* of a feature is the span of its image by f_{R}:

- The vertical spans of the trunks are given by the points in $\mathrm{Ext}_0^+(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}})$;
- The vertical spans of the branches that are oriented downwards are given by the points in $\mathrm{Ord}_0(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}})$;
- The vertical spans of the branches that are oriented upwards are given by the points in $\mathrm{Rel}_1(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}})$;
- The vertical spans of the holes are given by the points in $\mathrm{Ext}_1^-(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}})$.

These correspondences provide a dictionary to read off the structure of the Reeb graph from the corresponding extended persistence diagram. See Figure 4 for an illustration.

Note that it is a bag-of-features type descriptor, taking an inventory of all the features (trunks, branches, holes) together with their vertical spans, but leaving aside the actual layout of the features. As a consequence, it is an incomplete descriptor: two Reeb graphs with the same persistence diagram may not be isomorphic.

Bottleneck distance. We now define the commonly used metric between persistence diagrams.

Definition 4 *Given two persistence diagrams D, D', a* partial matching *between D and D' is a subset Γ of $D \times D'$ such that:*

$$\forall p \in D, \text{ there is at most one } p' \in D' \text{ such that } (p, p') \in \Gamma,$$

$$\forall p' \in D', \text{ there is at most one } p \in D \text{ such that } (p, p') \in \Gamma.$$

Furthermore, Γ must match points of the same type (ordinary, relative, extended) and of the same homological dimension only. Let Δ be the diagonal $\Delta = \{(x, x) : x \in \mathbb{R}\}$. The cost *of Γ is:*

$$\text{cost}(\Gamma) = \max\left\{\max_{p \in D} \delta_D(p), \max_{p' \in D'} \delta_{D'}(p')\right\},$$

where

$$\delta_D(p) = \|p - p'\|_\infty \text{ if } \exists p' \in D' \text{ such that } (p, p') \in \Gamma, \text{ otherwise } \delta_D(p) = \inf_{q \in \Delta} \|p - q\|_\infty,$$

$$\delta_{D'}(p') = \|p - p'\|_\infty \text{ if } \exists p \in D \text{ such that } (p, p') \in \Gamma, \text{ otherwise } \delta_{D'}(p') = \inf_{q \in \Delta} \|p' - q\|_\infty.$$

Definition 5 *Let D, D' be two persistence diagrams. The* bottleneck distance *between D and D' is:*

$$d_\Delta(D, D') = \inf_\Gamma \text{ cost}(\Gamma),$$

where Γ ranges over all partial matchings between D and D'.

Note that d_Δ is only a pseudometric and not a true metric, because diagrams which only differ at the diagonal will have zero distance.

Definition 6 *Let $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ be two combinatorial graphs with real-valued functions $f_1 : V_1 \to \mathbb{R}$ and $f_2 : V_2 \to \mathbb{R}$ attached to their nodes. The* persistence metric d_Δ *between the pairs (G_1, f_1) and (G_2, f_2) is:*

$$d_\Delta(G_1, G_2) = d_\Delta\left(\text{Dg}(G_1, f_1), \text{Dg}(G_2, f_2)\right).$$

For a Morse-type function f defined on $\mathcal{X}$ and for a finite point cloud $\mathbb{X}_n \subset \mathcal{X}$, we can thus consider $\text{Dg}(\text{R}_f(\mathcal{X})) = \text{Dg}(\text{R}_f(\mathcal{X}), f_\text{R})$ and $\text{Dg}(\text{M}_n) = \text{Dg}(\text{M}_n, f_\mathcal{I})$, with $f_\mathcal{I}$ as in Definition 3. In this context the bottleneck distance $d_\Delta(\text{R}_f(\mathcal{X}), \text{M}_n) = d_\Delta(\text{Dg}(\text{R}_f(\mathcal{X})), \text{Dg}(\text{M}_n))$ is well defined and we use this quantity to assess if the Mapper M_n is a good approximation of the Reeb graph $\text{R}_f(\mathcal{X})$. Moreover, note that, even though d_Δ is only a pseudometric, it has been shown to be a true metric *locally* for Reeb graphs by Carrière and Oudot (2017a).

As noted in Carrière and Oudot (2017b), the choice of $f_\mathcal{I}$ is in some sense arbitrary since any function defined on the nodes of the Mapper that respects the ordering of the intervals of $\mathcal{I}$ carries the same information in its extended persistence diagram. To avoid this issue, Carrière and Oudot (2017b) define a pruned version of $\text{Dg}(\text{R}_f(\mathcal{X}), f_\text{R})$ as a canonical descriptor for the Mapper. The problem with this approach is that computing this canonical descriptor requires to know the critical values of f_R beforehand. Here, by considering $\text{Dg}(\text{M}_n, f_\mathcal{I})$ instead, the descriptor becomes computable. Moreover, one can see from the proofs in the Appendix that the canonical descriptor and its arbitrary version actually enjoy the same rate of convergence, up to some constant.

2.3 An approximation inequality for Mapper

We are now ready to give the key ingredient of this paper to derive a statistical analysis of the Mapper. The ingredient is an upper bound on the bottleneck distance between the Reeb graph of a pair $(\mathcal{X}, f)$ and the Mapper computed with the same filter function f and a specific cover $\mathcal{I}$ of a sampled point cloud $\mathbb{X}_n \subset \mathcal{X}$. From now on, it is assumed that the underlying space $\mathcal{X}$ is a smooth and compact submanifold embedded in $\mathbb{R}^D$, and that the filter function f is Morse-type on $\mathcal{X}$.

Regularity of the filter function. Intuitively, approximating a Reeb graph computed with a filter function f that has large variations is more difficult than for a smooth filter function, for some notion of regularity that we now specify. Our result is given in a general setting by considering the modulus of continuity of f. In our framework, f is assumed to be Morse-type and thus uniformly continuous on the compact set $\mathcal{X}$. Following for instance Section 6 in DeVore and Lorentz (1993), we define the exact modulus of continuity of f as:

$$\omega_f(\delta) = \sup_{\|x - x'\| \leq \delta} |f(x) - f(x')|$$

for any $\delta > 0$, where $\|\cdot\|$ denotes the Euclidean norm in $\mathbb{R}^D$. Then ω_f satisfies :

1. $\omega_f(\delta) \to \omega(0) = 0$ when $\delta \to 0$;
2. ω_f is non-negative and non-decreasing on $\mathbb{R}^+$;
3. ω_f is subadditive : $\omega_f(\delta_1 + \delta_2) \leq \omega_f(\delta_1) + \omega_f(\delta_2)$ for any $\delta_1, \delta_2 > 0$;
4. ω_f is continous on $\mathbb{R}^+$.

In this paper we say that a function ω defined on $\mathbb{R}^+$ is *a modulus of continuity* if it satisfies the four properties above and we say that it is *a modulus of continuity for f* if, in addition, we have

$$|f(x) - f(x')| \leq \omega(\|x - x'\|),$$

for any $x, x' \in \mathcal{X}$.

Theorem 7 *Assume that $\mathcal{X}$ has positive reach* rch *and convexity radius ρ. Let $\mathbb{X}_n$ be a point cloud of n points, all lying in $\mathcal{X}$. Assume that the filter function f is Morse-type on $\mathcal{X}$. Let ω be a modulus of continuity for f. Finally, let r, g be Mapper parameters defined as per Equations (1) and (2). If the three following conditions hold:*

$$\delta \leq \frac{1}{4} \min\{\text{rch}, \rho\}, \tag{3}$$

$$\max\{|f(X) - f(X')| : X, X' \in \mathbb{X}_n \text{ and } \|X - X'\| \leq \delta\} < gr, \tag{4}$$

$$4 d_\text{H}(\mathcal{X}, \mathbb{X}_n) \leq \delta, \tag{5}$$

where d_H denotes the Hausdorff distance, then the Mapper $\text{M}_n = \text{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$ with parameters r, g and δ is such that:

$$d_\Delta\left(\text{R}_f(\mathcal{X}), \text{M}_n\right) \leq r + 2\omega(\delta). \tag{6}$$

Remark 8 *Using the edge-based MultiNerve Mapper—as defined in Section 8 of Carrière and Oudot (2017b)—allows to weaken Assumption (4) since gr can be replaced by r in the corresponding equation, and r can be replaced by $r/2$ in Equation (6).*

Analysis of the hypotheses. On the one hand, the scale parameter δ of the neighborhood graph could not be smaller than the approximation error corresponding to the Hausdorff distance between the sample and the underlying space $\mathcal{X}$ (Assumption (5)). On the other hand, it must be smaller than the reach and convexity radius to provide a correct estimation of the geometry and topology of $\mathcal{X}$ (Assumption (3)). The quantity gr corresponds to the minimum scale at which the filter's codomain is analyzed. This minimum resolution has to be compared with the regularity of the filter at scale δ (Assumption (4)). Indeed the pre-images of a filter with strong variations will be more difficult to analyze than when the filter does not vary too fast.

Analysis of the upper bound. The upper bound given in (6) makes sense in that the approximation error is controlled by the resolution level in the codomain and by the regularity of the filter. If one uses a filter with strong variations, or if the grid in the codomain has a too rough resolution, then the approximation will be poor. On the other hand, a sufficiently dense sampling is required in order to take r small, as prescribed in the assumptions.

Lipschitz filters. A large class of filters used for the Mapper are actually Lipschitz functions and of course, in this case, one can take $\omega(\delta) = c\delta$ for some positive constant c. In particular, $c = 1$ for linear projections (PCA, SVD, Laplacian or coordinate filter for instance). The distance to a measure (DTM) is also a 1-Lipschitz function, see Chazal et al. (2011). On the other hand, the modulus of continuity of filter functions defined from estimators, e.g. density estimators, is less obvious although still well-defined.

Filter approximation. In some situations, the filter function $\hat{f}$ used to compute the Mapper is only an approximation of the filter function f with which the Reeb graph is computed. In this context, the pair $(\mathbb{X}_n, \hat{f})$ appears as an approximation of the pair $(\mathcal{X}, f)$. The following result is directly derived from Theorem 7 and Theorem 5.1 in Carrière and Oudot (2017b) (that derives stability for Mappers building on the stability theorem of extended persistence diagrams proved by Cohen-Steiner et al. (2009)):

Corollary 9 *Let $\hat{f} : \mathcal{X} \to \mathbb{R}$ be a Morse-type filter function approximating f. Assume that Assumptions (3) and (5) of Theorem 7 are satisfied, and assume moreover that*

$$\max\{\max\{|f(X) - f(X')|, |\hat{f}(X) - \hat{f}(X')|\} \,:\, X, X' \in \mathbb{X}_n, \|X - X'\| \leq \delta\} < gr. \qquad (7)$$

Then, the Mapper $\hat{\mathrm{M}}_n = \mathrm{M}_{r,g,\delta}(\mathbb{X}_n, \hat{f}(\mathbb{X}_n))$ built on $\mathbb{X}_n$ with filter function $\hat{f}$ and parameters r, g, δ satisfies:

$$d_\Delta(\mathrm{R}_f(\mathcal{X}), \hat{\mathrm{M}}_n) \leq 2r + 2\omega(\delta) + \max_{1 \leq i \leq n} |f(X_i) - \hat{f}(X_i)|.$$

3. Statistical Analysis of Mapper

From now on, the set of observations $\mathbb{X}_n$ is assumed to be composed of n independent points $X_1, ..., X_n$ sampled from a probability distribution $\mathbb{P}$ in $\mathbb{R}^D$ (endowed with its Borel algebra). We assume that each point X_i comes with a filter value which is represented by a random variable Y_i. Contrarily to the X_i's, the filter values Y_i's are not necessarily independent. In the following, we consider two different settings: in the first one, $Y_i = f(X_i)$, where the

filter f is a deterministic function, in the second one, $Y_i = \hat{f}(X_i)$ where $\hat{f}$ is an estimator of the filter function f. In the latter case, the Y_i's are obviously dependent. We first provide the following proposition, whose proof is deferred to Appendix A.4, which states that computing probabilities on the Mapper makes sense:

Proposition 10 *For any fixed choice of parameters r, g, δ and for any fixed $n \in \mathbb{N}$, the function*

$$\Phi : \begin{cases} (\mathbb{R}^D)^n \times \mathbb{R}^n & \to & \mathcal{R} \\ (\mathbb{X}_n, \mathbb{Y}_n) & \mapsto & \mathrm{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n) \end{cases}$$

is measurable, where $\mathcal{R}$ denotes the set of Reeb graphs computed from Morse-type functions.

3.1 Statistical Model for the Mapper

In this section, we study the convergence of the Mapper for a general generative model and a class of filter functions. We first introduce the generative model and next we present different settings depending on the nature of the filter function.

Generative model. The set of observations $\mathbb{X}_n$ is assumed to be composed of n independent points $X_1, ..., X_n$ sampled from a probability distribution $\mathbb{P}$ in $\mathbb{R}^D$. The support of $\mathbb{P}$ is denoted $\mathcal{X}_\mathbb{P}$ and is assumed to be a smooth and compact submanifold of $\mathbb{R}^D$ with positive reach and positive convexity radius, as in the setting of Theorem 7. We also assume that $0 < \mathrm{diam}(\mathcal{X}_\mathbb{P}) \leq L$. Next, the probability distribution $\mathbb{P}$ is assumed to be (a, b)-standard for some constants $a > 0$ and $b \geq D$, that is for any Euclidean ball $B(x, t)$ centered on $x \in \mathcal{X}$ with radius t :

$$\mathbb{P}(B(x, t)) \geq \min(1, at^b).$$

This assumption is popular in the literature about set estimation (see for instance Cuevas, 2009; Cuevas and Rodríguez-Casal, 2004). It is also widely used in the TDA literature (Chazal et al., 2015b; Fasy et al., 2014; Chazal et al., 2015a). For instance, when $b = D$, this assumption is satisfied when the distribution is absolutely continuous with respect to the Hausdorff measure on $\mathcal{X}_\mathbb{P}$. We introduce the set $\mathcal{P}_{a,b} = \mathcal{P}_{a,b,\kappa,\rho,L}$ which is composed of all the (a, b)-standard probability distributions for which the support $\mathcal{X}_\mathbb{P}$ is a smooth and compact submanifold of $\mathbb{R}^D$ with reach larger than κ, convexity radius larger than ρ and diameter less than L.

Filter functions in the statistical setting. The filter function $f : \mathcal{X}_\mathbb{P} \to \mathbb{R}$ for the Reeb graph is assumed as before to be a Morse-type function. Two different settings have to be considered regarding how the filter function is defined. In the first setting, the same filter function is used to define the Reeb graph and the Mapper. The Mapper can be defined by taking the exact values of the filter function at the observation points $f(X_1), \ldots, f(X_n)$. Note that this does not mean that the function f is completely known since, in our framework, knowing f would imply to know its domain and thus $\mathcal{X}_\mathbb{P}$ would be known which is of course not the case in practice. This first setting is referred to as the *exact filter setting* in the following. It corresponds to the situations where the Mapper algorithm is used with coordinate functions for instance. In the second setting, the filter function used for the Mapper is not available and an estimation of this filter function has to be computed from the data. This second setting is referred to as the *inferred filter setting* in

the following. It corresponds to PCA or Laplacian eigenfunctions, distance functions (such as the DTM), or regression and density estimators.

Risk of the Mapper. We study, in various settings, the problem of inferring a Reeb graph using Mappers and we use the metric d_Δ to assess the performance of the Mapper, seen as an estimator of the Reeb graph. Hence, we study the following quantity:

$$\mathbb{E}\left[d_\Delta\left(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_\mathbb{P})\right)\right],$$

where M_n is computed with the exact filter f or the inferred filter $\hat{f}$, depending on the context.

3.2 Reeb graph inference with exact filter and known generative model

We first consider the exact filter setting in the simplest situation where the parameters a and b of the generative model are known. In this setting, for a given neighborhood graph parameter δ, gain g and resolution r, the Mapper $\mathrm{M}_n = \mathrm{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$ is computed with $\mathbb{Y}_n = f(\mathbb{X}_n)$.

Parameter selection. We now tune the triple of parameters (r, g, δ) depending on the parameters a and b. More precisely, we take:

$$\text{an arbitrary } g \in \left(\frac{1}{3}, \frac{1}{2}\right), \quad \delta_n = 8\left(\frac{2\log(n)}{an}\right)^{1/b}, \quad r_n = \frac{V_n(\delta_n)^+}{g}, \tag{8}$$

where $V_n(\delta_n) = \max\{|f(X) - f(X')| : X, X' \in \mathbb{X}_n, \|X - X'\| \leq \delta_n\}$, and $V_n(\delta_n)^+$ denotes a value that is strictly larger but arbitrarily close to $V_n(\delta_n)$.

Upper bound. We give below a general upper bound on the risk of M_n with these parameters, which depends on the regularity of the filter function and on the parameters of the generative model. We show a uniform convergence over a class of possible filter functions. This class of filters necessarily depends on the support of $\mathbb{P}$, so we define the class of filters for each probability measure in $\mathcal{P}_{a,b}$. For any $\mathbb{P} \in \mathcal{P}_{a,b}$, we let $\mathcal{F}(\mathbb{P}, \omega)$ denote the set of filter functions $f : \mathcal{X}_\mathbb{P} \to \mathbb{R}$ such that f is Morse-type on $\mathcal{X}_\mathbb{P}$ with $\omega_f \leq \omega$.

Proposition 11 *Let ω be a modulus of continuity for f such that $\omega(x)/x$ is a non-increasing function on $\mathbb{R}^+$. For n large enough, the Mapper computed with parameters (r_n, g, δ_n) as per Equation (8) satisfies*

$$\sup_{\mathbb{P}\in\mathcal{P}_{a,b}} \mathbb{E}\left[\sup_{f\in\mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\mathrm{R}_f(\mathcal{X}_\mathbb{P}), \mathrm{M}_n\right)\right] \leq C\,\omega\left(\frac{2\cdot 8^b}{a}\frac{\log(n)}{n}\right)^{1/b}$$

where the constant C only depends on a, b, and on the geometric parameters of the model.

Assuming that $\omega(x)/x$ is non-increasing is not a very strong assumption. This property is satisfied in particular when ω is concave, as in the case of concave majorant (see for instance Section 6 in DeVore and Lorentz (1993)). As expected, we see that the rate of convergence of the Mapper to the Reeb graph directly depends on the regularity of the

filter function and on the parameter b which roughly represents the intrinsic dimension of the data. For Lipschitz filter functions, the rate is similar to the one for persistence diagram inference in Chazal et al. (2015b), namely it corresponds to the one of support estimation for the Hausdorff metric (see for instance Cuevas and Rodríguez-Casal (2004)) and Genovese et al. (2012a)). In the other cases where the filters only admit a concave modulus of continuity, we see that the "distortion" created by the filter function slows down the convergence of the Mapper to the Reeb graph.

We now give a lower bound that matches with the upper bound of Proposition 11.

Proposition 12 *Let ω be a modulus of continuity for f. Then, for any estimator $\hat{\mathrm{R}}_n$ of $\mathrm{R}_f(\mathcal{X}_\mathbb{P})$,, we have*

$$\sup_{\mathbb{P}\in\mathcal{P}_{a,b}} \mathbb{E}\left[\sup_{f\in\mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\mathrm{R}_f(\mathcal{X}_\mathbb{P}), \hat{\mathrm{R}}_n\right)\right] \geq C\,\omega\left(\frac{1}{an}\right)^{\frac{1}{b}},$$

where the constant C only depends on a, b and on the geometric parameters of the model.

Propositions 11 and 12 together show that, with the choice of parameters given before, M_n is minimax optimal up to a logarithmic factor $\log(n)$ inside the modulus of continuity. Note that the lower bound is also valid whether or not the coefficients a and b and the filter function f and its modulus of continuity are given.

3.3 Reeb graph inference with exact filter and unknown generative model

We still assume that the exact values $\mathbb{Y}_n = f(\mathbb{X}_n)$ of the filter on the point could can be computed and that at least a modulus of continuity for the filter is known. However, the parameters a and b are not assumed to be known anymore. We adapt a subsampling approach proposed by Fasy et al. (2014). As before, for a given neighborhood graph parameter δ, gain g and resolution r, the Mapper $\mathrm{M}_n = \mathrm{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$ is computed with $\mathbb{Y}_n = f(\mathbb{X}_n)$.

Parameter selection. We introduce the sequence $s_n = \frac{n}{(\log n)^{1+\beta}}$ for some fixed value $\beta > 0$. Let $\hat{\mathbb{X}}_n^{s_n}$ be an arbitrary subset of $\mathbb{X}_n$ that contains s_n points. Then, we take:

$$\text{an arbitrary } g \in \left(\frac{1}{3}, \frac{1}{2}\right), \quad \delta_n = d_{\mathrm{H}}(\hat{\mathbb{X}}_n^{s_n}, \mathbb{X}_n), \quad r_n = \frac{V_n(\delta_n)^+}{g}, \tag{9}$$

where V_n^+ is defined as in Equation (8).

Upper bound. Using these parameters, we can then derive the following upper bound:

Proposition 13 *Let ω be a modulus of continuity for f such that $x \mapsto \omega(x)/x$ is a non-increasing function. Then, using the same notations as in the previous section, the Mapper M_n computed with parameters (r_n, g, δ_n) as per Equation (9) satisfies*

$$\sup_{\mathbb{P}\in\mathcal{P}_{a,b}} \mathbb{E}\left[\sup_{f\in\mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\mathrm{R}_f(\mathcal{X}_\mathbb{P}), \mathrm{M}_n\right)\right] \leq C\,\omega\left(\frac{C'\log(n)^{2+\beta}}{n}\right)^{1/b},$$

where the constants C, C' only depends on a, b, and on the geometric parameters of the model.

Up to logarithmic factors inside the modulus of continuity, we find that this Mapper is still minimax optimal over the class $\mathcal{P}_{a,b}$ by Proposition 12.

3.4 Reeb graph inference with inferred filter and unknown generative model

One of the nice properties of the Mapper is that it can be easily computed with any filter function, including estimated filter functions such as PCA eigenfunctions, eccentricity functions, DTM functions, Laplacian eigenfunctions, density estimators, regression estimators, and many other filters directly estimated from the data. In this section, we assume that the *true filter* f is unknown but can be estimated from the data using an estimator $\hat{f}$. Without loss of generality, we assume that both f and $\hat{f}$ are defined on $\mathbb{R}^D$. As before, parameters a and b are not assumed to be known and we have to tune the triple of parameters (r_n, g, δ_n).

Parameter selection. In this context, the quantity V_n^+ of Equations (8) and (9) cannot be computed as before because there is no direct access to the values of f: we only know an estimation $\hat{f}$ of it. However, in many cases, a modulus of continuity ω_1 for f is known, which makes possible the tuning of the parameters. For instance, PCA (and kernel) projectors, eccentricity functions, DTM functions (see Chazal et al. (2011)) are all 1-Lipschitz functions, and Corollary 14 below can be applied.

Let $\hat{V}_n(\delta_n) = \max\{|\hat{f}(X) - \hat{f}(X')| \,:\, X, X' \in \mathbb{X}_n, \|X - X'\| \leq \delta_n\}$, and let ω_1 be a modulus of continuity for f. Then, we take:

$$\text{an arbitrary } g \in \left(\frac{1}{3}, \frac{1}{2}\right), \quad \delta_n = d_{\mathrm{H}}(\hat{\mathbb{X}}_n^{s_n}, \mathbb{X}_n), \quad r_n = \frac{\max\{\omega_1(\delta_n), \hat{V}_n(\delta_n)\}^+}{g}. \tag{10}$$

Upper bound. Following the lines of the proof of Proposition 13 and applying Corollary 9, we obtain:

Corollary 14 *Let $f : \mathbb{R}^D \to \mathbb{R}$ be a Morse-type filter function and let $\hat{f} : \mathbb{R}^D \to \mathbb{R}$ be a Morse-type estimator of f. Let ω_1 (resp. ω_2) be a modulus of continuity for f (resp. $\hat{f}$). Let $\omega = \max\{\omega_1, \omega_2\}$ such that $x \mapsto \omega(x)/x$ is a non-increasing function. Let also $\hat{\mathrm{M}}_n = \mathrm{M}_{r_n,g,\delta_n}(\mathbb{X}_n, \hat{f}(\mathbb{X}_n))$ be the Mapper built on $\mathbb{X}_n$ with function $\hat{f}$ and parameters g, δ_n, r_n as in Equation (10). Then, $\hat{\mathrm{M}}_n$ satisfies*

$$\mathbb{E}\left[d_\Delta\left(\mathrm{R}_f(\mathcal{X}_\mathbb{P}), \hat{\mathrm{M}}_n\right)\right] \leq C\omega\left(\frac{C'\log(n)^{2+\beta}}{n}\right)^{\frac{1}{b}} + \mathbb{E}\left[\max_{1\leq i\leq n} |f(X_i) - \hat{f}(X_i)|\right],$$

where the constants C, C' only depends on a, b, and on the geometric parameters of the model.

Note that ω_1 has to be known to compute $\hat{\mathrm{M}}_n$ in Corollary 14 since it appears in the definition of r_n. On the contrary, ω_2—and thus ω—is not required to tune the parameters.

PCA eigenfunctions. In the setting of this article, the measure μ has a finite second moment. Following Biau and Mas (2012), we define the covariance operator $\Gamma(\cdot) = \mathbb{E}(\langle X, \cdot\rangle X)$ and we let Π_k denote the orthogonal projection onto the space spanned by the k-th eigenvector of Γ. In practice, we consider the empirical version of the covariance operator

$$\hat{\Gamma}_n(\cdot) = \frac{1}{n}\sum_{i=1}^n \langle X_i, \cdot\rangle X_i$$

and the empirical projection $\hat{\Pi}_k$ onto the space spanned by the k-th eigenvector of $\hat{\Gamma}_n$. According to Biau and Mas (2012)(see also Blanchard et al. (2007); Shawe-Taylor et al. (2005)), we have

$$\mathbb{E}\left[\|\Pi_k - \hat{\Pi}_k\|_\infty\right] = O\left(\frac{1}{\sqrt{n}}\right).$$

This, together with Corollary 14 and the fact that both Π_k and $\hat{\Pi}_k$ are 1-Lipschitz, gives that the rate of convergence of the Mapper of $\hat{\Pi}_k(\mathbb{X}_n)$ computed with parameters δ_n, g and r_n as in Equation (10) (which gives $r_n = g^{-1}\delta_n^+$) satisfies

$$\mathbb{E}\left[d_\Delta\left(\mathrm{R}_{\Pi_k}(\mathcal{X}_\mathbb{P}), \mathrm{M}_{r_n,g,\delta_n}(\mathbb{X}_n, \hat{\Pi}_k(\mathbb{X}_n))\right)\right] = O\left(\max\left\{\left(\frac{\log(n)^{2+\beta}}{n}\right)^{\frac{1}{b}}, \frac{1}{\sqrt{n}}\right\}\right).$$

Hence, the rate of convergence of Mapper is not deteriorated by using $\hat{\Pi}_k$ instead of Π_k if the intrinsic dimension b of the support of μ is at least 2.

The distance to measure. It is well known that TDA methods may fail completely in the presence of outliers. To address this issue, Chazal et al. (2011) introduced an alternative distance function which is robust to noise, the *distance-to-measure* (DTM). A similar analysis as with the PCA filter can be carried out with the DTM filter using the rates of convergence proven in Chazal et al. (2016b).

4. Confidence sets for Reeb signatures

4.1 Confidence sets for extended persistence diagrams

In practice, computing a Mapper M_n and its signature $\mathrm{Dg}(\mathrm{M}_n, f_\mathcal{I})$ is not sufficient: we need to know how accurate these estimations are. One natural way to answer this problem is to provide a confidence set for the Mapper using the bottleneck distance. For $\alpha \in (0, 1)$, we look for some value $\eta_{n,\alpha}$ such that

$$\mathbb{P}\left(d_\Delta(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_\mathbb{P})) \geq \eta_{n,\alpha}\right) \leq \alpha$$

or at least such that

$$\limsup_{n\to\infty} \mathbb{P}\left(d_\Delta(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_\mathbb{P})) \geq \eta_{n,\alpha}\right) \leq \alpha.$$

Let

$$\mathcal{M}_\alpha = \{\mathrm{R} \in \mathcal{R} \,:\, d_\Delta(\mathrm{M}_n, \mathrm{R}) \leq \alpha\}$$

be the closed ball of radius α in the bottleneck distance and centered at the Mapper M_n in the space of Reeb graphs $\mathcal{R}$. Following Fasy et al. (2014), we can visualize the signatures of the points belonging to this ball in various ways. One first option is to center a box of side length 2α at each point of the extended persistence diagram of M_n—see the right columns of Figure 5 and Figure 6 for instance. An alternative solution is to visualize the confidence set by adding a band at (vertical) distance 2α from the diagonal (the bottleneck distance being defined for the ℓ_∞ norm). The points outside the band are then considered as significant topological features, see Fasy et al. (2014) for more details.

Several methods have been proposed in Fasy et al. (2014) and Chazal et al. (2014) to define confidence sets for persistence diagrams. We now adapt these ideas to provide confidence sets for Mappers. Except for the bottleneck bootstrap (see Section 4.3), all the methods proposed in these two articles rely on the stability results for persistence diagrams, which say that persistence diagrams equipped with the bottleneck distance are stable under Hausdorff or Wasserstein perturbations of the data. Confidence sets for diagrams are then directly derived from confidence sets in the sample space. Here, we follow a similar strategy using Theorem 7, as explained in the next section.

4.2 Confidence sets derived from Theorem 7

In this section, we always assume that an upper bound ω on the exact modulus of continuity ω_f of the filter function is known. We start with the following remark: if we can take δ of the order of $d_{\mathrm{H}}(\mathcal{X}_{\mathbb{P}}, \mathbb{X}_n)$ in Theorem 7 and if all the conditions of the theorem are satisfied, then $d_\Delta(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_{\mathbb{P}}))$ can be bounded in terms of $\omega(d_{\mathrm{H}}(\mathcal{X}_{\mathbb{P}}, \mathbb{X}_n))$. This means that we can adapt the methods of Fasy et al. (2014) to Mappers.

Known generative model. Let us first consider the simplest situation where the parameters a an b are also known. Following Section 3.2, we choose for g, δ_n, r_n as per Equation (8). Let $\varepsilon_n = d_{\mathrm{H}}(\mathcal{X}_{\mathbb{P}}, \mathbb{X}_n)$. As shown in the proof of Proposition 11 (see Appendix A.5), for n large enough, Assumption (3) and (4) are always satisfied and then

$$\mathbb{P}\left(d_\Delta(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_{\mathbb{P}})) \geq \eta\right) \leq \mathbb{P}\left(\delta_n \geq \omega^{-1}\left(\frac{\eta}{g^{-1}+2}\right)\right).$$

Consequently,

$$\begin{aligned}\mathbb{P}\left(d_\Delta(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_{\mathbb{P}})) \geq \eta\right) &\leq \mathbb{P}\left(d_\Delta(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_{\mathbb{P}})) \geq \eta \cap \varepsilon_n \leq 4\delta_n\right) + \mathbb{P}\left(\varepsilon_n > 4\delta_n\right) \\ &\leq \mathbb{I}_{\omega(\delta_n) \geq \frac{g}{1+2g}\eta} + \min\left\{1, \frac{2^b}{2\log(n)n}\right\} \\ &= \Phi_n(\eta).\end{aligned}$$

where Φ_n depends on the parameters of the model (or some bounds on these parameters) which are here assumed to be known. Hence, given a probability level α, one has:

$$\mathbb{P}\left(d_\Delta(\mathrm{M}_n, \mathrm{R}_f(\mathcal{X}_{\mathbb{P}})) \geq \Phi_n^{-1}(\alpha)\right) \leq \alpha.$$

Unknown generative model. We now assume that a and b are unknown. To compute confidence sets for the Mapper in this context, we approximate the distribution of $d_{\mathrm{H}}(\mathcal{X}_{\mathbb{P}}, \mathbb{X}_n)$ using the distribution of $d_{\mathrm{H}}(\hat{\mathbb{X}}_n^{s_n}, \mathbb{X}_n)$ conditionally to $\mathbb{X}_n$. There are $N_1 = \binom{n}{s_n}$ subsets of size s_n inside $\mathbb{X}_n$, so we let $\mathbb{X}_{s_n}^1, \ldots, \mathbb{X}_{s_n}^{N_1}$ denote all the possible configurations. Define

$$L_n(t) = \frac{1}{N_1}\sum_{k=1}^{N_1} \mathbb{I}_{d_{\mathrm{H}}\left(\mathbb{X}_{s_n}^k, \mathbb{X}_n\right) > t}.$$

Let s be the function on $\mathbb{N}$ defined by $s(n) = s_n$ and let $s_n^2 = s(s(n))$. There are $N_2 = \binom{n}{s_n^2}$ subsets of size s_n^2 inside $\mathbb{X}_n$. Again, we let $\mathbb{X}_{s_n^2}^k$, $1 \leq k \leq N_2$, denote these configurations

and we also introduce

$$F_n(t) = \frac{1}{N_2}\sum_{k=1}^{N_2} \mathbb{I}_{d_{\mathrm{H}}\left(\mathbb{X}_{s_n^2}^k, \mathbb{X}_{s_n}\right) > t}.$$

Proposition 15 *Let $\eta > 0$. Then, one has the following confidence set:*

$$\mathbb{P}\left(d_\Delta(\mathrm{R}_f(\mathcal{X}_{\mathbb{P}}), \mathrm{M}_n) \geq \eta\right) \leq F_n\left(\frac{1}{4}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) + L_n\left(\frac{1}{4}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) + o\left(\frac{s_n}{n}\right)^{\frac{1}{4}}.$$

Both F_n and L_n can be computed in practice, or at least approximated using Monte Carlo procedures. The upper bound on $\mathbb{P}\left(d_\Delta(\mathrm{R}_f(\mathcal{X}_{\mathbb{P}}), \mathrm{M}_n) \geq \eta\right)$ then provides an asymptotic confidence region for the persistence diagram of the Mapper M_n, which can be explicitly computed in practice. See the green squares in the first row of Figure 5. The main drawback of this approach is that it requires knowing a modulus of continuity ω and, more importantly, the number of observations has to be very large, which is not the case on our examples in Section 5.

Modulus of continuity of the filter function. As shown in Proposition 15, the modulus of continuity of the filter function is a key quantity to describe the confidence regions. Inferring the modulus of continuity of the filter from the data is a tricky problem. Fortunately, in practice, even in the inferred filter setting, a modulus of continuity for the function is known in many situations. For instance, projections such as PCA eigenfunctions and DTM functions are 1-Lipschitz.

4.3 Bottleneck Bootstrap

The two methods given before both require an explicit upper bound on the modulus of continuity of the filter function. Moreover, these methods both rely on the approximation result Theorem 7, which often leads to conservative confidence sets. An alternative strategy is the bottleneck bootstrap introduced in Chazal et al. (2014), and which we now apply to our framework.

Bootstrap. The bootstrap is a general method for estimating standard errors and computing confidence intervals. Let $\mathbb{P}_n$ be the empirical measure defined from the sample $(X_1, Y_1), \ldots, (X_n, Y_n)$. Let $(X_1^*, Y_1^*) \ldots, (X_n^*, Y_n^*)$ be a sample from $\mathbb{P}_n$ and let also M_n^* be the random Mapper defined from this sample. We then take for $\hat{\eta}_{n,\alpha}$ the quantity $\hat{\eta}_{n,\alpha}^*$ defined by

$$\mathbb{P}\left(d_\Delta(\mathrm{M}_n^*, \mathrm{M}_n) > \hat{\eta}_{n,\alpha}^* \,|\, X_1, \ldots, X_n\right) = \alpha. \tag{11}$$

Note that $\hat{\eta}_{n,\alpha}^*$ can be easily estimated with Monte Carlo procedures. It has been shown in Chazal et al. (2014) that the bottleneck bootstrap is valid when computing the sublevel sets of a density estimator. The validity of the bottleneck bootstrap has not been proven for the extended persistence diagram of any distance function. For Mapper, it would require writing $d_\Delta(\mathrm{M}_n^*, \mathrm{M}_n)$ in terms of the distance between the extrema of the filter function and the ones of the interpolation of the filter function on the δ-neighborhood graph. We leave this problem open in this article.

Extension of the analysis. As pointed out in Section 2.1, many versions of the Mapper exist in the literature. One of them, called the *edge-based MultiNerve Mapper* $\overline{\mathrm{M}}^{\triangle}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$, is described in Section 8 of Carrière and Oudot (2017b). The main advantage of this version is that it allows for finer resolutions than the usual Mapper while remaining fast to compute. Our analysis can actually handle this version as well by replacing gr by r in Assumption (4) of Theorem 7—see Remark 8, and changing constants accordingly in the proofs. In particular, this improves the resolution r_n in Equation (9) since $g^{-1}V_n(\delta_n)^+$ becomes $V_n(\delta_n)^+$. Hence, we use this edge-based version in Section 5, where this improvement on the resolution r_n allows us to compensate for the low number of observations.

5. Numerical experiments

In this section, we provide few examples of parameter selections and confidence regions (which are unions of squares in the extended persistence diagrams) obtained with bottleneck bootstrap. The interpretation of these regions is that squares that intersect the diagonal, which are drawn in pink color, represent topological features in the Mappers that may be horizontal or artifacts due to the cover, and that may not be present in the Reeb graph. We show in Figure 5 various Mappers (in each node of the Mappers, the left number is the cluster ID and the right number is the number of observations in that cluster) and 85 percent confidence regions computed on various data sets. All δ parameters and resolutions were computed with Equation (9) (the δ parameters were also averaged over $N = 100$ subsamplings with $\beta = 0.001$), and all gains were set to 40%. The code we used is available in the Gudhi open source library (see Carrière (2017)). The confidence regions were computed by bootstrapping data 100 times. Note that computing confidence regions with Proposition 15 is possible, but the numbers of observations in all of our data sets were too low, leading to conservative confidence regions that did not allow for interpretation.

5.1 Mappers and confidence regions

Synthetic example. We computed the Mapper of an embedding of the Klein bottle into $\mathbb{R}^4$ with 10,000 points with the height function. In order to illustrate the conservativity of confidence regions computed with Proposition 15, we also plot these regions for an embedding with 10,000,000 points using the fact that the height function is 1-Lipschitz. Corresponding squares are drawn in green color. Their very large sizes show that Proposition 15 requires a very large number of observations in practice. See the first row of Figure 5.

3D shapes. We computed the Mapper of an ant shape and a human shape from Chen et al. (2009) embedded in $\mathbb{R}^3$ (with 4,706 and 6,370 points respectively) Both Mappers were computed with the height function. One can see that the confidence squares for the features that are almost horizontal (such as the small branches in the Mapper of the ant) intersect indeed the diagonal. See the second and third rows of Figure 5.

Miller-Reaven data set. The first data set comes from the Miller-Reaven diabetes study that contains 145 observations of patients suffering or not from diabete. Observations were mapped into $\mathbb{R}^5$ by computing various medical features. Data can be obtained in the "locfit" R-package. In Reaven and Miller (1979), the authors identified two groups of diseases with

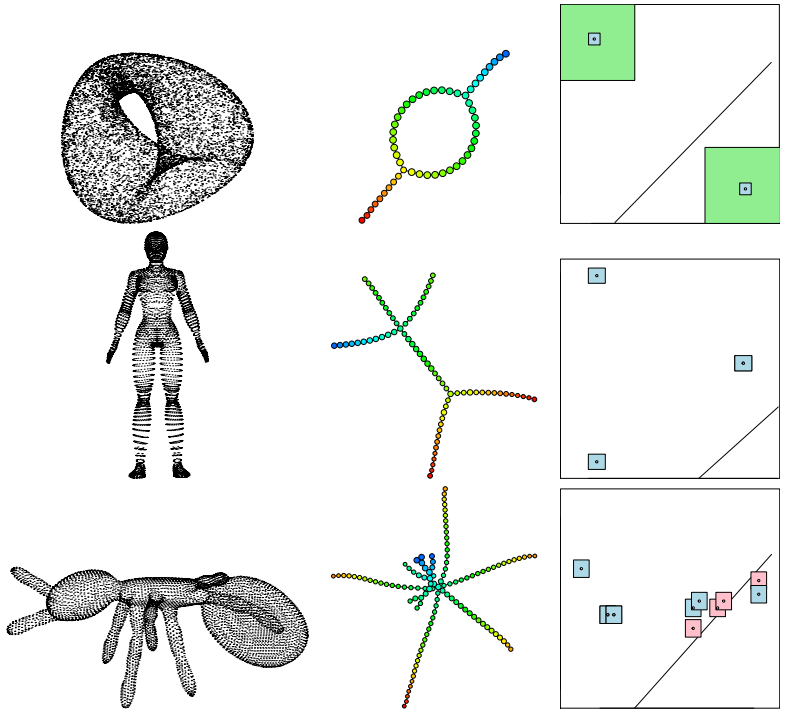

Figure 5: Mappers computed with automatic tuning (middle) and 85 percent confidence regions for their topological features (right) are provided for an embedding of the Klein Bottle into $\mathbb{R}^4$ (first row), a 3D human shape (second row) and a 3D ant shape (third row).

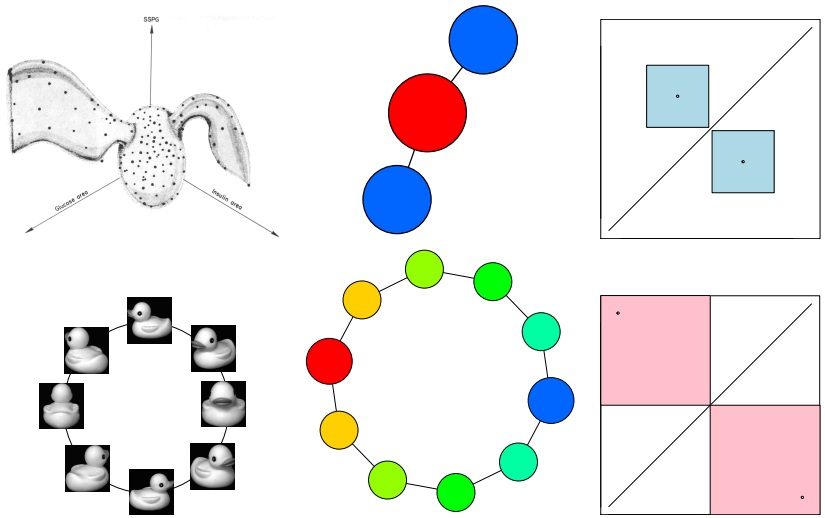

Figure 6: Mappers computed with automatic tuning (middle) and 85 percent confidence regions for their topological features (right) are provided for the Reaven-Miller data set (first row) and the COIL data set (second row).

the projection pursuit method, and in Singh et al. (2007), the authors applied Mapper with hand-crafted parameters to get back this result. Here, we normalized the data to zero mean and unit variance, and we obtained the two flares in the Mapper computed with the eccentricity function. Moreover, these flares are at least 85 percent sure since the confidence squares on the corresponding points in the extended persistence diagrams do not intersect the diagonal. See the first row of Figure 6.

COIL data set. The second data set is an instance of the 16,384-dimensional COIL data set of Nene et al. (1996). It contains 72 observations, each of which being a picture of a duck taken at a specific angle. Despite the low number of observations and the large number of dimensions, we managed to retrieve the intrinsic loop lying in the data using the first PCA eigenfunction. However, the low number of observations made the bootstrap fail since the confidence squares computed around the points that represent this loop in the extended persistence diagram intersect the diagonal. See the second row of Figure 6.

5.2 Noisy data

Denoising Mapper. An important drawback of Mapper is its sensitivity to noise and outliers. See the crater data set in Figure 7, for instance. Several answers have been proposed for recovering the correct persistence homology from noisy data. The idea is to

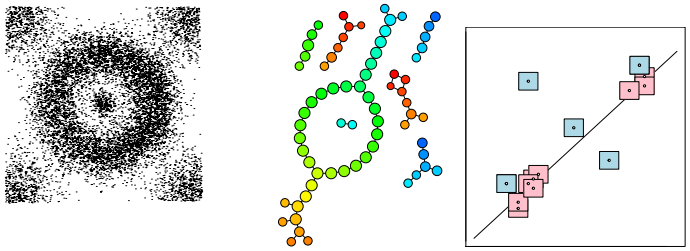

Figure 7: Mappers computed with automatic tuning (middle) and 85 percent confidence regions for their topological features (right) are provided for a noisy crater in the Euclidean plane.

use an alternative filtration of simplicial complexes instead of the Rips filtration. A first option is to consider the upper level sets of a density estimator rather than the distance to the sample (see Section 4.4 in Fasy et al. (2014)). Another solution is to consider the sublevel sets of the DTM and apply persistence homology inference in Chazal et al. (2014).

Crater data set. To handle noise in our crater data set, we simply smoothed the data set by computing the empirical DTM with 10 neighbors on each point and removing all points with DTM less than 40 percent of the maximum DTM in the data set. Then we computed the Mapper with the height function. One can see that all topological features in the Mapper that are most likely artifacts due to noise (like the small loops and connected components) have corresponding confidence squares that intersect the diagonal in the extended persistence diagram. See Figure 7.

6. Conclusion

In this article, we provided a statistical analysis of the Mapper. Namely, we proved the fact that the Mapper is a measurable construction in Proposition 10, and we used the approximation Theorem 7 to show that the Mapper is a minimax optimal estimator of the Reeb graph in various contexts—see Propositions 11, 12 and 13—and that corresponding confidence regions can be computed—see Proposition 15 and Section 4.3. Along the way, we derived rules of thumb to automatically tune the parameters of the Mapper with Equations (8), (9) and (10). Finally, we provided few examples of our methods on various data sets in Section 5.

Future directions. We plan to investigate several questions for future work.

- We will work on adapting results from Chazal et al. (2014) to prove the validity of bootstrap methods for computing confidence regions on the Mapper, since we only used bootstrap methods empirically in this article.

- We believe that using weighted versions of δ-neighborhood graphs, as defined in Buchet et al. (2015), would improve the quality of the confidence regions on the Mapper features, and would probably be a better way to deal with noise that our current solution.
- We plan to adapt our statistical setting to the question of selecting variables, which is one of the main applications of the Mapper in practice.

Appendix A. Proofs

A.1 Preliminary results

In order to prove the results of this article, we need to state several preliminary definitions and theorems. All of them can be found, together with their proofs, in Dey and Wang (2013) and Carrière and Oudot (2017b). In this section, we let $\mathbb{X}_n \subset \mathcal{X}$ be a point cloud of n points sampled on a smooth and compact submanifold $\mathcal{X}$ embedded in $\mathbb{R}^D$, with positive reach rch and convexity radius ρ. Since δ-neighborhood graphs can be seen as 1-skeletons of Rips complexes with parameter δ, as per Definition 55 in Carrière and Oudot (2017b), and since many results are phrased with Rips complexes in the literature, we also use these complexes to state our results in this section. Let $f : \mathcal{X} \to \mathbb{R}$ be a Morse-type filter function, $\mathcal{I}$ be an open cover of the range of f with resolution r and gain $g < \frac{1}{2}$ (which ensures that no more than two cover elements can intersect at once, i.e. the cover is minimal), and $|\mathrm{Rips}_\delta(\mathbb{X}_n)|$ denote a geometric realization of the Rips complex built on top of $\mathbb{X}_n$ with parameter δ, and $f^{\mathrm{PL}} : |\mathrm{Rips}_\delta(\mathbb{X}_n)| \to \mathbb{R}$ be the piecewise-linear interpolation of f on the simplices of $\mathrm{Rips}_\delta(\mathbb{X}_n)$.

Definition 16 *Let $G = (\mathbb{X}_n, E)$ be a graph built on top of $\mathbb{X}_n$. Let $e = (X, X') \in E$ be an edge of G, and let $I(e)$ be the open interval $(\min\{f(X), f(X')\}, \max\{f(X), f(X')\})$. Then e is said to be* intersection-crossing *if there is a pair of consecutive intervals $I, J \in \mathcal{I}$ such that $\emptyset \neq I \cap J \subseteq I(e)$.*

Theorem 17 (Lemma 61 and 62 in Carrière and Oudot (2017b)). *Let $\mathrm{Rips}^1_\delta(\mathbb{X}_n)$ denote the 1-skeleton of $\mathrm{Rips}_\delta(\mathbb{X}_n)$. If $\mathrm{Rips}^1_\delta(\mathbb{X}_n)$ has no intersection-crossing edges, then $\mathrm{M}_{r,g,\delta}(\mathbb{X}_n, f(\mathbb{X}_n))$ and $\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}})$ are isomorphic as combinatorial graphs.*

Theorem 18 (Theorem 54 in Carrière and Oudot (2017b)). *Let $f : \mathcal{X} \to \mathbb{R}$ be a Morse-type function. Then, we have the following inequality between extended persistence diagrams:*

$$d_\Delta(\mathrm{Dg}(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}}), \mathrm{Dg}(\mathrm{M}_{r,g}(\mathcal{X}, f), f_{\mathcal{I}})) \leq r. \tag{12}$$

Moreover, given another Morse-type function $\hat{f} : \mathcal{X} \to \mathbb{R}$, we have:

$$d_\Delta(\mathrm{Dg}(\mathrm{M}_{r,g}(\mathcal{X}, f), f_{\mathcal{I}}), \mathrm{Dg}(\mathrm{M}_{r,g}(\mathcal{X}, \hat{f}), \hat{f}_{\mathcal{I}})) \leq r + \|f - \hat{f}\|_\infty. \tag{13}$$

Theorem 19 (Theorem 4.6, Remark 2 in Dey and Wang (2013) and Theorem 59 in Carrière and Oudot (2017b)). *If $4d_{\mathrm{H}}(\mathcal{X}, \mathbb{X}_n) \leq \delta \leq \min\{\mathrm{rch}/4, \rho/4\}$, then:*

$$d_\Delta(\mathrm{Dg}(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}}), \mathrm{Dg}(\mathrm{R}_{f^{\mathrm{PL}}}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|), f^{\mathrm{PL}}_{\mathrm{R}})) \leq 2\omega(\delta).$$

Note that the original version of this theorem is only proven for Lipschitz functions in Dey and Wang (2013), but it extends at no cost to functions with modulus of continuity.

A.2 Proof of Theorem 7

Let $|\mathrm{Rips}_\delta(\mathbb{X}_n)|$ denote a geometric realization of the Rips complex built on top of $\mathbb{X}_n$ with parameter δ. Moreover, let $f^{\mathrm{PL}} : |\mathrm{Rips}_\delta(\mathbb{X}_n)| \to \mathbb{R}$ be the piecewise-linear interpolation of f on the simplices of $\mathrm{Rips}_\delta(\mathbb{X}_n)$, whose 1-skeleton is denoted by $\mathrm{Rips}^1_\delta(\mathbb{X}_n)$. Since $(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}})$ is a metric space, we also consider its Reeb graph $\mathrm{R}_{f^{\mathrm{PL}}}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|)$, with induced function $f^{\mathrm{PL}}_{\mathrm{R}}$, and its Mapper $\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}})$, with induced function $f^{\mathrm{PL}}_{\mathcal{I}}$. See Figure 8. Then, the following inequalities lead to the result:

$$\begin{aligned}
d_\Delta(\mathrm{R}_f(\mathcal{X}), \mathrm{M}_n) &= d_\Delta\left(\mathrm{Dg}(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}}), \mathrm{Dg}(\mathrm{M}_n, f_{\mathcal{I}})\right) \\
&= d_\Delta\left(\mathrm{Dg}(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}}), \mathrm{Dg}(\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}}), f^{\mathrm{PL}}_{\mathcal{I}})\right) && (14) \\
&\leq d_\Delta\left(\mathrm{Dg}(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}}), \mathrm{Dg}(\mathrm{R}_{f^{\mathrm{PL}}}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|), f^{\mathrm{PL}}_{\mathrm{R}})\right) \\
&\quad + d_\Delta\left(\mathrm{Dg}(\mathrm{R}_{f^{\mathrm{PL}}}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|), f^{\mathrm{PL}}_{\mathrm{R}}), \mathrm{Dg}(\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}}), f^{\mathrm{PL}}_{\mathcal{I}})\right) && (15) \\
&\leq 2\omega(\delta) + r. && (16)
\end{aligned}$$

Let us prove every (in)equality:

Equality (14). Let $X_1, X_2 \in \mathbb{X}_n$ such that (X_1, X_2) is an edge of $\mathrm{Rips}^1_\delta(\mathbb{X}_n)$ i.e. $\|X_1 - X_2\| \leq \delta$. Then, according to (4): $|f(X_1) - f(X_2)| < gr$. Hence, there is no $s \in \{1, \ldots, S-1\}$ such that $I_s \cap I_{s+1} \subseteq [\min\{f(X_1), f(X_2)\}, \max\{f(X_1), f(X_2)\}]$. It follows that there are no intersection-crossing edges in $\mathrm{Rips}^1_\delta(\mathbb{X}_n)$. Then, according to Theorem 17, there is a graph isomorphism $i : \mathrm{M}_n = \mathrm{M}_{r,g,\delta}(\mathbb{X}_n, f(\mathbb{Y}_n)) \to \mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}})$. Since $f_{\mathcal{I}} = f^{\mathrm{PL}}_{\mathcal{I}} \circ i$ by definition of $f_{\mathcal{I}}$ and $f^{\mathrm{PL}}_{\mathcal{I}}$, the equality follows.

Inequality (15). This inequality is just an application of the triangle inequality.

Inequality (16). According to (3), we have $\delta \leq \min\{\mathrm{rch}/4, \rho/4\}$. According to (5), we also have $\delta \geq 4d_{\mathrm{H}}(\mathcal{X}, \mathbb{X}_n)$. Hence, we have

$$d_\Delta(\mathrm{Dg}(\mathrm{R}_f(\mathcal{X}), f_{\mathrm{R}}), \mathrm{Dg}(\mathrm{R}_{f^{\mathrm{PL}}}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|), f^{\mathrm{PL}}_{\mathrm{R}})) \leq 2\omega(\delta),$$

according to Theorem 19. Moreover, we have

$$d_\Delta(\mathrm{Dg}(\mathrm{R}_{f^{\mathrm{PL}}}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|), f^{\mathrm{PL}}_{\mathrm{R}}), \mathrm{Dg}(\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}}), f^{\mathrm{PL}}_{\mathcal{I}})) \leq r,$$

according to Equation (12).

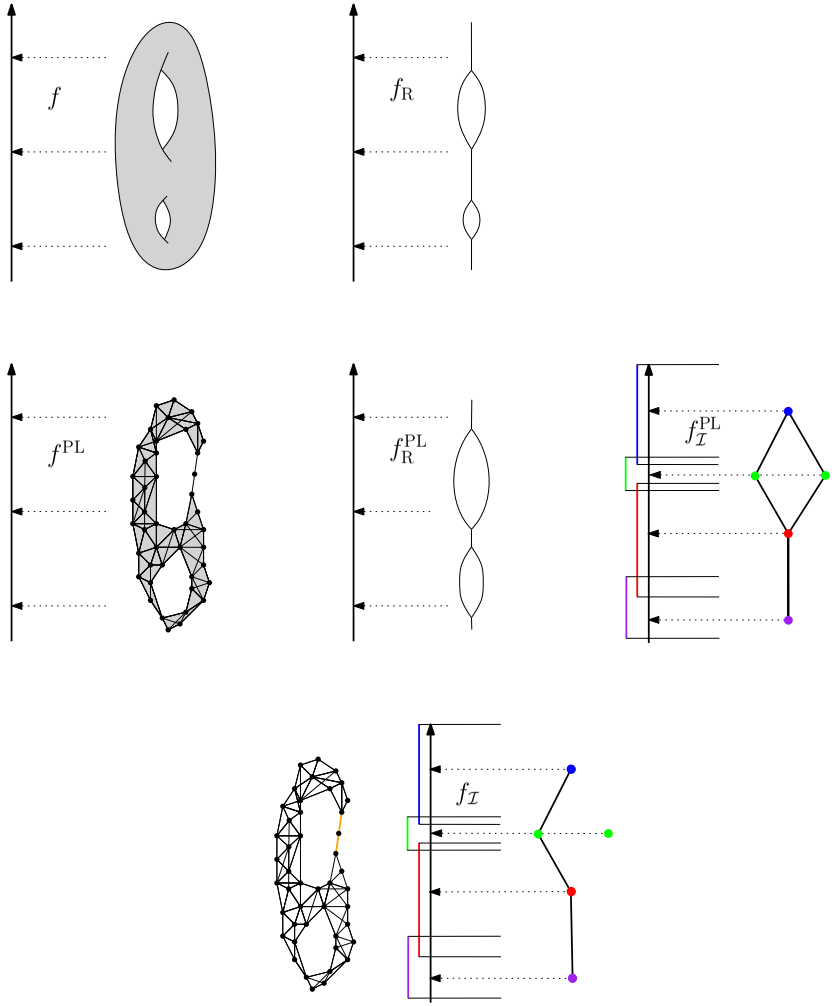

Figure 8: Examples of the function defined on the original space (left column), its induced function defined on the Reeb graph (middle column) and the function defined on the Mapper (right column). Note that the Mapper computed from the geometric realization of the Rips complex (middle row, right) is not isomorphic to the standard Mapper (last row), since there are two intersection-crossing edges in the Rips complex (outlined in orange).

A.3 Proof of Corollary 9

Let $|\mathrm{Rips}_\delta(\mathbb{X}_n)|$ denote a geometric realization of the Rips complex built on top of $\mathbb{X}_n$ with parameter δ. Moreover, let $f^{\mathrm{PL}} : |\mathrm{Rips}_\delta(\mathbb{X}_n)| \to \mathbb{R}$ be the piecewise-linear interpolation of f on the simplices of $\mathrm{Rips}_\delta(\mathbb{X}_n)$, whose 1-skeleton is denoted by $\mathrm{Rips}^1_\delta(\mathbb{X}_n)$. Similarly, let $\hat{f}^{\mathrm{PL}}$ be the piecewise-linear interpolation of $\hat{f}$ on the simplices of $\mathrm{Rips}^1_\delta(\mathbb{X}_n)$. As before, since $(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}})$ and $(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, \hat{f}^{\mathrm{PL}})$ are metric spaces, we also consider their Mappers $\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}})$ and $\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, \hat{f}^{\mathrm{PL}})$. Then, the following inequalities lead to the result:

$$
\begin{aligned}
&d_\Delta(\mathrm{R}_f(\mathcal{X}), \hat{\mathrm{M}}_n) \leq d_\Delta(\mathrm{R}_f(\mathcal{X}), \mathrm{M}_n) + d_\Delta(\mathrm{M}_n, \hat{\mathrm{M}}_n) \text{ by the triangle inequality} \\
&\quad = d_\Delta(\mathrm{R}_f(\mathcal{X}), \mathrm{M}_n) + d_\Delta(\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}}), \mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, \hat{f}^{\mathrm{PL}})) \qquad (17) \\
&\quad \leq r + 2\omega(\delta) + d_\Delta(\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}}), \mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, \hat{f}^{\mathrm{PL}})) \text{ by Theorem 7} \\
&\quad \leq r + 2\omega(\delta) + r + \|f^{\mathrm{PL}} - \hat{f}^{\mathrm{PL}}\|_\infty \text{ by Equation (13)} \\
&\quad = 2r + 2\omega(\delta) + \max\{|f(X) - \hat{f}(X)| \,:\, X \in \mathbb{X}_n\}
\end{aligned}
$$

Let us prove Equality (17). By definition of r, there are no intersection-crossing edges for both f and $\hat{f}$. According to Theorem 17, $\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, f^{\mathrm{PL}})$ and M_n are isomorphic and similarly for $\mathrm{M}_{r,g}(|\mathrm{Rips}_\delta(\mathbb{X}_n)|, \hat{f}^{\mathrm{PL}})$ and $\hat{\mathrm{M}}_n$. See also the proof of Equality (14).

A.4 Proof of Proposition 10

We check that not only the topological signature of the Mapper but also the Mapper itself is a measurable object and thus can be seen as an estimator of a target Reeb graph. This problem is more complicated than for the statistical framework of persistence diagram inference, for which the existing stability results give for free that persistence estimators are measurable for adequate sigma algebras.

Let $\bar{\mathbb{R}} = \mathbb{R} \cup \{+\infty\}$ denote the extended real line. Given a fixed integer $n \geq 1$, let $\mathcal{C}_{[n]}$ be the set of abstract simplicial complexes over a fixed set of n vertices. We see $\mathcal{C}_{[n]}$ as a subset of the power set $2^{2^{[n]}}$, where $[n] = \{1, \cdots, n\}$, and we implicitly identify $2^{[n]}$ with the set $[2^n]$ via the map assigning to each subset $\{i_1, \cdots, i_k\}$ the integer $1 + \sum_{j=1}^{k} 2^{i_j - 1}$. Given a fixed parameter $\delta > 0$, we define the application

$$
\Phi_1 : \left\{ \begin{array}{rcl} (\mathbb{R}^D)^n \times \mathbb{R}^n & \to & \mathcal{C}_{[n]} \times \bar{\mathbb{R}}^{2^{[n]}} \\ (\mathbb{X}_n, \mathbb{Y}_n) & \mapsto & (K, f_K) \end{array} \right.
$$

where K is the abstract Rips complex of parameter δ over the n labeled points in $\mathbb{R}^D$, minus the intersection-crossing edges and their cofaces, and where f_K is a function defined by:

$$
f_K : \left\{ \begin{array}{rcl} 2^{[n]} & \to & \bar{\mathbb{R}} \\ \sigma & \mapsto & \left\{ \begin{array}{ll} \max_{i \in \sigma} \mathbb{Y}_i & \text{if } \sigma \in K \\ +\infty & \text{otherwise.} \end{array} \right. \end{array} \right.
$$

The space $(\mathbb{R}^D)^n \times \mathbb{R}^n$ is equipped with the standard topology, denoted by T_1, inherited from $\mathbb{R}^{(D+1)n}$. The space $\mathcal{C}_{[n]} \times \bar{\mathbb{R}}^{2^{[n]}}$ is equipped with the product, denoted by T_2 hereafter, of the discrete topology on $\mathcal{C}_{[n]}$ and the topology induced by the extended distance $d(f,g) = \max\{|f(\sigma) - g(\sigma)| \,:\, \sigma \in 2^{[n]}, f(\sigma) \text{ or } g(\sigma) \neq +\infty\}$ on $\bar{\mathbb{R}}^{2^{[n]}}$. In particular, $K \neq K' \Rightarrow d(f_K, f_{K'}) = +\infty$.

Note that the map $(\mathbb{X}_n, \mathbb{Y}_n) \mapsto K$ is piecewise-constant, with jumps located at the hypersurfaces defined by $\|X_i - X_j\|^2 = \delta^2$ (for combinatorial changes in the Rips complex) or $Y_i = \text{cst} \in \text{End}((r,g))$ (for changes in the set of intersection-crossing edges) in $(\mathbb{R}^D)^n \times \mathbb{R}^n$, where $\text{End}((r,g))$ denotes the set of endpoints of elements of the gomic (r,g). We can then define a finite measurable partition $(\mathcal{C}_\ell)_{\ell \in L}$ of $(\mathbb{R}^D)^n \times \mathbb{R}^n$ whose boundaries are included in these hypersurfaces, and such that $(\mathbb{X}_n, \mathbb{Y}_n) \mapsto K$ is constant over each set $\mathcal{C}_\ell$. As a byproduct, we have that $(\mathbb{X}_n, \mathbb{Y}_n) \mapsto f$ is continuous over each set $\mathcal{C}_\ell$.

We now define the operator

$$\Phi_2 : \left\{ \begin{array}{rcl} \mathcal{C}_{[n]} \times \bar{\mathbb{R}}^{2^{[n]}} & \to & \mathcal{A} \\ (K, f) & \mapsto & (|K|, f^{\text{PL}}) \end{array} \right.$$

where $\mathcal{A}$ denotes the class of topological spaces filtered by Morse-type functions, and where f^{PL} is the piecewise-linear interpolation of f on the geometric realization $|K|$ of K. For a fixed simplicial complex K, the extended persistence diagram of the lower-star filtration induced by f and of the sublevel sets of f^{PL} are identical—see e.g. Morozov (2008), therefore the map Φ_2 is distance-preserving (hence continuous) in the pseudometrics d_Δ on the domain and codomain. Since the topology T_2 on $\mathcal{C}_{[n]} \times \bar{\mathbb{R}}^{2^n}$ is a refinement[2] of the topology induced by d_Δ, the map Φ_2 is also continuous when $\mathcal{C}_{[n]} \times \bar{\mathbb{R}}^{2^{[n]}}$ is equipped with T_2.

Let now $\Phi_3 : \mathcal{A} \to \mathcal{R}$ map each Morse-type pair $(\mathcal{X}, f)$ to its Mapper $\text{M}_f(\mathcal{X}, \mathcal{I})$, where $\mathcal{I} = (r,g)$ is the gomic induced by r and g. Note that, similarly to Φ_1, the map Φ_3 is piecewise-constant, since combinatorial changes in $\text{M}_f(\mathcal{X}, \mathcal{I})$ are located at the regions $\text{Crit}(f) \cap \text{End}(\mathcal{I}) \neq \emptyset$. Hence, Φ_3 is measurable in the pseudometric d_Δ. For more details on Φ_3, we refer the reader to Definition 7.6 in Carrière and Oudot (2017b).

Moreover, $\text{M}_{f^{\text{PL}}}(|K|, \mathcal{I})$ is isomorphic to $\text{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$ by Theorem 17 since all of the intersection-crossing edges were removed in the construction of K. Hence, the map Φ defined by $\Phi = \Phi_3 \circ \Phi_2 \circ \Phi_1$ is a measurable map that sends $(\mathbb{X}_n, \mathbb{Y}_n)$ to $\text{M}_{r,g,\delta}(\mathbb{X}_n, \mathbb{Y}_n)$.

A.5 Proof of Proposition 11

We fix some parameters $a > 0$ and $b \geq 1$. First note that Assumption (4) is always satisfied by definition of r_n. Next, there exists $n_0 \in \mathbb{N}$ such that for any $n \geq n_0$, Assumption (3) is satisfied because $\delta_n \to 0$ and $\omega(\delta_n) \to 0$ as $n \to +\infty$. Moreover, n_0 can be taken the same for all $f \in \bigcup_{\mathbb{P} \in \mathcal{P}(a,b)} \mathcal{F}(\mathbb{P}, \omega)$.

Let $\varepsilon_n = d_{\text{H}}(\mathcal{X}, \mathbb{X}_n)$. Under the (a,b)-standard assumption, it is well known that (see for instance Cuevas and Rodríguez-Casal (2004); Chazal et al. (2015b)):

$$\mathbb{P}\left(\varepsilon_n \geq u\right) \leq \min\left\{1, \frac{4^b}{au^b} \mathrm{e}^{-a\left(\frac{u}{2}\right)^b n}\right\}, \forall u > 0. \tag{18}$$

2. This is because singletons are open balls in the discrete topology, and also because of the stability theorem for persistence diagrams—see Chazal et al. (2016a); Cohen-Steiner et al. (2007)

In particular, regarding the complementary of (5) we have:

$$\mathbb{P}\left(\varepsilon_n > \frac{\delta_n}{4}\right) \leq \min\left\{1, \frac{2^b}{2\log(n)n}\right\}. \tag{19}$$

Recall that $\text{diam}(\mathcal{X}_\mathbb{P}) \leq L$. Let $\bar{C} = \omega(L)$ be a constant that only depends on the parameters of the model. Then, for any $\mathbb{P} \in \mathcal{P}(a,b)$, we have:

$$\sup_{f \in \mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\text{R}_f(\mathcal{X}_\mathbb{P}), \text{M}_n\right) \leq \bar{C}. \tag{20}$$

For $n \geq n_0$, we have :

$$\begin{aligned} \sup_{f \in \mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\text{R}_f(\mathcal{X}_\mathbb{P}), \text{M}_n\right) = & \sup_{f \in \mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\text{R}_f(\mathcal{X}_\mathbb{P}), \text{M}_n\right) \mathbb{I}_{\varepsilon_n > \delta_n/4} \\ & + \sup_{f \in \mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\text{R}_f(\mathcal{X}_\mathbb{P}), \text{M}_n\right) \mathbb{I}_{\varepsilon_n \leq \delta_n/4} \end{aligned}$$

and thus

$$\begin{aligned} \mathbb{E}\left[\sup_{f \in \mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\text{R}_f(\mathcal{X}_\mathbb{P}), \text{M}_n\right)\right] & \leq \bar{C}\mathbb{P}\left(\varepsilon_n > \frac{\delta_n}{4}\right) + r_n + 2\omega(\delta_n) \\ & \leq \bar{C}\min\left\{1, \frac{2^b}{2\log(n)n}\right\} + \left(\frac{1+2g}{g}\right)\omega(\delta_n) \end{aligned} \tag{21}$$

where we have used (20), Theorem 7 and the fact that $V_n(\delta_n)^+$ can be chosen less or equal to $\omega(\delta_n)$. For n large enough, the first term in (21) is of the order of δ_n^b, which can be upper bounded by δ_n and thus by $\omega(\delta_n)$ (up to a constant) since $\omega(\delta)/\delta$ is non-increasing. Since $\frac{1+2g}{g} < 6$ because $\frac{1}{3} < g < \frac{1}{2}$, we get that the risk is bounded by $\omega(\delta_n)$ for $n \geq n_0$ up to a constant that only depends on the parameters of the model. The same inequality is of course valid for any n by taking a larger constant, because n_0 itself only depends on the parameters of the model.

A.6 Proof of Proposition 12

The proof follows closely Section B.2 in Chazal et al. (2015b). Let $\mathcal{X}_0 = [0, a^{-1/b}] \subset \mathbb{R}^D$. Obviously, $\mathcal{X}_0$ is a smooth and compact submanifold of $\mathbb{R}^D$. Let $\mathcal{U}(\mathcal{X}_0)$ be the uniform measure on $\mathcal{X}_0$. Let $\mathcal{P}_{a,b,\mathcal{X}_0}$ denote the set of (a,b)-standard measures whose support is included in $\mathcal{X}_0$. Let $x_0 = 0 \in \mathcal{X}_0$ and $\{x_n\}_{n \in \mathbb{N}^*} \in \mathcal{X}_0^\mathbb{N}$ such that $\|x_n - x_0\| = (an)^{-1/b}$. Now, let

$$f_0 : \left\{ \begin{array}{ll} \mathcal{X}_0 & \to \mathbb{R} \\ x & \mapsto \omega(\|x - x_0\|) \end{array} \right.$$

By definition, we have $f_0 \in \mathcal{F}(\mathcal{U}(\mathcal{X}_0), \omega)$ because $\text{Dg}(\mathcal{X}_0, f_0) = \{(0, \omega(a^{-1/b}))\}$ since f_0 is increasing by definition of ω. Finally, given any measure $\mathbb{P} \in \mathcal{P}_{a,b,\mathcal{X}_0}$, we let $\theta_0(\mathbb{P}) =$

$\mathrm{R}_{f_0|_{\mathcal{X}_\mathbb{P}}}(\mathcal{X}_\mathbb{P})$. Then, we have:

$$\begin{aligned}
&\sup_{\mathbb{P}\in\mathcal{P}_{a,b}} \mathbb{E}\left[\sup_{f\in\mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\mathrm{R}_f(\mathcal{X}_\mathbb{P}),\hat{\mathrm{R}}_n\right)\right] \\
&\quad\geq \sup_{\mathbb{P}\in\mathcal{P}_{a,b,\mathcal{X}_0}} \mathbb{E}\left[\sup_{f\in\mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\mathrm{R}_f(\mathcal{X}_\mathbb{P}),\hat{\mathrm{R}}_n\right)\right] \\
&\quad\geq \sup_{\mathbb{P}\in\mathcal{P}_{a,b,\mathcal{X}_0}} \mathbb{E}\left[d_\Delta\left(\mathrm{R}_{f_0|_{\mathcal{X}_\mathbb{P}}}(\mathcal{X}_\mathbb{P}),\hat{\mathrm{R}}_n\right)\right] = \sup_{\mathbb{P}\in\mathcal{P}_{a,b,\mathcal{X}_0}} \mathbb{E}\left[\rho\left(\theta_0(\mathbb{P}),\hat{\mathrm{R}}_n\right)\right],
\end{aligned}$$

where $\rho = d_\Delta$. For any $n\in\mathbb{N}^*$, we let $\mathbb{P}_{0,n} = \delta_{x_0}$ be the Dirac measure on x_0 and $\mathbb{P}_{1,n} = (1-\frac{1}{n})\mathbb{P}_{0,n} + \frac{1}{n}\mathcal{U}([x_0,x_n])$. As a Dirac measure, $\mathbb{P}_{0,n}$ is obviously in $\mathcal{P}_{a,b,\mathcal{X}_0}$. We now check that $\mathbb{P}_{1,n}\in\mathcal{P}_{a,b,\mathcal{X}_0}$.

- Let us study $\mathbb{P}_{1,n}(B(x_0,r))$.

  Assume $r\leq(an)^{-1/b}$. Then

  $$\begin{aligned}
  \mathbb{P}_{1,n}(B(x_0,r)) = 1-\frac{1}{n}+\frac{1}{n}\frac{r}{(an)^{-1/b}} &\geq \left(1-\frac{1}{n}+\frac{1}{n}\right)\left(\frac{r}{(an)^{-1/b}}\right)^b \\
  &\geq \left(\frac{1}{2}+\frac{1}{n}\right)anr^b \geq ar^b.
  \end{aligned}$$

  Assume $r>(an)^{-1/b}$. Then

  $$\mathbb{P}_{1,n}(B(x_0,r)) = 1 \geq \min\{ar^b\}.$$

- Let us study $\mathbb{P}_{1,n}(B(x_n,r))$. Assume $r\leq(an)^{-1/b}$. Then

  $$\mathbb{P}_{1,n}(B(x_n,r)) = \frac{1}{n}\frac{r}{(an)^{-1/b}} \geq \frac{1}{n}\left(\frac{r}{(an)^{-1/b}}\right)^b = ar^b.$$

  Assume $r>(an)^{-1/b}$. Then

  $$\mathbb{P}_{1,n}(B(x_n,r)) = 1 \geq \min\{ar^b\}.$$

- Let us study $\mathbb{P}_{1,n}(B(x,r))$, where $x\in(x_0,x_n)$. Assume $r\leq x$. Then

  $$\mathbb{P}_{1,n}(B(x,r)) \geq \frac{1}{n}\frac{r}{(ab)^{-1/b}} \geq ar^b \text{ (see previous case).}$$

  Assume $r>x$. Then $\mathbb{P}_{1,n}(B(x,r)) = 1-\frac{1}{n}+\frac{1}{n}\frac{\left(x+\min\{r,\ (an)^{-1/b}-x\}\right)}{(an)^{-1/b}}$.

  If $\min\{r,\ (an)^{-1/b}-x\} = r$, then we have

  $$\mathbb{P}_{1,n}(B(x,r)) \geq 1-\frac{1}{n}+\frac{1}{n}\frac{r}{(ab)^{-1/b}} \geq ar^b \text{ (see previous case).}$$

  Otherwise, we have

  $$\mathbb{P}_{1,n}(B(x,r)) = 1 \geq \min\{ar^b\}.$$

Thus $\mathbb{P}_{1,n}$ is in $\mathcal{P}_{a,b,\mathcal{X}_0}$ as well. Hence, we apply Le Cam's lemma (see Section B) to get:

$$\sup_{\mathbb{P}\in\mathcal{P}_{a,b,\mathcal{X}_0}} \mathbb{E}\left[\rho\left(\theta_0(\mathbb{P}),\hat{\mathrm{R}}_n\right)\right] \geq \frac{1}{8}\rho(\theta_0(\mathbb{P}_{0,n}),\theta_0(\mathbb{P}_{1,n}))\left[1-\mathrm{TV}(\mathbb{P}_{0,n},\mathbb{P}_{1,n})\right]^{2n}.$$

By definition, we have:

$$\rho(\theta_0(\mathbb{P}_{0,n}),\theta_0(\mathbb{P}_{1,n})) = d_\Delta\left(\mathrm{R}_{f_0|_{\{x_0\}}}(\{x_0\}),\mathrm{R}_{f_0|_{[x_0,x_n]}}(\mathcal{U}[x_0,x_n])\right).$$

Since $\mathrm{Dg}\left(\mathrm{R}_{f_0|_{\{x_0\}}}(\{x_0\})\right) = \{(0,0)\}$ and $\mathrm{Dg}\left(\mathrm{R}_{f_0|_{[x_0,x_n]}}(\mathcal{U}[x_0,x_n])\right) = \{(f(x_0),f(x_n))\}$ because f_0 is increasing by definition of ω, it follows that

$$\rho(\theta_0(\mathbb{P}_{0,n}),\theta_0(\mathbb{P}_{1,n})) = \frac{1}{2}|f(x_n)-f(x_0)| = \frac{1}{2}\omega\left((an)^{-1/b}\right).$$

It remains to compute $\mathrm{TV}(\mathbb{P}_{0,n},\mathbb{P}_{1,n}) = \left|1-\left(1-\frac{1}{n}\right)\right|+\frac{1}{n}(an)^{-1/b} = \frac{1}{n}+o\left(\frac{1}{n}\right)$. The proposition follows then from the fact that $\left[1-\mathrm{TV}(\mathbb{P}_{0,n},\mathbb{P}_{1,n})\right]^{2n}\to\mathrm{e}^{-2}$.

A.7 Proof of Proposition 13

Let $\mathbb{P}\in\mathcal{P}_{a,b}$ and ω a modulus of continuity for f. Using the same notation as in the previous section, we have

$$\begin{aligned}
\mathbb{P}\left(\delta_n\geq u\right) &\leq \mathbb{P}\left(d_\mathrm{H}(\mathbb{X}_n,\mathcal{X}_\mathbb{P})\geq\frac{u}{2}\right)+\mathbb{P}\left(d_\mathrm{H}(\mathbb{X}_n^{s_n},\mathcal{X}_\mathbb{P})\geq\frac{u}{2}\right) \\
&\leq \mathbb{P}\left(\varepsilon_n\geq\frac{u}{2}\right)+\mathbb{P}\left(\varepsilon_{s_n}\geq\frac{u}{2}\right). \qquad (22)
\end{aligned}$$

Note that for any $f\in\mathcal{F}(\mathbb{P},\omega)$, according to (6) and (20)

$$d_\Delta\left(\mathrm{R}_f(\mathcal{X}_\mathbb{P}),\mathrm{M}_n\right) \leq \left[r+2\omega(\delta)\right]\mathbb{I}_{\Omega_n}+\bar{C}\,\mathbb{I}_{\Omega_n^c} \qquad (23)$$

where Ω_n is the event defined by

$$\Omega_n = \{4\delta_n\leq\min\{\kappa,\rho\}\}\cap\{4\varepsilon_n\leq\delta_n\}.$$

This gives

$$\begin{aligned}
\mathbb{E}\left[\sup_{f\in\mathcal{F}(P,\omega)} d_\Delta\left(\mathrm{M}_n,\mathrm{R}_f(\mathcal{X})\right)\right] \leq &\underbrace{\int_0^{\bar{C}}\mathbb{P}\left(\omega(\delta_n)\geq\frac{g}{1+2g}\alpha\right)\mathrm{d}\alpha}_{(A)}+\underbrace{\bar{C}\mathbb{P}\left(\varepsilon_n\geq\frac{\delta_n}{4}\right)}_{(B)} \\
&+\underbrace{\bar{C}\mathbb{P}\left(\delta_n\geq\min\left\{\frac{\kappa}{4},\frac{\rho}{4}\right\}\right)}_{(D)}.
\end{aligned}$$

Let us bound the three terms (A), (B) and (C).

- **Term** (C). It can be bounded using (22) then (18).

- **Term** (B). Let $t_n = 2\left(\frac{2\log(n)}{an}\right)^{1/b}$ and $A_n = \{\varepsilon_n < t_n\}$. We first prove that $\delta_n \geq 4\varepsilon_n$ on the event A_n, for n large enough. We follow the lines of the proof of Theorem 3 in Section 6 in Fasy et al. (2014).

  Let q_n be the t_n-*packing number* of $\mathcal{X}_{\mathbb{P}}$, i.e. the maximal number of Euclidean balls $B(X, t_n) \cap \mathcal{X}_{\mathbb{P}}$, where $X \in \mathcal{X}_{\mathbb{P}}$, that can be packed into $\mathcal{X}_{\mathbb{P}}$ without overlap. It is known (see for instance Lemma 17 in Fasy et al. (2014)) that $q_n = \Theta(t_n^{-d})$, where d is the (intrinsic) dimension of $\mathcal{X}_{\mathbb{P}}$. Let $\mathrm{Pack}_n = \{c_1, \cdots, c_{q_n}\}$ be a corresponding packing set, i.e. the set of centers of a family of balls of radius t_n whose cardinality achieves the packing number q_n. Note that $d_{\mathrm{H}}(\mathrm{Pack}_n, \mathcal{X}_{\mathbb{P}}) \leq 2t_n$. Indeed, for any $X \in \mathcal{X}_{\mathbb{P}}$, there must exist $c \in \mathrm{Pack}_n$ such that $\|X - c\| \leq 2t_n$, otherwise X could be added to Pack_n, contradicting the fact that Pack_n is maximal. By contradiction, assume $\epsilon_n < t_n$ and $\delta_n \leq 4\epsilon_n$. Then:

$$\begin{aligned} d_{\mathrm{H}}(\mathbb{X}_n^{s_n}, \mathrm{Pack}_n) &\leq d_{\mathrm{H}}(\mathbb{X}_n^{s_n}, \mathbb{X}_n) + d_{\mathrm{H}}(\mathbb{X}_n, \mathcal{X}_{\mathbb{P}}) + d_{\mathrm{H}}(\mathcal{X}_{\mathbb{P}}, \mathrm{Pack}_n) \\ &\leq 5 d_{\mathrm{H}}(\mathbb{X}_n, \mathcal{X}_{\mathbb{P}}) + 2t_n \leq 7t_n. \end{aligned}$$

  Now, one has $\frac{s_n}{q_n} = \Theta\left(\frac{n^{1-b/d}}{\log(n)^{1-b/d+\beta}}\right)$. Since $b \geq D \geq d$ by definition, it follows that $s_n = o(q_n)$. In particular, this means that $d_{\mathrm{H}}(\mathbb{X}_n^{s_n}, \mathrm{Pack}_n) > 7t_n$ for n large enough, which yields a contradiction.

  Hence, one has $\delta_n \geq 4\varepsilon_n$ on the event A_n. Thus, one has:

$$\mathbb{P}\left(\varepsilon_n \geq \frac{\delta_n}{4}\right) \leq \underbrace{\mathbb{P}\left(\varepsilon_n \geq \frac{\delta_n}{4} \mid A_n\right)}_{=0} \mathbb{P}(A_n) + \mathbb{P}(A_n^c) = \mathbb{P}(A_n^c).$$

  Finally, the probability of A_n^c is bounded with (18):

$$\mathbb{P}(A_n^c) \leq \frac{2^b}{2\log(n)n}.$$

- **Term** (A). This is the dominating term. First, note that since ω is increasing, one has for all $u > 0$:

$$\mathbb{P}(\omega(\delta_n) \geq u) = \mathbb{P}\left(\delta_n \geq \omega^{-1}(u)\right). \tag{24}$$

  Then, using (22) and (24), we have:

$$(A) \leq \int_0^{\bar{C}} \mathbb{P}\left(\varepsilon_n \geq \frac{1}{2}\omega^{-1}\left(\frac{g\alpha}{1+2g}\right)\right) \mathrm{d}\alpha + \int_0^{\bar{C}} \mathbb{P}\left(\varepsilon_{s_n} \geq \frac{1}{2}\omega^{-1}\left(\frac{g\alpha}{1+2g}\right)\right) \mathrm{d}\alpha.$$

  We only bound the first integral, but the analysis extends verbatim to the second integral when replacing n by s_n. Let

$$\alpha_n = \frac{1+2g}{g}\omega\left[\left(\frac{4^b \log(n)}{an}\right)^{1/b}\right].$$

Since $x \mapsto \frac{\omega(x)}{x}$ is non-increasing, it follows that $x \mapsto \frac{\omega^{-1}(x)}{x}$ is non-decreasing, and

$$\omega^{-1}(x) \geq \frac{x}{y}\omega^{-1}(y), \ \forall x \geq y > 0. \tag{25}$$

Taking inspiration from Section B.2 in Chazal et al. (2015b) and using (18), we have the following inequalities:

$$\begin{aligned} &\int_0^{\bar{C}} \mathbb{P}\left(\varepsilon_n \geq \frac{1}{2}\omega^{-1}\left(\frac{g\alpha}{1+2g}\right)\right) \mathrm{d}\alpha \\ &\leq \alpha_n + \frac{8^b}{a}\int_{\alpha_n}^{\bar{C}} \frac{1}{\omega^{-1}\left(\frac{g\alpha}{1+2g}\right)^b} \exp\left[-\frac{an}{4^b}\omega^{-1}\left(\frac{g\alpha}{1+2g}\right)^b\right] \mathrm{d}\alpha \\ &\leq \alpha_n + \frac{8^b}{a}\int_{\alpha_n}^{\bar{C}} \frac{\alpha_n^b}{\left[\alpha\omega^{-1}\left(\frac{g\alpha_n}{1+2g}\right)\right]^b} \exp\left[-\frac{an\alpha^b}{(4\alpha_n)^b}\omega^{-1}\left(\frac{g\alpha_n}{1+2g}\right)^b\right] \mathrm{d}\alpha \\ &\leq \alpha_n + \alpha_n \frac{2^b 4n^{1-1/b}}{ba^{1/b}\omega^{-1}\left(\frac{g\alpha_n}{1+2g}\right)} \int_{u \geq \frac{an}{4^b}\omega^{-1}\left(\frac{g\alpha_n}{1+2g}\right)^b} u^{1/b-2}\mathrm{e}^{-u}\mathrm{d}u \\ &= \alpha_n + \alpha_n \frac{2^b n}{b\log(n)^{1/b}} \int_{u \geq \log(n)} u^{1/b-2}\mathrm{e}^{-u}\mathrm{d}u \leq \left(1 + \frac{2^b}{b\log(n)^2}\right)\alpha_n \text{ since } b \geq 1 \\ &\leq C(b)\alpha_n, \end{aligned}$$

where we used (25) with $x = \frac{g\alpha}{1+2g}$ and $y = \frac{g\alpha_n}{1+2g}$ for the second inequality. The constant $C(b)$ only depends on b.

Hence, since $\frac{1+2g}{g} < 6$, there exist constants $K, K' > 0$ that depend only of the geometric parameters of the model such that:

$$(A) \leq K\omega\left(\frac{K'\log(s_n)}{s_n}\right)^{1/b}.$$

Final bound. Since $s_n = n\log(n)^{-(1+\beta)}$, by gathering all four terms, there exist constants $C, C' > 0$ such that:

$$\mathbb{E}\left[\sup_{f \in \mathcal{F}(\mathbb{P},\omega)} d_\Delta\left(\mathrm{R}_f(\mathcal{X}_{\mathbb{P}}), \mathrm{M}_n\right)\right] \leq C\omega\left(\frac{C'\log(n)^{2+\beta}}{n}\right)^{1/b}.$$

A.8 Proof of Proposition 15

We have the following bound by using (23) in the proof of Proposition 13:

$$\begin{aligned} &\mathbb{P}\left(d_\Delta(, \mathrm{R}_f(\mathcal{X}_{\mathbb{P}}), \mathrm{M}_n) \geq \eta\right) \\ &\leq \mathbb{P}\left(\omega(\delta_n) \geq \frac{g}{1+2g}\eta\right) + \mathbb{P}\left(\varepsilon_n \geq \frac{\delta_n}{4}\right) + \mathbb{P}\left(\delta_n \geq \min\left\{\frac{\kappa}{4}, \frac{\rho}{4}\right\}\right) \\ &\leq \mathbb{P}\left(\varepsilon_n \geq \frac{1}{2}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) + \mathbb{P}\left(\varepsilon_{s_n} \geq \frac{1}{2}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) + o\left(\frac{1}{n\log(n)}\right). \end{aligned}$$

Following the lines of Section 6 in Fasy et al. (2014), subsampling approximations give

$$\mathbb{P}\left(\varepsilon_n \geq \frac{1}{2}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) \leq L_n\left(\frac{1}{4}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) + o\left(\frac{s_n}{n}\right)^{1/4},$$

and

$$\mathbb{P}\left(\varepsilon_{s_n} \geq \frac{1}{2}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) \leq F_n\left(\frac{1}{4}\omega^{-1}\left(\frac{g}{1+2g}\eta\right)\right) + o\left(\frac{s_n^2}{s_n}\right)^{1/4}.$$

The result follows by taking $s_n = n\log(n)^{-(1+\beta)}$.

Appendix B. Le Cam's lemma

The version of Le Cam's lemma given below is from Yu (1997) (see also Genovese et al., 2012b). Recall that the total variation distance between two distributions $\mathbb{P}_0$ and $\mathbb{P}_1$ on a measured space $(\mathcal{X}, \mathcal{B})$ is defined by

$$\mathrm{TV}(\mathbb{P}_0, \mathbb{P}_1) = \sup_{B\in\mathcal{B}} |\mathbb{P}_0(B) - \mathbb{P}_1(B)|.$$

Moreover, if $\mathbb{P}_0$ and $\mathbb{P}_1$ have densities p_0 and p_1 for the same measure λ on $\mathcal{X}$, then

$$\mathrm{TV}(\mathbb{P}_0, \mathbb{P}_1) = \frac{1}{2}\ell_1(p_0, p_1) = \int_{\mathcal{X}} |p_0 - p_1| d\lambda.$$

Lemma 20 *Let $\mathcal{P}$ be a set of distributions. For $\mathbb{P} \in \mathcal{P}$, let $\theta(\mathbb{P})$ take values in a pseudo-metric space $(\mathbb{X}, \rho)$. Let $\mathbb{P}_0$ and $\mathbb{P}_1$ in $\mathcal{P}$ be any pair of distributions. Let $X_1, \ldots, X_n$ be drawn i.i.d. from some $\mathbb{P} \in \mathcal{P}$. Let $\hat{\theta} = \hat{\theta}(X_1, \ldots, X_n)$ be any estimator of $\theta(\mathbb{P})$, then*

$$\sup_{\mathbb{P}\in\mathcal{P}} \mathbb{E}_{\mathbb{P}^n}\left[\rho(\theta, \hat{\theta})\right] \geq \frac{1}{8}\rho\left(\theta(\mathbb{P}_0), \theta(\mathbb{P}_1)\right)\left[1 - \mathrm{TV}(\mathbb{P}_0, \mathbb{P}_1)\right]^{2n}.$$

Appendix C. Extended Persistence

Let f be a real-valued function on a topological space $\mathcal{X}$. Given an interval I and a scalar value $t \in \mathbb{R}$, we let $\mathcal{X}^I$ denote $f^{-1}(I)$ and $\mathcal{X}^t = f^{-1}(t)$. The family $\{\mathcal{X}^{(-\infty,\alpha]}\}_{\alpha\in\mathbb{R}}$ of sublevel sets of f defines a *filtration*, that is, it is nested with respect to the inclusion: $\mathcal{X}^{(-\infty,\alpha]} \subseteq \mathcal{X}^{(-\infty,\beta]}$ for all $\alpha \leq \beta \in \mathbb{R}$. The family $\{\mathcal{X}^{[\alpha,+\infty)}\}_{\alpha\in\mathbb{R}}$ of superlevel sets of f is also nested but in the opposite direction: $\mathcal{X}^{[\alpha,+\infty)} \supseteq \mathcal{X}^{[\beta,+\infty)}$ for all $\alpha \leq \beta \in \mathbb{R}$. We can turn it into a filtration by reversing the real line. Specifically, let $\mathbb{R}^{\mathrm{op}} = \{\tilde{x} \mid x \in \mathbb{R}\}$, ordered by $\tilde{x} \leq \tilde{y} \Leftrightarrow x \geq y$. We index the family of superlevel sets by $\mathbb{R}^{\mathrm{op}}$, so now we have a filtration: $\{\mathcal{X}^{[\tilde{\alpha},+\infty)}\}_{\tilde{\alpha}\in\mathbb{R}^{\mathrm{op}}}$, with $\mathcal{X}^{[\tilde{\alpha},+\infty)} \subseteq \mathcal{X}^{[\tilde{\beta},+\infty)}$ for all $\tilde{\alpha} \leq \tilde{\beta} \in \mathbb{R}^{\mathrm{op}}$.

Extended persistence connects the two filtrations at infinity as follows. Replace each superlevel set $\mathcal{X}^{[\tilde{\alpha},+\infty)}$ by the pair of spaces $(\mathcal{X}, \mathcal{X}^{[\tilde{\alpha},+\infty)})$ in the second filtration. This maintains the filtration property since we have $(\mathcal{X}, \mathcal{X}^{[\tilde{\alpha},+\infty)}) \subseteq (\mathcal{X}, \mathcal{X}^{[\tilde{\beta},+\infty)})$ for all $\tilde{\alpha} \leq \tilde{\beta} \in \mathbb{R}^{\mathrm{op}}$. Then, let $\mathbb{R}_{\mathrm{Ext}} = \mathbb{R} \sqcup \{+\infty\} \sqcup \mathbb{R}^{\mathrm{op}}$, where the order is completed by $\alpha < +\infty < \tilde{\beta}$ for all $\alpha \in \mathbb{R}$ and $\tilde{\beta} \in \mathbb{R}^{\mathrm{op}}$. This poset is isomorphic to $(\mathbb{R}, \leq)$. Finally, define the *extended filtration* of f over $\mathbb{R}_{\mathrm{Ext}}$ by:

$$\begin{aligned} F_\alpha &= \mathcal{X}^{(-\infty,\alpha]} && \text{for } \alpha \in \mathbb{R} \\ F_{+\infty} &= \mathcal{X} \equiv (\mathcal{X}, \emptyset) \\ F_{\tilde{\alpha}} &= (\mathcal{X}, \mathcal{X}^{[\tilde{\alpha},+\infty)}) && \text{for } \tilde{\alpha} \in \mathbb{R}^{\mathrm{op}}, \end{aligned}$$

where we have identified the space $\mathcal{X}$ with the pair of spaces $(\mathcal{X}, \emptyset)$. This is a well-defined filtration since we have $\mathcal{X}^{(-\infty,\alpha]} \subseteq \mathcal{X} \equiv (\mathcal{X}, \emptyset) \subseteq (\mathcal{X}, \mathcal{X}^{[\tilde{\beta},+\infty)})$ for all $\alpha \in \mathbb{R}$ and $\tilde{\beta} \in \mathbb{R}^{\mathrm{op}}$. The subfamily $\{F_\alpha\}_{\alpha\in\mathbb{R}}$ is called the *ordinary* part of the filtration, and the subfamily $\{F_{\tilde{\alpha}}\}_{\tilde{\alpha}\in\mathbb{R}^{\mathrm{op}}}$ is called the *relative* part. See Figure 9 for an illustration.

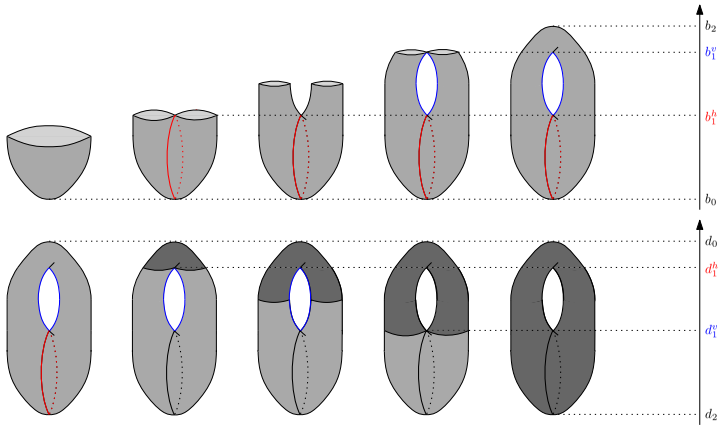

Figure 9: The extended filtration of the height function on a torus. The upper row displays the ordinary part of the filtration while the lower row displays the relative part. The red and blue cycles both correspond to extended points in dimension 1. The point corresponding to the red cycle is located above the diagonal ($d_1^h > b_1^h$), while the point corresponding to the blue cycle is located below the diagonal ($d_1^v > b_1^v$).

Applying the homology functor H_* to this filtration gives the so-called *extended persistence module* $\mathbb{V}$ of f:

$$\begin{aligned} V_\alpha &= H_*(F_\alpha) = H_*(\mathcal{X}^{(-\infty,\alpha]}) && \text{for } \alpha \in \mathbb{R} \\ V_{+\infty} &= H_*(F_{+\infty}) = H_*(\mathcal{X}) \cong H_*(\mathcal{X}, \emptyset) \\ V_{\tilde{\alpha}} &= H_*(F_{\tilde{\alpha}}) = H_*(\mathcal{X}, \mathcal{X}^{[\tilde{\alpha},+\infty)}) && \text{for } \tilde{\alpha} \in \mathbb{R}^{\mathrm{op}}, \end{aligned}$$

and where the linear maps between the spaces are induced by the inclusions in the extended filtration.

For Morse-type functions, the extended persistence module can be decomposed as a finite direct sum of half-open *interval modules*—see e.g. Chazal et al. (2016a):

$$\mathbb{V} \simeq \bigoplus_{k=1}^{n} \mathbb{I}[b_k, d_k),$$

where each summand $\mathbb{I}[b_k, d_k)$ is made of copies of the field of coefficients at each index $\alpha \in [b_k, d_k)$, and of copies of the zero space elsewhere, the maps between copies of the field being identities. Each summand represents the lifespan of a *homological feature* (connected component, hole, void, etc.) within the filtration. More precisely, the *birth time* b_k and *death time* d_k of the feature are given by the endpoints of the interval. Then, a convenient way to represent the structure of the module is to plot each interval in the decomposition as a point in the extended plane, whose coordinates are given by the endpoints. Such a plot is called the *extended persistence diagram* of f, denoted $\mathrm{Dg}(f)$. The distinction between ordinary and relative parts of the filtration allows to classify the points in $\mathrm{Dg}(f)$ in the following way:

- points whose coordinates both belong to $\mathbb{R}$ are called *ordinary* points; they correspond to homological features being born and then dying in the ordinary part of the filtration;
- points whose coordinates both belong to $\mathbb{R}^{\mathrm{op}}$ are called *relative* points; they correspond to homological features being born and then dying in the relative part of the filtration;
- points whose abscissa belongs to $\mathbb{R}$ and whose ordinate belongs to $\mathbb{R}^{\mathrm{op}}$ are called *extended* points; they correspond to homological features being born in the ordinary part and then dying in the relative part of the filtration.

Note that ordinary points lie strictly above the diagonal $\Delta = \{(x, x) \mid x \in \mathbb{R}\}$ and relative points lie strictly below Δ, while extended points can be located anywhere, including on Δ, e.g. cc that lie inside a single critical level. It is common to decompose $\mathrm{Dg}(f)$ according to this classification:

$$\mathrm{Dg}(f) = \mathrm{Ord}(f) \sqcup \mathrm{Rel}(f) \sqcup \mathrm{Ext}^{+}(f) \sqcup \mathrm{Ext}^{-}(f),$$

where by convention $\mathrm{Ext}^{+}(f)$ includes the extended points located on the diagonal Δ.

Abstract

We present a *Distributionally Robust Optimization (DRO)* approach to estimate a robustified regression plane in a linear regression setting, when the observed samples are potentially contaminated with adversarially corrupted outliers. Our approach mitigates the impact of outliers by hedging against a family of probability distributions on the observed data, some of which assign very low probabilities to the outliers. The set of distributions under consideration are close to the empirical distribution in the sense of the Wasserstein metric. We show that this DRO formulation can be relaxed to a convex optimization problem which encompasses a class of models. By selecting proper norm spaces for the Wasserstein metric, we are able to recover several commonly used regularized regression models. We provide new insights into the regularization term and give guidance on the selection of the regularization coefficient from the standpoint of a confidence region. We establish two types of performance guarantees for the solution to our formulation under mild conditions. One is related to its out-of-sample behavior (prediction bias), and the other concerns the discrepancy between the estimated and true regression planes (estimation bias). Extensive numerical results demonstrate the superiority of our approach to a host of regression models, in terms of the prediction and estimation accuracies. We also consider the application of our robust learning procedure to outlier detection, and show that our approach achieves a much higher AUC (Area Under the ROC Curve) than M-estimation (Huber, 1964, 1973).
Keywords: Robust Learning, Distributionally Robust Optimization, Wasserstein Metric, Regularized Regression, Generalization Guarantees.

1. Introduction

Consider a linear regression model with response $y \in \mathbb{R}$, predictor vector $\mathbf{x} \in \mathbb{R}^{m-1}$, regression coefficient $\boldsymbol{\beta}^* \in \mathbb{R}^{m-1}$ and error $\epsilon \in \mathbb{R}$:

$$y = \mathbf{x}'\boldsymbol{\beta}^* + \epsilon.$$

Given samples $(\mathbf{x}_i, y_i), i = 1, \ldots, N$, we are interested in estimating $\boldsymbol{\beta}^*$. The *Ordinary Least Squares (OLS)* minimizes the sum of squared residuals $\sum_{i=1}^N (y_i - \mathbf{x}_i'\boldsymbol{\beta})^2$, and works well if all the N samples are generated from the underlying true model. However, when faced with adversarial perturbations in the training data, the OLS estimator will deviate from the true regression plane to reduce large residuals. Alternatively, one can choose to minimize the sum of absolute residuals $\sum_{i=1}^N |y_i - \mathbf{x}_i'\boldsymbol{\beta}|$, as done in *Least Absolute Deviation (LAD)*, to mitigate the influence of large residuals. Another commonly used approach for hedging against outliers is M-estimation (Huber, 1964, 1973), which minimizes a symmetric loss function $\rho(\cdot)$ of the residuals in the form $\sum_{i=1}^N \rho(y_i - \mathbf{x}_i'\boldsymbol{\beta})$, which downweights the influence of samples with large absolute residuals. Several choices for $\rho(\cdot)$ include the Huber function (Huber, 1964, 1973), the Tukey's Biweight function (Rousseeuw and Leroy, 2005), the logistic function (Coleman et al., 1980), the Talwar function (Hinich and Talwar, 1975), and the Fair function (Fair, 1974).

Both LAD and M-estimation are not resistant to large deviations in the predictors. For contamination present in the predictor space, high breakdown value methods are required. Examples include the *Least Median of Squares (LMS)* (Rousseeuw, 1984), which minimizes the median of the absolute residuals, the *Least Trimmed Squares (LTS)* (Rousseeuw, 1985), which minimizes the sum of the q smallest squared residuals, and S-estimation (Rousseeuw and Yohai, 1984), which has a higher statistical efficiency than LTS with the same breakdown value. A combination of the high breakdown value method and M-estimation is the MM-estimation (Yohai, 1987). It has a higher statistical efficiency than S-estimation. We refer the reader to the book of Rousseeuw and Leroy (2005) for a detailed description of these robust regression methods.

The aforementioned robust estimation procedures focus on modifying the objective function in a heuristic way with the intent of minimizing the effect of outliers. A more rigorous line of research explores the underlying stochastic program that leads to the sample-based estimation procedures. For example, the OLS objective can be viewed as minimizing the expected squared residual under the uniform empirical distribution over the samples. It has been well recognized that optimizing under the empirical distribution yields estimators that are sensitive to perturbations in the data and suffer from overfitting. The reason is that when the data $(\mathbf{x}, y)$ are adversarially corrupted by outliers, the observed samples do not represent well the true underlying distribution of the data. Yet, the samples are typically the only information available. Instead of equally weighting all the samples as in the empirical distribution, we may wish to include more informative distributions that "drive out" the corrupted samples. One way to realize this is to hedge the expected loss against a family of distributions that include the true data-generating mechanism with a high confidence; an approach called *Distributionally Robust Optimization (DRO)*. DRO minimizes the worst-case expected loss over a probabilistic ambiguity set $\mathcal{P}$ that is constructed from the observed samples and characterized by certain known properties of the true data-generating distribution. For example, Mehrotra and Zhang (2014) study the distributionally robust least squares problem with $\mathcal{P}$ defined through either moment constraints, norm bounds with moment constraints, or a confidence region over a reference probability measure. Compared to the single distribution-based stochastic optimization, DRO often results in better out-of-sample performance due to its distributional robustness.

The existing literature on DRO can be split into two main branches according to the way in which $\mathcal{P}$ is defined. One is through a moment ambiguity set, which contains all distributions that satisfy certain moment constraints (see Popescu, 2007; Delage and Ye, 2010; Goh and Sim, 2010; Zymler et al., 2013; Wiesemann et al., 2014). In many cases, it leads to a tractable DRO problem but has been criticized for yielding overly conservative solutions (Wang et al., 2016). The other is to define $\mathcal{P}$ as a ball of distributions using some probabilistic distance functions such as the ϕ-divergences (Bayraksan and Love, 2015), which include the Kullback-Leibler (KL) divergence (Hu and Hong, 2013; Jiang and Guan, 2015) as a special case, the Prokhorov metric (Erdoğan and Iyengar, 2006), and the Wasserstein distance (Esfahani and Kuhn, 2015; Gao and Kleywegt, 2016; Zhao and Guan, 2015; Luo and Mehrotra, 2017; Blanchet and Murthy, 2016). Deviating from the stochastic setting, there are also some works focusing on deterministic robustness. El Ghaoui and Lebret (1997) consider the least squares problem with unknown but bounded, non-random disturbance and solve it in polynomial time. Xu et al. (2010) study the robust linear regression problem with norm-bounded feature perturbation and show that it is equivalent to the ℓ_1-regularized regression. See Yang and Xu (2013); Bertsimas and Copenhaver (2017) which also use a deterministic robustness approach.

In this paper we consider a DRO problem with $\mathcal{P}$ containing distributions that are close to the discrete empirical distribution in the sense of Wasserstein distance. The reason for choosing the Wasserstein metric is two-fold. On one hand, the Wasserstein ambiguity set is rich enough to contain both continuous and discrete relevant distributions, while other metrics such as the KL divergence, exclude all continuous distributions if the nominal distribution is discrete (Esfahani and Kuhn, 2015; Gao and Kleywegt, 2016). Furthermore, considering distributions within a KL distance from the empirical, does not allow for probability mass outside the support of the empirical distribution. On the other hand, measure concentration results guarantee that the Wasserstein set contains the true data-generating distribution with high confidence for a sufficiently large sample size (Fournier and Guillin, 2015). Moreover, the Wasserstein metric takes into account the closeness between support points while other metrics such as the ϕ-divergence only consider the probabilities of these points. The image retrieval example in Gao and Kleywegt (2016) suggests that the probabilistic ambiguity set constructed based on the KL divergence prefers the pathological distribution to the true distribution, whereas the Wasserstein distance does not exhibit such a problem. The reason lies in that ϕ-divergence does not incorporate a notion of closeness between two points, which in the context of image retrieval represents the perceptual similarity in color.

Our DRO problem minimizes the worst-case absolute residual over a Wasserstein ball of distributions, and could be relaxed to the following form:

$$\inf_{\boldsymbol{\beta}} \frac{1}{N} \sum_{i=1}^{N} |y_i - \mathbf{x}_i'\boldsymbol{\beta}| + \epsilon \|(-\boldsymbol{\beta}, 1)\|_*, \tag{1}$$

where ϵ is the radius of the Wasserstein ball, and $\|\cdot\|_*$ is the dual norm of the norm space where the Wasserstein metric is defined on. Formulation (1) incorporates a wide class of models whose specific form depends on the notion of transportation cost embedded in the Wasserstein metric (see Section 2). Although the Wasserstein DRO formulation

simply reduces to regularized regression models, we want to emphasize a few new insights brought by this methodology. First, the regularization term controls the conservativeness of the Wasserstein set, or the amount of ambiguity in the data, which differentiates itself from the heuristically added regularizers in traditional regression models that serve the purpose of preventing overfitting, error/variance reduction, or sparsity recovery. Second, the regularization term is determined by the dual norm of the regression coefficient, which controls the *growth rate* of the ℓ_1-loss function, and the radius of the Wasserstein set. This connection provides guidance on the selection of the regularization coefficient and may lead to significant computational savings compared to cross-validation. DRO essentially enables new and more accurate interpretations of the regularizer, and establishes its dependence on the *growth rate* of the loss, the underlying metric space and the reliability of the observed samples.

The connection between robustness and regularization has been established in several works. The earliest one may be credited to El Ghaoui and Lebret (1997), who show that minimizing the worst-case squared residual within a Frobenius norm-based perturbation set is equivalent to Tikhonov regularization. In more recent works, using properly selected uncertainty sets, Xu et al. (2010) have shown the equivalence between robust linear regression with feature perturbations and the *Least Absolute Shrinkage and Selection Operator (LASSO)*. Yang and Xu (2013) extend this to more general LASSO-like procedures, including versions of the grouped LASSO. Bertsimas and Copenhaver (2017) give a comprehensive characterization of the conditions under which robustification and regularization are equivalent for regression models with deterministic norm-bounded perturbations on the features. For classification problems, Xu et al. (2009) show the equivalence between the regularized Support Vector Machines (SVMs) and a robust optimization formulation, by allowing potentially correlated disturbances in the covariates. Shafieezadeh-Abadeh et al. (2015) consider a robust version of logistic regression under the assumption that the probability distributions under consideration lie in a Wasserstein ball, and they show that the regularized logistic regression is a special case of this robust formulation. Recently, Shafieezadeh-Abadeh et al. (2017); Gao et al. (2017) have provided a unified framework for connecting the Wasserstein DRO with regularized learning procedures, for various regression and classification models.

Our work is motivated by the problem of identifying patients who receive an abnormally high radiation exposure in CT exams, given the patient characteristics and exam-related variables (Chen et al., 2018). This could be casted as an outlier detection problem; specifically, estimating a robustified regression plane that is immunized against outliers and learns the underlying true relationship between radiation dose and the relevant predictors. We focus on robust learning of the parameter in regression models under distributional perturbations residing within a Wasserstein ball. While the applicability of the Wasserstein DRO methodology is not restricted to regression analysis (Sinha et al., 2017; Gao et al., 2017; Shafieezadeh-Abadeh et al., 2017), or a particular form of the loss function (as long as it satisfies certain smoothness conditions (Gao et al., 2017)), we focus on the absolute residual loss in linear regression in light of our motivating application and for the purpose of enhancing robustness. Our contributions can be summarized as follows:

1. We develop a DRO approach to robustify linear regression using an ℓ_1 loss function and an ambiguity set around the empirical distribution of the training samples defined based on the Wasserstein metric. The formulation is general enough to in-

clude any norm-induced Wasserstein metric and incorporate additional regularization constraints on the regression coefficients (e.g., ℓ_1-norm constraints). It provides an intuitive connection between the amount of ambiguity allowed and a regularization penalty term in the robust formulation, which provides a natural way to adjust the latter.

2. We establish novel performance guarantees on both the out-of-sample loss (prediction bias) and the discrepancy between the estimated and the true regression coefficients (estimation bias). Our guarantees elucidate the role of the regularizer, which is related to the dual norm of the regression coefficients, in bounding the biases and are in concert with the theoretical foundation that leads to the regularized problem. The generalization error bound, in particular, builds a connection between the loss function and the form of the regularizer via Rademacher complexity, providing a rigorous explanation for the commonly observed good out-of-sample performance of regularized regression. On the other hand, the estimation error bound corroborates the validity of the ℓ_1-loss function, which tends to incur a lower estimation bias than other candidates such as the ℓ_2 and ℓ_∞ losses. Our results are novel in the robust regression setting and different from earlier work in the DRO literature, enabling new perspectives and interpretations of the norm-based regularization, and providing justifications for the ℓ_1-loss-based learning algorithms.

3. We empirically explore three important aspects of the Wasserstein DRO formulation, including the advantages of the ℓ_1-loss function, the selection of a proper norm for the Wasserstein metric, and the implication of penalizing the *extended regression coefficient* $(-\boldsymbol{\beta}, 1)$, by comparing with a series of regression models on a number of synthetic datasets. We show the superiority of the Wasserstein DRO approach, presenting a thorough analysis under four different experimental setups. We also consider the application of our methodology to outlier detection and compare with M-estimation in terms of the ability of identifying outliers (*ROC (Receiver Operating Characteristic)* curves). The Wasserstein DRO formulation achieves significantly higher *AUC (Area Under Curve)* values.

The rest of the paper is organized as follows. In Section 2, we introduce the Wasserstein metric and derive the general Wasserstein DRO formulation in a linear regression framework. Section 3 establishes performance guarantees for both the general formulation and the special case where the Wasserstein metric is defined on the ℓ_1-norm space. Numerical experimental results are presented in Section 4. We conclude the paper in Section 5.

Notational conventions: We use boldfaced lowercase letters to denote vectors, ordinary lowercase letters to denote scalars, boldfaced uppercase letters to denote matrices, and calligraphic capital letters to denote sets. $\mathbb{E}$ denotes expectation and $\mathbb{P}$ probability of an event. All vectors are column vectors. For space saving reasons, we write $\mathbf{x} = (x_1, \ldots, x_{\dim(\mathbf{x})})$ to denote the column vector $\mathbf{x}$, where $\dim(\mathbf{x})$ is the dimension of $\mathbf{x}$. We use prime to denote the transpose of a vector, $\|\cdot\|$ for the general norm operator, $\|\cdot\|_2$ for the ℓ_2 norm, $\|\cdot\|_1$ for the ℓ_1 norm, and $\|\cdot\|_\infty$ for the infinity norm. $\mathcal{P}(\mathcal{Z})$ denotes the set of probability measures supported on $\mathcal{Z}$. $\mathbf{e}_i$ denotes the i-th unit vector, $\mathbf{e}$ the vector of ones, $\mathbf{0}$ a vector of zeros, and $\mathbf{I}$ the identity matrix. Given a norm $\|\cdot\|$ on $\mathbb{R}^m$, the dual

norm $\|\cdot\|_*$ is defined as: $\|\boldsymbol{\theta}\|_* \triangleq \sup_{\|\mathbf{z}\|\leq 1} \boldsymbol{\theta}'\mathbf{z}$. For a function $h(\mathbf{z})$, its convex conjugate $h^*(\cdot)$ is defined as: $h^*(\boldsymbol{\theta}) \triangleq \sup_{\mathbf{z}\in \text{dom } h} \{\boldsymbol{\theta}'\mathbf{z} - h(\mathbf{z})\}$, where dom h denotes the domain of the function h.

2. Problem Statement and Justification of Our Formulation

Consider a linear regression problem where we are given a predictor/feature vector $\mathbf{x} \in \mathbb{R}^{m-1}$, and a response variable $y \in \mathbb{R}$. Our goal is to obtain an accurate estimate of the regression plane that is robust with respect to the adversarial perturbations in the data. We consider an ℓ_1-loss function $h_{\boldsymbol{\beta}}(\mathbf{x}, y) \triangleq |y - \mathbf{x}'\boldsymbol{\beta}|$, motivated by the observation that the absolute loss function is more robust to large residuals than the squared loss (see Fig. 1). Moreover, the estimation error analysis presented in Section 3.2 suggests that the ℓ_1-loss function leads to a smaller estimation bias than others. Our Wasserstein DRO problem using the ℓ_1-loss function is formulated as:

$$\inf_{\boldsymbol{\beta}\in\mathcal{B}} \sup_{\mathbb{Q}\in\Omega} \mathbb{E}^{\mathbb{Q}}\big[|y - \mathbf{x}'\boldsymbol{\beta}|\big], \tag{2}$$

where $\boldsymbol{\beta}$ is the regression coefficient vector that belongs to some set $\mathcal{B}$. $\mathcal{B}$ could be $\mathbb{R}^{m-1}$, or $\mathcal{B} = \{\boldsymbol{\beta} : \|\boldsymbol{\beta}\|_1 \leq l\}$ if we wish to induce sparsity, with l being some pre-specified number. $\mathbb{Q}$ is the probability distribution of $(\mathbf{x}, y)$, belonging to some set Ω which is defined as:

$$\Omega \triangleq \{\mathbb{Q} \in \mathcal{P}(\mathcal{Z}) : W_p(\mathbb{Q},\ \hat{\mathbb{P}}_N) \leq \epsilon\},$$

where $\mathcal{Z}$ is the set of possible values for $(\mathbf{x}, y)$; $\mathcal{P}(\mathcal{Z})$ is the space of all probability distributions supported on $\mathcal{Z}$; ϵ is a pre-specified radius of the Wasserstein ball; and $W_p(\mathbb{Q},\ \hat{\mathbb{P}}_N)$ is the order-p Wasserstein distance between $\mathbb{Q}$ and $\hat{\mathbb{P}}_N$ (see definition in (3)), with $\hat{\mathbb{P}}_N$ the uniform empirical distribution over samples. The formulation in (2) is robust since it minimizes over the regression coefficients the worst case expected loss, that is, the expected loss maximized over all probability distributions in the ambiguity set Ω.

Before deriving a tractable reformulation for (2), let us first define the Wasserstein metric. Let $(\mathcal{Z}, s)$ be a metric space where $\mathcal{Z}$ is a set and s is a metric on $\mathcal{Z}$. The Wasserstein metric of order $p \geq 1$ defines the distance between two probability distributions $\mathbb{Q}_1$ and $\mathbb{Q}_2$ in the following way:

$$W_p(\mathbb{Q}_1, \mathbb{Q}_2) \triangleq \left(\min_{\Pi\in\mathcal{P}(\mathcal{Z}\times\mathcal{Z})} \left\{\int_{\mathcal{Z}\times\mathcal{Z}} \big(s((\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2))\big)^p\ \Pi\big(d(\mathbf{x}_1, y_1), d(\mathbf{x}_2, y_2)\big)\right\}\right)^{1/p}, \tag{3}$$

where Π is the joint distribution of $(\mathbf{x}_1, y_1)$ and $(\mathbf{x}_2, y_2)$ with marginals $\mathbb{Q}_1$ and $\mathbb{Q}_2$, respectively. The Wasserstein distance between $\mathbb{Q}_1$ and $\mathbb{Q}_2$ represents the cost of an optimal mass transportation plan, where the cost is measured through the metric s. The order p should be selected in such a way as to ensure that the worst-case expected loss is meaningfully defined, i.e.,

$$\mathbb{E}^{\mathbb{Q}}\big[h_{\boldsymbol{\beta}}(\mathbf{x}, y)\big] < \infty,\ \forall \mathbb{Q} \in \Omega. \tag{4}$$

Notice that the ambiguity set Ω is centered at the empirical distribution $\hat{\mathbb{P}}_N$ and has radius ϵ. It may be desirable to translate (4) into:

$$\left|\mathbb{E}^{\mathbb{Q}}\big[h_{\boldsymbol{\beta}}(\mathbf{x}, y)\big] - \mathbb{E}^{\hat{\mathbb{P}}_N}\big[h_{\boldsymbol{\beta}}(\mathbf{x}, y)\big]\right| < \infty,\ \forall \mathbb{Q} \in \Omega. \tag{5}$$

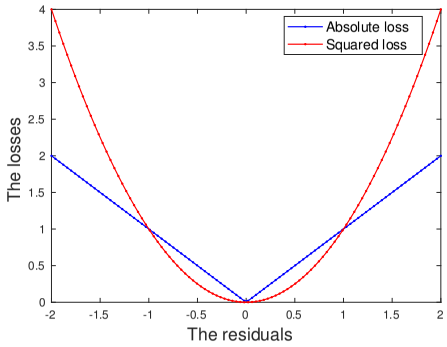

Figure 1: Comparison between ℓ_1 and ℓ_2 loss functions.

We want to relate (5) with the Wasserstein distance $W_p(\mathbb{Q}, \hat{\mathbb{P}}_N)$, which is no larger than ϵ for all $\mathbb{Q} \in \Omega$. The LHS of (5) could be written as:

$$\begin{aligned}
&\left|\mathbb{E}^{\mathbb{Q}}\big[h_{\boldsymbol{\beta}}(\mathbf{x},y)\big] - \mathbb{E}^{\hat{\mathbb{P}}_N}\big[h_{\boldsymbol{\beta}}(\mathbf{x},y)\big]\right| \\
=&\left|\int_{\mathcal{Z}} h_{\boldsymbol{\beta}}(\mathbf{x}_1,y_1)\mathbb{Q}(d(\mathbf{x}_1,y_1)) - \int_{\mathcal{Z}} h_{\boldsymbol{\beta}}(\mathbf{x}_2,y_2)\hat{\mathbb{P}}_N(d(\mathbf{x}_2,y_2))\right| \\
=&\left|\int_{\mathcal{Z}} h_{\boldsymbol{\beta}}(\mathbf{x}_1,y_1)\int_{\mathcal{Z}} \Pi_0(d(\mathbf{x}_1,y_1),d(\mathbf{x}_2,y_2)) - \int_{\mathcal{Z}} h_{\boldsymbol{\beta}}(\mathbf{x}_2,y_2)\int_{\mathcal{Z}} \Pi_0(d(\mathbf{x}_1,y_1),d(\mathbf{x}_2,y_2))\right| \\
\leq&\int_{\mathcal{Z}\times\mathcal{Z}} \big|h_{\boldsymbol{\beta}}(\mathbf{x}_1,y_1) - h_{\boldsymbol{\beta}}(\mathbf{x}_2,y_2)\big|\Pi_0(d(\mathbf{x}_1,y_1),d(\mathbf{x}_2,y_2)),
\end{aligned} \tag{6}$$

where Π_0 is the joint distribution of $(\mathbf{x}_1,y_1)$ and $(\mathbf{x}_2,y_2)$ with marginals $\mathbb{Q}$ and $\hat{\mathbb{P}}_N$, respectively. Comparing (6) with (3), we see that for (5) to hold, the following quantity which characterizes the *growth rate* of the loss function needs to be bounded:

$$\mathrm{GR}_{h_{\boldsymbol{\beta}}}((\mathbf{x}_1,y_1),(\mathbf{x}_2,y_2)) \triangleq \frac{\big|h_{\boldsymbol{\beta}}(\mathbf{x}_1,y_1) - h_{\boldsymbol{\beta}}(\mathbf{x}_2,y_2)\big|}{\big(s((\mathbf{x}_1,y_1),(\mathbf{x}_2,y_2))\big)^p},\ \forall (\mathbf{x}_1,y_1),(\mathbf{x}_2,y_2) \in \mathcal{Z}. \tag{7}$$

A formal definition of the growth rate is due to Gao and Kleywegt (2016), which takes the limit of (7) as $s((\mathbf{x}_1,y_1),(\mathbf{x}_2,y_2)) \to \infty$, to eliminate its dependence on $(\mathbf{x},y)$. One important aspect they have pointed out is that when the growth rate of the loss function is infinite, strong duality for the worst-case problem $\sup_{\mathbb{Q}\in\Omega}\mathbb{E}^{\mathbb{Q}}\big[h_{\boldsymbol{\beta}}(\mathbf{x},y)\big]$ fails to hold, in which case the DRO problem (2) becomes intractable. Assuming that the metric s is

induced by some norm $\|\cdot\|$, the bounded *growth rate* requirement is expressed as follows:

$$\begin{aligned}
&\limsup_{\|(\mathbf{x}_1,y_1)-(\mathbf{x}_2,y_2)\|\to\infty} \frac{|h_{\boldsymbol{\beta}}(\mathbf{x}_1,y_1) - h_{\boldsymbol{\beta}}(\mathbf{x}_2,y_2)|}{\|(\mathbf{x}_1,y_1)-(\mathbf{x}_2,y_2)\|^p} \leq \limsup_{\|(\mathbf{x}_1,y_1)-(\mathbf{x}_2,y_2)\|\to\infty} \frac{|y_1 - \mathbf{x}_1'\boldsymbol{\beta} - (y_2 - \mathbf{x}_2'\boldsymbol{\beta})|}{\|(\mathbf{x}_1,y_1)-(\mathbf{x}_2,y_2)\|^p} \\
\leq &\limsup_{\|(\mathbf{x}_1,y_1)-(\mathbf{x}_2,y_2)\|\to\infty} \frac{\|(\mathbf{x}_1,y_1)-(\mathbf{x}_2,y_2)\|\|(-\boldsymbol{\beta},1)\|_*}{\|(\mathbf{x}_1,y_1)-(\mathbf{x}_2,y_2)\|^p} < \infty,
\end{aligned} \tag{8}$$

where $\|\cdot\|_*$ is the dual norm of $\|\cdot\|$, and the second inequality is due to the Cauchy-Schwarz inequality. Notice that by taking $p = 1$, (8) is equivalently translated into the condition that $\|(-\boldsymbol{\beta},1)\|_* < \infty$, which we will see in Section 3 is an essential requirement to guarantee a good generalization performance for the Wasserstein DRO estimator. The growth rate essentially reveals the underlying metric space used by the Wasserstein distance. Taking $p > 1$ leads to zero growth rate in the limit of (8), which is not desirable since it removes the Wasserstein ball structure from our formulation and renders it an optimization problem over a singleton distribution. This will be made more clear in the following analysis. We thus choose the order-1 Wasserstein metric with s being induced by some norm $\|\cdot\|$ to define our DRO problem.

Next, we will discuss how to convert (2) into a tractable formulation. Suppose we have N independently and identically distributed realizations of $(\mathbf{x},y)$, denoted by $(\mathbf{x}_i,y_i), i = 1,\ldots,N$. We make the assumption that $(\mathbf{x},y)$ comes from a mixture of two distributions, with probability q from the outlying distribution $\mathbb{P}_{out}$ and with probability $1-q$ from the true distribution $\mathbb{P}$. Recall that $\hat{\mathbb{P}}_N$ is the discrete uniform distribution over the N samples. Our goal is to generate estimators that are consistent with the true distribution $\mathbb{P}$. We claim that when q is small, if the Wasserstein ball radius ϵ is chosen judiciously, the true distribution $\mathbb{P}$ will be included in the set Ω while the outlying distribution $\mathbb{P}_{out}$ will be excluded. To see this, consider a simple example where $\mathbb{P}$ is a discrete distribution that assigns equal probability to 10 data points equally spaced between 0.1 and 1, and $\mathbb{P}_{out}$ assigns probability 0.5 to two data points 1 and 2. We generate 100 samples and plot the Wasserstein distances from $\hat{\mathbb{P}}_N$ for both $\mathbb{P}$ and $\mathbb{P}_{out}$. From Fig. 2 we observe that for q below 0.5, the true distribution $\mathbb{P}$ is closer to $\hat{\mathbb{P}}_N$ whereas the outlying distribution $\mathbb{P}_{out}$ is further away. If the radius ϵ is chosen between the red $(*-)$ and blue $(\circ-)$ lines, the Wasserstein ball that we are hedging against will exclude the outlying distribution and the resulting estimator will be robust to the adversarial perturbations. Moreover, as q becomes smaller, the gap between the red and blue lines becomes larger. One implication from this observation is that as the data becomes purer, the radius of the Wasserstein ball tends to be smaller, and the confidence in the observed samples is higher. For large q values, the DRO formulation seems to fail. However, as outliers are defined to be the data points that do not conform to the majority of data, we can safely claim that $\mathbb{P}_{out}$ is the distribution of the minority and q is always below 0.5.

We now consider the inner supremum in (2). Esfahani and Kuhn (2015, Theorem 6.3) show that when the set $\mathcal{Z}$ is closed and convex, and the loss function $h_{\boldsymbol{\beta}}(\mathbf{x},y)$ is convex in $(\mathbf{x},y)$,

$$\sup_{\mathbb{Q}\in\Omega} \mathbb{E}^{\mathbb{Q}}[h_{\boldsymbol{\beta}}(\mathbf{x},y)] \leq \kappa\epsilon + \frac{1}{N}\sum_{i=1}^{N} h_{\boldsymbol{\beta}}(\mathbf{x}_i,y_i),\ \forall \epsilon \geq 0, \tag{9}$$

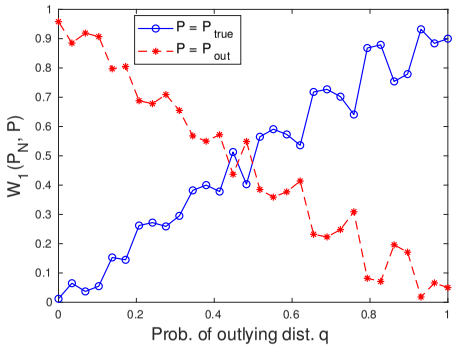

Figure 2: The order-1 Wasserstein distances from the empirical distribution.

where $\kappa(\boldsymbol{\beta}) = \sup\{\|\boldsymbol{\theta}\|_* : h^*_{\boldsymbol{\beta}}(\boldsymbol{\theta}) < \infty\}$, with $h^*_{\boldsymbol{\beta}}(\cdot)$ the convex conjugate function of $h_{\boldsymbol{\beta}}(\mathbf{x}, y)$. Through (9), we can relax problem (2) by minimizing the right hand side of (9) instead of the worst-case expected loss. Moreover, as shown in Esfahani and Kuhn (2015), (9) becomes an equality when $\mathcal{Z} = \mathbb{R}^m$. In Theorem 2.1, we compute the value of $\kappa(\boldsymbol{\beta})$ for the specific ℓ_1 loss function we use. The proof of this Theorem and all results hereafter are included in Appendix A.

Theorem 2.1 *Define $\kappa(\boldsymbol{\beta}) = \sup\{\|\boldsymbol{\theta}\|_* : h^*_{\boldsymbol{\beta}}(\boldsymbol{\theta}) < \infty\}$, where $\|\cdot\|_*$ is the dual norm of $\|\cdot\|$, and $h^*_{\boldsymbol{\beta}}(\cdot)$ is the conjugate function of $h_{\boldsymbol{\beta}}(\cdot)$. When the loss function is $h_{\boldsymbol{\beta}}(\mathbf{x}, y) = |y - \mathbf{x}'\boldsymbol{\beta}|$, we have $\kappa(\boldsymbol{\beta}) = \|(-\boldsymbol{\beta}, 1)\|_*$.*

Due to Theorem 2.1, (2) could be formulated as the following optimization problem:

$$\inf_{\boldsymbol{\beta}\in\mathcal{B}} \epsilon\|(-\boldsymbol{\beta}, 1)\|_* + \frac{1}{N}\sum_{i=1}^{N} |y_i - \mathbf{x}_i'\boldsymbol{\beta}|. \tag{10}$$

Note that the regularization term of (10) is the product of the *growth rate* of the loss and the Wasserstein ball radius. The growth rate is closely related to the way the Wasserstein metric defines the transportation costs on the data $(\mathbf{x}, y)$. As mentioned earlier, a zero growth rate diminishes the effect of the Wasserstein distributional uncertainty set, and the resulting formulation would simply be an empirical loss minimization problem. The parameter ϵ controls the conservativeness of the formulation, whose selection depends on the sample size, the dimensionality of the data, and the confidence that the Wasserstein ball contains the true distribution (see eq. (8) in Esfahani and Kuhn, 2015). Roughly speaking, when the sample size is large enough, and for a fixed confidence level, ϵ is inversely proportional to $N^{1/m}$.

Formulation (10) incorporates a class of models whose specific form depends on the norm space we choose, which could be application-dependent and practically useful. For example, when the Wasserstein metric s is induced by $\|\cdot\|_2$ and the set $\mathcal{B}$ is the intersection of a

polyhedron with convex quadratic inequalities, (10) is a convex quadratic problem which can be solved to optimality very efficiently. Specifically, it could be converted to:

$$\begin{aligned} \min_{a,\ b_1,\ldots,b_N,\ \boldsymbol{\beta}} \quad & a\epsilon + \frac{1}{N}\sum_{i=1}^{N} b_i \\ \text{s.t.} \quad & \|\boldsymbol{\beta}\|_2^2 + 1 \le a^2, \\ & y_i - \mathbf{x}_i'\boldsymbol{\beta} \le b_i,\ i = 1,\ldots,N, \\ & -(y_i - \mathbf{x}_i'\boldsymbol{\beta}) \le b_i,\ i = 1,\ldots,N, \\ & a,\ b_i \ge 0,\ i = 1,\ldots,N, \\ & \boldsymbol{\beta} \in \mathcal{B}. \end{aligned} \tag{11}$$

When the Wasserstein metric is defined using $\|\cdot\|_1$ and the set $\mathcal{B}$ is a polyhedron, (10) is a linear programming problem:

$$\begin{aligned} \min_{a,\ b_1,\ldots,b_N,\ \boldsymbol{\beta}} \quad & a\epsilon + \frac{1}{N}\sum_{i=1}^{N} b_i \\ \text{s.t.} \quad & a \ge \boldsymbol{\beta}'\mathbf{e}_i,\ i = 1,\ldots,m-1, \\ & a \ge -\boldsymbol{\beta}'\mathbf{e}_i,\ i = 1,\ldots,m-1, \\ & y_i - \mathbf{x}_i'\boldsymbol{\beta} \le b_i,\ i = 1,\ldots,N, \\ & -(y_i - \mathbf{x}_i'\boldsymbol{\beta}) \le b_i,\ i = 1,\ldots,N, \\ & a \ge 1, \\ & b_i \ge 0,\ i = 1,\ldots,N, \\ & \boldsymbol{\beta} \in \mathcal{B}. \end{aligned} \tag{12}$$

More generally, when the coordinates of $(\mathbf{x}, y)$ differ from each other substantially, a properly chosen, positive definite weight matrix $\mathbf{M} \in \mathbb{R}^{m\times m}$ could scale correspondingly different coordinates of $(\mathbf{x}, y)$ by using the $\mathbf{M}$-weighted norm:

$$\|(\mathbf{x}, y)\|_{\mathbf{M}} = \sqrt{(\mathbf{x}, y)'\mathbf{M}(\mathbf{x}, y)}.$$

It can be shown that (10) in this case becomes:

$$\inf_{\boldsymbol{\beta}\in\mathcal{B}} \epsilon\sqrt{(-\boldsymbol{\beta}, 1)'\mathbf{M}^{-1}(-\boldsymbol{\beta}, 1)} + \frac{1}{N}\sum_{i=1}^{N} |y_i - \mathbf{x}_i'\boldsymbol{\beta}|. \tag{13}$$

We note that this Wasserstein DRO framework could be applied to a broad class of loss functions and the tractable reformulations have been derived in Shafieezadeh-Abadeh et al. (2017); Gao et al. (2017) for regression and classification models. We adopt the absolute residual loss in this paper to enhance the robustness of the formulation, which is the focus of our work and serves the purpose of estimating robust parameters that are immunized against perturbations/outliers. Notice that (10) coincides with the regularized LAD models (Pollard, 1991; Wang et al., 2006), except that we are regularizing a variant of the regression coefficient. We would like to highlight several novel viewpoints that are

brought by the Wasserstein DRO framework and justify the value and novelty of (10). First, (10) is obtained as an outcome of a fundamental DRO formulation, which enables new interpretations of the regularizer from the standpoint of distributional robustness, and provides rigorous theoretical foundation on why the ℓ_2-regularizer prevents overfitting to the training data. The regularizer could be seen as a control over the amount of ambiguity in the data and reveals the reliability of the contaminated samples. Second, the geometry of the Wasserstein ball is embedded in the regularization term, which penalizes the regression coefficient on the dual Wasserstein space, with the magnitude of penalty being the radius of the ball. This offers an intuitive interpretation and provides guidance on how to set the regularization coefficient. Moreover, different from the traditional regularized LAD models that directly penalize the regression coefficient $\boldsymbol{\beta}$, we regularize the vector $(-\boldsymbol{\beta}, 1)$, where the 1 takes into account the transportation cost along the y direction. Penalizing only on $\boldsymbol{\beta}$ corresponds to an infinite transportation cost along y. Our model is more general in this sense, and establishes the connection between the metric space on data and the form of the regularizer.

3. Performance Guarantees

Having obtained a tractable reformulation for the Wasserstein DRO problem, we next establish guarantees on the predictive power and estimation quality for the solution to (10). Two types of results will be presented in this section, one of which bounds the prediction bias of the estimator on new, future data (given in Section 3.1). The other one that bounds the discrepancy between the estimated and true regression planes (estimation bias), is given in Section 3.2.

3.1 Out-of-Sample Performance

In this subsection we investigate generalization characteristics of the solution to (10), which involves measuring the error generated by our estimator on a new random sample $(\mathbf{x}, y)$. We would like to obtain estimates that not only explain the observed samples well, but, more importantly, possess strong generalization abilities. The derivation is mainly based on *Rademacher complexity* (see Bartlett and Mendelson, 2002), which is a measurement of the complexity of a class of functions. We would like to emphasize the applicability of such a proof technique to general loss functions, as long as their empirical Rademacher complexity could be bounded. The bound we derive for the prediction bias depends on both the sample average loss (the training error) and the dual norm of the regression coefficient (the regularizer), which corroborates the validity and necessity of our regularized formulation. Moreover, the generalization result also builds a connection between the loss function and the form of the regularizer via Rademacher complexity, which enables new insights into the regularization term and explains the commonly observed good out-of-sample performance of regularized regression in a rigorous way. We first make several mild assumptions that are needed for the generalization result.

Assumption A *The norm of the uncertainty parameter $(\mathbf{x}, y)$ is bounded above almost surely, i.e., $\|(\mathbf{x}, y)\| \leq R$.*

Assumption B *The dual norm of $(-\boldsymbol{\beta}, 1)$ is bounded above within the feasible region, namely,*

$$\sup_{\boldsymbol{\beta} \in \mathcal{B}} \|(-\boldsymbol{\beta}, 1)\|_* = \bar{B}.$$

Under these two assumptions, the absolute loss could be bounded via the Cauchy-Schwarz inequality.

Lemma 3.1 *For every feasible $\boldsymbol{\beta}$, it follows*

$$|y - \mathbf{x}'\boldsymbol{\beta}| \leq \bar{B}R, \quad \textit{almost surely.}$$

With the above result, the idea is to bound the generalization error using the empirical *Rademacher complexity* of the following class of loss functions:

$$\mathcal{H} = \{(\mathbf{x}, y) \mapsto h_{\boldsymbol{\beta}}(\mathbf{x}, y) : h_{\boldsymbol{\beta}}(\mathbf{x}, y) = |y - \mathbf{x}'\boldsymbol{\beta}|,\ \boldsymbol{\beta} \in \mathcal{B}\}.$$

We need to show that the empirical Rademacher complexity of $\mathcal{H}$, denoted by $\mathcal{R}_N(\mathcal{H})$, is upper bounded. The following result, similar to Lemma 3 in Bertsimas et al. (2015), provides a bound that is inversely proportional to the square root of the sample size.

Lemma 3.2

$$\mathcal{R}_N(\mathcal{H}) \leq \frac{2\bar{B}R}{\sqrt{N}}.$$

Let $\hat{\boldsymbol{\beta}}$ be an optimal solution to (10), obtained using the samples $(\mathbf{x}_i, y_i)$, $i = 1, \ldots, N$. Suppose we draw a new i.i.d. sample $(\mathbf{x}, y)$. In Theorem 3.3 we establish bounds on the error $|y - \mathbf{x}'\hat{\boldsymbol{\beta}}|$.

Theorem 3.3 *Under Assumptions A and B, for any $0 < \delta < 1$, with probability at least $1 - \delta$ with respect to the sampling,*

$$\mathbb{E}[|y - \mathbf{x}'\hat{\boldsymbol{\beta}}|] \leq \frac{1}{N}\sum_{i=1}^{N} |y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}| + \frac{2\bar{B}R}{\sqrt{N}} + \bar{B}R\sqrt{\frac{8\log(2/\delta)}{N}}\ , \tag{14}$$

and for any $\zeta > \frac{2\bar{B}R}{\sqrt{N}} + \bar{B}R\sqrt{\frac{8\log(2/\delta)}{N}}$,

$$\mathbb{P}\left(|y - \mathbf{x}'\hat{\boldsymbol{\beta}}| \geq \frac{1}{N}\sum_{i=1}^{N} |y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}| + \zeta\right) \leq \frac{\frac{1}{N}\sum_{i=1}^{N} |y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}| + \frac{2\bar{B}R}{\sqrt{N}} + \bar{B}R\sqrt{\frac{8\log(2/\delta)}{N}}}{\frac{1}{N}\sum_{i=1}^{N} |y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}| + \zeta}. \tag{15}$$

There are two probability measures in the statement of Theorem 3.3. One is related to the new data $(\mathbf{x}, y)$, while the other is related to the samples $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_N, y_N)$. The expectation in (14) (and the probability in (15)) is taken w.r.t. the new data $(\mathbf{x}, y)$. For a given set of samples, (14) (and (15)) holds with probability at least $1-\delta$ w.r.t. the measure of samples. Theorem 3.3 essentially says that given typical samples, the expected loss on new data using our Wasserstein DRO estimator could be bounded above by the average sample loss plus extra terms that depend on the supremum of $\|(-\boldsymbol{\beta}, 1)\|_*$ (our regularizer), and

are proportional to $1/\sqrt{N}$. This result validates the dual norm-based regularized regression from the perspective of generalization ability, and could be generalized to any bounded loss function. It also provides implications on the form of the regularizer. For example, if given an ℓ_2-loss function, the dependency on $\bar{B}$ for the generalization error bound will be of the form $\bar{B}^2$, which suggests using $\|(-\boldsymbol{\beta}, 1)\|_*^2$ as a regularizer, reducing to a variant of ridge regression (Hoerl and Kennard, 1970) for $\|\cdot\|_2$ induced Wasserstein metric.

We also note that the upper bounds in (14) and (15) do not depend on the dimension of $(\mathbf{x}, y)$. This dimensionality-free characteristic implies direct applicability of our Wasserstein approach to high-dimensional settings and is particularly useful in many real applications where, potentially, hundreds of features may be present. Theorem 3.3 also provides guidance on the number of samples that are needed to achieve satisfactory out-of-sample performance.

Corollary 3.4 *Suppose $\hat{\boldsymbol{\beta}}$ is the optimal solution to (10). For a fixed confidence level δ and some threshold parameter $\tau \geq 0$, to guarantee that the percentage difference between the expected absolute loss on new data and the sample average loss is less than τ, that is,*

$$\frac{\mathbb{E}[|y - \mathbf{x}'\hat{\boldsymbol{\beta}}|] - \frac{1}{N}\sum_{i=1}^N |y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}|}{\bar{B}R} \leq \tau,$$

the sample size N must satisfy

$$N \geq \left[\frac{2(1 + \sqrt{2\log(2/\delta)}\ )}{\tau}\right]^2. \tag{16}$$

Corollary 3.5 *Suppose $\hat{\boldsymbol{\beta}}$ is the optimal solution to (10). For a fixed confidence level δ, some $\tau \in (0, 1)$ and $\gamma \geq 0$, to guarantee that*

$$\mathbb{P}\left(\frac{|y - \mathbf{x}'\hat{\boldsymbol{\beta}}| - \frac{1}{N}\sum_{i=1}^N |y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}|}{\bar{B}R} \geq \gamma\right) \leq \tau,$$

the sample size N must satisfy

$$N \geq \left[\frac{2(1 + \sqrt{2\log(2/\delta)}\ )}{\tau \cdot \gamma + \tau - 1}\right]^2, \tag{17}$$

provided that $\tau \cdot \gamma + \tau - 1 > 0$.

In Corollaries 3.4 and 3.5, the sample size is inversely proportional to both δ and τ, which is reasonable since the more confident we want to be, the more samples we need. Moreover, the smaller τ is, the stricter a requirement we impose on the performance, and thus more samples are needed.

3.2 Discrepancy between Estimated and True Regression Planes

In addition to the generalization performance, we are also interested in the accuracy of the estimator. In this section we seek to bound the difference between the estimated and true regression coefficients, under a certain distributional assumption on $(\mathbf{x}, y)$. Throughout the

section we will use $\hat{\boldsymbol{\beta}}$ to denote the estimated regression coefficients, obtained as an optimal solution to (18), and $\boldsymbol{\beta}^*$ for the true (unknown) regression coefficients. The bound we will derive turns out to be related to the Gaussian width (see definition in the Appendix) of the unit ball in $\|\cdot\|_\infty$, the sub-Gaussian norm of the uncertainty parameter $(\mathbf{x}, y)$, as well as the geometric structure of the true regression coefficients. We note that this proof technique may be applied to several other loss functions, e.g., ℓ_2 and ℓ_∞ losses, with slight modifications. However, we will see that the ℓ_1-loss function incurs a relatively low estimation bias compared to others, further demonstrating the superiority of our absolute error minimization formulation.

To facilitate the analysis, we will use the following equivalent form of problem (10):

$$\begin{aligned} \min_{\boldsymbol{\beta}} \quad & \|(-\boldsymbol{\beta}, 1)\|_* \\ \text{s.t.} \quad & \|(-\boldsymbol{\beta}, 1)'\mathbf{Z}\|_1 \leq \gamma_N, \\ & \boldsymbol{\beta} \in \mathcal{B}, \end{aligned} \tag{18}$$

where $\mathbf{Z} = [(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_N, y_N)]$ is the matrix with columns $(\mathbf{x}_i, y_i), i = 1, \ldots, N$, and γ_N is some exogenous parameter related to ϵ. One can show that for properly chosen γ_N, (18) produces the same solution with (10) (Bertsekas, 1999). (18) is similar to (11) in Chen and Banerjee (2016), with the difference lying in that we impose a constraint on the error instead of the gradient, and we consider a more general notion of norm on the coefficient. On the other hand, due to their similarity, we will follow the line of development in Chen and Banerjee (2016). Still, our analysis is self-contained and the bound we obtain is in a different form, which provides meaningful insights into our specific problem. We list below the assumptions that are needed to bound the estimation error.

Assumption C *The ℓ_2 norm of $(-\boldsymbol{\beta}, 1)$ is bounded above within the feasible region, namely,*

$$\sup_{\boldsymbol{\beta} \in \mathcal{B}} \|(-\boldsymbol{\beta}, 1)\|_2 = \bar{B}_2.$$

Assumption D (Restricted Eigenvalue Condition) *For some set $\mathcal{A}(\boldsymbol{\beta}^*) = cone\{\mathbf{v} | \|(-\boldsymbol{\beta}^*, 1) + \mathbf{v}\|_* \leq \|(-\boldsymbol{\beta}^*, 1)\|_*\} \cap \mathbb{S}^m$ and some positive scalar $\underline{\alpha}$, where $\mathbb{S}^m$ is the unit sphere in the m-dimensional Euclidean space,*

$$\inf_{\mathbf{v} \in \mathcal{A}(\boldsymbol{\beta}^*)} \mathbf{v}'\mathbf{Z}\mathbf{Z}'\mathbf{v} \geq \underline{\alpha},$$

where $\mathbb{S}^m$ denotes the unit sphere in the m-dimensional Euclidean space.

Assumption E *The true coefficient $\boldsymbol{\beta}^*$ is a feasible solution to (18), i.e.,*

$$\|\mathbf{Z}'(-\boldsymbol{\beta}^*, 1)\|_1 \leq \gamma_N, \quad \boldsymbol{\beta}^* \in \mathcal{B}.$$

Assumption F *$(\mathbf{x}, y)$ is a centered sub-Gaussian random vector (see definition in the Appendix), i.e., it has zero mean and satisfies the following condition:*

$$\|\|(\mathbf{x}, y)\|\|_{\psi_2} = \sup_{\mathbf{u} \in \mathbb{S}^m} \left\|\left|(\mathbf{x}, y)'\mathbf{u}\right|\right\|_{\psi_2} \leq \mu.$$

Assumption G *The covariance matrix of* $(\mathbf{x}, y)$ *has bounded positive eigenvalues. Set* $\mathbf{\Gamma} = \mathbb{E}[(\mathbf{x}, y)(\mathbf{x}, y)']$*; then,*

$$0 < \lambda_{min} \triangleq \lambda_{min}(\mathbf{\Gamma}) \leq \lambda_{max}(\mathbf{\Gamma}) \triangleq \lambda_{max} < \infty.$$

Notice that both $\underline{\alpha}$ in Assumption D and γ_N in Assumption E are related to the random observation matrix $\mathbf{Z}$. A probabilistic description for these two quantities will be provided later. We next present a preliminary result, similar to Lemma 2 in Chen and Banerjee (2016), that bounds the ℓ_2-norm of the estimation bias in terms of a quantity that is related to the geometric structure of the true coefficients. This result gives a rough idea on the factors that affect the estimation error, and shows the advantages of using the ℓ_1-loss from the perspective of its dual norm. The bound derived in Theorem 3.6 is crude in the sense that it is a function of several random parameters that are related to the random observation matrix $\mathbf{Z}$. This randomness will be described in a probabilistic way in the subsequent analysis.

Theorem 3.6 *Suppose the true regression coefficient vector is* $\boldsymbol{\beta}^*$ *and the solution to (18) is* $\hat{\boldsymbol{\beta}}$*. For the set* $\mathcal{A}(\boldsymbol{\beta}^*) = cone\{\mathbf{v} |\ \|(-\boldsymbol{\beta}^*, 1) + \mathbf{v}\|_* \leq \|(-\boldsymbol{\beta}^*, 1)\|_*\} \cap \mathbb{S}^m$*, under Assumptions A, D, and E, we have:*

$$\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*\|_2 \leq \frac{2R\gamma_N}{\underline{\alpha}} \Psi(\boldsymbol{\beta}^*), \tag{19}$$

where $\Psi(\boldsymbol{\beta}^*) = \sup_{\mathbf{v} \in \mathcal{A}(\boldsymbol{\beta}^*)} \|\mathbf{v}\|_*$.

Notice that the bound in (19) does not explicitly depend on the sample size N. If we change to the ℓ_2-loss function, problem (18) will become:

$$\begin{aligned} \min_{\boldsymbol{\beta}} \quad & \|(-\boldsymbol{\beta}, 1)\|_* \\ \text{s.t.} \quad & \|(-\boldsymbol{\beta}, 1)'\mathbf{Z}\|_2 \leq \gamma_N, \\ & \boldsymbol{\beta} \in \mathcal{B}. \end{aligned}$$

The proof of Theorem 3.6 still applies with slight modification. We will find out that in the case of ℓ_2-loss, the estimation error bound takes the following form:

$$\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*\|_2 \leq \frac{2R\sqrt{N}\gamma_N}{\underline{\alpha}} \Psi(\boldsymbol{\beta}^*).$$

Similarly, the ℓ_∞-loss, which considers only the maximum absolute loss among the samples, turns (18) into:

$$\begin{aligned} \min_{\boldsymbol{\beta}} \quad & \|(-\boldsymbol{\beta}, 1)\|_* \\ \text{s.t.} \quad & \|(-\boldsymbol{\beta}, 1)'\mathbf{Z}\|_\infty \leq \gamma_N, \\ & \boldsymbol{\beta} \in \mathcal{B}. \end{aligned}$$

The corresponding bound becomes:

$$\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*\|_2 \leq \frac{2RN\gamma_N}{\underline{\alpha}} \Psi(\boldsymbol{\beta}^*).$$

We see that by using either ℓ_2 or ℓ_∞-loss, an explicit dependency on N is introduced. As a result, the estimation error bounds become worse. The reason is that for the ℓ_1-loss function, its dual norm operator only picks out the maximum absolute coordinate and thus avoids the dependence on the dimension, which in our case is the sample size (see Eq.(28)), whereas other norms, e.g., ℓ_2-norm, sum over all the coordinates and thus introduce a dependence on N.

As mentioned earlier, (19) provides a random upper bound, revealed in $\underline{\alpha}$ and γ_N, that depends on the randomness in $\mathbf{Z}$. We therefore would like to replace these two parameters by non-random quantities. The $\underline{\alpha}$ acts as the minimum eigenvalue of the matrix $\mathbf{ZZ}'$ restricted to a subspace of $\mathbb{R}^m$, and thus a proper substitute should be related to the minimum eigenvalue of the covariance matrix of $(\mathbf{x}, y)$, i.e., the $\mathbf{\Gamma}$ matrix (cf. Assumption G), given that $(\mathbf{x}, y)$ is zero mean. See Lemmas 3.7, 3.8 and 3.9 for the derivation.

Lemma 3.7 *Consider the set* $\mathcal{A}_{\mathbf{\Gamma}} = \{\mathbf{w} \in \mathbb{S}^m | \mathbf{\Gamma}^{-1/2}\mathbf{w} \in cone(\mathcal{A}(\boldsymbol{\beta}^*))\}$*, where* $\mathcal{A}(\boldsymbol{\beta}^*)$ *is defined as in Theorem 3.6, and* $\mathbf{\Gamma} = \mathbb{E}[(\mathbf{x}, y)(\mathbf{x}, y)']$*. Under Assumptions F and G, when the sample size* $N \geq C_1 \bar{\mu}^4 (w(\mathcal{A}_{\mathbf{\Gamma}}))^2$*, where* $\bar{\mu} = \mu\sqrt{\frac{1}{\lambda_{min}}}$*, and* $w(\mathcal{A}_{\mathbf{\Gamma}})$ *is the Gaussian width of* $\mathcal{A}_{\mathbf{\Gamma}}$*, with probability at least* $1 - \exp(-C_2 N/\bar{\mu}^4)$*, we have*

$$\mathbf{v}'\mathbf{ZZ}'\mathbf{v} \geq \frac{N}{2}\mathbf{v}'\mathbf{\Gamma}\mathbf{v}, \quad \forall\ \mathbf{v} \in \mathcal{A}(\boldsymbol{\beta}^*),$$

where C_1 *and* C_2 *are positive constants.*

Note that the sample size requirement stated in Lemma 3.7 depends on the Gaussian width of $\mathcal{A}_{\mathbf{\Gamma}}$, where $\mathcal{A}_{\mathbf{\Gamma}}$ relates to $\mathcal{A}(\boldsymbol{\beta}^*)$. The following lemma shows that their Gaussian widths are also related. This relation is built upon the square root of the eigenvalues of $\mathbf{\Gamma}$, which measures the extent to which $\mathcal{A}_{\mathbf{\Gamma}}$ expands $\mathcal{A}(\boldsymbol{\beta}^*)$.

Lemma 3.8 (Lemma 4 in Chen and Banerjee (2016)) *Let* μ_0 *be the* ψ_2*-norm of a standard Gaussian random vector* $\mathbf{g} \in \mathbb{R}^m$*, and* $\mathcal{A}_{\mathbf{\Gamma}}$*,* $\mathcal{A}(\boldsymbol{\beta}^*)$ *be defined as in Lemma 3.7. Then, under Assumption G,*

$$w(\mathcal{A}_{\mathbf{\Gamma}}) \leq C_3 \mu_0 \sqrt{\frac{\lambda_{max}}{\lambda_{min}}} \Big(w(\mathcal{A}(\boldsymbol{\beta}^*)) + 3 \Big),$$

for some positive constant C_3*.*

Combining Lemmas 3.7 and 3.8, and expressing the covariance matrix $\mathbf{\Gamma}$ using its eigenvalues, we arrive at the following result.

Corollary 3.9 *Under Assumptions F and G, and the conditions in Lemmas 3.7 and 3.8, when* $N \geq \bar{C}_1 \bar{\mu}^4 \mu_0^2 \cdot \frac{\lambda_{max}}{\lambda_{min}} \Big(w(\mathcal{A}(\boldsymbol{\beta}^*)) + 3 \Big)^2$*, with probability at least* $1 - \exp(-C_2 N/\bar{\mu}^4)$*,*

$$\mathbf{v}'\mathbf{ZZ}'\mathbf{v} \geq \frac{N\lambda_{min}}{2}, \quad \forall\ \mathbf{v} \in \mathcal{A}(\boldsymbol{\beta}^*),$$

where $\bar{C}_1$ *and* C_2 *are positive constants.*

Next, we derive the smallest possible value of γ_N such that $\boldsymbol{\beta}^*$ is feasible. The derivation uses the dual norm operator of the ℓ_1-loss, resulting in a bound that depends on the Gaussian width of the unit ball in the dual norm space ($\|\cdot\|_\infty$). See Lemma 3.10 for details.

Lemma 3.10 *Under Assumptions C and F, for any feasible $\boldsymbol{\beta}$, with probability at least $1 - C_4 \exp(-\frac{C_5^2 (w(\mathcal{B}_u))^2}{4\rho^2})$,*

$$\|(-\boldsymbol{\beta}, 1)'\mathbf{Z}\|_1 \leq C\mu \bar{B}_2 w(\mathcal{B}_u),$$

where $\mathcal{B}_u$ is the unit ball of norm $\|\cdot\|_\infty$, $\rho = \sup_{\mathbf{v}\in\mathcal{B}_u} \|\mathbf{v}\|_2$, and C_4, C_5, C positive constants.

We note that for other loss functions, e.g., the ℓ_2 and ℓ_∞ losses, similar results can be obtained, where $\mathcal{B}_u$ is defined to be the unit $\|\cdot\|_*^{\text{loss}}$-ball in $\mathbb{R}^m$, with $\|\cdot\|_*^{\text{loss}}$ being the dual norm of the loss. Combining Theorem 3.6, Corollary 3.9 and Lemma 3.10, we have the following main performance guarantee result that bounds the estimation bias of the solution to (18).

Theorem 3.11 *Under Assumptions A, C, D, E, F, G, and the conditions of Theorem 3.6, Corollary 3.9 and Lemma 3.10, when $N \geq \bar{C}_1 \bar{\mu}^4 \mu_0^2 \cdot \frac{\lambda_{max}}{\lambda_{min}} \Big(w(\mathcal{A}(\boldsymbol{\beta}^*)) + 3 \Big)^2$, with probability at least $1 - \exp(-C_2 N/\bar{\mu}^4) - C_4 \exp(-C_5^2 (w(\mathcal{B}_u))^2/(4\rho^2))$,*

$$\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*\|_2 \leq \frac{\bar{C} R \bar{B}_2 \mu}{N \lambda_{min}} w(\mathcal{B}_u) \Psi(\boldsymbol{\beta}^*). \tag{20}$$

From (20) we see that the bias is decreased as the sample size increases and the uncertainty embedded in $(\mathbf{x}, y)$ (revealed in R and μ) is reduced. The estimation error bound depends on the geometric structure of the true coefficients, defined using the dual norm space of the Wasserstein metric, the Gaussian width of the unit $\|\cdot\|_*^{\text{loss}}$-ball in $\mathbb{R}^m$, and the minimum eigenvalue of the covariance matrix of $(\mathbf{x}, y)$, with a convergence rate $1/N$ for the ℓ_1-loss we applied. As mentioned earlier, other loss functions may incur a dependence on N in the numerator of the bound, thus resulting in a slower convergence rate, which substantiates the benefit of using an ℓ_1-loss function.

4. Simulation Experiments on Synthetic Datasets

In this section we will explore the robustness of the Wasserstein formulation in terms of its *Absolute Deviation (AD)* loss function and the dual norm regularizer on the *extended regression coefficient* $(-\boldsymbol{\beta}, 1)$. Recall that our Wasserstein formulation is in the following form:

$$\inf_{\boldsymbol{\beta}\in\mathcal{B}} \frac{1}{N} \sum_{i=1}^{N} |y_i - \mathbf{x}_i'\boldsymbol{\beta}| + \epsilon \|(-\boldsymbol{\beta}, 1)\|_*. \tag{21}$$

We will focus on the following three aspects of this formulation:

1. How to choose a proper norm $\|\cdot\|$ for the Wasserstein metric?
2. Why do we penalize the extended regression coefficient $(-\boldsymbol{\beta}, 1)$ rather than $\boldsymbol{\beta}$?
3. What is the advantage of the AD loss compared to the *Squared Residuals (SR)* loss?

To answer Question 1, we will connect the choice of $\|\cdot\|$ for the Wasserstein metric with the characteristics/structures of the data $(\mathbf{x}, y)$. Specifically, we will design two sets of experiments, one with a dense regression coefficient $\boldsymbol{\beta}^*$, where all coordinates of $\mathbf{x}$ play a role in determining the value of the response y, and another with a sparse $\boldsymbol{\beta}^*$ implying that only a few predictors are relevant/important in predicting y. Two Wasserstein formulations will be tested and compared, one induced by the $\|\cdot\|_2$ (Wasserstein ℓ_2), which leads to an ℓ_2-regularizer in (21), and the other one induced by the $\|\cdot\|_\infty$ (Wasserstein ℓ_∞) and resulting in an ℓ_1-regularizer in (21). Intuitively, and based on the past experience in implementing the regularization techniques, the Wasserstein ℓ_2 should outperform the Wasserstein ℓ_∞ in the dense setting, while in the sparse setting, the reverse is true. Researchers have well identified the sparsity inducing property of the ℓ_1-regularizer and provided a nice geometrical interpretation for it (Friedman et al., 2001). Here, we try to offer a different explanation from the perspective of the Wasserstein DRO formulation, through projecting the sparsity of $\boldsymbol{\beta}^*$ onto the $(\mathbf{x}, y)$ space and establishing a *sparse* distance metric that only extracts a subset of coordinates from $(\mathbf{x}, y)$ to measure the closeness between samples.

For the second question, we first note that if the Wasserstein metric is induced by the following metric s_c:

$$s_c(\mathbf{x}, y) = \|(\mathbf{x}, cy)\|_2,$$

for a positive constant c, then as $c \to \infty$, the resulting Wasserstein DRO formulation becomes:

$$\inf_{\boldsymbol{\beta}\in\mathcal{B}} \frac{1}{N} \sum_{i=1}^{N} |y_i - \mathbf{x}_i'\boldsymbol{\beta}| + \epsilon \|\boldsymbol{\beta}\|_2,$$

which is the ℓ_2-regularized LAD. This can be proved by recognizing that $s_c(\mathbf{x}, y) = \|(\mathbf{x}, y)\|_{\mathbf{M}}$, with $\mathbf{M} \in \mathbb{R}^{m\times m}$ a diagonal matrix whose diagonal elements are $(1, \ldots, 1, c^2)$, and then applying (13). Alternatively, if we let

$$s_c(\mathbf{x}, y) = \|(\mathbf{x}, cy)\|_\infty,$$

it can be shown that as $c \to \infty$, the corresponding Wasserstein formulation becomes:

$$\inf_{\boldsymbol{\beta}\in\mathcal{B}} \frac{1}{N} \sum_{i=1}^{N} |y_i - \mathbf{x}_i'\boldsymbol{\beta}| + \epsilon \|\boldsymbol{\beta}\|_1,$$

which is the ℓ_1-regularized LAD (see proof in the Appendix). It follows that regularizing over $\boldsymbol{\beta}$ implies an infinite transportation cost along y. In other words, for two data points $(\mathbf{x}_1, y_1)$ and $(\mathbf{x}_2, y_2)$, if $y_1 \neq y_2$, then they are considered to be infinitely far away. By contrast, our Wasserstein formulation, which regularizes over the extended regression coefficient $(-\boldsymbol{\beta}, 1)$, stems from a finite cost along y that is equally weighted with $\mathbf{x}$. We will see the disadvantages of penalizing only $\boldsymbol{\beta}$ in the analysis of the experimental results.

To answer Question 3, we will compare against several commonly used regression models that employ the SR loss function, e.g., ridge regression (Hoerl and Kennard, 1970), LASSO (Tibshirani, 1996), and *Elastic Net (EN)* (Zou and Hastie, 2005). We will also compare against M-estimation (Huber, 1964, 1973), which uses a variant of the SR loss and is equivalent to solving a weighted least squares problem, where the weights are determined

by the residuals. These models will be compared under two different experimental setups, one involving adversarial perturbations in both $\mathbf{x}$ and y, and the other with perturbations only in $\mathbf{x}$. The purpose is to investigate the behavior of these approaches when the noise in y is substantially reduced. As shown by Fig. 1, compared to the SR loss, the AD loss is less vulnerable to large residuals, and hence, it is advantageous in the scenarios where large perturbations appear in y. We are interested in studying whether its performance is consistently good when the corruptions appear mainly in $\mathbf{x}$.

We next describe the data generation process. Each training sample has a probability q of being drawn from the outlying distribution, and a probability $1-q$ of being drawn from the true (clean) distribution. Given the true regression coefficient $\boldsymbol{\beta}^*$, we generate the training data as follows:

- Generate a uniform random variable on $[0,1]$. If it is no larger than $1-q$, generate a clean sample as follows:
  1. Draw the predictor $\mathbf{x} \in \mathbb{R}^{m-1}$ from the normal distribution $N_{m-1}(\mathbf{0}, \boldsymbol{\Sigma})$, where $\boldsymbol{\Sigma}$ is the covariance matrix of $\mathbf{x}$, which is just the top left block of the matrix $\boldsymbol{\Gamma}$ in Assumption G. Specifically, $\boldsymbol{\Gamma} = \mathbb{E}[(\mathbf{x}, y)(\mathbf{x}, y)']$ is equal to
  $$\boldsymbol{\Gamma} = \begin{pmatrix} \boldsymbol{\Sigma} & \boldsymbol{\Sigma}\boldsymbol{\beta}^* \\ (\boldsymbol{\beta}^*)'\boldsymbol{\Sigma} & (\boldsymbol{\beta}^*)'\boldsymbol{\Sigma}\boldsymbol{\beta}^* + \sigma^2 \end{pmatrix},$$
  with σ^2 being the variance of the noise term. In our implementation, $\boldsymbol{\Sigma}$ has diagonal elements equal to 1 (unit variance) and off-diagonal elements equal to ρ, with ρ the correlation between predictors.
  2. Draw the response variable y from $N(\mathbf{x}'\boldsymbol{\beta}^*, \sigma^2)$.
- Otherwise, depending on the experimental setup, generate an outlier that is either:
  - Abnormal in both $\mathbf{x}$ and y, with outlying distribution:
    1. $\mathbf{x} \sim N_{m-1}(\mathbf{0}, \boldsymbol{\Sigma}) + N_{m-1}(5\mathbf{e}, \mathbf{I})$, or $\mathbf{x} \sim N_{m-1}(\mathbf{0}, \boldsymbol{\Sigma}) + N_{m-1}(\mathbf{0}, 0.25\mathbf{I})$;
    2. $y \sim N(\mathbf{x}'\boldsymbol{\beta}^*, \sigma^2) + 5\sigma$.
  - Abnormal only in $\mathbf{x}$:
    1. $\mathbf{x} \sim N_{m-1}(\mathbf{0}, \boldsymbol{\Sigma}) + N_{m-1}(5\mathbf{e}, \mathbf{I})$;
    2. $y \sim N(\mathbf{x}'\boldsymbol{\beta}^*, \sigma^2)$.
- Repeat the above procedure for N times, where N is the size of the training set.

To test the generalization ability of various formulations, we generate a test dataset containing M samples from the clean distribution. It is worth noting that only clean samples are included in the test set, since we only care about the prediction accuracy on clean data points, and our estimator is supposed to be consistent with the clean distribution and stay away from the outlying one. We are interested in studying the performance of various methods as the following factors are varied:

- *Signal to Noise Ratio (SNR)*, defined as:
  $$\text{SNR} = \frac{(\boldsymbol{\beta}^*)'\boldsymbol{\Sigma}\boldsymbol{\beta}^*}{\sigma^2},$$
  which is equally spaced between 0.05 and 2 on a log scale.
- The correlation between predictors: ρ, which takes values in $(0.1, 0.2, \ldots, 0.9)$.

The performance metrics we use include:

- *Mean Squared Error (MSE)* on the test dataset, which is defined to be $\sum_{i=1}^{M}(y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}})^2/M$, with $\hat{\boldsymbol{\beta}}$ being the estimate of $\boldsymbol{\beta}^*$ obtained from the training set, and $(\mathbf{x}_i, y_i),\ i = 1, \ldots, M$, being the observations from the test dataset;
- *Relative Risk (RR)* of $\hat{\boldsymbol{\beta}}$ defined as:
  $$\text{RR}(\hat{\boldsymbol{\beta}}) \triangleq \frac{(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*)'\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*)}{(\boldsymbol{\beta}^*)'\boldsymbol{\Sigma}\boldsymbol{\beta}^*}.$$
- *Relative Test Error (RTE)* of $\hat{\boldsymbol{\beta}}$ defined as:
  $$\text{RTE}(\hat{\boldsymbol{\beta}}) \triangleq \frac{(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*)'\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*) + \sigma^2}{\sigma^2}.$$
- *Proportion of Variance Explained (PVE)* of $\hat{\boldsymbol{\beta}}$ defined as:
  $$\text{PVE}(\hat{\boldsymbol{\beta}}) \triangleq 1 - \frac{(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*)'\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*) + \sigma^2}{(\boldsymbol{\beta}^*)'\boldsymbol{\Sigma}\boldsymbol{\beta}^* + \sigma^2}.$$

For the metrics that evaluate the accuracy of the estimator, i.e., the RR, RTE and PVE, we list below two types of scores, one achieved by the best possible estimator $\hat{\boldsymbol{\beta}} = \boldsymbol{\beta}^*$, called the perfect score, and the other one achieved by the null estimator $\hat{\boldsymbol{\beta}} = 0$, called the null score.

- RR: a perfect score is 0 and the null score is 1.
- RTE: a perfect score is 1 and the null score is SNR+1.
- PVE: a perfect score is $\frac{\text{SNR}}{\text{SNR}+1}$, and the null score is 0.

During the training process, all the regularization parameters are tuned on a separate validation dataset. Specifically, we divide all the N training samples into two sets, dataset 1 and dataset 2 (validation set). For a pre-specified range of values for the penalty parameters, dataset 1 is used to train the models and derive $\hat{\boldsymbol{\beta}}$, and the performance of $\hat{\boldsymbol{\beta}}$ is evaluated on dataset 2. We choose the regularization parameter that yields the minimum *Median Absolute Deviation (MAD)* on the validation set. Using MAD as a selection criterion serves to hedge against the potentially large noise in the validation samples. As to the range of values for the tuned parameters, we borrow ideas from Hastie et al. (2017), where the

LASSO was tuned over 50 values ranging from $\lambda_m = \|\mathbf{X}'\mathbf{y}\|_\infty$ to a small fraction of λ_m on a log scale, with $\mathbf{X} \in \mathbb{R}^{N\times(m-1)}$ the design matrix whose i-th row is $\mathbf{x}_i'$, and $\mathbf{y} = (y_1, \ldots, y_N)$ the response vector. In our experiments, this range is properly adjusted for procedures that use the AD loss. Specifically, for Wasserstein ℓ_2 and ℓ_∞, ℓ_1- and ℓ_2-regularized LAD, the range of values for the regularization parameter is:

$$\sqrt{\exp\Big(\mathrm{lin}\Big(\log(0.005 * \|\mathbf{X}'\mathbf{y}\|_\infty), \log(\|\mathbf{X}'\mathbf{y}\|_\infty), 50\Big)\Big)},$$

where $\mathrm{lin}(a, b, n)$ is a function that takes in scalars a, b and n (integer) and outputs a set of n values equally spaced between a and b; the exp function is applied elementwise to a vector. The square root operator is in consideration of the AD loss that is the square root of the SR loss if evaluated on a single sample.

The regularization coefficient ϵ in formulation (10), which is the radius of the Wasserstein ball, allows for a more efficient tuning procedure. It has been noted in Esfahani and Kuhn (2015) that for a large enough sample size, ϵ is inversely proportional to $N^{1/m}$. This proportionality could be used as a guidance on setting ϵ, where only the proportional factor needs to be tuned (using cross-validation or a separate validation dataset as described earlier). In our implementation, given the small size of the simulated datasets, we will still adopt the validation dataset approach to tune the regularization parameter.

4.1 Dense $\boldsymbol{\beta}^*$, outliers in both $\mathbf{x}$ and y

In this subsection, we choose a dense regression coefficient $\boldsymbol{\beta}^*$, set the intercept $\beta_0^* = 0.3$, and the coefficient for each predictor x_i to be $\beta_i^* = 0.5, i = 1, \ldots, 20$. The adversarial perturbations are present in both $\mathbf{x}$ and y. Specifically, the outlying distribution is described by:

1. $\mathbf{x} \sim N_{m-1}(\mathbf{0}, \boldsymbol{\Sigma}) + N_{m-1}(5\mathbf{e}, \mathbf{I})$;
2. $y \sim N(\mathbf{x}'\boldsymbol{\beta}^*, \sigma^2) + 5\sigma$.

We generate 10 datasets consisting of $N = 100, M = 60$ observations. The probability of a training sample being drawn from the outlying distribution is $q = 30\%$. The mean values of the performance metrics (averaged over the 10 datasets), as we vary the SNR and the correlation between predictors, are shown in Figs. 3 and 4. Note that when SNR is varied, the correlation between predictors is set to 0.8 times a random noise uniformly distributed on the interval $[0.2, 0.4]$. When the correlation ρ is varied, the SNR is fixed to 0.5.

It can be seen that as the SNR decreases or the correlation between the predictors increases, the estimation problem becomes harder, and the performance of all approaches gets worse. In general the Wasserstein ℓ_2 achieves the best performance in terms of all four metrics. Specifically,

- It is better than the ℓ_2-regularized LAD, which assumes an infinite transportation cost along y.
- It is better than the Wasserstein ℓ_∞ and ℓ_1-regularized LAD which use the ℓ_1-regularizer.

- It is better than the approaches that use the SR loss function.

Empirically we have found out that in most cases, the approaches that use the AD loss, including the ℓ_1- and ℓ_2-regularized LAD, and the Wasserstein ℓ_∞ formulation, drive all the coordinates of $\boldsymbol{\beta}$ to zero, due to the relatively small magnitude of the AD loss compared to the norm of the coefficient, so that the regularizer dominates the solution. The approaches that use the SR loss, e.g., ridge regression and EN, do not exhibit such a problem, since the squared residuals weaken the dominance of the regularization term.

Overall the ℓ_2-regularizer outperforms the ℓ_1-regularizer, since the true regression coefficient is dense, which implies that a proper distance metric on the $(\mathbf{x}, y)$ space should take into account all the coordinates. From the perspective of the Wasserstein DRO framework, the ℓ_1-regularizer corresponds to an $\|\cdot\|_\infty$-based distance metric on the $(\mathbf{x}, y)$ space that only picks out the most influential coordinate to determine the closeness between data points, which in our case is not reasonable since every coordinate plays a role (reflected in the dense $\boldsymbol{\beta}^*$). In contrast, if $\boldsymbol{\beta}^*$ is sparse, using the $\|\cdot\|_\infty$ as a distance metric on $(\mathbf{x}, y)$ is more appropriate. A more detailed discussion of this will be presented in Sections 4.3 and 4.4.

4.2 Dense $\boldsymbol{\beta}^*$, outliers only in $\mathbf{x}$

In this subsection we will experiment with the same $\boldsymbol{\beta}^*$ as in Section 4.1, but with perturbations only in $\mathbf{x}$, i.e., for a given $\mathbf{x}$ of the outlier, the corresponding y value is drawn in the same way as the clean samples. Our goal is to investigate the performance of the Wasserstein formulation when the response y is not subjected to large perturbations. The motivation for introducing the AD loss in the Wasserstein formulation is to hedge against large residuals, as illustrated in Fig. 1. We are interested in comparing the AD and SR loss functions when the residuals have moderate magnitudes.

Interestingly, we have observed that although the ℓ_1- and ℓ_2-regularized LAD, as well as the Wasserstein ℓ_∞ formulation, exhibit unsatisfactory performance, the Wasserstein ℓ_2, which shares the same loss function with them, is able to achieve a comparable performance with the best among all – EN and ridge regression (see Figs. 5 and 6). Notably, the ℓ_2-regularized LAD, which is just slightly different from our Wasserstein ℓ_2 formulation, shows a much worse performance. This is because the ℓ_2-regularized LAD implicitly assumes an infinite transportation cost along y, which gives zero tolerance to the variation in the response. For example, given two data points $(\mathbf{x}_1, y_1)$ and $(\mathbf{x}_2, y_2)$, as long as $y_1 \neq y_2$, the distance between them is infinity. Therefore, a reasonable amount of fluctuation, caused by the intrinsic randomness of y, would be overly exaggerated by the underlying metric used by the ℓ_2-regularized LAD. In contrast, our Wasserstein approach uses a proper notion of norm to evaluate the distance in the $(\mathbf{x}, y)$ space and is able to effectively distinguish abnormally high variations from moderate, acceptable noise.

It is also worth noting that the formulations with the AD loss, e.g., ℓ_2- and ℓ_1-regularized LAD, and the Wasserstein ℓ_∞, perform worse than the approaches with the SR loss. One reasonable explanation is that the AD loss, introduced primarily for hedging against large perturbations in y, is less useful when the noise in y is moderate, in which case the sensitivity to response noise is needed. Although the AD loss is not a wise choice, penalizing

the extended coefficient vector $(-\boldsymbol{\beta}, 1)$ seems to make up, making the Wasserstein ℓ_2 a competitive method even when the perturbations appear only in $\mathbf{x}$.

4.3 Sparse $\boldsymbol{\beta}^*$, outliers in both x and y

In this subsection we will experiment with a sparse $\boldsymbol{\beta}^*$. The intercept is set to $\beta_0^* = 3$, and the coefficients for the 20 predictors are set to $\boldsymbol{\beta}^* = (0.05, 0, 0.006, 0, -0.007, 0, 0.008, 0, \ldots, 0)$. The adversarial perturbations are present in both $\mathbf{x}$ and y. Specifically, the distribution of outliers is characterized by:

1. $\mathbf{x} \sim N_{m-1}(\mathbf{0}, \boldsymbol{\Sigma}) + N_{m-1}(\mathbf{0}, 0.25\mathbf{I})$;
2. $y \sim N(\mathbf{x}'\boldsymbol{\beta}^*, \sigma^2) + 5\sigma$.

Our goal is to study the impact of the sparsity of $\boldsymbol{\beta}^*$ on the choice of the norm space for the Wasserstein metric. We know that the ℓ_1-regularizer works better than the ℓ_2-regularizer for sparse data, which has been validated by our results in Figs. 7 and 8. We will see that the Wasserstein ℓ_∞ formulation significantly outperforms the Wasserstein ℓ_2. An intuitively appealing interpretation for the sparsity inducing property of the ℓ_1-regularizer is made available by the Wasserstein DRO framework, which we explain as follows. The sparse regression coefficient $\boldsymbol{\beta}^*$ implies that only a few predictors are relevant to the regression model, and thus when measuring the distance in the $(\mathbf{x}, y)$ space, we need a metric that only extracts the subset of relevant predictors. The $\|\cdot\|_\infty$, which takes only the most influential coordinate of its argument, roughly serves this purpose. Compared to the $\|\cdot\|_2$ which takes into account all the coordinates, most of which are redundant due to the sparsity assumption, $\|\cdot\|_\infty$ results in a better performance, and hence, the Wasserstein ℓ_∞ formulation that stems from the $\|\cdot\|_\infty$ distance metric on $(\mathbf{x}, y)$ and induces the ℓ_1-regularizer is expected to outperform others.

We note that the ℓ_1-regularized LAD achieves similar performance to ours, since replacing $\|\boldsymbol{\beta}\|_1$ by $\|(-\boldsymbol{\beta}, 1)\|_1$ only adds a constant term to the objective function. The generalization performance (mean MSE) of the AD loss-based formulations is consistently better than those with the SR loss, since the AD loss is less affected by large perturbations in y. Also note that choosing a wrong norm for the Wasserstein metric, e.g., the Wasserstein ℓ_2, could lead to an enormous estimation error, whereas with a right norm space, we are guaranteed to outperform all others. Even when the SNR is very low, our performance is at least as good as the null estimator (see Fig. 7). Although EN and LASSO achieve similar performance to ours for moderate SNR values, they have a chance of performing even worse than the null estimator when there is little signal/information to learn from.

4.4 Sparse $\boldsymbol{\beta}^*$, outliers only in x

In this subsection, we will use the same sparse coefficient as in Section 4.3, but the perturbations are present only in $\mathbf{x}$. Specifically, for outliers, their predictors and responses are drawn from the following distributions:

1. $\mathbf{x} \sim N_{m-1}(\mathbf{0}, \boldsymbol{\Sigma}) + N_{m-1}(5\mathbf{e}, \mathbf{I})$;
2. $y \sim N(\mathbf{x}'\boldsymbol{\beta}^*, \sigma^2)$.

Figure 8: The impact of predictor correlation on the performance metrics: sparse $\boldsymbol{\beta}^*$, outliers in both $\mathbf{x}$ and y.

Not surprisingly, the Wasserstein ℓ_∞ and the ℓ_1-regularized LAD achieve the best performance. Notice that in Section 4.3, where perturbations appear in both $\mathbf{x}$ and y, the AD loss-based formulations have smaller generalization and estimation errors than the SR loss-based formulations. When we reduce the variation in y, the SR loss seems superior to the AD loss, if we restrict attention to the improperly regularized (ℓ_2-regularizer) formulations (see Fig. 9). For the ℓ_1-regularized formulations, our Wasserstein ℓ_∞ formulation, as well as the ℓ_1-regularized LAD, is comparable with the EN and LASSO. Moreover, when there is little information to utilize (low SNR), EN and LASSO are worse than the null estimator, whereas our performance is at least as good as the null estimator.

We summarize below our main findings from all sets of experiments we have presented:

1. When a proper norm space is selected for the Wasserstein metric, the Wasserstein DRO formulation outperforms all others in terms of the generalization and estimation qualities.

2. Penalizing the extended regression coefficient $(-\boldsymbol{\beta}, 1)$ implicitly assumes a more reasonable distance metric on $(\mathbf{x}, y)$ and thus leads to a better performance.

3. The AD loss is remarkably superior to the SR loss when there is large variation in the response y.

4. The Wasserstein DRO formulation shows a more stable estimation performance than others when the correlation between predictors is varied.

4.5 An outlier detection example

As an application, we consider an unlabeled two-class classification problem, where our goal is to identify the abnormal class of data points based on the predictor and response information using the Wasserstein formulation. We do not know a priori whether the samples are normal or abnormal, and thus classification models do not apply. The commonly used regression model for this type of problem is the M-estimation (Huber, 1964, 1973), against which we will compare in terms of the outlier detection capability.

The data are generated in the same fashion as before. For clean samples, all predictors $x_1, \ldots, x_{30}$ come from a normal distribution with mean 7.5 and standard deviation 4.0. The response is a linear function of the predictors with $\beta_0^* = 0.3$, $\beta_1^* = \cdots = \beta_{30}^* = 0.5$, plus a Gaussian distributed noise term with zero mean and standard deviation σ. The outliers concentrate in a cloud that is randomly placed in the interior of the $\mathbf{x}$-space. Specifically, their predictors are uniformly distributed on $(u - 0.125, u + 0.125)$, where u is a uniform random variable on $(7.5 - 3 \times 4, 7.5 + 3 \times 4)$. The response values of the outliers are at a δ_R distance off the regression plane.

$$y = \beta_0^* + \beta_1^* x_1 + \cdots + \beta_{30}^* x_{30} + \delta_R.$$

We will compare the performance of the Wasserstein ℓ_2 formulation (10) with the ℓ_1-regularized LAD and M-estimation with three cost functions – Huber (Huber, 1964, 1973), Talwar (Hinich and Talwar, 1975), and Fair (Fair, 1974). The performance metrics include

the *Receiver Operating Characteristic (ROC)* curve which plots the true positive rate against the false positive rate, and the related *Area Under Curve (AUC)*.

Notice that all the regression methods under consideration only generate an estimated regression coefficient. The identification of outliers is based on the residual and estimated standard deviation of the noise. Specifically,

$$\text{Outlier} = \begin{cases} \text{YES}, & \text{if } |\text{residual}| > \text{threshold} \times \hat{\sigma}, \\ \text{NO}, & \text{otherwise}, \end{cases}$$

where $\hat{\sigma}$ is the standard deviation of residuals in the entire training set. ROC curves are obtained through adjusting the threshold value.

The regularization parameters for Wasserstein DRO and regularized LAD are tuned using a separate validation set as done in previous sections. We would like to highlight a salient advantage of our approach reflected in its robustness w.r.t. the choice of ϵ. In Fig. 11 we plot the out-of-sample AUC as the radius ϵ (regularization parameter) varies, for the ℓ_2-induced Wasserstein DRO and the ℓ_1-regularized LAD. For the Wasserstein DRO curve, when ϵ is small, the Wasserstein ball contains the true distribution with low confidence and thus AUC is low. On the other hand, too large ϵ makes our solution overly conservative. Note that the robustness of our approach, indicated by the flatness of the Wasserstein DRO curve, constitutes another advantage, whereas the performance of LAD dramatically deteriorates once the regularizer deviates from the optimum. Moreover, the maximal achievable AUC for Wasserstein DRO is significantly higher than LAD.

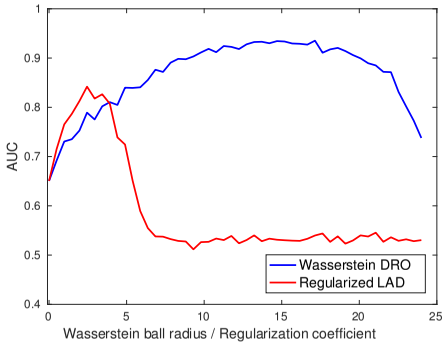

Figure 11: Out-of-sample AUC v.s. Wasserstein ball radius (regularization coefficient).

In Fig. 12 we show the ROC curves for different approaches, where q represents the percentage of outliers, and δ_R the outlying distance along y. We see that the Wasserstein DRO formulation consistently outperforms all other approaches, with its ROC curve lying well above others. In general, all approaches have better performance when the percentage of outliers is lower, and the outlying distance is larger. The approaches that use the AD loss function (e.g., Wasserstein DRO and regularized LAD) tend to outperform those that adopt

the SR loss (e.g., M-estimation which uses a variant of the SR loss). The superiority of our formulation could be attributed to the AD loss function, and the distributional robustness since we hedge against a family of plausible distributions, including the true distribution with high confidence. By contrast, M-estimation adopts an *Iteratively Reweighted Least Squares (IRLS)* procedure which assigns weights to data points based on the residuals from previous iterations, and then solves a weighted least squares estimation problem. With such an approach, there is a chance of exaggerating the influence of outliers while downplaying the importance of clean observations, especially when the initial residuals are obtained through *Ordinary Least Squares (OLS)*.

5. Conclusions

We presented a novel ℓ_1-loss based robust learning procedure using *Distributionally Robust Optimization (DRO)* in a linear regression framework, through which a delicate connection between the metric space on data and the regularization term has been established. The Wasserstein metric was utilized to construct the ambiguity set and a tractable reformulation was derived. It is worth noting that the linear law assumption does not necessarily limit the applicability of our model. In fact, by appropriately pre-processing the data, one can

often find a roughly linear relationship between the response and transformed explanatory variables. Our Wasserstein formulation incorporates a class of models whose specific form depends on the norm space that the Wasserstein metric is defined on. We provide out-of-sample generalization guarantees, and bound the estimation bias of the general formulation. Extensive numerical examples demonstrate the superiority of the Wasserstein formulation and shed light on the advantages of the ℓ_1-loss, the implication of the regularizer, and the selection of the norm space for the Wasserstein metric. We also presented an outlier detection example as an application of this robust learning procedure. A remarkable advantage of our approach rests in its flexibility to adjust the form of the regularizer based on the characteristics of the data.

Appendix A. Omitted Definitions and Proofs

This section includes proofs for the theorems and lemmas, in the order they appear in the paper.

A.1 Proof of Theorem 2.1

Proof We will adopt the notation $\mathbf{z} \triangleq (\mathbf{x}, y), \tilde{\boldsymbol{\beta}} \triangleq (-\boldsymbol{\beta}, 1)$ for ease of analysis. First rewrite $\kappa(\boldsymbol{\beta})$ as:

$$\kappa(\boldsymbol{\beta}) = \sup\Big\{\|\boldsymbol{\theta}\|_* : \sup_{\mathbf{z}|\mathbf{z}'\tilde{\boldsymbol{\beta}}\geq 0} \{(\boldsymbol{\theta}-\tilde{\boldsymbol{\beta}})'\mathbf{z}\} < \infty, \quad \sup_{\mathbf{z}|\mathbf{z}'\tilde{\boldsymbol{\beta}}\leq 0} \{(\boldsymbol{\theta}+\tilde{\boldsymbol{\beta}})'\mathbf{z}\} < \infty\Big\}.$$

Consider now the two linear optimization problems A and B:

$$\text{Problem A:} \quad \begin{array}{ll} \max & (\boldsymbol{\theta}-\tilde{\boldsymbol{\beta}})'\mathbf{z} \\ \text{s.t.} & \mathbf{z}'\tilde{\boldsymbol{\beta}} \geq 0. \end{array}$$

$$\text{Problem B:} \quad \begin{array}{ll} \max & (\boldsymbol{\theta}+\tilde{\boldsymbol{\beta}})'\mathbf{z} \\ \text{s.t.} & \mathbf{z}'\tilde{\boldsymbol{\beta}} \leq 0. \end{array}$$

Form the dual problems using dual variables r_A and r_B, respectively:

$$\text{Dual-A:} \quad \begin{array}{ll} \min & 0 \cdot r_A \\ \text{s.t.} & \tilde{\boldsymbol{\beta}} r_A = \boldsymbol{\theta} - \tilde{\boldsymbol{\beta}}, \\ & r_A \leq 0, \end{array}$$

$$\text{Dual-B:} \quad \begin{array}{ll} \min & 0 \cdot r_B \\ \text{s.t.} & \tilde{\boldsymbol{\beta}} r_B = \boldsymbol{\theta} + \tilde{\boldsymbol{\beta}}, \\ & r_B \geq 0. \end{array}$$

We want to find the set of $\boldsymbol{\theta}$ such that the optimal values of problems A and B are finite. Then, Dual-A and Dual-B need to have non-empty feasible sets, which implies the following two conditions:

$$\exists\, r_A \leq 0, \quad \text{s.t.} \quad \tilde{\boldsymbol{\beta}} r_A = \boldsymbol{\theta} - \tilde{\boldsymbol{\beta}}, \tag{22}$$

$$\exists\, r_B \geq 0, \quad \text{s.t.} \quad \tilde{\boldsymbol{\beta}} r_B = \boldsymbol{\theta} + \tilde{\boldsymbol{\beta}}. \tag{23}$$

For all i with $\tilde{\beta}_i \leq 0$, (22) implies $\theta_i - \tilde{\beta}_i \geq 0$ and (23) implies $\theta_i \leq -\tilde{\beta}_i$. On the other hand, for all j with $\tilde{\beta}_j \geq 0$, (22) and (23) imply $-\tilde{\beta}_j \leq \theta_j \leq \tilde{\beta}_j$. It is not hard to conclude that:

$$|\theta_i| \leq |\tilde{\beta}_i|, \quad \forall\, i.$$

It follows,

$$\kappa(\boldsymbol{\beta}) = \sup\{\|\boldsymbol{\theta}\|_* : |\theta_i| \leq |\tilde{\beta}_i|,\ \forall i\} = \|\tilde{\boldsymbol{\beta}}\|_*.$$

■

A.2 Proof of Lemma 3.2

Proof Suppose that $\sigma_1, \ldots, \sigma_N$ are i.i.d. uniform random variables on $\{1, -1\}$. Then, by the definition of the Rademacher complexity and Lemma 3.1,

$$\begin{aligned} \mathcal{R}_N(\mathcal{H}) &= \mathbb{E}\left[\sup_{h\in\mathcal{H}} \frac{2}{N}\left|\sum_{i=1}^N \sigma_i h_{\boldsymbol{\beta}}(\mathbf{x}_i, y_i)\right| \middle| (\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_N, y_N)\right] \\ &\leq \frac{2\bar{B}R}{N}\mathbb{E}\left[\left|\sum_{i=1}^N \sigma_i\right|\right] \\ &\leq \frac{2\bar{B}R}{N}\mathbb{E}\left[\sqrt{\sum_{i=1}^N \sigma_i^2}\,\right] \\ &= \frac{2\bar{B}R}{\sqrt{N}}. \end{aligned}$$

■

A.3 Proof of Theorem 3.3

Proof We use Theorem 8 in Bartlett and Mendelson (2002), setting the following correspondences with the notation used there: $\mathcal{L}(\mathbf{x}, y) = \phi(\mathbf{x}, y) = |y - \mathbf{x}'\boldsymbol{\beta}|$. This yields the

bound (14) on the expected loss. For Eq. (15), we apply Markov's inequality to obtain:

$$\mathbb{P}\Big(|y-\mathbf{x}'\hat{\boldsymbol{\beta}}| \geq \frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}|+\zeta\Big) \leq \frac{\mathbb{E}[|y-\mathbf{x}'\hat{\boldsymbol{\beta}}|]}{\frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}|+\zeta} \leq \frac{\frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}|+\frac{2\bar{B}R}{\sqrt{N}}+\bar{B}R\sqrt{\frac{8\log(2/\delta)}{N}}}{\frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}|+\zeta}.$$

■

A.4 Proof of Corollary 3.4

Proof The percentage difference requirement can be translated into:

$$\frac{2}{\sqrt{N}}+\sqrt{\frac{8\log(2/\delta)}{N}} \leq \tau,$$

from which (16) can be easily derived. ■

A.5 Proof of Corollary 3.5

Proof Based on Theorem 3.3, we just need the following inequality to hold:

$$\frac{\frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}|+\frac{2\bar{B}R}{\sqrt{N}}+\bar{B}R\sqrt{\frac{8\log(2/\delta)}{N}}}{\frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}|+\gamma\bar{B}R} \leq \tau,$$

which is equivalent to:

$$\frac{\gamma\bar{B}R-\frac{2\bar{B}R}{\sqrt{N}}-\bar{B}R\sqrt{\frac{8\log(2/\delta)}{N}}}{\frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}|+\gamma\bar{B}R} \geq 1-\tau. \tag{24}$$

We cannot obtain a lower bound for N by directly solving (24) since N appears in a summation operator. A proper relaxation to (24) is:

$$\frac{\gamma-\frac{2}{\sqrt{N}}-\sqrt{\frac{8\log(2/\delta)}{N}}}{1+\gamma} \geq 1-\tau, \tag{25}$$

due to the fact that $\frac{1}{N}\sum_{i=1}^{N}|y_i-\mathbf{x}_i'\hat{\boldsymbol{\beta}}| \leq \bar{B}R$. By solving (25), we obtain (17). ■

A.6 Sub-Gaussian Random Variables and Gaussian Width

Definition 1 (Sub-Gaussian random variable) *A random variable z is sub-Gaussian if the ψ_2-norm defined below is finite, i.e.,*

$$\|z\|_{\psi_2} \triangleq \sup_{q\geq 1}\frac{\mathbb{E}|z|^q}{\sqrt{q}} < +\infty.$$

An equivalent property for sub-Gaussian random variables is that their tail distribution decays as fast as a Gaussian, namely,

$$\mathbb{P}(|z|\geq t) \leq 2\exp\{-t^2/C^2\}, \quad \forall t\geq 0,$$

for some constant C.

A random vector $\mathbf{z}\in\mathbb{R}^m$ is sub-Gaussian if $\mathbf{z}'\mathbf{u}$ is sub-Gaussian for any $\mathbf{u}\in\mathbb{R}^m$. The ψ_2-norm of a vector $\mathbf{z}$ is defined as:

$$\|\mathbf{z}\|_{\psi_2} \triangleq \sup_{\mathbf{u}\in\mathbb{S}^m}\big\|\|\mathbf{z}'\mathbf{u}\|\big\|_{\psi_2},$$

where $\mathbb{S}^m$ denotes the unit sphere in the m-dimensional Euclidean space. For the properties of sub-Gaussian random variables/vectors, please refer to the book by Vershynin (2017).

Definition 2 (Gaussian width) *For any set $\mathcal{A}\subseteq\mathbb{R}^m$, its Gaussian width is defined as:*

$$w(\mathcal{A}) \triangleq \mathbb{E}\Big[\sup_{\mathbf{u}\in\mathcal{A}}\mathbf{u}'\mathbf{g}\Big], \tag{26}$$

where $\mathbf{g}\sim\mathcal{N}(\mathbf{0},\mathbf{I})$ is an m-dimensional standard Gaussian random vector.

A.7 Proof of Theorem 3.6

In all the following proofs related to Section 3.2, we will adopt the notation $\mathbf{z}\triangleq(\mathbf{x},y)$, $\mathbf{z}_i\triangleq(\mathbf{x}_i,y_i)$, $\tilde{\boldsymbol{\beta}}\triangleq(-\boldsymbol{\beta},1)$, $\tilde{\boldsymbol{\beta}}_{\text{est}}\triangleq(-\hat{\boldsymbol{\beta}},1)$, $\tilde{\boldsymbol{\beta}}_{\text{true}}\triangleq(-\boldsymbol{\beta}^*,1)$ for ease of exposition.

Proof Since both $\hat{\boldsymbol{\beta}}$ and $\boldsymbol{\beta}^*$ are feasible (the latter due to Assumption E), we have:

$$\|\mathbf{Z}'\tilde{\boldsymbol{\beta}}_{\text{est}}\|_1 \leq \gamma_N,$$
$$\|\mathbf{Z}'\tilde{\boldsymbol{\beta}}_{\text{true}}\|_1 \leq \gamma_N,$$

from which we derive that $\|\mathbf{Z}'(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})\|_1 \leq 2\gamma_N$. Since $\hat{\boldsymbol{\beta}}$ is an optimal solution to (18) and $\boldsymbol{\beta}^*$ a feasible solution, it follows that $\|\tilde{\boldsymbol{\beta}}_{\text{est}}\|_* \leq \|\tilde{\boldsymbol{\beta}}_{\text{true}}\|_*$. This implies that $\boldsymbol{\nu}=\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}$ satisfies the condition $\|\tilde{\boldsymbol{\beta}}_{\text{true}}+\mathbf{v}\|_* \leq \|\tilde{\boldsymbol{\beta}}_{\text{true}}\|_*$ included in the definition of $\mathcal{A}(\boldsymbol{\beta}^*)$ and, furthermore, $(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})/\|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_2 \in \mathcal{A}(\boldsymbol{\beta}^*)$. Together with Assumption D, this yields

$$(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})'\mathbf{Z}\mathbf{Z}'(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}) \geq \underline{\alpha}\|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_2^2. \tag{27}$$

On the other hand, from the Cauchy-Schwarz inequality:

$$\begin{aligned}(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})'\mathbf{Z}\mathbf{Z}'(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}) &\leq \|\mathbf{Z}'(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})\|_1\|\mathbf{Z}'(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})\|_\infty \\ &\leq 2\gamma_N\max_i|\mathbf{z}_i'(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})| \\ &\leq 2\gamma_N\max_i\|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_*\|\mathbf{z}_i\| \\ &\leq 2R\gamma_N\|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_*.\end{aligned} \tag{28}$$

Combining (27) and (28), we have:

$$\begin{aligned}\|\hat{\boldsymbol{\beta}}-\boldsymbol{\beta}^*\|_2 &= \|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_2\\ &\le \frac{2R\gamma_N}{\underline{\alpha}}\frac{\|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_*}{\|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_2}\\ &\le \frac{2R\gamma_N}{\underline{\alpha}}\Psi(\boldsymbol{\beta}^*),\end{aligned}$$

where the last step follows from the fact that $(\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}})/\|\tilde{\boldsymbol{\beta}}_{\text{est}}-\tilde{\boldsymbol{\beta}}_{\text{true}}\|_2 \in \mathcal{A}(\boldsymbol{\beta}^*)$. ■

A.8 Proof of Lemma 3.7

Proof Define $\hat{\boldsymbol{\Gamma}}=\frac{1}{N}\sum_{i=1}^N \mathbf{z}_i\mathbf{z}_i'$. Consider the set of functions $\mathcal{F}=\{f_{\mathbf{w}}(\mathbf{z})=\mathbf{z}'\boldsymbol{\Gamma}^{-1/2}\mathbf{w} | \mathbf{w}\in \mathcal{A}_{\boldsymbol{\Gamma}}\}$. Then, for any $f_{\mathbf{w}}\in\mathcal{F}$,

$$\begin{aligned}\mathbb{E}[f_{\mathbf{w}}^2] &= \mathbb{E}[\mathbf{w}'\boldsymbol{\Gamma}^{-1/2}\mathbf{z}\mathbf{z}'\boldsymbol{\Gamma}^{-1/2}\mathbf{w}]\\ &= \mathbf{w}'\boldsymbol{\Gamma}^{-1/2}\mathbb{E}[\mathbf{z}\mathbf{z}']\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\\ &= \mathbf{w}'\mathbf{w}\\ &= 1,\end{aligned}$$

where we used $\boldsymbol{\Gamma}=\mathbb{E}[\mathbf{z}\mathbf{z}']$ and the fact that $\mathbf{w}\in\mathcal{A}_{\boldsymbol{\Gamma}}$.

For any $f_{\mathbf{w}}\in\mathcal{F}$ we have

$$\begin{aligned}|||f_{\mathbf{w}}|||_{\psi_2} &= \left|\left|\left|\mathbf{z}'\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\right|\right|\right|_{\psi_2}\\ &= \left|\left|\left|\mathbf{z}'\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\right|\right|\right|_{\psi_2}\frac{\|\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\|_2}{\|\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\|_2}\\ &= \left|\left|\left|\mathbf{z}'\frac{\boldsymbol{\Gamma}^{-1/2}\mathbf{w}}{\|\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\|_2}\right|\right|\right|_{\psi_2}\|\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\|_2\\ &\le \mu\sqrt{\mathbf{w}'\boldsymbol{\Gamma}^{-1}\mathbf{w}}\\ &\le \mu\sqrt{\frac{1}{\lambda_{\min}}\|\mathbf{w}\|_2^2}\\ &= \mu\sqrt{\frac{1}{\lambda_{\min}}} = \bar{\mu},\end{aligned}$$

where the first inequality used Assumption F and the second inequality used Assumption G.

Applying Theorem D from Mendelson et al. (2007), for any $\theta>0$ and when

$$\tilde{C}_1\bar{\mu}\gamma_2(\mathcal{F},|||\cdot|||_{\psi_2})\le\theta\sqrt{N},$$

with probability at least $1-\exp(-\tilde{C}_2\theta^2N/\bar{\mu}^4)$ we have

$$\begin{aligned}\sup_{f_{\mathbf{w}}\in\mathcal{F}}\left|\frac{1}{N}\sum_{i=1}^N f_{\mathbf{w}}^2(\mathbf{z}_i)-\mathbb{E}[f_{\mathbf{w}}^2]\right| &= \sup_{f_{\mathbf{w}}\in\mathcal{F}}\left|\frac{1}{N}\sum_{i=1}^N \mathbf{w}'\boldsymbol{\Gamma}^{-1/2}\mathbf{z}_i\mathbf{z}_i'\boldsymbol{\Gamma}^{-1/2}\mathbf{w}-1\right|\\ &= \sup_{\mathbf{w}\in\mathcal{A}_{\boldsymbol{\Gamma}}}\left|\mathbf{w}'\boldsymbol{\Gamma}^{-1/2}\hat{\boldsymbol{\Gamma}}\boldsymbol{\Gamma}^{-1/2}\mathbf{w}-1\right|\\ &\le \theta,\end{aligned}\tag{29}$$

where $\tilde{C}_1$ is some positive constant and $\gamma_2(\mathcal{F},|||\cdot|||_{\psi_2})$ is defined in Mendelson et al. (2007) as a measure of the size of the set $\mathcal{F}$ with respect to the metric $|||\cdot|||_{\psi_2}$. Using $\theta=1/2$, and properties of $\gamma_2(\mathcal{F},|||\cdot|||_{\psi_2})$ outlined in Chen and Banerjee (2016), we can set N to satisfy

$$\begin{aligned}\tilde{C}_1\bar{\mu}\gamma_2(\mathcal{F},|||\cdot|||_{\psi_2}) &\le \tilde{C}_1\bar{\mu}^2\gamma_2(\mathcal{A}_{\boldsymbol{\Gamma}},\|\cdot\|_2)\\ &\le \tilde{C}_1\bar{\mu}^2C_0w(\mathcal{A}_{\boldsymbol{\Gamma}})\\ &\le \frac{1}{2}\sqrt{N},\end{aligned}$$

for some positive constant C_0, where we used Eq. (44) in Chen and Banerjee (2016). This implies

$$N\ge C_1\bar{\mu}^4(w(\mathcal{A}_{\boldsymbol{\Gamma}}))^2$$

for some positive constant C_1. Thus, for such N and with probability at least $1-\exp(-C_2N/\bar{\mu}^4)$, for some positive constant C_2, (29) holds with $\theta=1/2$. This implies that for all $\mathbf{w}\in\mathcal{A}_{\boldsymbol{\Gamma}}$,

$$\left|\mathbf{w}'\boldsymbol{\Gamma}^{-1/2}\hat{\boldsymbol{\Gamma}}\boldsymbol{\Gamma}^{-1/2}\mathbf{w}-1\right|\le\frac{1}{2}$$

or

$$\mathbf{w}'\boldsymbol{\Gamma}^{-1/2}\hat{\boldsymbol{\Gamma}}\boldsymbol{\Gamma}^{-1/2}\mathbf{w}\ge\frac{1}{2}=\frac{1}{2}\mathbf{w}'\boldsymbol{\Gamma}^{-1/2}\boldsymbol{\Gamma}\boldsymbol{\Gamma}^{-1/2}\mathbf{w}.$$

By the definition of $\mathcal{A}_{\boldsymbol{\Gamma}}$, for any $\mathbf{v}\in\mathcal{A}(\boldsymbol{\beta}^*)$,

$$\mathbf{v}'\hat{\boldsymbol{\Gamma}}\mathbf{v}\ge\frac{1}{2}\mathbf{v}'\boldsymbol{\Gamma}\mathbf{v}.$$

Noting that $\hat{\boldsymbol{\Gamma}}=(1/N)\mathbf{Z}\mathbf{Z}'$ yields the desired result. ■

A.9 Proof of Lemma 3.8

We follow the proof of Lemma 4 in Chen and Banerjee (2016), adapted to our setting. We include all key steps for completeness.

Proof Recall the definition of the Gaussian width $w(\mathcal{A}_{\boldsymbol{\Gamma}})$ (cf. (26)):

$$w(\mathcal{A}_{\boldsymbol{\Gamma}})=\mathbb{E}\Big[\sup_{\mathbf{u}\in\mathcal{A}_{\boldsymbol{\Gamma}}}\mathbf{u}'\mathbf{g}\Big],$$

where $\mathbf{g} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. We have:

$$\begin{aligned}\sup_{\mathbf{w}\in\mathcal{A}_{\mathbf{\Gamma}}} \mathbf{w}'\mathbf{g} &= \sup_{\mathbf{w}\in\mathcal{A}_{\mathbf{\Gamma}}} \mathbf{w}'\mathbf{\Gamma}^{-1/2}\mathbf{\Gamma}^{1/2}\mathbf{g} \\ &= \sup_{\mathbf{w}\in\mathcal{A}_{\mathbf{\Gamma}}} \|\mathbf{\Gamma}^{-1/2}\mathbf{w}\|_2 \frac{\mathbf{w}'\mathbf{\Gamma}^{-1/2}}{\|\mathbf{\Gamma}^{-1/2}\mathbf{w}\|_2}\mathbf{\Gamma}^{1/2}\mathbf{g} \\ &\le \sqrt{\frac{1}{\lambda_{\min}}} \sup_{\mathbf{v}\in\mathrm{cone}(\mathcal{A}(\boldsymbol{\beta}^*))\cap\mathbb{B}^m} \mathbf{v}'\mathbf{\Gamma}^{1/2}\mathbf{g},\end{aligned}$$

where $\mathbb{B}^m$ is the unit ball in the m-dimensional Euclidean space and the inequality used Assumption G and the fact that $\mathbf{w}'\mathbf{\Gamma}^{-1/2}/\|\mathbf{\Gamma}^{-1/2}\mathbf{w}\|_2 \in \mathbb{B}^m$ and $\mathbf{w} \in \mathcal{A}_{\mathbf{\Gamma}}$.

Define $\mathcal{T} = \mathrm{cone}(\mathcal{A}(\boldsymbol{\beta}^*)) \cap \mathbb{B}^m$, and consider the stochastic process $\{S_{\mathbf{v}} = \mathbf{v}'\mathbf{\Gamma}^{1/2}\mathbf{g}\}_{\mathbf{v}\in\mathcal{T}}$. For any $\mathbf{v}_1, \mathbf{v}_2 \in \mathcal{T}$,

$$\begin{aligned}\|\!|S_{\mathbf{v}_1} - S_{\mathbf{v}_2}|\!\|_{\psi_2} &= \Big|\!\Big|\!\Big|(\mathbf{v}_1 - \mathbf{v}_2)'\mathbf{\Gamma}^{1/2}\mathbf{g}\Big|\!\Big|\!\Big|_{\psi_2} \\ &= \|\mathbf{\Gamma}^{1/2}(\mathbf{v}_1 - \mathbf{v}_2)\|_2 \Big|\!\Big|\!\Big|\frac{(\mathbf{v}_1 - \mathbf{v}_2)'\mathbf{\Gamma}^{1/2}\mathbf{g}}{\|\mathbf{\Gamma}^{1/2}(\mathbf{v}_1 - \mathbf{v}_2)\|_2}\Big|\!\Big|\!\Big|_{\psi_2} \\ &\le \|\mathbf{\Gamma}^{1/2}(\mathbf{v}_1 - \mathbf{v}_2)\|_2 \sup_{\mathbf{u}\in\mathbb{S}^m} \|\!|\mathbf{u}'\mathbf{g}|\!\|_{\psi_2} \\ &= \mu_0\|\mathbf{\Gamma}^{1/2}(\mathbf{v}_1 - \mathbf{v}_2)\|_2 \\ &\le \mu_0\sqrt{\lambda_{\max}}\|\mathbf{v}_1 - \mathbf{v}_2\|_2,\end{aligned}$$

where the last step used Assumption G.

Then, by the tail behavior of sub-Gaussian random variables (see Hoeffding bound, Thm. 2.6.2 in (Vershynin, 2017)), we have:

$$\mathbb{P}(|S_{\mathbf{v}_1} - S_{\mathbf{v}_2}| \ge \delta) \le 2\exp\Big(-\frac{C_{01}\delta^2}{\mu_0^2\lambda_{\max}\|\mathbf{v}_1 - \mathbf{v}_2\|_2^2}\Big),$$

for some positive constant C_{01}.

To bound the supremum of $S_{\mathbf{v}}$, we define the metric $s(\mathbf{v}_1, \mathbf{v}_2) = \mu_0\sqrt{\lambda_{\max}}\|\mathbf{v}_1 - \mathbf{v}_2\|_2$. Then, by Lemma B in Chen and Banerjee (2016),

$$\begin{aligned}\mathbb{E}\Big[\sup_{\mathbf{v}\in\mathcal{T}} \mathbf{v}'\mathbf{\Gamma}^{1/2}\mathbf{g}\Big] &\le C_{02}\gamma_2(\mathcal{T}, s) \\ &= C_{02}\mu_0\sqrt{\lambda_{\max}}\gamma_2(\mathcal{T}, \|\cdot\|_2) \\ &\le C_3\mu_0\sqrt{\lambda_{\max}}w(\mathcal{T}),\end{aligned}$$

for positive constants C_{02}, C_3, where $\gamma_2(\mathcal{T}, s)$ is the γ_2-functional we referred to in the proof of Lemma 3.7. Since $\mathcal{T} = \mathrm{cone}(\mathcal{A}(\boldsymbol{\beta}^*)) \cap \mathbb{B}^m \subseteq \mathrm{conv}(\mathcal{A}(\boldsymbol{\beta}^*) \cup \{\mathbf{0}\})$, by Lemma 2 in Maurer et al. (2014),

$$\begin{aligned}w(\mathcal{T}) &\le w(\mathrm{conv}(\mathcal{A}(\boldsymbol{\beta}^*) \cup \{\mathbf{0}\})) \\ &= w(\mathcal{A}(\boldsymbol{\beta}^*) \cup \{\mathbf{0}\}) \\ &\le \max\{w(\mathcal{A}(\boldsymbol{\beta}^*)), w(\{\mathbf{0}\})\} + 2\sqrt{\ln 4} \\ &\le w(\mathcal{A}(\boldsymbol{\beta}^*)) + 3.\end{aligned}$$

Thus,

$$\begin{aligned}w(\mathcal{A}_{\mathbf{\Gamma}}) &= \mathbb{E}\Big[\sup_{\mathbf{w}\in\mathcal{A}_{\mathbf{\Gamma}}} \mathbf{w}'\mathbf{g}\Big] \\ &\le \sqrt{\frac{1}{\lambda_{\min}}}\mathbb{E}\Big[\sup_{\mathbf{v}\in\mathcal{T}} \mathbf{v}'\mathbf{\Gamma}^{1/2}\mathbf{g}\Big] \\ &\le C_3\sqrt{\frac{1}{\lambda_{\min}}}\mu_0\sqrt{\lambda_{\max}}w(\mathcal{T}) \\ &\le C_3\mu_0\sqrt{\frac{\lambda_{\max}}{\lambda_{\min}}}\Big(w(\mathcal{A}(\boldsymbol{\beta}^*)) + 3\Big).\end{aligned}$$

■

A.10 Proof of Corollary 3.9

Proof Combining Lemmas 3.7 and 3.8, and using the fact that for any $\mathbf{v} \in \mathcal{A}(\boldsymbol{\beta}^*)$,

$$\frac{N}{2}\mathbf{v}'\mathbf{\Gamma}\mathbf{v} \ge \frac{N\lambda_{\min}}{2},$$

we can derive the desired result. ■

A.11 Proof of Lemma 3.10

Proof By the definition of dual norm, we know that:

$$\|\tilde{\boldsymbol{\beta}}'\mathbf{Z}\|_1 = \sup_{\mathbf{v}\in\mathcal{B}_u} \tilde{\boldsymbol{\beta}}'\mathbf{Z}\mathbf{v} = \sup_{\mathbf{v}\in\mathcal{B}_u} \sum_{i=1}^N v_i\tilde{\boldsymbol{\beta}}'\mathbf{z}_i.$$

Since $v_i\tilde{\boldsymbol{\beta}}'\mathbf{z}_i,\ i = 1, \ldots, N$ are independent centered sub-Gaussian random variables, and

$$\Big|\!\Big|\!\Big|v_i\tilde{\boldsymbol{\beta}}'\mathbf{z}_i\Big|\!\Big|\!\Big|_{\psi_2} \le \mu\|v_i\tilde{\boldsymbol{\beta}}\|_2,$$

we have that $\sum_{i=1}^N v_i\tilde{\boldsymbol{\beta}}'\mathbf{z}_i$ is also a centered sub-Gaussian random variable with

$$\begin{aligned}\Big|\!\Big|\!\Big|\sum_{i=1}^N v_i\tilde{\boldsymbol{\beta}}'\mathbf{z}_i\Big|\!\Big|\!\Big|_{\psi_2}^2 &\le C_{03}^2\sum_{i=1}^N \mu^2\|v_i\tilde{\boldsymbol{\beta}}\|_2^2 \\ &= C_{03}^2\mu^2\|\tilde{\boldsymbol{\beta}}\|_2^2\|\mathbf{v}\|_2^2,\end{aligned}$$

for a positive constant C_{03}.

Consider the stochastic process $\{S_{\mathbf{v}} = \tilde{\boldsymbol{\beta}}'\mathbf{Z}\mathbf{v}\}_{\mathbf{v}\in\mathcal{B}_u}$. As in the proof of Lemma 3.8,

$$\|\!|S_{\mathbf{v}_1} - S_{\mathbf{v}_2}|\!\|_{\psi_2} \le C_{03}\mu\|\tilde{\boldsymbol{\beta}}\|_2\|\mathbf{v}_1 - \mathbf{v}_2\|_2.$$

By the tail behavior of sub-Gaussian random variables (Vershynin, 2017), we know:

$$\mathbb{P}(|S_{\mathbf{v}_1} - S_{\mathbf{v}_2}| \geq \delta) \leq 2\exp\Big(-\frac{C_{04}\delta^2}{\mu^2\|\tilde{\boldsymbol{\beta}}\|_2^2\|\mathbf{v}_1 - \mathbf{v}_2\|_2^2}\Big),$$

for a positive constant C_{04}.

Define the metric $s(\mathbf{v}_1, \mathbf{v}_2) = \mu\|\tilde{\boldsymbol{\beta}}\|_2\|\mathbf{v}_1 - \mathbf{v}_2\|_2$. Then, by Lemma B in Chen and Banerjee (2016),

$$\mathbb{P}\Big(\sup_{\mathbf{v}_1,\mathbf{v}_2\in\mathcal{B}_u} |S_{\mathbf{v}_1} - S_{\mathbf{v}_2}| \geq C_{05}\big(\gamma_2(\mathcal{B}_u, s) + \delta\cdot\mathrm{diam}(\mathcal{B}_u, s)\big)\Big) \leq C_4\exp(-\delta^2),$$

for positive constants C_{05}, C_4. Also,

$$\begin{aligned}
\gamma_2(\mathcal{B}_u, s) &= \mu\|\tilde{\boldsymbol{\beta}}\|_2\gamma_2(\mathcal{B}_u, \|\cdot\|_2) \leq C_5\mu\|\tilde{\boldsymbol{\beta}}\|_2 w(\mathcal{B}_u),\\
\mathrm{diam}(\mathcal{B}_u, s) &= \sup_{\mathbf{v}_1,\mathbf{v}_2\in\mathcal{B}_u} s(\mathbf{v}_1, \mathbf{v}_2)\\
&= \mu\|\tilde{\boldsymbol{\beta}}\|_2 \sup_{\mathbf{v}_1,\mathbf{v}_2\in\mathcal{B}_u} \|\mathbf{v}_1 - \mathbf{v}_2\|_2\\
&\leq 2\mu\|\tilde{\boldsymbol{\beta}}\|_2 \sup_{\mathbf{v}\in\mathcal{B}_u} \|\mathbf{v}\|_2\\
&= 2\mu\|\tilde{\boldsymbol{\beta}}\|_2\rho,
\end{aligned}$$

for positive constants C_5. Therefore, noting that $\sup_{\mathbf{v}_1,\mathbf{v}_2\in\mathcal{B}_u} |S_{\mathbf{v}_1} - S_{\mathbf{v}_2}| \geq 2\sup_{\mathbf{v}\in\mathcal{B}_u} S_{\mathbf{v}}$, we obtain

$$\begin{aligned}
&\mathbb{P}\Big(\sup_{\mathbf{v}\in\mathcal{B}_u} S_{\mathbf{v}} \geq C_{05}\Big(\frac{C_5}{2}\mu\|\tilde{\boldsymbol{\beta}}\|_2 w(\mathcal{B}_u) + \delta\mu\|\tilde{\boldsymbol{\beta}}\|_2\rho\Big)\Big)\\
\leq\ &\mathbb{P}\Big(\sup_{\mathbf{v}_1,\mathbf{v}_2\in\mathcal{B}_u} |S_{\mathbf{v}_1} - S_{\mathbf{v}_2}| \geq C_{05}\big(\gamma_2(\mathcal{B}_u, s) + \delta\mathrm{diam}(\mathcal{B}_u, s)\big)\Big)\\
\leq\ &C_4\exp(-\delta^2).
\end{aligned}$$

Set $\delta = \frac{C_5 w(\mathcal{B}_u)}{2\rho}$; then with probability at least $1 - C_4\exp(-\frac{C_5^2(w(\mathcal{B}_u))^2}{4\rho^2})$,

$$\sup_{\mathbf{v}\in\mathcal{B}_u} S_{\mathbf{v}} \leq C\mu\bar{B}_2 w(\mathcal{B}_u).$$

The result follows. ■

A.12 Proof of the Result in Section 4

We will show that if the Wasserstein metric is defined by the following metric s_c:

$$s_c(\mathbf{x}, y) = \|(\mathbf{x}, cy)\|_\infty,$$

then as $c \to \infty$, the corresponding Wasserstein DRO formulation becomes:

$$\inf_{\boldsymbol{\beta}\in\mathcal{B}} \frac{1}{N}\sum_{i=1}^N |y_i - \mathbf{x}_i'\boldsymbol{\beta}| + \epsilon\|\boldsymbol{\beta}\|_1,$$

which is the ℓ_1-regularized LAD.

Proof We first define a new notion of norm on $(\mathbf{x}, y)$ where $\mathbf{x} = (x_1, \ldots, x_{m-1})$:

$$\|(\mathbf{x}, y)\|_{\mathbf{w},p} \triangleq \|(x_1 w_1, \ldots, x_{m-1}w_{m-1}, yw_m)\|_p,$$

for some m-dimensional weighting vector $\mathbf{w} = (w_1, \ldots, w_m)$, and $p \geq 1$. Then, $s_c(\mathbf{x}, y) = \|(\mathbf{x}, y)\|_{\mathbf{w},\infty}$ with $\mathbf{w} = (1, \ldots, 1, c)$. To obtain the Wasserstein DRO formulation, the key is to derive the dual norm of $\|\cdot\|_{\mathbf{w},\infty}$. Hölder's inequality (Rogers, 1888) will be used for the derivation. We state it below for convenience.

Theorem 1 (Hölder's inequality) *Suppose we have two scalars $p, q > 1$ and $1/p + 1/q = 1$. For any two vectors $\mathbf{a} = (a_1, \ldots, a_n)$ and $\mathbf{b} = (b_1, \ldots, b_n)$, the following holds.*

$$\sum_{i=1}^n |a_i b_i| \leq \|\mathbf{a}\|_p\|\mathbf{b}\|_q.$$

We will use the notation $\mathbf{z} \triangleq (\mathbf{x}, y)$. Based on the definition of dual norm, we are interested in solving the following optimization problem for $\tilde{\boldsymbol{\beta}} \in \mathbb{R}^m$:

$$\begin{aligned}
\max_{\mathbf{z}}\quad & \mathbf{z}'\tilde{\boldsymbol{\beta}}\\
\text{s.t.}\quad & \|\mathbf{z}\|_{\mathbf{w},\infty} \leq 1.
\end{aligned} \tag{30}$$

The optimal value of problem (30), which is a function of $\tilde{\boldsymbol{\beta}}$, gives the dual norm evaluated at $\tilde{\boldsymbol{\beta}}$. Using Hölder's inequality, we can write

$$\mathbf{z}'\tilde{\boldsymbol{\beta}} = \sum_{i=1}^m (w_i z_i)\Big(\frac{1}{w_i}\tilde{\beta}_i\Big) \leq \|\mathbf{z}\|_{\mathbf{w},\infty}\|\tilde{\boldsymbol{\beta}}\|_{\mathbf{w}^{-1},1} \leq \|\tilde{\boldsymbol{\beta}}\|_{\mathbf{w}^{-1},1},$$

where $\mathbf{w}^{-1} \triangleq (\frac{1}{w_1}, \ldots, \frac{1}{w_m})$. The last inequality is due to the constraint $\|\mathbf{z}\|_{\mathbf{w},\infty} \leq 1$. It follows that the dual norm of $\|\cdot\|_{\mathbf{w},\infty}$ is just $\|\cdot\|_{\mathbf{w}^{-1},1}$. Back to our problem setting, using $\mathbf{w} = (1, \ldots, 1, c)$, and evaluating the dual norm at $(-\boldsymbol{\beta}, 1)$, we have the following Wasserstein DRO formulation as $c \to \infty$:

$$\lim_{c\to\infty}\inf_{\boldsymbol{\beta}\in\mathcal{B}} \frac{1}{N}\sum_{i=1}^N |y_i - \mathbf{x}_i'\boldsymbol{\beta}| + \epsilon\|(-\boldsymbol{\beta}, 1)\|_{\mathbf{w}^{-1},1} = \inf_{\boldsymbol{\beta}\in\mathcal{B}} \frac{1}{N}\sum_{i=1}^N |y_i - \mathbf{x}_i'\boldsymbol{\beta}| + \epsilon\|\boldsymbol{\beta}\|_1.$$

Abstract

Many of the recent trajectory optimization algorithms alternate between linear approximation of the system dynamics around the mean trajectory and conservative policy update. One way of constraining the policy change is by bounding the Kullback-Leibler (KL) divergence between successive policies. These approaches already demonstrated great experimental success in challenging problems such as end-to-end control of physical systems. However, the linear approximation of the system dynamics can introduce a bias in the policy update and prevent convergence to the optimal policy. In this article, we propose a new model-free trajectory-based policy optimization algorithm with guaranteed monotonic improvement. The algorithm backpropagates a local, quadratic and time-dependent Q-Function learned from trajectory data instead of a model of the system dynamics. Our policy update ensures exact KL-constraint satisfaction without simplifying assumptions on the system dynamics. We experimentally demonstrate on highly non-linear control tasks the improvement in performance of our algorithm in comparison to approaches linearizing the system dynamics. In order to show the monotonic improvement of our algorithm, we additionally conduct a theoretical analysis of our policy update scheme to derive a lower bound of the change in policy return between successive iterations.

Keywords: Reinforcement Learning, Policy Optimization, Trajectory Optimization, Robotics

1. Introduction

Trajectory Optimization methods based on stochastic optimal control (Todorov, 2006; Theodorou et al., 2009; Todorov and Tassa, 2009) have been very successful in learning high dimensional controls in complex settings such as end-to-end control of physical systems (Levine and Abbeel, 2014). These methods are based on a time-dependent linearization of the dynamics model around the mean trajectory in order to obtain a closed form update of the policy as a Linear-Quadratic Regulator (LQR). This linearization is then repeated locally for the new policy at every iteration. However, this iterative process does not offer convergence guarantees as the linearization of the dynamics might introduce a bias and impede the algorithm from converging to the optimal policy. To circumvent this limitation, we propose in this paper a novel model-free trajectory-based policy optimization algorithm (MOTO) couched in the approximate policy iteration framework. At each iteration, a Q-Function is estimated locally around the current trajectory distribution using a time-dependent quadratic function. Afterwards, the policy is updated according to a new information-theoretic trust region that bounds the KL-divergence between successive policies in closed form.

MOTO is well suited for high dimensional continuous state and action spaces control problems. The policy is represented by a time-dependent stochastic linear-feedback controller which is updated by a Q-Function propagated backward in time. We extend the work of (Abdolmaleki et al., 2015), which was proposed in the domain of stochastic search (having no notion of state space nor that of sequential decisions), to that of sequential decision making and show that our policy class can be updated under a KL-constraint in closed form, when the learned Q-Function is a quadratic function of the state and action space. In order to maximize sample efficiency, we rely on importance sampling to reuse transition samples from policies of all time-steps and all previous iterations in a principled way. MOTO is able to solve complex control problems despite the simplicity of the Q-Function thanks to two key properties: i) the learned Q-Function is fitted to samples of the current policy, which ensures that the function is *valid locally* and ii) the closed form update of the policy ensures that the KL-constraint is satisfied exactly irrespective of the number of samples or the non-linearity of the dynamics, which ensures that the Q-Function is *used locally*.

The experimental section demonstrates that on tasks with highly non-linear dynamics MOTO outperforms similar methods that rely on a linearization of these dynamics. Additionally, it is shown on a simulated Robot Table Tennis Task that MOTO is able to scale to high dimensional tasks while keeping the sample complexity relatively low; amenable to a direct application to a physical system.

Compared to Akrour et al. (2016), we report new experimental results comparing MOTO to TRPO (Schulman et al., 2015), a state-of-the-art reinforcement learning algorithm. These results showcase settings in which the time-dependent linear-Gaussian policies used by MOTO are a suitable alternative to neural networks. We also conduct a theoretical analysis of the policy update (Sec. 5) and lower bound the increase in policy return between successive iterations of the algorithm. The resulting lower bound validates the use of an expected KL-constraint (Sec. 3.1) in a trajectory-based policy optimization setting for ensuring a monotonic improvement of the policy return. Prior theoretical studies reported similar results when the *maximum* (over the state space) KL is upper bounded which is hard to enforce in practice (Schulman et al., 2015). Leveraging standard trajectory optimization assumptions, we extend prior analysis of the policy update to the specific setting of MOTO when only the *expected* policy KL is bounded.

2. Notation

Consider an undiscounted finite-horizon Markov Decision Process (MDP) of horizon T with state space $\mathcal{S} = \mathbb{R}^{\mathrm{d}_s}$ and action space $\mathcal{A} = \mathbb{R}^{\mathrm{d}_a}$. The transition function $p(\boldsymbol{s}_{t+1}|\boldsymbol{s}_t, \boldsymbol{a}_t)$,

which gives the probability (density) of transitioning to state $\boldsymbol{s}_{t+1}$ upon the execution of action $\boldsymbol{a}_t$ in $\boldsymbol{s}_t$, is assumed to be time-independent; while there are T time-dependent reward functions $r_t : \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$. A policy π is defined by a set of time-dependent density functions π_t, where $\pi_t(\boldsymbol{a}|\boldsymbol{s})$ is the probability of executing action $\boldsymbol{a}$ in state $\boldsymbol{s}$ at time-step t. The goal is to find the optimal policy $\pi^* = \{\pi_1^*, \dots, \pi_T^*\}$ maximizing the policy return $J(\pi) = \mathbb{E}_{\boldsymbol{s}_1, \boldsymbol{a}_1, \dots}\left[\sum_{t=1}^{T} r_t(\boldsymbol{s}_t, \boldsymbol{a}_t)\right]$, where the expectation is taken w.r.t. all the random variables $\boldsymbol{s}_t$ and $\boldsymbol{a}_t$ such that $\boldsymbol{s}_1 \sim \rho_1$ follows the distribution of the initial state, $\boldsymbol{a}_t \sim \pi_t(.|\boldsymbol{s}_t)$ and $\boldsymbol{s}_{t+1} \sim p(\boldsymbol{s}_{t+1}|\boldsymbol{s}_t, \boldsymbol{a}_t)$.

As is common in Policy Search (Deisenroth et al., 2013), our algorithm operates on a restricted class of parameterized policies $\pi_{\boldsymbol{\theta}}, \boldsymbol{\theta} \in \mathbb{R}^{\mathrm{d}_\theta}$ and is an iterative algorithm comprising two main steps, *policy evaluation* and *policy update*. Throughout this article, we will assume that each time-dependent policy is parameterized by $\boldsymbol{\theta}_t = \{K_t, \boldsymbol{k}_t, \Sigma_t\}$ such that $\pi_{\boldsymbol{\theta}_t}$ is of linear-Gaussian form $\pi_{\boldsymbol{\theta}_t}(\boldsymbol{a}|\boldsymbol{s}) = \mathcal{N}(K_t s + \boldsymbol{k}_t, \Sigma_t)$, where the gain matrix K_t is a $d_a \times d_s$ matrix, the bias term $\boldsymbol{k}_t$ is a d_a dimensional column vector and the covariance matrix Σ_t, which controls the exploration of the policy, is of dimension $d_a \times d_a$; yielding a total number of parameters across all time-steps of $d_\theta = T(d_a d_s + \frac{1}{2} d_a(d_a + 3))$.

The policy at iteration i of the algorithm is denoted by π^i and following standard definitions, the Q-Function of π^i at time-step t is given by $Q_t^i(\boldsymbol{s}, \boldsymbol{a}) = \mathbb{E}_{\boldsymbol{s}_t, \boldsymbol{a}_t, \dots}\left[\sum_{t'=t}^{T} r_{t'}(\boldsymbol{s}_{t'}, \boldsymbol{a}_{t'})\right]$ with $(\boldsymbol{s}_t, \boldsymbol{a}_t) = (\boldsymbol{s}, \boldsymbol{a})$ and $\boldsymbol{a}_{t'} \sim \pi_{t'}^i(.|\boldsymbol{s}_{t'}), \forall t' > t$. While the V-Function is given by $V_t^i(\boldsymbol{s}) = \mathbb{E}_{\boldsymbol{a} \sim \pi_t(.|\boldsymbol{s})}\left[Q_t^\pi(\boldsymbol{s}, \boldsymbol{a})\right]$ and the Advantage Function by $A_t^i(\boldsymbol{s}, \boldsymbol{a}) = Q_t^i(\boldsymbol{s}, \boldsymbol{a}) - V_t^i(\boldsymbol{s})$. Furthermore the state distribution at time-step t, related to policy π^i, is denoted by $\rho_t^i(\boldsymbol{s})$. In order to keep the notations uncluttered, the time-step or the iteration number is occasionally dropped when a definition applies similarly for all time-steps or iteration number.

3. Model-free Policy Update for Trajectory-based Policy Optimization

MOTO alternates between policy evaluation and policy update. At each iteration i, the policy evaluation step generates a set of M rollouts[1] from the policy π^i in order to estimate a (quadratic) Q-Function $\tilde{Q}^i$ (Sec. 4.1) and a (Gaussian) state distribution $\tilde{\rho}^i$ (Sec. 4.3). Using these quantities, an information-theoretic policy update is derived at each time-step that uses a KL-bound as a trust region to obtain the policy π^{i+1} of the next iteration.

3.1 Optimization Problem

The goal of the policy update is to return a new policy π^{i+1} that maximizes the Q-Function $\tilde{Q}^i$ in expectation under the state distribution $\tilde{p}_i$ of the previous policy π^i. In order to limit policy oscillation between iterations (Wagner, 2011), the KL w.r.t. π^i is upper bounded. The use of the KL divergence to define the step-size of the policy update has already been successfully applied in prior work (Peters et al., 2010; Levine and Abbeel, 2014; Schulman et al., 2015). Additionally, we lower bound the entropy of π^{i+1} in order to better control

1. A rollout is a Monte Carlo simulation of a trajectory according to ρ_1, π and p or the execution of π on a physical system.

the reduction of exploration yielding the following non-linear program:

$$\underset{\pi}{\text{maximize}} \quad \int\int \tilde{\rho}_t^i(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})\tilde{Q}_t^i(\boldsymbol{s}, \boldsymbol{a})\mathrm{d}a\mathrm{d}s, \tag{1}$$

$$\text{subject to} \quad \mathbb{E}_{s \sim \tilde{\rho}_t^i(\boldsymbol{s})}\left[\mathrm{KL}(\pi(.|\boldsymbol{s}) \parallel \pi_t^i(.|\boldsymbol{s}))\right] \leq \epsilon, \tag{2}$$

$$\mathbb{E}_{s \sim \tilde{\rho}_t^i(\boldsymbol{s})}\left[\mathcal{H}\left(\pi(.|\boldsymbol{s})\right)\right] \geq \beta. \tag{3}$$

The KL between two distributions p and q is given by $\mathrm{KL}(p \parallel q) = \int p(x) \log \frac{p(x)}{q(x)} \mathrm{d}x$ while the entropy $\mathcal{H}$ is given by $\mathcal{H} = -\int p(x) \log p(x) \mathrm{d}x$. The step-size ϵ is a hyper-parameter of the algorithm kept constant throughout the iterations while β is set according to the entropy of the current policy π_t^i, $\beta = \mathbb{E}_{s \sim \tilde{\rho}_t^i(\boldsymbol{s})}\left[\mathcal{H}\left(\pi_t^i(.|\boldsymbol{s})\right)\right] - \beta_0$ and β_0 is the entropy reduction hyper-parameter kept constant throughout the iterations.

Eq. (1) indicates that π_t^{i+1} maximizes $\tilde{Q}_t^i$ in expectation under its own action distribution and the state distribution of π_t^i. Eq. (2) bounds the average change in the policy to the step-size ϵ while Eq. (3) controls the exploration-exploitation trade-off and ensures that the exploration in the action space (which is directly linked to the entropy of the policy) is not reduced too quickly. A similar constraint was introduced in the stochastic search domain by (Abdolmaleki et al., 2015), and was shown to avoid premature convergence. This constraint is even more crucial in our setting because of the inherent *non-stationarity* of the objective function being optimized at each iteration. The cause for the non-stationarity of the objective optimized at time-step t in the policy update is twofold: i) updates of policies $\pi_{t'}$ with time-step $t' > t$ will modify in the next iteration of the algorithm $\tilde{Q}_t$ as a function of s and a and hence the optimization landscape as a function of the policy parameters, ii) updates of policies with time-step $t' < t$ will induce a change in the state distribution ρ_t. If the policy had unlimited expressiveness, the optimal solution of Eq. (1) would be to choose $\arg\max_a \tilde{Q}_t$ irrespective of ρ_t. However, due to the restricted class of the policy, any change in ρ_t will likely change the optimization landscape including the position of the optimal policy parameter. Hence, Eq. (3) ensures that exploration in action space is maintained as the optimization landscape evolves and avoids premature convergence.

3.2 Closed Form Update

Using the method of Lagrange multipliers, the solution of the optimization problem in section 3.1 is given by

$$\pi_t'(\boldsymbol{a}|\boldsymbol{s}) \propto \pi_t(\boldsymbol{a}|\boldsymbol{s})^{\eta^*/(\eta^* + \omega^*)} \exp\left(\frac{\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a})}{\eta^* + \omega^*}\right), \tag{4}$$

with η^* and ω^* being the optimal Lagrange multipliers related to the KL and entropy constraints respectively. Assuming that $\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a})$ is of quadratic form in a and s

$$\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a}) = \frac{1}{2}\boldsymbol{a}^T Q_{aa}\boldsymbol{a} + \boldsymbol{a}^T Q_{as}\boldsymbol{s} + \boldsymbol{a}^T \boldsymbol{q}_a + q(\boldsymbol{s}), \tag{5}$$

with $q(\boldsymbol{s})$ grouping all terms of $\tilde{Q}_t(\boldsymbol{s},\boldsymbol{a})$ that do not depend[2] on a, then $\pi'_t(\boldsymbol{a}|\boldsymbol{s})$ is again of linear-Gaussian form

$$\pi'_t(\boldsymbol{a}|\boldsymbol{s}) = \mathcal{N}(\boldsymbol{a}|FL\boldsymbol{s} + F\boldsymbol{f}, F(\eta^* + \omega^*)),$$

such that the gain matrix, bias and covariance matrix of π'_t are function of matrices F and L and vector $\boldsymbol{f}$ where

$$F = (\eta^*\Sigma_t^{-1} - Q_{aa})^{-1}, \qquad L = \eta^*\Sigma_t^{-1}K_t + Q_{as}, \qquad \boldsymbol{f} = \eta^*\Sigma_t^{-1}\boldsymbol{k}_t + \boldsymbol{q}_a.$$

Note that $\eta\Sigma_t^{-1} - Q_{aa}$ needs to be invertible and positive semi-definite as it defines the new covariance matrix of the linear-Gaussian policy. For this to hold, either $Q_t(\boldsymbol{s},.)$ needs to be concave in a (i.e. Q_{aa} is negative semi-definite), or η needs to be large enough (and for any Q_{aa} such η always exists). A too large η is not desirable as it would barely yield a change to the current policy (too small KL divergence) and could negatively impact the convergence speed. Gradient based algorithms for learning model parameters with a specific semi-definite shape are available (Bhojanapalli et al., 2015) and could be used for learning a concave Q_t. However, we found in practice that the resulting η was always small enough (resulting in a maximally tolerated KL divergence of ϵ between successive policies) while F remains well defined, without requiring additional constraints on the nature of Q_{aa}.

3.3 Dual Minimization

The Lagrangian multipliers η and ω are obtained by minimizing the convex dual function

$$g_t(\eta,\omega) = \eta\epsilon - \omega\beta + (\eta+\omega)\int \tilde{\rho}_t(\boldsymbol{s}) \log\left(\int \pi_t(\boldsymbol{a}|\boldsymbol{s})^{\eta/(\eta+\omega)} \exp\left(\tilde{Q}_t(\boldsymbol{s},\boldsymbol{a})/(\eta+\omega)\right) \mathrm{d}\boldsymbol{a}\right) \mathrm{d}\boldsymbol{s}.$$

Exploiting the structure of the quadratic Q-Function $\tilde{Q}_t$ and the linear-Gaussian policy $\pi_t(\boldsymbol{a}|\boldsymbol{s})$, the inner integral over the action space can be evaluated in closed form and the dual simplifies to

$$g(\eta,\omega) = \eta\epsilon_t - \omega\beta_t + \int \rho_t(\boldsymbol{s})(\boldsymbol{s}^T M\boldsymbol{s} + \boldsymbol{s}^T\boldsymbol{m} + m_0)\mathrm{d}\boldsymbol{s}.$$

The dual function further simplifies, by additionally assuming normality of the state distribution $\tilde{\rho}_t(\boldsymbol{s}) = \mathcal{N}(\boldsymbol{s}|\boldsymbol{\mu}_s, \Sigma_s)$, to the function

$$g_t(\eta,\omega) = \eta\epsilon - \omega\beta + \boldsymbol{\mu}_s^T M\boldsymbol{\mu}_s + \mathrm{tr}(\Sigma_s M) + \boldsymbol{\mu}_s^T\boldsymbol{m} + m_0,$$

which can be efficiently optimized by gradient descent to obtain η^* and ω^*. The full expression of the dual function, including the definition of M, $\boldsymbol{m}$ and m_0 in addition to the partial derivatives $\frac{\partial g_t(\eta,\omega)}{\partial\eta}$ and $\frac{\partial g_t(\eta,\omega)}{\partial\omega}$ are given in Appendix A.

2. Constant terms and terms depending on s but not a won't appear in the policy update. As such, and albeit we only refer in this article to $Q_t(\boldsymbol{s},\boldsymbol{a})$, the Advantage Function $A_t(\boldsymbol{s},\boldsymbol{a})$ can be used interchangeably in lieu of $Q_t(\boldsymbol{s},\boldsymbol{a})$ for updating the policy.

4. Sample Efficient Policy Evaluation

The KL constraint introduced in the policy update gives rise to a non-linear optimization problem. This problem can still be solved in closed form for the class of linear-Gaussian policies, if the learned function $\tilde{Q}_t^i$ is quadratic in $\boldsymbol{s}$ and $\boldsymbol{a}$. The first subsection introduces the main supervised learning problem solved during the policy evaluation for learning $\tilde{Q}_t^i$ while the remaining subsections discuss how to improve its sample efficiency.

4.1 The Q-Function Supervised Learning Problem

In the remainder of the section, we will be interested in finding the parameter $\boldsymbol{w}$ of a linear model $\tilde{Q}_t^i = \langle \boldsymbol{w}, \phi(\boldsymbol{s},\boldsymbol{a})\rangle$, where the feature function ϕ contains a bias and all the linear and quadratic terms of s and a, yielding $1 + (d_a + d_s)(d_a + d_s + 3)/2$ parameters. $\tilde{Q}_t^i$ can subsequently be written as in Eq. (5) by extracting Q_{aa}, Q_{as} and $\boldsymbol{q}_a$ from $\boldsymbol{w}$.

At each iteration i, M rollouts are performed following π^i. Let us initially assume that $\tilde{Q}_t^i$ is learned only from samples $\mathcal{D}_t^i = \{\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]}, \boldsymbol{s}_{t+1}^{[k]}; k = 1..M\}$ gathered from the execution of the M rollouts. The parameter $\boldsymbol{w}$ of $\tilde{Q}_t^i$ is learned by regularized linear least square regression

$$\boldsymbol{w} = \arg\min_{\boldsymbol{w}} \frac{1}{M}\sum_{k=1}^{M}\left(\langle \boldsymbol{w}, \phi(\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]})\rangle - \hat{Q}_t^i(\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]})\right)^2 + \lambda\boldsymbol{w}^T\boldsymbol{w}, \tag{6}$$

where the target value $\hat{Q}_t^i(\boldsymbol{s}^{[k]}, \boldsymbol{a}^{[k]})$ is a noisy estimate of the true value $Q_t^i(\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]})$. We will distinguish two cases for obtaining the estimate $\hat{Q}_t^i(\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]})$.

4.1.1 Monte-Carlo Estimate

This estimate is obtained by summing the future rewards for each trajectory k, yielding $\hat{Q}_t^i(\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]}) = \sum_{t'=t}^{T} r_{t'}(\boldsymbol{s}_{t'}^{[k]}, \boldsymbol{a}_{t'}^{[k]})$. This estimator is known to have no bias but high variance. The variance can be reduced by averaging over multiple rollouts, assuming we can reset to states $\boldsymbol{s}_t^{[k]}$. However, such an assumption would severely limit the applicability of the algorithm on physical systems.

4.1.2 Dynamic Programming

In order to reduce the variance, this estimate exploits the V-Function to reduce the noise of the expected rewards of time-steps $t' > t$ through the following identity

$$\hat{Q}_t^i(\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]}) = r_t(\boldsymbol{s}_t^{[k]}, \boldsymbol{a}_t^{[k]}) + \hat{V}_{t+1}^i(\boldsymbol{s}_{t+1}^{[k]}), \tag{7}$$

which is unbiased if $\hat{V}_{t+1}^i$ is. However, we will use for $\hat{V}_{t+1}^i$ an approximate V-Function $\tilde{V}_{t+1}^i$ learned recursively in time. This approximation might introduce a bias which will accumulate as t goes to 1. Fortunately, $\tilde{V}$ is not restricted by our algorithm to be of a particular class as it does not appear in the policy update. Hence, the bias can be reduced by increasing the complexity of the function approximator class. Nonetheless, in this article, a quadratic function will also be used for the V-Function which worked well in our experiments.

The V-Function is learned by first assuming that $\tilde{V}^i_{T+1}$ is the zero function.[3] Subsequently and recursively in time, the function $\tilde{V}^i_{t+1}$ and the transition samples in $\mathcal{D}^i_t$ are used to fit the parametric function $\tilde{V}^i_t$ by minimizing the loss $\sum_{k=1}^{M} \left(\hat{Q}^i_t(\boldsymbol{s}^{[k]}_t, \boldsymbol{a}^{[k]}_t) - \tilde{V}^i_t(\boldsymbol{s}^{[k]}_t)\right)^2$.

In addition to reducing the variance of the estimate $\hat{Q}^i_t(\boldsymbol{s}^{[k]}_t, \boldsymbol{a}^{[k]}_t)$, the choice of learning a V-Function is further justified by the increased possibility of reusing sample transitions from all time-steps and previous iterations.

4.2 Sample Reuse

In order to improve the sample efficiency of our approach, we will reuse samples from different time-steps and iterations using importance sampling. Let the expected loss which $\tilde{Q}^i_t$ minimizes under the assumption of an infinite number of samples be

$$\boldsymbol{w} = \arg\min_{\boldsymbol{w}} \mathbb{E}[\ell^i_t(\boldsymbol{s}, \boldsymbol{a}, \boldsymbol{s}'; \boldsymbol{w})],$$

where the loss ℓ^i_t is the inner term within the sum in Eq. (6); the estimate $\hat{Q}^i_t(\boldsymbol{s}^{[k]}_t, \boldsymbol{a}^{[k]}_t)$ is taken as in Eq. (7) and the expectation is with respect to the current state $\boldsymbol{s} \sim \rho^i_t$, the action $\boldsymbol{a} \sim \pi^i_t(.|\boldsymbol{s})$ and the next state $\boldsymbol{s}' \sim p(.|\boldsymbol{s}, \boldsymbol{a})$.

4.2.1 Reusing samples from different time-steps

To use transition samples from all time-steps when learning $\tilde{Q}^i_t$, we rely on importance sampling, where the importance weight (IW) is given by the ratio between the state-action probability of the current time-step $z^i_t(\boldsymbol{s}, \boldsymbol{a}) = \rho^i_t(\boldsymbol{s})\pi^i_t(\boldsymbol{a}|\boldsymbol{s})$ divided by the time-independent state-action probability of π^i given by $z^i(\boldsymbol{s}, \boldsymbol{a}) = \frac{1}{T}\sum_{t=1}^{T} z^i_t(\boldsymbol{s}, \boldsymbol{a})$. The expected loss minimized by $\tilde{Q}^i_t$ becomes

$$\min_{\boldsymbol{w}} \mathbb{E}\left[\frac{z^i_t(\boldsymbol{s}, \boldsymbol{a})}{z^i(\boldsymbol{s}, \boldsymbol{a})} \ell^i_t(\boldsymbol{s}, \boldsymbol{a}, \boldsymbol{s}'; \boldsymbol{w}) \mid (\boldsymbol{s}, \boldsymbol{a}) \sim z^i(\boldsymbol{s}, \boldsymbol{a})\right]. \tag{8}$$

Since the transition probabilities are not time-dependent they cancel out from the IW. Upon the computation of the IW, weighted least square regression is used to minimize an empirical estimate of (8) for the data set $\mathcal{D}^i = \cup_{t=1}^{T} \mathcal{D}^i_t$. Note that the (numerator of the) IW needs to be recomputed at every time-step for all samples $(\boldsymbol{s}, \boldsymbol{a}) \in \mathcal{D}^i$. Additionally, if the rewards are time-dependent, the estimate $\hat{Q}^i_t(\boldsymbol{s}^{[k]}_t, \boldsymbol{a}^{[k]}_t)$ in Eq. (7) needs to be recomputed with the current time-dependent reward, assuming the reward function is known.

4.2.2 Reusing samples from previous iterations

Following a similar reasoning, at a given time-step t, samples from previous iterations can be reused for learning $\tilde{Q}^i_t$. In this case, we have access to the samples of the state-action distribution $z^{1:i}_t(\boldsymbol{s}, \boldsymbol{a}) \propto \sum_{j=1}^{i} z^j_t(\boldsymbol{s}, \boldsymbol{a})$. The computation of $z^{1:i}_t$ requires the storage of all previous policies and state distributions. Thus, we will in practice limit ourselves to the K last iterations.

3. Alternatively one could assume the presence of a final reward $R_{T+1}(\boldsymbol{s}_{t+1})$, as is usually formulated in control tasks (Bertsekas, 1995), to which V^i_{T+1} could be initialized to.

Finally, both forms of sample reuse will be combined for learning $\tilde{Q}^i_t$ under the complete data set up to iteration i, $\mathcal{D}^{1:i} = \cup_{j=1}^{i} \mathcal{D}^j$ using weighted least square regression where the IW are given by $z^i_t(\boldsymbol{s}, \boldsymbol{a})/z^{1:i}(\boldsymbol{s}, \boldsymbol{a})$ with $z^{1:i}(\boldsymbol{s}, \boldsymbol{a}) \propto \sum_{t=1}^{T} z^{1:i}_t(\boldsymbol{s}, \boldsymbol{a})$.

4.3 Estimating the State Distribution

To compute the IW, the state distribution at every time-step ρ^i_t needs to be estimated. Since M rollouts are sampled for every policy π^i only M state samples are available for the estimation of ρ^i_t, necessitating again the reuse of previous samples to cope with higher dimensional control tasks.

4.3.1 Forward propagation of the state distribution

The first investigated solution for the estimation of the state distribution is the propagation of the estimate $\tilde{\rho}^i_t$ forward in time. Starting from $\tilde{\rho}^i_1$ which is identical for all iterations, importance sampling is used to learn $\tilde{\rho}^i_{t+1}$ with $t > 1$ from samples $(\boldsymbol{s}_t, \boldsymbol{a}_t, \boldsymbol{s}_{t+1}) \in \mathcal{D}^{1:i}_t$ by weighted maximum-likelihood; where each sample $\boldsymbol{s}_{t+1}$ is weighted by $z^i_t(\boldsymbol{s}_t, \boldsymbol{a}_t)/z^{1:i}_t(\boldsymbol{s}_t, \boldsymbol{a}_t)$. And the computation of this IW only depends on the previously estimated state distribution $\tilde{\rho}^i_t$. In practice however, the estimate $\tilde{\rho}^i_t$ might entail errors despite the use of all samples from past iterations, which are propagated forward leading to a degeneracy of the number of effective samples in latter time-steps.

4.3.2 State distribution of a mixture policy

The second considered solution for the estimation of $\tilde{\rho}^i_t$ is heuristic but behaved better in practice. It is based on the intuition that the KL constraint of the policy update will yield state distributions that are close to each other (see Sec. 5 for a theoretical justification of the closeness in state distributions) and state samples from previous iterations can be reused in a simpler manner. Specifically, $\tilde{\rho}^i_t$ will be learned from samples of the mixture policy $\pi^{1:i} \propto \sum_{j=1}^{i} \gamma^{i-j}\pi^j$ which selects a policy from previous iterations with an exponentially decaying (w.r.t. the iteration number) probability and executes it for a whole rollout. In practice, the decay factor γ is selected according to the dimensionality of the problem, the number of samples per iterations M and the KL upper bound ϵ (intuitively, a smaller ϵ yields closer policies and henceforth more reusable samples). The estimated state distribution $\tilde{\rho}^i_t$ is learned as a Gaussian distribution by weighted maximum likelihood from samples of $\mathcal{D}^{1:i}_t$ where a sample of iteration j is weighted by γ^{i-j}.

4.4 The MOTO Algorithm

MOTO is summarized in Alg. 1. The innermost loop is split between policy evaluation (Sec. 4) and policy update (Sec. 3). For every time-step t, once the state distribution $\tilde{\rho}^i_t$ is estimated, the IWs of all the transition samples are computed and used to learn the Q-Function (and the V-Function using the same IWs, if dynamic programming is used when estimating the Q-Function), concluding the policy evaluation part. Subsequently, the components of the quadratic model $\tilde{Q}^i_t$ that depend on the action are extracted and used to find the optimal dual parameters η^* and ω^* that are respectively related to the KL and the entropy constraint, by minimizing the convex dual function g^i_t using gradient descent.

Algorithm 1 Model-Free Trajectory-based Policy Optimization (MOTO)

Input: Initial policy π^0, number of trajectories per iteration M, step-size ϵ and entropy reduction rate β_0
Output: Policy π^N
for $i = 0$ **to** $N-1$ **do**
  Sample M trajectories from π^i
  for $t = T$ **to** 1 **do**
    Estimate state distribution $\tilde{\rho}_t^i$ (Sec. 4.3)
    Compute IW for all $(\boldsymbol{s}, a, s') \in \mathcal{D}^{1:i}$ (Sec. 4.2)
    Estimate the Q-Function $\tilde{Q}_t^i$ (Sec. 4.1)
    Optimize: $(\eta^*, \omega^*) = \arg\min g_t^i(\eta, \omega)$ (Sec. 3.3)
    Update π_t^{i+1} using η^*, ω^*,$\tilde{\rho}_t^i$ and $\tilde{Q}_t^i$ (Sec. 3.2)
  end for
end for

The policy update then uses η^* and ω^* to return the new policy π_{t+1} and the process is iterated.

In addition to the simplification of the policy update, the rationale behind the use of a local quadratic approximation for Q_t^i is twofold: i) since Q_t^i is only optimized locally (because of the KL constraint), a quadratic model would potentially contain as much information as a Hessian matrix in a second order gradient descent setting ii) If $\tilde{Q}_t$ in Eq. (4) is an arbitrarily complex model then it is common that π_t', of linear-Gaussian form, is fit by weighted maximum-likelihood (Deisenroth et al., 2013); it is clear though from Eq. (4) that however complex $\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a})$ is, if both π_t and π_t' are of linear-Gaussian form then there exist a quadratic model that would result in the same policy update. Additionally, note that $\tilde{Q}_t$ is not used when learning $\tilde{Q}_{t-1}$ (sec. 4.1) and hence the bias introduced by $\tilde{Q}_t$ will not propagate back. For these reasons, we think that choosing a more complex class for $\tilde{Q}_t$ than that of quadratic functions might not necessarily lead to an improvement of the resulting policy, for the class of linear-Gaussian policies.

5. Monotonic Improvement of the Policy Update

We analyze in this section the properties of the constrained optimization problem solved during our policy update. Kakade and Langford (2002) showed that in the approximate policy iteration setting, a monotonic improvement of the policy return can be obtained if the successive policies are close enough. While in our algorithm the optimization problem defined in Sec. 3.1 bounds the expected policy KL under the state distribution of the current iteration i, it does not tell us how similar the policies are under the new state distribution and a more careful analysis needs to be conducted.

The analysis we present builds on the results of Kakade and Langford (2002) to lower-bound the change in policy return $J(\pi^{i+1}) - J(\pi^i)$ between the new policy π^{i+1} (solution of the optimization problem defined in Sec. 3.1) and the current policy π^i. Unlike Kakade and Langford (2002), we enforce closeness between successive policies with a KL constraint instead of by mixing π^{i+1} and π^i. Related results were obtained when a KL constraint is

used in Schulman et al. (2015). Our main contribution is to extend these results to the trajectory optimization setting with continuous states and actions and where the expected KL between the policies is bounded instead of the maximum KL over the state space (which is hard to achieve in practice).

In what follows, p and q denote the next policy π^{i+1} and the current policy π^i respectively. We will denote the state distribution and policy at time-step t by p_t and $p_t(.|\boldsymbol{s})$ respectively (and similarly for q). First, we start by writing the difference between policy returns in term of advantage functions.

Lemma 1 *For any two policies p and q, and where A_t^q denotes the advantage function at time-step t of policy q, the difference in policy return is given by*

$$J(p) - J(q) = \sum_{t=1}^{T} \mathbb{E}_{\boldsymbol{s}\sim p_t, \boldsymbol{a}\sim p_t(.|\boldsymbol{s})} \left[A_t^q(\boldsymbol{s}, \boldsymbol{a})\right].$$

The proof of Lemma 1 is given by the proof of Lemma 5.2.1 in (Kakade, 2003). Note that Lemma 1 expresses the change in policy return in term of expected advantage under the current state distribution while we optimize the advantage function under the state distribution of policy q, which is made apparent in Lemma 2.

Lemma 2 *Let $\epsilon_t = \mathrm{KL}(p_t \parallel q_t)$ be the KL divergence between state distributions $p_t(.)$ and $q_t(.)$ and let $\delta_t = \max_s |\mathbb{E}_{\boldsymbol{a}\sim p_t(.|\boldsymbol{s})}[A_t^q(\boldsymbol{s}, \boldsymbol{a})]|$, then for any two policies p and q we have*

$$J(p) - J(q) \geq \sum_{t=1}^{T} \mathbb{E}_{\boldsymbol{s}\sim q_t, \boldsymbol{a}\sim p_t(.|\boldsymbol{s})} \left[A_t^q(\boldsymbol{s}, \boldsymbol{a})\right] - 2\sum_{t=1}^{T} \delta_t \sqrt{\frac{\epsilon_t}{2}}.$$

Proof

$$\begin{aligned}
\mathbb{E}_{s\sim p_t, a\sim p_t(.|\boldsymbol{s})} \left[A_t^q(\boldsymbol{s}_t, \boldsymbol{a}_t)\right] &= \int p_t(\boldsymbol{s}) \int p_t(\boldsymbol{a}_t|\boldsymbol{s}_t) A_t^q(\boldsymbol{s}_t, \boldsymbol{a}_t), \\
&= \int q_t(\boldsymbol{s}) \int p_t(\boldsymbol{a}_t|\boldsymbol{s}_t) A_t^q(\boldsymbol{s}_t, \boldsymbol{a}_t) \\
&\quad + \int (p_t(\boldsymbol{s}) - q_t(\boldsymbol{s})) \int p_t(\boldsymbol{a}_t|\boldsymbol{s}_t) A_t^q(\boldsymbol{s}_t, \boldsymbol{a}_t), \\
&\geq \mathbb{E}_{s\sim q_t, a\sim p_t(.|\boldsymbol{s})} \left[A_t^q(\boldsymbol{s}, \boldsymbol{a})\right] - \delta_t \int (p_t(\boldsymbol{s}) - q_t(\boldsymbol{s})), \\
&\geq \mathbb{E}_{s\sim q_t, a\sim p_t(.|\boldsymbol{s})} \left[A_t^q(\boldsymbol{s}, \boldsymbol{a})\right] - 2\delta_t \frac{1}{2} \int |p_t(\boldsymbol{s}) - q_t(\boldsymbol{s})|, \\
&\geq \mathbb{E}_{s\sim q_t, a\sim p_t(.|\boldsymbol{s})} \left[A_t^q(\boldsymbol{s}, \boldsymbol{a})\right] - 2\delta_t \sqrt{\frac{1}{2}\mathrm{KL}(p_t \parallel q_t)}. \\
&\qquad \text{(Pinsker's inequality)}
\end{aligned}$$

Summing over the time-steps and using Lemma 1 completes the proof. ■

Lemma 2 lower-bounds the change in policy return by the advantage term optimized during the policy update and a negative change that quantifies the change in state distributions between successive policies. The core of our contribution is given by Lemma 3 which

relates the change in state distribution to the expected KL constraint between policies of our policy update.

Lemma 3 *If for every time-step, the state distributions p_t and q_t are Gaussian and the policies $p_t(.|\boldsymbol{s}_t)$ and $q_t(.|\boldsymbol{s}_t)$ are linear-Gaussian and if $\mathbb{E}_{s\sim q_t}\left[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))\right] \leq \epsilon$ for every time-step then $\mathrm{KL}(p_t \parallel q_t) = \mathcal{O}(\epsilon)$ as $\epsilon \to 0$ for every time-step.*

Proof We will demonstrate the lemma by induction noting that for $t = 1$ the state distributions are identical and hence their KL is zero. Assuming $\epsilon_t = \mathrm{KL}(p_t \parallel q_t) = \mathcal{O}(\epsilon)$ as $\epsilon \to 0$, let us compute the KL between state distributions for $t+1$

$$\begin{aligned}
\mathrm{KL}(p_{t+1} \parallel q_{t+1}) &= \int p_{t+1}(\boldsymbol{s}') \log \frac{p_{t+1}(\boldsymbol{s}')}{q_{t+1}(\boldsymbol{s}')}, \\
&\leq \iiint p_t(\boldsymbol{s},\boldsymbol{a}) p(\boldsymbol{s}'|\boldsymbol{a},\boldsymbol{s}) \log \frac{p_t(\boldsymbol{s},\boldsymbol{a}) p(\boldsymbol{s}'|\boldsymbol{a},\boldsymbol{s})}{q_t(\boldsymbol{s},\boldsymbol{a}) p(\boldsymbol{s}'|\boldsymbol{a},\boldsymbol{s})}, \qquad \text{(log sum inequality)} \\
&= \int p_t(\boldsymbol{s}') \int p_t(\boldsymbol{a}|\boldsymbol{s}') \log \frac{p_t(\boldsymbol{s}') p_t(\boldsymbol{a}|\boldsymbol{s}')}{q_t(\boldsymbol{s}') q_t(\boldsymbol{a}|\boldsymbol{s}')}, \\
&= \epsilon_t + \mathbb{E}_{s\sim p_t}[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))]. \qquad (9)
\end{aligned}$$

Hence we have bounded the KL between state distributions at $t+1$ by the KL between state distributions and the expected KL between policies of the previous time-step t. Now we will express the KL between policies under the new state distributions, given by $\mathbb{E}_{s\sim p_t}[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))]$, in terms of KL between policies under the previous state distribution, $\mathbb{E}_{s\sim q_t}\left[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))\right]$ which is bounded during policy update by ϵ, and $\mathrm{KL}(p_t \parallel q_t)$. To do so, we will use the assumption that the state distribution and the policy are Gaussian and linear-Gaussian. The complete demonstration is given in Appendix B, and we only report the following result

$$\mathbb{E}_{s\sim p_t}[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))] \leq 2\epsilon \left(3\epsilon_t + d_s + 1\right). \qquad (10)$$

It is now easy to see that the combination of (9) and (10) together with the induction hypothesis yields $\mathrm{KL}(p_{t+1} \parallel q_{t+1}) = \mathcal{O}(\epsilon)$ as $\epsilon \to 0$. ■

Finally, the combination of Lemma 2 and Lemma 3 results in the following theorem, lower-bounding the change in policy return.

Theorem 4 *If for every time-step the state distributions p_t and q_t are Gaussian and the policies $p_t(.|\boldsymbol{s}_t)$ and $q_t(.|\boldsymbol{s}_t)$ are linear-Gaussian and if $\mathbb{E}_{s\sim q_t}\left[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))\right] \leq \epsilon$ for every time-step then*

$$J(p) - J(q) \geq \sum_{t=1}^{T} \mathbb{E}_{s\sim q_t, a\sim p_t(.|\boldsymbol{s})}\left[A_t^q(\boldsymbol{s},\boldsymbol{a})\right] - \sum_{t=1}^{T} \delta_t \mathcal{O}(\sqrt{\epsilon}).$$

Theorem 4 shows that we are able to obtain similar bounds than those derived in (Schulman et al., 2015) for our continuous state-action trajectory optimization setting with a bounded KL policy update in expectation under the previous state distribution. While, it

is not easy to apply Theorem 4 in practice to choose an appropriate step-size ϵ since $A_t^q(\boldsymbol{s},\boldsymbol{a})$ is generally only known approximately, Theorem 4 still shows that our constrained policy update will result in small changes in the overall behavior of the policy between successive iterations which is crucial in the approximate RL setting.

6. Related Work

In the Approximate Policy Iteration scheme (Szepesvari, 2010), policy updates can potentially decrease the expected reward, leading to policy oscillations (Wagner, 2011), unless the updated policy is 'close' enough to the previous one (Kakade and Langford, 2002). Bounding the change between π^i and π^{i+1} during the policy update step is thus a well studied idea in the Approximate Policy Iteration literature. Already in 2002, Kakade and Langford proposed the Conservative Policy Iteration (CPI) algorithm where the new policy π^{i+1} is obtained as a mixture of π^i and the greedy policy w.r.t. Q^i. The mixture parameter is chosen such that a lower bound of $J(\pi^{i+1}) - J(\pi^i)$ is positive and improvement is guaranteed. However, convergence was only asymptotic and in practice a single policy update would require as many samples as other algorithms would need to find the optimal solution (Pirotta et al., 2013b). Pirotta et al. (2013b) refined the lower bound of CPI by adding an additional term capturing the closeness between policies (defined as the matrix norm of the difference between the two policies), resulting in a more aggressive updates and better experimental results. However, both approaches only considered discrete action spaces. Pirotta et al. (2013a) provide an extension to continuous domains but only for single dimensional actions.

When the action space is continuous, which is typical in e.g. robotic applications, using a stochastic policy and updating it under a KL constraint to ensure 'closeness' of successive policies has shown several empirical successes (Daniel et al., 2012; Levine and Koltun, 2014; Schulman et al., 2015). However, only an empirical sample estimate of the objective function is generally optimized (Peters et al., 2010; Schulman et al., 2015), which typically requires a high number of samples and precludes it from a direct application to physical systems. The sample complexity can be reduced when a model of the dynamics is available (Levine and Koltun, 2014) or learned (Levine and Abbeel, 2014). In the latter work, empirical evidence suggests that good policies can be learned on high dimensional continuous state-action spaces with only a few hundred episodes. The counter part being that time-dependent dynamics are assumed to be linear, which is a simplifying assumption in many cases. Learning more sophisticated models using for example Gaussian Processes was experimented by Deisenroth and Rasmussen (2011) and Pan and Theodorou (2014) in the Policy Search and Trajectory Optimization context, but it is still considered to be a challenging task, see Deisenroth et al. (2013), chapter 3.

The policy update in Eq. (4) resembles that of (Peters et al., 2010; Daniel et al., 2012) with three main differences. First, without the assumption of a quadratic Q-Function, an additional weighted maximum likelihood step is required for fitting π^{i+1} to weighted samples as in the r.h.s of Eq. (4), since this policy might not be of the same policy class. As a result, the KL between π^i and π^{i+1} is no longer respected. Secondly, we added an entropy constraint in order to cope with the inherent non-stationary objective function maximized by the policy (Eq. 1) and to ensure that exploration is sustained, resulting in better quality

policies. Thirdly, their sample based optimization algorithm requires the introduction of a number of dual variables typically scaling at least linearly with the dimension of the state space, while we only have to optimize over two dual variables irrespective of the state space.

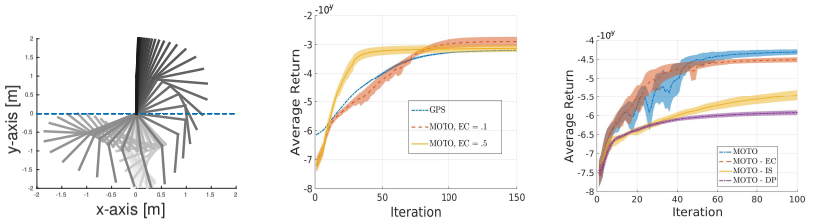
Most trajectory optimization methods are based on stochastic optimal control. These methods linearize the system dynamics and update the policy in closed form as a LQR. Instances of such algorithms are for example iLQG (Todorov, 2006), DDP (Theodorou et al., 2010), AICO (Toussaint, 2009) and its more robust variant (Rückert et al., 2014) and the trajectory optimization algorithm used in the GPS algorithm (Levine and Abbeel, 2014). These methods share the same assumptions as MOTO for ρ_t^i and π_t^i respectively considered to be of Gaussian and linear-Gaussian form. These methods face issues in maintaining the stability of the policy update and, similarly to MOTO, introduce additional constraints and regularizers to their update step. DDP, iLQG and AICO regularize the update by introducing a damping term in the matrix inversion step, while GPS uses a KL bound on successive trajectory distributions. However, as demonstrated in Sec. 7, the quadratic approximation of the Q-Function performed by MOTO seems to be empirically less detrimental to the quality of the policy update than the linearization of the system dynamics around the mean trajectory performed by related approaches.

7. Experimental Validation

MOTO is experimentally validated on a set of multi-link swing-up tasks and on a robot table tennis task. The experimental section aims at analyzing the proposed algorithm from four different angles: i) the quality of the returned policy comparatively to state-of-the-art trajectory optimization algorithms, ii) the effectiveness of the proposed variance reduction and sample reuse schemes, iii) the contribution of the added entropy constraint during policy updates in finding better local optima and iv) the ability of the algorithm to scale to higher dimensional problems. The experimental section concludes with a comparison to TRPO (Schulman et al., 2015), a state-of-the-art reinforcement learning algorithm that bounds the KL between successive policies; showcasing settings in which the time-dependent linear-Gaussian policies used by MOTO are a suitable alternative to neural networks.

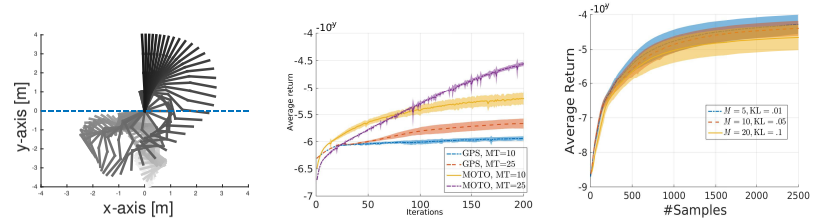
7.1 Multi-link Swing-up Tasks

A set of swing-up tasks involving a multi-link pole with respectively two and four joints (Fig. 1.a and 2.a) is considered in this section. The set of tasks includes several variants with different torque and joint limits, introducing additional non-linearities in the dynamics and resulting in more challenging control problems for trajectory optimization algorithms based on linearizing the dynamics. The state space consists of the joint positions and joint velocities while the control actions are the motor torques. In all the tasks, the reward function is split between an action cost and a state cost. The action cost is constant throughout the time-steps while the state cost is time-dependent and is equal to zero for all but the 20 last time-steps. During this period, a quadratic cost penalizes the state for not being the null vector, i.e. having zero velocity and reaching the upright position. Examples of successful swing-ups learned with MOTO are depicted in Fig. 1.a and 2.a.



(a) (b) (c)

Figure 1: a) Double link swing-up policy found by MOTO. b) Comparison between GPS and MOTO on the double link swing-up task (different torque limits and state costs are applied compared to c) and f). c) MOTO and its variants on the double link swing-up task: MOTO without the entropy constraint (EC), importance sampling (IS) or dynamic programming (DP). All plots are averaged over 15 runs.



(a) (b) (c)

Figure 2: a) Quad link swing-up policy found by MOTO. b) Comparison between GPS and MOTO on the quad link swing-up task with restricted joint limits and two different torque limits. c) MOTO on the double link swing-up task for varying number of rollouts per episode and step-sizes. All plots are averaged over 15 runs.

MOTO is compared to the trajectory optimization algorithm proposed in Levine and Abbeel (2014), that we will refer to as GPS.[4] We chose to compare MOTO and GPS as both use a KL constraint to bound the change in policy. As such, the choice of approximating the Q-Function with time-dependent quadratic models (as done in MOTO) in order to solve the policy update instead of linearizing the system dynamics around the mean trajectory (as done in most trajectory optimization algorithms) is better isolated. GPS and MOTO both use a time-dependent linear-Gaussian policy. In order to learn the linear

4. This is a slight abuse of notation as the GPS algorithm of (Levine and Abbeel, 2014) additionally feeds the optimized trajectory to an upper level policy. However, in this article, we are only interested in the trajectory optimization part.

model of the system dynamics, GPS reuses samples from different time-steps by learning a Gaussian mixture model on all the samples and uses this model as a prior to learn a joint Gaussian distribution $p(\boldsymbol{s}_t, \boldsymbol{a}_t, \boldsymbol{s}_{t+1})$ for every time-step. To single out the choice of linearizing the dynamics model or lack thereof from the different approaches to sample reuse, we give to both algorithm a high number of samples (200 and 400 rollouts per iteration for the double and quad link respectively) and bypass any form of sample reuse for both algorithms.

Fig. 1.b compares GPS to two configurations of MOTO on the double-link swing up task. The same initial policy and step-size ϵ are used by both algorithm. However, we found that GPS performs better with a smaller initial variance, as otherwise actions quickly hit the torque limits making the dynamics modeling harder. Fig. 1.b shows that even if the dynamics of the system are not linear, GPS manages to improve the policy return, and eventually finds a swing-up policy. The two configurations of MOTO have an entropy reduction constant β_0 of .1 and .5. The effect of the entropy constraint is similar to the one observed in the stochastic search domain by (Abdolmaleki et al., 2015). Specifically, a smaller entropy reduction constant β_0 results in an initially slower convergence but ultimately leads to higher quality policies. In this particular task, MOTO with $\beta_0 = .1$ manages to slightly outperform GPS.

Next, GPS and MOTO are compared on the quad link swing-up task. We found this task to be significantly more challenging than the double link and to increase the difficulty further, soft joint limits are introduced on the three last joints in the following way: whenever a joint angle exceeds in absolute value the threshold $\frac{2}{3}\pi$, the desired torque of the policy is ignored in favor of a linear-feedback controller that aims at pushing back the joint angle within the constrained range. As a result, Fig. 2.b shows that GPS can barely improve its average return (with the torque limits set to 25, as in the double link task.) while MOTO performs significantly better. Finally, the torque limits are reduced even further but MOTO still manages to find a swing-up policy as demonstrated by Fig. 2.a.

In the last set of comparisons, the importance of each of the components of MOTO is assessed on the double link experiment. The number of rollouts per iteration is reduced to $M = 20$. Fig. 1.c shows that: i) the entropy constraint provides an improvement on the quality of the policy in the last iterations in exchange of a slower initial progress, ii) importance sampling greatly helps in speeding-up the convergence and iii) the Monte-Carlo estimate of $\hat{Q}_i^t$ is not adequate for the smaller number of rollouts per iterations, which is further exacerbated by the fact that sample reuse of transitions from different time-steps is not possible with the Monte-Carlo estimate.

Finally, we explore on the double-link swing-up task several values of M, trying to find the balance between performing a small number of rollouts per iterations with a small step-size ϵ versus having a large number of rollouts for the policy evaluation that would allow to take larger update steps. To do so, we start with an initial $M = 20$ and successively divide this number by two until $M = 5$. In each case, the entropy reduction constant is set such that, for a similar number of rollouts, the entropy is reduced by the same amount, while we choose γ', the discount of the state sample weights as $\gamma' = \gamma^{M/M'}$ to yield again

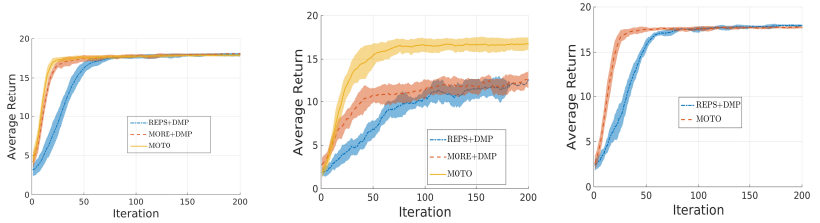


Figure 3: a) Comparison on the robot table tennis task with no noise on the initial velocity of the ball. b) Comparison on the robot table tennis task with Gaussian noise during the ball bounce on the table. c) Comparison on the robot table tennis task with initial velocity sampled uniformly in a 15cm range.

a similar sample decay after the same number of rollouts have been performed. Tuning ϵ was, however, more complicated and we tested several values on non-overlapping ranges for each M and selected the best one. Fig. 2.c shows that, on the double link swing-up task, a better sample efficiency is achieved with a smaller M. However, the improvement becomes negligible from $M = 10$ to $M = 5$. We also noticed a sharp decrease in the number of effective samples when M tends to 1. In this limit case, the complexity of the mixture policy $z^{1:i}$ in the denominator of the importance ratio increases with the decrease of M and might become a poor representation of the data set. Fitting a simpler state-action distribution that is more representative of the data can be the subject of future work in order to further improve the sample efficiency of the algorithm, which is crucial for applications on physical systems.

7.2 Robot Table Tennis

The considered robot table tennis task consists of a simulated robotic arm mounted on a floating base, having a racket on the end effector. The task of the robot is to return incoming balls using a forehand strike to the opposite side of the table (Fig. 4). The arm has 9 degrees of freedom comprising the six joints of the arm and the three linear joints of the base allowing (small) 3D movement. Together with the joint velocities and the 3D position of the incoming ball, the resulting state space is of dimension $d_s = 21$ and the action space is of dimension $d_a = 9$ and consists of direct torque commands.

We use the analytical player of Mülling et al. (2011) to generate a single forehand stroke, which is subsequently used to learn from demonstration the initial policy π^1. The analytica player comprises a waiting phase (keeping the arm still), a preparation phase, a hitting phase and a return phase, which resets the arm to the waiting position of the arm. Only the preparation and the hitting phase are replaced by a learned policy. The total control time for the two learned phases is of 300 time-steps at 500hz, although for the MOTO

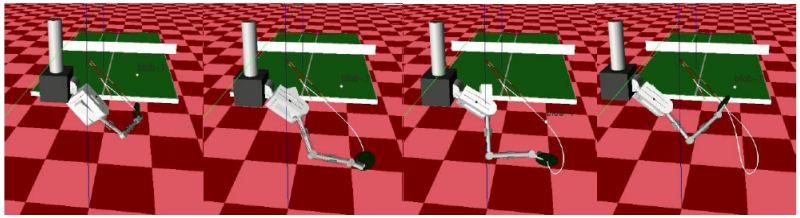

Figure 4: Robot table tennis setting and a forehand stroke learned by MOTO upon a spinning ball.

algorithm we subsequently divide the control frequency by a factor of 10 resulting in a time-dependent policy of 30 linear-Gaussian controllers.

The learning from demonstration step is straightforward and only consists in averaging the torque commands of every 10 time-steps and using these quantities as the initial bias for each of the 30 controllers. Although this captures the basic template of the forehand strike, no correlation between the action and the state (e.g. the ball position) is learned from demonstration as the initial gain matrix K for all the time-steps is set to the null matrix. Similarly, the exploration in action space is uninformed and initially set to the identity matrix.

Three settings of the task are considered, a noiseless case where the ball is launched with the same initial velocity, a varying context setting where the initial velocity is sampled uniformly within a fixed range and the noisy bounce setting where a Gaussian noise is added to both the x and y velocities of the ball upon bouncing on the table, to simulate the effect of a spin.

We compare MOTO to the policy search algorithm REPS (Kupcsik et al., 2013) and the stochastic search algorithm MORE (Abdolmaleki et al., 2015) that shares a related information-theoretic update. Both algorithms will optimize the parameters of a Dynamical Movement Primitive (DMP) (Ijspeert and Schaal, 2003). A DMP is a non-linear attractor system commonly used in robotics. The DMP is initialized from the same single trajectory and the two algorithm will optimize the goal joint positions and velocities of the attractor system. Note that the DMP generates a trajectory of states, which will be tracked by a linear controller using the inverse dynamics. While MOTO will directly output the torque commands and does not rely on this model.

Fig. 3.a and 3.c show that our algorithm converges faster than REPS and to a smaller extent than MORE in both the noiseless and the varying context setting. This is somewhat surprising since MOTO with its time-dependent linear policy have a much higher number of parameters to optimize than the 18 parameters of the DMP's attractor. However, the resulting policy in both cases is slightly less good than that of MORE and REPS. Note that for the varying context setting, we used a contextual variant of REPS that learns a mapping from the initial ball velocity to the DMP's parameters. MORE, on the other hand couldn't be compared in this setting. Finally, Fig. 3.b shows that our policy is successfully

capable of adapting to noise at ball bounce, while the other methods fail to do so since the trajectory of the DMP is not updated once generated.

7.3 Comparison to Neural Network Policies

Recent advances in reinforcement learning using neural network policies and supported by the ability of generating and processing large amounts of data allowed impressive achievements such as playing Atari at human level (Mnih et al., 2015) or mastering the game of Go (Silver et al., 2016). On continuous control tasks, success was found by combining trajectory optimization and supervised learning of a neural network policy (Levine and Abbeel, 2014), or by directly optimizing the policy's neural network using reinforcement learning (Lillicrap et al., 2015; Schulman et al., 2015). The latter work, side-stepping trajectory optimization to directly optimize a neural network policy raises the question as to whether the linear-Gaussian policies used in MOTO and related algorithms provide any benefit compared to neural network policies.

To this end, we propose to compare on the multi-link swing-up tasks of Sec. 7.1, MOTO learning a time-dependent linear-Gaussian policy to TRPO (Schulman et al., 2015) learning a neural network policy. We chose TRPO as our reinforcement learning baseline for its state-of-the-art performance and because of its similar policy update than that of MOTO (both bound the KL between successive policies). Three variants of TRPO are considered while for MOTO, we refrain from using importance sampling (Sec. 4.2) since similar techniques such as off-policy policy evaluation can be used for TRPO.

First, MOTO is compared to a default version of TRPO using OpenAI's baselines implementation (Dhariwal et al., 2017) where TRPO optimizes a neural network for both learning the policy and the V-Function. Default parameters are used except for the KL divergence constraint where we set $\epsilon = .1$ for TRPO to match MOTO's setting. Note that because the rewards are time-dependent (distance to the upright position penalized only for the last 20 steps, see Sec. 7.1) we add time as an additional entry to the state description. Time entry is in the interval $[0, 1]$ (current time-step divided by horizon T) and is fed to both the policy and V-Function neural networks. This first variant of TRPO answers the question: is there any benefit for using MOTO with its time-dependent linear-Gaussian policy instead of a state-of-the-art deep RL implementation with a neural network policy.

The second considered baseline uses the same base TRPO algorithm but replaces the policy evaluation using a neural network V-Function with the same policy evaluation used by MOTO (Sec. 4), back-propagating a quadratic V-Function. In this variant of TRPO the time-entry is dropped for the V-Function. This second baseline better isolates the policy update, which is the core of both algorithms, from the learning of the V-Function which could be interchanged.

Finally, we consider a third variant of TRPO that uses both the quadratic V-Function and a time-dependent linear-Gaussian policy with diagonal covariance matrix (standard formulation and implementation of TRPO does not support full covariance exploration noise). The time entry is dropped for both the V-Function and the policy in this third baseline. While both algorithms bound the KL divergence between successive policies, there are still a few differentiating factors between this third baseline and MOTO. First, TRPO bounds the KL of the whole policy while MOTO solves a policy update for each time-step independently

(but still results in a well-founded approximate policy iteration algorithm as discussed in Sec. 5). In practice the KL divergence upon update for every time-step for MOTO is often equal to ϵ and hence both MOTO and TRPO result in the same KL divergence of the overall policy (in expectation of the state distribution) while the KL divergence of the sub-policies (w.r.t. the time-step) may vary. Secondly, MOTO performs a quadratic approximation of the Q-Function and solves the policy update exactly while TRPO performs a quadratic approximation of the KL constraint and solves the policy update using conjugate gradient descent. TRPO does not solve the policy update in closed form because it would require a matrix inversion and the matrix to invert has the dimensionality of the number of policy parameters. In contrast, MOTO can afford the closed form solution because the matrix to invert has the dimensionality of the action space which is generally significantly smaller than the number of policy parameters.

Fig. 5 shows the learning performance of MOTO and three TRPO variants on the double link and quadruple link swing-up tasks (Sec. 7.1). In both tasks MOTO outperforms all three TRPO variants albeit when TRPO is combined with the quadratic V-Function (second variant), it initially outperforms MOTO on the double link swing-up task. The quadratic V-Function befits these two tasks in particular and the quadratic regulation setting more generally because the reward is a quadratic function of the state-action pair (here the negative squared distance to the upright position and a quadratic action cost). However, MOTO makes better use of the task's nature and largely outperforms the third variant of TRPO despite having a similar policy evaluation step and using the same policy class. In conclusion, while neural networks can be a general purpose policy class demonstrating success on a wide variety of tasks, on specific settings such as on quadratic regulator tasks, trajectory-based policy optimization is able to outperform deep RL algorithms. MOTO in particular, which does not rely on a linearization of the dynamics around the mean trajectory is able to handle quadratic reward problems with highly non-linear dynamics such as the quadruple link swing-up task and outperform state-of-the-art trajectory optimization algorithms (Sec. 7.1) as a result.

8. Conclusion

We proposed in this article MOTO, a new trajectory-based policy optimization algorithm that does not rely on a linearization of the dynamics. Yet, an efficient policy update could be derived in closed form by locally fitting a quadratic Q-Function. We additionally conducted a theoretical analysis of the constrained optimization problem solved during the policy update. We showed that the upper bound on the expected KL between successive policies leads to only a small drift in successive state distributions which is a key property in the approximate policy iteration scheme.

The use of a KL constraint is widely spread including in other trajectory optimization algorithms. The experiments demonstrate however that our algorithm has an increased robustness towards non-linearities of the system dynamics when compared to a closely related trajectory optimization algorithm. It appears as such that the simplification resulting from considering a local linear approximation of the dynamics is more detrimental to the overall convergence of the algorithm than a local quadratic approximation of the Q-Function.

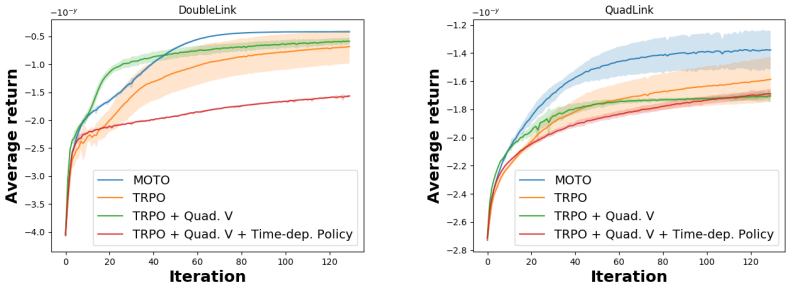

Figure 5: Comparisons on multi-link swing-up tasks between MOTO and TRPO. TRPO uses a neural network policy and V-Function (default) or a quadratic V-Function and a time-dependent linear-Gaussian policy as in MOTO. Quadratic V-Function is a good fit for such tasks and allows MOTO to outperform neural network policies on the double and quadruple link swing-up tasks. Rewards of the original task divided by 1e4 to accomodate with the neural network V-Function. Plots averaged over 11 independent runs.

On simulated robotics tasks, we demonstrated the merits of our approach compared to direct policy search algorithms that optimize commonly used low dimensional parameterized policies. The main strength of our approach is its ability to learn reactive policies capable of adapting to external perturbations in a sample efficient way. However, the exploration scheme of our algorithm based on adding Gaussian noise at every time-step is less structured than that of low dimensional parameterized policies and can be harmful to the robot. One of the main addition that would ease the transition from simulation to physical systems is thus to consider the safety of the exploration scheme of the algorithm. On a more technical note, and as the V-Function can be of any shape in our setting, the use of a more complex function approximator such as a deep network can be considered in future extensions to allow for a more refined bias-variance trade-off.

Acknowledgments

The research leading to these results has received funding from the DFG Project LearnRobotS under the SPP 1527 Autonomous Learning, from the Intel Corporation, and from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 640554 (SKILLS4ROBOTS). Computing time for the experiments was granted from Lichtenberg cluster.

Appendix A. Dual Function Derivations

Recall the quadratic form of the Q-Function $\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a})$ in the action a and state s

$$\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a}) = \frac{1}{2}\boldsymbol{a}^T Q_{aa}\boldsymbol{a} + \boldsymbol{a}^T Q_{as}\boldsymbol{s} + \boldsymbol{a}^T \boldsymbol{q}_a + q(\boldsymbol{s}).$$

The new policy $\pi'_t(\boldsymbol{a}|\boldsymbol{s})$ solution of the constrained maximization problem is again of linear-Gaussian form and given by

$$\pi'_t(\boldsymbol{a}|\boldsymbol{s}) = \mathcal{N}(\boldsymbol{a}|FL\boldsymbol{s} + F\boldsymbol{f}, F(\eta^* + \omega^*)),$$

such that the gain matrix, bias and covariance matrix of π'_t are function of matrices F and L and vector $\boldsymbol{f}$ where

$$F = (\eta^*\Sigma_t^{-1} - Q_{aa})^{-1}, \qquad L = \eta^*\Sigma_t^{-1}K_t + Q_{as},$$
$$\boldsymbol{f} = \eta^*\Sigma_t^{-1}\boldsymbol{k}_t + \boldsymbol{q}_a,$$

with η^* and ω^* being the optimal Lagrange multipliers related to the KL and entropy constraints, obtained by minimizing the dual function

$$g_t(\eta, \omega) \;=\; \eta\epsilon - \omega\beta + (\eta + \omega)\int \tilde{\rho}_t(\boldsymbol{s}) \log\left(\int \pi(\boldsymbol{a}|\boldsymbol{s})^{\eta/(\eta+\omega)} \exp\left(\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a})/(\eta + \omega)\right)\right).$$

From the quadratic form of $\tilde{Q}_t(\boldsymbol{s}, \boldsymbol{a})$ and by additionally assuming that the state distribution is approximated by $\tilde{\rho}_t(\boldsymbol{s}) = \mathcal{N}(\boldsymbol{s}|\boldsymbol{\mu}_s, \Sigma_s)$, the dual function simplifies to

$$g_t(\eta, \omega) = \eta\epsilon - \omega\beta + \boldsymbol{\mu}_s^T M\boldsymbol{\mu}_s + \mathrm{tr}(\Sigma_s M) + \boldsymbol{\mu}_s^T\boldsymbol{m} + m_0,$$

where M, $\boldsymbol{m}$ and m_0 are defined by

$$M = \frac{1}{2}\left(L^T F L - \eta K_t^T\Sigma_t^{-1}K_t\right), \; \boldsymbol{m} = L^T F\boldsymbol{f} - \eta K_t^T\Sigma_t^{-1}\boldsymbol{k}_t,$$
$$m_0 = \frac{1}{2}(\boldsymbol{f}^T F\boldsymbol{f} - \eta\boldsymbol{k}_t^T\Sigma_t^{-1}\boldsymbol{k}_t - \eta\log|2\pi\Sigma_t| + (\eta + \omega)\log|2\pi(\eta + \omega)F|).$$

The convex dual function g_t can be efficiently minimized by gradient descent and the policy update is performed upon the computation of η^* and ω^*. The gradient w.r.t. η and ω is given by[5]

$$\frac{\partial g_t(\eta, \omega)}{\partial \eta} = \mathrm{cst} + \mathrm{lin} + \mathrm{quad}$$
$$\mathrm{cst} = \epsilon - \frac{1}{2}\left(\boldsymbol{k}_t - F\boldsymbol{f}\right)^T\Sigma_t^{-1}\left(\boldsymbol{k}_t - F\boldsymbol{f}\right) - \frac{1}{2}[\log|2\pi\Sigma_t| - \log|2\pi(\eta + \omega)F| + (\eta + \omega)\mathrm{tr}(\Sigma_t^{-1}F) - d_a].$$
$$\mathrm{lin} = \left((K_t - FL)\boldsymbol{\mu}_s\right)^T\Sigma_t^{-1}(F\boldsymbol{f} - \boldsymbol{k}_t).$$
$$\mathrm{quad} = \boldsymbol{\mu}_s^T(K_t + FL)^T\Sigma_t^{-1}(K_t + FL)\boldsymbol{\mu}_s + \mathrm{tr}(\Sigma_s(K_t + FL)^T\Sigma_t^{-1}(K_t + FL))$$
$$\frac{\partial g_t(\eta, \omega)}{\partial \omega} = -\beta + \frac{1}{2}(d_a + \log|2\pi(\eta + \omega)F|).$$

5. cst, lin, quad, F, L and $\boldsymbol{f}$ all depend on η and ω. We dropped the dependency from the notations for compactness. d_a is the dimensionality of the action.

Appendix B. Bounding the Expected Policy KL Under the Current State Distribution

Let the state distributions and policies be parameterized as following: $p_t(\boldsymbol{s}) = \mathcal{N}(\boldsymbol{s}|\boldsymbol{\mu}_p, \Sigma_p)$, $q_t(\boldsymbol{s}) = \mathcal{N}(\boldsymbol{s}|\boldsymbol{\mu}_q, \Sigma_q)$, $p_t(\boldsymbol{a}|\boldsymbol{s}) = \mathcal{N}(\boldsymbol{a}|K\boldsymbol{s} + \boldsymbol{b}, \Sigma)$ and $q_t(\boldsymbol{a}|\boldsymbol{s}) = \mathcal{N}(\boldsymbol{a}|K'\boldsymbol{s} + \boldsymbol{b}', \Sigma')$. The change of the state distribution in the expected KL constraint of our policy update, given by $\mathbb{E}_{\boldsymbol{s}\sim q_t}[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))]$ from state distribution q_t to p_t will only affect the part of the KL that depends on the state.

We give as a reminder the general formula for the KL between two Gaussian distributions $l = \mathcal{N}(\boldsymbol{\mu}, \Sigma)$ and $l' = \mathcal{N}(\boldsymbol{\mu}', \Sigma')$

$$\mathrm{KL}(l \parallel l') = \frac{1}{2}\left(\mathrm{tr}(\Sigma'^{-1}\Sigma) + (\boldsymbol{\mu} - \boldsymbol{\mu}')^T\Sigma'^{-1}(\boldsymbol{\mu} - \boldsymbol{\mu}') - dim + \log\frac{|\Sigma'|}{|\Sigma|}\right).$$

For the linear-Gaussian policies, and since only the mean of the policies depend on the state, the change of state distribution in the expected KL will only affect the term

$$(K\boldsymbol{s} - K'\boldsymbol{s})^T\Sigma'(K\boldsymbol{s} - K'\boldsymbol{s}) = \boldsymbol{s}^T M\boldsymbol{s},$$

with p.s.d. matrix $M = (K - K')^T\Sigma'(K - K')$. Thus it suffices to bound the expectation $\int p_t(\boldsymbol{s})\boldsymbol{s}^T M\boldsymbol{s}$ since the rest of the KL terms are already bounded by ϵ, yielding

$$\mathbb{E}_{s\sim p_t}[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))] \leq \epsilon + \frac{1}{2}\int p_t(\boldsymbol{s})\boldsymbol{s}^T M\boldsymbol{s},$$
$$= \epsilon + \frac{1}{2}\left(\boldsymbol{\mu}_p M\boldsymbol{\mu}_p + \mathrm{tr}(M\Sigma_p)\right),$$

where we exploited the Gaussian nature of p_t in the second line of the equation. We will now bound both $\boldsymbol{\mu}_p M\boldsymbol{\mu}_p$ and $\mathrm{tr}(M\Sigma_p)$. First, note that for any two p.d. matrices Σ and Σ' we have

$$\mathrm{tr}(\Sigma'^{-1}\Sigma) + -d_s + \log\frac{|\Sigma'|}{|\Sigma|} \geq 0. \tag{11}$$

This immediately follows from the non-negativity of the KL. Since, if for some Σ and Σ', eq. (11) is negative then the KL for two Gaussian distributions having Σ and Σ' as covariance matrices and sharing the same mean would be negative which is not possible. Hence it also follows that

$$(\boldsymbol{\mu}_q - \boldsymbol{\mu}_p)^T\Sigma_q^{-1}(\boldsymbol{\mu}_q - \boldsymbol{\mu}_p) \leq 2\epsilon_t, \tag{12}$$

from the bounded KL induction hypothesis between p_t and q_t.

For the expected policy KL, since the part that does not depend on s is positive as in eq. (11), it can thus be dropped out yielding

$$\mathbb{E}_{s\sim q_t}[\mathrm{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))] \leq \epsilon \Rightarrow \int q_t(\boldsymbol{s})\boldsymbol{s}^T M\boldsymbol{s} \leq 2\epsilon,$$
$$\Rightarrow \boldsymbol{\mu}_q M\boldsymbol{\mu}_q + \mathrm{tr}(M\Sigma_q) \leq 2\epsilon. \tag{13}$$

Also note that for any p.s.d. matrices A and B, $\text{tr}(AB) \geq 0$. Letting $\boldsymbol{x} = \boldsymbol{\mu}_p - \boldsymbol{\mu}_q$, we have

$$\begin{aligned}\boldsymbol{x}^T M \boldsymbol{x} &= \text{tr}(\boldsymbol{x}\boldsymbol{x}^T M),\\ &= \text{tr}(\Sigma_q^{-1}\boldsymbol{x}\boldsymbol{x}^T M \Sigma_q),\\ &\leq \text{tr}(\Sigma_q^{-1}\boldsymbol{x}\boldsymbol{x}^T)\text{tr}(M\Sigma_q),\\ &\leq 4\epsilon_t\epsilon.\end{aligned}$$

Third line is due to Cauchy-Schwarz inequality and positiveness of traces while the last one is from eq. (12) and (13). Finally, from the reverse triangular inequality, we have

$$\begin{aligned}\boldsymbol{\mu}_p M \boldsymbol{\mu}_p &\leq \boldsymbol{x}^T M \boldsymbol{x} + \boldsymbol{\mu}_q M \boldsymbol{\mu}_q,\\ &\leq 2\epsilon(1 + 2\epsilon_t),\end{aligned}$$

Which concludes the bounding of $\boldsymbol{\mu}_p M \boldsymbol{\mu}_p$.

To bound $\text{tr}(M\Sigma_p)$ we can write

$$\begin{aligned}\text{tr}(M\Sigma_p) &= \text{tr}(M\Sigma_q\Sigma_q^{-1}\Sigma_p),\\ &\leq \text{tr}(M\Sigma_q)\text{tr}(\Sigma_q^{-1}\Sigma_p).\end{aligned}$$

We know how to bound $\text{tr}(M\Sigma_q)$ from Eq. (13). While $\text{tr}(\Sigma_q^{-1}\Sigma_p)$ appears in the bounded KL between state distributions. Bounding $\text{tr}(\Sigma_q^{-1}\Sigma_p)$ is equivalent to solving $\max \sum \lambda_i$ under constraint $\sum \lambda_i - d_s - \sum \log \lambda_i \leq 2\epsilon_t$, where the $\{\lambda_i\}$ are the eigenvalues of $\Sigma_q^{-1}\Sigma_p$. For any solution $\{\lambda_i\}$, we can keep the same optimization objective using equal $\{\lambda_i'\}$ where for each i, $\lambda_i' = \bar{\lambda} = \sum \lambda_i / d_s$ is the average lambda. This transformation will at the same time reduce the value of the constraint since $-d_s \log \bar{\lambda} \leq -\sum \log \lambda_i$ from Jensen's inequality. Hence the optimum is reached when all the λ_i are equal, and the constraint is active (i.e. $d_s\bar{\lambda} - d_s - d_s \log \bar{\lambda} = 2\epsilon_t$). Finally, the constraint is at a minimum for $\bar{\lambda} = 1$, hence $\bar{\lambda} > 1$. The maximum is reached at

$$\begin{aligned}& d_s\bar{\lambda} - d_s - d_s \log \bar{\lambda} = 2\epsilon_t\\ \Leftrightarrow & \bar{\lambda} - \log \bar{\lambda} = \frac{2\epsilon_t}{d_s} + 1\\ \Rightarrow & \bar{\lambda} \leq \left(\frac{2\epsilon_t}{d_s} + 1\right)\frac{e}{e-1}\\ \Rightarrow & \text{tr}(\Sigma_q^{-1}\Sigma_p) \leq 4\epsilon_t + 2d_s \qquad (14)\end{aligned}$$

The equation in the second line has a unique solution ($f(\lambda) = \lambda - \log \lambda$ is a strictly increasing function for $\lambda > 1$) for which no closed form expression exists. We thus lower bound f by $g(\lambda) = \frac{e-1}{e}\lambda$ and solve the equation for g which yields an upper bound of the original equation that is further simplified in the last inequality.
Eq. (13) and (14) yield $\text{tr}(M\Sigma_p) \leq 2\epsilon(4\epsilon_t + 2d_s)$ and grouping all the results yields

$$\mathbb{E}_{s\sim p_t}[\text{KL}(p_t(.|\boldsymbol{s}) \parallel q_t(.|\boldsymbol{s}))] \leq 2\epsilon\,(3\epsilon_t + d_s + 1)$$

Abstract

This paper presents a unified framework for smooth convex regularization of discrete optimal transport problems. In this context, the regularized optimal transport turns out to be equivalent to a matrix nearness problem with respect to Bregman divergences. Our framework thus naturally generalizes a previously proposed regularization based on the Boltzmann-Shannon entropy related to the Kullback-Leibler divergence, and solved with the Sinkhorn-Knopp algorithm. We call the regularized optimal transport distance the rot mover's distance in reference to the classical earth mover's distance. By exploiting alternate Bregman projections, we develop the alternate scaling algorithm and non-negative alternate scaling algorithm, to compute efficiently the regularized optimal plans depending on whether the domain of the regularizer lies within the non-negative orthant or not. We further enhance the separable case with a sparse extension to deal with high data dimensions. We also instantiate our framework and discuss the inherent specificities for well-known regularizers and statistical divergences in the machine learning and information geometry communities. Finally, we demonstrate the merits of our methods with experiments using synthetic data to illustrate the effect of different regularizers, penalties and dimensions, as well as real-world data for a pattern recognition application to audio scene classification.

Keywords: alternate projections, convex analysis, regularized optimal transport, rot mover's distance, statistical divergences

1. Introduction

A recurrent problem in statistical machine learning is the choice of a relevant distance measure to compare probability distributions. Various information divergences are famous, among which Euclidean, Mahalanobis, Kullback-Leibler, Itakura-Saito, Hellinger, χ^2, ℓ_p (quasi-)norm, total variation, logistic loss function, or more general Csiszár and Bregman divergences and parametric families of such divergences such as α- and β-divergences.

An alternative family of distances between probability distributions can be introduced in the framework of optimal transport (OT). Rather than performing a pointwise comparison of the distributions, the idea is to quantify the minimal effort for moving the probability mass of one distribution to the other, where the transport plan to move the mass is optimized according to a given ground cost. This makes OT distances suitable and robust in certain applications, notably in the field of computer vision where the discrete OT distance, also known as earth mover's distance (EMD), has been popularized to compare histograms of features for pattern recognition tasks (Rubner et al., 2000).

Despite its appealing theoretical properties, intuitive formulation, and excellent performance in various problems of information retrieval, the computation of the EMD involves solving a linear program whose cost quickly becomes prohibitive with the data dimension. In practice, the best algorithms currently proposed, such as the network simplex (Ahuja et al., 1993), scale at least with a super-cubic complexity. Embeddings of the distributions can be used to approximate the EMD with linear complexity (Indyk and Thaper, 2003; Grauman and Darrell, 2004; Shirdhonkar and Jacobs, 2008), and the network simplex can be modified to run in quadratic time (Gudmundsson et al., 2007; Ling and Okada, 2007; Pele and Werman, 2009). Nevertheless, the distortions inherent to such embeddings (Naor and Schechtman, 2007), and the exponential increase of costs incurred by such modifications, make these approaches inapplicable for dimensions higher than four. Instead, multi-scale strategies (Oberman and Ruan, 2015) and shortcut paths (Schmitzer, 2016a) can speed up the estimation of the exact optimal plan. These approaches are yet limited to particular convex costs such as ℓ_2, while other costs such as ℓ_1 and truncated or compressed versions are often preferred in practice for an increased robustness to data outliers (Pele and Werman, 2008, 2009; Rabin et al., 2009). For general applications, a gain in performance can also be obtained with a cost directly learned from labeled data (Cuturi and Avis, 2014). The aforementioned accelerated methods that are dedicated to ℓ_2 or convex costs are thus not adapted in this context.

On another line of research, the regularization of the transport plan, for example via graph modeling (Ferradans et al., 2014), has been considered to deal with noisy data, though this latter approach does not address the computational issue of efficiency for high dimensions. In this continuity, an entropic regularization was shown to admit an efficient algorithm with quadratic complexity that speeds up the computation of solutions by several orders of magnitude, and to improve performance on applications such as handwritten digit recognition (Cuturi, 2013). In addition, a tailored computation can be obtained via convolution for specific ground costs (Solomon et al., 2015). Since the introduction of the entropic regularization, OT has benefited from extensive developments in the machine learning community, with applications such as label propagation (Solomon et al., 2014), domain adaptation (Courty et al., 2015), matrix factorization (Zen et al., 2014), dictionary learning (Rolet et al., 2016; Schmitz et al., 2018), barycenter computation (Cuturi and Peyré, 2016), geodesic principal component analysis (Bigot et al., 2013; Seguy and Cuturi, 2015; Cazelles et al., 2017), data fitting (Frogner et al., 2015), statistical inference (Bernton et al.,

2017), training of Boltzmann machines (Montavon et al., 2016) and generative adversarial networks (Arjovsky et al., 2017; Bousquet et al., 2017; Genevay et al., 2017).

With the entropic regularization, the gain in computational time is only important for high dimensions or large levels of regularization. For low regularization, advanced optimization strategies can still be used to obtain a significant speed-up (Thibault et al., 2017; Schmitz et al., 2018). It is also a well-known effect that the entropic regularization overspreads the transported mass, which may be undesirable for certain applications as in the case of interpolation purposes. An interesting perspective of these works, however, is that many more regularizers are worth investigating to solve OT problems both efficiently and robustly (Galichon and Salanié, 2015; Muzellec et al., 2018; Blondel et al., 2017). This is the idea we address in the present work, focusing on smooth convex regularization.

1.1 Notations

For the sake of simplicity, we consider distributions with same dimension d, and thus work with the Euclidean space $\mathbb{R}^{d\times d}$ of square matrices. It is straightforward, however, to extend all results for a different number of bins m, n by using rectangular matrices in $\mathbb{R}^{m\times n}$ instead. We denote the null matrix of $\mathbb{R}^{d\times d}$ by $\mathbf{0}$, and the matrix full of ones by $\mathbf{1}$. The Frobenius inner product between two matrices $\boldsymbol{\pi}, \boldsymbol{\xi} \in \mathbb{R}^{d\times d}$ is defined by:

$$\langle \boldsymbol{\pi}, \boldsymbol{\xi} \rangle = \sum_{i=1}^{d}\sum_{j=1}^{d} \pi_{ij}\xi_{ij} \ . \tag{1}$$

When the intended meaning is clear from the context, we also write $\mathbf{0}$ for the null vector of $\mathbb{R}^d$, and $\mathbf{1}$ for the vector full of ones. The notation $\cdot^\top$ represents the transposition operator for matrices or vectors. The probability simplex of $\mathbb{R}^d$ is defined as follows:

$$\Sigma_d = \{\mathbf{p} \in \mathbb{R}^d_+ \colon \mathbf{p}^\top \mathbf{1} = 1\} \ . \tag{2}$$

The operator $\mathrm{diag}(\mathbf{v})$ transforms a vector $\mathbf{v} \in \mathbb{R}^d$ into a diagonal matrix $\boldsymbol{\pi} \in \mathbb{R}^{d\times d}$ such that $\pi_{ii} = v_i$, for all $1 \leq i \leq d$. The operator $\mathrm{vec}(\boldsymbol{\pi})$ transforms a matrix $\boldsymbol{\pi} \in \mathbb{R}^{d\times d}$ into a vector $\mathbf{x} \in \mathbb{R}^{d^2}$ such that $x_{i+(j-1)d} = \pi_{ij}$, for all $1 \leq i, j \leq d$. The operator $\mathrm{sgn}(x)$ for $x \in \mathbb{R}$ returns $-1, 0, +1$, if x is negative, null, positive, respectively. Functions of a real variable, such as the absolute value, sign, exponential or power functions, are considered element-wise when applied to matrices. The max operator and inequalities between matrices should also be interpreted element-wise. Matrix divisions are similarly considered element-wise, whereas element-wise matrix multiplications, also known as Hadamard or Schur products, are denoted by $\odot$ to remove any ambiguity with standard matrix multiplications. Lastly, addition or subtraction of a scalar and a matrix should be understood element-wise by replicating the scalar.

1.2 Background and Related Work

Given two probability vectors $\mathbf{p}, \mathbf{q} \in \Sigma_d$, and a cost matrix $\boldsymbol{\gamma} \in \mathbb{R}^{d\times d}_+$ whose coefficients γ_{ij} represent the cost of moving the mass from bin p_i to q_j, the total cost of a given transport plan, or coupling, $\boldsymbol{\pi} \in \Pi(\mathbf{p}, \mathbf{q})$ can be quantified as $\langle \boldsymbol{\pi}, \boldsymbol{\gamma} \rangle$. An optimal cost is then obtained

by solving a linear program:

$$d_{\boldsymbol{\gamma}}(\mathbf{p}, \mathbf{q}) = \min_{\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma} \rangle \ , \tag{3}$$

with the transport polytope of $\mathbf{p}$ and $\mathbf{q}$, also known as the polytope of couplings between $\mathbf{p}$ and $\mathbf{q}$, defined as the following polyhedron:

$$\Pi(\mathbf{p}, \mathbf{q}) = \{\boldsymbol{\pi} \in \mathbb{R}^{d\times d}_+ \colon \boldsymbol{\pi}\mathbf{1} = \mathbf{p}, \boldsymbol{\pi}^\top \mathbf{1} = \mathbf{q}\} \ . \tag{4}$$

The EMD associated to the cost matrix $\boldsymbol{\gamma}$ is given by $d_{\boldsymbol{\gamma}}$ and is a true distance metric on the probability simplex Σ_d whenever $\boldsymbol{\gamma}$ is itself a distance matrix. In general, the optimal plans, or earth mover's plans, have at most $2d-1$ nonzero entries, and consist either of a single vertex or of a whole facet of the transport polytope. One of the earth mover's plans can be obtained with the network simplex (Ahuja et al., 1993) among other approaches. For a general cost matrix $\boldsymbol{\gamma}$, the complexity of solving an OT problem scales at least in $O(d^3 \log d)$ for the best algorithms currently proposed, including the network simplex, and turns out to be super-cubic in practice as well.

Cuturi (2013) proposed a new family of OT distances, called Sinkhorn distances, from the perspective of maximum entropy. The idea is to smooth the original problem with a strictly convex regularization via the Boltzmann-Shannon entropy. The primal problem involves the entropic regularization as an additional constraint:

$$d'_{\boldsymbol{\gamma},\alpha}(\mathbf{p}, \mathbf{q}) = \min_{\boldsymbol{\pi} \in \Pi_\alpha(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma} \rangle \ , \tag{5}$$

with the regularized transport polytope defined as follows:

$$\Pi_\alpha(\mathbf{p}, \mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p}, \mathbf{q}) \colon E(\boldsymbol{\pi}) \leq E(\mathbf{p}\mathbf{q}^\top) + \alpha\} \ , \tag{6}$$

where $\alpha \geq 0$ is a regularization term and E is minus the Boltzmann-Shannon entropy as defined in (28). It is also straightforward to prove that we have:

$$\Pi_\alpha(\mathbf{p}, \mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p}, \mathbf{q}) \colon K(\boldsymbol{\pi} \| \mathbf{1}) \leq K(\mathbf{p}\mathbf{q}^\top \| \mathbf{1}) + \alpha\} \ , \tag{7}$$

$$\Pi_\alpha(\mathbf{p}, \mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p}, \mathbf{q}) \colon K(\boldsymbol{\pi} \| \mathbf{p}\mathbf{q}^\top) \leq \alpha\} \ . \tag{8}$$

where K is the Kullback-Leibler divergence as defined in (27). This enforces the solution to have sufficient entropy, or equivalently small enough mutual information, by constraining it to the Kullback-Leibler ball of radius $K(\mathbf{p}\mathbf{q}^\top \| \mathbf{1}) + \alpha$, respectively α, and center the matrix $\mathbf{1} \in \mathbb{R}^{d\times d}_{++}$, respectively the transport plan $\mathbf{p}\mathbf{q}^\top \in \mathbb{R}^{d\times d}_{++}$, which have maximum entropy. The dual problem exploits a Lagrange multiplier to relax the entropic regularization as a penalty:

$$d_{\boldsymbol{\gamma},\lambda}(\mathbf{p}, \mathbf{q}) = \langle \boldsymbol{\pi}^\star_\lambda, \boldsymbol{\gamma} \rangle \ , \tag{9}$$

with the regularized optimal plan $\boldsymbol{\pi}^\star_\lambda$ defined as follows:

$$\boldsymbol{\pi}^\star_\lambda = \operatorname*{argmin}_{\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma} \rangle + \lambda E(\boldsymbol{\pi}) \ , \tag{10}$$

where $\lambda > 0$ is a regularization term. The problem can then be solved empirically in quadratic complexity with linear convergence using the Sinkhorn-Knopp algorithm (Sinkhorn

and Knopp, 1967) based on iterative matrix scaling, where rows and columns are rescaled in turn so that they respectively sum up to $\mathbf{p}$ and $\mathbf{q}$ until convergence. Finally, it is easy to prove that we have:

$$\boldsymbol{\pi}^\star_\lambda = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle + \lambda K(\boldsymbol{\pi}\|\mathbf{1}) \ , \tag{11}$$

$$\boldsymbol{\pi}^\star_\lambda = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle + \lambda K(\boldsymbol{\pi}\|\mathbf{p}\mathbf{q}^\top) \ . \tag{12}$$

This again shows that the regularization enforces the solution to have sufficient entropy, or equivalently small enough mutual information, by shrinking it toward the matrix $\mathbf{1}$ and the joint distribution $\mathbf{p}\mathbf{q}^\top$ which have maximum entropy.

Benamou et al. (2015) revisited the entropic regularization in a geometrical framework with iterative information projections. They showed that computing a Sinkhorn distance in dual form actually amounts to the minimization of a Kullback-Leibler divergence:

$$\boldsymbol{\pi}^\star_\lambda = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} K(\boldsymbol{\pi}\|\exp(-\boldsymbol{\gamma}/\lambda)) \ . \tag{13}$$

Precisely, this amounts to computing the Kullback-Leibler projection of $\exp(-\boldsymbol{\gamma}/\lambda) \in \mathbb{R}^{d\times d}_{++}$ onto the transport polytope $\Pi(\mathbf{p},\mathbf{q})$. In this context, the Sinkhorn-Knopp algorithm turns out to be a special instance of Bregman projection onto the intersection of convex sets via alternate projections. Specifically, we see $\Pi(\mathbf{p},\mathbf{q})$ as the intersection of the non-negative orthant with two affine subspaces containing all matrices with rows and columns summing to $\mathbf{p}$ and $\mathbf{q}$ respectively, and we alternate projection on these two subspaces according to the Kullback-Leibler divergence until convergence.

Kurras (2015) further studied this equivalence in the wider context of iterative proportional fitting. He notably showed that the Sinkhorn-Knopp and alternate Bregman projections can be extended to account for infinite entries in the cost matrix $\boldsymbol{\gamma}$, and thus null entries in the regularized optimal plan. Hence, it is possible to develop a sparse version of the entropic regularization to OT problems. This becomes interesting to store the $d \times d$ matrix variables and perform the required computations when the data dimension gets large.

Dhillon and Tropp (2007) had already enlightened such an equivalence in the field of matrix analysis. They actually considered the estimation of contingency tables with fixed marginals as a matrix nearness problem based on the Kullback-Leibler divergence. In more detail, they use a rough estimate $\boldsymbol{\xi} \in \mathbb{R}^{d\times d}_{++}$ to produce a contingency table $\boldsymbol{\pi}^\star$ that has fixed marginals $\mathbf{p},\mathbf{q}$ by Kullback-Leibler projection of $\boldsymbol{\xi}$ onto $\Pi(\mathbf{p},\mathbf{q})$:

$$\boldsymbol{\pi}^\star = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} K(\boldsymbol{\pi}\|\boldsymbol{\xi}) \ . \tag{14}$$

They showed that alternate Bregman projections specialize to the Sinkhorn-Knopp algorithm in this context. However, no relationship to OT problems was highlighted.

1.3 Contributions and Organization

Our main contribution is to formulate a unified framework for discrete regularized optimal transport (ROT) by considering a large class of smooth convex regularizers. We call the

underlying distance the rot mover's distance (RMD) and show that a given ROT problem actually amounts to the minimization of an associated Bregman divergence. This allows the derivation of two schemes that we call the alternate scaling algorithm (ASA) and the non-negative alternate scaling algorithm (NASA), to compute efficiently the regularized optimal plans depending on whether the domain of the regularizer lies within the non-negative orthant or not. These schemes are based on the general form of alternate projections for Bregman divergences. They also exploit the Newton-Raphson method to approximate the projections for separable divergences. The separable case is further enhanced with a sparse extension to deal with high data dimensions. We also instantiate our two generic schemes with widely-used regularizers and statistical divergences.

The proposed framework naturally extends the Sinkhorn-Knopp algorithm for the regularization based on the Boltzmann-Shannon entropy (Cuturi, 2013), or equivalently the minimization of a Kullback-Leibler divergence (Benamou et al., 2015), and their sparse version (Kurras, 2015), which turn out to be special instances of ROT problems. It also relates to matrix nearness problems via minimization of Bregman divergences, and it is straightforward to construct more general estimators for contingency tables with fixed marginals than the classical estimator based on the Kullback-Leibler divergence (Dhillon and Tropp, 2007). Lastly, it brings some new insights between transportation theory (Villani, 2009) and information geometry (Amari and Nagaoka, 2000), where Bregman divergences are known to possess a dually flat structure with a generalized Pythagorean theorem in relation to information projections.

The remainder of this paper is organized as follows. In Section 2, we introduce some necessary preliminaries. In Section 3, we present our theoretical results for a unified framework of ROT problems. We then derive the algorithmic methods for solving ROT problems in Section 4. We also discuss the inherent specificities of ROT problems for classical regularizers and associated divergences in Section 5. In Section 6, we provide experiments to illustrate our methods on synthetic data and real-world audio data in a classification problem. Finally, in Section 7, we draw some conclusions and perspectives for future work.

2. Theoretical Preliminaries

In this section, we introduce the required preliminaries to our framework. We begin with elements of convex analysis (Section 2.1) and of Bregman geometry (Section 2.2). We proceed with theoretical results for convergence of alternate Bregman projections (Section 2.3) and of the Newton-Raphson method (Section 2.4).

2.1 Convex Analysis

Let $\mathcal{E}$ be a Euclidean space with inner product $\langle\cdot,\cdot\rangle$ and induced norm $\|\cdot\|$. The boundary, interior and relative interior of a subset $\mathcal{X} \subseteq \mathcal{E}$ are respectively denoted by $\mathrm{bd}(\mathcal{X})$, $\mathrm{int}(\mathcal{X})$, and $\mathrm{ri}(\mathcal{X})$, where we recall that for a convex set $\mathcal{C}$, we have:

$$\mathrm{ri}(\mathcal{C}) = \{\mathbf{x}\in\mathcal{C} \colon \forall \mathbf{y}\in\mathcal{C}, \exists\lambda>1, \lambda\mathbf{x}+(1-\lambda)\mathbf{y}\in\mathcal{C}\} \ . \tag{15}$$

In convex analysis, scalar functions are defined over the whole space $\mathcal{E}$ and take values in the extended real number line $\mathbb{R}\cup\{-\infty,+\infty\}$. The effective domain, or simply domain,

of a function f is then defined as the set:

$$\operatorname{dom} f = \{\mathbf{x} \in \mathcal{E} \colon f(\mathbf{x}) < +\infty\} \ . \tag{16}$$

A convex function f is proper if $f(\mathbf{x}) < +\infty$ for at least one $\mathbf{x} \in \mathcal{E}$ and $f(\mathbf{x}) > -\infty$ for all $\mathbf{x} \in \mathcal{E}$, and it is closed if its lower level sets $\{\mathbf{x} \in \mathcal{E} \colon f(\mathbf{x}) \leq \alpha\}$ are closed for all $\alpha \in \mathbb{R}$. If $\operatorname{dom} f$ is closed, then f is closed, and a proper convex function is closed if and only if it is lower semi-continuous. Moreover, a closed function f is continuous relative to any simplex, polytope or polyhedral subset in $\operatorname{dom} f$. It is also well-known that a convex function f is always continuous in the relative interior $\operatorname{ri}(\operatorname{dom} f)$ of its domain.

A function f is essentially smooth if it is differentiable on $\operatorname{int}(\operatorname{dom} f) \neq \emptyset$ and verifies $\lim_{k \to +\infty} \|\nabla f(\mathbf{x}_k)\| = +\infty$ for any sequence $(\mathbf{x}_k)_{k \in \mathbb{N}}$ from $\operatorname{int}(\operatorname{dom} f)$ that converges to a point $\mathbf{x} \in \operatorname{bd}(\operatorname{dom} f)$. A function f is of Legendre type if it is a closed proper convex function that is also essentially smooth and strictly convex on $\operatorname{int}(\operatorname{dom} f)$.

The Fenchel conjugate $f^\star$ of a function f is defined for all $\mathbf{y} \in \mathcal{E}$ as follows:

$$f^\star(\mathbf{y}) = \sup_{\mathbf{x} \in \operatorname{int}(\operatorname{dom} f)} \langle \mathbf{x}, \mathbf{y} \rangle - f(\mathbf{x}) \ . \tag{17}$$

The Fenchel conjugate $f^\star$ is always a closed convex function. Moreover, if f is a closed convex function, then $(f^\star)^\star = f$, and f is of Legendre type if and only if $f^\star$ is of Legendre type. In this latter case, the gradient mapping ∇f is a homeomorphism between $\operatorname{int}(\operatorname{dom} f)$ and $\operatorname{int}(\operatorname{dom} f^\star)$, with inverse mapping $(\nabla f)^{-1} = \nabla f^\star$, which guarantees the existence of dual coordinate systems $\mathbf{x}(\mathbf{y}) = \nabla f^\star(\mathbf{y})$ and $\mathbf{y}(\mathbf{x}) = \nabla f(\mathbf{x})$ on $\operatorname{int}(\operatorname{dom} f)$ and $\operatorname{int}(\operatorname{dom} f^\star)$.

Finally, we say that a function f is cofinite if it verifies:

$$\lim_{\lambda \to +\infty} f(\lambda \mathbf{x})/\lambda = +\infty \ , \tag{18}$$

for all nonzero $\mathbf{x} \in \mathcal{E}$. Intuitively, it means that f grows super-linearly in every direction. In particular, a closed proper convex function is cofinite if and only if $\operatorname{dom} f^\star = \mathcal{E}$.

2.2 Bregman Geometry

Let ϕ be a convex function on $\mathcal{E}$ that is differentiable on $\operatorname{int}(\operatorname{dom} \phi) \neq \emptyset$. The Bregman divergence generated by ϕ is defined as follows:

$$B_\phi(\mathbf{x} \| \mathbf{y}) = \phi(\mathbf{x}) - \phi(\mathbf{y}) - \langle \mathbf{x} - \mathbf{y}, \nabla \phi(\mathbf{y}) \rangle \ , \tag{19}$$

for all $\mathbf{x} \in \operatorname{dom} \phi$ and $\mathbf{y} \in \operatorname{int}(\operatorname{dom} \phi)$. We have $B_\phi(\mathbf{x} \| \mathbf{y}) \geq 0$ for any $\mathbf{x} \in \operatorname{dom} \phi$ and $\mathbf{y} \in \operatorname{int}(\operatorname{dom} \phi)$. If in addition ϕ is strictly convex on $\operatorname{int}(\operatorname{dom} \phi)$, then $B_\phi(\mathbf{x} \| \mathbf{y}) = 0$ if and only if $\mathbf{x} = \mathbf{y}$. Bregman divergences are also always convex in the first argument, and are invariant under adding an arbitrary affine term to their generator.

Bregman divergences are not symmetric and do not verify the triangle inequality in general, and thus are not necessarily distances in the strict sense. However, they still enjoy some nice geometrical properties that somehow generalize the Euclidean geometry. In particular, they verify a four-point identity similar to a parallelogram law:

$$B_\phi(\mathbf{x} \| \mathbf{y}) + B_\phi(\mathbf{x}' \| \mathbf{y}') = B_\phi(\mathbf{x}' \| \mathbf{y}) + B_\phi(\mathbf{x} \| \mathbf{y}') - \langle \mathbf{x} - \mathbf{x}', \nabla \phi(\mathbf{y}) - \nabla \phi(\mathbf{y}') \rangle \ , \tag{20}$$

for all $\mathbf{x}, \mathbf{x}' \in \operatorname{dom} \phi$ and $\mathbf{y}, \mathbf{y}' \in \operatorname{int}(\operatorname{dom} \phi)$. A special instance of this relation gives rise to a three-point property similar to a triangle law of cosines:

$$B_\phi(\mathbf{x} \| \mathbf{y}) = B_\phi(\mathbf{x} \| \mathbf{y}') + B_\phi(\mathbf{y}' \| \mathbf{y}) - \langle \mathbf{x} - \mathbf{y}', \nabla \phi(\mathbf{y}) - \nabla \phi(\mathbf{y}') \rangle \ , \tag{21}$$

for all $\mathbf{x} \in \operatorname{dom} \phi$ and $\mathbf{y}, \mathbf{y}' \in \operatorname{int}(\operatorname{dom} \phi)$.

Suppose now that ϕ is of Legendre type, and let $\mathcal{C} \subseteq \mathcal{E}$ be a closed convex set such that $\mathcal{C} \cap \operatorname{int}(\operatorname{dom} \phi) \neq \emptyset$. Then, for any point $\mathbf{y} \in \operatorname{int}(\operatorname{dom} \phi)$, the following problem:

$$P_{\mathcal{C}}(\mathbf{y}) = \operatorname*{argmin}_{\mathbf{x} \in \mathcal{C}} B_\phi(\mathbf{x} \| \mathbf{y}) \ , \tag{22}$$

has a unique solution, then called the Bregman projection of $\mathbf{y}$ onto $\mathcal{C}$. This solution actually belongs to $\mathcal{C} \cap \operatorname{int}(\operatorname{dom} \phi)$, and is also characterized as the unique point $\mathbf{y}' \in \mathcal{C} \cap \operatorname{int}(\operatorname{dom} \phi)$ that verifies the variational relation:

$$\langle \mathbf{x} - \mathbf{y}', \nabla \phi(\mathbf{y}) - \nabla \phi(\mathbf{y}') \rangle \leq 0 \ , \tag{23}$$

for all $\mathbf{x} \in \mathcal{C} \cap \operatorname{dom} \phi$. This characterization is equivalent to a well-known generalized Pythagorean theorem for Bregman divergences, which states that the Bregman projection of $\mathbf{y}$ onto $\mathcal{C}$ is the unique point $\mathbf{y}' \in \mathcal{C} \cap \operatorname{int}(\operatorname{dom} \phi)$ that verifies the following inequality:

$$B_\phi(\mathbf{x} \| \mathbf{y}) \geq B_\phi(\mathbf{x} \| \mathbf{y}') + B_\phi(\mathbf{y}' \| \mathbf{y}) \ , \tag{24}$$

for all $\mathbf{x} \in \mathcal{C} \cap \operatorname{dom} \phi$. When $\mathcal{C}$ is further an affine subspace, or more generally when the Bregman projection further belongs to $\operatorname{ri}(\mathcal{C})$, the scalar product actually vanishes:

$$\langle \mathbf{x} - \mathbf{y}', \nabla \phi(\mathbf{y}) - \nabla \phi(\mathbf{y}') \rangle = 0 \ , \tag{25}$$

leading to an equality in the generalized Pythagorean theorem:

$$B_\phi(\mathbf{x} \| \mathbf{y}) = B_\phi(\mathbf{x} \| \mathbf{y}') + B_\phi(\mathbf{y}' \| \mathbf{y}) \ . \tag{26}$$

A famous example of Bregman divergence is the Kullback-Leibler divergence, defined for matrices $\boldsymbol{\pi} \in \mathbb{R}_+^{d \times d}$ and $\boldsymbol{\xi} \in \mathbb{R}_{++}^{d \times d}$ as follows:

$$K(\boldsymbol{\pi} \| \boldsymbol{\xi}) = \sum_{i=1}^{d} \sum_{j=1}^{d} \left(\pi_{ij} \log \left(\frac{\pi_{ij}}{\xi_{ij}} \right) - \pi_{ij} + \xi_{ij} \right) \ . \tag{27}$$

This divergence is generated by a function of Legendre type for $\boldsymbol{\pi} \in \mathbb{R}_+^{d \times d}$ given by minus the Boltzmann-Shannon entropy:

$$E(\boldsymbol{\pi}) = K(\boldsymbol{\pi} \| \mathbf{1}) = \sum_{i=1}^{d} \sum_{j=1}^{d} \left(\pi_{ij} \log(\pi_{ij}) - \pi_{ij} + 1 \right) \ , \tag{28}$$

with the convention $0 \log(0) = 0$. Another well-known example is the Itakura-Saito divergence, defined for matrices $\boldsymbol{\pi}, \boldsymbol{\xi} \in \mathbb{R}_{++}^{d \times d}$ as follows:

$$I(\boldsymbol{\pi} \| \boldsymbol{\xi}) = \sum_{i=1}^{d} \sum_{j=1}^{d} \left(\frac{\pi_{ij}}{\xi_{ij}} - \log \left(\frac{\pi_{ij}}{\xi_{ij}} \right) - 1 \right) \ . \tag{29}$$

This divergence is generated by a function of Legendre type for $\boldsymbol{\pi} \in \mathbb{R}^{d\times d}_{++}$ given by minus the Burg entropy:

$$F(\boldsymbol{\pi}) = \sum_{i=1}^{d}\sum_{j=1}^{d}(\pi_{ij} - \log \pi_{ij} - 1) \ . \tag{30}$$

On the one hand, these examples belong to a particular type of so-called separable Bregman divergences between matrices on $\mathbb{R}^{d\times d}$, that can be seen as the aggregation of element-wise Bregman divergences between scalars on $\mathbb{R}$:

$$B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}) = \sum_{i=1}^{d}\sum_{j=1}^{d} B_{\phi_{ij}}(\pi_{ij}\|\xi_{ij}) \ , \tag{31}$$

$$\phi(\boldsymbol{\pi}) = \sum_{i=1}^{d}\sum_{j=1}^{d} \phi_{ij}(\pi_{ij}) \ . \tag{32}$$

Often, all element-wise generators ϕ_{ij} are chosen equal, and are thus simply written as ϕ with a slight abuse of notation. Other examples of such divergences are discussed in Section 5, and include the logistic loss function generated by minus the Fermi-Dirac entropy, or the squared Euclidean distance generated by the Euclidean norm.

On the other hand, a classical example of non-separable Bregman divergence is half the squared Mahalanobis distance, defined for matrices $\boldsymbol{\pi}, \boldsymbol{\xi} \in \mathbb{R}^{d\times d}$ as follows:

$$M(\boldsymbol{\pi}\|\boldsymbol{\xi}) = \frac{1}{2}\mathrm{vec}(\boldsymbol{\pi} - \boldsymbol{\xi})^\top \mathbf{P}\, \mathrm{vec}(\boldsymbol{\pi} - \boldsymbol{\xi}) \ , \tag{33}$$

for a positive-definite matrix $\mathbf{P} \in \mathbb{R}^{d^2\times d^2}$. This divergence is generated by a function of Legendre type for $\boldsymbol{\pi} \in \mathbb{R}^{d\times d}$ given by a quadratic form:

$$Q(\boldsymbol{\pi}) = \frac{1}{2}\mathrm{vec}(\boldsymbol{\pi})^\top \mathbf{P}\, \mathrm{vec}(\boldsymbol{\pi}) \ . \tag{34}$$

This example is also discussed in Section 5.

2.3 Alternate Bregman Projections

Let ϕ be a function of Legendre type with Fenchel conjugate $\phi^\star = \psi$. In general, computing Bregman projections onto an arbitrary closed convex set $\mathcal{C} \subseteq \mathcal{E}$ such that $\mathcal{C} \cap \mathrm{int}(\mathrm{dom}\,\phi) \neq \emptyset$ is nontrivial. Sometimes, it is possible to decompose $\mathcal{C}$ into the intersection of finitely many closed convex sets:

$$\mathcal{C} = \bigcap_{l=1}^{s} \mathcal{C}_l \ , \tag{35}$$

where the individual Bregman projections onto the respective sets $\mathcal{C}_1, \ldots, \mathcal{C}_s$ are easier to compute. It is then possible to obtain the Bregman projection onto $\mathcal{C}$ by alternate projections onto $\mathcal{C}_1, \ldots, \mathcal{C}_s$ according to Dykstra's algorithm.

In more detail, let $\sigma\colon \mathbb{N} \to \{1, \ldots, s\}$ be a control mapping that determines the sequence of subsets onto which we project. For a given point $\mathbf{x}_0 \in \mathcal{C} \cap \mathrm{int}(\mathrm{dom}\,\phi)$, the Bregman

projection $P_{\mathcal{C}}(\mathbf{x}_0)$ of $\mathbf{x}_0$ onto $\mathcal{C}$ can be approximated with Dykstra's algorithm by iterating the following updates:

$$\mathbf{x}_{k+1} \leftarrow P_{\mathcal{C}_{\sigma(k)}}(\nabla\psi(\nabla\phi(\mathbf{x}_k) + \mathbf{y}^{\sigma(k)})) \ , \tag{36}$$

where the correction terms $\mathbf{y}^1, \ldots, \mathbf{y}^s$ for the respective subsets are initialized with the null element of $\mathcal{E}$, and are updated after projection as follows:

$$\mathbf{y}^{\sigma(k)} \leftarrow \mathbf{y}^{\sigma(k)} + \nabla\phi(\mathbf{x}_k) - \nabla\phi(\mathbf{x}_{k+1}) \ . \tag{37}$$

Under some technical conditions, the sequence of updates $(\mathbf{x}_k)_{k\in\mathbb{N}}$ then converges in norm to $P_{\mathcal{C}}(\mathbf{x}_0)$ with a linear rate. Several sets of such conditions have been studied, notably by Tseng (1993), Bauschke and Lewis (2000), Dhillon and Tropp (2007).

We here use the conditions proposed by Dhillon and Tropp (2007), which reveal to be the less restrictive ones in our framework. Specifically, the convergence of Dykstra's algorithm is guaranteed as soon as the function ϕ is cofinite, the constraint qualification $\mathrm{ri}(\mathcal{C}_1) \cap \cdots \cap \mathrm{ri}(\mathcal{C}_s) \cap \mathrm{int}(\mathrm{dom}\,\phi) \neq \emptyset$ holds, and the control mapping σ is essentially cyclic, that is, there exists a number $t \in \mathbb{N}$ such that σ takes each output value at least once during any t consecutive input values. If a given $\mathcal{C}_l$ is a polyhedral set, then the relative interior can be dropped from the constraint qualification. Hence, when all subsets $\mathcal{C}_l$ are polyhedral, the constraint qualification simply reduces to $\mathcal{C} \cap \mathrm{int}(\mathrm{dom}\,\phi) \neq \emptyset$, which is already enforced for the definition of Bregman projections.

Finally, if all subsets $\mathcal{C}_l$ are further affine, then we can relax other assumptions. Notably, we do not require ϕ to be cofinite (18), or equivalently $\mathrm{dom}\,\psi = \mathcal{E}$, but only $\mathrm{dom}\,\psi$ to be open. The control mapping need not be essentially cyclic anymore, as long as it takes each output value an infinite number of times. More importantly, we can completely drop the correction terms from the updates, leading to a simpler technique known as projections onto convex sets (POCS):

$$\mathbf{x}_{k+1} \leftarrow P_{\mathcal{C}_{\sigma(k)}}(\mathbf{x}_k) \ . \tag{38}$$

2.4 Newton-Raphson Method

Let f be a continuously differentiable scalar function on an open interval $I \subseteq \mathbb{R}$. Assume f is increasing on a non-empty closed interval $[x^-, x^+] \subset I$, and write $y^- = f(x^-)$ and $y^+ = f(x^+)$. Then, for any $y \in [y^-, y^+]$, the equation $f(x) = y$ has at least one solution $x^\star \in [x^-, x^+]$. Such a solution can be approximated by iterative updates according to the Newton-Raphson method:

$$x \leftarrow \max\left\{x^-, \min\left\{x^+, x - \frac{f(x) - y}{f'(x)}\right\}\right\} \ , \tag{39}$$

where the fraction takes infinite values when $f'(x) = 0$ and $f(x) \neq y$, and a null value by convention when $f'(x) = 0$ and $f(x) = y$. It is well-known that the Newton-Raphson method converges to a solution $x^\star$ as soon as x is initialized sufficiently close to $x^\star$. Convergence is then quadratic provided that $f'(x^\star) \neq 0$. However, this local convergence has little importance in practice because it is hard to quantify the required proximity to the solution.

(A) Affine constraints	(B) Polyhedral constraints
(A1) ϕ is of Legendre type.	(B1) ϕ is of Legendre type.
(A2) $(0,1)^{d\times d} \subseteq \operatorname{dom}\phi$.	(B2) $(0,1)^{d\times d} \subseteq \operatorname{dom}\phi$.
(A3) $\operatorname{dom}\phi \subseteq \mathbb{R}_+^{d\times d}$.	(B3) $\operatorname{dom}\phi \nsubseteq \mathbb{R}_+^{d\times d}$.
(A4) $\operatorname{dom}\psi$ is open.	(B4) $\operatorname{dom}\psi = \mathbb{R}^{d\times d}$.
(A5) $\mathbb{R}_-^{d\times d} \subset \operatorname{dom}\psi$.	

Table 1: Set of assumptions for the considered regularizers ϕ.

Thorlund-Petersen (2004) elucidated results on global convergence of the Newton-Raphson method. He proved a necessary and sufficient condition of convergence for an arbitrary value $y \in [y^-, y^+]$ and from any starting point $x \in [x^-, x^+]$. This condition is that for any $a, b \in [x^-, x^+]$, $f(b) > f(a)$ implies:

$$f'(a) + f'(b) > \frac{f(b) - f(a)}{b - a} \ . \tag{40}$$

In particular, a sufficient condition is that the underlying function f is an increasing convex or increasing concave function on $[x^-, x^+]$, or can be decomposed as the sum of such functions. In addition, if f satisfies the necessary and sufficient condition and is strictly increasing with $f'(x) > 0$ for all $x \in [x^-, x^+]$, then initializing with a boundary point $x^- \neq x^\star$ or $x^+ \neq x^\star$ ensures that the entire sequence of updates is interior to (x^-, x^+), so that we can actually drop the min and max truncation operators in the updates:

$$x \leftarrow x - \frac{f(x) - y}{f'(x)} \ . \tag{41}$$

3. Mathematical Formulation

In this section, we develop a unified framework to define ROT problems. We start by drawing some technical assumptions for our generalized framework to hold (Section 3.1). We then formulate primal ROT problems and study their properties (Section 3.2). We also formulate dual ROT problems and discuss their properties in relation to primal ones (Section 3.3). Finally, we provide some geometrical insights to summarize our developments in the light of information geometry (Section 3.4).

3.1 Technical Assumptions

Some mild technical assumptions are required on the convex regularizer ϕ and its Fenchel conjugate $\psi = \phi^*$ for the proposed framework to hold. Some assumptions relate to required conditions for the definition of Bregman projections and convergence of the algorithms, while others are more specific to ROT problems. In our framework, we also need to distinguish between two situations where the underlying closed convex set can be described as the intersection of either affine subspaces or polyhedral subsets. The two sets of assumptions (A) and (B) are summarized in Table 1.

For the first assumptions (A1) and (B1), we recall that a closed proper convex function is of Legendre type if and only if it is essentially smooth and strictly convex on the interior

of its domain (Section 2.1). This is required for the definition of Bregman projections (Section 2.2). In addition, it guarantees the existence of dual coordinate systems on $\operatorname{int}(\operatorname{dom}\phi)$ and $\operatorname{int}(\operatorname{dom}\psi)$ via the homeomorphism $\nabla\phi = \nabla\psi^{-1}$:

$$\boldsymbol{\pi}(\boldsymbol{\theta}) = \nabla\psi(\boldsymbol{\theta}) \ , \tag{42}$$

$$\boldsymbol{\theta}(\boldsymbol{\pi}) = \nabla\phi(\boldsymbol{\pi}) \ . \tag{43}$$

With a slight abuse of notation, we omit the reparameterization to simply denote corresponding primal and dual parameters by $\boldsymbol{\pi}$ and $\boldsymbol{\theta}$.

The second assumptions (A2) and (B2) imply that $\operatorname{ri}(\Pi(\mathbf{p}, \mathbf{q})) \subset \operatorname{dom}\phi$ and ensure the constraint qualification $\Pi(\mathbf{p}, \mathbf{q}) \cap \operatorname{int}(\operatorname{dom}\phi) \neq \emptyset$ for Bregman projection onto the transport polytope, independently of the input distributions $\mathbf{p}, \mathbf{q}$ as long as they do not have null or unit entries. We assume hereafter that this implicitly holds, and discuss in the practical considerations (Section 4.6) how our methods actually generalize to deal explicitly with null or unit entries in the input distributions.

The third assumptions (A3) and (B3) separate between two cases depending on whether $\operatorname{dom}\phi$ lies within the non-negative orthant or not for the alternate Bregman projections (Section 2.3). In the former case, non-negativity is already ensured by the domain of the regularizer, so that the underlying closed convex set is made of two affine subspaces for the row and column sum constraints, and the POCS method can be considered. The fourth assumption (A4) thus requires that $\operatorname{dom}\psi$ be open for convergence of this algorithm. In the latter case, there is one additional polyhedral subset for the non-negative constraints and Dykstra's algorithm should be used. The fourth assumption (B4) hence further requires that $\operatorname{dom}\psi = \mathbb{R}^{d\times d}$, or equivalently that ϕ be cofinite (18), for convergence. In both cases, we remark that we necessarily have $\operatorname{dom}\psi = \operatorname{dom}\nabla\psi$.

The fifth assumption (A5) in the affine constraints ensures that $-\boldsymbol{\gamma}/\lambda$ belongs to $\operatorname{dom}\nabla\psi$ for definition of ROT problems, independently of the non-negative cost matrix $\boldsymbol{\gamma}$ and positive regularization term λ. Notice that this is already guaranteed by the fourth assumption in the polyhedral constraints. We also show in the sparse extension (Section 4.5) how to deal with infinite entries in the cost matrix $\boldsymbol{\gamma}$ for separable regularizers, so as to enforce null entries in the regularized optimal plan.

On the one hand, some common regularizers under assumptions (A) are the Boltzmann-Shannon entropy associated to the Kullback-Leibler divergence, the Burg entropy associated to the Itakura-Saito divergence, and the Fermi-Dirac entropy associated to the logistic loss function. To solve the underlying ROT problems, we employ our method called ASA based on the POCS technique, where alternate Bregman projections onto the two affine subspaces for the row and column sum constraints are considered (Section 4.3). On the other hand, examples under assumptions (B) include the Euclidean norm associated to the Euclidean distance, and the quadratic form associated to the Mahalanobis distance. For these ROT problems, we use our second method called NASA based on Dykstra's algorithm, where correction terms and a further Bregman projection onto the polyhedral non-negative orthant are needed (Section 4.4).

3.2 Primal Problem

We start our primal formulation with the following lemmas and definition for the RMD.

Lemma 1 *The regularizer ϕ attains its global minimum uniquely at $\boldsymbol{\xi}' = \nabla\psi(\mathbf{0})$.*

Proof Using the assumptions (A4) and (A5), respectively (B4), we have that $\mathbf{0} \in \operatorname{dom}\psi = \operatorname{int}(\operatorname{dom}\psi)$. Thus, there exists a unique $\boldsymbol{\xi}' \in \operatorname{int}(\operatorname{dom}\phi)$ such that $\nabla\phi(\boldsymbol{\xi}') = \mathbf{0}$, or equivalently $\boldsymbol{\xi}' = \nabla\psi(\mathbf{0})$, via the homeomorphism $\nabla\phi = \nabla\psi^{-1}$ ensured by assumption (A1), respectively (B1). Hence, ϕ attains its global minimum uniquely at $\boldsymbol{\xi}'$ by strict convexity on $\operatorname{int}(\operatorname{dom}\phi)$. ■

Lemma 2 *The restriction of the regularizer ϕ to the transport polytope $\Pi(\mathbf{p},\mathbf{q})$ attains its global minimum uniquely at the Bregman projection $\boldsymbol{\pi}'$ of $\boldsymbol{\xi}'$ onto $\Pi(\mathbf{p},\mathbf{q})$.*

Proof Using the assumption (A2), respectively (B2), we have that $\Pi(\mathbf{p},\mathbf{q}) \cap \operatorname{int}(\operatorname{dom}\phi) \neq \emptyset$. Since $\boldsymbol{\xi}' \in \operatorname{int}(\operatorname{dom}\phi)$ and $\Pi(\mathbf{p},\mathbf{q})$ is a closed convex set, the Bregman projection $\boldsymbol{\pi}'$ of $\boldsymbol{\xi}'$ onto $\Pi(\mathbf{p},\mathbf{q})$ according to the function ϕ of Legendre type is well-defined. Moreover, it is characterized by the variational relation (23) as follows:

$$\langle \boldsymbol{\pi} - \boldsymbol{\pi}', \nabla\phi(\boldsymbol{\pi}')\rangle \geq 0 \ , \tag{44}$$

for all $\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q}) \cap \operatorname{dom}\phi$. We also have $B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}') > 0$ when $\boldsymbol{\pi} \neq \boldsymbol{\pi}'$ by strict convexity of ϕ on $\operatorname{int}(\operatorname{dom}\phi)$. As a result, we have:

$$\phi(\boldsymbol{\pi}) - \phi(\boldsymbol{\pi}') > \langle \boldsymbol{\pi} - \boldsymbol{\pi}', \nabla\phi(\boldsymbol{\pi}')\rangle \ . \tag{45}$$

Combining the two inequalities, we obtain $\phi(\boldsymbol{\pi}) > \phi(\boldsymbol{\pi}')$ and the restriction of ϕ to $\Pi(\mathbf{p},\mathbf{q})$ attains its global minimum uniquely at $\boldsymbol{\pi}'$. ■

Lemma 3 *The restriction of the cost $\langle\cdot,\boldsymbol{\gamma}\rangle$ to the regularized transport polytope:*

$$\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q})\colon \phi(\boldsymbol{\pi}) \leq \phi(\boldsymbol{\pi}') + \alpha\} \ , \tag{46}$$

where $\alpha \geq 0$, attains its global minimum.

Proof The regularized transport polytope is the intersection of the compact set $\Pi(\mathbf{p},\mathbf{q})$ with a lower level set of ϕ which is also closed since ϕ is closed. Hence, $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ is compact and the restriction of $\langle\cdot,\boldsymbol{\gamma}\rangle$ to $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ attains its global minimum by continuity on a compact set. ■

Definition 4 *The primal rot mover's distance is the quantity defined as:*

$$d'_{\boldsymbol{\gamma},\alpha,\phi}(\mathbf{p},\mathbf{q}) = \min_{\boldsymbol{\pi}\in\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})} \langle\boldsymbol{\pi},\boldsymbol{\gamma}\rangle \ . \tag{47}$$

A minimizer $\boldsymbol{\pi}'^{\star}_{\alpha}$ is then called a primal rot mover's plan.

Remark 1 *For the sake of notation, we omit the dependence on $\mathbf{p},\mathbf{q},\boldsymbol{\gamma},\phi$ in the index of primal rot mover's plans $\boldsymbol{\pi}'^{\star}_{\alpha}$.*

The regularization enforces the associated minimizers to have small enough Bregman information $\phi(\boldsymbol{\pi}'^{\star}_{\alpha}) \leq \phi(\boldsymbol{\pi}') + \alpha$ compared to the minimal one $\phi(\boldsymbol{\pi}')$ for transport plans. We also have a geometrical interpretation where the solutions are constrained to a Bregman ball whose center $\boldsymbol{\xi}'$ is the matrix with minimal Bregman information.

Proposition 5 *The regularized transport polytope is the intersection of the transport polytope with the Bregman ball of radius $B_\phi(\boldsymbol{\pi}'\|\boldsymbol{\xi}') + \alpha$ and center $\boldsymbol{\xi}'$:*

$$\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q})\colon B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}') \leq B_\phi(\boldsymbol{\pi}'\|\boldsymbol{\xi}') + \alpha\} \ . \tag{48}$$

Proof Expanding the Bregman divergences from their definition (19), we obtain:

$$B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}') = \phi(\boldsymbol{\pi}) - \phi(\boldsymbol{\xi}') - \langle \boldsymbol{\pi} - \boldsymbol{\xi}', \nabla\phi(\boldsymbol{\xi}')\rangle \ , \tag{49}$$

$$B_\phi(\boldsymbol{\pi}'\|\boldsymbol{\xi}') = \phi(\boldsymbol{\pi}') - \phi(\boldsymbol{\xi}') - \langle \boldsymbol{\pi}' - \boldsymbol{\xi}', \nabla\phi(\boldsymbol{\xi}')\rangle \ . \tag{50}$$

Since $\nabla\phi(\boldsymbol{\xi}') = \mathbf{0}$, the last terms with scalar products vanish, leading to:

$$\phi(\boldsymbol{\pi}) - \phi(\boldsymbol{\pi}') = B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}') - B_\phi(\boldsymbol{\pi}'\|\boldsymbol{\xi}') \ . \tag{51}$$

Therefore, in the definition (46) of $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$, we have $\phi(\boldsymbol{\pi}) \leq \phi(\boldsymbol{\pi}') + \alpha$ if and only if $\boldsymbol{\pi}$ is in the Bregman ball of radius $B_\phi(\boldsymbol{\pi}'\|\boldsymbol{\xi}') + \alpha$ and center $\boldsymbol{\xi}'$. ■

Under some additional conditions, this geometrical interpretation still holds with a Bregman ball whose center $\boldsymbol{\pi}'$ has minimal Bregman information for transport plans.

Proposition 6 *If $\boldsymbol{\pi}' \in \operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$, then the regularized transport polytope is the intersection of the transport polytope with the Bregman ball of radius α and center $\boldsymbol{\pi}'$:*

$$\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q})\colon B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}') \leq \alpha\} \ . \tag{52}$$

Proof Since $\boldsymbol{\pi}' \in \operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$, there is equality in the generalized Pythagorean theorem (26):

$$B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}') = B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}') + B_\phi(\boldsymbol{\pi}'\|\boldsymbol{\xi}') \ . \tag{53}$$

The regularized transport polytope as seen from (48) is then the intersection of the transport polytope $\Pi(\mathbf{p},\mathbf{q})$ with the Bregman ball of radius α and center $\boldsymbol{\pi}'$. ■

Remark 2 *The proposition also holds trivially when the global minimum is attained on the transport polytope, that is, when $\boldsymbol{\xi}' = \boldsymbol{\pi}'$.*

Corollary 7 *Under assumptions (A), the regularized transport polytope is the intersection of the transport polytope with the Bregman ball of radius α and center $\boldsymbol{\pi}'$:*

$$\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q})\colon B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}') \leq \alpha\} \ . \tag{54}$$

Proof This is a result of $\boldsymbol{\pi}' \in \Pi(\mathbf{p},\mathbf{q}) \cap \operatorname{int}(\operatorname{dom}\phi) = \operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$ when $\operatorname{dom}\phi \subseteq \mathbb{R}_+^{d\times d}$. Indeed, we then have $\operatorname{ri}(\Pi(\mathbf{p},\mathbf{q})) \subset \Pi(\mathbf{p},\mathbf{q})$ and $\operatorname{ri}(\Pi(\mathbf{p},\mathbf{q})) \subset \operatorname{int}(\operatorname{dom}\phi)$, so that $\operatorname{ri}(\Pi(\mathbf{p},\mathbf{q})) \subseteq \Pi(\mathbf{p},\mathbf{q}) \cap \operatorname{int}(\operatorname{dom}\phi)$. Conversely, let $\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q}) \cap \operatorname{int}(\operatorname{dom}\phi)$ so that $\boldsymbol{\pi} \in \mathbb{R}_{++}^{d\times d}$. Then, for a given $\overline{\boldsymbol{\pi}} \in \Pi(\mathbf{p},\mathbf{q})$, let us pose $\boldsymbol{\pi}_\lambda = \lambda\boldsymbol{\pi} + (1-\lambda)\overline{\boldsymbol{\pi}}$ for $\lambda > 1$. We easily have $\boldsymbol{\pi}_\lambda \mathbf{1} = \mathbf{p}$ and $\boldsymbol{\pi}_\lambda^\top \mathbf{1} = \mathbf{q}$. Moreover, since all entries of $\boldsymbol{\pi}$ are positive and that of $\overline{\boldsymbol{\pi}}$ are non-negative, we can always choose a given λ sufficiently close to 1 such that $\boldsymbol{\pi}_\lambda \in \mathbb{R}_+^{d\times d}$. We then have $\boldsymbol{\pi}_\lambda \in \Pi(\mathbf{p},\mathbf{q})$ so that $\boldsymbol{\pi} \in \operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$ as characterized by (15), and thus $\Pi(\mathbf{p},\mathbf{q}) \cap \operatorname{int}(\operatorname{dom}\phi) \subseteq \operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$. ■

Remark 3 *Under assumptions (B), the Bregman projection $\boldsymbol{\pi}'$ does not necessarily lie within* $\operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$. *Hence, the geometrical interpretation in terms of a Bregman ball might break down, although the solutions are still constrained to have a small enough Bregman information above that of $\boldsymbol{\pi}'$.*

Although Sinkhorn distances verify the triangular inequality when $\boldsymbol{\gamma}$ is a distance matrix, thanks to specific chain rules and information inequalities for the Bolzmann-Shannon entropy and Kullback-Leibler divergence, it is not necessarily the case for the RMD with other regularizations, even for separable regularizers. Hence, the RMD does not provide a true distance metric on Σ_d in general even if $\boldsymbol{\gamma}$ is a distance matrix. Nonetheless, the RMD is symmetric as soon as ϕ is invariant by transposition, which holds for separable regularizers $\phi_{ij} = \phi$, and $\boldsymbol{\gamma}$ is symmetric. We now study some properties of the RMD that hold for general regularizers.

Property 1 *The primal rot mover's distance $d'_{\boldsymbol{\gamma},\alpha,\phi}(\mathbf{p},\mathbf{q})$ is a decreasing convex and continuous function of α.*

Proof The fact that it is decreasing is a direct consequence of the regularized transport polytope $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ growing with α. The convexity can be proved as follows. Let $\alpha_0, \alpha_1 \geq 0$, and $0 < \lambda < 1$. We pose $\alpha_\lambda = (1-\lambda)\alpha_0 + \lambda\alpha_1 \geq 0$. We also choose arbitrary rot mover's plans $\boldsymbol{\pi}'^\star_{\alpha_0}, \boldsymbol{\pi}'^\star_{\alpha_1}, \boldsymbol{\pi}'^\star_{\alpha_\lambda}$. We finally pose $\boldsymbol{\pi}_\lambda = (1-\lambda)\boldsymbol{\pi}'^\star_{\alpha_0} + \lambda\boldsymbol{\pi}'^\star_{\alpha_1}$. By convexity of ϕ, we have:

$$\begin{aligned}
\phi(\boldsymbol{\pi}_\lambda) &\leq (1-\lambda)\phi(\boldsymbol{\pi}'^\star_{\alpha_0}) + \lambda\phi(\boldsymbol{\pi}'^\star_{\alpha_1}) && (55)\\
&\leq (1-\lambda)(\alpha_0 + \phi(\boldsymbol{\pi}')) + \lambda(\alpha_1 + \phi(\boldsymbol{\pi}')) && (56)\\
&= \alpha_\lambda + \phi(\boldsymbol{\pi}') \ . && (57)
\end{aligned}$$

Hence, $\boldsymbol{\pi}_\lambda \in \Pi_{\alpha_\lambda,\phi}(\mathbf{p},\mathbf{q})$, and by construction we have $\langle \boldsymbol{\pi}'^\star_{\alpha_\lambda}, \boldsymbol{\gamma}\rangle \leq \langle \boldsymbol{\pi}_\lambda, \boldsymbol{\gamma}\rangle$, or equivalently:

$$\langle \boldsymbol{\pi}'^\star_{\alpha_\lambda}, \boldsymbol{\gamma}\rangle \leq (1-\lambda)\langle \boldsymbol{\pi}'^\star_{\alpha_0}, \boldsymbol{\gamma}\rangle + \lambda\langle \boldsymbol{\pi}'^\star_{\alpha_1}, \boldsymbol{\gamma}\rangle \ . \quad (58)$$

The continuity for $\alpha > 0$ is a direct consequence of convexity for $\alpha > 0$, since a convex function is always continuous on the relative interior of its domain. Lastly, the continuity at $\alpha = 0$ can be seen as follows. Let $(\alpha_k)_{k\in\mathbb{N}}$ be a sequence of positive numbers that converges to 0. We choose arbitrary rot mover's plans $(\boldsymbol{\pi}'^\star_{\alpha_k})_{k\in\mathbb{N}}$. By compactness of $\Pi(\mathbf{p},\mathbf{q})$, we can extract a subsequence of rot mover's plans that converges in norm to a point $\boldsymbol{\pi}'^\star \in \Pi(\mathbf{p},\mathbf{q})$.

For the sake of simplicity, we do not relabel this subsequence. By construction, we have $\phi(\boldsymbol{\pi}') \leq \phi(\boldsymbol{\pi}'^\star_{\alpha_k}) \leq \phi(\boldsymbol{\pi}') + \alpha_k$, and $\phi(\boldsymbol{\pi}'^\star_{\alpha_k})$ converges to $\phi(\boldsymbol{\pi}')$. By lower semi-continuity of ϕ, we thus have $\phi(\boldsymbol{\pi}'^\star) \leq \phi(\boldsymbol{\pi}')$. Since the global minimum of ϕ on $\Pi(\mathbf{p},\mathbf{q})$ is attained uniquely at $\boldsymbol{\pi}'$, we must have $\boldsymbol{\pi}'^\star = \boldsymbol{\pi}'$, and the original sequence also converges in norm to $\boldsymbol{\pi}'$. By continuity of the total cost $\langle\cdot,\boldsymbol{\gamma}\rangle$ on $\mathbb{R}^{d\times d}$, $\langle \boldsymbol{\pi}'^\star_{\alpha_k}, \boldsymbol{\gamma}\rangle$ converges to $\langle \boldsymbol{\pi}', \boldsymbol{\gamma}\rangle$. Hence, the limit of the RMD when α tends to 0 from above is $\langle \boldsymbol{\pi}', \boldsymbol{\gamma}\rangle$, which equals the RMD for $\alpha = 0$ as shown in the next property. ■

Property 2 *When $\alpha = 0$, the primal rot mover's distance reduces to:*

$$d'_{\boldsymbol{\gamma},0,\phi}(\mathbf{p},\mathbf{q}) = \langle \boldsymbol{\pi}', \boldsymbol{\gamma}\rangle \ , \quad (59)$$

and the unique primal rot mover's plan is the transport plan with minimal Bregman information:

$$\boldsymbol{\pi}'^\star_0 = \boldsymbol{\pi}' \ . \quad (60)$$

Proof Since $\boldsymbol{\pi}'$ is the unique global minimizer of ϕ on $\Pi(\mathbf{p},\mathbf{q})$, the regularized transport polytope reduces to the singleton $\Pi_{0,\phi}(\mathbf{p},\mathbf{q}) = \{\boldsymbol{\pi} \in \Pi(\mathbf{p},\mathbf{q}) \colon \phi(\boldsymbol{\pi}) \leq \phi(\boldsymbol{\pi}')\} = \{\boldsymbol{\pi}'\}$. The property follows immediately. ■

Property 3 *When α tends to $+\infty$, the primal rot mover's distance converges to the earth mover's distance:*

$$\lim_{\alpha\to+\infty} d'_{\boldsymbol{\gamma},\alpha,\phi}(\mathbf{p},\mathbf{q}) = d_{\boldsymbol{\gamma}}(\mathbf{p},\mathbf{q}) \ . \quad (61)$$

Proof Let $\boldsymbol{\pi}^\star \in \Pi(\mathbf{p},\mathbf{q})$ be an earth mover's plan so that $d_{\boldsymbol{\gamma}}(\mathbf{p},\mathbf{q}) = \langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma}\rangle$. By continuity of the total cost $\langle\cdot,\boldsymbol{\gamma}\rangle$ on $\mathbb{R}^{d\times d}$, we have that for all $\epsilon > 0$, there exists an open neighborhood of $\boldsymbol{\pi}^\star$ such that $\langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle \leq \langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma}\rangle + \epsilon$ for any transport plan $\boldsymbol{\pi}$ within this neighborhood. We can always choose a transport plan such that $\boldsymbol{\pi} \in \operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$. Since $\operatorname{ri}(\Pi(\mathbf{p},\mathbf{q})) \subset \operatorname{dom}\phi$, $\phi(\boldsymbol{\pi})$ is finite and we can fix $\alpha_\epsilon = \phi(\boldsymbol{\pi}) - \phi(\boldsymbol{\pi}') \geq 0$. Hence, $\boldsymbol{\pi} \in \Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ for any $\alpha \geq \alpha_\epsilon$, and we have $d_{\boldsymbol{\gamma}}(\mathbf{p},\mathbf{q}) \leq d'_{\boldsymbol{\gamma},\alpha,\phi}(\mathbf{p},\mathbf{q}) \leq \langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle \leq d_{\boldsymbol{\gamma}}(\mathbf{p},\mathbf{q}) + \epsilon$. ■

Property 4 *If $[0,1)^{d\times d} \subseteq \operatorname{dom}\phi$, then there exists a minimal $\alpha' \geq 0$ such that for all $\alpha \geq \alpha'$, the primal rot mover's distance reduces to the earth mover's distance:*

$$d'_{\boldsymbol{\gamma},\alpha,\phi}(\mathbf{p},\mathbf{q}) = d_{\boldsymbol{\gamma}}(\mathbf{p},\mathbf{q}) \ . \quad (62)$$

Proof The extra condition guarantees that $\Pi(\mathbf{p},\mathbf{q}) \subset \operatorname{dom}\phi$, and thus that ϕ is bounded on the closed set $\Pi(\mathbf{p},\mathbf{q})$. The property is then a direct consequence of $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q}) = \Pi(\mathbf{p},\mathbf{q})$ for α large enough. ■

Property 5 *If $[0,1)^{d\times d} \subseteq \operatorname{dom}\phi$ and ϕ is strictly convex on $[0,1)^{d\times d}$, then the unique primal rot mover's plan for $\alpha = \alpha'$ is the earth mover's plan $\boldsymbol{\pi}_0^\star$ with minimal Bregman information:*

$$\boldsymbol{\pi}'^\star_{\alpha'} = \boldsymbol{\pi}_0^\star \ . \tag{63}$$

Proof First, we recall that the set of earth mover's plans $\boldsymbol{\pi}^\star$ is either a single vertex or a whole facet of $\Pi(\mathbf{p},\mathbf{q})$. Hence, it forms a closed convex subset in $\Pi(\mathbf{p},\mathbf{q})$, and there is a unique earth mover's plan $\boldsymbol{\pi}_0^\star$ with minimal Bregman information by strict convexity of ϕ on this subset. Second, it is trivial that all primal rot mover's plan $\boldsymbol{\pi}'^\star_{\alpha'}$ must be earth mover's plans. If there is a single vertex as earth mover's plan, then the property follows immediately. Otherwise, we can see the property geometrically as follows. The whole facet of earth mover's plans is orthogonal to $\boldsymbol{\gamma}$. Nevertheless, by strict convexity of ϕ on $[0,1)^{d\times d}$, the facet must be tangent to $\Pi_{\alpha',\phi}(\mathbf{p},\mathbf{q})$ at the unique earth mover's plan $\boldsymbol{\pi}_0^\star$ with minimal Bregman information $\phi(\boldsymbol{\pi}_0^\star) = \phi(\boldsymbol{\pi}') + \alpha'$, and $\boldsymbol{\pi}_0^\star$ is also the rot mover's plan $\boldsymbol{\pi}'^\star_{\alpha'}$. Another way to prove the property more formally is as follows. Suppose that a primal rot mover's plan $\boldsymbol{\pi}^\star$ is not the earth mover's plan with minimal Bregman information. We thus have $\phi(\boldsymbol{\pi}_0^\star) < \phi(\boldsymbol{\pi}^\star) \leq \phi(\boldsymbol{\pi}') + \alpha'$. We can then choose a smaller α' such that $\phi(\boldsymbol{\pi}_0^\star) \leq \phi(\boldsymbol{\pi}') + \alpha'$ and the RMD still equals the EMD for this smaller value, and actually all values in between by monotonicity. This leads to a contradiction and $\boldsymbol{\pi}_0^\star$ must be the earth mover's plan with minimal Bregman information. ■

Remark 4 *When $\alpha > \alpha'$, the regularized transport polytope might grow to include several earth mover's plans with different Bregman information, which are then all minimizers for the RMD. When we do not have strict convexity outside $(0,1)^{d\times d}$, there might also be multiple earth mover's plans with minimal Bregman information.*

If $[0,1)^{d\times d} \subseteq \operatorname{dom}\phi$, then it is easy to check that the strict convexity of ϕ on $[0,1)^{d\times d}$ is always verified when ϕ is separable under assumptions (A) or (B), or when $[0,1)^{d\times d} \subset \operatorname{int}(\operatorname{dom}\phi)$ under assumptions (B). This holds for almost all typical regularizers, notably for all regularizers considered in this paper except from minus the Burg entropy as defined in (30) and associated to the Itakura-Saito divergence in (29). For this latter regularizer, the solutions for an increasing α all lie within $\operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$, and the RMD never reaches the EMD. In such cases where the minimal α' does not exist, we can use the convention $\alpha' = +\infty$ since the RMD always converges to the EMD in the limit when α tends to $+\infty$. We can then prove that there is a unique rot mover's plan $\boldsymbol{\pi}'^\star_{\alpha}$ as long as $0 < \alpha < \alpha'$, which can be seen informally as follows. The solutions geometrically lie at the intersection of $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ and of a supporting hyperplane with normal $\boldsymbol{\gamma}$. By strict convexity of ϕ on $\operatorname{ri}(\Pi(\mathbf{p},\mathbf{q}))$, this intersection is a singleton inside the polytope. When the intersection reaches a facet, the only facet that can coincide locally with the hyperplane is the one that contains the earth mover's plans. Hence, we also have a singleton on the boundary of the polytope before reaching an earth mover's plan. We formally prove this uniqueness result next by exploiting duality.

3.3 Dual Problem

We now present the following two lemmas before defining our dual formulation for the RMD.

Lemma 8 *The regularized cost $\langle\cdot,\boldsymbol{\gamma}\rangle + \lambda\phi(\cdot)$, where $\lambda > 0$, attains its global minimum uniquely at $\boldsymbol{\xi} = \nabla\psi(-\boldsymbol{\gamma}/\lambda)$.*

Proof The regularized cost is convex with same domain as ϕ, and is strictly convex on $\operatorname{int}(\operatorname{dom}\phi)$. Thus, it attains its global minimum at a unique point $\boldsymbol{\xi} \in \operatorname{int}(\operatorname{dom}\phi)$ if and only if $\boldsymbol{\gamma} + \lambda\nabla\phi(\boldsymbol{\xi}) = \mathbf{0}$, or equivalently $\nabla\phi(\boldsymbol{\xi}) = -\boldsymbol{\gamma}/\lambda$. By assumptions (A4) and (A5), respectively (B4), $-\boldsymbol{\gamma}/\lambda \in \operatorname{dom}\nabla\psi$, so that the global minimum is attained uniquely at $\boldsymbol{\xi} = \nabla\psi(-\boldsymbol{\gamma}/\lambda)$ in virtue of the homeomorphism in (42) and (43). ■

Lemma 9 *The restriction of the regularized cost $\langle\cdot,\boldsymbol{\gamma}\rangle + \lambda\phi(\cdot)$ to the transport polytope $\Pi(\mathbf{p},\mathbf{q})$ attains its global minimum uniquely.*

Proof We notice that the regularized cost is equal to a Bregman divergence up to a positive factor and additive constant:

$$\langle\boldsymbol{\pi},\boldsymbol{\gamma}\rangle + \lambda\phi(\boldsymbol{\pi}) - \lambda\phi(\boldsymbol{\xi}) = \lambda B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}) \ . \tag{64}$$

Hence, its minimization over the closed convex set $\Pi(\mathbf{p},\mathbf{q})$ is equivalent to the Bregman projection of $\boldsymbol{\xi} \in \operatorname{int}(\operatorname{dom}\phi)$ onto $\Pi(\mathbf{p},\mathbf{q})$ according to the function ϕ of Legendre type. Since $\Pi(\mathbf{p},\mathbf{q}) \cap \operatorname{int}(\operatorname{dom}\phi) \neq \emptyset$, this projection exists and is unique. ■

Definition 10 *The dual rot mover's distance is the quantity defined as:*

$$d_{\boldsymbol{\gamma},\lambda,\phi}(\mathbf{p},\mathbf{q}) = \langle\boldsymbol{\pi}_\lambda^\star,\boldsymbol{\gamma}\rangle \ , \tag{65}$$

where the dual rot mover's plan $\boldsymbol{\pi}_\lambda^\star$ is given by:

$$\boldsymbol{\pi}_\lambda^\star = \underset{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})}{\operatorname{argmin}} \ \langle\boldsymbol{\pi},\boldsymbol{\gamma}\rangle + \lambda\phi(\boldsymbol{\pi}) \ . \tag{66}$$

Remark 5 *For the sake of notation, we omit the dependence on $\mathbf{p},\mathbf{q},\boldsymbol{\gamma},\phi$ in the index of dual rot mover's plans $\boldsymbol{\pi}_\lambda^\star$.*

We proceed with the following proposition that enlightens the relation between the RMD and associated Bregman divergence.

Proposition 11 *The dual rot mover's plan is the Bregman projection of $\boldsymbol{\xi}$ onto the transport polytope:*

$$\boldsymbol{\pi}_\lambda^\star = \underset{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})}{\operatorname{argmin}} \ B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}) \ . \tag{67}$$

Proof This is a consequence of the proof for Lemma 9. Indeed, from the definition in (66), we see that the rot mover's plan also minimizes (64). Therefore, it is the unique Bregman projection of $\boldsymbol{\xi}$ onto the transport polytope. ■

We have a geometrical interpretation where the regularization shrinks the solution toward the matrix $\boldsymbol{\xi}'$ that has minimal Bregman information.

Proposition 12 *The dual rot mover's plan $\boldsymbol{\pi}^\star_\lambda$ can be obtained as:*

$$\boldsymbol{\pi}^\star_\lambda = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle + \lambda B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}') \ . \tag{68}$$

Proof Developing the Bregman divergence based on its definition (19), we have:

$$B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}') = \phi(\boldsymbol{\pi}) - \phi(\boldsymbol{\xi}') - \langle \boldsymbol{\pi} - \boldsymbol{\xi}', \nabla\phi(\boldsymbol{\xi}')\rangle \ . \tag{69}$$

Since $\nabla\phi(\boldsymbol{\xi}') = \mathbf{0}$, the last term with scalar product vanishes and we are left out with $\phi(\boldsymbol{\pi})$ plus a constant term with respect to $\boldsymbol{\pi}$. Hence, we can replace $\phi(\boldsymbol{\pi})$ by $B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}')$ in the minimization (66) that defines $\boldsymbol{\pi}^\star_\lambda$. ■

Under some additional conditions, this interpretation can also be seen as shrinking toward the transport plan $\boldsymbol{\pi}'$ with minimal Bregman information.

Proposition 13 *If $\boldsymbol{\pi}' \in \mathrm{ri}(\Pi(\mathbf{p},\mathbf{q}))$, then the dual rot mover's plan $\boldsymbol{\pi}^\star_\lambda$ can be obtained as:*

$$\boldsymbol{\pi}^\star_\lambda = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle + \lambda B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}') \ . \tag{70}$$

Proof If $\boldsymbol{\pi}' \in \mathrm{ri}(\Pi(\mathbf{p},\mathbf{q}))$, then we have equality in the generalized Pythagorean theorem (26), leading to:

$$B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}') = B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}') + B_\phi(\boldsymbol{\pi}'\|\boldsymbol{\xi}') \ . \tag{71}$$

Since the last term is constant with respect to $\boldsymbol{\pi}$, we can replace $B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}')$ by $B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}')$ in the minimization (68) that characterizes $\boldsymbol{\pi}^\star_\lambda$. ■

Remark 6 *The proposition also holds trivially when the global minimum is attained on the transport polytope, that is, when $\boldsymbol{\xi}' = \boldsymbol{\pi}'$.*

Corollary 14 *Under assumptions (A), the dual rot mover's plan $\boldsymbol{\pi}^\star_\lambda$ can be obtained as:*

$$\boldsymbol{\pi}^\star_\lambda = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} \langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle + \lambda B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}') \ . \tag{72}$$

Proof This is a result of $\boldsymbol{\pi}' \in \Pi(\mathbf{p},\mathbf{q}) \cap \mathrm{int}(\mathrm{dom}\,\phi) = \mathrm{ri}(\Pi(\mathbf{p},\mathbf{q}))$ when $\mathrm{dom}\,\phi \subseteq \mathbb{R}_+^{d\times d}$, as shown in the proof of Corollary 7. ■

In the sequel, we also extend naturally the definition of the dual RMD for $\lambda = 0$ as the EMD. We then do not necessarily have uniqueness of dual rot mover's plans for $\lambda = 0$, and the geometrical interpretation in terms of a Bregman projection does not hold anymore for $\lambda = 0$. However, we have the following theorem based on duality theory that shows the equivalence between primal and dual ROT problems.

Theorem 15 *For all $\alpha > 0$, there exists $\lambda \geq 0$ such that the primal and dual rot mover's distances are equal:*

$$d'_{\boldsymbol{\gamma},\alpha,\phi}(\mathbf{p},\mathbf{q}) = d_{\boldsymbol{\gamma},\lambda,\phi}(\mathbf{p},\mathbf{q}) \ . \tag{73}$$

Moreover, if $\alpha < \alpha'$, then a corresponding value is such that $\lambda > 0$, and the primal and dual rot mover's plans are unique and equal:

$$\boldsymbol{\pi}'^\star_\alpha = \boldsymbol{\pi}^\star_\lambda \ . \tag{74}$$

Proof The primal problem can be seen as the minimization $p^\star$ of the cost $\langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle$ on $\Pi(\mathbf{p},\mathbf{q})$ subject to $\phi(\boldsymbol{\pi}) - \phi(\boldsymbol{\pi}') - \alpha \leq 0$. The domain of this constrained convex problem is $\mathcal{D} = \Pi(\mathbf{p},\mathbf{q}) \cap \mathrm{dom}\,\phi \neq \emptyset$. The Lagrangian on $\mathcal{D}\times\mathbb{R}$ is given by $\mathcal{L}(\boldsymbol{\pi},\lambda) = \langle \boldsymbol{\pi}, \boldsymbol{\gamma}\rangle + \lambda(\phi(\boldsymbol{\pi}) - \phi(\boldsymbol{\pi}') - \alpha)$, and its minimization over $\mathcal{D}$ for a fixed $\lambda \geq 0$ has the same solutions $\boldsymbol{\pi}^\star$ as the dual problem. In addition, Slater's condition for convex problems, stating that there is a strictly feasible point in the relative interior of the domain, is verified as long as $\alpha > 0$. Indeed, we have $\mathrm{ri}(\mathcal{D}) = \mathrm{ri}(\Pi(\mathbf{p},\mathbf{q}))$. The existence of a strictly feasible point $\phi(\boldsymbol{\pi}) < \phi(\boldsymbol{\pi}') + \alpha$ then holds by continuity of ϕ at $\boldsymbol{\pi}' \in \mathrm{int}(\mathrm{dom}\,\phi)$. As a result, we have strong duality with a zero duality gap $p^\star = d^\star$, where $d^\star$ is the maximization of $g(\lambda)$ subject to $\lambda \geq 0$. Moreover, if $d^\star$ is finite, then it is attained at least once at a point $\lambda^\star$. This is the case since we already know that $p^\star$ is finite. Since $p^\star$ is also attained at least once at a point $\boldsymbol{\pi}^\star$ solution of the primal problem, we have the following chain:

$$\begin{aligned}
p^\star &= d^\star && (75)\\
&= \min_{\boldsymbol{\pi}\in\mathcal{D}} \mathcal{L}(\boldsymbol{\pi},\lambda^\star) && (76)\\
&\leq \mathcal{L}(\boldsymbol{\pi}^\star,\lambda^\star) && (77)\\
&= \langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma}\rangle + \lambda^\star(\phi(\boldsymbol{\pi}^\star) - \phi(\boldsymbol{\pi}') - \alpha) && (78)\\
&\leq \langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma}\rangle && (79)\\
&= p^\star \ . && (80)
\end{aligned}$$

Therefore, all inequalities are in fact equalities, $\boldsymbol{\pi}^\star$ also minimizes the Lagrangian over $\mathcal{D}$ and thus is a solution of the dual problem. In other words, the primal and dual RMD for α and $\lambda^\star$ are equal, and the primal solutions must be dual solutions too. For $\alpha < \alpha'$, the RMD has not reached the EMD yet, and thus we must have $\lambda^\star > 0$. Hence, the dual solution is unique, so that the primal solution is unique too and equal to the dual one. ■

Remark 7 *Corresponding values of α and λ depend on $\mathbf{p},\mathbf{q},\boldsymbol{\gamma},\phi$. In addition, there might be multiple values of λ that correspond to a given α.*

Again, the RMD does not verify the triangular inequality in general, and hence does not provide a true distance metric on Σ_d even if $\boldsymbol{\gamma}$ is a distance matrix. Nevertheless, we still have the result that the RMD is symmetric as soon as ϕ is invariant by transposition, which holds for separable regularizers $\phi_{ij} = \phi$, and $\boldsymbol{\gamma}$ is symmetric. We also obtain properties for the dual RMD that are similar to the ones for the primal RMD.

Property 6 *The dual rot mover's distance $d_{\boldsymbol{\gamma},\lambda,\phi}(\mathbf{p},\mathbf{q})$ is an increasing and continuous function of λ.*

Proof The fact that it is increasing can be seen as follows. Let $0 \leq \lambda_1 < \lambda_2$. By construction, we have the following inequalities:

$$\langle \boldsymbol{\pi}^\star_{\lambda_1}, \boldsymbol{\gamma} \rangle + \lambda_1 \phi(\boldsymbol{\pi}^\star_{\lambda_1}) \leq \langle \boldsymbol{\pi}^\star_{\lambda_2}, \boldsymbol{\gamma} \rangle + \lambda_1 \phi(\boldsymbol{\pi}^\star_{\lambda_2}) \ , \tag{81}$$

$$\langle \boldsymbol{\pi}^\star_{\lambda_2}, \boldsymbol{\gamma} \rangle + \lambda_2 \phi(\boldsymbol{\pi}^\star_{\lambda_2}) \leq \langle \boldsymbol{\pi}^\star_{\lambda_1}, \boldsymbol{\gamma} \rangle + \lambda_2 \phi(\boldsymbol{\pi}^\star_{\lambda_1}) \ . \tag{82}$$

Subtracting these two inequalities, we obtain that $\phi(\boldsymbol{\pi}^\star_{\lambda_1}) \geq \phi(\boldsymbol{\pi}^\star_{\lambda_2})$. Reinserting this result in the first inequality, we finally get $\langle \boldsymbol{\pi}^\star_{\lambda_1}, \boldsymbol{\gamma} \rangle \leq \langle \boldsymbol{\pi}^\star_{\lambda_2}, \boldsymbol{\gamma} \rangle$. The continuity of the dual RMD results from that of the primal RMD. Let $\lambda \geq 0$, and choose an arbitrary dual rot mover's plan $\boldsymbol{\pi}^\star_\lambda$ and earth mover's plan $\boldsymbol{\pi}^\star$. On the one hand, we have $\langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma} \rangle \leq \langle \boldsymbol{\pi}^\star_\lambda, \boldsymbol{\gamma} \rangle$. On the other hand, we have $\langle \boldsymbol{\pi}^\star_\lambda, \boldsymbol{\gamma} \rangle + \lambda \phi(\boldsymbol{\pi}^\star_\lambda) \leq \langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle + \lambda \phi(\boldsymbol{\pi}')$, and thus $\langle \boldsymbol{\pi}^\star_\lambda, \boldsymbol{\gamma} \rangle \leq \langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle + \lambda(\phi(\boldsymbol{\pi}') - \phi(\boldsymbol{\pi}^\star_\lambda)) \leq \langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle$. Suppose we have a discontinuity of the dual RMD at λ. Then by monotonicity, there is a value $\langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma} \rangle < d < \langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle$ that is not in the image of the dual RMD. But d is in the image of the primal RMD for a given $\alpha > 0$ by continuity. It means that $\nexists \lambda > 0$ such that $\langle \pi^\star_\lambda, C \rangle = d$, whereas, by continuity of the primal problem, we know that there exist $\alpha > 0$ such that $\langle \pi^\star_\alpha, C \rangle \geq d$. This is in contradiction with the duality result in Theorem 15, which implies that the image of the primal RMD for $\alpha > 0$ must be included in that of the dual RMD for $\lambda \geq 0$. ■

Property 7 *When λ tends to $+\infty$, the dual rot mover's distance converges to:*

$$\lim_{\lambda \to +\infty} d_{\boldsymbol{\gamma},\lambda,\phi}(\mathbf{p},\mathbf{q}) = \langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle \ , \tag{83}$$

and the dual rot mover's plan converges in norm to the transport plan with minimal Bregman information:

$$\lim_{\lambda \to +\infty} \boldsymbol{\pi}^\star_\lambda = \boldsymbol{\pi}' \ . \tag{84}$$

Proof Let $(\lambda_k)_{k \in \mathbb{N}}$ be a sequence of positive numbers that tends to $+\infty$, and $(\boldsymbol{\pi}^\star_{\lambda_k})_{k \in \mathbb{N}}$ the associated rot mover's plans. By compactness of $\Pi(\mathbf{p},\mathbf{q})$, we can extract a subsequence of rot mover's plans that converges in norm to a point $\boldsymbol{\pi}^\star \in \Pi(\mathbf{p},\mathbf{q})$. For the sake of simplicity, we do not relabel this subsequence. By construction, we have $\langle \boldsymbol{\pi}^\star_{\lambda_k}, \boldsymbol{\gamma} \rangle + \lambda_k \phi(\boldsymbol{\pi}') \leq \langle \boldsymbol{\pi}^\star_{\lambda_k}, \boldsymbol{\gamma} \rangle + \lambda_k \phi(\boldsymbol{\pi}^\star_{\lambda_k}) \leq \langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle + \lambda_k \phi(\boldsymbol{\pi}')$. The scalar products are bounded, so dividing the inequalities by λ_k and taking the limit, we obtain that $\phi(\boldsymbol{\pi}^\star_{\lambda_k})$ converges to $\phi(\boldsymbol{\pi}')$. By lower semi-continuity of ϕ, we thus have $\phi(\boldsymbol{\pi}^\star) \leq \phi(\boldsymbol{\pi}')$. Since the global minimum of ϕ on $\Pi(\mathbf{p},\mathbf{q})$ is attained uniquely at $\boldsymbol{\pi}'$, we must have $\boldsymbol{\pi}^\star = \boldsymbol{\pi}'$, and the original sequence also converges in norm to $\boldsymbol{\pi}'$. Hence, the dual rot mover's plan $\boldsymbol{\pi}_\lambda$ converges in norm to $\boldsymbol{\pi}'$ when λ tends to $+\infty$. By continuity of the total cost $\langle \cdot, \boldsymbol{\gamma} \rangle$ on $\mathbb{R}^{d \times d}$, $\langle \boldsymbol{\pi}^\star_{\lambda_k}, \boldsymbol{\gamma} \rangle$ converges to $\langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle$. Hence, the limit of the RMD when λ tends to $+\infty$ is $\langle \boldsymbol{\pi}', \boldsymbol{\gamma} \rangle$. ■

Property 8 *When λ tends to 0, the dual rot mover's distance converges to the earth mover's distance:*

$$\lim_{\lambda \to 0} d_{\boldsymbol{\gamma},\lambda,\phi}(\mathbf{p},\mathbf{q}) = d_{\boldsymbol{\gamma}}(\mathbf{p},\mathbf{q}) \ . \tag{85}$$

Proof This is a direct consequence of the dual RMD being continuous at $\lambda = 0$. ■

Property 9 *If $[0,1)^{d \times d} \subseteq \operatorname{dom} \phi$ and ϕ is strictly convex on $[0,1)^{d \times d}$, then the dual rot mover's plan converges in norm when λ tends to 0 to the earth mover's plan $\boldsymbol{\pi}^\star_0$ with minimal Bregman information:*

$$\lim_{\lambda \to 0} \boldsymbol{\pi}^\star_\lambda = \boldsymbol{\pi}^\star_0 \ . \tag{86}$$

Proof Let $(\lambda_k)_{k \in \mathbb{N}}$ be a sequence of positive numbers that converges to 0, and $(\boldsymbol{\pi}^\star_{\lambda_k})_{k \in \mathbb{N}}$ the associated rot mover's plans. By compactness of $\Pi(\mathbf{p},\mathbf{q})$, we can extract a subsequence of rot mover's plans that converges in norm to a point $\boldsymbol{\pi}^\star \in \Pi(\mathbf{p},\mathbf{q})$. For the sake of simplicity, we do not relabel this subsequence. By construction, we have $\langle \boldsymbol{\pi}^\star_0, \boldsymbol{\gamma} \rangle + \lambda_k \phi(\boldsymbol{\pi}^\star_{\lambda_k}) \leq \langle \boldsymbol{\pi}^\star_{\lambda_k}, \boldsymbol{\gamma} \rangle + \lambda_k \phi(\boldsymbol{\pi}^\star_{\lambda_k}) \leq \langle \boldsymbol{\pi}^\star_0, \boldsymbol{\gamma} \rangle + \lambda_k \phi(\boldsymbol{\pi}^\star_0)$. The regularizer ϕ is continuous on the polytope $\Pi(\mathbf{p},\mathbf{q}) \subseteq \operatorname{dom} \phi$, so taking the limit, we obtain that $\langle \boldsymbol{\pi}^\star_{\lambda_k}, \boldsymbol{\gamma} \rangle$ converges to $\langle \boldsymbol{\pi}^\star_0, \boldsymbol{\gamma} \rangle$. Therefore, $\boldsymbol{\pi}^\star$ must be an earth mover's plan. Now dividing by λ_k and taking the limit, we obtain that $\phi(\boldsymbol{\pi}^\star) \leq \phi(\boldsymbol{\pi}^\star_0)$. Since $\boldsymbol{\pi}^\star_0$ is the unique earth mover's plan with minimal Bregman information, we must have $\boldsymbol{\pi}^\star = \boldsymbol{\pi}^\star_0$. ■

3.4 Geometrical Insights

Our primal and dual formulations enlighten some intricate relations between optimal transportation theory (Villani, 2009) and information geometry (Amari and Nagaoka, 2000), where Bregman divergences are known to possess a dually flat structure with a generalized Pythagorean theorem for information projections. A schematic view of the underlying geometry for ROT problems is represented in Figure 1, and can be discussed as follows.

Our constructions start from the global minimizer $\boldsymbol{\xi}'$ of the regularizer ϕ (Lemma 1). The Bregman projection $\boldsymbol{\pi}'$ of $\boldsymbol{\xi}'$ onto the transport polytope $\Pi(\mathbf{p},\mathbf{q})$ has minimal Bregman information on $\Pi(\mathbf{p},\mathbf{q})$ (Lemma 2). The linear cost restricted to the regularized transport polytope $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ also attains its global minimum (Lemma 3). Such a minimizer $\boldsymbol{\pi}'^\star_\alpha$ is a primal rot mover's plan (Definition 4). We can interpret $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ as the intersection of $\Pi(\mathbf{p},\mathbf{q})$ with the Bregman ball of radius $B_\phi(\boldsymbol{\pi}' \| \boldsymbol{\xi}') + \alpha$ and center $\boldsymbol{\xi}'$ (Proposition 5). In certain cases, $\Pi_{\alpha,\phi}(\mathbf{p},\mathbf{q})$ is also the intersection of $\Pi(\mathbf{p},\mathbf{q})$ with the Bregman ball of radius α and center $\boldsymbol{\pi}'$, as a result of the generalized Pythagorean theorem $B_\phi(\boldsymbol{\pi} \| \boldsymbol{\xi}') = B_\phi(\boldsymbol{\pi} \| \boldsymbol{\pi}') + B_\phi(\boldsymbol{\pi}' \| \boldsymbol{\xi}')$ (Proposition 6, Corollary 7). All in all, this enforces the solutions to have small enough Bregman information, by constraining them to lie close to the matrix $\boldsymbol{\xi}'$ or transport plan $\boldsymbol{\pi}'$ with minimal Bregman information.

In our developments, we next introduce the global minimizer $\boldsymbol{\xi}$ of the regularized cost (Lemma 8). The regularized cost restricted to $\Pi(\mathbf{p},\mathbf{q})$ also attains its global minimum uniquely (Lemma 9). This minimizer defines the dual rot mover's plan $\boldsymbol{\pi}^\star_\lambda$ (Definition 10). Actually, $\boldsymbol{\pi}^\star_\lambda$ can be seen as the Bregman projection of $\boldsymbol{\xi}$ onto $\Pi(\mathbf{p},\mathbf{q})$ (Proposition 11). The regularization by the Bregman information is also equivalent to regularizing the solution toward $\boldsymbol{\xi}'$ (Proposition 12). In some cases, this can also be seen as regularizing toward $\boldsymbol{\pi}'$, as a result of the generalized Pythagorean theorem $B_\phi(\boldsymbol{\pi} \| \boldsymbol{\xi}') = B_\phi(\boldsymbol{\pi} \| \boldsymbol{\pi}') + B_\phi(\boldsymbol{\pi}' \| \boldsymbol{\xi}')$ (Proposition 13, Corollary 14). Again, this enforces the solutions to have small enough

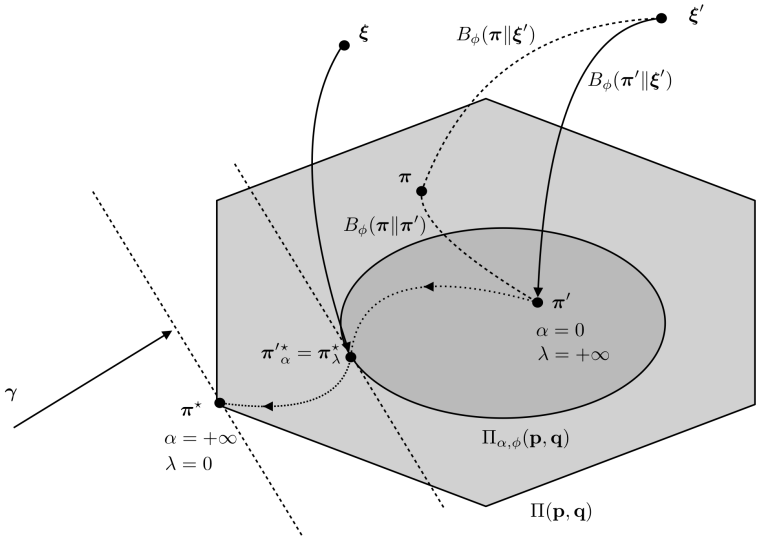

Figure 1: Geometry of regularized optimal transport.

Bregman information, by shrinking them toward the matrix $\boldsymbol{\xi}'$ or transport plan $\boldsymbol{\pi}'$ with minimal Bregman information.

We have duality between the primal and dual formulations, so that primal and dual rot mover's plans follow the same path on $\Pi(\mathbf{p},\mathbf{q})$ from no regularization ($\alpha = +\infty$, $\lambda = 0$) to full regularization ($\alpha = 0$, $\lambda = +\infty$) (Theorem 15). In the limit of no regularization, we obviously retrieve an earth mover's plan $\boldsymbol{\pi}^\star$ for the cost matrix $\boldsymbol{\gamma}$. By duality, it is also intuitive that the additional constraint for the primal formulation, seen in the equivalent forms of $\phi(\boldsymbol{\pi})$, $B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}')$ or $B_\phi(\boldsymbol{\pi}\|\boldsymbol{\pi}')$, leads to an analog penalty for the dual formulation in the same respective form.

Since $\boldsymbol{\xi}' = \mathbf{1}$, $\boldsymbol{\pi}' = \mathbf{p}\mathbf{q}^\top$, $\boldsymbol{\xi} = \exp(-\boldsymbol{\gamma}/\lambda)$, for minus the Boltzmann-Shannon entropy and Kullback-Leibler divergence, we retrieve the existing results discussed in Section 1.2 as a specific case (Cuturi, 2013; Benamou et al., 2015). In addition, we can readily generalize the estimation of contingency tables with fixed marginals to a matrix nearness problem based on other divergences than the Kullback-Leibler divergence (Dhillon and Tropp, 2007). Given a rough estimate $\boldsymbol{\xi} \in \operatorname{int}(\operatorname{dom}\phi)$, a contingency table with fixed marginals $\mathbf{p},\mathbf{q}$ can be estimated by Bregman projection of $\boldsymbol{\xi}$ onto $\Pi(\mathbf{p},\mathbf{q})$:

$$\boldsymbol{\pi}^\star = \operatorname*{argmin}_{\boldsymbol{\pi}\in\Pi(\mathbf{p},\mathbf{q})} B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi}) \ . \tag{87}$$

This simply amounts to solving a dual ROT problem with an arbitrary penalty $\lambda > 0$ and a cost matrix $\boldsymbol{\gamma} = -\lambda\nabla\phi(\boldsymbol{\xi})$.

Finally, since Bregman divergences are invariant under adding an affine term to their generator, it is straightforward to generalize ROT problems by shrinking toward an arbitrary prior matrix $\boldsymbol{\xi},\boldsymbol{\xi}' \in \operatorname{int}(\operatorname{dom}\phi)$, or transport plan $\boldsymbol{\pi}' \in \Pi(\mathbf{p},\mathbf{q})$. This is indeed equivalent to translating the regularizer by the appropriate amount $\phi(\boldsymbol{\pi}) + \langle\boldsymbol{\pi},\boldsymbol{\delta}\rangle$, so that the global minimizer is now attained at the desired point. Equivalently, this amounts to translating the cost matrix as $\boldsymbol{\gamma} + \lambda\boldsymbol{\delta}$ instead.

4. Algorithmic Derivations

In this section, we introduce algorithmic methods to solve ROT problems. We focus without lack of generality on the dual problem, which can be solved efficiently via alternate Bregman projections. The primal problem can then easily be solved for $0 < \alpha < \alpha'$ by a bisection search on $\lambda > 0$. For $\alpha = 0$, we could simply use alternate Bregman projections to project $\nabla\psi(\mathbf{0})$ instead of $\nabla\psi(-\boldsymbol{\gamma}/\lambda)$ in virtue of Lemmas 1 and 2, which actually corresponds to the special case $\boldsymbol{\gamma} = \mathbf{0}$ in our algorithms, though this is not really relevant in practice since this completely removes the linear influence of the total cost from the ROT problem. In the limit $\alpha \geq \alpha'$, a classical OT solver such as the network simplex can directly be used. We first study the underlying Bregman projections in their generic form (Section 4.1) and specifically develop the case of separable divergences (Section 4.2). We then derive the two generic schemes of ASA (Section 4.3) and NASA (Section 4.4) to solve dual ROT problems, depending on whether the domain of the smooth convex regularizer lies within the non-negative orthant or not. We also enhance both algorithms in the separable case with a sparse extension (Section 4.5), and finally discuss some practical considerations of our methods (Section 4.6). To simplify notations, we omit the penalty value λ in the index and simply write $\boldsymbol{\pi}^\star$ for the rot mover's plan.

4.1 Generic Projections

The closed convex transport polytope $\Pi(\mathbf{p},\mathbf{q})$ is the intersection of the non-negative orthant:

$$\mathcal{C}_0 = \mathbb{R}_+^{d\times d} \ , \tag{88}$$

which is a polyhedral subset, with two affine subspaces:

$$\mathcal{C}_1 = \{\boldsymbol{\pi} \in \mathbb{R}^{d\times d} \colon \boldsymbol{\pi}\mathbf{1} = \mathbf{p}\} \ , \tag{89}$$

$$\mathcal{C}_2 = \{\boldsymbol{\pi} \in \mathbb{R}^{d\times d} \colon \boldsymbol{\pi}^\top\mathbf{1} = \mathbf{q}\} \ . \tag{90}$$

The Bregman projection $\boldsymbol{\pi}^\star$ onto $\Pi(\mathbf{p},\mathbf{q})$ can then be obtained by alternate Bregman projections onto $\mathcal{C}_0,\mathcal{C}_1,\mathcal{C}_2$, where we expect that these latter projections are easier to compute.

On the one hand, the Karush-Kuhn-Tucker conditions for Bregman projection $\boldsymbol{\pi}_0^\star$ of a given matrix $\overline{\boldsymbol{\pi}} \in \operatorname{int}(\operatorname{dom}\phi)$ onto $\mathcal{C}_0$ are necessary and sufficient, and write as follows:

$$\boldsymbol{\pi}_0^\star \geq \mathbf{0} \ , \tag{91}$$

$$\nabla\phi(\boldsymbol{\pi}_0^\star) - \nabla\phi(\overline{\boldsymbol{\pi}}) \geq \mathbf{0} \ , \tag{92}$$

$$(\nabla\phi(\boldsymbol{\pi}_0^\star) - \nabla\phi(\overline{\boldsymbol{\pi}})) \odot \boldsymbol{\pi}_0^\star = \mathbf{0} \ . \tag{93}$$

While these conditions are nontrivial to solve in general, we shall see that they admit an elegant solver specific to the non-separable squared Mahalanobis distances defined in (33) and generated by the quadratic form in (34). In addition, they also greatly simplify for separable divergences, which encompass all other divergences used in this paper.

On the other hand, the Lagrangians with Lagrange multipliers $\boldsymbol{\mu}, \boldsymbol{\nu} \in \mathbb{R}^d$ for the Bregman projections $\boldsymbol{\pi}_1^\star$ and $\boldsymbol{\pi}_2^\star$ of a given matrix $\overline{\boldsymbol{\pi}} \in \operatorname{int}(\operatorname{dom}\phi)$ onto $\mathcal{C}_1$ and $\mathcal{C}_2$ respectively write as follows:

$$\mathcal{L}_1(\boldsymbol{\pi}, \boldsymbol{\mu}) = \phi(\boldsymbol{\pi}) - \langle \boldsymbol{\pi}, \nabla\phi(\overline{\boldsymbol{\pi}}) \rangle + \boldsymbol{\mu}^\top(\boldsymbol{\pi}\mathbf{1} - \mathbf{p}) \ , \tag{94}$$

$$\mathcal{L}_2(\boldsymbol{\pi}, \boldsymbol{\nu}) = \phi(\boldsymbol{\pi}) - \langle \boldsymbol{\pi}, \nabla\phi(\overline{\boldsymbol{\pi}}) \rangle + \boldsymbol{\nu}^\top(\boldsymbol{\pi}^\top\mathbf{1} - \mathbf{q}) \ . \tag{95}$$

Their gradients are given on $\operatorname{int}(\operatorname{dom}\phi)$ by:

$$\nabla\mathcal{L}_1(\boldsymbol{\pi}, \boldsymbol{\mu}) = \nabla\phi(\boldsymbol{\pi}) - \nabla\phi(\overline{\boldsymbol{\pi}}) + \boldsymbol{\mu}\mathbf{1}^\top \ , \tag{96}$$

$$\nabla\mathcal{L}_2(\boldsymbol{\pi}, \boldsymbol{\nu}) = \nabla\phi(\boldsymbol{\pi}) - \nabla\phi(\overline{\boldsymbol{\pi}}) + \mathbf{1}\boldsymbol{\nu}^\top \ , \tag{97}$$

and vanish at $\boldsymbol{\pi}_1^\star, \boldsymbol{\pi}_2^\star \in \operatorname{int}(\operatorname{dom}\phi)$ if and only if:

$$\boldsymbol{\pi}_1^\star = \nabla\psi(\nabla\phi(\overline{\boldsymbol{\pi}}) - \boldsymbol{\mu}\mathbf{1}^\top) \ , \tag{98}$$

$$\boldsymbol{\pi}_2^\star = \nabla\psi(\nabla\phi(\overline{\boldsymbol{\pi}}) - \mathbf{1}\boldsymbol{\nu}^\top) \ . \tag{99}$$

By duality, the Bregman projections onto $\mathcal{C}_1, \mathcal{C}_2$ are thus equivalent to finding the unique vectors $\boldsymbol{\mu}, \boldsymbol{\nu}$, such that the rows of $\boldsymbol{\pi}_1^\star$ sum up to $\mathbf{p}$, respectively the columns of $\boldsymbol{\pi}_2^\star$ sum up to $\mathbf{q}$:

$$\nabla\psi(\nabla\phi(\overline{\boldsymbol{\pi}}) - \boldsymbol{\mu}\mathbf{1}^\top)\mathbf{1} = \mathbf{p} \ , \tag{100}$$

$$\nabla\psi(\nabla\phi(\overline{\boldsymbol{\pi}}) - \mathbf{1}\boldsymbol{\nu}^\top)^\top\mathbf{1} = \mathbf{q} \ . \tag{101}$$

Similarly, solving for the Lagrange multipliers is an expensive problem in general, since the search space is of dimension d and we evaluate matrix functions of size $d \times d$. This is because a given entry μ_i, ν_j can actually modify any entry of the $d \times d$ matrix functions being evaluated. Again, we shall see that they can nevertheless be computed efficiently for separable divergences as well as the non-separable Mahalanobis distances.

4.2 Separable Case

Assuming that the regularizer ϕ is separable, the underlying Bregman projections can be computed more efficiently. To keep notations simple, we focus on separable divergences with same element-wise regularizer, and thus chiefly omit the indices $\phi_{ij} = \phi$. We emphasize, however, that it is straightforward to apply all our methods for separable divergences with different element-wise regularizers, which notably enables weighting a given element-wise regularizer.

In case of separability, the Karush-Kuhn-Tucker conditions for projection onto $\mathcal{C}_0$ simplify to provide a closed-form solution on primal parameters:

$$\pi_{0,ij}^\star = \max\{0, \overline{\pi}_{ij}\} \ . \tag{102}$$

Since ϕ' is increasing, this is equivalent on dual parameters to:

$$\theta_{0,ij}^\star = \max\{\phi'(0), \overline{\theta}_{ij}\} \ . \tag{103}$$

Now turning to projections onto $\mathcal{C}_1, \mathcal{C}_2$ for primal parameters $\pi_{1,ij}^\star, \pi_{2,ij}^\star$, we can divide the initial problems into d parallel subproblems in search space of dimension 1 each. This is much more efficient to solve than in the non-separable case. This can be summarized as looking for d separate Lagrange multipliers μ_i, respectively ν_j, such that:

$$\sum_{j=1}^{d} \psi'(\overline{\theta}_{ij} - \mu_i) = p_i \ , \tag{104}$$

$$\sum_{i=1}^{d} \psi'(\overline{\theta}_{ij} - \nu_j) = q_j \ . \tag{105}$$

Finding the optimal values $\mu_i, \nu_j \in \mathbb{R}$ through ψ' and the sums over rows or columns, however, is still nontrivial in general.

An analytical solution can be obtained in specific cases. Intuitively, we need to factor μ_i, ν_j out of ψ' as additive or multiplicative terms. This is related to Pexider's functional equations, which hold only for functions with a linear form $\psi'(\theta) = a\theta + b$, or exponential form $\psi'(\theta) = a\exp(b\theta)$, with $a, b \in \mathbb{R}$. This leads to regularizers with a quadratic form $\phi(\pi) = a\pi^2 + b\pi + c$, or entropic form $\phi(\pi) = a\pi\log\pi + b\pi + c$, with $a, b, c \in \mathbb{R}$. The constants a, b actually only scale and translate the cost matrix, whereas the constant c has no effect. Referring to Table 1, the quadratic case holds under assumptions (B), and thus requires Dykstra's algorithm for alternate Bregman projections with correction terms to ensure non-negativity by projection onto the polyhedral non-negative orthant. The entropic case holds under assumptions (A), using the POCS technique for alternate Bregman projection with no correction terms since the non-negativity is already ensured by the domain of the regularizer. The latter case reduces to the regularization of Cuturi (2013) and Benamou et al. (2015), so that we actually end up with the Sinkhorn-Knopp algorithm. Hence, the Euclidean norm associated to the squared Euclidean distance, and the entropic case associated to the Kullback-Leibler divergence, are reasonably the only two existing analytical schemes to find the sum constraint projections. For other ROT problems, available solvers for line search can be employed instead.

For simplicity, we assume hereafter that ψ is twice continuously differentiable with ψ'' positive and ψ' verifying the necessary and sufficient condition (40) on its whole domain. Therefore, we can use the Newton-Raphson method with guarantees of global convergence. This encompasses most of the common regularizers, and notably all regularizers used in this paper except from the Fermi-Dirac entropy, ℓ_p norms and Hellinger distance. When the condition (40) for global convergence is not met on the whole domain, it is still possible to apply the Newton-Raphson method after careful initialization, so as to restrict to a smaller interval where the condition holds. This is discussed in more detail with practical examples for the Fermi-Dirac entropy, ℓ_p norms and Hellinger distance in Section 5, where the first-order derivatives are increasing convex on half of the domain and increasing concave on the other half. When the second-order derivatives do not exist, are not continuous or vanish at some points, a similar strategy can be applied. This is again discussed for the ℓ_p norms in

Section 5, where the second-order derivative is undefined or vanishes at 0 depending on the value of the parameter. If such an initialization is not possible, then a bisection search can always be applied instead of the Newton-Raphson method.

To apply the Newton-Raphson method, we exploit the following functions:

$$f(\mu_i) = -\sum_{j=1}^{d} \psi'(\overline{\theta}_{ij} - \mu_i) \ , \tag{106}$$

$$g(\nu_j) = -\sum_{i=1}^{d} \psi'(\overline{\theta}_{ij} - \nu_j) \ , \tag{107}$$

defined respectively on the open intervals $(\hat{\theta}_i - \overline{\theta}, +\infty)$ and $(\check{\theta}_j - \overline{\theta}, +\infty)$, where $0 < \overline{\theta} \leq +\infty$ is such that $\operatorname{dom} \psi = (-\infty, \overline{\theta})$, and $\hat{\theta}_i = \max\{\overline{\theta}_{ij}\}_{1 \leq j \leq d}$, $\check{\theta}_j = \max\{\overline{\theta}_{ij}\}_{1 \leq i \leq d}$. Their continuous derivatives are given by:

$$f'(\mu_i) = \sum_{j=1}^{d} \psi''(\overline{\theta}_{ij} - \mu_i) \ , \tag{108}$$

$$g'(\nu_j) = \sum_{i=1}^{d} \psi''(\overline{\theta}_{ij} - \nu_j) \ , \tag{109}$$

and are positive, so that f, g are strictly increasing on their whole domain, and thus on any closed interval with endpoints consisting of a feasible point and a solution. By construction, f, g also verify the necessary and sufficient condition (40) for global convergence, and we know that there are unique solutions to $f(\mu_i) = -p_i$ and $g(\nu_j) = -q_j$. Hence, the Newton-Raphson updates:

$$\mu_i \leftarrow \mu_i + \frac{\sum_{j=1}^{d} \psi'(\overline{\theta}_{ij} - \mu_i) - p_i}{\sum_{j=1}^{d} \psi''(\overline{\theta}_{ij} - \mu_i)} \ , \tag{110}$$

$$\nu_j \leftarrow \nu_j + \frac{\sum_{i=1}^{d} \psi'(\overline{\theta}_{ij} - \nu_j) - q_j}{\sum_{i=1}^{d} \psi''(\overline{\theta}_{ij} - \nu_j)} \ , \tag{111}$$

converge to the optimal solutions with a quadratic rate for any feasible starting points. By construction, we also know that initialization can be done with $\mu_i \leftarrow 0$, $\nu_j \leftarrow 0$. To avoid storing the intermediate Lagrange multipliers, the updates can then directly be written on dual parameters:

$$\theta^\star_{1,ij} \leftarrow \theta^\star_{1,ij} - \frac{\sum_{j=1}^{d} \psi'(\theta^\star_{1,ij}) - p_i}{\sum_{j=1}^{d} \psi''(\theta^\star_{1,ij})} \ , \tag{112}$$

$$\theta^\star_{2,ij} \leftarrow \theta^\star_{2,ij} - \frac{\sum_{i=1}^{d} \psi'(\theta^\star_{2,ij}) - q_j}{\sum_{i=1}^{d} \psi''(\theta^\star_{2,ij})} \ , \tag{113}$$

after initialization by $\theta^\star_{1,ij} \leftarrow \overline{\theta}_{ij}$, $\theta^\star_{2,ij} \leftarrow \overline{\theta}_{ij}$.

Algorithm 1 Alternate scaling algorithm.

$\boldsymbol{\theta}^\star \leftarrow -\boldsymbol{\gamma}/\lambda$
repeat
  $\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \boldsymbol{\mu}\mathbf{1}^\top$, where $\boldsymbol{\mu}$ uniquely solves $\nabla\psi(\boldsymbol{\theta}^\star - \boldsymbol{\mu}\mathbf{1}^\top)\mathbf{1} = \mathbf{p}$
  $\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \mathbf{1}\boldsymbol{\nu}^\top$, where $\boldsymbol{\nu}$ uniquely solves $\nabla\psi(\boldsymbol{\theta}^\star - \mathbf{1}\boldsymbol{\nu}^\top)^\top\mathbf{1} = \mathbf{q}$
until convergence
$\boldsymbol{\pi}^\star \leftarrow \nabla\psi(\boldsymbol{\theta}^\star)$

4.3 Alternate Scaling Algorithm

Under assumptions (A), we can drop the non-negative constraint since it is already ensured by $\operatorname{dom}\phi \subseteq \mathbb{R}_+^{d \times d}$ (Table 1). The POCS technique in its basic form (38) then states that the projection of $\boldsymbol{\xi}$ onto $\Pi(\mathbf{p}, \mathbf{q})$ can be obtained by alternate Bregman projections onto the affine subspaces $\mathcal{C}_1$ and $\mathcal{C}_2$ with linear convergence. Clearly, the underlying control mapping takes each output value an infinite number of times. Since we have just two sets, the only possible alternative in the control mapping is to swap the order of projections starting from $\mathcal{C}_2$ instead of $\mathcal{C}_1$, which actually amounts to swapping the input distributions $\mathbf{p}, \mathbf{q}$ and transposing the cost matrix $\boldsymbol{\gamma}$, to obtain the transposed of the rot mover's plan. We thus focus on the first choice without lack of generality.

Starting from $\boldsymbol{\xi}$ and writing the successive vectors $\boldsymbol{\mu}^{(k)}, \boldsymbol{\nu}^{(k)}$ along iterations, we have the following sequence:

$$\nabla\psi(-\boldsymbol{\gamma}/\lambda) \rightarrow \nabla\psi\left(-\boldsymbol{\gamma}/\lambda - \boldsymbol{\mu}^{(1)}\mathbf{1}^\top\right) \tag{114}$$

$$\rightarrow \nabla\psi\left(-\boldsymbol{\gamma}/\lambda - \boldsymbol{\mu}^{(1)}\mathbf{1}^\top - \mathbf{1}\boldsymbol{\nu}^{(1)\top}\right) \tag{115}$$

$$\rightarrow \dots \tag{116}$$

$$\rightarrow \nabla\psi\left(-\boldsymbol{\gamma}/\lambda - \boldsymbol{\mu}^{(1)}\mathbf{1}^\top - \mathbf{1}\boldsymbol{\nu}^{(1)\top} - \dots - \boldsymbol{\mu}^{(k)}\mathbf{1}^\top\right) \tag{117}$$

$$\rightarrow \nabla\psi\left(-\boldsymbol{\gamma}/\lambda - \boldsymbol{\mu}^{(1)}\mathbf{1}^\top - \mathbf{1}\boldsymbol{\nu}^{(1)\top} - \dots - \boldsymbol{\mu}^{(k)}\mathbf{1}^\top - \mathbf{1}\boldsymbol{\nu}^{(k)\top}\right) \tag{118}$$

$$\rightarrow \dots \tag{119}$$

$$\rightarrow \boldsymbol{\pi}^\star \ . \tag{120}$$

In other terms, we obtain the rot mover's plan $\boldsymbol{\pi}^\star$ by scaling iteratively the rows and columns of the successive estimates through $\nabla\psi$. An efficient algorithm, called ASA, is to store a unique $d \times d$ matrix in dual parameter space and update it by alternating the projections in primal parameter space (Algorithm 1). The updates have a complexity in $O(d^2)$ once the vectors $\boldsymbol{\mu}, \boldsymbol{\nu}$ are obtained.

In the separable case, the projections can be obtained by iterating the respective Newton-Raphson update steps, which can be written compactly with matrix and vector operations (Algorithm 2). The complexity for the updates are now clearly in $O(d^2)$. In more detail, each update step features one vector row or column replication, one vector element-wise division, one vector subtraction, one matrix subtraction, two matrix row or column sums, and two element-wise matrix function evaluations. Because of separability, we can expect

Algorithm 2 Alternate scaling algorithm in the separable case.

$\boldsymbol{\theta}^\star \leftarrow -\boldsymbol{\gamma}/\lambda$
repeat
  repeat
    $\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \frac{\psi'(\boldsymbol{\theta}^\star)\mathbf{1} - \mathbf{p}}{\psi''(\boldsymbol{\theta}^\star)\mathbf{1}}\mathbf{1}^\top$
  until convergence
  repeat
    $\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \mathbf{1}\frac{\mathbf{1}^\top\psi'(\boldsymbol{\theta}^\star) - \mathbf{q}^\top}{\mathbf{1}^\top\psi''(\boldsymbol{\theta}^\star)}$
  until convergence
until convergence
$\boldsymbol{\pi}^\star \leftarrow \psi'(\boldsymbol{\theta}^\star)$

the required number of iterations for convergence in the different loops to be independent of the data dimension, and thus expect a quadratic empirical complexity as well.

4.4 Non-negative Alternate Scaling Algorithm

Under assumptions (B), we must now include the non-negative constraint since $\operatorname{dom}\phi \nsubseteq \mathbb{R}_+^{d\times d}$ (Table 1). We suggest to ensure non-negativity of each update, and thus follow a cycle of projections onto $\mathcal{C}_0, \mathcal{C}_1, \mathcal{C}_0, \mathcal{C}_2$. The underlying control mapping is a fortiori essentially cyclic. For practical reasons, we also ensure non-negativity of the output solution with a final projection onto $\mathcal{C}_0$. Again, swapping the order of projections onto $\mathcal{C}_1, \mathcal{C}_2$ is equivalent to swapping the input distributions $\mathbf{p}, \mathbf{q}$ and transposing the cost matrix $\boldsymbol{\gamma}$ to obtain the transposed of the rot mover's plan. Other control mappings could also be exploited, for example by ensuring non-negativity every two or more sum constraint projections. We do not discuss such variants here and focus on the above-mentioned sequence. The non-negative orthant being polyhedral but not affine, we also need to incorporate correction terms $\boldsymbol{\vartheta}, \boldsymbol{\varrho}, \boldsymbol{\varsigma}$ for all three projections. In more detail, the projections are computed after correction so that we do not directly project the obtained updates $\boldsymbol{\theta}^\star$ but the corrected updates $\overline{\boldsymbol{\theta}} = \boldsymbol{\theta}^\star + \boldsymbol{\vartheta}$, $\overline{\boldsymbol{\theta}} = \boldsymbol{\theta}^\star + \boldsymbol{\varrho}$, and $\overline{\boldsymbol{\theta}} = \boldsymbol{\theta}^\star + \boldsymbol{\varsigma}$ for the respective subsets. The correction terms are also updated as the difference $\overline{\boldsymbol{\theta}} - \boldsymbol{\theta}^\star$ between the projected point and its projection. Dykstra's algorithm (36) for Bregman divergences with corrections (37) then guarantees that the projection of $\boldsymbol{\xi}$ onto $\Pi(\mathbf{p}, \mathbf{q})$ is obtained with linear convergence.

A general algorithm, called NASA, is to store $d \times d$ matrices for projected points, projections and correction terms in dual parameter space, update them accordingly and finally go back to primal parameter space (Algorithm 3). The updates have a complexity in $O(d^2)$ once the Karush-Kuhn-Tucker conditions are solved or Lagrange multipliers $\boldsymbol{\mu}, \boldsymbol{\nu}$ are obtained.

In the separable case, the non-negativity constraint can be obtained analytically and the sequence of updates greatly simplifies. Starting from $\boldsymbol{\xi}$ and writing the successive vectors $\boldsymbol{\mu}^{(k)}, \boldsymbol{\nu}^{(k)}$ along iterations, we have:

$$
\begin{aligned}
\psi'(-\boldsymbol{\gamma}/\lambda) &\to \psi'\big(\max\{\phi'(\mathbf{0}), -\boldsymbol{\gamma}/\lambda\}\big) \\
&\to \psi'\Big(\max\{\phi'(\mathbf{0}), -\boldsymbol{\gamma}/\lambda\} - \boldsymbol{\mu}^{(1)}\mathbf{1}^\top\Big)
\end{aligned}
$$

Algorithm 3 Non-negative alternate scaling algorithm.

$\boldsymbol{\theta}^\star \leftarrow -\boldsymbol{\gamma}/\lambda$
$\boldsymbol{\vartheta} \leftarrow \mathbf{0}$
$\boldsymbol{\varrho} \leftarrow \mathbf{0}$
$\boldsymbol{\varsigma} \leftarrow \mathbf{0}$
$\overline{\boldsymbol{\theta}} \leftarrow \boldsymbol{\theta}^\star + \boldsymbol{\vartheta}$
$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}$, where $\boldsymbol{\theta}$ uniquely solves $\nabla\psi(\boldsymbol{\theta}) \geq \mathbf{0}$, $\boldsymbol{\theta} \geq \overline{\boldsymbol{\theta}}$, $(\boldsymbol{\theta} - \overline{\boldsymbol{\theta}}) \odot \nabla\psi(\boldsymbol{\theta}) = \mathbf{0}$
$\boldsymbol{\vartheta} \leftarrow \overline{\boldsymbol{\theta}} - \boldsymbol{\theta}^\star$
repeat
  $\overline{\boldsymbol{\theta}} \leftarrow \boldsymbol{\theta}^\star + \boldsymbol{\varrho}$
  $\boldsymbol{\theta}^\star \leftarrow \overline{\boldsymbol{\theta}} - \boldsymbol{\mu}\mathbf{1}^\top$, where $\boldsymbol{\mu}$ uniquely solves $\nabla\psi(\overline{\boldsymbol{\theta}} - \boldsymbol{\mu}\mathbf{1}^\top)\mathbf{1} = \mathbf{p}$
  $\boldsymbol{\varrho} \leftarrow \overline{\boldsymbol{\theta}} - \boldsymbol{\theta}^\star$
  $\overline{\boldsymbol{\theta}} \leftarrow \boldsymbol{\theta}^\star + \boldsymbol{\vartheta}$
  $\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}$, where $\boldsymbol{\theta}$ uniquely solves $\nabla\psi(\boldsymbol{\theta}) \geq \mathbf{0}$, $\boldsymbol{\theta} \geq \overline{\boldsymbol{\theta}}$, $(\boldsymbol{\theta} - \overline{\boldsymbol{\theta}}) \odot \nabla\psi(\boldsymbol{\theta}) = \mathbf{0}$

$$

An efficient algorithm then exploits the differences $\boldsymbol{\tau}^{(k)} = \boldsymbol{\mu}^{(k)} - \boldsymbol{\mu}^{(k-1)}$ and $\boldsymbol{\sigma}^{(k)} = \boldsymbol{\nu}^{(k)} - \boldsymbol{\nu}^{(k-1)}$ to scale the rows and columns (Algorithm 4). We store $d \times d$ matrices as well as difference vectors instead of correction matrices. The algorithm can then be interpreted as producing interleaved updates between the projections according to the max operator and according to the respective scalings. The updates in NASA now clearly have a complexity in $O(d^2)$ when using the Newton-Raphson method for scaling, with similar matrix and vector operations to ASA in the separable case, and an expected empirical complexity that is quadratic.

4.5 Sparse Extension

In the separable case, it is possible to develop a sparse extension of both our methods ASA and NASA. Storing and updating full $d \times d$ matrices becomes expensive with the data dimension. Instead, we allow for infinite entries in the cost matrix $\boldsymbol{\gamma}$, meaning that the transport of mass between certain bins is proscribed. As a result, the corresponding entries of $\boldsymbol{\pi}^\star$ must be null. Eventually, we can drop all these entries so that we just need to store and update the remaining ones. The RMD via the Frobenius inner product $\langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma} \rangle$ is then computed without accounting for discarded entries, or equivalently by setting indefinite element-wise products $0 \times \infty = 0$ by convention, so it naturally costs nothing to move no mass on a path that is forbidden. This leads to an expected complexity in $O(r)$, where r is

the number of finite entries in $\boldsymbol{\gamma}$. Typically, r can be chosen in the order of magnitude of d, so as to obtain a linear instead of quadratic empirical complexity.

In practice, both ASA and NASA are compatible with this strategy. We always have $\lim_{\theta \to -\infty} \psi'(\theta) = 0$ under assumptions (A) for ASA. Under assumptions (B) for NASA, this limit might be finite or infinite but is necessarily negative, so also leads to 0 after enforcing non-negativity by projection onto the non-negative orthant. As a result, the obtained sequence of projections preserves the desired zeros in both algorithms, and an infinite element-wise cost does lead to no mass transport at all between the corresponding bins. In theory, we can understand this extension in light of the dual formulation seen as a Bregman projection in (67). Under assumptions (B), we always have $0 \in \operatorname{int}(\operatorname{dom}\phi)$ and thus $B_\phi(0\|0) = 0$. Hence, Dykstra's algorithm is readily applicable in the sparse version. Under assumptions (A), however, we have $0 \notin \operatorname{int}(\operatorname{dom}\phi)$, and even sometimes $0 \notin \operatorname{dom}\phi$ as for the Itakura-Saito divergence. We can nonetheless extend the domain of the element-wise divergence at the origin by continuity on the diagonal, that is, by setting it null as $B_\phi(0\|0) = 0$. This is akin to considering absolutely continuous measures, also known as dominated measures, and Radon-Nikodym derivatives to generalize the definition of Bregman divergences. Kurras (2015) then showed that the POCS method still holds with this convention by introducing a notion of locally affine spaces.

With such a sparse extension, however, we must take care that a sparse solution does exist, meaning that there is a transport plan in the transport polytope that has the desired zeros. For example, if all entries of $\boldsymbol{\gamma}$ are infinite, then there are obviously no possible sparse solutions since we enforce all entries of the plan to be null. A necessary condition for the existence of a sparse solution is that for any entry q_j, all entries p_k from which we are allowed to transport mass must provide enough total mass to fill q_j completely. Similarly, for any entry p_i, all entries q_k to which we are allowed to transport mass must require enough total mass to empty p_i completely. Unfortunately, sufficient conditions are not so intuitive. Idel (2016, Theorem 4.1) studied such problems thoroughly and elucidated several necessary and sufficient conditions for sparse solutions to exist, but these conditions are nontrivial to use from in practice. Kurras (2015) advocates trying first to compute a solution with the desired sparsity, and if no solution can be found, then gradually reduce sparsity until a solution is found. This might still speed up computation drastically because of the linear instead of quadratic complexity. Lastly, we remark that it is not evident to propose a sparse extension for the non-separable case in general, since a given entry of $\boldsymbol{\gamma}$ might influence all entries of $\boldsymbol{\pi}^\star$.

4.6 Practical Considerations

As noticed by Cuturi (2013) and Benamou et al. (2015), the Sinkhorn-Knopp algorithm might fail to converge because of numerical instability when the penalty λ gets small. In particular, unless taking special care of numerical stabilization (Schmitzer, 2016b), a direct limitation is the machine precision under which some entries of $\exp(-\boldsymbol{\gamma}/\lambda)$ are represented as zeros in memory. Such issues occur similarly for other regularizations, notably via the representation $\nabla\psi(-\boldsymbol{\gamma}/\lambda)$ of the unconstrained solution to project. Therefore, the proposed methods are actually competitive in a range where the penalty λ is not too small, and for which the rot mover's plan $\boldsymbol{\pi}^\star$ exhibits a significant amount of smoothing. Hence, we do

not target the same problems as traditional schemes such as interior point methods or the network simplex.

In addition, the different Bregman projections in our algorithms are most of the time approximate up to a given tolerance depending on the termination criterion used for convergence. Exceptions occur for the sum constraints with the Euclidean distance or Kullback-Leibler divergence, as well as the non-negativity constraints in the separable case, which are obtained analytically. A natural question to raise is then whether our algorithms still converge when the projections are approximate only. However, this is relatively hard to answer in theory. We did not observe in practice any problem of convergence when using sufficiently good approximations. Furthermore, first approximations can be quite rough without affecting convergence as long as final approximations are good enough. Sometimes, even alternating a single or two steps of the Newton-Raphson method throughout the main iterations the algorithm still works, though this is not systematic. Thus, we advocate for safety to use a tight tolerance for the auxiliary projections.

We also observed numerical instability of the Newton-Raphson updates for separable divergences under assumptions (A). This is due to the denominator being based on ψ'' with limit $\lim_{\theta \to -\infty} \psi''(\theta) = 0$, that is, for entries π close to zero. It is possible, however, to make the updates of μ_i, ν_j much more stable in practice by using the max truncation operator, despite theoretical guarantees of convergence without it. Specifically, we know that the entries $\pi^\star_{1,ij}$ must lie between 0 and p_i, and $\pi^\star_{2,ij}$ between 0 and q_j. Hence, we can lower bound μ_i and ν_j by $\hat{\theta}_i - \phi'(p_i)$ and $\hat{\theta}_j - \phi'(q_j)$, respectively. Interestingly, this also speeds up the convergence of the updates significantly when the initialization by 0 is far from the actual solution.

A possible termination criterion for the main and auxiliary iterations is to compute the marginal difference between the updated matrix and $\mathbf{p}, \mathbf{q}$. In the auxiliary iterations for the two scaling projections, we compare the sums of rows or columns to $\mathbf{p}$ or $\mathbf{q}$ respectively, and in the main iterations of the algorithm, we compare both marginals simultaneously. Typically, we can use the ℓ_p (quasi-)norm with $0 < p \leq +\infty$ to assess the marginal difference, and the auxiliary tolerance should be at least the main one for sufficient precision of the approximations. Two alternative quantities in absolute or relative scales can also be used for termination, either the variation with ℓ_p (quasi-)norm in the updated matrix or in the updated distance. Here the auxiliary tolerance should be at least the square of the main one. This seems reasonable for $\boldsymbol{\pi}^\star$ given the quadratic rate of convergence for the Newton-Raphson method versus the linear one for alternate Bregman projections, as well as for $\langle \boldsymbol{\pi}^\star, \boldsymbol{\gamma} \rangle$ under the Cauchy-Schwarz inequality. In all cases, convergence can be checked either after each iteration or after a given number of iterations to reduce the underlying cost of computing the termination criterion. We can also fix a maximum number of main and auxiliary iterations to limit the overall running time.

Regarding implementation, the matrix and vector operations used for ASA and NASA in the separable case are well-suited for fast calculation on a GPU and for processing of multiple input distributions in parallel. By working directly in the primal parameter space, the Sinkhorn-Knopp algorithm is also readily suited for dealing with sparse plans, based on existing libraries. In more general ROT problems, however, a specific library should be written for the sparse extension because null entries in the transport plan are not represented by null entries in the dual parameter space, so that tailored data structures and operations

for such matrices need to be coded. Therefore, we only implemented and will focus in our experiments on the non-sparse version of our methods.

Finally, although we implicitly assumed throughout that the entries of $\mathbf{p}$ and $\mathbf{q}$ are strictly comprised between 0 and 1 for theoretical issues, it is often possible in practice to deal explicitly with null or unit entries in the input distributions. Intuitively, no mass can be moved from or to a null entry, so the transport plans have null rows and columns for the corresponding null entries of $\mathbf{p}$ and $\mathbf{q}$, respectively. In the separable case, we can thus simply remove these entries, solve the reduced ROT problem, and reinsert the corresponding null entries in the rot mover's plan $\boldsymbol{\pi}^\star$. The same reasoning as for the sparse extension can be made to show that our two algorithms still hold with this strategy from a theoretical standpoint. In the non-separable case, however, this is not as straightforward again because the influences of the different entries of $\boldsymbol{\pi}^\star$ are interleaved through the regularizer ϕ. Nonetheless, as long as we have $[0,1)^{d \times d} \subset \operatorname{int}(\operatorname{dom} \phi)$ under assumptions (B), then we have $\Pi(\mathbf{p}, \mathbf{q}) \subset \operatorname{int}(\operatorname{dom} \phi)$ and we can apply NASA without modification. This is notably the case for the Mahalanobis distances whose domain is $\mathbb{R}^{d \times d}$. For a non-separable regularizer under assumptions (A), it is not easy to account for null entries because the constraint qualification $\Pi(\mathbf{p}, \mathbf{q}) \cap \operatorname{int}(\operatorname{dom} \phi) \neq \emptyset$ never holds due to mandatory null entries in the transport plans. Nevertheless, common regularizers under assumptions (A), including the ones used in this paper, are separable in general. Lastly, it is direct to cope with unit entries in $\mathbf{p}$ or $\mathbf{q}$ in all cases, since the transport polytope then reduces to a singleton, so that there is a unique transport plan $\mathbf{p}\mathbf{q}^\top$ which is the rot mover's plan.

5. Classical Regularizers and Divergences

In this section, we discuss the specificities of the ASA (Algorithm 1) and NASA (Algorithm 3) methods to solve ROT problems for classical regularizers and associated divergences. We start with several separable regularizers under assumptions (A), based on the Boltzmann-Shannon entropy related to the Kullback-Leibler divergence (`BSKL`, Section 5.1), the Burg entropy related to the Itakura-Saito divergence (`BIS`, Section 5.2), and the Fermi-Dirac entropy related to a logistic loss function (`FDLOG`, Section 5.3), as well as the parametric families of β-potentials related to the β-divergences (`BETA`, Section 5.4). We then discuss the separable ℓ_p quasi-norms (`LPQN`, Section 5.5), which require a slight adaptation of assumptions (A). We also consider separable regularizers under assumptions (B) related to ℓ_p norms (`LPN`, Section 5.6), as well as the Euclidean norm related to the Euclidean distance (`EUC`, Section 5.7) and the Hellinger distance (`HELL`, Section 5.8). Finally, we study a non-separable regularizer under assumptions (B) via quadratic forms in relation to Mahalanobis distances (Section 5.9). We plot all separable regularizers in Figure 2. All regularizers and their corresponding divergences are also summed up in Table 2. Lastly, we provide in Table 3 the related terms based on derivatives that are needed to instantiate the separable versions of ASA (Algorithm 2) or NASA (Algorithm 4) accordingly.

5.1 Boltzmann-Shannon Entropy and Kullback-Leibler Divergence

Assumptions (A) hold for minus the Boltzmann-Shannon entropy $\pi \log \pi - \pi + 1$ associated to the Kullback-Leibler divergence. Hence, the ROT problem can be solved with the ASA scheme. In addition, the updates in the POCS technique can be written analytically, leading

$\phi(\pi)$ / $\phi(\boldsymbol{\pi})$	$B_\phi(\pi\|\xi)$ / $B_\phi(\boldsymbol{\pi}\|\boldsymbol{\xi})$	$\operatorname{dom}\phi$	$\operatorname{dom}\psi$
Boltzmann-Shannon entropy $\pi\log\pi-\pi+1$	*Kullback-Leibler divergence* $\pi\log\frac{\pi}{\xi}-\pi+\xi$	$\mathbb{R}_+$	$\mathbb{R}$

ℓ_p quasi-norms $(0<p<1)$ $-\pi^p$	$-p\pi^{p-1}$	$p^{-\frac{1}{p-1}}(-\theta)^{\frac{1}{p-1}}$	$-\frac{p^{-\frac{1}{p-1}}}{p-1}(-\theta)^{\frac{1}{p-1}-1}$
ℓ_p norms $(1<p<+\infty)$ $\lvert\pi\rvert^p$	$p\ \operatorname{sgn}(\pi)\lvert\pi\rvert^{p-1}$	$p^{-\frac{1}{p-1}}\ \operatorname{sgn}(\theta)\lvert\theta\rvert^{\frac{1}{p-1}}$	$\frac{p^{-\frac{1}{p-1}}}{p-1}\lvert\theta\rvert^{\frac{1}{p-1}-1}$
Euclidean norm $\frac{1}{2}\pi^2$	π	θ	1
Hellinger distance $-(1-\pi^2)^{\frac{1}{2}}$	$\pi(1-\pi^2)^{-\frac{1}{2}}$	$\theta(1+\theta^2)^{-\frac{1}{2}}$	$(1+\theta^2)^{-\frac{3}{2}}$

Table 3: Separable regularizers and related terms based on derivatives.

This can be optimized by remarking that the iterates $\boldsymbol{\pi}^{\star(k)}$ after each couple of projections verify:

$$\boldsymbol{\pi}^{\star(k)} = \operatorname{diag}(\mathbf{u}^{(k)})\boldsymbol{\xi}\operatorname{diag}(\mathbf{v}^{(k)}) \ , \tag{123}$$

where $\boldsymbol{\xi}=\exp(-\boldsymbol{\gamma}/\lambda)$, and vectors $\mathbf{u}^{(k)},\mathbf{v}^{(k)}$ satisfy the following recursion:

$$\mathbf{u}^{(k)} = \frac{\mathbf{p}}{\boldsymbol{\xi}\mathbf{v}^{(k-1)}} \ , \tag{124}$$

$$\mathbf{v}^{(k)} = \frac{\mathbf{q}}{\boldsymbol{\xi}^\top\mathbf{u}^{(k)}} \ , \tag{125}$$

with convention $\mathbf{v}^{(0)}=\mathbf{1}$. This allows a fast implementation by performing only matrix-vector multiplications using a fixed matrix $\boldsymbol{\xi}=\exp(-\boldsymbol{\gamma}/\lambda)$. We can further save one element-wise vector multiplication per update:

$$\mathbf{u} \leftarrow \frac{\mathbf{1}}{\operatorname{diag}\left(\frac{\mathbf{1}}{\mathbf{p}}\right)\boldsymbol{\xi}\,\mathbf{v}} \ , \tag{126}$$

$$\mathbf{v} \leftarrow \frac{\mathbf{1}}{\operatorname{diag}\left(\frac{\mathbf{1}}{\mathbf{q}}\right)\boldsymbol{\xi}^\top\mathbf{u}} \ , \tag{127}$$

where the matrices $\operatorname{diag}\left(\frac{\mathbf{1}}{\mathbf{p}}\right)\boldsymbol{\xi}$ and $\operatorname{diag}\left(\frac{\mathbf{1}}{\mathbf{q}}\right)\boldsymbol{\xi}^\top$ are precomputed and stored.

5.2 Burg Entropy and Itakura-Saito Divergence

Assumptions (A) also hold for minus the Burg entropy $\pi - \log\pi - 1$ associated to the Itakura-Saito divergence, so the ROT problem can be solved with the ASA scheme. Eventually, the Newton-Raphson steps to update the alternate projections in POCS technique can be written as follows:

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \frac{(1-\boldsymbol{\theta}^\star)^{-1}\,\mathbf{1} - \mathbf{p}}{(1-\boldsymbol{\theta}^\star)^{-2}\,\mathbf{1}}\,\mathbf{1}^\top \ , \tag{128}$$

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \mathbf{1}\,\frac{\mathbf{1}^\top(1-\boldsymbol{\theta}^\star)^{-1} - \mathbf{q}^\top}{\mathbf{1}^\top(1-\boldsymbol{\theta}^\star)^{-2}} \ . \tag{129}$$

Each step can be optimized by computing first an element-wise matrix inverse $(1-\boldsymbol{\theta}^\star)^{-1}$ for the numerator, and then performing an element-wise matrix multiplication of this matrix by itself to obtain a matrix for the denominator instead of applying an additional element-wise matrix power. Since ψ' is convex and strictly increasing with ψ'' positive everywhere, the convergence of the updates is guaranteed.

5.3 Fermi-Dirac Entropy and Logistic Loss Function

Assumptions (A) again hold for minus the Fermi-Dirac entropy $\pi\log\pi + (1-\pi)\log(1-\pi)$, also known as bit entropy, associated to a logistic loss function. The ROT problem can thus be solved with the ASA scheme, and the Newton-Raphson steps to update the alternate projections in the POCS technique can be written as follows:

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \frac{\frac{\exp\boldsymbol{\theta}^\star}{1+\exp\boldsymbol{\theta}^\star}\,\mathbf{1} - \mathbf{p}}{\frac{\exp\boldsymbol{\theta}^\star}{(1+\exp\boldsymbol{\theta}^\star)^2}\,\mathbf{1}}\,\mathbf{1}^\top \ , \tag{130}$$

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \mathbf{1}\,\frac{\frac{\exp\boldsymbol{\theta}^\star}{1+\exp\boldsymbol{\theta}^\star} - \mathbf{q}^\top}{\mathbf{1}^\top\frac{\exp\boldsymbol{\theta}^\star}{(1+\exp\boldsymbol{\theta}^\star)^2}} \ . \tag{131}$$

Each step can be optimized by storing first the element-wise matrix exponential $\exp\boldsymbol{\theta}^\star$, then applying an element-wise matrix division by the temporary matrix $1+\exp\boldsymbol{\theta}^\star$ to obtain a matrix for the numerator, and lastly performing an element-wise matrix division of these two matrices to obtain a matrix for the denominator and thus save an additional element-wise matrix power as well as several element-wise matrix exponentials. However, even if ψ' is strictly increasing with ψ'' positive everywhere, ψ' is neither convex nor concave and does not verify the necessary and sufficient condition (40) for global convergence of the Newton-Raphson method.

Nevertheless, ψ' is convex on $\mathbb{R}_-$ and concave on $\mathbb{R}_+$. It thus divides for a given $1 \leq i \leq d$, respectively $1 \leq j \leq d$, the real line into at most $d+1$ intervals $-\infty < \hat{\theta}_i^{(1)} \leq \hat{\theta}_i^{(2)} \leq \cdots \leq \hat{\theta}_i^{(d-1)} \leq \hat{\theta}_i^{(d)} < +\infty$, respectively $-\infty < \check{\theta}_j^{(1)} \leq \check{\theta}_j^{(2)} \leq \cdots \leq \check{\theta}_j^{(d-1)} \leq \check{\theta}_j^{(d)} < +\infty$, with the values $(\hat{\theta}_i^{(k)})_{1\leq k\leq d}$ from row i of $\overline{\boldsymbol{\theta}}$, respectively $(\check{\theta}_j^{(k)})_{1\leq k\leq d}$ from column j of $\overline{\boldsymbol{\theta}}$, sorted

in increasing order. On each of these intervals, the necessary and sufficient condition (40) is verified since we can decompose $f(\mu_i)$, respectively $g(\nu_j)$, as the sum of an increasing convex and an increasing concave function. Hence, we have global convergence on the interval that contains the solution. It is further possible to restrict the search to the two last intervals only. Indeed, we have $\sum_{j=1}^d \psi'(\overline{\theta}_{ij} - \hat{\theta}_i^{(d-1)}) \geq \psi'(\hat{\theta}_i^{(d-1)} - \hat{\theta}_i^{(d-1)}) + \psi'(\hat{\theta}_i^{(d)} - \hat{\theta}_i^{(d-1)}) \geq 2\psi'(0) = 1$, so that $\hat{\theta}_i^{(d-1)} < \mu_i < +\infty$. Similarly, we have $\sum_{i=1}^d \psi'(\overline{\theta}_{ij} - \check{\theta}_j^{(d-1)}) \geq \psi'(\check{\theta}_j^{(d-1)} - \check{\theta}_j^{(d-1)}) + \psi'(\check{\theta}_j^{(d)} - \check{\theta}_j^{(d-1)}) \geq 2\psi'(0) = 1$, so that $\check{\theta}_j^{(d-1)} < \nu_j < +\infty$. As a result, it suffices to initialize μ_i with $\hat{\theta}_i = \hat{\theta}_i^{(d)} = \max\{\overline{\theta}_{ij}\}_{1\leq j\leq d}$, respectively ν_j with $\check{\theta}_j = \check{\theta}_j^{(d)} = \max\{\overline{\theta}_{ij}\}_{1\leq i\leq d}$, to guarantee convergence of the updates.

5.4 β-potentials and β-divergences

Assumptions (A) hold for the β-potentials $(\pi^\beta - \beta\pi + \beta - 1)/(\beta(\beta-1))$ with $0 < \beta < 1$, associated to the so-called β-divergences. Hence, the ROT problem can be solved with the ASA scheme, and the Newton-Raphson steps to update the alternate projections in the POCS technique can be written as follows:

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \frac{((\beta-1)\boldsymbol{\theta}^\star + 1)^{\frac{1}{\beta-1}}\,\mathbf{1} - \mathbf{p}}{((\beta-1)\boldsymbol{\theta}^\star + 1)^{\frac{1}{\beta-1}-1}\,\mathbf{1}}\,\mathbf{1}^\top \ , \tag{132}$$

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star - \mathbf{1}\,\frac{\mathbf{1}^\top((\beta-1)\boldsymbol{\theta}^\star + 1)^{\frac{1}{\beta-1}} - \mathbf{q}^\top}{\mathbf{1}^\top((\beta-1)\boldsymbol{\theta}^\star + 1)^{\frac{1}{\beta-1}-1}} \ . \tag{133}$$

Each step can be optimized by computing first the temporary matrix $(\beta-1)\boldsymbol{\theta}^\star + 1$, then applying an element-wise matrix power of $1/(\beta-1) - 1$ to this temporary matrix to obtain a matrix for the denominator, and lastly performing an element-wise matrix multiplication of these two matrices to obtain a matrix for the numerator and thus save one element-wise matrix power. Since ψ' is convex and strictly increasing with ψ'' positive, the convergence of the updates is guaranteed.

Interestingly, the regularizer tends to minus the Burg and Boltzmann-Shannon entropies in the limit $\beta = 0$ and $\beta = 1$, respectively. Therefore, the β-divergences interpolate between the Itakura-Saito and Kullback-Leibler divergences. We finally remark that the regularizer can also be defined for other values of the parameter β using the same formula, but do not verify assumptions (A) for these values.

5.5 ℓ_p quasi-norms

Considering regularizers $-\pi^p$ with $0 < p < 1$, all assumptions (A) are verified except from (A5) since $\mathbb{R}_-^{d\times d} \not\subset \operatorname{dom}\psi = \mathbb{R}_{--}^{d\times d}$. Hence, our primal formulation does not hold here because $\mathbf{0} \notin \operatorname{dom}\nabla\psi$. However, it is straightforward to check that our dual formulation for ROT problems with the ASA scheme can still be applied as long as the cost matrix $\boldsymbol{\gamma}$ does not have null entries so that $-\boldsymbol{\gamma}/\lambda \in \operatorname{dom}\nabla\psi$. Eventually, the Newton-Raphson steps to update the alternate projections in the POCS technique can be written as follows:

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star + \frac{(-\boldsymbol{\theta}^\star)^{\frac{1}{p-1}}\,\mathbf{1} - p^{\frac{1}{p-1}}\,\mathbf{p}}{\frac{1}{p-1}(-\boldsymbol{\theta}^\star)^{\frac{1}{p-1}-1}\,\mathbf{1}}\,\mathbf{1}^\top \ , \tag{134}$$

$$\boldsymbol{\theta}^\star \leftarrow \boldsymbol{\theta}^\star + \mathbf{1}\,\frac{\mathbf{1}^\top\,(-\boldsymbol{\theta}^\star)^{\frac{1}{p-1}} - p^{\frac{1}{p-1}}\,\mathbf{q}^\top}{\frac{1}{p-1}\,\mathbf{1}^\top\,(-\boldsymbol{\theta}^\star)^{\frac{1}{p-1}-1}} \enspace . \tag{135}$$

Each step can be optimized by computing first the temporary matrix $-\boldsymbol{\theta}^\star$, then applying an element-wise matrix power of $1/(p-1)-1$ to obtain a matrix for the denominator, and lastly performing an element-wise matrix multiplication of these two matrices to obtain a matrix for the numerator and thus save one element-wise matrix power. Since ψ' is convex and strictly increasing with ψ'' positive everywhere, the convergence of the updates is guaranteed.

5.6 ℓ_p norms

Assumptions (B) hold for the ℓ_p norms $|\pi|^p$ with $1 < p < +\infty$, so the ROT problem can be solved with the NASA scheme. For $p \neq 2$, the Newton-Raphson steps to update the alternate projections in Dykstra's algorithm can be written as follows:

$$\boldsymbol{\tau} \leftarrow \boldsymbol{\tau} + \frac{\left\{\operatorname{sgn}(\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top) \odot |\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top|^{\frac{1}{p-1}}\right\}\mathbf{1} - p^{\frac{1}{p-1}}\,\mathbf{p}}{\frac{1}{p-1}|\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top|^{\frac{1}{p-1}-1}\,\mathbf{1}} \enspace , \tag{136}$$

$$\boldsymbol{\sigma} \leftarrow \boldsymbol{\sigma} + \frac{\mathbf{1}^\top\left\{\operatorname{sgn}(\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top) \odot |\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top|^{\frac{1}{p-1}}\right\} - p^{\frac{1}{p-1}}\,\mathbf{q}^\top}{\frac{1}{p-1}\,\mathbf{1}^\top\,|\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top|^{\frac{1}{p-1}-1}} \enspace . \tag{137}$$

Denoting $\overline{\boldsymbol{\theta}} = \boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top$ or $\overline{\boldsymbol{\theta}} = \boldsymbol{\theta}^\star - \mathbf{1}\boldsymbol{\sigma}^\top$ in the respective updates, each step can be optimized by computing first the temporary matrix $|\overline{\boldsymbol{\theta}}|$, then applying an element-wise matrix power of $1/(p-1)-1$ to obtain a matrix for the denominator, and lastly performing an element-wise matrix multiplication of these two matrices and of $\operatorname{sgn}\overline{\boldsymbol{\theta}}$ to obtain a matrix for the numerator and thus save one element-wise matrix power as well as several vector replications and matrix subtractions. However, even if ψ' is strictly increasing with $\psi'' > 0$ on $\mathbb{R}^*$, ψ' is neither convex nor concave and does not verify the necessary and sufficient condition (40) for global convergence of the Newton-Raphson method. Moreover, ψ'' vanishes at 0 for $p < 2$, and ψ' is not differentiable at 0 for $p > 2$.

Nevertheless, ψ' is concave on $\mathbb{R}_-$ and convex on $\mathbb{R}_+$ for $p < 2$, as well as convex on $\mathbb{R}_-$ and concave on $\mathbb{R}_+$ for $p > 2$. It thus divides for a given $1 \leq i \leq d$, respectively $1 \leq j \leq d$, the real line into at most $d+1$ intervals $-\infty < \hat{\theta}_i^{(1)} \leq \hat{\theta}_i^{(2)} \leq \cdots \leq \hat{\theta}_i^{(d-1)} \leq \hat{\theta}_i^{(d)} < +\infty$, respectively $-\infty < \check{\theta}_j^{(1)} \leq \check{\theta}_j^{(2)} \leq \cdots \leq \check{\theta}_j^{(d-1)} \leq \check{\theta}_j^{(d)} < +\infty$, with the values $(\hat{\theta}_i^{(k)})_{1\leq k\leq d}$ from row i of $\overline{\boldsymbol{\theta}}$, respectively $(\check{\theta}_j^{(k)})_{1\leq k\leq d}$ from column j of $\overline{\boldsymbol{\theta}}$, sorted in increasing order. The necessary and sufficient condition (40) is verified on the interior of each of these intervals since we can decompose $f(\mu_i)$, respectively $g(\nu_j)$, as the sum of an increasing convex and an increasing concave function. Hence, we have global convergence on the interior of the interval that contains the solution. In both cases, we must remove the finite endpoints to ensure differentiability of ψ' and positivity of ψ''. It is also further possible to prune the last interval from the search. Indeed, we have $\sum_{j=1}^d \psi'(\overline{\theta}_{ij} - \hat{\theta}_i^{(d)}) \leq \sum_{j=1}^d \psi'(0) = 0$, so that $\mu_i < \hat{\theta}_i = \hat{\theta}_i^{(d)} = \max\{\overline{\theta}_{ij}\}_{1\leq j\leq d}$. Similarly, we have $\sum_{i=1}^d \psi'(\overline{\theta}_{ij} - \check{\theta}_j^{(d)}) \leq \sum_{i=1}^d \psi'(0) = 0$, so that $\nu_j < \check{\theta}_j = \check{\theta}_j^{(d)} = \max\{\overline{\theta}_{ij}\}_{1\leq i\leq d}$. Lastly, we can restrict the first interval with a finite lower bound instead. Indeed, we have $\sum_{j=1}^d \psi'(\overline{\theta}_{ij} - \hat{\theta}_i^{(1)} + \phi'(p_i/d)) \geq \sum_{j=1}^d \psi'(\phi'(p_i/d)) = p_i$, so that $\mu_i \geq \hat{\theta}_i^{(1)} - \phi'(p_i/d)$. Similarly, we have $\sum_{i=1}^d \psi'(\overline{\theta}_{ij} - \check{\theta}_j^{(1)} + \phi'(q_j/d)) \geq \sum_{i=1}^d \psi'(\phi'(q_j/d)) = q_j$, so that $\nu_j \geq \check{\theta}_j^{(1)} - \phi'(q_j/d)$. As a result, we can perform at most d binary searches in parallel to determine within which of the remaining bounded intervals the solutions μ_i, respectively ν_j, lie. Initialization is then done with the midpoint to guarantee convergence of the updates. A given search thus requires a worst-case logarithmic number of tests, each of which requires a linear number of operations, for a total complexity in $O(d^2 \log d)$ instead of $O(d^2)$ if no such binary search were needed.

Now for $p = 2$, the regularizer specializes to the Euclidean norm, leading to the squared Euclidean distance as the associated divergence. In addition, the formula for ψ'' still holds with the convention $0^0 = 1$, and ψ'' is actually constant equal to $1/2$. Eventually, the projections can be written in closed form, and we can resort to the analytical algorithm derived in the next example specifically for the Euclidean distance, after doubling the penalty λ to account for the regularizer being halved.

5.7 Euclidean Norm and Euclidean Distance

Assumptions (B) hold for half the Euclidean norm $\pi^2/2$ associated to half the squared Euclidean distance. Therefore, the ROT problem can be solved with the NASA scheme, where Dykstra's algorithm can actually be written in closed form. Specifically, the non-negative projection reduces to:

$$\boldsymbol{\pi}^\star \leftarrow \max\{\mathbf{0}, \widetilde{\boldsymbol{\pi}}\} \enspace , \tag{138}$$

and is interleaved with the scaling projections which amount to offsetting the rows and columns of $\widetilde{\boldsymbol{\pi}}$ by an amount such that the rows and columns of $\boldsymbol{\pi}^\star$ sum up to $\mathbf{p}$ and $\mathbf{q}$ respectively:

$$\widetilde{\boldsymbol{\pi}} \leftarrow \widetilde{\boldsymbol{\pi}} - \frac{1}{d}(\boldsymbol{\pi}^\star\mathbf{1} - \mathbf{p})\,\mathbf{1}^\top \enspace , \tag{139}$$

$$\widetilde{\boldsymbol{\pi}} \leftarrow \widetilde{\boldsymbol{\pi}} - \frac{1}{d}\,\mathbf{1}\,(\mathbf{1}^\top\boldsymbol{\pi}^\star - \mathbf{q}^\top) \enspace . \tag{140}$$

As a remark, we notice that half the squared Euclidean distance can be seen as a β-divergence using the provided formula for $\beta = 2$. However, the β-divergence generated is not of Legendre type because the domain is restricted to $\mathbb{R}_+$, whereas it could actually be extended to $\mathbb{R}$ so that the regularizer would then be of Legendre type. This is why we fall under assumptions (B) rather than assumptions (A) in this case.

5.8 Hellinger Distance

Assumptions (B) hold for the regularizer $-(1-\pi^2)^{\frac{1}{2}}$ akin to a Hellinger distance. Hence, the ROT problem can be solved with the NASA scheme, and the Newton-Raphson steps to

update the alternate projections in Dykstra's algorithm can be written as follows:

$$\boldsymbol{\tau} \leftarrow \boldsymbol{\tau} + \frac{\left\{(\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top) \odot \left(1 + (\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top)^2\right)^{-\frac{1}{2}}\right\}\mathbf{1} - \mathbf{p}}{\left(1 + (\boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top)^2\right)^{-\frac{3}{2}}\mathbf{1}}\ , \tag{141}$$

$$\boldsymbol{\sigma} \leftarrow \boldsymbol{\sigma} + \frac{\mathbf{1}^\top\left\{(\boldsymbol{\theta}^\star - \mathbf{1}\boldsymbol{\sigma}^\top) \odot \left(1 + (\boldsymbol{\theta}^\star - \mathbf{1}\boldsymbol{\sigma}^\top)^2\right)^{-\frac{1}{2}}\right\} - \mathbf{q}^\top}{\mathbf{1}^\top\left(1 + (\boldsymbol{\theta}^\star - \mathbf{1}\boldsymbol{\sigma}^\top)^2\right)^{-\frac{3}{2}}}\ . \tag{142}$$

Denoting $\overline{\boldsymbol{\theta}} = \boldsymbol{\theta}^\star - \boldsymbol{\tau}\mathbf{1}^\top$ or $\overline{\boldsymbol{\theta}} = \boldsymbol{\theta}^\star - \mathbf{1}\boldsymbol{\sigma}^\top$ in the respective updates, each step can be optimized by computing first the temporary matrix $1/(1+\overline{\boldsymbol{\theta}}^2)$, then applying an element-wise matrix square root to this temporary matrix, performing an element-wise matrix multiplication of these two matrices to obtain a matrix for the denominator, and lastly an element-wise matrix multiplication of the temporary matrix with $\overline{\boldsymbol{\theta}}$ to obtain a matrix for the numerator and thus save one element-wise matrix power as well as several vector replications and matrix subtractions. However, even if ψ' is strictly increasing with ψ'' positive everywhere, ψ' is neither convex nor concave and does not verify the necessary and sufficient condition (40) for global convergence of the Newton-Raphson method.

Nevertheless, ψ' is convex on $\mathbb{R}_-$ and concave on $\mathbb{R}_+$. It thus divides for a given $1 \leq i \leq d$, respectively $1 \leq j \leq d$, the real line into at most $d+1$ intervals $-\infty < \hat{\theta}_i^{(1)} \leq \hat{\theta}_i^{(2)} \leq \cdots \leq \hat{\theta}_i^{(d-1)} \leq \hat{\theta}_i^{(d)} < +\infty$, respectively $-\infty < \check{\theta}_j^{(1)} \leq \check{\theta}_j^{(2)} \leq \cdots \leq \check{\theta}_j^{(d-1)} \leq \check{\theta}_j^{(d)} < +\infty$, with the values $(\hat{\theta}_i^{(k)})_{1\leq k\leq d}$ from row i of $\overline{\boldsymbol{\theta}}$, respectively $(\check{\theta}_j^{(k)})_{1\leq k\leq d}$ from column j of $\overline{\boldsymbol{\theta}}$, sorted in increasing order. On each of these intervals, the necessary and sufficient condition (40) is verified since we can decompose $f(\mu_i)$, respectively $g(\nu_j)$, as the sum of an increasing convex and an increasing concave function. Hence, we have global convergence on the interval that contains the solution. It is further possible to prune the last interval from the search. Indeed, we have $\sum_{j=1}^d \psi'(\overline{\theta}_{ij} - \hat{\theta}_i^{(d)}) \leq \sum_{j=1}^d \psi'(0) = 0$, so that $\mu_i < \hat{\theta}_i = \hat{\theta}_i^{(d)} = \max\{\overline{\theta}_{ij}\}_{1\leq j\leq d}$. Similarly, we have $\sum_{i=1}^d \psi'(\overline{\theta}_{ij} - \check{\theta}_j^{(d)}) \leq \sum_{i=1}^d \psi'(0) = 0$, so that $\nu_j < \check{\theta}_j = \check{\theta}_j^{(d)} = \max\{\overline{\theta}_{ij}\}_{1\leq i\leq d}$. Lastly, we can restrict the first interval with a finite lower bound instead. Indeed, we have $\sum_{j=1}^d \psi'(\overline{\theta}_{ij} - \hat{\theta}_i^{(1)} + \phi'(p_i/d)) \geq \sum_{j=1}^d \psi'(\phi'(p_i/d)) = p_i$, so that $\mu_i \geq \hat{\theta}_i^{(1)} - \phi'(p_i/d)$. Similarly, we have $\sum_{i=1}^d \psi'(\overline{\theta}_{ij} - \check{\theta}_j^{(1)} + \phi'(q_j/d)) \geq \sum_{i=1}^d \psi'(\phi'(q_j/d)) = q_j$, so that $\nu_j \geq \check{\theta}_j^{(1)} - \phi'(q_j/d)$. As a result, we can perform d binary searches in parallel to determine within which of the remaining intervals the solutions μ_i, respectively ν_j, lie. Initialization is then done with the midpoint to guarantee convergence of the updates. A given search requires a worst-case logarithmic number of tests, each of which requires a linear number of operations, for a total complexity in $O(d^2 \log d)$ instead of $O(d^2)$ if no such binary search were needed.

5.9 Quadratic Forms and Mahalanobis Distances

Assumptions (B) hold for the quadratic forms $(1/2)\,\mathrm{vec}(\boldsymbol{\pi})^\top \mathbf{P}\,\mathrm{vec}(\boldsymbol{\pi})$ with positive-definite matrix $\mathbf{P} \in \mathbb{R}^{d^2\times d^2}$, associated to the Mahalanobis distances, so the ROT problem can be

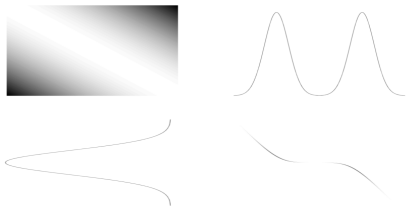

Figure 3: Earth mover's plan $\boldsymbol{\pi}^\star$ for the cost matrix $\boldsymbol{\gamma}$ and input distributions $\mathbf{p}, \mathbf{q}$.

solved with the NASA scheme. For a diagonal matrix $\mathbf{P}$, the regularizer is separable and the Newton-Raphson steps to update the alternate projections in Dykstra's algorithm are similar to that for the Euclidean distance with appropriate weights. For a non-diagonal matrix $\mathbf{P}$, however, the regularizer is not separable anymore and we must resort to the generic NASA scheme.

In this general case, the scaling projections amount to convex quadratic programs with linear equality constraints. They can be solved using classical techniques such as the range-space and null-space approaches, Krylov subspace methods or active set strategies. The non-negative projection reduces to a convex quadratic program with a linear inequality constraint. It can be solved elegantly with an iterative algorithm for non-negative quadratic programming proposed by Sha et al. (2007) using multiplicative updates with a complexity in $O(d^4)$. All in all, we recommend using a sparse matrix $\mathbf{P}$ with a block-diagonal structure and an order of magnitude of d^2 non-null entries, so as to obtain a quadratic instead of quartic empirical complexity.

6. Experimental Results

In this section, we present the results of our methods on different experiments. We first design an synthetic test to showcase the behavior of different regularizers and penalties on the output solutions or computational times (Section 6.1). We then consider a pattern recognition application to audio scene classification on a real-world dataset (Section 6.2).

6.1 Synthetic Data

We start by visualizing the effects of different regularizers ϕ and varying penalties λ on synthetic data. For the input distributions, we discretize and normalize continuous densities on a uniform grid $(x_i)_{1\leq i\leq d}$ of $[0,1]$ with dimension $d = 256$. We use for $\mathbf{p}$ a univariate normal with mean 0.5 and variance 0.2, and for $\mathbf{q}$ a mixture of two normals with equal weights, respective means 0.25 and 0.75, and same variance 0.1. We set the cost matrix $\boldsymbol{\gamma}$ as the squared Euclidean distance $\gamma_{ij} = (x_i - x_j)^2$ on the grid. The input distributions (bottom left and top right), cost matrix (top left) and unique earth mover's plan (bottom right) computed for classical OT using the solver of Rubner et al. (2000) with standard settings, are shown in Figure 3.

We test all separable regularizers ϕ introduced in Section 5. Because these regularizers have different ranges in the sensible values of the rot mover's plans $\boldsymbol{\pi}^\star$, we manually tune the penalties λ so that they feature similar amounts of regularization. For ease of comparison, we set $\lambda = \overline{\lambda}\,\lambda'$, with $\overline{\lambda}$ constant for each ϕ, and λ' varying similarly for all ϕ. The limit case when λ tends to infinity is simply obtained by setting $\boldsymbol{\gamma}/\lambda = \mathbf{0}$ in the algorithms, except from ℓ_p quasi-norms for which we use $\lambda = 10^{10}$. The null values of $\boldsymbol{\gamma}$ are also fixed to 10^{-12} for ℓ_p quasi-norms. We do not limit the number of iterations in the different algorithms, and use a small tolerance of 10^{-8} for convergence with the ℓ_∞ norm on the marginal difference checked after each iteration as a termination criterion.

The rot mover's plans obtained for ROT for $d = 256$ with the different regularizers and penalties are visualized in Figure 4. We first observe that all rot mover's plans converge to the earth mover's plan for low values of the penalty as shown theoretically in Property 9. Nevertheless, the rot mover's plans exhibit different shapes depending on the regularizers for intermediary and large values of the penalty. In the limit when the penalty grows to infinity, we obtain the transport plan with minimal Bregman information as shown theoretically in Property 7. In particular, this leads to $\mathbf{p}\mathbf{q}^\top$ with an ellipsoidal shape for `BSKL` (Boltzmann-Shannon entropy and Kullback-Leibler divergence), meaning that the mass is relatively spread among neighbor bins. The same pattern is observed for `FDLOG` (Fermi-Dirac entropy and logistic loss function), which can be explained in this synthetic example by the rot mover's plans having low values and the two regularizers being equivalent up to a constant in the neighborhood of zero. The profile gets more rectangular for `BIS` (Burg entropy and Itakura-Saito divergence), implying that the mass is even more spread across the different bins. Using an intermediary value $\beta = 0.5$ in `BETA` (β-potentials and β-divergences) allows the interpolation between these two limits of a rectangle for $\beta = 1$ and an ellipsoid for $\beta = 0$, so that the parameter β actually helps to control the spread of mass in the regularization. We observe similar results for `LPQN` (ℓ_p quasi-norms) with an ellipsoid for $p = 0.9$, a rectangle for $p = 0.1$, and a shape in between for $p = 0.5$. When the power parameter further increases in `LPN` (ℓ_p norms), we obtain new shapes that feature less spread of mass. These shapes for $p = 1.1$ and $p = 1.5$ now interpolate up to a lozenge for $p = 2$ in `EUC` (Euclidean norm and Euclidean distance), so that the parameter p also provides control on the spread of mass. A similar diamond profile is obtained for `HELL` (Hellinger distance), which is due again to the rot mover's plans having low values and the two regularizers being equivalent up to a constant in the neighborhood of zero. Lastly, we remark that varying the penalty between the two extremes allows a smooth interpolation of the earth mover's plan and optimal plan with minimal Bregman information, while keeping similar shapes and effects in terms of spreading of mass.

We next report in Table 4 the computational times required to reach convergence for the different regularizers and penalties. As a stopping criterion, we use the relative variation with tolerance 10^{-2} in ℓ_2 norm for the main loop of alternate Bregman projections, and the absolute variation with tolerance 10^{-5} in ℓ_2 norm for the auxiliary loops of the Newton-Raphson method. We use the same synthetic data as above but also vary the dimension d to assess its influence on speed. As already observed specifically for Sinkhorn distances (Cuturi, 2013), computing ROT distances is faster for important regularization with larger values of λ. The regularizers under assumptions (A) do not require the extra projections onto the non-negative orthant, and thus intuitively require less computational effort than the ones

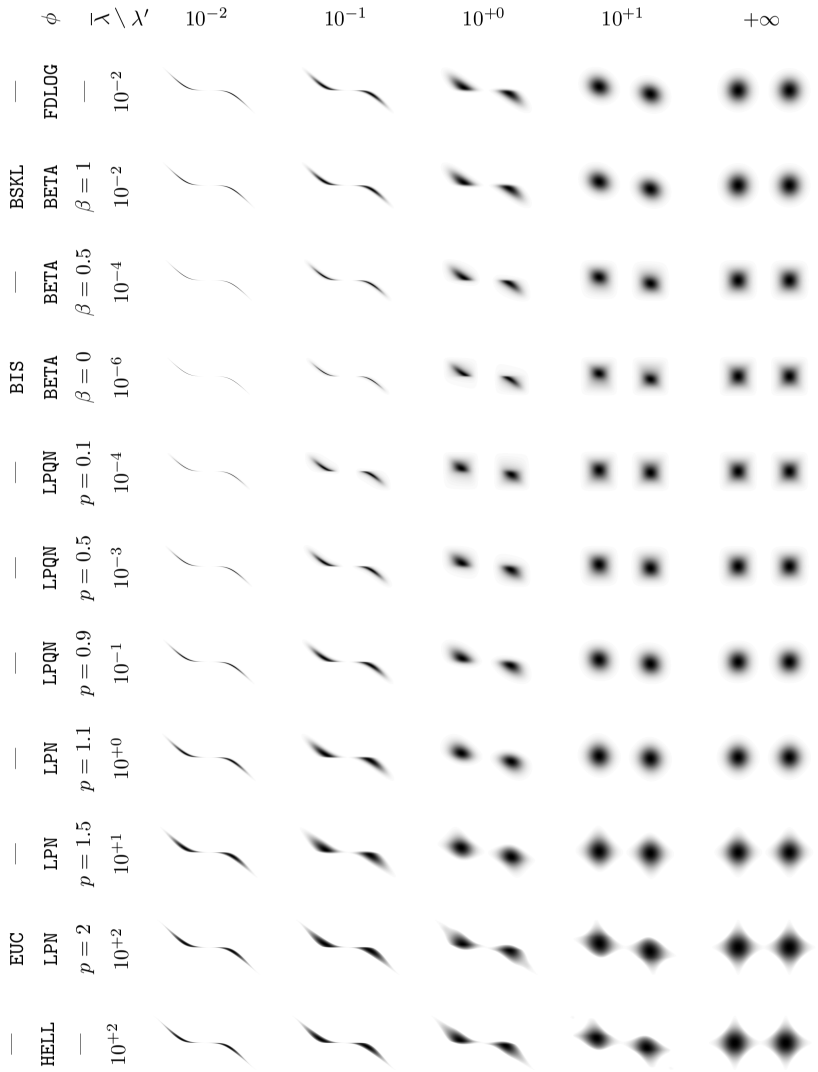

Figure 4: Rot mover's plans $\boldsymbol{\pi}^\star$ for different regularizers ϕ and penalties $\lambda = \overline{\lambda}\,\lambda'$.

that verify assumptions (B). In addition, we notice that when the projections have closed-form expressions, the algorithms are also faster. The results further illustrate the influence of the data dimension d and the difference between ROT and classical OT performances. For a low dimension d, the RMD is competitive with EMD in his historical implementation `EMD OLD` (Rubner et al., 2000). The super-cubic complexity of the EMD with `EMD OLD` becomes prohibitive as the data dimension increases in contrast to the RMD which scales better. It should nevertheless be underlined that for reasonable dimensions, fast computation of the EMD can be obtained with a more recent, optimized implementation of the network simplex solver `EMD NEW` (Bonneel et al., 2011). For higher dimensions, the super-cubic complexity makes `EMD NEW` less attractive, though it stays competitive with the RMD under a dimension $d = 4096$.

As a consequence, a numerical alternative to our algorithms for solving ROT problems with reasonable dimensions is to rely on conditional gradient methods similar to (Ferradans et al., 2014). Indeed, such methods imply the iterative resolution of linearized ROT problems, that can be reformulated as EMD problems and therefore be solved with the fast network simplex approach (Bonneel et al., 2011). Lastly, for a fair interpretation of the above timing results, we must mention that the two EMD schemes tested were run under MATLAB from native C/C++ implementations[1,2] via compiled MEX files[3,4]. Hence, these EMD codes are quite optimized in comparison to our pure MATLAB prototype codes[5] for the RMD. It is thus plausible that optimized C/C++ implementations of our algorithms would be even more competitive in this context.

6.2 Audio Classification

We now assess our methods in the context of audio classification, and specifically address the task of acoustic scene classification where the goal is to assign a test recording to one of predefined classes that characterizes the environment in which it was captured. We consider the framework of the DCASE 2016 IEEE AASP challenge with the TUT Acoustic Scenes 2016 database (Mesaros et al., 2016). The data set consists of audio recordings at 44.1 kHz sampling rate and 24-bit resolution. The metadata contains ground-truth annotations on the type of acoustic scene for all files, with a total of 15 classes: home, office, library, café/restaurant, grocery store, city center, residential area, park, forest path, beach, car, train, bus, tram, metro station. The audio material is cut into 30-second segments, and is split into two subsets of 75%–25% containing respectively 78–26 segments per class for development and evaluation, resulting in a total of 1170–390 files for training and testing. A 4-fold cross-validation setup is given with the training set. The classification accuracy, that is, the number of correctly classified segments among the total number of segments, is used as a score to evaluate systems.

A baseline system is also provided with the database for comparison. This system is based on Mel-frequency cepstral coefficient (MFCC) timbral features with Gaussian mixture model (GMM) classification. One GMM with diagonal covariance matrix is learned per class

Table 4: Computational times in seconds required to reach convergence for different regularizers ϕ and penalties $\lambda = \overline{\lambda}\,\lambda'$, with varying dimensions d.

by expectation-maximization (EM), after concatenating and normalizing in mean and variance the extracted MFCCs from the training segments in that class. A test file is assigned to the class whose trained GMM leads to maximum likelihood for the extracted MFCCs for that file, where the MFCCs are considered as independent samples and normalized with the learned mean and variance for the respective classes. The baseline system is ran with its default parameters: 40 ms frame size, 20 ms hop size, 60-dimensional MFCCs comprising 20 static (including energy) plus 20 delta and 20 acceleration coefficients extracted with

standard settings in RASTAMAT, 16 GMM components learned with standard settings in VOICEBOX.

Since MFCCs potentially take negative values, OT tools cannot be applied directly to this kind of features. Therefore, the common approach is to compute OT appropriately on GMMs estimated from MFCCs instead. Our proposed system follows this principle, and is implemented in the very same pipeline as the baseline for a fair comparison, with the following differences. One GMM is learned by EM for each training segment instead of class. Any normalization on the MFCCs per class is thus removed. Since less components are typically required to model one segment compared to one class, the spurious GMM components are further discarded as post-processing by keeping only those with weight and variances all greater than 10^{-2}. Instead of applying a GMM classifier, all individual models are exploited to train a support vector machine (SVM) classifier. An exponential kernel for the SVM is designed by introducing a distance between two mixtures P, Q based on the RMD as follows:

$$\kappa(P,Q) = \exp(-d_{\boldsymbol{\gamma},\lambda,\phi}(\boldsymbol{\omega},\boldsymbol{\upsilon})/\tau) \ , \tag{143}$$

where the exponential decay rate $\tau > 0$ is a kernel parameter, and $\boldsymbol{\omega}, \boldsymbol{\upsilon} \in \Sigma_d$ are the respective weights of the $d = 16$ (or less) components for the two GMMs P, Q. The cost matrix $\boldsymbol{\gamma} \in \mathbb{R}_+^{d\times d}$ depends on P, Q and is the square root of a symmetrized Kullback-Leibler divergence, called the Jeffrey divergence, between the pairwise Gaussian components:

$$\gamma_{ij} = \sqrt{\frac{1}{4}\sum_{k=1}^{l} \frac{(\sigma_{ik}^2 - \varsigma_{jk}^2)^2 + (\sigma_{ik}^2 + \varsigma_{jk}^2)(\mu_{ik} - \nu_{jk})^2}{\sigma_{ik}^2 \varsigma_{jk}^2}} \ , \tag{144}$$

where $\boldsymbol{\mu}_i$ and $\boldsymbol{\sigma}_i^2$, respectively $\boldsymbol{\nu}_j$ and $\boldsymbol{\varsigma}_j^2$, are the means and variances of the $l = 60$ MFCC features for component i in the first mixture P, respectively component j in the second mixture Q. The SVM classifier is implemented with standard settings in LIBSVM, and requires an additional soft-margin parameter $C > 0$ to be tuned. Notice that, even if the kernel is not positive-definite, LIBSVM is still able to provide a relevant classification by guaranteeing convergence to a stationary point (Lin and Lin, 2003; Haasdonk, 2005; Alabdulmohsin et al., 2014). All separable regularizers ϕ from Section 5 with different penalties $\lambda > 0$ are tested for the RMD in comparison to the EMD. The two distances between $\mathbf{p}, \mathbf{q}$ and $\mathbf{q}, \mathbf{p}$ with cost matrix $\boldsymbol{\gamma}$ transposed are computed and averaged, so as to remove any asymmetry due to practical issues. The number of iterations is limited to 100 for the main loop of the algorithm and to 10 for the auxiliary loops of the Newton-Raphson method, and the tolerance is set to 10^{-6} in all loops for convergence with the ℓ_∞ norm on the marginal difference checked after each iteration as a termination criterion. The parameters τ, $C \in 10^{\{-1,+0,+1,+2\}}$ and penalty $\lambda \in \Lambda$, where Λ is a manually chosen set of four successive powers of ten depending on the range of the regularizer ϕ, are tuned automatically by cross-validation.

The obtained results on this experiment in terms of accuracy per system are reported in Table 5. The optimal penalties $\lambda \in \Lambda$ selected by cross-validation for each regularizer ϕ are also included, while the optimal parameters τ, C are not displayed since they actually all equal 10^{+1} independently of the kernel used. We first notice that the proposed system `SVM` (support vector machine classifier) consistently outperforms the baseline system `GMM`

(Gaussian mixture model classifier). This proves the benefits of incorporating individual information per sound via an SVM rather than exploiting global information per class with a GMM. This further demonstrates the relevance of OT and more general ROT problems for the design of kernels between GMMs in the SVM pipeline. We also notice that `RMD` (rot mover's distance kernel) is at least competitive with `EMD` (earth mover's distance kernel) for all proposed regularizers, except from `EUC` which does not perform as well. This might be a consequence of the regularization profile for `EUC`, or equivalently `LPN` with $p = 2$, which does not spread enough mass across similar bins, implying a lack of robustness to slight variations in the means and variances of the GMM components. Reducing the power parameter in `LPN` brings back to a competitive system with `EMD` for $p = 1.1$, and even a better trade-off with improved accuracy for $p = 1.5$. We obtain similar results for `LPQN` with $p = 0.9$ and $p = 0.5$, with now the best compromise for the lowest power value $p = 0.1$ which clearly outperforms `EMD`. As a remark, the accuracy for `LPN` and `LPQN` is not unimodal with respect to p which controls the spread of mass in the regularization. We suspect this is because the performance is a function of both the spread of mass and the amount of regularization, whose coupling allows for similar compromises in terms of results within different regimes of use. Concerning `BETA` now, we observe that the existing Sinkhorn-Knopp algorithm `BSKL` for $\beta = 1$ does not improve the accuracy compared to `EMD`. Increasing the spread of mass with $\beta = 0$ in `BIS` is even worse. The best performance is obtained with a range in between for $\beta = 0.5$, which slightly improves results over `EMD`. Using `LOG` here slightly degrades the performance compared to `EMD` and `BSKL`. Interestingly, the overall best accuracy on this application is obtained for `HELL` which beats all other systems, including `EUC`, by a safe margin. In contrast to the experiment on synthetic data with dimension 256 presented in Section 6.1, where both `BSKL` and `LOG`, respectively `EUC` and `HELL`, behave similarly due to equivalence up to a constant for low values in the transport plans, the range of the transport plans here is much higher since the dimension of the input distributions is at most 16 (typically less than 10). This raises the importance of choosing a good regularizer depending on the actual task and its inherent design criteria such as the data dimension.

7. Conclusion

In this paper, we formulated a unified framework for smooth convex regularization of discrete OT problems. We also derived some algorithmic methods to solve such ROT problems, and detailed their specificities for classical regularizers and associated divergences from the literature. We finally designed a synthetic experiment to illustrate our proposed methods, and proved the relevance of ROT problems and the RMD on a real-world application to audio scene classification. The obtained results are encouraging for further development of the present work, and we now discuss some interesting perspectives for future investigation.

Firstly, we want to assess the effect of other regularizers on the solutions, notably when adding an affine term. From a geometrical viewpoint, such a transformation is equivalent to simply translating the cost matrix, with no effect on the Bregman divergence itself. For a given regularizer, we could therefore parametrize a whole family of interpolating regularizers, and tune the translation parameter according to the application. In particular, a recent work developed independently of ours makes use of Tsallis entropies to regularize OT problems with ad hoc solvers (Muzellec et al., 2018). These regularizers could be integrated readily to

Table 5: Results of the experiment on audio classification.

our more general framework based on alternate Bregman projections, since Tsallis entropies are equivalent to β-potentials and ℓ_p (quasi)-norms up to an affine term.

In another direction, we would like to extend some theoretical results that hold for the Boltzmann-Shannon entropy and associated Kullback-Leibler divergence. Specifically, it is known that the related rot mover's plan converges in norm to the earth mover's plan with an exponential rate as the penalty decreases (Cominetti and San Martín, 1994). It is not straightforward, however, to generalize this to other regularizers and divergences. In addition, it would be worth elucidating some technical restrictions under which metric properties such as the triangular inequality can be proved similarly to Sinkhorn distances.

We also plan to study other pattern recognition tasks in text, image and audio signal processing. Intuitive possibilities include retrieval and classification for various kinds of data modeled via histograms of features or GMMs. Among potential approaches, this can be addressed by exploiting the RMD either directly in a nearest-neighbor search, or in the design of kernels for an SVM as done here for acoustic scenes. For such tasks, it would be relevant to provide insight into the choice of a good regularizer for the actual problem, or develop methods for automatic tuning of regularization parameters, and for learning the cost matrix from the data as can be done for the EMD (Cuturi and Avis, 2014). Even if we mostly focused on separable regularizers, it would be relevant to further use the quadratic forms associated to Mahalanobis distances in certain applications, and maybe propose a parametric learning scheme for the quadratic regularizer from the data.

Lastly, a more prospective idea is to use the RMD instead of Sinkhorn distances in the recent works built on the entropic regularization mentioned in Section 1. We also think that variational ROT problems could be formulated for statistical inference, notably parameter estimation in finite mixture models by minimizing loss functions based on the RMD (Dessein et al., 2017). This would leverage new applications of our ROT framework for more general machine learning problems. Such developments are yet involved and require some theoretical effort before reaching enough maturity to address practical setups.

Acknowledgments

This study has been carried out with financial support from the French State, managed by the French National Research Agency (ANR) in the frame of the "Investments for the future" Program IdEx Bordeaux (ANR-10-IDEX-03-02), Cluster of excellence CPU, and the GOTMI project (ANR-16-CE33-0010-01). The authors would like to thank Annamaria Mesaros for her kind help with the evaluation on the DCASE 2016 IEEE AASP challenge, Charles-Alban Deledalle for his valuable advice on the use of the computing platform PlaFRIM, and Marco Cuturi for the insightful discussions about this work.

Abstract

Engine for Likelihood-Free Inference (ELFI) is a Python software library for performing likelihood-free inference (LFI). ELFI provides a convenient syntax for arranging components in LFI, such as priors, simulators, summaries or distances, to a network called ELFI graph. The components can be implemented in a wide variety of languages. The stand-alone ELFI graph can be used with any of the available inference methods without modifications. A central method implemented in ELFI is Bayesian Optimization for Likelihood-Free Inference (BOLFI), which has recently been shown to accelerate likelihood-free inference up to several orders of magnitude by surrogate-modelling the distance. ELFI also has an inbuilt support for output data storing for reuse and analysis, and supports parallelization of computation from multiple cores up to a cluster environment. ELFI is designed to be extensible and provides interfaces for widening its functionality. This makes the adding of new inference methods to ELFI straightforward and automatically compatible with the inbuilt features.

∗. Equal contribution

Keywords: Likelihood-free inference, approximate Bayesian computation, Python, BOLFI, parallel computing

1. Introduction

Engine for Likelihood-Free Inference (ELFI) is a statistical software package for likelihood-free inference written in Python. The term "likelihood-free inference" (LFI) refers to a family of inference methods that can be used when the likelihood function is not computable or otherwise available, but it is possible to simulate from the model (see e.g. Lintusaari et al., 2017). Other names for likelihood-free inference or closely related approaches include Approximate Bayesian Computation (ABC) (see e.g. Marin et al., 2012; Lintusaari et al., 2017), simulator-based inference, approximative Bayesian inference and indirect inference.

In LFI, generative models are commonly composed of priors and user-specified simulators. The inference is based on the outputs of the generative model, that is, on the simulated data for various parameter configurations, as opposed to the likelihoods of the observed data under the configurations. To facilitate the inference, the observed and simulated data are usually summarized after which distances between the summaries are taken. In ELFI, the simulators, summaries, distances, etc. are called components and can be implemented in a wide variety of languages.

One of the main features in ELFI is the convenient syntax of combining all of the components into a single network (Figure 1) that we call an ELFI graph. Once the ELFI graph is specified, it can be used with any of the available inference algorithms. ELFI also supports parallelization of the inference from a single computer up to a computational cluster, and storing the generated data for reuse, post-processing and further analysis. ELFI has emerged from the prior research on the subject by the authors (Lintusaari et al., 2016; Gutmann and Corander, 2016; Lintusaari et al., 2017; Kangasrääsiö et al., 2017) and was used by Kangasrääsiö et al. (2017) and Kangasrääsiö and Kaski (2017).

2. Software Design Principles

ELFI is designed to support likelihood-free inference research both from the practitioners' and methodologists' point of view. We aim for an easy-to-use ecosystem where practitioners will find the state-of-the-art inference methods, whereas methodologists will find simulators along with accompanying ELFI graphs and data to aid in method development and assessment.

2.1 Features for Practitioners

For practitioners ELFI provides a convenient interface for quickly arranging the components needed in LFI into an ELFI graph. Inherently ELFI graphs are directed acyclic graphs (DAGs), that represent how quantities used by the inference algorithm (e.g. distances) are computed (Figure 1). The DAG structure makes it possible to construct detailed hierarchies between the components (nodes). Under the hood, the ELFI graph is converted to a computation graph that will include e.g. nodes for the observed data (see the documentation[1] for more details). The nodes (components) are either data or operations that output data. Users are free to implement components as needed, but ELFI provides also ready made implementations for common components. Once specified, the ELFI graph can be directly

```python
# Define the simulator, the summary and the observed data
def simulator(t1, t2, batch_size=1, random_state=None):
    # Implementation comes here. Return `batch_size`
    # simulations wrapped to a NumPy array.
def summary(data, argument=0):
    # Implementation comes here...
y = # Observed data, as one element of a batch.

# Specify the ELFI graph
t1 = elfi.Prior('uniform', -2, 4)
t2 = elfi.Prior('normal', t1, 5)  # depends on t1
SIM = elfi.Simulator(simulator, t1, t2, observed=y)
S1 = elfi.Summary(summary, SIM)
S2 = elfi.Summary(summary, SIM, 2)
d = elfi.Distance('euclidean', S1, S2)

# Run the rejection sampler
rej = elfi.Rejection(d, batch_size=10000)
result = rej.sample(1000, threshold=0.1)
```

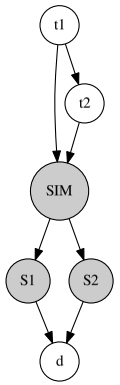

Figure 1: Example of an ELFI graph and of running ABC rejection sampling in ELFI. The observed data are given to the operation that produces corresponding output. Two summaries are defined, where summary S2 is given an additional argument 2.

used with any of the available inference methods. We have provided an initial set of methods that can handle different types of scenarios: basic rejection sampling for cheap simulators, the general-purpose sequential Monte Carlo as well as BOLFI (Gutmann and Corander, 2016) for expensive simulators. BOLFI combines probabilistic modelling of the distance with decision-making under uncertainty to decide for which parameter value to next run the simulator, significantly reducing the number of simulations needed.

Since likelihood-free inference often requires a moderate amount of experimentation (e.g. trying different summary statistics) it is important that specifying the components is made flexible and that already generated data can be reused. We found the DAG structure to be ideal for these tasks. First, ELFI allows any part of the ELFI graphs (e.g. nodes and their dependencies) to be redefined keeping the rest of the structure intact. Second, ELFI provides automatic storing of the full output of any node (e.g. the simulator). These data will be automatically reused when for example the summaries are changed, potentially resulting in significant savings in compute time. These features are demonstrated in the ELFI tutorial in the documentation.

Another important factor is the ability to use non-Python components in the ELFI graph. For instance, it may not always be practical or even possible to rewrite existing simulators in Python. ELFI provides both tools and examples in the documentation on how to use simulators written in other languages.

Other practical features include the ability to progress the inference iteratively and to stop early if necessary. The provided visualization functions support assessing the current state of the inference. Finally, the ELFI graph can be saved to a file and shared with

others. ELFI also guarantees that the results will be identical for the same seeds making the reproduction of the results easy.

2.2 Features for Methodologists

For methodologists ELFI provides a convenient platform for testing new algorithms with models from the literature (e.g. Ricker, 1954; Marin et al., 2012; Lintusaari et al., 2017) and comparing their performance against existing algorithms. The framework provides means for parallelization, data storing, seeding of pseudo random number generation and other important technicalities out of the box. The documentation includes instructions on how to implement new algorithms for ELFI. One of the major benefits is that all existing ELFI graphs will be usable with the new algorithms without modifications.

3. Performance and Scalability

Performance is an important factor in computationally heavy inference such as LFI. ELFI uses batches of computations to control execution performance and parallelization. A batch consists of a fixed number of consecutive evaluations of a node in the ELFI graph before moving to the next (e.g. 100 draws from the prior and then 100 simulations using those parameters). The standard parallelization strategy is to compute multiple batches in parallel. This provides several benefits. First, the computation of a single batch can often be vectorized with, for example, NumPy (van der Walt et al., 2011) for many of the basic operations (e.g. computing summaries or distances), making them efficient in Python. This is especially beneficial when experimenting with different summaries and distances with precomputed simulations. Batches are also often relatively constant in their time and memory consumption, allowing flexibility in planning the parallel execution of multiple batches. This helps in avoiding unnecessary message passing, progressing the inference in meaningful steps, and makes it possible to know in advance the size of the returned output data for storing purposes.

4. Comparison to Other Similar Software

There exist multiple LFI libraries for parameter inference. Many of them are either restricted to a specific problem domain (Liepe et al., 2014; Cornuet et al., 2014; Louppe et al., 2016), or require existing simulated data (Thornton, 2009; Csilléry et al., 2012; Nunes and Prangle, 2015). Edward (Tran et al., 2016) provides some LFI methods with a GPU acceleration, but requires the simulator to be differentiable. ELFI makes no extra requirements for the simulator (or other components), and can also be used with implementations taking benefit of hardware accelerations (e.g. GPU). General-purpose LFI software similar to ELFI are, to our knowledge, ABCtoolbox (Wegmann et al., 2010), EasyABC (Jabot et al., 2013), and ABCpy (Dutta et al., 2017). A relatively recent categorization of LFI software is provided by Nunes and Prangle (2015).

Among the general-purpose LFI software, only ELFI separates the LFI component specification from inference (Table 1). The graph-based specification provides considerable flexibility in both defining the components and experimenting with them. For example, it

Software	Language	Latest release	Data reuse	Parallelization	Graph-based	Iterative processing
ABCtoolbox	C++	2009	Partial	cluster (manual)	✗	✗
EasyABC	R	2015	Partial	local	✗	✗
ABCpy	Python	2017	✗	local and cluster	✗	✗
ELFI	Python	2017	✓	local and cluster	✓	✓

Table 1: Comparison of general-purpose LFI frameworks

is possible to embed multiple simulators into a single ELFI graph without modifying their codes. We refer the reader to the documentation for illustrations.[1]

Regarding parallelization, EasyABC supports multiple cores on a single computer while the others can also run in cluster environments. By default, ABCpy uses Spark (Zaharia et al., 2010) and ELFI ipyparallel for parallelization but both can be used with alternative backends.[2] ABCtoolbox does not provide a parallel solution out of the box.

ABCtoolbox, EasyABC and ELFI support reusing generated data. ELFI is more flexible in that it allows the output of any node of the ELFI graph to be stored, and it automatically uses that data to compute the output of its current or future child nodes. There is thus no need to manually transform existing data.

Only ELFI supports advancing the inference sample-by-sample, which facilitates debugging and enables e.g. convergence monitoring and early stopping. Also, ELFI is currently the only general-purpose software to implement the BOLFI method (Gutmann and Corander, 2016), which can handle expensive-to-evaluate simulators outside the reach of other methods.

5. Source Code and Dependencies

ELFI has been designed to be open source and modular, and can be extended through interfaces. For instance, it is possible to add new types of components, data stores or parallel clients. All the dependencies of ELFI are also open source.

ELFI is written in Python and is officially tested under Linux and MacOS but also works in Windows. The code style follows PEP 8 and documentation NumPy format. Code development uses the continuous integration practice with code review and automated tests to ensure the quality and usability of the software. The venue for distributing the source is GitHub that among the above features also allows anyone to raise issues regarding the software and make pull requests for new features.[3] Online documentation is hosted in the Read The Docs.[1] ELFI also has a community chat for the users.

Abstract

We consider the problem of streaming kernel regression, when the observations arrive sequentially and the goal is to recover the underlying mean function, assumed to belong to an RKHS. The variance of the noise is not assumed to be known. In this context, we tackle the problem of tuning the regularization parameter adaptively at each time step, while maintaining tight confidence bounds estimates on the value of the mean function at each point. To this end, we first generalize existing results for finite-dimensional linear regression with fixed regularization and known variance to the kernel setup with a regularization parameter allowed to be a measurable function of past observations. Then, using appropriate self-normalized inequalities we build upper and lower bound estimates for the variance, leading to Bernstein-like concentration bounds. The latter is used in order to define the adaptive regularization. The bounds resulting from our technique are valid uniformly over all observation points and all time steps, and are compared against the literature with numerical experiments. Finally, the potential of these tools is illustrated by an application to kernelized bandits, where we revisit the Kernel UCB and Kernel Thompson Sampling procedures, and show the benefits of the novel adaptive kernel tuning strategy.

Keywords: kernel, regression, online learning, adaptive tuning, bandits

1. Introduction

Many applications require solving an online optimization problem for an unknown, noisy, function defined over a possibly large domain space. Kernel regression methods can learn such possibly non-linear functions by sharing information gathered across observations. These techniques are being used in many fields where they serve a variety of applications like hyperparameters optimization (Snoek et al., 2012), active preference learning (Brochu et al., 2008), and reinforcement learning (Marchant and Ramos, 2014; Wilson et al., 2014). The idea is generally to rely on kernel regression to estimate a function that can be used for decision making and selecting the next observation point. Algorithmically speaking, standard kernel regression involves a regularization parameter that accounts for both the complexity of the unknown target function, and the variance of the noise. While most theoretical approaches rely on a fixed regularization parameter, in practice, people have often used heuristics in order to tune this parameter adaptively with time.

This however comes at the price of loosing theoretical guarantees. Indeed, in order for theoretical guarantees (based on concentration inequalities) to hold, existing approaches (Srinivas et al., 2010; Valko et al., 2013) require the regularization parameter in the kernel regression to be a fixed quantity. Further, they assume a prior and tight knowledge of the variance of the noise, which is unrealistic in practice. The reason for this cumbersome assumption is to adjust the regularization parameter in the kernel regression based on this deterministic quantity, as such a choice of regularization conveys a natural Bayesian interpretation (Rasmussen and Williams, 2006). Following this intuition, given an empirical estimate of the function noise based on gathered observations, one should be able to tune the regularization automatically. This is however non-trivial, first due to the streaming nature of the data, that allows the noise to be a measurable function of the past observations, second because concentration bounds on the empirical variance are currently unknown in such a general kernel setup, and finally because all existing theoretical bounds require the regularization parameter to be a deterministic constant, while we require here a parameterization that explicitly depends on past observations. The goal of this work is to provide the rigorous tools for performing an online tuning of the kernel regularization while preserving theoretical guarantees and confidence intervals in the context of streaming kernel regression with unknown noise. We thus hope to provide a sound method for adaptive tuning that is both interesting from a practical perspective and retains theoretical guarantees.

We gently start our contributions by Theorem 1 that generalizes existing concentration results (such as in Abbasi-Yadkori et al. (2011); Wang and de Freitas (2014)), and is explicitly stated for a regularization parameter that may differ from the noise. This result paves the way to an even more general result (Theorem 2) that holds when the regularization is tuned online at each step. Afterwards, we introduce a streaming variance estimator (Theorem 3) that yields empirical upper- and lower-bounds on the function noise. Plugging-in the resulting estimates leads to empirical Bernstein-like concentration results (Corollary 1) for the kernel regression, where we use the variance estimates in order to tune the regularization parameter. Section 4 presents an application to kernelized bandits, where regret bounds for Kernel UCB and Kernel Thompson Sampling procedures are derived. Section 5 discusses our results and compares them against other approaches. Finally, Section 6 shows the potential of all the previously introduced results while comparing them to existing alternatives through different numerical experiments. We postpone most of the proofs to the appendix.

2. Kernel streaming regression with a predictable noise process

Let us consider a sequential regression problem. At each time step $t \in \mathbb{N}$, a learner picks a point $x_t \in \mathcal{X} \subset \mathbb{R}^d$ and gets the observation

$$y_t = f_\star(x_t) + \xi_t \,,$$

where $f_\star$ is an unknown function assumed to belong to some function space $\mathcal{F}$, and ξ_t is a random noise. In the following, we assume a sub-Gaussian streaming predictable model:

Assumption 1 (Predictability) *The process generating the observations is* predictable *in the sense that there is a filtration $\mathcal{H} = (\mathcal{H}_t)_{t\in\mathbb{N}}$ such that x_t is $\mathcal{H}_{t-1}$-measurable and y_t is $\mathcal{H}_t$-measurable. Such an example is given by $\mathcal{H}_t = \sigma(x_1, \dots, x_{t+1}, y_1, \dots, y_t)$.*

Assumption 2 (Sub-Gaussian streaming model) *In the sub-Gaussian streaming predictable model, for some non-negative constant σ^2, the following holds*

$$\forall t \in \mathbb{N}, \forall \gamma \in \mathbb{R}, \quad \ln \mathbb{E}\Big[\exp(\gamma \xi_t)\Big|\mathcal{H}_{t-1}\Big] \leqslant \frac{\gamma^2\sigma^2}{2}\,.$$

Let $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a kernel function (that is continuous, symmetric positive definite) on a compact set $\mathcal{X}$ equipped with a positive finite Borel measure, and denote $\mathcal{K}$ the corresponding RKHS.

Information gain This quantity measures the information obtained about function $f_\star$ by sampling at points $(x_1, \dots, x_t)$. It is defined (Cover and Thomas, 1991) as the *mutual information* between $f_\star$ and the observations $(y_1, \dots, y_t)$:

$$I(y_1, \dots, y_t; f_\star) = H(y_1, \dots, y_t) - H(y_1, \dots, y_t|f_\star),$$

that is the difference between the *marginal entropy* and the *conditional entropy* of the distributions of observations. The information gain thus quantifies the reduction of uncertainty about $f_\star$ following these observations. For a multidimensional Gaussian, we have $H(\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})) = \frac{1}{2}\ln|2\pi e\boldsymbol{\Sigma}|$, such that for $\lambda = \sigma^2$ (Srinivas et al., 2010),

$$\gamma_t(\sigma^2) = I(y_1, \dots, y_t; f_\star) = \frac{1}{2}\ln\det(I_t + \sigma^{-2}\mathbf{K}_t),$$

where $\mathbf{K}_t = (k(s, s'))_{s,s'\leqslant t}$. In the linear case when $k(x, x') = x^\top x'$ for $x \in \mathbb{R}^d$, the information gain typically scales as $\gamma_t(\sigma^2) = \mathcal{O}(d\ln t)$ (Srinivas et al., 2010). The information gain can be shown to scale with the *effective dimensionality* (Valko et al., 2013) instead of the dimension, where effective dimensions correspond to the most informative ones. More effective dimensions require more observations for a good space coverage, which increases the information gain. We now extend the information gain to any regularization λ.

Definition 1 (Information gain with unknown variance) *We define the information gain at time t for a regularization parameter λ to be*

$$\gamma_t(\lambda) = \frac{1}{2}\sum_{t'=1}^{t}\ln\left(1 + \frac{1}{\lambda}k_{\lambda,t'-1}(x_{t'}, x_{t'})\right).$$

This generalization is natural in view of Theorem 1 below. The information gain is inversely proportional to the regularization λ. By controlling the flexibility of the regression model, the regularization limits the impact of a new observation on the resulting model, therefore limiting the information that can be gained out of it.

Concentration We first provide a result bounding the prediction error of a standard regularized kernel estimate, where the regularization is given by a fixed parameter $\lambda > 0$.

Theorem 1 (Streaming kernel least-squares (Maillard, 2016)) *Assume we are in the sub-Gaussian streaming predictable model. For a parameter $\lambda \in \mathbb{R}$, let us define the posterior mean and variances after observing $Y_t = (y_1, \dots, y_t)^\top \in \mathbb{R}^{t\times 1}$ as*

$$\begin{cases} f_{\lambda,t}(x) = & k_t(x)^\top(\mathbf{K}_t + \lambda I_t)^{-1}Y_t \\ s^2_{\lambda,t}(x) = & \frac{\sigma^2}{\lambda}k_{\lambda,t}(x,x) \text{ with } k_{\lambda,t}(x,x) = k(x,x) - k_t(x)^\top(\mathbf{K}_t + \lambda I_t)^{-1}k_t(x)\,. \end{cases}$$

where $k_t(x) = (k(x, x_{t'}))_{t'\leqslant t}$ is a $t \times 1$ (column) vector and $\mathbf{K}_t = (k(x_s, x_{s'}))_{s,s'\leqslant t}$. Then $\forall\delta \in [0, 1]$, with probability higher than $1-\delta$, it holds simultaneously over all $x \in \mathcal{X}$ and $t \geqslant 0$,

$$|f_\star(x) - f_{\lambda,t}(x)| \leqslant \sqrt{\frac{k_{\lambda,t}(x,x)}{\lambda}}\left[\sqrt{\lambda}\|f_\star\|_{\mathcal{K}} + \sigma\sqrt{2\ln(1/\delta) + 2\gamma_t(\lambda)}\right],$$

where the quantity $\gamma_t(\lambda) = \frac{1}{2}\sum_{t'=1}^{t}\ln\left(1+\frac{1}{\lambda}k_{\lambda,t'-1}(x_{t'}, x_{t'})\right)$ *is the information gain.*

Remark 1 *This result should be considered as an extension of Abbasi-Yadkori et al. (2011, Theorem 2) from finite-dimensional to possibly infinite dimensional function space. More specifically, when considering the linear kernel, the result of Theorem 1 recovers exactly Theorem 2 from Abbasi-Yadkori et al. (2011). The generalization is non trivial as the Laplace method must be amended in order to be applied beyond the linear case.*

Remark 2 *This result holds uniformly over all $x \in \mathcal{X}$ and most importantly over all $t \geqslant 0$, thanks to a random stopping time construction (related to the occurrence of* bad events*) and a self-normalized inequality handling this stopping time. This is in contrast with results such as Wang and de Freitas (2014), that are only stated separately for each t.*

The case when $\lambda = \lambda_\star \overset{\text{def}}{=} \sigma^2/\|f_\star\|^2_{\mathcal{K}}$ is of special interest, since we get on the one hand

$$\begin{aligned} f_{\lambda_\star,t}(x) &= k_t(x)^\top(\mathbf{K_t} + \lambda_\star I_t)^{-1}Y_t \\ s^2_{\lambda_\star,t}(x) &= \|f_\star\|^2_{\mathcal{K}}k_t(x,x) \text{ with } k_t(x,x) = k(x,x) - k_t(x)^\top(\mathbf{K_t} + \lambda_\star I_t)^{-1}k_t(x) \end{aligned}$$

and on the other hand

$$|f_\star(x) - f_{\lambda_\star,t}(x)| \leqslant \|f_\star\|_{\mathcal{K}}\sqrt{k_t(x,x)}\left[1 + \sqrt{2\ln(1/\delta) + 2\gamma_t(\lambda_\star)}\right].$$

In practice however, neither $\|f_\star\|^2_{\mathcal{K}}$ nor σ^2 may be known exactly. In this paper, we make the following assumption on the former:

Assumption 3 (Bounded norm in RKHS) *An upper bound C is given on $\|f_\star\|_{\mathcal{K}}$. This essentially means that the kernel is well chosen for capturing $f_\star$. For more details, see Canu et al. (2009); Loustau (2009); Wasserman (2017).*

Then, we want to build an estimate of σ^2 at each time t in order to tune λ. Using a sequence of regularization parameters $(\lambda_t)_{t\geqslant 1}$ that is tuned adaptively based on the past observations requires to modify the previous result (it is only valid for a deterministic λ) into the following more general statement:

Theorem 2 (Streaming kernel least-squares with online tuning) *Under the same assumption as Theorem 1, let $\boldsymbol{\lambda} = (\lambda_t)_{t\geqslant 1}$ be a predictable positive sequence of parameters, that is λ_t is $\mathcal{H}_{t-1}$-measurable for each t. Assume that for each t, $\lambda_t \geqslant \lambda_\star$ holds for a positive constant $\lambda_\star$. Let us define the modified posterior mean and variances after observing $Y_t \in \mathbb{R}^t$ as*

$$\begin{cases} f_{\boldsymbol{\lambda},t}(x) &= k_t(x)^\top (\mathbf{K}_t + \lambda_{t+1} I_t)^{-1} Y_t \\ s^2_{\boldsymbol{\lambda},t}(x) &= \frac{\sigma^2}{\lambda_{t+1}} k_{\lambda_{t+1},t}(x,x) \text{ with } k_{\lambda,t}(x,x) = k(x,x) - k_t(x)^\top (\mathbf{K}_t + \lambda I_t)^{-1} k_t(x)\,, \end{cases}$$

where $k_t(x) = (k(x,x_{t'}))_{t'\leqslant t}$, and $\mathbf{K}_t = (k(x_s,x_{s'}))_{s,s'\leqslant t}$. Then for all $\delta \in [0,1]$, with probability higher than $1-\delta$, it holds simultaneously over all $x \in \mathcal{X}$ and $t \geqslant 0$

$$|f_\star(x) - f_{\boldsymbol{\lambda},t}(x)| \leqslant \sqrt{\frac{k_{\lambda_{t+1},t}(x,x)}{\lambda_{t+1}}} \left[\sqrt{\lambda_{t+1}}\|f_\star\|_{\mathcal{K}} + \sigma\sqrt{2\ln(1/\delta) + 2\gamma_t(\lambda_\star)}\right].$$

The proof is presented in Appendix A.

The regularization parameter λ_{t+1} is therefore used in conjunction with previous data up to time t to provide the posterior regression model (mean and variance) that is used in return to acquire the next observation y_{t+1} on point x_{t+1}.

Remark 3 *Since λ_t is allowed to be $\mathcal{H}_{t-1}$-measurable, this gives theoretical guarantees for virtually any adaptive tuning procedure of the regularization parameter.*

Remark 4 *The assumption that $\lambda_t \geqslant \lambda_\star$ will be naturally satisfied for the choice of regularization we consider.*

3. Variance estimation

We now focus on the estimation of the variance parameter of the noise in the case when it is unknown, or loosely known. Theorem 2 suggests to define the sequence $(\lambda_t)_{t\geqslant 1}$ by

$$\lambda_t = \sigma^2_{+,t-1}/C^2 \quad \text{with} \quad \sigma_{+,t} = \min\{\tilde{\sigma}_{+,t}, \sigma_{+,t-1}\} \quad \text{and} \quad \sigma_{+,0} = \sigma_+\,, \tag{1}$$

where $\sigma_+ \geqslant \sigma$ is an initial loose upper bound on σ and $\tilde{\sigma}_{+,t}$ is an upper-bound estimate on σ built from all observations gathered up to time t (inclusively). This ensures that λ_t is $\mathcal{H}_{t-1}$ measurable for all t and satisfies $\lambda_t \geqslant \lambda_\star$ with high probability, where $\lambda_\star = \sigma^2/C^2$. The crux is now to define the upper-bound estimate $\sigma_{+,t}$ on σ. In order to get a variance estimate, one obviously requires more than the sub-Gaussian assumption, since the term σ^2 has no reason to be tight (the inequality remains valid when σ^2 is replaced with any larger value). In order to convey the minimality of σ^2, we assume that the noise sequence is both σ-sub-Gaussian and second-order[1] σ-sub-Gaussian, in the sense that

$$\forall t, \forall \gamma < \frac{1}{2\sigma^2} \quad \ln \mathbb{E}\left[\exp(\gamma \xi_t^2) \middle| \mathcal{H}_{t-1}\right] \leqslant -\frac{1}{2}\ln\left(1 - 2\gamma\sigma^2\right).$$

1. The term on the right-hand side corresponds to the cumulant generating function of the chi-squared distribution with 1 degree of freedom. This assumption naturally holds for Gaussian variables.

Remark 5 *To avoid any technicality, one may assume that $\xi_t|\mathcal{H}_{t-1}$ is exactly $\mathcal{N}(0,\sigma^2)$, in which case it is trivially second-order σ-sub-Gaussian.*

Now let $\widehat{\sigma}^2_{\lambda,T} = \frac{1}{T}\sum_{t=1}^T (y_t - f_{\lambda,T}(x_t))^2$ denote the (slightly biased) variance estimate for a regularization parameter λ.

Theorem 3 (Streaming kernel variance estimate) *Assume we are in the predictable second-order σ-sub-Gaussian streaming regression model, with a predictable positive sequence $\boldsymbol{\lambda}$ such that $\lambda_t \geqslant \lambda_\star$ holds for all t. Let us introduce the following quantities*

$$C_t(\delta) = \ln(e/\delta)\left[1 + \ln(\pi^2 \ln(t)/6)/\ln(1/\delta)\right], \qquad D_{\lambda,t}(\delta) = 2\ln(1/\delta) + 2\gamma_t(\lambda)$$
$$\text{and finally} \quad \alpha = \max\left(1 - \sqrt{\tfrac{C_t(\delta')}{t}} - \sqrt{\tfrac{C_t(\delta')+2D_{\lambda_\star,t}(\delta')}{t}}, 0\right).$$

Then, let us introduce the following variance bounds, defined differently depending on whether a deterministic upper bound $\sigma_+ \geqslant \sigma$ is known (case 1) or not (case 2).

$$\sigma_{+,t}(\lambda,\lambda_\star) = \begin{cases} \widehat{\sigma}_{\lambda,t} + \sigma_+\left(\sqrt{\frac{C_t(\delta')}{t}} + \sqrt{\frac{C_t(\delta')+2D_{\lambda_\star,t}(\delta')}{t}}\right) + \sqrt{\frac{2\sigma_+\|f_\star\|_{\mathcal{K}}\sqrt{\lambda D_{\lambda_\star,t}(\delta')}}{t}} & \text{(case 1)} \\ \frac{1}{\alpha^2}\left(\sqrt{\widehat{\sigma}_{\lambda,t}\alpha + \frac{\|f_\star\|_{\mathcal{K}}\sqrt{\lambda D_{\lambda_\star,t}(\delta')}}{2t}} + \sqrt{\frac{\|f_\star\|_{\mathcal{K}}\sqrt{\lambda D_{\lambda_\star,t}(\delta')}}{2t}}\right)^2 & \text{(case 2)} \end{cases}$$

$$\sigma_{-,t}(\lambda) = \begin{cases} \widehat{\sigma}_{\lambda,t} - \sigma_+\sqrt{\frac{2C_t(\delta')}{t}} - \|f_\star\|_{\mathcal{K}}\sqrt{\frac{\lambda}{t}\left(1 - \frac{1}{\max_{t'\leqslant t}(1+\frac{1}{\lambda}k_{\lambda,t'-1}(x_{t'},x_{t'}))}\right)} & \text{(case 1)} \\ \left[\widehat{\sigma}_{\lambda,t} - \|f_\star\|_{\mathcal{K}}\sqrt{\frac{\lambda}{t}\left(1 - \frac{1}{\max_{t'\leqslant t}(1+\frac{1}{\lambda}k_{\lambda,t'-1}(x_{t'},x_{t'}))}\right)}\right]\left(1 + \sqrt{\frac{2C_t(\delta')}{t}}\right)^{-1} & \text{(case 2).} \end{cases}$$

Then with probability higher than $1-3\delta'$, it holds simultaneously for all $t \geqslant 0$

$$\sigma_{-,t}(\lambda_t) \leqslant \sigma \leqslant \sigma_{+,t}(\lambda_t,\lambda_\star)\,.$$

The proof is presented in Appendix B.

Remark 6 *The case when absolutely no bound is known on the noise σ^2 is challenging in practice. In this case, it is intuitive that one should not be able to recover the noise with too few samples. The bound stated in Theorem 3 (see Appendix B) supports this intuition, as when the number of observations is too small, then $\alpha = 0$ and the corresponding bound becomes trivial ($\sigma \leqslant \infty$).*

Remark 7 *In the variance bounds of Theorem 6 the term $\|f_\star\|_{\mathcal{K}}$ appears systematically with the factor $\sqrt{\lambda}$. This suggests we need to choose λ proportional to $1/\|f_\star\|^2_{\mathcal{K}}$, which gives further justification to the target $\lambda_\star = \sigma^2/C^2$, where C is a known upper bound on $\|f_\star\|$.*

Remark 8 *In practice, we advice to choose the best of case 1 and case 2 bounds when $\sigma_+ \geqslant \sigma$ is known.*

Because $\lambda_\star$ is not known in practice, the quantity $\sigma_{+,t}(\lambda_t, \lambda_\star)$ is not computable directly. However, we observe that $\sigma_{+,t}(\lambda_t, \lambda_\star)$ scales with $D_{\lambda_\star,t}$ (directly and through α), and that $D_{\lambda_\star,t}$ scales with the information gain $\gamma_t(\lambda_\star)$. Recall that the information gain scales inversely with the regularization. Hence we have that for any $\lambda_- \leqslant \lambda_\star$, we also have $\sigma_{+,t}(\lambda, \lambda_-) \geqslant \sigma_{+,t}(\lambda, \lambda_\star)$. Therefore, in order to *estimate* the upper bound $\sigma_{+,t}(\lambda, \lambda_\star)$, one only needs a lower-bound on $\lambda_\star$. Let us define

$$\sigma_{-,t} = \max\{\tilde{\sigma}_{-,t}, \sigma_{-,t-1}\} \quad \text{with} \quad \sigma_{-,0} = \sigma_-\,, \tag{2}$$

where $0 \leqslant \sigma_- \leqslant \sigma$ is a initial lower-bound on σ and $\tilde{\sigma}_{-,t}$ is a lower-bound estimate on σ built from all observations gathered up to time t (inclusively). Then, one way to proceed is, at each time step $t \geqslant 1$, to build an estimate $\tilde{\sigma}_{-,t} = \sigma_{-,t}(\lambda)$, which in return can be used to compute the lower quantity $\lambda_- = \sigma^2_{-,t}/C^2 \leqslant \sigma^2/C^2 = \lambda_\star$, and obtain the estimate $\tilde{\sigma}_{+,t} = \sigma_{+,t}(\lambda, \lambda_-) \geqslant \sigma_{+,t}(\lambda, \lambda_\star)$. This "sandwich estimates" procedure allows us to build an upper bound without prior knowledge of $\lambda_\star$, and then compute the predictable sequence $\boldsymbol{\lambda}$ as described by Equation 1. Given Theorem 3, we have that $\sigma_{-,t}(\lambda_t) \leqslant \sigma$ such that $\lambda_- \leqslant \lambda_\star$ and $\sigma_{+,t}(\lambda_t, \lambda_-) \geqslant \sigma$, hence $\lambda_t \geqslant \lambda_\star$, simultaneously for all $t \geqslant 0$, with high probability. Further replacing the variance σ with its estimate $\sigma_{+,t}$ using a union bound in the result of Theorem 2, we derive confidence bounds that are *fully computable empirically* in the context where the regularization parameter is adaptively tuned and the function noise is unknown. This is summarized in the following empirical Bernstein-style inequality:

Corollary 1 (Kernel empirical-Bernstein inequality) *Assume that $C \geqslant \|f_\star\|_{\mathcal{K}}$. Let us define the following noise lower-bound for each $t \geqslant 1$*

$$\sigma_{-,t} = \max\{\sigma_{-,t}(\lambda_{t-1}), \sigma_{-,t-1}\}$$

and define $\lambda_- = \sigma^2_{-,t}/C^2$ as the corresponding lower bound on $\lambda_\star$. Then, let us define the following noise upper bound for each $t \geqslant 1$

$$\sigma_{+,t} = \min\{\sigma_{+,t}(\lambda_{t-1}, \lambda_-), \sigma_{+,t-1}\}\,.$$

Define the regularization parameterizing the regression model used for acquiring observation at time t to be $\lambda_t = \sigma^2_{+,t}/C^2$, according to Equation 1. Then with probability higher than $1 - 4\delta$, the following is valid simultaneously for all $x \in \mathcal{X}$ and $t \geqslant 0$,

$$\big|f_\star(x) - f_{\lambda_t,t}(x)\big| \leqslant \sqrt{\frac{k_{\lambda_t,t}(x,x)}{\lambda_t}}\, B_{\lambda_t,t}(\delta) \qquad \textit{where}$$

$$B_{\lambda_t,t}(\delta) = \sqrt{\lambda_t}C + \sigma_{+,t}\sqrt{2\ln(1/\delta) + 2\gamma_t(\lambda_-)}\,. \tag{3}$$

Proof Let E_f denote the event that

$$|f_\star(x) - f_{\boldsymbol{\lambda},t}(x)| \leqslant \sqrt{\frac{k_{\lambda_{t+1},t}(x,x)}{\lambda_{t+1}}}\Big[\sqrt{\lambda_{t+1}}\|f_\star\|_{\mathcal{K}} + \sigma\sqrt{2\ln(1/\delta) + 2\gamma_t(\lambda_\star)}\Big]$$

simultaneously for all $x \in \mathcal{X}$ and $t \geqslant 0$, and let $E_{\boldsymbol{\lambda}}$ denote the event that $\lambda_t \geqslant \lambda_\star$ holds for all t. We can decompose

$$\mathbb{P}[E_f^c] \leqslant \mathbb{P}[E_f^c \cap E_{\boldsymbol{\lambda}}] + \mathbb{P}[E_f^c \cap E_{\boldsymbol{\lambda}}^c] \leqslant \mathbb{P}[E_f^c \cap E_{\boldsymbol{\lambda}}] + \mathbb{P}[E_{\boldsymbol{\lambda}}^c]$$

By Theorem 2, we have that $\mathbb{P}[E_f^c \cap E_{\boldsymbol{\lambda}}] \leqslant \delta$. We need to show that $\lambda_t \geqslant \lambda_\star$ for all $t \geqslant 0$ by tuning λ_t with the proposed procedure. Let us look at what happens at each time t. Using the proposed procedure, we have $\lambda_0 = \sigma^2_+/C^2 \geqslant \lambda_\star$. Then we have

$$\begin{aligned}
\sigma_{-,1}(\lambda_0) &\leqslant \sigma \quad \text{L1}\\
\sigma_{+,1}(\lambda_0, \sigma_{-,1}(\lambda_0)^2/C^2) &\geqslant \sigma \quad \text{U1}\\
\to \lambda_1 = \sigma_{+,1}(\lambda_0, \sigma_{-,1}(\lambda_0)^2/C^2)^2/C^2 &\geqslant \lambda_\star\\
\sigma_{-,2}(\lambda_1) &\leqslant \sigma \quad \text{L2}\\
\sigma_{+,2}(\lambda_1, \sigma_{-,2}(\lambda_1)^2/C^2) &\geqslant \sigma \quad \text{U2}\\
\to \lambda_2 = \sigma_{+,2}(\lambda_1, \sigma_{-,1}(\lambda_1)^2/C^2)^2/C^2 &\geqslant \lambda_\star\\
&\dots
\end{aligned}$$

such that $E_{\boldsymbol{\lambda}}$ holds given that steps L1, U1, L2, U2, ... hold simultaneously. Therefore, $\mathbb{P}[E_{\boldsymbol{\lambda}}^c]$ is bounded by the probability that these steps do not hold simultaneously. Following Theorem 3, we have that $\mathbb{P}[E_{\boldsymbol{\lambda}}^c] \leqslant 3\delta$ and thus $\mathbb{P}[E_f^c] \leqslant 4\delta$. Naturally, under the event $E_{\boldsymbol{\lambda}}$, we have $\sigma_{+,t} \geqslant \sigma$ and $\lambda_- \leqslant \lambda_\star$. Therefore, given $C \geqslant \|f_\star\|_{\mathcal{K}}$, we have

$$\sqrt{\lambda_{t+1}}\|f_\star\|_{\mathcal{K}} + \sigma\sqrt{2\ln(1/\delta) + 2\gamma_t(\lambda_\star)} \leqslant \sqrt{\lambda_{t+1}}C + \sigma_{+,t}\sqrt{2\ln(1/\delta) + 2\gamma_t(\lambda_-)}.$$

■

Remark 9 *This result is especially interesting since it provides a fully empirical confidence envelope function around $f_\star$. When an initial bound on the noise σ_+ is known and considered to be tight, one may simply choose the constant deterministic sequence $\boldsymbol{\lambda} = (\lambda, \dots, \lambda)$, in which case the same result holds for $\lambda_- = \lambda$ and $\sigma_{+,t} = \sigma_+$.*

We observe from Theorem 3 that the tightness of the noise estimates depends on the λ parameter that is used for computing $\tilde{\sigma}_{-,t}$ and $\tilde{\sigma}_{+,t}$. Since $\sigma^2/C^2 \leqslant \lambda_t \leqslant \sigma^2_+/C^2$ holds with high probability by construction, using such an adaptive λ_t should yield tighter bounds than using a fixed σ^2_+/C^2. This is supported by the numerical experiments of Section 6.2.

4. Application to kernelized bandits

Here is a direct application of our results in the framework of stochastic multi-armed bandits with structured arms embedded in an RKHS (Srinivas et al., 2010; Valko et al., 2013). At each time step $t \geqslant 1$, a bandit algorithm recommends a point x_t to sample from a compact set $\mathbb{X} \subseteq \mathcal{X}$, and observes a noisy outcome $y_t = f_\star(x_t) + \xi_t$, where $\xi_t \sim \mathcal{N}(0, \sigma^2)$. Let $x_\star = \operatorname{argmax}_{x \in \mathbb{X}} f_\star(x)$ denote the optimal arm. The goal of an algorithm is to pick a sequence of points $(x_t)_{t \leqslant T}$ that minimizes the cumulative regret

$$\mathfrak{R}_T = \sum_{t=1}^{T} f_\star(x_\star) - f_\star(x_t). \tag{4}$$

In this context, one needs to build tight confidence sets on the mean of each arm, and this will be given by Corollary 1. We illustrate our technique on two main bandit strategies: Upper Confidence Bound (UCB) (Auer et al., 2002) and Thompson Sampling (TS) (Thompson, 1933); both are adapted here to the kernel setting with unknown variance.

The following extension of Lemma 7 from Wang and de Freitas (2014) (see also Srinivas et al. (2012)) to the case when the variance is estimated plays an important role in the regret analysis of both algorithms.

Lemma 1 (From sum of variances to information gain) *Let us assume that the kernel is bounded by 1 in the sense that* $\sup_{x\in\mathcal{X}} k(x,x) \leqslant 1$. *Let* $\boldsymbol{\lambda}$ *be any sequence such that* $\forall \lambda \in \boldsymbol{\lambda}, \lambda \geqslant \sigma^2/C^2$. *For instance, this is satisfied with high probability when using Equation 1. Then, it holds*

$$\sum_{t=1}^{T} s^2_{\boldsymbol{\lambda},t-1}(x_t) = \sigma^2 \sum_{t=1}^{T} \frac{1}{\lambda_t} k_{\lambda_t,t-1}(x_t,x_t) \leqslant \frac{2C^2}{\ln(1+C^2/\sigma^2)} \gamma_T(\sigma^2/C^2)\,.$$

In the sequel, it is useful to bound the confidence bound term $B_{\lambda_t,t}(\delta)$ from Equation 3.

Lemma 2 (Deterministic bound on the confidence bound) *Assume that we are given a constant* $0 < \sigma_- < \sigma$, *so that* $\sigma_{t,-} \geqslant \sigma_-$ *holds for all* t. *Then for all* $t \leqslant T$, *the confidence bound term is upper-bounded by the following deterministic quantity*

$$B_{\lambda_t,t}(\delta) \leqslant \sigma_+ \left(1 + \sqrt{2\ln(1/\delta) + 2\gamma_T(\sigma^2_-/C^2)}\right).$$

Further, we have $\gamma_t(\sigma^2_{t,-}/C^2) = \gamma_t(\sigma^2_-/C^2) + O(1/\sqrt{t})$.

Remark 10 *The term* σ_+ *can be replaced with a more refined term* $\sigma + O(1/\sqrt{t})$ *thanks to the confidence bounds on the variance estimates.*

Kernel UCB with unknown variance The upper bound on the error can be used directly in order to build a UCB-style algorithm. Formally, the vanilla UCB algorithm (Auer et al., 2002) corresponding to our setting picks at time t the arm

$$x_t \in \operatorname*{argmax}_{x\in\mathbb{X}} f^+_{\lambda_t,t-1}(x) \quad \text{where} \quad f^+_{\lambda,t}(x) = f_{\lambda,t}(x) + \sqrt{\frac{k_{\lambda,t}(x,x)}{\lambda}} B_{\lambda,t}(\delta)\,. \tag{5}$$

Following the regret proof strategy of Abbasi-Yadkori et al. (2011), with some minor modifications, yields the following guarantee on the regret of this strategy:

Theorem 4 (Kernel UCB with unknown noise and adaptive regularization) *With probability higher than* $1-\delta$, *the regret of Kernel UCB with adaptive regularization and variance estimation satisfies for all* $T \geqslant 0$ *(recall that* $B_{\lambda_{t+1},t}(\delta)$ *is defined in Equation 3):*

$$\mathfrak{R}_T \leqslant 2\sum_{t=1}^{T} \sqrt{\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}} B_{\lambda_t,t-1}(\delta/4)\,.$$

In particular, we have

$$\mathfrak{R}_T \;\leqslant\; 2\frac{\sigma_+}{\sigma}\Big(1 + \sqrt{2\ln(4/\delta) + 2\gamma_T(\sigma^2_-/C^2)}\Big) C \sqrt{T \frac{2\gamma_T(\sigma^2/C^2)}{\ln(1+C^2/\sigma^2)}}\,.$$

Remark 11 *This result that holds simultaneously over all time horizon* T *extends that of Abbasi-Yadkori et al. (2011) first to kernel regression and then to the case when the variance of the noise is unknown. This should also be compared to Valko et al. (2013) that assumes bounded observations, which implies a bounded noise (with known bound) and a bounded* $f_\star$, *and Srinivas et al. (2010) that provides looser bounds.*

Kernel TS with unknown variance Another application of our confidence bounds is in the analysis of Thompson sampling in the kernel scenario. Before presenting the result, let us say a few words about the design of TS algorithm in a kernel setting. Such an algorithm requires sampling from a posterior distribution over the arms. It is natural to consider a Gaussian posterior with posterior means and variances given by the kernel estimates. However, it has been noted in a series of papers (Agrawal and Goyal, 2013; Abeille and Lazaric, 2017) that, in order to obtain provable regret minimization guarantees, the posterior variance should be inflated (although in practice, the vanilla version without inflation may work better). Following these lines of research, and owing to our novel confidence bounds, we derive the following TS algorithm using a posterior variance inflation factor v_t^2.

Algorithm 1 Kernel TS with adaptive variance estimation and regularization tuning.

Input: discrete space $\mathbb{X}$.

Parameters: regularization sequence $\boldsymbol{\lambda}$, variance inflation factor v_t^2 for each t.

for all $t \geqslant 1$ **do**
  compute the posterior mean $\widehat{\mathbf{f}}_{t-1} = (f_{\lambda_t,t-1}(x))_{x\in\mathbb{X}}$
  compute the posterior covariance $\widehat{\boldsymbol{\Sigma}}_{t-1} = \frac{\sigma^2_{+,t-1}}{\lambda_t}\big(k_{\lambda_t,t-1}(x,x')\big)_{x,x'\in\mathbb{X}}$
  sample $\tilde{f}_t = \mathcal{N}(\widehat{\mathbf{f}}_{t-1}, v_t^2\widehat{\boldsymbol{\Sigma}}_{t-1})$
  play $x_t = \operatorname{argmax}_{x\in\mathbb{X}} \tilde{f}_t(x)$
  observe outcome $y_t = f_\star(x_t) + \xi_t$
end for

Remark 12 *The algorithm does not know the variance* σ^2 *of the noise, but uses an upper estimate* $\sigma^2_{+,t-1}$.

Remark 13 *We assume that the set of arms* $\mathbb{X}$ *is* discrete. *This is merely for practical reasons since otherwise updating the estimate of* $f_\star$ *in a RKHS requires memory and computational times that are unbounded with* t. *This also simplifies the analysis.*

The following regret bound can then be obtained after some careful but easy adaptation of Agrawal and Goyal (2013). We provide the proof of this result in Appendix C, which can be of independent interest, being a more rigorous and somewhat simpler rewriting of the original proof technique from Agrawal and Goyal (2013).

Theorem 5 (Regularized Kernel TS with variance estimate) *Assume that the maximal instantaneous pseudo-regret* $R = \max_{x\in\mathbb{X}}\big(f_\star(x_\star) - f_\star(x)\big)$ *is finite. Then, the regret of Kernel TS (Algorithm 1) with* $v_t = \frac{B_{\lambda_t,t-1}(\delta/4)}{\sigma_{+,t-1}}$ *after* T *episodes is* $\mathcal{O}(C\sqrt{T\ln(T|\mathbb{X}|)}\gamma_T(\sigma^2/C^2))$

with probability $1-3\delta$. *More precisely, with probability* $1-3\delta$, *the regret is bounded for all* $T \geqslant 0$:

$$\mathfrak{R}_T \;\leqslant\; C_{1,T}\Bigg(\sum_{t=1}^{T}\sqrt{\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}}B_{\lambda_t,t-1}(\delta/4)\Bigg) + C_2R\sqrt{T\ln(1/\delta)} + 4\pi eR\delta\,,$$

where $C_{1,T} = (4\sqrt{\pi e}+1)\Big(1+\sqrt{2\ln\Big(\frac{T(T+1)|\mathbb{X}|}{\sqrt{\pi}\delta}\Big)}\Big)$ *and* $C_2 = \sqrt{8\pi e(1+\delta\sqrt{4\pi e})^2}$.

Further, we have

$$\mathfrak{R}_T \;\leqslant\; C_{1,T}\frac{\sigma_+}{\sigma}\Big(1+\sqrt{2\ln(4/\delta)+2\gamma_T(\sigma_-^2/C^2)}\Big)C\sqrt{T\frac{2\gamma_T(\sigma^2/C^2)}{\ln(1+C^2/\sigma^2)}} + C_2R\sqrt{T\ln(1/\delta)} + 4\pi eR\delta\,.$$

Remark 14 *As our confidence intervals do not require a bounded noise, likewise we can control the regret with high probability without requiring bounded observations, contrary to earlier works such as Valko et al. (2013).*

5. Discussion and related works

Concentration results Theorem 1 extends the self-normalized bounds of Abbasi-Yadkori et al. (2011) from the setting of linear function spaces to that of an RKHS with sub-Gaussian noise. Based on a nontrivial adaptation of the Laplace method, it yields self-normalized inequalities in a setting of possibly infinite dimension. It generalizes the following result of Wang and de Freitas (2014) to kernel regression with $\lambda \neq \sigma^2$, which was already a generalization of a previous result by Srinivas et al. (2010) for bounded noise. It is also more general than the concentration result from Valko et al. (2013), for kernel regression with $\lambda \neq \sigma^2$, which holds *under the assumption of bounded observations.*

Lemma 3 (Proposition 1 from Wang and de Freitas (2014)) *Let* $f_\star$ *denote a function in the RKHS* $\mathcal{K}$ *induced by kernel* k *and let us define the posterior mean and variances with* $\lambda = \sigma^2$, *for (arbitrary) data* $(x_{t'})_{t'\leqslant t}$. *Assuming* σ*-sub-Gaussian noise variables, then for all* $\delta' \in (0,1)$ *we have that*

$$\mathbb{P}\big[\exists x \in \mathcal{X} : |f_{\lambda,t}(x) - f_\star(x)| \geqslant \ell_{\lambda,t+1}(\delta')k_{\lambda,t}^{1/2}(x,x)\big] \leqslant \delta', \quad \textit{where}$$

$$\ell_{\lambda,t}^2(\delta') = \|f_\star\|_{\mathcal{K}}^2 + \sqrt{8\gamma_{t-1}(\lambda)\ln\frac{2}{\delta'}} + \sqrt{2\ln\frac{4}{\delta'}}\|f_\star\|_{\mathcal{K}} + 2\gamma_{t-1}(\lambda) + 2\sigma\ln\frac{2}{\delta'}$$

and $\gamma_t(\lambda) = \frac{1}{2}\sum_{t'=1}^{t}\ln\big(1+\frac{1}{\lambda}k_{\lambda,t'-1}(x_{t'},x_{t'})\big)$ *is the information gain.*

Remark 15 *This results provides a bound that is valid for each* t, *with probability higher than* $1-\delta$. *In contrast, results from Abbasi-Yadkori et al. (2011), as well as Theorem 1 hold with probability higher than* $1-\delta$, *uniformly for all* t, *and are thus much stronger in this sense.*

Theorem 2 extends Theorem 1 to the case when *the regularization is tuned online* based on gathered observations. To the best of our knowledge, no such result exists in the literature at the time of writing this paper. Moreover, Theorem 3 provides variance estimates with confidence bounds scaling with $1/\sqrt{t}$, in the spirit of the results from Maurer and Pontil (2009), that were provided in the i.i.d. case. Thus, Theorem 3 also appears to be new. Finally, Corollary 1 further specifies Theorem 2 to the situation where the regularization is tuned according to Theorem 3, yielding a fully adaptive regularization procedure with explicit confidence bounds.

Bandits optimization When applied to the setting of multi-armed bandits, Theorems 5 and 4 respectively extend linear TS (Agrawal and Goyal, 2013; Abeille and Lazaric, 2017) and UCB (Li et al., 2010; Chu et al., 2011) to the RKHS setting. Similar extensions have been provided in the literature: GP-UCB (Srinivas et al., 2010) generalizes UCB from the linear to the RKHS setting through the use of Gaussian processes; this corresponds to the case when $\lambda = \sigma^2$. The bounds they provide in the case when the target function belongs to an RKHS is however quite loose. KernelUCB (Valko et al., 2013) also generalizes UCB from the linear to the RKHS setting through the use of kernel regression. However the analysis of this algorithm was out of reach of their proof technique (that requires independence between arms) and they analyze instead the arguably less appealing variant called SupKernelUCB. Also, the analysis of both GP-UCB and SupKernelUCB in the agnostic setting are respectively limited to bounded noise and bounded observations.

6. Illustrative numerical experiments

In this section, we illustrate the results introduced in the previous Sections 2 and 3 on a few examples. The first one is the concentration result on the mean from Theorem 1, the second one is the variance estimate from Theorem 3, and the last one combines the formers by using the noise estimate to tune $\lambda_{t+1} = \sigma_t^2/C^2$ in Theorem 2, which corresponds to Corollary 1. We finally show the performance of kernelized bandits techniques using the provided variance estimates and adaptative regularization schemes.

We conduct the experiments using the function $f_\star$ shown by Figure 1, which has norm $\|f_\star\|_{\mathcal{K}} = \|\theta_\star\|_2 = 2.06$ in the RKHS induced by a Gaussian kernel $\quad k(x,x') = e^{-\frac{(x-x')^2}{2\rho^2}}$ with length scale $\rho = 0.3$. This function results from the linear product between features $\varphi(x)$, explicited using a Taylor expansion[2], and a randomly generated parameter vector $\theta_\star$. We consider the space $\mathcal{X} = [0,1]$ and zero-centered Gaussian noise with $\sigma = 0.1$. All further experiments use the upper-bound $C = 5$ on $\|f_\star\|_{\mathcal{K}}$ and the lower-bound $\sigma_- = 0.01$ on σ.

6.1 Kernel concentration bound with fixed regularization

The following experiments compare the concentration result given by Theorem 1 with the kernel concentration bounds from Wang and de Freitas (2014) reported by Lemma 3. The true noise $\sigma = 0.1$ is assumed to be known and all observations are uniformly sampled from $\mathcal{X}$. In both cases, we use a fixed confidence level $\delta = 0.1$. Figure 2 shows that for $\lambda = \sigma^2$, the

2. If $x \in \mathbb{R}$, the i-th feature of a Gaussian kernel $\varphi(x) = e^{-\frac{x^2}{2\rho^2}}\frac{x^{i-1}}{\rho^{i-1}\sqrt{(i-1)!}}$ (Cotter et al., 2011).

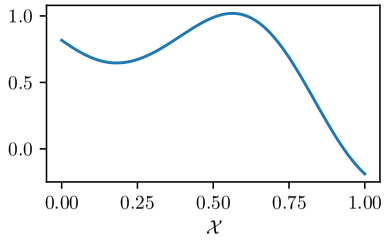

Figure 1: Test function $f_\star$ used in the following numerical experiments.

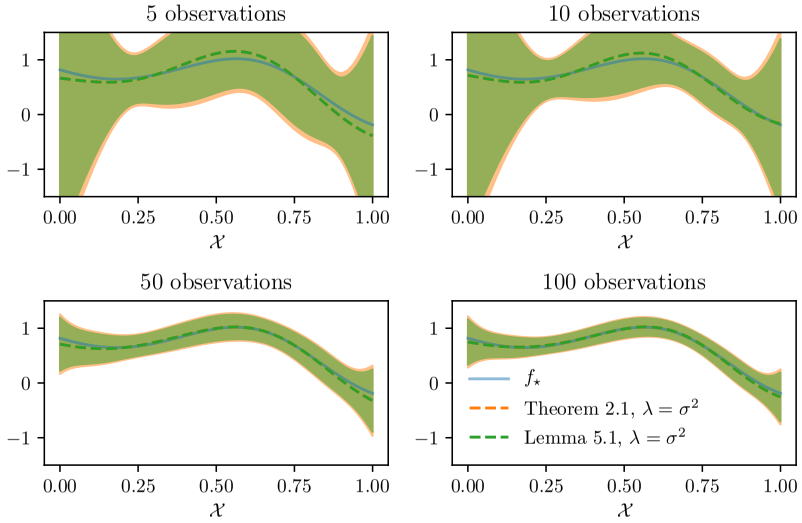

Figure 2: Confidence interval of Theorem 1 and Lemma 3 (Wang and de Freitas, 2014).

result given by Theorem 1 recovers the confidence envelope of Wang and de Freitas (2014). Note however that the confidence bound that we plot for Theorem 1 are valid *uniformly* over all time steps, while the one derived from Wang and de Freitas (2014) is only valid separately for each time. Further, Theorem 1 generalizes the latter result to the case where $\lambda \neq \sigma^2$. For illustration, Figure 3 illustrates the confidence envelopes in the special case where $\lambda = \sigma^2/C^2$, which also shows the potential benefit of such a tuning.

6.2 Empirical variance estimate

We now illustrate the convergence rate of the noise estimates $\sigma_{-,t} = \max\{\sigma_{-,t}(\lambda), \sigma_{-,t-1}\}$ and $\sigma_{+,t} = \min\{\sigma_{+,t}(\lambda, \lambda_-), \sigma_{+,t-1}\}$ computed using Theorem 3, where $\lambda_- = \sigma^2_{-,t}/C^2$

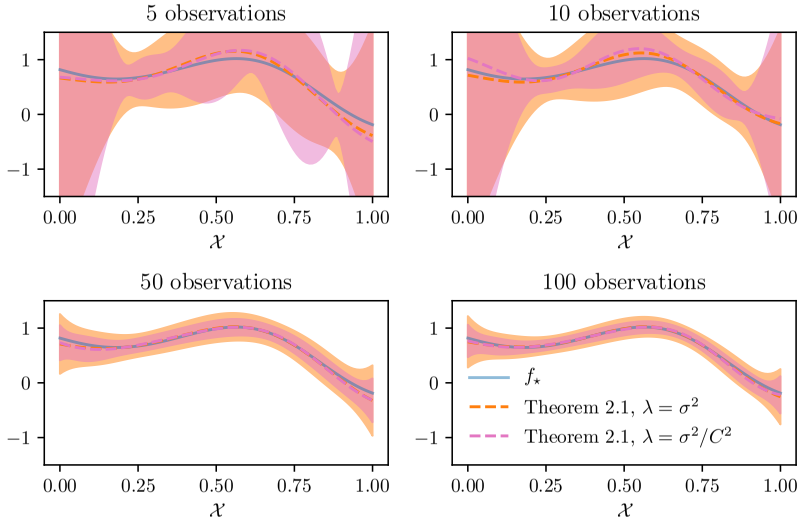

Figure 3: Confidence interval of Theorem 1 for different λ.

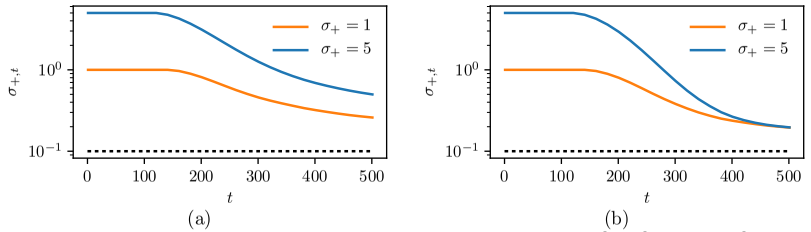

Figure 4: Noise estimate from Theorem 3 with σ_+ for a) fixed $\lambda = \sigma_+^2/C^2$; b) $\lambda = \sigma^2_{+,t-1}/C^2$. Dotted line indicates σ.

and $\delta = 0.1$. All observations are uniformly sampled from $\mathcal{X}$. Section 3 suggests that $\lambda = \sigma^2_{+,t-1}/C^2$ should provide tighter bounds than a fixed $\lambda = \sigma_+^2/C^2$. Figure 4 shows that this is indeed the case especially for large values of t. We also see that the adaptive update of λ converges to the same value, whatever the initial bound σ_+. This is especially interesting when σ_+ is a loose initial upper bound on σ.

In practice, the bound of Theorem 3 not using the knowledge of σ_+ may be useful even when σ_+ is known. This is illustrated by Figure 5a that plots the upper-bound variance estimate $\sigma_{+,t}(\lambda, \lambda_-)$ for $\lambda = \sigma^2_{+,t-1}/C^2$ in both cases. In practice, we suggest to use the minimum of the bound using the knowledge of σ_+ (case 1) and of the agnostic one (case 2) to

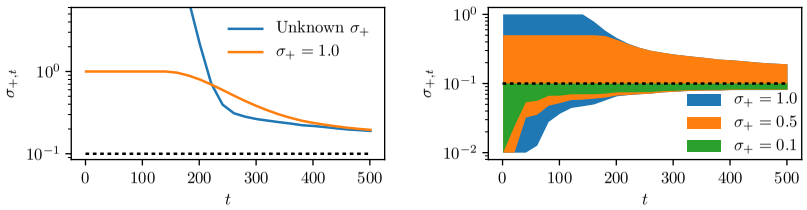

Figure 5: Variance estimate a) from Theorem 3, with and without σ_+; b) as minimum of the bounds and σ_+, for different upper-bounds. Dotted line indicates σ.

set $\sigma_{+,t}(\lambda, \lambda_-)$ and the maximum for $\sigma_{-,t}(\lambda)$. Figure 5b shows the resulting noise estimate envelopes for different σ_+ values (recall that $\sigma = 0.1$).

6.3 Kernel concentration bound with adaptive regularization

We now combine the previous experiments and use the estimated noise in order to tune the regularization. Recall that we consider $\sigma_{-,0} = \sigma_-$, $\sigma_{+,0} = \sigma_+$, and $\lambda_0 = \sigma_+^2/C^2$. On each time $t \geqslant 1$, we estimate the noise lower-bound $\sigma_{-,t} = \max\{\sigma_{-,t}(\lambda_{t-1}), \sigma_{-,t-1}\}$ using Theorem 3 and set $\lambda_- = \sigma_{-,t}^2/C^2$. We then compute the upper-bound noise estimate $\sigma_{+,t} = \min\{\sigma_{+,t}(\lambda_{t-1}, \lambda_-), \sigma_{+,t-1}\}$ using Theorem 3 and set $\lambda_t = \sigma_{+,t}^2/C^2$. We are now ready to compute the confidence interval given by Corollary 1. Note that $\delta = 0.1$ is used everywhere and all observations are uniformely sampled from $\mathcal{X}$. Figure 6 illustrates the resulting confidence envelope of this fully empirical model for noise upper-bound $\sigma_+ = 1$ (recall that the noise satisfies $\sigma = 0.1$) plotted against the confidence envelope obtained with Theorem 1 with fixed $\lambda = \sigma_+^2/C^2$. We observe the improvement of the confidence intervals with the number of observations. Recall that this setting is especially challenging since the variance is unknown, the regularization parameter is tuned online, and the confidence bounds are valid uniformly over all time steps.

6.4 Kernelized bandits optimization

In this section, we now evaluate the potential of kernelized bandits algorithms with variance estimate. We consider $\mathbb{X}$ as the linearly discretized space $\mathcal{X} = [0, 1]$ into 100 arms. Recall that the goal is to minimize the cumulative regret (Equation 4) and that we are optimizing the function shown by Figure 1 with $\sigma = 0.1$. We evaluate Kernel UCB (Equation 5) and Kernel TS (Algorithm 1 with $v_t = B_{\lambda_t, t-1}(\delta)/\sigma_{+,t-1}$) with three different configurations:

a) the oracle, that is with fixed $\lambda_t = \sigma^2/C^2$, assuming knowledge of σ;
b) the fixed $\lambda_t = \sigma_+^2/C^2$, that is the best one can do without prior knowledge of σ^2;
c) the adaptative regularization tuned with Corollary 1.

All configurations use $C = 5$. Kernel UCB uses $\delta = 0.1/4$ and Kernel TS uses $\delta = 0.1/12$ such that their regret bounds respectively hold with probability 0.9. Recall that observations are now sampled from $\mathbb{X}$ using the bandits algorithms (they are not i.i.d.). Configurations b) and c) use $\sigma_+ = 1$, while the oracle a) uses $\sigma_+ = \sigma$. Figure 7 shows the cumulative regret

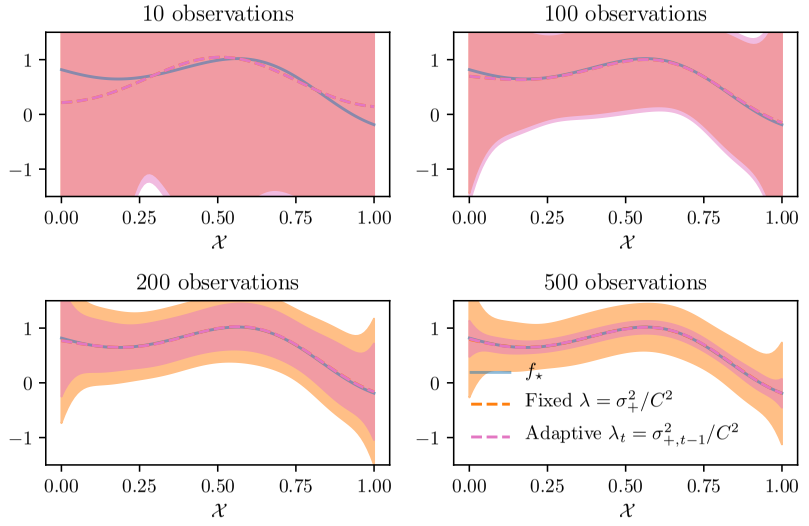

Figure 6: Confidence interval using fixed (Theorem 1) and adaptive (Corollary 1) regularization, for $\sigma_+ = 1$ and $\delta = 0.1$.

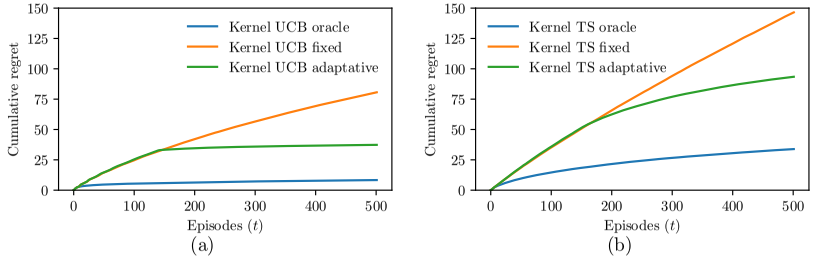

Figure 7: Averaged cumulative regret along episodes for a) Kernel UCB and b) Kernel TS.

averaged over 100 repetitions. Note that the oracle corresponds to the best performance that could be expected by Kernel UCB and Kernel TS given knowledge of the noise. The plots confirm that adaptively tuning the regularization using the variance estimates can lead to a major improvement compared to using a fixed, non-accurate guess: after an initial burn-in phase, the regret of the adaptively tuned algorithm increases at the same rate as that of the oracle algorithm knowing the noise exactly. The fact that Kernel UCB outperforms Kernel TS much implies that inflating the variance in Kernel TS, as suggested per the theory presented previously, may not be optimal in practice. Further attention should be given to this question.

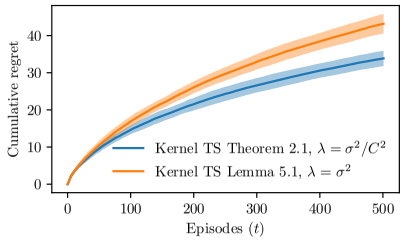

Figure 8: Averaged cumulative regret and one standard deviation along episodes for Kernel TS oracle with Theorem 1 and Lemma 3 (Wang and de Freitas, 2014).

In order to evaluate the benefit of the concentration bound provided by Theorem 1, we compare the Kernel TS (Algorithm 1) oracle using $v_t = B_{\lambda,t-1}/\sigma$ and $\lambda = \sigma^2/C^2$, where $B_{\lambda,t-1}$ is given by Theorem 1, against $v_t = \ell_t(\delta)$ where $\ell_t(\delta)$ is given by Lemma 3 (Wang and de Freitas, 2014) with $\delta = 0.1$. Figure 8 shows that the concentration bound given by Theorem 1 improves the performance of Kernel TS compared with existing concentration results (Wang and de Freitas, 2014). It highlights the relevance of expliciting the regularization parameter, which allows us to take advantage of regularization rates that may be better adapted.

7. Conclusion

This work addresses two problems: the online tuning of the regularization parameter in streaming kernel regression and the online estimation of the noise variance. To this extent, we introduce novel concentration bounds on the posterior mean estimate in streaming kernel regression with fixed and explicit regularization (Theorem 1), which we then extend to the setting where the regularization parameter is tuned (Theorem 2). We further introduce upper- and lower-bound estimates of the noise variance (Theorem 3). Putting these tools together, we show how the estimate of the noise variance can be used to tune the kernel regularization in an online fashion (Corollary 1) while retaining theoretical guarantees. We also show how to use the proposed results in order to derive kernelized variations of the most common bandits algorithms UCB and Thompson sampling, for which regret bounds are also provided (Theorems 4 and 5).

All the proposed results and tools are illustrated through numerical experiments. The obtained results show the relevance of the introduced kernel regression concentration intervals for explicit regularization, which hold when the regularization does not correspond to the noise variance. The potential of the proposed regularization tuning procedure is illustrated through the application to kernelized bandits, where the benefits of adaptive regularization is undeniable when the noise variance is unknown (this is usually the case in practice). Finally, one must note that a major strength of the tools proposed in this work is to allow for an adaptively tuned regularization parameter while preserving theoretical guarantees, which is not the case when regularization is tuned for example by cross-validation.

Future work includes a natural extension of these techniques to obtain an empirical estimate of the kernel length scales. This information is often assumed to be known, while in practice it is often not available. Although some preliminary work has been done in that direction (Wang and de Freitas, 2014), designing theoretically motivated algorithms addressing these concerns would help to fill an important gap between theory and practice. On a different matter, the current work gives the basis for performing Thompson sampling in RKHS, and could be extended to the contextual setting in a near future, as was done with CGP-UCB (Krause and Ong, 2011; Valko et al., 2013).

Appendix A. Laplace method for tuned kernel regression

In this section, we want to control the term $|f_{\lambda,t}(x) - f_\star(x)|$ simultaneously over all $t \leqslant T$. To this end, we resort to a version of the Laplace method carefully extended to the RKHS setting.

Before proceeding, we note that since $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a kernel function (that is continuous, symmetric positive definite) on a compact set $\mathcal{X}$ equipped with a positive finite Borel measure μ, then there is an at most countable sequence $(\sigma_i, \psi_i)_{i\in\mathbb{N}^\star}$ where $\sigma_i \geqslant 0$, $\lim_{i\to\infty} \sigma_i = 0$ and $\{\psi_i\}$ form an orthonormal basis of $L_{2,\mu}(\mathcal{X})$, such that

$$k(x,y) = \sum_{j=1}^{\infty} \sigma_j \psi_j(x)\psi_j(y') \quad \text{and} \quad \|f_\star\|_{\mathcal{K}}^2 = \sum_{j=1}^{\infty} \frac{\langle f, \psi_j\rangle_{L_{2,\mu}}^2}{\sigma_j}$$

Let $\varphi_i = \sqrt{\sigma_i}\psi_i$. Note that $\|\varphi_i\|_{L_2} = \sqrt{\sigma_i}$, $\|\varphi_i\|_{\mathcal{K}} = 1$. Further, if $f = \sum_i \theta_i\varphi_i$, then $\|f_\star\|_{\mathcal{K}}^2 = \sum_i \theta_i^2$ and $\|f_\star\|_{L_2}^2 = \sum_i \theta_i^2\sigma_i$. In particular f belongs to the RKHS if and only if $\sum_i \theta_i^2 < \infty$. For $\varphi(x) = (\varphi_1(x), \dots)$ and $\theta = (\theta_1, \dots)$, we now denote $\theta^\top\varphi(x)$ for $\sum_{i\in\mathbb{N}} \theta_i\varphi_i(x)$, by analogy with the finite dimensional case. Note that $k(x,y) = \varphi(x)^\top\varphi(y)$.

In the sequel, the following Martingale control will be a key component of the analysis.

Lemma 4 (Hilbert Martingale Control) *Assume that the noise sequence $\{\xi_t\}_{t=0}^{\infty}$ is conditionally σ^2-sub-Gaussian*

$$\forall t \in \mathbb{N}, \forall \gamma \in \mathbb{R}, \quad \ln \mathbb{E}[\exp(\gamma\xi_t)|\mathcal{H}_{t-1}] \leqslant \frac{\gamma^2\sigma^2}{2}\,.$$

Let τ be a stopping time with respect to the filtration $\{\mathcal{H}_t\}_{t=0}^{\infty}$ generated by the variables $\{x_t, \xi_t\}_{t=0}^{\infty}$. For any $\mathbf{q} = (q_1, q_2, \dots)$ such that $\mathbf{q}^\top \varphi_i(x) = \sum_{i\in\mathbb{N}} q_i \varphi(x) < \infty$, and deterministic positive λ, let us denote

$$M_{m,\lambda}^{\mathbf{q}} = \exp\left(\sum_{t=1}^{m} \frac{\mathbf{q}^\top \varphi(x_t)}{\sqrt{\lambda}}\xi_t - \frac{\sigma^2}{2}\sum_{t=1}^{m}\frac{(\mathbf{q}^\top\varphi(x_t))^2}{\lambda}\right)$$

Then, for all such $\mathbf{q}$ the quantity $M_{\tau,\lambda}^{\mathbf{q}}$ is well defined and satisfies

$$\ln \mathbb{E}[M_{\tau,\lambda}^{\mathbf{q}}] \leqslant 0\,.$$

Proof The only difficulty in the proof is to handle the stopping time. Indeed, for all $m \in \mathbb{N}$, thanks to the conditional R-sub-Gaussian property, it is immediate to show that $\{M_{m,\lambda}^{\mathbf{q}}\}_{m=0}^{\infty}$ is a non-negative super-martingale and actually satisfies $\ln \mathbb{E}[M_{m,\lambda}^{\mathbf{q}}] \leqslant 0$.

By the convergence theorem for nonnegative super-martingales, $M_{\infty}^{\mathbf{q}} = \lim_{m\to\infty} M_{m,\lambda}^{\mathbf{q}}$ is almost surely well-defined, and thus $M_{\tau,\lambda}^{\mathbf{q}}$ is well-defined (whether $\tau < \infty$ or not) as well. In order to show that $\ln \mathbb{E}[M_{\tau,\lambda}^{\mathbf{q}}] \leqslant 0$, we introduce a stopped version $Q_m^{\mathbf{q}} = M_{\min\{\tau,m\},\lambda}^{\mathbf{q}}$ of $\{M_{m,\lambda}^{\mathbf{q}}\}_m$. Now $\mathbb{E}[M_{\tau,\lambda}^{\mathbf{q}}] = \mathbb{E}[\liminf_{m\to\infty} Q_m^{\mathbf{q}}] \leqslant \liminf_{m\to\infty} \mathbb{E}[Q_m^{\mathbf{q}}] \leqslant 1$ by Fatou's lemma, which concludes the proof. We refer to (Abbasi-Yadkori et al., 2011) for further details. ■

We are now ready to prove the following result.

Proof of Theorem 2 (Streaming Kernel Least-Squares) We make use of the features in an explicit way. Let $\lambda = \lambda_{t+1}$. For $f_\star \in \mathcal{K}$, we denote $\theta^\star$ its corresponding parameter sequence. We let $\mathbf{\Phi}_t = (\varphi(x_{t'}))_{t'\leqslant t}$ be a $t\times\infty$ matrix built from the features and introduce the bi-infinite matrix $V_{\lambda,t} = I + \frac{1}{\lambda}\mathbf{\Phi}_t^\top\mathbf{\Phi}_t$ as well as the noise vector $E_t = (\xi_1, \dots, \xi_t)$. In order to control the term $|f_{\boldsymbol{\lambda},t} - f_\star(x)|$, we first decompose the estimation term. Indeed, using the feature map, it holds that

$$\begin{aligned}
f_{\boldsymbol{\lambda},t}(x) &= k_t(x)^\top(\mathbf{K_t} + \lambda I_t)^{-1}Y_t \\
&= \varphi(x)^\top\mathbf{\Phi}_t^\top(\mathbf{\Phi}_t\mathbf{\Phi}_t^\top + \lambda I_t)^{-1}Y_t \\
&= \varphi(x)^\top\mathbf{\Phi}_t^\top\left(\frac{I_t}{\lambda} - \frac{1}{\lambda}\mathbf{\Phi}_t\big(\lambda I + \mathbf{\Phi}_t^\top\mathbf{\Phi}_t\big)^{-1}\mathbf{\Phi}_t^\top\right)Y_t \\
&= \varphi(x)^\top(\mathbf{\Phi}_t^\top\mathbf{\Phi}_t + \lambda I)^{-1}\mathbf{\Phi}_t^\top(\mathbf{\Phi}_t\theta^\star + E_t)
\end{aligned}$$

where in the third line, we used the Shermann-Morrison formula. From this, simple algebra yields

$$f_{\boldsymbol{\lambda},t}(x) - f^\star(x) = \frac{1}{\lambda}\varphi(x)^\top V_{\lambda,t}^{-1}\big(\mathbf{\Phi}_t^\top E_t - \lambda\theta^\star\big)\,.$$

We then obtain, from a simple Hölder inequality using the appropriate matrix norm, the following decomposition, that is valid provided that all terms involved are finite.

$$|f_{\boldsymbol{\lambda},t}(x) - f(x)| \leqslant \frac{1}{\sqrt{\lambda}}\|\varphi(x)\|_{V_{\lambda,t}^{-1}}\left[\frac{1}{\sqrt{\lambda}}\|\mathbf{\Phi}_t^\top E_t\|_{V_{\lambda,t}^{-1}} + \sqrt{\lambda}\|\theta^\star\|_{V_{\lambda,t}^{-1}}\right]$$

Now, we note that a simple application of the Shermann-Morrison formula yields

$$\|\varphi(x)\|_{V_{\lambda,t}^{-1}}^2 = k_t(x,x)\,.$$

On the other hand, the last term of the bound is controlled as $\|\theta^\star\|_{V_{\lambda,t}^{-1}} \leqslant \|\theta^\star\|$. Thus,

$$|f_{\boldsymbol{\lambda},t}(x) - f(x)| \leqslant \frac{k_{\boldsymbol{\lambda},t}^{1/2}(x,x)}{\sqrt{\lambda_{t+1}}}\left[\frac{1}{\sqrt{\lambda_{t+1}}}\|\mathbf{\Phi}_t^\top E_t\|_{V_{\lambda_{t+1},t}^{-1}} + \sqrt{\lambda_{t+1}}\|\theta^\star\|_2\right].$$

In order to control the remaining term, $\frac{1}{\sqrt{\lambda_{t+1}}}\|\mathbf{\Phi}_t^\top E_t\|_{V_{\lambda_{t+1},t}^{-1}}$, for all t, we now want to apply Lemma 4. However, the lemma does not apply since λ_{t+1} is $\mathcal{H}_t$-measurable. Thus, before proceeding, we upper-bound it by the similar expression involving $\lambda_\star$:

$$\begin{aligned}
\frac{1}{\lambda}\|\mathbf{\Phi}_t^\top E_t\|_{V_{\lambda,t}^{-1}}^2 &= E_t^\top\frac{\mathbf{\Phi}_t^\top}{\lambda}(I + \frac{1}{\lambda}\mathbf{\Phi}_t^\top\mathbf{\Phi}_t)^{-1}\frac{\mathbf{\Phi}_t}{E}_t \\
&= E_t^\top\mathbf{\Phi}_t^\top(\lambda I + \mathbf{\Phi}_t^\top\mathbf{\Phi}_t)^{-1}\mathbf{\Phi}_t E_t \\
&\leqslant E_t^\top\mathbf{\Phi}_t^\top(\lambda_\star I + \mathbf{\Phi}_t^\top\mathbf{\Phi}_t)^{-1}\mathbf{\Phi}_t E_t\,,
\end{aligned}$$

where in the last line, we use the fact that the function $f : \lambda \to u^\top(\lambda I + A)^{-1}u$, for $u = \mathbf{\Phi}_t E_t$ and $A = \mathbf{\Phi}_t^\top\mathbf{\Phi}_t$ is non increasing (see Lemma 5 below). Thus, $\frac{1}{\sqrt{\lambda_{t+1}}}\|\mathbf{\Phi}_t^\top E_t\|_{V_{\lambda_{t+1},t}^{-1}} \leqslant \frac{1}{\sqrt{\lambda_\star}}\|\mathbf{\Phi}_{\lambda_\star,t}^\top E_t\|_{V_{\lambda_\star,t}^{-1}}$. Next, we introduce a random stopping time τ, to be defined later and apply Lemma 4.

More precisely, let $Q \sim \mathcal{N}(0, I)$ be an infinite Gaussian random sequence which is independent of all other random variables. We denote $Q^\top\varphi(x) = \sum_{i\in\mathbb{N}} Q_i\varphi_i(x)$. For all x, $k(x,x) = \sum_{i\in\mathbb{N}}\varphi_i^2(x) < \infty$ and thus $\mathbb{V}(Q^\top\varphi(x)) < \infty$. We define $M_{m,\lambda_\star} = \mathbb{E}[M_{m,\lambda_\star}^Q]$. Clearly, we still have $\mathbb{E}[M_{\lambda_\star,\tau}] = \mathbb{E}[\mathbb{E}[M_{m,\lambda_\star}^Q]|Q] \leqslant 1$. Since $V_{\lambda_\star,\tau} = I + \frac{1}{\lambda_\star}\mathbf{\Phi}_\tau^\top\mathbf{\Phi}_\tau$, elementary algebra gives

$$\begin{aligned}
\det(V_{\lambda_\star,\tau}) &= \det(V_{\lambda_\star,\tau-1} + \frac{1}{\lambda_\star}\varphi(x_\tau)\varphi(x_\tau)^\top) = \det(V_{\lambda_\star,\tau-1})(1 + \frac{1}{\lambda_\star}\|\varphi(x_\tau)\|_{V_{\lambda_\star,\tau-1}^{-1}}^2) \\
&= \det(V_{\lambda_\star,0})\prod_{t'=1}^{\tau}\left(1 + \frac{1}{\lambda_\star}\|\varphi(x_{t'})\|_{V_{\lambda_\star,t'-1}^{-1}}^2\right),
\end{aligned}$$

where we used the fact that the eigenvalues of a matrix of the form $I + xx^\top$ are all ones except for the eigenvalue $1 + \|x\|^2$ corresponding to x. Then, note that $\det(V_{\lambda_\star,0}) = 1$ and thus

$$\begin{aligned}
\ln(\det(V_{\lambda_\star,\tau})) &= \sum_{t'=1}^{\tau}\ln(1 + \frac{1}{\lambda_\star}\|\varphi(x_{t'})\|_{V_{\lambda_\star,t'-1}^{-1}}^2) \\
&= \frac{1}{2}\sum_{t'=1}^{\tau}\ln\left(1 + \frac{1}{\lambda_\star}k_{\lambda_\star,t'-1}(x_{t'},x_{t'})\right).
\end{aligned}$$

In particular, $\ln(\det(V_{\lambda_\star,\tau}))$ is finite. The only difficulty in the proof is now to handle the possibly infinite dimension. To this end, it is enough to take a look at the approximations

using the d first dimension of the sequence for each d. We note $Q_d, M_{\lambda_\star,\tau}, \Phi_{\tau,d}$ and $V_{\tau,d}$ the restriction of the corresponding quantities to the components $\{1,\dots,d\}$. Thus Q_d is Gaussian $\mathcal{N}(0, I_d)$. Following the steps from Abbasi-Yadkori et al. (2011), we obtain that

$$M_{m,d,\lambda_\star} = \frac{1}{\det(V_{\lambda_\star,m,d})^{1/2}} \exp\left(\frac{1}{2\sigma^2\lambda_\star}\|\mathbf{\Phi}_{m,d}^\top E_m\|^2_{V^{-1}_{\lambda_\star,m,d}}\right).$$

Note also that $\mathbb{E}[M_{\tau,d,\lambda_\star}] \leqslant 1$ for all $d \in \mathbb{N}$. Thus, we obtain by an application of Fatou's lemma that

$$\begin{aligned}\mathbb{P}\bigg(\lim_{d\to\infty} \frac{\|\mathbf{\Phi}_{\tau,d}^\top E_\tau\|^2_{V^{-1}_{\lambda_\star,\tau,d}}}{2\sigma^2\lambda_\star \log\Big(\det(V_{\lambda_\star,\tau,d})^{1/2}/\delta\Big)} > 1\bigg) &\leqslant \mathbb{E}\bigg[\lim_{d\to\infty} \frac{\delta \exp\left(\frac{1}{2\lambda_\star\sigma^2}\|\mathbf{\Phi}_{\tau,d}^\top E_\tau\|^2_{V^{-1}_{\tau,d}}\right)}{\det(V_{\lambda_\star,\tau,d})^{1/2}}\bigg] \\ &\leqslant \delta \lim_{d\to\infty} \mathbb{E}[M_{\tau,d,\lambda_\star}] \leqslant \delta\,.\end{aligned}$$

We conclude by defining τ following Abbasi-Yadkori et al. (2011), by

$$\tau(\omega) = \min\left\{t \geqslant 0; \omega \in \Omega \text{ s.t. } \|\mathbf{\Phi}_t^\top E_t\|^2_{V^{-1}_{\lambda_\star,t}} > 2\sigma^2\lambda_\star \log\Big(\det(V_{\lambda_\star,t})^{1/2}/\delta\Big)\right\}.$$

Then τ is a random stopping time and

$$\mathbb{P}\bigg(\exists t, \|\mathbf{\Phi}_t^\top E_t\|^2_{V^{-1}_{\lambda_\star,t}} > 2\sigma^2\lambda_\star \log\Big(\det(V_{\lambda_\star,t})^{1/2}/\delta\Big)\bigg) = \mathbb{P}(\tau < \infty) \leqslant \delta.$$

Finally, combining this result with the previous remarks we obtain that with probability higher than $1-\delta$, uniformly over $x \in \mathcal{X}$ and $t \leqslant T$, it holds that

$$|f_{\boldsymbol{\lambda},t} - f_\star(x)| \leqslant \frac{k^{1/2}_{\boldsymbol{\lambda},t}(x,x)}{\sqrt{\lambda_{t+1}}}\left[\sqrt{2\sigma^2 \ln\left(\frac{\det(I + \frac{1}{\lambda_\star}\Phi_t^\top\Phi_t)^{1/2}}{\delta}\right)} + \sqrt{\lambda_{t+1}}\|f_\star\|_{\mathcal{K}}\right].$$

■

Lemma 5 (Technical lemma) *The function $f : \lambda \mapsto u^\top(\lambda I + A)^{-1}u$, where A is a semi-definite positive matrix and u is any vector, is non-decreasing on $\lambda \in \mathbb{R}^+$.*

Proof Indeed, let $h > 0$. By the Sherman-Morrison formula, we obtain

$$f(\lambda+h) = f(\lambda) - hu^\top(\lambda I + A)^{-1}(I + h(\lambda I + A)^{-1})^{-1}(\lambda I + A)^{-1}u\,.$$

Thus, since $\lambda I + A$ is also semi-definite positive, we have

$$\lim_{h\to 0} \frac{f(\lambda+h) - f(\lambda)}{h} = -u^\top(\lambda I + A)^{-1}(\lambda I + A)^{-1}u \leqslant 0\,.$$

■

Appendix B. Variance estimation

In this section, we give the proof of Theorem 3. To this end, we proceed in two steps. First, we provide an upper bound and lower bound on the variance estimate in the next theorem. Then, we use these bounds in order to derive the final statement.

Theorem 6 (Regularized variance estimate) *Under the second-order sub-Gaussian predictable assumption, for any random stopping time τ for the filtration of the past, with probability higher than $1-3\delta$, it holds*

$$\begin{aligned}\sqrt{\widehat{\sigma}^2_{k,\lambda,\tau}} &\leqslant \sigma\left[1 + \sqrt{\frac{2C_\tau(\delta)}{\tau}}\right] + \|f^\star\|_{\mathcal{K}}\sqrt{\frac{\lambda}{\tau}}\sqrt{1 - \frac{1}{\max_{t\leqslant\tau}(1 + k_{\lambda,t-1}(x_t,x_t))}} \\ \sqrt{\widehat{\sigma}^2_{k,\lambda,\tau}} &\geqslant \sigma\left[1 - \sqrt{\frac{C_\tau(\delta)}{\tau}} - \sqrt{\frac{C_\tau(\delta) + 2D_{\lambda_\star,\tau}(\delta)}{\tau}}\right] - \sqrt{\frac{2\sigma\lambda^{1/2}\|f^\star\|_{\mathcal{K}}\sqrt{D_{\lambda_\star,\tau}(\delta)}}{\tau}}\,.\end{aligned}$$

where we introduced for convenience the constants $C_\tau(\delta) = \ln(e/\delta)\big[1+\ln(\pi^2\ln(\tau)/6)/\ln(1/\delta)\big]$ and $D_{\lambda_\star,\tau}(\delta) = 2\ln(1/\delta) + \sum_{t=1}^\tau \ln(1+\frac{1}{\lambda_\star}k_{\lambda_\star,t-1}(x_t,x_t))$.

Proof We use the feature maps and start with the following decomposition

$$\begin{aligned}\tau\widehat{\sigma}^2_{k,\lambda,\tau} &= \sum_{t=1}^\tau (y_t - f_{\lambda,\tau}(x_t))^2 = \sum_{t=1}^\tau (y_t - \langle\theta_{\lambda,\tau}, \varphi(x_t)\rangle)^2 \\ &= (\theta^\star - \theta_{\lambda,\tau})^\top G_\tau(\theta^\star - \theta_{\lambda,\tau}) + \|E_\tau\|^2 + 2(\theta^\star - \theta_{\lambda,\tau})^\top\Phi_\tau^\top E_\tau\,. \qquad (6)\end{aligned}$$

where $\theta^\star - \theta_{\lambda,\tau} = (I - G^{-1}_{\lambda,\tau}G_\tau)\theta^\star - G^{-1}_{\lambda,\tau}\mathbf{\Phi}_\tau^\top E_\tau$ with $G_{\lambda,\tau} = \lambda I + G_\tau$ and $G_\tau = \Phi_\tau^\top\Phi_\tau$.

On the one hand, we can control the first term in (6) via

$$\begin{aligned}&(\theta^\star - \theta_{\lambda,\tau})^\top G_\tau(\theta^\star - \theta_{\lambda,\tau}) \\ &= [(I - G^{-1}_{\lambda,\tau}G_\tau)\theta^\star - G^{-1}_{\lambda,\tau}\Phi_\tau^\top E_\tau]^\top G_\tau[(I - G^{-1}_{\lambda,\tau}G_\tau)\theta^\star - G^{-1}_{\lambda,\tau}\Phi_\tau^\top E_\tau] \\ &= [\lambda\theta^\star - \Phi_\tau^\top E_\tau]^\top G^{-1}_{\lambda,\tau}G_\tau G^{-1}_{\lambda,\tau}[\lambda\theta^\star - \Phi_\tau^\top E_\tau] \\ &= [\lambda\theta^\star - \Phi_\tau^\top E_\tau]^\top [G^{-1}_{\lambda,\tau} - \lambda G^{-2}_{\lambda,\tau}][\lambda\theta^\star - \Phi_\tau^\top E_\tau] \\ &= \|\Phi_\tau^\top E_\tau\|^2_{G^{-1}_{\lambda,\tau}} - \lambda\|\Phi_\tau^\top E_\tau\|^2_{G^{-2}_{\lambda,\tau}} + \lambda^2\|\theta^\star\|^2_{G^{-1}_{\lambda,\tau}} - \lambda^3\|\theta^\star\|^2_{G^{-2}_{\lambda,\tau}} \\ &\quad -2\lambda\theta^{\star\top}[G^{-1}_{\lambda,\tau} - \lambda G^{-2}_{\lambda,\tau}]\Phi_\tau^\top E_\tau\end{aligned}$$

where we used the fact that $I - G^{-1}_{\lambda,\tau}G_\tau = \lambda G^{-1}_{\lambda,\tau}$ and then that $G^{-1}_{\lambda,\tau}G_\tau G^{-1}_{\lambda,\tau} = G^{-1}_{\lambda,\tau} - \lambda G^{-2}_{\lambda,\tau}$. Likewise, we control the third term in (6) via

$$\begin{aligned}2(\theta^\star - \theta_{\lambda,\tau})^\top\Phi_\tau^\top E_\tau &= 2[(I - G^{-1}_{\lambda,\tau}G_\tau)\theta^\star - G^{-1}_{\lambda,\tau}\Phi_\tau^\top E_\tau]^\top\Phi_\tau^\top E_\tau \\ &= 2[\lambda\theta^\star - \Phi_\tau^\top E_\tau]^\top G^{-1}_{\lambda,\tau}\Phi_\tau^\top E_\tau \\ &= 2\lambda\theta^{\star\top}G^{-1}_{\lambda,\tau}\Phi_\tau^\top E_\tau - 2\|\Phi_\tau^\top E_\tau\|^2_{G^{-1}_{\lambda,\tau}}\,.\end{aligned}$$

Combining these two bounds, we have

$$\begin{aligned}
&\sum_{t=1}^{\tau}(y_t-\langle\theta_{\lambda,\tau},\varphi(x_t)\rangle)^2\\
&= \|E_\tau\|^2-\|\Phi_\tau^\top E_\tau\|^2_{G_{\lambda,\tau}^{-1}}-\lambda\|\Phi_\tau^\top E_\tau\|^2_{G_{\lambda,\tau}^{-2}}\\
&\quad+\lambda^2\|\theta^\star\|^2_{G_{\lambda,\tau}^{-1}}-\lambda^3\|\theta^\star\|^2_{G_{\lambda,\tau}^{-2}}+2\lambda^2\theta^{\star\top}G_{\lambda,\tau}^{-2}\Phi_\tau^\top E_\tau\\
&\leqslant \|E_\tau\|^2+\frac{\lambda^2}{\lambda_{\min(G_{\lambda,\tau})}}\|\theta^\star\|_2^2\Big(1-\frac{\lambda}{\lambda_{\max}(G_{\lambda,\tau})}\Big)+2\frac{\lambda^2}{\lambda_{\min^{3/2}(G_{\lambda,\tau})}}\|\theta^\star\|_2\|\Phi_\tau^\top E_\tau\|_{G_{\lambda,\tau}^{-1}}\\
&\geqslant \|E_\tau\|^2+\frac{\lambda^2}{\lambda_{\max}(G_{\lambda,\tau})}\|\theta^\star\|_2^2\Big(1-\frac{\lambda}{\lambda_{\min(G_{\lambda,\tau})}}\Big)-2\frac{\lambda^2}{\lambda_{\min^{3/2}(G_{\lambda,\tau})}}\|\theta^\star\|_2\|\Phi_\tau^\top E_\tau\|_{G_{\lambda,\tau}^{-1}}\\
&\quad-\|\Phi_\tau^\top E_\tau\|^2_{G_{\lambda,\tau}^{-1}}\Big(1+\frac{\lambda}{\lambda_{\min(G_{\lambda,\tau})}}\Big).
\end{aligned}$$

Now, from Lemma 6, it holds on an event Ω_1 of probability higher than $1-\delta$,

$$0\leqslant\|\Phi_\tau^\top E_\tau\|^2_{G_{\lambda,\tau}^{-1}}=\frac{1}{\lambda}\|\Phi_\tau^\top E_\tau\|^2_{V_{\lambda,\tau}^{-1}}\leqslant\frac{1}{\lambda_\star}\|\Phi_\tau^\top E_\tau\|^2_{V_{\lambda_\star,\tau}^{-1}}\leqslant\sigma^2 D_{\lambda_\star,\tau}(\delta)\,.$$

On the other hand, we control the second term $\|E_\tau\|^2$ by Lemma 6 below, and obtain that with probability higher than $1-2\delta$,

$$\begin{aligned}
\|E_\tau\|^2 &\leqslant \tau\sigma^2+2\sigma^2\sqrt{2\tau C_\tau(\delta)}+2\sigma^2C_\tau(\delta)\\
\|E_\tau\|^2 &\geqslant \tau\sigma^2-2\sigma^2\sqrt{\tau C_\tau(\delta)}\,,
\end{aligned}$$

where $C_\tau(\delta)=\ln(e/\delta)(1+c_\tau/\ln(1/\delta))$.

Thus, combining these two results with a union bound, we deduce that with probability higher than $1-3\delta$ it holds that

$$\begin{aligned}
\widehat{\sigma}^2_{\lambda,\tau} &\leqslant \sigma^2+2\sigma^2\sqrt{\frac{2C_\tau(\delta)}{\tau}}+\frac{2\sigma^2C_\tau(\delta)}{\tau}\\
&\quad+\frac{\lambda^2}{\tau\lambda_{\min(G_{\lambda,\tau})}}\|\theta^\star\|_2^2\Big(1-\frac{\lambda}{\lambda_{\max}(G_{\lambda,\tau})}\Big)-2\frac{\sigma\lambda^2}{\tau\lambda_{\min^{3/2}(G_{\lambda,\tau})}}\|\theta^\star\|_2\sqrt{D_{\lambda_\star,\tau}(\delta)}\\
\widehat{\sigma}^2_{\lambda,\tau} &\geqslant \sigma^2-2\sigma^2\sqrt{\frac{C_\tau(\delta)}{\tau}}+\frac{\lambda^2}{\tau\lambda_{\max}(G_{\lambda,\tau})}\|\theta^\star\|_2^2\Big(1-\frac{\lambda}{\lambda_{\min(G_{\lambda,\tau})}}\Big)\\
&\quad-2\frac{\lambda^2\sigma}{\tau\lambda_{\min^{3/2}(G_{\lambda,\tau})}}\|\theta^\star\|_2\sqrt{D_{\lambda_\star,\tau}(\delta)}-\frac{\sigma^2D_{\lambda_\star,\tau}(\delta)}{\tau}\Big(1+\frac{\lambda}{\lambda_{\min(G_{\lambda,\tau})}}\Big).
\end{aligned}$$

We can now derive a bound on $\sqrt{\widehat{\sigma}^2_{\lambda,\tau}}$. Indeed,

$$\begin{aligned}
\widehat{\sigma}^2_{\lambda,\tau} &\leqslant \Big(\sigma+\sqrt{\frac{2\sigma^2C_\tau(\delta)}{\tau}}\Big)^2+\frac{\lambda^2}{\tau\lambda_{\min(G_{\lambda,\tau})}}\|\theta^\star\|_2^2\Big(1-\frac{\lambda}{\lambda_{\max}(G_{\lambda,\tau})}\Big)\\
\widehat{\sigma}^2_{\lambda,\tau} &\geqslant \Big(\sigma-\sqrt{\frac{\sigma^2C_\tau(\delta)}{\tau}}\Big)^2-\frac{\sigma^2}{\tau}\Big(C_\tau(\delta)+D_{\lambda_\star,\tau}(\delta)\Big(1+\frac{\lambda}{\lambda_{\min(G_{\lambda,\tau})}}\Big)\Big)\\
&\quad-\frac{2\lambda^2\sigma}{\tau\lambda_{\min^{3/2}(G_{\lambda,\tau})}}\|\theta^\star\|_2\sqrt{D_{\lambda_\star,\tau}(\delta)}\,.
\end{aligned}$$

Thus, using the inequality $\sqrt{a+b}\leqslant\sqrt{a}+\sqrt{b}$, on both inequalities, we get

$$\begin{aligned}
\sqrt{\widehat{\sigma}^2_{\lambda,\tau}} &\leqslant \sigma+\sigma\sqrt{\frac{2C_\tau(\delta)}{\tau}}+\frac{\lambda\|\theta^\star\|_2}{\sqrt{\tau\lambda_{\min(G_{\lambda,\tau})}}}\sqrt{1-\frac{\lambda}{\lambda_{\max}(G_{\lambda,\tau})}}\\
\sqrt{\widehat{\sigma}^2_{\lambda,\tau}} &\geqslant \sigma-\sigma\sqrt{\frac{C_\tau(\delta)}{\tau}}-\sigma\sqrt{\frac{C_\tau(\delta)+D_{\lambda_\star,\tau}(\delta)\Big(1+\frac{\lambda}{\lambda_{\min(G_{\lambda,\tau})}}\Big)}{\tau}}\\
&\quad-\lambda\sqrt{\frac{2\sigma\|\theta^\star\|_2\sqrt{D_{\lambda_\star,\tau}(\delta)}}{\tau\lambda_{\min^{3/2}(G_{\lambda,\tau})}}}\,.
\end{aligned}$$

■

Corollary 1 (Extension of Corollary 3.13 in Maillard (2016)) *With probability higher than $1-3\delta'$, it holds simultaneously over all $t\geqslant 0$,*

$$\begin{aligned}
\sigma &\leqslant \frac{1}{\alpha^2}\left(\sqrt{\frac{\sqrt{\lambda}\|f_\star\|_{\mathcal{K}}\sqrt{D_{t,\lambda_\star}(\delta')}}{2t}}+\sqrt{\frac{\sqrt{\lambda}\|f_\star\|_{\mathcal{K}}\sqrt{D_{\lambda_\star,t}(\delta')}}{2t}+\widehat{\sigma}_{\lambda,t}\alpha}\right)^2\\
\sigma &\geqslant \left[\widehat{\sigma}_{\lambda,t}-\|f_\star\|_{\mathcal{K}}\sqrt{\frac{\lambda}{t}\Big(1-\frac{1}{\max_{t'\leqslant t}(1+k_{\lambda,t'-1}(x_{t'},x_{t'}))}\Big)}\right]\Big(1+\sqrt{\frac{2C_t(\delta')}{t}}\Big)^{-1},
\end{aligned}$$

where $\alpha=\max\Big(1-\sqrt{\frac{C_t(\delta')}{t}}-\sqrt{\frac{C_t(\delta')+2D_{\lambda_\star,t}(\delta')}{t}},0\Big)$. Further, if an upper bound $\sigma^+\geqslant\sigma$ is known, one can derive the following inequalities that hold with probability higher than $1-3\delta'$,

$$\begin{aligned}
\sigma &\leqslant \widehat{\sigma}_{\lambda,t}+\sigma^+\left(\sqrt{\frac{C_t(\delta')}{t}}+\sqrt{\frac{C_t(\delta')+2D_{\lambda_\star,t}(\delta')}{t}}\right)+\sqrt{\frac{2\sigma^+\lambda^{1/2}\|f_\star\|_{\mathcal{K}}\sqrt{D_{t,\lambda_\star}(\delta')}}{t}}\\
\sigma &\geqslant \widehat{\sigma}_{\lambda,t}-\sigma^+\sqrt{\frac{2C_t(\delta')}{t}}-\|f_\star\|_{\mathcal{K}}\sqrt{\frac{\lambda}{t}\Big(1-\frac{1}{\max_{t'\leqslant t}(1+k_{\lambda,t'-1}(x_{t'},x_{t'}))}\Big)}.
\end{aligned}$$

Proof Using Theorem 6, it holds with high probability that

$$\underbrace{\widehat{\sigma}_{\lambda,\tau}}_{A} \geqslant \sigma\Big[\underbrace{1-\sqrt{\frac{C_\tau(\delta')}{\tau}}-\sqrt{\frac{C_\tau(\delta')+2D_{\lambda_\star,\tau}(\delta')}{\tau}}}_{C}\Big]-\sqrt{\sigma}\underbrace{\sqrt{\frac{2\sqrt{\lambda}\|f_\star\|_{\mathcal{K}}\sqrt{D_{\lambda_\star,\tau}(\delta')}}{\tau}}}_{B}.$$

The inequality rewrites $A \geqslant \sigma C - \sqrt{\sigma}B$. Now, let $y^2 = \sigma$. If $C > 0$, the inequality holds provided that $y \geqslant 0$ and $A + yB - Cy^2 \geqslant 0$, that is when $0 \leqslant y \leqslant \frac{B+\sqrt{B^2+4AC}}{2C}$. We conclude by choosing the stopping time τ corresponding to the probability of *bad events*, as in the proof of Theorem 2, then by remarking that $t \mapsto C_t(\delta')$ is an increasing function. ■

Lemma 6 (Lemma 5.10 from Maillard (2016)) *Assume that T_n is a random stopping time that satisfies $T_n \leqslant n$ almost surely, then*

$$\mathbb{P}\Big[\frac{1}{T_n}\sum_{i=1}^{T_n}\xi_i^2 \geqslant \sigma^2 + 2\sigma^2\sqrt{\frac{2\ln(e/\delta)}{T_n}} + 2\sigma^2\frac{\ln(e/\delta)}{T_n}\Big] \leqslant \Big(\lceil\ln(n)\ln(e/\delta)\rceil\Big)\delta\,,$$

$$\mathbb{P}\Big[\frac{1}{T_n}\sum_{i=1}^{T_n}\xi_i^2 \leqslant \sigma^2 - 2\sigma^2\sqrt{\frac{\ln(e/\delta)}{T_n}}\Big] \leqslant \Big(\lceil\ln(n)\ln(e/\delta)\rceil\Big)\delta\,.$$

Further, for a random stopping time T, and if we introduce $c_T = \ln(\pi^2\ln^2(T)/6)$, then

$$\mathbb{P}\Big[\frac{1}{T}\sum_{i=1}^{T}\xi_i^2 \geqslant \sigma^2 + 2\sigma^2\sqrt{\frac{2\ln(e/\delta)(1+c_T/\ln(1/\delta))}{T}} + 2\sigma^2\frac{\ln(e/\delta)(1+c_T/\ln(1/\delta))}{T}\Big] \leqslant \delta\,,$$

$$\mathbb{P}\Big[\frac{1}{T}\sum_{i=1}^{T}\xi_i^2 \leqslant \sigma^2 - 2\sigma^2\sqrt{\frac{\ln(e/\delta)(1+c_T/\ln(1/\delta))}{T}}\Big] \leqslant \delta\,.$$

Appendix C. Application to stochastic multi-armed bandits

Proof of Lemma 1 Using the facts that $\min\{r,\alpha\} \leqslant (\alpha/\ln(1+\alpha))\ln(1+r)$ and $\min_{\lambda\in\boldsymbol{\lambda}}\lambda \geqslant \sigma^2/C^2$:

$$\begin{aligned}\sum_{t=1}^{T} s^2_{\boldsymbol{\lambda},t-1}(x_t) &= \sigma^2\sum_{t=1}^{T}\frac{1}{\lambda_t}k_{\lambda_t,t-1}(x_t,x_t)\\ &\leqslant \sigma^2\sum_{t=1}^{T}\frac{C^2}{\sigma^2}k_{\sigma^2/C^2,t-1}(x_t,x_t)\\ &= \sigma^2\sum_{t=1}^{T}\min\Big\{\frac{C^2}{\sigma^2}k_{\sigma^2/C^2,t-1}(x_t,x_t),\frac{C^2}{\sigma^2}\Big\}\\ &\leqslant \frac{2C^2}{\ln(1+C^2/\sigma^2)}\gamma_T(\sigma^2/C^2).\end{aligned}$$

In particular, we obtain by a Cauchy-Schwarz inequality,

$$\sum_{t=1}^{T}\sqrt{\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}} \leqslant \sqrt{T\frac{2C^2/\sigma^2}{\ln(1+C^2/\sigma^2)}\gamma_T(\sigma^2/C^2)}\,.$$

■

Proof of Lemma 2 We want to control the quantity $B_{\lambda_t,t}(\delta)$. First of all, recall from Equation 3 that

$$\begin{aligned}B_{\lambda_t,t}(\delta) &= \sqrt{\lambda_t}C + \sigma_{+,t}\sqrt{2\ln(1/\delta)+2\gamma_t(\lambda_-)}\\ &\leqslant \sigma_+ + \sigma_+\sqrt{2\ln(1/\delta)+2\gamma_t(\sigma^2_{t,-}/C^2)}\,,\end{aligned}$$

where we use the facts that $\lambda_t \leqslant \sigma_+^2/C^2$ and $\lambda_- \geqslant \sigma^2_{t,-}/C^2$. Then, using that $\sigma^2_{t,-} \geqslant \sigma_-$, that $\gamma_t(\cdot)$ is non-increasing and non-decreasing with t, it comes

$$B_{\lambda_t,t}(\delta) \leqslant \sigma_+ + \sigma_+\sqrt{2\ln(1/\delta)+2\gamma_T(\sigma^2_-/C^2)}\,.$$

Alternatively one may use Theorem 6 in order to control the random variables $\sigma_{t,+}$ and $\sigma_{t,-}$ in a tighter way. For instance, by Theorem 6, we easily obtain that with high probability, for all t,

$$\begin{aligned}\sigma \geqslant \sigma_{t,-} \;\geqslant\; \sigma &- \frac{\sigma}{\sqrt{t}}\frac{\Big[(\sqrt{2}+1)\sqrt{C_t(\delta)}-\sqrt{C_t(\delta)+2D_{\lambda_\star,t}(\delta)}\Big]}{1+\sqrt{2C_t(\delta)/t}}\\ &- \frac{\sqrt{2\sigma\lambda^{1/2}\|f^\star\|_{\mathcal{K}}\sqrt{D_{\lambda_\star,t}(\delta)}}+C\sqrt{\lambda}\sqrt{1-\frac{1}{\max_{t\leqslant t}(1+k_{\lambda,t-1}(x_t,x_t))}}}{\sqrt{t}(1+\sqrt{2C_t(\delta)/t})}\,,\end{aligned}$$

that is the estimate satisfies $\sigma \geqslant \sigma_{t,-} \geqslant \sigma - O(1/\sqrt{t})$. This in turns implies that $\gamma_t(\sigma^2_{-,t}/C^2) \leqslant \gamma_t(\sigma^2/C^2) + O(1/\sqrt{t})$. Likewise, it can be shown that $\sigma \leqslant \sigma_{t,+} \leqslant \sigma + O(1/\sqrt{t})$, which yields

$$B_{\lambda_t,t}(\delta) \leqslant \sigma\Big(1+\sqrt{2\ln(1/\delta)+2\gamma_T(\sigma^2_-/C^2)}\Big)+o(1)\,.$$

■

Proof of Theorem 4 (UCB algorithm for kernel bandits) Let r_t denote the instantaneous regret at time t and $f^+(x_t)$ denote the optimistic value at the chosen point x_t, built from the confidence set used by the UCB algorithm. The following holds with probability higher than $1-4\delta$ for each time-step t

$$\begin{aligned}r_t(\lambda_t) &= f_\star(x_\star) - f_\star(x_t) \leqslant f^+_{t-1}(x_t) - f_\star(x_t)\\ &\leqslant |f^+_{t-1}(x_t) - f_{\lambda_t,t-1}(x_t)| + |f_{\lambda_t,t-1}(x_t) - f_\star(x_t)|\\ &\leqslant 2\sqrt{\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}}B_{\lambda_t,t-1}(\delta)\,.\end{aligned}$$

Thus, we deduce that with probability higher than $1-4\delta$:

$$\mathfrak{R}_T \;=\; \sum_{t=1}^{T} r_t(\lambda) \leqslant 2\sum_{t=1}^{T}\sqrt{\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}}B_{\lambda_t,t-1}(\delta)\,.$$

We then use Lemma 2 in order to control the term $B_{\lambda_t,t-1}(\delta)$, and Lemma 1 in order to control the sum of $\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}$. This yields the following bound on the regret:

$$\mathfrak{R}_T \;\leqslant\; 2\sigma_+\Big(1+\sqrt{2\ln(1/\delta)+2\gamma_T(\sigma_-^2/C^2)}\Big)\sqrt{T\frac{2C^2/\sigma^2}{\ln(1+C^2/\sigma^2)}\gamma_T(\sigma^2/C^2)}\,.$$

■

Proof of Theorem 5 (TS algorithm for kernel bandits) We closely follow the proof technique of Agrawal and Goyal (2013), while clarifying and simplifying some steps. The general idea is to split the arms into two groups: *saturated arms* and *unsaturated arms*. The former designates arms where samples $\tilde{f}_t$ have low probability of dominating $f_\star(x_\star)$ while the latter designates the other case. This is related to the *optimism* (Abeille and Lazaric, 2017), that is the possibility of sampling a value that is higher than the optimum. Let $\widehat{E}_t$ and $\tilde{E}_t$ be the events that $\tilde{f}_t$ and $\tilde{f}_t$ are concentrated around their respective means. More precisely, for a given confidence level δ, we introduce

$$\begin{aligned}\widehat{E}_{t,\delta} &= \{\forall x\in\mathcal{X}, |f_\star(x)-f_{\lambda_t,t-1}(x)|\leqslant \widehat{C}_{t,\delta}(x)\}\\ \tilde{E}_{t,\delta} &= \{\forall x\in\mathcal{X}, |f_{\lambda_t,t-1}(x)-\tilde{f}_t(x)|\leqslant \tilde{C}_{t,\delta}(x)\}\,,\end{aligned}$$

for some quantities $\widehat{C}_{t,\delta}(x), \tilde{C}_{t,\delta}(x)$ to be defined.

Controlling the event $\widehat{E}_{t,\delta}$ Choosing the confidence bound to be

$$\widehat{C}_{t,\delta}(x) = \sqrt{\frac{k_{\lambda_t,t-1}(x,x)}{\lambda_t}}B_{\lambda_t,t-1}(\delta/4)\,,$$

then the event $\widehat{E}_{t,\delta}$ is controlled as $\mathbb{P}\Big(\forall t\geqslant 0,\ \widehat{E}_{t,\delta}\Big)\geqslant 1-\delta$.

Controlling the event $\tilde{E}_{t,\delta}$ On the other hand, since $\tilde{f}_t(x)|\mathcal{H}_{t-1}=\mathcal{N}(f_{\lambda_t,t-1}(x),\mathbf{V}_t)$ where we introduced the notation $\mathbf{V}_t = v_t^2\frac{\sigma_{+,t-1}^2}{\lambda_t}(k_{\lambda_t,t-1}(x,x'))_{x,x'\in\mathbb{X}}$, then we have by a simple union bound over $x\in\mathbb{X}$,

$$\mathbb{P}(\tilde{E}_{t,\delta}^c|\mathcal{H}_{t-1}) \leqslant \sum_{x\in\mathbb{X}}\frac{1}{\sqrt{\pi}z_x}e^{-z_x^2/2}$$

provided that $z_x = \frac{\tilde{C}_{t,\delta}(x)}{v_t\sqrt{\frac{\sigma_{+,t-1}^2}{\lambda_t}k_{\lambda_t,t-1}(x,x)}} \geqslant 1$ for all $x\in\mathbb{X}$. This motivates the following definition,

$$\tilde{C}_{t,\delta}(x) = c_{t,\delta}v_t\sqrt{\frac{\sigma_{+,t-1}^2}{\lambda_t}k_{\lambda_t,t-1}(x,x)}\,,$$

for a well-chosen sequence $(c_{t,\delta})_t$. The choice $c_{t,\delta}=\max\{\sqrt{2\ln(t(t+1)|\mathbb{X}|/\sqrt{\pi}\delta)},1\}$ ensures that

$$\begin{aligned}\mathbb{P}(\exists t\geqslant 0\ \tilde{E}_{t,\delta}^c|\mathcal{H}_{t-1}) &\leqslant \sum_{t\geqslant 0}\frac{|\mathbb{X}|}{\sqrt{\pi}c_{t,\delta}}e^{-c_{t,\delta}^2/2} = \sum_{t\geqslant 0}\frac{\delta}{c_{t,\delta}t(t+1)}\\ &\leqslant \sum_{t\geqslant 0}\frac{\delta}{t(t+1)} = \delta,\end{aligned}$$

from which we obtain $\mathbb{P}\Big(\forall t\geqslant 0,\ \tilde{E}_{t,\delta}\Big)\geqslant 1-\delta$.

Summary By definition of the events, under $\widehat{E}_{t,\delta}$ and $\tilde{E}_{t,\delta}$, it thus holds that

$$\begin{aligned}\forall x\in\mathcal{X},\ \Big|f_\star(x)-\tilde{f}_t(x)\Big| &\leqslant \Big|f_\star(x)-f_{\lambda_t,t-1}(x)\Big|+\Big|f_{\lambda_t,t-1}(x)-\tilde{f}_t(x)\Big|\\ &\leqslant \widehat{C}_{t,\delta}(x)+\tilde{C}_{t,\delta}(x)\\ &= \sqrt{\frac{k_{\lambda_t,t-1}(x,x)}{\lambda_t}}\Big(B_{\lambda_t,t-1}(\delta/4)+c_{t,\delta}v_t\sigma_{+,t-1}\Big)\\ &= s_{\boldsymbol{\lambda},t-1}(x)\Big(\underbrace{\frac{B_{\lambda_t,t-1}(\delta/4)}{\sigma}+c_{t,\delta}v_t\frac{\sigma_{+,t-1}}{\sigma}}_{g_t(\delta)}\Big)\,.\end{aligned}$$

Saturated arms It is now convenient to introduce the set of saturated times a time t

$$\mathcal{S}_{t,\delta} = \Big\{x\in\mathbb{X} : f_\star(x_\star)-f_\star(x) > s_{\boldsymbol{\lambda},t-1}(x)g_t(\delta)\Big\} \quad\text{together with}\quad x_{\mathcal{S},t} = \operatorname*{argmin}_{x\notin\mathcal{S}_{t,\delta}} s_{\boldsymbol{\lambda},t-1}(x)\,.$$

We remark that by construction $\star\notin\mathcal{S}_{t,\delta}$ for all t. Now, by the strategy of the Kernel TS algorithm, $x_t=\operatorname{argmax}_{x\in\mathbb{X}}\tilde{f}_t(x)$. Thus, we deduce that on the event $\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}$

$$\begin{aligned}f_\star(x_\star)-f_\star(x_t) &= f_\star(x_\star)-f_\star(x_{\mathcal{S},t})+f_\star(x_{\mathcal{S},t})-f_\star(x_t)\\ &\leqslant s_{\boldsymbol{\lambda},t-1}(x_{\mathcal{S},t})g_t(\delta)+\Big(f_\star(x_{\mathcal{S},t})-\tilde{f}_t(x_{\mathcal{S},t})\Big)\\ &\quad+\Big(\underbrace{\tilde{f}_t(x_{\mathcal{S},t})-\tilde{f}_t(x_t)}_{\leqslant 0}\Big)+\Big(\tilde{f}_t(x_t)-f_\star(x_t)\Big)\\ &\leqslant 2s_{\boldsymbol{\lambda},t-1}(x_{\mathcal{S},t})g_t(\delta)+s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\,.\end{aligned}$$

Also, $f_\star(x_\star)-f_\star(x_t)\leqslant R$, where $R=\max_{x\in\mathbb{X}}f_\star(x_\star)-f_\star(x)<\infty$. We then remark that by definition of $x_{\mathcal{S},t}$, we have

$$\begin{aligned}\mathbb{E}[s_{\boldsymbol{\lambda},t-1}(x_t)|\mathcal{H}_{t-1}] &\geqslant \mathbb{E}[s_{\boldsymbol{\lambda},t-1}(x_t)\mathbb{I}\{x_t\notin\mathcal{S}_{t,\delta}\}|\mathcal{H}_{t-1}]\\ &\geqslant \mathbb{E}[s_{\boldsymbol{\lambda},t-1}(x_{\mathcal{S},t})\mathbb{I}\{x_t\notin\mathcal{S}_{t,\delta}\}|\mathcal{H}_{t-1}]\\ &= s_{\boldsymbol{\lambda},t-1}(x_{\mathcal{S},t})\mathbb{P}\Big(x_t\notin\mathcal{S}_{t,\delta}\Big|\mathcal{H}_{t-1}\Big)\,.\end{aligned}$$

Likewise,

$$\min\{s_{\boldsymbol{\lambda},t-1}(x_{\mathcal{S},t})g_t(\delta),R\} \leqslant \frac{\mathbb{E}[\min\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta),R\}|\mathcal{H}_{t-1}]}{\mathbb{P}\Big(x_t \notin \mathcal{S}_{t,\delta}\Big|\mathcal{H}_{t-1}\Big)}\,.$$

Since on the other hand, $(f_\star(x_\star)-f_\star(x_t))\mathbb{I}\{x_t\notin\mathcal{S}_{t,\delta}\}\leqslant s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\mathbb{I}\{x_t\notin\mathcal{S}_{t,\delta}\}$, we deduce that on the event $\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}$ we have

$$\begin{aligned}
f_\star(x_\star)-f_\star(x_t) &\leqslant \min\Big\{2s_{\boldsymbol{\lambda},t-1}(x_{\mathcal{S},t})g_t(\delta)+s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta),R\Big\}\mathbb{I}\{x_t\in\mathcal{S}_{t,\delta}\}\\
&\quad +s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\mathbb{I}\{x_t\notin\mathcal{S}_{t,\delta}\}\\
&\leqslant \min\Big\{2s_{\boldsymbol{\lambda},t-1}(x_{\mathcal{S},t})g_t(\delta),R\Big\}\mathbb{I}\{x_t\in\mathcal{S}_{t,\delta}\}+s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\\
&\leqslant \frac{\mathbb{E}[\min\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta),R\}|\mathcal{H}_{t-1}]}{\mathbb{P}\Big(x_t\notin\mathcal{S}_{t,\delta}\Big|\mathcal{H}_{t-1}\Big)}\mathbb{I}\{x_t\in\mathcal{S}_{t,\delta}\}+s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\,.
\end{aligned}$$

Lower bounding the denominator At this point, we note that on the event $\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}$, for all $x\in\mathcal{S}_{t,\delta}$,

$$\tilde{f}_t(x)\leqslant f_\star(x)+s_{\boldsymbol{\lambda},t-1}(x)g_t(\delta)\leqslant f_\star(x_\star)\,,$$

while on the other hand we have the inclusion $\quad\{\forall x\in\mathcal{S}_{t,\delta},\ \tilde{f}_t(x_\star)>\tilde{f}_t(x)\}\subset\{x_t\notin\mathcal{S}_{t,\delta}\}$. Thus, combining these two properties, we deduce that

$$\begin{aligned}
&\{x_t\in\mathcal{S}_{t,\delta}\}\cap\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}\\
&\quad\subset\ \Big\{\exists x\in\mathcal{S}_{t,\delta},\tilde{f}_t(x_\star)\leqslant\tilde{f}_t(x)\Big\}\cap\Big\{\forall x\in\mathcal{S}_{t,\delta},\tilde{f}_t(x)\leqslant f_\star(x_\star)\Big\}\\
&\quad\subset\ \Big\{\tilde{f}_t(x_\star)\leqslant f_\star(x_\star)\Big\}\,.
\end{aligned}$$

Further, using that $\tilde{f}_t(x)|\mathcal{H}_{t-1}=\mathcal{N}(f_{\lambda_t,t-1}(x),\mathbf{V}_t)$ yields

$$\begin{aligned}
&\{x_t\in\mathcal{S}_{t,\delta}\}\cap\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}\\
&\quad\subset\ \Big\{\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\leqslant f_\star(x_\star)-f_{\lambda_t,t-1}(x_\star)\Big\}\cap\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}\\
&\quad\subset\ \Big\{\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\leqslant\widehat{C}_{t,\delta}(x_\star)\Big\}\subset\Big\{\big|\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\big|\leqslant\widehat{C}_{t,\delta}(x_\star)\Big\}\,,
\end{aligned}$$

from which we obtain

$$\Big\{\big|\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\big|>\widehat{C}_{t,\delta}(x_\star)\Big\}\cap\widehat{E}_{t,\delta}\subset\{x_t\notin\mathcal{S}_{t,\delta}\}\cup\tilde{E}^c_{t,\delta}\,.$$

Thus, we have proved that

$$\begin{aligned}
\mathbb{P}\Big(x_t\notin\mathcal{S}_{t,\delta}\Big|\mathcal{H}_{t-1}\Big) &\geqslant \mathbb{P}\Big(\big|\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\big|>\widehat{C}_{t,\delta}(x_\star),\widehat{E}_{t,\delta}\Big|\mathcal{H}_{t-1}\Big)-\mathbb{P}\Big(\tilde{E}^c_{t,\delta}\Big|\mathcal{H}_{t-1}\Big)\\
&= \mathbb{P}\Big(\big|\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\big|>\widehat{C}_{t,\delta}(x_\star)\Big|\mathcal{H}_{t-1}\Big)\mathbb{I}\{\widehat{E}_{t,\delta}\}-\mathbb{P}\Big(\tilde{E}^c_{t,\delta}\Big|\mathcal{H}_{t-1}\Big)\,.
\end{aligned}$$

Anti-concentration We now resort to an anti-concentration result for Gaussian variables (Abramowitz and Stegun, 1964). More precisely, the following inequality holds

$$\mathbb{P}\Big(\Big|\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\Big|>\widehat{C}_{t,\delta}(x_\star)\Big|\mathcal{H}_{t-1}\Big)\geqslant\frac{1}{2\sqrt{\pi}z}e^{-z^2/2}$$

where we introduced the $\mathcal{H}_{t-1}$-measurable random variable

$$z \;=\; \frac{\widehat{C}_{t,\delta}(x_\star)}{v_t\sigma_{+,t-1}\sqrt{\frac{k_{\lambda_t,t-1}(\star,\star)}{\lambda_t}}}=\frac{B_{\lambda_t,t-1}(\delta/4)}{v_t\sigma_{+,t-1}}\,,\qquad\text{provided that } z\geqslant 1\,.$$

Taking $v_t=\frac{B_{\lambda_t,t-1}(\delta/4)}{\sigma_{+,t-1}\sqrt{2\alpha_t\ln(\beta_t)}}$ for constants α_t,β_t such that $2\alpha_t\ln(\beta_t)\geqslant 1$ thus yields

$$\mathbb{P}\Big(\Big|\tilde{f}_t(x_\star)-f_{\lambda_t,t-1}(x_\star)\Big|>\widehat{C}_{t,\delta}(x_\star)\Big|\mathcal{H}_{t-1}\Big)\geqslant p_t\overset{\text{def}}{=}\frac{\beta_t^{-\alpha_t}}{2\sqrt{\pi}\sqrt{2\alpha_t\ln(\beta_t)}}\,.$$

Summary At this point of the proof, we have proved that

$$\begin{aligned}
&(f_\star(x_\star)-f_\star(x_t))\mathbb{I}\{\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}\}\\
&\leqslant \frac{\mathbb{E}[\min\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta),R\}|\mathcal{H}_{t-1}]\mathbb{I}\{x_t\in\mathcal{S}_{t,\delta}\}}{p_t\mathbb{I}\{\widehat{E}_{t,\delta}\}-\mathbb{P}(\tilde{E}^c_{t,\delta}\,|\mathcal{H}_{t-1})}\mathbb{I}\{\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}\}\\
&\qquad +s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\mathbb{I}\{\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}\}\\
&\leqslant \mathbb{E}[\min\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta),R\}|\mathcal{H}_{t-1}]\Big(\frac{1}{p_t}+\frac{\mathbb{P}(\tilde{E}^c_{t,\delta}|\mathcal{H}_{t-1})}{p_t^2}\Big)+s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\,,
\end{aligned}$$

where in the second inequality, we used the property $\frac{1}{p-q}=\frac{1}{p}+\frac{q}{p(p-q)}\leqslant\frac{1}{p}+\frac{q}{p^2}$, for $p>q$. Combining the bound on $\mathbb{P}(\tilde{E}^c_{t,\delta}|\mathcal{H}_{t-1})$ and the definition of p_t, we obtain

$$\begin{aligned}
&(f_\star(x_\star)-f_\star(x_t))\mathbb{I}\{\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}\}\\
&\leqslant \mathbb{E}[\min\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta),R\}|\mathcal{H}_{t-1}]\Big(\sqrt{8\pi\alpha_t\ln(\beta_t)}\beta_t^{\alpha_t}+\delta\frac{8\pi\alpha_t\ln(\beta_t)\beta_t^{2\alpha_t}}{c_{t,\delta}t(t+1)}\Big)\\
&\qquad +s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\,.
\end{aligned}$$

Pseudo-regret Summing-up the previous terms over $t\geqslant 1$, we obtain that the pseudo-regret of the Kernel TS strategy satisfies, on the event $\bigcap_{t\geqslant1}\widehat{E}_{t,\delta}\cap\tilde{E}_{t,\delta}$ that holds with probability higher than $1-2\delta$,

$$\begin{aligned}
\mathfrak{R}_T \;\leqslant\; \sum_{t=1}^T\Big[&\mathbb{E}[\min\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta),R\}|\mathcal{H}_{t-1}]\sqrt{8\pi\alpha_t\ln(\beta_t)}\beta_t^{\alpha_t}\Big(1+\delta\frac{\sqrt{8\pi\alpha_t\ln(\beta_t)}\beta_t^{\alpha_t}}{c_{t,\delta}t(t+1)}\Big)\\
&+s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\Big]\,,
\end{aligned}$$

where $c_{t,\delta} = \max\{\sqrt{2\ln(t(t+1)|\mathbb{X}|/\sqrt{\pi}\delta)}, 1\}$, and the constants α_t, β_t must be such that $2\alpha_t \ln(\beta_t) \geqslant 1$ and $\sqrt{8\pi\alpha_t \ln(\beta_t)}\beta_t^{\alpha_t} \geqslant 1$. Also, let us recall that

$$\begin{aligned} g_t(\delta) &= \frac{B_{\lambda_t,t-1}(\delta/4)}{\sigma} + c_{t,\delta} v_t \frac{\sigma_{+,t-1}}{\sigma} \\ &= \frac{B_{\lambda_t,t-1}(\delta/4)}{\sigma}\Big(1 + \frac{c_{t,\delta}}{\sqrt{2\alpha_t \ln(\beta_t)}}\Big)\,. \end{aligned}$$

In particular, the specific choice $\alpha_t = 1/2\ln(\beta_t)$ where $\beta_t > 1$ (which satisfies $1 \geqslant 1$ and $\sqrt{4\pi e} \geqslant 1$) yields

$$\begin{aligned} \mathfrak{R}_T &\leqslant \sum_{t=1}^T \mathbb{E}\Big[\min\{2s_{\boldsymbol{\lambda},t-1}(x_t)\frac{B_{\lambda_t,t-1}(\delta/4)}{\sigma}\Big(1+c_{t,\delta}\Big), R\}\Big|\mathcal{H}_{t-1}\Big]\eta_t + s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta) \\ &= \sum_{t=1}^T \mathbb{E}\Big[\min\big\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta), R\big\}\Big|\mathcal{H}_{t-1}\Big]\eta_t + s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\,, \end{aligned}$$

where we introduced the deterministic quantity $\eta_t = \sqrt{4\pi e}\Big(1 + \delta\frac{\sqrt{4\pi e}}{c_{t,\delta}t(t+1)}\Big)$.

Concentration In order to finish the proof, we now relate the sum of the terms $\mathbb{E}[s_{\boldsymbol{\lambda},t-1}(x_t)|\mathcal{H}_{t-1}]$ to the sum of the terms $s_{\boldsymbol{\lambda},t-1}(x_t)$, for $t \geqslant 1$. More precisely, let us introduce the following random variable

$$X_t = \mathbb{E}\Big[\min\big\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta), R\big\}\Big|\mathcal{H}_{t-1}\Big]\eta_t - \min\big\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta), R\big\}\eta_t\,.$$

By construction, $\mathbb{E}[X_t|\mathcal{H}_{t-1}] = 0$ and $|X_t| \leqslant R\eta_t$. Thus, by an application of Azuma-hoeffding's inequality for martingales, we obtain that for all $\delta \in (0,1)$, with probability higher than $1-\delta$,

$$\sum_{t=1}^T X_t \leqslant \sqrt{2\sum_{t=1}^T R^2\eta_t^2 \ln(1/\delta)}\,,$$

and thus that on an event of probability higher than $1-3\delta$,

$$\mathfrak{R}_T \leqslant \sum_{t=1}^T \min\big\{2s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta), R\big\}\eta_t + s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta) + \sqrt{2\sum_{t=1}^T R^2\eta_t^2\ln(1/\delta)}\,.$$

Replacing η_t with its expression, that is

$$\begin{aligned} \eta_t &= \sqrt{4\pi e}\Big(1 + \delta\frac{\sqrt{4\pi e}}{\max\{\sqrt{2\ln(t(t+1)|\mathbb{X}|/\sqrt{\pi}\delta)}, 1\}t(t+1)}\Big) \\ &\leqslant \sqrt{4\pi e}\Big(1 + \delta\frac{\sqrt{4\pi e}}{t(t+1)}\Big)\,, \end{aligned}$$

we deduce that with probability higher than $1-3\delta$,

$$\begin{aligned} \mathfrak{R}_T &\leqslant (4\sqrt{\pi e}+1)\Big(\sum_{t=1}^T s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\Big) + R\delta 4\pi e + R\sqrt{8\pi e\sum_{t=1}^T(1+\delta\frac{\sqrt{4\pi e}}{t(t+1)})^2\ln(1/\delta)} \\ &\leqslant (4\sqrt{\pi e}+1)\Big(\sum_{t=1}^T s_{\boldsymbol{\lambda},t-1}(x_t)g_t(\delta)\Big) + R\delta 4\pi e + \sqrt{8\pi e(1+\delta\sqrt{4\pi e})^2}R\sqrt{T\ln(1/\delta)} \\ &= (4\sqrt{\pi e}+1)\Big(\sum_{t=1}^T \sqrt{\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}}B_{\lambda_t,t-1}(\delta/4)(1+c_{t,\delta})\Big) \\ &\quad + R\delta 4\pi e + \sqrt{8\pi e(1+\delta\sqrt{4\pi e})^2}R\sqrt{T\ln(1/\delta)}\,. \end{aligned}$$

This concludes the proof of the main result, since $c_{t,\delta} \leqslant c_{T,\delta}$.

Final bound Then, using Lemma 2 we can rewrite the regret as

$$\begin{aligned} \mathfrak{R}_T &= (4\sqrt{\pi e}+1)(1+c_{T,\delta})\sigma_+\Big(1+\sqrt{2\ln(4/\delta)+2\gamma_T(\sigma_-^2/C^2)}\Big)\sum_{t=1}^T\sqrt{\frac{k_{\lambda_t,t-1}(x_t,x_t)}{\lambda_t}} \\ &\quad + R\delta 4\pi e + \sqrt{8\pi e(1+\delta\sqrt{4\pi e})^2}R\sqrt{T\ln(1/\delta)}\,. \end{aligned}$$

Using Lemma 1 together with a Cauchy-Schwarz inequality, we finally obtain

$$\begin{aligned} \mathfrak{R}_T &= (4\sqrt{\pi e}+1)(1+c_{T,\delta})\sigma_+\Big(1+\sqrt{2\ln(4/\delta)+2\gamma_T(\sigma_-^2/C^2)}\Big)\sqrt{\frac{2TC^2/\sigma^2}{\ln\Big(1+\frac{C^2}{\sigma^2}\Big)}\gamma_T(\sigma^2/C^2)} \\ &\quad + R\delta 4\pi e + \sqrt{8\pi e(1+\delta\sqrt{4\pi e})^2}R\sqrt{T\ln(1/\delta)}\,. \end{aligned}$$

Abstract

We consider the problem of learning a linear subspace from data corrupted by outliers. Classical approaches are typically designed for the case in which the subspace dimension is small relative to the ambient dimension. Our approach works with a dual representation of the subspace and hence aims to find its orthogonal complement; as such, it is particularly suitable for subspaces whose dimension is close to the ambient dimension (subspaces of high relative dimension). We pose the problem of computing normal vectors to the inlier subspace as a non-convex ℓ_1 minimization problem on the sphere, which we call Dual Principal Component Pursuit (DPCP) problem. We provide theoretical guarantees under which every global solution to DPCP is a vector in the orthogonal complement of the inlier subspace. Moreover, we relax the non-convex DPCP problem to a recursion of linear programs whose solutions are shown to converge in a finite number of steps to a vector orthogonal to the subspace. In particular, when the inlier subspace is a hyperplane, the solutions to the recursion of linear programs converge to the global minimum of the non-convex DPCP problem in a finite number of steps. We also propose algorithms based on alternating minimization and iteratively re-weighted least squares, which are suitable for dealing with large-scale data. Experiments on synthetic data show that the proposed methods are able to handle more outliers and higher relative dimensions than current state-of-the-art methods, while experiments in the context of the three-view geometry problem in computer vision suggest that the proposed methods can be a useful or even superior alternative to traditional RANSAC-based approaches for computer vision and other applications.

Keywords: Outliers, Robust Principal Component Analysis, High Relative Dimension, ℓ_1 Minimization, Non-Convex Optimization, Linear Programming, Trifocal Tensor

1. Introduction

Principal Component Analysis (PCA) is one of the oldest (Pearson, 1901; Hotelling, 1933) and most fundamental techniques in data analysis, with ubiquitous applications in engineering (Moore, 1981), economics and sociology (Vyas and Kumaranayake, 2006), chemistry (Ku et al., 1995), physics (Loyd et al., 2014) and genetics (Price et al., 2006) to name a few; see Jolliffe (2002) for more applications. Given a data matrix $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{D\times L}$ of L data points of coordinate dimension D, PCA gives a closed form solution to the problem of finding a d-dimensional linear subspace $\hat{\mathcal{S}}$ that is closest, in the Euclidean sense, to the columns of $\boldsymbol{\mathcal{X}}$. Although the optimization problem associated with PCA is non-convex, it does admit a simple solution by means of the Singular Value Decomposition (SVD) of $\boldsymbol{\mathcal{X}}$. In fact, $\hat{\mathcal{S}}$ is the subspace spanned by the first d left singular vectors of $\boldsymbol{\mathcal{X}}$.

Using $\hat{\mathcal{S}}$ as a model for the data $\boldsymbol{\mathcal{X}}$ is meaningful when the data are known to have an approximately linear structure of underlying dimension d, i.e., they lie close to a d-dimensional subspace $\mathcal{S}$. In practice, the principal components of $\boldsymbol{\mathcal{X}}$ are known to be well-behaved under mild levels of noise, i.e., the principal angles between $\hat{\mathcal{S}}$ and $\mathcal{S}$ are relatively small, and in fact, $\hat{\mathcal{S}}$ is optimal when the noise is Gaussian (Jolliffe, 2002). However, very often in applications the data are corrupted by outliers, i.e., the data matrix has the form $\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}}\ \boldsymbol{\mathcal{O}}]\,\boldsymbol{\Gamma}$, where the M columns of $\boldsymbol{\mathcal{O}} \in \mathbb{R}^{D\times M}$ are points of $\mathbb{R}^D$ whose angles from the underlying ground truth subspace $\mathcal{S}$ associated with the inlier points $\boldsymbol{\mathcal{X}}$ are large, and $\boldsymbol{\Gamma}$ is an unknown permutation. In such cases, the principal angles between $\mathcal{S}$ and its PCA estimate $\hat{\mathcal{S}}$ will in general be large, even when M is small. This is to be expected since, by definition, the principal components of $\tilde{\boldsymbol{\mathcal{X}}}$ are orthogonal directions of maximal correlation with *all* the points of $\tilde{\boldsymbol{\mathcal{X}}}$. This phenomenon, together with the fact that outliers are almost always present in real datasets, has given rise to the important problem of outlier detection in PCA.

Traditionally, outlier detection has been a major area of study in robust statistics with notable methods being *Influence-based Detection*, *Multivariate Trimming*, M*-Estimators*, *Iteratively Reweighted Least Squares* (IRLS) and *Random Sampling Consensus* (RANSAC) (Huber, 1981; Jolliffe, 2002). These methods are usually based on non-convex optimization problems and in practice converge only to a local minimum. In addition, their theoretical analysis is usually limited and their computational complexity may be large (e.g., in the case of RANSAC). Recently, two attractive methods have appeared (Xu et al., 2012; Soltanolkotabi and Candès, 2012) that are directly based on convex optimization and are inspired by *low-rank representation* (Liu et al., 2010) and *compressed sensing* (Candès and Wakin, 2008). Even though both of these methods admit theoretical guarantees and efficient implementations, they are in principle applicable only in the case of subspaces of small relative dimension (i.e., $d/D \ll 1$). On the other hand, the theoretical guarantees of the recent REAPER method of Lerman et al. (2015) seem to suggest that the method is able to handle any subspace dimension.

In this paper we adopt a *dual* approach to the problem of robust PCA in the presence of outliers, which allows us to explicitly transcend the low relative dimension regime of modern methods such as Xu et al. (2012) or Soltanolkotabi and Candès (2012), and even be able to handle as many as 70% outliers for hyperplanes (subspaces of maximal relative dimension $(D-1)/D$), a regime where other modern (Lerman et al., 2015) or classic (Huber, 1981) methods fail. The key idea of our approach comes from the fact that, in the absence of noise, the inliers $\boldsymbol{\mathcal{X}}$ lie inside any hyperplane $\mathcal{H}_1 = \mathrm{Span}(\boldsymbol{b}_1)^\perp$ that contains the underlying linear subspace $\mathcal{S}$ associated with the inliers. This suggests that, instead of attempting to fit directly a low-dimensional linear subspace to the entire dataset $\tilde{\boldsymbol{\mathcal{X}}}$, as done e.g. in Xu et al. (2012), we can search for a *maximal hyperplane* $\mathcal{H}_1$ that contains as many points of the dataset as possible. When the inliers $\boldsymbol{\mathcal{X}}$ are in general position (to be made precise shortly) inside $\mathcal{S}$, and the outliers $\boldsymbol{\mathcal{O}}$ are in general position in $\mathbb{R}^D$, such a maximal hyperplane will contain the entire set of inliers together with possibly a few outliers. Then one may remove all points that lie outside this hyperplane and be left with an easier robust PCA problem that could potentially be addressed by existing methods. Alternatively, one can continue by finding a second maximal hyperplane $\mathcal{H}_2 = \mathrm{Span}(\boldsymbol{b}_2)^\perp$, with the new dual principal component $\boldsymbol{b}_2$ perpendicular to the first one, i.e., $\boldsymbol{b}_2 \perp \boldsymbol{b}_1$, and so on, until $c := D-d$ such maximal hyperplanes $\mathcal{H}_1, \ldots, \mathcal{H}_c$ have been found, leading to a *Dual Principal Component Analysis (DPCA)* of $\tilde{\boldsymbol{\mathcal{X}}}$. In

such a case, the inlier subspace is precisely equal to $\bigcap_{i=1}^{c} \mathcal{H}_i$, and a point is an outlier if and only if it lies outside this intersection.

We formalize the problem of searching for maximal hyperplanes with respect to $\tilde{\boldsymbol{\mathcal{X}}}$ as an ℓ_0 cosparsity-type problem (Nam et al., 2013), which we relax to a non-convex ℓ_1 problem on the sphere, referred to as the Dual Principal Component Pursuit (DPCP) problem. We provide theoretical guarantees under which every global solution of the DPCP problem is a vector orthogonal to the linear subspace associated with the inliers, i.e., it is a dual principal component. Moreover, we relax the non-convex DPCP problem to a recursion of linear programming problems and we show that, under mild conditions, their solutions converge to a dual principal component in a finite number of steps. In particular, when the inlier subspace is a hyperplane, then the solutions of the linear programming recursion converge to the global minimum of the non-convex problem in a finite number of steps. Furthermore, we propose algorithms based on alternating minimization and IRLS that are suitable for dealing with large-scale data. Extensive experiments on synthetic data show that the proposed methods are able to handle more outliers and subspaces of higher relative dimension d/D than state-of-the-art methods (Fischler and Bolles, 1981; Xu et al., 2012; Soltanolkotabi and Candès, 2012; Lerman et al., 2015), while experiments with real face and object images show that our DPCP-based methods perform on par with state-of-the-art methods.

Notation The shorthand RHS stands for *Right-Hand-Side* and similarly for LHS. The notation $\cong$ stands for *isomorphism* in whatever category the objects lying to the LHS and RHS of the symbol belong to. The notation $\simeq$ denotes approximation. For any positive integer n let $[n] := \{1, 2, \ldots, n\}$. For any positive number α let $\lceil \alpha \rceil$ denote the smallest integer that is greater than α. For sets $\mathcal{A}, \mathcal{B}$, the set $\mathcal{A} \setminus \mathcal{B}$ is the set of all elements of $\mathcal{A}$ that do not belong to $\mathcal{B}$. If $\mathcal{S}$ is a subspace of $\mathbb{R}^D$, then $\dim(\mathcal{S})$ denotes the dimension of $\mathcal{S}$ and $\pi_{\mathcal{S}} : \mathbb{R}^D \to \mathcal{S}$ is the orthogonal projection of $\mathbb{R}^D$ onto $\mathcal{S}$. For vectors $\boldsymbol{b}, \boldsymbol{b}' \in \mathbb{R}^D$ we let $\angle \boldsymbol{b}, \boldsymbol{b}'$ be the acute angle between $\boldsymbol{b}$ and $\boldsymbol{b}'$, defined as the unique angle $\theta \in [0\ 90^\circ]$ such that $\cos\theta = \left|\boldsymbol{b}^\top \boldsymbol{b}'\right|$. If $\boldsymbol{b}$ is a vector of $\mathbb{R}^D$ and $\mathcal{S}$ a linear subspace of $\mathbb{R}^D$, the principal angle of $\boldsymbol{b}$ from $\mathcal{S}$ is $\angle \boldsymbol{b}, \pi_{\mathcal{S}}(\boldsymbol{b})$. The symbol $\oplus$ denotes direct sum of subspaces. The orthogonal complement of a subspace $\mathcal{S}$ in $\mathbb{R}^D$ is $\mathcal{S}^\perp$. If $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s$ are elements of $\mathbb{R}^D$, we denote by $\mathrm{Span}(\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s)$ the subspace of $\mathbb{R}^D$ spanned by these elements. $\mathbb{S}^{D-1}$ denotes the unit sphere of $\mathbb{R}^D$. For a vector $\boldsymbol{w} \in \mathbb{R}^D$ we define $\hat{\boldsymbol{w}} := \boldsymbol{w} / \left\|\boldsymbol{w}\right\|_2$, if $\boldsymbol{w} \neq \boldsymbol{0}$, and $\hat{\boldsymbol{w}} := 0$ otherwise. Given a square matrix $\boldsymbol{C}$, $\mathrm{Diag}(\boldsymbol{C})$ denotes the vector of diagonal elements of $\boldsymbol{C}$. Given a square matrix $\boldsymbol{P}$, the notation $\boldsymbol{0} \leq \boldsymbol{P} \leq \boldsymbol{I}$ indicates that $\boldsymbol{P}, \boldsymbol{I} - \boldsymbol{P}$ are positive semi-definite matrices. With a mild abuse of notation we will be treating on several occasions matrices as sets, i.e., if $\boldsymbol{\mathcal{X}}$ is $D \times N$ and $\boldsymbol{x}$ a point of $\mathbb{R}^D$, the notation $\boldsymbol{x} \in \boldsymbol{\mathcal{X}}$ signifies that $\boldsymbol{x}$ is a column of $\boldsymbol{\mathcal{X}}$. Similarly, if $\boldsymbol{\mathcal{O}}$ is a $D \times M$ matrix, the notation $\boldsymbol{\mathcal{X}} \cap \boldsymbol{\mathcal{O}}$ signifies the points of $\mathbb{R}^D$ that are common columns of $\boldsymbol{\mathcal{X}}$ and $\boldsymbol{\mathcal{O}}$. The notation Sign denotes the sign function $\mathrm{Sign} : \mathbb{R} \to \{-1, 0, 1\}$ defined as

$$\mathrm{Sign}(x) = \begin{cases} x/|x| & \text{if } x \neq 0, \\ 0 & \text{if } x = 0. \end{cases} \tag{1}$$

Finally, we note that the ith entry of the subdifferential of the ℓ_1-norm $\|\boldsymbol{z}\|_1 = \sum_{i=1}^{D} |z_i|$ of a vector $\boldsymbol{z} = (z_1, \ldots, z_D)^\top$ is a set-valued function on $\mathbb{R}^D$ defined as

$$\mathrm{Sgn}(z_i) = \begin{cases} \mathrm{Sign}(z_i) & \text{if } z_i \neq 0, \\ [-1, 1] & \text{if } z_i = 0. \end{cases} \tag{2}$$

2. Prior Art

We begin by briefly reviewing some state-of-the-art methods for learning a linear subspace from data $\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}}\ \boldsymbol{\mathcal{O}}]\,\boldsymbol{\Gamma}$ in the presence of outliers. The literature on this subject is vast and our account is far from exhaustive; with a few exceptions, we mainly focus on modern methods based on convex optimization. For methods from robust statistics see Huber (1981); Jolliffe (2002), for online subspace learning methods see Balzano et al. (2010); Feng et al. (2013), for regression-type methods see Wang et al. (2015), while for fast and other methods the reader is referred to the excellent literature review of Lerman and Zhang (2014) or the recent survey by Lerman and Maunu (2018). Finally, we note that preliminary results associated with the present work have been published in the form of a conference paper[1] (Tsakiris and Vidal, 2015). While the present paper was under review, we extended our approach to clustering data from multiple subspaces (Tsakiris and Vidal, 2017), which can also be thought of as a robust PCA problem but with structured outliers. This is a continuation of the present work, which certainly builds on the concepts and algorithms presented here, yet requires sufficiently distinct machinery to be fully established.

RANSAC One of the oldest and most popular outlier detection methods for PCA is *Random Sampling Consensus (RANSAC)* (Fischler and Bolles, 1981). The idea behind RANSAC is simple: alternate between randomly sampling a subset of cardinality d from the dataset and computing a d-dimensional subspace from this subset, until a subspace $\hat{\mathcal{S}}$ is found that maximizes the number of points in the entire dataset that approximately lie in $\hat{\mathcal{S}}$ within some error. RANSAC is typically used when the ambient dimension D is small (say $D \leq 20$), yielding high quality subspace estimates regardless of the subspace relative dimension d/D. However, as D increases, RANSAC becomes inefficient for large values of d/D, except when the outlier ratio is very small, as otherwise a prohibitive number of trials may be required in order to obtain outlier-free samples and thus furnish reliable models. Additionally, RANSAC requires as input an estimate for the dimension of the subspace as well as a thresholding parameter, which is used to distinguish outliers from inliers; naturally the performance of RANSAC is very sensitive to these two parameters.
