If we add a second component ($K_z = 2$), then we can make $p_0(\theta)$ skewed, as shown (with the approximations) in Fig. 1. In this case, we expect $\mathbb{E}_{q_\alpha}[\theta_1]$ to be more accurate than the Laplace approximation $\mathbb{E}_{q_{Lap}}[\theta_1]$ because $\mathcal{Q}_{mf}$ is more expressive than $\mathcal{Q}_{Lap}$. This intuition is born out in the left panel of Fig. 1. Since $\hat{\theta}_{Lap}$ uses only information at the mode, it fails to take into account the mass to the right of the mode, and the Laplace approximation's mean is too far to the left. The MFVB approximation, in contrast, is quite accurate for the posterior mean of θ_1, even though it gets the overall shape of the distribution wrong.

This example also shows why, in general, one cannot naively form a "Laplace approximation" to the posterior centered at the variational mean rather than at the MAP. As shown in the left panel of Fig. 1, in this case the posterior distribution is actually convex at the MFVB mean. Consequently, a naive second-order approximation to the log posterior centered at the MFVB mean would imply a negative variance.

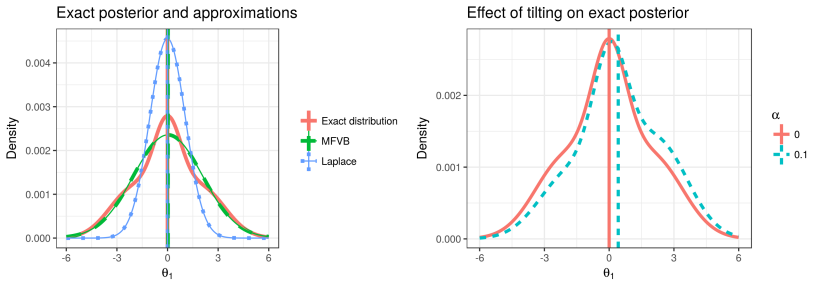

Figure 3: A univariate over-dispersed distribution. Vertical lines show the location of the means.

The perturbation $\rho(\theta, \alpha) = \alpha\theta_1$ is sometimes also described as a "tilting," and the right panel of Fig. 1 shows the effect of tilting on this posterior approximation. Tilting increases skew, but the MFVB approximation remains accurate, as shown in Fig. 2. Since local sensitivity of the expectation of θ_1 to α is the variance of θ_1 (see Eq. (13)), we have in Fig. 2 that:

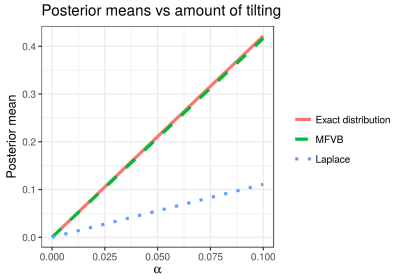
- The slope of the exact distribution's line is $\mathrm{Cov}_{p_0}(\theta_1)$;
- The slope of the MFVB line is the LRVB variance $\mathrm{Cov}^{LR}_{q_0}(\theta_1)$; and
- The slope of the Laplace line is $\mathrm{Cov}^{Lap}_{q_{Lap}}(\theta_1)$.

Since the MFVB and exact lines nearly coincide, we expect the LRVB variance estimate to be quite accurate for this example. Similarly, since the slope of the Laplace approximation line is lower, we expect the Laplace variance to underestimate the exact variance. This outcome, which can be seen visually in the left-hand panel of Fig. 2, is shown quantitatively in the corresponding table in the right-hand panel. The columns of the table contain information for the exact distribution and the three approximations. The first row, labeled "mean," shows $\mathbb{E}[\theta_1]$ and the second row, labeled "var," shows $\mathrm{Cov}(\theta_1)$. (The "LRVB" entry for the mean is blank because LRVB differs from MFVB only in covariance estimates.) We conclude that, in this case, Condition 1 holds for $\mathcal{Q}_{mf}$ but not for $\mathcal{Q}_{Lap}$.

5.1.3 A Univariate Over-dispersed Distribution

Having seen how MFVB can outperform the Laplace approximation for a univariate skewed distribution, we now apply that intuition to see why the linear response covariance can be superior to the Laplace approximation covariance for over-dispersed but symmetric distributions. Such a symmetric but over-dispersed distribution, formed with $K_z = 3$ components, is shown in Fig. 3 together with its approximations. By symmetry, both the MFVB and Laplace means are exactly correct (up to Monte Carlo error), as can be seen in the left panel of Fig. 3.

However, the right panel of Fig. 3 shows that symmetry is not maintained as the distribution is tilted. For $\alpha > 0$, the distribution becomes skewed to the right. Thus, by the intuition from the previous section, we expect the MFVB mean to be more accurate as the distribution is tilted and α increases from zero. In particular, we expect that the Laplace approximation's mean will not shift enough as α varies, i.e., that the Laplace approximation variance will be underestimated. Fig. 4 shows that this is indeed the case. The slopes in the left panel once again correspond to the estimated variances shown in the table, and, as expected the LRVB variance estimate is superior to the Laplace approximation variance.



Metric	Exact	LRVB	MFVB	Laplace
mean	-0.001		0.027	-0.000
var	4.218	4.153	4.161	1.107

Figure 4: Effect of tilting on a univariate over-dispersed distribution.

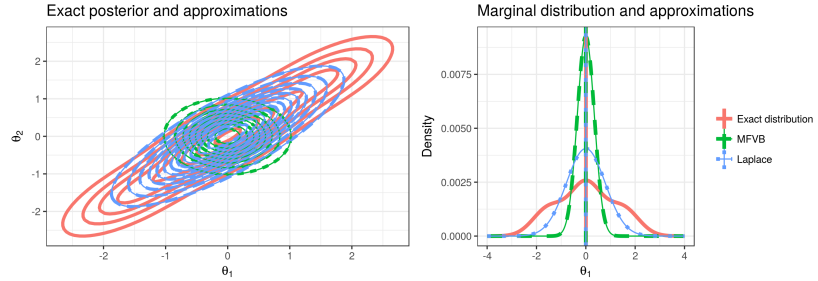


Figure 5: A bivariate over-dispersed distribution.

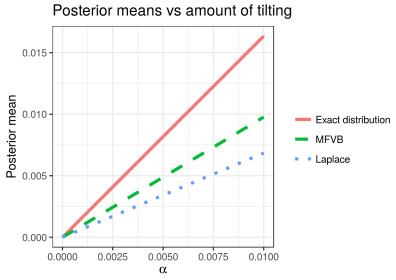
In this case, Condition 1 holds for $\mathcal{Q}_{mf}$. For the Laplace approximation, $\mathbb{E}_{q_{Lap}}[g(\theta)] = \mathbb{E}_{p_0}[g(\theta)]$ for $\alpha = 0$, so $\mathcal{Q}_{Lap}$ satisfies Eq. (11) of Condition 1 for α near zero, the derivatives of the two expectations with respect to α are quite different, so Eq. (12) of Condition 1 does not hold for $\mathcal{Q}_{Lap}$.

5.1.4 A BIVARIATE OVER-DISPERSED DISTRIBUTION

In the previous two examples the mean field approximation in $\mathcal{Q}$ did not matter, since the examples were one-dimensional. The only reason that the variational approximation was different from the exact $p_0(\theta)$ was the normal assumption in $\mathcal{Q}_{mf}$. Indeed, the tables in Fig. 2 and Fig. 4 show that the MFVB variance estimate is also reasonably close to the exact variance. In order to demonstrate why the LRVB variance can be better than both the Laplace approximation and the MFVB approximation, we turn to a bivariate, correlated, over-dispersed $p_0(\theta)$. For this we use $K_z = 3$ correlated normal distributions, shown in the left panel of Fig. 5. The right panel of Fig. 5 shows the marginal distribution of θ_1, in which the over-dispersion can be seen clearly. As Fig. 5 shows, unlike in the previous two examples, the mean field approximation causes $q_0(\theta)$ to dramatically underestimate the marginal variance of θ_1. Consequently, the MFVB means will also be under-responsive to the skew introduced by tilting with α. Though the Laplace approximation has a larger marginal variance, it remains unable to take skewness into account. Consequently, as seen in Fig. 6, the LRVB variance, while not exactly equal to the correct variance, is still an improvement over the Laplace covariance, and a marked improvement on the badly under-estimated MFVB variance.



Metric	Exact	LRVB	MFVB	Laplace
mean	0.005		-0.002	-0.000
var	1.635	0.976	0.241	0.684

Figure 6: Effect of tilting on a bivariate over-dispersed distribution.

One might say, in this case, that Condition 1 does not hold for either $\mathcal{Q}_{mf}$ or $\mathcal{Q}_{Lap}$, or, if it does, it is with a liberal interpretation of the "approximately equals" sign. However, the expressiveness of $\mathcal{Q}_{mf}$ allows LRVB to improve on the Laplace approximation, and the linear response allows it to improve over the MFVB approximation, and so LRVB gives the best of both worlds.

Thinking about problems in terms of these three simple models can provide intuition about when and whether Condition 1 might be expected to hold in a sense that is practically useful.

5.2 Automatic Differentiation Variational Inference (ADVI)

In this section we apply our methods to automatic differentiation variational inference (ADVI) (Kucukelbir et al., 2017). ADVI is a "black-box" variational approximation and optimization procedure that requires only that the user provide the log posterior, $\log p_0(\theta)$, up to a constant that does not depend on θ. To achieve this generality, ADVI employs:

- A factorizing normal variational approximation,[2]
- An unconstraining parameterization,
- The "re-parameterization trick," and
- Stochastic gradient descent.

ADVI uses a family employing the factorizing normal approximation

$$\mathcal{Q}_{ad} := \left\{ q(\theta) : q(\theta) = \prod_{k=1}^{K} \mathcal{N}(\theta_k | \mu_k, \exp(2\zeta_k)) \right\}.$$

That is, $\mathcal{Q}_{ad}$ is a fully factorizing normal family with means μ_k and log standard deviations ζ_k. Because we are including exponential family assumptions in the definition of MFVB (as described in Section 3.1), $\mathcal{Q}_{ad}$ is an instance of a mean-field family $\mathcal{Q}_{mf}$. In the notation of Eq. (7),

$$\eta = (\mu_1, ..., \mu_K, \zeta_1, ..., \zeta_K)^\intercal, \tag{22}$$

2. Kucukelbir et al. (2017) describe a non-factorizing version of ADVI, which is called "fullrank" ADVI in Stan. The factorizing version that we describe here is called "meanfield" ADVI in Stan. On the examples we describe, in the current Stan implementation, we found that fullrank ADVI provided much worse approximations to the MCMC posterior means than the meanfield version, and so we do not consider it further.

$\Omega_\eta = \mathbb{R}^{2K}$, λ is the Lebesgue measure, and the objective function Eq. (8) is

$$KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right) = -\int \mathcal{N}\left(\theta_k|\mu_k, \exp\left(2\zeta_k\right)\right)\log p_0\left(\theta\right)\lambda\left(d\theta\right) - \sum_{k=1}^{K}\zeta_k,$$

where we have used the form of the univariate normal entropy up to a constant.

The unconstraining parameterization is required because the use of a normal variational approximation dictates that the base measure on the parameters $\theta \in \mathbb{R}^K$ be supported on all of $\mathbb{R}^K$. Although many parameters of interest, such as covariance matrices, are not supported on $\mathbb{R}^K$, there typically exist differentiable maps from an unconstrained parameterization supported on $\mathbb{R}^K$ to the parameter of interest. Software packages such as Stan automatically provide such transforms for a broad set of parameter types. In our notation, we will take these constraining maps to be the function of interest, $g\left(\theta\right)$, and take θ to be unconstrained. Note that, under this convention, the prior $p\left(\theta|\alpha\right)$ must be a density in the unconstrained space. In practice (e.g., in the Stan software package), one usually specifies the prior density in the constrained space and converts it to a density $p\left(\theta|\alpha\right)$ in the unconstrained space using the determinant of the Jacobian of the constraining transform $g\left(\cdot\right)$.

The re-parameterization trick allows easy approximation of derivatives of the (generally intractable) objective $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$. By defining z_k using the change of variable

$$z_k := \left(\theta_k - \mu_k\right)/\exp\left(\zeta_k\right), \tag{23}$$

$KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$ can be re-written as an expectation with respect to a standard normal distribution. We write $\theta = \exp\left(\zeta\right)\circ z + \mu$ by using the component-wise Hadamard product $\circ$. Then

$$KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right) = -\mathbb{E}_z\left[\log p_0\left(\exp\left(\zeta\right)\circ z + \mu\right)\right] - \sum_{k=1}^{K}\zeta_k + Constant.$$

The expectation is still typically intractable, but it can be approximated using Monte Carlo and draws from a K-dimensional standard normal distribution. For a fixed number M of draws $z_1, ..., z_M$ from a standard K-dimensional normal, we can define the approximate KL divergence

$$\widehat{KL}\left(\eta\right) := -\frac{1}{M}\sum_{m=1}^{M}\log p_0\left(\exp\left(\zeta\right)\circ z_m + \mu\right) - \sum_{k=1}^{K}\zeta_k + Constant. \tag{24}$$

For any fixed M,

$$\mathbb{E}\left[\frac{\partial}{\partial\eta}\widehat{KL}\left(\eta\right)\right] = \frac{\partial}{\partial\eta}KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right),$$

so gradients of $\widehat{KL}\left(\eta\right)$ are unbiased for gradients of the exact KL divergence. Furthermore, for fixed draws $z_1, ..., z_M$, $\widehat{KL}\left(\eta\right)$ can be easily differentiated (using, again, the re-parameterization trick). Standard ADVI uses this fact to optimize $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$ using the unbiased gradient draws $\frac{\partial}{\partial\eta}\widehat{KL}\left(\eta\right)$ and a stochastic gradient optimization method, where the stochasticity comes from draws of the standard normal random variable z. Note that stochastic gradient methods typically use a new draw of z at every gradient step.

5.2.1 LINEAR RESPONSE FOR ADVI (LR-ADVI)

Since ADVI uses a factorizing normal approximation, the intuition from Section 5.1 may be expected to apply. In particular, we might expect that the ADVI means $\hat{\mu}$ might be a good approximation to $\mathbb{E}_{p_0}\left[\theta\right]$, that the ADVI variances $\exp\left(2\hat{\zeta}\right)$ would be under-estimates of the posterior variance $\mathrm{Cov}_{p_0}\left(\theta\right)$, so that using $\mathrm{Cov}_{q_0}^{LR}\left(\theta\right)$ could improve the approximations to the posterior variance. We refer to LRVB covariances calculated using an ADVI approximation as LR-ADVI.

To apply linear response to an ADVI approximation, we need to be able to approximate the Hessian of $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$ and to be assured that we have found an optimal η_0^*. But, by using a stochastic gradient method, ADVI avoids ever actually calculating the expectation in $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$. Furthermore even if a stochastic gradient method finds an point that is close to the optimal value of $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$ it may not be close to an optimum of $\widehat{KL}\left(\eta\right)$ for a particular finite M. Indeed, we found that, even for very large M, the optimum found by ADVI's stochastic gradient method is typically not close enough to an optimum of the approximate $\widehat{KL}\left(\eta\right)$ for sensitivity calculations to be useful. Sensitivity calculations are based on differentiating the fixed point equation given by the gradient being zero (see the proof in Appendix D), and do not apply at points for which the gradient is not zero either in theory nor in practice.

Consequently, in order to calculate the local sensitivity, we simply eschew the stochastic gradient method and directly optimize $\widehat{KL}\left(\eta\right)$ for a particular choice of M. (We will discuss shortly how to choose M.) We can then use $\widehat{KL}\left(\eta\right)$ in Eq. (10) rather than the exact KL divergence. Directly optimizing $\widehat{KL}\left(\eta\right)$ both frees us to use second-order optimization methods, which we found to converge more quickly to a high-quality optimum than first-order methods, and guarantees that we are evaluating the Hessian $\mathbf{H}_{\eta\eta}$ at an optimum of the objective function used to calculate Eq. (10).

As M approaches infinity, we expect the optimum of $\widehat{KL}\left(\eta\right)$ to approach the optimum of $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$ by the standard frequentist theory of estimating equations (Keener, 2010, Chapter 9). In practice we must fix a particular finite M, with larger M providing better approximations of the true KL divergence but at increased computational cost. We can inform this tradeoff between accuracy and computation by considering the frequentist variability of η_0^* when randomly sampling M draws of the random variable z used to approximate the intractable integral in $\widehat{KL}\left(\eta\right)$. Denoting this frequentist variability by $\mathrm{Cov}_z\left(\eta_0^*\right)$, standard results (Keener, 2010, Chapter 9) give that

$$\mathrm{Cov}_z\left(\eta_0^*\right) \approx \mathbf{H}_{\eta\eta}^{-1}\mathrm{Cov}_z\left(\left.\frac{\partial}{\partial\eta}\widehat{KL}\left(\eta\right)\right|_{\eta_0^*}\right)\mathbf{H}_{\eta\eta}^{-1}. \tag{25}$$

A sufficiently large M will be one for which $\mathrm{Cov}_z\left(\eta_0^*\right)$ is adequately small. One notion of "adequately small" might be that the ADVI means found with $\widehat{KL}\left(\eta\right)$ are within some fraction of a posterior standard deviation of the optimum of $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$. Having chosen a particular M, we can calculate the frequentist variability of μ^* using $\mathrm{Cov}_{q_0}^{LR}\left(g\left(\theta\right)\right)$ and estimate the posterior standard deviation using Eq. (14). If we find that each μ^* is probably within 0.5 standard deviations of the optimum of $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$, we can keep the results; otherwise, we increase M and try again. In the examples we consider here, we found that the relatively modest $M = 10$ satisfies this condition and provides sufficiently accurate results.

Finally, we note a minor departure from Eq. (14) when calculating $\mathrm{Cov}_{q_0}^{LR}\left(g\left(\theta\right)\right)$ from $\mathbf{H}_{\eta\eta}$. Recall that, in this case, we are taking $g\left(\cdot\right)$ to be ADVI's constraining transform, and that Eq. (14) requires the Jacobian, $\mathbf{g}_\eta$, of this transform. At the time of writing, the design of the Stan software package did not readily support automatic calculation of $\mathbf{g}_\eta$, though it did support rapid evaluation of $g\left(\theta\right)$ at particular values of θ. Consequently, we used linear response to estimate $\mathrm{Cov}_{q_0}^{LR}\left(\theta\right)$, drew a large number N_s of Monte Carlo draws from $\theta_n \sim \mathcal{N}\left(\mu, \mathrm{Cov}_{q_0}^{LR}\left(\theta\right)\right)$ for $n = 1, ..., N_s$, and then used these draws to form a Monte Carlo estimate of the sample covariance of $g\left(\theta\right)$. Noting that $\mathbb{E}_{q_\alpha}\left[\theta\right] = \mu$, and recalling the definition of η for ADVI in Eq. (22), by Eq. (14) we have

$$\mathrm{Cov}_{q_0}^{LR}\left(\theta\right) = \frac{\partial\mathbb{E}_{q_\alpha}\left[\theta\right]}{\partial\eta^\intercal}\mathbf{H}_{\eta\eta}^{-1}\frac{\partial\mathbb{E}_{q_\alpha}\left[\theta^\intercal\right]}{\partial\eta} = \begin{pmatrix} I_K & 0 \\ 0 & 0 \end{pmatrix}\mathbf{H}_{\eta\eta}^{-1}\begin{pmatrix} I_K & 0 \\ 0 & 0 \end{pmatrix},$$

which is the upper-left quarter of the matrix $\mathbf{H}_{\eta\eta}^{-1}$. In addition to obviating the need for $\mathbf{g}_\eta$, this approach also allowed us to take into account possible nonlinearities in $g\left(\cdot\right)$ at little additional computational cost.

5.2.2 RESULTS

We present results from four models taken from the Stan example set, namely the models `election88` ("Election model"), `sesame_street1` ("Sesame Street model"), `radon_vary_intercept_floor` ("Radon

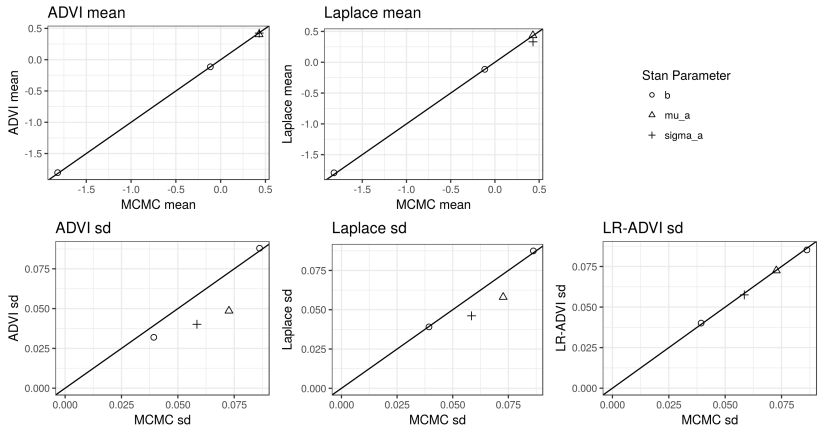


Figure 7: Election model

model"), and `cjs_cov_randeff` ("Ecology model"). We experimented with many models from the Stan examples and selected these four as representative of the type of model where LR-ADVI can be expected to provide a benefit—specifically, they are models of a moderate size. For very small models, MCMC runs quickly enough in Stan that fast approximations are not necessary, and for very large models (with thousands of parameters) the relative advantages of LR-ADVI and the Laplace approximation diminish due to the need to calculate $\mathbf{H}_{\eta\eta}$ or $\mathbf{H}_{Lap}$ using automatic differentiation.[3] The size of the data and size of the parameter space for our four chosen models are shown in Fig. 11. We also eliminated from consideration models where Stan's MCMC algorithm reported divergent transitions or where Stan's ADVI algorithm returned wildly inaccurate posterior mean estimates.

For brevity, we do not attempt to describe the models or data in any detail here; rather, we point to the relevant literature in their respective sections. The data and Stan implementations themselves can be found on the Stan website (Stan Team, 2017) as well as in Appendix F.

To assess the accuracy of each model, we report means and standard deviations for each of Stan's model parameters as calculated by Stan's MCMC and ADVI algorithms and a Laplace approximation, and we report the standard deviations as calculated by $\mathrm{Cov}_{q_0}^{LR}\left(g\left(\theta\right)\right)$. Recall that, in our notation, $g\left(\cdot\right)$ is the (generally nonlinear) map from the unconstrained latent ADVI parameters to the constrained space of the parameters of interest. The performance of ADVI and Laplace vary, and only LR-ADVI provides a consistently good approximation to the MCMC standard deviations. LR-ADVI was somewhat slower than a Laplace approximation or ADVI alone, but it was typically about five times faster than MCMC; see Section 5.2.7 for detailed timing results.

5.2.3 ELECTION MODEL ACCURACY

We begin with `election88`, which models binary responses in a 1988 poll using a Bernoulli hierarchical model with normally distributed random effects for state, ethnicity, and gender and a logit link. The model and data are described in detail in Gelman and Hill (2006, Chapter 14). Fig. 7 shows that both the Laplace approximation and ADVI do a reasonable job of matching to MCMC, though LR-ADVI is slightly more accurate for standard deviations.

3. We calculated $\mathbf{H}_{\eta\eta}$ using a custom branch of Stan's automatic differentiation software (Carpenter et al., 2015) that exposes Hessians and Hessian-vector products in the `Rstan modelfit` class. When this custom branch is merged with the main branch of Stan, it will be possible to implement LR-ADVI for generic Stan models.

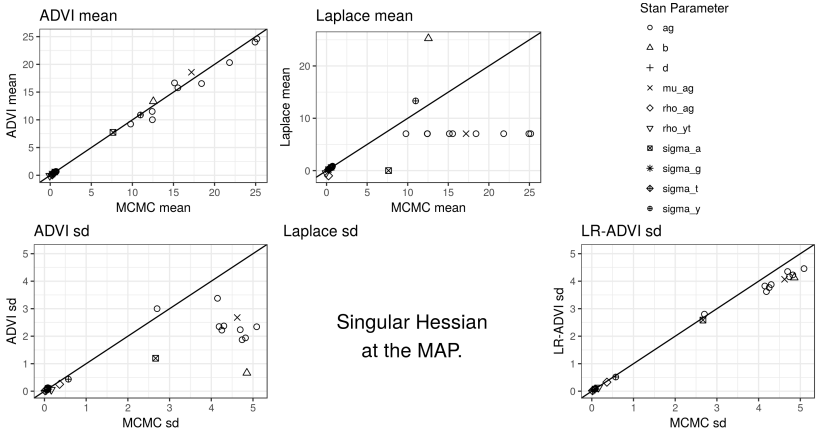

Figure 8: Sesame Street model

5.2.4 SESAME STREET MODEL ACCURACY

Next, we show results for `sesame_street1`, an analysis of a randomized controlled trial designed to estimate the causal effect of watching the television show Sesame Street on a letter-recognition test. To control for different conditions in the trials, a hierarchical model is used with correlated multivariate outcomes and unknown covariance structure. The model and data are described in detail in Gelman and Hill (2006, Chapter 23).

As can be seen in Fig. 8, the MAP under-estimates the variability of the random effects ag, and, in turn, under-estimates the variance parameter $sigma\_a$. Because the MAP estimate of $sigma\_a$ is close to zero, the log posterior has a very high curvature with respect to the parameter ag at the MAP, and the Hessian used for the Laplace approximation is numerically singular. ADVI, which integrates out the uncertainty in the random effects, provides reasonably good estimates of the posterior means but underestimates the posterior standard deviations due to the mean-field assumption. Only LR-ADVI provides accurate estimates of posterior uncertainty.

5.2.5 RADON MODEL ACCURACY

We now turn to `radon_vary_intercept_floor`, a hierarchical model of radon levels in Minnesota homes described in Gelman and Hill (2006, Chapters 16 and 21). This model is relatively simple, with univariate normal observations and unknown variances. Nevertheless, the Laplace approximation again produces a numerically singular covariance matrix. The ADVI means are reasonably accurate, but the standard deviations are not. Only LR-ADVI produces an accurate approximation to the MCMC posterior standard deviations.

5.2.6 ECOLOGY MODEL ACCURACY

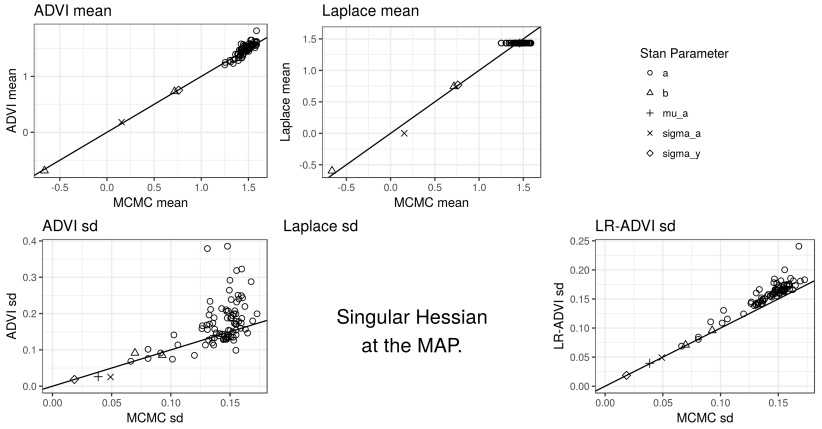

Figure 9: Radon model

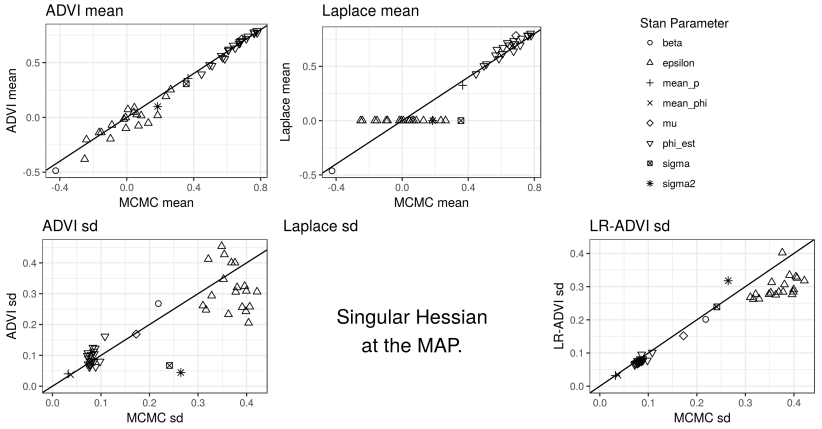

Figure 10: Ecology model

Finally, we consider a more complicated mark-recapture model from ecology known as the Cormack-Jolly-Seber (CJS) model. This model is described in detail in Kéry and Schaub (2011, Chapter 7), and discussion of the Stan implementation can be found in Stan Team (2015, Section 15.3).

The Laplace approximation is again degenerate, and the ADVI standard deviations again deviate considerably from MCMC. In this case, the ADVI means are also somewhat inaccurate, and some of the LR-ADVI standard deviations are mis-estimated in turn. However, LR-ADVI remains by far the most accurate method for approximating the MCMC standard errors.

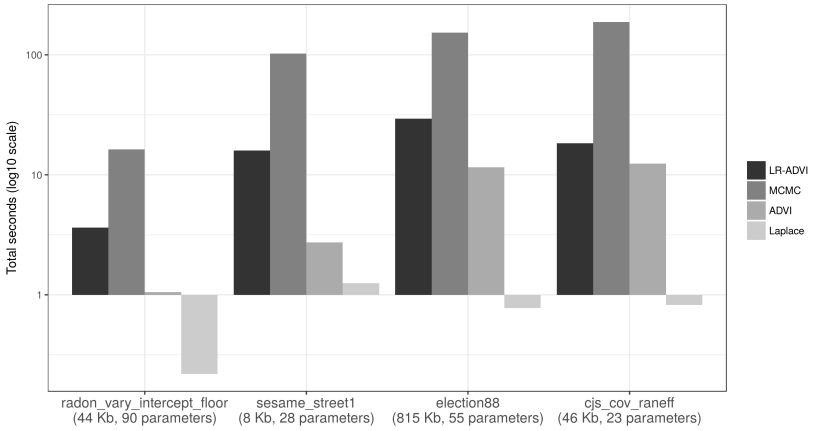

Figure 11: Comparision of timing in ADVI experiments

5.2.7 TIMING RESULTS

Detailed timing results for the ADVI experiments are shown in Fig. 11. Both the Laplace approximation and ADVI alone are faster than LR-ADVI, which in turn is about five times faster than MCMC. We achieved the best results optimizing $\widehat{KL}(\eta)$ by using the conjugate gradient Newton's trust region method (`trust-ncg` of `scipy.optimize`), but the optimization procedure still accounted for an appreciable proportion of the time needed for LR-ADVI.

5.3 Criteo Dataset

We now apply our methods to a real-world data set using a logistic regression with random effects, which is an example of a generalized linear mixed model (GLMM) (Agresti and Kateri, 2011, Chapter 13). This data and model have several advantages as an illustration of our methods: the data set is large, the model contains a large number of imprecisely-estimated latent variables (the unknown random effects), the model exhibits the sparsity of $\mathbf{H}_{\eta\eta}$ that is typical in many MFVB applications, and the results exhibit the same shortcomings of the Laplace approximation seen above. For this model, we will evaluate both posterior covariances and prior sensitivities.

5.3.1 DATA AND MODEL

We investigated a custom subsample of the 2014 Criteo Labs conversion logs data set (Criteo Labs, 2014), which contains an obfuscated sample of advertising data collected by Criteo over a period of two months. Each row of the data set corresponds to a single user click on an online advertisement. For each click, the data set records a binary outcome variable representing whether or not the user subsequently "converted" (i.e., performed a desired task, such as purchasing a product or signing up for a mailing list). Each row contains two timestamps (which we ignore), eight numerical covariates, and nine factor-valued covariates. Of the eight numerical covariates, three contain 30% or more missing data, so we discarded them. We then applied a per-covariate normalizing transform to the distinct values of those remaining. Among the factor-valued covariates, we retained only the one with the largest number of unique values and discarded the others.

These data-cleaning decisions were made for convenience. The goal of the present paper is to demonstrate our inference methods, not to draw conclusions about online advertising.

Although the meaning of the covariates has been obfuscated, for the purpose of discussion we will imagine that the single retained factor-valued covariate represents the identity of the advertiser, and the numeric covariates represent salient features of the user and/or the advertiser (e.g., how often the user has clicked or converted in the past, a machine learning rating for the advertisement quality, etc.). As such, it makes sense to model the probability of each row's binary outcome (whether or not the user converted) as a function of the five numeric covariates and the advertiser identity using a logistic GLMM. Specifically, we observe binary conversion outcomes, y_{it}, for click i on advertiser t, with probabilities given by observed numerical explanatory variables, x_{it}, each of which are vectors of length $K_x = 5$. Additionally, the outcomes within a given value of t are correlated through an unobserved random effect, u_t, which represents the "quality" of advertiser t, where the value of t for each observation is given by the factor-valued covariate. The random effects u_t are assumed to follow a normal distribution with unknown mean and variance. Formally,

$$\begin{aligned} y_{it}|p_{it} &\sim \text{Bernoulli}\left(p_{it}\right), \text{ for } t = 1, ..., T \text{ and } i = 1, ..., N_t \\ p_{it} &:= \frac{e^{\rho_{it}}}{1 + e^{\rho_{it}}} \quad \text{where} \quad \rho_{it} := x_{it}^T \beta + u_t \\ u_t|\mu, \tau &\sim \mathcal{N}\left(\mu, \tau^{-1}\right). \end{aligned}$$

Consequently, the unknown parameters are $\theta = (\beta^\intercal, \mu, \tau, u_1, ..., u_T)^\intercal$. We use the following priors:

$$\begin{aligned} \mu|\mu_0, \tau_\mu &\sim \mathcal{N}\left(\mu_0, \tau_\mu^{-1}\right) \\ \tau|\alpha_\tau, \beta_\tau &\sim \text{Gamma}\left(\alpha_\tau, \beta_\tau\right) \\ \beta|\beta_0, \tau_\beta, \gamma_\beta &\sim \mathcal{N}\left(\begin{pmatrix} \beta_0 \\ \vdots \\ \beta_0 \end{pmatrix}, \begin{pmatrix} \tau_\beta & \gamma_\beta & \gamma_\beta \\ \gamma_\beta & \ddots & \gamma_\beta \\ \gamma_\beta & \gamma_\beta & \tau_\beta \end{pmatrix}^{-1}\right). \end{aligned}$$

Note that we initially take $\gamma_\beta = 0$ so that the prior information matrix on β is diagonal. Nevertheless, by retaining γ_β as a hyperparameter we will be able to assess the sensitivity to the assumption of a diagonal prior in Section 5.3.6. The remaining prior values are given in Appendix H. It is reasonable to expect that a modeler would be interested both in the effect of the numerical covariates and in the quality of individual advertisers themselves, so we take the parameter of interest to be $g(\theta) = (\beta^\intercal, u_1, ..., u_T)^\intercal$.

To produce a data set small enough to be amenable to MCMC but large and sparse enough to demonstrate our methods, we subsampled the data still further. We randomly chose 5000 distinct advertisers to analyze, and then subsampled each selected advertiser to contain no more than 20 rows each. The resulting data set had $N = 61895$ total rows. If we had more observations per advertiser, the "random effects" u_t would have been estimated quite precisely, and the nonlinear nature of the problem would not have been important; these changes would thus have obscured the benefits of using MFVB versus the Laplace approximation. In typical internet data sets a large amount of data comes from advertisers with few observations each, so our subsample is representative of practically interesting problems.

5.3.2 INFERENCE AND TIMING

We estimated the expectation and covariance of $g(\theta)$ using four techniques: MCMC, the Laplace approximation, MFVB, and linear response (LRVB) methods. For MCMC, we used Stan (Stan Team, 2015), and to calculate the MFVB, Laplace, and LRVB estimates we used our own Python code using `numpy`, `scipy`, and `autograd` (Jones et al., 2001; Maclaurin et al., 2015). As described in Section 5.3.3, the MAP estimator did not estimate $\mathbb{E}_{p_0}[g(\theta)]$ very well, so we do not report standard deviations or sensitivity measures for the Laplace approximations. The summary of the computation time for all these methods is shown in Table 1, with details below.

Method	Seconds
MAP (optimum only)	12
VB (optimum only)	57
VB (including sensitivity for β)	104
VB (including sensitivity for β and u)	553
MCMC (Stan)	21066

Table 1: Timing results

For the MCMC estimates, we used Stan to draw 5000 MCMC draws (not including warm-up), which took 351 minutes. We estimated all the prior sensitivities of Section 5.3.6 using the Monte Carlo version of the covariance in Eq. (5).

For the MFVB approximation, we use the following mean field exponential family approximations:

$$\begin{aligned} q(\beta_k) &= \mathcal{N}\left(\beta_k; \eta_{\beta_k}\right), \text{ for } k = 1, ..., K_x \\ q(u_t) &= \mathcal{N}\left(u_t; \eta_{u_t}\right), \text{ for } t = 1, ..., T \\ q(\tau) &= \text{Gamma}\left(\tau; \eta_\tau\right) \\ q(\mu) &= \mathcal{N}\left(\mu; \eta_\mu\right) \\ q(\theta) &= q(\tau)\, q(\mu) \prod_{k=1}^{K_x} q(\beta_k) \prod_{t=1}^{T} q(u_t). \end{aligned}$$

With these choices, evaluating the variational objective requires the following intractable univariate variational expectation:

$$\mathbb{E}_{q(\theta;\eta)}\left[\log\left(1 - p_{it}\right)\right] = \mathbb{E}_{q(\theta;\eta)}\left[\log\left(1 - \frac{e^{\rho_{it}}}{1 + e^{\rho_{it}}}\right)\right].$$

We used the re-parameterization trick and four points of Gauss-Hermite quadrature to estimate this integral for each observation. See Appendix H for more details.

We optimized the variational objective using the conjugate gradient Newton's trust region method, `trust-ncg`, of `scipy.optimize`. One advantage of `trust-ncg` is that it performs second-order optimization but requires only Hessian-vector products, which can be computed quickly by `autograd` without constructing the full Hessian. The MFVB fit took 57 seconds, roughly 370 times faster than MCMC with Stan.

With variational parameters for each random effect u_t, $\mathbf{H}_{\eta\eta}$ is a 10014×10014 dimensional matrix. Consequently, evaluating $\mathbf{H}_{\eta\eta}$ directly as a dense matrix using `autograd` would have been prohibitively time-consuming. Fortunately, our model can be decomposed into global and local parameters, and the Hessian term $\mathbf{H}_{\eta\eta}$ in Theorem 2 is extremely sparse. In the notation of Section 4.5, take $\theta_{glob} = (\beta^\intercal, \mu, \tau)^\intercal$, take $\theta_{loc,t} = u_t$, and stack the variational parameters as $\eta = \left(\eta_{glob}^\intercal, \eta_{loc,1}, ..., \eta_{loc,T}\right)^\intercal$. The cross terms in $\mathbf{H}_{\eta\eta}$ between the local variables vanish:

$$\frac{\partial^2 KL\left(q(\theta;\eta)\,||p_\alpha(\theta)\right)}{\partial \eta_{loc,t_1} \partial \eta_{loc,t_2}} = 0 \text{ for all } t_1 \neq t_2.$$

Equivalently, note that the full likelihood in Appendix H, Eq. (31), has no cross terms between u_{t_1} and u_{t_2} for $t_1 \neq t_2$. As the dimension T of the data grows, so does the length of η. However, the dimension of η_{glob} remains constant, and $\mathbf{H}_{\eta\eta}$ remains easy to invert. We show an example of the sparsity pattern of the first few rows and columns of $\mathbf{H}_{\eta\eta}$ in Fig. 12 .

Taking advantage of this sparsity pattern, we used `autograd` to calculate the Hessian of the KL divergence one group at a time and assembled the results in a sparse matrix using the `scipy.sparse` Python

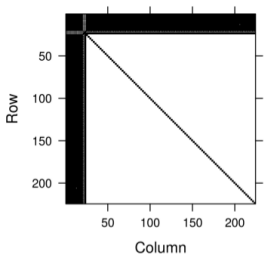

Figure 12: Sparsity pattern of top-left sub-matrix of $\mathbf{H}_{\eta\eta}$ for the logit GLMM model. The axis numbers represent indices within η, and black indicates non-zero entries of $\mathbf{H}_{\eta\eta}$.

package. Even so, calculating the entire sparse Hessian took 323 seconds, and solving the system $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_\eta^\intercal$ using `scipy.sparse.linalg.spsolve` took an additional 173 seconds. These results show that the evaluation and inversion of $\mathbf{H}_{\eta\eta}$ was several times more costly than optimizing the variational objective itself. (Of course, the whole procedure remains much faster than running MCMC with Stan.)

We note, however, that instead of the direct approach to calculating $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_\eta^\intercal$ one can use the conjugate gradient algorithm of `sp.sparse.linalg.cg` (Wright and Nocedal, 1999, Chapter 5) together with the fast Hessian-vector products of `autograd` to query one column at a time of $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_\eta^\intercal$. On a typical column of $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_\eta^\intercal$ in our experiment, calculating the conjugate gradient took only 9.4 seconds (corresponding to 81 Hessian-vector products in the conjugate gradient algorithm). Thus, for example, one could calculate the columns of $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_\eta^\intercal$ corresponding to the expectations of the global variables β in only $9.4 \times K_x = 46.9$ seconds, which is much less time than it would take to compute the entire $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_\eta^\intercal$ for both β and every random effect in u.

For the Laplace approximation, we calculated the MAP estimator and $\mathbf{H}_{Lap}$ using Python code similar to that used for the MFVB estimates. We observe that the MFVB approximation to posterior means would be expected to improve on the MAP estimator only in cases when there is both substantial uncertainty in some parameters and when this uncertainty, through nonlinear dependence between parameters, affects the values of posterior means. These circumstances obtain in the logistic GLMM model with sparse per-advertiser data since the random effects u_t will be quite uncertain and the other posterior means depend on them through the nonlinear logistic function.

5.3.3 POSTERIOR APPROXIMATION RESULTS

In this section, we assess the accuracy of the MFVB, Laplace, and LRVB methods as approximations to $\mathbb{E}_{p_0}[g(\theta)]$ and $\mathrm{Cov}_{p_0}(g(\theta))$. We take the MCMC estimates as ground truth. Although, as discussed in Section 5.3, we are principally interested in the parameters $g(\theta) = (\beta^\intercal, u_1, ..., u_T)^\intercal$, we will report the results for all parameters for completeness. For readability, the tables and graphs show results for a random selection of the components of the random effects u.

5.3.4 POSTERIOR MEANS

We begin by comparing the posterior means in Table 2, Fig. 13, and Fig. 14. We first note that, despite the long running time for MCMC, the β_1 and μ parameters did not mix well in the MCMC sample, as is reflected in the MCMC standard error and effective number of draws columns of Table 2. The x_{it} data corresponding to β_1 contained fewer distinct values than the other columns of x, which perhaps led to some co-linearity between β_1 and μ in the posterior. This co-linearity could have caused both poor MCMC mixing

Parameter	MCMC	MFVB	MAP	MCMC std. err.	Eff. # of MCMC draws
β_1	1.454	1.447	1.899	0.02067	33
β_2	0.031	0.033	0.198	0.00025	5000
β_3	0.110	0.110	0.103	0.00028	5000
β_4	-0.172	-0.173	-0.173	0.00016	5000
β_5	0.273	0.273	0.280	0.00042	5000
μ	2.041	2.041	3.701	0.04208	28
τ	0.892	0.823	827.724	0.00051	1232
u_{1431}	1.752	1.757	3.700	0.00937	5000
u_{4150}	1.217	1.240	3.699	0.01022	5000
u_{4575}	2.427	2.413	3.702	0.00936	5000
u_{4685}	3.650	3.633	3.706	0.00862	5000

Table 2: Results for the estimation of the posterior means

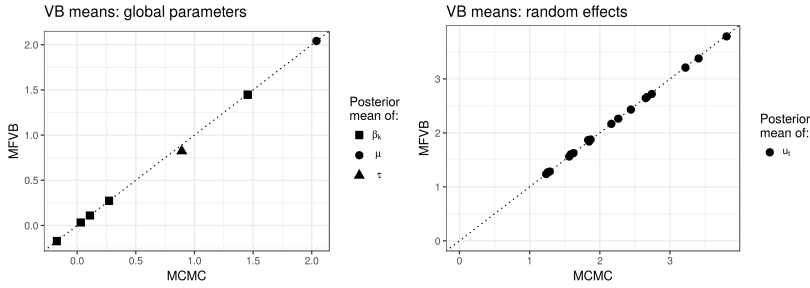

Figure 13: Comparison of MCMC and MFVB means

and, perhaps, excessive measured prior sensitivity, as discussed below in Section 5.3.6. Although we will report the results for both β_1 and μ without further comment, the reader should bear in mind that the MCMC "ground truth" for these two parameters is somewhat suspect.

The results in Table 2 and Fig. 13 show that MFVB does an excellent job of approximating the posterior means in this particular case, even for the random effects u and the related parameters μ and τ. In contrast, the MAP estimator does reasonably well only for certain components of β and does extremely poorly for the random effects parameters. As can be seen in Fig. 14, the MAP estimate dramatically overestimates the information τ of the random effect distribution (that is, it underestimates the variance). As a consequence, it estimates all the random effects to have essentially the same value, leading to mis-estimation of some location parameters, including both μ and some components of β. Since the MAP estimator performed so poorly at estimating the random effect means, we will not consider it any further.

5.3.5 POSTERIOR COVARIANCES

We now assess the accuracy of our estimates of $\mathrm{Cov}_{p_0}(g(\theta))$. The results for the marginal standard deviations are shown in Table 3 and Fig. 15. We refer to the standard deviations of $\mathrm{Cov}_{q_0}(g(\theta))$ as the "uncorrected MFVB" estimate, and of $\mathrm{Cov}_{q_0}^{LR}(g(\theta))$ as the "LRVB" estimate. The uncorrected MFVB variance estimates of β are particularly inaccurate, but the LRVB variances match the exact posterior closely.

In Fig. 16, we compare the off-diagonal elements of $\mathrm{Cov}_{q_0}^{LR}(g(\theta))$ and $\mathrm{Cov}_{p_0}(g(\theta))$. These covariances are zero, by definition, in the uncorrected MFVB estimates $\mathrm{Cov}_{q_0}(g(\theta))$. The left panel of Fig. 16 shows the

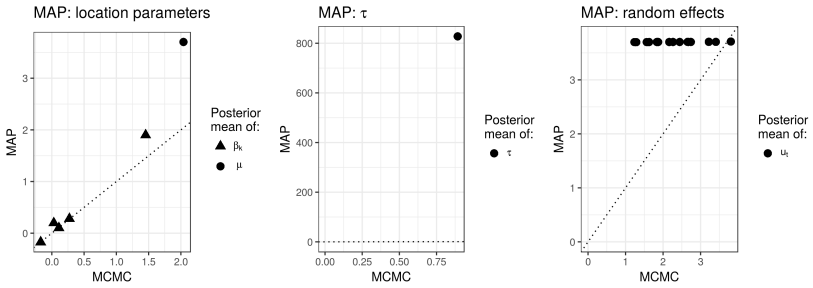

Figure 14: Comparison of MCMC and Laplace means

Parameter	MCMC	LRVB	Uncorrected MFVB
β_1	0.118	0.103	0.005
β_2	0.018	0.018	0.004
β_3	0.020	0.020	0.004

u_{4685}	0.610	0.607	0.579

Table 3: Standard deviation results

estimated covariances between the global parameters and all other parameters, including the random effects, and the right panel shows only the covariances amongst the random effects. The LRVB covariances are quite accurate, particularly when we recall that the MCMC draws of μ may be inaccurate due to poor mixing.

5.3.6 PARAMETRIC SENSITIVITY RESULTS

Finally, we compare the MFVB prior sensitivity measures of Section 4.4 to the covariance-based MCMC sensitivity measures of Section 2.1. Since sensitivity is of practical interest only when it is of comparable order to the posterior uncertainty, we report sensitivities normalized by the appropriate standard deviation. That is, we report $\hat{\mathbf{S}}_{\alpha_0} / \sqrt{\text{diag}\left(\hat{\text{Cov}}_{p_0}\left(g\left(\theta\right)\right)\right)}$, and $\mathbf{S}^q_{\alpha_0} / \sqrt{\text{diag}\left(\text{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right)\right)}$, etc., where $\text{diag}\left(\cdot\right)$ denotes the diagonal vector of a matrix, and the division is element-wise. Note that we use the sensitivity-based variance estimates $\text{Cov}^{LR}_{q_0}$, not the uncorrected MFVB estimates Cov_{q_0}, to normalize the variational sensitivities. We refer to a sensitivity divided by a standard deviation as a "normalized" sensitivity.

The comparison between the MCMC and MFVB sensitivity measures is shown in Fig. 17. The MFVB and MCMC sensitivities correspond very closely, though the MFVB means appear to be slightly more sensitive to the prior parameters than the MCMC means. This close correspondence should not be surprising. As shown in Section 5.3.3, the MFVB and MCMC posterior means match quite closely. If we assume, reasonably, that they continue to match to first order in a neighborhood of our original prior parameters, then Condition 1 will hold and we would expect $\hat{\mathbf{S}}_{\alpha_0} \approx \mathbf{S}^q_{\alpha_0}$.

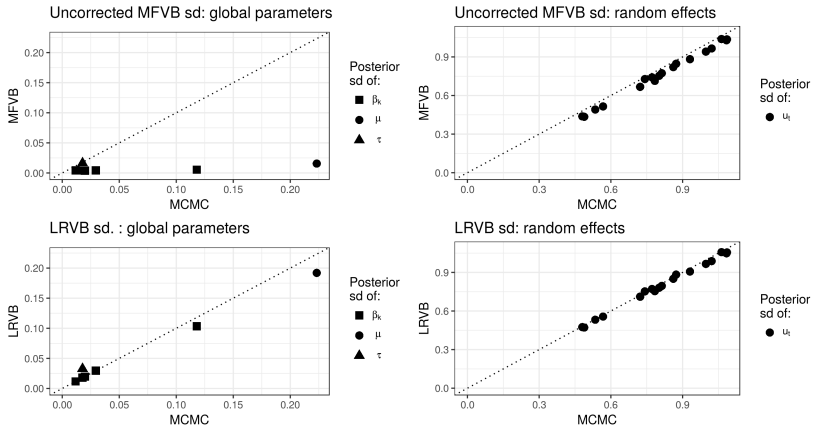

Figure 15: Comparison of MCMC, MFVB, and LRVB standard deviations

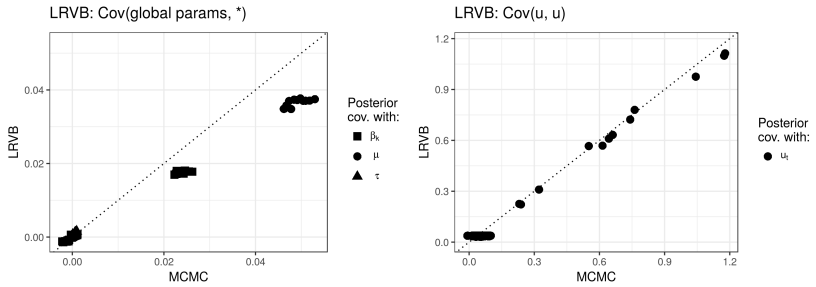

Figure 16: Comparison of MCMC and LRVB off-diagonal covariances

Table 4 shows the detailed MFVB normalized sensitivity results. Each entry is the sensitivity of the MFVB mean of the row's parameter to the column's prior parameter. One can see that several parameters are quite sensitive to the information parameter prior τ_μ. In particular, $\mathbb{E}_{p_\alpha}\left[\mu\right]$ and $\mathbb{E}_{p_\alpha}\left[\beta_1\right]$ are expected to change approximately -0.39 and -0.35 standard deviations, respectively, for every unit change in τ_μ. This size of change could be practically significant (assuming that such a change in τ_μ is subjectively plausible). To investigate this sensitivity further, we re-fit the MFVB model at a range of values of the prior parameter τ_μ, assessing the accuracy of the linear approximation to the sensitivity. The results are shown in Fig. 18. Even for very large changes in τ_μ—resulting in changes to $\mathbb{E}_{p_\alpha}\left[\mu\right]$ and $\mathbb{E}_{p_\alpha}\left[\beta_1\right]$ far in excess of two standard deviations—the linear approximation holds up reasonably well. Fig. 18 also shows a (randomly selected) random effect to be quite sensitive, though not to a practically important degree relative to its posterior standard deviation. The insensitivity of $\mathbb{E}_{p_\alpha}\left[\beta_2\right]$ is also confirmed. Of course, the accuracy of the linear approximation cannot be guaranteed to hold as well in general as it does in this particular case, and the quick

	β_0	τ_β	γ_β	μ_0	τ_μ	α_τ	$\beta\tau$

Table 4: MFVB normalized prior sensitivity results

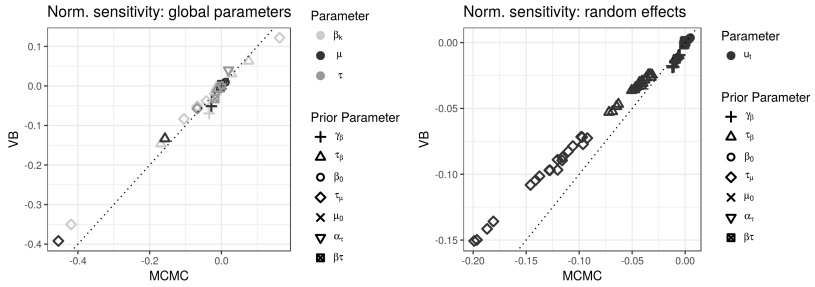

Figure 17: Comparison of MCMC and MFVB normalized parametric sensitivity results

and reliable evaluation of the linearity assumption without re-fitting the model remains interesting future work.

Since we started the MFVB optimization close to the new, perturbed optimum, each new MFVB fit took only 27.2 seconds on average. Re-estimating the MCMC posterior so many times would have been extremely time-consuming. (Note that importance sampling would be useless for prior parameter changes that moved the posterior so far from the original draws.) The considerable sensitivity of this model to a particular prior parameter, which is perhaps surprising on such a large data set, illustrates the value of having fast, general tools for discovering and evaluating prior sensitivity. Our framework provides just such a set of tools.

6. Conclusion

By calculating the sensitivity of MFVB posterior means to model perturbations, we are able to provide two important practical tools for MFVB posterior approximations: improved variance estimates and measures of prior robustness. When MFVB models are implemented in software that supports automatic differentiation, our methods are fast, scalable, and require little additional coding beyond the MFVB objective itself. In our experiments, we were able to calculate accurate posterior means, covariances, and prior sensitivity measures orders of magnitude more quickly than MCMC.

Appendices

Appendix A. Proof of Theorem 1

In this section we prove Theorem 1.

Proof Under Assumption 1, we can exchange differentiation and integration in $\frac{\partial}{\partial \alpha^\intercal}\int p_0(\theta)\exp(\rho(\theta,\alpha))\,g(\theta)\,\lambda(d\theta)$ and $\frac{\partial}{\partial \alpha^\intercal}\int p_0(\theta)\exp(\rho(\theta,\alpha))\,\lambda(d\theta)$ by Fleming (1965, Chapter 5-11, Theorem 18), which ultimately depends on the Lebesgue dominated convergence theorem. By Assumption 1, $\mathbb{E}_{p_\alpha}[g(\theta)]$ is well-defined for $\alpha \in \mathcal{A}_0$ and

$$\frac{\partial p_0(\theta)\exp(\rho(\theta,\alpha))}{\partial \alpha} = p_0(\theta)\exp(\rho(\theta,\alpha))\frac{\partial \rho(\theta,\alpha)}{\partial \alpha} \quad \lambda\text{-almost everywhere.}$$

Armed with these facts, we can directly compute

$$\begin{aligned}
\left.\frac{d\mathbb{E}_{p_\alpha}[g(\theta)]}{d\alpha^\intercal}\right|_{\alpha_0} &= \left.\frac{d}{d\alpha^\intercal}\frac{\int g(\theta)\,p_0(\theta)\exp(\rho(\theta,\alpha))\,\lambda(d\theta)}{\int p_0(\theta)\exp(\rho(\theta,\alpha))\,\lambda(d\theta)}\right|_{\alpha_0} \\
&= \frac{\left.\frac{\partial}{\partial \alpha^\intercal}\int g(\theta)\,p_0(\theta)\exp(\rho(\theta,\alpha))\,\lambda(d\theta)\right|_{\alpha_0}}{\int p_0(\theta)\exp(\rho(\theta,\alpha_0))\,\lambda(d\theta)} - \mathbb{E}_{p_0}[g(\theta)]\frac{\left.\frac{\partial}{\partial \alpha^\intercal}\int p_0(\theta)\exp(\rho(\theta,\alpha))\,\lambda(d\theta)\right|_{\alpha_0}}{\int p_0(\theta)\exp(\rho(\theta,\alpha_0))\,\lambda(d\theta)} \\
&= \frac{\int g(\theta)\,p_0(\theta)\exp(\rho(\theta,\alpha))\left.\frac{\partial \rho(\theta,\alpha)}{\partial \alpha}\right|_{\alpha_0}\lambda(d\theta)}{\int p_0(\theta)\exp(\rho(\theta,\alpha_0))\,\lambda(d\theta)} - \mathbb{E}_{p_0}[g(\theta)]\,\mathbb{E}_{p_0}\left[\left.\frac{\partial \rho(\theta,\alpha)}{\partial \alpha}\right|_{\alpha_0}\right] \\
&= \mathrm{Cov}_{p_0}\left(g(\theta), \left.\frac{\partial \rho(\theta,\alpha)}{\partial \alpha}\right|_{\alpha_0}\right).
\end{aligned}$$

■

Appendix B. Comparison With MCMC Importance Sampling

In this section, we show that using importance sampling with MCMC samples to calculate the local sensitivity in Eq. (1) is precisely equivalent to using the same MCMC samples to estimate the covariance in Eq. (4) directly. For this section, will suppose that Assumption 1 holds. Further suppose, without loss of generality, we have samples θ_i drawn IID from $p_0(\theta)$:

$$\begin{aligned}
\theta_n &\overset{iid}{\sim} p_0(\theta), \text{ for } n = 1, ..., N_s \\
\mathbb{E}_{p_0}[g(\theta)] &\approx \frac{1}{N_s}\sum_{n=1}^{N_s} g(\theta_n).
\end{aligned}$$

Typically we cannot compute the dependence of the normalizing constant $\int p(\theta')\exp(\rho(\theta',\alpha))\,\lambda(d\theta')$ on α, so we use the following importance sampling estimate for $\mathbb{E}_{p_\alpha}[g(\theta)]$ (Owen, 2013, Chapter 9):

$$\begin{aligned}
w_n &= \exp(\rho(\theta_n,\alpha) - \rho(\theta_n,\alpha_0)) \\
\tilde{w}_n &:= \frac{w_n}{\sum_{n'=1}^{N_s} w_{n'}} \\
\mathbb{E}_{p_\alpha}[g(\theta)] &\approx \sum_{n=1}^{N_s}\tilde{w}_n g(\theta_n).
\end{aligned}$$

Note that $\tilde{w}_n|_{\alpha_0} = \frac{1}{N_s}$, so the importance sampling estimate recovers the ordinary sample mean at α_0. The derivatives of the weights are given by

$$\begin{aligned}
\frac{\partial w_n}{\partial \alpha} &= w_n\frac{\partial \rho(\theta_n,\alpha)}{\partial \alpha} \\
\frac{\partial \tilde{w}_n}{\partial \alpha} &= \frac{\frac{\partial w_n}{\partial \alpha}}{\sum_{n'=1}^{N_s} w_{n'}} - \frac{w_n\sum_{n'=1}^{N_s}\frac{\partial w_{n'}}{\partial \alpha}}{\left(\sum_{n'=1}^{N_s} w_{n'}\right)^2} \\
&= \frac{w_n}{\sum_{n'=1}^{N_s} w_{n'}}\frac{\partial \rho(\theta_n,\alpha)}{\partial \alpha} - \frac{w_n}{\sum_{n'=1}^{N_s} w_{n'}}\sum_{n'=1}^{N_s}\frac{w_n}{\sum_{n'=1}^{N_s} w_{n'}}\frac{\partial \rho(\theta_{n'},\alpha)}{\partial \alpha} \\
&= \tilde{w}_n\frac{\partial \rho(\theta_n,\alpha)}{\partial \alpha} - \tilde{w}_n\sum_{n'=1}^{N_s}\tilde{w}_{n'}\frac{\partial \rho(\theta_{n'},\alpha)}{\partial \alpha}.
\end{aligned}$$

It follows that

$$\begin{aligned}
\left.\frac{\partial}{\partial \alpha}\sum_{n=1}^{N_s}\tilde{w}_n g(\theta_n)\right|_{\alpha_0} &= \sum_{n=1}^{N_s}\left(\tilde{w}_n\frac{\partial \rho(\theta_n,\alpha)}{\partial \alpha} - \tilde{w}_n\sum_{n'=1}^{N_s}\tilde{w}_{n'}\frac{\partial \rho(\theta_{n'},\alpha)}{\partial \alpha}\right)\Bigg|_{\alpha_0} g(\theta_n) \\
&= \frac{1}{N_s}\sum_{n=1}^{N_s}\left.\frac{\partial \rho(\theta_n,\alpha)}{\partial \alpha}\right|_{\alpha_0} g(\theta_n) - \left[\frac{1}{N_s}\sum_{n=1}^{N_s}\left.\frac{\partial \rho(\theta_n,\alpha)}{\partial \alpha}\right|_{\alpha_0}\right]\left[\frac{1}{N_s}\sum_{n=1}^{N_s} g(\theta_n)\right],
\end{aligned}$$

which is precisely the sample version of the covariance in Theorem 1.

Appendix C. Our Use of the Terms "Sensitivity" and "Robustness"

In this section we clarify our usage of the terms "robustness" and "sensitivity." The quantity $\mathbf{S}_{\alpha_0}^\intercal(\alpha - \alpha_0)$ measures the *sensitivity* of $\mathbb{E}_{p_\alpha}[g(\theta)]$ to perturbations in the direction $\Delta\alpha$. Intuitively, as sensitivity increases, robustness decreases, and, in this sense, sensitivity and robustness are opposites of one another. However, we emphasize that sensitivity is a clearly defined, measurable quantity and that robustness is a subjective judgment informed by sensitivity, but also by many other less objective considerations.

Suppose we have calculated $\mathbf{S}_{\alpha_0}$ from Eq. (1) and found that it has a particular value. To determine whether our model is robust, we must additionally decide

1. How large of a change in the prior, $||\alpha - \alpha_0||$, is plausible, and
2. How large of a change in $\mathbb{E}_{p_\alpha}[g(\theta)]$ is important.

The set of plausible prior values necessarily remains a subjective decision.[4] Whether or not a particular change in $\mathbb{E}_{p_\alpha}[g(\theta)]$ is important depends on the ultimate use of the posterior mean. For example, the posterior standard deviation can be a guide: if the prior sensitivity is swamped by the posterior uncertainty then it can be neglected when reporting our subjective uncertainty about $g(\theta)$, and the model is robust. Similarly, even if the prior sensitivity is much larger than the posterior standard deviation but small enough that it would not affect any actionable decision made on the basis of the value of $\mathbb{E}_{p_\alpha}[g(\theta)]$, then the model is robust. Intermediate values remain a matter of judgment. An illustration of the relationship between sensitivity and robustness is shown in Fig. 19.

Finally, we note that if $\mathcal{A}$ is small enough that $\mathbb{E}_{p_\alpha}[g(\theta)]$ is roughly linear in α for $\alpha \in \mathcal{A}$, then calculating Eq. (1) for all $\alpha \in \mathcal{A}$ and finding the worst case can be thought of as a first-order approximation to a global robustness estimate. Depending on the problem at hand, this linearity assumption may not be plausible except

4. This decision can be cast in a formal decision theoretic framework based on a partial ordering of subjective beliefs (Insua and Criado, 2000).

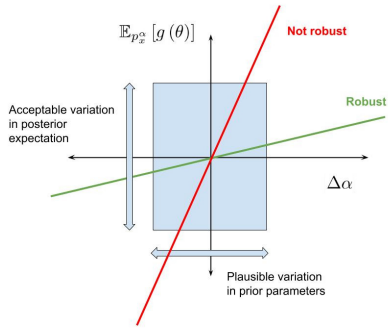

Figure 19: The relationship between robustness and sensitivity

for very small $\mathcal{A}$. This weakness is inherent to the local robustness approach. Nevertheless, even when the perturbations are valid only for a small $\mathcal{A}$, these easily-calculable measures may still provide valuable intuition about the potential modes of failure for a model.

If $g(\theta)$ is a scalar, it is natural to attempt to summarize the high-dimensional vector $\mathbf{S}_{\alpha_0}$ in a single easily reported number such as

$$\mathbf{S}_{\alpha_0}^{sup} := \sup_{\alpha:\|\alpha-\alpha_0\|\leq 1} \left|\mathbf{S}_{\alpha_0}^{\intercal}(\alpha-\alpha_0)\right|.$$

For example, the calculation of $\mathbf{S}_{\alpha_0}^{sup}$ is the principal ambition of Basu et al. (1996). The use of such summaries is also particularly common in work that considers function-valued perturbations (e.g., Gustafson, 1996b; Roos et al., 2015). (Function-valued perturbations can be connected to the finite-dimensional perturbations of the present work through the notion of the Gateaux derivative (Huber, 2011, Chapter 2.5), the elaboration of which we leave to future work.) Although the summary $\mathbf{S}_{\alpha_0}^{sup}$ has obvious merits, in the present work we emphasize the calculation only of $\mathbf{S}_{\alpha_0}$ in the belief that its interpretation is likely to vary from application to application and require some critical thought and subjective judgment. For example, the unit ball $\|\alpha-\alpha_0\|\leq 1$ (as in Basu et al. (1996)) may not make sense as a subjective description of the range of plausible variability of $p(\theta|\alpha)$. Consider, e.g.: why should the off-diagonal term of a Wishart prior plausibly vary as widely as the mean of some other parameter, when the two might not even have the same units? This problem is easily remedied by choosing an appropriate scaling of the parameters and thereby making the unit ball an appropriate range for the problem at hand, but the right scaling will vary from problem to problem and necessarily be a somewhat subjective choice, so we refrain from taking a stand on this decision. As another example, the worst-case function-valued perturbations of Gustafson (1996a,b) require a choice of a metric ball in function space whose meaning may not be intuitively obvious, may provide worst-case perturbations that depend on the data to a subjectively implausible degree, and may exhibit interesting but perhaps counter-intuitive asymptotic behavior for different norms and perturbation dimensions. Consequently, we do not attempt to prescribe a particular one-size-fits-all summary measure. The local sensitivity $\mathbf{S}_{\alpha_0}$ is a well-defined mathematical quantity. Its relationship to robustness must remain a matter of judgment.

Appendix D. Proof of Theorem 2

In this section we prove Theorem 2.

Proof For notational convenience, we will define

$$KL(\eta,\alpha) := KL(q(\theta;\eta)||p_\alpha(\theta)).$$

By Assumption 3, $\eta^*(\alpha)$ is both optimal and interior for all $\alpha\in\mathcal{A}_0$, and by Assumption 2, $KL(\eta,\alpha)$ is continuously differentiable in η. Therefore, the first-order conditions of the optimization problem in Eq. (8) give:

$$\left.\frac{\partial KL(\eta,\alpha)}{\partial\eta}\right|_{\eta=\eta^*(\alpha)} = 0 \text{ for all } \alpha\in\mathcal{A}_0. \tag{26}$$

$\left.\frac{\partial^2 KL(\eta,\alpha)}{\partial\eta\partial\eta^\intercal}\right|_{\alpha_0}$ is positive definite by the strict optimality of η^* in Assumption 3, and $\frac{\partial^2 KL(\eta,\alpha)}{\partial\eta\partial\alpha^\intercal}$ is continuous by Assumption 2. It follows that $\eta^*(\alpha)$ is a continuously differentiable function of α by application of the implicit function theorem to the first-order condition in Eq. (26) (Fleming, 1965, Chapter 4.6). So we can use the chain rule to take the total derivative of Eq. (26) with respect to α.

$$\begin{aligned}\frac{d}{d\alpha}\left(\left.\frac{\partial KL(\eta,\alpha)}{\partial\eta}\right|_{\eta=\eta^*(\alpha)}\right) &= 0 \text{ for all } \alpha\in\mathcal{A}_0 \Rightarrow\\ \left.\frac{\partial^2 KL(\eta,\alpha)}{\partial\eta\partial\eta^\intercal}\right|_{\eta=\eta^*(\alpha)}\frac{d\eta^*(\alpha)}{d\alpha^\intercal} + \left.\frac{\partial^2 KL(\eta,\alpha)}{\partial\eta\partial\alpha^\intercal}\right|_{\eta=\eta^*(\alpha)} &= 0 \text{ for all } \alpha\in\mathcal{A}_0.\end{aligned}$$

The strict optimality of $KL(\eta,\alpha)$ at $\eta^*(\alpha)$ in Assumption 3 requires that $\left.\frac{\partial^2 KL(\eta,t)}{\partial\eta\partial\eta^T}\right|_{\eta=\eta^*(\alpha)}$ be invertible. So we can evaluate at $\alpha=\alpha_0$ and solve to find that

$$\left.\frac{d\eta^*(\alpha)}{d\alpha^\intercal}\right|_{\alpha_0} = -\left(\frac{\partial^2 KL(\eta,\alpha)}{\partial\eta\partial\eta^\intercal}\right)^{-1}\left.\frac{\partial^2 KL(\eta,\alpha)}{\partial\eta\partial\alpha^\intercal}\right|_{\eta=\eta_0^*,\alpha=\alpha_0}.$$

$\mathbb{E}_{q_\alpha}[g(\theta)]$ is a continuously differentiable function of $\eta^*(\alpha)$ by Assumption 4. So by the chain rule and Assumption 2, we have that

$$\left.\frac{d\mathbb{E}_{q(\theta;\eta)}[g(\theta)]}{d\alpha^\intercal}\right|_{\alpha_0} = \left.\frac{\partial\mathbb{E}_{q(\theta;\eta)}[g(\theta)]}{\partial\eta}\frac{d\eta^*(\alpha)}{d\alpha^\intercal}\right|_{\eta=\eta_0^*,\alpha=\alpha_0}.$$

Finally, we observe that

$$\begin{aligned}KL(\eta,\alpha) &= \mathbb{E}_{q(\theta;\eta)}[\log q(\theta;\eta) - \log p(\theta) - \rho(\theta,\alpha)] + Constant \Rightarrow\\ \left.\frac{\partial^2 KL(\eta,\alpha)}{\partial\eta\partial\alpha^\intercal}\right|_{\eta=\eta_0^*,\alpha=\alpha_0} &= -\left.\frac{\partial^2\mathbb{E}_{q(\theta;\eta)}[\rho(\theta,\alpha)]}{\partial\eta\partial\alpha^\intercal}\right|_{\eta=\eta_0^*,\alpha=\alpha_0}.\end{aligned}$$

Here, the term $Constant$ contains quantities that do not depend on η. Plugging in gives the desired result. ■

Appendix E. Exactness of Multivariate Normal Posterior Means

In this section, we show that the MFVB estimate of the posterior means of a multivariate normal with known covariance is exact and that, as an immediate consequence, the linear response covariance recovers the exact posterior covariance, i.e., $\mathrm{Cov}_{q_0}^{LR}(\theta) = \mathrm{Cov}_{p_0}(\theta)$.

Suppose we are using MFVB to approximate a non-degenerate multivariate normal posterior, i.e.,

$$p_0(\theta) = \mathcal{N}(\theta;\mu,\mathbf{\Sigma})$$

for full-rank Σ. This posterior arises, for instance, given a multivariate normal likelihood $p(x|\mu) = \prod_{n=1:N} \mathcal{N}(x_n|\theta, \Sigma_x)$ with known covariance Σ_x and a conjugate multivariate normal prior on the unknown mean parameter $\theta \in \mathbb{R}^K$. Additionally, even when the likelihood is non-normal or the prior is not conjugate, the posterior may be closely approximated by a multivariate normal distribution when a Bayesian central limit theorem can be applied (Le Cam and Yang, 2012, Chapter 8).

We will consider an MFVB approximation to $p_0(\theta)$. Specifically, let the elements of the vector θ be given by scalars θ_k for $k = 1, ..., K$, and take the MFVB normal approximation with means m_k and variances v_k:

$$\mathcal{Q} = \left\{ q(\theta) : q(\theta) = \prod_{k=1}^{K} \mathcal{N}(\theta_k; m_k, v_k) \right\}.$$

In the notation of Eq. (9), we have $\eta_k = (m_k, v_k)^\intercal$ with $\Omega_\eta = \{\eta : v_k > 0, \forall k = 1, ..., K\}$. The optimal variational parameters are given by $\eta_k^* = (m_k^*, v_k^*)^\intercal$.

Lemma 1 *Let $p_0(\theta) = \mathcal{N}(\theta; \mu, \Sigma)$ for full-rank Σ and let $\mathcal{Q} = \left\{ q(\theta) : q(\theta) = \prod_{k=1}^{K} \mathcal{N}(\theta_k; m_k, v_k) \right\}$ be the mean field approximating family. Then there exists an $\eta^* = (m^*, v^*)$ that solves*

$$\eta^* = \underset{\eta : q(\theta;\eta) \in \mathcal{Q}}{\operatorname{argmin}} KL(q(\theta;\eta) \,||p_\alpha(\theta))$$

with $m^* = \mu$.

Proof Let $\operatorname{diag}(v)$ denote the $K \times K$ matrix with the vector v on the diagonal and zero elsewhere. Using the fact that the entropy of a univariate normal distribution with variance v is $\frac{1}{2}\log v$ plus a constant, the variational objective in Eq. (8) is given by

$$\begin{aligned}
KL(q(\theta;\eta) \,||p_\alpha(\theta)) &= \mathbb{E}_{q(\theta;\eta)}\left[\frac{1}{2}(\theta-\mu)^\intercal \Sigma^{-1}(\theta-\mu)\right] - \frac{1}{2}\sum_k \log v_k + Constant \\
&= \frac{1}{2}\operatorname{trace}\left(\Sigma^{-1}\mathbb{E}_{q(\theta;\eta)}\left[\theta\theta^\intercal\right]\right) - \mu^\intercal\Sigma^{-1}\mathbb{E}_{q(\theta;\eta)}[\theta] - \frac{1}{2}\sum_k \log v_k + Constant \\
&= \frac{1}{2}\operatorname{trace}\left(\Sigma^{-1}\left(mm^\intercal + \operatorname{diag}(v)\right)\right) - \mu^\intercal\Sigma^{-1}m - \frac{1}{2}\sum_k \log v_k + Constant \\
&= \frac{1}{2}\operatorname{trace}\left(\Sigma^{-1}\operatorname{diag}(v)\right) + \frac{1}{2}m^\intercal\Sigma^{-1}m - \mu^\intercal\Sigma^{-1}m - \frac{1}{2}\sum_k \log v_k + Constant.
\end{aligned} \tag{27}$$

The first-order condition for the optimal m^* is then

$$\begin{aligned}
\left.\frac{\partial KL(q(\theta;\eta) \,||p_0(\theta))}{\partial m}\right|_{m=m^*, v=v^*} = 0 \Rightarrow \\
\Sigma^{-1}m^* - \Sigma^{-1}\mu = 0 \Rightarrow \\
m^* = \mu.
\end{aligned}$$

The optimal variances follow similarly:

$$\begin{aligned}
\left.\frac{\partial KL(q(\theta;\eta) \,||p_0(\theta))}{\partial v_k}\right|_{m=m^*, v=v^*} = 0 \Rightarrow \\
\frac{1}{2}\left(\Sigma^{-1}\right)_{kk} - \frac{1}{2}\frac{1}{v_k^*} = 0 \Rightarrow \\
v_k^* = \frac{1}{\left(\Sigma^{-1}\right)_{kk}}.
\end{aligned}$$

Since $v_k^* > 0$, we have $\eta^* \in \Omega_\eta$.

Lemma 1 can be also be derived via the variational coordinate ascent updates (Bishop (2006, Section 10.1.2) and Giordano et al. (2015, Appendix B)). ■

Next, we show that Lemma 1 holds for all perturbations of the form $\rho(\theta, \alpha) = \alpha^\intercal\theta$ with $\alpha_0 = 0$ and that Assumptions 1–4 are satisfied for all finite α.

Lemma 2 *Under the conditions of Lemma 1, let $p_\alpha(\theta)$ be defined from Eq. (2) with $\rho(\theta, \alpha) = \alpha^\intercal\theta$ and $\alpha_0 = 0$. Take $g(\theta) = \theta$. Then, for all finite α, Assumptions 1–4 are satisfied, and Condition 1 is satisfied with equality.*

Proof Up to a constant that does not depend on θ, the log density of $p_\alpha(\theta)$ is

$$\begin{aligned}
\log p_\alpha(\theta) &= -\frac{1}{2}(\theta-\mu)^\intercal\Sigma^{-1}(\theta-\mu) + \alpha^\intercal\theta + Constant \\
&= -\frac{1}{2}\theta^\intercal\Sigma^{-1}\theta - \frac{1}{2}\mu^\intercal\Sigma^{-1}\mu + \left(\mu^\intercal\Sigma^{-1} + \alpha^\intercal\right)\theta + Constant.
\end{aligned}$$

Since θ is a natural sufficient statistic of the multivariate normal distribution and the corresponding natural parameter of $p_\alpha(\theta)$, $\Sigma^{-1}\mu + \alpha$, is interior when Σ is full-rank, $p_\alpha(\theta)$ is multivariate normal for any finite α. Assumption 1 follows immediately.

By inspection of Eq. (27), Assumption 2 is satisfied. Because Ω_η is an open set and Σ is positive definite, Assumption 3 is satisfied. Since $\mathbb{E}_{q(\theta;\eta)}[g(\theta)] = m$, Assumption 4 is satisfied. Finally, by Lemma 1, $\mathbb{E}_{q_\alpha}[\theta] = \mathbb{E}_{p_\alpha}[\theta]$, so Condition 1 is satisfied with equality. ■

It now follows immediately from Definition 6 that the linear response variational covariance exactly reproduces the exact posterior covariance for the multivariate normal distribution.

Corollary 4 *Under the conditions of Lemma 2,* $\operatorname{Cov}_{q_0}^{LR}(\theta) = \operatorname{Cov}_{p_0}(\theta)$.

Appendix F. ADVI Model Details

This section reports the Stan code for the models used in Section 5.2. For details on how to interpret the models as well as the unconstraining transforms, see the Stan manual (Stan Team, 2015). For the associated data, see the Stan example models wiki (Stan Team, 2017).

F.1 Election Model (`election88.stan`)

Listing 1: `election88.stan`

```

Appendix G. LKJ Priors for Covariance Matrices in Mean Field Variational Inference

In this section we briefly derive closed-form expressions for using an LKJ prior with a Wishart variational approximation.

Proposition 3 *Let $\mathbf{\Sigma}$ be a $K \times K$ positive definite covariance matrix. Define the $K \times K$ matrix $\mathbf{M}$ such that*

$$\mathbf{M}_{ij} = \begin{cases} \sqrt{\mathbf{\Sigma}_{ij}} & \text{if } i = j \\ 0 & \text{otherwise.} \end{cases}$$

Define the correlation matrix R as

$$\mathbf{R} = \mathbf{M}^{-1}\mathbf{\Sigma}\mathbf{M}^{-1}.$$

Define the LKJ prior on $\mathbf{R}$ with concentration parameter ξ (Lewandowski et al., 2009):

$$p_{\text{LKJ}}\left(\mathbf{R}|\xi\right) \propto |\mathbf{R}|^{\xi-1}.$$

Let $q\left(\mathbf{\Sigma}|\mathbf{V}^{-1}, \nu\right)$ be an inverse Wishart distribution with matrix parameter $\mathbf{V}^{-1}$ and ν degrees of freedom. Then

$$\mathbb{E}_q\left[\log|\mathbf{R}|\right] = \log\left|\mathbf{V}^{-1}\right| - \psi_K\left(\frac{\nu}{2}\right) - \sum_{k=1}^{K}\log\left(\left(\mathbf{V}^{-1}\right)_{kk}\right) + K\psi\left(\frac{\nu - K + 1}{2}\right) + Constant$$

$$\mathbb{E}_q\left[\log p_{\text{LKJ}}\left(\mathbf{R}|\xi\right)\right] = (\xi - 1)\,\mathbb{E}_q\left[\log|\mathbf{R}|\right] + Constant,$$

where $Constant$ does not depend on $\mathbf{V}$ or ν. Here, ψ_K is the multivariate digamma function.

Proof First note that

$$\begin{aligned} \log|\mathbf{\Sigma}| &= 2\log|\mathbf{M}| + \log|\mathbf{R}| \\ &= 2\sum_{k=1}^{K}\log\sqrt{\mathbf{\Sigma}_{kk}} + \log|\mathbf{R}| \\ &= \sum_{k=1}^{K}\log\mathbf{\Sigma}_{kk} + \log|\mathbf{R}| \Rightarrow \\ \log|\mathbf{R}| &= \log|\mathbf{\Sigma}| - \sum_{k=1}^{K}\log\mathbf{\Sigma}_{kk}. \end{aligned} \tag{28}$$

By Eq. B.81 in (Bishop, 2006), a property of the inverse Wishart distribution is the following relation.

$$E_q\left[\log|\mathbf{\Sigma}|\right] = \log\left|\mathbf{V}^{-1}\right| - \psi_K\left(\frac{\nu}{2}\right) - K\log 2, \tag{29}$$

where ψ_K is the multivariate digamma function. By the marginalization property of the inverse Wishart distribution,

$$\begin{aligned}\boldsymbol{\Sigma}_{kk} &\sim \text{InverseWishart}\left(\left(\mathbf{V}^{-1}\right)_{kk}, \nu - K + 1\right) \Rightarrow \\ E_q\left[\log \boldsymbol{\Sigma}_{kk}\right] &= \log\left(\left(\mathbf{V}^{-1}\right)_{kk}\right) - \psi\left(\frac{\nu - K + 1}{2}\right) - \log 2. \end{aligned} \tag{30}$$

Plugging Eq. (29) and Eq. (30) into Eq. (28) gives the desired result. ■

Appendix H. Logistic GLMM Model Details

In this section we include extra details about the model and analysis of Section 5. We will continue to use the notation defined therein. We use $Constant$ to denote any constants that do not depend on the prior parameters, parameters, or data. The log likelihood is

$$\begin{aligned}\log p\left(y_{it}|u_t, \beta\right) &= y_{it}\log\left(\frac{p_{it}}{1-p_{it}}\right) + \log\left(1-p_{it}\right) \\ &= y_{it}\rho + \log\left(1-p_{it}\right) + Constant \\ \log p\left(u|\mu,\tau\right) &= -\frac{1}{2}\tau\sum_{t=1}^{T}\left(u_t-\mu\right)^2 - \frac{1}{2}T\log\tau \\ &= -\frac{1}{2}\tau\sum_{t=1}^{T}\left(u_t^2 - \mu u_t + \mu^2\right) - \frac{1}{2}T\log\tau + Constant \\ \log p\left(\mu,\tau,\beta\right) &= -\frac{1}{2}\sigma_\mu^{-2}\left(\mu^2 + 2\mu\mu_0\right) + \\ &\quad \left(1-\alpha_\tau\right)\tau + \beta_\tau\log\tau + \\ &\quad -\frac{1}{2}\left(\text{trace}\left(\boldsymbol{\Sigma}_\beta^{-1}\beta\beta^T\right) + 2\text{trace}\left(\boldsymbol{\Sigma}_\beta^{-1}\beta_0\beta^T\right)\right). \end{aligned} \tag{31}$$

The prior parameters were taken to be

$$\begin{aligned}\mu_0 &= 0.000 \\ \sigma_\mu^{-2} &= 0.010 \\ \beta_0 &= 0.000 \\ \sigma_\beta^{-2} &= 0.100 \\ \alpha_\tau &= 3.000 \\ \beta_\tau &= 3.000. \end{aligned}$$

Under the variational approximation, ρ_{it} is normally distributed given x_{it}, with

$$\begin{aligned}\rho_{it} &= x_{it}^T\beta + u_t \\ \mathbb{E}_q\left[\rho_{it}\right] &= x_{it}^T\mathbb{E}_q\left[\beta\right] + \mathbb{E}_q\left[u_t\right] \\ \text{Var}_q\left(\rho_{it}\right) &= \mathbb{E}_q\left[\beta^T x_{it}x_{it}^T\beta\right] - \mathbb{E}_q\left[\beta\right]^T x_{it}x_{it}^T\mathbb{E}_q\left[\beta\right] + \text{Var}_q\left(u_t\right) \\ &= \mathbb{E}_q\left[\text{tr}\left(\beta^T x_{it}x_{it}^T\beta\right)\right] - \text{tr}\left(\mathbb{E}_q\left[\beta\right]^T x_{it}x_{it}^T\mathbb{E}_q\left[\beta\right]\right) + \text{Var}_q\left(u_t\right) \\ &= \text{tr}\left(x_{it}x_{it}^T\left(\mathbb{E}_q\left[\beta\beta^T\right] - \mathbb{E}_q\left[\beta\right]\mathbb{E}_q\left[\beta\right]^T\right)\right) + \text{Var}_q\left(u_t\right). \end{aligned}$$

We can thus use $n_{MC} = 4$ points of Gauss-Hermite quadrature to numerically estimate $\mathbb{E}_q\left[\log\left(1 - \frac{e^\rho}{1+e^\rho}\right)\right]$:

$$\begin{aligned}\rho_{it,s} &:= \sqrt{\text{Var}_q\left(\rho_{it}\right)}z_s + \mathbb{E}_q\left[\rho_{it}\right] \\ \mathbb{E}_q\left[\log\left(1 - \frac{e^{\rho_{it}}}{1+e^{\rho_{it}}}\right)\right] &\approx \frac{1}{n_{MC}}\sum_{s=1}^{n_{MC}}\log\left(1 - \frac{e^{\rho_{it,s}}}{1+e^{\rho_{it,s}}}\right) \end{aligned}$$

We found that increasing the number of points used for the quadrature did not measurably change any of the results. The integration points and weights were calculated using the `numpy.polynomial.hermite` module in Python (Jones et al., 2001).

Editor: Manfred Opper

Abstract

We develop an approximate formula for evaluating a cross-validation estimator of predictive likelihood for multinomial logistic regression regularized by an ℓ_1-norm. This allows us to avoid repeated optimizations required for literally conducting cross-validation; hence, the computational time can be significantly reduced. The formula is derived through a perturbative approach employing the largeness of the data size and the model dimensionality. An extension to the elastic net regularization is also addressed. The usefulness of the approximate formula is demonstrated on simulated data and the ISOLET dataset from the UCI machine learning repository. MATLAB and python codes implementing the approximate formula are distributed in (Obuchi, 2017; Takahashi and Obuchi, 2017).

Keywords: classification, multinomial logistic regression, cross-validation, linear perturbation, self-averaging approximation

1. Introduction

Multinomial classification is a ubiquitous task. There are several ways to treat this task, such as the naive Bayesian methods, neural networks, decision trees, and hierarchical classification schemes (Trevor et al., 2009). Among them, in this paper, we focus on multinomial logistic regression (MLR), which is simple but powerful enough to be used in many present day applications.

Let us denote each feature vector by $\boldsymbol{x}_\mu \in \mathbb{R}^N$ and its class by $y_\mu \in \{1, \cdots, L\}$, where $\mu = 1 \cdots, M$ denotes the index of given data. The MLR uses a linear structural model with parameters $\{\boldsymbol{w}_a \in \mathbb{R}^N\}_{a=1}^L$ and computes a class-a bias as an overlap:

$$u_{\mu a} = \boldsymbol{x}_\mu^\top \boldsymbol{w}_a. \tag{1}$$

A probability such that the feature vector $\boldsymbol{x}_\mu$ belongs to the class a is computed through a softmax function ϕ as:

$$\phi\left(a \middle| \{u_{\mu b}\}_{b=1}^L\right) = \frac{e^{u_{\mu a}}}{\sum_{b=1}^L e^{u_{\mu b}}}. \tag{2}$$

These define the MLR.

The maximum likelihood estimation is usually employed to train the MLR, though the learning result tends to be inefficient when the data size is not sufficiently larger than the model dimensionality or noises in relevant levels are present. A common technique to overcome this difficulty is to introduce a penalty or regularization. In this paper, we use an ℓ_1-regularization, which induces a sparse classifier as a learning result and is accepted to be effective. Given M data points $D^M \equiv \{(\boldsymbol{x}_\mu, y_\mu)\}_{\mu=1}^M$, the ℓ_1-regularized estimator is defined by the following optimization problem:

$$\{\hat{\boldsymbol{w}}_a(\lambda)\}_a = \underset{\{\boldsymbol{w}_a\}_a}{\arg\min} \left\{\mathcal{H}\left(\{\boldsymbol{w}_a\}_{a=1}^L \middle| D^M, \lambda\right)\right\}, \tag{3}$$

$$\mathcal{H}\left(\{\boldsymbol{w}_a\}_{a=1}^L \middle| D^M, \lambda\right) \equiv \sum_{\mu=1}^M q_\mu\left(\{\boldsymbol{w}_a\}_{a=1}^L\right) + \lambda \sum_{a=1}^L ||\boldsymbol{w}_a||_1, \tag{4}$$

$$q_\mu\left(\{\boldsymbol{w}_a\}_{a=1}^L\right) = -\ln \phi\left(y_\mu \middle| \left\{u_{\mu a} = \boldsymbol{x}_\mu^\top \boldsymbol{w}_a\right\}_{a=1}^L\right), \tag{5}$$

where we denote the negative log-likelihood as q_μ and define a regularized cost function or Hamiltonian $\mathcal{H}$.

The introduction of regularization causes another problem of model selection or hyperparameter estimation with respect to λ. A versatile framework providing a reasonable estimate is cross-validation (CV), but it has a disadvantage in terms of the computational cost. The literal CV requires repeated optimizations which can be a serious computational burden when the data size and the model dimensionality are large. The purpose of this paper is to resolve this problem by inventing an efficient approximation of CV.

Our technique is based on a perturbative expansion employing the largeness of the data size and the model dimensionality. Similar techniques were also developed for the Bayesian learning of simple perceptron and committee machine (Opper and Winther, 1996, 1997), for Gaussian process and support vector machine (Opper and Winther, 2000a,b; Vapnik and Chapelle, 2000), for linear regression with the ℓ_1-regularization (Obuchi and Kabashima, 2016; Rad and Maleki, 2018; Wang et al., 2018) and with the two-dimensional total variation (Obuchi et al., 2017). Actually, this perturbative approach is fairly general and can be applied to a wide class of generalized linear models with simple convex regularizations. For example in the present MLR case, it is easy to extend our result to the case where both the ℓ_1- and ℓ_2-regularizations exist (elastic net, Zou and Hastie, 2005), which is used in a common implementation (Friedman et al., 2010). The derivation of our approximate formula below is, however, conducted on the case of the ℓ_1-regularization only, for simplicity. The extension to the elastic net case is stated after the derivation.

The rest of the paper is organized as follows. In sec. 2, we state our formulation and how to derive the approximate formula. In sec. 3, we compare our approximation result with that of the literally conducted CV on simulated data and on the ISOLET dataset from UCI machine learning repository (Lichman, 2013). The accuracy and the computational time of our approximate formula are reported in comparison with the literal CV. The limitation of a simplified version of the approximation is also examined. The last section is devoted to the conclusion.

2. Formulation

In the maximum likelihood estimation framework, it is natural to employ a predictive likelihood as a criterion for model selection (Bjornstad, 1990; Ando and Tsay, 2010). We require a good estimator of the predictive likelihood, and the CV provides a simple realization of it. Particularly in this paper, we consider an estimator based on the leave-one-out (LOO) CV. The LOO solution is described by

$$\{\hat{\boldsymbol{w}}_a^{\backslash\mu}(\lambda)\}_a = \underset{\{\boldsymbol{w}_a\}_a}{\arg\min} \left\{ \mathcal{H}^{\backslash\mu}\left(\{\boldsymbol{w}_a\}_{a=1}^L \middle| D^M, \lambda \right) \right\}, \tag{6}$$

$$\mathcal{H}^{\backslash\mu}\left(\{\boldsymbol{w}_a\}_{a=1}^L \middle| D^M, \lambda \right) \equiv \mathcal{H}\left(\{\boldsymbol{w}_a\}_{a=1}^L \middle| D^M, \lambda \right) - q_\mu\left(\{\boldsymbol{w}_a\}_{a=1}^L \right). \tag{7}$$

Denoting the overlap of $\boldsymbol{x}_\mu$ with the LOO solution as $\hat{u}_{\mu a}^{\backslash\mu} = \boldsymbol{x}_\mu^\top \hat{\boldsymbol{w}}_a^{\backslash\mu}$, as well as that with the full solution $\hat{u}_{\mu a} = \boldsymbol{x}_\mu^\top \hat{\boldsymbol{w}}_a$, we can define the LOO estimator (LOOE) of the predictive negative log-likelihood as:

$$\epsilon_{\mathrm{LOO}}(\lambda) = \frac{1}{M}\sum_{\mu=1}^M q_\mu\left(\left\{ \hat{\boldsymbol{w}}_a^{\backslash\mu} \right\}_{a=1}^L \right) = -\frac{1}{M}\sum_{\mu=1}^M \ln \phi\left(y_\mu \middle| \{\hat{u}_{\mu a}^{\backslash\mu}\}_{a=1}^L \right). \tag{8}$$

In the following, the predictive negative log-likelihood is simply called prediction error. The minimum of the LOOE determines the optimal value of λ though its evaluation requires us to solve eq. (6) M times, which is computationally demanding.

2.0.1. Notations

Here, we fix the notations for a better flow of the derivation shown below. By summarizing the class index, we introduce a vector notation of the overlap as $\boldsymbol{u}_\mu = (u_{\mu a})_a \in \mathbb{R}^L$ and an extended vector representation of the weight vectors $\{\boldsymbol{w}_a\}_a$ as $\boldsymbol{W} = (\boldsymbol{w}_a)_a \in \mathbb{R}^{LN}$. The mth component of $\boldsymbol{W}$ can thus be decomposed into two parts as $m = (m_c, m_f)$ where $m_c \in \{1, \cdots, L\}$ denotes the class index and $m_f \in \{1, \cdots, N\}$ represents the component index of the feature vector. Namely we write $W_m = w_{m_c m_f}$. Correspondingly, we leverage a matrix $X^\mu \in \mathbb{R}^{L \times LN}$ to define a repetition representation of the feature vector $\boldsymbol{x}_\mu$: Each component is defined as:

$$X_{am}^\mu \equiv \delta_{am_c} x_{\mu m_f}. \tag{9}$$

This yields simple and convenient relations:

$$\boldsymbol{u}_\mu = X^\mu \boldsymbol{W},\ X^\mu = \left(\frac{\partial \boldsymbol{u}_\mu}{\partial \boldsymbol{W}} \right)^\top. \tag{10}$$

Further, the class-a probability of μth data at the full solution $\hat{\boldsymbol{W}} = (\hat{\boldsymbol{w}}_a)_a$ is denoted by:

$$p_{a|\mu} = \phi(a|\{\hat{u}_{\mu b}\}_b) = \frac{e^{\hat{u}_{\mu a}}}{\sum_{b=1}^L e^{\hat{u}_{\mu b}}} \tag{11}$$

These notations express the gradient and the Hessian of q_μ at the full solution as:

$$\nabla q_\mu(\hat{\boldsymbol{W}}) \equiv \left. \frac{\partial q_\mu}{\partial \boldsymbol{W}} \right|_{\boldsymbol{W}=\hat{\boldsymbol{W}}} = \frac{\partial \boldsymbol{u}_\mu}{\partial \boldsymbol{W}} \left. \frac{\partial}{\partial \boldsymbol{u}_\mu} q_\mu \right|_{\boldsymbol{u}_\mu = \hat{\boldsymbol{u}}_\mu} = (X^\mu)^\top \boldsymbol{b}^\mu, \tag{12}$$

$$\partial^2 q_\mu(\hat{\boldsymbol{W}}) \equiv \left. \frac{\partial^2 q_\mu}{\partial \boldsymbol{W} \partial \boldsymbol{W}'} \right|_{\boldsymbol{W}=\boldsymbol{W}'=\hat{\boldsymbol{W}}}$$
$$= \frac{\partial \boldsymbol{u}_\mu}{\partial \boldsymbol{W}} \left(\left. \frac{\partial^2 q_\mu}{\partial \boldsymbol{u}_\mu \partial \boldsymbol{u}'_\mu} \right|_{\boldsymbol{u}_\mu = \boldsymbol{u}'_\mu = \hat{\boldsymbol{u}}_\mu} \right) \left(\frac{\partial \boldsymbol{u}'_\mu}{\partial \boldsymbol{W}'} \right)^\top = (X^\mu)^\top F^\mu X^\mu, \tag{13}$$

where

$$\boldsymbol{b}^\mu \equiv (p_{1|\mu} - \delta_{1 y_\mu}, p_{2|\mu} - \delta_{2 y_\mu}, \cdots, p_{L|\mu} - \delta_{L y_\mu})^\top, \tag{14}$$

$$F_{ab}^\mu \equiv \delta_{ab} p_{a|\mu} - p_{a|\mu} p_{b|\mu}. \tag{15}$$

In addition, we denote the cost function Hessians at the respective solutions as:

$$G \equiv \partial^2 \mathcal{H}(\hat{\boldsymbol{W}}) = \sum_\mu \left(\partial^2 q_\mu(\hat{\boldsymbol{W}}) \right), \tag{16}$$

$$G^{\backslash\mu} \equiv \partial^2 \mathcal{H}^{\backslash\mu}(\hat{\boldsymbol{W}}^{\backslash\mu}) = \sum_{\nu(\neq\mu)} \left(\partial^2 q_\nu(\hat{\boldsymbol{W}}^{\backslash\mu}) \right). \tag{17}$$

Finally, we introduce the symbol $A(\boldsymbol{W}) \equiv \{m | W_m \neq 0\}$ representing the index set of the active components of $\boldsymbol{W}$ and $\hat{A} \equiv A(\hat{\boldsymbol{W}})$. Given $\hat{\boldsymbol{W}}$, we denote the active components of a vector $\boldsymbol{Y} \in \mathbb{R}^{LN}$ by the subscript as $\boldsymbol{Y}_{\hat{A}}$. A similar notation is used for any matrix and the symbol $*$ is assumed to represent all of the components in the corresponding dimension.

2.1. Approximate formula

For a simple derivation, it is important to consider that the $\boldsymbol{w}$-dependence of ϕ appears only in the overlap $u = \boldsymbol{x}^\top \boldsymbol{w}$. Hence, it is sufficient to provide the relation between $\hat{u}_{\mu a}$ and $\hat{u}_{\mu a}^{\backslash\mu}$ in order to derive the approximate formula.

A crucial assumption to derive the formula is that the active set is "common" between the full and LOO solutions, $\hat{\boldsymbol{W}} = (\hat{\boldsymbol{w}}_a)_a$ and $\hat{\boldsymbol{W}}^{\backslash\mu} = (\hat{\boldsymbol{w}}_a^{\backslash\mu})_a$; namely $\hat{A} = \hat{A}^{\backslash\mu} \equiv A(\hat{\boldsymbol{W}}^{\backslash\mu})$. Although this assumption is literally not true, we numerically confirmed that this approximately holds. In other words, the change of the active set is small enough compared to the size of the active set itself when considering the LOO operation when N and M are large. Moreover, in a related problem of an ℓ_1-regularized linear regression, the so-called LASSO, it has been shown that the contribution of the active set change vanishes in a limit $N, M \to \infty$ keeping $\alpha = M/N = O(1)$ (Obuchi and Kabashima, 2016). It is expected that the same holds in the present problem. Hence, we adopt this assumption in the following definition. Note that this idea of the active set constantness can be found in preceding analyses of support vector machine (Opper and Winther, 2000b; Vapnik and Chapelle, 2000).

Once the active set $\hat{A}$ is assumed to be known and unchanged by the LOO operation, it is easy to determine the active components of the full and LOO solutions $\hat{\boldsymbol{W}}$ and $\hat{\boldsymbol{W}}^{\backslash\mu}$.

The vanishing condition of the gradient of the cost function is the determining equation:

$$(\nabla\mathcal{H})_{\hat{A}} = 0 \Rightarrow \hat{\boldsymbol{W}}_{\hat{A}}, \tag{18}$$

$$\left(\nabla\mathcal{H}^{\backslash\mu}\right)_{\hat{A}} = (\nabla\mathcal{H})_{\hat{A}} - (\nabla q_\mu)_{\hat{A}} = 0 \Rightarrow \hat{\boldsymbol{W}}^{\backslash\mu}_{\hat{A}}. \tag{19}$$

The difference between the gradients is only ∇q_μ, and hence the difference between $\hat{\boldsymbol{W}}$ and $\hat{\boldsymbol{W}}^{\backslash\mu}$ is expected to be small. Denoting the difference as $\boldsymbol{d}^\mu = \hat{\boldsymbol{W}} - \hat{\boldsymbol{W}}^{\backslash\mu}$ and expanding eq. (19) with respect to $\boldsymbol{d}^\mu$ up to the first order, we obtain an equation determining $\boldsymbol{d}^\mu$:

$$\boldsymbol{d}^\mu_{\hat{A}} = -\left(G^{\backslash\mu}_{\hat{A}\hat{A}}\right)^{-1}\left(\nabla q_\mu(\hat{\boldsymbol{W}})\right)_{\hat{A}}. \tag{20}$$

Inserting this and eq. (12) into the definition $\boldsymbol{d}^\mu = \hat{\boldsymbol{W}} - \hat{\boldsymbol{W}}^{\backslash\mu}$ and multiplying X^μ from left, we obtain:

$$\hat{\boldsymbol{u}}^{\backslash\mu}_\mu \approx \hat{\boldsymbol{u}}_\mu + C^{\backslash\mu}_\mu \boldsymbol{b}^\mu, \tag{21}$$

$$C^{\backslash\mu}_\mu \equiv X^\mu_{*\hat{A}}\left(G^{\backslash\mu}_{\hat{A}\hat{A}}\right)^{-1}\left(X^\mu_{*\hat{A}}\right)^\top. \tag{22}$$

This equation implies that the matrix inversion operation is necessary for each μ, which still requires a significant computational cost. To avoid this, we employ an approximation and the Woodbury matrix inversion formula in conjunction with eqs. (13,16,17). The result is:

$$\left(G^{\backslash\mu}\right)^{-1} \equiv \left(\partial^2\mathcal{H}^{\backslash\mu}(\hat{\boldsymbol{W}}^{\backslash\mu})\right)^{-1} \approx \left(\partial^2\mathcal{H}^{\backslash\mu}(\hat{\boldsymbol{W}})\right)^{-1} = \left(G - (X^\mu)^\top F^\mu X^\mu\right)^{-1}$$
$$= G^{-1} - G^{-1}(X^\mu)^\top\left(-F^\mu + X^\mu G^{-1}(X^\mu)^\top\right)^{-1} X^\mu G^{-1}. \tag{23}$$

Inserting this into eq. (21) and simplifying several factors, we obtain:

$$\hat{\boldsymbol{u}}^{\backslash\mu}_\mu \approx \hat{\boldsymbol{u}}_\mu + C_\mu\left(I_L - F^\mu C_\mu\right)^{-1}\boldsymbol{b}^\mu, \tag{24}$$

where

$$C_\mu = X^\mu_{*\hat{A}}\left(G_{\hat{A}\hat{A}}\right)^{-1}\left(X^\mu_{*\hat{A}}\right)^\top. \tag{25}$$

Now, all of the variables on the righthand side of eq. (24) can be computed from the full solution $\hat{\boldsymbol{W}}$ only, which enables us to estimate the LOOE by leveraging a one-time optimization using all of the data D^M, while avoiding repeated optimizations.

We should mention the computational cost of this approximation: it is mainly scaled as $O(ML^2|\hat{A}| + ML|\hat{A}|^2 + |\hat{A}|^3)$. The first two terms come from the construction of $G_{\hat{A}\hat{A}}$ and C_μ, and the last one is derived from the inverse of G. If $|\hat{A}|$ is proportional to the feature dimensionality N, this computational cost is of the third order with respect to the system dimensionality N and M. This is admittedly not cheap and the computational cost for the k-fold literal CV with a moderate value of k becomes smaller than that for our approximation in a large dimensionality limit. We, however, stress that there actually exists a wide range of N and M values in which our approximation outperforms the literal

CV in terms of the computational time, as later demonstrated in sec. 3. Moreover, for treating much larger systems, we invent a further simplified approximation based on the above approximate formula. The computational cost of this simplified version is scaled only linearly with respect to the system parameters N and M. Its derivation is in sec. 2.2 and the precision comparison to the original approximation is in sec. 3.

Another sensitive issue is present in computing $\left(G_{\hat{A}\hat{A}}\right)^{-1}$. Occasionally the cost function Hessian G has zero eigenvalues and is not invertible. We handle this problem in the next subsection.

2.1.1. Handling zero modes

In the MLR, there is an intrinsic symmetry such that the model is invariant under the addition of any constant vector to the weight vectors of all classes:

$$\boldsymbol{w}_a \to \boldsymbol{w}_a + \boldsymbol{v}\ (\forall a). \tag{26}$$

In this sense, the weight vectors defining the same model are "degenerated" and our MLR is singular. For finite λ, this is not harmful because the regularization term resolves this singularity and selects an optimal one $\{\hat{\boldsymbol{w}}_a\}_a$ with the smallest value of $||\boldsymbol{w}_a||_1$ among the degenerated vectors. However, this does not mean that the associated Hessian is non-singular. The regularization term does not provide any direct contribution to the Hessian and as a result, the Hessian tends to have some zero modes. This prevents taking the inverse Hessian G^{-1} in eq. (25). How can we overcome this?

One possibility is to fix the weights of one certain class at constant values when solving the optimization problem (4). This is termed "gauge fixing" in physics, and one convenient gauge in the present problem will be the zero gauge in which the weights in a chosen class are fixed at zeros. This is actually found in some earlier implementations (Krishnapuram et al., 2005; Schmidt, 2010) and is preferable for our approximate formula because it removes the harmful zero modes of the Hessian from the beginning. However, some other implementations which are currently well accepted do not employ such gauge fixing (Friedman et al., 2010), and moreover even with gauge fixing very small eigenvalues sometimes accidentally emerge in the Hessian. Hence, for user convenience, we require another way of avoiding this problem.

Another possibility is to remove the zero modes by hand. By construction, the zero modes are associated to the model invariance. This implies that those zero modes are irrelevant and may be removed. In fact, we are only interested in the perturbations which truly change the model, and the modes which maintain the model unchanged are unnecessary. According to this consideration, we replace G^{-1} in eq. (25) with the zero-mode-removed inverse Hessian $\overline{G}^{-1}$. The computation of $\overline{G}^{-1}$ is straightforward: we perform the eigenvalue decomposition of $G_{\hat{A}\hat{A}}$ and obtain the eigenvalues $\{d_i\}_{i=1}^{|\hat{A}|}$ and eigenvectors $\{\boldsymbol{v}_i\}_{i=1}^{|\hat{A}|}$, which allows us to represent

$$G_{\hat{A}\hat{A}} = \sum_i d_i \boldsymbol{v}_i\boldsymbol{v}_i^\top = \sum_{i\in S^+} d_i\boldsymbol{v}_i\boldsymbol{v}_i^\top, \tag{27}$$

where S^+ denotes the index set of the modes with finite eigenvalues. Then, $\overline{G}^{-1}$ is defined as:

$$\overline{G}^{-1}_{\hat{A}\hat{A}} \equiv \sum_{i\in S^+} d_i^{-1} \boldsymbol{v}_i \boldsymbol{v}_i^\top. \tag{28}$$

Finally, we replace G^{-1} by $\overline{G}^{-1}$ in eq. (25), and obtain:

$$C_\mu = X^\mu_{*\hat{A}} \overline{G}^{-1}_{\hat{A}\hat{A}} \left(X^\mu_{*\hat{A}}\right)^\top. \tag{29}$$

By using this instead of eq. (25), the problem caused by the zero modes can be avoided.

2.1.2. Extension to the mixed regularization case

Let us briefly state how we can generalize the present result to the case of the mixed regularizations of the ℓ_1- and ℓ_2-terms (elastic net, Zou and Hastie, 2005). The problem to be solved can be defined as follows:

$$\{\hat{\boldsymbol{w}}_a(\lambda_1,\lambda_2)\}_a = \underset{\{\boldsymbol{w}_a\}_a}{\arg\min} \left\{ \sum_{\mu=1}^M q_\mu\left(\{\boldsymbol{w}_a\}_{a=1}^L\right) + \lambda_1 \sum_{a=1}^L ||\boldsymbol{w}_a||_1 + \frac{\lambda_2}{2}\sum_{a=1}^L ||\boldsymbol{w}_a||_2^2 \right\}. \tag{30}$$

where $||\cdot||_2$ denotes the ℓ_2 norm. Following the derivation in sec. 2.1, we realize that the derivation is essentially the same, and the difference only appears in the cost function Hessian:

$$G_{\mathrm{mxd}} = \sum_\mu \left(\partial^2 q_\mu(\hat{\boldsymbol{W}})\right) + \lambda_2 I_{NL}, \tag{31}$$

where I_K is the identity matrix of size K. As a result, we can compute the LOO solution by leveraging the same equation as eq. (24) by replacing the definition of C_μ, eq. (25), with:

$$C_\mu = X^\mu_{*\hat{A}} \left((G_{\mathrm{mxd}})_{\hat{A}\hat{A}}\right)^{-1} \left(X^\mu_{*\hat{A}}\right)^\top. \tag{32}$$

Thanks to the ℓ_2 term, the zero mode removal is not needed since the eigenvalues are lifted up by λ_2.

2.1.3. Binomial case

The binomial case $L = 2$ is particularly interesting in several applications and thus we write down the specific formula for this case.

In the binomial case, it is fairly common to express the class y as a binary $y = 0, 1$ and to use the following logit function:

$$\phi_{\mathrm{logit}}(y_\mu|u_\mu) = \frac{\delta_{y_\mu 1} + \delta_{y_\mu 0} e^{-u_\mu}}{1 + e^{-u_\mu}}, \tag{33}$$

where

$$u_\mu = \boldsymbol{x}_\mu^\top \boldsymbol{w}. \tag{34}$$

If we identify $y = 0$ in this case as $y = 1$ in the two-class MLR case, this is nothing but the two-class MLR with a zero gauge $\boldsymbol{w}_1 = \boldsymbol{0}$. Hence, there is no harmful zero mode in the Hessian and we can straightforwardly apply our approximate formula. The explicit form in this case is:

$$\hat{u}_\mu^{\backslash\mu} \approx \hat{u}_\mu + \frac{c^\mu}{1 - \frac{\partial^2 q_\mu}{\partial u_\mu^2} c^\mu} \frac{\partial q_\mu}{\partial u_\mu}, \tag{35}$$

where $q_\mu = -\ln \phi_{\mathrm{logit}}(y_\mu|u_\mu)$ and

$$\frac{\partial q_\mu}{\partial u_\mu} = \delta_{y_\mu 0} - \frac{e^{-u_\mu}}{1+e^{-u_\mu}}, \tag{36}$$

$$\frac{\partial^2 q_\mu}{\partial u_\mu^2} = \frac{e^{-u_\mu}}{(1+e^{-u_\mu})^2}, \tag{37}$$

$$G_{\hat{A}\hat{A}} = \sum_{\mu=1}^M \frac{\partial^2 q_\mu}{\partial u_\mu^2} \left(\boldsymbol{x}_\mu \boldsymbol{x}_\mu^\top\right)_{\hat{A}\hat{A}}, \tag{38}$$

$$c^\mu = \left(\boldsymbol{x}_\mu^\top\right)_{\hat{A}} \left(G_{\hat{A}\hat{A}}\right)^{-1} (\boldsymbol{x}_\mu)_{\hat{A}}, \tag{39}$$

and $\hat{A} = \{i|\hat{w}_i \neq 0\}$ is the active set of the full solution, as before.

Note that this approximation can be easily generalized to arbitrary differentiable output functions by replacing the logit function ϕ_{logit}. Readers are thus encouraged to implement approximate CVs in a variety of different problems.

2.2. Further simplified approximation

As mentioned above, the computational cost of our approximation is $O(ML^2|\hat{A}|+ML|\hat{A}|^2+|\hat{A}|^3)$ and should be reduced for treating larger systems. For this, we derive a further simplified approximation based on the invented approximate formula above. We call this a self-averaging (SA) approximation according to physics terminology.

The basic idea for simplifying our approximate formula is to assume that correlations between W_m and W_n are sufficiently weak. The meaning of "correlation" is not evident here, but as seen in sec. A the Hessian G can be connected to a (rescaled) covariance χ between W_m and W_n in a statistical mechanical formulation introducing a probability distribution of $\boldsymbol{W}$. Our weak correlation assumption requires that the correlation between different feature components is negligibly small; $\chi_{mn}(\equiv (1/\beta)\mathrm{cov}(W_m, W_n)) = \chi_{(m_f,m_c),(n_f,n_c)} = \delta_{m_f n_f}(\chi_{m_f})_{m_c n_c}$, where $m_c, n_c (= 1, \cdots, L)$ are the class indices and $m_f, n_f (= 1, \cdots, N)$ are the feature component indices defined thus far, and β is the rescaling factor. In this way, the Hessian is assumed to be expressed in a rather restricted form:

$$\left(G^{\backslash\mu}\right)^{-1}_{mn} \approx \begin{cases} \left(\chi_{m_f}\right)_{m_c n_c} \delta_{m_f n_f}, & (m,n \in \hat{A}) \\ 0, & (\text{otherwise}) \end{cases}, \tag{40}$$

Namely, the SA Hessian is allowed to take finite values if and only if the two indices share the same feature vector component. The dependence on the data index μ is also assumed

to be negligible, implying that strong heterogeneity among feature vectors is assumed to be absent.

To proceed with the computation, we require a closed equation to determine the $L \times L$ matrix χ_i for $i = 1, \cdots, N$. Its derivation is rather technical and is deferred to sec. A. The result is:

$$(\chi_i)_{\hat{A}_i \hat{A}_i} = \left(\lambda_2 I_{|\hat{A}_i|} + \sigma_x^2 \sum_{\nu=1}^{M} \left(\left(I_L + F^\nu C_{\mathrm{SA}} \right)^{-1} F^\nu \right)_{\hat{A}_i \hat{A}_i} \right)^{-1}, \tag{41}$$

where $\sigma_x^2 = \sum_\mu \sum_i x_{\mu i}^2 / (NM)$ and $\hat{A}_i = \{a | \hat{w}_{ai} \neq 0\}$ is the set of active class variables at the feature component i; the other components of χ_i related to inactive variables are zeros. The SA approximation of $C_\mu^{\backslash \mu}$, $C_{\mathrm{SA}} \in \mathbb{R}^{L \times L}$, is defined by:

$$C_{\mathrm{SA}} = \sigma_x^2 \sum_{i=1}^{N} \chi_i. \tag{42}$$

Using the solution of eqs. (41,42), the approximate formula is now simply expressed as:

$$\hat{\boldsymbol{u}}_\mu^{\backslash \mu} \approx \hat{\boldsymbol{u}}_\mu + C_{\mathrm{SA}} \boldsymbol{b}^\mu. \tag{43}$$

Note that there is no factor like $(I_L - F^\mu C_\mu)^{-1}$ in contrast to eq. (24), because we directly approximate $C_\mu^{\backslash \mu}$ in eq. (21).

When solving eqs. (41,42), the inverse at the right-hand side of eq. (41) becomes occasionally ill-defined again due to the presence of zero modes. In such cases, we should remove the zero modes as eq. (28). Putting $R = \lambda_2 I_L + \sigma_x^2 \sum_{\mu=1}^{M} \left(\left(I_L + F^\mu C_{\mathrm{SA}} \right)^{-1} F^\mu \right)$ and performing the eigenvalue decomposition, we define its zero-mode-removed inverse $\overline{R}^{-1}$ as:

$$R_{\hat{A}_i \hat{A}_i} = \sum_j d_j \boldsymbol{v}_j \boldsymbol{v}_j^\top = \sum_{j \in S^+} d_j \boldsymbol{v}_j \boldsymbol{v}_j^\top \Rightarrow \overline{R}^{-1}_{\hat{A}_i \hat{A}_i} = \sum_{j \in S^+} d_j^{-1} \boldsymbol{v}_j \boldsymbol{v}_j^\top, \tag{44}$$

where S^+ is the index set of the modes with finite eigenvalues. This requires a $O(L^3)$ computational cost at a maximum. Leveraging this approach, a naive way to solve eqs. (41,42) is a recursive substitution. If this converges in a constant time, irrespectively of the system parameters N, M and L, then the computational cost of the SA approximation is scaled as $O(NL^3 + ML^3)$. This is linear in the feature dimensionality N and the data size M and hence, its advantage is significant.

2.3. Summary of procedures

Here, we summarize the two versions of the approximation derived thus far as algorithmic procedures. We call the first version, based on eq. (24), the approximate CV or ACV, and call the second one, using eq. (43), the self-averaging approximate CV or SAACV. The procedures of ACV and SAACV are given in Alg. 1 and Alg. 2, respectively; they are written for the case of the mixed regularization (30). Comments are added for

Algorithm 1 Approximate CV of the MLR

procedure ACV($\hat{\boldsymbol{W}}(\lambda_1, \lambda_2), D^M, \lambda_2$)
  Compute the active set $\hat{A}$ from $\hat{\boldsymbol{W}}$
  Compute $\{\hat{\boldsymbol{u}}_\mu, X^\mu, \boldsymbol{b}^\mu, F^\mu\}_\mu$ by eqs. (1,9), (14) and (15)
  $G_{\hat{A}\hat{A}} \leftarrow \sum_{\mu=1}^{M} (X^\mu)^\top F^\mu X^\mu + \lambda_2 I_{|\hat{A}|}$ ▷ $O(ML|\hat{A}|^2 + ML^2|\hat{A}|)$
  if λ_2 is large enough **then** ▷ $O(|\hat{A}|^3)$
    $\overline{G}^{-1}_{\hat{A}\hat{A}} = \left(G_{\hat{A}\hat{A}} \right)^{-1}$
  else
    Compute $\overline{G}^{-1}_{\hat{A}\hat{A}}$ by eq. (28)
  end if
  for $\mu = 1, \cdots, M$ **do** ▷ $O(ML|\hat{A}|^2 + ML^2|\hat{A}| + ML^3)$
    $C_\mu \leftarrow X^\mu_{*\hat{A}} \overline{G}^{-1}_{\hat{A}\hat{A}} \left(X^\mu_{*\hat{A}} \right)^\top$
    $\hat{\boldsymbol{u}}_\mu^{\backslash \mu} \leftarrow \hat{\boldsymbol{u}}_\mu + C_\mu \left(I_L - F^\mu C_\mu \right)^{-1} \boldsymbol{b}^\mu$
  end for
  Compute ϵ_{LOO} from $\{\boldsymbol{u}_\mu^{\backslash \mu}\}_\mu$ by eq. (8)
  return ϵ_{LOO}
end procedure

specifying the time consuming parts in the entire procedures. In Alg. 2, we describe an actual implementation for solving C_{SA} by recursion, which is not fully specified in sec. 2.2. The symbol $||\cdot||_{\mathrm{F}}$ denotes the Frobenius norm and we set the threshold θ judging the convergence as $\theta = 10^{-6}$ in typical situations. We also set as 10^{-6} the threshold judging if λ_2 is large or not.

3. Numerical experiments

In this section, we examine the precision and actual computational time of ACV and SAACV in numerical experiments. Both simulated and actual datasets (from UCI machine learning repository, Lichman, 2013) are used.

For examination, we compute the errors also by literally conducting k-fold CV with some ks, and compare it to the result of our approximate formula. In principle, we should compare our approximate result with that of the LOO CV ($k = M$) because our formula approximates it. However for large M, the literal LOO CV requires huge computational burdens despite that the result is empirically not much different from that of the k-hold CV with moderate ks. Hence in some of the following experiments with large M, we use the 10-hold CV instead of the LOO CV. Further, to directly check the approximation accuracy, we also compute the normalized error difference defined as

$$\frac{\epsilon_{\mathrm{LOO}}^{\mathrm{approximate}} - \epsilon_{\mathrm{CV}}^{\mathrm{literal}}}{\epsilon_{\mathrm{CV}}^{\mathrm{literal}}}, \tag{45}$$

where $\epsilon_{\mathrm{CV}}^{\mathrm{literal}}$ denotes the literal CV estimator of the prediction error while $\epsilon_{\mathrm{LOO}}^{\mathrm{approximate}}$ is the approximated LOOE. Moreover, as a reference, we compute the negative log-likelihood of

Algorithm 2 Self-averaging approximate CV of the MLR

procedure SAACV($\hat{\boldsymbol{W}}(\lambda_1, \lambda_2), D^M, \lambda_2$)
  Compute the active sets $\{\hat{A}_i\}_{i=1}^N$ from $\hat{\boldsymbol{W}}$
  Compute $\{\boldsymbol{u}_\mu, X^\mu, \boldsymbol{b}_\mu, F^\mu\}_\mu$ by eqs. (1,9), (14) and (15)
  $t \leftarrow 0$ ▷ Start initialization
  for $i = 1, \cdots, N$ **do**
    $\left(\chi_i^{\setminus\mu}\right)^{(t)} \leftarrow 0$,
    $\left(\chi_i^{\setminus\mu}\right)^{(t)}_{\hat{A}_i\hat{A}_i} \leftarrow \sigma_x^{-2}$,
  end for
  $\Delta \leftarrow 100$ ▷ End initialization
  while $\Delta > \theta$ **do** ▷ Compute $C_{\rm SA}$ by recursion
    $C_{\rm SA}^{(t+1)} \leftarrow \sigma_x^2 \sum_{i=1}^N \left(\chi_i^{\setminus\mu}\right)^{(t)}$
    $R \leftarrow \sigma_x^2 \sum_{\mu=1}^M \left(I_L + F^\mu C_{\rm SA}^{(t+1)}\right)^{-1} F^\mu + \lambda_2 I_L$ ▷ $O(ML^3)$
    $\Delta \leftarrow 0$
    for $i = 1, \cdots, N$ **do** ▷ $O(NL^3)$
      if λ_2 is large enough
        $\overline{R}^{-1}_{\hat{A}_i\hat{A}_i} = \left(R_{\hat{A}_i\hat{A}_i}\right)^{-1}$
      else
        Compute $\overline{R}^{-1}_{\hat{A}_i\hat{A}_i}$ by eq. (44) from R
      end if then
      $\left(\chi_i^{\setminus\mu}\right)^{(t+1)}_{\hat{A}_i\hat{A}_i} \leftarrow \overline{R}^{-1}_{\hat{A}_i\hat{A}_i}$
      $\Delta \leftarrow \Delta + \left|\left|\left(\chi_i^{\setminus\mu}\right)^{(t+1)}_{\hat{A}_i\hat{A}_i} - \left(\chi_i^{\setminus\mu}\right)^{(t)}_{\hat{A}_i\hat{A}_i}\right|\right|_{\rm F}$
    end for
    $\Delta \leftarrow \Delta / N$
    $t \leftarrow t + 1$
  end while
  for $\mu = 1, \cdots, M$ **do**
    $\boldsymbol{u}_\mu^{\setminus\mu} \leftarrow \boldsymbol{u}_\mu + C_{\rm SA}^{(t)} \boldsymbol{b}^\mu$
  end for
  Compute $\epsilon_{\rm LOO}$ from $\{\boldsymbol{u}_\mu^{\setminus\mu}\}_\mu$ by eq. (8)
  return $\epsilon_{\rm LOO}$
end procedure

the full solution $\{\hat{\boldsymbol{w}}_a\}_{a=1}^L$ as:

$$\epsilon = \frac{1}{M} \sum_{\mu=1}^M q_\mu \left(\{\hat{\boldsymbol{w}}_a\}_{a=1}^L \right), \tag{46}$$

and call it the training error, hereafter. The training error is expected to be a monotonic increasing function with respect to λ, while the prediction one is supposed to be non-monotonic.

In all of the experiments, we used a single CPU of Intel(R) Xeon(R) E5-2630 v3 2.4GHz. To solve the optimization problems in eqs. (4,6), we employed *Glmnet* (Friedman et al., 2010) which is implemented as a *MEX* subroutine in MATLAB®. The two approximations were implemented as raw codes in MATLAB. This is not the most optimized approach, because as seen in Algs. 1,2 our approximate formula uses a number of *for* and *while* loops which are slow in MATLAB, and hence the comparison is not necessarily fair. However, even in this comparison there is a significant difference in the computational time between the literal CV and our approximations, as shown below.

In Glmnet, the corresponding optimization problem is parameterized as follows:

$$\{\hat{\boldsymbol{w}}_a(\tilde{\lambda}, \eta)\}_a = \mathop{\rm arg\,min}_{\{\boldsymbol{w}_a\}_a} \left\{ \frac{1}{M} \sum_{\mu=1}^M q_\mu \left(\{\boldsymbol{w}_a\}_{a=1}^L \right) + \tilde{\lambda} \left(\eta \sum_{a=1}^L ||\boldsymbol{w}_a||_1 + \frac{(1-\eta)}{2} \sum_{a=1}^L ||\boldsymbol{w}_a||_2^2 \right) \right\}. \tag{47}$$

In the following experiments, we present the results based on this parameterization. We basically prefer $\eta = 1$ in which the ℓ_2 term is absent, because the main contribution of the present paper is to overcome technical difficulties stemming from the ℓ_1 term. However, Glmnet or its employing algorithm occasionally loses its stability in some uncontrolled manner without the ℓ_2 term. Hence, in the following experiments we adaptively choose the value of η.[1]

A sensitive point which should be noted is the convergence problem of the algorithm for solving the present optimization problem. In Glmnet, a specialized version of coordinate descent methods is employed, and it requires a threshold δ to judge the algorithm convergence. Unless explicitly mentioned, we set this as $\delta = 10^{-8}$ being tighter than the default value. This is necessary since we treat problems of rather large sizes. A looser choice for δ rather strongly affects the literal CV result, while it does not change the full solution or the training error as much. As a result, our approximations employing only the full solution are rather robust against the choice of δ compared to the literal CV. This is also demonstrated below.

3.1. On simulated dataset

Let us start by testing with the simulated data. Suppose each "true" feature vector $\boldsymbol{w}_{0a}$ is independently identically drawn (i.i.d.) from the following Bernoulli-Gaussian prior:

$$\boldsymbol{w}_{0a} \sim \prod_{i=1}^N \{(1-\rho_0)\delta(w_{0ai}) + \rho_0 \mathcal{N}(0, 1/\rho_0)\}, \tag{48}$$

1. When employing our distributed codes implementing the approximate formula (Obuchi, 2017; Takahashi and Obuchi, 2017) in conjunction with Glmnet, the parameters λ_1 and λ_2 are read as $\lambda_1 = M\tilde{\lambda}\eta$ and $\lambda_2 = M\tilde{\lambda}(1-\eta)$.

where $\mathcal{N}(\mu, \sigma^2)$ denotes a Gaussian distribution whose mean and variance are μ and σ^2, respectively. The resultant feature vector $\boldsymbol{v}_a$ becomes $N\rho_0(\equiv K_0)$-sparse and its norm becomes $\sqrt{N}$ on average. Then, we choose a class y_μ from $\{1, \cdots, L\}$ uniformly and randomly, and generate an observed feature vector $\boldsymbol{x}_\mu$ by leveraging the following linear process:

$$\boldsymbol{x}_\mu = \frac{\boldsymbol{w}_{0y_\mu}}{\sqrt{N}} + \boldsymbol{\xi}, \tag{49}$$

where $\boldsymbol{\xi}$ is an observation noise each component of which is i.i.d. from a Gaussian $\mathcal{N}(0, \sigma_N^2)$.

For convenience, we introduce the ratio of the data size to the feature dimensionality, $\alpha = M/N$, and now obtain five parameters $\{N, L, \alpha, \rho_0, \sigma_\xi^2\}$ characterizing the experimental setup. It is rather heavy to obtain the dependence of all parameters and below, and hence we mainly focus on the dependence on L, σ_ξ^2, and N. Other parameters are set to be $\alpha = 2$ and $\rho_0 = 0.5$.

3.1.1. Result

Let us summarize the result on simulated data.

Fig. 1 shows the plots of the prediction and training errors against $\tilde{\lambda}$ for $L = 4, 8, 16$ at $N = 200$ and $\sigma_\xi^2 = 0.01$. This demonstrates that both approximations provide consistent results with the literal LOO CV, except at small $\tilde{\lambda}$s. This inconsistency at small $\tilde{\lambda}$s is considered to be due to a numerical instability occurring in the literal CV. Actually, for small $\tilde{\lambda}$s, we have observed that certain small changes in the data induce large differences in the literal CV result. This example demonstrates that our approximations provide robust curves even in such situations. Note that as L grows the number of estimated parameters $\{\boldsymbol{w}_a\}_{a=1}^L$ increases while the data size $M = \alpha N = 400$ is fixed, meaning that the problem becomes more and more underdetermined with the growth of L. Hence, Fig. 1 demonstrates that the developed approximations work irrespectively of how much the problem is underdetermined.

Fig. 2 exhibits the σ_ξ^2-dependence of the errors and the approximation results for $L = 8$ and $N = 200$. For the very weak noise case ($\sigma_\xi^2 = 0.001$, left), the difference between the predictive and training errors is negligible and hence all four curves are not discriminable. For the moderate ($\sigma_\xi^2 = 0.1$, middle) and large ($\sigma_\xi^2 = 1$, right) noise cases, the training curve is very different from the predictive ones. The approximation curves are again consistent with the literal LOO one.

Fig. 3 demonstrates how the approximation accuracy changes as the system size N grows. For small sizes $N = 50, 100$, a discriminable difference exists between the results of the approximations and the literal LOO CV, as well as the difference between the results of the two approximations. This is expected, because our derivation relies on the largeness of N and M. For large systems $N = 400, 800$, the difference among the two approximations and the literal CV is much smaller. Considering this example in conjunction with the middle panel of Fig. 1, we can recognize that our approximate formula becomes fairly precise for $N \geq 200$ in this parameter set. The normalized error difference corresponding to Fig. 3 is shown in Fig. 4. We can observe that the difference tends to be smaller as the system size increases, which is expected because the perturbation employed in our approximate formula is justified in the large N, M limit.

Finally, let us consider the actual computational time to evaluate $\{\hat{\boldsymbol{w}}_a\}_a$ and the approximate LOOEs, and observe its system size dependence. The left panel of Fig. 5 provides

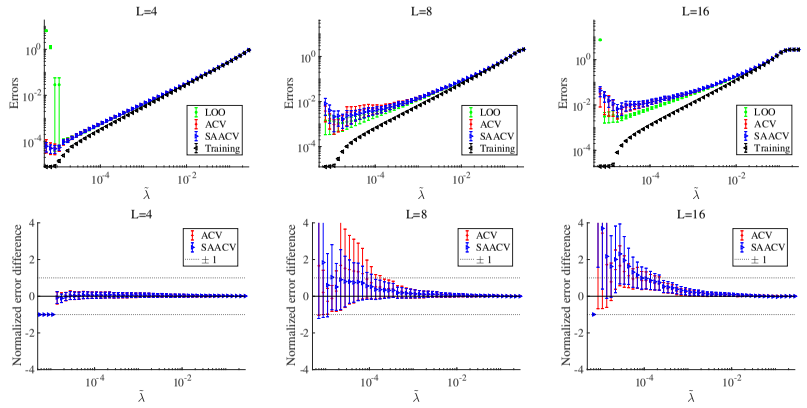

Figure 1: (Upper) Log-log plots of the errors against $\tilde{\lambda}$ for several values of the class number L. Other parameters are fixed at $N = 200$, $\sigma_\xi^2 = 0.01$, $\alpha = 2$ and $\rho_0 = 0.5$. The approximation results are consistent with the literal LOO CV results, except at small λs, which is presumably due to a numerical instability occurring in the literal CV at small λs. Here, $\eta = 0.9$. (Lower) The normalized error difference (45) plotted against $\tilde{\lambda}$. The parameters of each panel are them of the corresponding upper one. The horizontal dotted lines denote ± 1 and drawn for comparison. For small $\tilde{\lambda}$s the difference is not negligible, but the literal CV itself is not stable in that region and hence the error difference is not reliable.

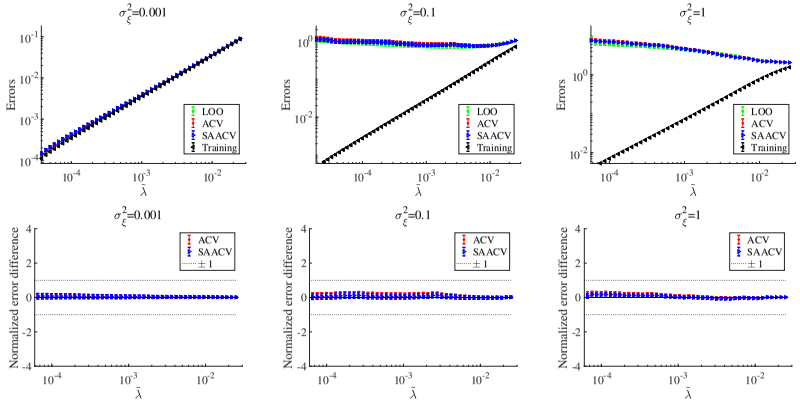

Figure 2: (Upper) Log-log plots of the errors against $\tilde{\lambda}$ for several noise strengths. Other parameters are fixed at $N = 200$, $L = 8$, $\alpha = 2$ and $\rho_0 = 0.5$. The approximation results are consistent with the literal LOO CV, irrespectively of the noise strength. The convergence threshold δ is set to be $\delta = 10^{-9}$ for the case $\sigma_\xi^2 = 1$. Here, $\eta = 1$. (Lower) The normalized error difference (45) plotted against $\tilde{\lambda}$. The parameters of each panel are them of the corresponding upper one. In the whole region the difference is negligibly small.

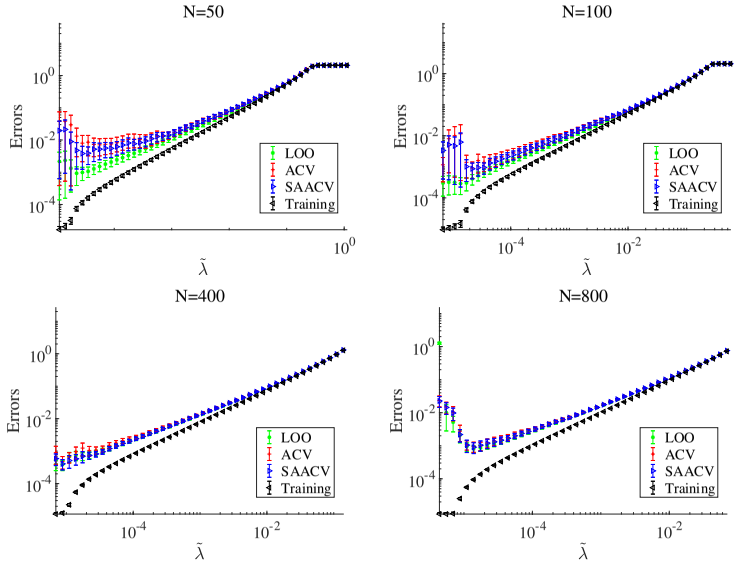

Figure 3: Log-log plots of the errors against $\tilde{\lambda}$ for several values of feature dimensionality N. Other parameters are fixed at $L = 8$, $\sigma_\xi^2 = 0.01$, $\alpha = 2$ and $\rho_0 = 0.5$. Here, $\eta = 0.9$.

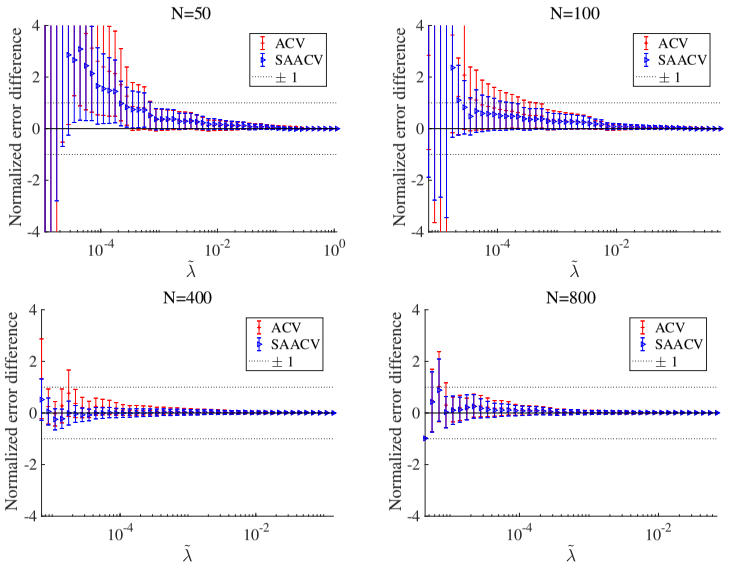

Figure 4: The plot of the normalized error difference corresponding to Fig. 3. The difference tends to be smaller as the system size increases.

the plot of the actual computational time against the system size. Here, the number of examined points of $\tilde{\lambda}$ to obtain a solution path is different from size to size, and hence the plotted time is given as the whole computational time to obtain the solution path divided by the number of $\tilde{\lambda}$s points. The left panel of Fig. 5 clearly displays the advantage and

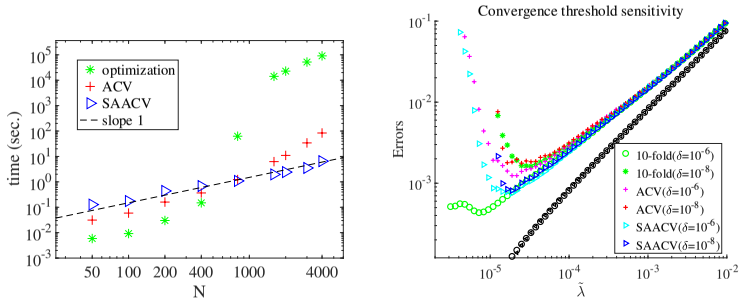

Figure 5: (Left) Actual computational time spent to find the solution of eq. (4) and that for ACV and SAACV, plotted against the feature dimensionality N in a double logarithmic scale. Note that the computational time for the k-fold CV is about k times larger than that for finding the solution of eq. (4), represented by the green asterisks. Parameters are fixed at $L = 8$, $\sigma_\xi^2 = 0.01$, $\alpha = 2$ and $\rho_0 = 0.5$. Here, $\eta = 1$. (Right) The errors are obtained for the two convergence thresholds $\delta = 10^{-6}$ and $\delta = 10^{-8}$. Error bars are omitted for visibility. For the tighter case $\delta = 10^{-8}$, the minimum value of $\tilde{\lambda}$ in the examined range is larger than that of the case $\delta = 10^{-6}$, though the systematic difference with the results of the literal LOO CV is already clear. The training errors of these two different δ, represented by black circles and left-pointing triangles, are completely overlapping. The system parameters are $N = 400$, $L = 8$, $\sigma_\xi^2 = 0.01$, $\alpha = 2$ and $\rho_0 = 0.5$. Here, $\eta = 1$.

disadvantage of the developed approximations. For small sizes, the computational time for optimization to obtain $\{\hat{\boldsymbol{w}}_a\}_a$ is shorter than the time to compute the approximate LOOEs, and hence the literal CV is better. However, for larger systems, the optimization cost increases rapidly and for $N \gtrsim 400$ the approximate CV is better. For $N \gtrsim 800$, the ACV cost exceeds that of SAACV. The SAACV cost behaves linearly as a function of N (see the black dashed line), and hence for larger systems of $N \gtrsim 800$ SAACV can be a very powerful tool. As a related issue, we mention the convergence problem of the algorithm. In the right panel of Fig. 5, we compare the errors at two different values of the convergence threshold δ. An important observation is that a significant difference exists in the literal CV results while other curves do not show a strong change. This implies that our approximate formula is rather robust and can be used with a rather loose convergence threshold or conversely, we can use the systematic deviation between the literal CV and our approximations as an

indicator to verify the tightness of the convergence threshold. This is beneficial, especially when treating large models, for which the convergence check is a common annoying task.

3.2. On real-world dataset

Next, we test the approximate formula on a real-world dataset. As shown above, our approximations become more precise if the model dimensionality and data size are large. Hence, we chose the ISOLET dataset which is a relatively large problem among classification tasks collected in the UCI machine learning repository (Lichman, 2013). The feature dimensionality, the data size, and the class number are $N = 617$, $M = 6238$, and $L = 26$, respectively. Here we apply the 10-fold CV, instead of the LOO CV because of the computational reason, and our approximations to this dataset. The result is given in Fig. 6. The

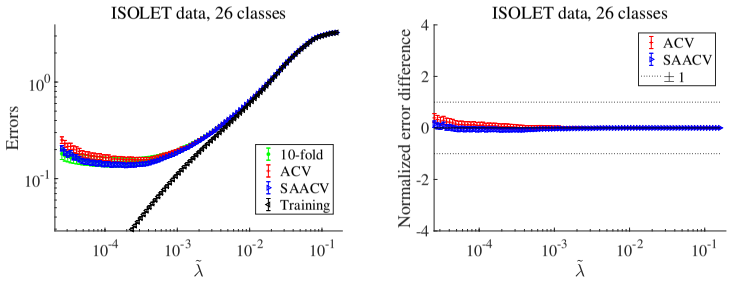

Figure 6: Approximate CV performance on the ISOLET data of $L = 26$ classes. The errors are shown in the left panel and the normalized error differences between the approximations and the 10-fold CV are in the right panel. At the estimated minimums of the prediction error, the accuracy rate for correctly classifying the test data is about 0.86 while the probability of recovering the training data is about 0.98, commonly among the literal CV and the two approximations. At the minimum value of $\tilde{\lambda}$, the leftmost point in the figure, the accuracy rates are different among the three different methods, and are 0.83, 0.78, and 0.81 for the literal CV, ACV and SAACV, respectively. Here, $\eta = 1$.

results of the approximations and of the 10-fold CV demonstrate a fairly good agreement, proving the actual effectiveness of the developed approximations. In an experiment, the actual computational time to obtain the result of the full simulation, of the 10-fold CV, of ACV, and of SAACV were 785, 7825, 5173, and 689 seconds, respectively. The system parameters $\{N, M, L\}$ are rather large in this problem and thus the advantage of ACV is not large, while the efficiency of SAACV stands out in such situations.

3.3. When does SAACV fail?

Two major factors neglected in SAACV are the correlations among feature components and the heterogeneity among feature vectors. If these factors are strong, the approximation accuracy of SAACV is expected to be degraded. In this section, we examine this point.

First, to test the impact of correlations in feature components, we add further constraints to the simulated data treated in sec. 3.1 and examine the approximation performance on the situation. Two cases are treated: the first is the case where the true feature vectors $\{\boldsymbol{w}_{0a}\}$ have common components among all the classes. The result of this case is shown in the left panels in Fig. 7. Here, the fraction of the common components to the non-zero components is $r_{\rm common} = 0.9$ and thus the overlap between feature vectors of different classes is rather large. The other is the case where the noise vector has strong correlations among the components. The result of this case is presented in the right panels in Fig. 7, in which the noise strength is $\sigma_\xi^2 = 1$ and the correlation coefficient of any pair of noise components is ${\rm Corr}(\xi_i, \xi_j) = 0.9$; hence the noise and the correlation are rather large. For both the cases, the performance of the approximate formula is fairly good, implying that SAACV is likely to perform well even when components of the feature vectors are correlated. Similar findings were actually obtained in the case of linear models (Obuchi and Kabashima, 2016). This is a preferable observation because it implies that the applicable limit of SAACV can be extended to a wider class of feature vectors than that is assumed in our present derivation in which the weakness of the correlations is assumed, as seen in sec. A. These also imply that there possibly exists another approximation formula taking into account the correlations but being similar to SAACV. A promising framework to derive such a formula might be the adaptive TAP method (Opper and Winther, 2001a,b, 2005). The adaptive TAP method itself requires a larger computational cost than that of SAACV but it is possible to reduce the computational cost up to the linear scaling with respect to N and M by employing an additional simplifying approximation (Kabashima and Vehkaperä, 2014; Çakmak and Opper, 2018). This is, however, rather technical and we leave it as a future work.

Second, to examine the effect of the heterogeneity among feature vectors, we introduce an amplifying factor Ω to control the norm of feature vectors. In particular, we multiply the factor Ω to the feature vectors of some chosen classes, as $\boldsymbol{x}_{\boldsymbol{\mu}} \to \Omega \boldsymbol{x}_{\boldsymbol{\mu}}$. Here, we use the simulated data identical to that for the center panels in Fig. 3 of the parameters $(N, L, \alpha, \rho_0, \sigma_\xi^2, \eta) = (200, 8, 2, 0.5, 0.1, 1)$, except that the amplifying factor $\Omega = 100$ is applied to the latter four classes $y = 5, 6, 7, 8$. The approximation performance on this dataset is shown in Fig. 8. We also examine the impact of the same heterogeneity on a real-world dataset in Fig. 9. Here, we treat the well-known MNIST data of handwritten digits (LeCun et al., 1998). For simplicity, we only use the data of two digits: 0 and 1. As a preprocessing, feature components with small variances are removed and only the $N = 350$ components of the largest variances are retained; the original size of the feature vector is $784 = 28 \times 28$ and thus almost the half of the components are discarded. Then, the usual standardization procedure is conducted. Further, we apply the amplifying factor $\Omega = 10$ to the class of 1 (right panels), while the case without the amplification (or $\Omega = 1$, left panels) is also examined for comparison. These two examples clearly show that ACV shows a consistency with the LOO CV behavior while SAACV does not, demonstrating that SAACV gives an inaccurate estimate of the CV error for datasets with strong heterogeneity. This kind of heterogeneity

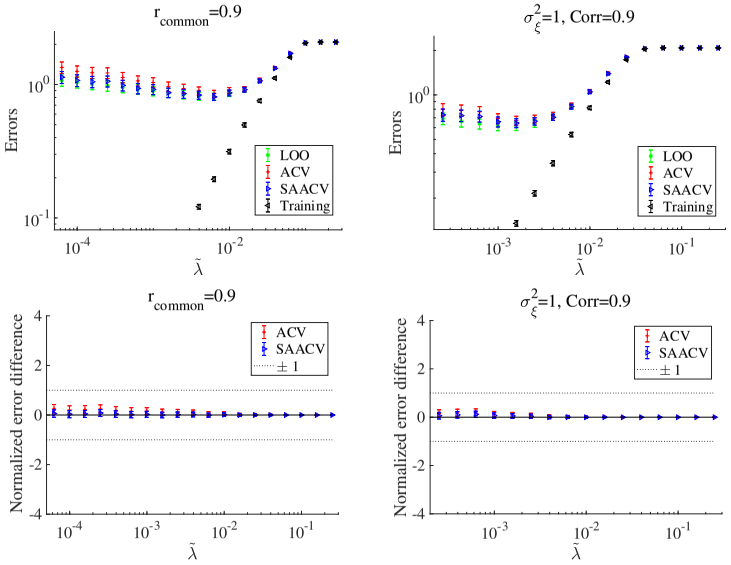

Figure 7: (Upper) Log-log plots of the errors against $\tilde{\lambda}$ for correlated feature vectors. The left panel is for the case with common components in true feature vectors while the right one is of the correlated noise case. Parameters $(N, L, \alpha, \rho_0, \eta) = (200, 8, 2, 0.5, 1)$ are common in both the cases, while the noise strengths and convergence thresholds are different: $(\sigma_\xi^2, \delta) = (0.1, 10^{-8})$ (left) and $(\sigma_\xi^2, \delta) = (1, 10^{-9})$ (right). (Lower) The normalized error difference (45) plotted against $\tilde{\lambda}$. The parameters of each panel are them of the corresponding upper one.

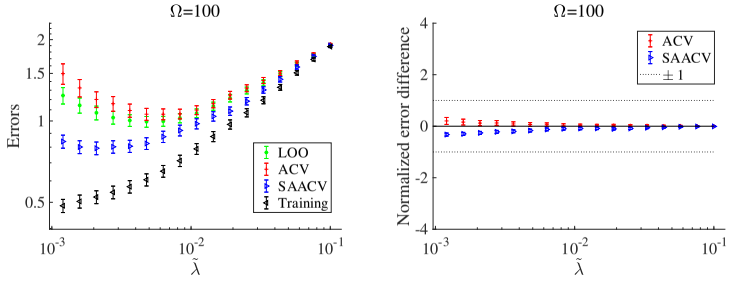

Figure 8: (Left) Log-log plots of the errors against $\tilde{\lambda}$ with strong heterogeneity in feature vectors. The same dataset as that of the center panels in Fig. 3 is used but the feature vectors for the classes $y_\mu = 5, 6, 7, 8$ are amplified as $\boldsymbol{x_\mu} \to \Omega \boldsymbol{x_\mu}$ by the factor $\Omega = 100$. The ACV result is consistent with the LOO CV one while that of SAACV is not. (Right) The normalized error difference corresponding to the left panel.

can naturally emerge in some applications: for example if we consider problems in medical statistics, a number of biological markers can give distinguishably large values for affected patients compared to unaffected ones, yielding larger values in norm for feature vectors of affected patients. This consideration suspects the efficiency of SAACV. We, however, stress that this kind of heterogeneity attributed to the belonging class can be absorbed by rescaling the weights as $\{\boldsymbol{w}_a\}_a \to \{\Omega_a^{-1}\boldsymbol{w}_a\}_a$, where Ω_a is chosen to homogenize the feature vector norm in different classes as $||\boldsymbol{x}_{y_\mu}\Omega_a||_2 \approx \text{const}$. For the ℓ_1 regularization case, this resultantly leads to the regularization coefficients which take different values adaptively to the belonging class as

$$\lambda \sum_a ||\boldsymbol{w}_a||_1 \to \sum_a \lambda \Omega_a ||\boldsymbol{w}_a||_1 = \sum_a \lambda_a ||\boldsymbol{w}_a||_1. \tag{50}$$

For this problem with adaptive regularization coefficients, our approximation formula can be applied in the completely same manner, which can be convinced by seeing Algs. 1,2 where the value of the regularization coefficient is not required as the argument. The ℓ_2-norm can also be handled, though the codes should be extended to take into account the groupwise coefficients as arguments. We argue that this rescaling is a natural prescription to treat strong heterogeneity among different classes, and once employing this prescription the weak point of SAACV is naturally cured.

As a noteworthy remark, we point out that the basic idea of SAACV is closely related to Wahba's generalized cross-validation (GCV) for linear regression (Golub et al., 1979). In GCV, the heterogeneity in coefficient corresponding to $C_\mu^{\backslash\mu}$ in SAACV is also neglected, and hence it shares the same weak point as SAACV, when it is regarded as an approximation of the CV estimator to generalization errors. We stress that this kind of approximation

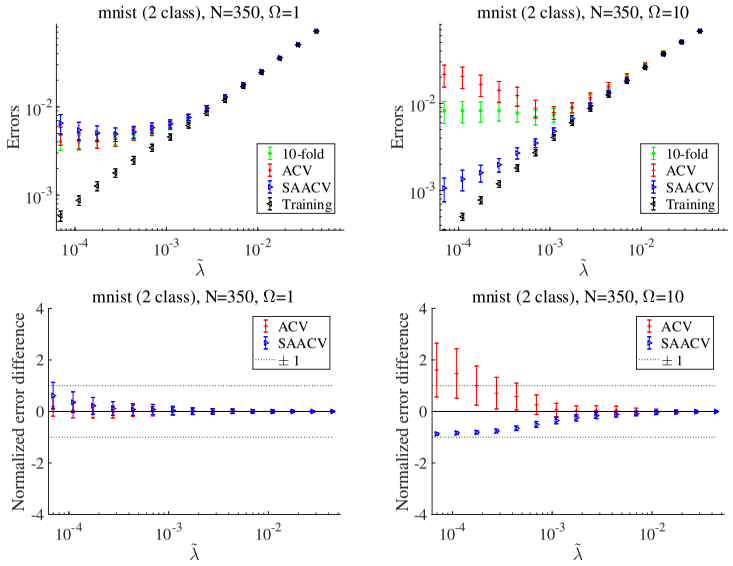

Figure 9: (Upper) Log-log plots of the errors against $\tilde{\lambda}$ of mnist handwritten data with two digits 0 and 1. The amplifying factor is not applied (or $\Omega = 1$) in the left panels while is applied ($\Omega = 10$) in the right ones. The strong heterogeneity among the classes affect the performance of SAACV. (Lower) The normalized error difference corresponding to the upper panels.

reducing the computational cost is again needed because the data size and the model dimensionality are increasing rapidly in recent years.

4. Conclusion

In this paper, we have developed an approximate formula for the CV estimator of the predictive likelihood of the multinomial logistic regression regularized by the ℓ_1-norm. An extension to the elastic net regularization has been also stated. We have demonstrated their advantages and disadvantages in numerical experiments using simulated and real-world datasets. Two versions of the approximation have been defined based on the developed formula. The first version, abbreviated as ACV, has a better performance, in terms of computational time, for middle size problems. It will eventually become worse than the literal k-fold CV with moderate ks as the problem size grows, because its computational time is scaled as a third-order polynomial of the feature dimensionality and data size, N and M, though such a tendency has not been observed in the investigated range of N. We have also defined the second version based on ACV, the computational time of which is just scaled linearly with respect to N and M. This second approximation is called SAACV, and it has been demonstrated that SAACV is slow for small size problems but has a great advantage for large size problems. Hence, we suggest leveraging the literal CV for small, ACV for middle, and SAACV for large size problems.

Our derivation is based on the perturbation which assumes that there is a small difference between the full and leave-one-out solutions. This assumption will not be satisfied for some specific cases. Even with this restriction, we expect the range of application of our formula is wide enough and we would like to encourage readers to leverage it in their own work. We have implemented MATLAB and python codes and they are available in (Obuchi, 2017; Takahashi and Obuchi, 2017).

The perturbative approach employed here is fairly general and can be applied to a wide class of generalized linear models with convex regularizations. The development of practical formulas for these cases will be of great assistance, given that we are living in the Big Data era.

Appendix A. The SA approximation

Let us derive eq. (41) in the SA approximation. We work on a framework called a cavity method in statistical physics or belief propagation (BP) in computer science. We start from

defining the so-called Boltzmann distribution:

$$P\left(\{\boldsymbol{w}_a\}_{a=1}^L \middle| D^M, \lambda\right) = \frac{1}{Z\left(D^M, \lambda\right)} e^{-\beta \mathcal{H}\left(\{\boldsymbol{w}_a\}_{a=1}^L \middle| D^M, \lambda\right)}$$
$$= \frac{e^{-\beta \sum_a \left(\lambda_1 ||\boldsymbol{w}_a||_1 + \frac{\lambda_2}{2} ||\boldsymbol{w}_a||_2^2\right)}}{Z\left(D^M, \lambda\right)} \prod_{\mu=1}^M \phi^\beta \left(y_\mu | \{u_{\mu a}\}_a\right). \tag{51}$$

In the $\beta \to \infty$ limit, this distribution converges to a point-wise measure of the solution of eq. (4) and hence, it is useful for analyzing eq. (51). We note that the BP is usually applied to graphical models having sparse tree-like structures, but is also applicable to ones with densely connected structures. In such applications, the BP can be regarded as a systematic implementation of the Thouless-Anderson-Palmer (TAP) approach (Thouless et al., 1977) in statistical physics, which can yield a set of self-consistent equations of the first and second moments of variables in statistical models when the models are of densely connected types. This approach has been applied to many different models in machine learning, which continuously yields evidences of its effectiveness (Opper and Winther, 1996, 1997, 2000a,b). When applied to densely connected models, certain correlations between variables have to be neglected to make the computation tractable; for that reason this approach, or the associated algorithm derived from it, is recently called approximate message passing (AMP) (Kabashima, 2003; Donoho et al., 2009). Basically, the AMP assumes that "interactions" between the variables are weak: in the present problem this implies $(1/M)\sum_{\mu=1}^M x_{\mu_i} x_{\mu_j} - \left((1/M)\sum_{\mu=1}^M x_{\mu_i}\right)\left((1/M)\sum_{\mu=1}^M x_{\mu_j}\right) \approx 0$ $(i \neq j)$. This treatment can be justified if each feature vector $\boldsymbol{x}_\mu$ is i.i.d.. Rigorous proofs of this fact are available for linear models and their some variants (Bayati and Montanari, 2011; Barbier et al., 2017). We implicitly assume this in the following derivation.

In this appendix, we introduce a new vector representation summarizing class variables: $\boldsymbol{w}_i = (w_{ai})_a$. Note that this is different from the notation used in the main body of this paper, $\boldsymbol{w}_a = (w_{ai})_i$ in which the feature components are summarized.

By regarding $\boldsymbol{w}_i$ as a single variable node, the BP decomposes eq. (51) into two types of messages as follows:

$$\tilde{M}_{\mu\to i}(\boldsymbol{w}_i) = \int \prod_{j(\neq i)} d\boldsymbol{w}_j \ \phi^\beta(\boldsymbol{u}_\mu) \prod_{j(\neq i)} M_{j\to\mu}(\boldsymbol{w}_j), \tag{52}$$

$$M_{i\to\mu}(\boldsymbol{w}_i) = e^{-\beta\left(\lambda_1 ||\boldsymbol{w}_i||_1 + \frac{\lambda_2}{2}||\boldsymbol{w}_i||_2^2\right)} \prod_{\nu(\neq\mu)} \tilde{M}_{\nu\to i}(\boldsymbol{w}_i), \tag{53}$$

where $\boldsymbol{u}_\mu = (u_{\mu a})_a$. A crucial observation to assess eqs. (52,53) is that the argument of the potential function $\phi(\boldsymbol{u}_\mu)$ has a sum of an extensive number of random variables; the central limit theorem thus justifies treating it as a Gaussian variable with the appropriate mean and variance. Hence, according to eq. (52) where $\boldsymbol{w}_i$ is special, we can divide the extensive sum as follows:

$$u_{\mu a} = \sum_j x_{\mu j} w_{aj} = x_{\mu i} w_{ai} + \sum_{j(\neq i)} x_{\mu j} w_{aj} \approx x_{\mu i} w_{ai} + \sum_{j(\neq i)} x_{\mu j} \langle w_{aj} \rangle^{\setminus \mu} + t_a, \tag{54}$$

where the second term on the right-hand side represents the mean of $\sum_{j(\neq i)} x_{\mu j} w_{aj}$, the symbol $\langle\cdot\rangle^{\setminus\mu}$ denotes the average over the Boltzmann distribution without the μth potential function, and $\boldsymbol{t}^\mu = (t_a^\mu)_a$ denotes the zero-mean Gaussian variables whose covariance is set to be that of $\left(\sum_{j(\neq i)} x_{\mu j} w_{aj}\right)_a$. This expression allows us to replace the integration $\int \prod_{j(\neq i)} d\boldsymbol{w}_j$ by that over $\boldsymbol{t}^\mu$ in eq. (52). This significantly simplifies the computation and yields:

$$\tilde{M}_{\mu\to i}(\boldsymbol{w}_i) \approx \int d\boldsymbol{t} \ e^{\beta\left(-\frac{1}{2}\boldsymbol{t}^\top (C_\mu^{\setminus\mu})^{-1}\boldsymbol{t} - q_\mu(\boldsymbol{w}_i, \boldsymbol{t})\right)} \equiv \int d\boldsymbol{t} \ e^{\beta f^\mu(\boldsymbol{w}_i, \boldsymbol{t})} \tag{55}$$

where $q_\mu(\boldsymbol{w}_i, \boldsymbol{t})$ is the negative log-likelihood whose argument $u_{\mu a}$ is approximated by eq. (54) and $C_\mu^{\setminus\mu}$ is the rescaled covariance of $\sum_{j(\neq i)} x_{\mu j} w_{aj}$ defined as

$$\chi_{(ai)(bj)}^{\setminus\mu} \equiv \beta\left(\langle w_{ai} w_{bj}\rangle^{\setminus\mu} - \langle w_{ai}\rangle^{\setminus\mu}\langle w_{bj}\rangle^{\setminus\mu}\right),$$
$$\left(C_\mu^{\setminus\mu}\right)_{ab} \equiv \sum_{i,j} x_{\mu i} x_{\mu j} \chi_{(ai)(bj)}^{\setminus\mu}. \tag{56}$$

In the second equation we added the contribution from i for simplicity. It does not affect the following result because the ith term contribution is small enough. Let us focus on the limit $\beta \to \infty$. This limit allows us to use the saddle-point method, or Laplace's method, with respect to $\boldsymbol{t}^\mu$. The associated saddle-point equation is:

$$\hat{\boldsymbol{t}}^\mu = -C_\mu^{\setminus\mu} \boldsymbol{b}^\mu(\boldsymbol{w}_i, \hat{\boldsymbol{t}}^\mu), \tag{57}$$

where $\boldsymbol{b}^\mu(\boldsymbol{w}_i, \hat{\boldsymbol{t}}^\mu)$ is the gradient of q_μ defined at eq. (14) but the argument $u_{\mu a}$ is approximated by eq. (54). Now, let us expand the exponent $f^\mu(\boldsymbol{w}_i, \boldsymbol{t})$ in eq. (55) with respect to the dynamical variables $\boldsymbol{w}_i$ up to the second order. Putting $z_a = \sum_i x_{\mu i} w_{ai}$, we can define the derivatives as:

$$\frac{\partial \hat{\boldsymbol{t}}^\mu}{\partial z_a} = -(I_L + C_\mu^{\setminus\mu} F^\mu)^{-1} C_\mu^{\setminus\mu} F_{*a}^\mu, \tag{58}$$

$$\frac{\partial f^\mu(\boldsymbol{w}_i, \hat{\boldsymbol{t}}^\mu)}{\partial z_a} = -b_a^\mu(\boldsymbol{w}_i, \hat{\boldsymbol{t}}^\mu), \tag{59}$$

$$\frac{\partial^2 f^\mu(\boldsymbol{w}_i, \hat{\boldsymbol{t}}^\mu)}{\partial z_a \partial z_b} = -F_{ab}^\mu - \left(\frac{\partial \hat{\boldsymbol{t}}^\mu}{\partial z_a}\right)^\top F_{*b}^\mu = -\left(\left(I_L + F^\mu C_\mu^{\setminus\mu}\right)^{-1} F^\mu\right)_{ab}. \tag{60}$$

Hence,

$$\tilde{M}_{\mu\to i}(\boldsymbol{w}_i) \propto e^{\beta\left((\boldsymbol{h}_i^\mu)^\top \boldsymbol{w}_i - \frac{1}{2}\boldsymbol{w}_i^\top \Gamma_i^\mu \boldsymbol{w}_i\right)} \tag{61}$$

where

$$\boldsymbol{h}_i^\mu = -x_{\mu i}\boldsymbol{b}^\mu,$$
$$\Gamma_i^\mu = x_{\mu i}^2 (I_L + F^\mu C_\mu^{\setminus\mu})^{-1} F^\mu. \tag{62}$$

Note that this second order expansion is justified in the limit $\beta \to \infty$.

Collecting all the messages except for μ, we can construct the LOO marginal distribution of $\boldsymbol{w}_i$ as:

$$P^{\backslash\mu}(\boldsymbol{w}_i) \propto e^{-\beta\left(\lambda_1||\boldsymbol{w}_i||_1+\frac{\lambda_2}{2}||\boldsymbol{w}_i||_2^2\right)} \prod_{\nu(\neq\mu)} \tilde{M}_{\nu\to i}(\boldsymbol{w}_i)$$
$$\propto e^{\beta\left((\sum_{\nu(\neq\mu)} \boldsymbol{h}_i^\mu)^\top \boldsymbol{w}_i - \frac{1}{2}\boldsymbol{w}_i^\top \left(\lambda_2 I_L + \sum_{\nu(\neq\mu)} \Gamma_i^\mu\right)\boldsymbol{w}_i - \lambda_1||\boldsymbol{w}_i||_1\right)}. \tag{63}$$

Now, we can close the equation for the rescaled variance $\left(\chi_i^{\backslash\mu}\right)_{ab} \equiv \chi^{\backslash\mu}_{(ai),(bi)}$, because we can compute the variance of $\boldsymbol{w}_i$ from eq. (63). By considering the scaling, we can recognize that the variances vanish in the speed of $O(\beta^{-2})$ if one of the two components or both are inactive. The active-active components of the variance are scaled by $O(\beta^{-1})$ and remain in the rescaled variance. Focusing on the limit $\beta \to \infty$, we thus obtain:

$$\left(\chi_i^{\backslash\mu}\right)_{\hat{A}_i\hat{A}_i} = \left(\lambda_2 I_{|\hat{A}_i|} + \left(\sum_{\nu(\neq\mu)} \Gamma_i^\nu\right)_{\hat{A}_i\hat{A}_i}\right)^{-1} \approx \left(\lambda_2 I_{|\hat{A}_i|} + \left(\sum_{\nu} \Gamma_i^\nu\right)_{\hat{A}_i\hat{A}_i}\right)^{-1}. \tag{64}$$

At the last step, the μth term is added since its contribution is expected to be small enough in the summation. This manifests that the μ-dependence of $\chi^{\backslash\mu}$ can be neglected and we rewrite it as $\chi^{\backslash\mu} = \chi$ hereafter. By considering the meaning of the Hessian, it is easy to understand that $G^{\backslash\mu}$ is identified with $\left(\lambda_2 I_L + \sum_{\nu(\neq\mu)} \Gamma_i^\nu\right)$. This yields eq. (40).

By assuming the vanishing correlation between $\boldsymbol{w}_i$ and $\boldsymbol{w}_j$ for $i \neq j$, we can write

$$\chi_{(ai)(bj)} \approx \delta_{ij} \begin{cases} (\chi_i)_{ab} & (a, b \in \hat{A}_i) \\ 0 & (\text{otherwise}) \end{cases}. \tag{65}$$

These leads to:

$$\left(C_\mu^{\backslash\mu}\right)_{ab} = \sum_{ij} x_{\mu i} x_{\mu j} \chi^{\backslash\mu}_{(ai)(bj)} \approx \sum_i x_{\mu i}^2 (\chi_i)_{ab} \approx \sigma_x^2 \sum_i (\chi_i)_{ab} \equiv (C_{\rm SA})_{ab} \tag{66}$$

The μ-dependence through $x_{\mu i}^2$ is neglected at the last step, because the sum $\sum_i$ would mask such a weak μ-dependence as long as strong heterogeneity in $\{x_{\mu i}\}_\mu$ is absent. Similarly, we may write the sum inside the parentheses of the righthand side of eq. (64) as:

$$\sum_\nu \Gamma_i^\nu \approx \sigma_x^2 \sum_\nu (I_L + F^\nu C_{\rm SA})^{-1} F^\nu. \tag{67}$$

Inserting eqs. (65-67) into eq. (64), we obtain eq. (41).

Careful readers may be concerned about the neglected μ-dependence of $\chi^{\backslash\mu}$, as well as that of $G^{\backslash\mu}$. If this can be neglected, may we replace $G^{\backslash\mu}$ with G from the beginning at eq. (21)? The answer is of course no. The reason is that the difference between $G^{\backslash\mu}$ and G is not negligible if they are "projected" onto X^μ as in eq. (21). If they are projected onto other directions perpendicular to X^μ, the difference is actually tiny and can be neglected, but for computing the factor $C_\mu^{\backslash\mu}$ we need to take into account this difference appropriately. This results in the additional factor $(I - F_\mu C_\mu)^{-1}$ in eq. (24). In the SA approximation, the

factor C is computed based on neglecting the difference between G and $G^{\backslash\mu}$. As a result we cannot discriminate the two factors C_μ and $C_\mu^{\backslash\mu}$. This consideration implies that our SA estimation of C, $C_{\rm SA}$, should be applied to $C_\mu^{\backslash\mu}$ in eq. (21) and should NOT be applied to C_μ in eq. (24), because the latter formula formally takes into account the difference in advance.

Abstract

Stochastic bandits have been widely studied since decades. A very large panel of settings have been introduced, some of them for the inclusion of some structure between actions. If actions are associated with feature vectors that underlie their usefulness, the discovery of a mapping parameter between such profiles and rewards can help the exploration process of the bandit strategies. This is the setting studied in this paper, but in our case the action profiles (constant feature vectors) are unknown beforehand. Instead, the agent is only given sample vectors, with mean centered on the true profiles, for a subset of actions at each step of the process. In this new bandit instance, policies have thus to deal with a doubled uncertainty, both on the profile estimators and the reward mapping parameters learned so far. We propose a new algorithm, called *SampLinUCB*, specifically designed for this case. Theoretical convergence guarantees are given for this strategy, according to various profile samples delivery scenarios. Finally, experiments are conducted on both artificial data and a task of focused data capture from online social networks. Obtained results demonstrate the relevance of the approach in various settings.

Keywords: Stochastic Linear Bandits, Profile-based Exploration, Upper Confidence Bounds

1. Introduction

Multi-armed bandits (MAB) correspond to online decision problems where, at each step of a sequential process, an agent has to choose an action - or arm - among a set of K actions, with the aim to maximize some cumulative reward function. In the so-called stochastic MAB setting, rewards collected for a given arm through time are assumed to be independently and identically distributed, following some hidden stationary distribution on every individual arm. The problem is therefore to deal with a tradeoff between exploitation - selecting actions according to some estimations about their usefulness - and exploration - selecting actions in order to increase the knowledge of their reward distribution. However, with classical stochastic bandit policies, the convergence towards the optimal arms can be slow when the number of actions becomes large.

On another hand, contextual bandits correspond to MAB settings where some side information can be leveraged to improve estimations of reward distributions. In these settings, a decision context is observed before selecting actions. This context can either correspond to a global decision feature vector or to specific feature vectors observed for each single action. Depending on the setting, these features can vary over time, which can help to predict reward fluctuations, or they can correspond to constant features on actions - that we call action profiles in the following - whose structure can be used to improve exploration policies over non-contextual approaches. In this paper we address the latter case, where we assume stationary distributions of rewards, but where distributions depend on constant profiles associated each arm. Reward distributions from the different arms are connected by a common unknown parameter to be learned (Filippi et al., 2010).

However, we introduce a new scenario where, for various possible reasons (technical, political, etc...), profile vectors are not available a priori. Instead, the agent gets sample vectors, centered on the true profiles, for a subset of actions at each decision step. This can happen in various situations where some restrictions limit our knowledge of the whole decision environment. For example in a focused data capture or technology intelligence scenario on social media, where an agent is asked to collect relevant information w.r.t. to a given need. Because of the extremely large number of accounts on media such as Twitter, the agent needs to focus on a subset of relevant users to follow at each time step (Gisselbrecht et al., 2015). However, given the strict restrictions set by the media, no knowledge about users is available beforehand. Profiles have therefore to be constructed from users activities, which are only observed for a small fraction of users at each step. As we will see later, the process which delivers profile samples can either be independent - e.g., an external process delivers activity samples for randomly chosen users at each step in the case of data capture from Twitter - or be included in the decision process - e.g., activity samples are only collected for followed users at the current time step.

To the best of our knowledge, this instance of contextual bandit has not been studied in the literature. Existing bandit approaches do not fit with this new setting. First, even if traditional algorithms such as `UCB` (Auer et al., 2002) could be applied, the information provided by the sample profile vectors would be entirely ignored. Our claim is that important benefits can arise from taking this available side-information into account. On the other hand, existing contextual bandit policies do not take into account uncertainty on context vectors, while we face here a bandit problem where uncertainty not only arises from regression parameters, as classically considered by contextual approaches, but also from the estimated profiles which serve as inputs for reward predictions at each step. The aim is to propose an approach able to leverage structural distributions of arms, based on noisy observations of their profiles, to improve over existing exploitation/exploration policies in bandit settings with partial side-information.

The contribution of this paper is threefold:

- We propose a new instance of the contextual bandit problem, based on constant contexts for each action, where action profiles are not known beforehand, but built from samples obtained at each iteration (3 cases are investigated regarding the sampling process);
- We design the *SampLinUCB* algorithm to solve this problem, for which we demonstrate some theoretical convergence guarantees;
- We experiment our proposal for both an artificial setting and a real-world task of focused data capture from Twitter, to empirically demonstrate the benefits of such a

profile-based approach with ony partial knowledge for exploitation/exploration problems.

The paper is organized as follows. In section 2, we present some background and related works. In section 3, we formalize the problem, propose our algorithm and derive the regret bound. Finally, section 4 reports our experiments.

2. Background: the Linear Stochastic Bandit

The multi-armed bandit problem, originally introduced in (Lai and Robbins, 1985) in its stationary form, has been widely studied in the literature. This learning problem aims at tackling the trade off between exploration and exploitation in decision processes where, at each step, an agent must choose an action - or arm - among a finite set of size K. After each decision, it receives a reward which quantifies the quality of the chosen action. The aim for the agent is to maximize the cumulative reward trough time, or equivalently to minimize the cumulative regret R_T at step T defined as:

$$R_T = \max_{i\in\{1,2,...,K\}} \sum_{t=1}^{T} r_{i,t} - \sum_{t=1}^{T} r_{i_t,t} \tag{1}$$

where i_t stands for the action selected at step t and $r_{i,t}$ the reward obtained by playing the action i at step t. This represents the amount of rewards that has been lost by selecting i_t at each step t, compared to what could be obtained by playing the optimal arm from the beginning to the end of the process. Note that, at each step t, only the reward for the chosen action $r_{i_t,t}$ is observed in practice, other ones remain unknown.

In the so-called stochastic case, one assume that rewards of an arm i are identically and independently sampled from a distribution with mean ν_i. Therefore, one usually rather consider the pseudo-regret of a policy, which introduces expectations of regret in the previous definition:

$$\hat{R}_T = T\nu_{i^*} - \sum_{t=1}^{T} \nu_{i_t} \tag{2}$$

where $i^\star$ stands as the arm with the best reward expectation.

One of the simplest and most straightforward algorithms to deal with the stochastic bandit problem is the well-known ϵ-greedy algorithm (Auer et al., 2002). This algorithm selects the arm with the best reward mean empirical estimation with probability $1-\epsilon$ and uniformly selects an arm among the whole set regardless their current estimations with probability ϵ. This guarantees to regularly reconsider estimations of all arms and therefore prevents from getting stuck on sub-optimal arms. However, the reward loss resulting from these blind selections prevents from ensuring a sub-linear upper bound of the pseudo-regret, unless setting an appropriate decay on ϵ. But this requires to know a lower bound on the difference of reward expectations between the best and the second best action (Auer et al., 2002).

Upper Confidence Bound algorithms (UCB) is another family of bandit approaches which define confident intervals for the reward expectations of each arm. Based on some concentration inequalities (Hoeffding, Bernstein, etc.), they propose optimistic policies which

consider possible deviations of the estimated mean of each arm. By using upper bounds of confidence intervals as selection scores, they ensure a cleaver balance between exploitation and exploration. Many extensions of the famous `UCB` algorithm proposed in (Auer et al., 2002) are known to guarantee a sub-linear bound of the pseudo-regret (see `UCBV` in (Audibert et al., 2009), `MOSS` in (Audibert and Bubeck, 2009) or `KL-UCB` in (Garivier, 2011)).

At last, Thompson sampling algorithms, originally proposed in (Thompson, 1933), develop a Bayesian approach to deal with uncertainty. By sampling from posterior distributions for the reward parameters, their exploration/exploitation mechanism is also proved to ensure a sub-linear regret (see (Kaufmann et al., 2012b) and (Agrawal and Goyal, 2012)).

The contextual bandit setting is an instance of the bandit problem where context vectors are observed before each decision step. Typically, contextual bandits assume a linear relation between context features and reward expectations. Formally, if we observe a context vector $x_{i,t} \in \mathbb{R}^d$ for each action $i \in \mathcal{K}$ at each time-step t, we consider the following assumption:

$$\exists \beta \in \mathbb{R}^d \text{ such that } r_{i,t} = x_{i,t}^\top \beta + \eta_{i,t} \tag{3}$$

where β is a mapping parameter between contexts and rewards, $\eta_{i,t}$ is a zero-mean conditionally R sub-Gaussian random noise, with constant $R > 0$ i.e: $\forall \lambda \in \mathbb{R} : \mathbb{E}[e^{\lambda \eta_{i,t}} | \mathcal{H}_{t-1}] \leq e^{\lambda^2 R^2/2}$, with $\mathcal{H}_{t-1} = \{(i_s, x_{i_s,s}, r_{i_s,s})\}_{s=1..t-1}$.

In this context, given a set $\mathcal{K}$ of K actions, any contextual bandit algorithm proceeds at each step $t \in \{1, 2, 3, \ldots, T\}$ as follows:

1. Observation of the context vector $x_{i,t} \in \mathbb{R}^d$ for each $i \in \{1, ..., K\}$;
2. According to the current estimate of β, selection of an action i_t and reception of the associated reward $r_{i_t,t}$;
3. Improvement of the selection policy by considering the new input $(i_t, x_{i_t,t}, r_{i_t,t})$ for the estimation of β.

Various contextual algorithms have been proposed in the literature. The first contextual bandit algorithm was introduced in (Auer, 2003). More recently the well-known `LinUCB` algorithm has been proposed for a task of personalized recommendation in (Li et al., 2010) and analyzed in (Chu et al., 2011). Both of these algorithms are UCB-like policies, each of them selecting the action whose upper bound of its reward confidence bound is the highest. Many other UCB approaches have been developed since then. In particular, algorithms such as `OFUL` or `ConfidenceBall` proposed in (Abbasi-Yadkori et al., 2011) and (Dani et al., 2008) have the advantage to enjoy a tighter regret upper bound (see also (Kaufmann et al., 2012a) and (Rusmevichientong and Tsitsiklis, 2010)). As in the stochastic bandit setting, Thompson sampling algorithms have also been designed for the contextual case, which also proved to be powerful, first empirically in (Chapelle and Li, 2011) and then theoretically in (Agrawal and Goyal, 2013) and (May et al., 2012).

In this paper, we consider a variant of the contextual bandit problem where contexts of actions are constant, which we call action profiles in the following. Hence, in our setting we assume that each action $i \in \mathcal{K}$ is associated with a profile vector $\mu_i \in \mathbb{R}^d$. The linear assumption of equation 3 becomes:

$$\exists \beta \in \mathbb{R}^d \textit{ such that } r_{i,t} = \mu_i^\top \beta + \eta_{i,t} \tag{4}$$

Thus, in this setting contexts cannot be used to anticipate some variations in the rewards expectations as it is traditionally the case in the literature about contextual bandit, but they can be leveraged to improve the exploration process, the use of a shared mapping parameter β allowing one to define areas of interest in the representation space of the actions. To illustrate this, the figure 1 represents the selection scores of a contextual algorithm (such as *OFUL* that we rely on in the following) at a given step for a simple case where $K = 4$ and $d = 2$. In this figure, green areas correspond to high scores, whereas red ones correspond to low scores areas. Color variations render the latent structure inferred by the model. In this setting, the algorithm would select the action 1, since its profile is located in the most promising area of the space. On the other hand, the action 3 is located in an area that is greatly less promising. The fact of using a common mapping parameter β allows one to perform a mutual learning, where observations on some actions inform on the usefulness of similar ones. This allows one to improve the exploration process by focusing more quickly on the useful areas: Imagine that a great number of actions are located in the red area of the figure. In that case, a classical bandit algorithm such as *UCB* would need to consider each of these actions several times to reveal their low reward expectation. On the other hand, a contextual bandit algorithm such as *OFUL* is able to avoid these actions really more quickly because of the proximity with other bad actions.

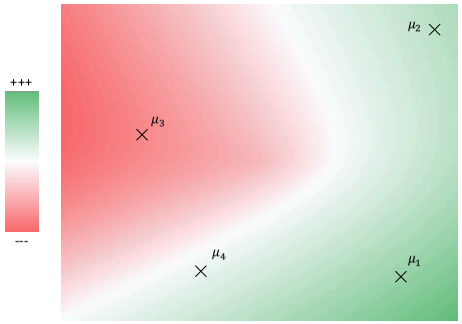

Figure 1: Illustration of `OFUL` scores for a profiles representation space.

This structured bandit setting has already been investigated in (Filippi et al., 2010). This work showed that great improvements could indeed be obtained by exploiting the structure of actions, since observations on some actions inform on the usefulness of similar ones. This comes down to a classical stochastic bandit where the pseudo-regret can be defined as follows:

$$\hat{R}_T = \sum_{t=1}^{\top} \mu_{i^\star}^\top \beta - \mu_{i_t}^\top \beta \tag{5}$$

where $\mu_i \in \mathbb{R}^d$ stands for the profile of the action $i \in \mathcal{K}$ and $\mu_{i^\star} = \underset{\mu_i, i=1..K}{\arg\max}\, \mu_i^\top \beta$ corresponds to the profile of the optimal action $i^\star$.

This is the setting which is studied in this paper. However, in our case the profile vectors are **unknown** to the agent beforehand, they have to be discovered iteratively during the process. Our problem differs from existing instances by the following two main aspects:

1. Action profiles are not directly available, one only get samples centered on them during the process;
2. At each step, one only get samples for a subset of actions.

In the following, we derive an UCB-based policy for this new setting.

3. Profile-Based Bandit with Unknown Profiles

In this section, we explore our new setting in which the set of profiles $\{\mu_1, .., \mu_K\}$ is not directly observed. Instead, at each iteration t, the agent is given a subset of actions $\mathcal{O}_t$ such that for every $i \in \mathcal{O}_t$, a sample $x_{i,t}$ of a random variable centered on μ_i is revealed. By assuming the same linear hypothesis as described in the previous section (formula 4), the relation of rewards with profiles can be re-written as follows for any time t, in order to introduce profile samples:

$$\begin{aligned} \forall s \leq t : r_{i,s} &= \mu_i^\top \beta + \eta_{i,s} \\ &= \hat{x}_{i,t}^\top \beta + (\mu_i - \hat{x}_{i,t})^\top \beta + \eta_{i,s} \\ &= \hat{x}_{i,t}^\top \beta + \epsilon_{i,t}^\top \beta + \eta_{i,s} \end{aligned} \tag{6}$$

where $\epsilon_{i,t} = \mu_i - \hat{x}_{i,t}$, $\hat{x}_{i,t} = \dfrac{1}{n_{i,t}} \sum\limits_{s \in T_{i,t}^{obs}} x_{i,s}$, with $T_{i,t}^{obs} = \{s \leq t, i \in \mathcal{O}_s\}$ and $n_{i,t} = |T_{i,t}^{obs}|$. In words, $n_{i,t}$ corresponds to the number of times a sample has been obtained for the action i until step t and $\hat{x}_{i,t}$ corresponds to the empirical mean of observed samples for i at time t. $\epsilon_{i,t}$ corresponds to the deviation of the estimator $\hat{x}_{i,t}$ from the true profile μ_i.

Compared to traditional contextual bandits, the uncertainty is double : as classically it arises from the β parameter estimator, but also from the profile estimators, since the algorithm must both estimate β and the profile vectors $\{\mu_1, .., \mu_K\}$ from observations. Figure 2[1] illustrates this new setting. Contrary to figure 1 where profiles are known, here we only get confidence areas for them, represented by circles centered on their corresponding empirical mean (represented by a blue cross). From the law of large numbers, the more observations for a given action we get, the lower the deviation between its true profile and its empirical estimator is. Therefore, the more knowledge we get about a given action, the smaller its confidence circle is. The best action is still the action 1, whose true profile (represented by a black cross) is in the greenest area. However, this information is unknown from the agent. A naive solution would be to directly use the empirical mean for each action in order to determine the selection scores. From the figure, this would lead to select the sub-optimal

1. Note that this is only an illustration of the general principle, in practice the surface of selection scores should also differ from figure 1, since β is estimated from biased inputs.

action 2, whose empirical mean is located in a greener area than the one of other actions. We propose to include the additional uncertainty in the selection scores by using the best location inside the confidence ellipsoid it is possible to reach for each action. This allows one to define an optimistic policy which would select the optimal action 1 in the example figure, whose confidence area contains the most promising profiles (i.e., includes the most green locations in the figure).

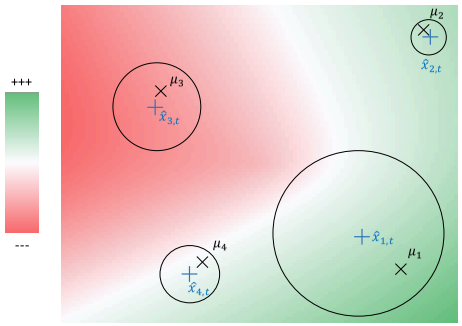

Figure 2: Illustration of the additional uncertainty arising from profile estimators.

In the following we propose to define an algorithm fitted for this setting. After deriving the algorithm in a generic context of samples delivery, we consider three different cases:

- **Case 1**: Every action delivers a profile sample at each step t (i.e., $\forall t$, $\mathcal{O}_t = \{1, ..., K\}$);
- **Case 2**: Each action i owns a probability p_i of sample delivery: at each step t, an action is included in $\mathcal{O}_t$ with probability p_i;
- **Case 3**: At each step t, only the action selected at the previous step delivers a sample (i.e., $\forall t$, $\mathcal{O}_t = i_{t-1}$).

The first case corresponds to the simplest case, where $\mathcal{O}_t$ is constant over time. The second case includes an additional difficulty since before any step, every action has not been observed the same number of times, which leads to different levels of uncertainty. The last case, probably the most interesting one for real-world applications, is the most difficult since decisions at each step not only affect knowledge about reward distributions but also profile estimations. For that case, it appears mandatory to take the uncertainty about profiles into account in the selection policy to guarantee the process to converge towards optimal actions.

After deriving confidence intervals for this new bandit instance, this section describes the proposed algorithm and analyzes its regret for the three settings listed above. Then, we consider the case where multiple actions can be performed at each step.

3.1. Confidence Intervals

In the following, we derive a series of propositions which will allow us to define a selection policy for our setting of profile-based bandit with unknown profiles. First, it is needed to define an estimator for the mapping parameter β, and the associated confidence ellipsoid. For that purpose, we rely on results from the theory of the self-normalized process (de la Peña et al., 2009). The next step is to define a way to mix it with the uncertainty on profiles to define an optimistic policy.

Proposition 1 *Let us consider that for any action i, all profile samples $x_{i,t} \in \mathbb{R}^d$ are iid from a distribution with mean $\mu_i \in \mathbb{R}^d$. Let us also assume that there exists a real number $L > 0$ such that $||x_{i,t}|| \leq L$ and a real number $S > 0$ such that $||\beta|| \leq S$. Then, for any $i \in \mathcal{K}$ and any step $s \leq t$, the random variable $\eta_{i,t,s} = \epsilon_{i,t}^\top \beta + \eta_{i,s}$ is conditionally sub-Gaussian with constant $R_{i,t} = \sqrt{R^2 + \frac{L^2 S^2}{n_{i,t}}}$.*

Proof Available in appendix A.1. ■

In this proposition, R is the constant of the sub-Gaussian random noise of the rewards (η_s from equation 6) and the notation $||x||$ stands as the norm of a vector x (i.e., $||x|| = \sqrt{x^T x}$). Since the noise $\eta_{i,t,s}$ is sub-Gaussian, it will be possible to apply the theory of self-normalized process for defining a confidence ellipsoid for β.

At step t, we can use the following set of observations to find an estimator for β: $\{(\hat{x}_{i_s,t}, r_{i_s,s})\}_{s=1..t-1}$ (i.e., at any decision step t, the reward $r_{i_s,s}$ observed at any previous step $s < t$ is associated with the profile of the selected action at step s, estimated knowing samples observed from step 1 to step t). The following notations are used in the remaining of the paper:

- $\eta'_{t-1} = (\eta_{i_s,s} + \epsilon_{i_s,t}^\top \beta)_{s=1..t-1}^\top$ the vector of noises of size $t-1$.
- $X_{t-1} = (\hat{x}_{i_s,t}^\top)_{s=1..t-1}$ the $(t-1) \times d$ matrix containing the empirical means of the selected actions, where the s-th row corresponds to the estimator at step t of the action selected at step s.
- $Y_{t-1} = (r_{i_s,s})_{s=1..t-1}^\top$ the rewards vector of size $t-1$.
- $A_{t-1} = diag(1/R_{i_s,t})_{s=1..t-1}$ the diagonal $(t-1) \times (t-1)$ matrix, where the s-th diagonal element equals $1/R_{i_s,t}$. Note that, for a specific action, the value of its corresponding coefficient increases with the number of observed samples for this action.

With these notations, the linear application from profiles to rewards can be written as:

$$Y_{t-1} = X_{t-1}\beta + \eta'_{t-1} \tag{7}$$

Proposition 2 *We note $\hat{\beta}_{t-1}$ the least square estimator of the parameter β at step t, according to the following l^2-regularized regression problem, where each element is weighted*

by the corresponding coefficient $1/R_{i_s,t}$*:*

$$\hat{\beta}_{t-1} = \arg\min_{\beta} \sum_{s=1}^{t-1} \frac{1}{R_{i_s,t}} (\beta^\top \hat{x}_{i_s,t} - r_{i_s,s})^2 + \lambda ||\beta||^2 \tag{8}$$

where $\lambda > 0$ *is the l2-regularization constant.*

We have:

$$\hat{\beta}_{t-1} = (X_{t-1}^\top A_{t-1} X_{t-1} + \lambda I)^{-1} X_{t-1}^\top A_{t-1} Y_{t-1} \tag{9}$$

Proof Let us rewrite the minimization problem such as:
$\hat{\beta}_{t-1} = \arg\min_{\beta} L$ with $L = (Y_{t-1} - X_{t-1}\beta)^\top A_{t-1}(Y_{t-1} - X_{t-1}\beta) + \lambda \beta^\top \beta$.
The gradient is given by:
$\nabla_\beta L = -2X_{t-1}^\top A_{t-1}(Y_{t-1} - X_{t-1}\beta) + 2\lambda\beta = 2(X_{t-1}^\top A_{t-1} X_{t-1} + \lambda I)\beta - 2X_{t-1}^\top A_{t-1} Y_{t-1}$
By canceling this gradient, we get the announced result. ■

This estimator of β uses empirical means of observed samples as inputs. Weighting each element according to the corresponding value $R_{i_s,t}$ allows one to consider the uncertainty associated with this approximation. It renders the confidence we have in the weighted input. Note that this coefficient tends towards a constant when the number of observed samples increases for the corresponding action. It allows one, according to the following proposition, to define a confidence ellipsoid for the estimator of β.

Proposition 3 *Let us define* $V_{t-1} = \lambda I + X_{t-1}^\top A_{t-1} X_{t-1} = \lambda I + \sum_{s=1}^{t-1} \frac{\hat{x}_{i_s,t} \hat{x}_{i_s,t}^\top}{R_{i_s,t}}$*. With the same assumptions as in proposition 1, for any* $0 < \delta < 1$*, with a probability at least equal to* $1 - \delta$*, the estimator* $\hat{\beta}_{t-1}$ *verifies for all* $t \geq 0$*:*

$$||\hat{\beta}_{t-1} - \beta||_{V_{t-1}} \leq \sqrt{2 \log\left(\frac{det(V_{t-1})^{1/2} det(\lambda I)^{-1/2}}{\delta}\right)} + \sqrt{\lambda} S = \alpha_{t-1} \tag{10}$$

where $||x||_V = \sqrt{x^\top V x}$ *is the V-norm of the vector* x*.*

Proof Available in appendix A.2. ■

This bound is very similar to the one defined in the `OFUL` algorithm (Abbasi-Yadkori et al., 2011) to build its confidence ellipsoid. However, a notable difference lies in the definition of the matrix V_t, in which weights in A_t are applied to cope with confidence differences between profile estimators. Without this weighting, no confidence ellipsoid could be found for β since no common bound could be defined for the various noises η_s' (see the proof of proposition 3 in appendix).

The following proposition can easily be deduced from the previous one to bound the expectation of reward with known profiles.

Proposition 4 *For every* $i \in \mathcal{K}$*, with probability greater than* $1 - \delta$*, we have for all* $t \geq 0$*:*

$$\beta^\top \mu_i \leq \hat{\beta}_{t-1}^\top \mu_i + \alpha_{t-1} ||\mu_i||_{V_{t-1}^{-1}} \tag{11}$$

Proof Available in appendix A.3 ■

This upper-bound for the expected reward contains two distinct terms: while the former corresponds to a classical exploitation term which estimates the expected reward with the current parameters, the latter corresponds to an exploration term since it takes into account the uncertainty on the reward parameter. If profiles were known, this could directly be used as a selection score for an UCB-like policy. However, in our setting, profiles are unknown. We have to consider confidence ellipsoids for the profiles of actions too. The following proposition defines confidence bounds for the profile estimators.

Proposition 5 *For every* $i \in \mathcal{K}$ *and any* $t > 0$*, with probability greater than* $1 - \delta/t^2$*, we have:*

$$||\hat{x}_{i,t} - \mu_i|| \leq \min(L \sqrt{\frac{2d}{n_{i,t}} \log\left(\frac{2dt^2}{\delta}\right)}, 2L) = \rho_{i,t,\delta} \tag{12}$$

Proof This inequality comes from the application of the Hoeffding's inequality to each dimension separately. The min operator comes from the base hypothesis $||x_{i,t}|| \leq L$, which can be more restrictive than the Hoeffding assumption. The proof is available in appendix A.4. ■

Contrary to the bound of the deviation of the mapping parameter β which holds simultaneously for all steps of the process, the one for the profile estimators is only valid for each step separately. To obtain a bound holding for every step simultaneously, which is important for the regret analysis (see section 3.3), we use the uniform bound principle. For a given action i, we have: $\mathbb{P}(\forall t, ||\hat{x}_{i,t} - \mu_i|| \leq \rho_{i,t,\delta}) = 1 - \mathbb{P}(\exists t, ||\hat{x}_{i,t} - \mu_i|| \geq \rho_{i,t,\delta}) \geq 1 - \sum_t \mathbb{P}(||\hat{x}_{i,t} - \mu_i|| \geq \rho_{i,t,\delta}) \geq 1 - \sum_t \delta/t^2$. This justifies the introduction of the t^2 term in the bound, which allows one to define a uniform probability over all steps since we have thereby: $\mathbb{P}(\forall t, ||\hat{x}_{i,t} - \mu_i|| \leq \rho_{i,t,\delta}) \geq 1 - \delta - \sum_{t=2}^{\infty} \delta/t^2 = 1 - \delta - \delta(\pi^2/6 - 1) \geq 1 - 2\delta$.

Now that we have defined probabilistic deviation bounds for the different estimators, we can use them conjointly to define the confidence interval of the reward expectation for the setting of unknown profiles, and thus to upper bound the expected reward for each action i.

Proposition 6 *For every* $i \in \mathcal{K}$ *and any* $t > 0$*, with probability greater than* $1 - \delta/t^2 - \delta$*, we have:*

$$\beta^\top \mu_i \leq \hat{\beta}_{t-1}^\top (\hat{x}_{i,t} + \overline{\epsilon}_{i,t}) + \alpha_{t-1} ||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} \tag{13}$$

with: $\overline{\epsilon}_{i,t} = \frac{\rho_{i,t,\delta} \hat{\beta}_{t-1}}{||\hat{\beta}_{t-1}||}$ $\tilde{\epsilon}_{i,t} = \frac{\rho_{i,t,\delta} \hat{x}_{i,t}}{\sqrt{\lambda} ||\hat{x}_{i,t}||_{V_{t-1}^{-1}}}$

Proof The proof is available in appendix A.5. ■

Compared to the bound given in proposition 4, we find the same two terms of exploitation and exploration. However in this case, profile vectors that are unknown are replaced by the estimator plus an additional term: $\bar{\epsilon}_{i,t}$ in the former part and $\tilde{\epsilon}_{i,t}$ in the latter one. These terms aim at coping with profile uncertainty, considering confidence ellipsoids for these profiles as defined in proposition 5. $\bar{\epsilon}_{i,t}$ is collinear with $\hat{\beta}_{t-1}$. It is used to translate the estimator $\hat{x}_{i,t}$ so that $\beta^\top \mu_i$ is upper-bounded. $\tilde{\epsilon}_{i,t}$ is collinear with $\hat{x}_{i,t}$. It is used to translate the estimator $\hat{x}_{i,t}$ so that the V_{t-1}^{-1}-norm $||\mu_i||_{V_{t-1}^{-1}}$ is upper-bounded. This bound enables us to derive an optimistic policy in the next section.

3.2. SampLinUCB

In this section, we detail our policy for the setting of unknown profiles, called *SampLinUCB*, which is directly derived from the bound proposed in proposition 6. Its process is detailed in algorithm 1. In words, it proceeds as follows:

1. Initialization of the shared variables V and b used to estimate the mapping parameter β in lines 1 and 2. The $d \times d$ matrix V is initialized with an identity matrix times the regularization parameter λ (the greater λ is, the more the parameter β will be constrained to have components close to zero). The vector b is initialized as a null vector of size d.

2. Initialization of the individual variables n_i, $\hat{x}_i$, R_i, N_i and S_i for every action in $\mathcal{K}$ (lines 3 to 6). The two latter are additional scalar variables which enable efficient updates for the shared variables after context observations. N_i counts the number of times an action has been selected from the beginning, S_i sums the rewards collected by selecting i from the beginning.

3. At each iteration t, for each action $i \in \mathcal{O}_t$, observation of the sample $x_{i,t}$ (line 11) and update of individual variables n_i, $\hat{x}_i$ and R_i for action i (line 12) and shared parameters V and b according to these new individual values for i (line 10 and 13). Since shared parameters are simple sums of elements, they can be simply updated by first removing old values (line 10) and then adding the new ones when updated (line 13). This is efficiently done without requiring an important memory load thanks to scalar variables N_i and S_i.

4. Computation of the selection score $s_{i,t}$ (line 21) for each action i according to equation 14 detailed below, and selection of the action associated with the highest selection score (line 23) (except in the early stages $\leq K$ where all actions are selected in turn to initialize their counts in line 16).

5. Collection of the associated reward (line 25) and update of variables N_i, S_i, V and b according to this new outcome (lines 26 to 28).

Algorithm 1: `SampLinUCB`

1 $V = \lambda I_{d\times d}$ (Identity matrix of size d);
2 $b = 0_d$ (Null vector of size d);
3 **for** $i \in \mathcal{K}$ **do**
4 $N_i = 0$; $S_i = 0$;
5 $n_i = 0$; $\hat{x}_i = 0_d$; $R_i = +\infty$;
6 **end**
7 **for** $t = 1..T$ **do**
8 Reception of $\mathcal{O}_t$;
9 **for** $i \in \mathcal{O}_t$ **do**
10 $V = V - N_i \frac{\hat{x}_i \hat{x}_i^\top}{R_i}$; $b = b - S_i \frac{\hat{x}_i}{R_i}$;
11 Observation of $x_{i,t}$;
12 $n_i = n_i + 1$; $\hat{x}_i = \frac{(n_i - 1)\hat{x}_i + x_{i,t}}{n_i}$; $R_i = \sqrt{R^2 + \frac{L^2 S^2}{n_i}}$;
13 $V = V + N_i \frac{\hat{x}_i \hat{x}_i^\top}{R_i}$; $b = b + S_i \frac{\hat{x}_i}{R_i}$;
14 **end**
15 **if** $t \leq K$ **then**
16 Selection of $i_t = t$;
17 **end**
18 **else**
19 $\hat{\beta} = V^{-1} b$;
20 **for** $i \in \mathcal{K}$ **do**
21 Computation of $s_{i,t}$ according to formula 14 ;
22 **end**
23 Selection of $i_t = \arg\max_{i \in \mathcal{K}} \; s_{i,t}$;
24 **end**
25 Reception of $r_{i_t,t}$;
26 $N_{i_t} = N_{i_t} + 1$;
27 $S_{i_t} = S_{i_t} + r_{i_t,t}$;
28 $V = V + \frac{\hat{x}_{i_t} \hat{x}_{i_t}^\top}{R_{i_t}}$; $b = b + r_{i_t,t} \frac{\hat{x}_{i_t}}{R_{i_t}}$;
29 **end**

The selection score $s_{i,t}$ used in our policy for each action i at any step t is directly derived from proposition 6:

$$s_{i,t} = (\hat{x}_{i,t} + \bar{\epsilon}_{i,t})^\top \hat{\beta}_{t-1} + \alpha_{t-1} ||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} \tag{14}$$

For cases 2 and 3 of the profile delivery mechanism (see at the beginning of the section), there are actions i with $n_{i,t} = 0$ in the early steps of the process. No sample has ever been observed for these actions, which is problematic for the computation of $\rho_{i,t,\delta}$, and therefore

the computation of $\bar{\epsilon}_{i,t}$ and $\tilde{\epsilon}_{i,t}$. For the case 2, where we are not active on the process for observing contexts, this can be solved by simply ignoring actions until at least one sample of profile has been observed for them. For the case 3 however, samples are only obtained by selection. Thus, we need to force the observation of a sample for every action in the first steps. In that way, for actions with $n_{i,t} = 0$ at any step t, we arbitrarily set $s_{i,t} = +\infty$ in order to make the policy favor actions without any knowledge to initialize the process. Thus, in that case, algorithm 1 selects the K actions in turn in the K first steps of the process.

The selection score defined in formula 14 corresponds to the upper-bound of the expected reward for each action, as it is done in all UCB-based policies. Intuitively, it leads the algorithm to select actions whose profile estimator is either in an area with high potential, or is sufficiently uncertain to consider still likely that the action can be potentially useful. The goal is to quickly rule out bad actions, whose confidence ellipsoid does not include any potentially useful locations w.r.t. the current estimation of β. To better analyze the algorithm, we propose below a new formulation of the selection score.

Proposition 7 *The score $s_{i,t}$ from equation 14 can be re-written in the following way:*

$$s_{i,t} = \hat{x}_{i,t}^\top \hat{\beta}_{t-1} + \alpha_{t-1} ||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + \rho_{i,t,\delta} \left(||\hat{\beta}_{t-1}|| + \frac{\alpha_{t-1}}{\sqrt{\lambda}} \right) \tag{15}$$

Proof

$$\begin{aligned}
s_{i,t} &= (\hat{x}_{i,t} + \bar{\epsilon}_{i,t})^\top \hat{\beta}_{t-1} + \alpha_{t-1} ||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} \\
&= \hat{x}_{i,t}^\top \hat{\beta}_{t-1} + \frac{\rho_{i,t,\delta} \hat{\beta}_{t-1}^\top}{||\hat{\beta}_{t-1}||} \hat{\beta}_{t-1} + \alpha_{t-1} ||\hat{x}_{i,t} + \frac{\rho_{i,t,\delta} \hat{x}_{i,t}}{\sqrt{\lambda} ||\hat{x}_{i,t}||_{V_{t-1}^{-1}}}||_{V_{t-1}^{-1}} \\
&= \hat{x}_{i,t}^\top \hat{\beta}_{t-1} + \rho_{i,t,\delta} ||\hat{\beta}_{t-1}|| + \alpha_{t-1} \left(1 + \frac{\rho_{i,t,\delta}}{\sqrt{\lambda} ||\hat{x}_{i,t}||_{V_{t-1}^{-1}}} \right) ||\hat{x}_{i,t}||_{V_{t-1}^{-1}} \\
&= \hat{x}_{i,t}^\top \hat{\beta}_{t-1} + \alpha_{t-1} ||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + \rho_{i,t,\delta} \left(||\hat{\beta}_{t-1}|| + \frac{\alpha_{t-1}}{\sqrt{\lambda}} \right)
\end{aligned}$$

■

This new formulation of the selection score allows one to take a different look at the algorithm behavior. The first part of the score $\hat{x}_{i,t}^\top \hat{\beta}_{t-1} + \alpha_{t-1} ||\hat{x}_{i,t}||_{V_{t-1}^{-1}}$ is similar to a score that would use the classical `OFUL` algorithm (although with a different construction of V_t), with an exploitation term and a classical exploration term considering the uncertainty on the estimator of β. But it exhibits an additional part $\rho_{i,t,\delta} \left(||\hat{\beta}_{t-1}|| + \frac{\alpha_{t-1}}{\sqrt{\lambda}} \right)$ which is directly proportional to the coefficient $\rho_{i,t,\delta}$ and thus enables some exploration w.r.t. the uncertainty of the profile estimators. This highlights the premium granted to less observed actions. Note that for the case 1, this additional part is the same for every action. It therefore could be removed from the score since it does not permit to discriminate some action w.r.t any other one. However, this new exploration term is particularly useful for the

case 3, where observations of samples are directly connected to the selection policy, since it prevents from moving aside some optimal actions that have unluckily provided only not promising samples in the early steps.

To demonstrate that considering uncertainty on profiles is crucial in that case, let us consider a scenario where the optimal action $i^\star$ gets a null vector as the first profile sample. Then, in a setting where all profile samples are in $[0, L]^d$ and all rewards are in $[0, +\infty]$, it suffices that a sub-optimal action i gets a non-null vector as the first profile sample and a positive value as the first reward to lead to a linear regret from a given step. Indeed, since we only get samples with all components greater or equal than 0, i will never get a null vector as a profile estimator. On the other hand, while $i^\star$ is not selected, its profile estimator cannot change from the null vector. Thus, with a naive algorithm that would not include translations w.r.t. uncertainty of profiles, we would have $s_{i^\star,t} = \hat{x}_{i^\star,t}^\top \hat{\beta}_{t-1} + \alpha ||\hat{x}_{i^\star,t}||_{V_{t-1}^{-1}} = 0$ for all t until $i_t = i^\star$. Now, the least square estimator of β approximates observed reward values from estimated profiles. Since we have at least one non-null reward associated with a non-null profile estimator, β will always output a positive expected reward at least for one action. Thus, there is always an action i' with $s_{i',t} > 0$, which prevents from selecting the optimal action until the end of the process. This shows that a naive algorithm is not well fitted here, since it is likely to stay stuck on sub-optimal actions because of wrong knowledge about profiles. The point is now to show that the proposed additional term enables to solve this problem and ensures a sub-linear pseudo regret for our profile-based bandit algorithm with unknown profiles.

3.3. Regret

The following proposition establishes an upper bound for the cumulative pseudo-regret of the `SamplinUCB` algorithm proposed above. This is a generic bound for which no assumption is done on the process generating $\mathcal{O}_t$ at each step t.

Proposition 8 (Generic bound) *By choosing $\lambda \geq \max(1, L^2/\sqrt{R^2})$, with a probability greater than $1 - 3\delta$, the cumulative pseudo-regret of the algorithm `SampLinUCB` is upper-bounded by:*

$$\begin{aligned}
\hat{R}_T \leq\ & C + 4L \left(\sqrt{\frac{d}{\lambda} \log \left(\frac{1 + TL^2/\lambda}{\delta} \right)} + 2S \right) \sqrt{2d \log \left(\frac{2dT^2}{\delta} \right)} \sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} \\
& + 2 \left(\sqrt{d \log \left(\frac{1 + TL^2/\lambda}{\delta} \right)} + \sqrt{\lambda} S \right) \\
& \times \sqrt{Td \left(\sqrt{R^2 + L^2 S^2} \log \left(1 + \frac{TL^2}{\lambda d} \right) + \frac{4L^2}{\lambda} \log \left(\frac{2dT}{\delta} \right) \sum_{t=1}^{T} \frac{1}{n_{i_t,t}} \right)}
\end{aligned} \tag{16}$$

Proof Available in appendix A.6. ■

The study of dominant factors of the bound given above enables to obtain the following proposition for the three considered settings of the context delivery process, where we removed dependencies on L, λ, R and S to simplify the notations.

Proposition 9 (Bounds for the three profile delivery settings) *For each of the three considered settings for the profile delivery process, the upper bound of the cumulative pseudo-regret is*[2]*:*

- *For the case 1, with a probability greater than* $1-3\delta$*:*

$$\hat{R}_T = \mathcal{O}\left(d\log\left(\frac{T}{\delta}\right)\sqrt{T\log(T)}\right) \tag{17}$$

- *For the case 2, with a probability greater than* $(1-3\delta)(1-\delta)$*, and for* $T \geq 2\log(1/\delta)/p^2$*:*

$$\hat{R}_T = \mathcal{O}\left(d\log\left(\frac{T}{\delta}\right)\sqrt{T\frac{\log(T)}{p}}\right) \tag{18}$$

  where p *is the probability of profile delivery for any action at each step.*

- *For the case 3, with a probability greater than* $1-3\delta$*:*

$$\hat{R}_T = \mathcal{O}\left(d\log\left(\frac{T}{\delta}\right)\sqrt{TK\log(\frac{T}{K})}\right) \tag{19}$$

Proof The proofs for these three bounds are respectively given in appendix A.7.1, A.7.2 and A.7.3. ■

Thus, in every setting our `SamplinUCB` algorithm ensures a sub-linear upper bound for its cumulative pseudo-regret. The bound given for case 2 owns an additional dependency in p, the probability of context delivery for each action at each step. Obviously, the higher this probability is, the faster the uncertainty about profiles decreases. Note that this bound for case 2 is only valid from a given number of iterations inversely proportional to p^2, since it requires a minimal number of observations to hold. The bound for case 3 owns a dependency in the number of available actions K. This comes from the fact that only the selected action reveals its profile at each step, which re-introduces the need of considering each action a minimal number of times, as it is the case with traditional stationary approaches such as the classical `UCB` algorithm. However, as we show in our experiments below, the use of the structure of the actions, which enables some common learning of reward distributions, leads to greatly better results than existing stationary algorithms in various cases.

2. $\mathcal{O}$ renders the relation "dominated by", which means that $f = \mathcal{O}(g)$ implies that there exists a strictly positive constant C such that asymptotically we have: $|f| \leq C|g|$.

3.4. Extension to the multiple-plays setting

This short section extends our algorithm for the multiple-plays setting, where multiple actions are chosen at each step. Rather than only selecting a single action i_t at any step t, the algorithm has now to select a set $\mathcal{K}_t \subseteq \mathcal{K}$ of $k \geq 1$ actions for which it gets rewards. Algorithm 1 is therefore adapted to this setting, by simply selecting the k best actions at each step (those that get the best selection scores w.r.t. formula 14) rather than only the best one (line 23 of the algorithm). The aim is still to maximize the cumulative reward through time, where all rewards at any step t are simply summed to form the collected reward at step t (although other Lipschitz functions could have been considered for the collective reward construction from the k individual ones, such as proposed in Chen et al. (2013)).

Definition 1 *The cumulative pseudo-regret of our setting of bandit with multiple plays is defined as:*

$$\hat{R}_T = T\sum_{i\in\mathcal{K}^\star}\mu_i^\top\beta - \sum_{t=1}^{\top}\sum_{i\in\mathcal{K}_t}\mu_i^\top\beta \tag{20}$$

with $\mathcal{K}^\star$ *the set of* k *optimal actions, i.e. the* k *actions with the highest values* $\mu_i^\top\beta$*.*

Proposition 10 (Generic bound for the multiple-plays setting) *By choosing* $\lambda \geq \max(1, L^2/\sqrt{R^2})$*, with a probability greater than* $1-3\delta$*, the cumulative pseudo-regret for our* `SampLinUCB` *algorithm with multiple selections is upper bounded by:*

$$\begin{aligned}\hat{R}_T \leq\ & C + 4L\left(\sqrt{\frac{d}{\lambda}\log\left(\frac{1+TkL^2/\lambda}{\delta}\right)} + 2S\right)\sqrt{2d\log\left(\frac{2dT^2}{\delta}\right)}\sum_{t=1}^{T}\sum_{i\in\mathcal{K}_t}\frac{1}{\sqrt{n_{i,t}}} \\ & + 2\left(\sqrt{d\log\left(\frac{1+TkL^2/\lambda}{\delta}\right)} + \sqrt{\lambda}S\right) \\ & \times\sqrt{Td\left(\sqrt{R^2+L^2S^2}\log\left(1+\frac{TkL^2}{\lambda d}\right) + \frac{4L^2}{\lambda}\log\left(\frac{2dT}{\delta}\right)\sum_{t=1}^{T}\sum_{i\in\mathcal{K}_t}\frac{1}{n_{i,t}}\right)}\end{aligned} \tag{21}$$

Proof The proof is available in appendix A.8. ■

Equivalent bounds for the three cases of context delivery can be directly derived from this new generic bound by applying the same methods as in the previous section. This allows us to apply our algorithm for tasks where multiple actions can be triggered at each step, such as in the data capture task considered in our experiments in section 4.2.

4. Experiments

This section is divided in two parts. First, we propose a series of experiments on artificial data in order to observe the behavior of our approach in well-controlled environments. Then, we give results obtained on real-world data, for a task of data capture from social media.

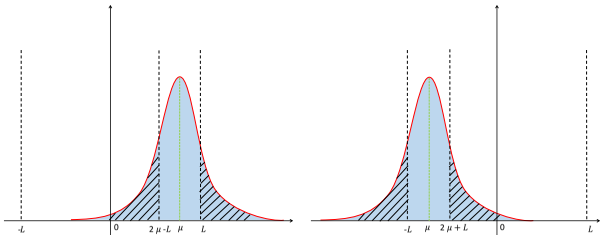
4.1. Artifical Data

4.1.1. Protocol

Data Generation: In order to assess the performances of the `SamplinUCB` algorithm, we propose to first experiment it in a context of simple selection ($k = 1$) on artificially generated data. For that purpose, we set the horizon T to 30000 iterations, the number of available actions K to 100 and the size of the profile space to $d = 5$ dimensions. Then, we sampled a mapping vector β randomly in $\left[-S/\sqrt{d}..S/\sqrt{d}\right]^d$, in order to fulfill the $||\beta|| \leq S = 1$ condition. For each arm i, we then sampled a random vector μ_i uniformly in $\left[-L/\sqrt{d}..L/\sqrt{d}\right]^d$ with $L = 1$. Finally, for each iteration $t \in \{1, ..., T\}$, we proceeded as follows to generate simulated data:

1. For each action $i \in \{1, ..., K\}$, we sampled a vector $x_{i,t}$ from the multivariate Gaussian $\mathcal{N}(\mu_i, \sigma^2 I)$. Note that, in order to assess the influence of profile samples variations on the performances of `SampLinUCB`, we tested different values for $\sigma \in \{0.5, 1.0, 2.0\}$. Moreover, in order to guarantee that $||x_{i,t}|| \leq L = 1$, while still getting sampled centered on μ_i, the Gaussian is truncated symmetrically around μ_i. This is illustrated by figure 3 for $d = 1$, where hatched areas correspond to excluded values. On the left is given the case with $\mu_i > 0$ and on the right the case with $\mu_i < 0$;

2. For each action $i \in \{1, ..., K\}$, we sampled a reward $r_{i,t}$ from a Gaussian with mean $\mu_i^\top \beta$ and variance $R^2 = 1$;



(a) Case $\mu > 0$ (b) Case $\mu < 0$

Figure 3: Profile Samples Generation Process: Truncated Gaussians

To emhasize the need of exploration on profiles, note that we set to null vectors the profile samples of the 100 first steps of each dataset. 100 datasets have been generated in such a way. The results given below correspond to averages on these artificial datasets.

Experimented Policies: We propose to compare `SampLinUCB` to the following bandit policies:

- `UCB`: the well-known `UCB` approach (Auer et al., 2002), which selects at each step the action with the best upper-confidence bound, estimated w.r.t. past rewards of actions, without any assumption about some latent structure of the actions;
- `UCBV`: the `UCBV` algorithm (Audibert et al., 2009) is an extension of `UCB`, where the variance of rewards for each action is included in the selection scores to lead the policy to ground their estimations in an higher number of observations for noisier actions.
- `UCB`$-\delta$: the `UCB`$-\delta$ algorithm (Abbasi-Yadkori et al., 2011) is a variant of `UCB` where optimism is ensured via a concentration inequality based on auto-normalised process (de la Peña et al., 2009), with a confidence level of $1 - \delta$. In our experiments, we set $\delta = 0.05$;
- `Thompson`: the `Thompson Sampling` algorithm (Thompson, 1933) introduces randomness in the exploration process by sampling reward expectations from their posterior at each time-step, following a Gaussian assumption of the rewards;
- `MOSS`: a variant of `UCB`, which usually obtains better results than the classical `UCB` but requires the knowledge about the horizon T (Audibert and Bubeck, 2009);

None of these approaches use any side information. Therefore, the only noise they have to deal with comes from the variance R^2 of the Gaussian distributions of rewards. For `SampLinUCB` an additional difficulty comes from the variations of the observed samples of profiles. The point is therefore to know whether these samples can be leveraged to exhibit some structure of the actions, that can benefit to stationary bandit tasks, despite such variations. Additionaly, the following two contextual baselines are considered in our experiments to analyze the performances of our approach:

- `LinUCB`: the very famous contextual approach that assumes a linear mapping between observed contexts and rewards (Li et al., 2010). In our case, observed profile samples correspond to the contexts that `LinUCB` takes into account in its selection policy. We consider this baseline in the interesting setting where contexts are only delivered for the selected arms (case 3 described above). In this setting, non selected arms deliver null context vectors for the next step;
- `MeanLinUCB`: this baseline corresponds to our approach but without the exploration term w.r.t. the profiles. Empirical means are considered as true profiles at each step of the process (this comes down to set $\rho_{i,t,\delta}$ to 0 for every arm and every step). As discussed above (see the last paragraph of section 3.2), such a baseline cannot guarantee a sub-linear regret since it can infinitely stay stuck on sub-optimal arms, but an empirical evaluation of its performances is useful to understand the benefits of the proposed approach.

To analyze the performances of `SampLinUCB`, we implement the three scenarios studied in previous sections. In the following, our approach is denoted `SampLinUCB_p=<p>`, where p

corresponds to the probability for any action to get a sample of its profile at every iteration. Different values for p are considered: $p \in \{0, 0.005, 0.01, 1\}$. Note that $p = 1$ corresponds to the case 1, while $p = 0$ refers to the case 3. In this latter instance, as considered in the previous sections, the samples delivery process is replaced by the ability to observe samples for the selected actions at each iteration. Note also that, for clarity and analysis purposes, in instances with $p > 0$ we do not observe samples for the selected actions (which exactly follows the cases studied in the previous section)[3]. In every instance, we set $\delta = 0.05$ for these experiments. Also, to avoid a too large exploration on profiles in the early steps, we multiplied each $\rho_{i,t,\delta}$ by a 0.01 coefficient, which still guarantees a sub-linear regret in the limit.

4.1.2. Results

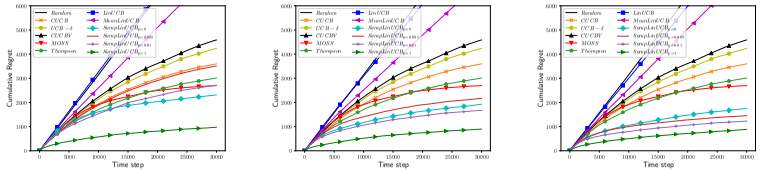
Figures 4(a), 4(b) and 4(c) report the evolution of the cumulative pseudo-regret through time for the tested policies, for σ values (variance of profile samples) respectively set to $\sigma = 2.0$, $\sigma = 1.0$ and $\sigma = 0.5$. Note that the curves of `UCB`, `UCB-`δ, `UCBV`, `Thompson` and `MOSS` are identical in every plot since their performances do not depend on the profile samples. We first notice from these plots that `UCB-`δ and `UCBV` do not provide good results on these data. It appears that these two policies over-explore during the whole bandit process. `Thompson` and `MOSS` obtain better results in average, but still far from the best contextual approach `SampLinUCB`$_{p=1}$. This confirms that using profiles of arms can be greatly advantegeous when there exist a linear correlation between these profiles and the associated rewards. In this setting (which corresponds to the case 1 studied above), the profiles are discovered step by step, but since we get a sample for every arm at each iteration, the estimators quickly converge towards the true profiles. This explains the very good results for this easy setting, and why there is nearly no differences in the results of `SampLinUCB`$_{p=1}$ for the three considered sample variances.

Let us now focus on the results provided by our `SampLinUCB` algorithm when only a subset of arms gets profile samples at each step of the process. As expected, the more the algorithm observes samples, the better it performs. However, we remark that `SampLinUCB`$_{p=0}$ obtains better results than `SampLinUCB`$_{p=0.005}$ for $\sigma = 2$ and $\sigma = 1$, and even better than `SampLinUCB`$_{p=0.01}$ when $\sigma = 2$ (while observing the same rate of samples as in this latter setting). This denotes a stronger robustness to the profile sample variance. By dynamically selecting the arms to observe, it is able to focus on the improvement of useful estimators rather than getting as many samples but for randomly selected arms (and potentially for arms that could be quickly discarded). In this interesting setting, `SampLinUCB` always outperforms non-contextual approaches for the studied sample variances, while we note a significant improvement of the results when the variance is low.

At last, we can note the very weak - near random - results obtained by `LinUCB`, which directly bases its strategy on the observed samples. More interesting are the weak results obtained by `MeanLinUCB`, which exhibits a linear regret. This emphasizes the crucial role of the profile exploration term of `SampLinUCB`: While `SampLinUCB`$_{p=0}$ is able to reconsider

3. Note that we could easily imagine tasks, which correspond to some mix of cases 2 and 3, where we both get samples from an external process and for the selected actions. For such cases, we can reasonably assume better results than those reported below for cases 2 and 3, since the process would benefit from both sample sources.

bad profiles observed in the early steps of the process, `MeanLinUCB` usually stays stuck on the first actions that provided a non-nul sample associated with a positive reward. If they are lucky, `LinUCB` and `MeanLinUCB` can exhibit good performances on some instances, but they are clearly not well fitted for the bandit setting considered in this paper.



(a) $\sigma = 2$ (b) $\sigma = 1$ (c) $\sigma = 0.5$

Figure 4: Cumulative pseudo-regret through time on artificial data with different settings for the profile samples delivery process (from very noisy samples on the left, to samples with low variance on the right).

To conclude, it appears from these first experiments that our `SampLinUCB` algorithm, while dealing with a doubled uncertainty (both on the mapping parameters and the profile estimators), is able to leverage the latent structure that it discovers through time from noisy samples of the profiles.

4.2. Real World Experiments: Social Data Capture

In this section we propose to apply our `SampLinUCB` algorithm to the task of dynamic data capture from Twitter introduced in (Gisselbrecht et al., 2015). According to a given information need, the aim is to collect relevant data from the streaming API proposed by Twitter. This API provides messages published by users on the social network in real-time. In this setting, each user account is associated with a stream of messages that can be monitored. However, for various reasons (notably w.r.t. constraints set by the social media), it is not possible to collect the whole activity of the social media. Only streams of messages published by a subset of k users can be monitored simultaneously ($k << K$). The aim is therefore to focus on users that are the most likely to publish messages that fit with the data need. The difficulty is that we do not know anything about the users beforehand, everything must be discovered during the capture process. We have thus to deal with an exploitation/exploration problem that suits well with the bandit setting studied in this paper.

Given a time period divided in T steps, the agent has to select, at each iteration $t \in \{1, ..., T\}$ of the process, a subset $\mathcal{K}_t$ of k user accounts to follow, among the whole set of possible users $\mathcal{K}$ ($\mathcal{K}_t \subseteq \mathcal{K}$). Given a relevance score $r_{i,t}$ assigned to the content posted by user $i \in \mathcal{K}_t$ during iteration t of the process (the set of tweets he posted during iteration t), the aim is to select at each iteration t the set of user accounts that maximize the sum of

collected scores:

$$\max_{(\mathcal{K}_t)_{t=1..T}} \sum_{t=1}^{T} \sum_{i \in \mathcal{K}_t} r_{i,t} \tag{22}$$

4.2.1. Rewards

In our experiments, we attempt to focus on users that have a great impact on some specified thematic. The *Follow Streaming* API of Twitter provides in real-time not only tweets posted by the followed users, but also all the re-tweets and replies to these users other users post on the network. Our reward function takes all of these messages into account to provide a reward score $r_{i,t}$ for each user $i \in \mathcal{K}_t$ after each capture period t:

$$r_{i,t} = tanh\left(\sum_{\omega \in \Omega_{i,t}} g_\gamma(\omega)\right) \tag{23}$$

where $\Omega_{i,t}$ contains the original messages from i, the re-tweets of messages from i and the replies to i during the period t, and g_γ is a function returning 1 if the content of the message as argument is judged as belonging to the desired thematic γ, 0 otherwise. To build this function g_γ, we trained a SVM topic classifier on the *20 Newsgroups* dataset (with TF bag of words representations of the texts, after stemming via the Porter Stemmer algorithm). We finally focus on 4 different topics γ: *Politics*, *Religion*, *Science* and *Sport*. Four different reward functions are therefore considered in the following (one for each topic).

4.2.2. Profiles

Following the setting of our profile based bandit, we assume that each user i of the social network is associated to an unknown vector μ_i corresponding to its profile. In these experiments, we assume that the profile of a user i corresponds to the mean of its content distribution: $\mu_i = \lim_{T\to\infty} \frac{1}{T} \sum_{t=1}^{T} x_{i,t}$, where $x_{i,t}$ is a given representation of the content posted by i during step $t-1$:

$$x_{i,t+1} = f(\sum_{\omega \in \Psi_{i,t}} \omega) \tag{24}$$

where $\Psi_{i,t} \subseteq \Omega_{i,t}$ contains all messages posted by i during step t and $\omega \in \mathbb{R}^m$ (with m the size of the vocabulary) is a TF bag of words representation of a message (after stemming via the Porter Stemmer algorithm). The function f aims at reducing the dimension of the representations, since the dimension d of the profile samples is the main factor of complexity in our algorithm, due to the required $d \times d$ matrix inversions. In order to reduce the dimension of profiles, we used a *Latent Dirichlet Allocation* method specifically designed for short texts (Hong and Davison, 2010), which aims at modeling texts as a mixture of topics. We set the number of topics to $d = 30$ and learned the LDA model on a preliminary 3-days random capture from Twitter.

4.2.3. Datasets

In order to be able to test different policies and simulate a real time decision process several times, we propose to conduct our experiments on offline datasets:

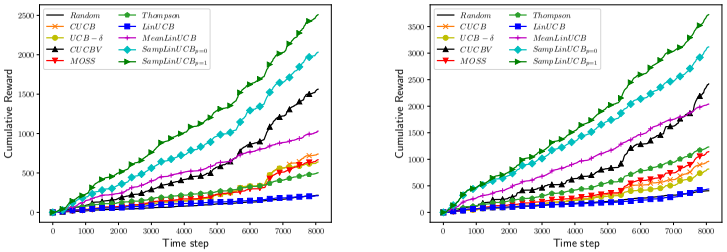
- *USElections*: dataset containing 3 587 961 messages produced by 5000 users during the ten days preceding the US presidential elections in 2012. The 5000 chosen accounts are the first ones who used either "Obama", "Romney" or "#USElections" from a preliminary random capture on Twitter.
- *OlympicGames*: dataset containing 15 010 322 messages produced by 5000 users in August 2016 during a period of three weeks covering the Olympic Games of Rio. The 5000 chosen accounts are the ones that were observed to use the most many hashtags "#Rio2016", "#Olympics", "#Olympics2016" or "#Olympicgames" within a period of preliminary random capture of three days before the Olympic Games.
- *Brexit*: dataset containing 2 118 235 messages produced by 5000 users during the first week of October 2016. The 5000 chosen accounts are the first ones who used "#Brexit" from a preliminary random capture from Twitter.

4.2.4. Results

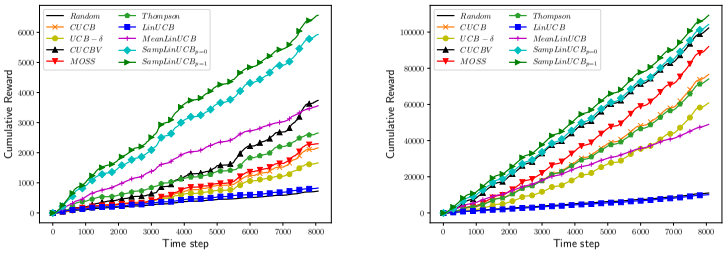
As done in (Gisselbrecht et al., 2015), we set k, the number of listened users at each time step, to 100, and the size of an iteration to 100 seconds. In these experiments, we assume $L = S = R = 1$ and we set $\delta = 0.05$ as done with artificial data.

Figures 5, 6 and 7 give the evolution of the cumulative reward through time for the datasets *USElections*, *OlympicGames* and *Brexit* respectively. In every case, we consider the four reward functions corresponding to the four topics *Politic*, *Religion*, *Science* and *Sport*. In order to lighten the plots, we only give in these figures the results of `SamplinUCB` for $p = 0$ and $p = 1$. In every plot, our algorithm is compared to the same baselines as described in section 4.1, where the policies are extended for the multiple-plays setting (as done in (Gisselbrecht et al., 2015)).

A first important observation from these plots is that in every setting, our algorithm `SampLinUCB` obtains better results than every other policy, even `CUCBV`, the extension of `UCBV` for the multiple-plays setting. Although `CUCBV` has demonstrated good performances for the task of social data capture (Gisselbrecht et al., 2015), where a high variance can be observed in the contents posted by users, the use of profiles associated to users of the networks enables an even more efficient exploration process. Globally, same manner as with artificial data, the performances of our approach increase with p, with a maximum reached when $p = 1$. Note however that the setting $p = 0$ (the case 3 studied above) is the most realistic one, since it does not use anything but the content collected by followed users at each step, which is the case in practice when collecting data from a social media such as Twitter. Interestingly, even for this setting the results obtained are always better than those of every compared approach. The improvement w.r.t. `CUCBV` is less significant for the `Sport` reward function for which greatly more rewards exist in the datasets (greatly more messages are categorized as sport), which allows non-contextual approaches to quickly



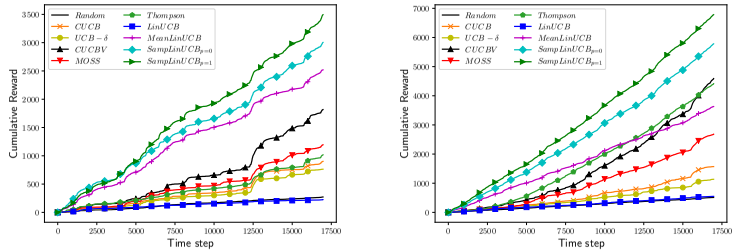
(a) Politic (b) Religion



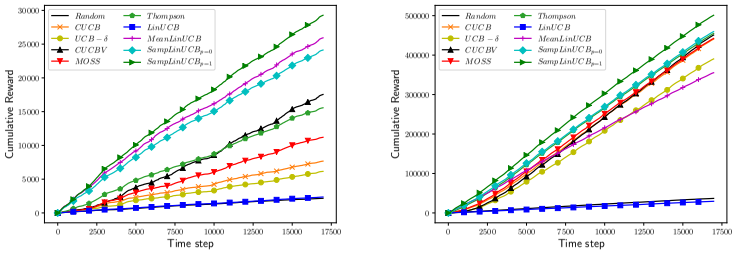
(c) Science (d) Sport

Figure 5: Evolution of the cumulative reward through time on the *USElections* dataset, according to the three considered reward functions *Politic*, *Religion*, *Science* and *Sport*.

collect knowledge about reward expectations of users. But for every other reward function `SampLinUCB`$_{p=0}$ always obtained results comprised between 1.5 and 3 times the ones obtained with the best non-contextual approach. Note also the crucial role of the exploration term for profile discovery ρ, since `MeanLinUCB`, which considers current empirical sample means as true profiles, always obtains greatly lower results than `SampLinUCB`$_{p=0}$ (except for the `Science` reward function on the `OlympicGames` and the `Brexit` datasets, where it benefits from good rewards and profile samples observed for some useful users in the initialization steps of the process). At last, as expected, `LinUCB`, which directly bases its selection policy on profile samples observed at the current step, obtains very bad results (near random). Since obtaining nul context vectors for every user not selected at the previous step, its selection mechanism very early focuses on a given set of users without ever reconsidering the others (except in the rare cases of context samples leading to negative reward expectations according to β). All these results highlight the interest of the proposed approach, based on confidence balls of the arm profiles, for tasks where contexts are only observed when the arms are selected .



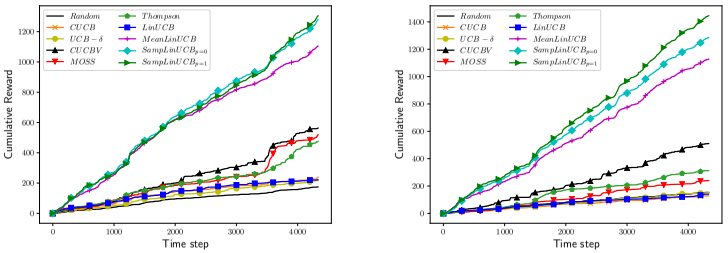
(a) Politic (b) Religion



(c) Science (d) Sport

Figure 6: Evolution of the cumulative reward through time on the *OlympicGames* dataset, according to the three considered reward functions *Politic*, *Religion*, *Science* and *Sport*.

Figures 8, 9 and 10 give the relative final cumulative rewards for different settings of the sample delivery process on the datasets *USElections*, *OlympicGames* et *Brexit* respectively (each score is normalized according to the score obtained when $p = 1$). Here we still observe that performances tend to decrease with p, for settings where $p > 0$. However it must be noticed that the setting $p = 0$ obtains results very close to other settings: it always obtains at least 80% of the final cumulative reward obtained when every user delivers a sample at each step of the process ($p = 1$). Better, in many cases `SampLinUCB`$_{p=0}$ succeeds in obtaining an higher final cumulative reward than $p = 0.01$ and $p = 0.02$. This is particularly true for the `Brexit` dataset where the dynamic selection of samples to be delivered appears very effective. On that dataset, `SampLinUCB`$_{p=0}$ even usually reaches the performances of `SampLinUCB`$_{p=0.05}$, while observing greatly less profile samples at each step (only 100 over 5000 at each iteration, which corresponds to the observation rate of the setting $p = 0.02$). While settings with $p > 0$ are greatly favored by the fact that they do not need to play an arm to get a sample of its profile, `SampLinUCB`$_{p=0}$ is not only active for the discovery of the mapping parameters, but also for the estimation of profiles. Its knowledge about profiles



(a) Politic (b) Religion

(c) Science (d) Sport

Figure 7: Evolution of the cumulative reward through time on the *Brexit* dataset, according to the three considered reward functions *Politic*, *Religion*, *Science* and *Sport*.

is directly connected to its selection strategy, with a selection score that favors promising actions with high uncertainty about their profile. This leads to an algorithm that efficiently deals with a trade-off between exploitation of good actions and exploration on both the mapping parameter and the profiles of actions.

5. Conclusion

In this paper, we focused on structured stochastic bandits, where rewards depend on some constant profile associated with actions. More specifically, we introduced the case where the associated profiles are unknown beforehand, and must be discovered from samples delivered during the process. This setting implies a doubled uncertainty, both on profile estimators and on reward predictors, for which we designed a dedicated algorithm, named `SamplinUCB`, that seeks at leveraging the structure of the unknown profiles in its exploration process. Various settings for the profile samples delivery process have been considered, for which we gave theoretical convergence guarantees. Finally, experiments on both artificial data

and a task of data capture from social networks demonstrate the very good behavior of the proposed approach. Ongoing works concern the inclusion of a non-stationary part in the selection strategy, where profiles may vary over time according to some evolving latent state of the actions.

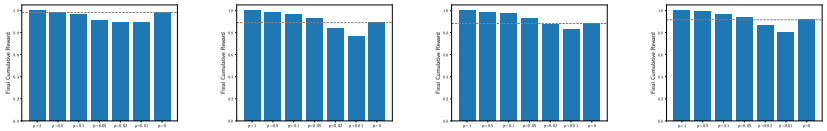
Appendix A. Appendix

A.1. Proof of proposition 1

The two following lemmas directly come from the definition of the sub-gaussian variables.

Lemma 1 *Let X be a random variable centered on 0. Then, X is said sub-gaussian with constant R if one of the two equivalent following conditions holds:*

- *Laplace Condition:* $\exists R > 0, \forall \lambda \in \mathbb{R}, \mathbb{E}[e^{\lambda X}] \leq e^{R^2\lambda^2/2}$



(a) Politic (b) Religion (c) Science (d) Sport

Figure 10: Final normalized cumulative rewards for `SampLinUCB` on *Brexit* with different p settings.

- *Sub-Gaussian Tail:* $\exists R > 0, \forall \gamma > 0, P(|X| \geq \gamma) \leq 2e^{-\gamma^2/(2R^2)}$

Lemma 2 *Let X_1 and X_2 be two sub-gaussian variables with respective constant R_1 and R_2. Let α_1 and α_2 be two real scalars. Then the variable $\alpha_1 X_1 + \alpha_2 X_2$ is sub-gaussian too, with constant $\sqrt{\alpha_1^2 R_1^2 + \alpha_2^2 R_2^2}$.*

The lemma 3 can be deduced from the application of the lemma 1 in the context of our specific problem of profile-bandit with unknown profiles, where the deviation of the profile estimators is a sub-gaussian variable.

Lemma 3 *Let us assume that for any i all samples $x_{i,t} \in \mathbb{R}^d$ observed for i at every step $t > 0$ are iid with mean $\mu_i \in \mathbb{R}^d$. Let us also assume that $||x_{i,t}|| \leq L$ for every i and t, and that $||\beta|| \leq S$. Then, for every i, and at each step t, $\beta^\top \epsilon_{i,t}$ is sub-gaussian with constant $\frac{LS}{\sqrt{n_{i,t}}}$ (with $\epsilon_{i,t} = \mu_i - \hat{x}_{i,t}$).*

Proof

By using the Cauchy-Schwarz inequality, for all i and at each step t we have: $|x_{i,t}^\top \beta| \leq ||\beta|| ||\hat{x}_{i,t}|| \leq LS$. Then, given that for all i, all samples $x_{i,t}$ are iid and $\mathbb{E}[x_{i,t}] = \mu_i$, we can apply the Hoeffding inequality to the random variable $\beta^\top \hat{x}_{i,t}$ with mean $\mu_i^\top \beta$:

$$\forall \gamma > 0, \mathbb{P}\left(|\beta^\top \hat{x}_{i,t} - \beta^\top \mu_i| > \gamma\right) = \mathbb{P}\left(|\beta^\top \epsilon_{i,t}| > \gamma\right) \leq 2e^{-\frac{n_{i,t}\gamma^2}{2S^2L^2}}$$

which allows us to say that $\epsilon_{i,t}^\top \beta$ is sub-gaussian with constant $\frac{LS}{\sqrt{n_{i,t}}}$. ■

We finally use the lemma 2 with the sum of $\beta^\top \epsilon_{i,t}$ and $\eta_{i,s}$ to prove the proposition 1, which establishes the random variable $\beta^\top \epsilon_{i,t} + \eta_{i,s}$ is conditionally sub-gaussian with constant $R_{i,t} = \sqrt{R^2 + \frac{L^2 S^2}{n_{i,t}}}$.

A.2. Proof of the proposition 3

To lighten notations, we removed the dependence on t in A and X. We have:

$$\begin{aligned}
\hat{\beta}_{t-1} &= \arg\min_\beta \sum_{s=1}^{t-1} \frac{1}{R_{i_s,t}} (\beta^\top \hat{x}_{i_s,t} - r_{i_s,s})^2 + \lambda ||\beta||^2 \\
&= (X^\top A X + \lambda I)^{-1} X^\top A Y \\
&= (X^\top A X + \lambda I)^{-1} X^\top A (X\beta + \eta') \\
&= (X^\top A X + \lambda I)^{-1} X^\top A \eta' + (X^\top A X + \lambda I)^{-1} (X^\top A X + \lambda I)\beta \\
&\quad - (X^\top A X + \lambda I)^{-1} \lambda I \beta \\
&= (X^\top A X + \lambda I)^{-1} X^\top A \eta' + \beta - \lambda (X^\top A X + \lambda I)^{-1} \beta
\end{aligned}$$

Then, the following main arguments of this proof come from the theory of auto-normalized process (de la Peña et al., 2009). By using a similar method to the one used in (Abbasi-Yadkori et al., 2011), we get:

$$||\hat{\beta}_{t-1} - \beta||_{V_{t-1}} \leq ||X^\top A \eta'||_{V_{t-1}^{-1}} + \lambda ||\beta||_{V_{t-1}^{-1}}$$

with $V_{t-1} = \lambda I + X^\top A X$, which is semi-definite positive since $\lambda > 0$. Since $||\beta|| \leq S$ and $||\beta||^2_{V_{t-1}^{-1}} \leq ||\beta||^2 / \lambda_{min}(V_{t-1}) \leq ||\beta||^2 / \lambda$, we get:

$$||\hat{\beta}_{t-1} - \beta||_{V_{t-1}} \leq ||X^\top A \eta'||_{V_{t-1}^{-1}} + \sqrt{\lambda} S$$

By using the proposition 1 of (Abbasi-Yadkori et al., 2011), and since we know from proposition 1 that $\frac{\eta_s'}{R_{i_s,t}}$ is sub-gaussian with constant 1, for any $\delta > 0$, with a probability of at least $1 - \delta$, for every $t \geq 0$ we have:

$$\begin{aligned}
||X^\top A \eta'||_{V_{t-1}^{-1}} &= ||\sum_{s=1}^{t-1} \frac{\eta_s'}{R_{i_s,t}} \hat{x}_{i_s,t}||_{V_{t-1}^{-1}} \\
&\leq \sqrt{2 \log\left(\frac{det(V_{t-1})^{1/2} det(\lambda I)^{-1/2}}{\delta}\right)} \\
&\leq \sqrt{d \log\left(\frac{1 + tL^2/\lambda}{\delta}\right)}
\end{aligned}$$

A.3. Proof of the proposition 4

Proof Let us assume that the inequality of the proposition 3 is valid. Therefore, we have for all $t > 0$ and every $i \in \mathcal{K}$:

$$\begin{aligned}\hat{\beta}_{t-1}^\top \mu_i + \alpha_{t-1}||\mu_i||_{V_{t-1}^{-1}} - \beta^\top \mu_i =& (\hat{\beta}_{t-1} - \beta)^\top \mu_i + \alpha_{t-1}||\mu_i||_{V_{t-1}^{-1}} \\ \geq & - ||\hat{\beta}_{t-1} - \beta||_{V_{t-1}}||\mu_i||_{V_{t-1}^{-1}} + \alpha_{t-1}||\mu_i||_{V_{t-1}^{-1}} \\ \geq & - \alpha_{t-1}||\mu_i||_{V_{t-1}^{-1}} + \alpha_{t-1}||\mu_i||_{V_{t-1}^{-1}} \\ =& 0\end{aligned}$$

■

A.4. Proof of the proposition 5

With $||x_{i,t}|| \leq L$, we know that, for any $j \in [1..d]$, $|x_{i,t}^j| \leq L$. Thus, we can apply the Hoeffding inequality to each dimension of the profile estimators:

$$\forall \gamma > 0 : \ \mathbb{P}\left(|\hat{x}_{i,t}^j - \mu_i^j| > \gamma/\sqrt{d}\right) \leq 2e^{-\frac{n_{i,t}\gamma^2}{2L^2 d}}$$

Then, by using the fact that $||\hat{x}_{i,t} - \mu_i|| \leq \frac{1}{\sqrt{d}} \sum_{i=1}^{d} |\hat{x}_{i,t}^i - \mu_i^i|$ and the uniform bound property, we get:

$$\mathbb{P}\left(||\hat{x}_{i,t} - \mu_i|| \leq \gamma\right) \geq 1 - 2de^{-\frac{n_{i,t}\gamma^2}{2L^2 d}}$$

Thus, for every $i \in \{1, \ldots, K\}$ and every step $t > 0$, with a probability of at least $1 - \delta/t^2$:

$$||\hat{x}_{i,t} - \mu_i|| \leq L\sqrt{\frac{2d}{n_{i,t}} \log\left(\frac{2dt^2}{\delta}\right)}$$

This bound for the deviation of the profile estimator can be less restrictive than the base assumption which states that for any $i \in \mathcal{K}$ and $t \geq 0$, $||x_{i,t}|| \leq L$. From this assumption we indeed know that, $||\hat{x}_{i,t}|| \leq L$, $||\mu_i|| \leq L$ and thus $||\hat{x}_{i,t} - \mu_i|| \leq 2L$.

We therefore consider the following bound that holds for any $t \geq 0$ with a probability greater than $1 - \delta/t^2$:

$$||\hat{x}_{i,t} - \mu_i|| \leq \min(L\sqrt{\frac{2d}{n_{i,t}} \log\left(\frac{2dt^2}{\delta}\right)}, 2L) = \rho_{i,t,\delta}$$

A.5. Proof of the proposition 6

Proof Let us assume that the inequality of the proposition 5 is valid. Therefore, we have:

- $||\mu_i||_{V_{t-1}^{-1}} - ||\hat{x}_{i,t}||_{V_{t-1}^{-1}} \leq ||\mu_i - \hat{x}_{i,t}||_{V_{t-1}^{-1}} \leq ||\mu_i - \hat{x}_{i,t}||/\sqrt{\lambda} \leq \rho_{i,t,\delta}/\sqrt{\lambda}$. Thus: $||\mu_i||_{V_{t-1}^{-1}} \leq ||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + \rho_{i,t,\delta}/\sqrt{\lambda} = ||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}}$, with $\tilde{\epsilon}_{i,t} = \rho_{i,t,\delta}\hat{x}_{i,t}/(\sqrt{\lambda}||\hat{x}_{i,t}||_{V_{t-1}^{-1}})$.

- $|\hat{\beta}_{t-1}^\top(\hat{x}_{i,t} - \mu_i)| \leq ||\hat{\beta}_{t-1}||||(\hat{x}_{i,t} - \mu_i)|| \leq \hat{\beta}_{t-1}^\top \bar{\epsilon}_{i,t}$, with $\bar{\epsilon}_{i,t} = \rho_{i,t,\delta}\hat{\beta}_{t-1}/||\hat{\beta}_{t-1}||$.

By using these two results and the uniform bound property, we can proof the proposition:

$$\begin{aligned}&\hat{\beta}_{t-1}^\top(\hat{x}_{i,t} + \bar{\epsilon}_{i,t}) + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} - \beta^\top \mu_i \\ =& (\hat{\beta}_{t-1} - \beta)^\top \mu_i + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} - \hat{\beta}_{t-1}^\top(\mu_i - \hat{x}_{i,t}) + \hat{\beta}_{t-1}^\top \bar{\epsilon}_{i,t} \\ \geq & - ||\hat{\beta}_{t-1} - \beta||_{V_{t-1}}||\mu_i||_{V_{t-1}^{-1}} + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} + \hat{\beta}_{t-1}^\top(\hat{x}_{i,t} - \mu_i + \bar{\epsilon}_{i,t}) \\ \geq & - \alpha_{t-1}||\mu_i||_{V_{t-1}^{-1}} + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} + \hat{\beta}_{t-1}^\top(\hat{x}_{i,t} - \mu_i + \bar{\epsilon}_{i,t}) \\ \geq & - \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} + \hat{\beta}_{t-1}^\top(\hat{x}_{i,t} - \mu_i + \bar{\epsilon}_{i,t}) \\ \geq & 0\end{aligned}$$

■

A.6. Proof of the proposition 8

Lemma 4 *For every $i \in \mathcal{K}$ and $t > 0$, with a probability of at least $1 - \delta/t^2 - \delta$, we have:*

$$\begin{aligned}&\hat{\beta}_{t-1}^\top(\hat{x}_{i,t} + \bar{\epsilon}_{i,t}) + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} - \beta^\top \mu_i \\ & \leq 2\alpha_t||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + 4\sqrt{d}(\alpha_{t-1}/\sqrt{\lambda} + S)\rho_{i,t,\delta}\end{aligned}$$

Proof

As for proposition 6, we assume that the inequality of proposition 5 holds. Then, noting that $||\bar{\epsilon}_{i,t}||_{V_{t-1}^{-1}} \leq ||\bar{\epsilon}_{i,t}||/\sqrt{\lambda} = \rho_{i,t,\delta}/\sqrt{\lambda}$ and $||\tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} = \rho_{i,t,\delta}/\sqrt{\lambda}$, we have:

$$\begin{aligned}&\hat{\beta}_{t-1}^\top(\hat{x}_{i,t} + \bar{\epsilon}_{i,t}) + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} - \beta^\top \mu_i \\ =& (\hat{\beta}_{t-1} - \beta)^\top \mu_i + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} - \hat{\beta}_{t-1}^\top(\mu_i - \hat{x}_{i,t}) + \hat{\beta}_{t-1}^\top \bar{\epsilon}_{i,t} \\ \leq & ||\hat{\beta}_{t-1} - \beta||_{V_{t-1}}||\mu_i||_{V_{t-1}^{-1}} + \alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} + \hat{\beta}_{t-1}^\top(\hat{x}_{i,t} - \mu_i + \bar{\epsilon}_{i,t}) \\ \leq & 2\alpha_{t-1}||\hat{x}_{i,t} + \tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} + 2||\hat{\beta}_{t-1}||_{V_{t-1}}||\bar{\epsilon}_{i,t}||_{V_{t-1}^{-1}} \\ \leq & 2\alpha_{t-1}||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + 2\alpha_{t-1}||\tilde{\epsilon}_{i,t}||_{V_{t-1}^{-1}} + 2(\alpha_{t-1} + S\sqrt{\lambda})||\bar{\epsilon}_{i,t}||_{V_{t-1}^{-1}} \\ \leq & 2\alpha_{t-1}||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + 4(\alpha_{t-1}/\sqrt{\lambda} + S)\rho_{i,t,\delta}\end{aligned}$$

■

Lemma 5 *For every t, with a probability of at least $1-\delta/t^2-\delta$, the instantaneous pseudo-regret of the algorithm* `SampLinUCB`*, noted $reg_t = \beta^\top \mu_{i^\star} - \beta^\top \mu_{i_t}$, is upper-bounded as:*

$$reg_t \leq \underbrace{2\alpha_{t-1}||\hat{x}_{i_t,t}||_{V_{t-1}^{-1}}}_{reg_t^{(1)}} + \underbrace{4(\alpha_{t-1}/\sqrt{\lambda}+S)\rho_{i_t,t,\delta}}_{reg_t^{(2)}}$$

Proof The previous lemma allows us to say that for all t:
$s_{i_t,t} \leq \beta^\top \mu_{i_t} + 2\alpha_{t-1}||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + 4(\alpha_{t-1}/\sqrt{\lambda}+S)\rho_{i,t,\delta}$
Now, given the selection policy of `SampLinUCB` and the proposition 6, we get for all t: $s_{i_t,t} \geq s_{i^\star,t} \geq \beta^\top \mu_{i^\star}$. Thus:
$reg_t \leq s_{i_t,t} - \beta^\top \mu_{i_t} \leq 2\alpha_{t-1}||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + 4(\alpha_{t-1}/\sqrt{\lambda}+S)\rho_{i,t,\delta}$

■

Next, we use the uniform bound property, the fact that $\sum_{t=2}^{\infty} \frac{\delta}{t^2} = \delta(\pi^2/6-1) \leq \delta$ and the fact that in the proposition 3 the bound is uniform (i.e., it holds for all step t simultaneously) to say that, with a probability of at least $1-2\delta$:

$$\begin{aligned}
\sum_{t=1}^{T} reg_t^{(2)} &\leq C + \sum_{t=2}^{T} 4(\alpha_{t-1}/\sqrt{\lambda}+S)\rho_{i_t,t,\delta} \\
&\leq C + \sum_{t=2}^{T} 4(\alpha_{t-1}/\sqrt{\lambda}+S)L\sqrt{\frac{2d}{n_{i,t}}\log\left(\frac{2dt^2}{\delta}\right)} \\
&\leq C + 4L(\alpha_T/\sqrt{\lambda}+S)\sqrt{2d\log\left(\frac{2dT^2}{\delta}\right)}\sum_{t=2}^{T}\frac{1}{\sqrt{n_{i_t,t}}}
\end{aligned}$$

On another hand, we have:

$$\begin{aligned}
\sum_{t=1}^{T} reg_t^{(1)} &\leq \sum_{t=1}^{T} 2\alpha_{t-1}||\hat{x}_{i_t,t}||_{V_{t-1}^{-1}}^2 \\
&\leq \sqrt{T\sum_{t=1}^{T} 4\alpha_{t-1}^2||\hat{x}_{i_t,t}||_{V_{t-1}^{-1}}^2} \\
&\leq 2\alpha_T\sqrt{T\sum_{t=1}^{T}||\hat{x}_{i_t,t}||_{V_{t-1}^{-1}}^2}
\end{aligned}$$

Now, it remains to upper-bound the term $\sum_{t=1}^{T}||\hat{x}_{i_t,t}||_{V_{t-1}^{-1}}^2$.

For that purpose, we introduce the following notation: $\nu_{i,t,\delta} = L\sqrt{2d/(n_{i,t})\log(2dT/\delta)}$. By using again the Hoeffding inequality, with a probability of at least $1-\delta/T$, we get for all $s \leq t-1$:

$$||\hat{x}_{i_s,t}|| \leq ||\mu_{i_s}|| + \nu_{i_s,t,\delta}$$

With $\check{\epsilon}_{i,t} = min(\nu_{i,t,\delta}, ||\mu_i||)\mu_i/||\mu_i||$, we get, for all $s \leq t-1$:

$$1/\sqrt{R_{i_s,s}}||\mu_{i_s} - \check{\epsilon}_{i_s,s}|| \leq 1/\sqrt{R_{i_s,t}}||\hat{x}_{i_s,t}||$$

Then, we arrive to:

$$V_{t-1} = \lambda I + \sum_{s=1}^{t-1}\frac{1}{R_{i_s,t}}\hat{x}_{i_s,t}\hat{x}_{i_s,t}^\top \geq \lambda I + \sum_{s=1}^{t-1}\frac{1}{R_{i_s,s}}(\mu_{i_s} - \check{\epsilon}_{i_s,s})(\mu_{i_s} - \check{\epsilon}_{i_s,s})^\top = W_{t-1}$$

Which means that for every vector x: $||x||_{V_{t-1}^{-1}} \leq ||x||_{W_{t-1}^{-1}}$.
Let us now define $\hat{\epsilon}_{i,t} = \nu_{i,t,\delta}\mu_i/(\sqrt{\lambda}||\mu_i||_{W_{t-1}^{-1}})$, such that for all $s \leq t-1$:

$$||\hat{x}_{i_s,t}||_{W_{t-1}^{-1}} \leq ||\mu_{i_s} + \hat{\epsilon}_{i_s,s}||_{W_{t-1}^{-1}}$$

and

$$||\hat{\epsilon}_{i_s,s}||_{W_{t-1}^{-1}} = \nu_{i_s,s,\delta}/\sqrt{\lambda}$$

Finally, by using the uniform bound property and the fact that $\sum_{t=1}^{T}\frac{\delta}{T} = \delta$, with a probability of at least $1-\delta$:

$$\begin{aligned}
\sum_{t=1}^{T}||\hat{x}_{i_t,t}||_{V_{t-1}^{-1}}^2 &\leq \sum_{t=1}^{T}||\hat{x}_{i_t,t}||_{W_{t-1}^{-1}}^2 \\
&\leq \sum_{t=1}^{T}||\mu_{i_t} + \hat{\epsilon}_{i_t,t}||_{W_{t-1}^{-1}}^2 \leq \sum_{t=1}^{T}||\mu_{i_t} + \hat{\epsilon}_{i_t,t} - \check{\epsilon}_{i_t,t} + \check{\epsilon}_{i_t,t}||_{W_{t-1}^{-1}}^2 \\
&\leq \sum_{t=1}^{T}||\mu_{i_t} - \check{\epsilon}_{i_t,t}||_{W_{t-1}^{-1}}^2 + \sum_{t=1}^{T}||\hat{\epsilon}_{i_t,t}||_{W_{t-1}^{-1}}^2 + \sum_{t=1}^{T}||\check{\epsilon}_{i_t,t}||_{W_{t-1}^{-1}}^2 \\
&\leq \sum_{t=1}^{T}||\mu_{i_t} - \check{\epsilon}_{i_t,t}||_{W_{t-1}^{-1}}^2 + \frac{2}{\lambda}\sum_{t=1}^{T}\nu_{i_t,t,\delta}^2 \\
&\leq \sum_{t=1}^{T}||\mu_{i_t} - \check{\epsilon}_{i_t,t}||_{W_{t-1}^{-1}}^2 + \frac{4L^2d}{\lambda}\log\left(\frac{2dT}{\delta}\right)\sum_{t=1}^{T}\frac{1}{n_{i_t,t}}
\end{aligned}$$

On another hand, we have:

$$\begin{aligned}
det(W_T) &= det(W_{T-1} + \frac{1}{R_{i_T,T}}(\mu_{i_T} - \check{\epsilon}_{i_T,T})(\mu_{a_T} - \check{\epsilon}_{i_T,T})^\top) \\
&= det(W_{T-1}) det(I + \frac{1}{R_{i_T,T}} W_{T-1}^{-1/2}(\mu_{i_T} - \check{\epsilon}_{i_T,T})(W_{T-1}^{-1/2}(\mu_{i_T} - \check{\epsilon}_{i_T,T}))^\top) \\
&= det(W_{T-1})(1 + \frac{1}{R_{i_T,T}} ||\mu_{i_T} - \check{\epsilon}_{i_T,T}||^2_{W_{T-1}^{-1}}) \\
&= det(\lambda I) \prod_{t=1}^{T} (1 + \frac{1}{R_{i_t,t}} ||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}})
\end{aligned}$$

Where we used the fact that all eigenvalues of $I + xx^\top$ equal 1 except one that is associated to the eigenvector x and thus equals $1 + ||x||^2$.

Since by assumption $\lambda > \max(1, L^2/\sqrt{R^2})$, we have:

$$\frac{1}{R_{i_t,t}} ||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}} \leq ||\hat{x}_{i_t,t}||^2/\sqrt{R^2}\lambda \leq L^2/\sqrt{R^2}\lambda \leq 1$$

Thus, by using the fact that $x \leq 2\log(1+x)$ when $0 \leq x \leq 1$, we get:

$$\begin{aligned}
2\log\left(\frac{det(W_T)}{det(\lambda I)}\right) &\geq \sum_{t=1}^{T} \frac{1}{R_{i_t,t}} ||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}} \\
&\geq \min_{t=1..T}\left(\frac{1}{R_{i_t,t}}\right) \sum_{t=1}^{T} ||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}} \\
&\geq 1/\sqrt{R^2 + L^2S^2} \sum_{t=1}^{T} ||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}}
\end{aligned}$$

As in the lemma 11 of (Abbasi-Yadkori et al., 2011), we also have:

$$\log\left(\frac{det(W_T)}{det(\lambda I)}\right) \leq d\log\left(1 + \frac{TL^2}{\lambda d}\right)$$

Which leads us to:

$$\sum_{t=1}^{T} ||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}} \leq \sqrt{R^2 + L^2S^2} d\log\left(1 + \frac{TL^2}{\lambda d}\right)$$

Finally, same manner as in the lemma 10 of Abbasi-Yadkori et al. (2011), the trace-determinant inequality gives:

$$\alpha_T \leq \sqrt{d\log\left(\frac{1 + TL^2/\lambda}{\delta}\right)} + \sqrt{\lambda}S$$

Gathering all these results together allows us to prove the announced result.

A.7. Proof of the proposition 9

Lemma 6 *When removing dependencies on L, λ, R and S, the bound from proposition 16 for the cumulative regret $\hat{R}_T$ can written as follows (when $T > d$):*

$$\hat{R}_T \leq C + C_1 d\log\left(\frac{T}{\delta}\right) \sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} + C_2 d\log\left(\frac{T}{\delta}\right) \sqrt{T \sum_{t=1}^{T} \frac{1}{n_{i_t,t}}}$$

with C,C_1 and C_2 three constants.

Proof From proposition 16, we have:

$$\hat{R}_T \leq C + \hat{R}_{T,1} + \hat{R}_{T,2}$$

where:

$$\begin{aligned}
\hat{R}_{T,1} &= 4L\left(\sqrt{\frac{d}{\lambda}\log\left(\frac{1 + TL^2/\lambda}{\delta}\right)} + 2S\right) \sqrt{2d\log\left(\frac{2dT^2}{\delta}\right)} \sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} \\
&\leq Constant \times d\sqrt{\log\left(\frac{T}{\delta}\right)\log\left(\frac{dT^2}{\delta}\right)} \sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} \\
&\leq Constant \times d\log\left(\frac{T}{\delta}\right) \sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} \qquad (\text{when } T > d > 0)
\end{aligned}$$

And

$$\begin{aligned}
\hat{R}_{T,2} &= 2\left(\sqrt{d\log\left(\frac{1 + TL^2/\lambda}{\delta}\right)} + \sqrt{\lambda}S\right) \\
&\times \sqrt{Td\left(\sqrt{R^2 + L^2S^2}\log\left(1 + \frac{TL^2}{\lambda d}\right) + \frac{4L^2}{\lambda}\log\left(\frac{2dT}{\delta}\right) \sum_{t=1}^{T} \frac{1}{n_{i_t,t}}\right)} \\
&\leq Constant \times \sqrt{d\log\left(\frac{T}{\delta}\right)} \sqrt{Td\left(\log(T) + \log\left(\frac{dT}{\delta}\right) \sum_{t=1}^{T} \frac{1}{n_{i_t,t}}\right)} \\
&\leq Constant \times \sqrt{d\log\left(\frac{T}{\delta}\right)} \sqrt{Td\log\left(\frac{dT}{\delta}\right) \sum_{t=1}^{T} \frac{1}{n_{i_t,t}}} \\
&\leq Constant \times d\log\left(\frac{T}{\delta}\right) \sqrt{T \sum_{t=1}^{T} \frac{1}{n_{i_t,t}}} \qquad (\text{when } T > d > 0)
\end{aligned}$$

■

Thanks to this lemma, we are ready to derive specific bounds for the three considered profile delivery settings.

A.7.1. Case 1:

On one hand, we have:

$$\sum_{t=1}^{T} \frac{1}{n_{i_t,t}} = \sum_{t=1}^{T} \frac{1}{t} \leq 1 + \log(T)$$

On the other hand, we have:

$$\sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} = \sum_{t=1}^{T} \frac{1}{\sqrt{t}} \leq \int_0^T \frac{1}{\sqrt{t}} \, \mathrm{d}t \leq 2\sqrt{T}$$

Finally, we get from lemma 6 that, when $T > d > 0$:

$$\hat{R}_{T,1} \leq C + C_1 d \log\left(\frac{T}{\delta}\right) \sqrt{T} + C_2 d \log\left(\frac{T}{\delta}\right) \sqrt{T \log(T)}$$

with C,C_1 and C_2 three constants. Since the last term is clearly the greatest, we get the announced result.

A.7.2. Case 2:

Lemma 7 *$\forall i, \forall t \geq \lceil 2\log(1/\delta)/p^2 \rceil$, with a probability of at least $1-\delta$:*

$$n_{i,t} \geq \frac{tp}{2}$$

Proof By the Hoeffding inequality, for all $\epsilon > 0$:

$$\mathbb{P}(n_{i,t} \geq tp - \epsilon) \geq 1 - e^{-2\epsilon^2/t}$$

By taking $\epsilon = tp/2$, we get:

$$\mathbb{P}(n_{i,t} \geq tp/2) \geq 1 - e^{-tp^2/2}$$

If $t \geq 2\log(1/\delta)/p^2$, then $1 - e^{-tp^2/2} \geq 1 - \delta$, which proves the lemma. ■

Let us note $u = ceil(2\log(1/\delta)/p^2)$. Thus, following lemma 7, with a probability of at least $1-\delta$, we have:

$$\begin{aligned}
\sum_{t=1}^{T} \frac{1}{n_{i_t,t}} &= \sum_{t=1}^{u} \frac{1}{n_{i_t,t}} + \sum_{t=u+1}^{T} \frac{1}{n_{i_t,t}} \\
&\leq u + \frac{2}{p} \sum_{t=u+1}^{T} \frac{1}{t} \\
&\leq u + \frac{2}{p} \int_u^T \frac{1}{t} \, \mathrm{d}t \\
&\leq u + \frac{2\log(T)}{p}
\end{aligned}$$

From another hand, still thanks to the lemma 7, with a probability of at least $1-\delta$:

$$\begin{aligned}
\sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} &= \sum_{t=1}^{u} \frac{1}{\sqrt{n_{i_t,t}}} + \sum_{t=u+1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} \\
&\leq u + \sqrt{\frac{2}{p}} \sum_{t=u+1}^{T} \frac{1}{\sqrt{t}} \\
&\leq u + \sqrt{\frac{2}{p}} \int_u^T \frac{1}{\sqrt{t}} \, \mathrm{d}t \\
&\leq u + 2\sqrt{\frac{2T}{p}}
\end{aligned}$$

Finally, we get from lemma 6 that, when $T > d > 0$:

$$\hat{R}_{T,1} \leq C + C_1 d \log\left(\frac{T}{\delta}\right) \sqrt{\frac{T}{p}} + C_2 d \log\left(\frac{T}{\delta}\right) \sqrt{T \frac{\log(T)}{p}}$$

with C,C_1 and C_2 three constants. Since the last term is clearly the greatest, we get the announced result.

A.7.3. Case 3:

First note that the sum $\sum_{t=1}^{T} \frac{1}{n_{i_t,t}}$ is maximized when each action has delivered exactly $\lfloor T/K \rfloor$ samples in the $\lfloor T/K \rfloor K$ first iterations (i.e., every action has been played as many times). Thus:

$$\begin{aligned}
\sum_{t=1}^{T} \frac{1}{n_{i_t,t}} &\leq \sum_{i=1}^{K} \sum_{t=1}^{\lfloor T/K \rfloor + 1} \frac{1}{t} \\
&\leq K \sum_{t=1}^{\lceil T/K \rceil} \frac{1}{t} \\
&\leq K(1 + \log(\lceil T/K \rceil))
\end{aligned}$$

With the same argument, we also get:

$$\begin{aligned}
\sum_{t=1}^{T} \frac{1}{\sqrt{n_{i_t,t}}} &\leq K \sum_{t=1}^{\lceil T/K \rceil} \frac{1}{\sqrt{t}} \\
&\leq 2K\sqrt{\lceil T/K \rceil}
\end{aligned}$$

Finally, by noting that $K\log(\lceil T/K \rceil) \sim K\log(T/K)$, that $K\sqrt{\lceil T/K \rceil} \sim \sqrt{KT}$ and by using the generic bound from the proposition 9, we get the announced result. Finally, since

$K\log(\lceil T/K\rceil) \sim K\log(T/K)$ and $K\sqrt{\lceil T/K\rceil} \sim \sqrt{KT}$, we get from lemma 6 that, when $T > d > 0$:

$$\hat{R}_{T,1} \leq C + C_1 d\log\left(\frac{T}{\delta}\right)\sqrt{KT} + C_2 d\log\left(\frac{T}{\delta}\right)\sqrt{TK\log(T/K)}$$

with C,C_1 and C_2 three constants. Since the last term is clearly the greatest, we get the announced result.

A.8. Proof of the proposition 10

We follow a similar method to the one presented in Qin et al. (2014) for the specific case of sums of individual rewards: Since we consider that the reward obtained by playing a set of actions at a given step t is the sum of rewards observed for every single played action at t, we have:

$$reg_t = \sum_{i\in\mathcal{K}^\star} \mu_i^\top \beta - \sum_{i\in\mathcal{K}_t} \mu_i^\top \beta$$

with $\mathcal{K}^\star$ the set of k optimal actions, i.e., those with greatest expectations $\mu_i^\top\beta$. Then, we use the fact that for every step t:

$$\sum_{i\in\mathcal{K}_t} s_{i,t} \geq \sum_{i\in\mathcal{K}_\star} s_{i^\star,t}$$

This leads to:

$$reg_t \leq \sum_{i\in\mathcal{K}_t} 2\alpha_{t-1}||\hat{x}_{i,t}||_{V_{t-1}^{-1}} + 4\sqrt{d}(\alpha_{t-1}/\sqrt{\lambda} + S)\rho_{i,t,\delta}$$

Where the matrix V_{t-1} is defined by considering the k played actions at each step: $V_{t-1} = \lambda I + \sum_{s=1}^{t-1}\sum_{i\in\mathcal{K}_s}\frac{1}{R_{i,t}}\hat{x}_{i,t}\hat{x}_{i,t}^\top$. The fact that we add k terms to the matrix V at each iteration implies two distinct things:

- First on the confidence ellipsoid of β. For k actions played at each step, we have:

  $$\alpha_T \leq \sqrt{d\log\left(\frac{1+kTL^2/\lambda}{\delta}\right)} + \sqrt{\lambda}S;$$

- On another hand on the upper-bounding of $\sum_{t=1}^{T}\sum_{i_t\in\mathcal{K}_t}||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}}$. We have:

  $$\sum_{t=1}^{T}\sum_{i_t\in\mathcal{K}_t}||\mu_{i_t} - \check{\epsilon}_{i_t,t}||^2_{W_{t-1}^{-1}} \leq \sqrt{R^2+L^2S^2}d\log\left(1+\frac{TkL^2}{\lambda d}\right)$$

Finally, we can use the same methods as in the previous proofs for deriving specific bounds from the generic one, where the selection of k actions at each step appears explicitly in the terms $\sum_{t=1}^{T}\sum_{i\in\mathcal{K}_t}\frac{1}{n_{i,t}}$ and $\sum_{t=1}^{T}\sum_{i\in\mathcal{K}_t}\frac{1}{\sqrt{n_{i,t}}}$.

A.9. Table of the main notations

T	number of steps of the process
$\mathcal{K}$	set of available actions
K	number of available arms
k	number of simultaneaous plays at each step
d	dimension of the arms' profiles
i_t	arm selected at step t
i^*	arm with the highest final cumulative reward
r_i	reward obtained by arm i at step t
$x_{i,t}$	profile sample vector observed for arm i at step t
$\hat{x}_{i,t}$	average of profile sample vectors observed for arm i until step t
L	upper-bound for the profiles' norm
$\mathcal{O}_t$	set of arms delivering a profile context at step t
$n_{i,t}$	number of samples observed for arm i until step t
μ_i	profile vector of arm i
β	mapping parameter between profiles and rewards
$\hat{\beta}_t$	estimator of β at step t
S	upper-bound for the β parameter norm
λ	l2-regularization constant of the β estimator
$\eta_{i,t}$	sub-gaussian noise of the reward of arm i at step t
R	sub-gaussian constant of the rewards distribution
$\epsilon_{i,t}$	deviation between the true profile of arm i and its estimator at step t ($\epsilon_{i,t} = \mu_i - \hat{x}_{i,t}$)
η'_{t-1}	vector of reward deviations of the first $t-1$ selected arms from their expectation at step t: $\eta'_{t-1} = (\eta_{i_s,s} + \epsilon_{i_s,t}^\top\beta)_{s=1..t-1}^\top$
$R_{i,t}$	sub-gaussian constant of the noise of the reward of i at step t w.r.t. $\hat{x}_{i,t}^\top\beta$
X_{t-1}	$(t-1)\times d$ matrix containing the empirical means of the selected actions, where the s-th row corresponds to the estimator at step t of the action selected at step s: $X_{t-1} = (\hat{x}_{i_s,t}^\top)_{s=1..t-1}$
Y_{t-1}	rewards vector of size $t-1$: $Y_{t-1} = (r_{i_s,s})_{s=1..t-1}^\top$
A_{t-1}	diagonal $(t-1)\times(t-1)$ matrix, where the s-th diagonal element equals $1/R_{i_s,t}$: $A_{t-1} = diag(1/R_{i_s,t})_{s=1..t-1}$
δ	parameter controling the confidence level of the regret bound
V_t^{-1}	variance-covariance matrix of the posterior distribution of β at step t
$\rho_{i,t,\delta}$	quantity used to bound the deviation of the estimators of profiles: $\rho_{i,t,\delta} = \min(L\sqrt{\frac{2d}{n_{i,t}}\log\left(\frac{2dt^2}{\delta}\right)}, 2L)$
$s_{i,t}$	selection score for arm i at step t
α_t	exploration coefficient at step t w.r.t. the confidence of the *beta* estimator
$\bar{\epsilon}_t$	quantity used to bound $\mu_i^\top\hat{\beta}_t$
$\tilde{\epsilon}_t$	quantity used to bound $\mu_i^\top(\beta - \hat{\beta}_t)$

Abstract

Recent research has shown the potential utility of deep Gaussian processes. These deep structures are probability distributions, designed through hierarchical construction, which are conditionally Gaussian. In this paper, the current published body of work is placed in a common framework and, through recursion, several classes of deep Gaussian processes are defined. The resulting samples generated from a deep Gaussian process have a Markovian structure with respect to the depth parameter, and the effective depth of the resulting process is interpreted in terms of the ergodicity, or non-ergodicity, of the resulting Markov chain. For the classes of deep Gaussian processes introduced, we provide results concerning their ergodicity and hence their effective depth. We also demonstrate how these processes may be used for inference; in particular we show how a Metropolis-within-Gibbs construction across the levels of the hierarchy can be used to derive sampling tools which are robust to the level of resolution used to represent the functions on a computer. For illustration, we consider the effect of ergodicity in some simple numerical examples.

Keywords: deep learning, deep Gaussian processes, deep kernels

1. Introduction

This section provides background on the study and application of Gaussian and deep Gaussian processes, outlines the contribution and setup of the paper, and establishes notation to be used in subsequent sections.

1.1 Background

Gaussian processes have proved remarkably successful as a tool for various statistical inference and machine learning tasks (Rasmussen and Williams, 2006; Kennedy and O'Hagan, 2001; Higdon et al., 2004; Stein, 1999). This success relates in part to the ease with which computations may be performed in the Gaussian framework, and also to the flexible ways in which Gaussian processes may be used, for example when combined with thresholding to perform classification tasks via probit models (Neal, 1997; Rasmussen and Williams, 2006) or to find interfaces in Bayesian inversion (Iglesias et al., 2016). Nonetheless there are limits to the sort of phenomena that are readily expressible via direct use of Gaussian processes, such as in the sparse data scenario, where the constructed probability distribution is far from posterior contraction. Recognizing this fact, there have been a number of interesting research activities which seek to represent new phenomena via the hierarchical cascading of Gaussians. Early work of this type includes the PhD thesis of Paciorek (2003) (see also Paciorek and Schervish, 2004) in which the aim is to reproduce spatially non-stationary phenomena, and this is achieved by means of a Gaussian process whose covariance function itself depends on another Gaussian process. This idea was recently re-visited by Roininen et al. (2016), using the precision operator viewpoint, rather than covariance function, and building on the explicit link between Gaussian processes and stochastic partial differential equations (SPDEs) (Lindgren et al., 2011). A different approach was adopted by Damianou and Lawrence (2013) where a Gaussian process was directly composed with another Gaussian process; furthermore the idea was implemented recursively, leading to what is referred to as deep Gaussian processes (DGP). These ingenious constructions open up new possibilities for problems in non-parametric inference and machine learning and the purpose of this paper is to establish, and utilize, a common framework for their study. Relevant to our analysis is the early work of Diaconis and Freedman (1999) which studied iterations of random Lipschitz functions and the conditions required for their convergence.

1.2 Our Contribution

In the paper we make three main contributions:

- We demonstrate a unifying perspective on the hierarchical Gaussian processes described in the previous subsection, leading to a wide class of deep Gaussian processes, with a common framework within which new deep Gaussian processes can be constructed.
- By exploiting the fact that this common framework has a Markovian structure, we interpret the depth of the process in terms of the ergodicity or non-ergodicity of this process; in simple terms ergodic constructions have effective depth given by the mixing time.

- We demonstrate how these processes may be used for inference; in particular we show how a Metropolis-within-Gibbs construction across the levels of the hierarchy can be used to derive sampling tools which are robust to the level of resolution used to represent the functions on a computer.

We also describe numerical experiments which illustrate the theory, and which demonstrate some of the limitations of the framework in the inference context, suggesting the need for further algorithmic innovation and theoretical understanding. We now summarize the results and contributions by direct reference to the main theorems in the paper.

- Theorem 4 shows that a composition-based deep Gaussian process will, with sufficiently many layers, produce samples that are approximately constant. This pathology can be avoided by, for example, increasing the width of each hidden layer, or allowing each layer to depend on the input layer.
- Theorem 8 shows the ergodicity of a class of discretized deep Gaussian processes, constructed using non-stationary covariance *functions*. As a consequence, there is little benefit in adding additional layers after a certain point. This observation elucidates the mechanism underlying the choices of DGPs with a small number of layers for inference in numerous papers (for example Cutajar et al., 2017; Salimbeni and Deisenroth, 2017; Dai et al., 2015).
- Theorem 14 establishes a similar result as Theorem 8 on function space, for a different class of deep Gaussian processes constructed using non-stationary covariance *operators*.
- Theorem 16 establishes the asymptotic properties of a deep Gaussian process formed by iterated convolution of fairly general classes of Gaussian random fields. Specifically it is shown that such processes will either converge weakly to zero or diverge as the number of layers is increased, and so they will provide little flexibility for inference in practice.

1.3 Overview

The general framework in which we place the existing literature, and which we employ to analyze deep Gaussian processes, and to construct algorithms for related inference tasks, is as follows. We consider sequences of functions $\{u_n\}$ which are conditionally Gaussian:

$$u_{n+1}|u_n \sim N\big(m(u_n), C(u_n)\big); \tag{CovOp}$$

here $m(u_n)$ denotes the mean function and $C(u_n)$ the covariance operator. We will also sometimes work with the covariance function representation, in which case we will write

$$u_{n+1}|u_n \sim \mathrm{GP}\big(m(x;u_n), c(x,x';u_n)\big). \tag{GP}$$

Note that the covariance function is the kernel of the covariance operator when the latter is represented as an integral operator over the approximate domain $D \subseteq \mathbb{R}^d$:

$$\big(C(u_n)\phi\big)(x) = \int c(x,x';u_n)\phi(x')dx'.$$

In most of the paper we consider the centred case where $m \equiv 0$, although the flexibility of allowing for non-zero mean will be important in some applications, as discussed in the conclusions. When the mean is zero, the iterations (CovOp) and (GP) can be written in the form

$$u_{n+1} = L(u_n)\xi_{n+1}, \tag{ZeroMean}$$

where $\{\xi_n\}$ form an i.i.d. Gaussian sequence and, for each u, $L(u)$ is a linear operator. For example if the ξ_n are white then the covariance operator is $C(u) = L(u)L(u)^\top$ with $\top$ denoting the adjoint operation and $L(u)$ is a Cholesky factor of $C(u)$. The formulation (ZeroMean) is useful in much of our analysis. For the purpose of this paper, we will refer to any sequence of functions constructed as in (ZeroMean) as a deep Gaussian process.

In section 2 we discuss the hierarchical Gaussian constructions referenced above, and place them in the setting of equations (CovOp), (GP) and (ZeroMean). Section 3 studies the ergodicity of the resulting deep Gaussian processes, using the Markov chain which defines them. In section 4 we provide supporting numerical experiments; we give illustrations of draws from deep Gaussian process priors, and we discuss inference. In the context of inference we describe a methodology for MCMC, using deep Gaussian priors, which is defined in the function space limit and is hence independent of the level of resolution used to represent the functions u_n; numerical illustrations are given. We conclude in section 5 in which we describe generalizations of the settings considered in this paper, and highlight future directions.

1.4 Notation

The structure of the deep Gaussian processes above means that they can be interpreted as Markov chains on a Hilbert space $\mathcal{H}$ of functions. Let $\mathcal{B}(\mathcal{H})$ denote the Borel σ-algebra on $\mathcal{H}$. We denote by $\mathsf{P} : \mathcal{H} \times \mathcal{B}(\mathcal{H}) \to \mathbb{R}$ the one-step transition probability distribution,

$$\mathsf{P}(u, A) = \mathbb{P}(u_n \in A \,|\, u_{n-1} = u), \tag{1}$$

and denote by $\mathsf{P}^n : \mathcal{H} \times \mathcal{B}(\mathcal{H}) \to \mathbb{R}$ the n-step transition probability distribution,

$$\mathsf{P}^n(u, A) = \mathbb{P}(u_n \in A \,|\, u_0 = u). \tag{2}$$

Thus, for example, in the case of the covariance operator construction (CovOp) we have

$$\mathsf{P}(u, \cdot) = N\big(0, C(u)\big),$$

when the mean is zero. This Markovian structure will be exploited when showing ergodicity, or lack of ergodicity, of the chains.

2. Four Constructions

This section provides examples of four constructions of deep Gaussian processes, all of which fall into our general framework. The reader will readily design others.

2.1 Composition

Let $D \subseteq \mathbb{R}^d$, $D' \subseteq \mathbb{R}^l$, $u_n : D \to \mathbb{R}^m$ and $F : \mathbb{R}^m \to D'$. If $\{\xi_n\}$ is a collection of i.i.d. centred Gaussian processes taking values in the space of continuous functions $C(D';\mathbb{R}^m)$ then we define the Markov chain

$$u_{n+1}(x) = \xi_{n+1}\Big(F\big(u_n(x)\big)\Big). \tag{3}$$

The case $m = l$, $F = \mathrm{id}$ and $D = D' = \mathbb{R}^m$ was introduced by Damianou and Lawrence (2013) and the generalization here is inspired by the formulation of Duvenaud et al. (2014). The case where two layers are employed could be interpreted as a form of warped Gaussian process: a generalization of Gaussian processes that have been used successfully in a number of inference problems (Snelson et al., 2004; Schmidt and O'Hagan, 2003).

We note that the mapping $\xi \mapsto \xi \circ F \circ u$ is linear, and we may thus define $L(u)$ by $L(u)\xi = \xi \circ F \circ u$; hence the Markov chain may be written in the form (ZeroMean). If $\xi_1 \sim N(0,\Sigma)$ then the Markov chain has the form (CovOp), with mean zero and $C(u) = L(u)\Sigma L(u)^*$; if $\xi_1 \sim \mathrm{GP}\big(0, k(z,z')\big)$ then the Markov chain has the form (GP) with mean zero and $c(x,x';u) = k\Big(F\big(u(x)\big), F\big(u(x')\big)\Big)$.

2.2 Covariance Function

Paciorek (2003) gives a general strategy to construct anisotropic versions of isotropic covariance functions. Let $\Sigma : \mathbb{R}^d \to \mathbb{R}^{d\times d}$ be such that $\Sigma(z)$ is symmetric positive definite for all $z \in \mathbb{R}^d$, and define the quadratic form

$$Q(x,x') = (x-x')^T \left(\frac{\Sigma(x)+\Sigma(x')}{2}\right)^{-1}(x-x'), \qquad x,x' \in \mathbb{R}^d.$$

If the isotropic correlation function $\rho_S(\cdot)$ is positive definite on $\mathbb{R}^d$, for all $d \in \mathbb{N}$, then the function

$$c(x,x') = \sigma^2 \frac{2^{\frac{d}{2}} \det(\Sigma(x))^{\frac{1}{4}} \det(\Sigma(x'))^{\frac{1}{4}}}{\det(\Sigma(x)+\Sigma(x'))^{\frac{1}{2}}} \rho_S(\sqrt{Q(x,x')})$$

is positive definite on $\mathbb{R}^d \times \mathbb{R}^d$ and may thus be used as a covariance function. We make these statements precise below. If we choose Σ to depend on u_n then this may be used as the basis of a deep Gaussian process. To be concrete we choose

$$\Sigma(x) = F\big(u(x)\big) I_d$$

where $F : \mathbb{R} \to \mathbb{R}_{\geq 0}$ for $u : D \subseteq \mathbb{R}^d \to \mathbb{R}$. We then write $c(x,x';u)$. Now let $u_n : D \to \mathbb{R}$ and consider the Markov chain (GP) in the mean zero case. Paciorek (2003) considered this iteration over one-step with $u_0 \sim \mathrm{GP}(0, \sigma^2\rho_S(\|x-x'\|))$ and u_1 was shown to exhibit interesting non-stationary effects. Here we generalize and consider the deep process that results from this construction for arbitrary $n \in \mathbb{N}$. By considering the covariance operator

$$\big(C(u)\varphi\big)(x) = \int_{\mathbb{R}^d} c(x,x';u)\varphi(x')\,\mathrm{d}x'$$

we may write the iteration in the form (CovOp). The form (ZeroMean) follows with $L(u) = C(u)^{\frac{1}{2}}$ and ξ_{n+1} being white noise.

Various generalizations of this construction are possible, for example allowing the pointwise variance of the process σ^2 to be spatially varying (Heinonen et al., 2016) and to depend on $u_n(x)$. These may be useful in applications, but we confine our analysis to the simpler setting for expository purposes; however in Remark 12 we discuss this generalization.

In order to make the statements made above precise, let $\rho_S : [0,\infty) \to \mathbb{R}$ be a stationary covariance kernel, where the covariance between locations x and y depends only on the Euclidean distance $\|x-y\|_2$. We make the following assumption on ρ_S.

Assumptions 1 *(i) The covariance kernel $\rho_S(\|x-y\|_2)$ is positive definite[1] on $\mathbb{R}^d \times \mathbb{R}^d$: for any $N \in \mathbb{N}$, $b \in \mathbb{R}^N \backslash \{0\}$ and pairwise distinct $\{x_i\}_{i=1}^N \subseteq \mathbb{R}^d$, we have*

$$\sum_{i=1}^N \sum_{j=1}^N b_i b_j \rho_S\big(\|x_i - x_j\|_2\big) > 0.$$

(ii) ρ_S is normalized to be a correlation kernel, i.e. $\rho_S(0) = 1$.

Using (Wendland, 2004, Theorem 6.11), sufficient conditions for ρ_S to fulfill Assumptions 1(i) are that ρ_S, as a function of $x-y$, is continuous, bounded and in $L^1(\mathbb{R}^d)$, with a Fourier transform that is non-negative and non-vanishing. These sufficient conditions are satisfied, for example, for the family of Matèrn covariance functions and the Gaussian covariance. To satisfy Assumptions 1(ii), any positive definite kernel $\tilde{\rho}_S$ can simply be rescaled by $\tilde{\rho}_S(0)$.

We now have the following proposition, a slightly weaker version of which is proved by Paciorek (2003), where it is shown that $\rho(\cdot,\cdot)$ is positive semi-definite if ρ_S is positive semi-definite. Our proof, which is in the Appendix, follows closely that of (Paciorek, 2003, Theorem 1), but sharpens the result using a characterization of positive definite kernels proved in (Wendland, 2004, Theorem 7.14).

Proposition 1 *Let Assumptions 1 hold. Suppose $\Sigma : \mathbb{R}^d \to \mathbb{R}^{d\times d}$ is such that $\Sigma(z)$ is symmetric positive definite for all $z \in \mathbb{R}^d$, and define the quadratic form*

$$Q(x,x') = (x-x')^T \left(\frac{\Sigma(x)+\Sigma(x')}{2}\right)^{-1}(x-x'), \qquad x,x' \in \mathbb{R}^d.$$

Then the function $\rho(\cdot,\cdot)$, defined by

$$\rho(x,x') = \frac{2^{\frac{d}{2}} |\Sigma(x)|^{\frac{1}{4}} |\Sigma(x')|^{\frac{1}{4}}}{|\Sigma(x)+\Sigma(x')|^{\frac{1}{2}}} \rho_S\Big(\sqrt{Q(x,x')}\Big),$$

is positive definite on $\mathbb{R}^d \times \mathbb{R}^d$, for any $d \in \mathbb{N}$, and is a non-stationary correlation function.

1. If the double sum in this definition is only non-negative, we say that the kernel ρ_S is positive semi-definite. We are thus adopting the terminology used by Wendland (2004), where the kernel ρ_S is called positive definite if the double sum in Assumptions 1(i) is positive, and positive semi-definite if the sum is non-negative. For historical reasons, there is an alternative terminology, used by for example Paciorek (2003), where our notion of positive definite is referred to as strictly positive definite, and our notion of positive semi-definite is referred to as positive definite.

Non-stationary covariance functions $c(x,y)$, for which $c(x,x) \neq 1$, can be obtained from the non-stationary correlation function $\rho(x,y)$ through multiplication by a standard deviation function $\sigma : \mathbb{R}^d \to \mathbb{R}$, in which case we have $c(x,y) = \sigma(x)\sigma(y)\rho(x,y)$. Since the product of two positive definite kernels is also positive definite by (Wendland, 2004, Theorem 6.2), the kernel $c(x,y)$ can be ensured to be positive definite by a proper choice of σ. We discuss generalizations such as this in the conclusions section 5.

We are interested in studying the behaviour of Gaussian processes with non-stationary correlation functions $\rho(x,y)$ of the form derived in Proposition 1, in the particular case where the matrices $\Sigma(z)$ are derived from another Gaussian process. Specifically, we consider the following hierarchy of conditionally Gaussian processes on a bounded domain $D \subseteq \mathbb{R}^d$ defined as follows:

$$u_0 \sim \mathrm{GP}(0, \rho_{\mathrm{S}}(\cdot)), \tag{4a}$$

$$u_{n+1}|u_n \sim \mathrm{GP}(0, \rho(\cdot,\cdot;u_n)), \quad \text{for } n \in \mathbb{N}. \tag{4b}$$

Here, $\rho(\cdot,\cdot;u_n)$ denotes a non-stationary correlation function constructed from $\rho_{\mathrm{S}}(\cdot)$ as in Proposition 1, with the map Σ defined through u_n. Typical choices for Σ are $\Sigma(z) = (u_n(z))^2\,\mathrm{I}_d$ and $\Sigma(z) = \exp(u_n(z))\,\mathrm{I}_d$. Choices such as the first of these lead to the possibility of positive semi-definite Σ and, in the worst case, $\Sigma \equiv 0$. If $\Sigma \equiv 0$ the resulting correlation function is given by

$$\rho_{\mathrm{S}}(0) = 1, \quad \text{and} \quad \rho_{\mathrm{S}}(r) = 0 \quad \text{for any } r > 0.$$

This does not correspond to any (function valued) Gaussian process on $\mathbb{R}^d$ (Kallianpur, 2013): heuristically the resulting process would be a white noise process, but normalized to zero. However, it is possible to sample from any set of finite dimensional distributions when $\Sigma \equiv 0$: the correlation matrix is then the identity. To allow for the possibility of $F(\cdot)$ taking the value zero, we therefore only study the finite dimensional process defined as follows:

$$\mathbf{u}_0 \sim N(0, \mathbf{R}_{\mathrm{S}}), \tag{5a}$$

$$\mathbf{u}_{n+1} \mid \mathbf{u}_n \sim N(0, \mathbf{R}(\mathbf{u}_n)), \quad \text{for } n \in \mathbb{N}. \tag{5b}$$

The vector $\mathbf{u}_n$ has entries $(\mathbf{u}_n)_i = u_n(x_i)$. Here, $\mathbf{R}_{\mathrm{S}}$ is the covariance matrix with entries $(\mathbf{R}_{\mathrm{S}})_{ij} = \rho_{\mathrm{S}}(\|x_i - x_j\|_2)$, and $\mathbf{R}(\mathbf{u}_n)$ is the covariance matrix with entries $(\mathbf{R}(\mathbf{u}_n))_{ij} = \rho(x_i, x_j; u_n)$. The set $\{x_j\}$ comprises a finite set of points in $\mathbb{R}^d$.

We may now generalize Proposition 1 to allow for Σ becoming zero. In order to do this we make the following assumptions:

Assumptions 2 *(i) We have $\Sigma(z) = G(z)\mathrm{I}_d$, for some non-negative, bounded function $G : \mathbb{R} \to \mathbb{R}_{\geq 0}$.*

(ii) The correlation function ρ_{S} is continuous, with $\lim_{r\to\infty} \rho_{\mathrm{S}}(r) = 0$.

We then have the following result on the positive-definiteness of $\rho(\cdot,\cdot)$,

Proposition 2 *Let Assumptions 1 and 2 hold. Then the kernel $\rho(\cdot,\cdot)$ defined in Proposition 1 is positive definite on $\mathbb{R}^d \times \mathbb{R}^d$.*

Remark 3 *This proposition applies to the process (5) with $\Sigma(z) = F\big(u_n(z)\big)\mathrm{I}_d$ and $F : \mathbb{R} \to \mathbb{R}_{\geq 0}$ locally bounded, by taking $G = F \circ u_n$, proving that $\rho(\cdot,\cdot;u_n)$ is positive definite on $D \times D$ for all bounded functions u_n on D. Here we generalize the notion of positive-definite in the obvious way to apply on $D \subseteq \mathbb{R}^d$ rather than on the whole of $\mathbb{R}^d$.*

2.3 Covariance Operator

Here we demonstrate how precision (inverse covariance) operators may be used to make deep Gaussian processes. Because precision operators encode conditional independence and sparsity this can be a very attractive basis for fast computations (Lindgren et al., 2011). Our approach is inspired by the hierarchical Gaussian process introduced by Roininen et al. (2016), where one-step of the Markov chain which we introduce here was considered. Let $D \subseteq \mathbb{R}^d$, $u_n : D \to \mathbb{R}$ and $X := C(D;\mathbb{R})$. Assume that $F : \mathbb{R} \to \mathbb{R}_{\geq 0}$ is a bounded function. Let C_- be a covariance operator associated to a Gaussian process taking values in X and let P be the associated precision operator. Define the multiplication operator $\Gamma(u)$ by $\big(\Gamma(u)v\big)(x) = F\big(u(x)\big)v(x)$ and the covariance operator $C(u)$ by

$$C(u)^{-1} = P + \Gamma(u)$$

and consider the Markov chain (CovOp) with mean zero; this defines our deep Gaussian process. We note that formulation (GP) can be obtained by observing that the covariance function $c(u) := c(x,x';u)$ is the Green's function associated with the precision operator for $C(u)$:

$$C(u)^{-1}c(\cdot,x';u) = \delta_{x'}(\cdot)$$

where $\delta_{x'}$ is a Dirac delta function centred at point x'. Computationally we will typically choose P to be a differential operator, noting that then fast methods may be employed to sample the Gaussian process $u_{n+1}|u_n$ by means of SPDEs (Lindgren et al., 2011; Dashti and Stuart, 2017). If P is chosen as a differential operator, then the order of this operator will be related to the order of regularity of samples, and F will be related to the length scale of the samples. These relations are made explicit in the case of certain Whittle-Matérn distributions when F is constant (Lindgren et al., 2011); some boundary effects may be present when $D \neq \mathbb{R}^d$, though methodology is available to ameliorate these (Daon and Stadler, 2018). As in the previous subsection, the form (ZeroMean) follows with $L(u) = C(u)^{\frac{1}{2}}$ and ξ_{n+1} being white noise.

Generalizations of the construction in this subsection are possible, and we highlight these in subsection 5; however for expository purposes we confine our analysis to the setting described in this subsection. For theoretical investigation of the equivalence, as measures, of Gaussians defined by addition of an operator to a given precision operator (see Pinski et al., 2015).

2.4 Convolution

We consider the case (ZeroMean) where $L(u)\xi := u * \xi$ is a convolution. To be concrete we let $D = [0,1]^d$ and construct a sequence of functions $u_n : D \to \mathbb{R}$ (or $u_n : D \to \mathbb{C}$) defined via the iteration

$$u_{n+1}(x) = (u_n * \xi_{n+1})(x) := \int_{[0,1]^d} u_n(x-y)\xi_{n+1}(y)\,dy,$$

where $\{\xi_n\}$ are a sequence of i.i.d. centred real-valued Gaussian random functions on D. Here we implicitly work with periodic extension of u_n from D to the whole of $\mathbb{R}^d$ in order to define the convolution.

3. The Role of Ergodicity

The purpose of this section is to demonstrate that the iteration (ZeroMean) is, in many situations, ergodic. This has the practical implication that the effective depth of the deep Gaussian process is limited by the mixing time of the Markov chain. In some cases the ergodic behaviour may be trivial (convergence to a constant). Furthermore, even if the chain is not ergodic, the large iteration number dynamics may blow-up, prohibiting use of the iteration at significant depth. The take home message is that in many cases the effective depth is not that great. Great care will be needed to design deep Gaussian processes whose depth, and hence approximation power, is substantial. This issue was first identified by Duvenaud et al. (2014), and we here provide a more general analysis of the phenomenon within the broad framework we have introduced for deep Gaussian processes.

3.1 Composition

We first consider the case where the iteration is defined by (3), which includes examples considered by Damianou and Lawrence (2013); Duvenaud et al. (2014). Duvenaud et al. (2014) observed that after a number of iterations, sample paths are approximately piecewise constant. We investigate this effect in the context of ergodicity. We first make two observations:

(i) if u_0 is piecewise constant, then u_n is piecewise constant for all $n \in \mathbb{N}$;

(ii) if u_0 has discontinuity set Z_0, and Z_n denotes the discontinuity set of the nth iterate, then $\mathsf{Z}_{n+1} \subseteq \mathsf{Z}_n$ for all $n \in \mathbb{N}$.

Due to point (ii) above, if the sequence $\{u_n\}$ is to be ergodic, then necessarily it must be the case that $\mathsf{Z}_n \to \varnothing$, or else the process will have retained knowledge of the initial condition. In particular, if the initial condition is piecewise constant, then ergodicity would force the limit to be constant in space.

In what follows we assume that the iteration is given by

$$u_{n+1}(x) = \xi_{n+1}\big(u_n(x)\big), \quad \xi^j_{n+1} \sim \mathrm{GP}\big(0, h(\|x - x'\|_2)\big) \text{ i.i.d.}$$

where h is a stationary covariance function. We therefore make the choice $m = l$ and $F = \mathrm{id}$ in (3) so that we are in the same setup as Damianou and Lawrence (2013); Duvenaud et al. (2014); the inclusion of more general maps F is discussed in Remark 5. Then for any $x, x' \in \mathbb{R}$ we have

$$\begin{pmatrix} u^j_{n+1}(x) \\ u^j_{n+1}(x') \end{pmatrix} \Bigg| u_n \sim N\Bigg(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} h(0) & h\big(\|u_n(x) - u_n(x')\|_2\big) \\ h\big(\|u_n(x) - u_n(x')\|_2\big) & h(0) \end{pmatrix} \Bigg).$$

A common choice of covariance function is the squared exponential kernel:

$$h(z) = \sigma^2 e^{-z^2/2w^2} \tag{6}$$

where $\sigma^2, w^2 > 0$ are scalar parameters. In Duvenaud et al. (2014), in the case $m = d = 1$, the choice $\sigma^2/w^2 = \pi/2$ is made above to ensure that the expected magnitude of the derivative remains constant through iterations. We show in the next proposition that if σ^2, w^2 are chosen such that $\sigma^2 < w^2/m$, then the limiting process is trivial in a sense to be made precise.

Theorem 4 *Assume that $h(\cdot)$ is given by the squared exponential kernel (6) and that u_0 is bounded on bounded sets almost-surely. Then if $\sigma^2 < w^2/m$,*

$$\mathbb{P}\big(\|u_n(x) - u_n(x')\|_2 \to 0 \text{ for all } x, x' \in D\big) = 1$$

where $\mathbb{P}$ denotes the law of the process $\{u_n\}$ over the probability space Ω.

Proof Since $1 - e^{-x} \leq x$ for $x \geq 0$ it follows that, for all $z \in \mathbb{R}$,

$$2h(0) - 2h(z) \leq \frac{\sigma^2}{w^2} z^2,$$

with equality when $z = 0$. Then we have

$$\begin{aligned} \mathbb{E}\big(\|u_n(x) - u_n(x')\|_2^2 \big| u_{n-1}\big) &= \sum_{j=1}^m \mathbb{E}\big(|u^j_n(x) - u^j_n(x')|^2 \big| u_{n-1}\big) \\ &= \sum_{j=1}^m \big(2h(0) - 2h\big(\|u_{n-1}(x) - u_{n-1}(x')\|_2\big)\big) \\ &\leq m\frac{\sigma^2}{w^2}\|u_{n-1}(x) - u_{n-1}(x')\|_2^2 \end{aligned}$$

and so using induction and the tower property of conditional expectations,

$$\begin{aligned} \mathbb{E}\|u_n(x) - u_n(x')\|_2^2 &\leq \left(\frac{m\sigma^2}{w^2}\right)\mathbb{E}\|u_{n-1}(x) - u_{n-1}(x')\|_2^2 \\ &\leq \left(\frac{m\sigma^2}{w^2}\right)^n \mathbb{E}\|u_0(x) - u_0(x')\|_2^2 \\ &\leq \left(\frac{m\sigma^2}{w^2}\right)^n \kappa(x, x') \end{aligned}$$

for some constant $\kappa(x, x')$. By the Markov inequality, we see that for any $\varepsilon > 0$,

$$\mathbb{P}\big(\|u_n(x) - u_n(x')\|_2 \geq \varepsilon\big) \leq \frac{1}{\varepsilon^2}\left(\frac{m\sigma^2}{w^2}\right)^n \kappa(x, x'), \tag{7}$$

and so, since $\sigma^2 < w^2/m$, applying the first Borel-Cantelli lemma we deduce that

$$\mathbb{P}\left(\bigcap_{n=1}^\infty \bigcup_{m=n}^\infty \{\|u_m(x) - u_m(x')\|_2 \geq \varepsilon\}\right) = 0.$$

We therefore have that

$$\begin{aligned}\mathbb{P}(\|u_n(x)-u_n(x')\|_2\to 0) &= \mathbb{P}\left(\bigcap_{k=1}^{\infty}\bigcup_{n=1}^{\infty}\bigcap_{m=n}^{\infty}\{\|u_m(x)-u_m(x')\|_2<1/k\}\right)\\ &= 1-\mathbb{P}\left(\bigcup_{k=1}^{\infty}\left(\bigcap_{n=1}^{\infty}\bigcup_{m=n}^{\infty}\{\|u_m(x)-u_m(x')\|_2\geq 1/k\}\right)\right)\\ &\geq 1-\sum_{k=1}^{\infty}\mathbb{P}\left(\bigcap_{n=1}^{\infty}\bigcup_{m=n}^{\infty}\{\|u_m(x)-u_m(x')\|_2\geq 1/k\}\right)=1.\end{aligned}$$

Hence given any $x,x'\in D$, we can find $\Omega(x,x')\subseteq\Omega$ with $\mathbb{P}(\Omega(x,x'))=1$ such that for any $\omega\in\Omega(x,x')$, $\|u_n(x;\omega)-u_n(x';\omega)\|_2\to 0$. Let $\{q_j\}$ be a countable dense subset of D, and define

$$\Omega_* = \bigcap_{i,j\in\mathbb{N}}\Omega\left(q_i,q_j\right),$$

noting that $\mathbb{P}(\Omega_*)=1$. Then for any $\omega\in\Omega_*$ and any $x,x'\in\{q_j\}$, $\|u_n(x;\omega)-u_n(x';\omega)\|_2\to 0$. Since sample paths are almost-surely continuous, the above can be extended to all $x,x'\in D$, so that

$$\mathbb{P}\big(\|u_n(x)-u_n(x')\|_2\to 0 \text{ for all } x,x'\in D\big)=1.$$

■

Remark 5 *1. If a more general transformation map $F:\mathbb{R}^m\to D'$ is included, then the above result still holds provided we take $\sigma^2<w^2/(\|F'\|_\infty m)$. The convergence to a constant hence occurs when the length scale w is large or $\|F'\|_\infty$ is small (so each Gaussian random field doesn't change too rapidly across the domain), or when the amplitude σ is small (so inputs are not warped too far).*

2. The condition of the above theorem is less likely to be satisfied as the width m of each layer is increased, and so this triviality pathology is unlikely to arise for large m; this may be observed in practice numerically.

3. Following Neal (1995); Duvenaud et al. (2014), recent works (such as Dai et al., 2015; Cutajar et al., 2017) connect all layers to the input layer in order to avoid certain pathologies. The Markovian structure of the process is maintained in this case: with the above notation, the process is then defined by

$$u_{n+1}(x)=\xi_{n+1}(u_n(x),x),\quad \xi_{n+1}^j\sim\mathrm{GP}\big(0,h(\|x-x'\|_2)\big)\ i.i.d,$$

where now $\xi_n:\mathbb{R}^m\times\mathbb{R}^d\to\mathbb{R}^m$. Defining $\beta=m\sigma^2/w^2<1$, if $\sigma\geq 1$ we may use the same argument as the proof above to deduce that

$$\mathbb{E}\big(\|u_n(x)-u_n(x')\|_2^2|u_{n-1}\big)\leq\beta\|u_{n-1}(x)-u_{n-1}(x')\|_2^2+\beta\|x-x'\|_2^2,$$

which leads to

$$\mathbb{E}\|u_n(x)-u_n(x')\|_2^2\leq\beta^n\mathbb{E}\|u_0(x)-u_0(x')\|_2^2+\beta\left(\frac{1-\beta^n}{1-\beta}\right)\|x-x'\|_2^2.$$

The right hand side does not vanish as $n\to\infty$, and so we can no longer use the first Borel-Cantelli lemma to reach the same conclusion as the case where the layers are not connected to the input layer. This could provide some intuition as to why including the connection of each layer to the input layer provides greater stability than not doing so.

3.2 Covariance Function

In order to study ergodicity of the deep Gaussian process defined through covariance functions, we will restrict attention in the remainder of this subsection to hierarchies of finite-dimensional multivariate Gaussian random variables as in (5). Note that although we have here defined $\mathbf{u}_0\sim N(0,\mathbf{R}_S)$, following e.g. Paciorek (2003), the ergodicity of the deep Gaussian process will be proved for fixed $\mathbf{u}_0\in\mathbb{R}^N$ (cf. Theorem 8). The following result is immediate from Proposition 2.

Corollary 6 *Let Assumptions 1 and 2 hold. Then the covariance matrix $\mathbf{R}(\mathbf{u}_n)$ is positive definite for all $\mathbf{u}_n\in C$, for any compact subset of $C\subseteq\mathbb{R}^N$.*

Note that, because we have chosen to work with a correlation kernel, we have

$$\mathrm{Tr}\big(\mathbf{R}(\mathbf{u}_n)\big)=N. \tag{8}$$

We will use this fact explicitly in the ergodicity proof; however it may be relaxed as discussed in the Remark 12 below.

We view the sequence of random variables $\{\mathbf{u}_n\}_{n=0}^\infty$ as a Markov chain, with $\mathbf{u}_0\in\mathbb{R}^N$ given, and we want to show the existence of a stationary distribution. Recall the one-step transition kernel P of the Markov chain given by (1), and its $n-$fold composition given by (2). In order to prove ergodicity of the Markov chain we will follow the proof technique of Mattingly et al. (2002); Meyn and Tweedie (2012), which establishes geometric ergodicity with the following proposition.

Proposition 7 *Suppose the Markov chain $\{\mathbf{u}_n\}_{n=0}^\infty$ satisfies, for some compact set $C\in\mathcal{B}(\mathbb{R}^N)$, the following:*

(i) For some $y^*\in int(C)$ and for any $\delta>0$, we have

$$\mathsf{P}(u,\mathcal{B}_\delta(y^*))>0\qquad \text{for all } u\in C.$$

(ii) The transition kernel $\mathsf{P}(u,\cdot)$ possesses a density $p(u,y)$ in C, precisely

$$\mathsf{P}(u,A)=\int_A p(u,y)\,\mathrm{d}y,\quad \text{for all } u\in C,\ A\in\mathcal{B}(\mathbb{R}^N)\cap\mathcal{B}(C),$$

and $p(u,y)$ is jointly continuous on $C\times C$.

(iii) There is a function $V : \mathbb{R}^N \to [1,\infty)$, with $\lim_{u\to\infty} V(u) = \infty$, and real numbers $\alpha \in (0,1)$ and $\beta \in [0,\infty)$ such that

$$\mathbb{E}(V(\mathbf{u}_{n+1}) \,|\, \mathbf{u}_n) \leq \alpha V(\mathbf{u}_n) + \beta.$$

If we can choose the compact set C such that

$$C = \left\{ u : V(u) \leq \frac{2\beta}{\gamma - \alpha} \right\},$$

for some $\gamma \in (\sqrt{\alpha}, 1)$, then there exists a unique invariant measure π. Furthermore, there is $r(\gamma) \in (0,1)$ and $\kappa(\gamma) \in (0,\infty)$ such that for all $\mathbf{u}_0 \in \mathbb{R}^N$ and all measurable g with $|g(u)| \leq V(u)$ for all $u \in \mathbb{R}^N$, we have

$$|\mathbb{E}^{\mathsf{P}^n(\mathbf{u}_0,\cdot)}(g) - \pi(g)| \leq \kappa r^n V(\mathbf{u}_0).$$

We may verify the assumptions of Proposition 7 leading to the following theorem concerning the ergodicity of deep Gaussian processes defined via the covariance function:

Theorem 8 *Suppose Assumptions 1 and 2 hold. Then the Markov chain $\{\mathbf{u}_n\}_{n=0}^{\infty}$ satisfies the assumptions of Proposition 7. As a consequence, there exists $\varepsilon \in (0,1)$ such that for any $\mathbf{u}_0 \in \mathbb{R}^N$, there is a $K(\mathbf{u}_0) > 0$ with*

$$\|\mathsf{P}^n(\mathbf{u}_0,\cdot) - \pi\|_{TV} \leq K(1-\varepsilon)^n \quad \text{for all } n \in \mathbb{N},$$

and so the chain is ergodic.

The proof rests on the following three lemmas, and is given after stating and proving them. The first lemma shows that, on average, the norm of states of the chain remains constant as the length of the chain is increased. The second shows that, given any current state in $\mathbb{R}^N$ and any ball around the origin in $\mathbb{R}^N$, there is a positive probability that the next state will belong to that ball. The third lemma shows that the probability that the Markov chain moves to a set may be found via integration of a continuous function over that set.

Lemma 9 (Boundedness) *Suppose Assumptions 1 and 2 hold. For all $n \in \mathbb{N}$, we have*

$$\mathbb{E}\big(\|\mathbf{u}_{n+1}\|_2^2 \,|\, \mathbf{u}_n\big) = N.$$

Proof Let $n \geq 0$. Since the random variable $\mathbf{u}_{n+1}|\mathbf{u}_n$ has zero mean, the linearity of expectation implies (using (8)) that

$$\mathbb{E}\left(\|\mathbf{u}_{n+1}\|_2^2 \,|\, \mathbf{u}_n\right) = \mathbb{E}\left(\sum_{j=1}^{N} (\mathbf{u}_{n+1})_j^2 \,\middle|\, \mathbf{u}_n \right) = \mathrm{Tr}(\mathbf{R}(\mathbf{u}_n)) = N,$$

for all $n \in \mathbb{N}$. ■

Lemma 10 (Positive probability of a ball around zero) *Suppose Assumptions 1 and 2 hold. For all $u \in \mathbb{R}^N$ and $\delta > 0$, we have*

$$\mathsf{P}\big(u, \mathcal{B}_\delta(0)\big) > 0.$$

Proof We have the equality $\mathbf{u}_{n+1}|(\mathbf{u}_n = u) = \sqrt{\mathbf{R}(u)}\xi_{n+1}$ in distribution, where $\sqrt{\mathbf{R}(u)}$ denotes the Cholesky factor of the correlation matrix $\mathbf{R}(u)$ and $\xi_{n+1} \sim \mathrm{N}(0, \mathrm{I}_N)$. Then

$$\begin{aligned}
\mathsf{P}\big(u, \mathcal{B}_\delta(0)\big) &= \mathbb{P}\big(\|\mathbf{u}_n\|_2 \leq \delta \,|\, \mathbf{u}_{n-1} = u\big) \\
&= \mathbb{P}\Big(\big\|\sqrt{\mathbf{R}(u)}\xi_{n+1}\big\|_2 \leq \delta\Big) \\
&\geq \mathbb{P}\Big(\big\|\sqrt{\mathbf{R}(u)}\big\|_2 \big\|\xi_{n+1}\big\|_2 \leq \delta\Big) \\
&= \mathbb{P}\Big(\big\|\xi_{n+1}\big\|_2 \leq \delta \big\|\sqrt{\mathbf{R}(u)}\big\|_2^{-1}\Big).
\end{aligned}$$

To show that the latter probability is positive, we need to show that $\delta\big\|\sqrt{\mathbf{R}(u)}\big\|_2^{-1} > 0$. Since $\delta > 0$ is fixed, we only need to show $\big\|\sqrt{\mathbf{R}(u)}\big\|_2 < \infty$. Since $\big\|\sqrt{\mathbf{R}(u)}\big\|_2^2 = \rho(\mathbf{R}(u))$, the spectral radius of $\mathbf{R}(u)$, we have

$$\big\|\sqrt{\mathbf{R}(u)}\big\|_2^2 = \rho(\mathbf{R}(u)) \leq \mathrm{Tr}(\mathbf{R}(u)) = N.$$

The claim then follows. ■

Lemma 11 (Transition probability has a density) *Suppose Assumptions 1 and 2 hold. Then the transition probability $\mathsf{P}\big(u,\cdot\big)$ has a jointly continuous density $p(u,y)$ for all $u \in C$, for any compact set $C \subseteq \mathbb{R}^N$.*

Proof We have $\mathbf{u}_{n+1}|(\mathbf{u}_n = u) \sim N(0, \mathbf{R}(u))$, and the existence of a jointly continuous density of the transition probability in C follows if $\mathbf{R}(u)$ is positive definite for all $u \in C$. The claim then follows by Proposition 2. ■

We may now use the three preceding lemmas to prove the main ergodic theorem for deep Gaussian processes defined through the covariance function.

Proof of Theorem 8 Lemma 10 shows that assumption (i) is satisfied, for any C containing $y^* = 0$, and Lemma 11 shows that assumption (ii) is satisfied, for any compact set C. It follows from Lemma 9 that assumption (iii) is satisfied, with $V(u) = \|u\|_2^2 + 1$, any $\alpha \in (0,1)$ and $\beta = N + 1$. Now choose $\alpha = 1/4$ and $\gamma = 3/4 \in (\sqrt{\alpha}, 1)$, so that the set

$$C = \left\{ u : V(u) \leq \frac{2\beta}{\gamma - \alpha} \right\} = \big\{ u : \|u\|_2^2 \leq 4N + 4 \big\}$$

is compact. Then there is a unique invariant measure π, and there is $r(\gamma) \in (0,1)$ and $\kappa(\gamma) \in (0,\infty)$ such that for $\mathbf{u}_0 \in \mathbb{R}^N$ and all measurable g with $|g(u)| \leq V(u)$ for all $u \in \mathbb{R}^N$, we have

$$|\mathbb{E}^{\mathsf{P}^n(\mathbf{u}_0,\cdot)}(g) - \pi(g)| \leq \kappa r^n V(\mathbf{u}_0). \tag{9}$$

Since $V(u) \geq 1$ for all $u \in \mathbb{R}^N$, the above holds in particular for all measurable g with $\|g\|_\infty \leq 1$. Taking the supremum over all such g in (9) yields the given total variation bound, with $K = \kappa V(\mathbf{u}_0)$ and $\varepsilon = 1 - r$. ■

Remark 12 *(Covariance vs correlation kernels) In this subsection we have restricted our attention to correlation kernels $\rho_S(\|x_i - x_j\|_2)$ and $\rho(x_i, x_j; u_n)$, rather than more general covariance kernels*

$$c_S(\|x_i - x_j\|_2) = \sigma_S^2 \rho_S(\|x_i - x_j\|_2),$$
$$c(x_i, x_j; u_n) = \sigma(x_i; u_n)\sigma(x_j; u_n)\rho(x_i, x_j; u_n),$$

for stationary and non-stationary marginal standard deviation functions $\sigma_S \in (0, \infty)$ and $\sigma : \mathbb{R}^d \to (0, \infty)$ respectively. This restriction is solely for ease of presentation; the analysis presented readily extends to $c(x_i, x_j; u_n)$, under suitable assumptions on σ. In particular the analysis may be adapted to the case of general covariance kernels $c_S(\|x_i - x_j\|_2)$ and $c(x_i, x_j; u_n)$ under the assumption that there exist positive constants σ^-, σ^+ such that $\sigma^- \leq \sigma(z) \leq \sigma^+$, for all $z \in \mathbb{R}^d$. When general covariances are used then it is possible to ensure that every multivariate Gaussian random variable in the hierarchy is of the same amplitude by scaling the corresponding covariance matrix $\mathbf{C}(\mathbf{u}_n)$ to have constant trace N at each iteration n; the average variance over all points $\{x_i\}_{i=1}^N$ is then 1 for every n.

3.3 Covariance Operator

We consider the class of covariance operators introduced in section 2.3 and show that, under precise assumptions detailed below, the iteration (ZeroMean) produces an ergodic Markov chain. Unlike the previous subsection, where we worked on $\mathbb{R}^N$, here we will work on the separable Hilbert space $\mathcal{H} = L^2(D; \mathbb{R})$. To begin with, define the precision operators (densely defined on $\mathcal{H}$: Hairer et al., 2005; Pinski et al., 2015),

$$C_-^{-1} = P,$$
$$C_+^{-1} = P + F_+ I,$$
$$C(u)^{-1} = P + \Gamma(u), \quad u \in \mathcal{H},$$

and the probability measures

$$\mu_- = N(0, C_-),$$
$$\mu_+ = N(0, C_+),$$
$$\mu(\cdot\,; u) = N(0, C(u)), \quad u \in \mathcal{H}.$$

Throughout the rest of this section we make the following assumptions on C_- and F:

Assumptions 3 *1. The operator $C_- : \mathcal{H} \to \mathcal{H}$ is symmetric and positive, and its eigenvalues $\{\lambda_j^2\}$ have algebraic decay $\lambda_j^2 \asymp j^{-r}$ for some $r > 1$.*

2. The function $F : \mathcal{H} \to \mathbb{R}$ is continuous, and there exists $F_+ \geq 0$ such that $0 \leq F(u) \leq F_+$ for all $u \in \mathcal{H}$.

Remark 13 *1. The assumption on algebraic decay of the eigenvalues can be relaxed to the operator C_- being trace-class on $\mathcal{H}$; however the arguments that follow are cleaner when we assume this explicit decay which, of course, implies the trace condition. Note also that, under the stated assumption on algebraic decay, Gaussian measures on $L^2(D; \mathbb{R})$ will be supported on $X = C(D; \mathbb{R})$ under mild conditions on the eigenfunctions of C_- (Dashti and Stuart, 2017) so that $F\big(u(x)\big)$ will be defined for all $x \in D$ rather than x a.e. in D. Then $\Gamma(u)v$ makes sense pointwise when $v \in X$.*

2. The assumed form of the precision operator together with Assumptions 3 mean that the resulting family of measures $\{\mu(\cdot; u)\}_{u \in \mathcal{H}}$ will be mutually equivalent. This allows for the total variation metric between measures to be used, and a concise proof of ergodicity to be obtained. If the measures were singular, a different metric such as the Wasserstein metric would be required to quantify the convergence.

We now prove the following ergodic theorem for the deep Gaussian processes constructed through covariance operators.

Theorem 14 *Let Assumptions 3 hold, and let the Markov chain $\{u_n\}$ be given by (ZeroMean) with $L(u) = C(u)^{\frac{1}{2}}$ as defined above. Then there exists a unique invariant distribution π, and there exists $\varepsilon > 0$ such that for any $u_0 \in \mathcal{H}$,*

$$\|\mathsf{P}^n(u_0, \cdot) - \pi\|_{TV} \leq (1 - \varepsilon)^n \quad \text{for all } n \in \mathbb{N}.$$

In particular, the chain is ergodic.

The following lemma will be used to show a minorization condition, as well as establish further notation, key to the proof of Theorem 14 which follows it. It essentially shows a stronger form of equivalence of the family of measures $\{\mu(\cdot, u)\}_{u \in \mathcal{H}}$.

Lemma 15 *Let Assumptions 3 hold. Then there exists $\varepsilon > 0$ such that for any $u, v \in \mathcal{H}$,*

$$\frac{\mathrm{d}\mu(\cdot\,; u)}{\mathrm{d}\mu_+}(v) \geq \varepsilon.$$

Proof The assumptions on F mean that the measures $\mu(\cdot\,; u)$, μ_- and μ_+ are mutually absolutely continuous, with

$$\frac{\mathrm{d}\mu(\cdot\,; u)}{\mathrm{d}\mu_-}(v) = \frac{1}{Z(u)} \exp\Big(-\frac{1}{2}\langle v, F(u)v\rangle\Big),$$
$$Z(u) = \mathbb{E}^{\mu_-}\Big[\exp\Big(-\frac{1}{2}\langle v, F(u)v\rangle\Big)\Big];$$
$$\frac{\mathrm{d}\mu_+}{\mathrm{d}\mu_-}(v) = \frac{1}{Z_+} \exp\Big(-\frac{1}{2}\langle v, F_+ v\rangle\Big),$$
$$Z_+ = \mathbb{E}^{\mu_-}\Big[\exp\Big(-\frac{1}{2}\langle v, F_+ v\rangle\Big)\Big].$$

Observe that we may bound $Z(u) \leq 1$ uniformly in $u \in H$ since $F \geq 0$. Additionally, we have that

$$Z_+ \geq \mathbb{E}^{\mu_-}\left[\exp\left(-\frac{1}{2}\langle v, F_+ v\rangle\right)\mathbb{1}_{\|v\|^2\leq 1}\right] \geq \exp\left(-\frac{1}{2}F_+\right)\mu_-\big(\|v\|^2 \leq 1\big) =: \varepsilon > 0.$$

Note that ε is positive since $\mathcal{H}$ is separable, and thus all balls have positive measure (Hairer, 2009). It follows that

$$\begin{aligned}\frac{\mathrm{d}\mu(\cdot\,;u)}{\mathrm{d}\mu_+}(v) &= \frac{\mathrm{d}\mu(\cdot\,;u)}{\mathrm{d}\mu_-}(v) \times \left(\frac{\mathrm{d}\mu_+}{\mathrm{d}\mu_-}(v)\right)^{-1} \\ &= \frac{1}{Z(u)}\exp\left(-\frac{1}{2}\langle v, F(u)v\rangle\right) \times Z_+ \exp\left(\frac{1}{2}\langle v, F_+ v\rangle\right) \\ &\geq \varepsilon \exp\left(\frac{1}{2}\langle v, (F_+ - F(u))v\rangle\right) \\ &\geq \varepsilon\end{aligned}$$

since F_+ bounds F above uniformly. ■

Proof of Theorem 14 We first establish existence of at least one invariant distribution by showing that chain $\{u_n\}$ is (strong) Feller, and that for each $u_0 \in \mathcal{H}$ the family $\{\mathsf{P}^n(u_0, \cdot)\}$ of transition kernels is tight. To see the former, let $f : \mathcal{H} \to \mathbb{R}$ be any bounded measurable function. We have that, for any $v \in \mathcal{H}$,

$$\begin{aligned}(\mathsf{P}f)(u) &:= \int_{\mathcal{H}} f(v)\mathsf{P}(u, \mathrm{d}v) \\ &= \int_{\mathcal{H}} f(v)\frac{1}{Z(u)}\exp\left(-\frac{1}{2}\langle v, F(u)v\rangle\right)\mu_-(\mathrm{d}v).\end{aligned}$$

Since $F(u) \leq F_+$ it follows that $Z(u)$ is bounded below by a positive constant, uniformly with respect to u. Additionally F is continuous and non-negative, and so the integrand is bounded and continuous with respect to u. Hence given any sequence $u^{(k)} \to u$ in $\mathcal{H}$, we may apply the dominated convergence theorem to see that $(\mathsf{P}f)(u^{(k)}) \to (\mathsf{P}f)(u)$. The function $\mathsf{P}f$ is therefore continuous, and so the chain $\{u_n\}$ is strong Feller.

We now show tightness. The assumptions on the operator $C_- : \mathcal{H} \to \mathcal{H}$ imply that it is trace-class, and so in particular compact. It is also positive and symmetric, and so by the spectral theorem, admits a complete orthonormal system of eigenvectors $\{\varphi_j\}$ with corresponding positive eigenvalues $\{\lambda_j^2\}$ such that $\lambda_j^2 \to 0$. Given $s > 0$, define the subspace $\mathcal{H}^s \subset \mathcal{H}$ by

$$\mathcal{H}^s = \left\{ v \in \mathcal{H} \;\middle|\; \|v\|_{\mathcal{H}^s}^2 := \sum_{j=1}^{\infty} j^{2s}|\langle \varphi_j, v\rangle|^2 < \infty \right\}.$$

It is standard to show that $\mathcal{H}^s$ is compactly embedded in $\mathcal{H}$ for any $s > 0$ (see for example Robinson, 2001, Appendix A.2). By the Karhunen-Loéve theorem, any $v \sim \mu_-$ may be represented as

$$v = \sum_{j=1}^{\infty} \lambda_j \xi_j \varphi_j, \quad \xi_j \sim N(0,1) \text{ i.i.d.}$$

Hence, by the orthonormality of the $\{\varphi_j\}$ and the assumed decay of the eigenvalues, we have that

$$\mathbb{E}^{\mu_-}\big(\|v\|_{\mathcal{H}^s}^2\big) = \sum_{j=1}^{\infty} j^{2s}\lambda_j^2 \asymp \sum_{j=1}^{\infty} j^{2s-r}$$

and so

$$\mathbb{E}^{\mu_-}\big(\|v\|_{\mathcal{H}^s}^2\big) < \infty \quad \text{if and only if} \quad s < \frac{r}{2} - \frac{1}{2}.$$

Since $r > 1$ by assumption, we can always choose $s > 0$ such that this holds; fix such an s in what follows. Observe that, for any $n \in \mathbb{N}$,

$$\begin{aligned}\mathbb{E}\big(\|u_n\|_{\mathcal{H}^s}^2\big) &= \mathbb{E}\big(\mathbb{E}\big(\|u_n\|_{\mathcal{H}^s}^2 \big| u_{n-1}\big)\big) \\ &= \mathbb{E}\big(\mathbb{E}^{\mu(\cdot\,;u_{n-1})}\big(\|v\|_{\mathcal{H}^s}^2\big)\big) \\ &= \mathbb{E}\left(\int_{\mathcal{H}} \|v\|_{\mathcal{H}^s}^2 \frac{1}{Z(u_{n-1})}\exp\left(-\frac{1}{2}\langle v, F(u_{n-1})v\rangle\right)\mu_-(\mathrm{d}v)\right) \\ &\leq \frac{1}{Z_+}\mathbb{E}^{\mu_-}\big(\|v\|_{\mathcal{H}^s}^2\big) \\ &=: M < \infty.\end{aligned}$$

We have bounded $Z(u_{n-1}) \geq Z_+$ using that $F(u_{n-1}) \leq F_+$. Applying the Chebychev inequality, we have for each $n \in N$ and $R > 0$

$$\mathbb{P}\big(\|u_n\|_{\mathcal{H}^s} > R\big) \leq \frac{\mathbb{E}\big(\|u_n\|_{\mathcal{H}^s}^2\big)}{R^2} \leq \frac{M}{R^2},$$

and so given any $\kappa > 0$,

$$\mathbb{P}\left(\|u_n\|_{\mathcal{H}^s} \leq \sqrt{\frac{M}{\kappa}}\right) \geq 1 - \kappa.$$

This can be rewritten as

$$\mathsf{P}^n(u_0, K_\kappa) \geq 1 - \kappa$$

where $K_\kappa = \big\{u \in \mathcal{H} \,\big|\, \|u\|_{\mathcal{H}^s} \leq \sqrt{M/\kappa}\big\}$ is compact in $\mathcal{H}$, since $\mathcal{H}^s$ is compactly embedded in $\mathcal{H}$; this shows tightness of the sequence of probability measures $\mathsf{P}^n(u_0, \cdot)$. Since tightness implies boundedness in probability on average, an application of (Meyn and Tweedie, 2012, Theorem 12.0.1) gives existence of an invariant distribution.

Lemma 15 shows that $\{u_n\}$ satisfies a global minorization condition for the one-step transition probabilities: for any $u_0 \in \mathcal{H}$ and any measurable $A \subseteq \mathcal{H}$,

$$\mathsf{P}\big(u_0, A\big) = \mathbb{E}^{\mu(\cdot\,;u_0)}\big(\mathbb{1}_A(v)\big) = \mathbb{E}^{\mu_+}\left(\frac{\mathrm{d}\mu(\cdot\,;u_0)}{\mathrm{d}\mu_+}(v)\mathbb{1}_A(v)\right) \geq \varepsilon\mu_+(A).$$

Combined with the existence of an invariant distribution above, a short coupling argument (Meyn and Tweedie, 2012, Theorem 16.2.4) gives the result with the same ε as above. ■

3.4 Convolution

The convolution iteration has the advantage that, through use of Fourier series and the law of large numbers, its long time behaviour can be completely characterized analytically. We consider the convolution as a random map on $\mathcal{H} = L^2(D;\mathbb{C})$, $D = (0,1)^d$. The iteration is given by

$$u_{n+1}(x) = (u_n * \xi_{n+1})(x) := \int_D u_n(x-y)\xi_{n+1}(y)\,dy, \quad \xi_{n+1} \sim N(0,C) \text{ i.i.d.} \tag{10}$$

where we implicitly work with periodic extensions to define the convolution. We assume that C is a negative fractional power of a differential operator so that it diagonalizes in Fourier space; such a form of covariance operator is common in applications, as it includes, for example, Whittle-Matérn distributions (Lindgren et al., 2011). For example, we may take

$$C = (I - \triangle)^{-\alpha}, \quad D(-\triangle) = H^2_{\text{per}}([0,1]^d) \subset \mathcal{H},$$

in which case the samples $\xi_{n+1} \sim N(0,C)$ will (almost surely) possess s fractional Sobolev and Hölder derivatives for any $s < \alpha - d/2$ (see Dashti and Stuart, 2017, for details).

We choose the orthonormal Fourier basis

$$\varphi_k(x) = e^{2\pi i k\cdot x}, \quad k \in \mathbb{Z}^d,$$

which are the eigenvectors of C; we denote the corresponding eigenvalues $\{\lambda_k^2\}$. Given $u \in \mathcal{H}$ and $k \in \mathbb{Z}^d$, define the Fourier coefficient $\hat{u}(k) \in \mathbb{C}$ by

$$\hat{u}(k) := \langle \varphi_k, u\rangle_{L^2} = \int_D \overline{\varphi_k(x)}u(x)\,\mathrm{d}x.$$

Then it can be readily checked that for any $u, v \in \mathcal{H}$ and $k \in \mathbb{Z}^d$,

$$\widehat{(u*v)}(k) = \hat{u}(k)\hat{v}(k). \tag{11}$$

We use this property to establish the following theorem.

Theorem 16 *Let $C : \mathcal{H} \to \mathcal{H}$ be a negative fractional power of a differential operator such that C is positive, symmetric and trace-class, with eigenvectors $\{\psi_k\}$ and eigenvalues $\{\lambda_k^2\}$. Define the Markov chain $\{u_n\}$ by (10). Then for any $u_0 \in \mathcal{H}$,*

$$\lim_{n\to\infty} |\hat{u}_n(k)|^2 = \begin{cases} 0 & |\lambda_k|^2 < 2e^\gamma \\ \infty & |\lambda_k|^2 > 2e^\gamma \end{cases} \quad \textit{almost surely}$$

where $\gamma \approx 0.577$ is the Euler-Mascheroni constant. In particular, if $|\lambda_k|^2 < 2e^\gamma$ for all $k \in \mathbb{Z}^d$, then every Fourier coefficient of u_n tends to zero almost surely and hence $u_n \rightharpoonup 0$ in $\mathcal{H}$ almost surely.

Proof First observe that by the Karhunen-Loéve theorem, we may express $\xi_{n+1} \sim N(0,C)$ as

$$\xi_{n+1} = \sum_{k\in\mathbb{Z}^d} \lambda_k \eta_{n,k}\varphi_k, \quad \eta_{n,k} \sim N(0,1) \text{ i.i.d.}$$

and so, since $\{\varphi_k\}$ is orthonormal,

$$\hat{\xi}_{n+1}(k) = \lambda_k \eta_{n,k}.$$

Then by the property (11), we see that for each $k \in \mathbb{Z}^d$ and $n \in \mathbb{N}$,

$$\hat{u}_{n+1}(k) = \hat{u}_n(k)\hat{\xi}_{n+1}(k) = \hat{u}_n(k)\lambda_k\eta_{n,k} \tag{12}$$

where the second equality is in distribution. The problem has now been reduced to an independent family of scalar problems. We can write $\hat{u}_n(k)$ explicitly as

$$\hat{u}_n(k) = \hat{u}_0(k)\prod_{j=1}^n \lambda_k \eta_{j,k}. \tag{13}$$

Now observe that

$$\begin{aligned} |\hat{u}_n(k)|^2 &= |\hat{u}_0(k)|^2 \prod_{j=1}^n |\lambda_k|^2 |\eta_{j,k}|^2 \\ &= |\hat{u}_0(k)|^2 \exp\left(n \cdot \frac{1}{n}\sum_{j=1}^n \log\left(|\lambda_k|^2|\eta_{j,k}|^2\right)\right) \\ &= |\hat{u}_0(k)|^2 \exp\left(n \cdot \left(\frac{1}{n}\sum_{j=1}^n \log|\eta_{j,k}|^2 + \log|\lambda_k|^2\right)\right). \end{aligned} \tag{14}$$

By the strong law of large numbers, the scaled sum inside the exponential converges almost surely to $\mathbb{E}(\log|\eta_{1,k}|^2)$. This can be calculated as

$$\mathbb{E}(\log|\eta_{1,k}|^2) = -\gamma - \log 2.$$

If the bracketed term inside the exponential in (14) is eventually negative almost surely, then the limit of $|u_n(k)|^2$ will be zero almost surely. This is guaranteed when $-\gamma - \log 2 + \log|\lambda_k|^2 < 0$, i.e. $|\lambda_k|^2 < 2e^\gamma$. Similarly we get divergence if the bracketed term is eventually positive, which happens when $|\lambda_k|^2 > 2e^\gamma$. ■

Remark 17 *It is interesting to note that we may take expectations in (12) to establish that*

$$\mathbb{E}|\hat{u}_n(k)|^2 = |\hat{u}_0(k)|^2|\lambda_k|^{2n}$$

and so

$$\lim_{n\to\infty} \mathbb{E}|\hat{u}_n(k)|^2 = \begin{cases} 0 & |\lambda_k|^2 < 1 \\ \infty & |\lambda_k|^2 > 1 \end{cases}.$$

In particular, if $|\lambda_k|^2 \in (1, 2e^\gamma)$, then $|\hat{u}_n(k)|^2$ converges to zero almost surely, but diverges in mean square.

Via a slight modification of the above proof to account for different boundary conditions, we have the following result.

Corollary 18 *Let $D = (0,1)$ and let $\{u_n\}$ be defined by the iteration (10), where each ξ_{n+1} is a Brownian bridge. Then $u_n \rightharpoonup 0$ almost surely.*

Proof The Brownian bridge on $[0,1]$ has covariance operator $(-\triangle)^{-1}$, where

$$D(-\triangle) = \{u \in H^2_{\text{per}}([0,1]) \,|\, u(0) = u(1) = 0\}.$$

The result of Theorem 16 cannot be applied directly, since the basis functions $\{\varphi_k\}$ do not satisfy the boundary conditions. The eigenfunctions with the correct boundary conditions are given by

$$\psi_j(x) = \sqrt{2}\sin(j\pi x) = \frac{1}{\sqrt{2}i}\big(\varphi_j(x) - \varphi_{-j}(x)\big), \quad j \geq 1$$

with corresponding eigenvalues $\alpha_j^2 = (\pi^2 j^2)^{-1}$. A Brownian bridge $\xi_{n+1} \sim N(0, (-\triangle)^{-1})$ can then be expressed as

$$\xi_{n+1} = \sum_{j=1}^{\infty} \alpha_j \zeta_{n,j} \psi_j, \quad \zeta_{n,j} \sim N(0,1) \text{ i.i.d.}$$

by the Karhunen-Loéve theorem. We calculate

$$\begin{aligned}
\hat{u}_{n+1}(k) &= \hat{u}_n(k)\hat{\xi}_n(k) \\
&= \hat{u}_n(k) \sum_{j=1}^{\infty} \alpha_j \zeta_{n,j} \langle \varphi_k, \psi_j \rangle \\
&= \hat{u}_n(k) \sum_{j=1}^{\infty} \alpha_j \zeta_{n,j} \frac{1}{\sqrt{2}i} \big(\langle \varphi_k, \varphi_j \rangle - \langle \varphi_k, \varphi_{-j} \rangle \big) \\
&= \hat{u}_n(k) \frac{\text{sgn}(k)\alpha_{|k|}}{\sqrt{2}i} \zeta_{n,|k|} \\
&= \hat{u}_n(k) \lambda_k \eta_{n,k}, \quad \eta_{n,k} \sim N(0,1).
\end{aligned}$$

We can now proceed as in Theorem 16 to deduce that $|u_n(k)|^2 \to 0$ whenever $|\lambda_k|^2 < 2e^\gamma$; note that the correlations between $\hat{u}_n(k)$ and $\hat{u}_n(-k)$ do not affect the argument. Now observe that $|\lambda_k|^2 = (2\pi^2 k^2)^{-1} < 1 < 2e^\gamma$ for all k, and the result follows. ■

Remark 19 *The preceding results also holds if we replace the Brownian bridge by a Gaussian process with precision operator the negative Laplacian subject to Neumann boundary conditions and spatial mean zero; the eigenfunctions are then*

$$\psi_j(x) = \sqrt{2}\cos(j\pi x) = \frac{1}{\sqrt{2}}\big(\varphi_j(x) + \varphi_{-j}(x)\big), \quad j \geq 1.$$

The argument is identical, except no sgn(k) *term appears in λ_k.*

4. Numerical Illustrations

We now study two of the constructions of deep Gaussian processes numerically. In subsection 4.1 we look at realizations of the deep Gaussian process constructed using the covariance function formulation, and in subsection 4.2 we perform similar experiments for the covariance operator formulations. Finally we consider Bayesian inverse problems, in which we choose deep Gaussian processes as our prior distributions; we introduce a function space MCMC algorithm, which scales well under mesh refinement of the functions to be inferred, for sampling.

For the composition construction, numerical experiments are given by, for example, Damianou and Lawrence (2013); Duvenaud et al. (2014). We do not provide numerical experiments for the convolution construction; Theorem 16 tells us that interesting behaviour cannot be expected in this case.

4.1 Covariance Function

We start by investigating typical realizations of a deep Gaussian process, constructed through anisotropic covariance kernels as in section 2.2. As the basis of our construction, we choose a stationary Gaussian correlation kernel, given by

$$\rho_S(r) = \exp(-r^2), \qquad r > 0.$$

The function F determining the length scale of the kernel $\rho(\cdot, \cdot; u_n)$ is chosen as $F(x) = x^2$, such that $\Sigma(z) = (u_n(z))^2 \, \mathrm{I}_d$. Similar results are obtained with other choices of F in terms of the distribution of samples u_n. The choice of F does, however, influence the conditioning of the correlation matrix $\mathbf{R}(\mathbf{u}_n)$, and the choice $F(x) = \exp(x)$, for example, can lead to numerical instabilities. As described in section 2.2, we will sample from the finite dimensional distributions obtained by sampling from the Gaussian process at a finite number of points in the domain D. To generate the samples, we use the command `mvnrnd` in MATLAB, and when plotting the samples, we use linear interpolation.

In Figure 1, we show four independent realizations of the first seven layers $u_0, \ldots, u_6$, where u_0 is taken as a sample of the stationary Gaussian process with correlation kernel ρ_S. The domain D is here chosen as the interval $(0,1)$, and the sampling points are given by the uniform grid $x_i = \frac{i-1}{256}$, for $i = 1, \ldots, 257$. Each column in Figure 1 corresponds to one realization, and each row corresponds to a given layer u_n, the first row showing u_0. We can clearly see the non-stationary behaviour in the samples when progressing through the levels. We note that the ergodicity of the chain is also reflected in the samples, with the distribution of the samples u_n looking similar for larger values of n.

Figure 2 shows the same information as Figure 1, in the case where the domain D is $(0,1)^2$ and the sampling points are the tensor product of the one-dimensional points $x_i^1 = \frac{i-1}{64}$, for $i = 1, \ldots, 65$.

4.2 Covariance Operator

We now consider the covariance operator construction of the deep Gaussian process. In order to produce more interesting behaviour in the samples, we move away from the absolutely continuous setting considered in section 3.3 by introducing a rescaling of $C(u)$ that depends

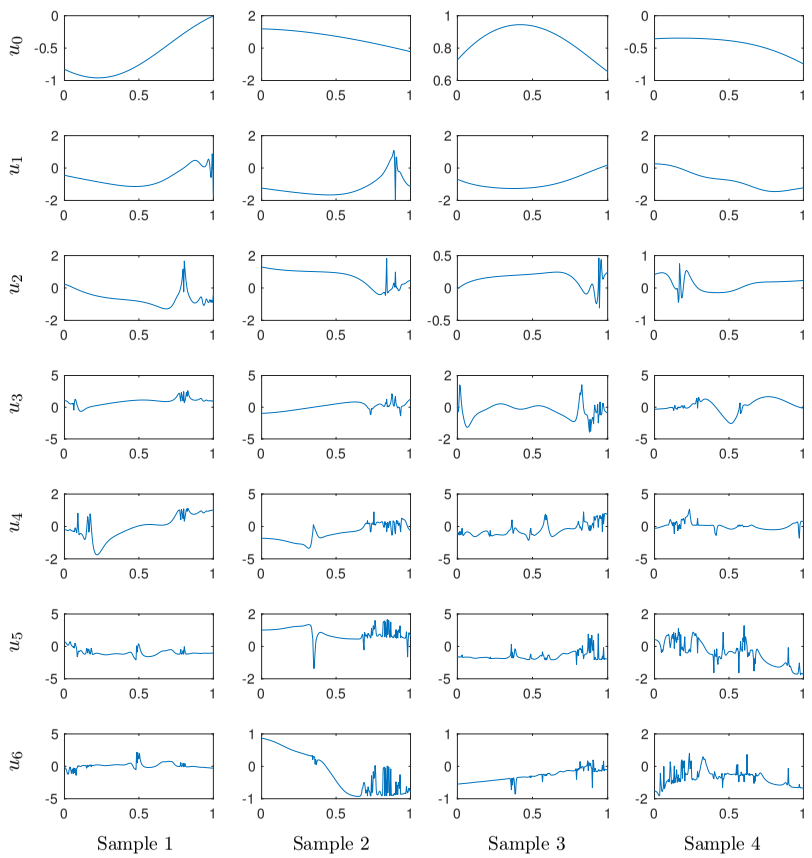

Figure 1: Four independent realizations of the first seven layers of a deep Gaussian process, in one spatial dimension, using the covariance kernel construction described in subsection 2.2. Each column corresponds to an independent chain, and layers $u_0, u_1, \ldots, u_6$ are shown from top-to-bottom.

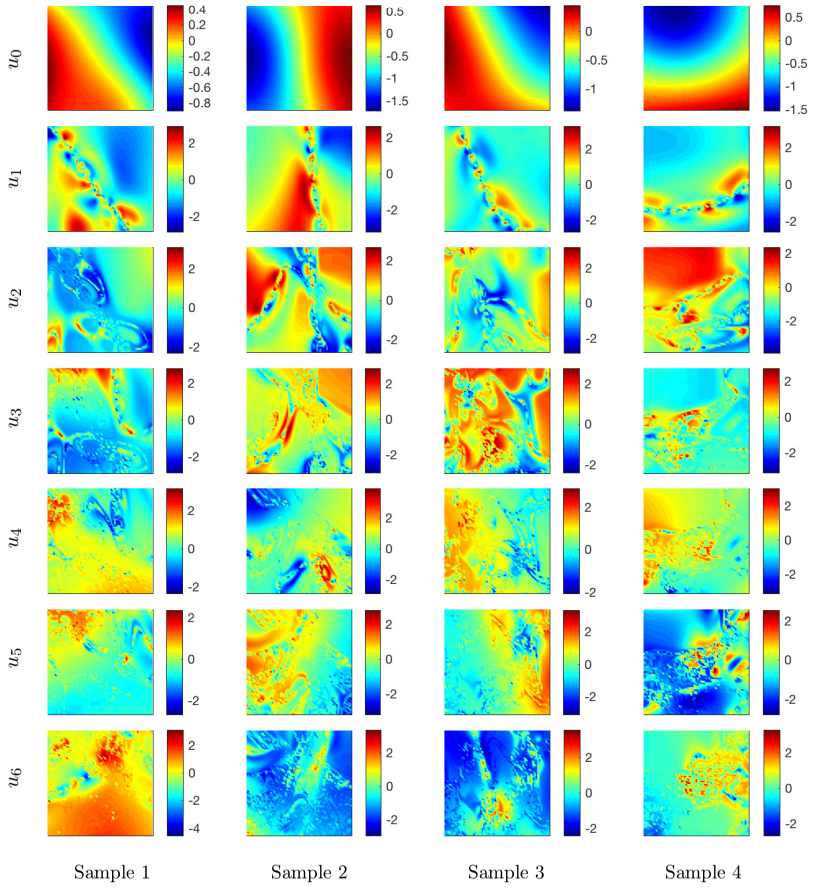

Figure 2: Four independent realizations of the first seven layers of a deep Gaussian process, in two spatial dimensions, using the covariance kernel construction described in subsection 2.2. Each column corresponds to an independent chain, and layers $u_0, u_1, \ldots, u_6$ are shown from top-to-bottom.

on u. This scaling is chosen so that the amplitude of samples is $\mathcal{O}(1)$ with respect to u. The rescaled family can be shown to satisfy Assumptions 3, and a minorization condition as in Lemma 15 can also be shown to hold when the state space is finite-dimensional. From this we can deduce that the resulting discretized process will still be ergodic.

Assume $D \subseteq \mathbb{R}^d$ and define the negative Laplacian $-\triangle$ on $D(-\triangle)$,

$$D(-\triangle) = \left\{ u \in H^2(D;\mathbb{R}) \;\middle|\; \frac{\mathrm{d}u}{\mathrm{d}\nu}(x) = 0 \text{ for } x \in \partial D \right\},$$

where ν is the outward normal to ∂D. Given $\alpha > d/2$, $\sigma > 0$, we define $P = -\triangle$ and

$$C(u)^{-1} = \sigma^{-2}(P + \Gamma(u))^{\alpha/2}\Gamma(u)^{d/2-\alpha}(P + \Gamma(u))^{\alpha/2} \tag{15}$$

where $\big(\Gamma(u)v\big)(x) = F\big(u(x)\big)v(x)$. The scaling introduced is inspired by the SPDE representation of Whittle-Matérn distributions (Lindgren et al., 2011); if $F(u) = \tau^2$ is chosen to be constant, then modulo boundary conditions, samples from a centred Gaussian distribution with covariance $C(u)$ are samples from a Whittle-Matérn distribution. In particular, τ corresponds to the inverse length-scale of samples, and samples almost-surely have s Sobolev and Hölder and derivatives for any $s < \alpha - d/2$.

For numerical experiments, we take

$$F(u) = \min\{F_- + ae^{bu^2}, F_+\}$$

for some $F_+, F_-, a, b > 0$. In particular, in one spatial dimension we take $F_+ = 150^2$, $F_- = 200$, $a = 100$ and $b = 2$. In two dimensions, we take $F_+ = 150^2$, $F_- = 50$, $a = 25$ and $b = 0.3$. We take $\alpha = 4$ in both cases, and choose σ such that $\mathbb{E}\big(u(x)^2\big) \approx 1$. These parameter choices were made empirically to ensure interesting structure of the samples. In order to generate samples at a given level, the negative Laplacian P is constructed using a finite-difference method. Given u, the operator $A(u)$ is then computed,

$$A(u) := \sigma^{-1}\Gamma(u)^{d/4-\alpha/2}(P + \Gamma(u))^{\alpha/2},$$

so that $v \sim N(0, C(u))$ solves the SPDE $A(u)v = \xi$, where ξ is white noise.

In Figure 3 we show samples of the deep Gaussian process on domain $D = (0,1)$, sampled on the uniform grid $x_i = \frac{i-1}{1000}$, for $i = 1, \ldots, 1001$. We show 4 independent realizations of the first seven layers of the process—each row corresponds to a given layer u_n. The anisotropy of the length-scale is evident in levels beyond u_0, and the effect of ergodicity is evident, with deeper levels having similar properties. Compared to the covariance function construction, local effects are less prominent, though a greater level of anisotropy could potentially be obtained by making an alternative choice of $F(\cdot)$. Figure 4 shows the same experiments on domain $D = (0,1)^2$, sampled on the tensor product of the one-dimensional points $x_i^1 = \frac{i-1}{150}$, for $i = 1, \ldots, 151$, and the same effects are observed. Figure 5 shows the trace of the norm of a DGP $\{u_n\}$ with $d = 1$, along with the running mean of these norms; the rapid convergence of the mean reflects the ergodicity of the chain.

We emphasize that our perspective on inference includes quite general inverse problems, and is not limited to the problems of regression and classification which dominate much of

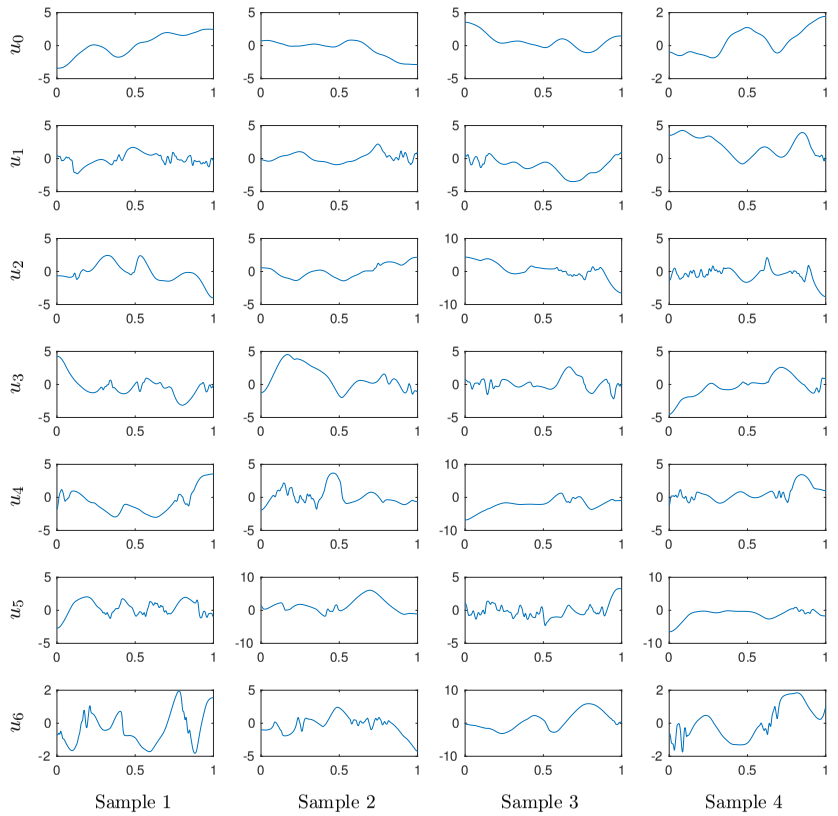

Figure 3: Four independent realizations of the first seven layers of a deep Gaussian process, in one spatial dimension, using the covariance operator construction described in subsection 4.2. Each column corresponds to an independent chain, and layers $u_0, u_1, \ldots, u_6$ are shown from top-to-bottom.

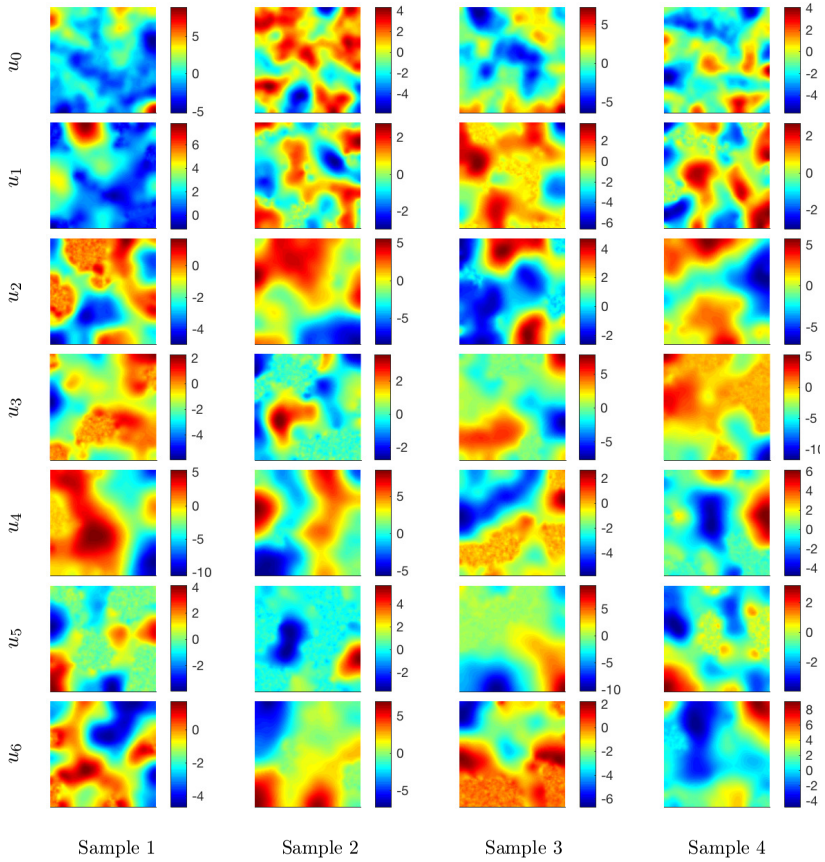

Figure 4: Four independent realizations of the first seven layers of a deep Gaussian process, in two spatial dimensions, using the covariance operator construction described in subsection 4.2. Each column corresponds to an independent chain, and layers $u_0, u_1, \ldots, u_6$ are shown from top-to-bottom.

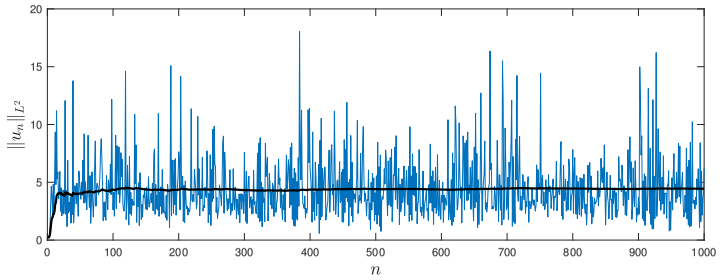

Figure 5: The trace of the norm of u_n versus n for a 1000 layer DGP $\{u_n\}$ as in Figure 3. The thick black curve shows the running mean of the norms.

classical machine learning; this broad perspective on the potential for the methodology affects the choice of algorithms that we study as we do not exploit any of the special structures that arise in regression and classification.

The deep Gaussian processes discussed in the previous sections were introduced with the idea of providing flexible prior distributions for inference, for example in inverse problems. The structure of such problems is as follows. We have data $y \in \mathbb{R}^J$ arising via the model

$$y = \mathcal{G}(u) + \eta \tag{16}$$

where η is a realization of some additive noise, and $\mathcal{G} : X \to \mathbb{R}^J$ is a (typically non-linear) forward map. The map $\mathcal{G}$ may involve, for example, solution of a partial differential equation which takes function u as input, or point evaluations of a function u, regression. In this paper we will fix $X = \mathcal{H}^N$, writing $u = (u_0, \ldots, u_{N-1}) \in X$; our prior beliefs on u will then be characterized by the first N states of a Markov chain of a form considered in the previous sections. Note that the map $\mathcal{G}$ could incorporate a projection map if the dependence is only upon a single state u_{N-1}; indeed this is the canonical example—the variables $(u_0, \ldots, u_{N-2})$ are viewed as hyperparameters in a prior on the parameter u_{N-1}.

4.2.1 Algorithms

We now turn to the design of algorithms for the Bayesian inference problems of sampling $u|y$. As already mentioned above, we are typically only interested in sampling the deepest layer $u_{N-1}|y$. However, due to the hierarchical definition of u_{N-1} given all the components of u, our algorithms work with the full set of layers u. Since the components of u are functions, and hence infinite dimensional objects in general, a guiding principle is to design algorithms which are well-defined on function space, an approach to MCMC inference reviewed by Cotter et al. (2013); the value of this approach is that it leads to algorithms whose mixing time is not dependent on the number of mesh points used to represent the function to be inferred. For simplicity of exposition we assume that the observational noise η is distributed

as $N(0,\Gamma)$; this is not central to our developments but makes the exposition concrete. Recalling that the Markov chain defining the prior beliefs is given by (ZeroMean), we can consider the unknowns in the problem to be the variables $u = (u_0, \ldots, u_{N-1})$, which are correlated under the prior, or the variables $\xi = (\xi_0, \ldots, \xi_{N-1})$, where we define $\xi_0 = u_0$, which are independent under the prior. These variables are related via $u = T(\xi)$, where the components of the deterministic map $T : X \to X$ are defined iteratively by

$$\begin{aligned} T_1(\xi_0, \ldots, \xi_{N-1}) &= \xi_0, \\ T_{n+1}(\xi_0, \ldots, \xi_{N-1}) &= L(T_n(\xi_0, \ldots, \xi_{N-1}))\xi_n, \quad n = 1, \ldots, N-1. \end{aligned}$$

The data may then be expressed in terms of ξ rather than u:

$$y = \tilde{\mathcal{G}}(\xi) + \eta = \mathcal{G}(T(\xi)) + \eta \tag{17}$$

where our prior belief on ξ is that its components are i.i.d. Gaussians. To be consistent with the notation introduced by Papaspiliopoulos et al. (2007); Yu and Meng (2011), (16) will be referred to as the *centred* model and (17) will be referred to as the *non-centred* model. The space $\mathcal{H}$ may be chosen differently in the centred and non-centred cases.

Associated with the two data models are two likelihoods: $\mathbb{P}(y|u)$ and $\mathbb{P}(y|\xi)$. Assuming that the observational noise $\eta \sim N(0,\Gamma)$ is Gaussian, where $\Gamma \in \mathbb{R}^{J\times J}$ is a positive definite covariance matrix, the likelihoods are given by

$$\begin{aligned} \mathbb{P}(y|u) &= \frac{1}{Z(y)} \exp\big(-\Phi(u;y)\big), \quad \Phi(u;y) := \frac{1}{2}\big|\Gamma^{-\frac{1}{2}}(y - \mathcal{G}(u))\big|^2, \\ \mathbb{P}(y|\xi) &= \frac{1}{\tilde{Z}(y)} \exp\big(-\tilde{\Phi}(\xi;y)\big), \quad \tilde{\Phi}(\xi;y) := \frac{1}{2}\big|\Gamma^{-\frac{1}{2}}(y - \tilde{\mathcal{G}}(\xi))\big|^2. \end{aligned}$$

We may then apply Bayes' theorem to write down the posterior distributions $\mathbb{P}(u|y)$ and $\mathbb{P}(\xi|y)$:

$$\begin{aligned} \mathbb{P}(u|y) &\propto \mathbb{P}(y|u)\mathbb{P}(u) \propto \exp\big(-\Phi(u;y)\big)\mathbb{P}(u), \\ \mathbb{P}(\xi|y) &\propto \mathbb{P}(y|\xi)\mathbb{P}(\xi) \propto \exp\big(-\tilde{\Phi}(\xi;y)\big)\mathbb{P}(\xi). \end{aligned}$$

We know (Cotter et al., 2013) that it is straightforward to design algorithms to sample $\mathbb{P}(\xi|y)$ which are well-defined in infinite dimensions, exploiting the fact that $\mathbb{P}(\xi)$ is Gaussian. An example of such an algorithm given by Algorithm 1.

This algorithm produces a chain $\{\xi^{(k)}\}_{k\in\mathbb{N}}$ that samples $\mathbb{P}(\xi|y)$ in stationarity; and $\{T(\xi^{(k)})\}_{k\in\mathbb{N}}$ will be samples of $\mathbb{P}(u|y)$. By working in non-centred coordinates we have been able to design this algorithm which is well-defined on function space. If we were to work with the centred coordinates u directly, the algorithm would not be well-defined on function space: in infinite dimensions, each family of measures $\{\mathbb{P}(u_n|u_{n-1})\}_{u_{n-1}\in\mathcal{H}}$ will typically be mutually singular, and so a proposed update $u \mapsto \hat{u}$ will almost surely be rejected. To see why this rejection occurs in practice, in high finite dimensions K, notice that the acceptance probability for an update $u \mapsto \hat{u}$ will involve the ratios of the Gaussian densities $N(u_n; 0, C(u_{n-1}))$ and $N(u_n; 0, C(\hat{u}_{n-1}))$. These densities will decay to zero as the dimension K is increased, and their ratio will only be well-defined in the limit if the measures are equivalent; consequently, the Markov chain will mix very poorly. Working with the

Algorithm 1 Non-Centred Algorithm

1. Fix $\beta_0, \ldots, \beta_{N-1} \in (0,1]$ and define $B = \mathrm{diag}(\beta_j)$. Choose initial state $\xi^{(0)} \in X$, and set $u^{(0)} = T(\xi^{(0)}) \in X$. Set $k = 0$.
2. Propose $\hat{\xi}^{(k)} = (I - B^2)^{\frac{1}{2}}\xi^{(k)} + B\zeta_j^{(k)}, \quad \zeta^{(k)} \sim N(0, I)$.
3. Set $\xi^{(k+1)} = \hat{\xi}^{(k)}$ with probability
$$\alpha_k = \min\left\{1, \exp\Big(\Phi\big(T(\xi^{(k)});y\big) - \Phi\big(T(\hat{\xi}^{(k)});y\big)\Big)\right\};$$
otherwise set $\xi^{(k+1)} = \xi^{(k)}$.
4. Set $k \mapsto k+1$ and go to 1.

non-centred coordinates ξ, the prior does not appear in the acceptance probability and so this issue is circumvented. Another advantage of using the non-centred coordinates is that there is no need to calculate the (divergent) log determinants which appear in the centred acceptance probability, avoiding potential numerical issues. These issues are discussed in greater depth and generality by Chen et al. (2018). For the reasons set-out in that paper, including those above, we have used only the non-centred algorithm in what follows. When the forward model $\mathcal{G}(u) = Au$ is linear, the non-centred algorithm can be combined with standard Gaussian process regression techniques via the identity

$$\mathbb{P}(\mathrm{d}u_N|y) = \int_X \mathbb{P}(\mathrm{d}u_N|u_{N-1}, y)\mathbb{P}(\mathrm{d}u_{N-1}|y).$$

The distribution $\mathbb{P}(\mathrm{d}u_N|u_{N-1}, y) = N(m_y(u_{N-1}), C_y(u_{N-1}))$ is Gaussian, where expressions for m_y, C_y are known, and so direct sampling methods are available. On the other hand, we have that $\mathbb{P}(y|u_{N-1}) = N(0, AC(u_{N-1})A^* + \Gamma)$, and so we may use the non-centred algorithm to robustly sample the measure

$$\begin{aligned} \mathbb{P}(\mathrm{d}u_{N-1}|y) &= \exp(-\Psi(u_{N-1};y))\mathbb{P}(\mathrm{d}u_{N-1}), \\ \Psi(u_{N-1};y) &= \frac{1}{2}\|y\|^2_{AC(u_{N-1})A^*+\Gamma} + \frac{1}{2}\log\det(AC(u_{N-1})A^* + \Gamma), \end{aligned}$$

after reparametrizing in terms of ξ. This approach can be viable even when the data is particularly informative so that Φ is very singular—this singularity does not in general pass to Ψ. It is this approach that we use for the simulations in the following subsections. An alternative approach not based on MCMC would be to use the non-centred parameterization of the Ensemble Kalman Filter (Chada et al., 2018) which we have successfully implemented in the context of the deep Gaussian processes of this paper, but do not show here for reasons of brevity.

4.3 Application to Regression

We consider the application of the non-centered algorithm described above to simple regression problems in one and two spatial dimensions.

4.3.1 One-Dimensional Simulations

We consider first the case $D = (0, 1)$, where the forward map is given by a number of point evaluations: $\mathcal{G}_j(u) = u(x_j)$ for some sequence $\{x_j\}_{j=1}^J \subseteq D$. We compare the quality of reconstruction versus both the number of point evaluations and the number of levels in the deep Gaussian prior. We use the same parameters for the family of covariance operators as in subsection 4.2. The base layer u_0 is taken to be Gaussian with covariance of the form (15), with $\Gamma(u) \equiv 20^2$.

The true unknown field $u^\dagger$ is given by the indicator function $u^\dagger = \mathbb{1}_{(0.3,0.7)}$, shown in Figure 6. It is generated on a mesh of 400 points, and three data sets are created wherein it is observed on uniform grids of $J = 25$, 50 and 100 points, and corrupted by white noise with standard deviation $\gamma = 0.02$. Sampling is performed on a mesh of 200 points to avoid an inverse crime (Kaipio and Somersalo, 2006). 10^6 samples are generated per chain, with the first 2×10^5 discarded as burn-in when calculating means. The jump parameters β_j are adaptively tuned to keep acceptance rates close to 30%.

In these experiments the deepest field is labelled as u_N, rather than as u_{N-1} as in the statement of the algorithm; this is purely for notational convenience, of course. In Figure 7 the means of the deepest field u_N and of the length-scales associated with each hidden layer are shown, that is, approximations to $\mathbb{E}(u_N)$ and $\mathbb{E}\big(F(u_j)^{\frac{1}{2}}\big)$ for each $j = 0, \ldots, N-1$. We see that, in all cases, the reconstructions of $u^\dagger$ are visually similar when two or more layers are used, and similar length-scale fields $\mathbb{E}\big(F(u_{N-1})^{\frac{1}{2}}\big)$ are obtained in these cases. The sharpness of these length-scale fields is related to the amount of data. Additionally, when $N = 4$ and $J = 100$ the location of the discontinuities is visible in the estimate for $\mathbb{E}\big(F(u_{N-2})^{\frac{1}{2}}\big)$, suggesting the higher quality data can influence the process more deeply. When $J = 50$ or $J = 25$, this layer does not appear to be significantly informed. When a single layer prior is used, the reconstruction fails to accurately capture the discontinuities. Figure 7 also shows bands of quantiles of the values $u(x)$ under the posterior, illustrating their distribution; in particular the lack of symmetry and disagreement of the means and medians show that the posterior is clearly non-Gaussian. Uncertainty increases both as the number of observations J and the layer n in the chain is increased. Note in particular the over-confidence of the shallow Gaussian process posterior: the truth is not contained within 95% credible intervals in all cases.

In Table 1 we show the L^1-errors between the true field and the posterior means arising from the different setups. The errors decrease as the number of observation points is increased, as would be expected. Additionally, when $J = 100$ and $J = 50$, the accuracy of the reconstruction increases with the number of layers, though the most significant increase occurs when increasing from 1 to 2 layers. When $J = 25$, the error increases beyond 2 layers, suggesting that some balance is required between the quality of the data and the flexibility of the prior.

In Figure 8 we replace the uniformly spaced observations with 10^6 randomly placed observations, to illustrate the effect of very high quality data. With 3 or 4 layers, more anisotropic behavior is observed in the length-scale field. Additionally, the layer u_{N-2} is much more strongly informed than the cases with fewer observations, though the layer u_{N-3} in the case $N = 4$ does not appear to be informed at all, indicating a limitation on how deeply the process can be influenced by data. The corresponding errors are shown in Table 1—as

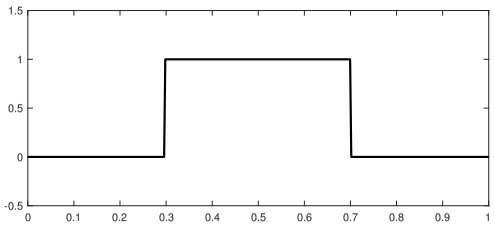

Figure 6: The true field used to generate the data for the one-dimensional inverse problem.

J	1 layer	2 layers	3 layers	4 layers
100	0.0485	0.0200	0.0198	**0.0196**
50	0.0568	0.0339	0.0339	**0.0337**
25	0.0746	**0.0658**	0.0667	0.0670
10^6	0.0131	0.000145	**0.000133**	**0.000133**

Table 1: The L^1-errors $\|u^\dagger - \mathbb{E}(u_N)\|_{L^1}$ between the true field and sample means for the one-dimensional simulations shown in Figure 7, for different numbers of data points J and layers N. Also shown are the corresponding errors for the simulations shown in Figure 8

.

in the cases $N = 50, 100$, more layers increases the accuracy of the mean, with diminishing returns for each additional layer. Note that higher accuracy could be attained in the single layer case by adjusting the constant length-scale parameter.

Finally, in Figure 9, we consider the same experiment as in Figure 7, except observations are limited to the subset $(0, 0.5)$ of the domain. Uncertainty is naturally higher in the unobserved portion of the domain. Uncertainty also increases in the observed layer u_N as N is increased; this could suggest that deep Gaussian processes may provide better generalization to unseen data than shallow Gaussian processes—note that the truth has much higher probability under the posterior with 4 layers versus just 1.

4.3.2 Two-Dimensional Simulations

We now consider the case $D = (0, 1)^2$, again where the forward map is given by a number of point evaluations. We fix the number of point observations $J = 2^{10}$, on a $2^5 \times 2^5$ uniform grid. We again compare quality of reconstruction versus the number of point evaluations and the number of levels in the deep Gaussian prior, and use the same parameters for the

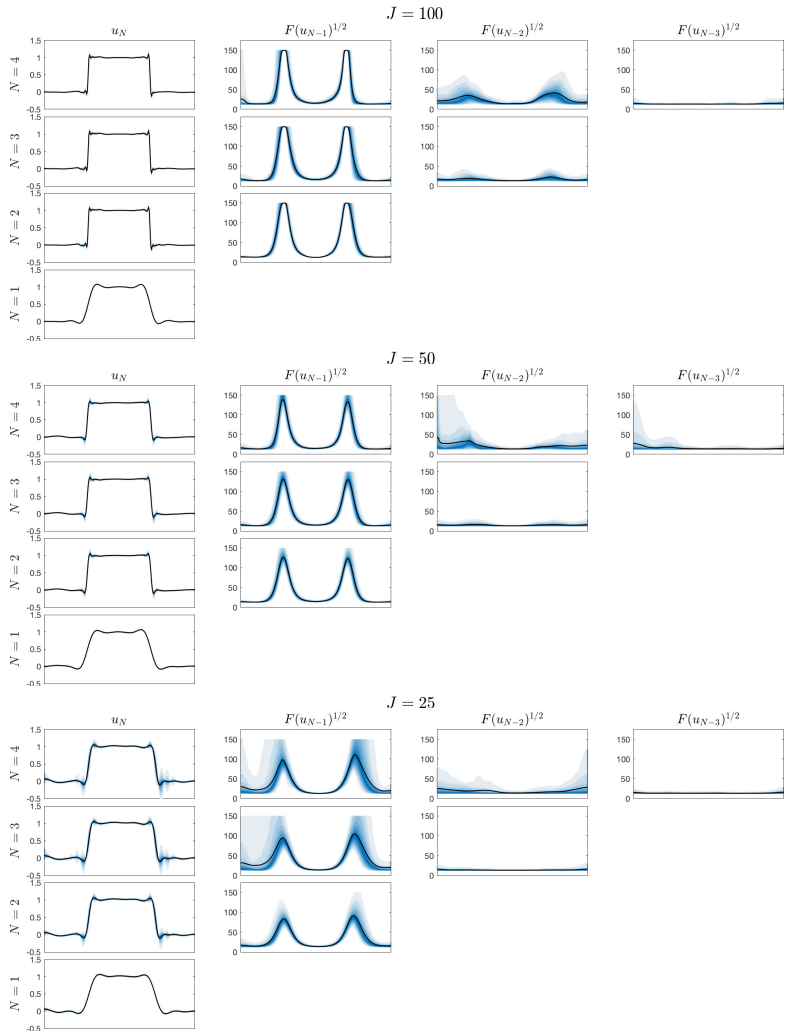

Figure 7: Estimates of posterior means (solid curves) and $5-95\%$ quantiles (shaded regions) arising from one-dimensional inverse problem. Number of data points taken are $J = 100$ (top block), $J = 50$ (middle block), $J = 25$ (bottom block). From left-to right, results for u_N, $F(u_{N-1})^{\frac{1}{2}}$, $F(u_{N-2})^{\frac{1}{2}}$, $F(u_{N-3})^{\frac{1}{2}}$ are shown. From top-to-bottom within each block, $N = 4, 3, 2, 1$.

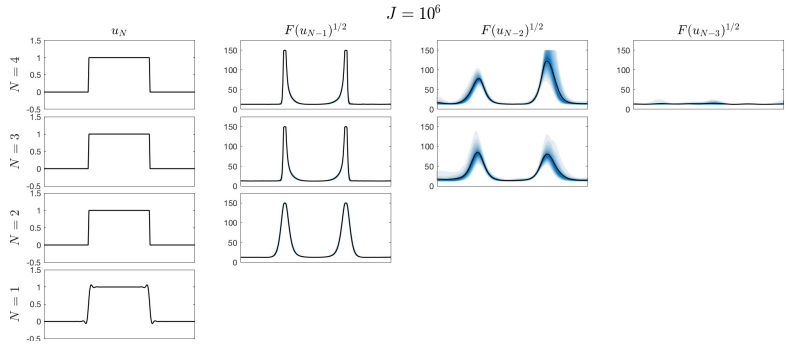

Figure 8: Estimates of posterior means (solid curves) and $5-95\%$ quantiles (shaded regions) arising from one-dimensional inverse problem, with $J = 10^6$ data points. From left-to right, results for u_N, $F(u_{N-1})^{\frac{1}{2}}$, $F(u_{N-2})^{\frac{1}{2}}$, $F(u_{N-3})^{\frac{1}{2}}$ are shown. From top-to-bottom, $N = 4, 3, 2, 1$.

family of covariance operators as in subsection 4.2. The base layer u_0 is taken to be Gaussian with covariance of the form (15), with $\Gamma(u) \equiv 20^2$.

The true unknown field $u^\dagger$ is constructed as a linear combination of truncated trigonometric functions with different length-scales, and shown in Figure 10 along with its contours. It is given by

$$\begin{aligned} u^\dagger(x,y) = &\cos(2\pi x)\cos(2\pi y) + \sin(4\pi x)\sin(4\pi y)\mathbb{1}_{(1/4,3/4)^2}(x,y) \\ &+ \sin(8\pi x)\sin(8\pi y)\mathbb{1}_{(1/2,3/4)^2}(x,y) \\ &+ \sin(16\pi x)\sin(16\pi y)\mathbb{1}_{(1/4,1/2)^2}(x,y). \end{aligned}$$

It is generated on a uniform square mesh of 2^{14} points, and two data sets are created wherein it is observed on uniform square grid of $J = 2^{10}, 2^8$ points, and corrupted by white noise with standard deviation $\gamma = 0.02$. Sampling is performed on a mesh of 2^{12} points to again avoid an inverse crime. 4×10^5 samples are generated per chain, with the first 2×10^5 discarded as burn-in when calculating means. Again the jump parameters β_j are adaptively tuned to keep acceptance rates close to 30%.

In Figure 11, analogously to Figure 7, the means of u_N and of the length-scales associated with each layer are shown, for $N = 1, 2, 3$. When $J = 2^{10}$, reconstructions are similar, though quality is generally proportional to the number of layers. In particular the, effect of too short a length-scale is evident in the case $N = 1$, in the regions where the length-scale should be larger, and conversely the effect of too long a length-scale is evident in the cases $N = 1, 2$ in the region where the length-scale should be the shortest. In the cases $N = 2, 3$, the length-scale fields $\mathbb{E}\big(F(u_{N-1})^{\frac{1}{2}}\big)$ are similar, though in the case $N = 3$ more accurately captures the true length-scales. When $J = 2^8$ the reconstructions are again similar, though

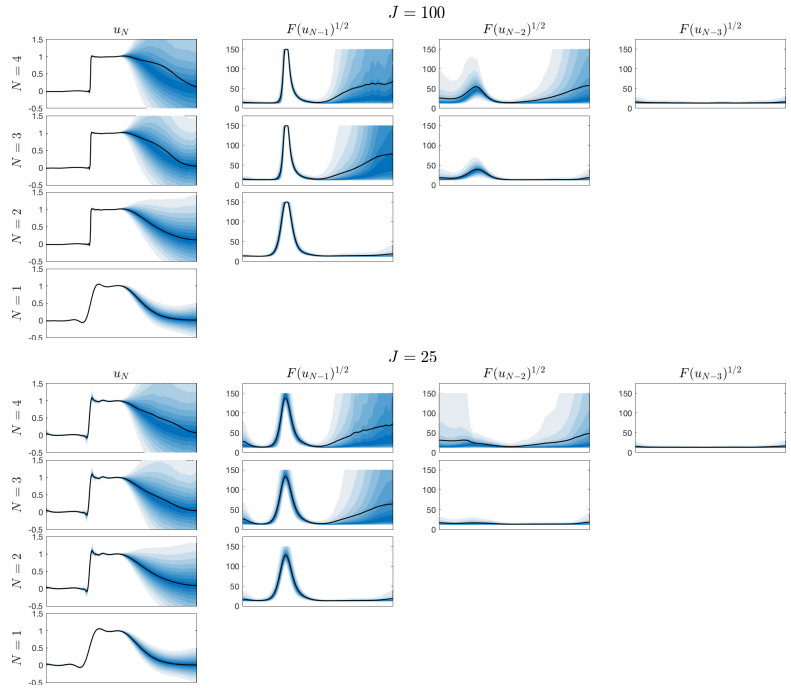

Figure 9: Estimates of posterior means (solid curves) and $5-95\%$ quantiles (shaded regions) arising from one-dimensional inverse problem. Number of data points taken are $J = 100$ (top block), $J = 25$ (bottom block). From left-to right, results for u_N, $F(u_{N-1})^{\frac{1}{2}}$, $F(u_{N-2})^{\frac{1}{2}}$, $F(u_{N-3})^{\frac{1}{2}}$ are shown. From top-to-bottom within each block, $N = 4, 3, 2, 1$.

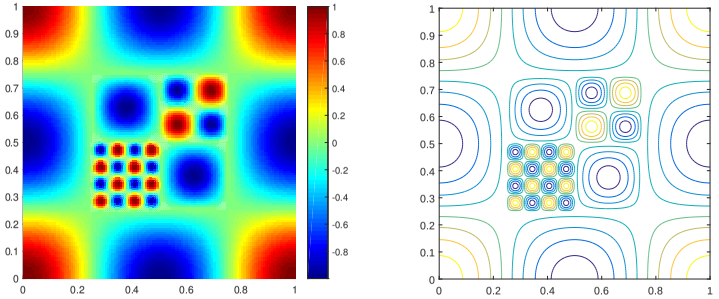

Figure 10: The true field used to generate the data for the two-dimensional inverse problem.

J	1 layer	2 layers	3 layers
2^{10}	0.0856	0.0813	**0.0681**
2^8	0.1310	**0.1260**	0.1279

Table 2: The L^2-errors $\|u^\dagger - \mathbb{E}(u_N)\|_{L^2}$ between the true field and sample means for the two-dimensional simulations shown in Figure 11, for different numbers of data points J and layers N.

there is now less accuracy in the shapes of the contours. In particular, the effect of too short a length-scale is especially evident in the case $N = 1$. The values of the reconstructed fields in the area of shortest length-scale are inaccurate in all cases—the positions of the observation points meant that the actual values of the peaks were not reflected in the data. The fields $\mathbb{E}\big(F(u_{N-1})^{\frac{1}{2}}\big)$ have similar structure to the case $J = 2^{10}$, though less accurately represent the true length scales. The L^2-errors between the means and the truth are shown in Table 2

5. Conclusions, Discussion, and Actionable Advice

In this section we provide an overview of the advantages and disadvantages of each of the four different DGP constructions considered in the paper, and summarize actionable advice that can be taken from the theoretical and numerical results that have been presented. We then outline a number of directions that would be interesting for future study.

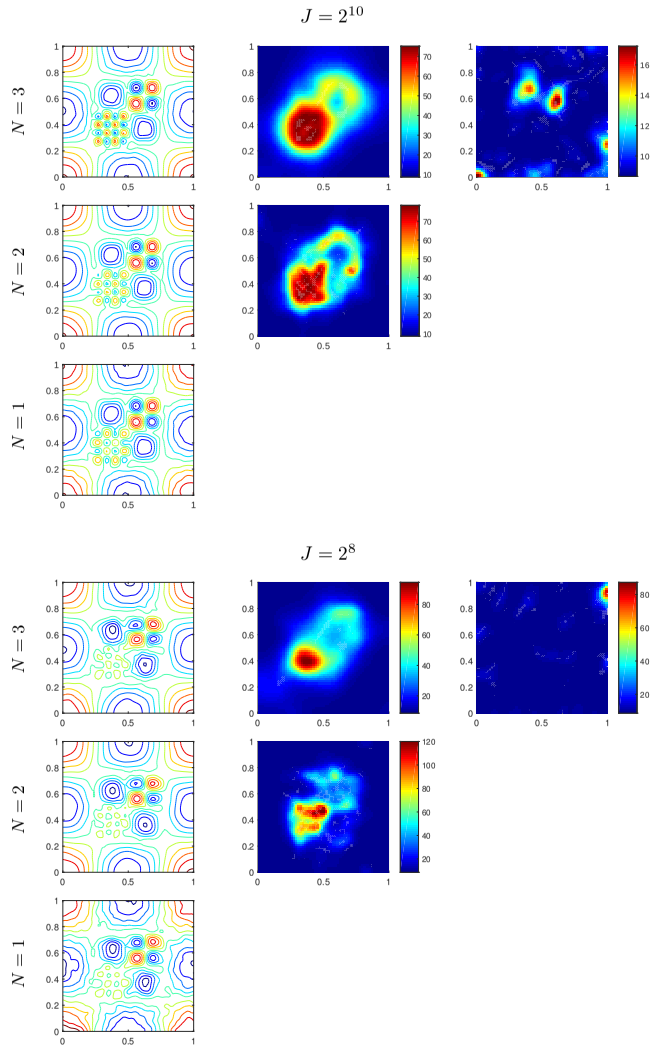

Figure 11: Estimates of posterior means arising from two-dimensional inverse problem. (Top block) $J = 2^{10}$, (Bottom block) $J = 2^8$. From left-to right, $\mathbb{E}\big(u_N\big)$, $\mathbb{E}\big(F(u_{N-1})^{\frac{1}{2}}\big)$, $\mathbb{E}\big(F(u_{N-2})^{\frac{1}{2}}\big)$. From top-to-bottom within each block, $N = 3, 2, 1$.

5.1 Comparison of Deep GP Constructions

We have considered four different constructions of deep GPs and we now discuss their relative merits. We also consider the context of variational inference which is popular in machine learning primarily because of its tractability. We emphasize however that it forms an uncontrolled approximation of the true posterior distribution and may fail to adequately represent the posterior distribution, and uncertainty in particular.

The **composition** construction is the classical construction introduced by Damianou and Lawrence (2013), building a hierarchy of layers using a stationary covariance function and composition. It has received the most study, and methods for variational inference have already been established. It has the advantage of scaling well with respect to data dimension d, however accurate sampling methods such as MCMC are intractable for large numbers of data points, due to the requirement to construct and factor dense covariance matrices at every step.

The **covariance function** construction builds the hierarchy using a stationary covariance function, and iteratively modifying its associated length scale. It has the advantage that each layer can be readily interpreted as the anisotropic length-scale field of the following layer. Its scaling properties are similar to those of the composition construction, however variational inference methods for this construction have not yet been studied.

The **covariance operator** construction builds the hierarchy using an SPDE representation of stationary Matèrn fields, and again iteratively modifies their associated length scale. It allows for fast sampling in low data dimension d via the use of PDE solvers, even when the number of data points is large. Accurate sampling via MCMC methods is tractable with this construction, due to the low cost of constructing and storing the inverse covariance (precision) matrix. Inference when d is large appears to be intractable at present, due to the requirement of dense meshes for PDE solvers.

Finally, the **convolution** construction builds the hierarchy via iterative convolution of Gaussian random fields. It has the advantage of being amenable to analysis, however the results of this analysis indicate that it would likely be a poor construction to use for inference due to trivial behaviour for large depth.

To summarize the numerical results on illustrative regression problems from the previous section, if the data is high quality, a small number of layers in the DGP will be sufficient as the problem becomes closer to interpolation. Conversely, if the data is low quality the likelihood is not strong enough to inform deeper layers in the DGP, and so a small number of layers is again sufficient. As a consequence, when the data lies between these two cases, and the truth has sufficiently rich structure, the use of deeper processes may be advantageous, but care is required to limit the number of layers employed.

5.2 Summary and Future Work

There are a number of interesting ways in which this work may be generalized. Within the context of covariance operators it is of interest to construct covariances $C(u)$ which are defined as $L^{-\alpha}$ with L being the divergence form elliptic operator

$$Lu = -\nabla \cdot \big(F(u)\nabla u\big).$$

Such a construction allows for the conditional distributions of the layers to be viewed as stationary on deformed spaces (Lindgren et al., 2011, §3.4), or to incorporate anisotropy in specific directions (Roininen et al., 2014, §3.1). Similar notions of anisotropy in different directions can be incorporated into the covariance function formulation by choosing the length scale $\Sigma(z)$ different to a multiple of the identity matrix. Additionally, we could consider a non-zero mean in the iteration (GP), as considered by Duvenaud et al. (2014); Salimbeni and Deisenroth (2017), allowing for forcing of the system. For example, with the choice $m(u_n) = u_n$ and a rescaling of the covariance, we obtain the ResNet-type iteration

$$u_{n+1} = u_n + \sqrt{\triangle t} L(u_n)\xi_{n+1}.$$

This may be viewed as a discretization of the continuous-time stochastic differential equation

$$\mathrm{d}u = L(u)L(u)^\top \mathrm{d}W,$$

analogously to what has been considered for neural networks (Haber and Ruthotto, 2017). Study of these systems could be insightful, for example deriving conditions to ensure a lack of ergodicity and hence arbitrary depth. As before $\top$ denotes the adjoint operation.

And finally it is possible to consider processes outside the four categories considered here; for example the one-step transition from u_n to u_{n+1} might be defined via stochastic integration against i.i.d. Brownian motions.

We have shown how a number of ideas in the literature may be recursed to produce deep Gaussian processes, different from those introduced by Damianou and Lawrence (2013). We have studied the effective depth of these processes, either through demonstrating ergodicity, or through showing convergence to a trivial solution (such as 0 or ∞). Together these results demonstrate that, as also shown by Duvenaud et al. (2014) for the original construction of deep Gaussian processes, care is needed in order to design processes with significant depth. Nonetheless, even a few layers can be useful for inference purposes, and we have demonstrated this also. It is an interesting question to ask precisely how the approximation power and effective depth are affected by the number of layers of the process, both in the non-ergodic case, and in the ergodic case before stationarity has been reached.

We also emphasize that the analysis in the paper is based solely on the deep Gaussian process u_n, and not the conditioned process $u_n|y$ in the inference problem with observed data y. The ergodicity properties of u_n do not directly carry over to $u_n|y$. As we have seen in the numerical experiments, the number of layers required in the inference problem in practice depends on the information content in the observed data y, and the analysis in this paper does not fully answer the question as to how many. The results in this paper do show, however, that in the case of ergodic constructions, the expressive power of the *prior* distribution in the inference problem does not increase past a certain number of layers. This provides some justification for using only a moderate number of layers in a deep Gaussian process prior in inference problems.

There are interesting approximation theory questions around deep processes, such as those identified in the context of neural networks by Pinkus (1999). There are also interesting questions around the use of these deep processes for inversion; in particular it seems hard to get significant value from using depth of more than two or three layers for noisy inverse problems. On the algorithmic side the issue of efficiently sampling these deep processes

(even over only two layers), when conditioned on possibly nonlinear observations remains open. We have used non-centred parameterizations because these may be sampled using function-space MCMC (Cotter et al., 2013; Chen et al., 2018); but centred methods, or mixtures, may be desirable for some applications.

Appendix A. Proofs for Section 2

Proof of Proposition 1 The stationary kernel ρ_{S} is positive definite by Assumption 1, and so by (Wendland, 2004, Theorem 7.14), we have

$$\rho_{\mathrm{S}}(r) = \int_0^\infty \exp(-r^2 t)\,\mathrm{d}\nu(t) \quad \text{for all } r \in [0,\infty),$$

for a finite, non-negative Borel measure ν on $[0,\infty)$ that is not concentrated at 0 (i.e. it is not a multiple of the Dirac measure centred at 0).

For any $x \in \mathbb{R}^d$ and $t \in [0,\infty)$, let us now define the matrix $\tilde{\Sigma}_t(x) := (4t)^{-1}\Sigma(x)$ and the functions

$$K_{x,t}(z) = \frac{1}{(2\pi)^{d/2}|\tilde{\Sigma}_t(x)|^{1/2}} \exp\Big(-\frac{1}{2}(x-z)^T \tilde{\Sigma}_t(x)^{-1}(x-z)\Big).$$

Here $|\cdot|$ denotes determinant and so the preceding is simply an expression for a normal density with mean x and covariance matrix $\tilde{\Sigma}_t(x)$ when $t > 0$; at $t = 0$, we simply have $K_{x,t}(z) = 0$, for all $x, z \in \mathbb{R}^d$. Then $\rho(x,x')$ is given by

$$\begin{aligned}
&\frac{2^{\frac{d}{2}}|\Sigma(x)|^{\frac{1}{4}}|\Sigma(x')|^{\frac{1}{4}}}{|\Sigma(x)+\Sigma(x')|^{\frac{1}{2}}}\rho_{\mathrm{S}}\Big(\sqrt{Q(x,x')}\Big) = \frac{2^{\frac{d}{2}}|\Sigma(x)|^{\frac{1}{4}}|\Sigma(x')|^{\frac{1}{4}}}{|\Sigma(x)+\Sigma(x')|^{\frac{1}{2}}}\int_0^\infty \exp\big(-tQ(x,x')\big)\,\mathrm{d}\nu(t)\\
&= \frac{2^{\frac{d}{2}}|\Sigma(x)|^{\frac{1}{4}}|\Sigma(x')|^{\frac{1}{4}}}{|\Sigma(x)+\Sigma(x')|^{\frac{1}{2}}}\int_0^\infty \exp\left(-t(x-x')^T\left(\frac{\Sigma(x)+\Sigma(x')}{2}\right)^{-1}(x-x')\right)\mathrm{d}\nu(t)\\
&= 2^{\frac{d}{2}}\int_0^\infty \frac{|\tilde{\Sigma}_t(x)|^{\frac{1}{4}}|\tilde{\Sigma}_t(x')|^{\frac{1}{4}}}{|\tilde{\Sigma}_t(x)+\tilde{\Sigma}_t(x')|^{\frac{1}{2}}}\exp\left(-\frac{1}{2}(x-x')^T\left(\tilde{\Sigma}_t(x)+\tilde{\Sigma}_t(x')\right)^{-1}(x-x')\right)\mathrm{d}\nu(t)\\
&= (2\pi)^{\frac{d}{2}}2^{\frac{d}{2}}\int_0^\infty |\tilde{\Sigma}_t(x)|^{\frac{1}{4}}|\tilde{\Sigma}_t(x')|^{\frac{1}{4}}\int_{\mathbb{R}^d} K_{x,t}(z)K_{x',t}(z)\,\mathrm{d}z\,\mathrm{d}\nu(t),
\end{aligned}$$

where in the last step, we have used the fact that the convolution $\int_{\mathbb{R}^d} K_{x,t}(z)K_{x',t}(z)\,\mathrm{d}z$ can be calculated explicitly using properties of normal random variables. More precisely, we

have

$$\int_{\mathbb{R}^d} K_{x,t}(z)K_{x',t}(z)\,\mathrm{d}z = \int_{\mathbb{R}^d} p_X(z-x)p_{X'}(z)\,\mathrm{d}z = \int_{\mathbb{R}^d} p_{X,X'}(z-x,z)\,\mathrm{d}z,$$

where p_X is the density of $X \sim N(0, \tilde{\Sigma}_t(x))$, $p_{X'}$ is the density of $X' \sim N(x', \tilde{\Sigma}_t(x'))$ and X and X' are independent. The change of variable from X, X' to W, X', where $W = X' - X$, has Jacobian 1, and so

$$\int_{\mathbb{R}^d} p_{X,X'}(z-x,z)\,\mathrm{d}z = \int_{\mathbb{R}^d} p_{W,X'}(z-(z-x),z)\,\mathrm{d}z = \int_{\mathbb{R}^d} p_{W,X'}(x,z)\,\mathrm{d}z = p_W(x).$$

Since $W = X' - X \sim N(x', \tilde{\Sigma}_t(x) + \tilde{\Sigma}_t(x'))$, we hence have

$$\begin{aligned}&\int_{\mathbb{R}^d} K_{x,t}(z)K_{x',t}(z)\,\mathrm{d}z \\ &\quad= \frac{1}{(2\pi)^{\frac{d}{2}}|\tilde{\Sigma}_t(x) + \tilde{\Sigma}_t(x')|^{\frac{1}{2}}} \exp\Big(-\frac{1}{2}(x-x')^T\Big(\tilde{\Sigma}_t(x) + \tilde{\Sigma}_t(x')\Big)^{-1}(x-x')\Big),\end{aligned}$$

as required.

Now, for any $b \in \mathbb{R}^N$ and pairwise distinct $\{x_i\}_{i=1}^N$, we then have

$$\begin{aligned}&\sum_{i=1}^N\sum_{j=1}^N b_i b_j \rho(x_i,x_j) \\ &= (2\pi)^{\frac{d}{2}}2^{\frac{d}{2}}\sum_{i=1}^N\sum_{j=1}^N b_i b_j \int_0^\infty \int_{\mathbb{R}^d} |\tilde{\Sigma}_t(x_i)|^{\frac{1}{4}} K_{x_i,t}(z)|\tilde{\Sigma}_t(x_j)|^{\frac{1}{4}} K_{x_j,t}(z)\,\mathrm{d}z\,\mathrm{d}\nu(t) \\ &= (2\pi)^{\frac{d}{2}}2^{\frac{d}{2}}\int_0^\infty \int_{\mathbb{R}^d} \left(\sum_{i=1}^N b_i |\tilde{\Sigma}_t(x_i)|^{\frac{1}{4}} K_{x_i,t}(z)\right)^2 \mathrm{d}z\,\mathrm{d}\nu(t) \\ &\geq 0,\end{aligned}$$

since the Borel measure ν is finite and non-negative. It remains to show that strict inequality also holds.

Firstly, we note that $|\tilde{\Sigma}_0(x_i)|^{\frac{1}{4}} K_{x_i,0}(z) = 0$, for all $x_i, z \in \mathbb{R}^d$, which means that the integrand with respect to t is identically equal to zero at $t = 0$. Secondly, we note that the points $\{x_i\}_{i=1}^N$ are pairwise distinct and the functions $\{|\tilde{\Sigma}_t(x_i)|^{\frac{1}{4}} K_{x_i,t}(\cdot)\}_{i=1}^N$ are hence linearly independent for any $t \in (0,\infty)$. It is thus impossible to make the integrand with respect to z identically equal to 0 for a.e. $z \in \mathbb{R}^d$. As a consequence the integrand with respect to t is positive for all $t \in (0,\infty)$. Since we know that the measure ν is not concentrated at 0 this completes the proof that ρ is positive definite on $\mathbb{R}^d \times \mathbb{R}^d$, for any $d \in \mathbb{N}$.

Finally, we note that the kernel ρ is clearly non-stationary, and is a correlation function since $\rho(x,x) = 1$, for any $x \in \mathbb{R}^d$. ■

Proof of Proposition 2 We note that the definition of positive definite in Assumptions 1(i) refers only to behaviour of the kernel on a finite set of pairwise distinct points $\{x_i\}_{i=1}^N$. By Assumption 2(i), the function G is non-negative and bounded. If $G(z) > 0$ for all $z \in \mathbb{R}^d$,

then the matrix $\Sigma(z)$ is positive definite for all $z \in \mathbb{R}^d$, and the fact that $\rho(\cdot,\cdot)$ is positive definite follows directly from Proposition 1.

It remains to investigate the case where $G(z) = 0$ for some $z \in \mathbb{R}^d$. We will prove that $\rho(\cdot,\cdot)$ is positive definite by showing that the correlation matrix $\mathbf{R}$, with entries $\mathbf{R}_{ij} = \rho(x_i,x_j)$, is positive definite for any pairwise disjoint points $\{x_i\}_{i=1}^N$. Without loss of generality, we will study the case $G(x_1) = 0$; the proof easily adapts to the case where $G(x_i) = 0$, for $i \neq 1$. To define $\rho(x_1,x_j)$ in this case, we start by assuming $G(x_1) > 0, G(x_j) > 0$, and then take limits.

With $\Sigma(z) = G(z)\mathrm{I}_d$, we have

$$\begin{aligned}Q(x_1,x_j) &= (x_1-x_j)^T\left(\frac{\Sigma(x_1)+\Sigma(x_j)}{2}\right)^{-1}(x_1-x_j) \\ &= 2\|x_1-x_j\|_2^2\Big(G(x_1)+G(x_j)\Big)^{-1},\end{aligned}$$

where $\|\cdot\|_2$ is the Euclidean norm, and

$$\frac{2^{\frac{d}{2}}\det(\Sigma(x_1))^{\frac{1}{4}}\det(\Sigma(x_j))^{\frac{1}{4}}}{\det(\Sigma(x_1)+\Sigma(x_j))^{\frac{1}{2}}} = \left(\frac{4G(x_1)G(x_j)}{\big(G(x_1)+G((x_j)\big)^2}\right)^{\frac{d}{4}}.$$

We now study separately three cases:

i) $x_j = x_1$: we have

$$\lim_{G(x_1)\to 0}\left(\frac{4G(x_1)G(x_1)}{\big(G(x_1)+G(x_1)\big)^2}\right)^{\frac{d}{4}} = \lim_{G(x_1)\to 0} 1 = 1, \tag{18}$$

and so using the algebra of limits, the continuity of ρ_{S}, (18) and the fact that $\rho_{\mathrm{S}}(0) = 1$, we have

$$\lim_{G(x_1)\to 0}\rho(x_1,x_1) = \lim_{G(x_1)\to 0}\rho_{\mathrm{S}}\Big(\sqrt{Q(x_1,x_1)}\Big) = \rho_{\mathrm{S}}(0) = 1.$$

ii) $x_j \neq x_1$ and $G(x_j) > 0$: we have

$$\lim_{G(x_1)\to 0} Q(x_1,x_j) = 2\|x_1-x_j\|_2^2\Big(G(x_j)\Big)^{-1},$$

and

$$\lim_{G(x_1)\to 0}\left(\frac{4G(x_1)G(x_j)}{\big(G(x_1)+G(x_j)\big)^2}\right)^{\frac{d}{4}} = 0. \tag{19}$$

Thus, using the continuity of ρ_{S}, together with (19) and the algebra of limits, we have

$$\lim_{G(x_1)\to 0}\rho(x_1,x_j) = 0.$$

iii) $x_j \neq x_1, G(x_j) = 0$: we obtain

$$\lim_{G(x_1),G(x_j)\to 0} Q(x_1, x_j) = \infty,$$

which by Assumptions 2(ii) implies that

$$\lim_{G(x_1),G(x_j)\to 0} \rho_S\Big(\sqrt{Q(x_1, x_j)}\Big) = 0.$$

Since $(a+b)^2 \geq 4ab$ for any positive numbers a and b, we have

$$0 \leq \left(\frac{4G(x_1)G(x_j)}{\big(G(x_1) + G((x_j)\big)^2}\right)^{\frac{d}{4}} \leq 1,$$

for any $G(x_1) > 0, G(x_j) > 0$, and hence

$$\lim_{G(x_1),G(x_j)\to 0} \rho(x_1, x_j) = 0.$$

Hence, when $G(x_i) > 0$, for $i = 2, \ldots, N$, we have $\lim_{G(x_1)\to 0} \mathbf{R} = \mathbf{R}^*$, where the matrix $\mathbf{R}^*$ has the first row and column equal to the first basis vector $e_1 = (1, 0, 0, \ldots, 0) \in \mathbb{R}^N$, and the remaining submatrix $\mathbf{R}^*_{N-1} \in \mathbb{R}^{N-1\times N-1}$ with entries $\rho(x_i, x_j)$, for $i, j = 2, \ldots, N$. The matrix $\mathbf{R}^*_{N-1}$ is positive definite by Proposition 1, from which we can conclude that $\mathbf{R}^*$ is positive definite also. A similar argument holds when $G(x_i) = 0$ for one or more indices $i \in \{2, \ldots, N\}$. ■

Abstract

We propose and analyze two new MCMC sampling algorithms, the Vaidya walk and the John walk, for generating samples from the uniform distribution over a polytope. Both random walks are sampling algorithms derived from interior point methods. The former is based on volumetric-logarithmic barrier introduced by Vaidya whereas the latter uses John's ellipsoids. We show that the Vaidya walk mixes in significantly fewer steps than the logarithmic-barrier based Dikin walk studied in past work. For a polytope in $\mathbb{R}^d$ defined by $n > d$ linear constraints, we show that the mixing time from a warm start is bounded as $\mathcal{O}\left(n^{0.5}d^{1.5}\right)$, compared to the $\mathcal{O}\left(nd\right)$ mixing time bound for the Dikin walk. The cost of each step of the Vaidya walk is of the same order as the Dikin walk, and at most twice as large in terms of constant pre-factors. For the John walk, we prove an $\mathcal{O}\left(d^{2.5} \cdot \log^4(n/d)\right)$ bound on its mixing time and conjecture that an improved variant of it could achieve a mixing time of $\mathcal{O}\left(d^2 \cdot \text{poly-log}(n/d)\right)$. Additionally, we propose variants of the Vaidya and John walks that mix in polynomial time from a deterministic starting point. The speed-up of the Vaidya walk over the Dikin walk are illustrated in numerical examples.

Keywords: MCMC methods, interior point methods, polytopes, sampling from convex sets

1. Introduction

Sampling from distributions is a core problem in statistics, probability, operations research, and other areas involving stochastic models (Geman and Geman, 1984; Brémaud, 1991; Ripley, 2009; Hastings, 1970). Sampling algorithms are a prerequisite for applying Monte Carlo methods to order to approximate expectations and other integrals. Recent decades have witnessed great success of Markov Chain Monte Carlo (MCMC) algorithms; for instance, see the handbook by Brooks et al. (2011) and references therein. These methods are based on constructing a Markov chain whose stationary distribution is equal to the target distribution, and then drawing samples by simulating the chain for a certain number of steps. An advantage of MCMC algorithms is that they only require knowledge of the target density up to a proportionality constant. However, the theoretical understanding of MCMC algorithms used in practice is far from complete. In particular, a general challenge is to bound the *mixing time* of a given MCMC algorithm, meaning the number of iterations—as a function of the error tolerance δ, problem dimension d and other parameters—for the chain to arrive at a distribution within distance δ of the target.

In this paper, we study a certain class of MCMC algorithms designed for the problem of drawing samples from the uniform distribution over a polytope. The polytope is specified in the form $\mathcal{K} := \{x \in \mathbb{R}^d \mid Ax \leq b\}$, parameterized by the matrix-vector pair $(A, b) \in \mathbb{R}^{n \times d} \times \mathbb{R}^n$. Our goal is to understand the mixing time for obtaining δ-accurate samples, and how it grows as a function of the pair (n, d).

The problem of sampling uniformly from a polytope is important in various applications and methodologies. For instance, it underlies various methods for computing randomized approximations to polytope volumes. There is a long line of work on sampling methods being used to obtain randomized approximations to the volumes of polytopes and other convex bodies (see, e.g., Lovász and Simonovits, 1990; Lawrence, 1991; Bélisle et al., 1993; Lovász, 1999; Cousins and Vempala, 2014). Polytope sampling is also useful in developing fast randomized algorithms for convex optimization (Bertsimas and Vempala, 2004) and sampling contingency tables (Kannan and Narayanan, 2012), as well as in randomized methods for approximately solving mixed integer convex programs (Huang and Mehrotra, 2013, 2015). Sampling from polytopes is also related to simulations of the hard-disk model in statistical physics (Kapfer and Krauth, 2013), as well as to simulations of error events for linear programming in communication (Feldman et al., 2005).

Many MCMC algorithms have been studied for sampling from polytopes, and more generally, from convex bodies. Some early examples include the Ball Walk (Lovász and Simonovits, 1990) and the hit-and-run algorithm (Bélisle et al., 1993; Lovász, 1999), which apply to sampling from general convex bodies. Although these algorithms can be applied to polytopes, they do not exploit any special structure of the problem. In contrast, the Dikin walk introduced by Kannan and Narayanan (2012) is specialized to polytopes, and thus can achieve faster convergence rates than generic algorithms. The Dikin walk was the first sampling algorithm based on a connection to interior point methods for solving linear programs. More specifically, as we discuss in detail below, it constructs proposal distributions based on the standard logarithmic barrier for a polytope. In a later paper, Narayanan (2016) extended the Dikin walk to general convex sets equipped with self-concordant barriers.

For a polytope defined by n constraints, Kannan and Narayanan (2012) proved an upper bound on the mixing time of the Dikin walk that scales linearly with n. In many applications, the number of constraints n can be much larger than the number of variables d. For example, we could imagine one using many hyperplane constraints to approximate complicated convex sets such as sphere or ellipsoid. For such problems, linear dependence on the number of constraints is not desirable. Consequently, it is natural to ask if it is possible to design a sampling algorithm whose mixing time scales in a sub-linear manner with the number of constraints. Our main contribution is to investigate and answer this question in affirmative—in particular, by designing and analyzing two sampling algorithms with provably faster convergence rates than the the Dikin walk while retaining its advantages over the ball walk and the hit-and-run methods.

JMLR 19(55):1-86, 2018

Our contributions: We introduce and analyze a new random walk, which we refer to as the *Vaidya walk* since it is based on the *volumetric-logarithmic barrier* introduced by Vaidya (1989). We show that for a polytope in $\mathbb{R}^d$ defined by n-constraints, the Vaidya walk mixes in $\mathcal{O}\left(n^{1/2}d^{3/2}\right)$ steps, whereas the Dikin walk (Kannan and Narayanan, 2012) has mixing time bounded as $\mathcal{O}\left(nd\right)$. So the Vaidya walk is better in the regime $n \gg d$. We also propose the *John walk*, which is based on the *John ellipsoidal algorithm* in optimization. We show that the John walk has a mixing time of $\mathcal{O}\left(d^{2.5} \cdot \log^4(n/d)\right)$ and conjecture that a variant of it could achieve $\mathcal{O}\left(d^2 \cdot \text{poly-log}(n/d)\right)$ mixing time. We show that when compared to the Dikin walk, the per-iteration computational complexities of the Vaidya walk and the John walk are within a constant factor and a poly-logarithmic in n/d factor respectively. Thus, in the regime $n \gg d$, the overall upper bound on the complexity of generating an approximately uniform sample follows the order Dikin walk $\gg$ Vaidya walk $\gg$ John walk.

The remainder of the paper is organized as follows. In Section 2, we discuss many polynomial-time random walks on convex sets and polytopes, and motivate the starting point for the new random walks. In Section 3, we introduce the new random walks and state bounds on their rates of convergence and provide a sketch of the proof in Section 3.5. We discuss the computational complexity of the different random walks and demonstrate the contrast between the random walks for several illustrative examples in Section 4. We present the proof of the mixing time for the Vaidya walk in Section 5 and defer the analysis of the John walk to the appendix. We conclude with possible extensions of our work in Section 6.

Notation: For two sequences a_δ and b_δ indexed by $\delta \in I \subseteq \mathbb{R}$, we say that $a_\delta = \mathcal{O}\left(b_\delta\right)$ if there exists a universal constant $C > 0$ such that $a_\delta \leq C b_\delta$ for all $\delta \in I$. For a set $\mathcal{K} \subset \mathbb{R}^d$, the sets $\text{int}\left(\mathcal{K}\right)$ and $\mathcal{K}^c$ denote the interior and complement of $\mathcal{K}$ respectively. We denote the boundary of the set $\mathcal{K}$ by $\partial\mathcal{K}$. The Euclidean norm of a vector $x \in \mathbb{R}^d$ is denoted by $\|x\|_2$. For any square matrix M, we use $\det(M)$ and $\text{trace}(M)$ to denote the determinant and the trace of the matrix M respectively. For two distributions $\mathcal{P}_1$ and $\mathcal{P}_2$ defined on the same probability space $(\mathcal{X}, \mathcal{B}(\mathcal{X}))$, their total-variation (TV) distance is denoted by $\|\mathcal{P}_1 - \mathcal{P}_2\|_{\text{TV}}$ and is defined as follows

$$\|\mathcal{P}_1 - \mathcal{P}_2\|_{\text{TV}} = \sup_{A \in \mathcal{B}(\mathcal{X})} \left|\mathcal{P}_1(A) - \mathcal{P}_2(A)\right|.$$

Furthermore if $\mathcal{P}_1$ is absolutely continuous with respect to $\mathcal{P}_2$, then the KullbackLeibler divergence from $\mathcal{P}_2$ to $\mathcal{P}_1$ is defined as

$$\text{KL}(\mathcal{P}_1 \| \mathcal{P}_2) = \int_{\mathcal{X}} \log\left(\frac{d\mathcal{P}_1}{d\mathcal{P}_2}\right) d\mathcal{P}_1.$$

2. Background and problem set-up

In this section, we describe general MCMC algorithms and review the rates of convergence of existing random walks on convex sets. After introducing several random walks studied in past work, we introduce the Vaidya and John walks studied in this paper.

2.1 Markov chains and mixing

Suppose that we are interested in drawing samples from a *target distribution* π^* supported on a subset $\mathcal{X}$ of $\mathbb{R}^d$. A broad class of methods are based on first constructing a discrete-time Markov chain that is irreducible and aperiodic, and whose stationary distribution is equal to π^*, and then simulating this Markov chain for a certain number of steps k. As we describe below, the number of steps k to be taken is determined by a mixing time analysis.

In this paper, we consider the class of Markov chains that are of the *Metropolis-Hastings type* (Metropolis et al., 1953; Hastings, 1970); see the books by Robert (2004) and Brooks et al. (2011), as well as references therein, for further background. Any such chain is specified by an initial density π^0 over the set $\mathcal{X}$, and a *proposal function* $p : \mathcal{X} \times \mathcal{X} \in \mathbb{R}_+$, where $p(x, \cdot)$ is a density function for each $x \in \mathcal{X}$. At each time, given a current state $x \in \mathcal{X}$ of the chain, the algorithm first proposes a new vector $z \in \mathcal{X}$ by sampling from the proposal density $p(x, \cdot)$. It then accepts $z \in \mathcal{X}$ as the new state of the Markov chain with probability

$$\alpha(x, z) := \min\left\{1, \frac{\pi^*(z)p(z, x)}{\pi^*(x)p(x, z)}\right\}. \tag{1}$$

Otherwise, with probability equal to $1 - \alpha(x, z)$, the chain stays at x. Thus, the overall transition kernel p for the Markov chain is defined by the function

$$q(x, z) := p(x, z)\alpha(x, z) \qquad \text{for } z \neq x,$$

and a probability mass at x with weight $1 - \int_{\mathcal{X}} q(x, z)dz$. It should be noted that the purpose of the Metropolis-Hastings correction (1) is that ensure that the target distribution π^* satisfies the *detailed balanced condition*, meaning that

$$q(y, x)\pi^*(x) = q(x, y)\pi^*(y) \quad \text{for all } x, y \in \mathcal{X}. \tag{2}$$

It is straightforward to verify that the detailed balance condition (2) implies that the target density π^* is stationary for the Markov chain. Throughout this paper, we analyze the *lazy version* of the Markov chain, defined as follows: when at state x with probability $1/2$ the walk stays at x and with probability $1/2$ it makes a transition as per the original random walk. Given that the Markov chains discussed in this paper are also irreducible, the laziness ensures uniqueness of the stationary distribution.

Overall, this set-up defines an operator $\mathcal{T}_p$ on the space of probability distributions: given an initial distribution μ_0 with $\text{supp}(\mu_0) \subseteq \text{supp}(\pi^*)$, it generates a new distribution $\mathcal{T}_p(\mu_0)$, corresponding to the distribution of the chain at the next step. Moreover, for any positive integer $k = 1, 2, \ldots$, the distribution μ_k of the chain at time k is given by $\mathcal{T}_p^k(\mu_0)$, where $\mathcal{T}_p^k$ denotes the composition of $\mathcal{T}_p$ with itself k times. Furthermore, the transition distribution at any state x is given by $\mathcal{T}_p(\delta_x)$ where δ_x denotes the dirac-delta distribution with unit mass at x.

Given our assumptions and set-up, we are guaranteed that $\lim_{k\to\infty} \mathcal{T}_p^k(\mu_0) = \pi^*$—that is, if we were to run the chain for an infinite number of steps, then we would draw a sample from the target distribution π^*. In practice, however, any algorithm will be run only for a finite number of steps, which suffices to ensure only that the distribution from which the

sample has been drawn is "close" to the target π^*. In order to quantify the closeness, for a given tolerance parameter $\delta \in (0,1)$, we define the *δ-mixing time* as

$$k_{\text{mix}}(\delta;\mu_0) := \min\Big\{k \mid \|\mathcal{T}_p^k(\mu_0) - \pi^*\|_{\text{TV}} \le \delta\Big\}, \tag{3}$$

corresponding to the first time that the chain's distribution is within δ in TV norm of the target distribution, given that it starts with distribution μ_0.

In the analysis of Markov chains, it is convenient to have a rough measure of the distance between the initial distribution μ_0 and the stationary distribution. Warmness is one such measure: For a finite scalar M, the initial distribution μ_0 is said to be M-warm with respect to the stationary distribution π^* if

$$\sup_S \left(\frac{\mu_0(S)}{\pi^*(S)}\right) \le M, \tag{Warm-Start}$$

where the supremum is taken over all measurable sets S. A number of mixing time guarantees from past work (Lovász, 1999; Vempala, 2005) are stated in terms of this notion of M-warmness, and our results make use of it as well. In particular, we provide bounds on the quantity $\sup_{\mu_0 \in \mathcal{P}_M(\pi^*)} k_{\text{mix}}(\delta;\mu_0)$, where $\mathcal{P}_M(\pi^*)$ denotes the set of all distributions that are M-warm with respect to π^*. Naturally, as the value of M decreases, the task of generating samples from the target distribution gets easier. However, access to a warm-start may not be feasible for many applications and thus deriving bounds on mixing time of the Markov chain from a non warm-start is also desirable. Consequently, we provide modifications of our random walks which mix in polynomial time even from deterministic starting points.

2.2 Sampling from polytopes

In this paper, we consider the problem of drawing a sample uniformly from a polytope. Given a full-rank matrix $A \in \mathbb{R}^{n\times d}$ with $n \ge d$, we consider a polytope $\mathcal{K}$ in $\mathbb{R}^d$ of the form

$$\mathcal{K} := \big\{x \in \mathbb{R}^d \mid Ax \le b\big\}, \tag{4}$$

where $b \in \mathbb{R}^n$ is a fixed vector. Since the uniform distribution on the polytope $\mathcal{K}$ is the primary target distribution considered in the paper, in the sequel we use π^* exclusively to denote the uniform distribution on the polytope $\mathcal{K}$. There are various algorithms to sample a vector from the uniform distribution over $\mathcal{K}$, including the ball walk (Lovász and Simonovits, 1990) and hit-and-run algorithms (Lovász, 1999). To be clear, these two algorithms apply to the more general problem of sampling from a convex set; Table 1 shows their complexity, when applied to the polytope $\mathcal{K}$, relative to the Vaidya walk analyzed in this paper. Most closely related to our paper is the Dikin walk proposed by Kannan and Narayanan (2012), and a more general random walk on a Riemannian manifold studied by Narayanan (2016). Both of these random walks, as with the Vaidya and John walks, can be viewed as randomized versions of the interior point methods used to solve linear programs, and more generally, convex programs equipped with suitable barrier functions.

In order to motivate the form of the Vaidya and John walks proposed in this paper, we begin by discussing the ball walk and then the Dikin walk. For the sake of completeness, we end the section with a brief description another popular sampling algorithm Hit-and-run.

Ball walk: The ball walk of Lovász and Simonovits (1990) is simple to describe: when at a point $x \in \mathcal{K}$, it draws a new point u from a Euclidean ball of radius $r > 0$ centered at x. Here the radius r is a step size parameter in the algorithm. If the proposed point u belongs to the polytope $\mathcal{K}$, then the walk moves to u; otherwise, the walk stays at x. On the one hand, unlike the walks analyzed in this paper, the ball walk applies to any convex set, but on the other, its mixing time depends on the condition number $\gamma_{\mathcal{K}}$ of the set $\mathcal{K}$, given by

$$\gamma_{\mathcal{K}} = \inf_{R_{\text{in}},R_{\text{out}}>0}\Big\{\frac{R_{\text{out}}}{R_{\text{in}}} \quad | \quad \mathbb{B}(x,R_{\text{in}}) \subseteq \mathcal{K} \subseteq \mathbb{B}(y,R_{\text{out}}) \quad \text{for some } x,y \in \mathcal{K}\Big\}. \tag{5}$$

Mixing time of the ball walk has been improved greatly since it was introduced (Kannan et al., 1997, 2006; Lee and Vempala, 2018b). Nonetheless, as shown in Table 1, the mixing time of the ball walk gets slower when the condition of the set is large; for instance, it scales[1] as d^6 for a set with condition number $\gamma_{\mathcal{K}} = d^2$. One approach to tackle bad conditioning is to use rounding as a pre-processing step, where the set is rounded to bring it in a near-isotropic position, i.e., reduce the condition $\gamma_{\mathcal{K}}$ to near-constant before sampling from it. Nonetheless, these algorithms are themselves based on several rounds of sampling algorithms and the current best algorithm by Lovász and Vempala (2006b) puts a convex body into approximately isotropic position, i.e., $\mathcal{O}^*(\sqrt{d})$ rounding with a running time of $\mathcal{O}^*(d^4)$ where we have omitted the dependence on log-factors. If one has more information about the structure of the convex set (and not just oracle access as required by the ball walk), one can potentially exploit it to design fast sampling algorithms which are unaffected by the conditioning of the set thereby reducing the need of the (expensive) pre-processing step. One such algorithm is the Dikin walk for polytopes which we describe next.

Dikin walk: The Dikin walk (Kannan and Narayanan, 2012) is similar in spirit to the ball walk, except that it proposes a point drawn uniformly from a *state-dependent* ellipsoid known as the Dikin ellipsoid (Dikin, 1967; Nesterov and Nemirovskii, 1994). It then applies an accept-reject step to adjust for the difference in the volumes of these ellipsoids at different states. The state-dependent choice of the ellipsoid allows the Dikin walk to adapt to the boundary structure. A key property of the Dikin ellipsoid of unit radius—in contrast to the Euclidean ball that underlies the ball walk—is that it is always contained within $\mathcal{K}$, as is known from classic results on interior point methods (Nesterov and Nemirovskii, 1994). Furthermore, the Dikin walk is affine invariant, meaning that its behavior does not change under linear transformations of the problem. As a consequence, the Dikin mixing time does not depend on the condition number $\gamma_{\mathcal{K}}$. In a variant of this random walk (Narayanan, 2016), uniform proposals in the ellipsoid are replaced by Gaussian proposals with covariance specified by the ellipsoid, and it is shown that with high probability, the proposal falls within the polytope.

The Dikin walk is closely related to the interior point methods for solving linear programs. In order to understand the Vaidya and John walks, it is useful to understand this connection in more detail. Suppose that our goal is to optimize a convex function over the polytope $\mathcal{K}$. A barrier method is based on converting this constrained optimization problem to a sequence of unconstrained ones, in particular by using a barrier to enforce the linear

1. Although, very recently Lee and Vempala (2018b) improved the mixing time of the ball walk for isotropic sets which have $\gamma_{\mathcal{K}} = \mathcal{O}(\sqrt{d})$ improved from $\mathcal{O}\left(d^3\right)$ to $\mathcal{O}\left(d^{2.5}\right)$.

constraints defining the polytope. Letting $a_i^\top$ denote the i-th row vector of matrix A, the *logarithmic-barrier* for the polytope $\mathcal{K}$ given by the function

$$\mathcal{F}(x) := -\sum_{i=1}^{n} \log(b_i - a_i^T x). \tag{6}$$

For each $i \in [n]$, we define the scalar $s_{x,i} := (b_i - a_i^T x)$, and we refer to the vector $s_x := (s_{x,1}, \ldots, s_{x,n})^\top$ as the *slackness at* x.

Each step of an interior point algorithm (Boyd and Vandenberghe, 2004) involves (approximately) solving a linear system involving the Hessian of the barrier function, which is given by

$$\nabla^2 \mathcal{F}(x) := \sum_{i=1}^{n} \frac{a_i a_i^\top}{s_{x,i}^2}. \tag{7}$$

In the Dikin walk (Kannan and Narayanan, 2012), given a current iterate x, the algorithm chooses a point uniformly at random from the ellipsoid

$$\{u \in \mathbb{R}^d \mid (u-x)^\top D_x (u-x) \leq R\}, \tag{8}$$

where $D_x := \nabla^2 \mathcal{F}(x)$ is the Hessian of the log barrier function, and $R > 0$ is a user-defined radius. In an alternative form of the Dikin walk (Narayanan, 2016; Sachdeva and Vishnoi, 2016), the proposal vector $u \in \mathbb{R}^d$ is drawn randomly from a Gaussian centered at x, and with covariance equal to a scaled copy of $(D_x)^{-1}$. Note that in contrast to the ball walk, the proposal distribution now depends on the current state.

Vaidya walk: For the *Vaidya walk* analyzed in this paper, we instead generate proposals from the ellipsoids defined, for each $x \in \text{int}(\mathcal{K})$, by the positive definite matrix

$$V_x := \sum_{i=1}^{n} (\sigma_{x,i} + \beta_{\text{V}}) \frac{a_i a_i^\top}{s_{x,i}^2}, \qquad \text{where} \tag{9a}$$

$$\beta_{\text{V}} := d/n \quad \text{and} \quad \sigma_x := \left(\frac{a_1^\top (\nabla^2 \mathcal{F}_x)^{-1} a_1}{s_{x,1}^2}, \ldots, \frac{a_n^\top (\nabla^2 \mathcal{F}_x)^{-1} a_n}{s_{x,n}^2} \right)^\top. \tag{9b}$$

The entries of the the vector σ_x are known as the leverage scores assciated with the matrix $\nabla^2 \mathcal{F}_x$ from equation (7), and are commonly used to measure the importance of rows in a linear system (Mahoney, 2011). The matrix V_x is related to the Hessian of the function $x \mapsto \mathcal{V}_x$ given by

$$\mathcal{V}_x := \log\det \nabla^2 \mathcal{F}_x + \beta_{\text{V}} \mathcal{F}_x. \tag{10}$$

This particular combination of the *volumetric barrier* and the *logarithmic barrier* was introduced by Vaidya (1989) and Vaidya and Atkinson (1993) in the context of interior point methods, hence our name for the resulting random walk.

John walk: We now describe the John walk. For any vector $w \in \mathbb{R}^n$, let $W := \text{diag}(w)$ denote the diagonal matrix with $W_{ii} = w_i$ for each $i \in [n]$. Let $S_x = \text{diag}(s_x)$ denote the slackness matrix at x. It is easy to see that S_x is positive semidefinite for all $x \in \mathcal{K}$, and strictly positive definite for all $x \in \text{int}(\mathcal{K})$. The (scaled) inverse covariance matrix underlying the John walk is given by

$$J_x := \sum_{i=1}^{n} \zeta_{x,i} \frac{a_i a_i^\top}{s_{x,i}^2}, \tag{11}$$

where for each $x \in \text{int}(\mathcal{K})$, the weight vector $\zeta_x \in \mathbb{R}^n$ is obtained by solving the convex program

$$\zeta_x := \arg\min_{w \in \mathbb{R}^n} \left\{ \sum_{i=1}^{n} w_i - \frac{1}{\alpha_{\text{J}}} \log\det(A^\top S_x^{-1} W^{\alpha_{\text{J}}} S_x^{-1} A) - \beta_{\text{J}} \sum_{i=1}^{n} \log w_i \right\}, \tag{12}$$

with $\beta_{\text{J}} := d/2n$ and $\alpha_{\text{J}} := 1 - 1/\log_2(1/\beta_{\text{J}})$. Lee and Sidford (2014) proposed the convex program (12) associated with the *approximate John weights* ζ_x, with the aim of searching for the best member of a family of volumetric barrier functions. They analyzed the use of the John weights in the context of speeding up interior point methods for solving linear programs; here we consider them for improving the mixing time of a sampling algorithm. The convex program (12) is closely related to the problem of finding the largest ellipsoid at any interior point of the polytope, such that the ellipsoid is contained within the polytope. This problem of finding the largest ellipsoid was first studied by John (1948) who showed that each convex body in $\mathbb{R}^d$ contains a unique ellipsoid of maximal volume. The convex program (12) was used by Lee and Sidford (2014) to compute approximate John Ellipsoids for solving linear programs. In a recent work, Gustafson and Narayanan (2018) make use of the exact John ellipsoids and design a polynomial time sampling algorithm for polytopes. See Table 1 for the associated guarantees.

Hit-and-run: We conclude with a brief discussion with another popular sampling algorithm: Hit-and-run. It was introduced by Smith (1984) as a sampling algorithm for general distributions and it was later shown to have polynomial mixing time for sampling from convex sets (Lovász, 1999; Lovász and Vempala, 2003, 2006a). The algorithm proceeds as follows: when at point x, it firsts draws a random line through x and then samples from the one-dimensional marginal of the target distribution restricted to this line. For uniform sampling from convex sets, the second step simplifies to drawing a uniform point from the line restricted to the convex set. Mixing time bounds for this random walk are summarized in Table 1.

2.3 Mixing time comparisons of walks

Table 1 provides a summary of the mixing time bounds and per step complexity and the effective per sample complexity for various random walks, including the Vaidya and John walks analyzed in this paper. In addition to the Ball Walk, Hit-and-Run, Dikin, Vaidya and John walks, we also show scalings for the recently introduced Riemannian Hamiltonian Monte Carlo (RHMC) on polytopes by Lee and Vempala (2016) and the John's walk based on exact John ellipsoids studied by Gustafson and Narayanan (2018). The details of per

iteration cost for the new random walks is discussed in Section 4.1. We now compare and contrast the complexities of these random walks.

Unlike the Ball Walk or hit-and-run which are useful for general convex sets, the Dikin, Vaidya, John and RHMC walks are specialized for polytopes. These latter random walks exploit the definition of the polytope in a particular way so that the transition probability from a point x to y does not change under an affine transformation, i.e., $\mathbb{T}(x, y) = \mathbb{T}(Ax, Ay)$ where $\mathbb{T}$ denotes the transition kernel for the random walk. Consequently, the mixing time bounds for these random walks have no dependence on the condition number of the set $\gamma_{\mathcal{K}}$ (5). We can see from Table 1, that compared to the Ball walk and hit-and-run, Vaidya walk mixes significantly faster if $n \ll d\gamma_{\mathcal{K}}^2$. The condition number $\gamma_{\mathcal{K}}$ of polytopes with polynomially many faces can not be $\mathcal{O}(d^{\frac{1}{2}-\epsilon})$ for any $\epsilon > 0$ but can be arbitrarily larger, even exponential in dimension d (Kannan and Narayanan, 2012). For such polytopes, Vaidya walk mixes faster as long as $n \ll d^3$ (and even for larger n when $\gamma_{\mathcal{K}}$ is large). It takes $\mathcal{O}(\sqrt{n/d})$ fewer steps compared to Dikin walk and thus provides a practical speed up over all range of d.

From a warm start, the Riemannian Hamiltonian Monte Carlo on polytopes introduced by Lee and Vempala (2016) has $\mathcal{O}\left(nd^{2/3}\right)$ mixing time, and thus mixes faster (up to constants) compared than the Vaidya walk (respectively the John walk) when the number of constraints n is is bounded as $n \ll d^{5/3}$ (respectively $n \ll d^{11/6}$). For larger numbers of constraints, the Vaidya and John walks exhibit faster mixing. More generally, it is clear that the rate of John walk has *almost* the best order across all the walks for reasonably large values of $n \gg d^2$.

Finally, let us compare the (exact) John walk due to Gustafson and Narayanan (2018) with the (approximate) John walk studied in our paper. A notable feature of their random walk is that its mixing time is independent of the number of constraints and the per iteration cost also depends linearly on the number of constraints. Nonetheless, the dependence on d, for both the mixing time (d^7) and the per iteration cost ($nd^4 + d^8$) is quite poor. In contrast, the per iteration cost for our John walk is nd^2 and the mixing time has only a poly-logarithmic dependence on n.

2.4 Visualization of three walks' proposal distributions

In order to gain intuition about the three interior point based methods—namely, the Dikin, Vaidya and John walks—it is helpful to discuss how their underlying proposal distributions change as a function of the current point x. All three walks are based on Gaussian proposal distributions with inverse covariance matrices of the general form

$$\sum_{i=1}^{n} w_{x,i} \frac{a_i a_i^\top}{s_{x,i}^2},$$

where $w_{x,i} > 0$ corresponds to a state-dependent weight associated with the i-th constraint. The Dikin walk uses the weights $w_{x,i} = 1$; the Vaidya walk uses the weights $w_{x,i} = \sigma_{x,i} + \beta_{\mathrm{V}}$; and the John walk uses the weights $w_{x,i} = \zeta_{x,i}$. For simplicity, we refer to these weights as the Dikin, Vaidya and John weights. The i-th weight characterize the importance of the i-th linear constraint in constructing the inverse covariance matrix. A larger value of

Random walk	$\mathbf{k}_{\mathrm{mix}}(\delta; \mu_0)$	**Iteration cost**	**Per sample cost**
Ball walk$^{\#}$ (Kannan et al., 2006)	$d^2\gamma_{\mathcal{K}}^2$	nd	$nd^3\gamma_{\mathcal{K}}^2$
Hit-and-Run (Lovász and Vempala, 2006a)	$d^2\gamma_{\mathcal{K}}^2$	nd	$nd^3\gamma_{\mathcal{K}}^2$
Dikin walk (Kannan and Narayanan, 2012)	nd	nd^2	n^2d^3
RHMC walk (Lee and Vempala, 2018a)	$nd^{2/3}$	nd^2	$n^2d^{2.67}$
John's walk† (Gustafson and Narayanan, 2018)	d^7	$nd^4 + d^8$	$nd^{11} + d^{15}$
Vaidya walk (this paper)	$n^{1/2}d^{3/2}$	nd^2	$n^{1.5}d^{3.5}$
John walk (this paper)	$d^{5/2}\log^4\left(\frac{2n}{d}\right)$	$nd^2\log^2 n$	$nd^{4.5}$
Improved John walk‡ (this paper)	$d^2\,\kappa_{n,d}$	$nd^2\log^2 n$	nd^4

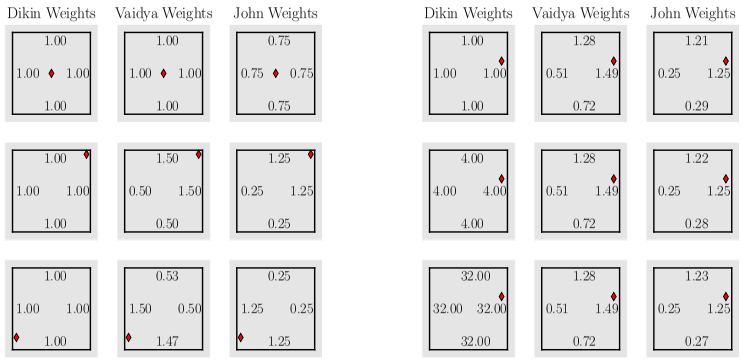
Table 1. Upper bounds on computational complexity of random walks on the polytope $\mathcal{K} = \{x \in \mathbb{R}^d | Ax \leq b\}$ defined by the matrix-vector pair $(A, b) \in \mathbb{R}^{n\times d} \times \mathbb{R}^n$ with a warm-start. For simplicity, here we ignore the logarithmic dependence on the warmness parameter and the tolerance δ. The iteration cost terms of order nd^2 arise from linear system solving, using standard and numerically stable algorithms, for n equations in d dimensions; algorithms with best possible theoretical complexity nd^ω for $\omega < 1.373$ are not numerically stable enough for practical use. $^{\#}$Mixing time of the Ball walk has been improved to $\mathcal{O}\left(d^2\gamma_{\mathcal{K}}\right)$ for near isotropic convex bodies by Lee and Vempala (2018b) during the submission period of this paper. While ball walk, Hit-and-run are affected by the condition number $\gamma_{\mathcal{K}}$ of the set, the Dikin and RHMC walks have quadratic dependence on the number of constraints n. †John's walk by Gustafson and Narayanan (2018) (based on the exact John ellipsoids) has linear dependence on n but poor dependence on d. In contrast, the Vaidya walk has sub-quadratic dependence on n and significantly better dependence on d. Furthermore, the John walk (based on approximate John's ellipsoids) analyzed in this paper has linear dependence with reasonable dependence on the dimensions d. ‡The mixing time bound for the improved John walk with poly-logarithmic factor $\kappa_{n,d}$ is conjectured.

the weight $w_{x,i}$ relative to the total weight $\sum_{i=1}^n w_{x,i}$ signifies more importance for the i-th linear constraint for the point x.

Figure 1a illustrates the difference in three weights as we move points inside the polytope $[-1, 1]^2$. When the point x is in the middle of the unit square formed by the four constraints, all walks exhibit equal weight for every constraint. When the point x is closer to the bottom-left boundary, the Vaidya and John weights assign larger weights to the bottom and the left constraints, while the weights for top and right constraints decrease. Note that the total sum of Vaidya weights and that of John weights remains constant independent of the position of the point x.

In Figure 1b-2b, we demonstrate that the Vaidya walk and the John walk are better at handling repeated constraints. Note that we can define the square $[-1, 1]^2$ as

$$[-1,1]^2 = \left\{ x \in \mathbb{R}^2 \,\middle|\, Ax \leq b, A = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ -1 & 0 \\ 0 & -1 \end{bmatrix}, b = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \right\}. \tag{13}$$



(a) Weights for different locations and a fixed number of constraints n.

(b) Effective weights for a fixed location and different number of constraints n

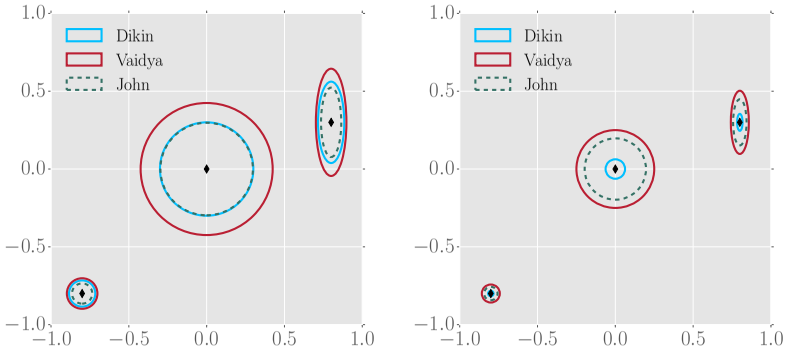
Figure 1. Visualization of the weights on the square with repeated constraints $\mathcal{S}_{n/4}$ for the different random walks. The number mentioned next to the boundary lines denotes the effective weight for the location x (denoted by diamond) for the corresponding constraint. **(a)** $n = 4$ is common across rows and $x = (0, 0)$ for the top row, $(0.9, 0.9)$ for the middle and $(-0.9, -0.7)$ for the bottom row. The Dikin weights are independent of x, the Vaidya and the John weights for a constraint increase if the location x is closer to it. **(b)** $x = (0.85, 0.30)$ is common across rows, and n=4 for the top row, $n = 16$ for the middle and n=128 for the bottom row. The effective Dikin weight for each constraint increases linearly with n but for the Vaidya and John walk adaptively, the weights get adjusted such that the sum of their weights is always of the order of the dimension d.

Simply repeating the rows of the matrix A several times changes the mathematical formulatiton of the polytope, but does not change the shape of the polytope. We define the square with constraints repeated $n/4$ times $\mathcal{S}_{n/4}$ as

$$\mathcal{S}_{n/4} = \left\{ x \in \mathbb{R}^2 \,\middle|\, A_{n/4} x \leq b_{n/4}, A_{n/4} = \begin{bmatrix} A \\ \vdots \\ \times(n/4) \end{bmatrix}, b_{n/4} = \begin{bmatrix} b \\ \vdots \\ \times(n/4) \end{bmatrix}, \right\} \tag{14}$$

where A and b were defined above. We denote effective weight for each distinct constraint as the sum of weights corresponding to the same constraint. Using this definition, the effective Dikin weight, which is $n/4$, is thus affected by the repeating of constraints. Consequently, the Dikin ellipsoid is much smaller for polytopes with repeated constraints. However, the Vaidya and John weights do not change as observed in the Figure 1b. Such a property of these two weights implies that the Vaidya and John ellipsoids are not too small even for very large number of constraints. And we observe such a phenomenon in Figures 2a-2b where the repetition of rows in the matrix A leads to very small Dikin ellipsoid but large Vaidya and John ellipsoid. A few other numerical computations also suggest that the Vaidya and John ellipsoids are moder adaptive when compared to Dikin ellipsoids when the

number of constraints is large. Nonetheless, such a claim is only based on heuristics and is presented simply to provide an intuition that the new ellipsoids are better behaved than Dikin ellipsoids and thereby motivated the design of the new random walks.



(a) $n = 32$

(b) $n = 2048$

Figure 2. Visualization of the proposal distribution on the square with repeated constraints $\mathcal{S}_{n/4}$ for the different random walks. **(a, b)** Unit ellipsoids associated with the covariances of the random walks at different states x on the square with repeated constraints $\mathcal{S}_{n/4}$. Clearly, all these ellipsoids adapt to the boundary but increasing n has a profound impact on the volume of the Dikin ellipsoids and comparatively less impact on the Vaidya and John ellipsoids.

3. Main results

With the basic background in place, we now describe the algorithms more precisely and state upper bounds on the mixing time of the Vaidya and John walks. In Section 3.4, we propose a variant of the John walk, known as the *improved John walk*, and conjecture that it has a better mixing time bound than that of the John walk.

3.1 Vaidya and John walks

In this subsection, we formally define the Vaidya and John walks. In Algorithm 1 and Algorithm 2, we summarize the steps of the Vaidya walk and the John walk.

Vaidya walk: The Vaidya walk with radius parameter $r > 0$, denoted by VW(r) for short, is defined by a Gaussian proposal distribution denoted as $\mathcal{P}_x^{\mathrm{v}}$: given a current state $x \in \mathrm{int}\,(\mathcal{K})$, it proposes a new point by sampling from the multivariate Gaussian distribution

$\mathcal{N}\left(x, \frac{r^2}{\sqrt{nd}} {V_x}^{-1}\right)$. In analytic terms, the proposal density at x is given by

$$p_x^{\mathrm{V}}(z) := p_{\mathrm{Vaidya}(r)}(x,z) = \sqrt{\det V_x}\left(\frac{nd}{2\pi r^2}\right)^{d/2} \exp\left(-\frac{\sqrt{nd}}{2r^2}\,(z-x)^\top V_x (z-x)\right). \quad (15)$$

As the target distribution for our walk is the uniform distribution on $\mathcal{K}$, the proposal step is followed by an accept-reject step as described in Section 2.1 (equation 1). Thus the overall transition distribution for the walk at state x is defined by a density given by

$$q_{\mathrm{Vaidya}(r)}(x,z) = \begin{cases} \min\left\{p_x^{\mathrm{V}}(z), p_z^{\mathrm{V}}(x)\right\}, & z \in \mathcal{K} \text{ and } z \neq x, \\ 0, & z \notin \mathcal{K}, \end{cases}$$

and a probability mass at x, given by $1 - \int_{z\in\mathcal{K}} \min\left\{p_x(z), p_z(x)\right\} dz$. We use $\mathcal{T}_{\mathrm{Vaidya}(r)}$ to denote the resulting transition operator for the Vaidya walk with parameter r.

Algorithm 1: Vaidya Walk with parameter r (VW(r))

Input: Parameter r and $x_0 \in \mathrm{int}\,(\mathcal{K})$
Output: Sequence $x_1, x_2, \ldots$

for $i = 0, 1, \ldots$ **do**
  With probability $\frac{1}{2}$ stay at the current state: $x_{i+1} \leftarrow x_i$ % *lazy step*
  With probability $\frac{1}{2}$ perform the following update:
    Proposal step: Draw $z_{i+1} \sim \mathcal{N}\left(x_i, \frac{r^2}{(nd)^{1/2}} V_{x_i}^{-1}\right)$
    Accept-reject step:
      if $z_{i+1} \notin \mathcal{K}$ *then* $x_{i+1} \leftarrow x_i$ % *reject an infeasible proposal*
      else
        compute $\alpha_{i+1} = \min\left\{1, p_{z_{i+1}}(x_{i+1})/p_{x_{i+1}}(z_{i+1})\right\}$
        With probability α_{i+1} accept the proposal: $x_{i+1} \leftarrow z_{i+1}$
        With probability $1 - \alpha_{i+1}$ reject the proposal: $x_{i+1} \leftarrow x_i$
end

John walk: The John walk is similar to the Vaidya walk except that the proposals at state $x \in \mathrm{int}\,(\mathcal{K})$ are generated from the multivariate Gaussian distribution $\mathcal{N}\left(x, \frac{r^2}{d^{3/2}\cdot\log_2^4(2n/d)} {J_x}^{-1}\right)$, where the matrix J_x is defined by equation (11), and $r > 0$ is a constant. The proposal distribution at $x \in \mathrm{int}\,(\mathcal{K})$ is denoted as $\mathcal{P}_x^{\mathrm{J}}$. The proposal step is then followed by an accept-reject step similarly defined as in the Vaidya walk. We use $\mathcal{T}_{\mathrm{John}(r)}$ to denote the resulting transition operator for the John walk with parameter r.

3.2 Mixing time bounds for warm start

We are now ready to state an upper bound on the mixing time of the Vaidya walk. In this and other theorem statements, we use c to denote a universal positive constant. Recall that π^* denotes the uniform distribution on the polytope $\mathcal{K}$, and, that $\mathcal{T}_{\mathrm{Vaidya}(r)}$ denotes the operator on distributions associated with the Vaidya walk.

Algorithm 2: John Walk with parameter r (JW(r))

Input: Parameter r and $x_0 \in \mathrm{int}\,(\mathcal{K})$
Output: Sequence $x_1, x_2, \ldots$

for $i = 0, 1, \ldots$ **do**
  With probability $\frac{1}{2}$ stay at the current state: $x_{i+1} \leftarrow x_i$ % *lazy step*
  With probability $\frac{1}{2}$ perform the following update:
    Proposal step: Draw $z_{i+1} \sim \mathcal{N}\left(x_i, \frac{r^2}{d^{3/2}} J_{x_i}^{-1}\right)$ % *this step is different than the Vaidya walk*
    Accept-reject step:
      if $z_{i+1} \notin \mathcal{K}$ *then* $x_{i+1} \leftarrow x_i$ % *reject an infeasible proposal*
      else
        compute $\alpha_{i+1} = \min\left\{1, p_{z_{i+1}}(x_{i+1})/p_{x_{i+1}}(z_{i+1})\right\}$
        With probability α_{i+1} accept the proposal: $x_{i+1} \leftarrow z_{i+1}$
        With probability $1 - \alpha_{i+1}$ reject the proposal: $x_{i+1} \leftarrow x_i$
end

Theorem 1 *Let μ_0 be any distribution that is M-warm with respect to π^* as defined in equation* (Warm-Start)*. For any $\delta \in (0, 1]$, the Vaidya walk with parameter $r_{\mathrm{V}} = 10^{-4}$ satisfies*

$$\|\mathcal{T}^k_{Vaidya(r_V)}(\mu_0) - \pi^*\|_{TV} \leq \delta \qquad \text{for all } \; k \geq cn^{1/2}d^{3/2}\log\left(\frac{\sqrt{M}}{\delta}\right). \quad (16)$$

The proof of Theorem 1 is provided in Section 5. Theorem 1 precisely quantifies the dependence of mixing time of the Vaidya walk on many parameters of interest such as dimension d, number of constraints n, the error tolerance δ and the warmness M. The specific choice $r_{\mathrm{V}} = 10^{-4}$ is for theoretical purposes; in practice, we find that substantially larger values can be used.[2] Our upper bound for the mixing time of the Vaidya walk has $\mathcal{O}(\sqrt{n/d})$ improvement over the current best upper bound for the mixing time of the Dikin walk. In Section 4.1, we show that the per iteration cost for the two walks is of the same order. Since $n \geq d$ for closed polytopes in $\mathbb{R}^d$, the effective cost until convergence (iteration complexity multiplied by number of iterations required) for the Vaidya walk is at least of the same order as of the Dikin walk, and significantly smaller when $n \gg d$. Comparing the provable mixing time upper bounds, the Vaidya walk has an advantage over the Dikin walk for the problems where the number of constraints is significantly larger than the number of variables involved. Our simulations also confirm this theoretical finding.

Let us now state our result for the mixing time of the John walk:

2. A larger than optimal r leads to an undesirable high rejection rate. In practice, we can fine tune r by performing a binary search over the interval $[10^{-4}, 1]$ and keeping track of the rejection rate of the samples during the run of the Markov chain for a given choice of r. A choice of $r > 1$ is obviously bad because then the Vaidya ellipsoid will have poor overlap with polytopes near the boundary, causing high rejection rate and slow down of the chain.

Theorem 2 *Suppose that $n \leq \exp(\sqrt{d})$, and let μ_0 be any distribution that is M-warm with respect to π^*. Then for any $\delta \in (0, 1]$, the John walk with parameter $r_{\scriptscriptstyle J} = 10^{-5}$ satisfies*

$$\|\mathcal{T}^k_{John(r_{\scriptscriptstyle J})}(\mu_0) - \pi^*\|_{TV} \leq \delta \qquad \text{for all } k \geq c\, d^{2.5}\, \log^4\left(\frac{n}{d}\right) \log\left(\frac{\sqrt{M}}{\delta}\right).$$

The proof of Theorem 2 is provided in Appendix D. Again the specific choice of $r_{\scriptscriptstyle J} = 10^{-5}$ is for theoretical purpose; in practice larger choices are possible. Note that the mixing time bound for the John walk depends only on the number of constraints n via a logarithmic factor, and so is almost independent of n. Consequently, it has a mixing time that is polynomial in d even if the number of constraints n scales exponentially in $\sqrt{d}$. Further, we show in Section 4.1 that the cost to execute one step of the John walk is of the same order as of the Dikin walk up to a poly-logarithmic factor in n. Thus, using John walk, we obtain improved mixing time bounds for the case when $n \gg d^2$.

3.3 Mixing time bounds from deterministic start

The mixing time bounds in Theorem 1 and 2 depend on the warmness M of the initial distribution. In some applications, it may not be easy to find an M-warm initial distribution. In such cases, we can consider starting the random walk from a deterministic point $x_0 \in \text{int}\,(\mathcal{K})$ that is not too close to the boundary $\partial\mathcal{K}$. Indeed, such a point can be found using standard optimization methods—e.g., using a Phase-I method for Newton's algorithm (see Boyd and Vandenberghe, 2004, Section 11.5.4).

Given such a deterministic initialization, our mixing time guarantees depend on the distance of the starting point from the boundary. This dependence involves the following notion of s-centrality:

Definition 3 *A point $x \in \text{int}\,(\mathcal{K})$ is called* s-central *if for any chord $\overline{ef}$ with end points $e, f \in \partial\mathcal{K}$ passing through x, we have $\|e - x\|_2 \,/\, \|f - x\|_2 \leq s$.*

Assuming that it is started at an s-central point x_0, the Dikin walk (Kannan and Narayanan, 2012, algorithm in section 2.1) has a polynomial mixing time. The authors showed that when the walk moves to a new state for the first time, the distribution of the iterate is $\mathcal{O}\left((\sqrt{n}s)^d\right)$-warm with respect to the distribution[3] π^*. Since only constant number of steps is required to get a warm start, for a deterministic start, we can just use the Dikin walk in the beginning to provide a warm start to the Vaidya (or John) walk. This motivates us to define the following hybrid walk.

Given an s-central point x_0, simulate the Dikin walk until we observe a new state. Note that due to *laziness* and the accept-reject step, the chain can stay at the starting point for several steps before making the first move a new state. Let k_1 denote the (random) number of steps taken to make the first move to a new state. After k_1 steps, we run the walk VW(r) with x_{k_1} as the initial point. We call such a walk as *s-central Dikin-start-Vaidya-walk* with parameter r. Let $\mathcal{T}_{\text{Dikin}}$ denote the transition kernel of the Dikin walk stated above. Then, we have the following mixing time bound for this hybrid walk.

3. Obtaining a warmness result for the Vaidya walk from a deterministic start from a central point is non-trivial and it is quite possible that the warmness does not improve. As a result, we simply invoke the established result for the Dikin walk.

Corollary 4 *Any s-central Dikin-start-Vaidya-walk with parameter $r = 10^{-4}$ satisfies*

$$\|\mathcal{T}^k_{Vaidya(r)}\left(\mathcal{T}^{k_1}_{Dikin}(\delta_{x_0})\right) - \pi^*\|_{TV} \leq \delta \qquad \text{for all } k \geq cn^{1/2}d^{5/2}\, \log\left(\frac{ns}{\delta}\right),$$

where k_1 is a geometric random variable with $\mathbb{E}\,[k_1] \leq c'$, and $c, c' > 0$ are universal constants.

The mixing rate is logarithmic in ns and has an extra factor of d compared to the bounds in Theorem 1. However, guaranteeing a warm start for a general polytope is hard but obtaining a central point involves only a few steps of optimization. Consequently, the hybrid walk and the guarantees from Corollary 4 come in handy for all such cases. Once again we observe that the upper bounds for mixing time are improved by a factor of $\mathcal{O}(\sqrt{n/d})$ when compared to the Dikin walk from an s-central start (Kannan and Narayanan, 2012; Narayanan, 2016) which had a mixing time of $\mathcal{O}\left(nd^2\right)$. The proof follows immediately from Theorem 1 by Kannan and Narayanan (2012) and Theorem 1 of this paper and is thereby omitted.

In a similar fashion, we can provide a polynomial time guarantee for a modified John walk from a deterministic start. We can consider a hybrid random walk that starts at an s-central point, simulates the Dikin walk until it makes the first move to a new state, and from there onwards simulates the John walk. Such a chain would have a mixing time of $\mathcal{O}\left(d^{3.5}\text{poly-log}(n, d, s)\right)$. For brevity, we omit a formal statement of this result.

3.4 Conjecture on improved John walk

From our analysis, we suspect that it is possible to improve the mixing time bound of $\mathcal{O}\left(d^{2.5}\text{poly-log}(n/d)\right)$ in Theorem 2 by considering a variant of the John walk. In particular, we conjecture that a random walk with proposal distribution given by $\mathcal{N}\left(x, \frac{r^2}{d\cdot\text{poly-log}(n/d)} {J_x}^{-1}\right)$ for a suitable choice of r has an $\mathcal{O}\left(d^2\text{poly-log}(n/d)\right)$ mixing time from a warm start. We refer to this random walk as the *improved John walk*, and denote its transition operator by $\mathcal{T}_{\text{John}^+}$. Let us now give a formal statement of our conjecture on its mixing rate.

Conjecture 5 *Let μ_0 be any M-warm distribution. Then for any $\delta \in (0, 1]$, the improved John walk with parameter $r = r_0$, satisfies the bound*

$$\|\mathcal{T}^k_{John^+}(\mu_0) - \pi^*\|_{TV} \leq \delta \qquad \text{for all } k \geq c\, d^2\, \log_2^{c'}\left(\frac{2n}{d}\right) \log\left(\frac{\sqrt{M}}{\delta}\right),$$

where r_0, c, c' are universal constants.

Note that this conjecture involves quadratic (degree two) scaling in d; this exponent of two matches the sum of exponents for d and n in the mixing time bounds for both the Dikin and Vaidya walks from a warm-start. Consquently, the improved John walk would have better performance than the Dikin, Vaidya and John walks for almost all ranges of (n, d), apart from possible poly-logarithmic factors in the ratio n/d.

3.5 Proof sketch

In this subsection, we provide a high-level sketch of the main ingredients of the main proof. It is well-known that mixing of a Markov chain is closely related to its *conductance*. Our

main proof relies on the work by Lovász (1999) that characterizes the conductance of Markov chains on a convex set using Hilbert metric. Precisely, Lovász (1999) showed that a Markov chain has good conductance if it makes jumps to regions with large overlaps from two nearby points and the mixing time depends inversely on the maximum Hilbert metric between such nearby points. Using this argument, it remains to make sure that the ellipsoid radius is chosen properly such that the ellipsoids remain inside the polytope and the ellipsoids corresponding to two different points x and y overlap a lot even if the points x and y are relatively far apart.

The conductance-based argument has been used for analyzing the ball walk (Lovász and Simonovits, 1990, 1993), Hit-and-run (Lovász, 1999; Lovász and Vempala, 2006a) and the Dikin walk (Kannan and Narayanan, 2012; Narayanan, 2016; Sachdeva and Vishnoi, 2016). We refer the reader to the survey by Vempala (2005) for a thorough discussion about the relation between the conductance and mixing time for Markov chains. Our proof techniques share a few features with the recent analyses of the Dikin walk by Kannan and Narayanan (2012) and Sachdeva and Vishnoi (2016). However, new technical ideas are needed in order to handle the state-dependent weights σ_x and ζ_x, as defined in equations (9b) and (12) respectively, that underlie the proposal distributions for the Vaidya and John walks. Note that these techniques are not present in the analysis of the Dikin walk, which is based on constant weights.

Specifically, we present the proof of Theorem 1 on the mixing time of the Vaidya walk in Section 5 and defer the intermediate technical results to Appendix A, B and C. We present the proof of Theorem 2 (mixing time bound for the John walk) in Appendix D and provide related auxiliary results and their proofs in Appendices E, F, G, H and I. As alluded to earlier, to keep the paper self-contained, we provide the proof of Lovász's Lemma in Appendix J.

4. Numerical experiments

In this section, we first analyze the per-iteration cost to implement of three walks. We show that while the Dikin walk has the best per-iteration cost, the per-iteration cost of the Vaidya walk is only twice of that of Dikin walk and the per-iteration cost of the John walk is only of order $\log_2(2n/d)$ larger. Second, we demonstrate the speed-up gained by the Vaidya walk over the Dikin walk for a warm start on different polytopes.

4.1 Per iteration cost

We now show that the per iteration cost of the Dikin, Vaidya and John walks is of the same order. The proposal step of Vaidya walk requires matrix operations like matrix inversion, matrix multiplication and singular value decomposition (SVD). The accept-reject step requires computation of matrix determinants, besides a few matrix inverses and matrix-vector products. The complexity of all aforementioned operations is $\mathcal{O}\left(nd^2\right)$. Thus, per iteration computational complexity for the Vaidya walk is $\mathcal{O}\left(nd^2\right)$.[4]

4. In theory, the matrix computations for the Dikin walk can be carried out in time nd^{ν} for an exponent $\nu < 1.373$, but such algorithms are not numerically stable enough for practical use.

Both the Dikin and Vaidya walks requires an SVD computation for inverting the Hessian of Dikin barrier $\nabla^2\mathcal{F}_x$. In addition for the Vaidya walk, we have to invert the matrix V_x, which leads to almost twice the computation time of the Dikin walk per step. This difference can be observed in practice.

For the John walk, we need to compute the weights ζ_x at each point which involves solving the program (12). Lee and Sidford (2014) argued that the convex program (12) for obtaining John walk's weights is strongly convex with a suitably chosen norm. They proved that solving this program requires $\log^2 n$ number of gradient steps, where the computational complexity of each gradient step is equivalent to that of solving an $n \times d$ linear system ($\mathcal{O}\left(nd^2\right)$ using a numerically stable routine). Thus, the overall cost for the John walk is of the same order as of the Dikin walk up to a poly-logarithmic factor in the pair (n, d).

In practice, for the John walk, the combined effect of logarithmic factors in the number of steps and the cost to implement each step cannot be ignored. This extra factor becomes a bottleneck for the overall run time for the convergence of the Markov chain. Consequently, the John walk is not suitable for polytopes with moderate values of n and d, and its mixing time bounds are computationally superior to the Dikin and Vaidya walks only for the polytopes with $n \gg d \gg 1$.

4.2 Simulations

We now present simulation results for the random walks in $\mathbb{R}^d$ for $d = 2, 10$ and 50 with initial distribution $\mu_0 = \mathcal{N}(0, \sigma_d^2 \mathbb{I}_d)$ and target distribution being uniform, on the following polytopes:

Set-up 1 : The set $[-1, 1]^2$ defined by different number of constraints.

Set-up 2 : The set $[-1, 1]^d$ for $d \in \{2, 3, 4, 5, 6, 7\}$ for $n = \{2d, 2d^2, 2d^3\}$ constraints.

Set-up 3 : Symmetric polytopes in $\mathbb{R}^2$ with n-randomly-generated-constraints.

Set-up 4 : The interior of regular n-polygons on the unit circle.

Set-up 5 : Hyper cube $[-1, 1]^d$ for $d = 10$ and 50.

We choose σ_d such that the warmness parameter M is bounded by 100. We provide implementations of the Dikin, Vaidya and John walks in python and a jupyter notebook at the github repository `https://github.com/rzrsk/vaidya-walk`.

We use the following three ways to compare the convergence rate of the Dikin and the Vaidya walks: (1) comparing the approximate mixing time of a particular subset of the polytope—smaller value is associated with a faster mixing chain; (2) comparing the plot of the empirical distribution of samples from multiple runs of the Markov chain after k steps—if it appears *more uniform* for smaller k, the chain is deemed to be faster; and (3) contrasting the sequential plots of one dimensional projection of samples for a single long run of the chain—*less smooth* plot is associated with effective and fast exploration leading to a faster mixing (Yu and Mykland, 1998). Note that MCMC convergence diagnostics is a hard problem, especially in high dimensions, and since the methods outlined above are heuristic in nature we expect our experiments to not fully match our theoretical results.

In **Set-up 1**, we consider the polytope $[-1, 1]^2$ which can be represented by exactly 4 linear constraints (see Section 2.4). Suppose that we repeat the rows of the matrix A, and

then run the Dikin and Vaidya walks with the new A. Given the larger number of constraints, our theory predicts that the random walks should mix more slowly. In Figure 3c and 3d, we plot the empirical distribution obtained by the Dikin walk and Vaidya walk, starting from 200 i.i.d initial samples, for $n = 64$ and 2048. The empirical distribution plot shows that having large n significantly slows the mixing rate of the Dikin walk, while the effect on the Vaidya walk is much less. Further, we also plot the scaling of the approximate mixing time $\hat{k}_{\text{mix}}$ (defined below) for this simulation as a function of the number of constraints n in Figure 3b. For **Set-up 2**, we plot $\hat{k}_{\text{mix}}$ as a function of the dimensions d in Figures 3e-3g, for the random walks on $[-1, 1]^d$ where the hypercube is parametrized by different number of constraints $n \in \{2d, 2d^2, 2d^3\}$. The approximate mixing time is defined with respect to the set $\mathcal{S}_d = \{x \in \mathbb{R}^d | \, |x_i| \geq c_d \ \forall i \in [d]\}$ where c_d is chosen such that $\pi^*(\mathcal{S}_d) = 1/2$. In particular, for a fixed value of n, let $\hat{\mathbb{T}}^k$ denote the empirical measure after k-iterations across 2000 experiments. The approximate mixing time $\hat{k}_{\text{mix}}$ is defined as

$$\hat{k}_{\text{mix}} := \min \left\{ k \middle| \pi^*(\mathcal{S}_d) - \hat{\mathbb{T}}^k(\mathcal{S}_d) \leq \frac{1}{20} \right\}, \tag{17}$$

We choose such a set since the set covers the regions near to the boundary of the polytope which are not covered well by the chosen initial distribution. We make the following observations:

1. The slopes of the best-fit lines, for $\hat{k}_{\text{mix}}$ versus n in the log-log plot in Figure 3b, are 0.88 and 0.45 for Dikin and Vaidya walks respectively. This observation reflects a near-linear and sub-linear dependence on n for a fixed d for the mixing time of the Dikin walk and the Vaidya walk respectively.

2. In Figures 3e-3g, once again we observe a more significant effect of increasing the number of constraints on the approximate mixing time $\hat{k}_{\text{mix}}$. We list the slopes of the best fit lines on these log-log plots in Table 2. These slopes correspond to the exponents for d for the approximate mixing time. From the table, we can observe that these experiments agree with the mixing time bounds of $\mathcal{O}(nd)$ for the Dikin walk and $\mathcal{O}\left(n^{0.5}d^{1.5}\right)$ for the Vaidya walk.

No. of Constraints	DW Theoretical	VW Theoretical	DW Experiments	VW Experiments
$n = 2d$	2.0	2.0	1.58	1.72
$n = 2d^2$	3.0	2.5	2.80	2.48
$n = 2d^3$	4.0	3.0	3.84	2.75

Table 2. Value of the exponent of dimensions d for the theoretical bounds on mixing time and the observed approximate mixing time of the Dikin walk (DW) and the Vaidya walk (VW) for $[-1, 1]^d$ described by $n = 2d, 2d^2, 2d^3$ constraints. The theoretical exponents are based on the mixing time bounds of $\mathcal{O}(nd)$ for the Dikin walk and $\mathcal{O}\left(n^{0.5}d^{1.5}\right)$ for the Vaidya walk. The experimental exponents are based on the results from the simulations described in **Set-up 2** in Section 4.2. Clearly, the exponents observed in practice are in agreement with the theoretical rates and imply the faster convergence of the Vaidya walk compared to the Dikin walk for large number of constraints.

In **Set-up 3**, we compare the plots of the empirical distribution of 200 runs of the Dikin walk and the Vaidya walk for different values of k, for symmetric polytopes in $\mathbb{R}^2$ with n-randomly-generated-constraints. We fix $b_i = 1$. To generate a_i, first we draw two uniform

random variables from $[0, 1]$ and then flip the sign of both of them with probability $1/2$ and assign these values to the vector a_i. The resulting polytope is always a subset of the square $\mathcal{K} = [-1, 1]^2$ and contains the diagonal line connecting the points $(-1, 1)$ and $(1, -1)$. From Figure 4a-4b, we observe that while there is no clear winner for the case $n = 64$, the Vaidya walk mixes mixes significantly faster than the Dikin walk for the polytope defined by 2048 constraints.

In **Set-up 4**, the constraint set is the regular n-polygons inscribed in the unit circle. A similar observation as in **Set-up 3** can be made from Figure 4c-4d: the Vaidya walk mixes at least as fast as the Dikin walk and mixes significantly faster for large n.

In **Set-up 5**, we examine the performance of the Dikin walk and the Vaidya walk on hyper-cube $[-1, 1]^d$ for $d = 10, 50$. We plot the one dimensional projections onto a random normal direction of all the samples from a single run up to $10,000$ steps. The Vaidya sequential plot looks more jagged than that of the Dikin walk for $d = 10, n = 5120$. For other cases, we do not have a clear winner. Such an observation is consistent with the $\mathcal{O}(\sqrt{n/d})$ speed up of the Vaidya walk which is apparent when the ratio n/d is large.

5. Proofs

We begin with auxiliary results in Section 5.1 which we use then to prove Theorem 1 in Section 5.2. Proofs of the auxiliary results are in Sections 5.3 and 5.4, and we defer other technical results to appendices.

5.1 Auxiliary results

Our proof proceeds by formally establishing the following property for the Vaidya walk: if two points are close, then their one-step transition distribution are also close. Consequently, we need to quantify the closeness between two points and the associated transition distributions. We measure the distance between two points in terms of the cross ratio that we define next. For a given pair of points $x, y \in \mathcal{K}$, let $e(x), e(y) \in \partial\mathcal{K}$ denote the intersection of the chord joining x and y with $\mathcal{K}$ such that $e(x), x, y, e(y)$ are in order (see Figure 6a). The cross-ratio $d_{\mathcal{K}}(x, y)$ is given by

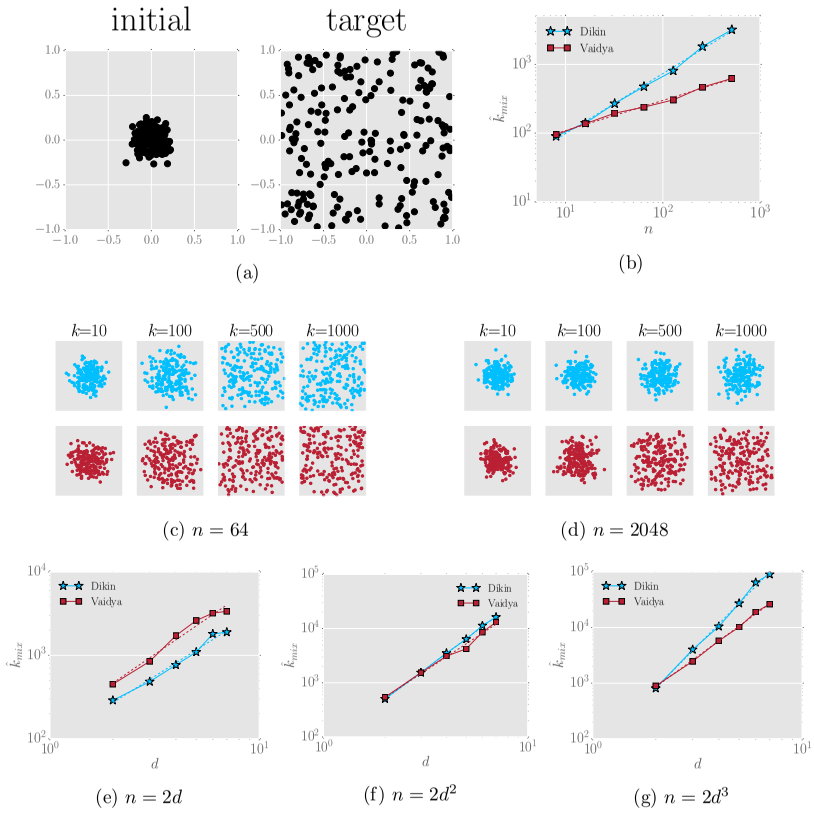
$$d_{\mathcal{K}}(x, y) := \frac{\|e(x) - e(y)\|_2 \, \|x - y\|_2}{\|e(x) - x\|_2 \, \|e(y) - y\|_2}. \tag{18}$$

The ratio $d_{\mathcal{K}}(x, y)$ is related to the Hilbert metric on $\mathcal{K}$, which is given by $\log(1 + d_{\mathcal{K}}(x, y))$; see the paper by Bushell (1973) for more details.

Consider a lazy reversible random walk on a bounded convex set $\mathcal{K}$ with transition operator $\mathcal{T}$ defined via the mapping $\mu_0 \mapsto \mu_0/2 + \tilde{\mathcal{T}}(\mu_0)/2$ and stationary with respect to the uniform distribution on $\mathcal{K}$ (denoted by π^*). (Recall that δ_x denote the dirac-delta distribution with unit mass at x.) The following lemma gives a bound on the mixing-time of the Markov chain.

Lemma 6 (Lovász's Lemma) *Suppose that there exist scalars $\rho, \Delta \in (0, 1)$ such that*

$$\|\tilde{\mathcal{T}}(\delta_x) - \tilde{\mathcal{T}}(\delta_y)\|_{TV} \leq 1 - \rho \qquad \text{for all } x, y \in \text{int}(\mathcal{K}) \text{ with } d_{\mathcal{K}}(x, y) < \Delta. \tag{19a}$$

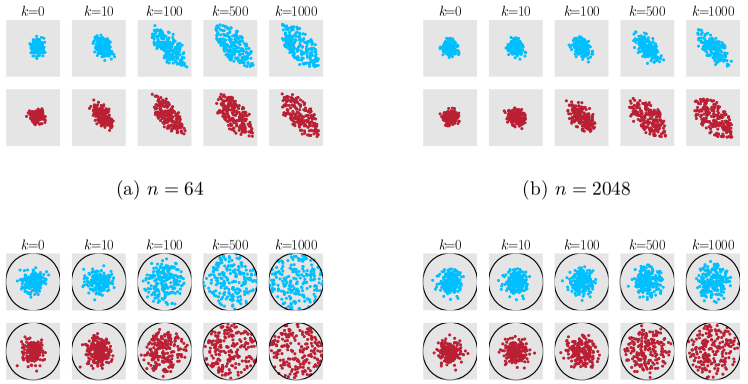


(a) (b) (c) $n = 64$ (d) $n = 2048$ (e) $n = 2d$ (f) $n = 2d^2$ (g) $n = 2d^3$

Figure 3. Comparison of the Dikin and Vaidya walks on the polytope $\mathcal{K} = [-1, 1]^2$. **(a)** Samples from the initial distribution $\mu_0 = \mathcal{N}(0, 0.04\,\mathbb{I}_2)$ and the uniform distribution on $[-1, 1]^2$. **(b)** Log-log plot of $\hat{k}_{\text{mix}}$ (17) versus the number of constraints (n) for a fixed dimension $d = 2$. **(c, d)** Empirical distribution of the samples for the Dikin walk (blue/top rows) and the Vaidya walk (red/bottom rows) for different values of n at iteration $k = 10, 100, 500$ and 1000. **(e, f, g)** Log-log plot of $\hat{k}_{\text{mix}}$ vs the dimension d, for $n \in \{2d, 2d^2, 2d^3\}$ for $d \in \{2, 3, 4, 5, 6, 7\}$. The exponents from these plots are summarized in Table 2. Note that increasing the number of constraints n has more profound effect on the Dikin walk in almost all the cases.

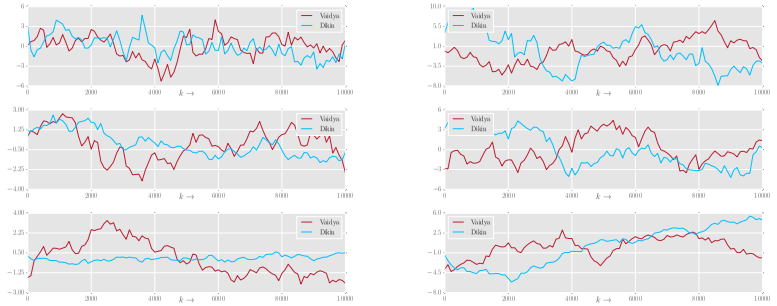
Then for every distribution μ_0 that is M-warm with respect to π^*, the lazy transition operator $\mathcal{T}$ satisfies

$$\|\mathcal{T}^k(\mu_0) - \pi^*\|_{TV} \leq \sqrt{M} \exp\left(-k\,\frac{\Delta^2 \rho^2}{4096}\right) \quad \forall \;\; k = 1, 2, \ldots. \tag{19b}$$



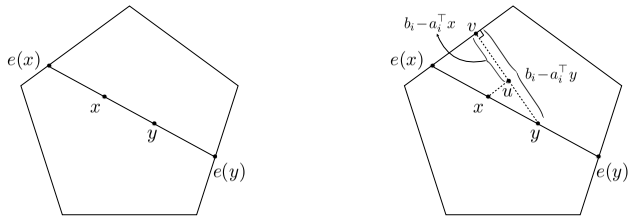
(a) $n = 64$ (b) $n = 2048$ (c) $n = 64$ (d) $n = 2048$

Figure 4. Empirical distribution of the samples from 200 runs for the Dikin walk (blue/top rows) and the Vaidya walk (red/bottom rows) at different iterations k. The 2-dimensional polytopes considered are: **(a, b)** random polytopes with n-constraints, and **(c, d)** regular n-polygons inscribed in the unit circle. For both sets of cases, we observe that higher n slows down the walks, with visibly more effect on the Dikin walk compared to the Vaidya walk.



(a) $d = 10$ (b) $d = 50$

Figure 5. Sequential plots of a one-dimensional random projection of the samples on the hyperbox $\mathcal{K} = [-1, 1]^d$, defined by n constraints. Each plot corresponds to one long run of the Dikin and Vaidya walks, and the projection is taken in a direction chosen randomly from the sphere. **(a)** Plots for $d = 10$ and $n \in \{20, 640, 5120\}$. **(b)** Plots for $d = 50$ and $n \in \{100, 400, 1600\}$. Relative to the Dikin walk, the Vaidya walk has a more jagged plot for pairs (n, d) in which the ratio n/d is relatively large: for instance, see the plots corresponding to $(n, d) = (640, 10)$ and $(5120, 10)$. The same claim cannot be made for pairs (n, d) for which the ratio n/d is relatively small; e.g., the plot with $(n, d) = (20, 10)$. These observations are consistent with our results that the Vaidya walk mixes more quickly by a factor of order $\mathcal{O}(\sqrt{n/d})$ over the Dikin walk.



(a) (b)

Figure 6. Polytope $\mathcal{K} = \{x \in \mathbb{R}^d | Ax \leq b\}$. (a) The points $e(x)$ and $e(y)$ denote the intersection points of the chord joining x and y with $\mathcal{K}$ such that $e(x), x, y, e(y)$ are in order. (b) A geometric illustration of the argument (23). It is straightforward to observe that $\|x-y\|_2/\|e(x)-x\|_2 = \|u-y\|_2/\|u-v\|_2 = \left|a_i^\top (y-x)\right| / \left(b_i - a_i^\top x\right)$.

This result is implicit in the paper by Lovász (1999), though not explicitly stated. In order to keep the paper self-contained, we provide a proof of this result in Appendix J.

Our proof of Theorem 1 is based on applying Lovász's Lemma; the main challenge in our work is to establish that our random walks satisfy the condition (19a) with suitable choices of Δ and ρ. In order to proceed with the proof, we require a few additional notations. Recall that the slackness at x was defined as $s_x := (b_1 - a_1^\top x, \ldots, b_n - a_n^\top x)^\top$. For all $x \in \text{int}\,(\mathcal{K})$, define the *Vaidya local norm of v at x* as

$$\|v\|_{V_x} := \left\|V_x^{1/2} v\right\|_2 = \sqrt{\sum_{i=1}^n (\sigma_{x,i} + \beta_{\text{V}}) \frac{(a_i^\top v)^2}{s_{x,i}^2}}, \tag{20a}$$

and the *Vaidya slack sensitivity at x* as

$$\theta_{V_x} := \left(\left\|\frac{a_1}{s_{x,1}}\right\|_{V_x}^2, \ldots, \left\|\frac{a_n}{s_{x,n}}\right\|_{V_x}^2\right)^\top = \left(\frac{a_1^\top V_x^{-1} a_1}{s_{x,1}^2}, \ldots, \frac{a_n^\top V_x^{-1} a_n}{s_{x,n}^2}\right)^\top. \tag{20b}$$

Similarly, we define the *John local norm of v at x* and the *John slack sensitivity at x* as

$$\|v\|_{J_x} := \left\|J_x^{1/2} v\right\|_2 \quad \text{and} \quad \theta_{J_x} := \left(\left\|\frac{a_1}{s_{x,1}}\right\|_{J_x}^2, \ldots, \left\|\frac{a_n}{s_{x,n}}\right\|_{J_x}^2\right)^\top. \tag{20c}$$

The following lemma provides useful properties of the leverage scores σ_x from equation (9b), the weights ζ_x obtained from solving the program (12), and the slack sensitivities θ_{V_x} and θ_{J_x}.

Lemma 7 *For any $x \in \text{int}\,(\mathcal{K})$, the following properties hold:*

(a) $\sigma_{x,i} \in [0,1]$ *for all* $i \in [n]$,

(b) $\sum_{i=1}^n \sigma_{x,i} = d$,

(c) $\theta_{V_x,i} \in \left[0, \sqrt{n/d}\right]$ *for all* $i \in [n]$,

(d) $\zeta_{x,i} \in [\beta_J, 1+\beta_J]$ *for all* $i \in [n]$,

(e) $\sum_{i=1}^n \zeta_{x,i} = 3d/2$, *and*

(f) $\theta_{J_x,i} \in [0,4]$ *for all* $i \in [n]$.

We prove this lemma in Section 5.3.

Let $\mathcal{P}_x^{\text{V}}$ to denote the proposal distribution of the random walk VW(r) at state x. Next, we state a lemma that shows that if two points $x, y \in \text{int}\,(\mathcal{K})$ are close in Vaidya local norm at x, then for a suitable choice of the parameter r, the proposal distributions $\mathcal{P}_x^{\text{V}}$ and $\mathcal{P}_y^{\text{V}}$ are close. In addition, we show that the proposals are accepted with high probability at any point $x \in \text{int}\,(\mathcal{K})$. To establish the latter result, we now define the non-lazy transition operator of the Vaidya walk. Since the Vaidya walk is lazy with probability $1/2$, there exists a valid (non-lazy) transition operator $\tilde{\mathcal{T}}_{\text{Vaidya}(r)}$ such that for any distribution μ_0, we have

$$\mathcal{T}_{\text{Vaidya}(r)}(\mu_0) = \mu_0/2 + \tilde{\mathcal{T}}_{\text{Vaidya}(r)}(\mu_0)/2.$$

We call $\tilde{\mathcal{T}}_{\text{Vaidya}}$ the non-lazy transition operator for the Vaidya walk. Note that the one-step non-lazy transition distribution $\tilde{\mathcal{T}}_{\text{Vaidya}(r)}(\delta_x)$ denotes the distribution of proposals after the accept-reject step if the chain was not lazy. Thus to establish that proposals are accepted with high probability, it suffices to establish that the transition distribution $\tilde{\mathcal{T}}_{\text{Vaidya}(r)}(\delta_x)$ at any point $x \in \mathcal{K}$ is close to the proposal distribution $\mathcal{P}_x^{\text{V}}$. We now state these two results formally:

Lemma 8 *There exists a continuous non-decreasing function $f : [0, 1/4] \to \mathbb{R}_+$ with $f(1/15) \geq 10^{-4}$ such that for any $\epsilon \in (0, 1/15]$, the random walk VW(r) with $r \in [0, f(\epsilon)]$ satisfies*

$$\|\mathcal{P}_x^V - \mathcal{P}_y^V\|_{TV} \leq \epsilon \quad \forall\ x, y \in \text{int}\,(\mathcal{K})\ \text{s.t.}\ \|x-y\|_{V_x} \leq \frac{\epsilon r}{2(nd)^{1/4}}, \quad \text{and} \tag{21a}$$

$$\|\tilde{\mathcal{T}}_{Vaidya(r)}(\delta_x) - \mathcal{P}_x^V\|_{TV} \leq 5\epsilon\ \forall\ x \in \text{int}\,(\mathcal{K}). \tag{21b}$$

See Section 5.4 for the proof of this lemma.

With these lemmas in hand, we are now equipped to prove Theorem 1. To simplify notation, for the rest of this section, we adopt the shorthands $\mathbb{T}_x = \tilde{\mathcal{T}}_{\text{Vaidya}(r)}(\delta_x)$, $\mathcal{P}_x = \mathcal{P}_x^{\text{V}}$ and $\|\cdot\|_{V_x} = \|\cdot\|_x$.

5.2 Proof of Theorem 1

In order to invoke Lovász's Lemma for the random walk VW(10^{-4}), we need to verify the condition (19a) for suitable choices of ρ and Δ. Doing so involves two main steps:

(A): First, we relate the cross-ratio $d_{\mathcal{K}}(x,y)$ to the local norm (20a) at x.

(B): Second, we use Lemma 8 to show that if $x, y \in \text{int}\,(\mathcal{K})$ are close in local-norm, then the transition distributions $\mathbb{T}_x$ and $\mathbb{T}_y$ are close in TV-distance.

Step (A): We claim that for all $x, y \in \text{int}(\mathcal{K})$, the cross-ratio can be lower bounded as

$$d_{\mathcal{K}}(x,y) \geq \frac{1}{\sqrt{2d}} \|x-y\|_x . \tag{22}$$

Note that we have

$$d_{\mathcal{K}}(x,y) = \frac{\|e(x)-e(y)\|_2 \|x-y\|_2}{\|e(x)-x\|_2 \|e(y)-y\|_2} \overset{(i)}{\geq} \max\left\{\frac{\|x-y\|_2}{\|e(x)-x\|_2}, \frac{\|x-y\|_2}{\|e(y)-y\|_2}\right\} \overset{(ii)}{\geq} \max\left\{\frac{\|x-y\|_2}{\|e(x)-x\|_2}, \frac{\|x-y\|_2}{\|e(y)-x\|_2}\right\},$$

where step (i) follows from the inequality $\|e(x)-e(y)\|_2 \geq \max\{\|e(y)-y\|_2, \|e(x)-x\|_2\}$; and step (ii) follows from the inequality $\|e(x)-x\|_2 \leq \|e(y)-x\|_2$. Furthermore, from Figure 6b, we observe that

$$\max\left\{\frac{\|x-y\|_2}{\|e(x)-x\|_2}, \frac{\|x-y\|_2}{\|e(y)-x\|_2}\right\} = \max_{i\in[n]} \left|\frac{a_i^\top (x-y)}{s_{x,i}}\right|. \tag{23}$$

This argument of equation (14) has also been used (Sachdeva and Vishnoi, 2016, lemma 9). Note that maximum of a set of non-negative numbers is greater than the mean of the numbers. Combining this fact with properties (a) and (b) from Lemma 7, we find that

$$d_{\mathcal{K}}(x,y) \geq \sqrt{\frac{1}{\sum_{i=1}^n (\sigma_{x,i}+\beta_{\text{V}})} \sum_{i=1}^n (\sigma_{x,i}+\beta_{\text{V}}) \frac{(a_i^\top (x-y))^2}{s_{x,i}^2}} = \frac{\|x-y\|_x}{\sqrt{2d}},$$

thereby proving the claim (22).

Step (B): By the triangle inequality, we have

$$\|\mathbb{T}_x - \mathbb{T}_y\|_{\text{TV}} \leq \|\mathbb{T}_x - \mathcal{P}_x\|_{\text{TV}} + \|\mathcal{P}_x - \mathcal{P}_y\|_{\text{TV}} + \|\mathcal{P}_y - \mathbb{T}_y\|_{\text{TV}}.$$

Thus, for any (r,ϵ) such that $\epsilon \in [0, 1/15]$ and $r \leq f(\epsilon)$, Lemma 8 implies that

$$\|\mathbb{T}_x - \mathbb{T}_y\|_{\text{TV}} \leq 11\epsilon, \quad \forall x, y \in \text{int}(\mathcal{K}) \text{ such that } \|x-y\|_x \leq \frac{r\epsilon}{2(nd)^{1/4}}.$$

Consequently, the walk VW(r) satisfies the assumptions of Lovász's Lemma with

$$\Delta := \frac{1}{\sqrt{2d}} \cdot \frac{r\epsilon}{2(nd)^{1/4}} \quad \text{and} \quad \rho := 1 - 11\epsilon.$$

Since $f(1/15) \geq 10^{-4}$, we can set $\epsilon = 1/15$ and $r = 10^{-4}$, whence

$$\Delta^2\rho^2 = \frac{(1-11\epsilon)^2\epsilon^2 r^2}{8d\sqrt{nd}} = \frac{4^2}{15^2}\frac{1}{15^2}\frac{1}{10^{-8}} \cdot \frac{1}{d\sqrt{nd}} \geq 10^{-12}\frac{1}{d\sqrt{nd}}.$$

Observing that $\Delta < 1$ yields the claimed upper bound for the mixing time of Vaidya Walk.

5.3 Proof of Lemma 7

In order to prove part (a), observe that for any $x \in \text{int}(\mathcal{K})$, the Hessian $\nabla^2\mathcal{F}_x := \sum_{i=1}^n a_i a_i^\top / s_{x,i}^2$ is a sum of rank one positive semidefinite (PSD) matrices. Also, we can write $\nabla^2\mathcal{F}_x = A_x^\top A_x$ where

$$A_x := \begin{bmatrix} a_1^\top / s_{x,1} \\ \vdots \\ a_n^\top / s_{x,n} \end{bmatrix}.$$

Since $\text{rank}(A_x) = d$, we conclude that the matrix $\nabla^2\mathcal{F}_x$ is invertible and thus, both the matrices $\nabla^2\mathcal{F}_x$ and $\left(\nabla^2\mathcal{F}_x\right)^{-1}$ are PSD. Since $\sigma_{x,i} = a_i^\top \left(\nabla^2\mathcal{F}_x\right)^{-1} a_i / s_{x,i}^2$, we have $\sigma_{x,i} \geq 0$. Further, the fact that $a_i a_i^\top / s_{x,i}^2 \preceq \nabla^2\mathcal{F}_x$ implies that $\sigma_{x,i} \leq 1$.

Turning to the proof of part (b), from the equality $\text{trace}(AB) = \text{trace}(BA)$, we obtain

$$\sum_{i=1}^n \sigma_{x,i} = \text{trace}\left(\sum_{i=1}^n \frac{a_i^\top \left(\nabla^2\mathcal{F}_x\right)^{-1} a_i}{s_{x,i}^2}\right) = \text{trace}\left(\left(\nabla^2\mathcal{F}_x\right)^{-1} \sum_{i=1}^n \frac{a_i a_i^\top}{s_{x,i}^2}\right) = \text{trace}(\mathbb{I}_d) = d.$$

Now we prove part (c). Using the fact that $\sigma_{x,i} \geq 0$, and an argument similar to part (a) we find that that the matrices V_x and V_x^{-1} are PSD. Since $\theta_{V_x,i} = a_i^\top V_x^{-1} a_i / s_{x,i}^2$, we have $\theta_{V_x,i} \geq 0$. It is straightforward to see that $\beta_{\text{V}} \nabla^2\mathcal{F}_x \preceq V_x$ which implies that $\theta_{V_x,i} \leq \sigma_{x,i}/\beta$. Further, we also have $(\sigma_{x,i}+\beta_{\text{V}}) \frac{a_i a_i^\top}{s_{x,i}^2} \preceq V_x$ and whence $\theta_{V_x,i} \leq 1/(\sigma_{x,i}+\beta_{\text{V}})$. Combining the two inequalities yields the claim.

The other parts of the Lemma follow from Lemma 13, 14 and 15 by Lee and Sidford (2014) and are thereby omitted here.

5.4 Proof of Lemma 8

We prove the lemma for the following function

$$f(\epsilon) := \min\left\{\frac{1}{20\left(1+\sqrt{2}\log^{\frac{1}{2}}\left(\frac{4}{\epsilon}\right)\right)}, \frac{\epsilon}{\sqrt{18\log(2/\epsilon)}}, \sqrt{\frac{\epsilon}{86\sqrt{3}\chi_2}}, \frac{\epsilon}{22\sqrt{5/3}\chi_3}, \sqrt{\frac{\epsilon}{50\sqrt{105}\chi_4}}\right\}, \tag{24}$$

where $\chi_k = (2e/k \cdot \log(4/\epsilon))^{k/2}$ for $k = 2, 3$ and 4. A numerical calculation shows that $f(1/15) \geq 10^{-4}$.

5.4.1 Proof of claim (21a)

In order to bound the total variation distance $\|\mathcal{P}_x - \mathcal{P}_y\|_{\text{TV}}$, we apply Pinsker's inequality, which provides an upper bound on the TV-distance in terms of the KL divergence:

$$\|\mathcal{P}_x - \mathcal{P}_y\|_{\text{TV}} \leq \sqrt{2\,\text{KL}(\mathcal{P}_x \| \mathcal{P}_y)}.$$

For Gaussian distributions, the KL divergence has a closed form expression. In particular, for two normal-distributions $\mathcal{G}_1 = \mathcal{N}(\mu_1, \Sigma_1)$ and $\mathcal{G}_2 = \mathcal{N}(\mu_2, \Sigma_2)$, the Kullback-Leibler

divergence between the two is given by

$$\mathrm{KL}(\mathcal{G}_1\|\mathcal{G}_2) = \frac{1}{2}\Big(\mathrm{trace}(\Sigma_1^{-1/2}\Sigma_2\Sigma_1^{-1/2}) - d - \log\det(\Sigma_1^{-1/2}\Sigma_2\Sigma_1^{-1/2}) + (\mu_1-\mu_2)^\top\Sigma_1^{-1}(\mu_1-\mu_2)\Big).$$

Recall from equation (15) that the proposal distribution for Vaidya walk is Gaussian, i.e., $\mathcal{P}_x = \mathcal{N}\left(x, \frac{r}{\sqrt{nd}}V_x^{-1}\right)$. Substituting $\mathcal{G}_1 = \mathcal{P}_x$ and $\mathcal{G}_2 = \mathcal{P}_y$ into the above expression and applying Pinsker's inequality, we find that

$$\begin{aligned}\|\mathcal{P}_x - \mathcal{P}_y\|_{\mathrm{TV}}^2 \le 2\,\mathrm{KL}(\mathcal{P}_y\|\mathcal{P}_x) &= \mathrm{trace}(V_x^{-1/2}V_yV_x^{-1/2}) - d - \log\det(V_x^{-1/2}V_yV_x^{-1/2}) + \frac{\sqrt{nd}}{r^2}\|x-y\|_x^2 \\ &= \left\{\sum_{i=1}^d\left(\lambda_i - 1 + \log\frac{1}{\lambda_i}\right)\right\} + \frac{\sqrt{nd}}{r^2}\|x-y\|_x^2, \qquad (25)\end{aligned}$$

where $\lambda_1, \ldots, \lambda_d > 0$ denote the eigenvalues of the matrix $V_x^{-1/2}V_yV_x^{-1/2}$, and we have used the facts that $\det(V_x^{-1/2}V_yV_x^{-1/2}) = \prod_{i=1}^d\lambda_i$ and $\mathrm{trace}(V_x^{-1/2}V_yV_x^{-1/2}) = \sum_{i=1}^d\lambda_i$. The following lemma is useful in bounding expression (25).

Lemma 9 *For any scalar $t \in [0, 1/12]$ and any pair $x, y \in \mathrm{int}(\mathcal{K})$ such that $\|x-y\|_x \le t/(nd)^{1/4}$, we have*

$$\left(1 - \frac{8t}{\sqrt{d}}\right)\mathbb{I}_d \preceq V_x^{-1/2}V_yV_x^{-1/2} \preceq \left(1 + \frac{8t}{\sqrt{d}}\right)\mathbb{I}_d,$$

where $\preceq$ denotes ordering in the PSD cone, and $\mathbb{I}_d$ is the d-dimensional identity matrix.

See Appendix B for the proof of this lemma.

For $\epsilon \in (0, 1/15]$ and $r \in [0, 1/12]$, we have $t = \epsilon r/2 \le 1/12$, whence the eigenvalues $\{\lambda_i, i \in [d]\}$ can be sandwiched as

$$\frac{1}{2} \le 1 - \frac{4\epsilon r}{\sqrt{d}} \le \lambda_i \le 1 + \frac{4\epsilon r}{\sqrt{d}} \quad \text{for all } i \in d. \qquad (26)$$

We are now ready to bound the TV distance between $\mathcal{P}_x$ and $\mathcal{P}_y$. Using the bound (25) and the inequality $\log\omega \le \omega - 1$, valid for $\omega > 0$, we obtain

$$\|\mathcal{P}_x - \mathcal{P}_y\|_{\mathrm{TV}}^2 \le \sum_{i=1}^d\left(\lambda_i - 2 + \frac{1}{\lambda_i}\right) + \frac{\sqrt{nd}}{r^2}\|x-y\|_x^2.$$

Using the assumption that $\|x-y\|_x \le \epsilon r/\left(2(nd)^{1/4}\right)$, and plugging in the bounds (26) for the eigenvalues $\{\lambda_i, i \in [d]\}$, we find that

$$\sum_{i=1}^d\left(\lambda_i - 2 + \frac{1}{\lambda_i}\right) + \frac{\sqrt{nd}}{r^2}\|x-y\|_x^2 \le 32\epsilon^2r^2 + \frac{\epsilon^2}{4}.$$

In asserting this inequality, we have used the facts that according to equation (26), for any $i \in [d]$,

$$\lambda_i - 2 + \frac{1}{\lambda_i} = \frac{(\lambda_i - 1)^2}{\lambda_i} \le 2\cdot\left(\frac{4\epsilon r}{\sqrt{d}}\right)^2.$$

Note that for any $r \in [0, 1/12]$ we have that $32r^2 \le 1/2$. Putting the pieces together yields $\|\mathcal{P}_x - \mathcal{P}_y\|_{\mathrm{TV}} \le \epsilon$, as claimed.

5.4.2 Proof of claim (21b)

Note that

$$\mathbb{T}_x(\{x\}) = \mathcal{P}_x(\mathcal{K}^c) + \int_{\mathcal{K}}\left(1 - \min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}\right)p_x(z)dz, \qquad (27)$$

where $\mathcal{K}^c$ denotes the complement of $\mathcal{K}$. Consequently, we find that

$$\begin{aligned}\|\mathcal{P}_x - \mathbb{T}_x\|_{\mathrm{TV}} &= \frac{1}{2}\left(\mathbb{T}_x(\{x\}) + \int_{\mathbb{R}^d}p_x(z)dz - \int_{\mathcal{K}}\min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}p_x(z)dz\right) \\ &= \frac{1}{2}\left(2 - 2\int_{\mathbb{R}^d}\min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}p_x(z)dz + 2\int_{\mathcal{K}^c}\min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}p_x(z)dz\right) \\ &\le \underbrace{\mathcal{P}_x(\mathcal{K}^c)}_{=:S_1} + \underbrace{1 - \mathbb{E}_{z\sim\mathcal{P}_x}\left[\min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}\right]}_{=:S_2}, \qquad (28)\end{aligned}$$

Consequently, it suffices to show that both S_1 and S_2 are small, where the probability is taken over the randomness in the proposal z. In particular, we show that $S_1 \le \epsilon$ and $S_2 \le 4\epsilon$.

Bounding the term S_1: Since z is multivariate Gaussian with mean x and covariance $\frac{r^2}{\sqrt{nd}}V_x^{-1}$, we can write

$$z \overset{d}{=} x + \frac{r}{(nd)^{1/4}}V_x^{-1/2}\xi, \qquad (29)$$

where $\xi \sim \mathcal{N}(0, \mathbb{I}_d)$ and $\overset{d}{=}$ denotes equality in distribution. Using equation (29) and definition (20b) of $\theta_{V_x,i}$, we obtain the bound

$$\frac{\left(a_i^\top(z-x)\right)^2}{s_{x,i}^2} = \frac{r^2}{(nd)^{\frac{1}{2}}}\left[\frac{a_i^\top V_x^{-1/2}\xi}{s_{x,i}}\right]^2 \overset{(i)}{\le} \frac{r^2}{(nd)^{\frac{1}{2}}}\theta_{V_x,i}\|\xi\|_2^2 \overset{(ii)}{\le} \frac{r^2}{d}\|\xi\|_2^2, \qquad (30)$$

where step (i) follows from Cauchy-Schwarz inequality, and step (ii) from the bound on $\theta_{V_x,i}$ from Lemma 7(c). Define the events

$$\mathcal{E} := \left\{\frac{r^2}{d}\|\xi\|_2^2 < 1\right\} \quad \text{and} \quad \mathcal{E}' := \{z \in \mathrm{int}(\mathcal{K})\}.$$

Inequality (30) implies that $\mathcal{E} \subseteq \mathcal{E}'$ and hence $\mathbb{P}[\mathcal{E}'] \ge \mathbb{P}[\mathcal{E}]$. Using a standard Gaussian tail bound and noting that $r \le \frac{1}{1+\sqrt{2/d\log(1/\epsilon)}}$, we obtain $\mathbb{P}[\mathcal{E}] \ge 1-\epsilon$ and whence $\mathbb{P}[\mathcal{E}'] \ge 1-\epsilon$. Thus, we have shown that $\mathbb{P}[z \notin \mathcal{K}] \le \epsilon$ which implies that $S_1 \le \epsilon$.

Bounding the term S_2: By Markov's inequality, we have

$$\mathbb{E}_{z\sim\mathcal{P}_x}\left[\min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}\right] \ge \alpha\mathbb{P}\left[p_z(x) \ge \alpha p_x(z)\right] \quad \text{for all } \alpha \in (0, 1]. \qquad (31)$$

By definition (15) of p_x, we obtain

$$\frac{p_z(x)}{p_x(z)} = \exp\left(-\frac{\sqrt{nd}}{2r^2}\left(\|z-x\|_z^2 - \|z-x\|_x^2\right) + \frac{1}{2}\left(\log\det V_z - \log\det V_x\right)\right).$$

The following lemma provides us with useful bounds on the two terms in this expression, valid for any $x \in \operatorname{int}(\mathcal{K})$.

Lemma 10 *For any $\epsilon \in (0, 1/15]$ and $r \in (0, f(\epsilon)]$, we have*

$$\mathbb{P}_{z\sim\mathcal{P}_x}\left[\frac{1}{2}\log\det V_z - \frac{1}{2}\log\det V_x \geq -\epsilon\right] \geq 1-\epsilon, \quad \textit{and} \tag{32a}$$

$$\mathbb{P}_{z\sim\mathcal{P}_x}\left[\|z-x\|_z^2 - \|z-x\|_x^2 \leq 2\epsilon\frac{r^2}{\sqrt{nd}}\right] \geq 1-\epsilon. \tag{32b}$$

See Appendix C for the proof of this claim.

Using Lemma 10, we now complete the proof. For $r \leq f(\epsilon)$, we obtain

$$\frac{p_z(x)}{p_x(z)} \geq \exp(-2\epsilon) \geq 1-2\epsilon$$

with probability at least $1-2\epsilon$. Substituting $\alpha = 1-2\epsilon$ in inequality (31) yields that $S_2 \leq 4\epsilon$, as claimed.

6. Discussion

In this paper, we focused on improving mixing rate of MCMC sampling algorithms for polytopes by building on the advancements in the field of interior point methods. We proposed and analyzed two different barrier based MCMC sampling algorithms for polytopes that outperforms the existing sampling algorithms like the ball walk, the hit-and-run and the Dikin walk for a large class of polytopes. We provably demonstrated the fast mixing of the Vaidya walk, $\mathcal{O}\left(n^{0.5}d^{1.5}\right)$ and the John walk, $\mathcal{O}\left(d^{2.5}\text{poly-log}(n/d)\right)$ from a warm start. Our numerical experiments, albeit simple, corroborated with our theoretical claims: the Vaidya walk mixes at least as fast the Dikin walk and significantly faster when the number of constraints is quite large compared to the dimension of the underlying space. For the John walk, the logarithmic factors were dominant in all our experiments and thereby we deemed the result of importance only for set-ups with polytopes in very high dimensions with number of constraints overwhelmingly larger than the dimensions. Besides, proving the mixing time guarantees for the improved John walk (Conjecture 5) is still an open question.

Narayanan (2016) analyzed a generalized version of the Dikin walk for arbitrary convex sets equipped with self-concordant barrier. From his results, we were able to derive mixing time bounds of $\mathcal{O}\left(nd^4\right)$ and $\mathcal{O}\left(d^5\text{poly-log}(n/d)\right)$ from a warm start for the Vaidya walk and the John walk respectively. Our proof takes advantage of the specific structure of the Vaidya and John walk, resulting a better mixing rate upper bound the the general analysis provided by Narayanan (2016).

While our paper has mainly focused on sampling algorithms on polytopes, the idea of using logarithmic barrier to guide sampling can be extended to more general convex sets. The self-concordance property of the logarithmic barrier for polytopes is extended by Anstreicher (2000) to more general convex sets defined by semidefinite constraints, namely, linear matrix inequality (LMI) constraints. Moreover, Narayanan (2016) showed that for a convex set in $\mathbb{R}^d$ defined by n LMI constraints and equipped with the log-determinant barrier—the semidefinite analog of the logarithmic barrier for polytopes—the mixing time of the Dikin walk from a warm start is $\mathcal{O}\left(nd^2\right)$. It is possible that an appropriate Vaidya walk on such sets would have a speed-up over the Dikin walk. Narayanan and Rakhlin (2013) used the Dikin walk to generate samples from time varying log-concave distributions with appropriate scaling of the radius for different class of distributions. We believe that suitable adaptations of the Vaidya and John walks for such cases would provide significant gains.

Appendix

Appendix A. Auxiliary results for the Vaidya walk

In this appendix, we first summarize a few notations used in the proofs related to Theorem 1, and collect the auxiliary results for the later proofs.

A.1 Notation

We begin with introducing the notation. Recall $A \in \mathbb{R}^{n\times d}$ is a matrix with $a_i^\top$ as its i-th row. For any positive integer p and any vector $v = (v_1, \ldots, v_p)^\top$, $\mathrm{diag}(v) = \mathrm{diag}(v_1, \ldots, v_p)$ denotes a $p\times p$ diagonal matrix with the i-th diagonal entry equal to v_i. Recall the definition of S_x:

$$S_x = \mathrm{diag}\left(s_{x,1}, \ldots, s_{x,n}\right) \text{ where } s_{x,i} = b_i - a_i^\top x \text{ for each } i \in [n]. \tag{33}$$

Furthermore, define $A_x = S_x^{-1}A$ for all $x \in \mathrm{int}\,(\mathcal{K})$, and let Υ_x denote the projection matrix for the column space of A_x, i.e.,

$$\Upsilon_x := A_x(A_x^\top A_x)^{-1}A_x^\top = A_x\nabla^2\mathcal{F}_x^{-1}A_x^\top. \tag{34}$$

Note that for the scores σ_x (9b), we have $\sigma_{x,i} = (\Upsilon_x)_{ii}$ for each $i \in [n]$. Let Σ_x be an $n \times n$ diagonal matrix defined as

$$\Sigma_x = \mathrm{diag}\left(\sigma_{x,1}, \ldots, \sigma_{x,n}\right). \tag{35}$$

Let $\sigma_{x,i,j} := (\Upsilon_x)_{ij}$, and let $\Upsilon_x^{(2)}$ denote the Hadamard product of Υ_x with itself, i.e.,

$$(\Upsilon_x^{(2)})_{ij} = \sigma_{x,i,j}^2 = \frac{\left(a_i^\top\nabla^2\mathcal{F}_x^{-1}a_j\right)^2}{s_{x,i}^2 s_{x,j}^2} \quad \text{for all } i,j \in [n]. \tag{36}$$

Using the shorthand $\theta_x := \theta_{V_x}$, we define

$$\Theta_x := \mathrm{diag}\left(\theta_{x,1}, \ldots, \theta_{x,m}\right) \text{ where } \theta_{x,i} = \frac{a_i^\top V_x^{-1}a_i}{s_{x,i}^2} \quad \text{for } i \in [n], \text{ and}$$

$$\Xi_x := (\theta_{x,i,j}^2) \text{ where } \theta_{x,i,j}^2 = \frac{\left(a_i^\top V_x^{-1}a_j\right)^2}{s_{x,i}^2 s_{x,j}^2} \quad \text{for } i,j \in [n].$$

In our new notation, we can re-write the Vaidya matrix V_x defined in equation (9a) as $V_x = A_x^\top\left(\Sigma_x + \beta_{\mathrm{V}}\mathbb{I}\right)A_x$, where $\beta_{\mathrm{V}} = d/n$.

A.2 Basic Properties

We begin by summarizing some key properties of various terms involved in our analysis.

Lemma 11 *For any vector $x \in \mathrm{int}\,(\mathcal{K})$, the following properties hold:*

(a) $\sigma_{x,i} = \sum_{j=1}^n \sigma_{x,i,j}^2 = \sum_{j,k=1}^n \sigma_{x,i,j}\sigma_{x,j,k}\sigma_{x,k,i}$ *for each* $i \in [n]$,

(b) $\Sigma_x \succeq \Upsilon_x^{(2)}$,

(c) $\sum_{i=1}^n \theta_{x,i}\,(\sigma_{x,i}+\beta_V) = d$,

(d) $\forall i \in [n],\ \theta_{x,i} = \sum_{j=1}^n (\sigma_{x,j}+\beta_V)\,\theta_{x,i,j}^2$, *for each* $i \in [n]$,

(e) $\theta_x^\top\,(\Sigma_x + \beta_V \mathbb{I})\,\theta_x = \sum_{i=1}^n \theta_{x,i}^2\,(\sigma_{x,i}+\beta_V) \le \sqrt{nd}$, *and*

(f) $\beta_V\,\nabla^2\mathcal{F}_x \preceq V_x \preceq (1+\beta_V)\,\nabla^2\mathcal{F}_x$.

where $\beta_V = d/n$ *was defined in equation* (9b).

Proof We prove each property separately.

Part (a): Using $\mathbb{I}_d = \nabla^2\mathcal{F}_x\left(\nabla^2\mathcal{F}_x\right)^{-1}$, we find that

$$\sigma_{x,i} = \frac{a_i^\top\left(\nabla^2\mathcal{F}_x\right)^{-1}\nabla^2\mathcal{F}_x\left(\nabla^2\mathcal{F}_x\right)^{-1}a_i}{s_{x,i}^2} = \frac{a_i^\top\left(\nabla^2\mathcal{F}_x\right)^{-1}\nabla^2\sum_{j=1}^n \frac{a_j^\top a_j}{s_{x,j}^2}\left(\nabla^2\mathcal{F}_x\right)^{-1}a_i}{s_{x,i}^2} = \sum_{i,j=1}^n \sigma_{x,i,j}^2.$$

Applying a similar trick twice and performing some algebra, we obtain

$$\sigma_{x,i} = \frac{a_i^\top\left(\nabla^2\mathcal{F}_x\right)^{-1}\nabla^2\mathcal{F}_x\left(\nabla^2\mathcal{F}_x\right)^{-1}\nabla^2\mathcal{F}_x\left(\nabla^2\mathcal{F}_x\right)^{-1}a_i}{s_{x,i}^2} = \sum_{i,j,k=1}^n \sigma_{x,i,j}\sigma_{x,j,k}\sigma_{x,k,i}.$$

Part (b): From part (a), we have that $\Sigma_x - \Upsilon_x^{(2)}$ is a symmetric and diagonally dominant matrix with non-negative entries on the diagonal. Applying Gershgorin's theorem (Bhatia, 2013; Horn and Johnson, 2012), we conclude that it is PSD.

Part (c): Since $\mathrm{trace}(AB) = \mathrm{trace}(BA)$, we have

$$\sum_{i=1}^n \theta_{x,i}\,(\sigma_{x,i}+\beta_V) = \mathrm{trace}\left(V_x^{-1}\sum_{i=1}^n (\sigma_{x,i}+\beta_V)\,\frac{a_i a_i^\top}{s_{x,i}^2}\right) = \mathrm{trace}\,(\mathbb{I}_d) = d.$$

Part (d): An argument similar to part (a) implies that

$$\theta_{x,i} = \frac{a_i^\top V_x^{-1} V_x V_x^{-1} a_i}{s_{x,i}^2} = \frac{a_i^\top V_x^{-1}\sum_{j=1}^n (\sigma_{x,i}+\beta_V)\,\frac{a_j^\top a_j}{s_{x,j}^2} V_x^{-1} a_i}{s_{x,i}^2} = \sum_{i,j=1}^n (\sigma_{x,i}+\beta_V)\,\theta_{x,i,j}^2.$$

Part (e): Using part (c) and Lemma 7(c) yields the claim.

Part (f): The left inequality is by the definition of V_x. The right inequality uses the fact that $\Sigma_x \preceq \mathbb{I}_d$. ■

We now prove an important result that relates the *slackness* s_x and s_y at two points, in terms of $\|x-y\|_x$.

Lemma 12 *For all* $x, y \in \mathrm{int}\,(\mathcal{K})$, *we have*

$$\left|1 - \frac{s_{y,i}}{s_{x,i}}\right| \le \left(\frac{n}{d}\right)^{\frac{1}{4}} \|x-y\|_x \quad \textit{for each } i \in [n].$$

Proof For any pair $x, y \in \mathrm{int}\,(\mathcal{K})$ and index $i \in [n]$, we have

$$\begin{aligned}\left(a_i^\top(x-y)\right)^2 = \left((V_x^{-\frac{1}{2}}a_i)^\top V_x^{\frac{1}{2}}(x-y)\right)^2 &\overset{(i)}{\le} \|V_x^{-\frac{1}{2}}a_i\|_2^2\,\|V_x^{\frac{1}{2}}(x-y)\|_2^2 \\ &= a_i^T V_x^{-1} a_i\ \|x-y\|_x^2 \\ &= \theta_{x,i}s_{x,i}^2\ \|x-y\|_x^2 \\ &\overset{(ii)}{\le} \sqrt{\frac{n}{d}}s_{x,i}^2\ \|x-y\|_x^2,\end{aligned}$$

where step (i) follows from the Cauchy-Schwarz inequality, and step (ii) uses the bound $\theta_{x,i}$ from Lemma 7(c). Noting the fact that $a_i^\top(x-y) = s_{y,i} - s_{x,i}$, the claim follows after simple algebra. ■

Appendix B. Proof of Lemma 9

In this appendix section, we prove Lemma 9 using results from the previous appendix. As a direct consequence of Lemma 12, we find that

$$\left|1 - \frac{s_{y,i}}{s_{x,i}}\right| \le \frac{t}{\sqrt{d}}, \quad \text{for any } x, y \in \mathrm{int}\,(\mathcal{K}) \text{ such that } \|x-y\|_x \le \frac{t}{(nd)^{1/4}}.$$

The Hessian $\nabla^2\mathcal{F}_y$ is thus sandwiched in terms of the Hessian $\nabla^2\mathcal{F}_x$ as

$$\left(1-\frac{t}{\sqrt{d}}\right)^2\nabla^2\mathcal{F}_x \preceq \nabla^2\mathcal{F}_y \preceq \left(1+\frac{t}{\sqrt{d}}\right)^2\nabla^2\mathcal{F}_x.$$

By the definition of $\sigma_{x,i}$ and $\sigma_{y,i}$, we have

$$\frac{\left(1-\frac{t}{\sqrt{d}}\right)^2}{\left(1+\frac{t}{\sqrt{d}}\right)^2}\sigma_{x,i} \le \sigma_{y,i} \le \frac{\left(1+\frac{t}{\sqrt{d}}\right)^2}{\left(1-\frac{t}{\sqrt{d}}\right)^2}\sigma_{x,i} \quad \text{for all } i \in [n]. \tag{37}$$

Consequently, we find that

$$\frac{\left(1-\frac{t}{\sqrt{d}}\right)^2}{\left(1+\frac{t}{\sqrt{d}}\right)^4}V_x \preceq V_y \preceq \frac{\left(1+\frac{t}{\sqrt{d}}\right)^2}{\left(1-\frac{t}{\sqrt{d}}\right)^4}V_x.$$

Note that

$$\frac{(1-\omega)^2}{(1+\omega)^4} \ge 1-8\omega \quad \text{and} \quad \frac{(1+\omega)^2}{(1-\omega)^4} \le 1+8\omega \quad \text{for any } \omega \in \left[0, \tfrac{1}{12}\right].$$

Applying this sandwiching pair of inequalities with $\omega = t/\sqrt{d}$ yields the claim.

Appendix C. Proof of Lemma 10

We begin by defining

$$\varphi_{x,i} := \frac{\sigma_{x,i} + \beta_{\mathrm{V}}}{s_{x,i}^2} \text{ for } i \in [n], \quad \text{and} \quad \Psi_x := \frac{1}{2} \log\det V_x, \quad \text{for all } x \in \operatorname{int}(\mathcal{K}). \tag{38}$$

Further, for any two points x and z, let $\overline{xz}$ denote the set of points on the line segment joining x and z. The proof of Lemma 10 is based on a Taylor series expansion, and so requires careful handling of σ, φ, Ψ and their derivatives. At a high level, the proof involves the following steps: (1) perform a Taylor series expansion around x and along the line segment $\overline{xz}$; (2) transfer the bounds of terms involving some point $y \in \overline{xz}$ to terms involving only x and z; and then (3) use concentration of Gaussian polynomials to obtain high probability bounds.

C.1 Auxiliary results for the proof of Lemma 10

We now introduce some auxiliary results involved in these three steps. The following lemma provides expressions for gradients of σ, φ and Ψ and bounds for directional Hessian of φ and Ψ. Let $e_i \in \mathbb{R}^d$ denote a vector with 1 in the i-th position and 0 otherwise. For any $h \in \mathbb{R}^d$ and $x \in \operatorname{int}(\mathcal{K})$, define $\eta_{x,h,i} = \eta_{x,i} := a_i^\top h / s_{x,i}$ for each $i \in [n]$.

Lemma 13 *The following relations hold;*

(a) Gradient of σ: $\nabla \sigma_{x,i} = 2A_x^\top (\Sigma_x - \Upsilon_x^{(2)}) e_i$ *for each* $i \in [n]$.

(b) Gradient of φ: $\nabla \varphi_{x,i} = \frac{2}{s_{x,i}^2} A_x^\top \left[2\Sigma_x + \beta_V \mathbb{I} - \Upsilon_x^{(2)}\right] e_i$ *for each* $i \in [n]$;

(c) Gradient of Ψ: $\nabla \Psi_x = A_x^\top \left(2\,\Sigma_x + \beta_V \mathbb{I} - \Upsilon_x^{(2)}\right) \theta_x$;

(d) Bound on $\nabla^2 \varphi$: $s_{x,i}^2 \left|\frac{1}{2} h^\top \nabla^2 \varphi_{x,i} h\right| \le 14\,(\sigma_{x,i} + \beta_V)\,\eta_{x,i}^2 + 11 \sum_{j=1}^n \sigma_{x,i,j}^2 \eta_{x,j}^2$ *for* $i \in [n]$;

(e) Bound on $\nabla^2 \Psi$: $\left|\frac{1}{2} h^\top \left(\nabla^2 \Psi_x\right) h\right| \le 13 \sum_{i=1}^n (\sigma_{x,i} + \beta_V)\,\theta_{x,i} \eta_{x,i}^2 + \frac{17}{2} \sum_{i,j=1}^n \sigma_{x,i,j}^2 \theta_{x,i} \eta_{x,j}^2$.

See Section C.6 for the proof of this claim.

The following lemma that shows that for a random variable $z \sim \mathcal{P}_x$, the slackness $s_{z,i}$ is close to $s_{x,i}$ with high probability.

Lemma 14 *For any $\epsilon \in (0, 1/4], r \in (0,1)$ and $x \in \operatorname{int}(\mathcal{K})$, we have*

$$\mathbb{P}_{z \sim \mathcal{P}_x}\left[\forall i \in [n], \forall v \in \overline{xz},\ \frac{s_{x,i}}{s_{v,i}} \in \left(1 - r\,(1+\delta), 1 + r\,(1+\delta)\right)\right] \ge 1 - \epsilon/4,$$

where $\delta = \sqrt{\frac{2\log(4/\epsilon)}{d}}$. Thus for any $d \ge 1$ and $r \le 1/\left[20\left(1 + \sqrt{2\log\left(\frac{4}{\epsilon}\right)}\right)\right]$, we have

$$\mathbb{P}_{z \sim \mathcal{P}_x}\left[\forall i \in [n], \forall v \in \overline{xz},\ \frac{s_{x,i}}{s_{v,i}} \in (0.95, 1.05)\right] \ge 1 - \epsilon/4.$$

See Section C.4 for the proof which is based on combining the bound on $\frac{s_{x,i}}{s_{v,i}}$ from Lemma 12 with standard Gaussian tail bounds.

This result comes in handy for transferring bounds for different expressions in Taylor expansion involving an arbitrary y on $\overline{xz}$ to bounds on terms involving simply x. The proof follows from Lemma 12 and a simple application of the standard Gaussian tail bounds and is thereby omitted. For brevity, we define the shorthand

$$\hat{a}_{x,i} = \frac{1}{s_{x,i}} V_x^{-1/2} a_i \quad \text{for each } i \in [n]. \tag{39}$$

In the following lemma, we state some tail bounds for particular Gaussian polynomials that arise in our analysis.

Lemma 15 *For any $\epsilon \in (0, 1/15]$, define $\chi_k = (2e/k \cdot \log(4/\epsilon))^{k/2}$ for $k = 2, 3$ and 4. Then for $\xi \sim \mathcal{N}(0, \mathbb{I}_d)$ and any $x \in \operatorname{int}(\mathcal{K})$ the following high probability bounds hold:*

$$\mathbb{P}\left[\sum_{i=1}^n (\sigma_{x,i} + \beta_V)\left(\hat{a}_{x,i}^\top \xi\right)^2 \le \chi_2 \sqrt{3} d\right] \ge 1 - \frac{\epsilon}{4}, \tag{40a}$$

$$\mathbb{P}\left[\left|\sum_{i=1}^n (\sigma_{x,i} + \beta_V)\left(\hat{a}_{x,i}^\top \xi\right)^3\right| \le \chi_3 \sqrt{15}\,(nd)^{1/4}\right] \ge 1 - \frac{\epsilon}{4}, \tag{40b}$$

$$\mathbb{P}\left[\left|\sum_{i,j=1}^n \sigma_{x,i,j}^2 \left(\left(\frac{\hat{a}_{x,i} + \hat{a}_{x,j}}{2}\right)^\top \xi\right)^3\right| \le \chi_3 \sqrt{15}\,(nd)^{1/4}\right] \ge 1 - \frac{\epsilon}{4}, \tag{40c}$$

$$\mathbb{P}\left[\sum_{i=1}^n (\sigma_{x,i} + \beta_V)\left(\hat{a}_{x,i}^\top \xi\right)^4 \le \chi_4 \sqrt{105}\,(nd)^{1/2}\right] \ge 1 - \frac{\epsilon}{4}. \tag{40d}$$

See Section C.5 for the proof of these claims.

Now we summarize the final ingredients needed for our proofs. Recall that the Gaussian proposal z is related to the current state x via the equation

$$z \overset{d}{=} x + \frac{r}{(nd)^{1/4}} V_x^{-1/2} \xi, \tag{41}$$

where $\xi \sim \mathcal{N}(0, \mathbb{I}_d)$. We also use the following elementary inequalities:

Cauchy-Schwarz inequality:	$\lvert u^\top v\rvert \le \lVert u\rVert_2 \lVert v\rVert_2$	(C-S)
AM-GM inequality:	$\nu\kappa \le \frac{1}{2}(\nu^2 + \kappa^2)$.	(AM-GM)
Sum of squares inequality:	$\frac{1}{2}\lVert a+b\rVert_2^2 \le \lVert a\rVert_2^2 + \lVert b\rVert_2^2$,	(SSI)

Note that the sum-of-squares inequality is simply a vectorized version of the AM-GM inequality. With these tools, we turn to the proof of Lemma 10. We split our analysis into parts.

C.2 Proof of claim (32a)

Using the second degree Taylor expansion, we have

$$\Psi_z - \Psi_x = (z-x)^\top \nabla\Psi_x + \frac{1}{2}(z-x)^\top \nabla^2\Psi_y (z-x), \quad \text{for some } y \in \overline{xz}.$$

We claim that for $r \le f(\epsilon)$, we have

$$\mathbb{P}_z\left[(z-x)^\top \nabla\Psi_x \ge -\epsilon/2\right] \ge 1-\epsilon/2, \quad \text{and} \tag{42a}$$

$$\mathbb{P}_z\left[\frac{1}{2}(z-x)\nabla^2\Psi_y (z-x) \ge -\epsilon/2\right] \ge 1-\epsilon/2. \tag{42b}$$

Note that the claim (32a) is a consequence of these two auxiliary claims, which we now prove.

C.2.1 Proof of bound (42a)

Equation (41) implies that $(z-x)^\top \nabla\Psi_x \sim \mathcal{N}\left(0, \frac{r^2}{\sqrt{nd}}\nabla\Psi_x^\top V_x^{-1}\nabla\Psi_x\right)$. We claim that

$$\nabla\Psi_x^\top V_x^{-1}\nabla\Psi_x \le 9\sqrt{nd} \quad \text{for all } x \in \operatorname{int}(\mathcal{K}). \tag{43}$$

We prove this inequality at the end of this subsection. Taking it as given for now, let $\xi' \sim \mathcal{N}(0, 9r^2)$. Then using inequality (43) and a standard Gaussian tail bound, we find that

$$\mathbb{P}\left[(z-x)^\top \nabla\Psi_x \ge -\omega\right] \ge \mathbb{P}\left[\xi' \ge -\omega\right] \ge 1 - \exp(-\omega^2/(18r^2)), \quad \text{valid for all } \omega \ge 0.$$

Setting $\omega = \epsilon/2$ and noting that $r \le \frac{\epsilon}{\sqrt{18\log(2/\epsilon)}}$ completes the claim.

C.2.2 Proof of bound (42b)

Let $\eta_{x,i} = \frac{a_i^\top(z-x)}{s_{x,i}} = \frac{r}{(mn)^{\frac{1}{4}}}\hat{a}_{x,i}^\top\xi$. Using Lemma 13(e), we have

$$\begin{aligned}\left|\frac{1}{2}(z-x)^\top\nabla^2\Psi_y(z-x)\right| &\le 13\sum_{i=1}^n(\sigma_{y,i}+\beta_{\mathrm{V}})\theta_{y,i}\frac{s_{x,i}^2}{s_{y,i}^2}\eta_{x,i}^2 + \frac{17}{2}\sum_{i,j=1}^n\sigma_{y,i,j}^2\theta_{y,i}\frac{s_{x,j}^2}{s_{y,j}^2}\eta_{x,j}^2 \\ &\le \frac{43}{2}\sqrt{\frac{n}{d}}\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})\frac{(\sigma_{y,i}+\beta_{\mathrm{V}})}{(\sigma_{x,i}+\beta_{\mathrm{V}})}\frac{s_{x,i}^2}{s_{y,i}^2}\eta_{x,i}^2. \end{aligned}\tag{44}$$

The last inequality comes from Lemma 7(c) and Lemma 11(a). Setting $\tau = 1.05$, we define the events $\mathcal{E}_1$ and $\mathcal{E}_2$ as follows:

$$\mathcal{E}_1 = \left\{\forall i \in [n], \frac{s_{x,i}}{s_{y,i}} \in [2-\tau, \tau]\right\}, \quad \text{and} \tag{45a}$$

$$\mathcal{E}_2 = \left\{\forall i \in [n], \frac{\sigma_{x,i}}{\sigma_{y,i}} \in \left[0, \frac{\tau^2}{(2-\tau)^2}\right]\right\}. \tag{45b}$$

It is straightforward to see that $\mathcal{E}_1 \subseteq \mathcal{E}_2$ following a similar argument we used to obtain equation (37) in the proof of Lemma 9. Since $r \le 1/\left[20\left(1+\sqrt{2}\log^{1/2}\left(\frac{4}{\epsilon}\right)\right)\right]$, Lemma 14 implies that $\mathbb{P}[\mathcal{E}_1] \ge 1-\epsilon/4$ whence $\mathbb{P}[\mathcal{E}_2] \ge 1-\epsilon/4$. Using these high probability bounds and the setting $\tau = 1.05$, we obtain that with probability at least $1-\epsilon/4$

$$\sqrt{\frac{n}{d}}\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})\frac{(\sigma_{y,i}+\beta_{\mathrm{V}})}{(\sigma_{x,i}+\beta_{\mathrm{V}})}\frac{s_{x,i}^2}{s_{y,i}^2}\eta_{x,i}^2 \le 2\sqrt{\frac{n}{d}}\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})\eta_{x,i}^2 = \frac{2r^2}{d}\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})(\hat{a}_{x,i}^\top\xi)^2. \tag{46}$$

Applying the high probability bound Lemma 15 (40a) and the condition

$$r \le \sqrt{\frac{\epsilon}{86\sqrt{3}\chi_2}}, \tag{47}$$

we obtain that with probability at least $1-\epsilon/2$,

$$\frac{1}{2}(z-x)^\top\nabla^2\Psi_y(z-x) \ge -\epsilon/2,$$

as claimed.

C.2.3 Proof of bound (43)

We now return to prove our earlier inequality (43). Using the expression for the gradient $\nabla\Psi_x$ from Lemma 13(c), we have that for any vector $u \in \mathbb{R}^n$

$$\begin{aligned} u^\top\nabla\Psi_x\nabla\Psi_x^\top u &= \left\langle u, A_x^\top\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)\theta_x\right\rangle^2 \\ &= \left\langle A_x u, \left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)\theta_x\right\rangle^2 \\ &= \left\langle (\Sigma_x+\beta_{\mathrm{V}}\mathbb{I})^{\frac{1}{2}}A_x u, (\Sigma_x+\beta_{\mathrm{V}}\mathbb{I})^{-1/2}\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)\theta_x\right\rangle^2 \\ &\le u^\top V_x u \cdot \theta_x^\top\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)(\Sigma_x+\beta_{\mathrm{V}}\mathbb{I})^{-1}\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)\theta_x \end{aligned}\tag{48}$$

where the last step follows from the Cauchy-Schwarz inequality. As a consequence of Lemma 11(b), the matrix $\Sigma_x - \Upsilon_x^{(2)}$ is PSD. Thus, we have

$$0 \preceq 2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I} \preceq 3(\Sigma_x + \beta_{\mathrm{V}}\mathbb{I}).$$

Consequently, we find that

$$0 \preceq \underbrace{(3\Sigma_x+3\beta_{\mathrm{V}}\mathbb{I})^{-1/2}\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)(3\Sigma_x+3\beta_{\mathrm{V}}\mathbb{I})^{-1/2}}_{=:L} \preceq \mathbb{I}.$$

We deduce that all eigenvalues of the matrix L lie in the interval $[0,1]$ and hence all the eigenvalues of the matrix L^2 belong to the interval $[0,1]$. As a result, we have

$$\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)(3\Sigma_x+3\beta_{\mathrm{V}}\mathbb{I})^{-1}\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right) \preceq (3\Sigma_x+3\beta_{\mathrm{V}}\mathbb{I}).$$

Thus, we obtain

$$\theta_x^\top \left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)(\Sigma_x + \beta_{\mathrm{V}}\mathbb{I})^{-1}\left(2\Sigma_x - \Upsilon_x^{(2)} + \beta_{\mathrm{V}}\mathbb{I}\right)\theta_x \le 9\theta_x^\top(\Sigma_x + \beta_{\mathrm{V}}\mathbb{I})\,\theta_x. \quad (49)$$

Finally, applying Lemma 11 and combining bounds (48) and (49) yields the claim.

C.3 Proof of claim (32b)

The quantity of interest can be written as

$$\|z-x\|_z^2 - \|z-x\|_x^2 = \sum_{i=1}^n \left(a_i^\top(z-x)\right)^2(\varphi_{z,i} - \varphi_{x,i}).$$

We can write $z = x + \alpha u$, where α is a scalar and u is a unit vector in $\mathbb{R}^d$. Then we have

$$\|z-x\|_z^2 - \|z-x\|_x^2 = \alpha^2 \sum_{i=1}^n \left(a_i^\top u\right)^2(\varphi_{z,i} - \varphi_{x,i}).$$

We apply a Taylor series expansion for $\sum_{i=1}^n \left(a_i^\top u\right)^2(\varphi_{z,i} - \varphi_{x,i})$ around the point x, along the line u. There exists a point $y \in \overline{xz}$ such that

$$\sum_{i=1}^n \left(a_i^\top u\right)^2(\varphi_{z,i} - \varphi_{x,i}) = \sum_{i=1}^n \left(a_i^\top u\right)^2\left((z-x)^\top\nabla\varphi_{x,i} + \frac{1}{2}(z-x)^\top\nabla^2\varphi_{y,i}(z-x)\right).$$

Multiplying both sides by α^2, and using the shorthand $\eta_{x,i} = \frac{a_i^\top(z-x)}{s_{x,i}}$, we obtain

$$\|z-x\|_z^2 - \|z-x\|_x^2 = \sum_{i=1}^n \eta_{x,i}^2 s_{x,i}^2 (z-x)^\top\nabla\varphi_{x,i} + \sum_{i=1}^n \eta_{x,i}^2 s_{x,i}^2 \frac{1}{2}(z-x)^\top\nabla^2\varphi_{y,i}(z-x). \quad (50)$$

Substituting the expression for $\nabla\varphi_{x,i}$ from Lemma 13(b) in equation (50) and performing some algebra, the first term on the RHS of equation (50) can be written as

$$\sum_{i=1}^n \eta_{x,i}^2 s_{x,i}^2 (z-x)^\top\nabla\varphi_{x,i} = 2\sum_{i=1}^n\left(\frac{7}{3}\sigma_{x,i} + \beta_{\mathrm{V}}\right)\eta_{x,i}^3 - \frac{1}{3}\sum_{i,j=1}^n \sigma_{x,i,j}^2\left(\eta_{x,i} + \eta_{x,j}\right)^3. \quad (51)$$

On the other hand, using Lemma 13 (d), we have

$$\frac{1}{2}s_{x,i}^2\left|(z-x)^\top\nabla^2\varphi_{y,i}(z-x)\right| \le \frac{s_{x,i}^2}{s_{y,i}^2}\left[14\left(\sigma_{y,i} + \beta_{\mathrm{V}}\right)\frac{s_{x,i}^2}{s_{y,i}^2}\eta_{x,i}^2 + 11\left(\sum_{j=1}^n \sigma_{y,i,j}^2\eta_{x,j}^2\frac{s_{x,j}^2}{s_{y,j}^2}\right)\right]. \quad (52)$$

Now, we use a fourth degree Gaussian polynomial to bound both the terms on the RHS of inequality (52). To do so, we use high probability bound for $s_{x,i}/s_{y,i}$. In particular, we use the high probability bounds for the events $\mathcal{E}_1$ and $\mathcal{E}_2$ defined in equations (45a) and (45b).

Multiplying both sides of inequality (52) by $\eta_{x,i}^2$ and summing over the index i, we obtain that with probability at least $1 - \epsilon/4$, we have

$$\begin{aligned}
\sum_{i=1}^n \eta_{x,i}^2 s_{x,i}^2\left|\frac{1}{2}(z-x)^\top\nabla^2\varphi_{y,i}(z-x)\right| &\le \left[14\sum_{i=1}^n(\sigma_{y,i}+\beta_{\mathrm{V}})\frac{s_{x,i}^4}{s_{y,i}^4}\eta_{x,i}^4 + 11\sum_{i,j=1}^n\sigma_{y,i,j}^2\eta_{x,i}^2\eta_{x,j}^2\frac{s_{x,i}^2 s_{x,j}^2}{s_{y,i}^2 s_{y,j}^2}\right] \\
&\overset{\text{(hpb.(45a))}}{\le} \tau^4\left[14\sum_{i=1}^n(\sigma_{y,i}+\beta_{\mathrm{V}})\eta_{x,i}^4 + 11\sum_{i,j=1}^n\sigma_{y,i,j}^2\eta_{x,i}^2\eta_{x,j}^2\right] \\
&\overset{\text{(AM-GM)}}{\le} \tau^4\left[14\sum_{i=1}^n(\sigma_{y,i}+\beta_{\mathrm{V}})\eta_{x,i}^4 + \frac{11}{2}\sum_{i,j=1}^n\sigma_{y,i,j}^2(\eta_{x,i}^4+\eta_{x,j}^4)\right] \\
&\overset{\text{(Lem. 11(a))}}{\le} 25\tau^4\sum_{i=1}^n(\sigma_{y,i}+\beta_{\mathrm{V}})\eta_{x,i}^4 \\
&\overset{\text{(hpb.(45b))}}{\le} 50\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})\eta_{x,i}^4, \quad (53)
\end{aligned}$$

where "hpb" stands for high probability bound for events $\mathcal{E}_1$ and $\mathcal{E}_2$. In the last step, we have used the fact that $\tau^6/(2-\tau)^2 \le 2$ for $\tau = 1.05$. Combining equations (50), (51) and (53) and noting that $\eta_{x,i} = r\hat{a}_i^\top\xi/(nd)^{1/4}$, we find that

$$\begin{aligned}
\left|\|z-x\|_z^2 - \|z-x\|_x^2\right| &\le \frac{14}{3}\left|\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})\eta_{x,i}^3\right| + \frac{8}{3}\left|\sum_{i,j=1}^n\sigma_{x,i,j}^2\left(\left(\eta_{x,i}+\eta_{x,j}\right)/2\right)^3\right| + 38\sum_{i=1}^n\sigma_{x,i}\eta_{x,i}^4 \\
&\le \frac{14}{3}\frac{r^3}{(nd)^{3/4}}\left|\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})\left(\hat{a}_{x,i}^\top\xi\right)^3\right| + \frac{8}{3}\frac{r^3}{(nd)^{3/4}}\left|\sum_{i,j=1}^n\sigma_{x,i,j}^2\left(\frac{1}{2}(\hat{a}_{x,i}+\hat{a}_{x,j})^\top\xi\right)^3\right| \\
&\quad + 50\frac{r^4}{nd}\sum_{i=1}^n(\sigma_{x,i}+\beta_{\mathrm{V}})(\hat{a}_{x,i}^\top\xi)^4, \quad (54)
\end{aligned}$$

where the last step follows from the fact that $0 \le \sigma_{x,i} \le \sigma_{x,i} + \beta_{\mathrm{V}}$. In order to show that $\left|\|z-x\|_z^2 - \|z-x\|_x^2\right|$ is bounded as $\mathcal{O}\left(1/\sqrt{nd}\right)$ with high probability, it suffices to show that with high probability, the third and fourth degree polynomials of $\hat{a}_{x,i}^\top\xi$, that appear in bound (54), are bounded by $\mathcal{O}\left((nd)^{1/4}\right)$ and $\mathcal{O}\left(\sqrt{nd}\right)$ respectively.

Applying the bounds (40b), (40c) and (40d) from Lemma 15, we have with probability at least $1-\epsilon$,

$$\|z-x\|_z^2 - \|z-x\|_x^2 \le \frac{r^3}{\sqrt{nd}}\left(\frac{22\sqrt{15}\chi_3}{3}\right) + \frac{r^4}{\sqrt{nd}}\left(50\sqrt{105}\chi_4\right).$$

Using the condition

$$r \le \min\left\{\frac{\epsilon}{22\sqrt{5/3}\chi_3}, \sqrt{\frac{\epsilon}{50\sqrt{105}\chi_4}}\right\}, \quad (55)$$

completes our proof of claim (32b).

C.4 Proof of Lemma 14

The proof is based on Lemma 12 and a simple application of the standard chi-square tail bounds. According to Lemma 12, we have that for $v \in \overline{xz}$,

$$\left|1 - \frac{s_{v,i}}{s_{x,i}}\right| \leq \left(\frac{n}{d}\right)^{\frac{1}{4}} \|x - v\|_x \leq \left(\frac{n}{d}\right)^{\frac{1}{4}} \|x - z\|_x .$$

According to equation (41), the proposal follows Gaussian distribution

$$\left(\frac{n}{d}\right)^{\frac{1}{4}} \|x - z\|_x = \frac{r}{d^{1/2}} \|\xi\|_2 ,$$

where $\xi \sim \mathcal{N}(0, \mathbb{I}_d)$. Using the standard chi-square tail bound we have that for $\delta > 0$,

$$\mathbb{P}\left[\|\xi\|_2 / \sqrt{d} \geq 1 + \delta\right] \leq \exp\left(-d\delta^2/2\right).$$

Plugging in $\delta = \sqrt{\frac{2}{d}} \log^{\frac{1}{2}}\left(\frac{4}{\epsilon}\right)$ concludes the lemma.

C.5 Proof of Lemma 15

The proof relies on the classical fact that the tails of a polynomial in Gaussian random variables decay exponentially independently of dimension. In particular, Theorem 6.7 by Janson (1997) ensures that for any integers $d, k \geq 1$, any polynomial $f : \mathbb{R}^d \to \mathbb{R}$ of degree k, and any scalar $t \geq (2e)^{k/2}$, we have

$$\mathbb{P}\left[|f(\xi)| \geq t\left(\mathbb{E}f(\xi)^2\right)^{\frac{1}{2}}\right] \leq \exp\left(-\frac{k}{2e}t^{2/k}\right), \tag{56}$$

where $\xi \sim \mathcal{N}(0, \mathbb{I}_n)$ denotes a standard Gaussian vector in n dimensions. Also, the following observations on the behavior of the vectors $\hat{a}_{x,i}$ defined in equation (39) are useful:

$$\|\hat{a}_{x,i}\|_2^2 = \theta_{x,i} \overset{(i)}{\leq} \sqrt{\frac{n}{d}} \quad \text{for all } i \in [n], \quad \text{and} \tag{57a}$$

$$(\hat{a}_{x,i}^\top \hat{a}_{x,j})^2 = \theta_{x,i,j}^2 \quad \text{for all } i, j \in [n], \tag{57b}$$

where inequality (i) follows from Lemma 7 (c).

C.5.1 Proof of bound (40a)

We have

$$\begin{aligned}
\mathbb{E}\left(\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\left(\hat{a}_{x,i}^\top \xi\right)^2\right)^2 &= \sum_{i,j=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})(\sigma_{x,j} + \beta_{\mathrm{V}})\,\mathbb{E}\left(\hat{a}_{x,i}^\top \xi\right)^2 \left(\hat{a}_{x,j}^\top \xi\right)^2 \\
&= \sum_{i,j=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})(\sigma_{x,j} + \beta_{\mathrm{V}})\left(\|\hat{a}_{x,i}\|_2^2 \|\hat{a}_{x,j}\|_2^2 + 2\left(\hat{a}_{x,i}^\top \hat{a}_{x,j}\right)^2\right) \\
&= \sum_{i,j=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})(\sigma_{x,j} + \beta_{\mathrm{V}})\left(\theta_{x,i}\theta_{x,j} + 2\theta_{x,i,j}^2\right) \\
&\overset{(i)}{=} d^2 + 2d \\
&\leq 3d^2,
\end{aligned}$$

where step (i) follows from properties (c) and (d) from Lemma 11. Applying the bound (56) with $k = 2, t = e\log(\frac{4}{\epsilon})$ yields the claim. We verify that for $\epsilon \in (0, 1/15]$, $t \geq 2e$.

C.5.2 Proof of bound (40b)

Using Isserlis' theorem (Isserlis, 1918) for Gaussian moments, we obtain

$$\begin{aligned}
\mathbb{E}\left(\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\left(\hat{a}_{x,i}^\top \xi\right)^3\right)^2 &= \sum_{i,j=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})(\sigma_{x,i} + \beta_{\mathrm{V}})\,\mathbb{E}\left(\hat{a}_{x,i}^\top \xi\right)^3 \left(\hat{a}_{x,j}^\top \xi\right)^3 \\
&= 9\underbrace{\sum_{i,j=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})(\sigma_{x,j} + \beta_{\mathrm{V}})\|\hat{a}_{x,i}\|_2^2 \|\hat{a}_{x,j}\|_2^2 \left(\hat{a}_{x,i}^\top \hat{a}_{x,j}\right)}_{=:N_1} \\
&\quad + 6\underbrace{\sum_{i,j=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})(\sigma_{x,j} + \beta_{\mathrm{V}})\left(\hat{a}_{x,i}^\top \hat{a}_{x,j}\right)^3}_{=:N_2}.
\end{aligned} \tag{58}$$

We claim that the two terms in this sum are bounded as $N_1 \leq \sqrt{nd}$ and $N_2 \leq \sqrt{nd}$. Assuming the claims as given, we now complete the proof. Plugging in the bounds for N_1 and N_2 in equation (58) we find that $\mathbb{E}\big(\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\left(\hat{a}_{x,i}^\top \xi\right)^3\big)^2 \leq 15\sqrt{nd}$. Applying the bound (56) with $k = 3, t = \left(\frac{2e}{3}\log(4/\epsilon)\right)^{3/2}$ yields the claim. We also verify that for $\epsilon \in (0, 1/15]$, $t \geq (2e)^{3/2}$. We now turn to proving the bounds on N_1 and N_2.

Bounding N_1: Let B be an $n \times d$ matrix with its i-th row given by $\sqrt{(\sigma_{x,i} + \beta_{\mathrm{V}})}\hat{a}_{x,i}^\top$. Observe that

$$\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\,\hat{a}_i \hat{a}_{x,i}^\top = V_x^{-1/2}\left(\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\frac{a_i a_i^\top}{s_{x,i}^2}\right)V_x^{-1/2} = V_x^{-1/2} V_x V_x^{-1/2} = \mathbb{I}_d. \tag{59}$$

Thus we have $B^\top B = \mathbb{I}_d$, which implies that $BB^\top$ is an orthogonal projection matrix. Letting $v \in \mathbb{R}^n$ be a vector such that $v_i = \sqrt{(\sigma_{x,i} + \beta_{\mathrm{V}})}\,\|\hat{a}_{x,i}\|_2^2$, we then have

$$\sum_{i,j=1}^n (\sigma_{x,i}+\beta_{\mathrm{V}})\|\hat{a}_{x,i}\|_2^2\,\hat{a}_{x,i}^\top\,(\sigma_{x,j}+\beta_{\mathrm{V}})\|\hat{a}_{x,j}\|_2^2\,\hat{a}_{x,j} = \left\|\sum_{i=1}^n (\sigma_{x,i}+\beta_{\mathrm{V}})\|\hat{a}_{x,i}\|_2^2\,\hat{a}_{x,i}\right\|_2^2 = \left\|B^\top v\right\|_2^2 \overset{(i)}{\leq} \|v\|_2^2,$$

where inequality (i) follows from the fact that $v^\top P v \leq \|v\|_2^2$ for any orthogonal projection matrix P. Equation (57a) implies that $v_i^2 = (\sigma_{x,i} + \beta_{\mathrm{V}})\,\theta_{x,i}^2$. Using Lemma 11(e), we find that

$$\|v\|_2^2 = \sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\,\theta_{x,i}^2 \leq \sqrt{nd}.$$

Bounding N_2: We see that

$$\sum_{i,j=1}^{n} (\sigma_{x,i}+\beta_{\mathrm{V}})(\sigma_{x,j}+\beta_{\mathrm{V}})\left(\hat{a}_{x,i}^{\top}\hat{a}_{x,j}\right)^3 \overset{\text{(C–S)}}{\leq} \sum_{i,j=1}^{n} (\sigma_{x,i}+\beta_{\mathrm{V}})(\sigma_{x,j}+\beta_{\mathrm{V}})\left(\hat{a}_{x,i}^{\top}\hat{a}_{x,j}\right)^2 \|\hat{a}_{x,i}\|_2 \|\hat{a}_{x,j}\|_2$$
$$\overset{\text{(eqns.(57a),(57b))}}{\leq} \sum_{i,j=1}^{n} (\sigma_{x,i}+\beta_{\mathrm{V}})(\sigma_{x,j}+\beta_{\mathrm{V}})\,\theta_{x,i,j}^2\sqrt{\theta_{x,i}\theta_{x,j}}$$
$$\overset{\text{(Lem. 7(c))}}{\leq} \sqrt{\frac{n}{d}} \sum_{i,j=1}^{n} (\sigma_{x,i}+\beta_{\mathrm{V}})(\sigma_{x,j}+\beta_{\mathrm{V}})\,\theta_{x,i,j}^2.$$

We now apply Lemma 11(d) followed by Lemma 11(c) to obtain the claimed bound on N_2.

C.5.3 Proof of bound (40c)

Let $c_{i,j} = \dfrac{(\hat{a}_{x,i}+\hat{a}_{x,j})}{2}$ for $i,j \in [n]$. Using Isserlis' theorem for Gaussian moments, we obtain

$$\mathbb{E}\left(\sum_{i,j=1}^{n} \sigma_{x,i,j}^2 \left(c_{i,j}^{\top}\xi\right)^3\right)^2 = \sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \mathbb{E}\left(c_{i,j}^{\top}\xi\right)^3\left(c_{k,l}^{\top}\xi\right)^3$$
$$= 9\underbrace{\sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \|c_{i,j}\|_2^2 \|c_{k,l}\|_2^2 \left(c_{i,j}^{\top}c_{k,l}\right)}_{=:C_1} + 6\underbrace{\sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \left(c_{i,j}^{\top}c_{k,l}\right)^3}_{=:C_2}$$

We claim that $C_1 \leq \sqrt{nd}$ and $C_2 \leq \sqrt{nd}$. Assuming the claims as given, the result follows using similar arguments as in the previous part. We now bound $C_i, i = 1,2$, using arguments similar to the ones used in Section C.5.2 to bound $N_i, i = 1,2$, respectively. The following bounds on $\|c_{i,j}\|_2^2$ are used in the arguments that follow:

$$\|c_{i,j}\|_2^2 \overset{\text{SSI}}{\leq} \frac{1}{2}\left(\|\hat{a}_i\|_2^2 + \|\hat{a}_j\|_2^2\right) = \frac{1}{2}(\theta_{x,i}+\theta_{x,j}) \tag{60a}$$
$$\overset{\text{Lem. 7(c)}}{\leq} \sqrt{\frac{n}{d}}. \tag{60b}$$

Bounding C_1: Let B be the same $n \times d$ matrix as in the proof of previous part with its i-th row given by $\sqrt{(\sigma_{x,i}+\beta_{\mathrm{V}})}\hat{a}_{x,i}^{\top}$. Define the vector $u \in \mathbb{R}^d$ with entries given by

$u_i = \sum_{j=1}^n \sigma_{x,i,j}^2 \|c_{i,j}\|_2^2/(\sigma_{x,i}+\beta_{\mathrm{V}})^{1/2}$. We have

$$\sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \|c_{i,j}\|_2^2 \|c_{k,l}\|_2^2 \left(c_{i,j}^{\top}c_{k,l}\right) \leq \left\|\sum_{i,j=1}^{n} \sigma_{x,i,j}^2 \|c_{i,j}\|_2^2 c_{i,j}\right\|_2^2$$
$$\overset{\text{(SSI)}}{\leq} \frac{1}{2}\left(\left\|\sum_{i,j=1}^{n} \sigma_{x,i,j}^2 \|c_{i,j}\|_2^2 \hat{a}_{x,i}\right\|_2^2 + \left\|\sum_{i,j=1}^{n} \sigma_{x,i,j}^2 \|c_{i,j}\|_2^2 \hat{a}_{x,j}\right\|_2^2\right)$$
$$= \left\|B^{\top}u\right\|_2^2$$
$$\overset{(i)}{\leq} \|u\|_2^2,$$

where inequality (i) follows from the fact that $v^{\top}Pv \leq \|v\|_2^2$ for any orthogonal projection matrix P. It is left to bound the term u_i^2. We see that

$$u_i^2 = \frac{1}{\sigma_{x,i}+\beta_{\mathrm{V}}} \sum_{j,k=1}^{n} \sigma_{x,i,j}^2\sigma_{x,i,k}^2 \|c_{i,j}\|_2^2 \|c_{i,k}\|_2^2 \overset{\text{(bnd. (60b))}}{\leq} \sqrt{\frac{n}{d}} \frac{1}{\sigma_{x,i}+\beta_{\mathrm{V}}} \sum_{j,k=1}^{n} \sigma_{x,i,j}^2\sigma_{x,i,k}^2 \|c_{i,j}\|_2^2$$
$$\overset{\text{(Lem. 11(a))}}{\leq} \sqrt{\frac{n}{d}} \frac{\sigma_{x,i}}{\sigma_{x,i}+\beta_{\mathrm{V}}} \sum_{j=1}^{n} \sigma_{x,i,j}^2 \|c_{i,j}\|_2^2$$
$$\overset{\text{(bnd. (60a))}}{\leq} \sqrt{\frac{n}{d}} \sum_{j=1}^{n} \sigma_{x,i,j}^2 \frac{\theta_{x,i}+\theta_{x,j}}{2}.$$

Now, summing over i and using symmetry of indices i,j, we find that

$$\|u\|_2^2 \leq \sqrt{\frac{n}{d}} \sum_{i=1}^{n}\sum_{j=1}^{n} \sigma_{x,i,j}^2\theta_{x,i} \overset{\text{(Lem. 11(a))}}{=} \sqrt{\frac{n}{d}} \sum_{i=1}^{n} \sigma_{x,i}\theta_{x,i} \overset{\text{(Lem. 11(c))}}{\leq} \sqrt{nd},$$

thereby implying that $C_1 \leq \sqrt{nd}$.

Bounding C_2: Using the Cauchy-Schwarz inequality and the bound (60b), we find that

$$\sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \left(c_{i,j}^{\top}c_{k,l}\right)^3 \leq \sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \left(c_{i,j}^{\top}c_{k,l}\right)^2 \|c_{i,j}\|_2 \|c_{k,l}\|_2$$
$$\leq \sqrt{\frac{n}{d}} \sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \left(c_{i,j}^{\top}c_{k,l}\right)^2.$$

Using SSI and the symmetry of pairs of indices (i,j) and (k,l), we obtain

$$\sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \left(c_{i,j}^{\top}c_{k,l}\right)^2 \leq \sum_{i,j,k,l=1}^{n} \sigma_{x,i,j}^2\sigma_{x,k,l}^2 \left(\hat{a}_{x,i}^{\top}\hat{a}_k\right)^2 = \sum_{i,k=1}^{n} \sigma_{x,i}\sigma_{x,k}\left(\hat{a}_{x,i}^{\top}\hat{a}_k\right)^2.$$

The resulting expression can be bounded as follows:

$$\sum_{i,k=1}^{n} \sigma_{x,i}\sigma_{x,k}\left(\hat{a}_{x,i}^{\top}\hat{a}_k\right)^2 \overset{\text{(eqn.(57b))}}{=} \sum_{i,k=1}^{n} \sigma_{x,i}\sigma_{x,k}\theta_{x,i,k}^2 \overset{\text{(Lem. 11(d))}}{\leq} \sum_{i=1}^{n} \sigma_{x,i}\theta_{x,i} \overset{\text{(Lem. 11(c))}}{\leq} n.$$

Putting the pieces together yields the claimed bound on C_2.

C.5.4 Proof of bound (40d)

Observe that $\hat{a}_{x,i}^\top \xi \sim \mathcal{N}(0, \theta_{x,i})$ and hence $\mathbb{E}\left(\hat{a}_{x,i}^\top \xi\right)^8 = 105\,\theta_{x,i}^4$. Thus we have

$$\begin{aligned}
\mathbb{E}\left(\sum_{i=1}^n \sigma_{x,i}\left(\hat{a}_{x,i}^\top \xi\right)^4\right)^2 &\overset{\text{C–S}}{\leq} \sum_{i,j=1}^n \sigma_{x,i}\sigma_{x,j}\left(\mathbb{E}\left(\hat{a}_{x,i}^\top \xi\right)^8\right)^{\frac{1}{2}}\left(\mathbb{E}\left(\hat{a}_{x,j}^\top \xi\right)^8\right)^{\frac{1}{2}} \\
&= 105\sum_{i,j=1}^n \sigma_{x,i}\sigma_{x,j}\theta_{x,i}^2\theta_{x,j}^2 \\
&= 105\left(\sum_{i=1}^n \sigma_{x,i}\theta_{x,i}^2\right)^2 \\
&\overset{\text{(Lem. 11}(e)\text{)}}{\leq} 105nd.
\end{aligned}$$

Applying the bound (56) with $k = 4, t = \left(\frac{e}{2}\log(4/\epsilon)\right)^2$ yields the result. We also verify that for $\epsilon \in (0, 1/15]$, we have $t \geq (2e)^2$

C.6 Proof of Lemma 13

We now derive the different expressions for derivatives and prove the bounds for Hessians of $x \mapsto \varphi_{x,i}$, $i \in [n]$ and $x \mapsto \Psi_x$. In this section we use the simpler notation $H_x := \nabla^2 \mathcal{F}_x$.

C.6.1 Gradient of σ

Using $s_{x+h,i} = (b_i - a_i^\top(x+h)) = s_{x,i} - a_i^\top h$, we define the Hessian difference matrix

$$\Delta_{x,h}^H := H_{x+h} - H_x = \sum_{i=1}^n a_i a_i^\top \left(\frac{1}{(s_{x,i} - a_i^\top h)^2} - \frac{1}{s_{x,i}^2}\right). \tag{61}$$

Up to second order terms, we have

$$\frac{1}{s_{x+h,i}^2} = \frac{1}{s_{x,i}^2}\left[1 + \frac{2a_i^\top h}{s_{x,i}} + \frac{3(a_i^\top h)^2}{s_{x,i}^2}\right] + \mathcal{O}\left(\|h\|_2^3\right), \tag{62a}$$

$$\Delta_{x,h}^H = \sum_{i=1}^n \frac{a_i a_i^\top}{s_{x,i}^2}\left[\frac{2a_i^\top h}{s_{x,i}} + \frac{3(a_i^\top h)^2}{s_{x,i}^2}\right] + \mathcal{O}\left(\|h\|_2^3\right), \tag{62b}$$

$$a_i^T H_{x+h}^{-1} a_i = a_i^\top H_x^{-1} a_i - a_i^\top H_x^{-1}\Delta_{x,h}^H H_x^{-1} a_i + a_i^\top H_x^{-1}\Delta_{x,h}^H H_x^{-1}\Delta_{x,h}^H H_x^{-1} a_i + \mathcal{O}\left(\|h\|_2^3\right). \tag{62c}$$

Collecting different first order terms in $\sigma_{x+h,i} - \sigma_{x,i}$, we obtain

$$\begin{aligned}
\sigma_{x+h,i} - \sigma_{x,i} &= 2\,\frac{a_i^\top H_x^{-1} a_i}{s_{x,i}^2}\frac{a_i^\top h}{s_{x,i}} - 2\,\frac{a_i^\top H_x^{-1}\left(\sum_{j=1}^n \frac{a_j a_j^\top}{s_{x,j}^2}\frac{a_j^\top h}{s_{x,j}}\right) H_x^{-1} a_i}{s_{x,i}^2} + \mathcal{O}\left(\|h\|_2^2\right) \\
&= 2\left[\sigma_{x,i}\frac{a_i^\top h}{s_{x,i}} - \sum_{j=1}^n \sigma_{x,i,j}^2\,\frac{a_j^\top h}{s_{x,j}}\right] + \mathcal{O}\left(\|h\|_2^2\right) \\
&= 2\left[(\Sigma_x - \Upsilon_x^{(2)})S_x^{-1}A\right]_i h + \mathcal{O}\left(\|h\|_2^2\right).
\end{aligned}$$

Dividing both sides by h and letting $h \to 0$ yields the claim.

C.6.2 Gradient of φ

Using the chain rule and the fact that $\nabla s_{x,i} = -a_i$, we find that

$$\begin{aligned}
\nabla\varphi_{x,i} &= \frac{\nabla\sigma_{x,i}}{s_{x,i}^2} - 2\,(\sigma_{x,i} + \beta_{\mathrm{V}})\frac{\nabla s_{x,i}}{s_{x,i}^3} \\
&= \frac{2}{s_{x,i}^2} A^\top S_x^{-1}\left[2\Sigma_x + \beta_{\mathrm{V}}\,\mathbb{I} - \Upsilon_x^{(2)}\right] e_i,
\end{aligned}$$

as claimed.

C.6.3 Gradient of Ψ

For convenience, let us restate equations (39) and (59):

$$\hat{a}_{x,i} = \frac{1}{s_{x,i}} V_x^{-1/2} a_i, \quad \text{and} \quad \sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\,\hat{a}_{x,i}\hat{a}_{x,i}^\top = \mathbb{I}_d.$$

For a unit vector h, we have

$$h^\top \nabla \log\det V_x = \lim_{\delta\to 0}\frac{1}{\delta}\left[\operatorname{trace}\log\left(\sum_{i=1}^n \frac{(\sigma_{x+\delta h,i} + \beta_{\mathrm{V}})}{\left(1 - \delta a_i^\top h/s_{x,i}\right)^2}\hat{a}_{x,i}\hat{a}_{x,i}^\top\right) - \operatorname{trace}\log\left(\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\,\hat{a}_{x,i}\hat{a}_{x,i}^\top\right)\right]. \tag{63}$$

Let $\log L$ denote the logarithm of the matrix L. Keeping track of the first order terms on RHS of equation (63), we find that

$$\begin{aligned}
&\operatorname{trace}\left[\log\left(\sum_{i=1}^n (\sigma_{x+\delta h,i} + \beta_{\mathrm{V}})\,\frac{\hat{a}_{x,i}\hat{a}_{x,i}^\top}{\left(1 - \delta a_i^\top h/s_{x,i}\right)^2}\right)\right] - \operatorname{trace}\left[\log\left(\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\,\hat{a}_{x,i}\hat{a}_{x,i}^\top\right)\right] \\
&= \operatorname{trace}\left[\log\left(\sum_{i=1}^n \left(\sigma_{x+\delta h,i} + \beta_{\mathrm{V}} + \delta h^\top\nabla\sigma_{x,i}\right)\left(1 + 2\delta\frac{a_i^\top h}{s_{x,i}^2}\right)\right)\right] - \operatorname{trace}\left[\log\left(\sum_{i=1}^n (\sigma_{x,i} + \beta_{\mathrm{V}})\,\hat{a}_{x,i}\hat{a}_{x,i}^\top\right)\right] + \mathcal{O}\left(\delta\right. \\
&= \operatorname{trace}\left[\sum_{i=1}^n \delta\left(2\,(\sigma_{x,i} + \beta_{\mathrm{V}})\,\frac{a_i^\top h}{s_{x,i}^2} + h^\top\nabla\sigma_{x,i}\right)\hat{a}_{x,i}\hat{a}_{x,i}^\top\right] + \mathcal{O}\left(\delta^2\right) \\
&= \delta\left(\sum_{i=1}^n \left(2\,(\sigma_{x,i} + \beta_{\mathrm{V}})\,\frac{a_i^\top h}{s_{x,i}^2} + h^\top\nabla\sigma_{x,i}\right)\theta_i\right) + \mathcal{O}\left(\delta^2\right),
\end{aligned}$$

where we have used the fact $\operatorname{trace}(\log \mathbb{I}) = 0$. Letting $\delta \to 0$ and substituting expression of $h^\top \nabla \sigma_x$ from part (a), we obtain

$$h^\top \nabla \log\det V_x = A_x^\top \left(4\Sigma_x + 2\beta_{\mathrm{V}}\mathbb{I} - 2\Upsilon_x^{(2)}\right)\Theta_x h.$$

C.6.4 Bound on Hessian $\nabla^2\varphi$

In terms of the shorthand $E_{ii} = e_i e_i^\top$, we claim that for any $h \in \mathbb{R}^d$,

$$h^\top \nabla^2 \varphi_{x,i} h = \frac{2}{s_{x,i}^2} h^\top A_x^\top \Big[E_{ii}\left(3\left(\Sigma_x + \beta_{\mathrm{V}}\mathbb{I}\right) + 7\Sigma_x - 8\operatorname{diag}(\Upsilon_x^{(2)} e_i)\right) E_{ii} + \operatorname{diag}(\Upsilon_x e_i)(4\Upsilon_x - 3\mathbb{I})\operatorname{diag}(\Upsilon_x e_i)\Big] A_x h. \tag{64}$$

Note that

$$\varphi_{x+h,i} - \varphi_{x,i} = \underbrace{\left(\frac{a_i^\top H_{x+h,i}^{-1} a_i}{s_{x+h,i}^4} - \frac{a_i^\top H_{x,i}^{-1} a_i}{s_{x,i}^4}\right)}_{=:A_1} + \underbrace{\beta_{\mathrm{V}}\left(\frac{1}{s_{x+h,i}^2} - \frac{1}{s_{x,i}^2}\right)}_{=:A_2}. \tag{65}$$

The second order Taylor expansion of $1/s_{x,i}^4$ is given by

$$\frac{1}{s_{x+h,i}^4} = \frac{1}{s_{x,i}^4}\left[1 + \frac{4a_i^\top h}{s_{x,i}} + \frac{10(a_i^\top h)^2}{s_{x,i}^2}\right] + \mathcal{O}\left(\|h\|_2^3\right).$$

Let B_1 and B_2 denote the second order terms, i.e., the terms that are of order $\mathcal{O}\left(\|h\|_2^2\right)$, in Taylor expansion of A_1 and A_2 around x, respectively. Borrowing terms from equations (62a)-(62c) and simplifying we obtain

$$B_1 = 10\sigma_{x,i}\frac{(a_i^\top h)^2}{s_{x,i}^2} - 8\frac{a_i^\top h}{s_{x,i}}\sum_{j=1}^n \frac{\sigma_{x,i,j}^2}{s_{x,i}^2}\frac{a_j^\top h}{s_{x,j}} - 3\sum_{j=1}^n \frac{\sigma_{x,i,j}^2}{s_{x,i}^2}\frac{(a_j^\top h)^2}{s_{x,j}^2} + 4\sum_{j=1}^n\sum_{l=1}^n \frac{\sigma_{x,i,j}}{s_{x,i}}\sigma_{x,j,l}\frac{\sigma_{x,l,i}}{s_{x,i}}\frac{a_j^\top h}{s_{x,j}}\frac{a_l^\top h}{s_{x,l}},$$

and $B_2 = 3\beta_{\mathrm{V}}\dfrac{(a_i^\top h)^2}{s_{x,i}^2}$.

Observing that the second order term in the Taylor expansion of $\varphi_{x+h,i}$ around x, is exactly $\frac{1}{2}h^\top\nabla^2\varphi_{x,i}h$ yields the claim (64). We now turn to prove the bound on the directional

Hessian. Recall $\eta_{x,i} = a_i^\top h / s_{x,i}$. We have

$$\begin{aligned}
&s_{y,i}^2\left|\frac{1}{2}h^\top\nabla^2\varphi_{x,i}h\right| \\
&= \left|3\left(\sigma_{x,i}+\beta_{\mathrm{V}}\right)\eta_{x,i}^2 + 7\sigma_{x,i}\eta_{x,i}^2 - 8\sum_{j=1}^n \sigma_{x,i,j}^2\eta_{x,j}\eta_{x,i} - 3\sum_{j=1}^n\sigma_{x,i,j}^2\eta_{x,j}^2 + 4\sum_{j,k=1}^n \sigma_{x,i,j}\sigma_{x,j,k}\sigma_{x,k,i}\eta_{x,j}\eta_{x,k}\right| \\
&\overset{(i)}{\le} 10\left(\sigma_{x,i}+\beta_{\mathrm{V}}\right)\eta_{x,i}^2 + 8\sum_{j=1}^n \sigma_{x,i,j}^2\left|\eta_{x,i}\eta_{x,j}\right| + 7\sum_{j=1}^n\sigma_{x,i,j}^2\eta_{x,j}^2 \\
&\overset{(ii)}{\le} 10\left(\sigma_{x,i}+\beta_{\mathrm{V}}\right)\eta_{x,i}^2 + 4\sum_{j=1}^n \sigma_{x,i,j}^2\left(\eta_{x,i}^2+\eta_{x,j}^2\right) + 7\sum_{j=1}^n\sigma_{x,i,j}^2\eta_{x,j}^2 \\
&\overset{(iii)}{\le} 10\left(\sigma_{x,i}+\beta_{\mathrm{V}}\right)\eta_{x,i}^2 + 4\sum_{j=1}^n \sigma_{x,i}\eta_{x,i}^2 + 4\sum_{j=1}^n\sigma_{x,i,j}^2\eta_{x,j}^2 + 7\sum_{j=1}^n\sigma_{x,i,j}^2\eta_{x,j}^2, \\
&\overset{(iv)}{\le} 14\left(\sigma_{x,i}+\beta_{\mathrm{V}}\right)\eta_{x,i}^2 + 11\sum_{j=1}^n\sigma_{x,i,j}^2\eta_{x,j}^2,
\end{aligned}$$

where step (i) follows from the fact that $\operatorname{diag}(\Upsilon_y e_i)\Upsilon_y\operatorname{diag}(\Upsilon_y e_i) \preceq \operatorname{diag}(\Upsilon_y e_i)\operatorname{diag}(\Upsilon_y e_i)$ since Υ_y is an orthogonal projection matrix; step (ii) follows from AM-GM inequality; step (iii) follows from the symmetry of indices i and j and Lemma 11(a), and step (iv) from the fact that $\sigma_{x,i} \le \sigma_{x,i} + \beta_{\mathrm{V}}$.

C.6.5 Bound on Hessian $\nabla^2\Psi$

We have

$$\begin{aligned}
\frac{1}{2}h^\top\left(\nabla^2\log\det V_x\right)h = &\frac{1}{2}\lim_{\delta\to 0}\frac{1}{\delta^2}\Bigg[\operatorname{trace}\log\left(\sum_{i=1}^n \frac{\left(\sigma_{x+\delta h,i}+\beta_{\mathrm{V}}\right)}{\left(1-\delta a_i^\top h/s_{x,i}\right)^2}\hat{a}_{x,i}\hat{a}_{x,i}^\top\right) \\
&+ \operatorname{trace}\log\left(\sum_{i=1}^n \frac{\left(\sigma_{x-\delta h,i}+\beta_{\mathrm{V}}\right)}{\left(1+\delta a_i^\top h/s_{x,i}\right)^2}\hat{a}_{x,i}\hat{a}_{x,i}^\top\right) \\
&- 2\operatorname{trace}\log\left(\sum_{i=1}^n\left(\sigma_x+\beta_{\mathrm{V}}\right)\hat{a}_{x,i}\hat{a}_{x,i}^\top\right)\Bigg].
\end{aligned} \tag{66}$$

Up to second order terms, we have

$$\begin{aligned}
&\text{trace}\left[\log\left(\sum_{i=1}^n (\sigma_{x+\delta h,i}+\beta_{\mathrm{V}})\,\frac{\hat{a}_{x,i}\hat{a}_{x,i}^\top}{\left(1-\delta a_i^\top h/s_{x,i}\right)^2}\right)\right]\\
&=\text{trace}\left[\log\left(\sum_{i=1}^n\left(\sigma_{x,i}+\beta_{\mathrm{V}}+\delta h^\top\nabla\sigma_{x,i}+\frac{1}{2}\delta^2 h^\top\nabla^2\sigma_{x,i}h\right)\left(1+2\delta\frac{a_i^\top h}{s_{x,i}}+3\delta^2\left(\frac{a_i^\top h}{s_{x,i}}\right)^2\right)\hat{a}_{x,i}\hat{a}_{x,i}^\top\right)\right]\\
&=\text{trace}\left[\sum_{i=1}^n\left(\sigma_{x,i}+\beta_{\mathrm{V}}+\delta h^\top\nabla\sigma_{x,i}+\frac{1}{2}\delta^2 h^\top\nabla^2\sigma_{x,i}h\right)\left(1+2\delta\frac{a_i^\top h}{s_{x,i}}+3\delta^2\left(\frac{a_i^\top h}{s_{x,i}}\right)^2\right)\hat{a}_{x,i}\hat{a}_{x,i}^\top\right]\\
&\quad-\text{trace}\left[\frac{1}{2}\left(\sum_{i=1}^n\left(\sigma_{x,i}+\beta_{\mathrm{V}}+\delta h^\top\nabla\sigma_{x,i}+\frac{1}{2}\delta^2 h^\top\nabla^2\sigma_{x,i}h\right)\left(1+2\delta\frac{a_i^\top h}{s_{x,i}}+3\delta^2\left(\frac{a_i^\top h}{s_{x,i}}\right)^2\right)\hat{a}_{x,i}\hat{a}_{x,i}^\top\right)^2\right].
\end{aligned}$$

We can similarly obtain the second order expansion of the term $\text{trace}\log\left(\sum_{i=1}^n\frac{(\sigma_{x-\delta h,i}+\beta_{\mathrm{V}})}{(1+\delta a_i^\top h/s_{x,i})^2}\hat{a}_{x,i}\hat{a}_{x,i}^\top\right)$.

Recall $\eta_{x,i}=\frac{a_i^\top h}{s_{x,i}}$. Using part (a) to substitute $h^\top\nabla\sigma_{x,i}$, we obtain

$$\begin{aligned}
\frac{1}{2}h^\top\left(\nabla^2\log\det V_x\right)h=&\sum_{i=1}^n\left(3\left(\sigma_{x,i}+\beta_{\mathrm{V}}\right)\eta_{x,i}^2+4\left(\sigma_{x,i}\eta_{x,i}^2-\sum_{j=1}^n\sigma_{x,i,j}^2\eta_{x,i}\eta_{x,j}\right)+\frac{1}{2}h^\top\nabla^2\sigma_{x,i}h\right)\theta_i\\
&-2\Bigg[\sum_{i,j=1}^n\left(2\sigma_{x,i}+\beta_{\mathrm{V}}\right)\left(2\sigma_{x,j}+\beta_{\mathrm{V}}\right)\eta_{x,i}\eta_{x,j}\theta_{x,i,j}^2-2\sum_{i,j,k=1}^n\left(2\sigma_{x,i}+\beta_{\mathrm{V}}\right)\sigma_{x,j,k}^2\theta_{x,i,k}^2\eta_{x,i}\eta_{x,j}\\
&+\sum_{i,j,k,l=1}^n\sigma_{x,i,l}^2\sigma_{x,j,k}^2\theta_{x,k,l}^2\eta_{x,i}\eta_{x,j}\Bigg].
\end{aligned}\tag{67}$$

We claim that the directional Hessian $h^\top\nabla^2\sigma_{x,i}h$ is given by

$$h^\top\nabla^2\sigma_{x,i}h=2\,h^\top A_x^\top\left[E_{ii}(3\Sigma_x-4\,\text{diag}(\Upsilon_x^{(2)}e_i))E_{ii}+\text{diag}(\Upsilon_x e_i)(4\Upsilon_x-3\mathbb{I})\,\text{diag}(\Upsilon_x e_i)\right]A_x h.\tag{68}$$

Assuming the claim at the moment we now bound $\left|h^\top\nabla^2\Psi_x h\right|$. To shorten the notation, we drop the x-dependence of the terms $\sigma_{x,i},\sigma_{x,i,j},\theta_{x,i}$ and $\eta_{x,i}$. Since Υ_x is an orthogonal projection matrix, we have

$$\text{diag}(\Upsilon_x e_i)\Upsilon_x\,\text{diag}(\Upsilon_x e_i)\preceq\text{diag}(\Upsilon_x e_i)\,\text{diag}(\Upsilon_x e_i).$$

Using this fact and substituting the expression for $h^\top\nabla^2\sigma_{x,i}h$ from equation (68) in equation (67), we obtain

$$\begin{aligned}
&\left|h^\top\nabla^2\Psi_x h\right|\\
&\le\sum_{i=1}^n\Bigg[3\Big(\sigma_i+\beta_{\mathrm{V}}\Big)\eta_i^2+4\big(\sigma_i\eta_i^2+\sum_{j=1}^n\sigma_{i,j}^2\eta_i\eta_j\big)+3\sigma_i\eta_i^2+4\sum_{j=1}^n\sigma_{i,j}^2\eta_i\eta_j+7\sum_{j=1}^n\sigma_{i,j}^2\eta_j^2\Bigg]\theta_i\\
&\quad+\Bigg[8\sum_{i,j=1}^n\left(\sigma_i+\beta_{\mathrm{V}}\right)\left(\sigma_j+\beta_{\mathrm{V}}\right)\eta_i\eta_j\theta_{i,j}^2+8\sum_{i,j,k=1}^n\left(\sigma_i+\beta_{\mathrm{V}}\right)\sigma_{j,k}^2\theta_{i,k}^2\eta_i\eta_j+2\sum_{i,j,k,l=1}^n\sigma_{i,l}^2\sigma_{j,k}^2\theta_{k,l}^2\eta_i\eta_j\Bigg].
\end{aligned}$$

Rearranging terms, we find that

$$\begin{aligned}
&\left|h^\top\nabla^2\Psi_x h\right|\\
&\le\sum_{i=1}^n\left[10\left(\sigma_i+\beta_{\mathrm{V}}\right)\eta_i^2+8\sum_{j=1}^n\sigma_{i,j}^2\eta_i\eta_j+7\sum_{j=1}^n\sigma_{i,j}^2\eta_j^2\right]\theta_i\\
&\quad+\left[8\sum_{i,j=1}^n\left(\sigma_i+\beta_{\mathrm{V}}\right)\left(\sigma_j+\beta_{\mathrm{V}}\right)\eta_i\eta_j\theta_{i,j}^2+8\sum_{i,j,k=1}^n\left(\sigma_i+\beta_{\mathrm{V}}\right)\sigma_{j,k}^2\theta_{i,k}^2\eta_i\eta_j+2\sum_{i,j,k,l=1}^n\sigma_{i,l}^2\sigma_{j,k}^2\theta_{k,l}^2\eta_i\eta_j\right]\\
&\overset{(i)}{\le}\sum_{i=1}^n\left[10\left(\sigma_i+\beta_{\mathrm{V}}\right)\eta_i^2+4\sum_{j=1}^n\sigma_{i,j}^2\left(\eta_i^2+\eta_j^2\right)+7\sum_{j=1}^n\sigma_{i,j}^2\eta_j^2\right]\theta_i\\
&\quad+\left[4\sum_{i,j=1}^n\big(\sigma_i+\beta_{\mathrm{V}}\big)\big(\sigma_j+\beta_{\mathrm{V}}\big)\theta_{i,j}^2(\eta_i^2+\eta_j^2)+4\sum_{i,j,k=1}^n\big(\sigma_i+\beta_{\mathrm{V}}\big)\sigma_{j,k}^2\theta_{i,k}^2(\eta_i^2+\eta_j^2)+\sum_{i,j,k,l=1}^n\sigma_{i,l}^2\sigma_{j,k}^2\theta_{k,l}^2(\eta_i^2+\eta_j^2)\right]
\end{aligned}$$

where in step (i) we have used the AM-GM inequality. Simplifying further, we obtain

$$\begin{aligned}
\left|h^\top\nabla^2\Psi_y h\right|&\le\sum_{i=1}^n\left[14\left(\sigma_i+\beta_{\mathrm{V}}\right)\eta_i^2+11\sum_{j=1}^n\sigma_{i,j}^2\eta_j^2\right]\theta_i+\left[\sum_{i=1}^n12\left(\sigma_i+\beta_{\mathrm{V}}\right)\theta_i\eta_i^2+\sum_{i,j=1}^n6\sigma_{i,j}^2\theta_i\eta_j^2\right]\\
&=26\sum_{i=1}^n\left(\sigma_i+\beta_{\mathrm{V}}\right)\theta_i\eta_i^2+17\sum_{i,j=1}^n\sigma_{i,j}^2\theta_i\eta_j^2.
\end{aligned}$$

Dividing both sides by two completes the proof.

Proof of claim (68)**:** In order to compute the directional Hessian of $x\mapsto\sigma_{x,i}$, we need to track the second order terms in equations (62a)-(62c). Collecting the second order terms (denoted by $\sigma_h^{(2)}$) in the expansion of $\sigma_{x+h,i}-\sigma_{x,i}$, we obtain

$$\begin{aligned}
\sigma_h^{(2)}=&\,3\,\frac{a_i^\top H_x^{-1}a_i}{s_{x,i}^2}\frac{(a_i^\top h)^2}{s_{x,i}^2}-4\,\frac{a_i^\top H_x^{-1}\left(\sum_{j=1}^n\frac{a_ja_j^\top}{s_{x,j}^2}\frac{a_j^\top h}{s_{x,j}}\right)H_x^{-1}a_i}{s_{x,i}^2}\frac{a_i^\top h}{s_{x,i}}\\
&-3\,\frac{a_i^\top H_x^{-1}\left(\sum_{j=1}^n\frac{a_ja_j^\top}{s_{x,j}^2}\frac{(a_j^\top h)^2}{s_{x,j}^2}\right)H_x^{-1}a_i}{s_{x,i}^2}\\
&+4\,\frac{a_i^\top H_x^{-1}\left(\sum_{j=1}^n\frac{a_ja_j^\top}{s_{x,j}^2}\frac{a_j^\top h}{s_{x,j}}\right)H_x^{-1}\left(\sum_{l=1}^n\frac{a_la_l^\top}{s_{x,l}^2}\frac{a_l^\top h}{s_{x,l}}\right)a_i}{s_{x,i}^2}.
\end{aligned}$$

We simply each term on the RHS one by one. Simplifying the first term, we obtain

$$3\,\frac{a_i^\top H_x^{-1}a_i}{s_{x,i}^2}\frac{(a_i^\top h)^2}{s_{x,i}^2}=3\,\sigma_{x,i}\eta_{x,i}^2=h^\top 3\,A_x^\top E_{ii}\Sigma_x E_{ii}A_x\,h.$$

For the second term, we have

$$4\,\frac{a_i^\top H_x^{-1}\left(\sum_{j=1}^n \frac{a_j a_j^\top}{s_{x,j}^2}\frac{a_j^\top h}{s_{x,j}}\right)H_x^{-1}a_i}{s_{x,i}^2}\frac{a_i^\top h}{s_{x,i}} = 4\,\eta_{x,i}\sum_{j=1}^n \sigma_{x,i,j}^2\,\eta_{x,j}$$
$$= 4\,h^\top A_x^\top E_{ii}\,\mathrm{diag}\left(\Upsilon_x^{(2)}e_i\right)E_{ii}A_x h.$$

The third term can be simplified as follows:

$$3\,\frac{a_i^\top H_x^{-1}\left(\sum_{j=1}^n \frac{a_j a_j^\top}{s_{x,j}^2}\frac{(a_j^\top h)^2}{s_{x,j}^2}\right)H_x^{-1}a_i}{s_{x,i}^2} = 3\sum_{j=1}^n \sigma_{x,i,j}^2\eta_{x,j}^2$$
$$= 3\,h^\top A_x^\top\,\mathrm{diag}\left(\Upsilon_x e_i\right)\mathrm{diag}\left(\Upsilon_x e_i\right)A_x h$$

For the last term, we find that

$$4\,\frac{a_i^\top H_x^{-1}\left(\sum_{j=1}^n \frac{a_j a_j^\top}{s_{x,j}^2}\frac{a_j^\top h}{s_{x,j}}\right)H_x^{-1}\left(\sum_{l=1}^n \frac{a_l a_l^\top}{s_{x,l}^2}\frac{a_l^\top h}{s_{x,l}}\right)a_i}{s_{x,i}^2} = 4\sum_{j,l=1}^n \sigma_{x,i,j}\,\sigma_{x,j,l}\,\sigma_{x,l,i}\,\eta_{x,j}\,\eta_{x,l}$$
$$= 4\,h^\top A_x^\top\,\mathrm{diag}\left(\Upsilon_x e_i\right)\Upsilon_x\,\mathrm{diag}\left(\Upsilon_x e_i\right)A_x h.$$

Putting together the pieces yields the expression (68).

Appendix D. Analysis of the John walk

We recap the key ideas of the John walk for convenience. We have designed a new proposal distribution by making use of an *optimal set of weights* to define the new covariance structure for the Gaussian proposals, where optimality is defined with respect to the convex program defined below (69). The optimality condition is closely related to the problem of finding the largest ellipsoid at any interior point of the polytope, such that the ellipsoid is contained within the polytope. This problem of finding the largest ellipsoid was first studied by John (1948) who showed that each convex body in $\mathbb{R}^d$ contains a unique ellipsoid of maximal volume. More recently, Lee and Sidford (2014) make use of approximate John Ellipsoids to improve the convergence rate of interior point methods for linear programming. We refer the readers to their paper for more discussion about the use of John Ellipsoids for optimization problems. In this work, we make use of these ellipsoids for designing sampling algorithms with better theoretical bounds on the mixing times.

The vector $\zeta_x = (\zeta_{x,1},\ldots,\zeta_{x,n})^\top$ defined in the John walk's inverse covariance matrix (11) is computed by solving the following optimization problem:

$$\zeta_x = \arg\min_{w\in\mathbb{R}^n} c_x(w) := \sum_{i=1}^n w_i - \frac{1}{\alpha_{\text{J}}}\log\det\left(A^\top S_x^{-1}W^{\alpha_{\text{J}}}S_x^{-1}A\right) - \beta_{\text{J}}\sum_{i=1}^n \log w_i, \qquad (69)$$

where the parameters $\alpha_{\text{J}}, \beta_{\text{J}}$ are given by

$$\alpha_{\text{J}} = 1 - \frac{1}{\log_2(2n/d)} \quad \text{and} \quad \beta_{\text{J}} = \frac{d}{2n},$$

and W denotes an $n\times n$ diagonal matrix with $W_{ii} = w_i$ for each $i\in[n]$. In particular, for our proposal the inverse covariance matrix is proportional to J_x, where

$$J_x = \sum_{i=1}^n \zeta_{x,i}\frac{a_i a_i^\top}{(b_i - a_i^\top x)^2}. \qquad (70)$$

where $\kappa := \kappa_{n,d} = \log_2(2n/d) = (1-\alpha_{\text{J}})^{-1}$.

Recall that for John walk with parameter $\frac{r}{d^{3/4}\kappa^2}$, the proposals at state x are drawn from the multivariate Gaussian distribution given by $\mathcal{N}\left(x, \frac{r^2}{d^{3/2}\kappa^4}J_x^{-1}\right)$, which we denote by $\mathcal{P}_x^{\text{J}}$. In particular, the proposal density at point $x\in\mathrm{int}\,(\mathcal{K})$ is given by

$$p_x(z) := p(x,z) = \sqrt{\det J_x}\left(\frac{\kappa^4 d^{3/2}}{2\pi r^2}\right)^{d/2}\exp\left(-\frac{\kappa^4 d^{3/2}}{2r^2}\,(z-x)^\top J_x(z-x)\right). \qquad (71)$$

Here we restate our result for the mixing time of the John walk.

Theorem 2 *Let μ_0 be any distribution that is M-warm with respect to π^* and let $n < \exp(\sqrt{d})$. Then for any $\delta\in(0,1]$, the John walk with parameter $r_{John} = 10^{-5}$ satisfies*

$$\|\mathcal{T}_{John(r)}^k(\mu_0) - \pi^*\|_{TV} \le \delta \qquad \textit{for all } k \ge C\,d^{2.5}\,\log_2^4\left(\frac{2n}{d}\right)\log\left(\frac{\sqrt{M}}{\delta}\right).$$

D.1 Auxiliary results

We begin by proving basic properties of the weights ζ_x which are used throughout the paper. For $x\in\mathrm{int}\,(\mathcal{K}), w\in\mathbb{R}^n_{++}$, define the projection matrix $\Upsilon_{x,w}$ as follows

$$\Upsilon_{x,w} = W^{\alpha/2}A_x(A_x^\top W^\alpha A_x)^{-1}A_x^\top W^{\alpha/2}, \qquad (72)$$

where $A_x = S_x^{-1}A$ and W is the $n\times n$ diagonal matrix with i-th diagonal entry given by w_i. Also, let

$$\sigma_{x,i} := (\Upsilon_{x,\zeta_x})_{ii} \quad \text{for } x\in\mathrm{int}\,(\mathcal{K}) \text{ and } i\in[n]. \qquad (73)$$

Define the *John slack sensitivity* θ_x^{J} as

$$\theta_x := \theta_x^{\text{J}} := \left(\frac{a_1^\top J_x^{-1}a_1}{s_{x,1}^2},\ldots,\frac{a_n^\top J_x^{-1}a_n}{s_{x,n}^2}\right)^\top \quad \text{for all } x\in\mathrm{int}\,(\mathcal{K}). \qquad (74)$$

Further, for any $x\in\mathrm{int}\,(\mathcal{K})$, define the *John local norm at x* as

$$\|\cdot\|_{J_x} : v\mapsto\left\|J_x^{1/2}v\right\|_2 = \sqrt{\sum_{i=1}^n \zeta_{x,i}\frac{(a_i^\top v)^2}{s_{x,i}^2}}. \qquad (75)$$

We now collect some basic properties of the weights ζ_x and the local sensitivity θ_x and restate parts of Lemma 7 for clarity here.

Lemma 3 *For any $x \in \text{int}(\mathcal{K})$, the following properties are true:*

(a) (Implicit weight formula) $\zeta_{x,i} = \sigma_{x,i} + \beta_J$ for all $i \in [n]$,

(b) (Uniformity) $\zeta_{x,i} \in [\beta_J, 1 + \beta_J]$ for all $i \in [n]$,

(c) (Total size) $\sum_{i=1}^n \zeta_{x,i} = 3d/2$, and

(d) (Slack sensitivity) $\theta_{x,i} \in [0, 4]$ for all $i \in [n]$.

Lemma 3 follows from Lemmas 14 and 15 by Lee and Sidford (2014) and thereby we omit its proof.

Next, we state a key lemma that is crucial for proving the convergence rate of John walk. In this lemma, we provide bounds on difference in total variation norm between the proposal distributions of two nearby points.

Lemma 4 *There exists a continuous non-decreasing function $h : [0, 1/30] \to \mathbb{R}_+$ with $h(1/30) \geq 10^{-5}$, such that for any $\epsilon \in (0, 1/30]$, the John walk with $r \in [0, h(\epsilon)]$ satisfies*

$$\|\mathcal{P}_x^J - \mathcal{P}_y^J\|_{TV} \leq \epsilon, \quad \text{for all } x, y \in \text{int}(\mathcal{K}) \text{ such that } \|x - y\|_{J_x} \leq \frac{\epsilon r}{2\kappa^2 d^{3/4}}, \quad \text{and} \tag{76a}$$

$$\|\mathcal{T}_{John(r)}(\delta_x) - \mathcal{P}_x^J\|_{TV} \leq 5\epsilon, \text{ for all } x \in \text{int}(\mathcal{K}). \tag{76b}$$

See Section D.3 for its proof.

With these lemmas in hand, we are now ready to prove Theorem 2.

D.2 Proof of Theorem 2

The proof is similar to the proof of Theorem 1, and relies on the Lovász's Lemma. Here onwards, we use the following simplified notation

$$\mathbb{T}_x = \mathcal{T}_{\text{John}(r)}(\delta_x), \mathcal{P}_x = \mathcal{P}_x^{\text{J}} \text{ and } \|\cdot\|_x = \|\cdot\|_{J_x}.$$

In order to invoke Lovász's Lemma, we need to show that for any two points $x, y \in \text{int}(\mathcal{K})$ with small cross-ratio $d_{\mathcal{K}}(x, y)$, the TV-distance $\|\mathbb{T}_x - \mathbb{T}_y\|_{\text{TV}}$ is also small.

We proceed with the proof in two steps: (A) first, we relate the cross-ratio $d_{\mathcal{K}}(x, y)$ to the John local norm of $x - y$ at x, and (B) we then use Lemma 4 to show that if $x, y \in \text{int}(\mathcal{K})$ are close in the John local-norm, then the transition kernels $\mathbb{T}_x$ and $\mathbb{T}_y$ are close in TV-distance.

Step (A): We claim that for all $x, y \in \text{int}(\mathcal{K})$, the cross-ratio can be lower bounded as

$$d_{\mathcal{K}}(x, y) \geq \frac{1}{\sqrt{3d/2}} \|x - y\|_x. \tag{77}$$

From the arguments in the proof of Theorem 1 (proof for the Vaidya Walk), we have

$$d_{\mathcal{K}}(x, y) \geq \max_{i \in [n]} \left| \frac{a_i^\top (x - y)}{s_{x,i}} \right|. \tag{78}$$

Using the fact that maximum of a set of non-negative numbers is greater than the weighted mean of the numbers and Lemma 3, we find that

$$d_{\mathcal{K}}(x, y) \geq \sqrt{\frac{1}{\sum_{i=1}^n \zeta_{x,i}} \sum_{i=1}^n \zeta_{x,i} \frac{(a_i^\top (x - y))^2}{s_{x,i}^2}} = \frac{\|x - y\|_x}{\sqrt{3d/2}},$$

thereby proving the claim (77).

Step (B): By the triangle inequality, we have

$$\|\mathbb{T}_x - \mathbb{T}_y\|_{\text{TV}} \leq \|\mathbb{T}_x - \mathcal{P}_x\|_{\text{TV}} + \|\mathcal{P}_x - \mathcal{P}_y\|_{\text{TV}} + \|\mathcal{P}_y - \mathbb{T}_y\|_{\text{TV}}.$$

Using Lemma 4, we obtain that

$$\|\mathbb{T}_x - \mathbb{T}_y\|_{\text{TV}} \leq 11\epsilon, \quad \forall x, y \in \text{int}(\mathcal{K}) \text{ such that } \|x - y\|_x \leq \frac{\epsilon r}{2\kappa^2 d^{3/4}}.$$

Consequently, the John walk satisfies the assumptions of Lovász's Lemma with

$$\Delta := \frac{1}{\sqrt{3d/2}} \cdot \frac{\epsilon r}{2\kappa^2 d^{3/4}} \quad \text{and} \quad \rho := 1 - 11\epsilon.$$

Plugging in $\epsilon = 1/30$, $r = 10^{-5}$, we obtain the claimed upper bound of $\mathcal{O}\left(\kappa^4 d^{5/2}\right)$ on the mixing time of the random walk.

D.3 Proof of Lemma 4

We prove the lemma for the following function,

$$h(\epsilon) = \min \left\{ \frac{1}{25\sqrt{1 + \sqrt{2}\log(4/\epsilon)}}, \frac{\epsilon}{(2\sqrt{32}\chi_{1,\epsilon})}, \sqrt{\frac{\epsilon}{386\sqrt{24}\chi_{2,\epsilon}}}, \frac{\epsilon}{5\sqrt{60}\chi_{3,\epsilon}}, \right.$$
$$\left. \sqrt{\frac{\epsilon}{8\sqrt{1680}\chi_{4,\epsilon}}}, \sqrt{\frac{\epsilon}{40\left(\chi_{2,\epsilon}\chi_{6,\epsilon}\sqrt{24}\sqrt{15120}\right)^{1/2}}}, \sqrt{\frac{\epsilon}{204800\chi_{2,\epsilon}\sqrt{24}\log(32/\epsilon)}} \right\}.$$

where $\chi_{1,\epsilon} = \log(2/\epsilon)$and $\chi_{k,\epsilon} = \left(2e/k \cdot \log(16/\epsilon)\right)^{k/2}$ for $k = 2, 3, 4$ and 6. A numerical calculation shows that $h(1/30) \geq 10^{-5}$.

We now prove the two parts (76a) (76b) of the Lemma separately.

D.3.1 Proof of claim (76a)

Applying Pinsker's inequality, and plugging in the closed formed expression for the KL divergence between two Gaussian distributions we find that

$$\|\mathcal{P}_x - \mathcal{P}_y\|_{\text{TV}}^2 \leq 2\,\text{KL}(\mathcal{P}_y \| \mathcal{P}_x) = \text{trace}(J_x^{-1/2} J_y J_x^{-1/2}) - d - \log\det(J_x^{-1/2} J_y J_x^{-1/2}) + \frac{\kappa^4 d^{3/2}}{r^2} \|x - y\|_x^2$$
$$= \sum_{i=1}^d \left(\lambda_i - 1 + \log\frac{1}{\lambda_i} \right) + \frac{\kappa^4 d^{3/2}}{r^2} \|x - y\|_x^2, \tag{79}$$

where $\lambda_1, \ldots, \lambda_d > 0$ denote the eigenvalues of the matrix $J_x^{-1/2} J_y J_x^{-1/2}$. To bound the expression (79), we make use of the following lemma:

Lemma 5 *For any scalar $t \in [0, 1/64]$ and pair of points $x, y \in \operatorname{int}(\mathcal{K})$ such that $\|x - y\|_x \le t/\kappa^2$, we have*

$$\left(1 - 48t + 4t^2\right) \mathbb{I}_d \preceq J_x^{-1/2} J_y J_x^{-1/2} \preceq \left(1 + 48t + 4t^2\right),$$

where $\preceq$ denotes ordering in the PSD cone and $\mathbb{I}_d$ denotes the d-dimensional identity matrix.

See Section F for the proof of this lemma.

For $\epsilon \in (0, 1/30]$ and $r = 10^{-5}$, we have $t = \epsilon r/(2d^{3/4}) \le 1/64$, whence the eigenvalues $\{\lambda_i, i \in [d]\}$ can be sandwiched as

$$1 - \frac{24\epsilon r}{d^{3/4}} + \frac{\epsilon^2 r^2}{d^{3/2}} \le \lambda_i \le 1 + \frac{24\epsilon r}{d^{3/4}} + \frac{\epsilon^2 r^2}{d^{3/2}} \quad \text{for all } i \in d. \tag{80}$$

We are now ready to bound the TV distance between $\mathcal{P}_x$ and $\mathcal{P}_y$. Using the bound (79) and the inequality $\log \omega \le \omega - 1$, valid for $\omega > 0$, we obtain

$$\|\mathcal{P}_x - \mathcal{P}_y\|_{\text{TV}}^2 \le \sum_{i=1}^{d} \left(\lambda_i - 2 + \frac{1}{\lambda_i}\right) + \frac{\kappa^4 d^{3/2}}{r^2} \|x - y\|_x^2.$$

Using the assumption that $\|x - y\|_x \le \epsilon r / \left(2\kappa^2 d^{3/4}\right)$, and plugging in the bounds (80) for the eigenvalues $\{\lambda_i, i \in [d]\}$, we find that

$$\sum_{i=1}^{d} \left(\lambda_i - 2 + \frac{1}{\lambda_i}\right) + \frac{\kappa^4 d^{3/2}}{r^2} \|x - y\|_x^2 \le \frac{2000\epsilon^2 r^2}{\sqrt{d}} + \frac{\epsilon^2}{4}.$$

In asserting this inequality, we have used the facts that

$$\frac{1}{1 - 24\omega + \omega^2} \le 1 + 24\omega + 1000\omega^2, \quad \text{and} \quad \frac{1}{1 + 24\omega + \omega^2} \le 1 - 24\omega + 1000\omega^2 \quad \text{for all } \omega \in \left[0, \tfrac{1}{100}\right].$$

Note that for any $r \in [0, 1/100]$, we have that $2000r^2/\sqrt{d} \le 1/2$. Putting the pieces together yields $\|\mathcal{P}_x - \mathcal{P}_y\|_{\text{TV}} \le \epsilon$, as claimed.

D.3.2 Proof of claim (76b)

We have

$$\|\mathcal{P}_x - \mathbb{T}_x\|_{\text{TV}} \le \underbrace{\frac{3}{2}\mathcal{P}_x(\mathcal{K}^c)}_{=: S_1} + \underbrace{1 - \mathbb{E}_{z \sim \mathcal{P}_x}\left[\min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}\right]}_{=: S_2}, \tag{81}$$

where $\mathcal{K}^c$ denotes the complement of $\mathcal{K}$. We now show that $S_1 \le \epsilon$ and $S_2 \le 4\epsilon$, from which the claim follows.

Bounding the term S_1: Note that for $z \sim \mathcal{N}(x, \frac{r^2}{\kappa^2 d^{3/2}} J_x^{-1})$, we can write

$$z \stackrel{d}{=} x + \frac{r}{\kappa d^{3/4}} J_x^{-1/2} \xi, \tag{82}$$

where $\xi \sim \mathcal{N}(0, \mathbb{I}_d)$ and $\stackrel{d}{=}$ denotes equality in distribution. Using equation (82) and definition (74) of $\theta_{x,i}$, we obtain the bound

$$\frac{\left(a_i^\top (z - x)\right)^2}{s_{x,i}^2} = \frac{r^2}{\kappa^2 d^{3/2}} \left[\frac{a_i^\top J_x^{-1/2} \xi}{s_{x,i}}\right]^2 \stackrel{(i)}{\le} \frac{r^2}{\kappa^2 d^{3/2}} \theta_{x,i} \|\xi\|_2^2 \stackrel{(ii)}{\le} \frac{4r^2}{d} \|\xi\|_2^2, \tag{83}$$

where step (i) follows from Cauchy-Schwarz inequality, and step (ii) from part (d) of Lemma 3. Define the events

$$\mathcal{E} := \left\{\frac{r^2}{d} \|\xi\|_2^2 < \frac{1}{4}\right\} \quad \text{and} \quad \mathcal{E}' := \{z \in \operatorname{int}(\mathcal{K})\}.$$

Inequality (83) implies that $\mathcal{E} \subseteq \mathcal{E}'$ and hence $\mathbb{P}[\mathcal{E}'] \ge \mathbb{P}[\mathcal{E}]$. Using a standard Gaussian tail bound and noting that $r \le \frac{1/2}{1 + \sqrt{2/d \log(2/\epsilon)}}$, we obtain $\mathbb{P}[\mathcal{E}] \ge 1 - \epsilon/2$ and whence $\mathbb{P}[\mathcal{E}'] \ge 1 - \epsilon/2$. Thus, we have shown that $\mathbb{P}[z \notin \mathcal{K}] \le \epsilon/2$ which implies that $S_1 \le \epsilon$.

Bounding the term S_2: By Markov's inequality, we have

$$\mathbb{E}_{z \sim \mathcal{P}_x}\left[\min\left\{1, \frac{p_z(x)}{p_x(z)}\right\}\right] \ge \alpha \mathbb{P}\left[p_z(x) \ge \alpha p_x(z)\right] \quad \text{for all } \alpha \in (0, 1]. \tag{84}$$

By definition (71) of p_x, we obtain

$$\frac{p_z(x)}{p_x(z)} = \exp\left(-\frac{d^{3/2}\kappa^4}{2r^2}\left(\|z - x\|_z^2 - \|z - x\|_x^2\right) + \frac{1}{2}\left(\log\det J_z - \log\det J_x\right)\right).$$

The following lemma provides us with useful bounds on the two terms in this expression, valid for any $x \in \operatorname{int}(\mathcal{K})$.

Lemma 6 *For any $\epsilon \in (0, \frac{1}{4}]$ and $r \in (0, h(\epsilon)]$, we have*

$$\mathbb{P}_{z \sim \mathcal{P}_x}\left[\frac{1}{2}\log\det J_z - \frac{1}{2}\log\det J_x \ge -\epsilon\right] \ge 1 - \epsilon, \quad \textit{and} \tag{85a}$$

$$\mathbb{P}_{z \sim \mathcal{P}_x}\left[\|z - x\|_z^2 - \|z - x\|_x^2 \le 2\epsilon \frac{r^2}{\kappa^4 d^{3/2}}\right] \ge 1 - \epsilon. \tag{85b}$$

We provide the of this lemma in Section G.

Using Lemma 6, we now complete the proof of the Theorem 2. For $r \le h(\epsilon)$, we obtain

$$\frac{p_z(x)}{p_x(z)} \ge \exp(-2\epsilon) \ge 1 - 2\epsilon$$

with probability at least $1 - 2\epsilon$. Substituting $\alpha = 1 - 2\epsilon$ in inequality (84) yields that $S_2 \le 4\epsilon$, as claimed.

Appendix E. Technical Lemmas for the John walk

We begin by summarizing a few key properties of various terms involved in our analysis.

Let $\Sigma_{x,w}$ be an $n \times n$ diagonal matrix defined as

$$\Sigma_{x,w} = \operatorname{diag}(\sigma_{x,w,i}, \ldots, \sigma_{x,w,n}) \text{ where } \sigma_{x,\zeta_x,w,i} = (\Upsilon_{x,w})_{ii}, i \in [n]. \tag{86a}$$

Let $\Upsilon^{(2)}_{x,w}$ denote the hadamard product of $\Upsilon_{x,w}$ with itself. Further define

$$\Lambda_{x,w} := \Sigma_{x,w} - \Upsilon^{(2)}_{x,w}. \tag{86b}$$

Lee and Sidford (2014) proved that the weight vector ζ_x is the unique solution of the following fixed point equation:

$$w_i = \sigma_{x,w,i} + \beta_{\text{J}}, i \in [n]. \tag{87a}$$

To simplify notation, we use the following shorthands:

$$\sigma_x = \sigma_{x,\zeta_x}, \quad \Upsilon_x = \Upsilon_{x,\zeta_x}, \quad \Upsilon^{(2)}_x = \Upsilon^{(2)}_{x,\zeta_x}, \quad \Sigma_x = \Sigma_{x,\zeta_x}, \quad \Lambda_x = \Lambda_{x,\zeta_x}. \tag{87b}$$

Thus, we have the following relation:

$$\zeta_x = \sigma_{x,\zeta_x} + \beta_{\text{J}}\mathbf{1} = \sigma_x + \beta_{\text{J}}\mathbf{1}. \tag{87c}$$

E.1 Deterministic expressions and bounds

We now collect some properties of various terms defined above.

Lemma 7 *For any $x \in \operatorname{int}(\mathcal{K})$, the following properties hold:*

(a) $\sigma_{x,i} = \sum_{j=1}^n \sigma^2_{x,i,j} = \sum_{j,k=1}^n \sigma_{x,i,j}\sigma_{x,j,k}\sigma_{x,k,i}$ *for each* $i \in [n]$,

(b) $\Sigma_x \succeq \Upsilon^{(2)}_x$,

(c) $\sum_{i=1}^n \zeta_{x,i}\theta_{x,i} = d$,

(d) $\theta_{x,i} = \sum_{j=1}^n \zeta_{x,i}\theta^2_{x,i,j}$, *for each* $i \in [n]$,

(e) $\theta_x^\top \Sigma_x \theta_x = \sum_{i=1}^n \theta^2_{x,i}\zeta_{x,i} \le 4d$, *and*

(f) $\beta_{\text{J}} \nabla^2 \mathcal{F}_x \preceq J_x \preceq (1+\beta_{\text{J}})\nabla^2\mathcal{F}_x$.

The proof is based on the ideas similar to Lemma 5 in the proof of the Vaidya walk and is thereby omitted.

The next lemma relates the change in *slackness* $s_{x,i} = b_i - a_i^\top x$ to the John-local norm at x.

Lemma 8 *For all $x, y \in \operatorname{int}(\mathcal{K})$, we have*

$$\max_{i\in[n]} \left| 1 - \frac{s_{y,i}}{s_{x,i}} \right| \le 2\|x-y\|_x.$$

Proof For any pair $x, y \in \operatorname{int}(\mathcal{K})$ and index $i \in [n]$, we have

$$\left(a_i^\top (x-y)\right)^2 \overset{(i)}{\le} \|J_x^{-\frac{1}{2}} a_i\|_2^2 \, \|J_x^{\frac{1}{2}}(x-y)\|_2^2 = \theta_{x,i} s^2_{x,i} \, \|x-y\|_x^2 \overset{(ii)}{\le} 4 s^2_{x,i} \, \|x-y\|_x^2,$$

where step (i) follows from the Cauchy-Schwarz inequality, and step (ii) uses the bound $\theta_{x,i}$ from Lemma 3(d). Noting the fact that $a_i^\top(x-y) = s_{y,i} - s_{x,i}$, the claim follows after simple algebra. ■

We now state various expressions and bounds for the first and second order derivatives of the different terms. To lighten notation, we introduce some shorthand notation. For any $y \in \operatorname{int}(\mathcal{K})$ and $h \in \mathbb{R}^d$, define the following terms:

$$d_{y,i} = \frac{a_i^\top h}{s_{y,i}}, \ i \in [n] \qquad D_y = \operatorname{diag}(d_{y,1}, \ldots, d_{y,n}), \tag{88a}$$

$$f_{y,i} = \frac{\nabla \zeta_{y,i}^\top h}{\zeta_{y,i}}, \ i \in [n] \qquad F_y = \operatorname{diag}(f_{y,1}, \ldots, f_{y,n}), \tag{88b}$$

$$\ell_{y,i} = \frac{1}{2} h^\top \nabla^2 \zeta_{y,i} h / \zeta_{y,i}, \ i \in [n] \qquad L_y = \operatorname{diag}(\ell_{y,1}, \ldots, \ell_{y,n}), \tag{88c}$$

$$\rho_y := (G_y - \alpha\Lambda_y) \begin{bmatrix} \ell_{y,1} \\ \vdots \\ \ell_{y,n} \end{bmatrix}, \tag{88d}$$

where for brevity in our notation we have omitted the dependence on h. The choice of h is specified as per the context. Further, we define for each $x \in \operatorname{int}(\mathcal{K})$ and $i \in [n]$

$$\varphi_{x,i} := \frac{\zeta_{x,i}}{s^2_{x,i}}, \qquad \text{and} \qquad \Psi_x := \frac{1}{2}\log\det J_x, \tag{89}$$

$$\hat{a}_{x,i} := \frac{J_x^{-1/2} a_{x,i}}{s^2_{x,i}}, \qquad \text{and} \qquad \hat{b}_{x,i} := J_x^{-1/2} A_x \Lambda_x (G_x - \alpha\Lambda_x)^{-1} e_i. \tag{90}$$

Next, we state expressions for gradients of ζ, φ and Ψ and bounds for directional Hessian of σ, φ and Ψ which are used in various Taylor series expansions and bounds in our proof.

Lemma 9 (Calculus) *For any $y \in \operatorname{int}(\mathcal{K})$ and $h \in \mathbb{R}^n$, the following relations hold;*

(a) Gradient of ζ: $(f_{y,1}, \ldots, f_{y,n})^\top = 2(G_y - \alpha\Lambda_y)^{-1}\Lambda_y A_y h$;

(b) Hessian of ζ:

$$\|\rho_y\|_1 \le 56\kappa^2 \sum_{i=1}^n \zeta_{y,i} d^2_{y,i}. \tag{91}$$

(c) Gradient of Ψ: $\nabla\Psi^\top h = \theta_y^\top G_y \left(\mathbb{I}_n + (G_y - \alpha\Lambda_y)^{-1}\Lambda_y\right) A_y h$.

(d) Gradient of φ: $\nabla\varphi_{y,i}^\top h = \varphi_{y,i}(2d_{y,i} + f_{y,i})$.

(e) Bound on $\nabla^2\Psi$: $\frac{1}{2}\left|h^\top(\nabla^2\Psi)h\right| \le \frac{1}{2}\left[\sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\left[9\,d_{y,i}^2 + 4f_{y,i}^2\right] + \left|\sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\ell_{y,i}\right|\right]$

(f) Bound on $\nabla^2\varphi$:

$$\left|\sum_{i=1}^n d_{y,i}^2 s_{y,i}^2 \frac{1}{2} h^\top \nabla^2\varphi_{y,i} h\right| \le 3\sum_{i=1}^n \zeta_{y,i} d_{y,i}^4 + 2\left|\sum_{i=1}^n \zeta_{y,i} d_{y,i}^3 f_{y,i}\right| + \left|\sum_{i=1}^n \zeta_{y,i} d_{y,i}^2 \ell_{y,i}\right|.$$

The proof is provided in Section H.1.

Next, we state some results that would be useful to provide explicit bounds for various terms like f_y, ℓ_y and ρ_y that appear in the statements of the previous lemma. Note that the following results do not have a corresponding analog in our analysis of the Vaidya walk.

Lemma 10 *For any* $c_1, c_2 \ge 0$, $y \in \operatorname{int}(\mathcal{K})$, *we have*

$$\left(c_1\mathbb{I}_n + c_2\Lambda_y\left(G_y - \alpha\Lambda_y\right)^{-1}\right) G_y \left(c_1\mathbb{I}_n + c_2\left(G_y - \alpha\Lambda_y\right)^{-1}\Lambda_y\right) \preceq \left(c_1 + c_2\right)^2 \kappa^2 G_y,$$

where $\preceq$ *denotes the ordering in the PSD cone.*

Lemma 11 *Let* μ_y *denote the* $n \times n$ *matrix* $\left(G_y - \alpha\Lambda_y\right)^{-1} G_y$, *and let* $\mu_{y,i,j}$ *denote its* ij*-th entry. Then for each* $i \in [n]$ *and* $y \in \operatorname{int}(\mathcal{K})$, *we have*

$$\mu_{y,i,i} \in [0, \kappa], \qquad \textit{and,} \tag{92a}$$

$$\sum_{j \ne i, j \in [n]} \frac{\mu_{y,i,j}^2}{\zeta_{y,j}} \le \kappa^3. \tag{92b}$$

Corollary 12 *Let* $e_i \in \mathbb{R}^n$ *denote the unit vector along* i*-th axis. Then for any* $y \in \operatorname{int}(\mathcal{K})$, *we have*

$$\left\|G_y\left(G_y - \alpha\Lambda_y\right)^{-1} e_i\right\|_1 \le 3\sqrt{d}\kappa^{3/2}, \qquad \textit{for all } i \in [n]. \tag{93}$$

Consequently, we also have $\left\|\left(G_y - \alpha\Lambda_y\right)^{-1} G_y\right\|_\infty \le 3\sqrt{d}\kappa^{3/2}$.

See Section H.2, H.3 and H.4 for the proofs of Lemma 10, Lemma 11 and Corollary 12 respectively.

E.2 Tail Bounds

We now collect lemmas that provide us with useful tail bounds.

We start with a result that shows that for a random variable $z \sim \mathcal{P}_x$, the slackness $s_{z,i}$ is close to $s_{x,i}$ with high probability and consequently the weights $\zeta_{z,i}$ are also close to $\zeta_{x,i}$. This result comes in handy for transferring the remainder terms in Taylor expansions to the reference point (around which the series is being expanded).

Lemma 13 *For any point* $x \in \operatorname{int}(\mathcal{K})$ *and* $r \le \frac{1}{25\cdot\sqrt{1+\sqrt{2}\log(4/\epsilon)}}$, *we have*

$$\mathbb{P}_{z\sim\mathcal{P}_x}\left[\forall i \in [n], \forall v \in \overline{xz},\ \frac{s_{x,i}}{s_{v,i}} \in [0.99, 1.01] \ \textit{ and } \frac{\zeta_{x,i}}{\zeta_{v,i}} \in [0.96, 1.04]\right] \ge 1 - \epsilon/4 \tag{94a}$$

See Section I.1 for the proof of this lemma.

Next, we state high probability results for some Gaussian polynomials. These results are useful to bound various polynomials of the form $\sum_{i=1}^n \zeta_{x,i} d_{x,i}^k$, where $d_{x,i} = a_i^\top(z - x)/s_{x,i}$ and z is drawn from the transition distribution for the John walk at point x.

Lemma 14 (Gaussian moment bounds) *To simplify notations, all subscripts on* x *are omitted in the following statements. For any* $\epsilon \in (0, 1/30]$, *define* $\chi_k := \chi_{k,\epsilon} = (2e/k \cdot \log(16/\epsilon))^{k/2}$, *for* $k = 2, 3, 4$ *and* 6, *then we have*

$$\mathbb{P}\left[\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^2 \le \chi_2\sqrt{24}d\right] \ge 1 - \frac{\epsilon}{16}, \tag{95a}$$

$$\mathbb{P}\left[\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^3 \le \chi_3\sqrt{60}d^{1/2}\right] \ge 1 - \frac{\epsilon}{16}, \tag{95b}$$

$$\mathbb{P}\left[\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^2\left(\hat{b}_i^\top\xi\right) \le \chi_3\sqrt{240}\kappa d^{1/2}\right] \ge 1 - \frac{\epsilon}{16}, \tag{95c}$$

$$\mathbb{P}\left[\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^4 \le \chi_4\sqrt{1680}d\right] \ge 1 - \frac{\epsilon}{16}, \tag{95d}$$

$$\mathbb{P}\left[\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^6 \le \chi_6\sqrt{15120}d\right] \ge 1 - \frac{\epsilon}{16}. \tag{95e}$$

See Section I.2 for the proof.

Appendix F. Proof of Lemma 5

As a direct consequence of Lemma 8, for any $x, y \in \operatorname{int}(\mathcal{K})$ such that $\|x - y\|_x \le t/\kappa^2$, we have

$$\max_{i\in[n]}\left|1 - \frac{s_{y,i}}{s_{x,i}}\right| \le \frac{2t}{\kappa^2}. \tag{96}$$

Bounding the terms in $\nabla^2\mathcal{F}_x$ one by one, we obtain

$$\left(1 - \frac{2t}{\kappa^2}\right)^2 \nabla^2\mathcal{F}_y \preceq \nabla^2\mathcal{F}_x \preceq \left(1 + \frac{2t}{\kappa^2}\right)^2 \nabla^2\mathcal{F}_y.$$

We claim that

$$\|\log\zeta_y - \log\zeta_x\|_\infty \le 16t. \tag{97}$$

Assuming the claim as given at the moment, we now complete the proof. Putting the result (97) in matrix form, we obtain that $\exp(-16t)\,\mathbb{I}_n \preceq G_x^{-1}G_y \preceq \exp(16t)\,\mathbb{I}_n$, and hence

$$\exp(-16t)\,\zeta_{x,i} \le \zeta_{y,i} \le \exp(16t)\,\zeta_{x,i}. \tag{98}$$

Consequently, using the definition of J_x we have,

$$\underbrace{\left(1-\frac{2t}{\kappa^2}\right)^2 \exp\left(-16t\right)}_{\omega_\ell} J_x \preceq J_y \preceq \underbrace{\left(1+\frac{2t}{\kappa^2}\right)^2 \exp\left(16t\right)}_{\omega_u} J_y.$$

Letting $\omega = 2t$, we obtain

$$\omega_\ell \geq (1-\omega)^2 \cdot \exp\left(-8\omega\right) \overset{(i)}{\geq} 1 - 24\omega + \omega^2, \quad \text{and} \quad \omega_u \leq (1+\omega)^2 \cdot \exp\left(8\omega\right) \overset{(ii)}{\leq} 1 + 24\omega + \omega^2,$$

where inequalities (i) and (ii) hold since $\omega \leq 1/24$. Putting the pieces together, we find that

$$\left(1 - 48t + 4t^2\right) J_x \preceq J_y \preceq \left(1 - 48t + 4t^2\right) J_x$$

for $t \in [0, 1/48]$.

Now, we return to the proof of our earlier claim (97). We use an argument based on the continuity of the function $x \mapsto \log \zeta_x$. (Such an argument appeared in a similar scenario in Lee and Sidford (2014).) For $\lambda \in [0,1]$, define $u_\lambda = \lambda y + (1-\lambda)\, x$. Let

$$\lambda^{\max} := \sup\left\{\lambda \in [0,1] \,\middle|\, \left\|\log \zeta_{u_\lambda} - \log \zeta_x\right\|_\infty \leq 16t\right\}. \tag{99}$$

It suffices to establish that $\lambda^{\max} = 1$. Note that $\lambda = 0$ is feasible on the RHS of equation (99) and hence $\lambda^{\max}$ exists. Now for any $\lambda \in [0, \lambda^{\max}]$ and $i \in \{1, \ldots, n\}$, there exists v on the segment $\overline{u_\lambda x}$ such that

$$\left|\log \zeta_{u_\lambda, i} - \log \zeta_{x,i}\right| = \left|\left(\frac{\nabla \zeta_{v,i}}{\zeta_{v,i}}\right)^\top (u_\lambda - x)\right| \overset{(i)}{\leq} \left\|G_v^{-1} G_v' \,(y-x)\right\|_\infty = 2\left\|\left(G_v - \alpha\Lambda_v\right)^{-1} \Lambda_v A_v \,(y-x)\right\|_\infty.$$

where in step (i) we have used the fact that $u_\lambda - x = \lambda(y-x)$ and $\lambda \in [0,1]$. We claim that

$$\left\|\left(G_v - \alpha\Lambda_v\right)^{-1} \Lambda_v v_1\right\|_\infty \leq \kappa \left\|v_1\right\|_\infty + 2\kappa^2 \left\|G_v^{1/2} v_1\right\|_2 \quad \text{for any } v_1 \in \mathbb{R}^n. \tag{100}$$

We prove the claim at the end of this section. We now derive bounds for the two terms on the RHS of the equation (100) for $v_1 = A_v(y-x)$. Note that

$$\left\|A_v\,(y-x)\right\|_\infty = \max_i \left|\frac{s_{y,i} - s_{x,i}}{s_{v,i}}\right| = \max_i \left|\frac{s_{y,i} - s_{x,i}}{s_{x,i}}\right| \left|\frac{s_{x,i}}{s_{v,i}}\right| \overset{(i)}{\leq} \frac{2t}{\kappa^2\left(1 - 2t/\kappa^2\right)} \overset{(ii)}{\leq} \frac{3t}{\kappa^2}.$$

Inequality (i) uses bound (96) and inequality (ii) follows by plugging in $t \leq 1/64$. Next, we have

$$\begin{aligned}
\left\|G_v^{1/2} A_v\,(y-x)\right\|_2^2 = \sum_{i=1}^n \zeta_{x,i} \frac{\left(a_i^\top\,(y-x)\right)^2}{s_{x,i}^2} \frac{\zeta_{v,i}}{\zeta_{x,i}} \frac{s_{v,i}^2}{s_{x,i}^2} &\overset{(i)}{\leq} \left\|x-y\right\|_x^2 \max_{i\in[n]} \frac{\zeta_{v,i}}{\zeta_{x,i}} \frac{s_{v,i}^2}{s_{x,i}^2} \\
&\overset{(ii)}{\leq} \frac{t^2}{\kappa^4}\left(1 + (16t) + (16t)^2\right)\left(1 + \frac{2t}{\kappa^2}\right)^2 \\
&\overset{(iii)}{\leq} \frac{1.5t}{\kappa^4},
\end{aligned}$$

where step (i) follows from the definition of the local norm; step (ii) follows from bounds (96) and (99) and the fact that $e^x \leq 1 + x + x^2$ for all $x \in [0, 1/4]$; and inequality (iii) follows by plugging in $t \leq 1/64$. Putting the pieces together, we obtain

$$\left\|\log \zeta_{u_\lambda} - \log \zeta_x\right\|_\infty \leq 2(\kappa \cdot 3t/\kappa^2 + 2\kappa^2 \cdot 1.5t/\kappa^4) \leq 12t < 16t.$$

The strict inequality is valid for $\lambda = \lambda^{\max}$. Consequently, using the continuity of $x \mapsto \log \zeta_x$, we conclude that $\lambda^{\max} = 1$.

It is left to prove claim (100). Let $w := \left(G_v - \alpha\Lambda_v\right)^{-1} \Lambda_v v_1$. which implies $\left(G_v - \alpha\Lambda_v\right) w = \Lambda_v v_1$. Plugging the expression of G_v and Λ_v, we have

$$\left((1-\alpha)\Sigma_v + \beta_\jmath \mathbb{I}_n + \alpha\Upsilon_v^{(2)}\right) w = \left(\Sigma_v - \Upsilon_v^{(2)}\right) v_1.$$

Writing component wise, we find that for any $i \in [n]$, we have

$$\begin{aligned}
\left|\left((1-\alpha)\sigma_{v,i} + \beta_\jmath\right) w_i\right| &\leq \alpha\left|e_i^\top \Upsilon_v^{(2)} w\right| + \sigma_{v,i}\left|v_{1,i}\right| + \left|e_i^\top \Upsilon_v^{(2)} v_1\right| \\
&\overset{(i)}{\leq} \alpha\sigma_{v,i}\left\|\Sigma_v^{1/2} w\right\|_2 + \sigma_{v,i}\left\|v_1\right\|_\infty + \sigma_{v,i}\left\|\Sigma_v^{1/2} v_1\right\|_2 \\
&\overset{(ii)}{\leq} \alpha\sigma_{v,i}\left\|G_v^{1/2} w\right\|_2 + \sigma_{v,i}\left\|v_1\right\|_\infty + \sigma_{v,i}\left\|G_v^{1/2} v_1\right\|_2 \\
&\overset{(iii)}{\leq} \alpha\sigma_{v,i}\kappa\left\|G_v^{1/2} v_1\right\|_2 + \sigma_{v,i}\left\|v_1\right\|_\infty + \sigma_{v,i}\left\|G_v^{1/2} v_1\right\|_2,
\end{aligned} \tag{101}$$

where inequality (ii) from the fact that $\Sigma_y \preceq G_y$ and inequality (iii) from Lemma 10 with $c_1 = 0, c_2 = 1$. To assert inequality (i), observe the following

$$\left|\sum_{j=1}^n \sigma_{y,i,j}^2 w_j\right| \leq \sum_{j=1}^n \sigma_{y,i,j}^2 \left|w_j\right| \overset{(a)}{\leq} \sigma_{y,i} \sum_{j=1}^n \sigma_{y,j}\left|w_j\right| \overset{(b)}{\leq} \sigma_{y,i} \sum_{j=1}^n \sqrt{\sigma_{y,j}}\left|w_j\right| = \sigma_{y,i}\left\|\Sigma_v^{1/2} w\right\|_2,$$

where step (a) follows from the fact that $\sigma_{y,i,j}^2 \leq \sigma_{y,i}\sigma_{y,j}$, and step (b) from the fac that $\sigma_{y,i} \in [0,1]$. Dividing both sides of inequality (101) by $((1-\alpha)\sigma_{v,i} + \beta_\jmath)$ and observing that $\sigma_{v,i}/\left((1-\alpha)\sigma_{v,i} + \beta_\jmath\right) \leq \kappa$, and $\alpha \in [0,1]$, yields the claim.

Appendix G. Proof of Lemma 6

We prove Lemma 6 in two parts: claim (85a) in Section G.1 and claim (85b) in Section G.2.

G.1 Proof of claim (85a)

Using the second order Taylor expansion, we have

$$\Psi_z - \Psi_x = (z-x)^\top \nabla\Psi_x + \frac{1}{2}(z-x)^\top \nabla^2\Psi_y\,(z-x), \quad \text{for some } y \in \overline{xz}.$$

We claim that for $r \leq h(\epsilon)$, we have

$$\mathbb{P}\left[(z-x)^\top \nabla\Psi_x \geq -\epsilon/2\right] \geq 1 - \epsilon/2, \text{ and} \tag{102a}$$

$$\mathbb{P}\left[\frac{1}{2}(z-x)\,\nabla^2\Psi_y\,(z-x) \geq -\epsilon/2\right] \geq 1 - \epsilon/2. \tag{102b}$$

Note that the claim (85a) follows from the above two claims.

G.1.1 Proof of bound (102a)

We observe that

$$(z-x)^\top \nabla\Psi_x \sim \mathcal{N}\left(0, \frac{r^2}{\kappa^2 n}\nabla\Psi_x^\top J_x^{-1}\nabla\Psi_x\right).$$

Let $E_x = \mathbb{I}_n + (G_x - \alpha\Lambda_x)^{-1}\Lambda_x$. Substituting the expression of $\nabla\Psi_x$ from Lemma 9 (c) and applying Cauchy-Schwarz inequality, we have that for any vector $v \in \mathbb{R}^d$

$$v^\top \nabla\Psi_x \nabla\Psi_x^\top v = (\theta_x^\top G_x E_x A_x v)^2 \le \left(v^\top A_x^\top G_x A_x v\right)\cdot\left(\theta_x^\top G_x E_x G_x^{-1} E_x G_x \theta_x\right). \tag{103}$$

Observe that

$$G_x^{1/2} E_x G_x^{-1/2} = \mathbb{I}_n + (\mathbb{I}_n - \alpha G_x^{-1/2}\Lambda_x G_x^{-1/2})^{-1}(G_x^{-1/2}\Lambda_x G_x^{-1/2}).$$

Now, using the intermediate bound (126) from the proof of Lemma 10, we obtain that

$$\mathbb{I}_n \preceq G_x^{1/2} E_x G_x^{-1/2} \preceq 2\kappa \mathbb{I}_n,$$

and hence $G_x \preceq G_x E_x G_x^{-1} E_x G_x \preceq 4\kappa^2 G_x$. Consequently, we have

$$\theta_x^\top G_x E_x G_x^{-1} E_x G_x \theta_x \le 4\kappa^2 \theta_x^\top G_x \theta_x = 4\kappa^2 \sum_{i=1}^n \zeta_{x,i}\theta_{x,i}^2 \le 16\kappa^2 d,$$

where the last step follows from Lemma 7. Putting the pieces together into equation (103), we obtain $\nabla\Psi_x\nabla\Psi_x^\top \preceq 16\kappa^2 d J_x$ whence $J_x^{-1/2}\nabla\Psi_x\nabla\Psi_x^\top J_x^{-1/2} \preceq 16\kappa^2 d\mathbb{I}_d$. Noting that the matrix $J_x^{-1/2}\nabla\Psi_x\nabla\Psi_x^\top J_x^{-1/2}$ has rank one, we have

$$\nabla\Psi_x^\top J_x^{-1}\nabla\Psi_x = \text{trace}\left(J_x^{-1/2}\nabla\Psi_x\nabla\Psi_x^\top J_x^{-1/2}\right) \le 16\kappa^2 d.$$

Using standard Gaussian tail bound, we have $\mathbb{P}\left((z-x)^\top\nabla\Psi_x \ge -\sqrt{32}\chi_1 r\right) \ge 1 - \exp\left(-\chi_1^2\right)$.

Choosing $\chi_1 = \log(2/\epsilon)$, and observing that

$$r \le \frac{\epsilon}{\left(2\sqrt{32}\chi_1\right)}, \tag{104}$$

yields the claim.

G.1.2 Proof of bound (102b)

In the following proof, we use $h = z - x$ for definitions (88a)-(88d). According to Lemma 9(e), we have

$$\left|\frac{1}{2}(z-x)^\top\nabla^2\Psi_y(z-x)\right| \le \sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\left[\frac{9}{2}d_{y,i}^2 + 2f_{y,i}^2\right] + \frac{1}{2}\left|\sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\ell_{y,i}\right|$$

We claim that

$$\sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\left[\frac{9}{2}d_{y,i}^2 + 2f_{y,i}^2\right] + \frac{1}{2}\left|\sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\ell_{y,i}\right| \le 386\sqrt{d}\kappa^4 \sum_{i=1}^n \zeta_{y,i}d_{y,i}^2. \tag{105}$$

Assuming the claim as given at the moment, we now complete the proof. Note that y is some particular point on $\overline{xz}$ and its dependence on z is hard to characterize. Consequently, we transfer all the terms with dependence on y, to terms with dependence on x only. We have

$$\sum_{i=1}^n \zeta_{y,i}d_{y,i}^2 = \sum_{i=1}^n \zeta_{x,i}d_{x,i}^2 \underbrace{\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{s_{x,i}^2}{s_{y,i}^2}}_{\tau_{y,i}}.$$

We now invoke the following high probability bounds implied by Lemma 13 and Lemma 14 (95a) respectively

$$\mathbb{P}\left[\sup_{y\in\overline{xz},i\in[n]}\tau_{y,i} \le 1.1\right] \ge 1-\epsilon/4, \quad \text{and,} \quad \mathbb{P}\left[\sum_{i=1}^n \zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^2 \le \chi_2\sqrt{24}d\right] \ge 1-\epsilon/16. \tag{106}$$

Since $h = z - x$, we have that $d_{x,i}^2 = \frac{r^2}{\kappa^2 d^{3/2}}\left(\hat{a}_{x,i}^\top\xi\right)^2$. Consequently, for

$$r \le \sqrt{\frac{\epsilon}{386\sqrt{24}\chi_2}}, \tag{107}$$

with probability at least $1-\epsilon/2$, we have

$$\left|\frac{1}{2}(z-x)^\top\nabla^2\Psi_y(z-x)\right| \overset{\text{eqn. (105)}}{\le} 386\sqrt{d}\kappa^4\sum_{i=1}^n \zeta_{y,i}d_{y,i}^2 \overset{\text{hpb (106)}}{\le} \epsilon,$$

which completes the proof.

We now turn to the proof of claim (105). First we observe the following relationship between the terms $d_{y,i}$ and $f_{y,i}$:

$$\sum_{i=1}^n \zeta_{y,i}f_{y,i}^2 \overset{(i)}{=} 4h^\top A_y^\top\Lambda_y\left(G_y-\alpha\Lambda_y\right)^{-1}G_y\left(G_y-\alpha\Lambda_y\right)^{-1}\Lambda_y A_y h \overset{(ii)}{\le} 4\kappa^2 h^\top A_y^\top G_y A_y h = 4\kappa^2\sum_{i=1}^n \zeta_{y,i}d_{y,i}^2, \tag{108}$$

where step (i) follows by plugging in the definition of $f_{y,i}$ (88b) and step (ii) by invoking Lemma 10 with $c_1 = 0$ and $c_2 = 1$. Next, we relate the term on the LHS of equation (105) involving $\ell_{y,i}$ to a polynomial in $d_{y,i}$. Using Lemma 9, we find that

$$\left|\sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\ell_{y,i}\right| = \left|\left(\left(G_y-\alpha\Lambda_y\right)^{-1}G_y\theta_y\right)^\top\left(G_y-\alpha\Lambda_y\right)\ell_y\right| \le \left\|\underbrace{\left(G_y-\alpha\Lambda_y\right)^{-1}G_y\theta_y}_{v_1}\right\|_\infty \left\|\underbrace{\left(G_y-\alpha\Lambda_y\right)\ell_y}_{\rho_y}\right\|_1,$$

where the last step follows from the Holder's inequality: for any two vectors $u, v \in \mathbb{R}^d$, we have that $u^\top v \le \|u\|_\infty \|v\|_1$. Substituting the bound for the norm $\|v_1\|_\infty$ from Corollary 12 and the bound on $\rho_{y,i}$ from Lemma 9(b), we obtain that

$$\left|\sum_{i=1}^n \zeta_{y,i}\,\theta_{y,i}\ell_{y,i}\right| \le 12\sqrt{n}\kappa^{3/2}\sum_{i=1}^n\left[7\zeta_{y,i}d_{y,i}^2+3\zeta_{y,i}f_{y,i}^2+\sum_{j=1}^n\left(13d_{y,j}^2+6f_{y,j}^2\right)\Upsilon_{y,i,j}^2\right] \le 672\sqrt{n}\kappa^4\sum_{i=1}^n\zeta_{y,i}d_{y,i}^2,$$

where the last step follows from Lemma 7(a) and the bound (108). The claim now follows.

G.2 Proof of claim (85b)

Writing $z = x + tu$, where t is a scalar and u is a unit vector in $\mathbb{R}^d$, we obtain

$$\|z-x\|_z^2 - \|z-x\|_x^2 = t^2\sum_{i=1}^n\left(a_i^\top u\right)^2(\varphi_{z,i}-\varphi_{x,i}).$$

Now, we use a Taylor series expansion for $\sum_{i=1}^n\left(a_i^\top u\right)^2(\varphi_{z,i}-\varphi_{x,i})$ around the point x, along the line u. There exists a point $y \in \overline{xz}$ such that

$$\sum_{i=1}^n\left(a_i^\top u\right)^2(\varphi_{z,i}-\varphi_{x,i}) = \sum_{i=1}^n\left(a_i^\top u\right)^2\left((z-x)^\top\nabla\varphi_{x,i}+\frac{1}{2}(z-x)^\top\nabla^2\varphi_{y,i}(z-x)\right).$$

Note that the point y in this discussion is not the same as the point y used in previous proofs, in particular in Section G.1. Multiplying both sides by t^2, and using the shorthand $d_{x,i} = \frac{a_i^\top(z-x)}{s_{x,i}}$, we obtain

$$\|z-x\|_z^2-\|z-x\|_x^2 = \sum_{i=1}^n d_{x,i}^2s_{x,i}^2(z-x)^\top\nabla\varphi_{x,i}+\sum_{i=1}^n d_{x,i}^2s_{x,i}^2\frac{1}{2}(z-x)^\top\nabla^2\varphi_{y,i}(z-x). \quad (109)$$

We claim that for $r \le h(\epsilon)$, we have

$$\mathbb{P}_{z\sim\mathbb{T}_x^{\mathrm{J}}}\left[\sum_{i=1}^n d_{x,i}^2s_{x,i}^2(z-x)^\top\nabla\varphi_{x,i} \le \epsilon\frac{r^2}{\kappa^4 d^{3/2}}\right] \ge 1-\epsilon/2, \text{ and} \quad (110a)$$

$$\mathbb{P}_{z\sim\mathbb{T}_x^{\mathrm{J}}}\left[\sup_{y\in\overline{xz}}\left(\sum_{i=1}^n d_{x,i}^2s_{x,i}^2\frac{1}{2}(z-x)^\top\nabla^2\varphi_{y,i}(z-x)\right) \le \epsilon\frac{r^2}{\kappa^4 d^{3/2}}\right] \ge 1-\epsilon/2. \quad (110b)$$

We now prove each claim separately.

G.2.1 Proof of bound (110a)

Using Lemma 9(d) and using $h = z - x$ where z is given by the relation (82), we find that

$$\begin{aligned}\sum_{i=1}^n d_{x,i}^2s_{x,i}^2(z-x)^\top\nabla\varphi_{x,i} &= \sum_{i=1}^n\zeta_{x,i}d_{x,i}^2(2d_{x,i}+f_{x,i})\\ &= \frac{r^3}{d^{9/4}\kappa^6}\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^3+\frac{2r^3}{d^{9/4}\kappa^6}\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^2\left(\hat{b}_{x,i}^\top\xi\right) \quad (111)\end{aligned}$$

Using high probability bounds for the two terms in equation (111) from Lemma 14, part (95b) and part (95c), we obtain that

$$\left|\sum_{i=1}^n d_{x,i}^2s_{x,i}^2(z-x)^\top\nabla\varphi_{x,i}\right| \le \frac{5\sqrt{60}\chi_3 r^3}{\kappa^5 d^{7/4}} \le \epsilon\frac{r^2}{\kappa^4 d^{3/2}},$$

with probability at least $1-\epsilon/2$. The last inequality uses the condition that

$$r \le \frac{\epsilon}{5\sqrt{60}\chi_3}. \quad (112)$$

The claim now follows.

G.2.2 Proof of bound (110b)

Note that $d_{x,i}s_{x,i} = a_i^\top h = d_{y,i}s_{y,i}$ for any h. Using this equality for $h = z - x$, we find that

$$\begin{aligned}\left|\sum_{i=1}^n d_{x,i}^2s_{x,i}^2\frac{1}{2}h^\top\nabla^2\varphi_{y,i}h\right| &= \left|\sum_{i=1}^n d_{y,i}^2s_{y,i}^2\frac{1}{2}h^\top\nabla^2\varphi_{y,i}h\right|\\ &\overset{(i)}{\le} 3\underbrace{\sum_{i=1}^n\zeta_{y,i}d_{y,i}^4}_{C_1}+2\underbrace{\left|\sum_{i=1}^n\zeta_{y,i}d_{y,i}^3f_{y,i}\right|}_{C_2}+\underbrace{\left|\sum_{i=1}^n\zeta_{y,i}d_{y,i}^2\ell_{y,i}\right|}_{C_3}, \quad (113)\end{aligned}$$

where step (i) follows from Lemma 9(f). We can write C_1 as follows

$$\sum_{i=1}^n\zeta_{y,i}d_{y,i}^4 = \sum_{i=1}^n\zeta_{x,i}d_{x,i}^4\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{d_{y,i}^4}{d_{x,i}^4} = \frac{r^4}{n^3\kappa^8}\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^4\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{d_{y,i}^4}{d_{x,i}^4}. \quad (114)$$

Now, we claim the following:

$$C_2 \le 2\frac{r^4}{n^3\kappa^7}\cdot\sqrt{\left[\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^2\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{d_{y,i}^2}{d_{x,i}^2}\right]\cdot\left[\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^6\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{d_{y,i}^6}{d_{x,i}^6}\right]}, \quad \text{and,} \quad (115a)$$

$$C_3 \le 56\frac{r^4}{n^3\kappa^{4.5}}\left(\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^2\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{d_{y,i}^2}{d_{x,i}^2}\right)\left(\max_i\left(\hat{a}_{x,i}^\top\xi\right)^2\frac{d_{y,i}^2}{d_{x,i}^2}+\sqrt{\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^4\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{d_{y,i}^4}{d_{x,i}^4}}\right) \quad (115b)$$

Assuming the claims as given, we now complete the proof. Using Lemma 13, we have

$$\mathbb{P}\left[\frac{\zeta_{y,i}}{\zeta_{x,i}}\frac{d_{y,i}^6}{d_{x,i}^6} \le 1.2\right] \ge 1-\epsilon/4,$$

and consequently

$$\begin{aligned}3C_1+2C_2+C_3 \le \frac{r^4}{d^3\kappa^{4.5}}\Bigg[&4\cdot\sum_{i=1}^n\zeta_{x,i}(\hat{a}_{x,i}^\top\xi)^4+10\cdot\left(\sum_{i=1}^n\zeta_{x,i}(\hat{a}_{x,i}^\top\xi)^2\cdot\sum_{i=1}^n\zeta_{x,i}(\hat{a}_{x,i}^\top\xi)^6\right)^{1/2}\\ &+100\cdot\sum_{i=1}^n\zeta_{x,i}\left(\hat{a}_{x,i}^\top\xi\right)^2\cdot\left(\max_i(\hat{a}_{x,i}^\top\xi)^2+\left(\sum_{i=1}^n\zeta_{x,i}(\hat{a}_{x,i}^\top\xi)^4\right)^{1/2}\right)\Bigg], \quad (116)\end{aligned}$$

with probability at least $1-\epsilon/4$. Now, we observe that for all $i \in [n]$ and $x \in \operatorname{int}(\mathcal{K})$, we have

$$\left(\hat{a}_{x,i}^\top \xi\right) \sim \mathcal{N}(0, \theta_{x,i}) \quad \text{and} \quad \theta_{x,i} \leq 4.$$

Invoking the standard tail bound for maximum of Gaussian random variables, we obtain

$$\mathbb{P}\left[\max_i \left|\left(\hat{a}_{x,i}^\top \xi\right)\right| \leq 8 \cdot \left(\sqrt{\log n} + \sqrt{\log(32/\epsilon)}\right)\right] \geq 1 - \epsilon/16.$$

Using the fact that $2c_1c_2 \geq c_1 + c_2$ for all $c_1, c_2 \geq 1$, we obtain

$$\mathbb{P}\left[\max_i \left|\left(\hat{a}_{x,i}^\top \xi\right)\right| \leq 16 \cdot \sqrt{\log n} \cdot \sqrt{\log(32/\epsilon)}\right] \geq 1 - \epsilon/16.$$

Combining this bound with the tail bounds for various Gaussian polynomials (95a), (95d), (95e) from Lemma 14, and substituting in inequality (116), we obtain that

$$\left|\sum_{i=1}^n d_{x,i}^2 s_{x,i}^2 \frac{1}{2} h^\top \nabla^2 \varphi_{y,i} h\right| \leq \frac{r^4}{\kappa^{6.5} d^3}\left[4 \cdot \chi_4 \sqrt{1680} d + 10\left(\chi_2 \sqrt{24} d \cdot \chi_6 \sqrt{15120} d\right)^{1/2} + 100 \cdot \chi_2 \sqrt{24} d \cdot \left(256 \cdot \log n \cdot \log(32/\epsilon) + \left(\chi_4 \sqrt{1680} d\right)^{1/2}\right)\right]$$

with probability at least $1-\epsilon/2$. In the above expression, the terms χ_i are a function of ϵ as defined in Lemma 14. In particular, $\chi_i = \chi_{i,\epsilon} = (2e/i \cdot \log(16/\epsilon))^{i/2}$ for $i \in \{2,3,4,6\}$. Observing that $256 \log(32/\epsilon) \geq \left(\chi_4 \sqrt{1680}\right)^{1/2}$, and that our choice of r satisfies

$$r^2 \leq \min\left\{\frac{\epsilon}{8\sqrt{1680}\chi_4}, \frac{\epsilon}{40\left(\chi_2\chi_6\sqrt{24}\sqrt{15120}\right)^{1/2}}, \frac{\epsilon}{204800\chi_2\sqrt{24}\log(32/\epsilon)}\right\}, \tag{117}$$

we obtain

$$\left|\sum_{i=1}^n d_{x,i}^2 s_{x,i}^2 \frac{1}{2} h^\top \nabla^2 \varphi_{y,i} h\right| \leq \frac{r^2}{\kappa^4 d^{3/2}}\left[\frac{\epsilon}{2} + \frac{\epsilon}{4} + \frac{\epsilon}{8}\left(\frac{\log n}{\sqrt{d}} + 1\right)\right].$$

Asserting the additional condition $\sqrt{d} \geq \log n$, yields the claim.

It is now left to prove the bounds (115a) and (115b). We prove these bounds separately.

Bounding C_2: Applying Cauchy-Schwarz inequality, we have

$$\left|\sum_{i=1}^n \zeta_{y,i} d_{y,i}^3 f_{y,i}\right| \leq \left(\sum_{i=1}^n \zeta_{y,i} f_{y,i}^2 \cdot \sum_{i=1}^n \zeta_{y,i} d_{y,i}^6\right)^{1/2}$$

Using the bound (108), we obtain

$$\sum_{i=1}^n \zeta_{y,i} f_{y,i}^2 \leq 4\kappa^2 \sum_{i=1}^n \zeta_{y,i} d_{y,i}^2 = 4\kappa^2 \sum_{i=1}^n \zeta_{x,i} d_{x,i}^2 \frac{\zeta_{y,i}}{\zeta_{x,i}} \frac{d_{y,i}^2}{d_{x,i}^2}.$$

Substituting $h = z - x$ where z is given by relation (82), we obtain that $d_{x,i} = \frac{r}{d^{3/4}\kappa} \hat{a}_{x,i}^\top \xi$, and thereby

$$\sum_{i=1}^n \zeta_{y,i} f_{y,i}^2 \leq 4\kappa^2 \frac{r^2}{d^{3/2}\kappa^4} \sum_{i=1}^n \zeta_{x,i} (\hat{a}_{x,i}^\top \xi)^2 \frac{\zeta_{y,i}}{\zeta_{x,i}} \frac{d_{y,i}^2}{d_{x,i}^2}.$$

Doing similar algebra, we obtain $\sum_{i=1}^n \zeta_{y,i} d_{y,i}^6 = \frac{r^6}{d^{9/2}\kappa^{12}} \sum_{i=1}^n \zeta_{x,i} \left(\hat{a}_{x,i}^\top \xi\right)^6 \frac{\zeta_{y,i}}{\zeta_{x,i}} \frac{d_{y,i}^6}{d_{x,i}^6}$. Putting the pieces together yields the claim.

Bounding C_3: Recall that $\rho_y = (G_y - \alpha\Lambda_y)\ell_y$ (Lemma 9) and $\mu_y = (G_y - \alpha\Lambda_y)^{-1} G_y$ (Lemma 11). We have

$$\left|\sum_{i=1}^n \zeta_{y,i} d_{y,i}^2 \ell_{y,i}\right| = \mathbf{1} D_y^2 G_y \ell_y = \underbrace{\mathbf{1} D_y^2 G_y (G_y - \alpha\Lambda_y)^{-1}}_{=: v_y^\top} \underbrace{(G_y - \alpha\Lambda_y)\ell_y}_{\rho_y}.$$

Using the definition of v_y and μ_y, we obtain

$$v_{y,i} := e_i^\top v_y = e_i^\top (G_y - \alpha\Lambda_y)^{-1} G_y D_y^2 \mathbf{1} = e_i^\top \mu_y D_y^2 \mathbf{1} = \mu_{y,i,i} d_{y,i}^2 + \sum_{j \in [n], j \neq i} \mu_{y,i,j} d_{y,j}^2.$$

Consequently, we have

$$\left|\sum_{i=1}^n v_{y,i} \rho_{y,i}\right| \leq \overbrace{\sum_{i=1}^n |\rho_{y,i}| \cdot \left|\mu_{y,i,i} d_{y,i}^2\right|}^{=:C_4} + \overbrace{\sum_{i=1}^n |\rho_{y,i}| \cdot \left(\sum_{j \in [n], j \neq i} \left|\mu_{y,i,j} d_{y,j}^2\right|\right)}^{=:C_5}$$

From Lemma 11, we have that $\mu_{y,i,i} \in [0, \kappa]$. Hence, we have $C_4 \leq \|\rho_y\|_1 \cdot \kappa \cdot \max_{i \in [n]} d_{y,i}^2$. To bound C_5, we note that

$$\sum_{j \in [n], j \neq i} \left|\mu_{y,i,j} d_{y,j}^2\right| \overset{(i)}{\leq} \left(\sum_{j \in [n], j \neq i} \frac{\mu_{y,i,j}^2}{\zeta_{y,j}} \cdot \sum_{j=1}^n \zeta_{y,j} d_{y,j}^4\right)^{1/2} \overset{(ii)}{\leq} \left(\kappa^3 \cdot \sum_{j=1}^n \zeta_{x,j} d_{x,j}^4 \frac{\zeta_{y,j}}{\zeta_{x,j}} \frac{d_{y,j}^4}{d_{x,j}^4}\right)^{1/2},$$

where step (i) follows from Cauchy-Schwarz inequality and step (ii) from Lemma 11. Putting the pieces together, we obtain that

$$\left|\sum_{i=1}^n \zeta_{y,i} d_{y,i}^2 \ell_{y,i}\right| \leq \|\rho_y\|_1 \cdot \left[\kappa \cdot \max_{i \in [n]} d_{y,i}^2 + \kappa^{3/2} \left(\sum_{j=1}^n \zeta_{x,j} d_{x,j}^4 \frac{\zeta_{y,j}}{\zeta_{x,j}} \frac{d_{y,j}^4}{d_{x,j}^4}\right)^{1/2}\right].$$

Using the bound on $\|\rho_y\|_1$ from Lemma 9, we have

$$\left|\sum_{i=1}^n \zeta_{y,i} d_{y,i}^2 \ell_{y,i}\right| \leq \left(56\kappa^2 \sum_{i=1}^n \zeta_{y,i} d_{y,i}^2\right) \cdot \left[\kappa \cdot \max_{i \in [n]} d_{y,i}^2 + \kappa^{3/2} \left(\sum_{j=1}^n \zeta_{x,j} d_{x,j}^4 \frac{\zeta_{y,j}}{\zeta_{x,j}} \frac{d_{y,j}^4}{d_{x,j}^4}\right)^{1/2}\right].$$

Substituting the expression for $d_{x,i} = \frac{r}{\kappa^2 d^{3/4}} \left(\hat{a}_{x,i}^\top \xi\right)$ yields the claim.

Appendix H. Proofs of Lemmas from Section E.1

In this section we collect proofs of lemmas from Section E.1. Each lemma is proved in a different subsection.

H.1 Proof of Lemma 9

Up to second order terms, we have

$$\frac{1}{s_{x+h,i}^2} = \frac{1}{s_{x,i}^2}\left[1 + \frac{2a_i^\top h}{s_{x,i}} + \frac{3(a_i^\top h)^2}{s_{x,i}^2}\right] + \mathcal{O}\left(\|h\|_2^3\right), \tag{118a}$$

$$\zeta_{y+h,i} = \zeta_{y,i} + h^\top \nabla \zeta_{y,i} + \frac{1}{2} h^\top \nabla^2 \zeta_{y,i} h + \mathcal{O}\left(\|h\|_2^3\right), \tag{118b}$$

$$\zeta_{y+h,i}^\alpha = \zeta_{y,i}^\alpha + \alpha \zeta_{y,i}^{\alpha-1}\left(h^\top \nabla \zeta_{y,i} + \frac{1}{2} h^\top \nabla^2 \zeta_{y,i} h\right) + \frac{\alpha(\alpha-1)}{2}\zeta_{y,i}^{\alpha-2}\left(h^\top \nabla \zeta_{y,i}\right)^2 + \mathcal{O}\left(\|h\|_2^3\right), \tag{118c}$$

Further, let

$$\tilde{J}_y := A_y^\top G_y^\alpha A_y = \sum_{i=1}^n \zeta_{y,i}^\alpha \frac{a_i a_i^\top}{s_{y,i}^2}. \tag{118d}$$

Using equations (118a) and (118c), and substituting $d_{y,i} = a_i^\top h / s_{y,i}$, $f_{y,i} = h^\top \nabla \zeta_{y,i}/\zeta_{y,i}$ and $\ell_{y,i} = \frac{1}{2} h^\top \nabla^2 \zeta_{y,i} h / \zeta_{y,i}$, we find that

$$\tilde{J}_{y+h} = \sum_{i=1}^n \left[1 + \alpha f_{y,i} + \alpha \ell_{y,i} + \frac{\alpha(\alpha-1)}{2} f_{y,i}^2\right]\left[1 + 2d_{y,i} + 3d_{y,i}^2\right]\zeta_{y,i}^\alpha \frac{a_i a_i^\top}{s_{y,i}^2} + \mathcal{O}\left(\|h\|_2^3\right).$$

Note that $d_{y,i}$ and $f_{y,i}$ are first order terms in $\|h\|_2$ and $\ell_{y,i}$ is a second order term in $\|h\|_2$.

Thus we obtain

$$\tilde{J}_{y+h} - \tilde{J}_y = \underbrace{\sum_{i=1}^n (2d_{y,i} + \alpha f_{y,i})\,\zeta_{y,i}^\alpha \frac{a_i a_i^\top}{s_{y,i}^2}}_{=:\Delta_{y,h}^{(1)}} + \underbrace{\sum_{i=1}^n \left[3d_{y,i}^2 + 2\alpha d_{y,i} f_{y,i} + \alpha \ell_{y,i} + \frac{\alpha(\alpha-1)}{2} f_{y,i}^2\right]\zeta_{y,i}^\alpha \frac{a_i a_i^\top}{s_{y,i}^2}}_{=:\Delta_{y,h}^{(2)}} + \mathcal{O}\left(\|h\|_2^3\right).$$

Let $\Delta_{y,h} := \Delta_{y,h}^{(1)} + \Delta_{y,h}^{(2)}$. Note that $\Delta_{y,h}^{(i)}$ denotes the i-th order term in $\|h\|_2$. Finally, the following expansion also comes in handy for our derivations:

$$a_i^T \tilde{J}_{y+h}^{-1} a_i = a_i^\top \tilde{J}_y^{-1} a_i - a_i^\top \tilde{J}_y^{-1} \Delta_{y,h} \tilde{J}_y^{-1} a_i + a_i^\top \tilde{J}_y^{-1} \Delta_{y,h} \tilde{J}_y^{-1} \Delta_{y,h} \tilde{J}_y^{-1} a_i + \mathcal{O}\left(\|h\|_2^3\right). \tag{118e}$$

H.1.1 Proof of part (a): Gradient of weights

The expression for the gradient $\nabla \zeta_{y,i}$ is derived in Lemma 14 of the paper (Lee and Sidford, 2014) and is thereby omitted.

H.1.2 Proof of part (b): Hessian of weights

We claim that

$$\begin{aligned}\rho_y = \left(\mathbb{I} - \alpha \Lambda_y G_y^{-1}\right)\begin{bmatrix} \frac{1}{2} h^\top \nabla^2 \zeta_{y,1} h \\ \cdots \\ \frac{1}{2} h^\top \nabla^2 \zeta_{y,m} h \end{bmatrix} &= (2D_y + \alpha F_y)\Upsilon_y^{(2)}(2D_y + \alpha F_y)\mathbf{1} \\ &+ \left(\Sigma_y - \Upsilon_y^{(2)}\right)\left[2\alpha D_y F_y + 3D_y^2 + \tau_\alpha F_y^2\right]\mathbf{1} \\ &+ \operatorname{diag}\left(\Upsilon_y (2D_y + \alpha F_y)\Upsilon_y (2D_y + \alpha F_y)\Upsilon_y\right),\end{aligned} \tag{119}$$

where we have used $\operatorname{diag}(B)$ to denote the diagonal vector $(B_{1,1}, \ldots, B_{n,n})$ of the matrix B. Deferring the proof of this expression for the moment, we now derive a bound on the ℓ_1 norm of ρ_y. Expanding the i-th term of $\rho_{y,i}$ from equation (119), we obtain

$$\begin{aligned}\rho_{y,i} = (2d_{y,i} + \alpha f_{y,i})\sum_{j=1}^n (2d_{y,j} + \alpha f_{y,j})\Upsilon_{y,i,j}^2 + \left[2\alpha d_{y,i} f_{y,i} + 3d_{y,i}^2 + \tau_\alpha f_{y,i}^2\right]\sigma_{y,i} \\ - \sum_{j=1}^n \left[2\alpha d_{y,j} f_{y,j} + 3d_{y,j}^2 + \tau_\alpha f_{y,j}^2\right]\Upsilon_{y,i,j}^2 + \sum_{j,l=1}^n (2d_{y,j} + \alpha f_{y,j})(2d_{y,l} + \alpha f_{y,l})\Upsilon_{y,i,j}\Upsilon_{y,j,l}\Upsilon_{y,l,i}.\end{aligned}$$

Recall that $\alpha = 1 - 1/\log_2(2n/d)$. Since $n \geq d$ for polytopes, we have $\alpha \in [0,1]$ and consequently $|\tau_\alpha| = |\alpha(\alpha-1)/2| \in [0,1]$. Further note that Υ_x is an orthogonal projection matrix, and hence we have

$$\operatorname{diag}(\Upsilon_x e_i)\Upsilon_x \operatorname{diag}(\Upsilon_x e_i) \preceq \operatorname{diag}(\Upsilon_x e_i)\operatorname{diag}(\Upsilon_x e_i).$$

Combining these observations with the AM-GM inequality, we have

$$|\rho_{y,i}| \leq 7\sigma_{y,i} d_{y,i}^2 + 3\sigma_{y,i} f_{y,i}^2 + \sum_{j=1}^n \left(13 d_{y,j}^2 + 6 f_{y,j}^2\right)\Upsilon_{y,i,j}^2.$$

Summing both sides over the index i, we find that

$$\sum_{i=1}^n |\rho_{y,i}| \overset{(i)}{\leq} \sum_{i=1}^n 20\sigma_{y,i} d_{y,i}^2 + 9\sigma_{y,i} f_{y,i}^2 \overset{(ii)}{\leq} \sum_{i=1}^n 20\zeta_{y,i} d_{y,i}^2 + 9\zeta_{y,i} f_{y,i}^2 \overset{(iii)}{\leq} 56\kappa^2 \sum_{i=1}^n \zeta_{y,i} d_{y,i}^2,$$

where step (i) follows from Lemma 7 (a), step (ii) from Lemma 3 (a) and step (iii) from the bound (108).

We now return to the proof of expression (119). Using equation (87c), we find that

$$\frac{1}{2} h^\top \nabla^2 \zeta_{y,i} h = \frac{1}{2} h^\top \nabla^2 \sigma_{y,i} h \quad \text{for all } i \in [n]. \tag{120}$$

Next, we derive the Taylor series expansion of $\sigma_{y,i}$. Using the definition of $\tilde{J}_x$ (118d) in equation (72), we find that $\sigma_{y,i} = \zeta_{y,i}^\alpha \frac{a_i^\top \tilde{J}_y^{-1} a_i}{s_{y,i}^2}$. To compute the difference $\sigma_{y+h,i} - \sigma_{y,i}$, we

use the expansions (118a), (118c) and (118e). Letting $\tau_\alpha = \alpha(\alpha-1)/2$, we have

$$\begin{aligned}
\sigma_{y+h,i} &= \zeta^\alpha_{y+h,i}\frac{a_i^\top \tilde{J}^{-1}_{y+h}a_i}{s^2_{y+h,i}} \\
&= \zeta^\alpha_{y,i}\frac{a_i^\top \tilde{J}^{-1}_{y+h}a_i}{s^2_{y,i}}\left[1+\alpha f_{y,i}+\alpha\ell_{y,i}+\tau_\alpha f_{y,i}^2\right]\left[1+2d_{y,i}+3d_{y,i}^2\right]+\mathcal{O}\left(\|h\|_2^3\right) \\
&= \sigma_{y,i}+(2d_{y,i}+\alpha f_{y,i})\sigma_{y,i}-\sum_{j=1}^n(2d_{y,j}+\alpha f_{y,j})\Upsilon^2_{y,i,j}+(2d_{y,i}+\alpha f_{y,i})\sum_{j=1}^n(2d_{y,j}+\alpha f_{y,j})\Upsilon^2_{y,i,j} \\
&\quad+2\alpha d_{y,i}f_{y,i}\sigma_{y,i}+\left[\alpha\ell_{y,i}+\tau_\alpha f_{y,i}^2+3d_{y,i}^2\right]\sigma_{y,i}-\sum_{j=1}^n\left[3d_{y,j}^2+2\alpha d_{y,j}f_{y,j}+\alpha\ell_{y,j}+\tau_\alpha f_{y,j}^2\right]\Upsilon^2_{y,i,j} \\
&\quad+\sum_{j,l=1}^n(2d_{y,j}+\alpha f_{y,j})(2d_{y,l}+\alpha f_{y,l})\Upsilon_{y,i,j}\Upsilon_{y,j,l}\Upsilon_{y,l,i}+\mathcal{O}\left(\|h\|_2^3\right).
\end{aligned}$$

We identify the second order (in $\mathcal{O}\left(\|h\|_2^2\right)$) terms in the previous expression. Using the equation (120), these are indeed the terms that correspond to the terms $\frac{1}{2}h^\top\nabla^2\zeta_{y,i}h$, $i\in[n]$. Substituting $\ell_{y,i}=\frac{1}{2}h^\top\nabla^2\zeta_{y,i}h/\zeta_{y,i}$, we have

$$\begin{aligned}
&\frac{1}{2}h^\top\nabla^2\zeta_{y,i}h \\
&=(2d_{y,i}+\alpha f_{y,i})\sum_{j=1}^n(2d_{y,j}+\alpha f_{y,j})\Upsilon^2_{y,i,j}+2\alpha d_{y,i}f_{y,i}\sigma_{y,i}+\left[\frac{\alpha}{2}\frac{h^\top\nabla^2\zeta_{y,i}h}{\zeta_{y,i}}+\tau_\alpha f_{y,i}^2+3d_{y,i}^2\right]\sigma_{y,i} \\
&-\sum_{j=1}^n\left[3d_{y,j}^2+2\alpha d_{y,j}f_{y,j}+\frac{\alpha}{2}\frac{h^\top\nabla^2\zeta_{y,j}h}{\zeta_{y,j}}+\tau_\alpha f_{y,j}^2\right]\Upsilon^2_{y,i,j}+\sum_{j,l=1}^n(2d_{y,j}+\alpha f_{y,j})(2d_{y,l}+\alpha f_{y,l})\Upsilon_{y,i,j}\Upsilon_{y,j,l}\Upsilon_{y,l,i}.
\end{aligned}$$

Collecting the different terms and doing some algebra yields the result (119).

H.1.3 Proof of part (c): Gradient of logdet

For a unit vector $h\in\mathbb{R}^d$, we have

$$h^\top\log\det J_y=\lim_{\delta\to0}\frac{1}{\delta}(\log\det J_{y+\delta h}-\log\det J_y)=\lim_{\delta\to0}\frac{1}{\delta}(\log\det J_y^{-1/2}J_{y+\delta h}J_y^{-1/2}-\log\det\mathbb{I}_d)$$

Let $\hat{a}_{y,i}:=J_{y,i}^{-1/2}a_i/s_{y,i}$ for each $i\in[n]$. Using the property $\log\det B=\operatorname{trace}\log B$, where $\log B$ denotes the logarithm of the matrix and that $\log\det\mathbb{I}_d=0$, we obtain

$$h^\top\log\det J_y=\lim_{\delta\to0}\frac{1}{\delta}\left[\operatorname{trace}\log\left(\sum_{i=1}^n\frac{\zeta_{y+\delta h}}{(1-\delta a_i^\top h/s_{y,i})}\hat{a}_{y,i}\hat{a}_{y,i}^\top\right)\right],$$

where we have substituted $s_{y+\delta h,i}=s_{y,i}-\delta a_i^\top h$. Keeping track of first order terms in δ, and noting that $\sum_{i=1}^n\zeta_{y,i}\hat{a}_{y,i}\hat{a}_{y,i}^\top=\mathbb{I}_d$, we find that

$$\begin{aligned}
\operatorname{trace}\log\left(\sum_{i=1}^n\frac{\zeta_{y+\delta h,i}}{(1-\delta a_i^\top h/s_{y,i})}\hat{a}_{y,i}\hat{a}_{y,i}^\top\right)&=\operatorname{trace}\log\left[\sum_{i=1}^n\left(\zeta_{y,i}+\delta h^\top\nabla\zeta_{y,i}\right)\left(1+\frac{2\delta a_i^\top h}{s_{y,i}}\right)\hat{a}_{y,i}\hat{a}_{y,i}^\top\right]+\mathcal{O}\left(\delta^2\right) \\
&=\operatorname{trace}\left[\sum_{i=1}^n\delta\left(\frac{2a_i^\top h}{s_{y,i}}+h^\top\nabla\zeta_{y,i}\right)\hat{a}_{y,i}\hat{a}_{y,i}^\top\right]+\mathcal{O}\left(\delta^2\right) \\
&=\sum_{i=1}^n\delta\left(\frac{2a_i^\top h}{s_{y,i}}+h^\top\nabla\zeta_{y,i}\right)\theta_{y,i}+\mathcal{O}\left(\delta^2\right)
\end{aligned}$$

where in the last step we have used the fact that $\operatorname{trace}(\hat{a}_{y,i}\hat{a}_{y,i}^\top)=\hat{a}_{y,i}^\top\hat{a}_{y,i}=\theta_{y,i}$ for each $i\in[n]$. Substituting the expression for $\nabla\zeta_y$ from part (a), and rearranging the terms yields the claimed expression in the limit $\delta\to0$.

H.1.4 Proof of part (d): Gradient of φ

Using the chain rule and the fact that $\nabla s_{y,i}=-a_i$, yields the result.

H.1.5 Proof of part (e)

We claim that

$$\frac{1}{2}h^\top\nabla^2\Psi_y h=\frac{1}{2}\left[\sum_{i=1}^n\zeta_{y,i}\theta_{y,i}(3d_{y,i}^2+2d_{y,i}f_{y,i}+\ell_{y,i})-\frac{1}{2}\sum_{i,j=1}^n\zeta_{y,i}\zeta_{y,j}\theta_{y,i,j}^2\left(2d_{y,i}+f_{y,i}\right)\left(2d_{y,j}+f_{y,j}\right)\right].$$

The desired bound on $\left|h^\top\nabla^2\Psi_y h\right|/2$ now follows from an application of AM-GM inequality with Lemma 7(d).

We now derive the claimed expression for the directional Hessian of the function Ψ. We have

$$\begin{aligned}
&\frac{1}{2}h^\top\left(\nabla^2\log\det J_y\right)h=\lim_{\delta\to0}\frac{1}{2\delta^2}(\log\det J_y^{-1/2}J_{y+\delta h}J_y^{-1/2}+\log\det J_y^{-1/2}J_{y-\delta h}J_y^{-1/2}-2\log\det\mathbb{I}_d) \\
&=\frac{1}{2}\lim_{\delta\to0}\frac{1}{\delta^2}\left[\operatorname{trace}\log\left(\sum_{i=1}^n\frac{\zeta_{y+\delta h}}{(1-\delta a_i^\top h/s_{y,i})}\hat{a}_{y,i}\hat{a}_{y,i}^\top\right)+\operatorname{trace}\log\left(\sum_{i=1}^n\frac{\zeta_{y-\delta h}}{(1+\delta a_i^\top h/s_{y,i})}\hat{a}_{y,i}\hat{a}_{y,i}^\top\right)\right].
\end{aligned}$$

Expanding the first term in the above expression, we find that

$$\begin{aligned}
&\operatorname{trace}\log\left(\sum_{i=1}^n\frac{\zeta_{y+\delta h,i}}{(1-\delta a_i^\top h/s_{y,i})}\hat{a}_{y,i}\hat{a}_{y,i}^\top\right) \\
&=\operatorname{trace}\log\underbrace{\left[\sum_{i=1}^n\left(\zeta_{y,i}+\delta h^\top\nabla\zeta_{y,i}+\frac{\delta^2}{2}h^\top\nabla^2\zeta_{y,i}h\right)\left(1+2\delta\frac{a_i^\top h}{s_{y,i}}+3\delta^2\frac{(a_i^\top h)^2}{s_{y,i}^2}\right)\hat{a}_{y,i}\hat{a}_{y,i}^\top\right]}_{=:\mathbb{I}_d+B}+\mathcal{O}\left(\delta^3\right).
\end{aligned}$$

Substituting the shorthand notation from equations (88a), (88b) and (88c), we have

$$B = \sum_{i=1}^{n} \zeta_{y,i} \left[\delta(2d_{y,i} + f_{y,i}) + \delta^2(3d_{y,i}^2 + 2d_{y,i}f_{y,i} + \ell_{y,i})\right] \hat{a}_{y,i}\hat{a}_{y,i}^\top + \mathcal{O}\left(\delta^3\right).$$

Now we make use of the following facts (1) $\operatorname{trace}\log(\mathbb{I}_d + B) = \operatorname{trace}\left[B - \frac{B^2}{2} + \mathcal{O}\left(\|B\|^3\right)\right]$, (2) for each $i, j \in [n]$, we have $\operatorname{trace}(\hat{a}_{y,i}\hat{a}_j^\top) = \hat{a}_{y,i}^\top \hat{a}_j = \theta_{y,i,j}$, and (3) for each $i \in [n]$, we have $\theta_{y,i,i} = \theta_{y,i}$. Thus we obtain

$$\begin{aligned}\operatorname{trace}\log\left(\sum_{i=1}^{n} \frac{\zeta_{y+\delta h,i}}{(1-\delta a_i^\top h/s_{y,i})}\hat{a}_{y,i}\hat{a}_{y,i}^\top\right) &= \sum_{i=1}^{n} \zeta_{y,i}\theta_{y,i}\left[\delta(2d_{y,i} + f_{y,i}) + \delta^2(3d_{y,i}^2 + 2d_{y,i}f_{y,i} + \ell_{y,i})\right] \\ &\quad - \frac{1}{2}\sum_{i,j=1}^{n} \zeta_{y,i}\zeta_{y,j}\theta_{y,i,j}^2\delta^2(2d_{y,i} + f_{y,i})(2d_{y,j} + f_{y,j}) + \mathcal{O}\left(\delta^3\right).\end{aligned}$$

Similarly, we can obtain an expression for $\operatorname{trace}\log\left(\sum_{i=1}^{n} \frac{\zeta_{y-\delta h}}{(1+\delta a_i^\top h/s_{y,i})}\hat{a}_{y,i}\hat{a}_{y,i}^\top\right)$. Putting the pieces together, we obtain

$$\frac{1}{2}h^\top\left(\nabla^2 \log\det J_y\right)h = \sum_{i=1}^{n} \zeta_{y,i}\theta_{y,i}(3d_{y,i}^2 + 2d_{y,i}f_{y,i} + \ell_{y,i}) - \frac{1}{2}\sum_{i,j=1}^{n} \zeta_{y,i}\zeta_{y,j}\theta_{y,i,j}^2(2d_{y,i} + f_{y,i})(2d_{y,j} + f_{y,j}). \tag{121}$$

H.1.6 Proof of part (f)

We claim that

$$\frac{1}{2}h^\top\nabla^2\varphi_{y,i}h = \varphi_{y,i}\left(2d_{y,i}f_{y,i} + 3d_{y,i}^2 + \ell_{y,i}\right). \tag{122}$$

The claim follows from a straightforward application of chain rule and substitution of the expressions for $\nabla\zeta_{y,i}$ and $\nabla^2\zeta_{y,i}$ in terms of the shorthand notation $d_{y,i}, f_{y,i}$ and $\ell_{y,i}$. Multiplying both sides of equation (122) with $d_{y,i}^2 s_{y,i}^2$ and summing over index i, we find that

$$\begin{aligned}\sum_{i=1}^{n} d_{y,i}^2 s_{y,i}^2 \frac{1}{2}h^\top\nabla\varphi_{y,i}^2 h = \sum_{i=1}^{n} d_{y,i}^2 s_{y,i}^2\varphi_{y,i}\left[\ell_{y,i} + 2d_{y,i}f_{y,i} + 3d_{y,i}^2\right] &= \sum_{i=1}^{n} d_{y,i}^2\zeta_{y,i}\left[\ell_{y,i} + 2d_{y,i}f_{y,i} + 3d_{y,i}^2\right] \\ &\le \sum_{i=1}^{n} d_{y,i}^2\zeta_{y,i}\left[\ell_{y,i} + f_{y,i}^2 + 4d_{y,i}^2\right],\end{aligned}$$

where in the last step we have used the AM-GM inequality. The claim follows.

H.2 Proof of Lemma 10

We claim that

$$0 \preceq G_y^{-1/2}\left(c_1\mathbb{I}_n + c_2\Lambda_y\left(G_y - \alpha\Lambda_y\right)^{-1}\right)G_y^{1/2} \preceq (c_1 + c_2)\,\kappa\mathbb{I}_n. \tag{123}$$

The proof of the lemma is immediate from this claim, as for any PSD matrix $H \le c\mathbb{I}_n$, we have $H^2 \le c^2\mathbb{I}_n$.

We now prove claim (123). Note that

$$G_y^{-1/2}\Lambda_y\left(G_y - \alpha\Lambda_y\right)^{-1}G_y^{1/2} = \underbrace{G_y^{-1/2}\Lambda_y G_y^{-1/2}}_{:=B_y}(\mathbb{I}_n - \alpha_\jmath G_y^{-1/2}\Lambda_y G_y^{-1/2})^{-1}. \tag{124}$$

Note that the RHS is equal to the matrix $B_y(\mathbb{I}_n - \alpha_\jmath B_y)^{-1}$ which is symmetric. Observe the following ordering of the matrices in the PSD cone

$$\Sigma_y + \beta_\jmath\mathbb{I}_n = G_y \succeq \Sigma_y \succeq \Lambda_y = \Sigma_y - \Upsilon_y^{(2)} \succeq 0.$$

For the last step we have used the fact that $\Sigma_y - \Upsilon_y^{(2)}$ is a diagonally dominant matrix with non negative entries on the diagonal to conclude that it is a PSD matrix. Consequently, we have

$$B_y = G_y^{-1/2}\Lambda_y G_y^{-1/2} \preceq \mathbb{I}_n. \tag{125}$$

Further, recall that $\alpha_\jmath = (1 - 1/\kappa) \Leftrightarrow \kappa = (1 - \alpha_\jmath)^{-1}$. As s result, we obtain

$$0 \preceq (\mathbb{I}_n - \alpha_\jmath G_y^{-1/2}\Lambda_y G_y^{-1/2})^{-1} \preceq \kappa\mathbb{I}_n.$$

Multiplying both sides by $B_y^{1/2}$ and using the relation (125), we obtain

$$0 \preceq B_y^{1/2}(\mathbb{I}_n - \alpha_\jmath G_y^{-1/2}\Lambda_y G_y^{-1/2})^{-1}B_y^{1/2} \preceq \kappa\mathbb{I}_n. \tag{126}$$

Using the fact that B_y commutes with $(\mathbb{I}_n - B_y)^{-1}$, we obtain $B_y(\mathbb{I}_n - \alpha_\jmath B_y)^{-1} \preceq \kappa\mathbb{I}_n$. Using observation (124) now completes the proof.

H.3 Proof of Lemma 11

Without loss of generality, we can first prove the result for $i = 1$. Let $\nu := \mu_y^\top e_1$ denote the first row of the matrix μ_y. Observe that

$$e_1 = \left(G_y - \alpha\Lambda_y\right)G_y^{-1}\nu = \nu - \alpha\Sigma_y G_y^{-1}\nu + \alpha\Upsilon_y^{(2)}G_y^{-1}\nu \tag{127}$$

We now prove bounds (92a) and (92b) separately.

Proof of bound (92a)**:** Multiplying the equation (127) on the left by $\nu^\top G_y^{-1}$, we obtain

$$\begin{aligned}g_1^{-1}\nu_1 &= \nu^\top G_y^{-1}\nu - \alpha\nu^\top G_y^{-1}\Sigma_y G_y^{-1}\nu + \alpha\nu^\top G_y^{-1}\Upsilon_y^{(2)}G_y^{-1}\nu \\ &\ge \nu^\top G_y^{-1}\nu - \alpha\nu^\top G_y^{-1}\Sigma_y G_y^{-1}\nu \\ &\ge \left(g_1^{-1} - \alpha\sigma_{y,1}/g_1^2\right)\nu_1^2.\end{aligned} \tag{128}$$

Rearranging terms, we obtain

$$0 \le \nu_1 \le \frac{\zeta_{y,1}}{\zeta_{y,1} - \alpha\sigma_{y,1}} \overset{(i)}{\le} \kappa, \tag{129}$$

where inequality (i) follows from the facts that $\zeta_{y,j} \ge \sigma_{y,j}$ and $(1 - \alpha) = \kappa$.

Proof of bound (92b)**:** In our proof, we use the following improved lower bound for the term $\mu_{y,1,1} = \nu_1$.

$$\nu_1 \geq \frac{\zeta_{y,1}}{\zeta_{y,1} - \alpha\sigma_{y,1} + \alpha\sigma_{y,1}^2}, \tag{130}$$

Deferring the proof of this claim at the moment, we now complete the proof.

We begin by deriving a weighted ℓ_2-norm bound for the vector $\tilde{\nu} = (\nu_2, \ldots, \nu_n)^\top$. Equation (128) implies

$$\zeta_{y,1}^{-1}\nu_1\left(1 - \nu_1 + \alpha\frac{\sigma_{y,1}}{\zeta_{y,1}}\nu_1\right) \geq \sum_{j=2}^n \nu_j^2\left(\zeta_{y,j}^{-1} - \alpha\zeta_{y,j}^{-2}\sigma_{y,j}\right) \overset{(i)}{\geq} (1-\alpha)\sum_{j=2}^n \frac{\nu_j^2}{\zeta_{y,j}},$$

where step (i) follows from the fact that $\zeta_{y,i} \geq \sigma_{y,i}$. Now, we upper bound the expression on the left hand side of the above inequality using the upper (129) and lower (130) bounds on ν_1:

$$\begin{aligned}
\zeta_{y,1}^{-1}\nu_1\left(1 - \nu_1 + \alpha\frac{\sigma_{y,1}}{\zeta_{y,1}}\nu_1\right) &\leq \zeta_{y,1}^{-1}\frac{\zeta_{y,1}}{\zeta_{y,1} - \alpha\sigma_{y,1}}\left(1 - \left(1 - \alpha\frac{\sigma_{y,1}}{\zeta_{y,1}}\right)\frac{\zeta_{y,1}}{\zeta_{y,1} - \alpha\sigma_{y,1} + \alpha\sigma_{y,1}^2}\right) \\
&= \frac{\alpha\sigma_{y,1}^2}{(\zeta_{y,1} - \alpha\sigma_{y,1})\left(\zeta_{y,1} - \alpha\sigma_{y,1} + \alpha\sigma_{y,1}^2\right)} \\
&\leq \kappa^2,
\end{aligned}$$

where in the last step we have used the facts that $\zeta_{y,1} \geq \sigma_{y,1}$ and $(1-\alpha)^{-1} = \kappa$. Putting the pieces together, we obtain $\sum_{j=2}^n \nu_j^2\zeta_{y,j}^{-1} \leq \kappa^3$, which is equivalent to our claim (92b) for $i = 1$.

It remains to prove our earlier claim (130). Writing equation (127) separately for the first coordinate and for the rest of the coordinates, we obtain

$$1 = \left(1 - \alpha\sigma_{y,1}\zeta_{y,1}^{-1} + \alpha\sigma_{y,1,1}^2\zeta_{y,j}^{-1}\right)\nu_1 + \alpha\sum_{j=2}^n \sigma_{y,1,j}^2\zeta_{y,j}^{-1}\nu_j, \quad \text{and} \tag{131a}$$

$$0 = \left(\mathbb{I}_{n-1} - \alpha\Sigma_y' G_y'^{-1}\right)\begin{pmatrix}\nu_2\\ \vdots \\ \nu_n\end{pmatrix} + \alpha\Upsilon_y'^{(2)}G_y'^{-1}\begin{pmatrix}\nu_2\\ \vdots \\ \nu_n\end{pmatrix} + \alpha\zeta_{y,1}^{-1}\nu_1\begin{pmatrix}\sigma_{y,1,2}^2\\ \vdots \\ \sigma_{y,1,n}^2\end{pmatrix}, \tag{131b}$$

where G_y' (respectively Σ_y', $\Upsilon_y'^{(2)}$) denotes the principal minor of G_y (respectively Σ_y, $\Upsilon_y^{(2)}$) obtained by excluding the first column and the first row. Multiplying both sides of the equation (131b) from the left by $\left(\nu_2, \cdots, \nu_n\right) G_y'^{-1}$, we obtain

$$0 = \sum_{j=2}^n \underbrace{\frac{1}{\zeta_{y,j}}\left(1 - \frac{\alpha\sigma_{y,j}}{\zeta_{y,j}}\right)\nu_j^2}_{c_{y,j}} + \underbrace{\alpha\left(\nu_2, \cdots, \nu_n\right) G_y'^{-1}\Upsilon_y'^{(2)}G_y'^{-1}\begin{pmatrix}\nu_2\\ \vdots \\ \nu_n\end{pmatrix}}_{C_{y.2}} + \alpha\frac{\nu_1}{\zeta_{y,1}}\sum_{j=2}^n \frac{\sigma_{y,j}^2}{\zeta_{y,j}}\nu_j. \tag{132}$$

Observing that $\alpha \in [0,1]$ and $\zeta_{y,j} \geq \sigma_{y,j}$ for all $y \in \operatorname{int}(\mathcal{K})$ and $j \in [n]$, we obtain $c_{y,j} \geq 0$. Further, note that $G_y'^{-1}\Upsilon_y'^{(2)}G_y'^{-1}$ is a PSD matrix and hence we have that $C_{y,2} \geq 0$. Putting the pieces together, we have

$$\alpha\frac{\nu_1}{\zeta_{y,1}}\sum_{j=2}^n \frac{\sigma_{y,j}^2}{\zeta_{y,j}}\nu_j \leq 0.$$

Combining this inequality with equation (131a) yields the claim.

H.4 Proof of Corollary 12

Without loss of generality, we can prove the result for $i = 1$. Applying Cauchy-Schwarz inequality, we have

$$\|\nu\|_1 = \nu_1 + \sum_{j=2}^n |\nu_j| \leq \nu_1 + \sqrt{\sum_{j=2}^n \frac{\nu_j^2}{\zeta_{y,j}} \cdot \sum_{j=2}^n \zeta_{y,j}} \leq \kappa + \kappa^{3/2} \cdot \sqrt{1.5\, d} \leq 3\sqrt{d}\kappa^{3/2},$$

where to assert the last inequality we have used Lemma 11 and Lemma 3(c). The claim (93) follows. Further, noting that the infinity norm of a matrix is the ℓ_1-norm of its transpose, we obtain $\left\| \left(G_y - \alpha\Lambda_y\right)^{-1} G_y \right\|_\infty \leq 3\sqrt{d}\kappa^{3/2}$ as claimed.

Appendix I. Proof of Lemmas from Section E.2

In this section, we collect proofs of auxiliary lemmas from Section E.2.

I.1 Proof of Lemma 13

Using Lemma 8, and the relation (82) we have

$$\left(1 - \frac{s_{z,i}}{s_{x,i}}\right)^2 \leq 4\frac{r^2}{\kappa^4 d^{3/2}}\xi^\top\xi, \tag{133}$$

where $\xi \sim \mathcal{N}(0, \mathbb{I}_d)$. Define

$$\Delta_s := \max_{i\in[n],\ v\in\overline{xz}} \left|1 - \frac{s_{v,i}}{s_{x,i}}\right|. \tag{134}$$

Using the standard Gaussian tail bound, we observe that $\mathbb{P}_{\xi\sim\mathcal{N}(0,\mathbb{I}_n)}\left[\xi^\top\xi \geq d(1+\delta)\right] \leq 1 - \epsilon/4$ for $\delta = \sqrt{\frac{2}{d}}$. Plugging this bound in the inequality (133) and noting that for all $v \in \overline{xz}$ we have $\|v - x\|_{J_x} \leq \|z - x\|_{J_x}$, we obtain that

$$\mathbb{P}_{z\sim\mathcal{P}_x}\left[\Delta_s \leq \frac{2r^2(1 + \sqrt{2/d}\log(4/\epsilon)}{\kappa^4\sqrt{d}}\right] \geq 1 - \epsilon/4.$$

Setting

$$r \leq 1/(25\sqrt{1 + \sqrt{2}\log(4/\epsilon)}), \tag{135}$$

and noting that $\kappa^4\sqrt{d} \geq 1$ implies the claim (94a). Hence, we obtain that $\Delta_s < .005/\kappa^2$ and consequently $\max_{i\in[n],v\in\overline{xz}} s_{x,i}/s_{v,i} \in (0.99, 1.01)$ with probability at least $1-\epsilon/4$.

We now claim that

$$\max_{i\in[n],v\in\overline{xz}} \frac{\zeta_{x,i}}{\zeta_{v,i}} \in \left[1-24\kappa^2\Delta_s, 1+24\kappa^2\Delta_s\right], \quad \text{if } \Delta_s \leq \frac{1}{32\kappa^2}.$$

The result follows immediately from this claim. To prove the claim, note that equation (98) implies that if $\Delta_s \leq \frac{1}{32\kappa^2}$, then

$$\frac{\zeta_{v,i}}{\zeta_{x,i}} \in (e^{-8\kappa^2\Delta_s}, e^{8\kappa^2\Delta_s}) \quad \text{for all } i\in[n] \text{ and } v\in\overline{xz},$$

which implies that

$$\max_{i\in[n],v\in\overline{xz}} \frac{\zeta_{x,i}}{\zeta_{v,i}} \in (e^{-8\kappa^2\Delta_s}, e^{8\kappa^2\Delta_s}).$$

Asserting the facts that $e^x \leq 1+3x$ and $e^{-x} \geq 1-3x$, for all $x\in[0,1]$ yields the claim.

I.2 Proof of Lemma 14

The proof once again makes use of the classical tail bounds for polynomials in Gaussian random variables. We restate the classical result stated in equation (136) for convenience. For any $d \geq 1$, any polynomial $P:\mathbb{R}^d \to \mathbb{R}$ of degree k, and any $t \geq (2e)^{k/2}$, we have

$$\mathbb{P}\left[|P(\xi)| \geq t\left(\mathbb{E}P(\xi)^2\right)^{\frac{1}{2}}\right] \leq \exp\left(-\frac{k}{2e}t^{2/k}\right), \tag{136}$$

where $\xi \sim \mathcal{N}(0,\mathbb{I}_n)$ denotes a standard Gaussian vector in n dimensions.

Recall the notation from equation (90) and observe that

$$\|\hat{a}_{x,i}\|_2^2 = \theta_{x,i}, \quad \text{and} \quad \hat{a}_{x,i}^\top \hat{a}_{x,j} = \theta_{x,i,j}. \tag{137}$$

We also have

$$\sum_{i=1}^n \zeta_{x,i}\hat{a}_{x,i}\hat{a}_{x,i}^\top = J_x^{-1/2}\sum_{i=1}^n \zeta_{x,i}\frac{a_i a_i^\top}{s_{x,i}^2}J_x^{-1/2} = \mathbb{I}_d. \tag{138}$$

Further, using Lemma 10 we obtain

$$\sum_{i=1}^n \zeta_{x,i}\hat{b}_{x,i}\hat{b}_{x,i}^\top = J_x^{-1/2}A_x\Lambda_x\left(G_x-\alpha\Lambda_x\right)^{-1}G_x\left(G_x-\alpha\Lambda_x\right)^{-1}\Lambda_x A_x^\top J_x^{-1/2} = 4\kappa^2\mathbb{I}_d. \tag{139}$$

Throughout this section, we consider a fixed point $x\in\operatorname{int}(\mathcal{K})$. For brevity in our notation, we drop the dependence on x for terms like $\zeta_{x,i}, \theta_{x,i}, \hat{a}_{x,i}$ (etc.) and denote them simply by $\zeta_i, \theta_i, \hat{a}_i$ respectively.

We introduce some matrices and vectors that would come in handy for our proofs.

$$B = \begin{bmatrix}\sqrt{\zeta_1}\hat{a}_1^\top \\ \vdots \\ \sqrt{\zeta_n}\hat{a}_n^\top\end{bmatrix}, \quad B_b = \begin{bmatrix}\sqrt{\zeta_1}\hat{b}_1^\top \\ \vdots \\ \sqrt{\zeta_n}\hat{b}_n^\top\end{bmatrix}, \quad v = \begin{bmatrix}\sqrt{\zeta_1}\|\hat{a}_1\|_2^2 \\ \vdots \\ \sqrt{\zeta_n}\|\hat{a}_n\|_2^2\end{bmatrix}, \quad \text{and} \quad v^{ab} = \begin{bmatrix}\sqrt{\zeta_1}\hat{a}_1^\top\hat{b}_1 \\ \vdots \\ \sqrt{\zeta_n}\hat{a}_n^\top\hat{b}_n\end{bmatrix}. \tag{140}$$

We claim that

$$BB^\top \preceq \mathbb{I}_n, \quad \text{and} \quad B_bB_b^\top \preceq 4\kappa^2\mathbb{I}_n. \tag{141a}$$

To see these claims, note that equation (138) implies that $B^\top B = \mathbb{I}_d$ and consequently, $BB^\top$ is an orthogonal projection matrix and $BB^\top \preceq \mathbb{I}_n$. Next, note that from equation (139) we have that $B_b^\top B_b \preceq \kappa^2\mathbb{I}_d$, which implies that $B_bB_b^\top \preceq \kappa^2\mathbb{I}_n$. In asserting both these arguments, we have used the fact that for any matrix B, the matrices $BB^\top$ and $B^\top B$ are PSD and have same set of eigenvalues.

Next, we bound the ℓ_2 norm of the vectors v and v^{ab}:

$$\|v\|_2^2 = \sum_{i=1}^n \zeta_i\theta_i^2 \overset{\text{Lem. 7 } (e)}{\leq} 4d, \quad \text{and} \tag{141b}$$

$$\left\|v^{ab}\right\|_2^2 = \sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\hat{b}_i\right)^2 \leq \sum_{i=1}^n \zeta_i\|\hat{a}_i\|_2^2\left\|\hat{b}_i\right\|_2^2 \leq 4\sum_{i=1}^n \zeta_i\left\|\hat{b}_i\right\|_2^2 = 4\operatorname{trace}(B_b^\top B_b) \overset{\text{eqn. (141a)}}{\leq} 16\kappa^2 d. \tag{141c}$$

We now prove the five claims of the lemma separately.

I.2.1 Proof of bound (95a)

Using Isserlis theorem (Isserlis, 1918) for fourth order Gaussian moments, we have

$$\mathbb{E}\left(\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^2\right)^2 = \sum_{i,j=1}^n \zeta_i\zeta_j\left(\|\hat{a}_i\|_2^2\|\hat{a}_j\|_2^2 + 2\left(\hat{a}_i^\top\hat{a}_j\right)^2\right) = \sum_{i,j=1}^n \zeta_i\zeta_j\left(\theta_i\theta_j + 2\theta_{i,j}^2\right) \leq 24d^2,$$

where the last follows from Lemma 7. Applying the bound (136) with $k=2$ and $t = e\log(\frac{16}{\epsilon})$. Note that the bound is valid since $t \geq (2e)$ for all $\epsilon\in(0,1/30]$.

I.2.2 Proof of bound (95b)

Applying Isserlis theorem for Gaussian moments, we obtain

$$\mathbb{E}\left(\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^3\right)^2 = 9\underbrace{\sum_{i,j=1}^n \zeta_i\zeta_j\|\hat{a}_i\|_2^2\|\hat{a}_j\|_2^2\left(\hat{a}_i^\top\hat{a}_j\right)}_{=:N_1} + 6\underbrace{\sum_{i,j=1}^n \zeta_i\zeta_j\left(\hat{a}_i^\top\hat{a}_j\right)^3}_{=:N_2}.$$

We claim that $N_1 \leq 4d$ and $N_2 \leq 4d$. Assuming these claims as given at the moment, we now complete the proof. We have $\mathbb{E}\left(\sum_{i=1}^n \zeta_i\left(\hat{a}_i^\top\xi\right)^3\right)^2 \leq 60d$. Applying the bound (136)

with $k = 3$ and $t = \left(\frac{2e}{3}\log\left(\frac{16}{\epsilon}\right)\right)^{3/2}$, and verifying that $t \geq (2e)^{3/2}$ for $\epsilon \in (0, 1/30]$ yields the claim.

We now turn to prove the bounds on N_1 and N_2. We have

$$N_1 = \sum_{i,j=1}^{n} \zeta_i \|\hat{a}_i\|_2^2 \hat{a}_i^\top \zeta_j \|\hat{a}_j\|_2^2 \hat{a}_j = \left\| \sum_{i=1}^{n} \zeta_i \|\hat{a}_i\|_2^2 \hat{a}_i \right\|_2^2 = \left\| B^\top v \right\|_2^2 \overset{\text{eqn. (141a)}}{\leq} \|v\|_2^2 \overset{\text{eqn. (141b)}}{\leq} 4d.$$

Next, applying Cauchy-Schwarz inequality and using equation (137), we obtain

$$N_2 = \sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right)^3 \leq \sum_{i,j=1}^{n} \zeta_i \zeta_j \theta_{i,j}^2 \sqrt{\theta_i \theta_j} \overset{\text{(Lem. 3 (d))}}{\leq} 4 \sum_{i,j=1}^{n} \zeta_i \zeta_j \theta_{i,j}^2 \overset{\text{(Lem. 7 (d))}}{\leq} 4 \sum_{i=1}^{n} \zeta_i \theta_i \quad = 4d.$$

I.2.3 Proof of bound (95c)

Using Isserlis theorem for Gaussian moments, we have

$$\mathbb{E}\left(\sum_{i=1}^{n} \zeta_i \left(\hat{a}_i^\top \xi\right)^2 \left(\hat{b}_{x,i}^\top \xi\right)\right)^2 = \underbrace{\sum_{i,j=1}^{n} \zeta_i \zeta_j \|\hat{a}_i\|_2^2 \|\hat{a}_j\|_2^2 \left(\hat{b}_i^\top \hat{b}_j\right)}_{:=N_3} + 4 \underbrace{\sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right) \left(\hat{a}_i^\top \hat{b}_i\right) \left(\hat{a}_j^\top \hat{b}_j\right)}_{:=N_4}$$
$$+ 4 \underbrace{\sum_{i,j=1}^{n} \zeta_i \zeta_j \|\hat{a}_i\|_2^2 \left(\hat{b}_i^\top \hat{a}_j\right) \left(\hat{a}_j^\top \hat{b}_j\right)}_{:=N_5} + 2 \underbrace{\sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right)^2 \left(\hat{b}_i^\top \hat{b}_j\right)}_{:=N_6} + 4 \underbrace{\sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right) \left(\hat{a}_i^\top \hat{b}_j\right) \left(\hat{b}_i^\top \hat{a}_j\right)}_{:=N_7}$$

We claim that all terms $N_k \leq 16\kappa^2 d, k \in \{3, 4, 5, 6, 7\}$. Putting the pieces together, we have

$$\mathbb{E}\left(\sum_{i=1}^{n} \zeta_i \left(\hat{a}_i^\top \xi\right)^2 \left(\hat{b}_{x,i}^\top \xi\right)\right)^2 \leq 240\kappa^2 d.$$

Applying the bound (136) with $k = 3$ and $t = \left(\frac{2e}{3}\log\left(\frac{16}{\epsilon}\right)\right)^{3/2}$ yields the claim. Note that for the given definition of t, we have $t \geq (2e)^{3/2}$ for $\epsilon \in (0, 1/30]$ so that the bound (136) is valid.

It is now left to prove the bounds on N_k for $k \in \{3, 4, 5, 6, 7\}$. We have

$$N_3 = \sum_{i,j=1}^{n} \zeta_i \|\hat{a}_i\|_2^2 \hat{b}_i^\top \zeta_j \|\hat{a}_j\|_2^2 \hat{b}_j = \left\| \sum_{i=1}^{n} \zeta_i \|\hat{a}_i\|_2^2 \hat{b}_i \right\|_2^2 = \left\| B_b^\top v \right\|_2^2 \overset{\text{eqn. (141a)}}{\leq} 4\kappa^2 \|v\|_2^2 \overset{\text{eqn. (141b)}}{=} 16\kappa^2 d,$$

$$N_4 = \sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right) \left(\hat{a}_i^\top \hat{b}_i\right) \left(\hat{a}_j^\top \hat{b}_j\right) = \left\| B^\top v^{ab} \right\|_2^2 \overset{\text{eqn. (141a)}}{\leq} \left\| v^{ab} \right\|_2^2 \overset{\text{eqn. (141c)}}{\leq} 16\kappa^2 d, \quad \text{and}$$

$$N_5 = \sum_{i,j=1}^{n} \zeta_i \zeta_j \|\hat{a}_i\|_2^2 \left(\hat{b}_i^\top \hat{a}_j\right) \left(\hat{a}_j^\top \hat{b}_j\right) = \left(B^\top v^{ab}\right)^\top \left(B_b^\top v\right) \overset{\text{C–S}}{\leq} \left\| B^\top v^{ab} \right\|_2 \left\| B_b^\top v \right\|_2 \leq 16\kappa^2 d.$$

For the term N_6, we have

$$\begin{aligned} N_6 = \sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right)^2 \left(\hat{b}_i^\top \hat{b}_j\right) &\overset{\text{(C–S)}}{\leq} \frac{1}{2} \sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right)^2 \left(\left\|\hat{b}_i\right\|_2^2 + \left\|\hat{b}_j\right\|_2^2\right) \\ &\overset{\text{(symm in } i,j)}{=} \sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\hat{a}_i^\top \hat{a}_j\right)^2 \left\|\hat{b}_i\right\|_2^2 \\ &\overset{\text{(eqn. (138))}}{\leq} \sum_{i=1}^{n} \zeta_i \|\hat{a}_i\|_2^2 \left\|\hat{b}_i\right\|_2^2 \\ &\overset{\text{(Lem. 3(d))}}{\leq} 4 \sum_{i=1}^{n} \zeta_i \left\|\hat{b}_i\right\|_2^2 \\ &\overset{\text{(eqn. (141c))}}{\leq} 16\kappa^2 d. \end{aligned}$$

The bound on the term N_7 can be obtained in a similar fashion.

I.2.4 Proof of bound (95d)

Observe that $\hat{a}_i^\top \xi \sim \mathcal{N}(0, \theta_i)$ and hence $\mathbb{E}\left(\hat{a}_i^\top \xi\right)^8 = 105\,\theta_i^4$. Thus, we have

$$\mathbb{E}\left(\sum_{i=1}^{n} \zeta_i \left(\hat{a}_i^\top \xi\right)^4\right)^2 \overset{\text{C–S}}{\leq} \sum_{i,j=1}^{n} \zeta_i \zeta_j \left(\mathbb{E}\left(\hat{a}_i^\top \xi\right)^8\right)^{\frac{1}{2}} \left(\mathbb{E}\left(\hat{a}_j^\top \xi\right)^8\right)^{\frac{1}{2}} = 105 \sum_{i,j=1}^{n} \zeta_i \zeta_j \theta_i^2 \theta_j^2 = 105 \left(\sum_{i=1}^{n} \zeta_i \theta_i^2\right)^2.$$

Now applying Lemma 7, we obtain that $\mathbb{E}\left(\sum_{i=1}^{n} \zeta_i \left(\hat{a}_i^\top \xi\right)^4\right)^2 \leq 1680d^2$. Consequently, applying the bound (136) with $k = 4$ and $t = \left(\frac{e}{2}\log\left(\frac{16}{\epsilon}\right)\right)^2$ and noting that $t \geq (2e)^2$ for $\epsilon \in (0, 1/30]$, yields the claim.

I.2.5 Proof of bound (95e)

Using the fact that $\mathbb{E}\left(\hat{a}_i^\top \xi\right)^{12} = 945\,\theta_i^6$ and an argument similar to the previous part yields that $\mathbb{E}\left(\sum_{i=1}^{n} \zeta_i \left(\hat{a}_i^\top \xi\right)^6\right)^2 \leq 15120d^2$.

Finally, applying the bound (136) with $k = 6$ and $t = \left(\frac{e}{3}\log\left(\frac{16}{\epsilon}\right)\right)^3$, and verifying that $t \geq (2e)^3$ for $\epsilon \in (0, 1/30]$, yields the claim.

Appendix J. Proof of Lovász's Lemma

We begin by formally defining the conductance (Φ) of a Markov chain on $(\mathcal{K}, \mathbb{B}(\mathcal{K}))$ with arbitrary transition operator $\mathcal{T}$ and stationary distribution π^*. We assume that the operator $\mathcal{T}$ is lazy and thereby the stationary distribution π^* is unique. Let $\mathbb{T}_x = \mathcal{T}(\delta_x)$ denote the transition distribution at point x, then the conductance Φ is defined as

$$\Phi := \inf_{\substack{\mathcal{S} \in \mathbb{B}(\mathcal{K}) \\ \pi^*(\mathcal{S}) \in (0, 1/2)}} \frac{\Phi(\mathcal{S})}{\pi^*(\mathcal{S})} \quad \text{where} \quad \Phi(\mathcal{S}) := \int_{\mathcal{S}} \mathbb{T}_u(\mathcal{K} \cap \mathcal{S}^c) d\pi^*(u) \quad \text{for any } \mathcal{S} \subseteq \mathcal{K}.$$

The conductance denotes the measure of the flow from a set to its complement relative to its own measure, when initialized in the stationary distribution. If the conductance is high, the following result shows that the Markov chain mixes fast.

Lemma 15 *(Lovász and Simonovits, 1993, Theorem 1.4) For any M-warm start μ_0, the mixing time of the Markov chain with conductance Φ is bounded as*

$$\left\|\mathcal{T}^k(\mu_0) - \pi^*\right\|_{TV} \leq \sqrt{M}\left(1 - \frac{\Phi^2}{2}\right)^k \leq \sqrt{M}\exp\left(-k\frac{\Phi^2}{2}\right).$$

Note that this result holds for a general distribution π^* although we apply for uniform π^*. The result can be derived from Cheeger's inequality for continuous-space discrete-time Markov chain and elementary results in Calculus. See, e.g., Theorem 1.4 and Corollary 1.5 by Lovász and Simonovits (1993) for a proof. For ease in notation define $\mathcal{K}\backslash\mathcal{S} := \mathcal{K} \cap \mathcal{S}^c$. We now state a key isoperimetric inequality.

Lemma 16 *(Lovász, 1999, Theorem 6) For any measurable sets $\mathcal{S}_1, \mathcal{S}_2 \subseteq \mathcal{K}$, we have*

$$\mathrm{vol}(\mathcal{K}\backslash\mathcal{S}_1\backslash\mathcal{S}_2) \cdot \mathrm{vol}(\mathcal{K}) \geq d_{\mathcal{K}}(\mathcal{S}_1, \mathcal{S}_2) \cdot \mathrm{vol}(\mathcal{S}_1) \cdot \mathrm{vol}(\mathcal{S}_2),$$

where $d_{\mathcal{K}}(\mathcal{S}_1, \mathcal{S}_2) := \inf_{x\in\mathcal{S}_1, y\in\mathcal{S}_2} d_{\mathcal{K}}(x, y)$.

Since π^* is the uniform measure on $\mathcal{K}$, this lemma implies that

$$\pi^*(\mathcal{K}\backslash\mathcal{S}_1\backslash\mathcal{S}_2) \geq d_{\mathcal{K}}(\mathcal{S}_1, \mathcal{S}_2) \cdot \pi^*(\mathcal{S}_1) \cdot \pi^*(\mathcal{S}_2). \tag{142}$$

In fact, such an inequality holds for an arbitrary log-concave distribution (Lovász and Vempala, 2003). In words, the inequality says that for a bounded convex set any two subsets which are far apart, can not have a large volume. Taking these lemmas as given, we now complete the proof.

Proof of (Lovász's) Lemma 6: We first bound the conductance of the Markov chain using the assumptions of the lemma. From Lemma 15, we see that the Markov chain mixes fast if all the sets $\mathcal{S}$ have a high conductance $\Phi(\mathcal{S})$. We claim that

$$\Phi \geq \frac{\rho\Delta}{64}, \tag{143}$$

from which the proof follows by applying Lemma 15. We now prove the claim (143) along the lines of Theorem 11 in the paper by Lovász (1999). In particular, we show that under the assumptions in the lemma, the sets with bad conductance are far apart and thereby have a small measure under π^*, whence the ratio $\Phi(\mathcal{S})/\pi^*(\mathcal{S})$ is not arbitrarily small. Consider a partition $\mathcal{S}_1, \mathcal{S}_2$ of the set $\mathcal{K}$ such that $\mathcal{S}_1$ and $\mathcal{S}_2$ are measurable. To prove claim (143), it suffices to show that

$$\frac{1}{\mathrm{vol}(\mathcal{K})}\int_{\mathcal{S}_1} \mathcal{T}_u(\mathcal{S}_2)du \geq \frac{\rho\Delta}{64} \cdot \min\left\{\pi^*(\mathcal{S}_1), \pi^*(\mathcal{S}_2)\right\}, \tag{144}$$

Define the sets

$$\mathcal{S}_1' := \left\{u \in \mathcal{S}_1 \middle| \tilde{\mathcal{T}}_u(\mathcal{S}_2) < \frac{\rho}{2}\right\}, \quad \mathcal{S}_2' := \left\{v \in \mathcal{S}_2 \middle| \tilde{\mathcal{T}}_v(\mathcal{S}_1) < \frac{\rho}{2}\right\}, \quad \text{and} \quad \mathcal{S}_3' := \mathcal{K}\backslash\mathcal{S}_1'\backslash\mathcal{S}_2'. \tag{145}$$

Case 1: If we have $\mathrm{vol}(\mathcal{S}_1') \leq \mathrm{vol}(\mathcal{S}_1)/2$ and consequently $\mathrm{vol}(\mathcal{K}\backslash\mathcal{S}_1') \geq \mathrm{vol}(\mathcal{S}_1)/2$, then

$$\int_{\mathcal{S}_1} \mathcal{T}_u(\mathcal{S}_2)du \overset{(i)}{\geq} \frac{1}{2}\int_{\mathcal{S}_1\backslash\mathcal{S}_1'} \tilde{\mathcal{T}}_u(\mathcal{S}_2)du \overset{(ii)}{\geq} \frac{\rho}{4}\mathrm{vol}(\mathcal{S}_1) \overset{(iii)}{\geq} \frac{\rho\Delta}{4} \cdot \min\left\{\mathrm{vol}(\mathcal{S}_1), \mathrm{vol}(\mathcal{S}_2)\right\},$$

which implies the inequality (144) since π^* is the uniform measure on $\mathcal{K}$. In the above sequence of inequalities, step (i) follows from the definition of the kernel $\mathcal{T}$, step (ii) follows from the definition of the set $\mathcal{S}_1'$ (145) and step (iii) from the fact that $\Delta < 1$. Dividing both sides by $\mathrm{vol}(\mathcal{K})$ yields the inequality (144) and we are done.

Case 2: It remains to establish the inequality (144) for the case when $\mathrm{vol}(\mathcal{S}_i') \geq \mathrm{vol}(\mathcal{S}_i)/2$ for each $i \in \{1, 2\}$. Now for any $u \in \mathcal{S}_1'$ and $v \in \mathcal{S}_2'$ we have

$$\left\|\tilde{\mathcal{T}}_u - \tilde{\mathcal{T}}_v\right\|_{\mathrm{TV}} \geq \tilde{\mathcal{T}}_u(\mathcal{S}_1) - \tilde{\mathcal{T}}_v(\mathcal{S}_1) = 1 - \tilde{\mathcal{T}}_u(\mathcal{S}_2) - \tilde{\mathcal{T}}_v(\mathcal{S}_1) > 1 - \rho,$$

and hence by assumption we have $d_{\mathcal{K}}(\mathcal{S}_1', \mathcal{S}_2') \geq \Delta$. Applying Lemma 16 and the definition of $\mathcal{S}_3'$ (145) we find that

$$\mathrm{vol}(\mathcal{S}_3') \cdot \mathrm{vol}(\mathcal{K}) \geq \Delta \cdot \mathrm{vol}(\mathcal{S}_1') \cdot \mathrm{vol}(\mathcal{S}_2') \geq \frac{\Delta}{4} \cdot \mathrm{vol}(\mathcal{S}_1) \cdot \mathrm{vol}(\mathcal{S}_2). \tag{146}$$

Using this inequality and the fact that for any $x \in [0, 1]$ we have $x(1-x) \geq \min\left\{x, (1-x)\right\}/2$ we obtain that

$$\pi^*(\mathcal{S}_3') \geq \frac{\Delta}{4} \cdot \pi^*(\mathcal{S}_1) \cdot \pi^*(\mathcal{S}_2) \geq \frac{\Delta}{8}\min\left\{\pi^*(\mathcal{S}_1), \pi^*(\mathcal{S}_2)\right\}. \tag{147}$$

We claim that

$$\int_{\mathcal{S}_1} \mathcal{T}_u(\mathcal{S}_2)du = \int_{\mathcal{S}_2} \mathcal{T}_v(\mathcal{S}_1)dv. \tag{148}$$

Assuming the claim as given, we now complete the proof. Using the equation (148), we have

$$\begin{aligned}
\frac{1}{\mathrm{vol}(\mathcal{K})}\int_{\mathcal{S}_1} \mathcal{T}_u(\mathcal{S}_2)du &= \frac{1}{2\,\mathrm{vol}(\mathcal{K})}\left(\int_{\mathcal{S}_1} \mathcal{T}_u(\mathcal{S}_2)du + \int_{\mathcal{S}_2} \mathcal{T}_v(\mathcal{S}_1)dv\right) \\
&\overset{(i)}{\geq} \frac{1}{2\,\mathrm{vol}(\mathcal{K})}\left(\frac{1}{2}\int_{\mathcal{S}_1\backslash\mathcal{S}_1'} \tilde{\mathcal{T}}_u(\mathcal{S}_2)du + \frac{1}{2}\int_{\mathcal{S}_2\backslash\mathcal{S}_2'} \tilde{\mathcal{T}}_v(\mathcal{S}_2)dv\right) \\
&\overset{(ii)}{\geq} \frac{\rho}{8}\frac{\mathrm{vol}(\mathcal{S}_3')}{\mathrm{vol}(\mathcal{K})} \\
&\overset{(iii)}{\geq} \frac{\rho\Delta}{64}\min\left\{\pi^*(\mathcal{S}_1), \pi^*(\mathcal{S}_2)\right\},
\end{aligned}$$

where step (i) follows from the definition of the kernel $\mathcal{T}$, step (ii) follows from the definition of the set $\mathcal{S}_3'$ (145) and step (iii) follows from the inequality (147). Putting together the pieces yields the claim (143).

It remains to prove the claim (148). We make use of the following result

$$\Phi(\mathcal{S}) = \Phi(\mathcal{K}\backslash\mathcal{S}) \quad \text{for any measurable } \mathcal{S} \subseteq \mathcal{K}. \tag{149}$$

Using equation (149) and noting that $\mathcal{S}_1 = \mathcal{K}\backslash\mathcal{S}_2$, we have

$$\frac{1}{\text{vol}(\mathcal{K})}\int_{\mathcal{S}_1}\mathcal{T}_u(\mathcal{S}_2)du = \int_{\mathcal{S}_1}\mathcal{T}_u(\mathcal{S}_2)\pi^*(u)du = \Phi(\mathcal{S}_1) = \Phi(\mathcal{K}\backslash\mathcal{S}_1) = \frac{1}{\text{vol}(\mathcal{K})}\int_{\mathcal{S}_2}\mathcal{T}_v(\mathcal{S}_1)dv,$$

which yields equation (148).

Proof of result (149)**:** Note that $\int_{\mathcal{K}}\mathcal{T}_u(\mathcal{S})d\pi^*(u) = \pi^*(\mathcal{S})$. Thus, we have

$$\Phi(\mathcal{K}\backslash\mathcal{S}) = \int_{\mathcal{K}\backslash\mathcal{S}}\mathcal{T}_u(\mathcal{S})d\pi^*(u) = \int_{\mathcal{K}}\mathcal{T}_u(\mathcal{S})d\pi^*(u) - \int_{\mathcal{S}}\mathcal{T}_u(\mathcal{S})d\pi^*(u) = \pi^*(\mathcal{S}) - \int_{\mathcal{S}}\mathcal{T}_u(\mathcal{S})d\pi^*(u).$$

Using the fact that $1 - \mathcal{T}_u(\mathcal{S}) = \mathcal{T}_u(\mathcal{K}\backslash\mathcal{S})$, we obtain

$$\pi^*(\mathcal{S}) - \int_{\mathcal{S}}\mathcal{T}_u(\mathcal{S})d\pi^*(u) = \int_{\mathcal{S}}d\pi^*(u) - \int_{\mathcal{S}}\mathcal{T}_u(\mathcal{S})d\pi^*(u) = \int_{\mathcal{S}}\mathcal{T}_u(\mathcal{K}\backslash\mathcal{S})d\pi^*(u) = \Phi(\mathcal{S}),$$

thereby yielding the claim (149).

Abstract

We study *TV regularization*, a widely used technique for eliciting structured sparsity. In particular, we propose efficient algorithms for computing prox-operators for ℓ_p-norm TV. The most important among these is ℓ_1-norm TV, for whose prox-operator we present a new geometric analysis which unveils a hitherto unknown connection to taut-string methods. This connection turns out to be remarkably useful as it shows how our geometry guided implementation results in efficient weighted and unweighted 1D-TV solvers, surpassing state-of-the-art methods. Our 1D-TV solvers provide the backbone for building more complex (two or higher-dimensional) TV solvers within a modular proximal optimization approach. We review the literature for an array of methods exploiting this strategy, and illustrate the benefits of our modular design through extensive suite of experiments on (i) image denoising, (ii) image deconvolution, (iii) four variants of fused-lasso, and (iv) video denoising. To underscore our claims and permit easy reproducibility, we provide all the reviewed and our new TV solvers in an easy to use multi-threaded C++, Matlab and Python library.

Keywords: proximal optimization, total variation, regularized learning, sparsity, non–smooth optimization

1. Introduction

Sparsity impacts the entire data analysis pipeline, touching algorithmic, modeling, as well as practical aspects. Most commonly, sparsity is elicited via ℓ_1-norm regularization (Tibshirani, 1996; Candès and Tao, 2004). However, numerous applications rely on more refined "structured" notions of sparsity, e.g., groupwise-sparsity (Meier et al., 2008; Liu and Zhang, 2009; Yuan and Lin, 2006; Bach et al., 2011), hierarchical sparsity (Bach, 2010; Mairal et al., 2010), gradient sparsity (Rudin et al., 1992; Vogel and Oman, 1996; Tibshirani et al., 2005), or sparsity over structured 'atoms' (Chandrasekaran et al., 2012).

Such regularizers typically arise in optimization problems of the form

$$\min_{\boldsymbol{x}\in\mathbb{R}^n} \quad \Phi(\boldsymbol{x}) := \ell(\boldsymbol{x}) + r(\boldsymbol{x}), \tag{1.1}$$

where $\ell : \mathbb{R}^n \to \mathbb{R}$ is a smooth loss function (often convex), while $r : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ is a lower semicontinuous, convex, and nonsmooth regularizer that induces sparsity.

We focus on instances of (1.1) where r is a weighted *anisotropic Total-Variation* (TV) regularizer[1], which for a vector $\boldsymbol{x} \in \mathbb{R}^n$ and fixed weights $\boldsymbol{w} \geq 0$ is defined as

$$r(\boldsymbol{x}) \stackrel{\text{def}}{=} \mathrm{Tv}_p^1(\boldsymbol{w};\boldsymbol{x}) \stackrel{\text{def}}{=} \Big(\sum\nolimits_{j=1}^{n-1} w_j|x_{j+1}-x_j|^p\Big)^{1/p} \quad p \geq 1. \tag{1.2}$$

More generally, if X is an order-m tensor in $\mathbb{R}^{\prod_{j=1}^m n_j}$ with entries $\mathsf{X}_{i_1,i_2,\ldots,i_m}$ ($1 \leq i_j \leq n_j$ for $1 \leq j \leq m$); we define the weighted *m-dimensional anisotropic TV* regularizer as

$$\mathrm{Tv}_{\boldsymbol{p}}^m(\mathsf{W};\mathsf{X}) \stackrel{\text{def}}{=} \sum_{k=1}^{m} \sum_{I_k=\{i_1,..,i_m\}\setminus i_k} \Big(\sum_{j=1}^{n_k-1} w_{I_k,j}|\mathsf{X}_{j+1}^{[k]} - \mathsf{X}_j^{[k]}|^{p_k}\Big)^{1/p_k}, \tag{1.3}$$

where $\mathsf{X}_j^{[k]} \equiv \mathsf{X}_{i_1,..,i_{k-1},j,i_{k+1},..,i_m}$, $w_{I_k,j} \geq 0$ are weights, and $\boldsymbol{p} \equiv [p_k \geq 1]$ for $1 \leq k \leq m$. If X is a matrix, expression (1.3) reduces to (note, $p, q \geq 1$)

$$\mathrm{Tv}_{p,q}^2(\mathsf{W};\mathsf{X}) = \sum_{i=1}^{n_1}\Big(\sum_{j=1}^{n_2-1} w_{1,j}|x_{i,j+1}-x_{i,j}|^p\Big)^{1/p} + \sum_{j=1}^{n_2}\Big(\sum_{i=1}^{n_1-1} w_{2,i}|x_{i+1,j}-x_{i,j}|^q\Big)^{1/q}, \tag{1.4}$$

These definitions look formidable; already 2D-TV (1.4) or even the simplest 1D-TV (1.2) are fairly complex, which further complicates the overall optimization problem (1.1). Fortunately, this complexity can be "localized" by invoking *prox-operators* (Moreau, 1962), which are now widely used across machine learning (Sra et al., 2011; Parikh et al., 2014).

The main idea of using prox-operators while solving (1.1) is as follows. Suppose Φ is a convex lsc function on a set $\mathcal{X} \subset \mathbb{R}^n$. The *prox-operator* of Φ is defined as the map

$$\mathrm{prox}_\Phi \stackrel{\text{def}}{=} \boldsymbol{y} \mapsto \operatorname*{argmin}_{\boldsymbol{x}\in\mathcal{X}} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + \Phi(\boldsymbol{x}) \quad \text{for} \quad \boldsymbol{y} \in \mathbb{R}^n. \tag{1.5}$$

A popular method based on prox-operators is the *proximal gradient method* (also known as 'forward backward splitting'), which performs a gradient (forward) step followed by a proximal (backward) step to iterate

$$\boldsymbol{x}_{k+1} = \mathrm{prox}_{\eta_k r}(\boldsymbol{x}_k - \eta_k \nabla\ell(\boldsymbol{x}_k)), \quad k = 0, 1, \ldots. \tag{1.6}$$

Numerous other proximal methods exist—see e.g., (Beck and Teboulle, 2009; Nesterov, 2007; Combettes and Pesquet, 2009; Kim et al., 2010; Schmidt et al., 2011).

To implement the proximal-gradient iteration (1.6) efficiently, we require a subroutine that computes the prox-operator prox_r. An additional concern is whether the overall algorithm requires an *exact* computation of prox_r, or merely a moderately *inexact* computation. This concern is justified: rarely does r admit an exact algorithm for computing prox_r. Fortunately, proximal methods easily admit inexactness, e.g., (Schmidt et al., 2011; Salzo and Villa, 2012; Sra, 2012), which allows approximate prox-operators (as long as the approximation is sufficiently accurate).

We study both exact and inexact prox-operators in this paper, contingent upon the ℓ_p-norm used and on the data dimensionality m.

∗. An initial version of this work was performed during 2013-14, when the author was with the Max Planck Institute for Intelligent Systems, Tübingen, Germany, and with Carnegie Mellon University, Pittsburgh.

1. We use the term "anisotropic" to refer to the specific TV penalties considered in this paper.

1.1. Contributions

In particular, we review, analyze, implement, and experiment with a variety of fast algorithms. The ensuing contributions of this paper are summarized below.

- Geometric analysis that leads to a new, efficient version of the classic Taut String Method (Davies and Kovac, 2001), whose origins can be traced back to (Barlow, 1972) – this version turns out to perform better than most of the recently developed TV proximity methods.
- A previously unknown connection between (a variation of) this classic algorithm and Condat's *unweighted* TV method (Condat, 2012). This connection provides a geometric, more intuitive interpretation and helps us define a hybrid taut-string algorithm that combines the strengths of both methods, while also providing a new efficient algorithm for *weighted* ℓ_1-norm 1D-TV proximity.
- Efficient prox-operators for general ℓ_p-norm ($p \geq 1$) 1D-TV. In particular,
  - For $p = 2$, we present a specialized Newton method based on the root-finding strategy of Moré and Sorensen (1983),
  - For the general $p \geq 1$ case we describe both "projection-free" and projection based first-order methods.
- Scalable proximal-splitting algorithms for computing 2D (1.4) and higher-D TV (1.3) prox-operators. We review an array of methods in the literature that use prox-splitting, and through extensive experiments show that a splitting strategy based on alternating reflections is the most effective in practice. Furthermore, this modular construction of 2D and higher-D TV solvers allows reuse of our fast 1D-TV routines and exploitation of the massive parallelization inherent in matrix and tensor TV.
- The final most important contribution of our paper is a well-tuned, multi-threaded open-source C++, Matlab and Python implementation of all the reviewed and developed methods.[2]

To complement our algorithms, we illustrate several applications of TV prox-operators to: (i) image and video denoising; (ii) image deconvolution; and (iii) four variants of fused-lasso.

Note: We have invested great efforts to ensure reproducibility of our results. In particular, given the vast attention that TV problems have received in the literature, we believe it is valuable to both users of TV and other researchers to have access to our code, data sets, and scripts, to independently verify our claims, if desired.[3]

1.2. Related Work

The literature on TV is too large to permit a comprehensive review here. Instead, we mention the most directly related work to help place our contributions in perspective.

We focus on *anisotropic*-TV, in contrast to *isotropic*-TV (Rudin et al., 1992). Several proposals for designing an anisotropic variant of TV have been proposed in the literature:

2. See https://github.com/albarji/proxTV
3. This material shall be made available at: http://suvrit.de/work/soft/tv.html

in this paper we use the definition given in Bioucas-Dias and Figueiredo (2007), which follows the already presented Equation (1.2). Alternative definitions of anisotropic TV include instances such as a general TV defined in the continuous domain in terms of Wulff shapes (Esedoglu and Osher, 2004), or making use of estimates of the directional information (Steidl and Teuber , 2009), to name a few. Although the definition used here is simpler, it arises frequently in image denoising and signal processing, and quite a few TV-based denoising algorithms exist (Zhu and Chan, 2008, see e.g.).

The anisotropic TV regularizers $\mathrm{Tv}_1^{1\mathrm{D}}$ and $\mathrm{Tv}_{1,1}^{2\mathrm{D}}$ arise in image denoising and deconvolution (Dahl et al., 2010), in the fused-lasso (Tibshirani et al., 2005), in logistic fused-lasso (Kolar et al., 2010), in change-point detection (Harchaoui and Lévy-Leduc, 2010), in graph-cut based image segmentation (Chambolle and Darbon, 2009), in submodular optimization (Jegelka et al., 2013); see also the related work in (Vert and Bleakley, 2010). This broad applicability and importance of anisotropic TV is the key motivation towards developing carefully tuned proximity operators.

There is a rich literature of methods tailored to anisotropic TV, e.g., those developed in the context of fused-lasso (Friedman et al., 2007; Liu et al., 2010), graph-cuts (Chambolle and Darbon, 2009), ADMM-style approaches (Combettes and Pesquet, 2009; Wahlberg et al., 2012), fast methods based on dynamic programming (Johnson, 2013) or KKT conditions analysis (Condat, 2012). However, it seems that anisotropic TV norms other than ℓ_1 have not been studied much in the literature, although recognized as a form of Sobolev semi-norms (Pontow and Scherzer, 2009).

For 1D-TV and for the particular ℓ_1 norm, there exist several direct methods that are exceptionally fast. We treat this problem in detail in Section 2, and hence refer the reader to that section for discussion of closely related work on fast solvers. We note here, however, that in contrast to many of the previous fast solvers, our solvers allow weights, a capability that can be very important in applications (Jegelka et al., 2013).

Regarding 2D-TV, Goldstein T. (2009) presented a so-called "Split-Bregman" (SB). It turns out that this method is essentially a variant of the well-known ADMM method. In contrast to the 2D approach presented here, the SB strategy followed by Goldstein T. (2009) is to rely on ℓ_1-soft thresholding substeps instead of 1D-TV substeps. From an implementation viewpoint, the SB approach is somewhat simpler, but not necessarily more accurate. Incidentally, sometimes such direct ADMM approaches turn out to be less effective than ADMM methods that rely on more complex 1D-TV prox-operators (Ramdas and Tibshirani, 2014).

It is worth highlighting that it is not just proximal solvers such as FISTA (Beck and Teboulle, 2009), SpaRSA (Wright et al., 2009), SALSA (Afonso et al., 2010), TwIST (Bioucas-Dias and Figueiredo, 2007), Trip (Kim et al., 2010), that can benefit from our fast prox-operators. All other 2D and higher-D TV solvers, e.g., (Yang et al., 2013), as well as the recent ADMM based trend-filtering solvers of Tibshirani (2014) immediately benefit, not only in speed but also by gaining the ability to solve weighted problems.

1.3. Summary of the Paper

The remainder of the paper is organized as follows. In Section 2 we consider prox operators for 1D-TV problems when using the most common ℓ_1 norm. The highlight of this section

is our analysis on taut-string TV solvers, which leads to the development a new hybrid method and a weighted TV solver (Sections 2.3, 2.4). Thereafter, we discuss variants of 1D-TV (Section 3), including a specialized Tv_2^{1D} solver, and a more general Tv_p^{1D} method based on a gradient projection strategy. Subsequently, we describe multi-dimensional TV problems and study their prox-operators in Section 4, paying special attention to 2D-TV; for both 2D and multi-D, prox-splitting methods are used. After these theoretical sections, we describe experiments and applications in Section 5. In particular, extensive experiments for 1D-TV are presented in Section 5.1 and Section 5.2; 2D-TV experiments are in Section 5.3, while an application of multi-D TV is the subject of Section 5.4. The appendices to the paper include further technical details and additional information about the experimental setup.

2. TV-L1: Fast Prox-Operators for Tv_1^{1D}

We begin with the 1D-TV problem (1.2) for an ℓ_1 norm choice, for which we review several carefully tuned algorithms. Using such well–tuned algorithms pays off: we can find fast, robust, and low-memory (in fact, in place) algorithms, which are not only of independent value, but also ideal building blocks for scalably solving 2D- and higher-D TV problems.

Computation of the ℓ_1-norm TV prox-operator can be compactly written as the problem

$$\min_{\boldsymbol{x}\in\mathbb{R}^n} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + \lambda\|\boldsymbol{D}\boldsymbol{x}\|_1, \tag{2.1}$$

where $\boldsymbol{D}$ is the *differencing matrix*, all zeros except $d_{ii} = -1$ and $d_{i,i+1} = 1$ $(1 \le i \le n-1)$.

To solve (2.1) we will analyze an approach based on the line of "taut-string" methods. We first introduce these methods for the unweighted *TV-L1* problem (2.1), before discussing the elementwise weighted TV problem (2.6). Most of the previous fastest methods handle only unweighted-TV. It is often nontrivial to extend them to handle weighted-TV, a problem that is crucial to several applications, e.g., segmentation (Chambolle and Darbon, 2009) and certain submodular optimization problems (Jegelka et al., 2013).

A remarkably efficient approach to TV-L1 was presented in (Condat, 2012). We will show Condat's fast algorithm can be interpreted as a "linearized" version of the taut-string approach, a view that paves the way to obtain an equally fast solver for weighted TV-L1.

Before proceeding we note that other than (Condat, 2012), other efficient methods to address unweighted Tv_1^{1D} proximity have been proposed. Johnson (2013) shows how solving Tv_p^{1D} proximity is equivalent to computing the data likelihood of an specific Hidden Markov Model (HMM), which suggests a dynamic programming approach based on the well-known Viterbi algorithm for HMMs. The resulting algorithm is very competitive, and guarantees an overall $O(n)$ performance while requiring approximately $8n$ storage. Another similarly performing algorithm was presented by Kolmogorov et al (2015) in the form of a message passing method. We will also consider these algorithms in our experimental comparison in §5.1.

Yet another family of methods is based on projected-Netwon (PN) techniques: we also present in Appendix E a PN approach for its instructive value, and also because it provides key subroutines for solving TV problems with $p > 1$. Our derivation may also be helpful to readers seeking to implement efficient prox-operators for problems that have structure

similar to TV, for instance ℓ_1-trend filtering (Kim et al., 2009; Tibshirani, 2014). Indeed, the PN approach proves to be foundational for the fast "group fused-lasso" algorithms of (Wytock et al., 2014).

2.1. The Taut-String Method for Tv_1^{1D}

While taut-string methods seem to be largely unknown in machine learning, they have been widely applied in statistics—see e.g., (Grasmair, 2007; Davies and Kovac, 2001; Barlow, 1972).

We start by transforming the problem as follows. For TV-L1, elementary manipulations, e.g., using Proposition A.4, yield the dual (re-written as a minimization problem)

$$\min_{\boldsymbol{u}} \ \tfrac{1}{2}\|\boldsymbol{D}^T\boldsymbol{u}\|_2^2 - \boldsymbol{u}^T\boldsymbol{D}\boldsymbol{y}, \ \text{s.t.} \ \|\boldsymbol{u}\|_\infty \le \lambda. \tag{2.2}$$

Without changing the minimizer, the objective (2.2) can be replaced by $\|\boldsymbol{D}^T\boldsymbol{u} - \boldsymbol{y}\|_2^2$, which then unfolds into

$$(u_1 - y_1)^2 + \sum\nolimits_{i=2}^{n-1} (-u_{i-1} + u_i - y_i)^2 + (-u_{n-1} - y_n)^2 .$$

Introducing the fixed extreme points $u_0 = u_n = 0$, we can replace the problem (2.2) by

$$\min_{\boldsymbol{u}} \ \sum\nolimits_{i=1}^{n} (-u_{i-1} + u_i - y_i)^2 , \ \text{s.t.} \ \|\boldsymbol{u}\|_\infty \le \lambda, \quad u_0 = u_n = 0. \tag{2.3}$$

Now we perform a change of variables by defining the new set of variables $\boldsymbol{s} = \boldsymbol{r} - \boldsymbol{u}$, where $r_i := \sum_{k=1}^{i} y_k$ is the cumulative sum of input signal values. Thus, (2.3) becomes

$$\min_{\boldsymbol{s}} \ \sum\nolimits_{i=1}^{n} (-r_{i-1} + s_{i-1} + r_i - s_i - y_i)^2 , \ \text{s.t.} \ \|\boldsymbol{s} - \boldsymbol{r}\|_\infty \le \lambda, \quad r_0 - s_0 = r_n - s_n = 0,$$

which upon simplification becomes

$$\min_{\boldsymbol{s}} \ \sum\nolimits_{i=1}^{n} (s_{i-1} - s_i)^2 , \quad \text{s.t.} \quad \|\boldsymbol{s} - \boldsymbol{r}\|_\infty \le \lambda, s_0 = 0, \ s_n = r_n. \tag{2.4}$$

Now the key trick: problem (2.4) can be shown to share the same optimum as

$$\min_{\boldsymbol{s}} \ \sum_{i=1}^{n} \sqrt{1 + (s_{i-1} - s_i)^2}, \ \text{s.t.} \ \|\boldsymbol{s} - \boldsymbol{r}\|_\infty \le \lambda, \quad s_0 = 0, \ s_n = r_n. \tag{2.5}$$

A proof of this relationship may be found in (Steidl et al., 2005); for completeness, and also because it will help us generalize to the weighted Tv_1^{1D} variant, we include an alternative proof in Appendix C.

The name "taut-string" is explained as follows. The objective in (2.5) can be interpreted as the Euclidean length of a polyline through the points $(i, \boldsymbol{s}_i)$. Thus, (2.5) seeks the minimum length polyline (the *taut-string*) crossing a tube of height λ with center the cumulative sum $\boldsymbol{r}$ and having the fixed endpoints (s_0, s_n). An example illustrating this description is shown in Figure 1.

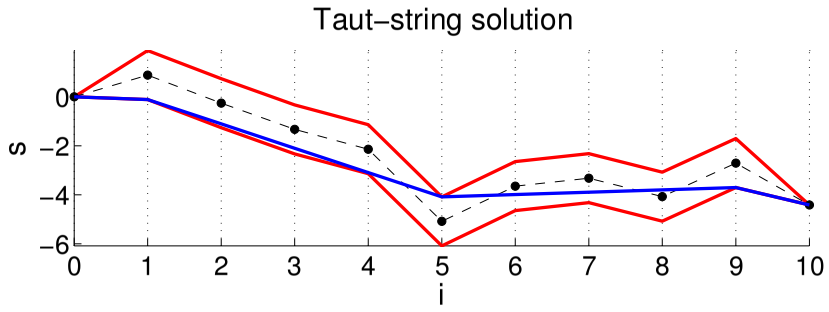

Figure 1: Example of the taut string method. The cumulative sum $\boldsymbol{r}$ of the input signal values $\boldsymbol{y}$ is shown as the dashed line; the black dots mark the points (i, r_i). The bottom and top of the λ-width tube are shown in red. The taut string solution $\boldsymbol{s}$ is shown as a blue line.

Once the taut string is found, the solution for the original TV problem (2.1) can be recovered by observing that

$$s_i - s_{i-1} \quad = \quad r_i - u_i - (r_{i-1} - u_{i-1}) \quad = \quad y_i - u_i + u_{i-1} \quad = \quad x_i,$$

where we used the primal-dual relation $\boldsymbol{x} = \boldsymbol{y} - \boldsymbol{D}^T\boldsymbol{u}$. Intuitively, the above argument shows that the solution to the TV-L1 proximity problem is obtained as the discrete gradient of the taut string, or as the slope of its segments.

It remains to describe how to find the taut string. The most widely used approach seems to be the one due to Davies and Kovac (2001). This approach starts from the fixed point $s_0 = 0$, and incrementally computes the *greatest convex minorant* of the upper bounds on the λ tube, as well as the *smallest concave majorant* of the lower bounds on the λ tube. When both curves intersect, the *left-most* point where either the majorant or the minorant touched the tube is used to fix a first segment of the taut string. The procedure is then resumed at the end of the identified segment, and iterated until all taut string segments have been obtained. Pseudocode of this method is presented as Algorithm 1, while an example of this procedure is shown in Figure 2.

It is important to note that since we have a discrete number of points in the tube, the greatest convex minorant can be expressed as a piecewise linear function with segments of monotonically increasing slope, while the smallest concave majorant is another piecewise linear function with segments of monotonically decreasing slope. Another relevant fact is that each segment in the tube upper/lower bound enters the minorant/majorant exactly once in the algorithm, and is also removed exactly once. This limits the extent of the inner loops in the algorithm, and in fact an analysis of the computational complexity of this behavior leads to an overall $O(n)$ performance (Davies and Kovac, 2001).

In spite of this, Condat (2012) notes that maintaining the minorant and majorant functions in memory is inefficient, and views a taut-string approach as potentially inferior to

Algorithm 1 Taut string algorithm for TV-L1-proximity

Inputs: input signal $\boldsymbol{y}$ of length n, regularizer λ.
Initialize $i = 0$, $concmajorant = \varnothing$, $convminorant = \varnothing$, $\boldsymbol{r}_i = \sum_{k=1}^{i} \boldsymbol{y}_k$.
while $i < n$ **do**
  Add new segment: $concmajorant = concmajorant \cup ((i-1, \boldsymbol{r}_{i-1} - \lambda) \to (i, \boldsymbol{r}_i - \lambda))$.
  while $concmajorant$ is not concave **do**
    Merge the last two segments of $concmajorant$
  end while
  Add new segment: $convminorant = convminorant \cup ((i-1, \boldsymbol{r}_{i-1} + \lambda) \to (i, \boldsymbol{r}_i + \lambda))$.
  while $convminorant$ is not convex **do**
    Merge the last two segments of $convminorant$
  end while
  if slope(left-most segment in $concmajorant$) > slope(lest-most segment in $convminorant$) **then**
    $break$ = left-most point where either the majorant or the minorant touched the tube
    if $break \in convminorant$ **then**
      Remove left-most segment of the minorant, add it to the taut-string solution $\boldsymbol{x}$.
      Majorant is recalculated as a straight line from $break$ to its last point.
    end if
    if $break \in concmajorant$ **then**
      Remove left-most segment of the majorant, add it to the taut-string solution $\boldsymbol{x}$.
      Minorant is recalculated as a straight line from $break$ to its last point.
    end if
  end if
  $i++$
end while
Add last segment from either the majorant or minorant to the solution $\boldsymbol{x}$.

his proposed method. To this observation we make two claims: Condat's method can be interpreted as a linearized version of the taut-string method (see Section 2.2); and that a careful implementation of the taut-string method can be highly competitive in practice.

2.1.1. Efficient Implementation of Taut-Strings

We propose now an efficient implementation of the taut-string method. The main idea is to carefully use double-ended queues (Knuth, 1997) to store the majorant and minorant information. Therewith, all majorant/minorant operations such as appending a segment or removing segments from either the beginning or the end of the majorant can be performend in constant time. Note however that usual double-ended queue implementations use doubly linked lists, dynamic arrays or circular buffers: these approaches require dynamically reallocating memory chunks at some of the insert or remove operations. But in the taut-string algorithm, the maximum number of segments of the majorant/minorant is just the size of the input signal (n), and also the number of segments to be inserted in the queue throughout the algorithm will be n. Making use of these facts we implement a specialized queue based on a contiguous array of fixed length n. New segments are added from the start of the array on, and a couple of pointers are maintained to keep track of the first and last valid segments in the array, much in the way of a circular buffer. This implementation, however, does not require of the usual circular logic. Overall, this double-ended queue

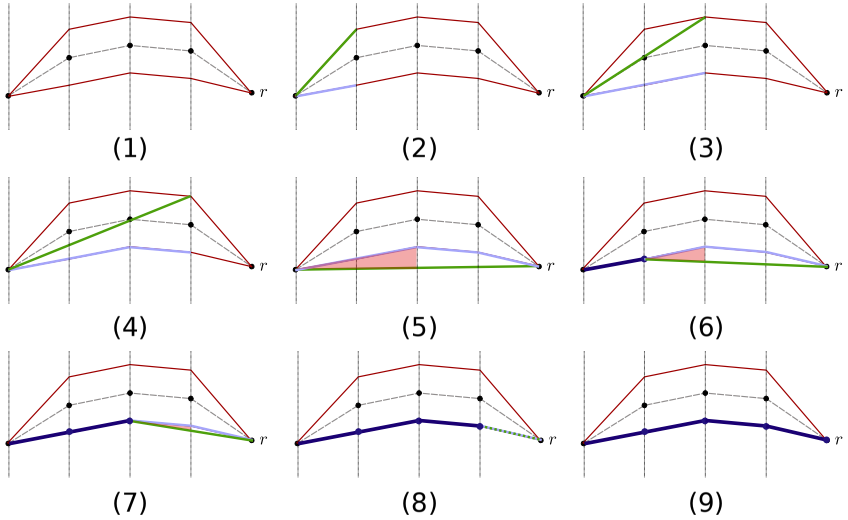

Figure 2: Example of the evolution of the taut string method. The smallest concave majorant (blue) and largest convex minorant (green) are updated are every step. At step (1) the algorithm is initialized. Steps (2) to (4) successfully manage to update majorant and minorant without producing crossings between them. Note how while the concave majorant keeps adding segments without issue, the convex minorant must remove and merge existing segments with new ones to mantain a convex function from the origin to the new points. At step (5) the end of the tube is reached, but the minorant and majorant slopes overlap, and so it is necessary to break the segment at the left-most point where the majorant/minorant touched the tube. Since the left-most touching point is in the concave majorant it's leftmost segment is removed and placed in the solution, while the convex minorant is updated as a straight line from the detected breakpoint to the last explored point, resulting in (6). The algorithm would then continue adding segments, but since the majorant/minorant slopes are still crossing, the procedure of fixing segments to the solution is repeated through steps (6), (7) and (8). Finally at step (9) the slopes are no longer crossing and the method would continue adding tube segments, but since the end of the tube has already been reached the algorithm stops.

requires a single memory allocation at the beginning of the algorithm, keeping the rest of queue operations free from memory management and all but the simplest pointer or index algebra.

We also store for each segment the following values: x length of the segment, y length and slope. Slopes might seem as redundant given the other two factors, but given the number of times the algorithm requires comparing slopes between segments (e.g., to preserve convexity/concavity) it pays off to precompute these values. This fact together with

other calculation and code optimization details produces our implementation; these can be reviewed in the code itself at `https://github.com/albarji/proxTV`.

2.2. Linearized Taut-String Method for $\mathbf{TV}_1^{\mathbf{1D}}$

We now present a variant, linearized version of the taut-string method. Surprisingly, the resulting algorithm turns out to be equivalent to the fast algorithm of Condat (2012), though now with a clearer interpretation based on taut-strings.

The key idea is to build linear approximations to the greatest convex minorant and smallest concave majorant, producing exactly the same results but significantly reducing the bookkeeping of the method to a handful of simple variables. We therefore replace the greatest convex minorant and smallest convex majorant by a *greatest affine minorant* and *smallest affine majorant*.

An example of the method is presented in Figure 3. A proof showing that this linearization does not change the resultant taut-string is given in Appendix D. In what follows, we describe the linearized method in depth.

Details. Linearized taut-string requires only the following bookkeeping variables:

1. i_0: index of the current segment start
2. $\bar{\delta}$: slope of the majorant
3. $\underline{\delta}$: slope of the minorant
4. $\bar{h}$: height of majorant w.r.t. the λ-tube center
5. $\underline{h}$: height of minorant w.r.t. λ-tube center
6. $\bar{i}$: index of last point where $\bar{\delta}$ was updated—potential majorant break point
7. $\underline{i}$: index of last point where $\underline{\delta}$ was updated—potential minorant break point.

Figure 4 gives a geometric interpretation of these variables; we use these variables to detect minorant-majorant intersections, without the need to compute or store them explicitly.

Algorithm 2 presents full pseudocode of the linearized taut-string method. Broadly, the algorithm proceeds in the same fashion as the classic taut-string method, updating the affine approximations to the majorant and minorant at each step, and introducing a breakpoint whenever the slopes of these two functions cross.

More precisely, at each each iteration the method steps one point further through the tube, updating the minorant/majorant slopes ($\underline{\delta}$, $\bar{\delta}$) as well as their heights at the current point ($\underline{h}$, $\bar{h}$). To check for minorant/majorant crossings it suffices to compare the slopes ($\underline{\delta}$, $\bar{\delta}$), or equivalently, to check whether the height of the minorant $\underline{h}$ falls below the tube bottom (since the minorant follows the tube ceiling) or the height of the majorant $\bar{h}$ grows above the tube ceiling (since the majorant follows the tube bottom). We make use of this last variant, since updating heights turns out to be slightly cheaper than updating slopes, and so it is faster to ensure no crossing will take place before performing such updates.

When a crossing is detected, we perform similar steps as in the classic taut-string method but with one significant difference: the algorithm is completely restarted at the newly introduced breakpoint. This restart idea is in contrast with the classic method, where we simply re-use the previously computed information about the minorant and majorant to update their estimates and continue working with them. In the linearized version we do

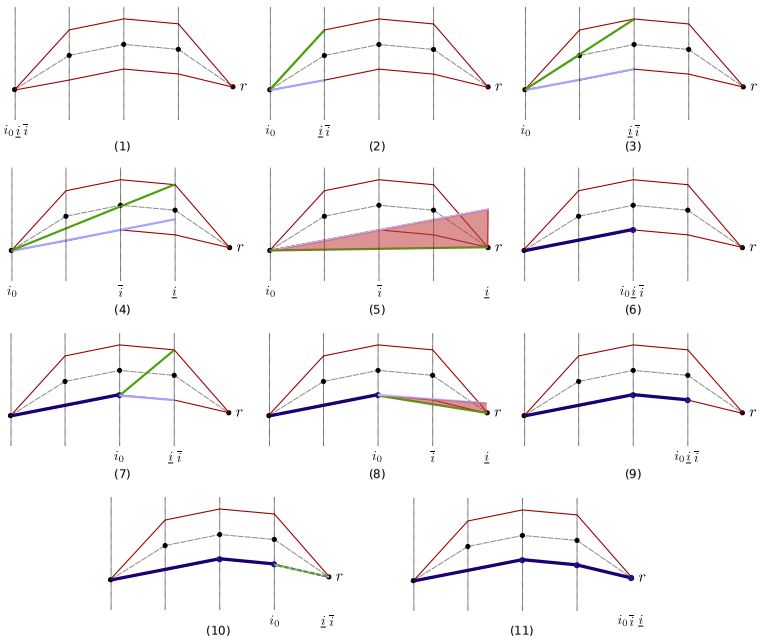

Figure 3: Example of the evolution of the linearized taut string method. The smallest affine majorant of the tube bottom (blue) and greatest affine minorant of the tube ceiling (green) are updated at every step. At step (1) the algorithm is initialized. Steps (2) to (4) successfully manage to update majorant/minorant without crossings. At step (5), however, the slopes cross, and so it is necessary to break the segment. Since the left-most tube touching point is the one in the majorant, the majorant is broken down at that point and its left-hand side is added to the solution, resulting in (6). The method is then restarted at the break point, with majorant/minorant being updated at step (7), though at step (8) once again a crossing is detected. Hence, at step (9) a breaking point is introduced again and the algorithm is restarted once more. Following this, step (10) manages to update majorant/minorant slopes up to the end of the tube, and so at step (11) the final segment is built using the (now equal) slopes.

not keep enough information to perform such an operation, so all data about minorant and majorant is discarded and the algorithm begins anew. Because of this choice the same tube segment might be reprocessed up to $O(n)$ times in the method, and therefore the overall worst case performance is $O(n^2)$. This fact was already observed in (Condat, 2012).

In what follows we describe the rationale behind the height update formulae.

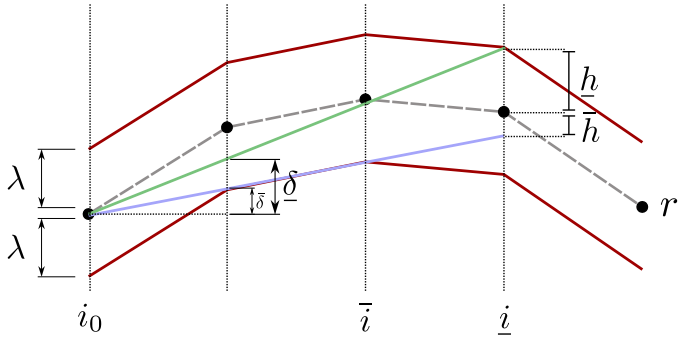

Figure 4: Illustration of the geometric concepts involved in the linearized taut string method. The greatest linear minorant (of the tube ceiling) is depicted in green, while the smallest linear majorant (of the tube bottom) is shown in blue. The δ slopes and h heights are presented updated up to the index shown as $\underline{\imath}$.

Height variables. To implement the method described above, the height variables h are not strictly necessary as they can be obtained from the slopes δ. However, explicitly including them leads to efficient updating rules at each iteration, as we show below.

Suppose we are updating the heights and slopes from their estimates at step $i-1$ to step i. Updating the heights is immediate given the slopes, since

$$h_i = h_{i-1} + \delta - y_i.$$

In other words, since we are following a line with slope δ, the change in height from one step to the next is given by precisely such a slope. Note, however, that in this algorithm we do not compute absolute heights but instead relative heights with respect to the λ–tube center. Therefore we need to account for the change in the tube center between steps $i-1$ and i, which is given by $r_i - r_{i-1} = y_i$. This completes the update, which is shown in Algorithm 2 as lines 4 and 11.

However, it is possible that the new height h runs over or under the tube. This would mean that we cannot continue using the current slope in the majorant or minorant, and a recalculation is needed, which again can be done efficiently by using the height information. Assume without loss of generality that the starting index of the current segment is 0 and the absolute height of the starting point of the segment is given by α. Then, for adjusting the minorant slope $\bar{\delta}_i$ so that it touches the tube ceiling at the current point, we note that

$$\bar{\delta}_i = \frac{\lambda + r_i - \alpha}{i} = \frac{\lambda + (\bar{h}_i - \bar{h}_i) + r_i - \alpha}{i},$$

where we have also added and subtracted the current value of $\bar{h}_i$. Observe that this value was computed using the estimate δ_{i-1} of the slope so far, so we can rewrite it as the projection of the initial point in the segment following such a slope, that is, as $\bar{h}_i = i\bar{\delta}_i - r_i + \alpha$. Doing

Algorithm 2 Linearized taut string algorithm for TV-L1-proximity

1: Initialize $i = \bar{i} = \underline{i} = \bar{h} = \underline{h} = 0$, $\underline{\delta} = y_0 + \lambda$, $\bar{\delta} = y_0 - \lambda$
2: **while** $i < n$ **do**
3: Find tube height: $\tilde{\lambda} = \lambda$ if $i < n-1$, else $\tilde{\lambda} = 0$
4: Update majorant height following current slope: $\bar{h} = \bar{h} + \bar{\delta} - y_i$.
5: /* Check for ceiling violation: majorant is above tube ceiling */
6: **if** $\bar{h} > \tilde{\lambda}$ **then**
7: Build valid segment up to last majorant breaking point: $\boldsymbol{x}_{i_0+1:\bar{i}} = \bar{\delta}$.
8: Start new segment after break: $(i_0, \underline{i}) = \bar{i}$, $\underline{\delta} = y_i + 2\lambda$, $\bar{\delta} = y_i$, $\underline{h} = \lambda$, $\bar{h} = -\lambda$, $i = \bar{i} + 1$
9: **continue**
10: **end if**
11: Update minorant height following current slope: $\underline{h} = \underline{h} + \underline{\delta} - y_i$.
12: /* Check for bottom violation: minorant is below tube bottom */
13: **if** $\underline{h} < -\tilde{\lambda}$ **then**
14: Build valid segment up to last minorant breaking point: $\boldsymbol{x}_{i_0+1:\underline{i}} = \underline{\delta}$.
15: Start new segment after break: $(i_0, \bar{i}) = \underline{i}$, $\underline{\delta} = y_i$, $\bar{\delta} = -2\lambda + y_i$, $\underline{h} = \lambda$, $\bar{h} = -\lambda$, $i = \underline{i} + 1$
16: **continue**
17: **end if**
18: /* Check if majorant height is below the floor */
19: **if** $\bar{h} \leq -\tilde{\lambda}$ **then**
20: Correct slope: $\bar{\delta} = \bar{\delta} + \frac{\tilde{\lambda} - \bar{h}}{i - i_0}$
21: The majorant now touches the floor: $\bar{h} = -\tilde{\lambda}$
22: This is a possible majorant breaking point: $\bar{i} = i$
23: **end if**
24: /* Check if minorant height is above the ceiling */
25: **if** $\underline{h} \geq \tilde{\lambda}$ **then**
26: Correct slope: $\underline{\delta} = \underline{\delta} + \frac{-\tilde{\lambda} - \underline{h}}{i - i_0}$
27: The minorant now touches the ceiling: $\underline{h} = \tilde{\lambda}$
28: This is a possible minorant breaking point: $\underline{i} = i$
29: **end if**
30: Continue building current segment: $i = i + 1$
31: **end while**
32: Build last valid segment: $\boldsymbol{x}_{i_0+1:n} = \bar{\delta}$.

so for one of the added heights $\bar{h}_i$ produces

$$\bar{\delta}_i = \frac{\lambda + (i\bar{\delta}_{i-1} - r_i + \alpha) - \bar{h}_i + r_i - \alpha}{i} = \bar{\delta}_{i-1} + \frac{\lambda - \bar{h}_i}{i},$$

which generates a simple updating rule. A similar derivation holds for the minorant. The resulting updates are included in the algorithm in lines 20 and 26. After recomputing this slope we need to adjust the corresponding height back to the tube: since the heights are relative to the tube center we can just set $\bar{h} = \lambda$, $\underline{h} = -\lambda$; this is done in lines 21 and 27.

Notice also that the special case of the last point in the tube where the taut-string must meet $s_n = r_n$ is handled by line 3, where $\tilde{\lambda}$ is set to 0 at such a point to enforce this constraint. Overall, one iteration of the method is very efficient, as mostly just additions and subtractions are involved with the sole exception of the division required for the slope updates, which are not performed at every iteration. Moreover, no additional memory is

	Classic	**Linearized (Condat's)**
Worst-case performance	$O(n)$	$O(n^2)$
In–memory	No	Yes
Other considerations	Fast bookkeeping through double-ended queues	Very fast iteration, cache friendly

Table 1: Comparison of the main features of reviewed taut-string algorithms.

required beyond the constant number of bookkeeping variables, and in-place updates are also possible because y_i values for already fixed sections of the taut-string are not required again, so the output $\boldsymbol{x}$ and the input $\boldsymbol{y}$ can both refer to the same memory locations.

The resulting algorithm turns out to be equivalent, almost line by line, to the method of Condat (2012), even though its theoretical grounds are radically different: while the approach presented here has a strong geometric basis due to its taut-string relationship, (Condat, 2012) is based solely on analysis of KKT conditions. Therefore, we have shown that Condat's fast TV method is, in fact, a linearized taut-string algorithm.

2.3. Comparison of Taut-String Methods and a Hybrid Strategy

Table 1 summarizes the main features of the classic and linearized taut-string methods reviewed so far. Although the classic taut-string method has been largely neglected in the machine learning literature, its guarantee in linear performance makes it an attractive choice. Furthermore, although we could not find any references on implementation details of this method, we have empirically seen that a very efficient solver can be produced by making use of a double-ended queue to bookkeep the majorant/minorant information.

In contrast to this, the linearized taut-string method (equivalent to Condat (2012)) features a much better performance per step in the tube traversal, mainly due to not requiring additional memory and making use of only a small constant number of variables, making the method friendly for CPU cache or registers calculation. As a tradeoff of keeping such scarce information in memory, the method does not guarantee linear performance, falling to a quadratic theoretical runtime in the worst case. This fact was already observed in (Condat, 2012), though such worst case was deemed as pathological, claiming a $O(n)$ performance in all practical situations. We shall review these claims in the experimental sections in this manuscript.

The key points of Table 1 show that no taut-string variant is clearly superior. While the classic method provides a safe linear time solution to the problem, the linearized method is potentially faster but riskier in terms of worst case performance. Following these observations we propose here a simple hybrid method combining both approaches: run the linearized algorithm up to a prefixed number of steps n^S, $S \in (1, 2)$, and if the solution has not yet been found, we switch to the classic method. We therefore limit the worst-case scenario to $O(n^S) + O(n) \simeq O(n^S)$, because once the classic method kicks, it will ensure an $O(n)$ performance guarantee.

Implementation of this hybrid method is easy upon realizing the similarities between algorithms: a switch–check is added to the linearized method every time a segment of the taut-string has been identified (Algorithm 2, lines 7, 14). If it is confirmed that the method

has already run for n^S steps without reaching the solution, the remaining part of the signal for which the taut-string has not yet been found is passed on to the classic method, whose solution is concatenated to the part the linearized method managed to find so far. We also report the empirical performance of this method in the experimental section.

2.4. Taut-string Methods for Weighted Tv_1^{1D}

Several applications TV require penalizing the discrete gradients individually, which can be done by solving the *weighted TV-L1* problem

$$\min_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + \sum_{i=1}^{n-1} w_i|x_{i+1}-x_i|, \tag{2.6}$$

where the weights $\{w_i\}_{i=1}^{n-1}$ are all positive. To solve (2.6) using a taut-string approach, we again begin with its dual (written as a minimization problem)

$$\min_{\boldsymbol{u}} \quad \tfrac{1}{2}\|\boldsymbol{D}^T\boldsymbol{u}\|_2^2 - \boldsymbol{u}^T\boldsymbol{D}\boldsymbol{y} \quad \text{s.t.} \quad |u_i| \le w_i, \quad 1 \le i < n. \tag{2.7}$$

Then, we repeat the derivation of the unweighted taut-string method but with a few key modifications. More precisely, we transform (2.7) by introducing $u_0 = u_n = 0$ to obtain

$$\min_{\boldsymbol{u}} \ \sum_{i=1}^{n} (y_i - u_i + u_{i-1})^2 \quad \text{s.t.} \ |u_i| \le w_i, \quad 1 \le i < n.$$

Then, we perform the change of variables $\boldsymbol{s} = \boldsymbol{r} - \boldsymbol{u}$, where $r_i := \sum_{k=1}^{i} y_k$, and consider

$$\min_{\boldsymbol{s}} \sum_{i=1}^{n} (s_i - s_{i-1})^2 \quad \text{s.t.} \ |s_i - r_i| \le w_i, \quad 1 \le i < n \ s_0 = 0, \ s_n = r_n.$$

Finally, applying Theorem C.1 we obtain the equivalent *weighted taut-string* problem

$$\min_{\boldsymbol{s}} \sum_{i=1}^{n} \sqrt{1 + (s_i - s_{i-1})^2} \quad \text{s.t.} \ |s_i - r_i| \le w_i, \ 1 \le i < n, \ s_0 = 0, \ s_n = r_n. \tag{2.8}$$

Problem (2.8) differs from its unweighted counterpart (2.5) in the constraints $|s_i - r_i| \le w_i$ $(1 \le i < n)$, which allow different weights for each component instead of using the same value λ. Our geometric intuition also carries over to the weighted problem, albeit with a slight modification: the tube we are trying to traverse now has varying widths at each step instead of the previous fixed λ width—Figure 5 illustrates this idea.

As a consequence of the above derivation and intuition, taut-string methods can be produced to solve the weighted Tv_1^{1D} problem. The original formulation of the classic taut-string method in (Davies and Kovac, 2001) defines the limits of the tube through possibly varying bottom and ceiling values (l_i, u_i) $\forall i$, and so this method easily extends to solve the weighted TV problem by assigning $l_i = r_i - w_i$, $u_i = r_i + w_i$. In our pseudocode in Algorithm 1 we just need to replace λ by the appropriate w_i values.

Similar considerations apply for the linearized version (Algorithm 2), in particular, when checking ceiling/floor violations as well as when checking slope recomputations and restarts, we must account for varying tube heights. Algorithm 3 presents the precise modifications that we must make to Algorithm 2 to handle weights. Regarding the convergence of this method, the proof of equivalence with the classic taut-string method still holds in the weighted case (see Appendix D).

The very same analysis as portrayed in Table 1 applies here: both the benefits and problems of the two taut-string solvers carry on to the weighted variant of the problem.

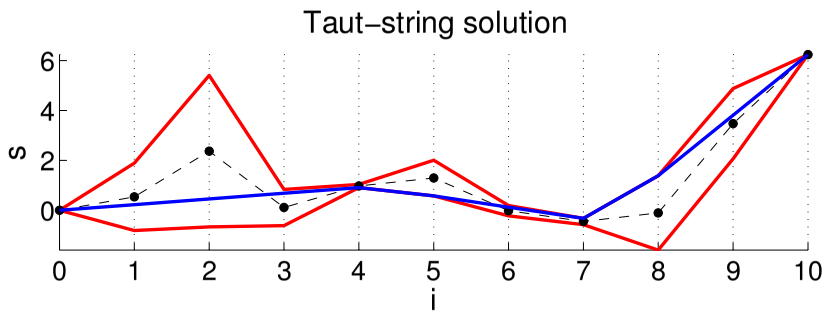

Figure 5: Example of the weighted taut string method with $\boldsymbol{w} = (1.35, 3.03, 0.73, 0.06, 0.71, 0.20, 0.12, 1.49, 1.41)$. The cumulative sum $\boldsymbol{r}$ of the input signal values $\boldsymbol{y}$ is shown as the dashed line, with the black dots marking the points $(i, \boldsymbol{r}_i)$. The bottom and ceiling of the tube are shown in red, which vary in width at each step following the weights $\boldsymbol{w}_i$. The weighted taut string solution $\boldsymbol{s}$ is shown as a blue line.

Algorithm 3 Modified lines for weighted version of Algorithm 2

3: Find tube height: $\tilde{\lambda} = w_{i+1}$ if $i < n-1$, else $\tilde{\lambda} = 0$
8: Start new segment after break: $(i_0, \underline{i}) = \bar{i}$, $\underline{\delta} = y_i + w_{i-1} + w_i$, $\bar{\delta} = y_i + w_{i-1} - w_i$, $\underline{h} = w_i$, $\bar{h} = -w_i$, $i = \bar{i} + 1$
15: Start new segment after break: $(i_0, \bar{i}) = \underline{i}$, $\underline{\delta} = y_i + w_{i-1} - w_i$, $\bar{\delta} = y_i + w_{i-1} + w_i$, $\underline{h} = w_i$, $\bar{h} = -w_i$, $i = \underline{i} + 1$

3. Other One-Dimensional TV Variants

While more infrequent, replacing the ℓ_1 norm of the standard TV regularizer by an ℓ_p-norm version can also be useful. In this section we focus first on a specialized solver for $p = 2$, before discussing a less efficient but more general solver for any ℓ_p with $p \ge 1$. We also briefly cover the $p = \infty$ case.

3.1. TV-L2: Proximity for Tv_2^{1D}

For TV-L2 proximity ($p = 2$) the dual to the prox-operator for (1.2) reduces to

$$\min_{\boldsymbol{u}} \ \phi(\boldsymbol{u}) := \tfrac{1}{2}\|\boldsymbol{D}^T\boldsymbol{u}\|_2^2 - \boldsymbol{u}^T\boldsymbol{D}\boldsymbol{y}, \ \text{ s.t. } \|\boldsymbol{u}\|_2 \le \lambda. \tag{3.1}$$

Problem (3.1) is nothing but a version of the well-known trust-region subproblem (TRS), for which a variety of numerical approaches are known (Conn et al., 2000).

We derive a specialized algorithm based on the classic Moré-Sorensen Newton (MSN) method of (Moré and Sorensen, 1983). This method in general can be quite expensive, but for (3.1) the Hessian is tridiagonal which can be well-exploited (see Appendix E). Curiously, experiments show that for a limited range of λ values, even ordinary gradient-projection

(GP) can be competitive. But for overall best performance, a hybrid MSN-GP approach is preferable.

Towards solving (3.1), consider its KKT conditions:

$$\begin{aligned} &(\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I})\boldsymbol{u} = \boldsymbol{D}\boldsymbol{y}, \\ &\alpha(\|\boldsymbol{u}\|_2 - \lambda) = 0, \quad \alpha \geq 0, \end{aligned} \tag{3.2}$$

where α is a Lagrange multiplier. There are two possible cases: either $\|\boldsymbol{u}\|_2 < \lambda$ or $\|\boldsymbol{u}\|_2 = \lambda$.

If $\|\boldsymbol{u}\|_2 < \lambda$, then the KKT condition $\alpha(\|\boldsymbol{u}\|_2 - \lambda) = 0$, implies that $\alpha = 0$ must hold and $\boldsymbol{u}$ can be obtained immediately by solving the linear system $\boldsymbol{D}\boldsymbol{D}^T\boldsymbol{u} = \boldsymbol{D}\boldsymbol{y}$. This can be done in $O(n)$ time owing to the bidiagonal structure of $\boldsymbol{D}$. Conversely, if the solution to $\boldsymbol{D}\boldsymbol{D}^T\boldsymbol{u} = \boldsymbol{D}\boldsymbol{y}$ lies in the interior of the ball $\|\boldsymbol{u}\|_2 \leq \lambda$, then it solves (3.2). Therefore, this case is trivial, and we need to consider only the harder case $\|\boldsymbol{u}\|_2 = \lambda$.

For any given α one can obtain the corresponding vector $\boldsymbol{u}$ as $\boldsymbol{u}_\alpha = (\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I})^{-1}\boldsymbol{D}\boldsymbol{y}$. Therefore, optimizing for $\boldsymbol{u}$ reduces to the problem of finding the "true" value of α.

An obvious approach is to solve $\|\boldsymbol{u}_\alpha\|_2^2 = \lambda^2$. Less obvious is the *MSN equation*

$$h_\alpha := \lambda^{-1} - \|\boldsymbol{u}_\alpha\|_2^{-1} = 0, \tag{3.3}$$

which has the benefit of being almost linear in the search interval, which results in fast convergence (Moré and Sorensen, 1983). Thus, the task is to find the root of the function h_α, for which we use Newton's method, which in this case leads to the iteration

$$\alpha \leftarrow \alpha - h_\alpha / h'_\alpha. \tag{3.4}$$

Some calculation shows that the derivative h' can be computed as

$$\frac{1}{h'_\alpha} = \frac{\|\boldsymbol{u}_\alpha\|_2^3}{\boldsymbol{u}_\alpha^T(\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I})^{-1}\boldsymbol{u}_\alpha}. \tag{3.5}$$

The key idea in MSN is to eliminate the matrix inverse in (3.5) by using the Cholesky decomposition $\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I} = \boldsymbol{R}_\alpha^T\boldsymbol{R}_\alpha$ and defining a vector $\boldsymbol{q}_\alpha = (\boldsymbol{R}_\alpha^T)^{-1}\boldsymbol{u}$, so that $\|\boldsymbol{q}_\alpha\|_2^2 = \boldsymbol{u}_\alpha^T(\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I})^{-1}\boldsymbol{u}_\alpha$. As a result, the Newton iteration (3.4) becomes

$$\begin{aligned} \alpha - \frac{h_\alpha}{h'_\alpha} &= \alpha - (\|\boldsymbol{u}_\alpha\|_2^{-1} - \lambda^{-1}) \cdot \frac{\|\boldsymbol{u}_\alpha\|_2^3}{\boldsymbol{u}_\alpha^T(\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I})^{-1}\boldsymbol{u}_\alpha}, \\ &= \alpha - \frac{\|\boldsymbol{u}_\alpha\|_2^2 - \lambda^{-1}\|\boldsymbol{u}_\alpha\|_2^3}{\|\boldsymbol{q}_\alpha\|_2^2}, \\ &= \alpha - \frac{\|\boldsymbol{u}_\alpha\|_2^2}{\|\boldsymbol{q}_\alpha\|_2^2}\left(1 - \frac{\|\boldsymbol{u}_\alpha\|_2}{\lambda}\right), \end{aligned}$$

and therefore

$$\alpha \quad \leftarrow \quad \alpha - \frac{\|\boldsymbol{u}_\alpha\|_2^2}{\|\boldsymbol{q}_\alpha\|_2^2}\left(1 - \frac{\|\boldsymbol{u}_\alpha\|_2}{\lambda}\right). \tag{3.6}$$

As shown for TV-L$_1$ (Appendix E), the tridiagonal structure of $(\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I})$ allows one to compute both $\boldsymbol{R}_\alpha$ and $\boldsymbol{q}_\alpha$ in linear time, so the overall iteration runs in $O(n)$ time.

Algorithm 4 MSN based TV-L2 proximity

Initialize: $\alpha = 0$, $\boldsymbol{u}_\alpha = 0$.
while $\left|\|\boldsymbol{u}_\alpha\|_2^2 - \lambda\right| > \epsilon_\lambda$ **or** $\text{gap}(\boldsymbol{u}_\alpha) > \epsilon_{\text{gap}}$ **do**
  Compute Cholesky decomp. $\boldsymbol{D}\boldsymbol{D}^T + \alpha\boldsymbol{I} = \boldsymbol{R}_\alpha^T\boldsymbol{R}_\alpha$.
  Obtain $\boldsymbol{u}_\alpha$ by solving $\boldsymbol{R}_\alpha^T\boldsymbol{R}_\alpha\boldsymbol{u}_\alpha = \boldsymbol{D}\boldsymbol{y}$.
  Obtain $\boldsymbol{q}_\alpha$ by solving $\boldsymbol{R}_\alpha^T\boldsymbol{q}_\alpha = \boldsymbol{u}_\alpha$.
  $\alpha = \alpha - \frac{\|\boldsymbol{u}_\alpha\|_2^2}{\|\boldsymbol{q}_\alpha\|_2^2}\left(1 - \frac{\|\boldsymbol{u}_\alpha\|_2}{\lambda}\right)$.
end while
return $\boldsymbol{u}_\alpha$

Algorithm 5 GP algorithm for TV-L$_2$ proximity

Initialize $\boldsymbol{u}^0 \in \mathbb{R}^N$, $t = 0$.
while ($\neg$ converged) **do**
  Gradient update: $\boldsymbol{v}^t = \boldsymbol{u}^t - \frac{1}{4}\nabla f(\boldsymbol{u}^t)$.
  Projection: $\boldsymbol{u}^{t+1} = \max(1 - \lambda/\|\boldsymbol{v}^t\|_2, 0) \cdot \boldsymbol{v}^t$.
  $t \leftarrow t + 1$.
end while
return $\boldsymbol{u}^t$.

The above ideas are presented as pseudocode in Algorithm 4. As a stopping criterion two conditions are checked: whether the duality gap is small enough, and whether $\boldsymbol{u}$ is close enough to the boundary. This latter check is useful because intermediate solutions could be dual-infeasible, thus making the duality gap an inadequate optimality measure on its own. In practice we use tolerance values $\epsilon_\lambda = 10^{-6}$ and $\epsilon_{\text{gap}} = 10^{-5}$.

Even though Algorithm 4 requires only linear time per iteration, it is fairly sophisticated, and in fact a much simpler method can be devised. This is illustrated here by a gradient-projection method with a *fixed* stepsize α_0, whose iteration is

$$\boldsymbol{u}^{t+1} = P_{\|\cdot\|_2 \leq \lambda}(\boldsymbol{u}^t - \alpha_0\nabla\phi(\boldsymbol{u}^t)). \tag{3.7}$$

The theoretically ideal choice for the stepsize α_0 is given by the inverse of the Lipschitz constant L of the gradient $\nabla\phi(\boldsymbol{u})$ (Nesterov, 2007; Beck and Teboulle, 2009). Since $\phi(\boldsymbol{u})$ is a convex quadratic, L is simply the largest eigenvalue of the Hessian $\boldsymbol{D}\boldsymbol{D}^T$. Owing to its special structure, the eigenvalues of the Hessian have closed-form expressions, namely $\lambda_i = 2 - 2\cos\left(\frac{i\pi}{n+1}\right)$ (for $1 \leq i \leq n$). The largest one is $\lambda_n = 2 - 2\cos\left(\frac{(n-1)\pi}{n}\right)$, which tends to 4 as $n \to \infty$; thus the choice $\alpha_0 = 1/4$ is a good and cheap approximation. Pseudocode showing the whole procedure is presented in Algorithm 5. Combining this with the fact that the projection $P_{\|\cdot\|_2 \leq \lambda}$ is also trivial to compute, the GP iteration (3.7) turns out to be very attractive. Indeed, sometimes it can even outperform the more sophisticated MSN method, though only for a very limited range of λ values. Therefore, in practice we recommend a hybrid of GP and MSN, as suggested by our experiments (see §5.2.1).

3.2. TV-Lp: Proximity for $\mathbf{Tv}_p^{1D}$

For TV-L_p proximity (for $1 < p < \infty$) the dual problem becomes

$$\min_{\boldsymbol{u}} \ \phi(\boldsymbol{u}) := \tfrac{1}{2}\|\boldsymbol{D}^T\boldsymbol{u}\|_2^2 - \boldsymbol{u}^T\boldsymbol{D}\boldsymbol{y}, \ \text{ s.t. } \|\boldsymbol{u}\|_q \leq \lambda, \tag{3.8}$$

where $q = 1/(1-1/p)$. Problem (3.8) is not particularly amenable to Newton-type approaches, as neither PN (Appendix E), nor MSN-type methods (§3.1) can be applied easily. It is partially amenable to gradient-projection (GP), for which the same update rule as in (3.7) applies, but unlike the $q = 2$ case, the projection step here is much more involved. Thus, to complement GP, we may favor the projection-free Frank-Wolfe (FW) method. As expected, the overall best performing approach is actually a hybrid of GP and FW. We summarize both choices below.

3.2.1. Efficient Projection onto the ℓ_q-ball

The problem of projecting onto the ℓ_q-norm ball is

$$\min_{\boldsymbol{w}} \quad d(\boldsymbol{w}) := \tfrac{1}{2}\|\boldsymbol{w}-\boldsymbol{u}\|_2^2, \quad \text{s.t. } \ \|\boldsymbol{w}\|_q \leq \lambda. \tag{3.9}$$

For this problem, it turns out to be more convenient to address its Fenchel dual

$$\min_{\boldsymbol{w}} \quad d^*(\boldsymbol{w}) := \tfrac{1}{2}\|\boldsymbol{w}-\boldsymbol{u}\|_2^2 + \lambda\|\boldsymbol{w}\|_p, \tag{3.10}$$

which is actually nothing but $\operatorname{prox}_{\lambda\|\cdot\|_p}(\boldsymbol{u})$. The optimal solution, say $\boldsymbol{w}^*$, to (3.9) can be obtained by solving (3.10), by using the Moreau-decomposition (A.6) which yields

$$\boldsymbol{w}^* = \boldsymbol{u} - \operatorname{prox}_{\lambda\|\cdot\|_p}(\boldsymbol{u}).$$

Projection (3.9) is computed many times within GP, so it is crucial to solve it rapidly and accurately. To this end, we first turn (3.10) into a differentiable problem and then derive a projected-Newton method following our approach presented in Appendix E.

Assume therefore, without loss of generality that $\boldsymbol{u} \geq 0$, so that $\boldsymbol{w} \geq 0$ also holds (the signs can be restored after solving this problem). Thus, instead of (3.10), we solve

$$\min_{\boldsymbol{w}} \quad d^*(\boldsymbol{w}) := \tfrac{1}{2}\|\boldsymbol{w}-\boldsymbol{u}\|_2^2 + \lambda\big(\textstyle\sum_i w_i^p\big)^{1/p} \quad \text{s.t. } \boldsymbol{w} \geq 0. \tag{3.11}$$

The gradient of d^* may be compactly written as

$$\nabla d^*(\boldsymbol{w}) = \boldsymbol{w} - \boldsymbol{u} + \lambda\|\boldsymbol{w}\|_p^{1-p}\boldsymbol{w}^{p-1}, \tag{3.12}$$

where $\boldsymbol{w}^{p-1}$ denotes elementwise exponentiation of $\boldsymbol{w}$. Elementary calculation yields

$$\begin{aligned}\tfrac{\partial^2}{\partial w_i \partial w_j} d^*(\boldsymbol{w}) &= \delta_{ij}\big(1 + \lambda(p-1)\big(\tfrac{w_i}{\|w\|_p}\big)^{p-2}\|\boldsymbol{w}\|_p^{-1}\big) + \lambda(1-p)\big(\tfrac{w_i}{\|w\|_p}\big)^{p-1}\big(\tfrac{w_j}{\|w\|_p}\big)^{p-1}\|\boldsymbol{w}\|_p^{-1} \\ &= \delta_{ij}\big(1 - c\hat{\boldsymbol{w}}_i^{p-2}\big) + c\bar{\boldsymbol{w}}_i\bar{\boldsymbol{w}}_j,\end{aligned}$$

where $c := \lambda(1-p)\|\boldsymbol{w}\|_p^{-1}$, $\hat{\boldsymbol{w}} := \boldsymbol{w}/\|\boldsymbol{w}\|_p$, $\bar{\boldsymbol{w}} := (\boldsymbol{w}/\|\boldsymbol{w}\|_p)^{p-1}$, and δ_{ij} is the Dirac delta. In matrix notation, this Hessian's diagonal plus rank-1 structure becomes apparent

$$\boldsymbol{H}(\boldsymbol{w}) = \operatorname{Diag}\big(1 - c\hat{\boldsymbol{w}}^{p-2}\big) + c\bar{\boldsymbol{w}}\cdot\bar{\boldsymbol{w}}^T \tag{3.13}$$

To develop an efficient Newton method it is imperative to exploit this structure. It is not hard to see that for a set of non-active variables $\bar{I}$ the reduced Hessian takes the form

$$\boldsymbol{H}_{\bar{I}}(\boldsymbol{w}) = \operatorname{Diag}\big(\mathbf{1} - c\hat{\boldsymbol{w}}_{\bar{I}}^{p-2}\big) + c\bar{\boldsymbol{w}}_{\bar{I}}\bar{\boldsymbol{w}}_{\bar{I}}^T. \tag{3.14}$$

With the shorthand $\Delta = \operatorname{Diag}\big(\mathbf{1} - c\hat{\boldsymbol{w}}_{\bar{I}}^{p-2}\big)$, the matrix-inversion lemma yields

$$\boldsymbol{H}_{\bar{I}}^{-1}(\boldsymbol{w}) = \big(\Delta + c\bar{\boldsymbol{w}}_{\bar{I}}\bar{\boldsymbol{w}}_{\bar{I}}^T\big)^{-1} = \Delta^{-1} - \frac{\Delta^{-1}c\bar{\boldsymbol{w}}_{\bar{I}}\bar{\boldsymbol{w}}_{\bar{I}}^T\Delta^{-1}}{1 + c\bar{\boldsymbol{w}}_{\bar{I}}^T\Delta^{-1}\bar{\boldsymbol{w}}_{\bar{I}}}. \tag{3.15}$$

Furthermore, since in PN the inverse of the reduced Hessian always operates on the reduced gradient, we can rearrange the terms in this operation for further efficiency; that is,

$$\boldsymbol{H}_{\bar{I}}(\boldsymbol{w})^{-1}\nabla_{\bar{I}}f(\boldsymbol{w}) = \boldsymbol{v}\odot\nabla_{\bar{I}}f(\boldsymbol{w}) - \frac{\big(\boldsymbol{v}\odot\bar{\boldsymbol{w}}_{\bar{I}}\big)\big(\boldsymbol{v}\odot\bar{\boldsymbol{w}}_{\bar{I}}\big)^T\nabla_{\bar{I}}f(\boldsymbol{w})}{1/c + \bar{\boldsymbol{w}}_{\bar{I}}\big(\boldsymbol{v}\odot\bar{\boldsymbol{w}}_{\bar{I}}\big)}, \tag{3.16}$$

where $\boldsymbol{v} := \big(\mathbf{1} - c\hat{\boldsymbol{w}}_{\bar{I}}^{p-2}\big)^{-1}$, and $\odot$ denotes componentwise product.

The relevant point of the above derivations is that the Newton direction, and thus the overall PN iteration can be computed in $O(n)$ time, which results in a highly effective solver.

3.2.2. Frank-Wolfe Algorithm for TV-L_p Proximity

The Frank-Wolfe (FW) algorithm (see e.g., Jaggi (2013) for a recent overview), also known as the conditional gradient method (Bertsekas, 1999) solves differentiable optimization problems over compact convex sets, and can be quite effective if we have access to a subroutine to solve linear problems over the constraint set.

The generic FW iteration is illustrated in Algorithm 6. FW offers an attractive strategy for TV-L_p because both the descent-direction as well as stepsizes can be computed easily. Specifically, to find the descent direction we need to solve

$$\min_{\boldsymbol{s}} \quad \boldsymbol{s}^T\left(\boldsymbol{D}\boldsymbol{D}^T\boldsymbol{u} - \boldsymbol{D}\boldsymbol{y}\right), \quad \text{s.t.} \quad \|\boldsymbol{s}\|_q \leq \lambda. \tag{3.17}$$

This problem can be solved by observing that $\max_{\|\boldsymbol{s}\|_q\leq 1}\boldsymbol{s}^T\boldsymbol{z}$ is attained by some vector $\boldsymbol{s}$ proportional to $\boldsymbol{z}$, of the form $|\boldsymbol{s}^*| \propto |\boldsymbol{z}|^{p-1}$. Therefore, $\boldsymbol{s}^*$ in (3.17) is found by taking $\boldsymbol{z} = \boldsymbol{D}\boldsymbol{D}^T\boldsymbol{u} - \boldsymbol{D}\boldsymbol{y}$, computing $\boldsymbol{s} = -\operatorname{sgn}(\boldsymbol{z})\odot|\boldsymbol{z}|^{p-1}$ and then rescaling $\boldsymbol{s}$ to meet $\|\boldsymbol{s}\|_q = \lambda$.

Algorithm 6 Frank-Wolfe (FW)

Inputs: f, compact convex set $\mathcal{D}$.
Initialize $\boldsymbol{x}_0 \in \mathcal{D}$, $t = 0$.
while stopping criteria not met **do**
  Find descent direction: $\min_{\boldsymbol{s}} \boldsymbol{s}\cdot\nabla f(\boldsymbol{x}_t)$ s.t. $\boldsymbol{s}\in\mathcal{D}$.
  Determine stepsize: $\min_\gamma f(\boldsymbol{x}_t + \gamma(\boldsymbol{s}-\boldsymbol{x}_t))$ s.t. $\gamma\in[0,1]$.
  Update: $\boldsymbol{x}_{t+1} = \boldsymbol{x}_t + \gamma(\boldsymbol{s}-\boldsymbol{x}_t)$
  $t \leftarrow t+1$.
end while
return $\boldsymbol{x}_t$.

The stepsize can also be computed in closed form owing to the objective function being quadratic. Note the update in FW takes the form $\boldsymbol{u} + \gamma(\boldsymbol{s} - \boldsymbol{u})$, which can be rewritten as $\boldsymbol{u} + \gamma\boldsymbol{d}$ with $\boldsymbol{d} = \boldsymbol{s} - \boldsymbol{u}$. Using this notation the optimal stepsize is obtained by solving

$$\min_{\gamma\in[0,1]} \tfrac{1}{2}\|\boldsymbol{D}^T(\boldsymbol{u} + \gamma\boldsymbol{d})\|_2^2 - (\boldsymbol{u} + \gamma\boldsymbol{d})^T\boldsymbol{D}\boldsymbol{y}.$$

A brief calculation on the above problem yields

$$\gamma^* = \min\left\{\max\left\{\hat{\gamma}, 1\right\}, 0\right\},$$

where $\hat{\gamma} = -(\boldsymbol{d}^T\boldsymbol{D}\boldsymbol{D}^T\boldsymbol{u} + \boldsymbol{d}^T\boldsymbol{D}\boldsymbol{y})/(\boldsymbol{d}^T\boldsymbol{D}\boldsymbol{D}^T\boldsymbol{d})$ is the unconstrained optimal stepsize. We note that following (Jaggi, 2013) we also check a "surrogate duality-gap"

$$g(\boldsymbol{x}) = \boldsymbol{x}^T\nabla f(\boldsymbol{x}) - \min_{\boldsymbol{s}\in\mathcal{D}} \boldsymbol{s}^T\nabla f(\boldsymbol{x}) = (\boldsymbol{x} - \boldsymbol{s}^*)^T\nabla f(\boldsymbol{x}),$$

at the end of each iteration. If this gap is smaller than the desired tolerance, the real duality gap is computed and checked; if it also meets the tolerance, the algorithm stops.

3.3. Prox Operator for TV-L$_\infty$

The final case is $\text{Tv}_\infty^{\text{1D}}$ proximity. We mention this case only for completeness. The dual to the prox-operator here is

$$\min_{\boldsymbol{u}} \quad \tfrac{1}{2}\|\boldsymbol{D}^T\boldsymbol{u}\|_2^2 - \boldsymbol{u}^T\boldsymbol{D}\boldsymbol{y}, \quad \text{s.t. } \|\boldsymbol{u}\|_1 \leq \lambda. \tag{3.18}$$

This problem can be again easily solved by invoking GP, where the only non-trivial step is projection onto the ℓ_1-ball. But the latter is an extremely well-studied operation (see e.g., Condat (2016); Liu and Ye (2009); Kiwiel (2008)), and so $O(n)$ time routines for this purpose are readily available. By integrating them in our GP framework an efficient prox solver is obtained.

4. Prox Operators for Multidimensional TV

We now move onto discussing how to use the efficient 1D-TV prox operators derived above within a prox-splitting framework to handle multidimensional TV (1.3) proximity.

4.1. Proximity Stacking

The basic composite objective (1.1) is a special case of the more general class of models where one may have several regularizers, so that we now solve

$$\min_{\boldsymbol{x}} \quad f(\boldsymbol{x}) + \sum\nolimits_{i=1}^{m} r_i(\boldsymbol{x}), \tag{4.1}$$

where each r_i (for $1 \leq i \leq m$) is lsc and convex.

Just like the basic problem (1.1), the more complex problem (4.1) can also be tackled via proximal methods. The key to doing so is to use *inexact proximal methods* along with a technique we should call **proximity stacking**. Inexact proximal methods allow one to use approximately computed prox operators without impeding overall convergence, while

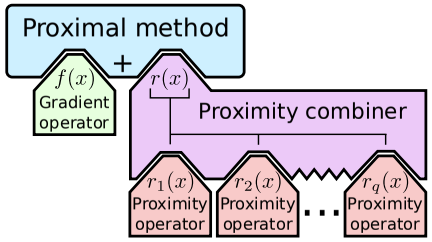

Figure 6: Design schema in proximal optimization for minimizing the function $f(\boldsymbol{x}) + \sum_{i=1}^m r_i(\boldsymbol{x})$. Proximal stacking makes the sum of regularizers appear as a single one to the proximal method, while retaining modularity in the design of each proximity step through the use of a combiner method. For non-smooth f the same schema applies by just replacing the f gradient operator by its corresponding proximity operator.

proximity stacking allows one to compute the prox operator for the entire sum $r(\boldsymbol{x}) = \sum_{i=1}^m r_i(\boldsymbol{x})$ by "stacking" the individual r_i prox operators. This stacking leads to a highly modular design; see Figure 6 for a visualization. In other words, proximity stacking involves computing the prox operator

$$\text{prox}_r(\boldsymbol{y}) := \operatorname*{argmin}_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|_2^2 + \sum\nolimits_{i=1}^{m} r_i(\boldsymbol{x}), \tag{4.2}$$

by iteratively invoking the individual prox operators prox_{r_i} and then combining their outputs. This mixing is done by means of a combiner method, which guarantees convergence to the solution of the overall $\text{prox}_r(\boldsymbol{y})$.

Different proximal combiners can used for computing prox_r (4.2). In what follows we briefly describe some of the possibilities. The crux of all of them is that their key steps will be proximity steps over the individual r_i terms. Thus, using proximal stacking and combination, any convex machine learning problem with multiple regularizers can be solved in a highly modular proximal framework. After this section we exemplify these ideas by applying them to two- and higher-dimensional TV proximity, which we then use within proximal solvers for addressing a wide array of applications.

4.1.1. Proximal Dykstra (PD)

The Proximal Dykstra method (Combettes and Pesquet, 2009) solves problems of the form

$$\min_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}) + r_2(\boldsymbol{x}),$$

which is a particular case of (4.2) for $m = 2$. The method follows the procedure detailed in Algorithm 7, which is guaranteed to converge to the desired solution. Using PD for proximal stacking for 2D Total-Variation was previously proposed in (Barbero and Sra, 2011).

It has also been shown that the application of this method is equivalent to performing alternating projections onto certain dual polytopes (Jegelka et al., 2013), a procedure whose

Algorithm 7 Proximal Dykstra

Inputs: r_1, r_2, input signal $\boldsymbol{y} \in \mathbb{R}^n$.
Initialize $\boldsymbol{x}_0 = \boldsymbol{y}$, $\boldsymbol{p}_0 = \boldsymbol{q}_0 = 0$, $t = 0$.
while stopping criteria not met **do**
  r_2 proximity operator: $\boldsymbol{z}_t = \text{prox}_{r_2}(\boldsymbol{x}_t + \boldsymbol{p}_t)$.
  r_2 step: $\boldsymbol{p}_{t+1} = \boldsymbol{x}_t + \boldsymbol{p}_t - \boldsymbol{z}_t$.
  r_1 proximity operator: $\boldsymbol{x}_{t+1} = \text{prox}_{r_1}(\boldsymbol{z}_t + \boldsymbol{q}_t)$.
  r_1 step: $\boldsymbol{q}_{t+1} = \boldsymbol{z}_t + \boldsymbol{q}_t - \boldsymbol{x}_{t+1}$.
  $t \leftarrow t + 1$.
end while
Return $\boldsymbol{x}_t$.

Algorithm 8 Parallel-Proximal Dykstra

Inputs: $r_1, \ldots, r_m$, input signal $\boldsymbol{y} \in \mathbb{R}^n$.
Initialize $\boldsymbol{x}_0 = \boldsymbol{y}$, $\boldsymbol{z}_0^i = 0$, for $i = 1, \ldots, m$; $t = 0$
while stopping criterion not met **do**
  for $i = 1$ to m in *parallel* **do**
    $\boldsymbol{p}_t^i = \text{prox}_{r_i}(\boldsymbol{z}_t^i)$
  end for
  $\boldsymbol{x}_{t+1} = \frac{1}{m}\sum_i \boldsymbol{p}_t^i$
  for $i = 1$ to m in *parallel* **do**
    $\boldsymbol{z}_{t+1}^i = \boldsymbol{x}_{t+1} + \boldsymbol{z}_t^i - \boldsymbol{p}_t^i$
  end for
  $t \leftarrow t + 1$
end while
Return $\boldsymbol{x}_t$

effectiveness varies depending on the relative orientation of such polytopes. A more efficient method based on reflections instead of projections is possible, as we will see below.

More generally, if more than two regularizers are present (i.e., $m > 2$), then it is more fitting to use *Parallel-Proximal Dykstra* (PPD) (Combettes, 2009) (see Alg. 8), a generalization obtained via the "product-space trick" of Pierra (1984). This parallel proximal method is attractive because it not only combines an arbitrary number of regularizers, but also allows parallelizing the calls to the individual prox operators. This feature allows us to develop a highly parallel implementation for multidimensional TV proximity (§4.3).

4.1.2. Alternating Reflections – Douglas-Rachford (DR)

The Douglas-Rachford (DR) method was originally devised for minimizing the sum of two (nonsmooth) convex functions (Combettes and Pesquet, 2009), in the form:

$$\min_{\boldsymbol{x}} \quad f_1(\boldsymbol{x}) + f_2(\boldsymbol{x}), \tag{4.3}$$

such that $(\text{ri dom } f_1) \cap (\text{ri dom } f_2) \neq \emptyset$. The method operates by iterating a series of reflections, and in its simplest form can be written as

$$\boldsymbol{z}_{k+1} = \tfrac{1}{2}\left[R_{f_1} R_{f_2} + I\right] \boldsymbol{z}_k, \tag{4.4}$$

where the *reflection operator* $R_\phi := 2\,\text{prox}_\phi - I$. This method is not cleanly applicable to problem (4.2) because of the squared norm term. Nevertheless in (Jegelka et al., 2013) a suitable transformation was proposed by making use of arguments from submodular optimization; a minimal background on this topic is given in Appendix A. We summarize the key ideas from (Jegelka et al., 2013) below.

Assume $m = 2$ and r_1, r_2 being Lovász extensions to some submodular functions (Total-Variation is the Lovász extension of a submodular graph-cut problem, see Bach (2013)). Defining $\hat{r}_1(\boldsymbol{x}) = r_1(\boldsymbol{x}) - \boldsymbol{x}^T\boldsymbol{y}$, $\hat{r}_1$ is also a Lovász extension of some submodular function (see Appendix A). Therefore, we may consider the problem

$$\text{prox}_r(\boldsymbol{y}) := \operatorname*{argmin}_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x}\|_2^2 + \hat{r}_1(\boldsymbol{x}) + r_2(\boldsymbol{x}),$$

which can be rewritten (using Proposition A.11) as

$$\min_{a,b} \|a - b\|_2, \quad \text{s.t.} \quad a \in -B_{\hat{r}_1},\, b \in B_{r_2}, \tag{4.5}$$

where B_r denotes the base polytope of submodular function corresponding to r (see Appendix A). The original solution can be recovered through $\boldsymbol{x} = \boldsymbol{a} - \boldsymbol{b}$. Problem (4.5) is still not in a form amenable to DR (4.3)—nevertheless, if we apply DR to the indicator functions of the sets $-B_{\hat{r}_1}, B_{r_2}$, that is, to the problem

$$\min_{\boldsymbol{x}} \quad \delta_{-B_{\hat{r}_1}}(\boldsymbol{x}) + \delta_{B_{r_2}}(\boldsymbol{x}),$$

it can be shown (Bauschke, 2004) that the sequence (4.4) generated by DR is divergent, but that after a correction through projection converges to the desired solution of (4.5). Such solution is given by the pair

$$\boldsymbol{b} = \Pi_{B_{r_2}}(\boldsymbol{z}_k), \quad \boldsymbol{a} = \Pi_{-B_{\hat{r}_1}}(\boldsymbol{b}). \tag{4.6}$$

Although in this derivation many concepts have been introduced, suprisingly all the operations in the algorithm can be reduced to performing proximity steps. Note first that the projections onto a base polytope required to get a solution (4.6) can be written in terms of proximity operators (Proposition A.12), which in this case implies

$$\Pi_{B_{r_2}}(\boldsymbol{z}) = \boldsymbol{z} - \text{prox}_{r_2}(\boldsymbol{z}),$$
$$\Pi_{-B_{\hat{r}_1}}(\boldsymbol{z}) = \boldsymbol{z} + \text{prox}_{\hat{r}_2}(-\boldsymbol{z}) = \boldsymbol{z} + \text{prox}_{r_2}(-\boldsymbol{z} + \boldsymbol{y}),$$

where we use the fact that for $f(\boldsymbol{x}) = \phi(\boldsymbol{x}) + \boldsymbol{u}^T\boldsymbol{x}$, $\text{prox}_f(\boldsymbol{x}) = \text{prox}_\phi(\boldsymbol{x} - \boldsymbol{u})$. The reflection operations in which the DR iteration is based (4.4) can also be written in terms of proximity steps, as we are applying DR to the indicator functions $\delta_{-B_{\hat{r}_1}}, \delta_{B_{r_2}}$, and proximity for an indicator function equals projection.

This alternating reflections variant of DR is presented in Algorithm 9. Note that in contrast with the original DR method, this variant does not require tuning any hyperparameters, thus enhancing its practicality.

Algorithm 9 Alternating reflections – Douglas Rachford (DR)

Inputs: r_1, r_2 Lovász extensions of some submodular function, input signal $\boldsymbol{y} \in \mathbb{R}^n$.
Initialize $\boldsymbol{z}_0 \in \mathbb{R}^n$, $t = 0$.
Define the following operations:
$\Pi_{-B_{\hat{r}_1}}(\boldsymbol{z}) \stackrel{\text{def}}{=} \boldsymbol{z} + \text{prox}_{r_1}(-\boldsymbol{z} + \boldsymbol{y})$.
$\Pi_{B_{r_2}}(\boldsymbol{z}) \stackrel{\text{def}}{=} \boldsymbol{z} - \text{prox}_{r_2}(\boldsymbol{z})$.
$R_{-B_{\hat{r}_1}}(\boldsymbol{z}) \stackrel{\text{def}}{=} 2\Pi_{-B_{\hat{r}_1}}(\boldsymbol{z}) - \boldsymbol{z}$.
$R_{B_{r_2}}(\boldsymbol{z}) \stackrel{\text{def}}{=} 2\Pi_{B_{r_2}}(\boldsymbol{z}) - \boldsymbol{z}$.
while stopping criteria not met **do**
$\boldsymbol{z}_{t+1} = \frac{1}{2}\left[R_{-B_{\hat{r}_1}} R_{B_{r_2}} + I\right] \boldsymbol{z}_k$
$t \leftarrow t + 1$.
end while
$\boldsymbol{b} = \Pi_{B_{r_2}}(z_t), \quad \boldsymbol{a} = \Pi_{-B_{\hat{r}_1}}(\boldsymbol{b})$.
Return $\boldsymbol{x}^* = \boldsymbol{a} - \boldsymbol{b}$.

4.1.3. Alternating-Direction Method of Multipliers (ADMM)

Although many times presented as a particular algorithm for solving problems involving the minimization of a certain objetive $f(x) + g(Lx)$ with L a linear operator (Combettes and Pesquet, 2009), the Alternating-Direction Method of Multipliers can be thought as a general splitting strategy for solving the unconstrained minimization of a sum of functions. This strategy boils down to transforming a problem in the form $\min_{\boldsymbol{x}} \sum_{i=1}^m f_i(\boldsymbol{x})$ into a saddle-point problem by introducing consensus constraints and incorporating them into the objective through augmented Lagrange multipliers,

$$\begin{aligned}\min_{\boldsymbol{x}} \quad \sum_{i=1}^m f_i(\boldsymbol{x}) &= \min_{\boldsymbol{x},\boldsymbol{z}_1,\ldots,\boldsymbol{z}_m} \quad \sum_{i=1}^m f_i(\boldsymbol{z}_i) \quad \text{s.t. } \boldsymbol{z}_1 = \boldsymbol{x}, \ldots, \boldsymbol{z}_m = \boldsymbol{x}, \\ &\equiv \min_{\boldsymbol{x},\boldsymbol{z}_1,\ldots,\boldsymbol{z}_m} \max_{\boldsymbol{u}_1,\ldots,\boldsymbol{u}_m} \quad \sum_{i=1}^m \left(f_i(\boldsymbol{z}_i) + \boldsymbol{u}_i^T(\boldsymbol{z}_i - \boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{z}_i - \boldsymbol{x}\|_2 \right).\end{aligned}$$

The method then proceeds to solve this problem by alternating steps of minimization on $\boldsymbol{x}$, minimization on every $\boldsymbol{z}_i$, and a gradient step on every $\boldsymbol{u}_i$.

In (Yang et al., 2013) a proposal using this method was presented to solve m–dimensional anisotropic TV (1.3). This approach applies equally to the more general proximal stacking framework under discussion here (4.2), by the transformation

$$\begin{aligned}\text{prox}_r(\boldsymbol{y}) &:= \operatorname*{argmin}_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|_2^2 + \textstyle\sum_{i=1}^m r_i(\boldsymbol{x}), \\ &\equiv \min_{\boldsymbol{x},\boldsymbol{z}_1,\ldots,\boldsymbol{z}_m} \max_{\boldsymbol{u}_1,\ldots,\boldsymbol{u}_m} \quad \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|_2^2 + \sum_{i=1}^m \left(f_i(\boldsymbol{z}_i) + \boldsymbol{u}_i^T(\boldsymbol{z}_i - \boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{z}_i - \boldsymbol{x}\|_2 \right).\end{aligned}$$

The steps for obtaining a solution then follow as Algorithm 10. Similar to Parallel Proximal Dykstra, this approach allows computing the prox-operator of each function r_i in parallel.

Algorithm 10 Alternating Direction Method of Multipliers (ADMM)

Inputs: $r_1, \ldots, r_m$, input signal $\boldsymbol{y} \in \mathbb{R}^n$.
Initialize $\boldsymbol{x}_0 = \boldsymbol{z}_0^i = \boldsymbol{y}$ for $i = 1, \ldots, m$; $t = 0$
while stopping criterion not met **do**
$\boldsymbol{x}_{t+1} = \frac{\boldsymbol{y} + \sum_{i=1}^m (\boldsymbol{u}_t^i + \rho \boldsymbol{z}_t^i)}{1 + m\rho}$.
for $i = 1$ to m in *parallel* **do**
$\boldsymbol{z}_t^i = \text{prox}_{\frac{\lambda}{\rho} r_i}(-\frac{1}{\rho}\boldsymbol{u}_t^i + \boldsymbol{x}_{t+1})$
$\boldsymbol{u}_{t+1}^i = \boldsymbol{u}_{t+1} + \rho(\boldsymbol{z}_{t+1}^i - \boldsymbol{x}_{t+1})$
end for
$t \leftarrow t + 1$
end while
Return $\boldsymbol{x}_t$

4.1.4. Dual Proximity Methods

Another family of approaches to solve (4.2) is to compute the global proximity operator using the Fenchel duals $\text{prox}_{r_i^*}$. This can be advantageous in settings where the dual prox-operator is easier to compute than the primal operator; isotropic Total-Variation problems are an instance of such a setting, and thus investigating this approach for their anisotropic variants is worthwhile.

Indeed, in the context of image processing a popular splitting approach is given by Chambolle and Pock (2011), which consider a problem in the form

$$\min_{\boldsymbol{x}} \quad F(\boldsymbol{K}\boldsymbol{x}) + G(\boldsymbol{x}),$$

for $\boldsymbol{K}$ some linear operator, F, G convex lower-semicontinuous functions. Through a strategy similar to ADMM an equivalent saddle point problem can be obtained,

$$\min_{\boldsymbol{x}} \max_{\boldsymbol{y}} \quad (\boldsymbol{K}\boldsymbol{x})^T\boldsymbol{y} + G(\boldsymbol{x}) - F^*(\boldsymbol{y}),$$

with F^* convex conjugate of F. This problem is then solved by alternating maximization on $\boldsymbol{y}$ and minimization on $\boldsymbol{x}$ through proximity steps, as

$$\begin{aligned}\boldsymbol{y}_{t+1} &= \text{prox}_{\sigma F^*}(\boldsymbol{y}_t + \sigma \boldsymbol{K}\bar{\boldsymbol{x}}_t) \\ \boldsymbol{x}_{t+1} &= \text{prox}_{\tau G}(\boldsymbol{x}_t - \tau \boldsymbol{K}^*\boldsymbol{y}_{t+1}) \\ \bar{\boldsymbol{x}}_{t+1} &= \boldsymbol{x}_{t+1} + \theta(\boldsymbol{x}_{t+1} - \boldsymbol{x}_t),\end{aligned}$$

where $\boldsymbol{K}^*$ is the conjugate transpose of $\boldsymbol{K}$. σ, τ and θ are algorithm parameters that should be either selected under some bounds (Chambolle and Pock, 2011, Algorithm 1) or readjusted every iteration making use of Lipschitz convexity of G (Chambolle and Pock, 2011, Algorithm 2), resulting in an accelerating scheme much in the style of FISTA (Beck and Teboulle, 2009). The overall procedure can also be shown to be an instance of preconditioned ADMM, where the preconditioning is given by the application of a proximity step for the maximization of $\boldsymbol{y}$ (instead of the usal dual gradient step of ADMM) and the auxiliary point $\bar{\boldsymbol{x}}$. Note also how proximity is computed over the dual F^* instead of the primal prox_F.

Now, this decomposition strategy can be applied for some instances of proximal stacking (4.2) when the r_i terms allow the particular composition

$$\sum_{i=1}^{m} r_i(\boldsymbol{x}) = F\left(\begin{bmatrix} \boldsymbol{K}_1 \\ \vdots \\ \boldsymbol{K}_m \end{bmatrix} \boldsymbol{x}\right) = F(\boldsymbol{K}\boldsymbol{x}),$$

which does not hold in general but holds for 2D TV (1.4) when taking the identities

$$F(\boldsymbol{x}) = \|\boldsymbol{x}\|_1, G(\boldsymbol{x}) = \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2,$$
$$\boldsymbol{K} = \begin{bmatrix} \boldsymbol{I}\otimes\boldsymbol{D} \\ \boldsymbol{D}\otimes\boldsymbol{I} \end{bmatrix},$$

with $\boldsymbol{D}$ the differencing matrix as before, $\otimes$ denotes Kronecker product, and $\boldsymbol{x}$ a vectorization of the 2D input. The iterates above can then be applied easily: proximity over G is trivial and proximity over F^* is also easy upon realizing that $\operatorname{prox}_{\|\cdot\|_1^*} = \operatorname{prox}_{\delta_{\|\cdot\|_\infty \le 1}} = \Pi_{\|\cdot\|_\infty \le 1}$, which is solved through thresholding.

A generalization of this approach is presented by Condat (2014), who considers

$$\min_{\boldsymbol{x}} \quad f(\boldsymbol{x}) + g(\boldsymbol{x}) + \sum_{i=1}^{m} r_i(\boldsymbol{L}_i\boldsymbol{x}),$$

a problem that cleanly fits into (4.2) with $f(\boldsymbol{x}) = \frac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2$, $g(\boldsymbol{x}) = 0$, $\boldsymbol{L} = \boldsymbol{I}$. The procedure to find a solution is proposed as

$$\begin{aligned}
\bar{\boldsymbol{x}}^{t+1} &= \operatorname{prox}_{\tau g^*}\left(\boldsymbol{x}^t - \tau\nabla f(\boldsymbol{x}^t) - \tau\sum_{i=1}^{m}\boldsymbol{L}_i^*\boldsymbol{u}_i^t\right) \\
\boldsymbol{x}_{n+1} &= \rho\bar{\boldsymbol{x}}^{t+1} + (1-\rho)\boldsymbol{x}^t \\
\bar{\boldsymbol{u}}_i^{t+1} &= \operatorname{prox}_{\sigma h_i^*}(\boldsymbol{u}_i^t + \sigma\boldsymbol{L}_i(2\bar{\boldsymbol{x}}_{t+1} - \boldsymbol{x}_t)) \quad \forall i = 1,\dots,m\,, \\
\boldsymbol{u}_i^{t+1} &= \rho\bar{\boldsymbol{u}}_i^{t+1} + (1-\rho)\boldsymbol{u}_i^t \quad \forall i = 1,\dots,m\,,
\end{aligned}$$

for τ, ρ parameters of the algorithm. When applying this procedure to 2D TV ($m = 2$, $r_1(\boldsymbol{x})$ = proximity over rows, $r_2(\boldsymbol{x})$ = proximity over columns) an algorithm almost equivalent to Chambolle and Pock (2011) is obtained, the only difference being that here the gradient of f is used, instead of the prox_G operation.

Yet another related method is the splitting approach of Kolmogorov et al (2015), which for $m = 2$ performs the following splitting:

$$\begin{aligned}
&\min_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}) + r_2(\boldsymbol{x}), \\
\equiv &\min_{\boldsymbol{x},\boldsymbol{x}'} \quad \|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}) + r_2(\boldsymbol{x}') \quad \text{s.t. } \boldsymbol{x} = \boldsymbol{x}', \\
\equiv &\min_{\boldsymbol{x},\boldsymbol{x}'}\max_{\boldsymbol{z}} \quad \|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}) + r_2(\boldsymbol{x}') + \boldsymbol{z}^T(\boldsymbol{x}-\boldsymbol{x}'), \\
\equiv &\min_{\boldsymbol{x}}\max_{\boldsymbol{z}} \quad \|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}) - r_2^*(\boldsymbol{z}) + \boldsymbol{x}^T\boldsymbol{z}.
\end{aligned}$$

where we have made use of the Fenchel dual $r_2^*(\boldsymbol{z}) = \max_{\boldsymbol{x}'} \boldsymbol{z}^T\boldsymbol{x}' - r_2(\boldsymbol{x}')$. This problem can be solved through a primal-dual minimization:

$$\begin{aligned}
\boldsymbol{z}^{t+1} &= \operatorname{prox}_{\sigma^t r_2^*}\left(\boldsymbol{z}^t + \sigma^t(\boldsymbol{x}^t + \theta^t(\boldsymbol{x}^t - \boldsymbol{x}^{t-1}))\right), \\
\boldsymbol{x}^{t+1} &= \operatorname{prox}_{\tau^t(\|\cdot-\boldsymbol{y}\|_2^2 + r_1)}\left(\boldsymbol{x}^t - \tau^t\boldsymbol{z}^{t+1}\right).
\end{aligned}$$

The primal proximity operator over the squared norm term plus r_1 can be rewritten in terms of $\operatorname{prox}_{r_1}$ as

$$\begin{aligned}
\operatorname{prox}_{\tau(r_1 + \frac{1}{2}\|\cdot-\boldsymbol{y}\|_2^2)}(\boldsymbol{w}) &= \operatorname*{argmin}_{\boldsymbol{x}} r_1(\boldsymbol{x}) + \frac{1+\tau^{-1}}{2}\|\boldsymbol{x} - (1+\tau^{-1})^{-1}(\boldsymbol{y} + \tau^{-1}\boldsymbol{w})\|_2^2, \\
&= \operatorname{prox}_{(1+\tau^{-1})^{-1}r_1}\left((1+\tau^{-1})^{-1}(\boldsymbol{y} + \tau^{-1}\boldsymbol{w})\right).
\end{aligned}$$

Regarding the dual step, in the previously presented methods the decompositions allowed to disentangle the effect of a linear operator L_i from each r_i. The present decomposition, however, does not take into account this possibility, thus increasing the complexity of computing r_2^*. To address this difficulty the Moreau decomposition (A.3) is helpful, as

$$\begin{aligned}
\operatorname{prox}_{\sigma r_2^*}(\boldsymbol{w}) &= \boldsymbol{w} - \sigma\left(\operatorname*{argmin}_{\boldsymbol{x}} r_2(\boldsymbol{x}) + \frac{\sigma}{2}\|\boldsymbol{x} - \sigma^{-1}\boldsymbol{w}\|_2^2\right), \\
&= \boldsymbol{w} - \sigma\operatorname{prox}_{\sigma^{-1}r_2}(\sigma^{-1}\boldsymbol{w}),
\end{aligned}$$

thus solving the dual proximity operator in terms of the primal $\operatorname{prox}_{r_2}$. Regarding the algorithm parameters θ, τ and σ, they can be adjusted at every iteration for greater performance making use of Lipschitz convexity (Chambolle and Pock, 2014).

Lastly, and again for $m = 2$, both r_1 and r_2 can be exploited in their dual forms as shown in Chambolle and Pock (2015) through the splitting

$$\begin{aligned}
&\min_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}) + r_2(\boldsymbol{x}), \\
\equiv &\min_{\boldsymbol{x},\boldsymbol{x}_1,\boldsymbol{x}_2} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}_1) + r_2(\boldsymbol{x}_2) \quad \text{s.t. } \boldsymbol{x} = \boldsymbol{x}_1, \boldsymbol{x} = \boldsymbol{x}_2 \\
\equiv &\min_{\boldsymbol{x},\boldsymbol{x}_1,\boldsymbol{x}_2}\max_{\boldsymbol{z}_1,\boldsymbol{z}_2} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + r_1(\boldsymbol{x}_1) + \boldsymbol{z}_1^T(\boldsymbol{x}-\boldsymbol{x}_1) + r_2(\boldsymbol{x}_2) + \boldsymbol{z}_2^T(\boldsymbol{x}-\boldsymbol{x}_2).
\end{aligned}$$

Minimizing this Lagrangian over $\boldsymbol{x}, \boldsymbol{x}_1, \boldsymbol{x}_2$ and making use of Fenchel duals we arrive at

$$\max_{\boldsymbol{z}_1,\boldsymbol{z}_2} \quad -\tfrac{1}{2}\|\boldsymbol{z}_1 + \boldsymbol{z}_2\|_2^2 - r_1^*(\boldsymbol{u}_1) - r_2(\boldsymbol{u}_2^*) + (\boldsymbol{u}_1 + \boldsymbol{u}_2)^T\boldsymbol{y},$$

which can be solved through an accelerated alternating minimization as

$$\begin{aligned}
t_{k+1} &= \frac{1 + \sqrt{1 + 4t_k^2}}{2}, \\
\bar{\boldsymbol{x}}^{k+1} &= \boldsymbol{x}_2^k + \frac{t_k - 1}{t_{k+1}}(\boldsymbol{x}_2^k - \boldsymbol{x}_2^{k-1}), \\
\boldsymbol{x}_1^{k+1} &= \operatorname{prox}_{r_1^*}(y - \bar{\boldsymbol{x}}_2^k), \\
\boldsymbol{x}_2^{k+1} &= \operatorname{prox}_{r_2^*}(y - \boldsymbol{x}_1^{k+1}),
\end{aligned}$$

where once again we can resort to the Moreau decomposition to compute the dual proximity operators.

4.2. Two-Dimensional TV

Recall that for a matrix $\boldsymbol{X} \in \mathbb{R}^{n_1 \times n_2}$, the anisotropic 2D-TV regularizer takes the form

$$\mathrm{Tv}^2_{p,q}(\boldsymbol{X}) := \sum_{i=1}^{n_1} \Big(\sum_{j=1}^{n_2-1} |x_{i,j+1} - x_{i,j}|^p \Big)^{1/p} + \sum_{j=1}^{n_2} \Big(\sum_{i=1}^{n_1-1} |x_{i+1,j} - x_{i,j}|^q \Big)^{1/q}. \quad (4.7)$$

This regularizer applies a $\mathrm{Tv}^{1\mathrm{D}}_p$ regularization over each row of $\boldsymbol{X}$, and a $\mathrm{Tv}^{1\mathrm{D}}_q$ regularization over each column. Introducing differencing matrices $\boldsymbol{D}_n$ and $\boldsymbol{D}_m$ for the row and column dimensions, the regularizer (4.7) can be rewritten as

$$\mathrm{Tv}^{2\mathrm{D}}_{p,q}(\boldsymbol{X}) = \sum_{i=1}^{n} \|\boldsymbol{D}_n \boldsymbol{x}_{i,:}\|_p + \sum_{j=1}^{m} \|\boldsymbol{D}_m \boldsymbol{x}_{:,j}\|_q, \quad (4.8)$$

where $\boldsymbol{x}_{i,:}$ denotes the i-th row of $\boldsymbol{X}$, and $\boldsymbol{x}_{:,j}$ its j-th column. The corresponding $\mathrm{Tv}^{2\mathrm{D}}_{p,q}$-proximity problem is

$$\min_{\boldsymbol{X}} \quad \tfrac{1}{2}\|\boldsymbol{X} - \boldsymbol{Y}\|^2_{\mathrm{F}} + \lambda\, \mathrm{Tv}^{2\mathrm{D}}_{p,q}(\boldsymbol{X}), \quad (4.9)$$

where we use the Frobenius norm $\|\boldsymbol{X}\|_{\mathrm{F}} = \sqrt{\sum_{ij} x^2_{i,j}} = \|\mathrm{vec}(\boldsymbol{X})\|_2$, where $\mathrm{vec}(\boldsymbol{X})$ is the vectorization of $\boldsymbol{X}$. Using (4.8), problem (4.9) becomes

$$\min_{\boldsymbol{X}} \quad \tfrac{1}{2}\|\boldsymbol{X} - \boldsymbol{Y}\|^2_{\mathrm{F}} + \lambda \Big(\sum\nolimits_i \|\boldsymbol{D}_n x_{i,:}\|_p \Big) + \lambda \Big(\sum\nolimits_j \|\boldsymbol{D}_m x_{:,j}\|_q \Big), \quad (4.10)$$

where the parentheses make explicit that $\mathrm{Tv}^{2\mathrm{D}}_{p,q}$ is a combination of two regularizers: one acting over the rows and the other over the columns. Formulation (4.10) fits the model solvable by the strategies presented above, though with an important difference: each of the two regularizers that make up $\mathrm{Tv}^{2\mathrm{D}}_{p,q}$ is itself composed of a sum of several (n or m) 1D-TV regularizers. Moreover, each of the 1D row (column) regularizers operates on a different row (columns), and can thus be solved independently.

4.3. Higher-Dimensional TV

Going even beyond $\mathrm{Tv}^{2\mathrm{D}}_{p,q}$ is the general multidimensional TV (1.3), which we recall below.

Let X be an order-m tensor in $\mathbb{R}^{\prod_{j=1}^m n_j}$, whose components are indexed as $\mathsf{X}_{i_1,i_2,\ldots,i_m}$ ($1 \le i_j \le n_j$ for $1 \le j \le m$); we define TV for X as

$$\mathrm{Tv}^m_{\boldsymbol{p}}(\mathsf{X}) \stackrel{\text{def}}{=} \sum_{k=1}^{m} \sum_{\{i_1,\ldots,i_m\}\setminus i_k} \Big(\sum_{j=1}^{n_k-1} |\mathsf{X}_{i_1,\ldots,i_{k-1},j+1,i_{k+1},\ldots,i_m} - \mathsf{X}_{i_1,\ldots,i_{k-1},j,i_{k+1},\ldots,i_m}|^{p_k} \Big)^{1/p_k}, \quad (4.11)$$

where $\boldsymbol{p} = [p_1, \ldots, p_m]$ is a vector of scalars $p_k \ge 1$. This corresponds to applying a 1D-TV to each of the 1D fibers of X along each of the dimensions.

Introducing the *multi-index* $\boldsymbol{i}(k) = (i_1, \ldots, i_{k-1}, i_{k+1}, \ldots, i_m)$, which iterates over every 1-dimensional fiber of X along the k-th dimension, the regularizer (4.11) can be written more compactly as

$$\mathrm{Tv}^m_{\boldsymbol{p}}(\mathsf{X}) = \sum_{k=1}^{m} \sum_{\boldsymbol{i}(k)} \|\boldsymbol{D}_{n_k} \boldsymbol{x}_{\boldsymbol{i}(k)}\|_{p_k}, \quad (4.12)$$

where $\boldsymbol{x}_{\boldsymbol{i}(k)}$ denotes a row of X along the k-th dimension, and $\boldsymbol{D}_{n_k}$ is a differencing matrix of appropriate size for the 1D-fibers along dimension k (of size n_k). The corresponding m-dimensional-TV proximity problem is

$$\min_{\mathsf{X}} \ \tfrac{1}{2}\|\mathsf{X} - \mathsf{Y}\|^2_{\mathrm{F}} + \lambda\, \mathrm{Tv}^m_{\boldsymbol{p}}(\mathsf{X}), \quad (4.13)$$

where $\lambda > 0$ is a penalty parameter, and the Frobenius norm for a tensor just denotes the ordinary sum-of-squares norm over the vectorization of such tensor.

Problem (4.13) looks very challenging, but it enjoys decomposability as suggested by (4.12) and made more explicit by writing it as a sum of $\mathrm{Tv}^{1\mathrm{D}}$ terms

$$\min_{\mathsf{X}} \ \tfrac{1}{2}\|\mathsf{X} - \mathsf{Y}\|^2_{\mathrm{F}} + \sum_{k=1}^{m} \sum_{\boldsymbol{i}(k)} \mathrm{Tv}^{1\mathrm{D}}_{p_k}\big(\boldsymbol{x}_{\boldsymbol{i}(k)}\big). \quad (4.14)$$

The proximity task (4.14) can be regarded as the sum of m proximity terms, each of which further decomposes into a number of inner $\mathrm{Tv}^{1\mathrm{D}}$ terms. These inner terms are trivial to address since, as in the 2D-TV case, each of the $\mathrm{Tv}^{1\mathrm{D}}$ terms operates on different entries of X. Regarding the m major terms, we can handle them by applying any of the combiner strategies presented above for $m > 2$, which ultimately yield the prox operator for $\mathrm{Tv}^m_{\boldsymbol{p}}$ by just repeatedly calling $\mathrm{Tv}^{1\mathrm{D}}$ prox operators. Most importantly, both proximal stacking and the natural decomposition of the problem provide a vast potential for parallel multithreaded computing, which is valuable when dealing with such complex and high-dimensional data.

5. Experiments and Applications

We will now demostrate the effectiveness of the various solvers covered in a wide array of experiments, as well as showing many of their practical applications. We will start by focusing on the $\mathrm{Tv}^{1\mathrm{D}}_1$ methods, moving then to other 1D-TV variants, and then to multidimensional TV.

All the solvers implemented for this paper were coded in C++ for efficiency. Our publicy available library **proxTV** includes all these implementations, plus bindings for easy usage in Matlab or Python: https://github.com/albarji/proxTV. Matrix operations have been implented by exploiting the LAPACK (Fortran) library (Anderson et al., 1999).

5.1. $\mathrm{Tv}^{1\mathrm{D}}_1$ Experiments and Applications

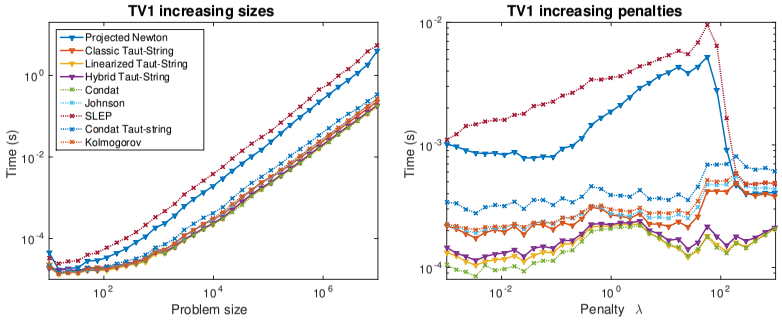
Since the most important components of the presented modular framework are the efficient $\mathrm{Tv}^{1\mathrm{D}}_1$ prox operators, let us begin by highlighting their empirical performance. We will do so both on synthetic and natural images data.

5.1.1. Running Time Results for Synthetic Data

We test the solvers under two scenarios of synthetic signals:

I) Increasing input size ranging from $n = 10^1$ to $n = 10^7$. A penalty $\lambda \in [0, 50]$ is chosen at random for each run, and the data vector $\boldsymbol{y}$ with uniformly random entries $y_i \in [-2\lambda, 2\lambda]$ (proportionally scaled to λ).

II) Varying penalty parameter λ ranging from 10^{-3} (negligible regularization) to 10^3 (the TV term dominates); here n is set to 1000 and y_i is randomly generated in the range $[-2, 2]$ (uniformly).



(a) (b)

Figure 7: Running times (in secs) for proposed and state of the art solvers for $\mathrm{Tv}_1^{1\mathrm{D}}$-proximity with increasing a) input sizes, b) penalties. Both axes are on a log-scale.

We benchmark the performance of the following methods, including both our proposals and state of the art methods found in the literature:

- Our proposed Projected Newton method (Appendix E).
- Our efficient implementation of the classic taut string method.
- Another implementation of the classic taut string method by Condat (2012).
- An implementation of the linearized taut string method.
- Our proposed hybrid taut string approach.
- The **FLSA** function (C implementation) of the SLEP library of Liu et al. (2009) for $\mathrm{Tv}_1^{1\mathrm{D}}$-proximity (Liu et al., 2010).
- The state-of-the-art method of Condat (2012), which we have seen to be equivalent to a linearized taut-string method.
- The dynamic programming method of Johnson (2013), which guarantees linear running time.
- The message passing method of Kolmogorov et al (2015), which allows generalization for computing a Total Variation regularizer on a tree.

Another implementation of the classic taut string method, found in the literature, has been added to the benchmark to test whether the implementation we have proposed is on par with the state of the art. We would like to note the surprising lack of widely available implementations of this method: the only working and efficient code we could find was part of the same paper where Condat's method was proposed.

For Projected Newton and SLEP a duality gap of 10^{-5} is used as the stopping criterion. For the hybrid taut-string method the switch parameter is set as $S = 1.05$. The rest of algorithms do not have parameters.

Timing results are presented in Figure 7 for both experimental scenarios. The following interesting facts are drawn from these results

- Direct methods (Taut string methods, Condat, Johnson, Kolmogorov) prove to be much faster than iterative methods (Projected Newton, SLEP).
- Although Condat's (and hence linearized taut string) method, has a theoretical worst-case performance of $O(n^2)$, the practical performance seems to follow an $O(n)$ behavior, at least for these synthetic signals.
- Even if Johnson and Kolmogorov methods have a guaranteed running time of $O(n)$, they turn out to be slower than the linearized taut string and Condat's methods. This is in line with our previous observations of the cache-friendly properties of in-memory methods; in contrast Johnson's method requires an extra $\sim 8n$ memory storage. Kolmogorov's method has less memory requirements but nevetheless shows similar behavior.
- The same performance observation applies to the classic taut string method. It is also noticeable that our implementation of this method turns out to be faster than previously available implementations (Condat's Taut-string), even becoming slightly faster than the state of the art Johnson and Kolmogorov methods. This result is surprising, and shows that the full potential of the classic taut-string method has been largely unexploited by the research community, or at least that proper efficient implementations of this method have not been made readily available so far.

5.1.2. Worst Case Scenario

The point about comparing $O(n)$ and $O(n^2)$ algorithms deserves more attention. As an illustrative experiment we have generated a signal following the worst case description in Condat (2012), and tested again the methods above on it, for increasing signal lengths. Figure 8 plots the results. Condat's method and consequently the linearized taut string method shows much worse performance than the rest of the direct methods. It is also remarkable how the hybrid method manages to avoid quadratic runtimes in this case.

5.1.3. Running Times on Natural Images

In the light of the previous results the following question arises: in practical settings, are the problems to be solved closer to the worst or the average runtime scenario? This fact will determine whether the guaranteed linear time or the more risky quadratic methods are more apt for practical use. To test this we devise the following experiment: we take a large benchmark of natural images and run each solver over all the rows and columns of all the images in the set, counting total running times, for different regularization values. The benchmark is made from images obtained from the data sets detailed in Table 2. We run this benchmark for the methods showing better performance in the experiments above: our implementation of the classic taut-string method, Condat's method ($\equiv$ linearized taut-string method), our proposed Hybrid taut-string method, Johnson's method and Kolmogorov et al's method.

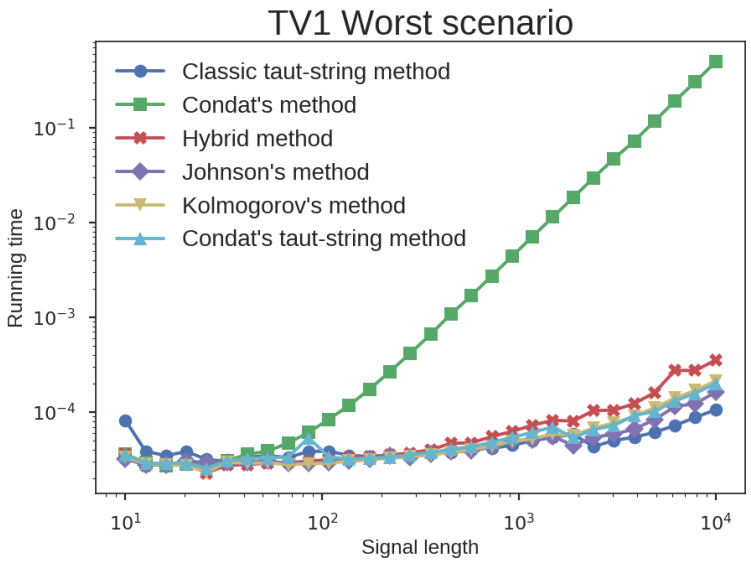


Figure 8: Running times (in secs) for proposed and state of the art solvers for Tv_1^{1D}-proximity in the worst-case scenario for Condat's method, for increasing input sizes. Both axes are on a log-scale.

Data set	Images	Average image size
INRIA holidays (Jegou et al, 2008)	812	1817 × 2233 × 3 px
LSVRC 2010 val set (Russakovsky et al, 2015)	50000	391 × 450 × 3 px

Table 2: Detail of image data sets used for large-scale Tv_1^{1D} experiments.

Figure 9 shows runtime results for different penalty values over the whole INRIA holidays data set (Jegou et al, 2008), while Figure 10 shows similar results for the whole Large Scale Visual Recognition Challenge 2010 validation data set (Russakovsky et al, 2015). The following facts of interest can be observed:

- Condat's method (linearized taut-string) shows top performance for low penalty values, but bad scaling when moving to higher penalties. This can be explained using the geometric intuition developed above: for large penalty values the width of the tube is very large, and thus the taut-string will be composed of very long segments.

This is troublesome for a linearized taut-string method, as each backtrack will require recomputing a large number of steps. On the contrary for smaller penalties the tube will be narrow, and the taut-string composed of many small segments, thus resulting in very cheap backtracking costs.

- The performance of Classic taut-string, Johnson and Kolmogorov becomes slightly worse for large penalties, but suffers significantly less than the linearized taut-string. Surprisingly, the best performing approach tends to be the classic taut-string method.

- The proposed hybrid strategy closely follows the performance of Condat's method for the low penalty regime, while adapting to a behaviour akin to Kolmogorov for large penalties, thus resulting in very good performances over the whole regularization spectrum.

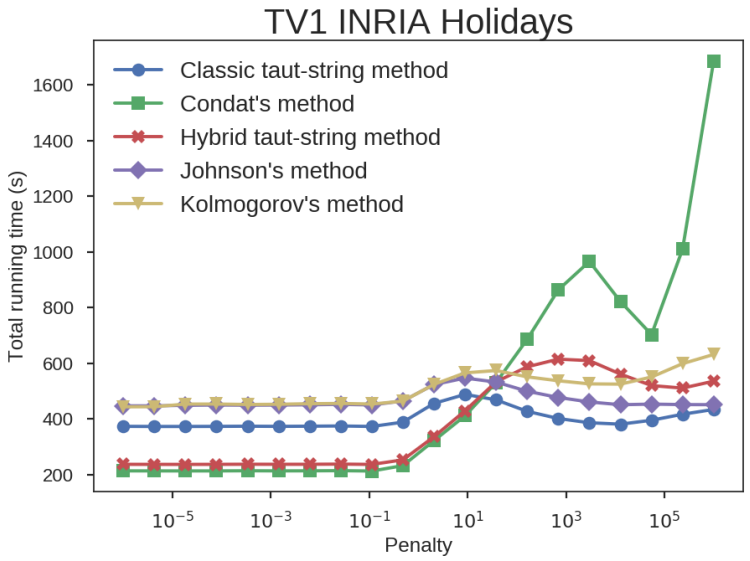

Figure 9: Running times (in secs) for the top performing proposed and state of the art solvers for Tv_1^{1D}-proximity over the whole INRIA Holidays data set, for increasing penalties.

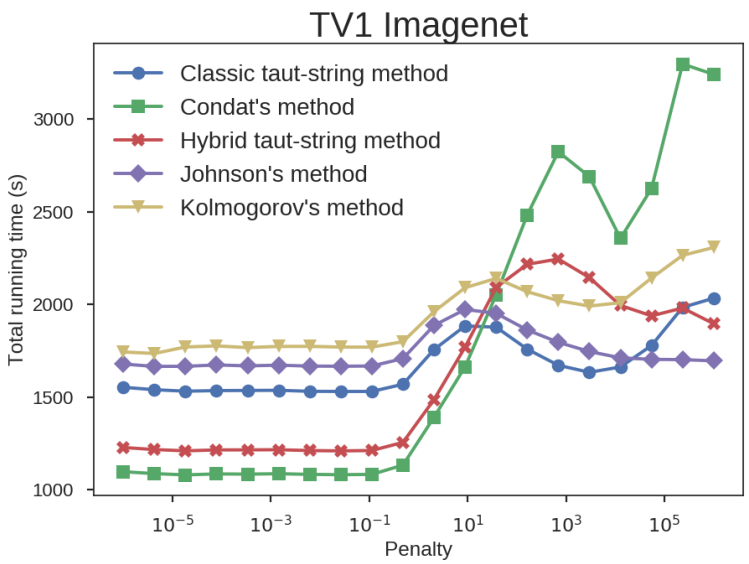

Figure 10: Running times (in secs) for the top performing proposed and state of the art solvers for $\mathrm{Tv}_1^{1\mathrm{D}}$-proximity over the whole Large Scale Visual Recognition Challenge 2010 validation data set, for increasing penalties.

5.1.4. Running Time Results for Weighted TV-L1

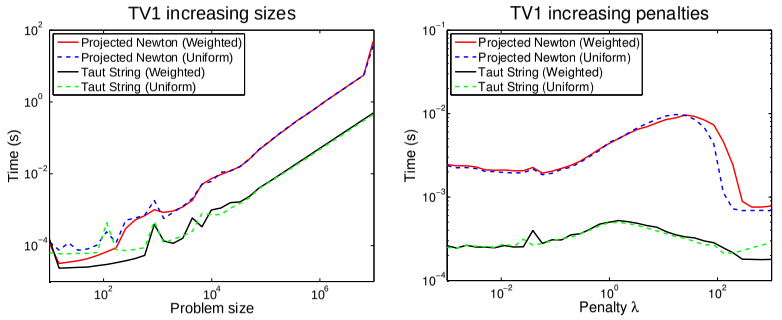
An advantage of the solvers proposed in this paper is their flexibility to easily deal with the more difficult, weighted version of the TV-L1 proximity problem. To illustrate this, Figure 11 shows the running times of the Projected Newton and (linearized) Taut String methods when solving both the standard and weighted TV-L1 prox operators.

Since for this set of experiments a whole vector of weights $\boldsymbol{w}$ is needed, we have adjusted the experimental scenarios as follows:

I) n is generated as in the general setting, penalties $\boldsymbol{w} \in [0, 100]$ are chosen at random for each run, and the data vector $\boldsymbol{y}$ with uniformly random entries $y_i \in [-2\lambda, 2\lambda]$, with λ the mean of $\boldsymbol{w}$, using also this λ choice for the uniform (unweighted) case.

II) λ and n are generated as in the general setting, and the weights vector $\boldsymbol{w}$ is drawn randomly from the uniform distribution $\boldsymbol{w}_i \in [0.5\lambda, 1.5\lambda]$.

As can be readily observed, performance for both versions of the problem is almost identical, even if the weighted problem is conceptually harder. Conversely, adapting the



(a) (b)

Figure 11: Running times (in secs) for Projected Newton and Taut String solvers for weighted and uniform $\mathrm{Tv}_1^{1\mathrm{D}}$-proximity with increasing a) input sizes, b) penalties. Both axes are on a log-scale.

other reviewed algorithms to address this problem while keeping up with performance is not a straightforward task.

We would also like to point out that in the paper Kumar et al (2015) a practical application of this method for energy minimization in computer vision is presented, where exactly the code behind this paper has been put to use.

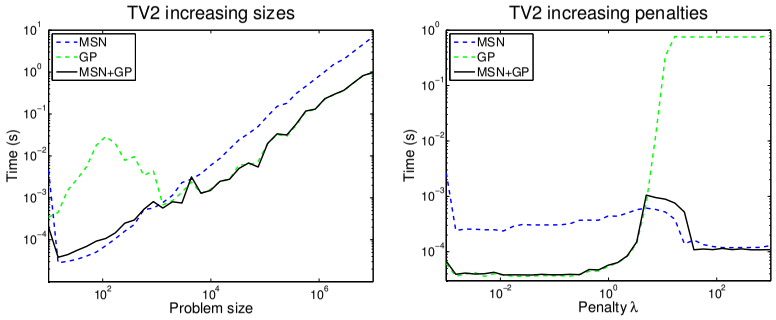
5.2. Experiments for other 1D-TV Variants

In this section we present experiments for other choices of the ℓ_p norm in $\mathrm{Tv}_p^{1\mathrm{D}}$, namely $p = 2$, $p = \infty$ and any general $p \geq 1$.

5.2.1. Running Time Results for TV-L2

Next we show results for $\mathrm{Tv}_2^{1\mathrm{D}}$ proximity. To our knowledge, this version of TV has not been explicitly treated before, so there do not exist highly-tuned solvers for it. Thus, we show running time results only for the MSN and GP methods. We use a duality gap of 10^{-5} as the stopping criterion; we also add an extra boundary check for MSN with tolerance 10^{-6} to avoid early stopping due to potentially infeasible intermediate iterates. Figure 12 shows results for the two experimental scenarios under test.

The results indicate that the performance of MSN and GP differs noticeably in the two experimental scenarios. While the results for the first scenario (Figure 12(a)) might suggest that GP converges faster than MSN for large inputs, it actually does so depending on the size of λ relative to $\|\boldsymbol{y}\|_2$. Indeed, the second scenario (Figure 12(b)) shows that although for small values of λ, GP runs faster than MSN, as λ increases, GP's performance worsens dramatically, so much that for moderately large λ, it is unable to find an acceptable solution even after 10,000 iterations (an upper limit imposed in our implementation). Conversely,



(a) (b)

Figure 12: Running times (in secs) for MSN, GP and a hybrid MSN+GP approach for $\mathrm{Tv}_2^{1\mathrm{D}}$-proximity with increasing a) input sizes, b) penalties. Both axes are on a log-scale.

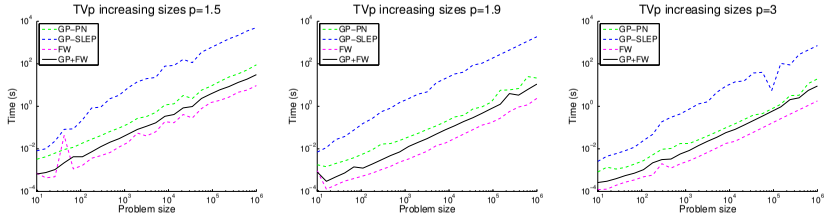
MSN finds a solution satisfying the stopping criterion under every situation, thus showing a more robust behavior.

These results suggest that it is preferable to employ a hybrid approach that combines the strengths of MSN and GP. Such a hybrid approach is guided using the following (empirically determined) rule of thumb: if $\lambda < \|\boldsymbol{y}\|_2$ use GP, otherwise use MSN. Further, as a safeguard, if GP is invoked but fails to find a solution within 50 iterations, the hybrid should switch to MSN. This combination guarantees rapid convergence in practice. Results for this hybrid approach are also included in the plots in Figure 12, and show how it successfully mimics the behavior of the better algorithm amongst MSN and GP.

5.2.2. Running Time Results for TV-Lp

Now we show results for $\mathrm{Tv}_p^{1\mathrm{D}}$ proximity. Again, to our knowledge efficient solvers for this version of TV are not available; still proposals for solving the ℓ_q-ball projection problem do exist. For these experiments we decided to use a method based on a zero finding approach readily available as the *epp* function in SLEP library (Liu et al., 2009). Consequently, we present here a comparison between this reference projection subroutine and our PN–based projection when embedded in our proposed Gradient Projection solver of §3.2. The alternative proposal given by the Frank–Wolfe algorithm of §3.2.2 is also present in the comparison. We use a duality gap of 10^{-5} as stopping criterion both for GP and FW. Figure 13 shows results for the two experimental scenarios under test, for p values of 1.5, 1.9 and 3.

A number of interesting conclusions can be drawn from the results. First, our Projected Newton ℓ_q-ball subroutine is far more efficient than *epp* when in the context of the GP solver. Two factors seem to be the cause of this: in the first place our Projected Newton



(a) (b) (c)

Figure 13: Running times (in secs) for GP with PN projection, GP with SLEP's *epp* projection, FW and a hybrid GP+FW algorithm, for $\mathrm{Tv}_p^{1\mathrm{D}}$-proximity with increasing input sizes and three different choices of p. Both axes are on a log-scale.

approach proves to be faster than the zero finding method used by *epp*. Secondly, in order for the GP solver to find a solution within the desired duality gap, the projection subroutine must provide very accurate results (about 10^{-12} in terms of duality gap). Given its Newton nature, our ℓ_q-ball subroutine scales better in term of running times as a factor of the desired accuracy, which explains he observed differences in performance.

It is also of relevance noting that Frank–Wolfe is significantly faster than Projected Newton. This should discourage the use of Projected Newton, but we find it to be extremely useful in the range of λ penalties where λ is large, but not enough to render the problem trivial ($\boldsymbol{w} = 0$ solution). In this range the two variants of PN and also FW are unable to find a solution within the desired duality gap (10^{-5}), getting stuck at suboptimal solutions. We solve this issue by means of a hybrid GP+FW algorithm, in which updates from both methods are interleaved at a ratio of 10 FW updates per 1 GP update, as FW updates are faster. As both algorithms guarantee improvement in each iteration but follow different procedures for doing so, they complement each other nicely, resulting in a superior method attaining the objective duality gap and performing faster than GP.

5.2.3. Running Time Results for TV-L∞

For completeness we also include results for our $\mathrm{Tv}_\infty^{1\mathrm{D}}$ solver based on GP + a standard ℓ_1-projection subroutine. Figure 15 presents running times for the two experimental scenarios under test. Since ℓ_1-projection is an easier problem than the general ℓ_q-projection the resultant algorithm converges faster to the solution than the general GP $\mathrm{Tv}_p^{1\mathrm{D}}$ prox solver, as expected.

5.2.4. Application: Proximal Optimization for Fused-Lasso

We now present a key application that benefits from our TV prox operators: **Fused-Lasso** (FL) (Tibshirani et al., 2005), a model that takes the form

$$\min_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{y}\|_2^2 + \lambda_1\|\boldsymbol{x}\|_1 + \lambda_2 \mathrm{Tv}_1^{1\mathrm{D}}(\boldsymbol{x}). \tag{5.1}$$

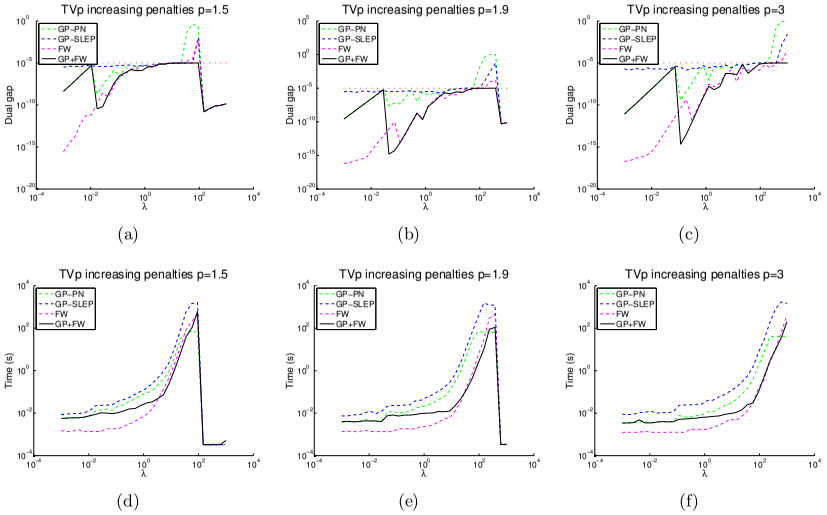


Figure 14: Attained duality gaps (a-c) and running times (d-f, in secs) for GP with PN projection, GP with SLEP's *epp* projection, FW and a hybrid GP+FW algorithm, for $\mathrm{Tv}_p^{1\mathrm{D}}$-proximity with increasing penalties and three different choices of p. Both axes are on a log-scale.

The ℓ_1-norm in (5.1) forces many x_i to be zero, while $\mathrm{Tv}_1^{1\mathrm{D}}$ favors nonzero components to appear in blocks of equal values $x_{i-1} = x_i = x_{i+1} = \ldots$. The FL model has been successfully applied in several bioinformatics applications (Tibshirani and Wang, 2008; Rapaport and Vert, 2008; Friedman et al., 2007), as it encodes prior knowledge about consecutive elements in microarrays becoming active at once.

Following the ideas presented in Sec. 4, since the FL model uses two regularizers, we can use Proximal Dykstra as the combiner to handle the prox operator. To illustrate the benefits of this framework in terms of reusability, we apply it to several variants of FL.

- **Fused-Lasso (FL):** Least-squares loss $+\ell_1 + \mathrm{Tv}_1^{1\mathrm{D}}$ as in (5.1)
- **ℓ_p-Variable Fusion (VF):** Least-squares loss $+\ell_1 + \mathrm{Tv}_p^{1\mathrm{D}}$. Though Variable Fusion was already studied by Land and Friedman (1997), their approach proposed an ℓ_p^p-like regularizer in the sense that $r(\boldsymbol{x}) = \sum_{i=1}^{n-1} |x_{i+1} - x_i|^p$ is used instead of the TV regularizer $\mathrm{Tv}_p^{1\mathrm{D}}(x) = \left(\sum_{i=1}^{n-1} |x_{i+1} - x_i|^p\right)^{1/p}$. Using Tv_p leads to a more conservative penalty that does not oversmooth the estimates. This FL variant seems to be new.

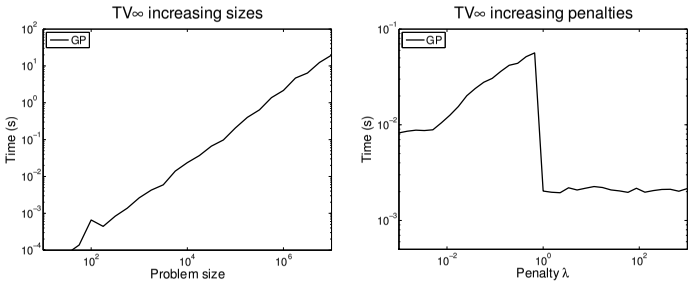

Figure 15: Running times (in secs) for GP for $\mathrm{Tv}_\infty^{1\mathrm{D}}$-proximity with increasing a) input sizes, b) penalties. Both axes are on a log-scale.

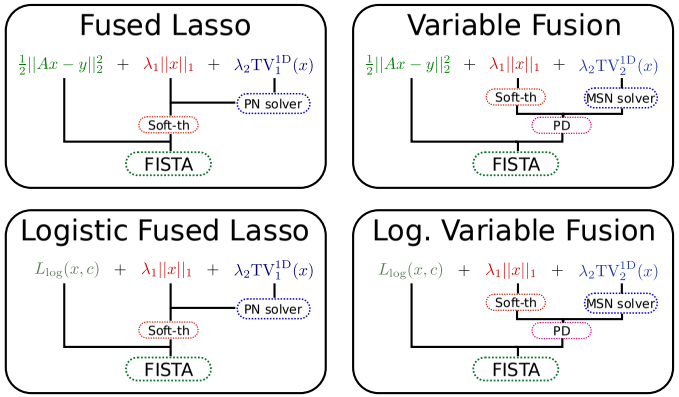

Figure 16: Fused-Lasso models addressed by proximal splitting.

- **Logistic-fused lasso (LFL):** Logistic-loss $+\ell_1 + \mathrm{Tv}_1^{1\mathrm{D}}$, where the loss takes the form $\ell(\boldsymbol{x}, c) = \sum_i \log\left(1 + e^{-y_i(\boldsymbol{a}_i^T \boldsymbol{x} + c)}\right)$, and can be used in a FL formulation to obtain models more appropriate for classification on a data set $\{(\boldsymbol{a}_i, y_i)\}$ (Kolar et al., 2010).
- **Logistic + ℓ_p-fusion (LVF):** Logistic loss $+\ell_1 + \mathrm{Tv}_p^{1\mathrm{D}}$.

To solve these variants of FL, all that remains is to compute the gradients of the loss functions, but this task is trivial. Each of these four models can be then solved easily by invoking any proximal splitting method by appropriately plugging in gradient and prox operators. Incidentally, the **SLEP** library (Liu et al., 2010) includes an implementation

of FISTA (Beck and Teboulle, 2009) carefully tuned for Fused Lasso, which we base our experiments on. Figure 16 shows a schematic of the algorithmic modules for solving each FL model.

Remark: A further algorithmic improvement can be obtained by realizing that for $r(\boldsymbol{x}) = \lambda_1\|\boldsymbol{x}\|_1 + \lambda_2 \mathrm{Tv}_1^{1\mathrm{D}}(\boldsymbol{x})$ the prox operator $\mathrm{prox}_r \equiv \mathrm{prox}_{\lambda_1\|\cdot\|_1} \circ \mathrm{prox}_{\lambda_2 \mathrm{Tv}_1^{1\mathrm{D}}(\cdot)}$. Such a decomposition does not usually hold, but it can be shown to hold for this particular case (Yu, 2013; Rinaldo, 2009; Tibshirani et al., 2005). Therefore, for FL and LFL we can compute the proximal operator for the combined regularizer r directly, thus removing the need for a combiner algorithm. This is also shown in Figure 16.

5.2.5. Fused-Lasso Experiments: Simulation

The standard FL model has been well-studied in the literature, so a number of practical algorithms addressing it have already been proposed. The aforementioned Fused-Lasso algorithm in the **SLEP** library can be regarded as the state of the art, making extensive use of an efficient proximity subroutine (FLSA). Our experiments on $\mathrm{Tv}_1^{1\mathrm{D}}$-proximity (§5.1) have already shown superiority of our prox solvers over FLSA; what remains to be checked is whether this benefit has a significant impact on the overall FL solver. To do so, we compare running times with synthetic data.

We generate random matrices $\boldsymbol{A} \in \mathbb{R}^{n\times m}$ with i.i.d. entries drawn from a zero mean, unit variance gaussian. We set the penalties to $\lambda_1 = \lambda_2 = 10$. We select the vector of responses $\boldsymbol{y}$ using the formula $\boldsymbol{y} = \mathrm{sgn}(\boldsymbol{A}\boldsymbol{x}_t + \boldsymbol{v})$, where $\boldsymbol{x}_t$, and $\boldsymbol{v}$ are random vectors whose entries have variances 1 and 0.01, respectively. The numerical results are summarized in Figure 17, which compares out of the box SLEP (version 4.0) (Liu et al., 2009) against the very same algorithm employing our fast taut–string $\mathrm{Tv}_1^{1\mathrm{D}}$ solver instead of the default FLSA subroutine of SLEP. Comparison is done by showing the relative distance to the problem's optimum versus time. The optimal values in each setting were estimated by running both algorithms for a very large number of iterations.

The plots show a clear trend: when the input matrices feature a very large column dimension the use of our taut-string $\mathrm{Tv}_1^{1\mathrm{D}}$ solver turns into speedups in optimization times, which however become negligible for matrices with a more balanced rows/columns ratio. This result is reasonable, as the vector x under optimization has size equal to the number of columns of the data matrix A. If A has a large number of columns the cost of solving $\mathrm{Tv}_1^{1\mathrm{D}}$ is significant, and thus any improvement in this step has a noticeable impact on the overall algorithm. Conversely, when the number of rows in A is large the cost of computing the gradient of the loss function ($\nabla \frac{1}{2}\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{y}\|_2^2 = \boldsymbol{A}^T(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{y})$) dominates, getting limited benefits from such improvements in prox computations. Therefore, it is for data with a very large number of features where our proposed method can provide a useful speedup.

5.2.6. Fused-Lasso Experiments: Microarray Classification

Now we report results of applying the four FL models on a series of problems from bioinformatics. We test the FL models on binary classification tasks for the following real microarray data sets: ArrayCGH (Stransky et al., 2006), Leukemias (Golub et al., 1999), Colon (U. Alon et al., 1999), Ovarian (Rogers et al., 2005) and Rat (Hua et al., 2009). Each data set was split into three equal parts (ensuring similar proportion of classes in every split) for

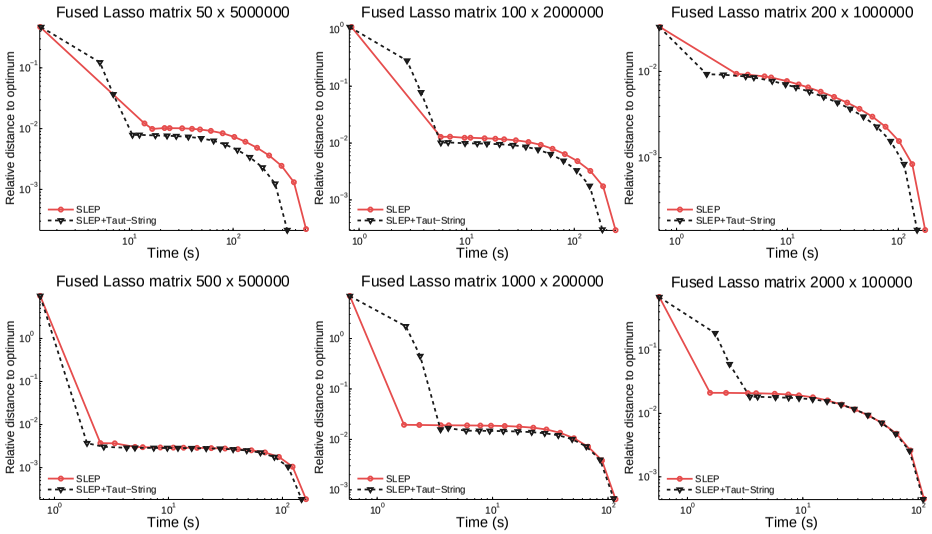

Figure 17: Relative distance to optimum vs time of the Fused Lasso optimizers under comparison, for the different layouts of synthetic matrices.

Data set	FL	VF-ℓ_2	LFL	LVF-ℓ_2
ArrayCGH	73.6%	73.6%	**84.2%**	73.6%
Leukemias	**92.0%**	88.0%	**92.0%**	88.0%
Colon	**77.2%**	**77.2%**	**77.2%**	**77.2%**
Ovarian	**88.8%**	83.3%	83.3%	83.3%
Rat	68.8%	65.5%	**72.1%**	**72.1%**

Table 3: Classification accuracies for the presented Fused–Lasso models on microarray data. For the Variable Fusion models an ℓ_2 version of TV was employed.

training, validation and test. The penalty parameters were found by exhaustive grid search in the range $\lambda_1, \lambda_2 \in [10^{-4}, 10^2]$ to maximize classification accuracy on the validation splits.

Table 3 shows test accuracies. In general, as expected the logistic-loss based FL models yield better classification accuracies than those based on least-squares, as such loss function tends to be more appropriate for classification problems. However the Ovarian data set proves to be an exception, showing better performance under a squared loss. Regarding

the TV-regularizer, the classic $\text{Tv}_1^{1\text{D}}$-penalty seems to perform better in general, with the $\text{Tv}_2^{1\text{D}}$-penalty showing competitive results in some settings.

5.3. 2D-TV: Experiments and Applications

We address now several practical applications that benefit from two-dimensional TV regularization; our results show again how the presented $\text{Tv}_{p,q}^{2\text{D}}$ prox operators fits in seamlessly into our modular framework to produce efficient proximal splitting solvers.

5.3.1. Image Denoising through Anisotropic Filtering

Our first example is related to the classic problem of image denoising, but with the twist that we deal with noise of an anisotropic character. More specifically, suppose that the true image $\mu \in \mathbb{R}^{n\times m}$ is contaminated by additive noise $\boldsymbol{N}$, so that only $\mu_0 = \mu + \boldsymbol{N}$ is observed. The denoising problem estimates μ given just the noisy version μ_0. This problem is highly ill-posed and as such not approachable unless additional assumptions on the noise (or on the underlying image) are made.

Isotropic and anisotropic models: an extremely common choice is to simply assume the noise to be gaussian, or some other zero-mean distribution. Under these conditions, a classic method to perform such denoising task is the **Rudin-Osher-Fatemi** (ROF) model (Rudin et al., 1992), which finds an approximation $\boldsymbol{X}$ to the original image by solving

$$\min_{\boldsymbol{X}} \quad \|\boldsymbol{X} - \mu_0\|_{\text{F}}^2 + \lambda \sum_{i=2}^{n}\sum_{j=2}^{m} \|\partial x_{i,j}\|_2, \tag{5.2}$$

where $\partial x_{i,j}$ is the *discrete gradient*

$$\partial x_{i,j} = \begin{bmatrix} x_{i,j} - x_{i-1,j} \\ x_{i,j} - x_{i,j-1} \end{bmatrix}.$$

That is, it is the vector of differences of $\boldsymbol{X}_{i,j}$ and its neighbors along both axes.

The objective of the first term in the ROF model is to penalize any deviation of $\boldsymbol{X}$ from the observed image μ_0, while the second term can be readily recognized as a mixed $(2,1)$-norm over the discrete gradient of $\boldsymbol{X}$. This regularizer models caters to some prior knowledge: in natural images sharp discontinuities in intensity between neighboring points only appear in borders of objects, while the rest of the pixels usually show smooth variations in intensity. It makes sense, therefore, to penalize large values of the gradient, as sharp changes have a higher probability of having being produced by noise. Conversely, as the mean of the noise is zero, it is also sensible to maintain the denoised image $\boldsymbol{X}$ close to the observed μ_0. Merging these two goals produces the ROF model (5.2).

A closer look at the ROF regularizer reveals that it follows the spirit of the reviewed 2D-TV regularizer which also penalizes sharp variations between neighboring pixels. Indeed, all such regularizers are broadly categorized as TV regularizers within the image processing community. It is clear, though, that the ROF regularizer (5.2) does not coincide with the $\text{Tv}_{p,q}^{2\text{D}}$ regularizer used in this paper. Some authors (Bioucas-Dias and Figueiredo, 2007) differentiate between these regularizers by naming the ROF approach as **isotropic TV** and the $\text{Tv}_{p,q}^{2\text{D}}$-style approach as **anisotropic TV**. This naming comes from the fact that

isotropic TV penalizes each component of the discrete gradient $\partial x_{i,j}$ following an ℓ_2 norm, whereas the anisotropic $\text{Tv}_{p,q}^{2\text{D}}$-norm and in particular $\text{Tv}_{1,1}^{2\text{D}}$-norm, penalize rows and columns independently.

While image filtering using isotropic TV is generally preferred for natural images denoising (Bioucas-Dias et al., 2006), in some settings anisotropic filtering can produce better results, and in fact has been favored by some authors in the past (Choksi et al., 2010; Li and Santosa, 1996). This is specially true on those images that present a "blocky" structure, and thus are better suited to the structure modeled by the $\text{Tv}_{p,q}^{2\text{D}}$-norm. Therefore, efficient methods to perform anisotropic filtering are also important.

Anisotropic denoising experiments: denoising using the anisotropic $\text{Tv}_{p,q}^{2\text{D}}$-norm reduces to solving

$$\min_{\boldsymbol{X}} \quad \|\boldsymbol{X} - \mu_0\|_{\text{F}}^2 + \lambda \text{Tv}_{p,q}^{2\text{D}}(\boldsymbol{X}). \tag{5.3}$$

But (5.3) is nothing but the $\text{Tv}_{p,q}^{2\text{D}}$-proximity problem, and hence can be directly solved by applying the 2D-TV prox operators described above. We solve (5.3) below for the choice $p = q = 1$ (which is common in practice), for the following selection of algorithms:

- Proximal Dykstra (§ 4.1.1)
- The Douglas-Rachford variant based on alternating projections (§ 4.1.2)
- The Split Bregman method of Goldstein T. (2009), which follows an ADMM–like approach to split the ℓ_1 norm apart from the discrete gradient operator, thus not requiring the use of a 1D-TV prox operator.
- Chambolle-Pock's method applied to 2D TV (§ 4.1.4).
- Condat's general splitting method (§ 4.1.4).
- Kolmogorov et al primal-dual method (§ 4.1.4).
- Yang's method (ADMM) (§ 4.1.3)
- The maximum flow approach by Goldfarb and Yin (2009), which shows the relationship between the 2D-TV proximity minimization and the maximum flow problem over a grid, and thus applies an efficient maximum flow method to solve a discrete-valued version of 2D-TV.

In Proximal Dykstra, Douglas-Rachford and ADMM we use the linearized taut–string strategy presented before as solver for the base proximity operators. All algorithm parameters were set as recommended in their corresponding papers or public implementations, except for Proximal Dykstra and Douglas-Rachford, which are parameter free. For Chambolle-Pock we tried both the scheme with fixed algorithm parameters (Chambolle and Pock, 2011, Algorithm 1) and the scheme with acceleration (Chambolle and Pock, 2011, Algorithm 2); however the accelerated version did not converge to the desired solution within enough accuracy (relative difference of 10^{-5}), therefore only the results for the fixed version are reported. For Kolmogorov we follow the recommendations in Chambolle and Pock (2014), taking into account the Lipschitz constants of the optimized functions and selecting the parameter updating strategy that produced faster performance in the experiments: $\theta^{t+1} = \frac{1}{\sqrt{1+\tau^t}}, \tau^{t+1} = \theta^{t+1}\tau^t, \sigma^{t+1} = \frac{\sigma^t}{\theta^{t+1}}, \theta^0 = 1, \tau^0 = \frac{1}{2}, \sigma^0 = 1$.

Image	Gaussian	Speckle	Poisson	Salt & Pepper
randomQR	0.2	0.3	∅	∅
shape	0.05	∅	∅	∅
trollface	∅	1	∅	∅
diagram	∅	∅	✓	∅
text	∅	∅	∅	0.1
comic	0.05	∅	✓	∅
contour	∅	∅	✓	0.4
phantom	∅	2	✓	∅

Table 4: Types of noise and parameters for each test image. A ∅ indicates that such noise was not applied for the image. *Gaussian* and *Speckle* correspond to gaussian additive and multiplicative (respectively) noises with zero mean and the indicated variance. *Salt & Pepper* noise turns into black or white the indicated fraction of image pixels. *Poisson* regenerates each pixel by drawing a random value from a Poisson distribution with mean equal to the original pixel value, thus producing a more realistic noise.

The images used in the experiments are displayed in Appendix F as Figure 25. To test the filters under a variety of scenarios, different kinds of noise were introduced for each image. Table 4 gives details on this, while the noisy images are shown in Figure 26. All QR barcode images used the same kind and parameters of noise. Noise was introduced using Matlab's *imnoise* function.

Values for the regularization parameter λ were found by maximizing the quality of the reconstruction, measured using **Improved Signal-to-Noise Ratio** (ISNR) (Afonso et al., 2010). ISNR is defined as

$$\mathrm{ISNR}(\boldsymbol{X}, \mu, \mu_0) = 10 \log_{10} \frac{\|\mu_0 - \boldsymbol{X}\|_{\mathrm{F}}^2}{\|\boldsymbol{X} - \mu\|_{\mathrm{F}}^2},$$

where μ is the original image, μ_0 its noisy variant, and $\boldsymbol{X}$ the reconstruction.

To compare the algorithms we run all of them for each image and measured its ISNR and relative distance to the optimal objective value of the current solution at each iteration through their execution. The only exception to this procedure is the method of Goldfarb and Yin, which is non–iterative and thus always returns an exact solution, and so we just measure the time required to finish. The optimal objective value was estimated by running all methods for a very large number of iterations and taking the minimum value of them all. This produced the plots shown in Figures 18–19. From them the following observations are of relevance:

- Condat's method and Chambolle-Pock's method are reduced to essentially the same algorithm when applied to the particular case of anisotropic 2D TV denoising. Furthermore, they seem to perform slowly when compared to other methods.
- ADMM (Yang's method) exhibits slow performance at the beginning, but when run for sufficient time is able to achieve a good approximation to the optimum.

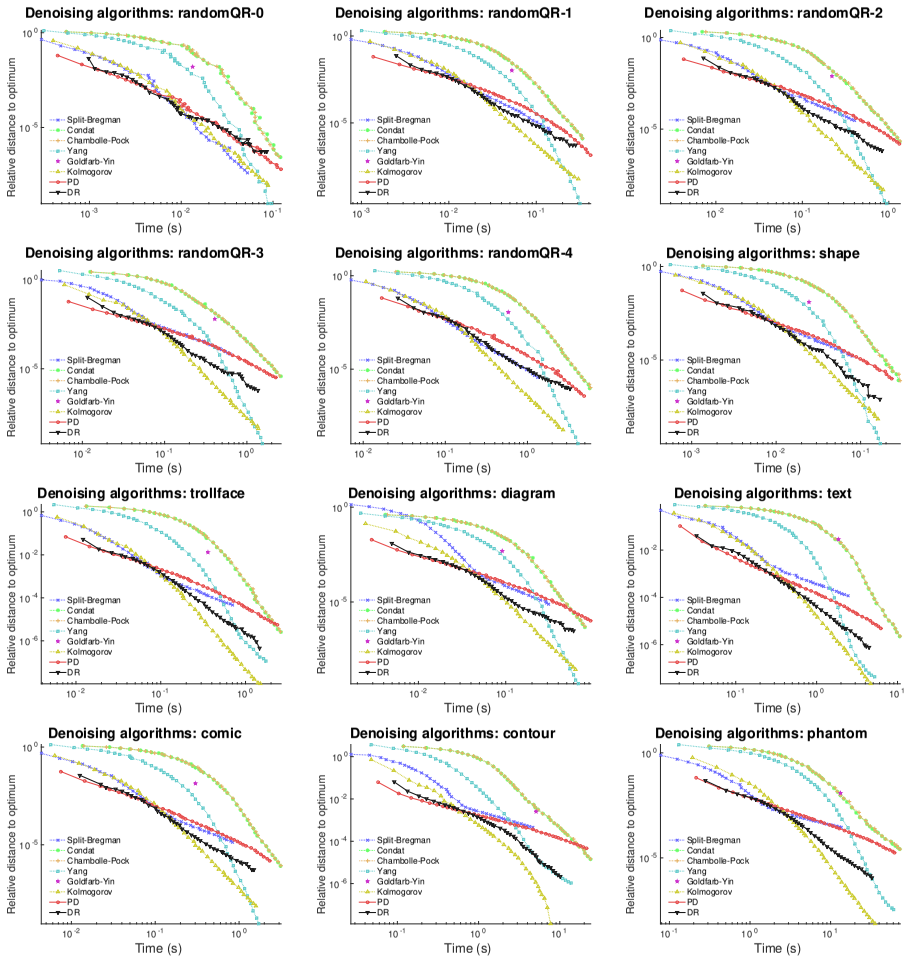

Figure 18: Relative distance to optimum vs time of the denoising 2D-TV algorithms under comparison, for the different images considered in the experiments.

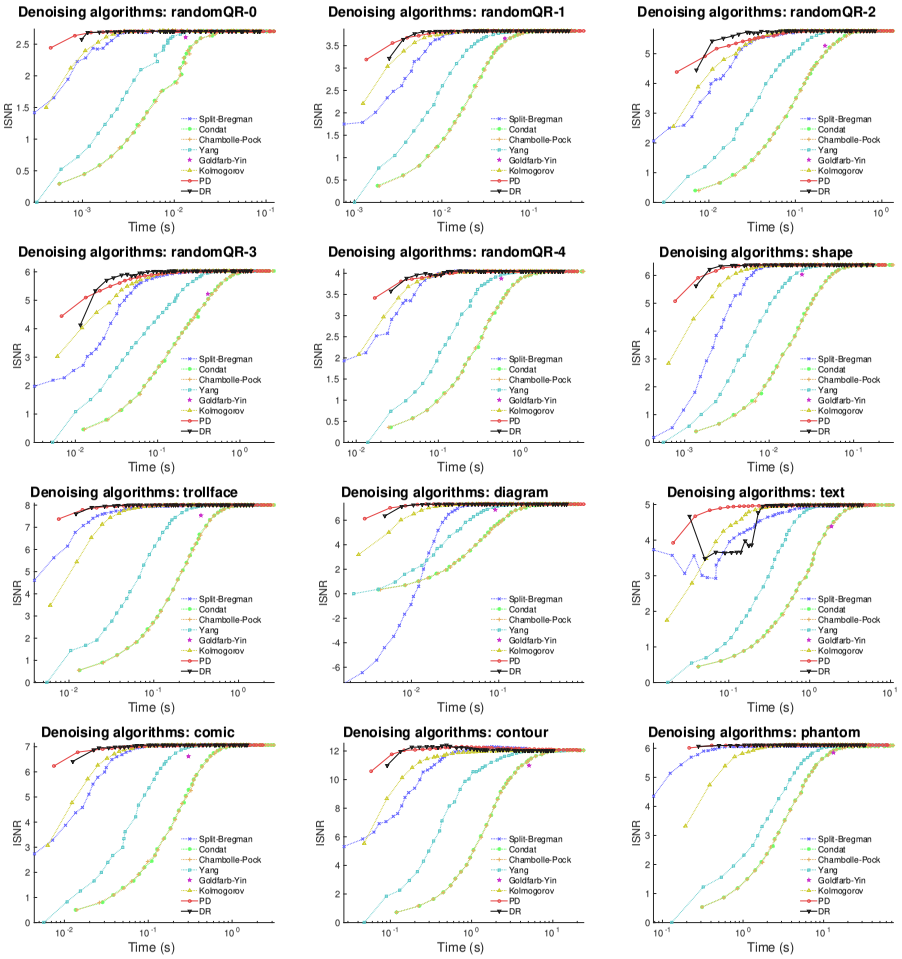

Figure 19: Increased Signal to Noise Ratio (ISNR) vs time of the denoising 2D-TV algorithms under comparison, for the different images considered in the experiments.

- The Split Bregman method, in spite of being an ADMM–like method much like Condat's or Chambolle-Pock, performs significantly better than those. We attribute this to the very efficient implementation provided by its authors, and to the fact that a fast approximate method is employed to compute the required matrix inversions throughout the method.

- The method by Goldfarb and Yin is slower than other approaches and seems to provide suboptimal solutions. We attribute this to the fact that this method solves a discrete (integer–rounded) approximation to the problem. We acknowledge that other methods exploiting the Total Variation - Minimum-cut relationship have been proposed with varying speed results, e.g. (Duan and Tai, 2012), however the suboptimality issues still apply.

- The method by Kolmogorov et al, when properly accelerated by a suitable choice of adaptive stepsizes, seems to be the best choice for finding very accurate solutions, though it is very closely followed by ADMM.

- The parameter free methods PD and DR are the fastest to achieve a mid-quality solution, with Douglas-Rachford performing better than Proximal Dykstra.

Considering these facts, the method of choice among the ones considered depends on the desired accuracy. We argue, however, that for the purpose of image processing a mid-quality solution is sufficient. The ISNR plots of Figure 19 certainly seem to support this, as the perceived quality of the reconstruction, roughly approximated by the ISNR, saturates rapidly and no significant improvements are obtained through further optimization. Given this, the proposed methods seem to be the best suited for the considered task.

For quick reference, Table 5 presents a summary of key points of the compared methods, along with some recommendations about when to put them to use.

5.3.2. Parallelization Experiments

In addition to the previous experiments and to illustrate the parallelization potential of the presented anisotropic filtering method, Figure 20 plots running times for the PD algorithm as the number of processor core ranges from 1 through 16. We see that for the smaller images, the gains due to more processors essentially flatten out by 8 cores, where synchronization and memory contention offsets potential computational gains (first row). For the larger images, there is steadier speedup as the number of cores increase (in each plot there seems to be a "bump" at 14 processors; we attribute this to a quirk of the multicore machine that we used). From all the plots, however, the message is clear: our TV prox operators exploit parallelization well, and show substantial speedups as more processor cores become available.

We should also note in passing that the Split Bregman method, which in the previous experiments showed a reasonable performance, turns out to be much harder to parallelize. This fact was already observed by Jie Wang et al. (2014) in the context of isotropic TV. Therefore when several processor cores are available the proposed modular strategy seems to be even more suitable to the task.

Method		Key points
Douglas Rachford	+	Fast convergence to medium-quality
	+	Embarrassingly parallel
	−	Slow for higher accuracies
	⇒	Ideal for standard denoising tasks
Proximal Dykstra	+	Attainable accuracies similar to DR
	−	But slower than DR
	⇒	Use DR instead
Split Bregman	+	Eventually performs similarly to DR
	−	Slow convergence at first iterations
	⇒	Use DR instead
Chambolle–Pock	−	Slow
	⇒	Use other method instead
Condat	+	Solves objectives involving a sum of smooth/non–smooth functions with linear operators
	−	Reduces to Chambolle–Pock when solving basic image denoising
	⇒	Use only when dealing with more complex functionals
ADMM (Yang)	+	More accurate
	−	Slightly slower than Kolmogorov
	−	Bad behavior for mid-quality solutions
	⇒	Use Kolmogorov instead
Kolmogorov	+	More accurate
	−	Slower than DR for low accuracies
	⇒	Useful when extremely accurate solutions are required
Goldfarb-Yin	+	Solves the discrete version of the problem
	−	Slow
	−	Poor accuracy for the continuous version
	⇒	Apply only when solving the discrete problem

Table 5: Summary of key points of the compared $\mathrm{Tv}^{\mathrm{2D}}_{1,1}$ proximity (denoising) methods.

5.3.3. Anisotropic Image Deconvolution

Taking a step forward we now confront the problem of **image deconvolution** (or image deblurring). This setting is more complex since the task of image recovery is made harder by the presence of a **convolution kernel** K that distorts the image as

$$\mu_0 = \boldsymbol{K} * \mu + \boldsymbol{N},$$

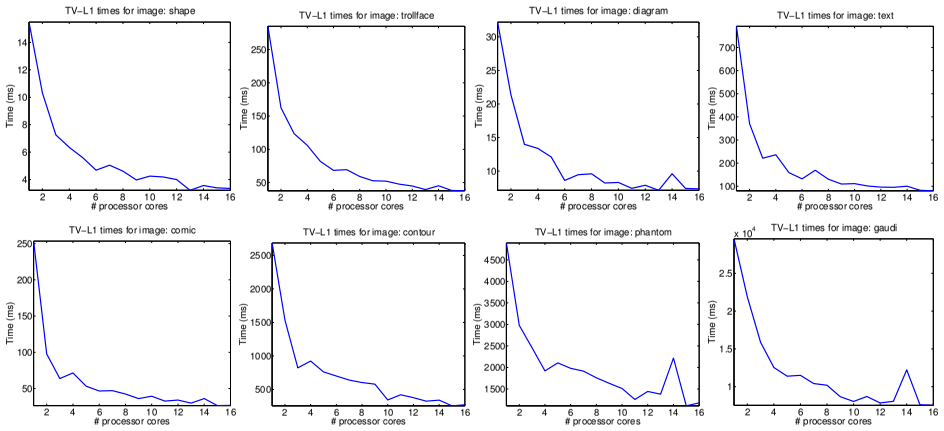

Figure 20: Multicore speedups on different images

where $\boldsymbol{N}$ is noise as before and $*$ denotes convolution. To recover the original image μ from the observed μ_0, it is common to solve the following deconvolution problem

$$\min_{\boldsymbol{X}} \quad \tfrac{1}{2}\|\boldsymbol{K} * \boldsymbol{X} - \mu\|_{\mathrm{F}}^2 + \lambda r(\boldsymbol{X}). \tag{5.4}$$

As before, the regularizer $r(\boldsymbol{X})$ can be isotropic or anisotropic TV, among others. Here we focus again on the anisotropic TV case to show how the presented solvers can also be used for this image task.

Problem (5.4) also fits the proximal splitting framework, and so we employ the popular FISTA (Beck and Teboulle, 2009) method for image processing. The gradient of the loss can be dealt efficiently by exploiting $\boldsymbol{K}$ being a convolution operator, which through the well–known convolution theorem is equivalent to a dot product in the frequencies space, and so the computation is done by means of fast Fourier transforms and products. Several other solvers that explicitly deal with convolution operators are also available (Afonso et al., 2010; Bioucas-Dias and Figueiredo, 2007). A notable solver specific for the isotropic case is given by the work of Krishnan and Fergus (2009), that handles even nonconvex isotropic TV-norms ($0 < p < 1$). But this approach does not extend to the anisotropic case, so we focus on general proximal splitting.

We use the same test images as for our denoising experiments (Figure 25), with identical noise patterns (Table 4) for the QR images, and gaussian noise with variance 0.05 for the rest. In addition, we convolve each image with a different type of kernel to assess the behavior for a variety of convolutions; Table 6 shows the kernels applied. We constructed these kernels using Matlab's *fspecial* function; the convolved images are shown in Figure 28.

The values for the regularizer λ were determined by maximizing the reconstruction quality measured in ISNR. Since deconvolution is much more expensive than denoising,

Image	Convolution	Parameters
randomQR	Motion	Length 5, Angle 35^o
shape	Average	Size 3×3
trollface	Disk	Radius 5
diagram	Motion	Length 5, Angle 0^o
text	Average	Size 1×10
comic	Gaussian	Size 15, Deviation 2
contour	Disk	Radius 5
phantom	Motion	Length 100, Angle 240^o

Table 6: Convolution kernels used for each test image. *Average* substitutes each pixel with the average of its surrounding $n \times m$ neighbors. *Disk* performs the same operation within a disk-shaped neighborhood of the shown radius. *Gaussian* uses a $n \times n$ neighborhood and assigns different weights to each neighbor following the value of a gaussian distribution of the indicated deviation centered at the current pixel. *Motion* emulates the distortions produced when taking a picture in motion, defining a neighborhood following a vector of the indicated length and angle.

instead of performing an exhaustive search for the best λ, we used a Focused Grid Search strategy (Barbero et al., 2008, 2009) to find the best performing values.

Any denoising subroutine can be plugged into the aforementioned deconvolution methods, however for comparison purposes we run our experiments with the best proposed method, Douglas Rachford (Alternating Reflections), and the best competing method among those reviewed from the literature, Kolmogorov et al. A key parameter in deconvolution performance is for how long should these methods be run at each FISTA iteration. To select this, we first run FISTA with 100 iterations of Douglas Rachford per step, for a large number of FISTA steps, and take the final objective value as an estimate of the optimum. Then we find the minimum number of Douglas Rachford and Kolmogorov iterations for which FISTA can achieve a relative distance to such optimum below 10^{-3}. The reason for doing this is that for larger distances the attained ISNR values are still far from convergence. This turned to be 5 iterations for Douglas Rachford an 10 for Kolmogorov. We then run FISTA for such configurations of the inner solvers, and others with a larger number of inner iterations, for comparison purposes.

Figures 21-22 show the evolution of objective values and ISNR for all the tested configurations. In general, Douglas Rachford seems to be slightly better at finding more accurate solutions, and also faster at converging to the final ISNR value. We explain this by the fact that the major advantage of Douglas Rachford is its aforementioned ability to find medium–quality solutions in a very small number of iterations: this is why with a small number of inner DR iterates we can converge to good ISRN levels.

For reference we also provide the resultant deconvoluted images as Figure 29.

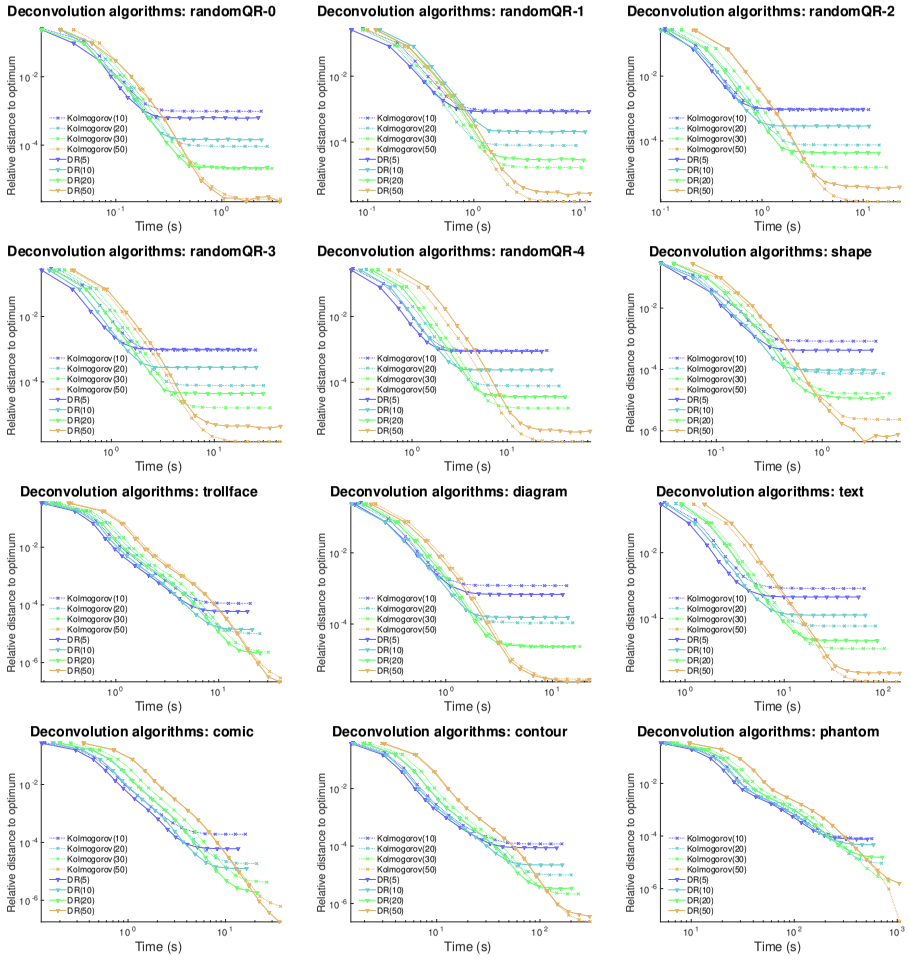

Figure 21: Relative distance to optimum vs time of the deconvolution 2D-TV algorithms under comparison, for the different images considered in the experiments.

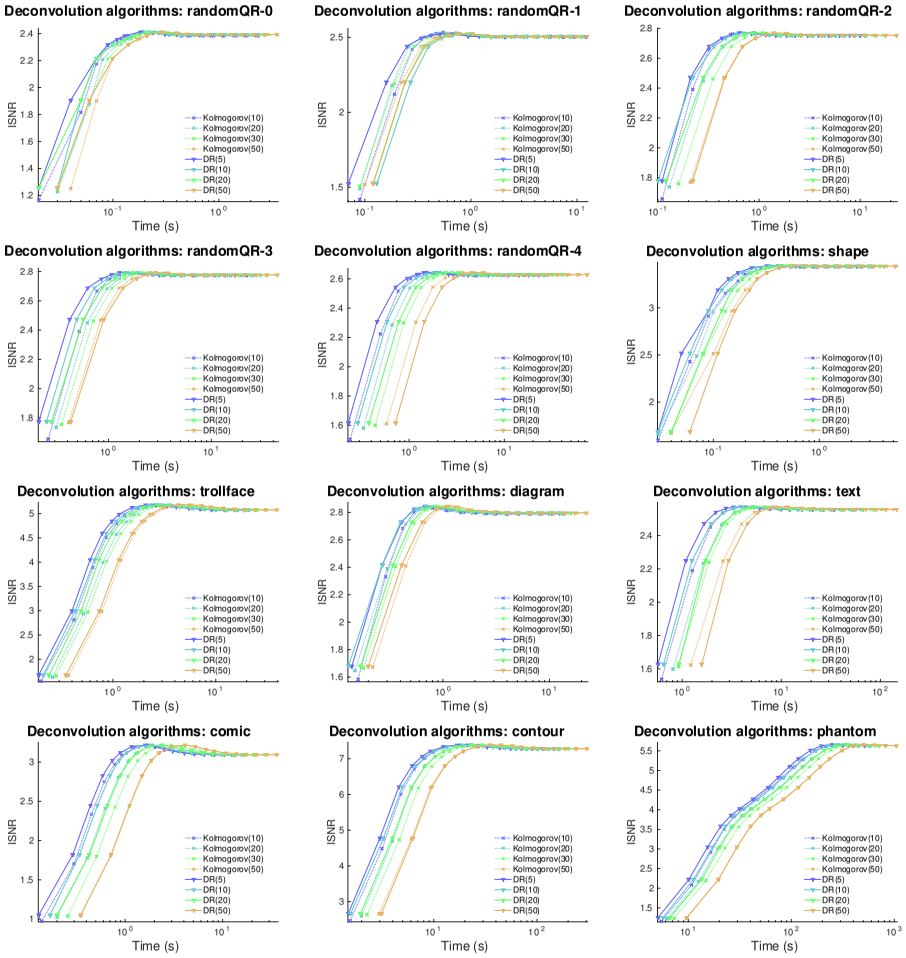

Figure 22: Increased Signal to Noise Ratio (ISNR) vs time of the deconvolution 2D-TV algorithms under comparison, for the different images considered in the experiments.

5.3.4. 2D Fused-Lasso Signal Approximator

The **Fused–Lasso Signal Approximator** (FLSA) (Friedman et al., 2007) can be regarded as a particular case of Fused-Lasso where the input matrix $\boldsymbol{A}$ is the identity matrix $\boldsymbol{I}$, i.e.,

$$\min_{\boldsymbol{x}} \quad \tfrac{1}{2}\|\boldsymbol{x}-\boldsymbol{y}\|_2^2 + \lambda_1\|\boldsymbol{x}\|_1 + \lambda_2 \mathrm{Tv}_1^{1\mathrm{D}}(\boldsymbol{x}).$$

This problem can be solved immediately using the methods presented in §5.2.4. A slightly less trivial problem is the one posed by the 2D variant of FLSA:

$$\min_{\boldsymbol{X}} \quad \tfrac{1}{2}\|\boldsymbol{X}-\boldsymbol{Y}\|_{\mathrm{F}}^2 + \lambda_1\|\mathrm{vec}(\boldsymbol{X})\|_1 + \lambda_2 \mathrm{Tv}_{1,1}^{2\mathrm{D}}(\boldsymbol{X}). \tag{5.5}$$

Friedman et al. (2007) used this model for denoising images where a large number of pixels are known to be completely black (intensity 0), which aligns well with the structure imposed by the ℓ_1 regularizer.

Akin to the 1D-case, 2D-FLSA (5.5) can also be solved by decomposing its computation into two prox operators (Friedman et al., 2007); formally,

$$\mathrm{prox}_{\lambda_1\|\cdot\|_1+\lambda_2\mathrm{Tv}_{1,1}^{2\mathrm{D}}(\cdot)}(\boldsymbol{Y}) = \mathrm{prox}_{\lambda_1\|\cdot\|_1}\big(\mathrm{prox}_{\lambda_2\mathrm{Tv}_{1,1}^{2\mathrm{D}}(\cdot)}(\boldsymbol{Y})\big).$$

Thus, to solve (5.5) we merely invoke one of the presented $\mathrm{Tv}_{1,1}^{2\mathrm{D}}$ prox operators and then apply soft-thresholding to the results. Since soft-thresholding is done in closed form, the performance of a 2D-FLSA solver depends only on its ability to compute $\mathrm{Tv}_{1,1}^{2\mathrm{D}}$-proximity efficiently. We can then safely claim that the results summarized in table 5 apply equivalently to 2D-FLSA, and so the proposed Douglas Rachford method performs best when reconstruction ISNR is the primary concern.

5.4. Application of Higher-Dimensional TV

We now apply the presented multidimensional TV regularizer to anisotropic filtering for **video denoising**. The extension to videos from images is natural. Say a video contains f frames of size $n \times m$ pixels; this video can be viewed as a 3D-tensor $\mathsf{X} \in \mathbb{R}^{n\times m\times f}$, on which a 3D-TV based filter can be effected by

$$\min_{\mathsf{X}} \quad \tfrac{1}{2}\|\mathsf{X}-\mathsf{U}_0\|_{\mathrm{F}}^2 + \lambda \mathrm{Tv}_{p_1,p_2,p_3}^{3\mathrm{D}}(\mathsf{X}), \tag{5.6}$$

where U_0 is the observed noisy video, and $\mathrm{Tv}_{p_1,p_2,p_3}^{3\mathrm{D}} = \mathrm{Tv}_{\boldsymbol{p}}^3$ with $\boldsymbol{p} = [p_1, p_2, p_3]$. Application of the filter (5.6) is nothing but computation of the prox operator, which can be done using the Parallel-Proximal Dykstra (PPD) algorithm presented in Sec. 4.

We apply this idea to the video sequences detailed in Table 7. All of the sequences are made of grayscale pixels. Figure 30 in the Appendix shows some of the frames of the *salesman* sequence. We noise every frame of these sequences by applying gaussian noise with zero mean and variance 0.01, using Matlab's *imnoise* function. Then we solve problem 5.6 for each sequence, adjusting the regularization value so as to maximize ISNR of the reconstructed signal. We test the following algorithms, which have been previously applied in the literature for solving 3D-TV, with the only exception Parallel Proximal Dykstra:

- Parallel Proximal Dykstra (§ 4.1.1).

Sequence	Frame resolution	Number of frames	Total number of pixels
salesman	288 × 352	50	5 million
coastguard	176 × 144	300	7.6 million
bicycle	720 × 576	30	12.4 million

Table 7: Size details of video sequences used in the video denoising experiments.

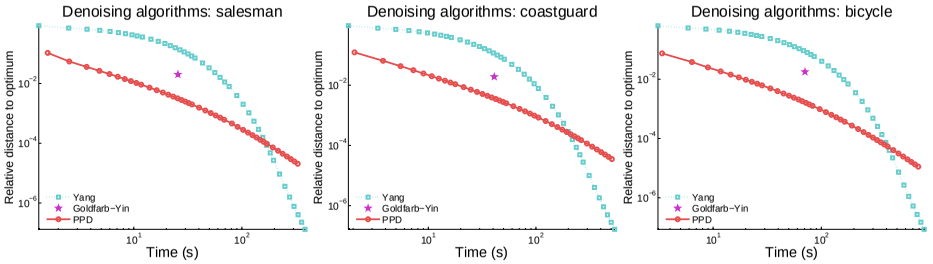

Figure 23: Relative distance to optimum vs time of the denoising 3D-TV algorithms under comparison, for the different video sequences considered in the experiments.

- Yang's method, which is based on ADMM (§ 4.1.1)
- The maximum flow approach by Goldfarb and Yin (2009), which features an implementation for 3D grids, thus solving a discrete-valued version of 3D-TV.

For both PPD and ADMM we again make use of linearized taut-string 1D TV solver. We must also point out that other image denoising methods seem amenable for extension into the multidimensional setting, such as Condat's and Chambolle-Pock methods. However in the light of our image denoising results we do not deem them as good choices for this problem. A more reasonable choice might be to extend Split-Bregman to multiple dimensions, but such an extension has not been implemented or proposed as far as we know. We would also like to note that we have considered extending the Douglas Rachford method to a multidimensional setting, however such task is complex and thus we decided to focus on Parallel Proximal Dykstra.

Similarly to our previous image denoising experiments, we ran the algorithms under comparison for each video sequence and measured its ISNR and relative distance to the optimal objective value of the current solution at each iteration through their execution. Again the exception is the Goldfarb-Yin method, which is non–iterative and so we only report the time required for its termination. The optimal objective value was estimated by running all methods for a very large number of iterations and taking the minimum value of them all. This produced the plots shown in Figures 23–24. From them the following observations are of relevance:

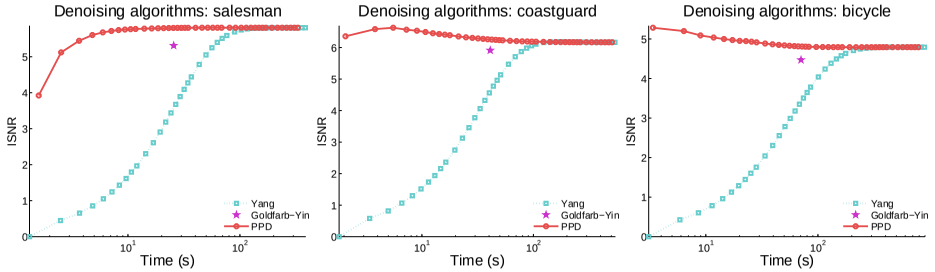

Figure 24: Increased Signal to Noise Ratio (ISNR) vs time of the denoising 3D-TV algorithms under comparison, for the different video sequences considered in the experiments.

- Following the pattern observed in the image denoising experiments, ADMM (Yang's method) is best suited for finding very accurate solutions.
- The method by Goldfarb and Yin again provides suboptimal solutions, due to the discrete approximation it uses.
- Parallel Proximal Dykstra is the fastest to achieve a mid-quality solution.
- Intermediate solutions prior to convergence of the PPD run result in better ISNR values for the *coastguard* and *bicycle* data sets. This hints that the denoising model used in this experiment may not be optimal for these kind of signals; indeed, more advanced denoising models abound in the signal processing literature. Hence we do not claim novel results in terms of ISNR quality, but just in solving this classic denoising model more efficiently.

The ISNR plots in Figure 24 also show how both Parallel Proximal Dykstra and ADMM (Yang's method) converge to equivalent solutions in practice. Therefore, for the purpose of video denoising PPD seems to be the best choice, unless for some reason a high degree of accuracy is required, for which ADMM should be preferred.

Acknowledgments

We thank R. Tibshirani for bringing (Johnson, 2013) to our attention, and S. Jegelka for alerting us to the importance of weighted total-variation problems.

Appendix A. Mathematical Background

We begin by recalling a few basic ideas from convex analysis; we recommend the recent book (Bauschke and Combettes, 2011) for more details.

Let $\mathcal{X} \subset \mathbb{R}^n$ be any set. A function $r : \mathcal{X} \to \mathbb{R} \cup \{-\infty, +\infty\}$ is called *lower semicontinuous* if for every $\boldsymbol{x} \in \mathcal{X}$ and a sequence $(\boldsymbol{x}_k)$ that converges to $\boldsymbol{x}$, it holds that

$$\boldsymbol{x}_k \to \boldsymbol{x} \implies r(\boldsymbol{x}) \leq \liminf_k r(\boldsymbol{x}_k). \tag{A.1}$$

The set of proper lsc convex functions on $\mathcal{X}$ is denoted by $\Gamma_0(\mathcal{X})$ (such functions are also called *closed convex functions*). The *indicator function* of a set C is defined as

$$\delta_C : \mathcal{X} \to [0, \infty] : \boldsymbol{x} \mapsto \begin{cases} 0, & \text{if } \boldsymbol{x} \in C; \\ \infty, & \text{if } \boldsymbol{x} \notin C, \end{cases} \tag{A.2}$$

which is lsc if and only if C is closed.

The *convex conjugate* of r is given by $r^*(\boldsymbol{z}) := \sup_{\boldsymbol{x} \in \operatorname{dom} r} \langle \boldsymbol{x}, \boldsymbol{z} \rangle - r(\boldsymbol{x})$, and a particularly important example is the Fenchel conjugate of a norm $\|\cdot\|$

$$\text{if } r = \|\cdot\|, \quad \text{then } \; r^* = \delta_{\|\cdot\|_* \leq 1}, \tag{A.3}$$

where the norm $\|\cdot\|_*$ is dual to $\|\cdot\|$. Let r and h be proper convex functions. The *infimal convolution* of r with h is the convex function given by $(r \square h)(\boldsymbol{x}) := \inf_{\boldsymbol{y} \in \mathcal{X}} \big(r(\boldsymbol{y}) + h(\boldsymbol{x} - \boldsymbol{y})\big)$. For our purposes, the most important special case is infimal convolution of a convex function with the squared euclidean norm, which yields the *Moreau envelope* (Moreau, 1962).

Proposition A.1 *Let $r \in \Gamma_0(\mathcal{X})$ and let $\gamma > 0$. The* Moreau envelope *of r indexed by γ is*

$$E_r^\gamma(\cdot) := r \,\square\, (\tfrac{1}{2\gamma}\|\cdot\|_2^2). \tag{A.4}$$

The Moreau envelope (A.4) *is convex, real-valued, and continuous.*

Proof See e.g. (Bauschke and Combettes, 2011, Prop. 12.15). ∎

Using the Moreau envelope (A.4), we now formally introduce prox operators.

Definition A.2 (Prox operator) *Let $r \in \Gamma_0(\mathcal{X})$, and let $\boldsymbol{y} \in \mathcal{X}$. Then* $\operatorname{prox}_r \boldsymbol{y}$ *is the unique point in $\mathcal{X}$ that satisfies $E_r^1(\boldsymbol{y}) = \min_{\boldsymbol{x} \in \mathcal{X}} (r(\boldsymbol{x}) + \frac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|_2^2)$, i.e.,*

$$\operatorname{prox}_r(\boldsymbol{y}) := \operatorname*{argmin}_{\boldsymbol{x} \in \mathcal{X}} r(\boldsymbol{x}) + \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|_2^2, \tag{A.5}$$

and the nonlinear map $\operatorname{prox}_r : \mathcal{X} \to \mathcal{X}$ is called the prox operator *of r.*

Sometimes the Fenchel conjugate r^* is easier to use than r; similarly, sometimes the operator $\operatorname{prox}_{r^*}$ is easier to compute than prox_r. The result below shows the connection.

Proposition A.3 (Moreau decomposition) *Let $r \in \Gamma_0(\mathcal{X})$, $\gamma > 0$, and $\boldsymbol{y} \in \mathcal{X}$. Then,*

$$\boldsymbol{y} = \operatorname{prox}_{\gamma r} \boldsymbol{y} + \gamma \operatorname{prox}_{r^*/\gamma}(\gamma^{-1}\boldsymbol{y}). \tag{A.6}$$

Proof A brief exercise; see e.g., (Bauschke and Combettes, 2011, Thm. 14.3). ∎

This decomposition provides the necessary tools to exploit useful primal–dual relations. For the sake of clarity we also present an additional result regarding a particular primal-dual relation that plays a key role in our algorithms.

Proposition A.4 *Let $f \in \Gamma_0(\mathcal{X})$ and $r \in \Gamma_0(\mathcal{Z})$. The problems below form a primal-dual pair.*

$$\inf_{\boldsymbol{x} \in \mathcal{X}} \quad f(\boldsymbol{x}) + r(\boldsymbol{B}\boldsymbol{x}) \quad \textit{s.t.} \quad \boldsymbol{B}\boldsymbol{x} \in \mathcal{Z} \tag{A.7}$$

$$\inf_{\boldsymbol{u} \in \mathcal{Z}} \quad f^*(-\boldsymbol{B}^T\boldsymbol{u}) + r^*(\boldsymbol{u}). \tag{A.8}$$

Proof Introduce an extra variable $\boldsymbol{z} = \boldsymbol{B}\boldsymbol{x}$, dual function is

$$g(\boldsymbol{u}) = \inf_{\boldsymbol{x} \in \mathcal{X}} \; f(\boldsymbol{x}) + \boldsymbol{u}^T\boldsymbol{B}\boldsymbol{x} + \inf_{\boldsymbol{z} \in \mathcal{Z}} \; r(\boldsymbol{z}) - \boldsymbol{u}^T\boldsymbol{z},$$

which upon rewriting using Fenchel conjugates yields (A.8). ∎

Notions on submodular optimization are also required to introduce some of the decomposition techniques for 2D-TV in this paper. For a more thorough read on this topic we recommend the monograph Bach (2013).

Definition A.5 (Submodular function) *A set-function $F : 2^V \to \mathbb{R}$, for 2^V the power set of some set V, is submodular if and only if it fulfills the diminishing returns property, that is, for $A \subseteq B \subseteq V$ and $k \in V$, $k \notin B$ we have*

$$F(A \cup \{k\}) - F(A) \geq F(B \cup \{k\}) - F(B).$$

Intuitively, a set-function is submodular if adding a new element to the set results in less value as the set grows in size.

Definition A.6 (Modular function) *A set-function $F : 2^V \to \mathbb{R}$, for 2^V the power set of some set V, $F(\emptyset) = 0$ is modular (and also submodular) if and only if there exists $\boldsymbol{s} \in \mathbb{R}^p$ such that $F(A) = \sum_{k \in A} \boldsymbol{s}_k$.*

That is, a function is modular if it always assigns the same value for each element added to the set, regardless of the other elements in the set. A common shorthand for modular functions is $s(A) = \sum_{k \in A} \boldsymbol{s}_k$.

Submodular functions can be thought as convex functions in the realm of discrete optimization, in the sense that they feature useful properties that allow for efficient optimization. Similarly, modular functions are connected to linear functions. To make such connections explicit we require of the following geometric concepts.

Definition A.7 (Base polytope) *The base polytope B_F of a submodular function F is the polyhedron given by*

$$B_F = \{y \in \mathbb{R}^n : y(A) \leq F(A) \; \forall A \subseteq V, \quad y(V) = F(V)\}.$$

That is, the base polytope is a polyhedron defined through linear inequality constraints on the values of F for every one of the n elements of the powerset 2^V, and an equality constraint for the complete set. This results in a combinatorial number of contraints, but fortunately this polytope will not be used directly.

Definition A.8 (Support function) *The support function h_A for some non-empty closed convex set $A \in \mathbb{R}^n$ is given by*

$$h_A(\boldsymbol{x}) = \sup\left\{\boldsymbol{x}^T\boldsymbol{a} : \boldsymbol{x} \in A\right\}.$$

The support function is useful when connected with the following definition.

Definition A.9 (Lovász extension) *Suppose a set-function F such that $F(\emptyset) = 0$. Its Lovász extension $f : \mathbb{R}^p \to \mathbb{R}$ is defined through the following mechanism. Take $\boldsymbol{w} \in \mathbb{R}^p$ input to f, and order its components in decreasing order $\boldsymbol{w}_{j_1} \geq \ldots \geq \boldsymbol{w}_{j_p}$, then*

$$f(\boldsymbol{w}) = \sum_{k=1}^{p}[F(\{j_1, \ldots, j_k\}) - F(\{j_1, \ldots, j_{k-1}\})].$$

Other equivalent definitions are possible: see Bach (2013) for details. The following result links all the definitions so far.

Proposition A.10 *For F submodular function such that $F(\emptyset) = 0$ we have*

- *Its Lovász extension f is a convex function.*
- *The support function of its base polytope is equal to its Lovász extension, that is, $h_{B_F}(\boldsymbol{x}) = f(\boldsymbol{x})$.*
- *The problem $\min_{S\subseteq V} F(S)$ is dual to $\min_{\boldsymbol{x}} f(\boldsymbol{x}) + \frac{1}{2}\|\boldsymbol{x}\|_2^2$, with $S^* = \{k|\boldsymbol{x}_k^* \geq 0\}$.*

For proofs on these points we refer to Bach (2013). The takeaway from them is that any minimization on a submodular function can be cast into a convex optimization problem. Furthermore, for those convex minimization problems whose objective turns out to be the Lovász extension of some other function, we can trace the steps the other way round, obtaining the minimization of a submodular function.

Consider now a composite problem $\min_{S\subseteq V}\sum_j F_j(S)$. The following results hold

Proposition A.11 *The problem $\min_{S\subseteq V}\sum_j F_j(S)$ is equivalent to $\min_x \sum_j f_j(x) + \frac{1}{2}\|x\|_2^2$, with $S^* = \{k|x_k^* \geq 0\}$. Furthermore it is also equivalent to $\min_{y_j\in B_{F_j}\,\forall j}\frac{1}{2}\|\sum_j y_j\|_2^2$, with $x^* = -\sum_j y_j^*$.*

Proof The first equivalence is a direct result of the properties of Lovász extensions (Bach, 2013), in particular that for F, G set-functions with Lovász extensions f, g, the Lovász extension of $F + G$ is $f + g$. For the second equivalence we have:

$$\begin{aligned}
\min_{\boldsymbol{x}} \sum_j f_j(\boldsymbol{x}) + \tfrac{1}{2}\|\boldsymbol{x}\|_2^2 &= \min_{\boldsymbol{x}} \sum_j h_{B_{F_j}} + \tfrac{1}{2}\|\boldsymbol{x}\|_2^2, \\
&= \min_{\boldsymbol{x}} \sum_j \max_{y_j\in B_{F_j}} \boldsymbol{y}_j^T\boldsymbol{x} + \tfrac{1}{2}\|\boldsymbol{x}\|_2^2, \\
&= \max_{\boldsymbol{y}_j\in B_{F_j}\,\forall j} \min_{\boldsymbol{x}} \left(\sum_j \boldsymbol{y}_j^T\boldsymbol{x} + \tfrac{1}{2}\|\boldsymbol{x}\|_2^2\right), \\
&= \min_{\boldsymbol{y}_j\in B_{F_j}\,\forall j} \tfrac{1}{2}\|\sum_j \boldsymbol{y}_j\|_2^2,
\end{aligned}$$

and the dual relationship $\boldsymbol{x}^* = -\sum_j \boldsymbol{y}_j^*$ comes from solving the inner $\min_{\boldsymbol{x}}$ problem for $\boldsymbol{x}$. ■

Therefore any decomposable submodular minimization, or sum of Lovász extensions plus ℓ_2 term, can be casted into a geometric problem in terms of the base polytopes. For two functions the resultant problem is of special interest if rewritten as

$$\min_{\substack{\boldsymbol{y}_1\in B_{F_1}\\ \boldsymbol{y}_2\in B_{F_2}}} \tfrac{1}{2}\|\boldsymbol{y}_1 + \boldsymbol{y}_2\|_2^2 \quad = \quad \min_{\substack{\boldsymbol{y}_1\in B_{F_1}\\ -\boldsymbol{y}_2\in -B_{F_2}}} \tfrac{1}{2}\|\boldsymbol{y}_1 - (-\boldsymbol{y}_2)\|_2^2 \quad = \quad \min_{\substack{\boldsymbol{a}\in B_{F_1}\\ \boldsymbol{b}\in -B_{F_2}}} \tfrac{1}{2}\|\boldsymbol{a} - \boldsymbol{b}\|_2^2$$

with $\boldsymbol{a} = \boldsymbol{y}_1$, $\boldsymbol{b} = -\boldsymbol{y}_2$, as this results in the classic geometric problem of finding the closest points between two convex sets. Many algorithms have been proposed to tackle problems in this form, most of them making use of alternating projection operations onto the two sets. Thus, a legitimate concern is how easy it is to compute such projections for B_{F_1} and $-B_{F_2}$.

Proposition A.12 *Given a submodular function F and its base polytope B_F, the projections $\Pi_{B_F}(\boldsymbol{z})$ and $\Pi_{-B_F}(\boldsymbol{z})$ of a point $\boldsymbol{z}$ onto B_F or its negated counterpart can be computed as*

$$\begin{aligned}
\Pi_{B_F}(\boldsymbol{z}) &= \boldsymbol{z} - \operatorname{prox}_f(\boldsymbol{z}), \\
\Pi_{-B_F}(\boldsymbol{z}) &= \boldsymbol{z} + \operatorname{prox}_f(-\boldsymbol{z}),
\end{aligned}$$

with prox *proximity operator of a function, f the Lovász extension of F.*

Proof We start with the proximity of f and work our way to a relationship with the projection operator,

$$\begin{aligned}
\operatorname{prox}_f(\boldsymbol{z}) &\equiv \min_{\boldsymbol{x}} f(\boldsymbol{x}) + \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{z}\|_2^2, \\
&= \max_{\boldsymbol{y}\in B_F} \min_{\boldsymbol{x}} \boldsymbol{y}^T\boldsymbol{x} + \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{z}\|_2^2, \\
&= \max_{\boldsymbol{y}\in B_F} \boldsymbol{y}^T(\boldsymbol{z} - \boldsymbol{y}) + \tfrac{1}{2}\|(\boldsymbol{z} - \boldsymbol{y}) - \boldsymbol{z}\|_2^2, \\
&= \min_{\boldsymbol{y}\in B_F} \tfrac{1}{2}\|\boldsymbol{y}\|_2^2 - \boldsymbol{y}^T\boldsymbol{z}, \\
&\equiv \min_{\boldsymbol{y}\in B_F} \tfrac{1}{2}\|\boldsymbol{y} - \boldsymbol{z}\|_2^2 = \Pi_{B_F}(\boldsymbol{z}),
\end{aligned}$$

where solving the inner minimization problem for $\boldsymbol{x}$ gives the primal–dual relationship $\boldsymbol{x}^* = \boldsymbol{z} - \boldsymbol{y}^*$. Using this we can obtain the solution for the projection problem from the proximity problem, as $\Pi_{B_F}(\boldsymbol{z}) = \boldsymbol{z} - \text{prox}_f(\boldsymbol{z})$. Projection onto the negated base polytope follows from the basic geometric argument $\Pi_{-B_F}(\boldsymbol{z}) = -\Pi_{B_F}(-\boldsymbol{z})$. ■

Appendix B. proxTV Toolbox

All the Total–Variation proximity solvers in this paper have been implemented as the **proxTV** toolbox for C++, Matlab and Python, available at `https://github.com/albarji/proxTV`. The toolbox has been designed to be used out of the box in a user friendly way; for instance, the top–level Matlab function `TV` solves Total–Variation proximity for a given signal under a variety of settings. For instance

>> TV(X, lambda)

solves Tv_1 proximity for a signal `X` of any dimension and a regularization value `lambda`. The weighted version of this problem is also seamlessly tackled by just providing a vector of weights of the appropriate length as the `lambda` parameter.

If a third parameter `p` is provided as

>> TV(X, lambda, p)

the general Tv_p proximity problem is addressed, whereupon an adequate solver is chosen by the library.

More advanced uses of the library are possible, allowing to specify which norm `p` and regularizer `lambda` values to use for each dimension of the signal, and even applying combinations of several different Tv_p regularizers along the same dimension. Please refer to the documentation within the toolbox for further information.

Appendix C. Proof on the Equality of Taut-String Problems

Theorem C.1 (Equality of taut-string problems) *Given the problems*

$$\min_{\boldsymbol{s}} \sum_{i=1}^{n} (\boldsymbol{s}_i - \boldsymbol{s}_{i-1})^2, \ s.t. \ |\boldsymbol{s}_i - \boldsymbol{r}_i| \leq \boldsymbol{w}_i \, \forall i = 1, \dots, n-1, \boldsymbol{s}_0 = 0, \boldsymbol{s}_n = \boldsymbol{r}_n, \tag{C.1}$$

and

$$\min_{\hat{\boldsymbol{s}}} \sum_{i=1}^{n} \sqrt{1 + (\hat{\boldsymbol{s}}_i - \hat{\boldsymbol{s}}_{i-1})^2}, \ s.t. \ |\hat{\boldsymbol{s}}_i - \boldsymbol{r}_i| \leq \boldsymbol{w}_i \, \forall i = 1, \dots, n-1, \hat{\boldsymbol{s}}_0 = 0, \hat{\boldsymbol{s}}_n = \boldsymbol{r}_n, \tag{C.2}$$

for a non-zero vector $\boldsymbol{w}$, both problems share the same minimum $\boldsymbol{s}^* = \hat{\boldsymbol{s}}^*$.

Proof

The Lagrangian of problem C.1 takes the form

$$L(\boldsymbol{s}, \boldsymbol{\alpha}, \boldsymbol{\beta}) = \sum_{i=1}^{n} (\boldsymbol{s}_i - \boldsymbol{s}_{i-1})^2 + \sum_{i=1}^{n-1} \boldsymbol{\alpha}_i (\boldsymbol{s}_i - \boldsymbol{r}_i - \boldsymbol{w}_i) + \sum_{i=1}^{n-1} \boldsymbol{\beta}_i (-\boldsymbol{w}_i - \boldsymbol{s}_i + \boldsymbol{r}_i),$$

and its Karush-Kuhn-Tucker optimality conditions are given by

$$(\boldsymbol{s}_{i+1} - \boldsymbol{s}_i) - (\boldsymbol{s}_i - \boldsymbol{s}_{i-1}) = \boldsymbol{\alpha}_i - \boldsymbol{\beta}_i, \tag{C.3}$$

$$|\boldsymbol{s}_i - \boldsymbol{r}_i| \leq \boldsymbol{w}_i, \tag{C.4}$$

$$\boldsymbol{\alpha}_i, \boldsymbol{\beta}_i \geq 0, \tag{C.5}$$

$$\boldsymbol{\alpha}_i (\boldsymbol{s}_i - \boldsymbol{r}_i - \boldsymbol{w}_i) = 0, \tag{C.6}$$

$$\boldsymbol{\beta}_i (-\boldsymbol{w}_i - \boldsymbol{s}_i + \boldsymbol{r}_i) = 0, \tag{C.7}$$

$\forall i = 1, \dots, n-1$, and where the first equation comes from the fact that $\frac{\partial L(\boldsymbol{s}, \boldsymbol{\alpha}, \boldsymbol{\beta})}{\partial \boldsymbol{s}} = 0$ at the minimum.

As the only difference between problems C.1 and C.2 is in the form of the objective, the KKT conditions for problem C.2 take the same form, but for the first one,

$$\frac{(\hat{\boldsymbol{s}}_{i+1} - \hat{\boldsymbol{s}}_i)}{\sqrt{1 + (\hat{\boldsymbol{s}}_{i+1} - \hat{\boldsymbol{s}}_i)^2}} - \frac{(\hat{\boldsymbol{s}}_i - \hat{\boldsymbol{s}}_{i-1})}{\sqrt{1 + (\hat{\boldsymbol{s}}_i - \hat{\boldsymbol{s}}_{i-1})^2}} = \hat{\boldsymbol{\alpha}}_i - \hat{\boldsymbol{\beta}}_i, \tag{C.8}$$

$$|\hat{\boldsymbol{s}}_i - \boldsymbol{r}_i| \leq \boldsymbol{w}_i, \tag{C.9}$$

$$\hat{\boldsymbol{\alpha}}_i, \hat{\boldsymbol{\beta}}_i \geq 0, \tag{C.10}$$

$$\hat{\boldsymbol{\alpha}}_i (\hat{\boldsymbol{s}}_i - \boldsymbol{r}_i - \boldsymbol{w}_i) = 0, \tag{C.11}$$

$$\hat{\boldsymbol{\beta}}_i (-\boldsymbol{w}_i - \hat{\boldsymbol{s}}_i + \boldsymbol{r}_i) = 0, \tag{C.12}$$

$\forall i = 1, \dots, n-1$, and where we use hat notation for the dual coefficients to tell them apart from those of problem C.1.

Suppose $\boldsymbol{s}^*$ minimizer to problem C.1, hence fulfilling the conditions C.3-C.7. In particular this means that it is feasible to assign values to the dual coefficients $\boldsymbol{\alpha}, \boldsymbol{\beta}$ in such a way that the conditions above are met. If we set $\hat{\boldsymbol{s}} = \boldsymbol{s}^*$ in the conditions C.8-C.12 the following observations are of relevance

- Condition C.9 becomes the same as condition C.4, and so it is immediately met.
- The operator $f(x) = \frac{x}{\sqrt{1+x^2}}$ is contractive and monotonous.
- The couple $(\boldsymbol{\alpha}_i, \boldsymbol{\beta}_i)$ cannot be both non–zero at the same time, since $\boldsymbol{\alpha}_i > 0$ enforces $\boldsymbol{s}_i = \boldsymbol{r}_i + \boldsymbol{w}_i$ and $\boldsymbol{\beta}_i > 0$ enforces $\boldsymbol{s}_i = \boldsymbol{r}_i - \boldsymbol{w}_i$, and $\boldsymbol{w}_i$ is non–zero.
- Hence and because $\boldsymbol{\alpha}_i, \boldsymbol{\beta}_i \geq 0$ and condition C.3 holds, when $(\boldsymbol{s}_{i+1} - \boldsymbol{s}_i) - (\boldsymbol{s}_i - \boldsymbol{s}_{i-1}) > 0$ then $\boldsymbol{\alpha}_i > 0$, $\boldsymbol{\beta}_i = 0$, and when $(\boldsymbol{s}_{i+1} - \boldsymbol{s}_i) - (\boldsymbol{s}_i - \boldsymbol{s}_{i-1}) < 0$ then $\boldsymbol{\alpha}_i = 0$, $\boldsymbol{\beta}_i > 0$.
- $f(\boldsymbol{s}_{i+1} - \boldsymbol{s}_i) - f(\boldsymbol{s}_i - \boldsymbol{s}_{i-1})$ has the same sign as $(\boldsymbol{s}_{i+1} - \boldsymbol{s}_i) - (\boldsymbol{s}_i - \boldsymbol{s}_{i-1})$, since f is monotonous and as such preserves ordering.
- Since f is contractive, condition C.8 can be met by setting $(\hat{\boldsymbol{\alpha}}_i, \hat{\boldsymbol{\beta}}_i) = (k\boldsymbol{\alpha}_i, k\boldsymbol{\beta}_i)$ for some $0 \leq k < 1$. Note that this works because $(\boldsymbol{\alpha}_i, \boldsymbol{\beta}_i)$ cannot be both zero at the same time.
- Condition C.10 is met for those choices of $\hat{\boldsymbol{\alpha}}_i, \hat{\boldsymbol{\beta}}_i$, as C.5 was met for $\boldsymbol{\alpha}_i, \boldsymbol{\beta}_i$ and $0 \leq k < 1$.

- Conditions C.11 and C.12 are also met for those choices of $\hat{\boldsymbol{\alpha}}_i, \hat{\boldsymbol{\beta}}_i$, as $\hat{\boldsymbol{\alpha}}_i(\boldsymbol{s}_i - \boldsymbol{r}_i - \boldsymbol{w}_i) = k\boldsymbol{\alpha}_i(\boldsymbol{s}_i - \boldsymbol{r}_i - \boldsymbol{w}_i) = 0$ and $\hat{\boldsymbol{\beta}}_i(-\boldsymbol{w}_i - \boldsymbol{s}_i + \boldsymbol{r}_i) = k\boldsymbol{\beta}_i(-\boldsymbol{w}_i - \boldsymbol{s}_i + \boldsymbol{r}_i) = 0$.

Therefore, all of the optimality conditions C.8-C.12 for problem C.2 are met for $\boldsymbol{s}^*$ solution of problem C.1, and so a minimum of problem C.1 is also a minimum for problem C.2.

The proof can be repeated the other way round by setting $\boldsymbol{s} = \hat{\boldsymbol{s}}^*$ optimal for problem C.2, defining the operator $f^{-1}(x) = \frac{x}{\sqrt{1-x^2}}$, and observing that this operator is monotonous and expansive, so we can establish $(\boldsymbol{\alpha}_i, \boldsymbol{\beta}_i) = (k\hat{\boldsymbol{\alpha}}_i, k\hat{\boldsymbol{\beta}}_i)$ for some $k \geq 1$ and the optimality conditions C.3-C.7 for problem C.1 are met following a similar reasoning to the one presented above. Thus, a minimum for problem C.2 is also a minimum for problem C.1, which joined with the previous result completes the proof. ■

Appendix D. Proof on the Equivalence of Linearized Taut-String Method

Proposition D.1 *Using affine approximations to the greatest convex minorant and the smallest concave majorant does not change the solution of the taut-string method.*

Proof Let us note $\cap(f)$ as the smallest concave majorant of some function f taking integer values, $\cup(f)$ as the greatest concave minorant, $\bar{a}(f)$ as the smallest affine majorant and $\underline{a}(f)$ as the greatest affine minorant. By definition we have

$$\underline{a}(f(i)) \leq \cup(f(i)) \leq f(i) \leq \cap(f(i)) \leq \bar{a}(f(i)) \quad \forall i \in \mathbb{Z}$$

Consider now the nature of the taut-string problem, where a vertically symmetric tube of radius λ_i at each section is modelled by following the majorant of the tube bottom $(f-\lambda)$ and the minorant of the tube ceiling $(f+\lambda)$. We work the inequalities above as:

$$f(i) - \lambda_i \leq \cap(f(i) - \lambda_i) \leq \bar{a}(f(i) - \lambda_i)$$
$$\underline{a}(f(i) + \lambda_i) \leq \cup(f(i) + \lambda_i) \leq f(i) + \lambda_i$$

We will show that an overlap of smallest concave majorant / greatest convex minorant takes place iff the same overlap happens when using the affine approximations. We formally define overlap as the setting where for a point i we have $\cup(f_i + \lambda_i) \leq \cap(f_i - \lambda_i)$.

One side of the implication is easy: if $\cup(f(i) + \lambda_i) \leq \cap(f(i) - \lambda)$ for some i, then using the relations above we have $\underline{a}(f(i) + \lambda_i) \leq \cup(f(i) + \lambda_i) \leq \cap(f(i) - \lambda_i) \leq \bar{a}(f(i) - \lambda_i)$, and so the affine approximation detects any overlap taking place in the concave/convex counterpart.

The opposite requires the key observation that in the taut-string method both majorant and minorant functions are clamped to the same point of origin: $f(0) = 0$ at the start of the method, or the point where the last segment was fixed after each restart. Let us assume $f(0) = 0$ without loss of generality. Suppose now that an overlap is detected by the affine approximation. Because of this affine nature the majorant/minorant slopes are constant,

i.e.

$$\bar{\delta}_1 = \bar{\delta}_2 = \ldots = \bar{\delta}_n = \bar{\delta}, \quad \underline{\delta}_1 = \underline{\delta}_2 = \ldots = \underline{\delta}_n = \underline{\delta}.$$

However, if we consider the convex/concave approximations these slopes can increase/decrease as the segment progresses, that is:

$$\delta_1^{\cup} \leq \delta_2^{\cup} \leq \ldots \leq \delta_n^{\cup}, \quad \delta_1^{\cap} \geq \delta_2^{\cap} \geq \ldots \geq \delta_n^{\cap}.$$

Consider now the majorant/minorant values, expressed through the slopes and taking into account the observation above about the starting point.

$$\cap(f(i) - \lambda_i) = \sum_{j=1}^{i} \delta_j^{\cap}, \quad \cup(f(i) + \lambda_i) \quad = \sum_{j=1}^{i} \delta_j^{\cup}, \quad \bar{a}(f(i) - \lambda_i) = i\bar{\delta}, \quad \underline{a}(f(i) + \lambda_i) \quad = i\underline{\delta}.$$

Since an overlap has been detected in the affine approximation, we have that for some point i

$$i\underline{\delta} = \underline{a}(f(i) + \lambda_i) \leq \bar{a}(f(i) - \lambda_i) = i\bar{\delta},$$

so $\underline{\delta} \leq \bar{\delta}$. Consider now the values of the affine minorant/majorant at the point immediately after the origin,

$$\underline{a}(f_1 - \lambda_1) = \underline{\delta}, \quad \bar{a}(f_1 + \lambda_1) = \bar{\delta}.$$

We will show now that the convex/convex counterpart must take exactly the same values at these points. To do so we take into account the following fact: there must exist points x and y, $x, y \leq i$, where

$$\underline{a}(f_x + \lambda_x) = f_x + \lambda_x = \cup(f_x + \lambda_x), \quad \bar{a}(f_y - \lambda_y) = f_y - \lambda_y = \cap(f_y - \lambda_y),$$

that is to say, the affine minorant/majorant must touch the tube ceiling/bottom at some point, otherwise we could obtain a greater minorant / smaller majorant by reducing this distance. The equalities to the convex minorant / concave majorant are then obtained by exploiting the inequalities at the beginning of the proof.

By the already presented inequalities $\cup(f_1 + \lambda_1) \geq \underline{a}(f_1 + \lambda_1)$, but let us suppose for a moment $\cup(f_1 + \lambda_1) > \underline{a}(f_1 + \lambda_1)$. This would imply $\delta_1^{\cup} > \underline{\delta}$. We then would have that at the touching point x

$$f_x + \lambda_x = \underline{a}(f_x + \lambda_x) = x\underline{\delta} < x\delta_1^{\cup} \leq \cup(f_1 + \lambda_1),$$

as the slopes in a convex minorant must be monotonically increasing. However, such function would not be a valid convex minorant, as it would grow over $f + \lambda$. Therefore $\cup(f_1 + \lambda_1) = \underline{a}(f_1 + \lambda_1)$ must hold. Using a symmetric argument, $\cap(f_1 - \lambda_1) = \bar{a}(f_1 - \lambda_1)$ can also be shown to hold. Joining this with the previous facts we have that

$$\cup(f_1 + \lambda_1) = \underline{a}(f_1 + \lambda_1) = \underline{\delta} \leq \bar{\delta} = \bar{a}(f_1 - \lambda_1) = \cap(f_1 - \lambda_1),$$

and therefore the overlap detected by the affine approximation is detected through its convex/concave version as well through $\cup(f_1 + \lambda_1) \leq \cap(f_1 - \lambda_1)$. ■

Appendix E. Projected-Newton for Weighted $\mathbf{Tv}_1^{\mathbf{1D}}$

In this appendix we present details of a projected-Newton (PN) approach to solving the weighted-TV problem (2.6). Although taut-string approaches are empirically superior to this PN approach, the details of this derivation prove to be useful when developing subroutines for handling ℓ_p-norm TV prox-operators, but perhaps their greatest use lies in presenting a general method that could be applied to other problems that have structures similar to TV, e.g., group total-variation (Alaız et al., 2013; Wytock et al., 2014) and ℓ_1-trend filtering (Kim et al., 2009; Tibshirani, 2014).

The weighted-TV dual problem (2.7) is a bound-constrained QP, so it could be solved using a variety of methods such as TRON (Lin and Moré, 1999), L-BFGS-B (Byrd et al., 1994), or projected-Newton (PN) (Bertsekas, 1982). Obviously, these methods will be inefficient if invoked off-the-shelf; exploitation of problem structure is a must for solving (2.7) efficiently. PN lends itself well to such structure exploitation; we describe the details below.

PN runs iteratively in three key steps: first it identifies a special subset of *active variables* and uses these to compute a *reduced* Hessian. Then, it uses this Hessian to scale the gradient and move in the direction opposite to it, damping with a stepsize, if needed. Finally, the next iterate is obtained by projecting onto the constraints, and the cycle repeats. PN can be regarded as an extension of the gradient-projection method (GP, Bertsekas (1999)), where the components of the gradient that make the updating direction infeasible are removed; in PN both the gradient and the Hessian are *reduced* to guarantee this feasibility.

At each iteration PN selects the active variables

$$I := \{i \mid (u_i = -w_i \text{ and } [\nabla\phi(\boldsymbol{u})]_i > \epsilon) \quad \text{or} \quad (u_i = w_i \text{ and } [\nabla\phi(\boldsymbol{u})]_i < -\epsilon)\}\,, \tag{E.1}$$

where $\epsilon \geq 0$ is small scalar. This corresponds to the set of variables at a bound, and for which the gradient points inside the feasible region; that is, for these variables to further improve the objective function we would have to step out of bounds. It is thus clear that these variables are of no use for this iteration, so we define the complementary set $\bar{I} := \{1 \dots n\} \setminus I$ of indices not in I, which are the variables we are interested in updating. From the Hessian $\boldsymbol{H} = \nabla^2\phi(u)$ we extract the *reduced Hessian* $\boldsymbol{H}_{\bar{I}}$ by selecting rows and columns indexed by $\bar{I}$, and in a similar way the *reduce gradient* $[\nabla\phi(\boldsymbol{u})]_{\bar{I}}$. Using these we perform a Newton–like "reduced" update in the form

$$\boldsymbol{u}_{\bar{I}} \leftarrow P(\boldsymbol{u}_{\bar{I}} - \alpha \boldsymbol{H}_{\bar{I}}^{-1}[\nabla\phi(\boldsymbol{u})]_{\bar{I}}), \tag{E.2}$$

where α is a stepsize, and P denotes projection onto the constraints, which for box–constraints reduces to simple element–wise projection. Note that only the variables in the set $\bar{I}$ are updated in this iterate, leaving the rest unchanged. While such update requires computing the inverse of the reduced Hessian $\boldsymbol{H}_{\bar{I}}$, which in the general case can amount to computational costs in the $O(n^3)$ order, we will see now how exploiting the structure of the problem allows us to perform all the steps above efficiently.

First, observe that for (2.7) the Hessian is

$$\boldsymbol{H} = \boldsymbol{D}\boldsymbol{D}^T = \begin{pmatrix} 2 & -1 & & & \\ -1 & 2 & -1 & & \\ & -1 & 2 & \ddots & \\ & & \ddots & \ddots & -1 \\ & & & -1 & 2 \end{pmatrix} \in \mathbb{R}^{(n-1)\times(n-1)}.$$

Next, observe that whatever the active set I, the corresponding reduced Hessian $\boldsymbol{H}_{\bar{I}}$ remains symmetric tridiagonal. This observation is crucial because then we can quickly compute the updating direction $\boldsymbol{d}_{\bar{I}} = \boldsymbol{H}_{\bar{I}}^{-1}[\nabla\phi(\boldsymbol{u})]_{\bar{I}}$, which can be done by solving the linear system $\boldsymbol{H}_{\bar{I}}\boldsymbol{d}_{\bar{I}} = [\nabla\phi(\boldsymbol{u}^t)]_{\bar{I}}$ as follows:

1. Compute the Cholesky decomposition $\boldsymbol{H}_{\bar{I}} = \boldsymbol{R}^T\boldsymbol{R}$.
2. Solve the linear system $\boldsymbol{R}^T\boldsymbol{v} = [\nabla\phi(\boldsymbol{u})]_{\bar{I}}$ to obtain $\boldsymbol{v}$.
3. Solve the linear system $\boldsymbol{R}\boldsymbol{d}_{\bar{I}} = \boldsymbol{v}$ to obtain $\boldsymbol{d}_{\bar{I}}$.

Because the reduced Hessian is also tridiagonal, its Cholesky decomposition can be computed in *linear time* to yield a bidiagonal matrix $\boldsymbol{R}$, which in turn allows to solve the subsequent linear systems also in linear time. Extremely efficient routines to perform all these tasks are available in the LAPACK libraries (Anderson et al., 1999).

The next crucial ingredient is efficient selection of the stepsize α. The original PN algorithm Bertsekas (1982) recommends Armijo-search along projection arc. However, for our problem this search is inordinately expensive. So we resort to a backtracking strategy using quadratic interpolation (Nocedal and Wright, 2000), which works admirably well. This strategy is as follows: start with an initial stepsize $\alpha_0 = 1$. If the current stepsize α_k does not provide sufficient decrease in ϕ, build a quadratic model using $\phi(\boldsymbol{u})$, $\phi(\boldsymbol{u} - \alpha_k\boldsymbol{d})$, and $\partial_{\alpha_k}\phi(\boldsymbol{u})$. Then, the stepsize α_{k+1} is set to the value that minimizes this quadratic model. In the event that at some point of the procedure the new α_{k+1} is larger than or too similar to α_k, its value is halved. In this fashion, quadratic approximations of ϕ are iterated until a good enough α is found. The goodness of a stepsize is measured using the following Armijo-like sufficient descent rule

$$\phi(\boldsymbol{u}) - \phi(P\left[\boldsymbol{u} - \alpha_k\boldsymbol{d}\right]) \geq \sigma \cdot \alpha_k \cdot (\nabla\phi(\boldsymbol{u}) \cdot \boldsymbol{d})\,,$$

where a tolerance $\sigma = 0.05$ works well practice.

Note that the gradient $\nabla\phi(\boldsymbol{u})$ might be misleading in the condition above if $\boldsymbol{u}$ has components at the boundary and $\boldsymbol{d}$ points outside this boundary (because then, due to the subsequent projection no real improvement would be obtained by stepping outside the feasible region). To address this concern, we modify the computation of the gradient $\nabla\phi(\boldsymbol{u})$, zeroing our the entries that relate to direction components pointing outside the feasible set.

The whole stepsize selection procedure is shown in Algorithm 11. The costliest operation in this procedure is the evaluation of ϕ, which, nevertheless can be done in linear time. Furthermore, in practice a few iterations more than suffice to obtain a good stepsize.

Overall, a full PN iteration as described above runs at $O(n)$ cost. Thus, by exploiting the structure of the problem, we manage to reduce the $O(n^3)$ cost per iteration of a general

Algorithm 11 Stepsize selection for Projected Newton

Initialize: $\alpha_0 = 1$, $k = 0$, $\boldsymbol{d}$, tolerance parameter σ
while $\phi(\boldsymbol{u}) - \phi(P[\boldsymbol{u} - \alpha_k \boldsymbol{d}]) < \sigma \cdot \alpha_k \cdot (\nabla\phi(\boldsymbol{u}) \cdot \boldsymbol{d})$ **do**
  Minimize quadratic model: $\alpha_{k+1} = \frac{\alpha_k^2 \partial_{\alpha_k}\phi(\boldsymbol{u})}{2(\phi(\boldsymbol{u}) - \phi(\boldsymbol{u} - \alpha_k) + \alpha_k \partial_{\alpha_k}\phi(\boldsymbol{u}))}$.
  if $\alpha_{k+1} > \alpha_k$ **or** $\alpha_{k+1} \simeq \alpha_k$, **then** $\alpha_{k+1} = \frac{1}{2}\alpha_k$.
  $k \leftarrow k + 1$
end while
return α_k

Algorithm 12 PN algorithm for TV-L1-proximity

Let $\boldsymbol{W} = \mathrm{Diag}(w_i)$; solve $\boldsymbol{D}\boldsymbol{D}^T\boldsymbol{W}\boldsymbol{u}^* = \boldsymbol{D}\boldsymbol{y}$.
if $\|\boldsymbol{W}^{-1}\boldsymbol{u}^*\|_\infty \leq 1$, **return** $\boldsymbol{u}^*$.
$\boldsymbol{u}^0 = P[\boldsymbol{u}^*]$, $t = 0$.
while $\mathrm{gap}(\boldsymbol{u}) > \epsilon$ **do**
  Identify set of active constraints I; let $\bar{I} = \{1 \dots n\} \setminus I$.
  Construct reduced Hessian $\boldsymbol{H}_{\bar{I}}$.
  Solve $\boldsymbol{H}_{\bar{I}}\boldsymbol{d}_{\bar{I}} = [\nabla\phi(\boldsymbol{u}^t)]_{\bar{I}}$.
  Compute stepsize α using backtracking + interpolation (Alg. 11).
  Update $\boldsymbol{u}_{\bar{I}}^{t+1} = P[\boldsymbol{u}_{\bar{I}}^t - \alpha\boldsymbol{d}_{\bar{I}}]$.
  $t \leftarrow t + 1$.
end while
return $\boldsymbol{u}^t$.

PN algorithm to a linear-cost method. The pseudocode of the resulting method is shown as Algorithm 12. Note that in the special case when the weights $\boldsymbol{W} := \mathrm{Diag}(w_i)$ are so large that the unconstrained optimum coincides with the constrained one, we can obtain $\boldsymbol{u}^*$ directly via solving $\boldsymbol{D}\boldsymbol{D}^T\boldsymbol{W}\boldsymbol{u}^* = \boldsymbol{D}\boldsymbol{y}$ (which can also be done at $O(n)$ cost). The duality gap of the current solution is used as a stopping criterion, where we use a tolerance of $\epsilon = 10^{-5}$ in practice.

Appendix F. Testing Images and Videos, and Experimental Results

The images used in the experiments are displayed in what follows, along with their noisy/denoised and convoluted/deconvoluted versions for each algorithm tested. QR barcode images were generated by encoding random text using Google chart API[4]. Images *shape* and *phantom* [5] are publicly available and frequently used in image processing. *trollface* and *comic* [6] are also publicly available. *gaudi*, used in the multicore experiments, is a high resolution 3197×3361 photograph of Gaudi's Casa Batlló[7]. The rest of the images were originally created by the authors.

4. `http://code.google.com/intl/en-EN/apis/chart/`
5. Extracted from `http://en.wikipedia.org/wiki/File:Shepp_logan.png`
6. Author: Francisco Molina. `http://www.afrikislife.net/english/`
7. Extracted from `http://www.flickr.com/photos/jeffschwartz/202423023/`

For the video experiments, the *salesman*, *coastguard* and *bicycle* sequences were used, which are publicly available at BM3D (2013). As an example, frames from the first video are displayed in what follows, along with their noisy/denoised versions.

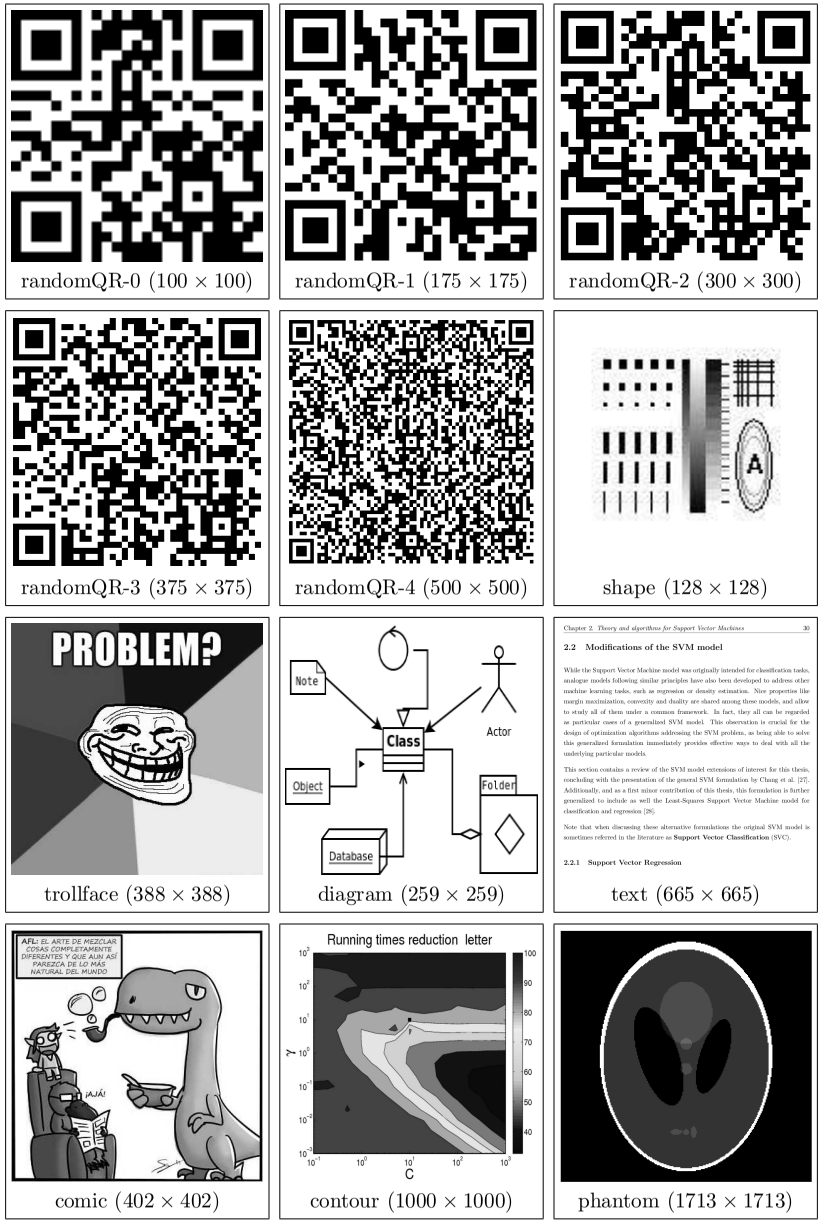

Figure 25: Test images used in the experiments together with their sizes in pixels. Images displayed have been scaled down to fit in page.

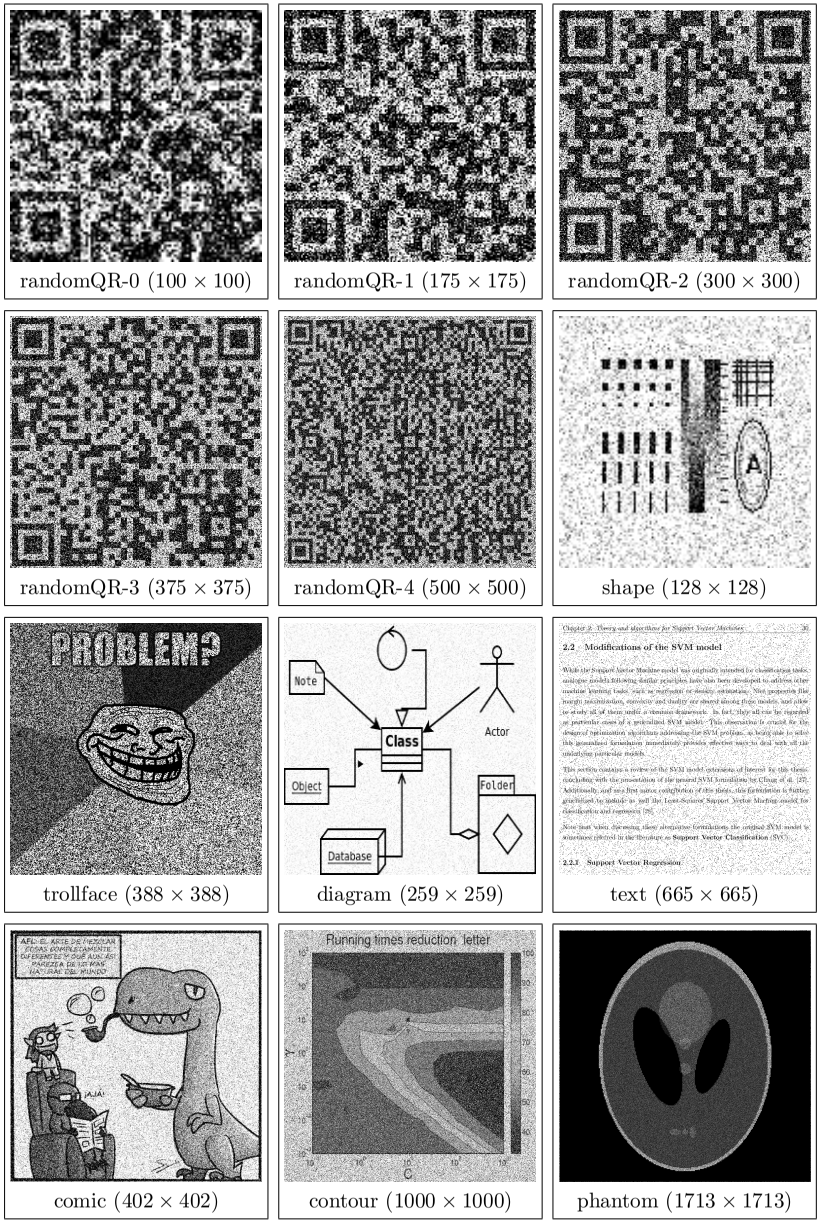

Figure 26: Noisy versions of images used in the experiments.

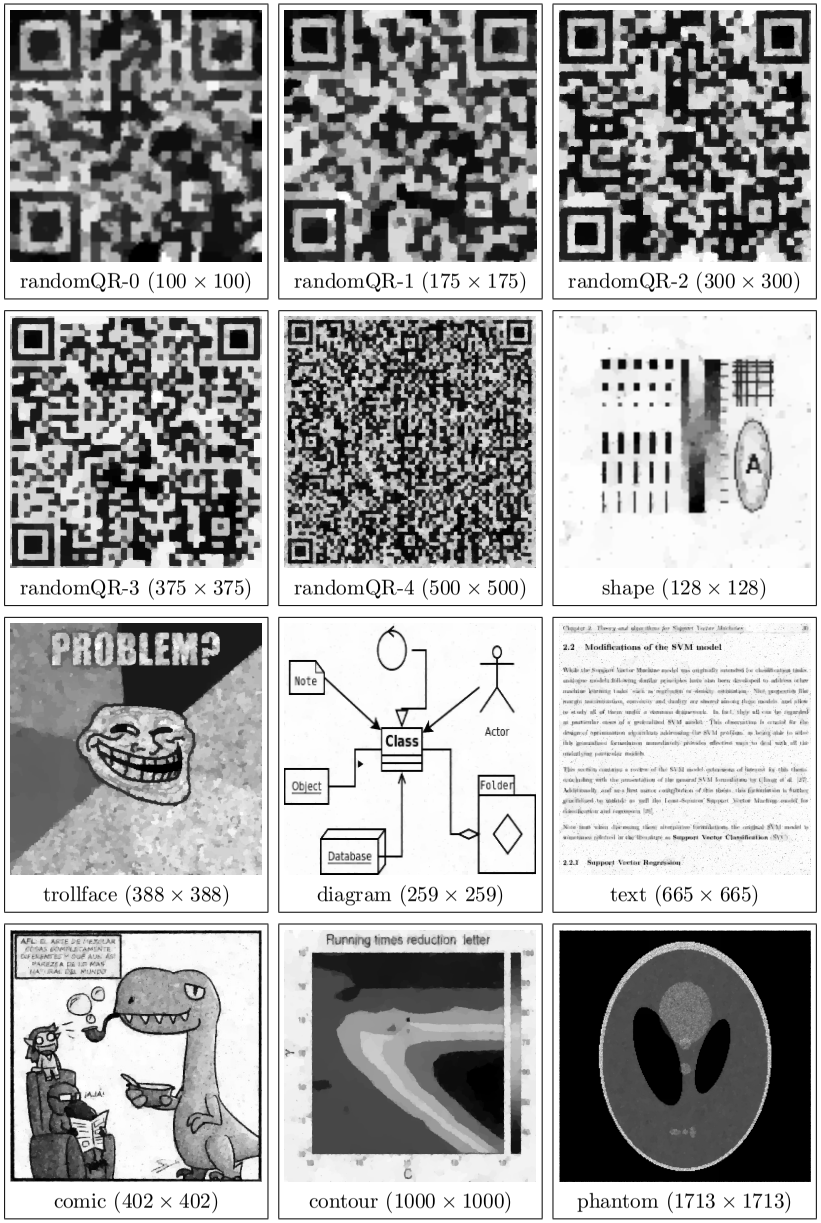

Figure 27: Denoising results for the test images.

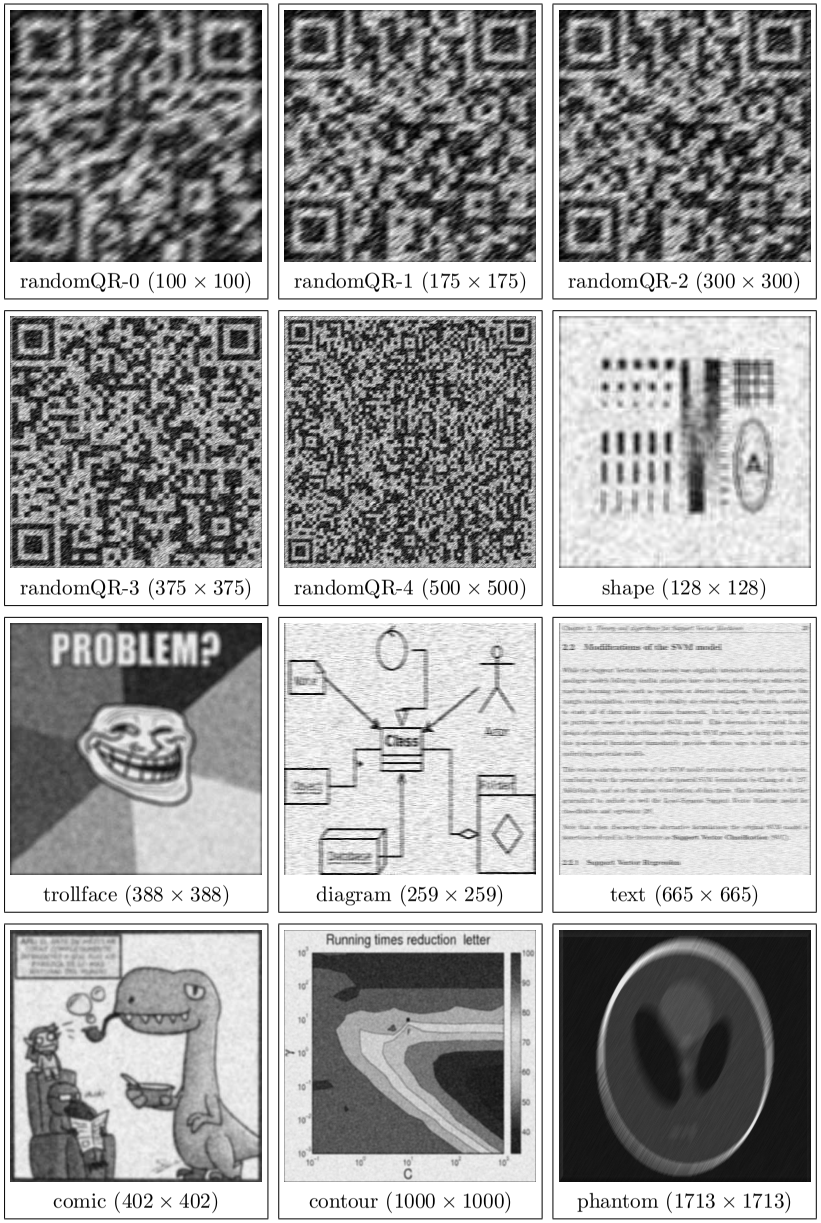

Figure 28: Noisy and convoluted versions of images used in the experiments.

Editor: David Blei

Abstract

We propose a new class of semiparametric exponential family graphical models for the analysis of high dimensional mixed data. Different from the existing mixed graphical models, we allow the nodewise conditional distributions to be semiparametric generalized linear models with unspecified base measure functions. Thus, one advantage of our method is that it is unnecessary to specify the type of each node and the method is more convenient to apply in practice. Under the proposed model, we consider both problems of parameter estimation and hypothesis testing in high dimensions. In particular, we propose a symmetric pairwise score test for the presence of a single edge in the graph. Compared to the existing methods for hypothesis tests, our approach takes into account of the symmetry of the parameters, such that the inferential results are invariant with respect to the different parametrizations of the same edge. Thorough numerical simulations and a real data example are provided to back up our theoretical results.

Keywords: Graphical Models, Exponential Family, High Dimensional Inference

1. Introduction

Given a d-dimensional random vector $\boldsymbol{X} = (X_1, \ldots, X_d)^T$, inferring the conditional independence among $\boldsymbol{X}$ and quantifying its uncertainty are important tasks in statistics. We propose a unified framework for modeling, estimation, and uncertainty assessment for a new type of graphical model, named as semiparametric exponential family graphical model. Let $G = (V, E)$ be an undirected graph with node set $V = \{1, 2, \ldots, d\}$ and edge set $E \subseteq \{(j, k)\colon 1 \le j < k \le d\}$. The semiparametric exponential family graphical model specifies the joint distribution of $\boldsymbol{X}$ such that for each $j \in V$, the conditional distribution of X_j given $\boldsymbol{X}_{\setminus j} := (X_1, \ldots, X_{j-1}, X_{j+1}, \ldots, X_d)^T$ is of the form

$$p(x_j \mid \boldsymbol{x}_{\setminus j}) = \exp\big[\eta_j(\boldsymbol{x}_{\setminus j}) \cdot x_j + f_j(x_j) - b_j(\eta_j, f_j)\big], \tag{1}$$

where $\boldsymbol{x}_{\setminus j} = (x_1, \ldots, x_{j-1}, x_{j+1}, \ldots, x_d)$, $\eta_j(\boldsymbol{x}_{\setminus j}) = \alpha_j + \sum_{k \neq j} \beta_{jk} x_k$ is the canonical parameter, $f_j(\cdot)$ is an unknown base measure function, and $b_j(\cdot, \cdot)$ is the log-partition function. Besides, we assume $\beta_{jk} = \beta_{kj}$ for all $j \neq k$. By definition, the unknown parameter contains $\{(\alpha_j, \beta_{jk}, f_j)\colon 1 \le j < k \le d\}$. To make the model identifiable, we set $\alpha_j = 0$ and absorb the term $\alpha_j x_j$ into $f_j(x_j)$. By the Hammersley-Clifford theorem (Besag, 1974), we have $\beta_{jk} \neq 0$ if and only if X_j and X_k are conditionally independent given $\{X_\ell\colon \ell \neq j, k\}$. Therefore, we set $(j, k) \in E$ if and only if $\beta_{jk} \neq 0$. The graph G thus characterizes the conditional independence relationship among the high dimensional distribution of $\boldsymbol{X}$. The key feature of the proposed model is that (1) it is a general semiparametric model and (2) it can be used to handle mixed data, which means that $\boldsymbol{X}$ may contain both continuous and discrete random variables. Unlike the existing mixed graphical models, we allow the nodewise conditional distributions to be semiparametric generalized linear models with unspecified base measure functions. Thus, our method does not need to specify the type of each node and is more convenient to apply in practice. In addition to the proposed new model, our paper has the following two novel contributions.

First, for the purpose of estimating β_{jk}, we extend the multistage relaxation algorithm (Zhang, 2010) and conduct a localized analysis for a more sophisticated loss function obtained by a statistical chromatography method (Liang and Qin, 2000; Diao et al., 2012; Chan, 2012; Ning et al., 2017b). The gradient and Hessian matrix of the loss function are nonlinear U-statistics with unbounded kernel functions. This makes our technical analysis more challenging than that in Zhang (2010). Under the assumption that the sparse eigenvalue condition holds locally, we prove the same optimal statistical rates for parameter estimation as in high dimensional linear models.

Second, we propose a symmetric pairwise score test for the null hypothesis $H_0\colon \beta_{jk} = 0$. This is equivalent to testing whether X_j and X_k are conditionally independent given $\{X_\ell\colon \ell \neq j, k\}$. Compared with Ning et al. (2017b), the novelty of our method is that we consider a more sophisticated cross type inference which incorporates the symmetry of the parameter, i.e., $\beta_{jk} = \beta_{kj}$. By considering this unique structure of the graphical model, our proposed method achieves the invariance property of the inferential results. That means the same p-values are obtained for testing $\beta_{jk} = 0$ and $\beta_{kj} = 0$. In contrast, the asymmetric method in Ning et al. (2017b) may lead to different conclusions for testing these two equivalent null hypotheses.

1.1. Related Works

There is a huge literature on estimating undirected graphical models (Lauritzen, 1996; Edwards, 2000; Whittaker, 2009). For modeling continuous data, the most commonly used methods are Gaussian graphical models (Yuan and Lin, 2007; Banerjee et al., 2008; Friedman et al., 2008; Ravikumar et al., 2011; Rothman et al., 2008; Lam and Fan, 2009; Shen et al., 2012; Yuan, 2010; Cai et al., 2011; Sun and Zhang, 2013; Guo et al., 2011; Danaher et al., 2014; Mohan et al., 2014; Meinshausen and Bühlmann, 2006; Peng et al., 2009; Friedman et al., 2010). To relax the Gaussian assumption, Liu et al. (2009); Xue et al. (2012b); Liu et al. (2012); Ning and Liu (2013) propose the Gaussian copula model and Voorman et al. (2014) study the joint additive models for graph estimation. For modeling binary data, the Ising graphical model is considered by Lee et al. (2006); Höfling and Tibshirani (2009);

Ravikumar et al. (2010); Xue et al. (2012a); Cheng et al. (2014). In addition to binary data, Allen and Liu (2012) and Yang et al. (2013b) consider the Poisson data and Guo et al. (2015) consider the ordinal data. Moreover, Yang et al. (2013a) propose exponential family graphical models, and Tan et al. (2014) propose a general framework for graphical models with hubs.

Recently, modeling the mixed data attracts increasing interests (Lee and Hastie, 2015; Fellinghauer et al., 2013; Cheng et al., 2017; Chen et al., 2015; Fan et al., 2017; Yang et al., 2014). Compared with Lee and Hastie (2015); Cheng et al. (2017); Chen et al. (2015); Yang et al. (2014), our model has the following two main advantages. First, it is a semiparametric model, which does not need to specify the parametric conditional distribution for each node. Therefore, it provides a more flexible modeling framework than the existing ones. Second, under our proposed model, the estimation and inference methods are easier to implement. Unlike these existing methods, we propose a unified estimation and inference procedure, which does not need to distinguish whether the node satisfies the Gaussian distribution or the Bernoulli distribution. In addition, our estimation and inference methods are more efficient than the nonparametric approach in Fellinghauer et al. (2013). Finally, our method is more convenient for modeling the count data than the latent Gaussian copula approach in Fan et al. (2017).

Though significant progress has been made towards developing new graph estimation procedures, the research on uncertainty assessment of the estimated graph lags behind. In low dimensions, Drton et al. (2007); Drton and Perlman (2008) establish confidence subgraph of Gaussian graphical models. In high dimensions, Ren et al. (2015); Janková and van de Geer (2015); Gu et al. (2015) study the confidence interval for a single edge under Gaussian (copula) graphical models and Liu et al. (2013) study the false discovery rate control. However, all these methods rely on the Gaussian or sub-Gaussian assumption and cannot be easily applied to the discrete data and more generally the mixed data in high dimensions.

1.2. Notation

We adopt the following notation throughout this paper. For any vector $\mathbf{v} = (v_1, \ldots, v_d)^T \in \mathbb{R}^d$, we define its support as $\mathrm{supp}(\mathbf{v}) = \{t\colon v_t \neq 0\}$. We define its ℓ_0-norm, ℓ_p-norm, and ℓ_∞-norm as $\|\mathbf{v}\|_0 = |\mathrm{supp}(\mathbf{v})|$, $\|\mathbf{v}\|_p = (\sum_{j\in[d]} |v_j|^p)^{1/p}$ and $\|\mathbf{v}\|_\infty = \max_{j\in[d]} |v_j|$, respectively, where $p > 1$. Let $\mathbf{v}^{\otimes 2} = \mathbf{v}\mathbf{v}^T$ be the Kronecker product of a vector $\mathbf{v}$ and itself. We write $\mathbf{v} \circ \mathbf{u} = (v_1u_1, \ldots, v_du_d)^T$ as the Hadamard product of two vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^d$. In addition, we use $|\mathbf{v}| = (|v_1|, \ldots, |v_d|)^T$ to denote the elementwise absolute value of vector $\mathbf{v}$ and define $\|\mathbf{v}\|_{\min} = \min_{j\in[d]} |v_j|$. For any matrix $\mathbf{A} = [a_{jk}] \in \mathbb{R}^{d_1\times d_2}$, let $\mathbf{A}_{S_1S_2} = [a_{jk}]_{j\in S_1, k\in S_2}$ be the submatrix of $\mathbf{A}$ with indices in $S_1 \times S_2$; let $\mathbf{A}_{j\setminus j} = [a_{jk}]_{k\neq j}$. Besides, let $\|\mathbf{A}\|_2$, $\|\mathbf{A}\|_1$, $\|\mathbf{A}\|_\infty$, $\|\mathbf{A}\|_{\ell_p}$ be the spectral norm, elementwise ℓ_1-norm, elementwise ℓ_∞-norm, and operator ℓ_p-norm of $\mathbf{A}$, respectively. Furthermore, for two matrices $\mathbf{A}_1$ and $\mathbf{A}_2$, we write $\mathbf{A}_1 \preceq \mathbf{A}_2$ if $\mathbf{A}_2 - \mathbf{A}_1$ is positive semidefinite and write $\mathbf{A}_1 \leq \mathbf{A}_2$ if every entry of $\mathbf{A}_2 - \mathbf{A}_1$ is nonnegative. For a function $f(\boldsymbol{x})\colon \mathbb{R}^d \to \mathbb{R}$, we write $\nabla f(\boldsymbol{x})$, $\nabla_S f(\boldsymbol{x})$, $\nabla^2 f(\boldsymbol{x})$ and $\partial f(\boldsymbol{x})$ as the gradient of $f(\boldsymbol{x})$, the gradient of $f(\boldsymbol{x})$ with respect to $\boldsymbol{x}_S$, the Hessian of $f(\boldsymbol{x})$, and the subgradient of $f(\boldsymbol{x})$, respectively. Moreover, we write $\{1, 2, \ldots, d\}$ as $[d]$. For a sequence of random vectors $\{\boldsymbol{Y}_i\}_{i\geq 1}$ and a random vector $\boldsymbol{Y}$, we write $\boldsymbol{Y}_i \rightsquigarrow \boldsymbol{Y}$ if $\{\boldsymbol{Y}_i\}_{i\geq 1}$ converges to $\boldsymbol{Y}$ in distribution.

Finally, for functions $f(n)$ and $g(n)$, we write $f(n) \lesssim g(n)$ to denote that $f(n) \leq cg(n)$ for a universal constant $c \in (0, +\infty)$ and we write $f(n) \asymp g(n)$ when $f(n) \lesssim g(n)$ and $g(n) \lesssim f(n)$ hold simultaneously.

1.3. Paper Organization

The rest of this paper is organized as follows. In §2 we introduce the semiparametric exponential family graphical models. In §3 we present our methods for graph estimation and uncertainty assessment. In §4 we lay out the assumptions and main theoretical results. We study the finite-sample performance of our method on both simulated and real-world datasets in §5 and conclude the paper in §6 with some discussion.

2. Semiparametric Exponential Family Graphical Models

The semiparametric exponential family graphical models are defined by specifying the conditional distribution of each variable X_j given the rest of the variables $\{X_k\colon k \neq j\}$.

Definition 1 (Semiparametric exponential family graphical model) *A d-dimensional random vector $\boldsymbol{X} = (X_1, \ldots, X_d)^T \in \mathbb{R}^d$ follows a semiparametric exponential graphical model with graph $G = (V, E)$ if for any node $j \in V$, the conditional density of X_j given $\boldsymbol{X}_{\setminus j}$ satisfies*

$$p(x_j \,|\, \boldsymbol{x}_{\setminus j}) = \exp\big[x_j(\boldsymbol{\beta}_j^T \boldsymbol{x}_{\setminus j}) + f_j(x_j) - b_j(\boldsymbol{\beta}_j, f_j)\big], \tag{2}$$

where $f_j(\cdot)$ is an unknown base measure function and $b_j(\cdot, \cdot)$ is a known log-partition function. In particular, $(j, k) \in E$ if and only if $\beta_{jk} \neq 0$.

This model is semiparametric since we treat both $\boldsymbol{\beta}_j = (\beta_{j1}, \ldots, \beta_{jj-1}, \beta_{jj+1}, \ldots, \beta_{jd})^T \in \mathbb{R}^{d-1}$ and the univariate function $f_j(\cdot)$ as parameters, where $\boldsymbol{\beta}_j$ and $f_j(\cdot)$ are the parametric and nonparametric components, respectively. Because the model in Definition 1 is only specified by the conditional distributions of each variable, it is important to understand the conditions under which a valid joint distribution of $\boldsymbol{X}$ exists. This problem has been addressed by Chen et al. (2015). As shown in their Proposition 1, one sufficient condition for the existence of joint distribution of $\boldsymbol{X}$ is that, (i) $\beta_{jk} = \beta_{kj}$ for $1 \leq j, k \leq d$ and (ii) $g(\boldsymbol{x}) := \exp\big[\sum_{j<k} \beta_{jk} x_j x_k + \sum_{j=1}^d f_j(x_j)\big]$ is integrable.

Hereafter, we assume that the above two conditions hold. Thus, there exists a joint probability distribution for the model defined in (2), whose density has the form of

$$p(\boldsymbol{x}) = \exp\bigg[\sum_{k<\ell} \beta_{k\ell} x_k x_\ell + \sum_{j=1}^d f_j(x_j) - A\big(\{\boldsymbol{\beta}_i, f_i\}_{i\in[d]}\big)\bigg], \tag{3}$$

where $\beta_{k\ell} \neq 0$ if and only if $(k, \ell) \in E$. Here $A(\cdot)$ is the log-partition function given by

$$A\big(\{\boldsymbol{\beta}_i, f_i\}_{i\in[d]}\big) := \log\bigg\{\int_{\mathbb{R}^d} \exp\bigg[\sum_{k<\ell} \beta_{k\ell} x_k x_\ell + \sum_{j=1}^d f_j(x_j)\bigg] \nu(\mathrm{d}\boldsymbol{x})\bigg\}, \tag{4}$$

where $\nu(\cdot)$ is a product measure satisfying $\nu(\mathrm{d}\boldsymbol{x}) = \prod_{j\in[d]} \nu_j(\mathrm{d}x_j)$, and each ν_j is either a Lebesgue or a counting measure on the domain of X_j, depending whether X_j is discrete or

continuous. Since $\beta_{k\ell} = \beta_{\ell k}$ for all pairs of nodes (k, ℓ), in the sequel, we will use $\beta_{k\ell}$ and $\beta_{\ell k}$ interchangeably for notational simplicity.

Furthermore, we remark that, without the knowledge of $\{f_j\}_{j\in[d]}$, estimating parameters $\{\boldsymbol{\beta}_j\}_{j\in[d]}$ is insufficient to learn the distribution of $\boldsymbol{X}$. In this paper, we focus on the statistical inference of the underlying conditional independence graph specified by $\{\boldsymbol{\beta}_j\}_{j\in[d]}$. In the next section, by adopting a loss function for $\{\boldsymbol{\beta}_j\}_{j\in[d]}$ that is free of the base measures, we obtain estimators of these parameters, which are used to construct an estimator of the underlying graph. Moreover, by further considering the hypothesis testing problem for each β_{jk}, we are able to assess the uncertainty of the estimated graph.

2.1. Examples

We provide some widely used parametric examples in the class of semiparametric exponential family graphical models.

Gaussian Graphical Models: The Gaussian graphical models assume that $\boldsymbol{X} \in \mathbb{R}^d$ follows a multivariate Gaussian distribution $N(\mathbf{0}, \boldsymbol{\Theta}^{-1})$, where $\boldsymbol{\Theta} \in \mathbb{R}^{d\times d}$ is the precision matrix satisfying $\boldsymbol{\Theta}_{jj} = 1$ for $j \in [d]$. The conditional distribution of X_j given $\boldsymbol{X}_{\backslash j}$ satisfies

$$X_j \,|\, \boldsymbol{X}_{\backslash j} = \boldsymbol{\alpha}_j^T \boldsymbol{X}_{\backslash j} + \epsilon_j \quad \text{with} \quad \epsilon_j \sim N(0,1),$$

where $\boldsymbol{\alpha}_j = \boldsymbol{\Theta}_{\backslash j,j}$. The conditional density is given by

$$p(x_j \,|\, \boldsymbol{x}_{\backslash j}) = \sqrt{1/(2\pi)}\exp\big[-x_j(\boldsymbol{\Theta}_{\backslash j,j}^T \boldsymbol{x}_{\backslash j}) - 1/2 \cdot x_j^2 - 1/2 \cdot (\boldsymbol{\Theta}_{\backslash j,j}^T \boldsymbol{x}_{\backslash j})^2\big].$$

Compared with (2), we obtain $\boldsymbol{\beta}_j = -\boldsymbol{\Theta}_{\backslash j,j}$, $f_j(x) = -x^2/2$ and $b_j(\boldsymbol{\beta}_j, f_j) = (\boldsymbol{\beta}_j^T \boldsymbol{x}_{\backslash j})^2/2 + \log(2\pi)/2$.

Ising Models: In an Ising model with no external field, $\boldsymbol{X}$ takes value in $\{0,1\}^d$ and the joint probability mass function $p(\boldsymbol{x}) \propto \exp(\sum_{j<k} \theta_{jk} x_j x_k)$. Let $\boldsymbol{\theta}_j = (\theta_{j1}, \ldots, \theta_{j,j-1}, \theta_{j,j+1}, \ldots, \theta_{jd})^T$. The conditional distribution of X_j given $\boldsymbol{X}_{\backslash j}$ is of the form

$$p(x_j \,|\, \boldsymbol{x}_{\backslash j}) = \frac{\exp\big(\sum_{k<\ell} \theta_{k\ell} x_k x_\ell\big)}{\sum_{x_j\in\{0,1\}} \exp\big(\sum_{k<\ell} \theta_{k\ell} x_k x_\ell\big)} = \exp\Big\{x_j\big(\boldsymbol{\theta}_j^T \boldsymbol{x}_{\backslash j}\big) - \log\big[1 + \exp(\boldsymbol{\theta}_j^T \boldsymbol{x}_{\backslash j})\big]\Big\}.$$

Therefore, in this case we have $\boldsymbol{\beta}_j = \boldsymbol{\theta}_j$, $f_j(x) = 0$ and $b_j(\boldsymbol{\beta}_j, f_j) = \log[1 + \exp(\boldsymbol{\beta}_j^T \boldsymbol{x}_{\backslash j})]$.

Exponential Graphical Models: For exponential graphical models, $\boldsymbol{X}$ takes values in $[0, +\infty)^d$ and the joint probability density satisfies $p(\boldsymbol{x}) \propto \exp(-\sum_{j=1}^d \phi_j x_j - \sum_{k<\ell} \theta_{k\ell} x_k x_\ell)$. In order to ensure that this probability distribution is normalizable, we require that $\phi_j > 0, \theta_{jk} \geq 0$ for all $j, k \in [d]$. Then we obtain the following conditional probability density of X_j given $\boldsymbol{X}_{\backslash j}$:

$$\begin{aligned} p(x_j \,|\, \boldsymbol{x}_{\backslash j}) &= \exp\Big(-\sum_{k=1}^d \phi_k x_k - \sum_{k<\ell} \theta_{k\ell} x_k x_\ell\Big) \Big/ \int_{x_j\geq 0} \exp\Big(-\sum_{k=1}^d \phi_k x_k - \sum_{k<\ell} \theta_{k\ell} x_k x_\ell\Big) \mathrm{d}x_j \\ &= \exp\big[-x_j\big(\phi_j + \boldsymbol{\theta}_j^T \boldsymbol{x}_{\backslash j}\big) - \log\big(\phi_j + \boldsymbol{\theta}_j^T \boldsymbol{x}_{\backslash j}\big)\big]. \end{aligned}$$

Thus, we have $\boldsymbol{\beta}_j = -\boldsymbol{\theta}_j$, $f_j(x) = -\phi_j x$ and $b_j(\boldsymbol{\beta}_j, f_j) = \log(\boldsymbol{\beta}_j^T \boldsymbol{x}_{\backslash j} + \phi_j)$.

Poisson Graphical Models: In a Poisson graphical model, every node X_j is a discrete random variable taking values in $\mathbb{N} = \{0, 1, 2, \ldots\}$. The joint probability mass function is given by

$$p(\boldsymbol{x}) \propto \exp\Big[\sum_{j=1}^d \phi_j x_j - \sum_{j=1}^d \log(x_j!) + \sum_{k<\ell} \theta_{k\ell} x_k x_\ell\Big].$$

Similar to the exponential graphical models, we also need to impose some restrictions on the parameters so that the probability mass function is normalizable. Here we require that $\theta_{jk} \leq 0$ for all $j, k \in [d]$. By direct computation, the conditional probability mass function of X_j given $\boldsymbol{X}_{\backslash j}$ is given by

$$p(x_j \,|\, \boldsymbol{x}_{\backslash j}) = \exp\big[x_j\big(\boldsymbol{\theta}_j^T \boldsymbol{x}_{\backslash j}\big) + \phi_j x_j - \log(x_j!) - b_j(\boldsymbol{\theta}_j, f_j)\big],$$

where we have $\boldsymbol{\beta}_j = \boldsymbol{\theta}_j$, $f_j(x) = \phi_j x - \log(x!)$ and $b_j(\boldsymbol{\beta}_j, f_j) = \log\big\{\sum_{y=0}^\infty \exp\big[y(\boldsymbol{\beta}_j^T \boldsymbol{x}_{\backslash j}) + f_j(y)\big]\big\}$.

3. Graph Estimation and Uncertainty Assessment

In this section, we lay out the procedures for graph estimation and uncertainty assessment. Throughout our analysis, we use $\{\boldsymbol{\beta}_i^*, f_i^*\}_{i\in[d]}$ to denote the true parameters, and $\mathbb{E}(\cdot)$ to denote the expectation with respect to the joint density in (3) with the true parameters. We first introduce a pseudo-likelihood loss function for the parametric components $\{\boldsymbol{\beta}_j\}_{j=1}^d$ that is invariant to the nuisance parameters $\{f_j\}_{j\in[d]}$. Based on such a loss function, we present an Adaptive Multi-stage Convex Relaxation algorithm to estimate each $\boldsymbol{\beta}_j^*$ by minimizing the loss function regularized by a nonconvex penalty function. We then proceed to introduce the inferential procedure for accessing the uncertainty of a given edge in the graph.

3.1. A Nuisance-Free Loss Function

For graph estimation, we treat $\boldsymbol{\beta}_j$ as the parameter of interest and the base measures $f_j(\cdot)$ as nuisance parameter. Let $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ be n i.i.d. copies of $\boldsymbol{X}$. Due to the presence of $f_j(\cdot)$, finding the conditional maximum likelihood estimator of $\boldsymbol{\beta}_j$ is intractable. To solve this problem, we exploit a pseudo-likelihood loss function proposed in Ning et al. (2017b) that is invariant to the nuisance parameters $\{f_j\}_{j\in[d]}$. This pseudo-likelihood loss is based on pairwise local order statistics, which have been previously studied in Liang and Qin (2000); Diao et al. (2012); Chan (2012) for semiparametric regression models. More details are presented as follows.

Let $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n$ be n data points that are realizations of $\boldsymbol{X}_1, \boldsymbol{X}_2, \ldots, \boldsymbol{X}_n$. For any $1 \leq i < i' \leq n$, let

$$\mathcal{A}_{ii'}^j := \big\{(X_{ij}, X_{i'j}) = (x_{ij}, x_{i'j}), \boldsymbol{X}_{i\backslash j} = \boldsymbol{x}_{i\backslash j}, \boldsymbol{X}_{i'\backslash j} = \boldsymbol{x}_{i'\backslash j}\big\}$$

be the event that we observe $\boldsymbol{X}_{i\backslash j} = \boldsymbol{x}_{i\backslash j}$ and $\boldsymbol{X}_{i'\backslash j} = \boldsymbol{x}_{i'\backslash j}$ and the order statistics of X_{ij} and $X_{i'j}$ (but not the relative ranks of X_{ij} and $X_{i'j}$). More specifically, we denote $\max\{X_{ij}, X_{i'j}\}$ and $\min\{X_{ij}, X_{i'j}\}$ by O_1 and O_2, and let o_1 and o_2 be the observed values of O_1 and O_2. Then $\mathcal{A}_{ii'}^j$ can be equivalently written as $\{O_1 = o_1, O_2 = o_2, \boldsymbol{X}_{i\backslash j} = \boldsymbol{x}_{i\backslash j}, \boldsymbol{X}_{i'\backslash j} = \boldsymbol{x}_{i'\backslash j}\}$.

Let $R \in \{(1,2),(2,1)\}$ be the relative rank of X_{ij} and $X_{i'j}$, and r be the observed value. Then, by definition, we have

$$\begin{aligned}&\mathbb{P}\big(X_{ij}=x_{ij}, X_{i'j}=x_{i'j} \,\big|\, \boldsymbol{X}_{i\backslash j}=\boldsymbol{x}_{i\backslash j}, \boldsymbol{X}_{i'\backslash j}=\boldsymbol{x}_{i'\backslash j}\big)\\ &\quad=\mathbb{P}\big(O_1=o_1, O_2=o_2 \,\big|\, \boldsymbol{X}_{i\backslash j}=\boldsymbol{x}_{i\backslash j}, \boldsymbol{X}_{i'\backslash j}=\boldsymbol{x}_{i'\backslash j}\big)\cdot\mathbb{P}\big(R=r \,\big|\, \mathcal{A}_{ii'}^j\big).\end{aligned}$$

Furthermore, we have

$$\begin{aligned}\mathbb{P}\big(R=r \,\big|\, \mathcal{A}_{ii'}^j\big) &= \left[1+\frac{\mathbb{P}(X_{ij}=x_{i'j}, X_{i'j}=x_{ij} \,|\, \mathcal{A}_{ii'}^j)}{\mathbb{P}(X_{ij}=x_{ij}, X_{i'j}=x_{i'j} \,|\, \mathcal{A}_{ii'}^j)}\right]^{-1}\\ &= \left[1+\frac{\mathbb{P}(X_{ij}=x_{i'j}, X_{i'j}=x_{ij} \,|\, \boldsymbol{X}_{i\backslash j}=\boldsymbol{x}_{i\backslash j}, \boldsymbol{X}_{i'\backslash j}=\boldsymbol{x}_{i'\backslash j})}{\mathbb{P}(X_{ij}=x_{ij}, X_{i'j}=x_{i'j} \,|\, \boldsymbol{X}_{i\backslash j}=\boldsymbol{x}_{i\backslash j}, \boldsymbol{X}_{i'\backslash j}=\boldsymbol{x}_{i'\backslash j})}\right]^{-1} = \big[1+R_{ii'}^j(\boldsymbol{\beta}_j)\big]^{-1},\end{aligned} \tag{5}$$

where $R_{ii'}^j(\boldsymbol{\beta}_j) := \exp[-(x_{ij}-x_{i'j})\boldsymbol{\beta}_j{}^T(\boldsymbol{x}_{i\backslash j}-\boldsymbol{x}_{i'\backslash j})]$. Based on the conditional likelihood in (5), we construct the following pseudo-likelihood loss function for $\boldsymbol{\beta}_j$:

$$L_j(\boldsymbol{\beta}_j) := \frac{2}{n(n-1)}\sum_{1\le i<i'\le n}\log\big[1+R_{ii'}^j(\boldsymbol{\beta}_j)\big]. \tag{6}$$

Obviously, $L_j(\cdot)$ only involves $\boldsymbol{\beta}_j$. Since its form resembles the logistic loss, to find a minimizer of this loss function, we could readily apply any logistic regression solver.

3.2. Adaptive Multi-stage Convex Relaxation Algorithm

Now we are ready to present the algorithm for parameter estimation. For high dimensional sparse estimation, to promote sparsity, we minimize the sum of the loss functions $L_j(\boldsymbol{\beta}_j)$ and some penalty function. Two of the most prevalent methods are the LASSO (ℓ_1-penalization) (Tibshirani, 1996) and the folded concave penalization (Fan et al., 2014). Although the ℓ_1-penalization enjoys good computational properties as a convex optimization problem, it is known to incur significant estimation bias for parameters with large absolute values (Zhang and Huang, 2008). In contrast, nonconvex penalties such as smoothly clipped absolute deviation (SCAD) penalty, minimax concave penalty (MCP) and capped-ℓ_1 penalty can eliminate such bias and attain improved rates of convergence. Therefore, we consider the nonconvex optimization problem

$$\widehat{\boldsymbol{\beta}}_j = \underset{\mathbb{R}^{d-1}}{\operatorname{argmin}}\ \Big\{L_j(\boldsymbol{\beta}_j)+\sum_{k\neq j}p_\lambda(|\beta_{jk}|)\Big\}, \tag{7}$$

where $\lambda>0$ is a regularization parameter and $p_\lambda(\cdot):[0,+\infty)\to[0,+\infty)$ is a penalty function satisfying the following three conditions:

(C.1) The penalty function $p_\lambda(u)$ is continuously nondecreasing and concave with $p_\lambda(0)=0$.

(C.2) The right-hand derivative at $u=0$ satisfies $p'_\lambda(0)=p'_\lambda(0+)=\lambda$.

(C.3) There exist constants $c_1\in[0,1]$ and $c_2\in(0,+\infty)$ such that $p'_\lambda(u+)\ge c_1\lambda$ for $u\in[0,c_2\lambda]$.

Note that we only require the penalty function to be right-differentiable. In what follows, we denote by $p'_\lambda(u)$ the right-hand derivative. By (C.1), $p'_\lambda(u)$ is nonincreasing and nonnegative in $[0,\infty)$. It is easy to verify that SCAD, MCP and capped-ℓ_1 penalty all satisfy (C.1)–(C.3).

Due to the penalty term, the optimization problem in (7) is nonconvex and may have multiple local solutions. To overcome such difficulty, we exploit the local linear approximation algorithm (Zou and Li, 2008; Fan et al., 2014) or equivalently, the multi-stage convex relaxation (Zhang, 2010; Zhang et al., 2013; Fan et al., 2018) to attain an estimator of $\boldsymbol{\beta}_j^*$. Compared with previous works that mainly focus on sparse linear regression, our loss function $L_j(\boldsymbol{\beta}_j)$ is a U-statistics based logistic loss, which requires nontrivial extensions of the existing theoretical analysis.

We present the proposed adaptive multi-stage convex relaxation method in Algorithm 1. Our algorithm solves a sequence of convex optimization problems corresponding to finer and finer convex relaxations of the original nonconvex optimization problem. More specifically, for each $j=1,\ldots,d$, in the first iteration, step 4 of Algorithm 1 is equivalent to a ℓ_1-regularized optimization problem and we obtain the first-step solution $\widehat{\boldsymbol{\beta}}_j^{(1)}$. Then, in each subsequent iteration, we solve an adaptive ℓ_1-regularized optimization problem where the weights of the penalty depend on the solution of the previous step. For example, in the ℓ-th iteration, the regularization parameter $\lambda_{jk}^{(\ell-1)}$ in (8) is updated using the $(\ell-1)$-th step estimator $\widehat{\boldsymbol{\beta}}_j^{(\ell-1)}$. Note that $p'_\lambda\big(|\beta_{jk}^{(\ell)}|\big)$ is the right-hand derivative of $p_\lambda(u)$ evaluated at $u=|\beta_{jk}^{(\ell)}|$.

Since the optimization problem in step 4 is convex, our method is computationally efficient. Besides, note that (8) with $\ell=1$ corresponds to the ℓ_1-regularized problem. Hence, our approach can be viewed as a refinement of LASSO. As we will show in §4.1, the estimator $\widehat{\boldsymbol{\beta}}_j$ of $\boldsymbol{\beta}_j^*$ constructed by Algorithm 1 attains the optimal statistical rates of convergence for parameter estimation.

Algorithm 1 Adaptive Multi-stage Convex Relaxation algorithm for parameter estimation

1: Initialize $\lambda_{jk}^{(0)}=\lambda$ for $1\le j,k\le d$.
2: **for** j= 1,2,. . . ,d **do**
3: **for** $\ell=1,2,\ldots,$ until convergence **do**
4: Solve the convex optimization problem

$$\widehat{\boldsymbol{\beta}}_j^{(\ell)} = \underset{\mathbb{R}^{d-1}}{\operatorname{argmin}}\Big\{L_j(\boldsymbol{\beta}_j)+\sum_{k\neq j}\lambda_{jk}^{(\ell-1)}|\beta_{jk}|\Big\}. \tag{8}$$

5: Update $\lambda_{jk}^{(\ell)}$ by $\lambda_{jk}^{(\ell)}=p'_\lambda(|\widehat{\beta}_{jk}^{(\ell)}|)$ for $1\le k\le d, k\neq j$.
6: **end for**
7: **Output** $\widehat{\boldsymbol{\beta}}_j=\widehat{\boldsymbol{\beta}}_j^{(\ell)}$, where ℓ is the number of iterations until convergence is attained.
8: **end for**

3.3. Graph Inference: Composite Pairwise Score Test

For any given $1 \le j < k \le d$, we are interested in testing if $(j,k) \in E$, i.e., we consider the hypothesis testing problem $H_0 : \beta^*_{jk} = 0$ versus $H_1 : \beta^*_{jk} \neq 0$. To simplify the notation, we write $\boldsymbol{\beta}_{j\backslash k} = (\beta_{j1}, \ldots, \beta_{jj-1}, \beta_{jj+1}, \ldots, \beta_{jk-1}, \beta_{jk+1}, \ldots, \beta_{jd})^T \in \mathbb{R}^{d-2}$ and denote the parameters associated with node j and node k by $\boldsymbol{\beta}_{j\vee k} := \big(\beta_{jk}; \boldsymbol{\beta}^T_{j\backslash k}, \boldsymbol{\beta}^T_{k\backslash j}\big)^T \in \mathbb{R}^{2d-3}$. In addition, let $\mathbf{H}^j := \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}^*_j)\big]$ be the expected Hessian of $L_j(\boldsymbol{\beta}_j)$ evaluated at $\boldsymbol{\beta}^*_j$. We define two submatrices $\mathbf{H}^j_{jk,j\backslash k}$ and $\mathbf{H}^j_{j\backslash k,j\backslash k}$ of $\mathbf{H}^j$ as

$$\mathbf{H}^j_{jk,j\backslash k} := \left[\mathbb{E}\frac{\partial^2 L_j(\boldsymbol{\beta}^*_j)}{\partial\beta_{jk}\partial\beta_{jv}}\right]_{v\neq k} \in \mathbb{R}^{d-2} \text{ and } \mathbf{H}^j_{j\backslash k,j\backslash k} := \left[\mathbb{E}\frac{\partial^2 L_j(\boldsymbol{\beta}^*_j)}{\partial\beta_{ju}\partial\beta_{jv}}\right]_{u\neq k, v\neq k} \in \mathbb{R}^{(d-2)\times(d-2)},$$

and we define $\mathbf{H}^k_{jk,k\backslash j}$ and $\mathbf{H}^k_{k\backslash j,k\backslash j}$ similarly. Furthermore, we define

$$\mathbf{w}^*_{j,k} = \mathbf{H}^j_{jk,j\backslash k}\big[\mathbf{H}^j_{j\backslash k,j\backslash k}\big]^{-1} \quad \text{and} \quad \mathbf{w}^*_{k,j} = \mathbf{H}^k_{jk,k\backslash j}\big[\mathbf{H}^k_{k\backslash j,k\backslash j}\big]^{-1}. \tag{9}$$

Following the general approach in Ning et al. (2017a); Neykov et al. (2018), the composite pairwise score function for parameter β_{jk} is defined as

$$S_{jk}(\boldsymbol{\beta}_{j\vee k}) = \nabla_{jk} L_j(\boldsymbol{\beta}_j) + \nabla_{jk} L_k(\boldsymbol{\beta}_k) - \mathbf{w}^{*T}_{j,k} \nabla_{j\backslash k} L_j(\boldsymbol{\beta}_j) - \mathbf{w}^{*T}_{k,j} \nabla_{k\backslash j} L_k(\boldsymbol{\beta}_k). \tag{10}$$

where we write $\nabla_{jk} L_j(\boldsymbol{\beta}_j) = \partial L_j(\boldsymbol{\beta}_j)/\partial\beta_{jk}$ and $\nabla_{j\backslash k} L_j(\boldsymbol{\beta}_j) = \partial L_j(\boldsymbol{\beta}_j)/\partial\boldsymbol{\beta}_{j\backslash k}$. Here, the last two terms in (10) are constructed to reduce the effect of nuisance parameters $\boldsymbol{\beta}_{j\backslash k}$ and $\boldsymbol{\beta}_{k\backslash j}$ on assessing the uncertainty of β^*_{jk}, which is the parameter of interest. A key feature of $S_{jk}(\boldsymbol{\beta}_{j\vee k})$ is that the symmetry of β_{jk} and β_{kj} (i.e., $\beta_{jk} = \beta_{kj}$) is taken into account, which is distinct from the existing works such as Ren et al. (2015); Janková and van de Geer (2015); Liu et al. (2013) for Gaussian graphical models and Ning et al. (2017b) in the regression setup.

Note that both $\mathbf{w}^*_{j,k}$ and $\mathbf{w}^*_{k,j}$ are computed from $\mathbf{H}$, which is unknown. We estimate them using the Dantzig-type estimators (Candés et al., 2007). Specifically, we define the empirical versions of $\mathbf{H}^j_{jk,j\backslash k}$ and $\mathbf{H}^j_{j\backslash k,j\backslash k}$ as

$$\nabla^2_{jk,j\backslash k} L_j(\boldsymbol{\beta}_j) = \left[\frac{\partial^2 L_j(\boldsymbol{\beta}_j)}{\partial\beta_{jk}\partial\beta_{jv}}\right]_{v\neq k} \quad \text{and} \quad \nabla^2_{j\backslash k,j\backslash k} L_j(\boldsymbol{\beta}_j) = \left[\frac{\partial^2 L_j(\boldsymbol{\beta}_j)}{\partial\beta_{ju}\partial\beta_{jv}}\right]_{u\neq k, v\neq k}.$$

We also define $\nabla^2_{jk,k\backslash j} L_k(\boldsymbol{\beta}_k)$ and $\nabla^2_{k\backslash j,k\backslash j} L_k(\boldsymbol{\beta}_k)$ similarly. Then we estimate $\mathbf{w}^*_{j,k}$ by solving

$$\widehat{\mathbf{w}}_{j,k} = \operatorname{argmin} \|\mathbf{w}\|_1 \quad \text{such that} \quad \big\|\nabla^2_{jk,j\backslash k} L_j(0, \widehat{\boldsymbol{\beta}}_{j\backslash k}) - \mathbf{w}^T \nabla^2_{j\backslash k,j\backslash k} L_j(0, \widehat{\boldsymbol{\beta}}_{j\backslash k})\big\|_\infty \le \lambda_D, \tag{11}$$

where $\widehat{\boldsymbol{\beta}}_j$ is the estimator of $\boldsymbol{\beta}^*_j$ obtained from Algorithm 1 and λ_D is a regularization parameter. An estimator $\widehat{\mathbf{w}}_{k,j}$ of $\mathbf{w}^*_{k,j}$ can be similarly obtained. Based on $\widehat{\mathbf{w}}_{j,k}$ and $\widehat{\mathbf{w}}_{k,j}$, we construct the composite pairwise score statistic for β^*_{jk} by

$$\widehat{S}_{jk} = \nabla_{jk} L_j(0, \widehat{\boldsymbol{\beta}}_{j\backslash k}) + \nabla_{jk} L_k\big(0, \widehat{\boldsymbol{\beta}}_{k\backslash j}\big) - \widehat{\mathbf{w}}^T_{j,k} \nabla_{j\backslash k} L_j\big(0, \widehat{\boldsymbol{\beta}}_{j\backslash k}\big) - \widehat{\mathbf{w}}^T_{k,j} \nabla_{k\backslash j} L_k\big(0, \widehat{\boldsymbol{\beta}}_{k\backslash j}\big). \tag{12}$$

Comparing (10) and (12), we see that $\widehat{S}_{jk}$ is obtained by replacing $\boldsymbol{\beta}_j$ and $\boldsymbol{\beta}_k$ in (10) by $(0, \widehat{\boldsymbol{\beta}}_{j\backslash k})$ and $(0, \widehat{\boldsymbol{\beta}}_{k\backslash j})$ respectively and replacing $\mathbf{w}^*_{j,k}$ and $\mathbf{w}^*_{k,j}$ in (10) by $\widehat{\mathbf{w}}_{j,k}$ and $\widehat{\mathbf{w}}_{k,j}$.

To obtain a valid hypothesis test, we need to establish the limiting distribution of $\widehat{S}_{jk}$ under the null hypothesis. Note that $\widehat{S}_{jk}$ is a linear combination of entries of $\nabla L_j(\boldsymbol{\beta}_j)$ and $\nabla L_k(\boldsymbol{\beta}_k)$, both of which are U-statistics. In the next section, we prove the asymptotic normality of $\widehat{S}_{jk}$. More specifically, under the null hypothesis, we have $\sqrt{n}\widehat{S}_{jk}/2 \rightsquigarrow N(0, \sigma^2_{jk})$, where the limiting variance can be estimated consistently by $\widehat{\sigma}^2_{jk}$ (More details will be explained in the following section). With a significance level $\alpha \in (0,1)$, the test function $\psi_{jk}(\alpha)$ is defined as

$$\psi_{jk}(\alpha) = \begin{cases} 1 & \text{if } \big|\sqrt{n}\widehat{S}_{jk}/(2\widehat{\sigma}_{jk})\big| > \Phi^{-1}(1-\alpha/2) \\ 0 & \text{if } \big|\sqrt{n}\widehat{S}_{jk}/(2\widehat{\sigma}_{jk})\big| \le \Phi^{-1}(1-\alpha/2) \end{cases}, \tag{13}$$

where $\Phi(t)$ is the cumulative distribution function of a standard normal random variable.

In sum, the composite pairwise score test for the null hypothesis $H_0 \colon \beta^*_{jk} = 0$ consists of the following four steps: (i) Calculate $\widehat{\boldsymbol{\beta}}_j$ and $\widehat{\boldsymbol{\beta}}_k$ from Algorithm 1; (ii) Obtain $\widehat{\mathbf{w}}_{j,k}$ and $\widehat{\mathbf{w}}_{k,j}$ by solving two Dantzig-type problems defined in (11); (iii) Compute the limiting variance $\widehat{\sigma}^2_{jk}$; (iv) Evaluate the test function (13).

4. Theoretical Properties

In this section, we present our theoretical results. We first prove that the proposed procedure attains the optimal rate of convergence for parameter estimation. Then, we provide theory for the composite pairwise score test.

4.1. Theoretical Results for Parameter Estimation

We first establish the rates of convergence of the adaptive multi-stage convex relaxation estimator. We begin by listing several required assumptions. The first is about moment conditions of $\{X_j\}$ and the local smoothness of the log-partition function $A(\cdot)$ defined in (4). This assumption also appears in Yang et al. (2013a) and Chen et al. (2015) as a pivotal technical condition for theoretical analysis.

Assumption 2 *For all $j \in [d]$, we assume that the first two moments of X_j are bounded. That is, there exist two constants κ_m and κ_v such that $|\mathbb{E}(X_j)| \le \kappa_m$ and $\mathbb{E}(X_j^2) \le \kappa_v$. Denote the true parameters by $\{\boldsymbol{\beta}^*_j, f^*_j\}_{j\in[d]}$ and define d univariate functions $\bar{A}_j(\cdot) \colon \mathbb{R} \to \mathbb{R}$ as*

$$\bar{A}_j(u) := \log\left\{\int_{\mathbb{R}^d} \exp\left[u x_j + \sum_{k<\ell} \beta^*_{k\ell} x_k x_\ell + \sum_{i=1}^d f^*_i(x_i)\right] \mathrm{d}\nu(\boldsymbol{x})\right\}, \quad j \in [d].$$

We assume that there exists a constant κ_h such that $\max_{u:\,|u|\le 1} \bar{A}''_j(u) \le \kappa_h$ for all $j \in [d]$.

Unlike the Ising graphical models, $\{X_j\}_{j\in[d]}$ are not bounded in general for semiparametric exponential family graphical models. Instead, we impose mild conditions as in

Assumption 2 to obtain a loose control of the tail behaviors of the distribution of $\boldsymbol{X}$. As shown in Yang et al. (2013a), Assumption 2 implies that for all $j \in [d]$,

$$\max\big\{\log \mathbb{E}[\exp(X_j)], \log \mathbb{E}[\exp(-X_j)]\big\} \leq \kappa_m + \kappa_h/2.$$

Markov inequality implies for any $x > 0$,

$$\mathbb{P}\big(|X_j| \geq x\big) \leq 2\exp(\kappa_m + \kappa_h/2) \cdot \exp(-x). \tag{14}$$

Thus, by setting $x = C\log d$ in (14) with constant C sufficiently large, we have $\|\boldsymbol{X}\|_\infty \leq C\log d$ with high probability. In addition to Assumption 2, we also impose conditions to control the curvature of function $L_j(\cdot)$.

Definition 3 (Sparse eigenvalue condition) *For any $j, s \in [d]$, we define the s-sparse eigenvalues of $\mathbb{E}[\nabla^2 L_j(\boldsymbol{\beta}_j^*)]$ as*

$$\rho_{j+}^*(s) \coloneqq \sup_{\mathbf{v}\in\mathbb{R}^{d-1}} \big\{\mathbf{v}^T \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]\mathbf{v} \colon \|\mathbf{v}\|_0 \leq s, \|\mathbf{v}\|_2 = 1\big\};$$
$$\rho_{j-}^*(s) \coloneqq \inf_{\mathbf{v}\in\mathbb{R}^{d-1}} \big\{\mathbf{v}^T \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]\mathbf{v} \colon \|\mathbf{v}\|_0 \leq s, \|\mathbf{v}\|_2 = 1\big\}.$$

Assumption 4 *Let $s^* = \max_{j\in[d]} \|\boldsymbol{\beta}_j^*\|_0$. We assume that for any $j \in [d]$, there exist an integer $k^* \geq 2s^*$ satisfying $\lim_{n\to\infty} k^*(\log^9 d/n)^{1/2} = 0$ and a positive number ρ_* such that the sparse eigenvalues of $\mathbb{E}[\nabla^2 L_j(\boldsymbol{\beta}_j^*)]$ satisfy*

$$0 < \rho_* \leq \rho_{j-}^*(2s^* + 2k^*) < \rho_{j+}^*(k^*) < +\infty \quad \text{and}$$
$$\rho_{j+}^*(k^*)\big/\rho_{j-}^*(2s^* + 2k^*) \leq 1 + 0.2k^*/s^* \quad \text{for any } j \in [d].$$

The condition $\rho_{j+}^*(k^*)\big/\rho_{j-}^*(2s^*+2k^*) \leq 1+0.2k^*/s^*$ requires the eigenvalue ratio $\rho_{j+}^*(k)/\rho_{j-}^*(2k+2s^*)$ to grow sub-linearly in k. Assumption 4 is commonly referred to as sparse eigenvalue condition, which is standard for sparse estimation problems and has been studied by Bickel et al. (2009); Raskutti et al. (2010); Zhang (2010); Negahban et al. (2012); Xiao and Zhang (2013); Loh and Wainwright (2015) and Wang et al. (2014). Our assumption is similar to that in Zhang (2010) and is weaker than the restricted isometry property (RIP) proposed in Candés and Tao (2005). We claim that this assumption is true in general and will be verified for Gaussian graphical models in the appendix.

Now we are ready to present the main theorem of this section. Recall that the penalty function $p_\lambda(u)$ satisfies conditions (C.1)–(C.3) in §3.2. We use $p'_\lambda(u)$ to denote its right-hand derivative. For convenience, we will set $p'_\lambda(u) = 1$ when $u < 0$.

Theorem 5 (ℓ_2- and ℓ_1-rates of convergence) *For all $j \in [d]$, we define the support of $\boldsymbol{\beta}_j^*$ as $S_j \coloneqq \big\{(j,k) \colon \beta_{jk}^* \neq 0, k \in [d]\big\}$ and let $s^* = \max_{j\in[d]} \|\boldsymbol{\beta}_j^*\|_0$. Let $\rho_* > 0$ be defined in Assumption 4. Under Assumptions 2 and 4, there exists an absolute constant $K > 0$ such that $\|\nabla L_j(\boldsymbol{\beta}_j^*)\|_\infty \leq K\sqrt{\log d/n}, \forall j \in [d]$ with probability at least $1 - (2d)^{-1}$. Moreover, the penalty function $p_\lambda(\cdot)$ in (7) satisfies (C.1)–(C.3) listed in §3.2 with $c_1 = 0.91$ and $c_2 \geq 24/\rho_*$ for condition (C.3). We set the regulization parameter $\lambda = C\sqrt{\log d/n}$ with $C \geq 25K$. We denote constants $\varrho = c_2(c_2\rho_* - 11)^{-1}$, $A_1 = 22\varrho$, $A_2 = 2.2c_2$, $B_1 = 32\varrho$,*

$B_2 = 3.2c_2$, $\gamma = 11c_2^{-1}\rho_*^{-1} < 1$, and define $\Upsilon_j \coloneqq [\sum_{(j,k)\in S_j} p'_\lambda(|\beta_{jk}^*| - c_2\lambda)^2]^{1/2}$. Then, with probability at least $1 - d^{-1}$, we have the following statistical rates of convergence:

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \leq A_1\big[\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + A_2\sqrt{s^*}\lambda\gamma^\ell \quad \text{and} \tag{15}$$
$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq B_1\sqrt{s^*}\big[\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + B_2 s^*\lambda\gamma^\ell, \forall j \in [d]. \tag{16}$$

By Theorem 5, the statistical rates are dominated by the second term if $p'_\lambda(|\beta_{jk}^*| - c_2\lambda)$ is not negligible. If the signal strength is large enough such that $p'_\lambda(\beta - c_2\lambda) = 0$ where $\beta = \min_{(j,k)\in S_j} |\beta_{jk}^*|$, after sufficient number of iterations, the statistical rates will be of the order

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 = \mathcal{O}_{\mathbb{P}}\big(\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2\big) \quad \text{and} \quad \big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 = \mathcal{O}_{\mathbb{P}}\big(\sqrt{s^*}\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2\big).$$

However, if the signals are uniformly small such that $p'_\lambda\big(|\beta_{jk}^*| - c_2\lambda\big) > 0$ for all $(j,k) \in S_j$, the rates of convergence will be of the order

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 = \mathcal{O}_{\mathbb{P}}\big(\sqrt{s^*}\lambda\big) \quad \text{and} \quad \big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 = \mathcal{O}_{\mathbb{P}}\big(s^*\lambda\big),$$

which are identical to the ℓ_2- and ℓ_1-rates of the LASSO estimator, respectively (Ning et al., 2017b). Thus $c_2\lambda$ can be viewed as the threshold of signal strength. Therefore, after sufficient numbers of iterations, the final estimator $\widehat{\boldsymbol{\beta}}_j$ obtained by Algorithm 1 attains the following more refined rates of convergence:

$$\big\|\widehat{\boldsymbol{\beta}}_j - \boldsymbol{\beta}_j^*\big\|_2 = \mathcal{O}_{\mathbb{P}}\Big(\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\Big) \text{ and } \big\|\widehat{\boldsymbol{\beta}}_j - \boldsymbol{\beta}_j^*\big\|_1 = \mathcal{O}_{\mathbb{P}}\Big(\sqrt{s^*}\big[\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big]\Big).$$

These statistical rates of convergence are optimal in the sense that they cannot be improved in terms of the order.

Finally, we comment that the sparsity level s^* in (15) and (16) can be replaced by the sparsity level of each $\boldsymbol{\beta}_j^*$. Let $s_j^* = \|\boldsymbol{\beta}_j^*\|_0$ be the sparsity level of $\boldsymbol{\beta}_j^*$ and λ_j be the regularization parameter for optimization problem (7) such that $\lambda_j \asymp \|\nabla L_j(\boldsymbol{\beta}_j^*)\|_\infty$. The statistical rates of convergence for each $\widehat{\boldsymbol{\beta}}_j^{(\ell)}$ can be improved to

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 = \mathcal{O}_{\mathbb{P}}\big(\sqrt{s_j^*}\lambda_j\big) \quad \text{and} \quad \big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 = \mathcal{O}_{\mathbb{P}}\big(s_j^*\lambda_j\big).$$

We use the uniform sparsity level $s^* = \max_{j\in[d]} s_j^*$ and the same regularization parameter λ for simplicity, but the proof can be easily adapted to individual s_j^* and λ_j for each $j \in [d]$.

4.2. Theoretical Results for Composite Pairwise Score Test

In the composite pairwise score test for the null hypothesis $H_0 : \beta_{jk}^* = 0$, we construct the test statistic by combining the loss functions $L_j(\cdot)$ and $L_k(\cdot)$ together because β_{jk} appears in both $L_j(\boldsymbol{\beta}_j)$ and $L_k(\boldsymbol{\beta}_k)$ (recall that we use β_{jk} and β_{kj} interchangeably). In the sequel, we present the theoretical results that guarantee the validity of the proposed inferential method.

Recall that we define the pairwise score function $S_{jk}(\boldsymbol{\beta}_{j\vee k})$ and the pairwise score statistic $\widehat{S}_{jk}$ in (10) and (12) respectively. According to a fixed pair of nodes (j,k), entries in

$\boldsymbol{\beta}_j$ and $\boldsymbol{\beta}_k$ can be categorized into three types: (i) β_{jk}, (ii) $\boldsymbol{\beta}_{j\backslash k} = (\beta_{j\ell}; \ell \neq k)^T$, and (iii) $\boldsymbol{\beta}_{k\backslash j} = (\beta_{k\ell}; \ell \neq j)^T$. Recall that we write $\boldsymbol{\beta}_{j\vee k} = (\beta_{jk}, \boldsymbol{\beta}_{j\backslash k}^T, \boldsymbol{\beta}_{k\backslash j}^T)^T$ for notational simplicity. Moreover, letting $L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big) := L_j(\boldsymbol{\beta}_j) + L_k(\boldsymbol{\beta}_j)$, the entries of $\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ are given by

$$\nabla_{jk} L_{jk}(\boldsymbol{\beta}_{j\vee k}) = \nabla_{jk} L_j(\boldsymbol{\beta}_j) + \nabla_{kj} L_k(\boldsymbol{\beta}_k); \quad \nabla_{j\backslash k} L_{jk}(\boldsymbol{\beta}_{j\vee k}) = \nabla_{j\backslash k} L_j(\boldsymbol{\beta}_j), \quad \text{and}$$
$$\nabla_{k\backslash j} L_{jk}(\boldsymbol{\beta}_{j\vee k}) = \nabla_{k\backslash j} L_k(\boldsymbol{\beta}_k).$$

Let $\widehat{\boldsymbol{\beta}}_j$ and $\widehat{\boldsymbol{\beta}}_k$ be the estimators of $\boldsymbol{\beta}_j^*$ and $\boldsymbol{\beta}_k^*$ obtained from Algorithm 1. Note that we can write the pairwise score function $S_{jk}(\cdot)$ and the test statistic $\widehat{S}_{jk}$ as

$$S_{jk}(\boldsymbol{\beta}_{j\vee k}) = \nabla_{jk} L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big) - \mathbf{w}_{j,k}^{*T} \nabla_{j\backslash k} L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big) - \mathbf{w}_{k,j}^{*\ T} \nabla_{k\backslash j} L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big) \quad \text{and} \tag{17}$$
$$\widehat{S}_{jk} = \nabla_{jk} L_{jk}\big(\widehat{\boldsymbol{\beta}}'_{j\vee k}\big) - \widehat{\mathbf{w}}_{j,k}^T \nabla_{j\backslash k} L_{jk}\big(\widehat{\boldsymbol{\beta}}'_{j\vee k}\big) - \widehat{\mathbf{w}}_{k,j}^T \nabla_{k\backslash j} L_{jk}\big(\widehat{\boldsymbol{\beta}}'_{j\vee k}\big), \tag{18}$$

where we write $\widehat{\boldsymbol{\beta}}'_{j\vee k} := \big(0, \widehat{\boldsymbol{\beta}}_{j\backslash k}^T, \widehat{\boldsymbol{\beta}}_{k\backslash j}^T\big)^T$, $\mathbf{w}_{j,k}^*$ and $\mathbf{w}_{k,j}^*$ are defined in (9), $\widehat{\mathbf{w}}_{j,k}$ is obtained from the Dantzig-type problem in (11), and $\widehat{\mathbf{w}}_{k,j}$ can be obtained similarly. To derive the asymptotic distribution of $\widehat{S}_{jk}$ under the null hypothesis, we first show that $\sqrt{n}\big[\widehat{S}_{jk} - S_{jk}(\boldsymbol{\beta}_{j\vee k}^*)\big] = o_{\mathbb{P}}(1)$. Then the problem is reduced to finding the limiting distribution of $S_{jk}(\boldsymbol{\beta}_{j\vee k}^*)$ under H_0. Thanks to its structure of being a U-statistics, we can characterize the limiting distribution of $S_{jk}(\boldsymbol{\beta}_{j\vee k}^*)$ using the method of Hájek projection (Van der Vaart, 2000), which approximates a U-statistic with a sum of independent random variables.

To begin with, we denote the kernel functions of $\nabla L_j(\boldsymbol{\beta}_j)$, $\nabla L_k(\boldsymbol{\beta}_k)$ and $\nabla L_{jk}(\boldsymbol{\beta}_{j\vee k})$ as $\mathbf{h}_{ii'}^j(\boldsymbol{\beta}_j)$, $\mathbf{h}_{ii'}^k(\boldsymbol{\beta}_k)$ and $\mathbf{h}_{ii'}^{jk}(\boldsymbol{\beta}_{j\vee k})$ respectively. It can be shown that $\mathbb{E}[\mathbf{h}_{ii'}^j(\boldsymbol{\beta}_j^*)] = \mathbb{E}[\mathbf{h}_{ii'}^k(\boldsymbol{\beta}_k^*)] = 0$; hence $\mathbf{h}_{ii'}^{jk}(\boldsymbol{\beta}_{j\vee k}^*)$ is also centered. We define

$$\mathbf{g}_{jk}(\boldsymbol{X}_i) := n/2 \cdot \mathbb{E}\big[\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)\big|\boldsymbol{X}_i\big] = \mathbb{E}\big[\mathbf{h}_{ii'}^{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)\big|\boldsymbol{X}_i\big] \quad \text{and} \tag{19}$$
$$\mathbf{U}_{jk} := \frac{2}{n} \sum_{i=1}^n \mathbf{g}_{jk}(\boldsymbol{X}_i) = \sum_{i=1}^n \mathbb{E}\big[\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)\big|\boldsymbol{X}_i\big]. \tag{20}$$

Thus $2/n \cdot \mathbf{g}_{jk}\big(\boldsymbol{X}_i\big)$ is the projection of $\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)$ onto the σ-filed generated by $\boldsymbol{X}_i$ and $\mathbf{U}_{jk}$ is the Hájek projection of $\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)$. Under mild conditions, $\mathbf{U}_{jk}$ in (20) is a good approximation of $\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)$, which enables us to characterize the limiting distribution of $S_{jk}(\boldsymbol{\beta}_{j\vee k}^*)$. We present the following assumption that guarantees the non-degeneracy of $\mathbf{g}_{jk}\big(\boldsymbol{X}_i\big)$.

Assumption 6 *Under Assumption 2, for $\mathbf{g}_{jk}(\boldsymbol{X}_i)$ defined in (19), we denote the covariance matrix of $\mathbf{g}_{jk}(\boldsymbol{X}_i)$ as $\boldsymbol{\Sigma}^{jk} := \mathbb{E}[\mathbf{g}_{jk}(\boldsymbol{X}_i)\mathbf{g}_{jk}(\boldsymbol{X}_i)^T]$. We assume that there exists a constant $c_\Sigma > 0$ such that $\lambda_{\min}(\boldsymbol{\Sigma}^{jk}) \geq c_\Sigma$ for all $1 \leq j < k \leq d$.*

Assumption 6 requires the minimum eigenvalue of $\boldsymbol{\Sigma}^{jk}$ to be bounded away from 0, which implies $\mathrm{Var}(\mathbf{v}^T\mathbf{U}_{jk}) \geq 4c_\Sigma$ for all $\mathbf{v} \in \mathbb{R}^{2d-3}$ with $\|\mathbf{v}\|_2 = 1$. Thus, this assumption guarantees the asymptotic variance of $\sqrt{n}S_{jk}(\boldsymbol{\beta}_{j\vee k}^*)$ is bounded away from 0. We also present the following assumption that specifies the scaling of the Dantzig selector problem in (11).

Assumption 7 *We assume that $\mathbf{H}^j$ is invertible for all $j \in [d]$. In addition, we assume that there exist an integer $s_0^\star$ and a positive number w_0 such that $\|\mathbf{w}_{j,k}^*\|_0 \leq s_0^\star - 1$ and $\|\mathbf{w}_{j,k}^*\|_1 \leq w_0$. Besides, the regularization parameter λ_D in (11) satisfies $\lambda_D \asymp \max\{1, w_0\} s^*\lambda \log^2 d$. Moreover, we assume that*

$$\lim_{n\to\infty} (1+w_0+w_0^2) s^*\lambda \log^2 d = 0, \quad \lim_{n\to\infty} (1+w_0) s_0^\star \lambda_D = 0, \quad \text{and} \quad \lim_{n\to\infty} \sqrt{n}(s^*+s_0^\star)\lambda\lambda_D = 0. \tag{21}$$

In addition, recall that we denote the s-sparse eigenvalues of $\mathbb{E}[\nabla^2 L_j(\boldsymbol{\beta}_j^*)]$ by $\rho_{j-}^*(s)$ and $\rho_{j+}^*(s)$. We further assume that there exist an integer $k_0^\star \geq s_0^\star$ and a positive number ν_* such that

$$\lim_{n\to\infty} k_0^\star \big(\log^9 d/n\big)^{1/2} = 0, \quad 0 < \nu_* \leq \rho_{j-}^*(s_0^\star + k_0^\star) < \rho_{j+}^*(k_0^\star) \leq \big(1 + 0.5k_0^\star/s_0^\star\big)\nu_*, \quad 1 \leq j \leq d.$$

If we can treat w_0 as a constant, and k^* and $k_0^\star$ is of the same order of s^* and $s_0^\star$, respectively, Assumption 7 is reduced to $\lambda_D \asymp s^*\lambda \log^2 d$, $s_0^\star\lambda_D = o(1)$, $s^*\lambda\log^2 d = o(1)$, and $(s^*+s^\star)\lambda\lambda_D = o(n^{1/2})$. Since $\lambda \asymp \sqrt{\log d/n}$, we can choose $\lambda_D = Cs^*(\log^5 d/n)^{1/2}$ with a sufficiently large C, provided $(s^* + s_0^\star)(\log^9 d/n)^{1/2} = o(1)$, $s_0^\star s^*(\log^5 d/n)^{1/2} = o(1)$, and $(s^* + s_0^\star)s^* \log^3 d/n = o(n^{-1/2})$. Hence this condition is fulfilled if

$$\log d = o\Big(\min\big\{(\sqrt{n}/s^*)^{2/9}, (\sqrt{n}/s_0^\star)^{2/9}, (\sqrt{n}/s^{*2})^{1/3}, (\sqrt{n}/s^*s^\star)^{1/3}\big\}\Big).$$

Now we are ready to present the main theorem of composite pairwise score test.

Theorem 8 *Under the Assumptions 2, 4, 6 and 7, it holds uniformly for all $j \neq k$ and $j, k \in [d]$ that $\sqrt{n}\widehat{S}_{jk} = \sqrt{n}S_{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big) + o_{\mathbb{P}}(1)$. Furthermore, we let $\widehat{\boldsymbol{\beta}}'_{j\vee k} = (0, \widehat{\boldsymbol{\beta}}_{j\backslash k}^T, \widehat{\boldsymbol{\beta}}_{k\backslash j}^T)^T$ and define $\widehat{\boldsymbol{\Sigma}}^{jk} := n^{-1}\sum_{i=1}^n \big\{(n-1)^{-1}\sum_{i'\neq i} \mathbf{h}_{ii'}^{jk}(\widehat{\boldsymbol{\beta}}'_{j\vee k})\big\}^{\otimes 2}$, where $\mathbf{h}_{ii'}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ is the kernel function of the second-order U-statistic $\nabla L_{jk}(\boldsymbol{\beta}_{j\vee k})$. In addition, we define $\widehat{\sigma}_{jk}$ by*

$$\widehat{\sigma}_{jk}^2 := \widehat{\boldsymbol{\Sigma}}_{jk,jk}^{jk} - 2\widehat{\boldsymbol{\Sigma}}_{jk,j\backslash k}^{jk}\widehat{\mathbf{w}}_{j,k} - 2\widehat{\boldsymbol{\Sigma}}_{jk,k\backslash j}^{jk}\widehat{\mathbf{w}}_{k,j} + \widehat{\mathbf{w}}_{j,k}^T\widehat{\boldsymbol{\Sigma}}_{j\backslash k,j\backslash k}^{jk}\widehat{\mathbf{w}}_{j,k} + \widehat{\mathbf{w}}_{k,j}^T\widehat{\boldsymbol{\Sigma}}_{k\backslash j,k\backslash j}^{jk}\widehat{\mathbf{w}}_{k,j}.$$

Then, under the null hypothesis $H_0\colon \beta_{jk}^* = 0$, we have $\sqrt{n}\widehat{S}_{jk}/(2\widehat{\sigma}_{jk}) \rightsquigarrow N(0,1)$.

By Theorem 8, to test the null hypothesis $H_0\colon \beta_{jk}^* = 0$ against the alternative hypothesis $H_1 : \beta_{jk}^* \neq 0$, we reject H_0 if the studentized test statistic $\sqrt{n}\widehat{S}_{jk}/(2\widehat{\sigma}_{jk})$ is too extreme. Recall that the test function of the composite pairwise score test with significance level α is deboted by $\psi_{jk}(\alpha)$ in (13). The associated p-value is defined as $p_\psi^{jk} := 2\big[1 - \Phi\big(\big|\sqrt{n}\widehat{S}_{jk}/(2\widehat{\sigma}_{jk})\big|\big)\big]$. By Theorem 8, under H_0, we have

$$\lim_{n\to\infty} \mathbb{P}\big(\psi_{jk}(\alpha) = 1 \mid H_0\big) = \alpha \quad \text{and} \quad p_\psi^{jk} \rightsquigarrow \mathrm{Unif}[0,1] \ \text{ under } H_0,$$

where $\mathrm{Unif}[0,1]$ is the uniform distribution over $[0,1]$.

We note that our inferential approach is still valid if we replace $\widehat{\boldsymbol{\beta}}'_{j\vee k}$ in (18) by other estimators of $\boldsymbol{\beta}_{j\vee k}^*$, provided such an estimator converges to $\boldsymbol{\beta}_{j\vee k}^*$ at an appropriate statistical rate. Our theory still holds after simple modification on the proof when controlling the order of the remainder terms.

Remark 9 *There are a number of recent works on the uncertainty assessment for high dimensional linear models or generalized linear models with ℓ_1-penalty; see Lee et al. (2016); Lockhart et al. (2014); Belloni et al. (2012, 2013); Zhang and Zhang (2014); Javanmard and Montanari (2014); van de Geer et al. (2014). These works utilize the convexity and the Karush-Kuhn-Tuker conditions of the LASSO problem. Compared with these works, our pairwise score test is constructed using a nonconvex penalty function and is applicable to a larger model class. Ning et al. (2017b) consider the score test for ℓ_1-penalized semiparametric generalized linear models in the regression setting. Compared with this work, we adopt a composite score test with a nonconvex penalty and relax many technical assumptions including the bounded covariate assumption. For nonconvex penalizations, Fan and Lv (2011); Bradic et al. (2011) establish the asymptotic normality for the low dimensional and nonzero parameters in high dimensional models based on the oracle properties. However, their approach depends on the minimal signal strength assumption, which is not needed in our approach.*

5. Numerical Results

In this section we study the finite-sample performance of the proposed graph inference methods on both simulated and real-world datasets.

5.1. Simulation Studies

We first examine the numerical performance of the proposed pairwise score tests for the null hypothesis $H_0 : \beta^*_{jk} = 0$. We simulate data from the following three settings:

(i) Gaussian graphical model. We set $n = 100$ and $d = 200$. The graph structure is a 4-nearest-neighbor graph, that is, for $j, k \in [d]$, $j \neq k$, node j is connected with node k if $|j - k| = 1, 2, d-2, d-1$. More specifically, we sample $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ from a Gaussian distribution $N_d(\mathbf{0}, \boldsymbol{\Sigma})$. For the precision matrix $\boldsymbol{\Theta} = \boldsymbol{\Sigma}^{-1}$, we set $\boldsymbol{\Theta}_{jj} = 1$, $\big|\boldsymbol{\Theta}_{jk}\big| = \mu \in [0, 0.25)$ for $|j - k| = 1, 2, d-2, d-1$ and $\boldsymbol{\Theta}_{jk} = 0$ for $2 \leq |j - k| \leq d - 2$. Note that μ denotes the signal strength of the graph inference problem and $\mu \leq 0.25$ ensures that $\boldsymbol{\Theta}$ is diagonal dominant and invertible.

(ii) Ising graphical model. We set $n = 100$ and $d = 200$. The graph structure is a 10×20 grid with the sparsity level $s^* = 4$. We use Markov Chain Monte Carlo method (MCMC) to simulate n data from an Ising model with joint distribution $p(\boldsymbol{x}) \propto \exp\big(\sum_{j \neq k} \beta^*_{jk} x_j x_k\big)$ (using the package `IsingSampler` (Epskamp, 2015)). We set $|\beta^*_{jk}| = \mu \in [0, 1]$ if there exists an edge connecting node j and node k, and $\beta^*_{jk} = 0$ otherwise.

(iii) Mixed graphical model. We set $n = 100$ and $d = 200$. The graph structure is a $10 \times 10 \times 2$ grid with the sparsity level $s^* = 5$. We set the nodes in the first layer to be binomial and nodes in the second layer to be Gaussian. We set $|\beta^*_{jk}| = \mu \in [0, 1]$ if there exists an edge connecting node j and node k, and $\beta^*_{jk} = 0$ otherwise. We refer to Lee and Hastie (2015) for details.

We denote the true parameters of the graphical models as $\{\beta^*_{jk}, j \neq k\}$. We also denote $\boldsymbol{\beta}^*_j = (\beta^*_{j1}, \ldots, \beta^*_{jd})^T$. For the Gaussian graphical model, we have $\beta^*_{jk} = \boldsymbol{\Theta}_{jk}$. We first

obtain a point estimate of $\boldsymbol{\beta}^*_j$ by solving (7) using Algorithm 1 with the capped-ℓ_1 penalty $p_\lambda(u) = \lambda \min\{u, \lambda\}$. The parameter λ is chosen by 10-fold cross validation as suggested by Ning et al. (2017b).

Recall that the form of the loss function $L_j(\boldsymbol{\beta}_j)$ is exactly the loss function for logistic regression, where we use Rademacher random variables $y_{ii'}$ as response and $y_{ii'}(x_{ij} - x_{i'j})\boldsymbol{\beta}_j^T(\boldsymbol{x}_{i\backslash j} - \boldsymbol{x}_{i'\backslash j})$ as covariates, Algorithm 1 can be easily implemented by using the ℓ_1-regularized logistic regression such as the `PICASSO` package (Ge et al., 2017). In particular, the algorithm converges quickly after a few iterations, indicating that it attains a good balance between computational efficiency and statistical accuracy. Once $\widehat{\boldsymbol{\beta}}_j$ is obtained, we solve the Dantzig-type problem (11) using $\widehat{\boldsymbol{\beta}}_j$ as input. We set the regularization parameter λ_D to be 1. In practice, the performance of the proposed method is not very sensitive to the choice of λ_D.

To examine the performance of our semiparametric modeling approach, we compare the pairwise score test with the desparsity method in van de Geer et al. (2014). Although this method is proposed for hypothesis tests in generalized linear models (GLMs), it can be adapted for graphical models by performing nodewise regression, assuming the base measures $\{f_j\}_{j \in [d]}$ are correctly specified. When testing $H_0 : \beta^*_{jk} = 0$ with $j < k$, we apply the desparsity method with X_j and $\boldsymbol{X}_{\backslash j}$ being the response and covariates, respectively. Furthermore, to show that combining both $L_j(\boldsymbol{\beta}_j)$ and $L_k(\boldsymbol{\beta}_k)$ is beneficial for inferring β^*_{jk}, we also compare our method with the asymmetric score test, which constructs a score test statistic similar to that in (12) based solely on $L_j(\boldsymbol{\beta}_j)$.

To examine the validity of our method, we test $H_0 : \beta^*_{jk} = 0$ versus $H_1 : \beta^*_{jk} \neq 0$ for all (j, k). Recall that $\beta^*_{jk} = \mu$ when there is an edge. Here, we let μ increase from 0 to a sufficiently large number. We calculate the type I errors and powers as

$$\text{Type I error} = \frac{\text{the number of rejected hypotheses when there is no edge}}{d(d-1)/2 - \text{the total number of edges}},$$

$$\text{Power} = \frac{\text{the number of rejected hypotheses when there is an edge}}{\text{the total number of edges}}.$$

We report the type I errors and powers of the hypothesis tests at the 0.05 significance level in Figure 1 and Figure 2, respectively. The simulation is repeated 100 times. As revealed in Figure 1, both the asymmetric and the pairwise score test achieve accurate type I errors, which is comparable to the desparsity method. Moreover, in terms of the power of the test, in Figure 2, the two score tests based on the loss function defined in (6) are less powerful than the desparsity method, which shows the loss of efficiency by only considering the relative rank. However, as shown in Figure 2-(b) and (c), the two score tests are nearly as powerful as the desparsity method in the Ising and mixed graphical models. In addition, we emphasize that for mixed graphical models the desparsity method needs to know the type (or distribution) of each nodes as a priori. Such phenomenon suggests that we may sacrifice little efficiency for model generality/robustness. Furthermore, comparing the performances of these two score tests, we see that the pairwise score test achieves uniformly higher power than the asymmetric one, which perfectly illustrates that taking into consideration of the symmetry of β^*_{jk} and β^*_{kj} may improve the inference accuracy.

5.2. Real Data Analysis

We then apply the proposed methods to analyze a publicly available dataset named `Computer Audition Lab 500-Song (CAL500)` dataset (Turnbull et al., 2008). The data can be obtained from the `Mulan` database (Tsoumakas et al., 2011). The `CAL500` dataset consists of 502 popular music tracks each of which is annotated by at least three listeners. The attributes of this dataset include two subsets: (i) continuous numerical features extracted from the time series of the audio signal and (ii) discrete binary labels assigned by human listeners to give semantic descriptions of the song. For each music track, short time Fourier transform is implemented for a sequence of half-overlapping 23ms time windows over the song's digital audio file. This procedure generates four types of continuous features: *spectral centroids, spectral flux, zero crossings* and a time series of Mel-frequency cepstral coefficient

(MFCC). For the MFCC vectors, every consecutive 502 short time windows are grouped together as a block window to produce the following four types of features: (i) overall mean of MFCC vectors in each block window, (ii) mean of standard deviations of MFCC vectors in each block window, (iii) standard deviation of the means of MFCC vectors in each block window, and (iv) standard deviation of the standard deviations of MFCC vectors in each block window. More details on the feature extraction can be found in Tzanetakis and Cook (2002). In addition to these continuous variables, binary variables in the `CAL500` dataset include a 174-dimensional array indicating the existence of each annotation. These 174 annotations can be grouped into six categories: emotions (36 variables), instruments (33), usages (15), genres (47), song characteristics (27) and vocal types (16). Our goal is to infer the association between these different types of variables using graphical models. This dataset has been analyzed in Cheng et al. (2017) where they exploit a nodewise group-LASSO regression to estimate the graph structure. In what follows, we use the proposed pairwise score test to examine the graph structure.

Similar to Turnbull et al. (2008) and Cheng et al. (2017), we only keep the MFCC features because they can be interpreted as the amplitude of the audio signal and the other continuous features are not readily interpretable. Unlike Cheng et al. (2017), we keep all the binary labels. Thus the processed dataset has $n = 502$ data points of dimension $d = 226$ with 52 continuous variables and 174 binary variables. We apply the pairwise score test to each pair of variables to determine the presence of an edge between them. The p-values for the null hypothesis that two variables are conditionally independence given the rest of variables are calculated. We then apply the Bonferroni correction to control the familywise error rate at 0.05. We set the nonconvex penalty function in optimization problem (7) to be capped-ℓ_1 penalty $p_\lambda(u) = \lambda \min\{u, \lambda\}$ with the regularization parameter λ selected by 10-fold cross-validation as in the previous section.

We compare the pairwise score test with the desparsity method and the asymmetric score test, which are constructed in the same way as in the simulation. We present the fitted graphs obtained by these three methods in Figure 3-(a)–(c), where we plot the connected components and omit the singletons. Moreover, in Figure 3-(d), we plot the intersection of these three graphs. To better display the graphical structure, we use a square to represent each type of 13 MFCC features respectively. If a node is connected to any node within the group of variables in a MFCC node, then we draw an edge. We use circles to represent the binary variables and use different colors to indicate their categories. The obtained graphs have some interesting properties. While all three tests create different graphs, the graphs obtained by the pairwise score test and the asymmetric score test have more common edges, which agrees with our simulation results. Indeed, our test can correct the inconsistency of the asymmetric score test, in the sense that the asymmetric score tests for $\beta^*_{jk} = 0$ and $\beta^*_{kj} = 0$ may yield different test results. To show this inconsistency problem, we also plot the graph obtained by the asymmetric score test based on the loss function $L_k(\boldsymbol{\beta}_k)$ in Figure 4 in the appendix. Comparing with Figure 3-(b), we can see that the asymmetric score test indeed leads to many contradictory edges.

In Figure 3, both the pairwise score test and this asymmetric score test discover that songs that are danceable (circle 92) are suited for parties (circle 93), but such a connection is not found by the desparsity method. This is also true for the connection between the rapping vocals (circle 119) and the rap genre (circle 48) and the edge between strong vocals

(circle 122) and songs with strong emotions (circle 19). Moreover, in all three graphs, the continuous features are densely connected within themselves, which is similar to the results in Cheng et al. (2017). All three tests find that the noisiness of the music (square 4) is connected with the quality of songs (circle 85). Furthermore, the common edges connecting two binary variables also display interesting patterns. For instance, we find that awakening emotions (circle 6) are connected with soothing emotions (circle 8); laid-back emotions (circle 14) are connected with songs with high energy (circle 32); sad emotions (circle 20) are connected with songs with positive feelings (circle 84); songs with female lead vocals (circle 62) are connected with those with male lead vocals (circle 66). In addition, songs using drum sets (circle 59) are connected with the electronica genre (circle 46), which is also connected with the acoustic texture (circle 88). All these edges have fairly intuitive explanations.

In summary, the proposed method reveals some interesting associations between these variables and can be used as a useful complement to analyze high dimensional datasets with more complex distributions.

6. Conclusion

We propose an integrated framework for uncertainty assessment of a new semiparametric exponential family graphical model. The novelty of our model is that the base measures of each nodewise conditional distribution are treated as unknown nuisance functions. Towards the goal of uncertainty assessment, we first adopt the adaptive multi-stage relaxation algorithm to perform the parameter estimation. Then we propose a composite pairwise score test of the graph structure. Our method provides a rigorous justification for the uncertainty assessment, and is further supported by extensive numerical results. In a followup paper (Tan et al., 2016), the proposed model is further extended to account for the unobserved latent variables in the graphical model.

(a). Pairwise score test. (b). Asymmetric score test.

(c). Desparsity method. (d). The common edges.

Figure 3: Estimated graphs in the `CAL500` dataset inferred by the pairwise score test, asymmetric score test, and the desparsity method. We plot the connected components of the estimated graph. In (a)-(c) we plot the graphs obtained by these three approaches, respectively, and plot the common edges in (d). For better illustration, we only plot the connected components, combine the same type of continuous variables, display them as a square and draw each binary variable as a circle. The edges of the estimated graph show the association between these variables.

Appendix A. Proof of the Main Results

In this appendix we lay out the proof of the main results. In §A.1 we prove the result of parameter estimation. The proof is based an induction argument that Algorithm 1 keeps penalizing most of the irrelevant features and gradually reduces the bias in relevant features.

A.1. Proof of Theorem 5

Proof We only need to prove the theorem for one node $j \in [d]$, the proof is identical for the rest. To begin with, we first define a few index sets that play a significant role in our analysis. For all $j \in [d]$, we let $S_j := \{(j,k)\colon \beta^*_{jk} \neq 0, k \in [d]\}$ be the support of $\boldsymbol{\beta}^*_j$. For the number of iterations $\ell = 1, 2, \ldots$, let $G^\ell_j := \big\{(j,k) \notin S_j\colon \lambda^{(\ell-1)}_{jk} \geq p'_\lambda(c_2\lambda), k \in [d]\big\}$. By condition (C.3) of the penalty function $p_\lambda(u)$ (see §3.2), we have $p'_\lambda(c_2\lambda) \geq 0.91\lambda$. In addition, we let J^ℓ_j be the largest k^* components of $\big[\widehat{\boldsymbol{\beta}}^{(\ell)}_j\big]_{G^\ell_j}$ in absolute value where k^* is defined in Assumption 4. In addition, we let $I^\ell_j = (G^\ell_j)^c \cup J^\ell_j$. Moreover, for notational simplicity, we denote $\big[\boldsymbol{\beta}_j\big]_{G^\ell_j}$, $\big[\boldsymbol{\beta}_j\big]_{G^\ell_j}$ and $\big[\boldsymbol{\beta}_j\big]_{I^\ell_j}$ as $\boldsymbol{\beta}_{G^\ell_j}$, $\boldsymbol{\beta}_{J^\ell_j}$ and $\boldsymbol{\beta}_{I^\ell_j}$ respectively when no ambiguity arises.

The key point of the proof is to show that the complement of G^ℓ_j is not too large. To be more specific, we show that $\big|(G^\ell_j)^c\big| \leq 2s^*$ for $\ell \geq 1$. Since $S_j \subset (G^\ell_j)^c$, $(G^\ell_j)^c \leq 2s^*$ implies $\big|(G^\ell_j)^c - S_j\big| \leq s^*$. Note that G^ℓ_j is the set of irrelevant features that are heavily penalized in the ℓ-th iteration of the algorithm, $(G^\ell_j)^c - S$ being a small set indicates that the most of the irrelevant features are heavily penalized in each step. We show that $\big|(G^\ell)^c\big| \leq 2s^*$ for each $\ell \geq 1$ by induction.

For $\ell = 1$, we have $G^1_j = S^c_j$ because $\lambda^{(0)}_{jk} = \lambda$ for all $j, k \in [d]$. Hence $\big|(G^1_j)^c\big| \leq s^*$. Now we assume that $\big|\big(G^\ell_j\big)^c\big| \leq 2s^*$ for some integer ℓ and our goal is to prove that $\big|\big(G^{\ell+1}_j\big)^c\big| \leq 2s^*$. Our proof is based on three technical lemmas. The first lemma shows that the regularization parameter λ in (7) is of the same order as $\|\nabla L_j(\boldsymbol{\beta}^*_j)\|_\infty$.

Lemma 10 *Under Assumptions 2 and 4, there exists a positive constants K such that, it holds with probability at least $1 - (2d)^{-1}$ that*

$$\big\|\nabla L_j(\boldsymbol{\beta}^*_j)\big\|_\infty \leq K\sqrt{\log d/n}, \quad \forall j \in [d]. \tag{22}$$

Proof See §C.1 for a proof. ∎

By this lemma, we conclude that the regularization parameter $\lambda \geq 25\big\|\nabla L_j(\boldsymbol{\beta}^*_j)\big\|_\infty$ with high probability. The following lemma bounds the ℓ_1- and ℓ_2-norms of $\widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j$ by the norms of its subvector under the induction assumption that $\big|(G^\ell_j)^c\big| \leq 2s^*$.

Lemma 11 *Letting the index sets S_j, G^ℓ_j, J^ℓ_j and I^ℓ_j be defined as above, we denote $\widetilde{G}^\ell_j := \big(G^\ell_j\big)^c$. Under the assumption that $|G^\ell_j| \leq 2s^*$, we have*

$$\big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j\big\|_2 \leq 2.2\big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_{I^\ell_j} - \boldsymbol{\beta}^*_{I^\ell_j}\big\|_2 \quad \textit{and} \quad \big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j\big\|_1 \leq 2.2\big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_{\widetilde{G}^\ell_j} - \boldsymbol{\beta}^*_{\widetilde{G}^\ell_j}\big\|_1. \tag{23}$$

Proof See §C.2 for a detailed proof. ∎

The next lemma guarantees that $\widehat{\boldsymbol{\beta}}^{(\ell)}_j$ stays in the ℓ_1-ball centered at $\boldsymbol{\beta}^*_j$ with radius r for $\ell \geq 1$ where r appears in Assumption 4. Moreover, by showing this property of Algorithm 1 , we obtain a crude rate for parameter estimation. We summarized this result in the next lemma.

Lemma 12 *For $\ell \geq 1$ and $j \in [d]$, we denote $\boldsymbol{\lambda}^{(\ell)}_{S_j} := (\lambda^{(\ell)}_{jk}, (j,k) \in S_j)^T$. Assuming that $\big|(G^\ell_j)^c\big| \leq 2s^*$, it holds with probability at least $1 - d^{-1}$ that, for all $j \in [d]$, the estimators $\widehat{\boldsymbol{\beta}}^{(\ell)}_j$ obtained in each iteration of Algorithm 1 satisfy*

$$\big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_{I^\ell_j} - \boldsymbol{\beta}^*_{I^\ell_j}\big\|_2 \leq 10\rho_*^{-1}\Big[\big\|\nabla_{\widetilde{G}^\ell_j} L_j(\boldsymbol{\beta}^*_j)\big\|_2 + \big\|\boldsymbol{\lambda}^{(\ell-1)}_{S_j}\big\|_2\Big], \quad \widetilde{G}^\ell_j := (G^\ell_j)^c. \tag{24}$$

This implies the following crude rates of convergence for $\widehat{\boldsymbol{\beta}}^{(\ell)}_j$:

$$\big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j\big\|_2 \leq 24\rho_*^{-1}\sqrt{s^*}\lambda \quad \textit{and} \quad \big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j\big\|_1 \leq 33\rho_*^{-1}s^*\lambda. \tag{25}$$

Proof See §C.3 for a detailed proof. ∎

Now we show that $\widetilde{G}^{\ell+1}_j = (G^{\ell+1}_j)^c$ satisfies $|\widetilde{G}^{\ell+1}_j| \leq 2s^*$, which concludes our induction. Letting $A := (G^{\ell+1}_j)^c - S_j$, by the definition of $G^{\ell+1}_j$, $(j,k) \in A$ implies that $(j,k) \notin S_j$ and $p'_\lambda\big(\big|\widehat{\beta}^{(\ell)}_{jk}\big|\big) \leq p'_\lambda(c_2\lambda)$. Hence by the concavity of $p_\lambda(\cdot)$, for any $(j,k) \in A$, $\big|\widehat{\beta}^{(\ell)}_{jk}\big| \geq c_2\lambda$. Therefore we have

$$\sqrt{|A|} \leq \big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_A\big\|_2/(c_2\lambda) = \big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_A - \boldsymbol{\beta}^*_A\big\|_2/(c_2\lambda) \leq 24\rho_*^{-1}\sqrt{s^*}/c_2 \leq \sqrt{s^*}, \tag{26}$$

where the first inequality follows from $|A| \leq \sum_{(j,k)\in A}\big|\widehat{\beta}^{(\ell)}_{jk}\big|^2/(c_2\lambda)^2$. Note that (26) implies that $\big|(G^{\ell+1}_j)^c\big| \leq 2s^*$. Therefore by induction, $\big|(G^\ell_j)^c\big| \leq 2s^*$ for any $\ell \geq 1$.

Now we have shown that for $\ell \geq 1$ and $j \in [d]$, $\big|(G^\ell_j)^c\big| \leq 2s^*$ and the crude statistical rates (25) hold. In what follows, we derive the more refined rates (15) and (16).

A refined bound for $\big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j\big\|_2$ and $\big\|\widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j\big\|_1$: For notional simplicity, we let $\boldsymbol{\delta}^{(\ell)} = \widehat{\boldsymbol{\beta}}^{(\ell)}_j - \boldsymbol{\beta}^*_j$ and omit subscript j in S_j, G^ℓ_j, J^ℓ_j and I^ℓ_j. We also denote $\widetilde{G}^\ell := (G^\ell)^c$. We first derive a recursive bound that links $\|\boldsymbol{\delta}^{(\ell)}_{I^\ell}\|_2$ to $\|\boldsymbol{\delta}^{(\ell-1)}_{I^{\ell-1}}\|_2$. Note that by (23), $\|\boldsymbol{\delta}^{(\ell)}\|_1 \leq 2.2\|\boldsymbol{\delta}^{(\ell)}_{\widetilde{G}^\ell}\|_1 \leq 2.2\sqrt{2s^*}\|\boldsymbol{\delta}^{(\ell)}_{\widetilde{G}^\ell}\|_2$. Hence we only need to control $\|\boldsymbol{\delta}^{(\ell)}_{I^\ell}\|_2$ to obtain the statistical rates of convergence for $\widehat{\boldsymbol{\beta}}^{(\ell)}_j$. By triangle inequality,

$$\big\|\nabla_{\widetilde{G}^\ell} L_j(\boldsymbol{\beta}^*_j)\big\|_2 \leq \big\|\nabla_S L_j(\boldsymbol{\beta}^*_j)\big\|_2 + \sqrt{|\widetilde{G}^\ell - S|}\big\|\nabla L_j(\boldsymbol{\beta}^*_j)\big\|_\infty.$$

Since $\lambda > 25\big\|\nabla L_j(\boldsymbol{\beta}^*_j)\big\|_\infty$, (26) implies that

$$\big\|\nabla_{\widetilde{G}^\ell} L_j(\boldsymbol{\beta}^*_j)\big\|_2 \leq \big\|\nabla_S L_j(\boldsymbol{\beta}^*_j)\big\|_2 + \big\|\boldsymbol{\delta}^{(\ell-1)}_A\big\|_2/(25c_2), \tag{27}$$

where $A := (G^\ell)^c - S \subset I^\ell$. Thus (27) can be written as

$$\big\|\nabla_{\widetilde{G}^\ell} L_j(\boldsymbol{\beta}^*_j)\big\|_2 \leq \big\|\nabla_S L_j(\boldsymbol{\beta}^*_j)\big\|_2 + \big\|\boldsymbol{\delta}^{(\ell-1)}_{I^\ell}\big\|_2/(25c_2). \tag{28}$$

Also notice that $\forall \beta_{jk} \in \mathbb{R}$, if $|\beta_{jk} - \beta^*_{jk}| \geq c_2\lambda$,

$$p'_\lambda(|\beta_{jk}|) \leq \lambda \leq |\beta_{jk} - \beta^*_{jk}|/c_2;$$

otherwise we have $|\beta^*_{jk}| - |\beta_{jk}| \leq |\beta_{jk} - \beta^*_{jk}| < c_2\lambda$ and thus $p'_\lambda(|\beta_{jk}|) \leq p'_\lambda\big(|\beta^*_{jk}| - c_2\lambda\big)$ by the concavity of $p_\lambda(\cdot)$. Hence the following inequality always holds:

$$p'_\lambda(|\beta_{jk}|) \leq p'_\lambda\big(|\beta^*_{jk}| - c_2\lambda\big) + |\beta_{jk} - \beta^*_{jk}|/c_2. \tag{29}$$

Applying (29) to $\widehat{\boldsymbol{\beta}}_j^{(\ell-1)}$ we have

$$\big\|\boldsymbol{\lambda}_S^{(\ell-1)}\big\|_2 \leq \Big[\sum_{(j,k)\in S} p'_\lambda\big(|\beta^*_{jk}| - c_2\lambda\big)^2\Big]^{1/2} + \Big[\sum_{(j,k)\in S} |\widehat{\beta}^{(\ell-1)}_{jk} - \beta^*_{jk}|^2\Big]^{1/2}\Big/c_2,$$

which leads to

$$\big\|\boldsymbol{\lambda}_S^{(\ell-1)}\big\|_2 \leq \Big[\sum_{(j,k)\in S} p'_\lambda\big(|\beta^*_{jk}| - c_2\lambda\big)^2\Big]^{1/2} + \big\|\boldsymbol{\delta}_{I^{\ell-1}}^{(\ell-1)}\big\|_2/c_2. \tag{30}$$

By (24), (28) and (30) we obtain

$$\big\|\boldsymbol{\delta}_{I^\ell}^{(\ell)}\big\|_2 \leq 10\rho_*^{-1}\big[\big\|\nabla_S L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + \gamma\|\boldsymbol{\delta}_{I^{\ell-1}}^{(\ell-1)}\|_2,$$

where $\gamma := 11(c_2\rho_*)^{-1}$ and we define $\Upsilon_j := \big[\sum_{(j,k)\in S} p'_\lambda\big(|\beta^*_{jk}| - c_2\lambda\big)^2\big]^{1/2}$ for notational simplicity. Note that since $c_2 \geq 24\rho_*^{-1}$, we have $\gamma < 1$. By recursion we obtain

$$\big\|\boldsymbol{\delta}_{I^\ell}^{(\ell)}\big\|_2 \leq 10\varrho\big[\big\|\nabla_S L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + \gamma^{\ell-1}\big\|\boldsymbol{\delta}_{I^1}^{(1)}\big\|_2, \tag{31}$$

where $\varrho := \rho_*^{-1} \cdot (1-\gamma)^{-1} = c_2(c_2\rho_* - 11)^{-1}$. Using $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \leq 2.2\big\|\widehat{\boldsymbol{\beta}}_{I_j^\ell}^{(\ell)} - \boldsymbol{\beta}_{I_j^\ell}^*\big\|_2$, we can bound $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2$ by

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \leq 22\varrho\big[\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + 2.2\gamma^{\ell-1}\big\|\boldsymbol{\delta}_{I_j^1}^{(1)}\big\|_2.$$

Note that for $\ell = 1$, by (24) we have

$$\big\|\boldsymbol{\delta}_{I_j^1}^{(1)}\big\|_2 \leq 10\rho_*^{-1}\sqrt{s^*}\big[\lambda + \sqrt{2}\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty\big] \leq 11\rho_*^{-1}\sqrt{s^*}\lambda = c_2\gamma\sqrt{s^*}\lambda. \tag{32}$$

then we establish the following bound for $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2$:

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \leq 22\varrho\big[\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + 2.2c_2\sqrt{s^*}\lambda\gamma^\ell. \tag{33}$$

Similarly, by $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq 2.2\sqrt{2s^*}\big\|\widehat{\boldsymbol{\beta}}_{I_j^\ell}^{(\ell)} - \boldsymbol{\beta}_{I_j^\ell}^*\big\|_2$, we obtain a bound on $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1$:

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq 32\sqrt{s^*}\varrho\big[\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + 2.2\gamma^{\ell-1}\sqrt{2s^*}\big\|\boldsymbol{\delta}_{I_j^1}^{(1)}\big\|_2. \tag{34}$$

By (32) we have $2.2\sqrt{2s^*}\big\|\boldsymbol{\delta}_{I_j^1}^{(1)}\big\|_2 \leq 3.2c_2\gamma s^*\lambda$, then the right-hand side of (34) can be bounded by

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq 32\sqrt{s^*}\varrho\big[\big\|\nabla_{S_j} L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \Upsilon_j\big] + 3.2c_2 s^*\lambda\gamma^\ell. \tag{35}$$

Therefore (15) and (16) can be implied by (33) and (35) respectively. Moreover, by Lemma 12, we conclude that the statistical rates (33) and (35) hold for all $j \in [d]$ with probability at least $1 - d^{-1}$. ■

A.2. Proof of Theorem 8

Proof We first remind the reader that, for $1 \leq j \neq k \leq d$, we denote

$$\boldsymbol{\beta}_{j\backslash k} = (\beta_{j1}, \ldots, \beta_{jj-1}, \beta_{jj+1}, \ldots, \beta_{jk-1}, \beta_{jk+1}, \ldots, \beta_{jd})^T \in \mathbb{R}^{d-2},$$

$\boldsymbol{\beta}_{j\vee k} = (\beta_{jk}, \boldsymbol{\beta}_{j\backslash k}, \boldsymbol{\beta}_{k\backslash j})^T \in \mathbb{R}^{2d-3}$ and $\widehat{\boldsymbol{\beta}}'_{j\vee k} = (0, \widehat{\boldsymbol{\beta}}_{j\backslash k}, \widehat{\boldsymbol{\beta}}_{k\backslash j})^T$. In addition, we define $\sigma^2_{jk} = \boldsymbol{\Sigma}^{jk}_{jk,jk} - 2\boldsymbol{\Sigma}^{jk}_{jk,j\backslash k}\mathbf{w}^*_{j,k} - 2\boldsymbol{\Sigma}^{jk}_{jk,k\backslash j}\mathbf{w}^*_{k,j} + \mathbf{w}^{*T}_{j,k}\boldsymbol{\Sigma}^{jk}_{j\backslash k,j\backslash k}\mathbf{w}^*_{j,k} + \mathbf{w}^{*T}_{k,j}\boldsymbol{\Sigma}^{jk}_{k\backslash j,k\backslash j}\mathbf{w}^*_{k,j}$. To prove the theorem our goal is to prove the following two arguments:

$$\lim_{n\to\infty}\max_{j<k}\sqrt{n}\big|\widehat{S}_{jk} - S_{jk}(\boldsymbol{\beta}^*_{j\vee k})\big| = 0 \quad \text{and} \quad \lim_{n\to\infty}\max_{j<k}|\widehat{\sigma}_{jk} - \sigma_{jk}| = 0. \tag{36}$$

Note that by Lemma 14, σ^2_{jk} is the asymptotic variance of $\sqrt{n}/2 \cdot S_{jk}(\boldsymbol{\beta}^*_{j\vee k})$. Thus combining (36) and Slutsky's theorem yields the theorem. By the the expression of $S_{jk}(\boldsymbol{\beta}^*_{j\vee k})$ and $\widehat{S}_{jk}$ in (17) and (18), under null hypothesis, for a fixed pair of nodes j and k, we have $\widehat{S}_{jk} - S_{jk}(\boldsymbol{\beta}^*_{j\vee k}) = I_{1j} + I_{2j} + I_{1k} + I_{2k}$ where I_{1j} and I_{2j} are defined as

$$I_{1j} := \big[\nabla_{jk}L_j(\widehat{\boldsymbol{\beta}}'_j) - \nabla_{jk}L_j(\boldsymbol{\beta}^*_j)\big] - \widehat{\mathbf{w}}^T_{j,k}\big[\nabla_{j\backslash k}L_j(\widehat{\boldsymbol{\beta}}'_j) - \nabla_{j\backslash k}L_j(\boldsymbol{\beta}^*_j)\big] \text{ and}$$
$$I_{2j} := (\mathbf{w}^*_{j,k} - \widehat{\mathbf{w}}_{j,k})^T\nabla_{j\backslash k}L_j(\boldsymbol{\beta}^*_j);$$

whereas I_{1k} and I_{2k} are defined by interchanging j and k in I_{1j} and I_{2j}:

$$I_{1k} := \big[\nabla_{kj}L_k(\widehat{\boldsymbol{\beta}}'_k) - \nabla_{jk}L_k(\boldsymbol{\beta}^*_k)\big] - \widehat{\mathbf{w}}^T_{k,j}\big[\nabla_{k\backslash j}L_k(\widehat{\boldsymbol{\beta}}'_k) - \nabla_{k\backslash j}L_k(\boldsymbol{\beta}^*_k)\big] \text{ and}$$
$$I_{2k} := (\mathbf{w}^*_{k,j} - \widehat{\mathbf{w}}_{k,j})^T\nabla_{k\backslash j}L_j(\boldsymbol{\beta}^*_k).$$

We first bound I_{1j}. Recall that $\widehat{\boldsymbol{\beta}}'_j = (0, \widehat{\boldsymbol{\beta}}_{j\backslash k})^T$. Note that under the null hypothesis, $\beta^*_{jk} = 0$, by the Mean-Value Theorem, there exists a $\widetilde{\boldsymbol{\beta}}_{j\backslash k} \in \mathbb{R}^{d-2}$ in the line segment between $\widehat{\boldsymbol{\beta}}_{j\backslash k}$ and $\boldsymbol{\beta}^*_{j\backslash k}$ such that

$$I_{1j} = \big[\widetilde{\boldsymbol{\Lambda}}_{jk,j\backslash k} - \widehat{\mathbf{w}}^T_{j,k}\widetilde{\boldsymbol{\Lambda}}_{j\backslash k,j\backslash k}\big]\big(\widehat{\boldsymbol{\beta}}_{j\backslash k} - \boldsymbol{\beta}^*_{j\backslash k}\big),$$

where $\widetilde{\boldsymbol{\Lambda}} := \nabla^2 L_j(0, \widetilde{\boldsymbol{\beta}}_{j\backslash k})$. We let $\boldsymbol{\delta} := \widehat{\boldsymbol{\beta}}'_j - \boldsymbol{\beta}^*_j$ and denote $\nabla^2 L_j(\widehat{\boldsymbol{\beta}}'_j)$ and $\nabla^2(\boldsymbol{\beta}^*_j)$ as $\boldsymbol{\Lambda}$ and $\boldsymbol{\Lambda}^*$ respectively. From the definition of Dantzig selector we obtain

$$|I_{1j}| \leq \underbrace{\|\boldsymbol{\Lambda}_{jk,j\backslash k} - \widehat{\mathbf{w}}^T\boldsymbol{\Lambda}_{j\backslash k,j\backslash k}\|_\infty\|\boldsymbol{\delta}_{j\backslash k}\|_1}_{I_{11}} + \underbrace{\|\boldsymbol{\Lambda}_{jk,j\backslash k} - \widetilde{\boldsymbol{\Lambda}}_{jk,j\backslash k}\|_\infty\|\boldsymbol{\delta}_{j\backslash k}\|_1}_{I_{12}}$$
$$+ \underbrace{\|\widehat{\mathbf{w}}^T(\boldsymbol{\Lambda}_{j\backslash k,j\backslash k} - \widetilde{\boldsymbol{\Lambda}}_{j\backslash k,j\backslash k})\boldsymbol{\delta}_{j\backslash k}\|_\infty}_{I_{13}}.$$

Theorem 5 implies that $\|\boldsymbol{\delta}\|_1 \leq Cs^*\lambda$ with probability tending to 1 for some constant $C > 0$. Then by the definition of Dantzig selector, $I_{11} \leq Cs^*\lambda\lambda_D$. with high probability. Moreover, the constant C is the same for all (j,k). By assumption 7, $I_{11} = o(n^{-1/2})$ with probability tending to one.

For term I_{12}, Hölder's inequality implies that

$$I_{12} \leq \|\boldsymbol{\Lambda}_{jk,j\backslash k} - \widetilde{\boldsymbol{\Lambda}}_{jk,j\backslash k}\|_\infty \|\boldsymbol{\delta}_{j\backslash k}\|_1. \tag{37}$$

By Lemma 26 we obtain

$$\|\boldsymbol{\Lambda} - \widetilde{\boldsymbol{\Lambda}}\|_\infty \leq \|\boldsymbol{\Lambda} - \boldsymbol{\Lambda}^*\|_\infty + \|\boldsymbol{\Lambda}^* - \widetilde{\boldsymbol{\Lambda}}\|_\infty \leq 2Cs^*\lambda \log^2 d. \tag{38}$$

Therefore combining (37) and (38) we have

$$I_{12} \leq 2Cs^{*2}\lambda^2 \log^2 d \lesssim s^*\lambda\lambda_D \quad \text{uniformly for } 1 \leq j < k \leq d.$$

Similarly by Hölder's inequality, we have

$$I_{13} \leq \|\widehat{\mathbf{w}}_{j,k}\|_1 \|\boldsymbol{\Lambda} - \widetilde{\boldsymbol{\Lambda}}\|_\infty \|\boldsymbol{\delta}\|_1. \tag{39}$$

Notice that by the optimality of $\widehat{\mathbf{w}}_{j,k}$, $\|\widehat{\mathbf{w}}_{j,k}\|_1 \leq \|\mathbf{w}^*_{j,k}\|_1 \leq w_0$. Combining (39) and (38) we have

$$I_{13} \leq Cw_0 s^{*2}\lambda^2 \log^2 d \lesssim s^*\lambda\lambda_D \quad \text{uniformly for } 1 \leq j < k \leq d.$$

where we use the fact that $\lambda_D \gtrsim \max\{1, w_0\} s^*\lambda \log^2 d$. Therefore we conclude that for all $j \in [d]$, $|I_{1j}| \lesssim s^*\lambda\lambda_D = o_{\mathbb{P}}(n^{-1/2})$. For I_{2j}, Hölder's inequality implies that $|I_{2j}| \leq \|\mathbf{w}^*_{j,k} - \widehat{\mathbf{w}}_{j,k}\|_1 \big\|\nabla L_j(\boldsymbol{\beta}^*_j)\big\|_\infty$. To control $\|\mathbf{w}^*_{j,k} - \widehat{\mathbf{w}}_{j,k}\|_1$, we need to the following lemma to obtain the estimation error of the Dantzig selector $\widehat{\mathbf{w}}_{j,k}$.

Lemma 13 *For $1 \leq j \neq k \leq d$, let $\widehat{\mathbf{w}}_{j,k}$ be the solution of the Dantzig-type optimization problem* (11) *and let $\mathbf{w}^*_{j,k} = \mathbf{H}^j_{jk,j\backslash k}(\mathbf{H}^j_{j\backslash k,j\backslash k})^{-1}$. Under Assumptions 2, 4, 6 and 7, with probability tending to one, we have*

$$\|\widehat{\mathbf{w}}_{j,k} - \mathbf{w}^*_{j,k}\|_1 \leq 37\nu_*^{-1} s_0^\star \lambda_D \quad \textit{for all} \quad 1 \leq j \neq k \leq d.$$

Proof See §D.2 for a detailed proof. ■

Now combining Lemma 13 and Theorem 10 we obtain that

$$|I_{2j}| \leq 37\nu_*^{-1} K_1 s_0^\star \lambda_D \sqrt{\log d/n} \asymp s_0^\star \lambda\lambda_D = o(n^{-1/2}).$$

Therefore we have shown that $I_{1j} + I_{2j} = o(n^{-1/2})$ with high probability. Similarly, we also have $I_{1k} + I_{2k} = o(n^{-1/2})$ with high probability. Moreover, since the bounds for $|I_{1j}|$ and $|I_{2j}|$ is independent of the choice of $(j,k) \in \{(j,k) \colon 1 \leq j \neq k \leq d\}$, we conclude that

$$\sqrt{n}\big[\widehat{S}_{jk} - S_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big)\big] = o_{\mathbb{P}}(1) \quad \text{uniformly for } 1 \leq j < k \leq d.$$

Our next lemma characterizes the limiting distribution of $\nabla L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big)$ and is pivotal for establishing the validity of the composite pairwise score test.

Lemma 14 *For any $\mathbf{b} \in \mathbb{R}^{2d-3}$ with $\|\mathbf{b}\|_2 = 1$ and $\|\mathbf{b}\|_0 \leq \widetilde{s}$, if $\lim_{n\to\infty} \widetilde{s}/n = 0$, we have*

$$\sqrt{n}/2 \cdot \mathbf{b}^T \nabla L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big) \rightsquigarrow N\big(0, \mathbf{b}^T \boldsymbol{\Sigma}^{jk} \mathbf{b}\big). \tag{40}$$

By Lemma 14 we obtain

$$\sqrt{n}/2 \cdot S\big(\boldsymbol{\beta}^*_{j\vee k}\big) = \nabla_{jk} L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big) - \mathbf{w}^{*T}_{j,k} \nabla_{j\backslash k} L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big) - \mathbf{w}^{*T}_{k,j} \nabla_{j\backslash k} L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big) \rightsquigarrow N(0, \sigma^2_{jk}),$$

where the asymptotic variance σ^2_{jk} is given by

$$\sigma^2_{jk} = \boldsymbol{\Sigma}^{jk}_{jk,jk} - 2\boldsymbol{\Sigma}^{jk}_{jk,j\backslash k}\mathbf{w}^*_{j,k} - 2\boldsymbol{\Sigma}_{jk,k\backslash j}\mathbf{w}^*_{k,j} + \mathbf{w}^{*T}_{j,k}\boldsymbol{\Sigma}^{jk}_{j\backslash k,j\backslash k}\mathbf{w}^*_{j,k} + \mathbf{w}^{*T}_{k,j}\boldsymbol{\Sigma}^{jk}_{k\backslash j,k\backslash j}\mathbf{w}^*_{k,j}.$$

For a more accurate estimation of $\widehat{S}_{jk} - S_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big)$, we have

$$\sqrt{n}\big|\widehat{S}_{jk} - S_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big)\big| \leq \sqrt{n}\big(|I_1| + |I_2|\big) \lesssim \sqrt{n}(s^* + s_0^*)\lambda\lambda_D. \tag{41}$$

Finally, the following lemma, whose proof is deferred to the supplementary material, shows that $\widehat{\sigma}_{jk}$ is a consistent estimator of σ_{jk}.

Lemma 15 *For $1 \leq j \neq k \leq d$, we denote the asymptotic variance of $\sqrt{n}/2 \cdot S_{jk}(\boldsymbol{\beta}^*_{j\vee k})$ as σ^2_{jk}. Under Assumptions 2, 4, 6 and 7, the estimator $\widehat{\sigma}_{jk}$ satisfies $\lim_{n\to\infty} \max_{j<k} |\widehat{\sigma}_{jk} - \sigma_{jk}| = 0$.*

Proof See §D.3 for a proof. ■

Since $\widehat{\sigma}_{jk}$ is consistent for σ_{jk} by Lemma 15 and σ_{jk} is bounded away from zero by Assumption 6, Slutsky's theorem implies that $\sqrt{n}\widehat{S}_{jk}/(2\widehat{\sigma}_{jk}) \rightsquigarrow N(0,1)$. ■

Appendix B. Additional Estimation Results

We present the additional results of parameter estimation. In §B.1 we verify the sparse eigenvalue condition for Gaussian graphical models, which justifies Assumption 4 in our paper. In §B.2 we derive a more refined statistical rates of convergence for the iterates of Algorithm 1.

B.1. Verify the Sparse Eigenvalue Condition for Gaussian Graphical Models

In this subsection, we verify the sparse eigenvalue condition for Gaussian graphical models. Moreover, we show that such condition holds uniformly over a ℓ_1-ball centered at the true parameter $\boldsymbol{\beta}^*_j$.

Proposition 16 *Suppose $\boldsymbol{X} \sim N(\mathbf{0}, \boldsymbol{\Sigma})$ is a Gaussian graphical model and let $\boldsymbol{\Theta} = \boldsymbol{\Sigma}^{-1}$ be the precision matrix. For all $j \in [d]$, the conditional distribution of X_j given $\boldsymbol{X}_{\backslash j}$ is a normal distribution with mean $\boldsymbol{\beta}^{*T}_j \boldsymbol{X}_{\backslash j}$ and variance $\boldsymbol{\Theta}^{-1}_{jj}$, where $\boldsymbol{\beta}^*_j = \boldsymbol{\Theta}_{j\backslash j}$. Let $L_j(\cdot)$ be the loss function defined in* (6). *We assume that there exist positive constants D, c_λ and C_λ such that $\|\boldsymbol{\Sigma}\|_\infty \leq D$ and $c_\lambda \leq \lambda_{\min}(\boldsymbol{\Sigma}) \leq \lambda_{\max}(\boldsymbol{\Sigma}) \leq C_\lambda$. We let $s^* = \max_{j\in[d]} \|\boldsymbol{\beta}^*_j\|_0$ and also assume that there exists a constant $C_\beta > 0$ such that $\|\boldsymbol{\beta}^*_j\|_2 \leq C_\beta$ for all $j \in [d]$.*

Suppose $r > 0$ is a real number such that $r = \mathcal{O}(1/\sqrt{s^*})$. Then, there exist $\rho_*, \rho^* > 0$ such that for all $j \in [d]$, and $s = 1, \ldots, d-1$,

$$\rho_* \leq \rho_-\big(\mathbb{E}\big[\nabla^2 L_j\big], \boldsymbol{\beta}_j^*; s, r\big) \leq \rho_+\big(\mathbb{E}\big[\nabla^2 L_j\big], \boldsymbol{\beta}_j^*; s, r\big) \leq \rho^*.$$

Proof We prove this lemma in two steps. For any $\boldsymbol{\beta}_j \in \mathbb{R}^{d-1}$ such that $\|\boldsymbol{\beta}_j - \boldsymbol{\beta}_j^*\|_1 \leq r$ and any $\mathbf{v} \in \mathbb{R}^{d-1}$ such that $\|\mathbf{v}\|_2 = 1$, we first give a lower bound for $\mathbf{v}^T\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]\mathbf{v}$ by truncation. Then we give an upper bound in the second step.

Step (i): Lower Bound of $\mathbf{v}^T\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]\mathbf{v}$. We denote $\mathbb{B}_j(r) \coloneqq \big\{\boldsymbol{\beta} \in \mathbb{R}^{d-1}\colon \|\boldsymbol{\beta} - \boldsymbol{\beta}_j^*\|_1 \leq r\big\}$. For two truncation levels $\tau > 0$ and $R > 0$, we denote $\mathcal{A}_{ii'} \coloneqq \big\{|X_{ij}| \leq \tau\big\} \cap \big\{|X_{i'j}| \leq \tau\big\}$, $\mathcal{B}_i \coloneqq \big\{\big|\boldsymbol{X}_{i\backslash j}^T\boldsymbol{\beta}_j\big| \leq R, \forall \boldsymbol{\beta}_j \in \mathbb{B}_j(r)\big\}$ and $\mathcal{B}_{i'} \coloneqq \big\{\big|\boldsymbol{X}_{i'\backslash j}^T\boldsymbol{\beta}_j^*\big| \leq R, \forall \boldsymbol{\beta}_j \in \mathbb{B}_j(r)\big\}$. The values of R and τ will be determined later. By the definition of $L_j(\cdot)$, for any $\boldsymbol{\beta}_j \in \mathbb{B}_j(r)$ and any $\mathbf{v} \in \mathbb{R}^{d-1}$ with $\|\mathbf{v}\|_2 = 1$, we have

$$\mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j)\mathbf{v} \geq \frac{2C_1(R,\tau)}{n(n-1)}\sum_{i<i'}\big(X_{ij} - X_{i'j}\big)^2\big[(\boldsymbol{X}_{i\backslash j} - \boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2 I(\mathcal{B}_i)T(\mathcal{B}_{i'})I(\mathcal{A}_{ii'}), \quad (42)$$

where $C_1(R,\tau) \coloneqq \exp(-4R\tau)\big[1+\exp(-4R\tau)\big]^{-2}$. For notational simplicity, we denote the right-hand side of (42) as $C_1(R,\tau)\mathbf{v}^T\boldsymbol{\Delta}\mathbf{v}$. By the properties of Gaussian graphical models, the conditional density of X_{ij} given $\mathcal{I}_i \coloneqq \big\{\boldsymbol{X}_{i\backslash j} = \boldsymbol{x}_{i\backslash j}\big\} \cap \mathcal{B}_i$ is

$$p\big(x_{ij}|\mathcal{I}_i\big) = p(\boldsymbol{x}_i|\mathcal{B}_i)\Big/\int_{\mathbb{R}} p(\boldsymbol{x}_i|\mathcal{B}_i)\mathrm{d}x_{ij} = p(x_{ij}|\boldsymbol{x}_{i\backslash j}),$$

where we use the fact that $p(\boldsymbol{x}_i|\mathbb{B}_i) = p(\boldsymbol{x}_i)/\mathbb{P}(\mathcal{B}_i)$ and that $\mathbb{P}(\mathcal{B}_i)$ is a constant. Recall that

$$p(x_{ij}|\boldsymbol{X}_{i\backslash j}) = \sqrt{\boldsymbol{\Theta}_{jj}/(2\pi)}\exp\big[-\boldsymbol{\Theta}_{jj}/2(x_{ij} - \boldsymbol{X}_{i\backslash j}^T\boldsymbol{\beta}_j^*)^2\big] \quad \text{where } \boldsymbol{\beta}_j^* = \boldsymbol{\Theta}_{j\backslash j}.$$

Thus the conditional expectation of $(X_{ij} - X_{i'j})^2 I(\mathcal{A}_{ij})$ given $\mathcal{I}_i$ and $\mathcal{I}_{i'}$ is

$$\begin{aligned}
&\mathbb{E}\Big[(X_{ij} - X_{i'j})^2 I(\mathcal{A}_{ii'})\Big|\mathcal{I}_i \cap \mathcal{I}_{i'}\Big] \\
&\quad = \boldsymbol{\Theta}_{jj}/(2\pi)\int_{-\tau}^{\tau}\int_{-\tau}^{\tau}(x_{ij} - x_{ij})^2\exp\Big\{-\boldsymbol{\Theta}_{jj}/2\big[(x_{ij} - \boldsymbol{\beta}_j^T\boldsymbol{x}_{i\backslash j})^2 + (x_{i'j} - \boldsymbol{\beta}_j^T\boldsymbol{x}_{i'\backslash j})^2\big]\Big\}\mathrm{d}x_{ij}\mathrm{d}x_{i'j}.
\end{aligned}$$

Note that on event $\mathcal{I}_i$, $|\boldsymbol{\beta}_j^T\boldsymbol{X}_{i\backslash j}| \leq R$, hence the expression above can be lower-bounded by

$$\begin{aligned}
&\mathbb{E}\Big[(X_{ij} - X_{i'j})^2 I(\mathcal{A}_{ii'})\Big|\mathcal{I}_i \cap \mathcal{I}_{i'}\Big] \\
&\quad \geq \boldsymbol{\Theta}_{jj}/(2\pi)\int_{-\tau}^{\tau}\int_{-\tau}^{\tau}(x_{ij} - x_{i'j})^2\exp\Big\{-\boldsymbol{\Theta}_{jj}/2\big[x_{ij}^2 + x_{i'j}^2 + 2R^2 + 2R(|x_{ij}| + |x_{i'j}|)\big]\Big\}\mathrm{d}x_{ij}\mathrm{d}x_{i'j}.
\end{aligned}$$

The last expression is positive and we denote it as $C_2(R,\tau)$ for simplicity. Thus by the law of total expectation we obtain

$$\mathbf{v}^T\mathbb{E}(\boldsymbol{\Delta})\mathbf{v} = \mathbf{v}^T\mathbb{E}\big[\mathbb{E}(\boldsymbol{\Delta}|\cap_{i=1}^n\mathcal{I}_i)\big]\mathbf{v} \geq C_2(R,\tau)\mathbb{E}\Big\{\big[(\boldsymbol{X}_{i\backslash j} - \boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2 I(\mathcal{B}_i)I(\mathcal{B}_j)\Big\}.$$

By Cauchy-Schwarz inequality we have

$$\mathbb{E}\Big\{\big[(\boldsymbol{X}_{i\backslash j} - \boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2\big[1 - I(\mathcal{B}_i)I(\mathcal{B}_{i'})\big]\Big\} \leq \sqrt{\mathbb{E}[(\boldsymbol{X}_{i\backslash j} - \boldsymbol{X}_{i'\backslash j})^T\mathbf{v}]^4}\sqrt{\mathbb{P}\big(\mathcal{B}_i^c \cup \mathcal{B}_{i'}^c\big)}. \quad (43)$$

Note that for Gaussian graphical model, the marginal distribution of $\boldsymbol{X}_{\backslash j}$ is $N(\mathbf{0}, \boldsymbol{\Sigma}_{\backslash j\backslash j})$. If we denote $\boldsymbol{\Sigma}_{\backslash j\backslash j}$ as $\boldsymbol{\Sigma}_1$, we have $(\boldsymbol{X}_{i\backslash j} - \boldsymbol{X}_{i'\backslash j})^T\mathbf{v} \sim N(\mathbf{0}, \sigma_v^2)$, $\boldsymbol{X}_{i\backslash j}^T\boldsymbol{\beta}_j^* \sim N(\mathbf{0}, \sigma_1^2)$ and $\boldsymbol{X}_{i\backslash j}^T\boldsymbol{\beta} \sim N(\mathbf{0}, \sigma_2^2)$ where $\sigma_v^2 = 2\mathbf{v}^T\boldsymbol{\Sigma}_1\mathbf{v}$, $\sigma_1^2 = \boldsymbol{\beta}_j^{*T}\boldsymbol{\Sigma}_1\boldsymbol{\beta}_j^*$ and $\sigma_2^2 = \boldsymbol{\beta}_j^T\boldsymbol{\Sigma}_1\boldsymbol{\beta}_j$. Hence we have $\mathbb{E}\big[(\boldsymbol{X}_{i\backslash j} - \boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^4 = 3\sigma_v^4$. Because the maximum eigenvalue of $\boldsymbol{\Sigma}_1$ is upper bounded by C_λ, we have $\sigma_1^2 \leq C_\lambda C_\beta^2$ and $\sigma_v^2 \leq 2C_\lambda$. Note that $\sigma_2^2 - \sigma_1^2 = \boldsymbol{\beta}_j^T\boldsymbol{\Sigma}_1\boldsymbol{\beta}_j - \boldsymbol{\beta}_j^{*T}\boldsymbol{\Sigma}_1\boldsymbol{\beta}_j^*$, the following lemma in linear algebra bounds this type of error.

Lemma 17 *Let $\mathbf{M} \in \mathbb{R}^{d\times d}$ be a symmetric matrix and vectors $\mathbf{v}_1$ and $\mathbf{v}_2 \in \mathbb{R}^d$, then*

$$\big|\mathbf{v}_1^T\mathbf{M}\mathbf{v}_1 - \mathbf{v}_2^T\mathbf{M}\mathbf{v}_2\big| \leq \|\mathbf{M}\|_\infty\|\mathbf{v}_1 - \mathbf{v}_2\|_1^2 + 2\|\mathbf{M}\mathbf{v}_2\|_\infty\|\mathbf{v}_1 - \mathbf{v}_2\|_1.$$

Proof Note that $\mathbf{v}_1^T\mathbf{M}\mathbf{v}_1 - \mathbf{v}_2^T\mathbf{M}\mathbf{v}_2 = (\mathbf{v}_1 - \mathbf{v}_2)^T\mathbf{M}(\mathbf{v}_1 - \mathbf{v}_2) + 2\mathbf{v}_2^T\mathbf{M}(\mathbf{v}_1 - \mathbf{v}_2)$, Hölder's inequality implies

$$\begin{aligned}
\big|\mathbf{v}_1^T\mathbf{M}\mathbf{v}_1 - \mathbf{v}_2^T\mathbf{M}\mathbf{v}_2\big| &\leq \big|(\mathbf{v}_1 - \mathbf{v}_2)^T\mathbf{M}(\mathbf{v}_1 - \mathbf{v}_2)\big| + 2\big|\mathbf{v}_2^T\mathbf{M}(\mathbf{v}_1 - \mathbf{v}_2)\big| \\
&\leq \|\mathbf{M}\|_\infty\|\mathbf{v}_1 - \mathbf{v}_2\|_1^2 + 2\|\mathbf{M}\mathbf{v}_2\|_\infty\|\mathbf{v}_1 - \mathbf{v}_2\|_1.
\end{aligned}$$

Hence, we conclude the proof of Lemma 17. ■

By Lemma 17, we have

$$\sigma_2^2 - \sigma_1^2 \leq \|\boldsymbol{\Sigma}_1\|_\infty\|\boldsymbol{\beta}_j - \boldsymbol{\beta}_j^*\|_1^2 + 2\|\boldsymbol{\Sigma}_1\boldsymbol{\beta}_j^*\|_\infty\|\boldsymbol{\beta}_j - \boldsymbol{\beta}_j^*\|_1. \quad (44)$$

By Hölder's inequality and the relation between ℓ_1-norm and ℓ_2-norm of a vector, we have $\|\boldsymbol{\Sigma}_1\boldsymbol{\beta}_j^*\|_\infty \leq \|\boldsymbol{\Sigma}_1\|_\infty\|\boldsymbol{\beta}_j^*\|_1 \leq \sqrt{s^*}C_\beta D$. Therefore the right-hand side of (44) can be bounded by

$$\sigma_2^2 - \sigma_1^2 \leq r^2 D + 2\sqrt{s^*}rC_\beta D,$$

which shows that σ_2^2 is also bounded because $r = \mathcal{O}(1/\sqrt{s^*})$. In addition, by the bound $1 - \Phi(x) \leq \exp(-x^2/2)/(x\sqrt{2\pi})$ for the standard normal distribution function, we obtain that

$$\begin{aligned}
\mathbb{P}\big(\mathcal{B}_i^c\big) &\leq \mathbb{P}\big(\boldsymbol{X}_{i\backslash j}^T\boldsymbol{\beta}_j^* > R\big) + \mathbb{P}\big(\boldsymbol{X}_{i\backslash j}^T\boldsymbol{\beta}_j > R\big) \\
&\leq c\sigma_1\exp\big[-R^2/(2\sigma_1^2)\big]/R + c\sigma_2\exp\big[-R^2/(2\sigma_2^2)\big]/R,
\end{aligned}$$

where the constant $c = 1/\sqrt{2\pi}$. We denote the last expression as $C_3(R)$, then the right-hand side of (43) can be upper-bounded by $\sqrt{3\sigma_v^4}\sqrt{2C_3(R)} \leq 2\sqrt{6C_3(R)}C_\lambda$. Hence we can choose a sufficiently large R such that $2\sqrt{6C_3(R)}C_\lambda = \lambda_{\min}(\boldsymbol{\Sigma})$ and we denote this particular choice of R as R_0.

Now we have

$$\mathbb{E}\Big\{\big[(\boldsymbol{X}_{i\backslash j} - \boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2\big[1 - I(\mathcal{B}_i)I(\mathcal{B}_{i'})\big]\Big\} \leq \lambda_{\min}(\boldsymbol{\Sigma})$$

Note that $\mathbb{E}\big\{[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}]^2\big\}=\sigma_v^2\geq 2\lambda_{\min}(\boldsymbol{\Sigma})$, we obtain that

$$\mathbf{v}^T\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]\mathbf{v}\geq C_1(R_0,\tau)C_2(R_0,\tau)\lambda_{\min}(\boldsymbol{\Sigma})\ \text{ for all }\ \tau\in\mathbb{R}.$$

Therefore we conclude that for all $\boldsymbol{\beta}_j\in\mathbb{R}^{d-1}$ such that $\|\boldsymbol{\beta}_j-\boldsymbol{\beta}_j^*\|_1\leq r$,

$$\mathbf{v}^T\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]\mathbf{v}\geq\max_{\tau\in\mathbb{R}}\big\{C_1(R_0,\tau)C_2(R_0,\tau)\big\}\lambda_{\min}(\boldsymbol{\Sigma}).\tag{45}$$

Step (ii): Upper Bound of $\mathbf{v}^T\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]\mathbf{v}$. For any $\boldsymbol{\beta}_j\in\mathbb{R}^{d-1}$ such that $\|\boldsymbol{\beta}_j-\boldsymbol{\beta}_j^*\|_1\leq r$ and for any $\mathbf{v}\in\mathbb{R}^{d-1}$ with $\|\mathbf{v}\|_2=1$, by the definition of $\nabla^2 L_j(\boldsymbol{\beta}_j)$ we have

$$\mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j)\mathbf{v}\leq(X_{ij}-X_{i'j})^2\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2.\tag{46}$$

Notice that conditioning on $\boldsymbol{X}_{i\backslash j}$, $X_{ij}\sim N\big(\boldsymbol{X}_{i\backslash j}^T\boldsymbol{\beta}_j^*,\boldsymbol{\Theta}_{jj}^{-1}\big)$, hence

$$\mathbb{E}\big[(X_{ij}-X_{i'j})^2\big|\boldsymbol{X}_{i\backslash j},\boldsymbol{X}_{i'\backslash j}\big]=\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\boldsymbol{\beta}_j^*\big]^2+2\boldsymbol{\Theta}_{jj}^{-1}.\tag{47}$$

Combining (46) and (47) we obtain

$$\begin{aligned}\mathbb{E}\big[\mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j)\mathbf{v}\big]&\leq\mathbb{E}\Big\{\mathbb{E}\big[(X_{ij}-X_{i'j})^2\big|\boldsymbol{X}_{i\backslash j},\boldsymbol{X}_{i'\backslash j}\big]\cdot\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2\Big\}\\&\leq 2\boldsymbol{\Theta}_{jj}^{-1}\mathbb{E}\big((\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big)^2+\mathbb{E}\Big\{\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\boldsymbol{\beta}_j^*\big]^2\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2\Big\}.\end{aligned}\tag{48}$$

Because $\boldsymbol{X}_{i\backslash j}\sim N(\mathbf{0},\boldsymbol{\Sigma}_1)$ where $\boldsymbol{\Sigma}_1:=\boldsymbol{\Sigma}_{\backslash j,\backslash j}$, and also note that the maximum eigenvalue of $\boldsymbol{\Sigma}_1$ is upper bounded by C_λ, we have

$$\mathbb{E}\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2=2\mathbf{v}^T\boldsymbol{\Sigma}_1\mathbf{v}\leq 2C_\lambda.$$

Moreover, by inequality $2ab\leq a^2+b^2$ we obtain

$$2\mathbb{E}\Big\{\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\boldsymbol{\beta}_j^*\big]^2\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^2\Big\}\leq\mathbb{E}\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\boldsymbol{\beta}_j^*\big]^4+\mathbb{E}\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^4.$$

Since $(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\sim N(0,\sigma_v^2)$ and $(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\boldsymbol{\beta}_j^*\sim N(0,2\sigma_1^2)$ where σ_v^2 and σ_1^2 are defined as $2\mathbf{v}^T\boldsymbol{\Sigma}_1\mathbf{v}$ and $\boldsymbol{\beta}_j^{*T}\boldsymbol{\Sigma}_1\boldsymbol{\beta}_j^*$ respectively, we obtain

$$\mathbb{E}\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\boldsymbol{\beta}_j^*\big]^4=3\sigma_v^4\leq 12C_\lambda^2\quad\text{and}\quad\mathbb{E}\big[(\boldsymbol{X}_{i\backslash j}-\boldsymbol{X}_{i'\backslash j})^T\mathbf{v}\big]^4=12\sigma_1^4\leq 12C_\lambda C_\beta^2.$$

Therefore we can bound the right-hand side of (48) by

$$\mathbb{E}\big[\mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j)\mathbf{v}\big]\leq 4\boldsymbol{\Theta}_{jj}^{-1}C_\lambda+6C_\lambda^2+6C_\lambda C_\beta^2.\tag{49}$$

Combining (45) and (49) we conclude that Proposition 16 holds with

$$\rho_*=\max_{\tau\in\mathbb{R}}\big\{C_1(R_0,\tau)C_2(R_0,\tau)\big\}\lambda_{\min}(\boldsymbol{\Sigma})\ \text{ and }\ \rho^*=4\boldsymbol{\Theta}_{jj}^{-1}C_\lambda+6C_\lambda^2+6C_\lambda C_\beta^2.$$

Therefore, we conclude the proof of Proposition 16. ■

B.2. Refined Statistical Rates of Parameter Estimation

In this subsection we show more refined statistical rates of convergence for the proposed estimators. In specific, we consider the case where $\boldsymbol{\beta}_j^*$ contains nonzero elements with both strong and week magnitudes.

Theorem 18 (Refined statistical rates of convergence) *Under Assumptions 2 and 4, we let K_1 and K_2 be the constants defined in Theorem 10 and also let $\rho_*>0$ and $r>0$ be defined in Assumption 4. For all $j\in[d]$, we define the support of $\boldsymbol{\beta}_j^*$ as $S_j:=\{(j,k)\colon\beta_{jk}^*\neq 0,k\in[d]\}$ and let $s^*=\max_{j\in[d]}\|\boldsymbol{\beta}_j^*\|_0$. The penalty function $p_\lambda(u):[0,+\infty)\to[0,+\infty)$ in (7) satisfies regularity conditions (C.1), (C.2) and (C.3) listed in §3.2 with $c_1=0.91$ and $c_2\geq 24/\rho_*$ for condition (C.3). We set the regularity parameter $\lambda=C\sqrt{\log d/n}$ such that $C\geq 25K_1$. Moreover, we assume that the penalty function $p_\lambda(u)$ satisfies an extra condition (C.4): there exists a constant $c_3>0$ such that $p_\lambda'(u)=0$ for $u\in\big[c_3\lambda,+\infty\big)$. Suppose that the support of $\boldsymbol{\beta}_j^*$ can be partitioned into $S_j=S_{1j}\cup S_{2j}$ where $S_{1j}=\big\{(j,k)\colon|\beta_{jk}^*|\geq(c_2+c_3)\lambda\big\}$ and $S_{2j}=S_j-S_{1j}$. We denote constants $A_1=22\varrho$, $A_2=2.2c_2$, $B_1=32\varrho$, $B_2=3.2c_2$, $\varrho=c_2(c_2\rho_*-11)^{-1}$, $\gamma=11c_2^{-1}\rho_*^{-1}<1$ and $a=1.04$; we let $s_{1j}^*=|S_{1j}|$ and $s_{2j}^*=|S_{2j}|$. With probability at least $1-d^{-1}$, we have the following more refined rates of convergence:*

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)}-\boldsymbol{\beta}_j^*\big\|_2\leq A_1\Big\{\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2+a\sqrt{s_{2j}^*}\lambda\Big\}+A_2\sqrt{s^*}\lambda\gamma^\ell\quad\textit{and}\tag{50}$$

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)}-\boldsymbol{\beta}_j^*\big\|_1\leq B_1\Big\{\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2+a\sqrt{s_{2j}^*}\lambda\Big\}+B_2 s^*\lambda\gamma^\ell,\forall j\in[d].\tag{51}$$

Proof Let $S_j=\{(j,k)\colon\beta_{jk}^*\neq 0,k\in[d]\}$ be the support of $\boldsymbol{\beta}_j^*$ and let index set G_j^ℓ, J_j^ℓ and I_j^ℓ be the same as defined in the proof of Theorem 5. For notational simplicity, we omit the subscript j in these index sets which stands for the j-th node of the graph; we simply write them as G^ℓ, J^ℓ and I^ℓ. Moreover, we let $\boldsymbol{\delta}^{(\ell)}=\widehat{\boldsymbol{\beta}}_j^{(\ell)}-\boldsymbol{\beta}_j^*$, it is shown in Lemma 12 that

$$\big\|\boldsymbol{\delta}_{I^\ell}^{(\ell)}\big\|_2\leq 10\rho_*^{-1}\Big(\big\|\nabla_{\widetilde{G}^\ell}L_j(\boldsymbol{\beta}_j^*)\big\|_2+\big\|\boldsymbol{\lambda}_{S_j}^{(\ell-1)}\big\|_2\Big);\ \ \widetilde{G}^\ell=(G^\ell)^c.\tag{52}$$

In the proof of Theorem 5, we show that $|\widetilde{G}^\ell|\leq 2s^*$ for all $j\in[d]$ and $\ell\geq 1$. Because $S_j=S_{1j}\cup S_{2j}$ where $S_{1j}=\big\{(j,k)\colon|\beta_{jk}^*|\geq(c_2+c_3)\lambda\big\}$ and $S_{2j}=S_j-S_{1j}$, then by triangle inequality we have

$$\big\|\nabla_{S_j}L_j(\boldsymbol{\beta}_j^*)\big\|_2\leq\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2+\sqrt{s_{2j}^*}\big\|\nabla_{S_{2j}}L_j(\boldsymbol{\beta}_j^*)\big\|_\infty.$$

Since $\lambda\geq 25\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty$ with high probability, by (28), we further have

$$\big\|\nabla_{\widetilde{G}^\ell}L_j(\boldsymbol{\beta}_j^*)\big\|_2\leq\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2+\sqrt{s_{2j}^*}\lambda/25+\big\|\boldsymbol{\delta}_{I^{\ell-1}}^{(\ell-1)}\big\|_2\big/(25c_2).\tag{53}$$

Note that by the definition of S_{1j}, for any $(j,k)\in S_{1j}$, $p_\lambda'\big(|\beta_{jk}|-c_2\lambda\big)\leq p_\lambda'(c_3\lambda)=0$, then we have

$$\Upsilon_j:=\lambda\Big[\sum_{(j,k)\in S_j}p_\lambda'\big(|\beta_{jk}^*|-c_2\lambda\big)^2\Big]^{1/2}=\lambda\Big[\sum_{(j,k)\in S_{2j}}p_\lambda'(|\beta_{jk}^*|-c_2\lambda)^2\Big]^{1/2}\leq\sqrt{s_{2j}^*}\lambda.$$

Therefore (30) is reduced to

$$\big\|\boldsymbol{\lambda}_{S_j}^{(\ell-1)}\big\|_2 \le \Upsilon_j + \big\|\boldsymbol{\delta}_{I^{\ell-1}}^{(\ell-1)}\big\|_2/c_2 \le \sqrt{s_{2j}^*}\lambda + \big\|\boldsymbol{\delta}_{I^{\ell-1}}^{(\ell-1)}\big\|_2\big/c_2. \tag{54}$$

Combining (52), (53) and (54) we obtain

$$\big\|\boldsymbol{\delta}_{I^\ell}^{(\ell)}\big\|_2 \le 10\rho_*^{-1}\Big\{\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + 1.04\sqrt{s_{2j}^*}\lambda + 1.04\big\|\boldsymbol{\delta}_{I^{\ell-1}}^{(\ell-1)}\big\|_2/c_2\Big\}.$$

Then by recursion, we obtain the following estimation error:

$$\big\|\boldsymbol{\delta}_{I^\ell}^{(\ell)}\big\|_2 \le 10\varrho\Big\{\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + 1.04\sqrt{s_{2j}^*}\lambda\Big\} + \gamma^{\ell-1}\big\|\boldsymbol{\delta}_{I^1}^{(1)}\big\|_2,$$

where $\gamma := 11c_2^{-1}\rho_*^{-1}$ and $\varrho := c_2(c_2\rho_* - 11)^{-1}$. Note that we assume $c_2 \ge 24\rho_*^{-1}$, for $k = 1$ by (32) we have

$$2.2\big\|\boldsymbol{\delta}_{I_1}^{(1)}\big\|_2 \le 2.2c_2\gamma\sqrt{s^*}\lambda \ \text{ and } \ 2.2\sqrt{2s^*}\big\|\boldsymbol{\delta}_{I_1}^{(1)}\big\|_2 \le 3.2c_2\gamma s^*\lambda.$$

Therefore, using the original notation, we obtain the refined rates of convergence by (23):

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \le 22\varrho\Big\{\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + 1.04\sqrt{s_{2j}^*}\lambda\Big\} + 2.2c_2\gamma^\ell\sqrt{s^*}\lambda \ \text{ and}$$
$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \le 32\varrho\sqrt{s^*}\Big\{\big\|\nabla_{S_{1j}}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + 1.04\sqrt{s_{2j}^*}\lambda\Big\} + 3.2c_2\gamma^\ell s^*\lambda,$$

where $s_{2j}^* = |S_{2j}|$. Moreover, it is easy to see that, with probability at least $1 - d^{-1}$, these convergence rates hold for all $j \in [d]$. ■

Appendix C. Proof of the Auxiliary Results for Estimation

In this appendix, we prove the main results for estimation results presented in §4.1. In this appendix, we prove the auxiliary results for estimation. In specific, we give detailed proofs of Lemmas 10, 11, and 12, which are pivotal for the proof of Theorem5. We first prove Lemmas 10, which gives an upper bound for $\|\nabla L_j(\boldsymbol{\beta}_j^*)\|_\infty$.

C.1. Proof of Lemma 10

Proof By definition, $\nabla L_j(\boldsymbol{\beta}_j^*)$ is a centered second-order U-statistic with kernel function $\mathbf{h}_{ii'}^j(\boldsymbol{\beta}_j^*) \in \mathbb{R}^{d-1}$, whose entries are given by

$$\big[\mathbf{h}_{ii'}^j(\boldsymbol{\beta}_j^*)\big]_{jk} = \frac{R_{ii'}^j(\boldsymbol{\beta}_j^*)(X_{ij} - X_{i'j})(X_{ik} - X_{i'k})}{1 + R_{ii'}^j(\boldsymbol{\beta}_j^*)}.$$

By the tail probability bound in (14), for any $i \in [n]$ and $j \in [d]$, we have

$$\begin{aligned}\mathbb{P}\big(|X_{ij}| > x, \forall i \in [n], \forall j \in [d]\big) &\le \sum_{i\in[n], j\in[d]} \mathbb{P}(|X_{ij}| > x) \\ &\le 2\exp(\kappa_m + \kappa_h/2)\exp(-x + \log d + \log n).\end{aligned} \tag{55}$$

By setting $x = C\log d$ for some constant C, we conclude that event $\mathcal{E} := \{|X_{ij}| \le C\log d, \forall i \in [n], \forall j \in [d]\}$ holds with probability at least $1 - (4d)^{-1}$. Following from the same argument as in Ning et al. (2017b), it is easy to show that, conditioning on $\mathcal{E}$, $\mathbf{h}_{ii'}^j(\boldsymbol{\beta}_j^*)$ is also centered. Note that conditioning on event $\mathcal{E}$, $\big\|\mathbf{h}_{ii'}^j(\boldsymbol{\beta}_j^*)\big\|_\infty \le C\log^2 d$ for some generic constant C and for all $i, i' \in [d]$ and $j \in [d]$. The following Bernstein's inequality for U-statistics, presented in Arcones (1995), gives an upper bound for the tail probability of $\nabla L_j(\boldsymbol{\beta}_j^*)$.

Lemma 19 (Bernstein's inequality for U-statistics) *Given n i.i.d. random variables $Z_1, \ldots Z_n$ taking values in a measurable space $(\mathbb{S}, \mathcal{B})$ and a symmetric and measurable kernel function $h\colon \mathbb{S}^m \to R$, we define the U-statistics with kernel h as*

$$U := \binom{n}{m}^{-1} \sum_{i_1 < \ldots < i_m} h(Z_{i_1}, \ldots, Z_{i_m}).$$

Suppose that $\mathbb{E}[h(Z_{i_1}, \ldots, Z_{i_m})] = 0$, $\mathbb{E}\big\{\mathbb{E}[h(Z_{i_1}, \ldots, Z_{i_m}) \mid Z_{i_1}]\big\}^2 = \sigma^2$, and $\|h\|_\infty \le b$ for some positive σ and b. There exists an absolute constant $K(m) > 0$ that only depends on m such that

$$\mathbb{P}(|U| > t) \le 4\exp\big\{-nt^2/[2m^2\sigma^2 + K(m)bt]\big\}, \ \forall t > 0. \tag{56}$$

Note that by (14), the fourth moment of $\boldsymbol{X}$ is bounded, which implies that $\mathbb{E}[\mathbf{h}_{ii'}^j(\boldsymbol{\beta}_j^*)]^2$ is uniformly bounded by an absolute constant for all $j \in [d]$. By Lemma 19, setting $b = C\log^2 d$ in (56) yields that

$$\mathbb{P}\big(\big|\nabla_{jk}L_j(\boldsymbol{\beta}_j^*)\big| > t\big|\mathcal{E}\big) \le 4\exp\Big[-nt^2\big/(C_1 + C_2\log^2 d\cdot t)\Big] \tag{57}$$

for some generic constants C_1 and C_2. Taking a union bound over $\{(j,k)\colon j,k \in [d], k \ne j\}$ we obtain

$$\max_{j\in[d]}\Big\{\mathbb{P}\big(\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty > t\big|\mathcal{E}\big)\Big\} \lesssim d^2\cdot\exp\big[-nt^2\big/(C_1 + C_2\log^2 d\cdot t)\big]. \tag{58}$$

Under Assumption 4 and conditioning on $\mathcal{E}$, by setting $t = K_1\sqrt{\log d/n}$ for a sufficiently large $K_1 > 0$, it holds probability greater than $1 - (4d)^{-1}$ that

$$\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \le K_1\sqrt{\log d/n} \ \ \forall j \in [d].$$

Note that $\mathcal{E}$ holds with probability at least $1 - (4d)^{-1}$, we conclude the proof of Lemma 10. ■

C.2. Proof of Lemma 11

Proof In what follows, for notational simplicity and readability, we omit j in the subscript and ℓ in the superscript by simply writing S_j, G_j^ℓ, J_j^ℓ and I_j^ℓ as S, G, J an I respectively. By the definition of G, $\big\|\boldsymbol{\lambda}_{G^\ell}^{(\ell-1)}\big\|_{\min} \ge p_\lambda'(\theta) \ge 0.91\lambda > 22.75\|\nabla L_j(\boldsymbol{\beta}_j^*)\|_\infty$. We prove this lemma

in two steps. In the **first step** we show that $\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\|_1 \leq 2.2\|\widehat{\boldsymbol{\beta}}_{G^c}^{\ell} - \boldsymbol{\beta}_{G^c}^*\|_1$. Suppose that $\widehat{\boldsymbol{\beta}}_j^{(\ell)}$ is the solution in the ℓ-th iteration and we denote $\nabla_{jk} L_j(\boldsymbol{\beta}_j) = \partial L_j(\boldsymbol{\beta}_j)/\partial \beta_{jk}$, the Karush-Kuhn-Tucker condition implies that

$$\nabla_{jk} L_j(\widehat{\boldsymbol{\beta}}_j^{(\ell)}) + \lambda_{jk}^{(\ell-1)} \mathrm{sign}(\widehat{\beta}_{jk}^{(\ell)}) = 0 \quad if \quad \widehat{\beta}_{jk}^{(\ell)} \neq 0;$$
$$\nabla_{jk} L_j(\widehat{\boldsymbol{\beta}}_j^{(\ell)}) + \lambda_{jk}^{(\ell-1)} \xi_{jk}^{(\ell)} = 0, \quad \xi_{jk}^{(\ell)} \in [-1,1] \quad if \quad \widehat{\beta}_{jk}^{(\ell)} = 0.$$

The above Karush-Kuhn-Tuker condition can be written in a compact form as

$$\nabla L_j(\widehat{\boldsymbol{\beta}}_j^{(\ell)}) + \boldsymbol{\lambda}_j^{(\ell-1)} \circ \boldsymbol{\xi}_j^{(\ell)} = 0, \tag{59}$$

where $\boldsymbol{\xi}_j^{(\ell)} \in \partial \|\widehat{\boldsymbol{\beta}}_j^{(\ell)}\|_1$ and $\boldsymbol{\lambda}_j^{(\ell-1)} = \big(\lambda_{j1}^{(\ell-1)}, \ldots, \lambda_{jj-1}^{(\ell-1)}, \lambda_{jj+1}^{(\ell-1)}, \ldots, \lambda_{jd}^{(\ell-1)}\big)^T \in \mathbb{R}^{d-1}$.

For notational simplicity, we let $\boldsymbol{\delta} = \widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^* \in \mathbb{R}^{d-1}$ and omit the superscript ℓ and subscript j in both $\boldsymbol{\lambda}_j^{(\ell-1)}$ and $\boldsymbol{\xi}_j^{(\ell)}$ by writing them as $\boldsymbol{\lambda}$ and $\boldsymbol{\xi}$. By definition, $I = G^c \cup J$. Note that we denote the support of $\boldsymbol{\beta}_j^*$ as S; we define $H := G^c - S$, then S, H and G is a partition of $\big\{(j,k)\colon k \in [d], k \neq j\big\}$.

By the Mean-Value theorem, there exists an $\alpha \in [0,1]$ such that $\widetilde{\boldsymbol{\beta}}_j := \alpha \boldsymbol{\beta}_j^* + (1-\alpha)\widehat{\boldsymbol{\beta}}_j^{(\ell)} \in \mathbb{R}^{d-1}$ satisfies

$$\nabla L_j(\widehat{\boldsymbol{\beta}}_j) - \nabla L_j(\boldsymbol{\beta}_j^*) = \nabla^2 L_j(\widetilde{\boldsymbol{\beta}}_j)\boldsymbol{\delta}.$$

Then (59) implies that

$$0 \leq \boldsymbol{\delta}^T \nabla^2 L_j(\widetilde{\boldsymbol{\beta}}_j)\boldsymbol{\delta} = -\underbrace{\big\langle \boldsymbol{\delta}, \boldsymbol{\lambda} \circ \boldsymbol{\xi} \big\rangle}_{\text{(i)}} - \underbrace{\big\langle \nabla L_j(\boldsymbol{\beta}_j^*), \boldsymbol{\delta} \big\rangle}_{\text{(ii)}}. \tag{60}$$

For term (ii) in (60), Hölder's inequality implies that

$$\text{(ii)} \geq -\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \|\boldsymbol{\delta}\|_1. \tag{61}$$

For term (i) in (60), recall that we denote $|\mathbf{v}|$ as the vector that takes entrywise absolute value for $\mathbf{v}$. By the fact that $\xi_{jk}^{(\ell)} \widehat{\beta}_{jk}^{(\ell)} = |\widehat{\beta}_{jk}^{(\ell)}|$, we have $\boldsymbol{\xi}_G \circ \boldsymbol{\delta}_G = |\boldsymbol{\delta}_G|$ and $\boldsymbol{\xi}_H \circ \boldsymbol{\delta}_H = |\boldsymbol{\delta}_H|$. Since $\boldsymbol{\delta}_{S^c} = \widehat{\boldsymbol{\beta}}_{S^c}^{(\ell)}$. Hölder's inequality implies that

$$\begin{aligned}\big\langle \boldsymbol{\delta}, \boldsymbol{\lambda} \circ \boldsymbol{\xi} \big\rangle &= \big\langle \boldsymbol{\delta}_S, (\boldsymbol{\lambda} \circ \boldsymbol{\xi})_S \big\rangle + \big\langle |\boldsymbol{\delta}_H|, \boldsymbol{\lambda}_H \big\rangle + \big\langle |\boldsymbol{\delta}_G|, \boldsymbol{\lambda}_G \big\rangle \\ &\geq -\|\boldsymbol{\delta}_S\|_1 \|\boldsymbol{\lambda}_S\|_\infty + \|\boldsymbol{\delta}_G\|_1 \|\boldsymbol{\lambda}_G\|_{\min} + \|\boldsymbol{\delta}_H\|_1 \|\boldsymbol{\lambda}_H\|_{\min}.\end{aligned} \tag{62}$$

Combining (60), (61) and (62) we have

$$-\|\boldsymbol{\delta}_S\|_1 \|\boldsymbol{\lambda}_S\|_\infty + \|\boldsymbol{\delta}_G\|_1 \|\boldsymbol{\lambda}_G\|_{\min} + \|\boldsymbol{\delta}_H\|_1 \|\boldsymbol{\lambda}_H\|_{\min} - \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \|\boldsymbol{\delta}\|_1 \leq 0. \tag{63}$$

By the definition of G, we have $\|\boldsymbol{\lambda}_G\|_{\min} \geq p'_\lambda(c_2\lambda) \geq 0.91\lambda$. Rearranging terms in (63) we have

$$p'_\lambda(c_2\lambda)\|\boldsymbol{\delta}_G\|_1 \leq \|\boldsymbol{\delta}_G\|_1 \|\boldsymbol{\lambda}_G\|_{\min} \leq \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \|\boldsymbol{\delta}\|_1 + \|\boldsymbol{\delta}_S\|_1 \|\boldsymbol{\lambda}_S\|_\infty.$$

Using the decomposability of the ℓ_1-norm, we have

$$\Big[p'_\lambda(c_2\lambda) - \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty\Big]\|\boldsymbol{\delta}_G\|_1 \leq \Big[\|\boldsymbol{\lambda}_S\|_\infty + \|\nabla L_j(\boldsymbol{\beta}_j^*)\|_\infty\Big]\|\boldsymbol{\delta}_{G^c}\|_1 \tag{64}$$

Recall that $\lambda > 25\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty$ and $p'_\lambda(\theta) \geq 0.91\lambda$, (64) implies

$$\big\|\boldsymbol{\delta}_G\big\|_1 \leq \frac{\lambda + \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty}{p'_\lambda(c_2\lambda) - \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty}\|\boldsymbol{\delta}_{G^c}\|_1 \leq 1.2\|\boldsymbol{\delta}_{G^c}\|_1, \tag{65}$$

where we use the fact that

$$\frac{\lambda + \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty}{p'_\lambda(c_2\lambda) - \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty} \leq \frac{\lambda + 0.04\lambda}{0.91\lambda - 0.04\lambda} \leq 1.2.$$

Going back to the original notation, (65) is equivalent to

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq 2.2\big\|\widehat{\boldsymbol{\beta}}_{\widetilde{G}_j^\ell}^{(\ell)} - \boldsymbol{\beta}_{\widetilde{G}_j^\ell}^*\big\|_1.$$

Now we show in the **second step** that $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \leq 2.2\big\|\widehat{\boldsymbol{\beta}}_{I_j^\ell}^{(\ell)} - \boldsymbol{\beta}_{I_j^\ell}^*\big\|_2$. Recall that J is the largest k^* components of $\widehat{\boldsymbol{\beta}}_G^{(\ell)}$ in absolute value where we omit the subscript j and superscript ℓ in the sets G_j^ℓ, J_j^ℓ and I_j^ℓ. By the definition of J we obtain that

$$\|\boldsymbol{\delta}_{I^c}\|_\infty \leq \|\boldsymbol{\delta}_J\|_1/k^* \leq \|\boldsymbol{\delta}_G\|_1/k^*, \quad \text{where} \quad \boldsymbol{\delta} = \widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*.$$

By inequality (65) and the fact that $G^c \subset I$, we further have

$$\|\boldsymbol{\delta}_{I^c}\|_\infty \leq 1.2/k^* \cdot \|\boldsymbol{\delta}_{G^c}\|_1 \leq 1.2/k^* \cdot \|\boldsymbol{\delta}_I\|_1. \tag{66}$$

Then by Hölder' inequality and (66) we obtain that

$$\|\boldsymbol{\delta}_{I^c}\|_2 \leq \big(\|\boldsymbol{\delta}_{I^c}\|_1 \|\boldsymbol{\delta}_{I^c}\|_\infty\big)^{1/2} \leq (1.2/k^*)^{1/2}\big(\|\boldsymbol{\delta}_I\|_1 \|\boldsymbol{\delta}_{I^c}\|_1\big)^{1/2}. \tag{67}$$

By the definition of index sets G and I, we have $I^c \subset G$ and $G^c \subset I$. Then by (65) and (67) we obtain

$$\|\boldsymbol{\delta}_{I^c}\|_2 \leq (1.2/k^*)^{1/2}\big(\|\boldsymbol{\delta}_{G^c}\|_1 \|\boldsymbol{\delta}_G\|_1\big)^{1/2} \leq 1.2\|\boldsymbol{\delta}_{G^c}\|_1/\sqrt{k^*}.$$

By the norm inequality between ℓ_1-norm and ℓ_2-norm, we have

$$\|\boldsymbol{\delta}_{I^c}\|_2 \leq 1.2\|\boldsymbol{\delta}_{G^c}\|_1/\sqrt{k^*} \leq 1.2\sqrt{2s^*/k^*}\|\boldsymbol{\delta}_{G^c}\|_2 \leq 1.2\|\boldsymbol{\delta}_I\|_2,$$

where we use $k^* \geq 2s^*$ and the induction assumption that $|G| \leq 2s^*$. Then triangle inequality for ℓ_2-norm yields that

$$\|\boldsymbol{\delta}\|_2 \leq \|\boldsymbol{\delta}_{I^c}\|_2 + \|\boldsymbol{\delta}_I\|_2 \leq 2.2\|\boldsymbol{\delta}_I\|_2. \tag{68}$$

Note that (65) and (68) are equivalent to

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \leq 2.2\big\|\widehat{\boldsymbol{\beta}}_{I_j^\ell}^{(\ell)} - \boldsymbol{\beta}_{I_j^\ell}^*\big\|_2 \ \text{ and } \ \big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq 2.2\big\|\widehat{\boldsymbol{\beta}}_{\widetilde{G}_j^\ell}^{(\ell)} - \boldsymbol{\beta}_{\widetilde{G}_j^\ell}^*\big\|_1,$$

where $\widetilde{G}_j^\ell = \big(G_j^{(\ell)}\big)^c$, which concludes the proof. ∎

C.3. Proof of Lemma 12

Proof We first show that $\widehat{\boldsymbol{\beta}}_j^{(\ell)}$ stays in the ℓ_1-ball centered at $\boldsymbol{\beta}_j^*$ with radius $r = C_\rho s^* \sqrt{\log d/n}$, where $C_\rho \geq 33\rho_*^{-1}$. For notational simplicity, we denote $\boldsymbol{\delta} = \widehat{\boldsymbol{\beta}}_j^{(\ell)} - \widehat{\boldsymbol{\beta}}_j$ and write S_j, G_j^ℓ, J_j^ℓ and I_j^ℓ as S, G, J an I respectively. We prove by contradiction. Suppose that $\|\boldsymbol{\delta}\|_1 > r$, then we define $\widetilde{\boldsymbol{\beta}}_j = \boldsymbol{\beta}_j^* + t(\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*) \in \mathbb{R}^{d-1}$ with $t \in [0,1]$ such that $\big\|\widetilde{\boldsymbol{\beta}}_j - \boldsymbol{\beta}_j^*\big\|_1 \leq r$. Letting $\widetilde{\boldsymbol{\delta}} := \widetilde{\boldsymbol{\beta}}_j - \boldsymbol{\beta}_j^*$, by (68) we obtain

$$\|\widetilde{\boldsymbol{\delta}}\|_2 = t\|\boldsymbol{\delta}\|_2 \leq 2.2t\|\boldsymbol{\delta}_I\|_2 = 2.2\|\widetilde{\boldsymbol{\delta}}_I\|_2. \tag{69}$$

Moreover, by Lemma (11) and the relation between ℓ_1- and ℓ_2-norms we have

$$\|\widetilde{\boldsymbol{\delta}}\|_1 = t\|\boldsymbol{\delta}\|_1 \leq 2.2t\|\boldsymbol{\delta}_{G^c}\|_1 \leq 2.2\sqrt{2s^*}\|\widetilde{\boldsymbol{\delta}}_I\|_2, \tag{70}$$

where we use the fact that $G^c \subset I$ and the induction assumption that $|G^c| \leq 2s^*$. By Mean-Value theorem, there exists a $\gamma \in [0,1]$ such that $\nabla L_j(\widetilde{\boldsymbol{\beta}}_j) - \nabla L_j(\boldsymbol{\beta}_j^*) = \nabla^2 L_j(\boldsymbol{\beta}_1)\widetilde{\boldsymbol{\delta}}$, where $\boldsymbol{\beta}_1 := \gamma\boldsymbol{\beta}_j^* + (1-\gamma)\widetilde{\boldsymbol{\beta}}_j \in \mathbb{R}^{d-1}$. In what follows we will derive an upper bound for $\|\widetilde{\boldsymbol{\delta}}_I\|_2$ from $\widetilde{\boldsymbol{\delta}}^T\nabla^2 L_j(\boldsymbol{\beta}_1)\widetilde{\boldsymbol{\delta}}$. Before doing that, we present two lemmas. The first one shows that the restricted correlation coefficients defined as follows are closely related to the sparse eigenvalues. This lemma also appear in Zhang (2010) and Zhang et al. (2013) for ℓ_2-loss.

Lemma 20 *(Local sparse eigenvalues and restricted correlation coefficients) Let m be a positive integer and $\mathbf{M}(\cdot)\colon \mathbb{R}^m \to \mathbb{S}^m$ be a mapping from $\mathbb{R}^m$ to the space of $m\times m$ symmetric matrices. We define the s-sparse eigenvalues of $\mathbf{M}(\cdot)$ over the ℓ_1-ball centered at $\mathbf{u}_0 \in \mathbb{R}^m$ with radius r as*

$$\rho_+\big(\mathbf{M}, \mathbf{u}_0; s, r\big) = \sup_{\mathbf{v},\mathbf{u}\in\mathbb{R}^m} \big\{\mathbf{v}^T\mathbf{M}(\mathbf{u})\mathbf{v}\colon \|\mathbf{v}\|_0 \leq s, \|\mathbf{v}\|_2 = 1, \|\mathbf{u}-\mathbf{u}_0\|_1 \leq r\big\};$$
$$\rho_-\big(\mathbf{M}, \mathbf{u}_0; s, r\big) = \inf_{\mathbf{v},\mathbf{u}\in\mathbb{R}^m} \big\{\mathbf{v}^T\mathbf{M}(\mathbf{u})\mathbf{v}\colon \|\mathbf{v}\|_0 \leq s, \|\mathbf{v}\|_2 = 1, \|\mathbf{u}-\mathbf{u}_0\|_1 \leq r\big\}.$$

In addition, we define the restricted correlation coefficients of $\mathbf{M}$ over the ℓ_1-ball centered at $\mathbf{u}_0$ with radius r as

$$\pi\big(\mathbf{M}, \mathbf{u}_0; s, k, r\big) := \sup_{\mathbf{v},\mathbf{w},\mathbf{u}\in\mathbb{R}^m} \bigg\{\frac{\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{w}_J\big\|\mathbf{v}_I\big\|_2}{\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\big\|\mathbf{w}_J\big\|_\infty}\colon I\cap J = \emptyset, |I|\leq s, |J|\leq k, \big\|\mathbf{u}-\mathbf{u}_0\big\|_1 \leq r\bigg\}.$$

Suppose that the local sparse eigenvalue $\rho_-\big(\mathbf{M}, \mathbf{u}_0; s+k, r\big) > 0$, then we have the following upper bound on the restricted correlation coefficient $\pi(\mathbf{M}, \mathbf{u}_0; s, k)$:

$$\pi\big(\mathbf{M}, \mathbf{u}_0; s, k, r\big) \leq \frac{\sqrt{k}}{2}\sqrt{\rho_+\big(\mathbf{M}, \mathbf{u}_0; k, r\big)\Big/\rho_-\big(\mathbf{M}, \mathbf{u}_0; s+k, r\big) - 1}.$$

Proof See §E.1.1 for a detailed proof. ∎

We denote the restricted correlation coefficients of $\nabla^2 L_j(\cdot)$ over the ℓ_1-ball centered at $\boldsymbol{\beta}_j^*$ with radius r as $\pi_j(s_1, s_2) := \pi\big(\nabla^2 L_j, \boldsymbol{\beta}_j^*; s_1, s_2, r\big)$ and denote the s-sparse eigenvalues $\rho_-\big(\nabla^2 L_j, \boldsymbol{\beta}_j^*; s, r\big)$ and $\rho_+\big(\nabla^2 L_j, \boldsymbol{\beta}_j^*; s, r\big)$ as $\rho_{j-}(s)$ and $\rho_{j+}(s)$ respectively. Applying Lemma 20 to $\pi_j(2s^*+k^*, k^*)$ we obtain

$$\pi_j(2s^*+k^*, k^*) \leq k^{*1/2}/2 \cdot \sqrt{\rho_{j+}(k^*)/\rho_{j-}(2s^*+2k^*) - 1}. \tag{71}$$

By the law of large numbers, if the sample size n is sufficiently large such that $\nabla^2 L_j$ is close to its expectation $\mathbb{E}\big[\nabla^2 L_j\big]$. When $\boldsymbol{\beta}_j$ is close to $\boldsymbol{\beta}_j^*$, by Assumption 4, we expect that the sparse eigenvalue condition also holds for $\nabla^2 L_j(\boldsymbol{\beta}_j)$ with high probability. The following lemma justifies this intuition.

Lemma 21 *Recall that we define the sparse eigenvalues of $\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]$ in Definition 3. Under Assumptions 2 and 4, if n is sufficiently large such that $\rho_* \gtrsim k^*\lambda\log^2 d$, with probability at least $1-(2d)^{-1}$, for all $j\in[d]$, there exists a constant $C_\rho \geq 33\rho_*^{-1}$ such that*

$$\rho_{j-}^*(2s^*+2k^*) - 0.05\rho_* \leq \rho_{j-}(2s^*+2k^*) < \rho_{j+}(k^*) \leq \rho_{j+}^*(k^*) + 0.05\rho_*, \quad \text{and}$$
$$\rho_{j+}(k^*)/\rho_{j-}(2s^*+2k^*) \leq 1 + 0.27k^*/s^*,$$

where we denote the local sparse eigenvalues $\rho_-\big(\nabla^2 L_j, \boldsymbol{\beta}_j^*; s, r\big)$ and $\rho_+\big(\nabla^2 L_j, \boldsymbol{\beta}_j^*; s, r\big)$ with $r = C_\rho\sqrt{\log d/n}$ as $\rho_{j-}(s)$ and $\rho_{j+}(s)$, respectively.

Proof See §E.1.2 for a detailed proof. ∎

Thus by Lemma 21 we have

$$\pi_j(2s^*+k^*, k^*) \leq 0.5\sqrt{0.27k^{*2}/s^*}. \tag{72}$$

By (65), (72) and $G^c \subset I$ we obtain

$$1 - 2\pi_j(2s^*+k^*, k^*)k^{*-1}\|\widetilde{\boldsymbol{\delta}}_G\|_1/\|\widetilde{\boldsymbol{\delta}}_I\|_2 \geq 1 - 1.2\sqrt{0.54} := \kappa_1, \tag{73}$$

where we denote $\kappa_1 := 1 - 1.2\sqrt{0.54} \geq 0.11$. Now we use the second lemma to get an lower bound of $\widetilde{\boldsymbol{\delta}}^T\nabla^2 L_j(\boldsymbol{\beta}_1)\widetilde{\boldsymbol{\delta}}$, which implies an upper bound for $\|\widetilde{\boldsymbol{\delta}}_I\|_2$.

Lemma 22 *Let $\mathbf{M}\colon \mathbb{R}^m \to \mathbb{S}^m$ be a mapping from $\mathbb{R}^m$ to the space of $m\times m$-symmetric matrices. Suppose that the sparse eigenvalue $\rho_-\big(\mathbf{M}, \mathbf{u}_0; s+k, r\big) > 0$, let the restricted correlation coefficients of $\mathbf{M}(\cdot)$ be defined in Lemma 20. We denote the restricted correlation coefficients $\pi\big(\mathbf{M}, \mathbf{u}_0; s, k, r\big)$ and s-sparse eigenvalue $\rho_-\big(\mathbf{M}, \mathbf{u}_0; s, r\big)$ as $\pi(s,k)$ and $\rho_-(s)$ respectively for notational simplicity. For any $\mathbf{v}\in\mathbb{R}^d$, let F be any index set such that $|F^c| \leq s$, let J be the set of indices of the largest k entries of $\mathbf{v}_F$ in absolute value and let $I = F^c \cup J$. For any $\mathbf{u}\in\mathbb{R}^d$ such that $\|\mathbf{u}-\mathbf{u}_0\|_2 \leq r$ and any $\mathbf{v}\in\mathbb{R}^d$ satisfying $1 - 2\pi(s+k,k)\|\mathbf{v}_F\|_1/\|\mathbf{v}_I\|_2 > 0$ we have*

$$\mathbf{v}^T\mathbf{M}(\mathbf{u})\mathbf{v} \geq \rho_-(s+k)\big[\|\mathbf{v}_I\|_2 - 2\pi(s+k,k)\|\mathbf{v}_F\|_1/k\big]\|\mathbf{v}_I\|_2.$$

Proof See §E.1.3 for a detailed proof. ■

Now applying Lemma 22 to $\nabla^2 L_j(\cdot)$ with $F=G$, $s=2s^*$ and $k=k^*$ we obtain

$$\widetilde{\boldsymbol{\delta}}^T\nabla^2 L_j(\boldsymbol{\beta}_1)\widetilde{\boldsymbol{\delta}} \geq \rho_{j-}(2s^*+k^*)\|\widetilde{\boldsymbol{\delta}}_I\|_2\big[\|\widetilde{\boldsymbol{\delta}}_I\|_2 - 2\pi_j(2s^*+k^*,k^*)/k^*\|\widetilde{\boldsymbol{\delta}}_G\|_1\big]. \tag{74}$$

Then by (73), the right-hand side of (74) can be lower bounded by

$$\widetilde{\boldsymbol{\delta}}^T\nabla^2\ell(\boldsymbol{\beta}_1)\widetilde{\boldsymbol{\delta}} \geq \kappa_1\rho_{j-}(2s^*+k^*)\|\widetilde{\boldsymbol{\delta}}_I\|_2^2 \geq 0.95\kappa_1\rho_*\|\widetilde{\boldsymbol{\delta}}_I\|_2^2 = \kappa_2\rho_*\|\widetilde{\boldsymbol{\delta}}_I\|_2^2, \tag{75}$$

where we let $\kappa_2 := 0.95\kappa_1 \geq 0.1$. Now we derive an upper bound for $\widetilde{\boldsymbol{\delta}}^T\nabla^2 L_j(\boldsymbol{\beta}_1)\widetilde{\boldsymbol{\delta}}$. We define the symmetric Bregman divergence of $L_j(\boldsymbol{\beta}_j)$ as $D_j(\boldsymbol{\beta}_1,\boldsymbol{\beta}_2) := \big\langle \boldsymbol{\beta}_1-\boldsymbol{\beta}_2, \nabla L_j(\boldsymbol{\beta}_1) - \nabla L_j(\boldsymbol{\beta}_2)\big\rangle$, where $\boldsymbol{\beta}_1,\boldsymbol{\beta}_2 \in \mathbb{R}^{d-1}$. Then by definition, $\widetilde{\boldsymbol{\delta}}^T\nabla^2\ell(\boldsymbol{\beta}_1)\widetilde{\boldsymbol{\delta}} = D_j(\widetilde{\boldsymbol{\beta}}_j,\boldsymbol{\beta}_j^*)$. The following lemma relates $D_j(\widetilde{\boldsymbol{\beta}}_j,\boldsymbol{\beta}_j^*)$ with $D_j(\widehat{\boldsymbol{\beta}}_j,\boldsymbol{\beta}_j^*)$.

Lemma 23 *Let $D_j(\boldsymbol{\beta}_1,\boldsymbol{\beta}_2) := \big\langle \boldsymbol{\beta}_1-\boldsymbol{\beta}_2, \nabla L_j(\boldsymbol{\beta}_1) - \nabla L(\boldsymbol{\beta}_2)\big\rangle$, $\boldsymbol{\beta}(t) = \boldsymbol{\beta}_1 + t(\boldsymbol{\beta}_2-\boldsymbol{\beta}_1)$, $t\in(0,1)$ be any point on the line segment between $\boldsymbol{\beta}_1$ and $\boldsymbol{\beta}_2$. Then we have*

$$D_j(\boldsymbol{\beta}(t),\boldsymbol{\beta}_1) \leq tD_j(\boldsymbol{\beta}_2,\boldsymbol{\beta}_1)$$

Proof See §E.1.4 for a detailed proof. ■

By Lemma 23 and (60),

$$D_j(\widetilde{\boldsymbol{\beta}}_j,\boldsymbol{\beta}_j^*) \leq tD_j(\widehat{\boldsymbol{\beta}}_j,\boldsymbol{\beta}_j^*) \leq \underbrace{-t\big\langle\nabla L_j(\boldsymbol{\beta}_j^*),\boldsymbol{\delta}\big\rangle}_{(i)}\underbrace{-t\big\langle\boldsymbol{\delta},\boldsymbol{\lambda}_j\circ\boldsymbol{\xi}_j\big\rangle}_{(ii)}. \tag{76}$$

For term (i) in (76), by Hölder's inequality we have

$$\begin{aligned}-t\big\langle\nabla L_j(\boldsymbol{\beta}_j^*),\boldsymbol{\delta}\big\rangle &\leq t\big\|\nabla_{G^c}L_j(\boldsymbol{\beta}_j^*)\big\|_2\|\boldsymbol{\delta}_{G^c}\|_2 + t\big\|\nabla_G L_j(\boldsymbol{\beta}_j^*)\big\|_\infty\|\boldsymbol{\delta}_G\|_1\\ &\leq \big\|\nabla_{G^c}L_j(\boldsymbol{\beta}_j^*)\big\|_2\|\widetilde{\boldsymbol{\delta}}_I\|_2 + \big\|\nabla_G L_j(\boldsymbol{\beta}_j^*)\big\|_\infty\|\widetilde{\boldsymbol{\delta}}_G\|_1,\end{aligned} \tag{77}$$

where the inequality follows from $G^c\subset I$. For term (ii) in (76), by (62) and Hölder's inequality we have

$$-t\big\langle\boldsymbol{\delta},\boldsymbol{\lambda}_j\circ\boldsymbol{\xi}_j\big\rangle \leq -\big\langle\boldsymbol{\delta}_S,(\boldsymbol{\lambda}_j\circ\boldsymbol{\xi}_j)_S\big\rangle - \big\langle|\widetilde{\boldsymbol{\delta}}_G|,\boldsymbol{\lambda}_G\big\rangle \leq \|\boldsymbol{\lambda}_S\|_2\|\widetilde{\boldsymbol{\delta}}_I\|_2 - p'_\lambda(c_2\lambda)\|\widetilde{\boldsymbol{\delta}}_G\|_1, \tag{78}$$

where we use the Hölder's inequality and the definition of G. Combining (75),(77) and (78) we obtain that

$$\begin{aligned}\kappa_2\rho_*\big\|\widetilde{\boldsymbol{\delta}}_I\big\|_2^2 &\leq \big(\big\|\nabla_{G^c}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \|\boldsymbol{\lambda}_S\|_2\big)\|\widetilde{\boldsymbol{\delta}}_I\|_2 + \big[\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty - p'_\lambda(c_2\lambda)\big]\|\widetilde{\boldsymbol{\delta}}_G\|_1\\ &\leq \big(\big\|\nabla_{G^c}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \|\boldsymbol{\lambda}_S\|_2\big)\big\|\widetilde{\boldsymbol{\delta}}_I\big\|_2,\end{aligned}$$

where the second inequality follows from $p'_\lambda(c_2\lambda) > \big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty$. From the inequality above and the induction assumption $|G^c|\leq 2s^*$ we obtain that

$$\big\|\widetilde{\boldsymbol{\delta}}_I\big\|_2 \leq 10\rho_*^{-1}\big(\big\|\nabla_{G^c}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \|\boldsymbol{\lambda}_S\|_2\big) \leq 10\rho_*^{-1}\sqrt{s^*}\big(\sqrt{2}\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty + \lambda\big). \tag{79}$$

Thus (70), (79) and the the fact that $25\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \leq \lambda$ imply that

$$\|\widetilde{\boldsymbol{\delta}}\|_1 \leq 22\sqrt{2}\rho_*^{-1}(1+\sqrt{2}/25)s^*\lambda < 33\rho_*^{-1}s^*\lambda \leq r, \tag{80}$$

where the last inequality follows from the definition of λ. Notice that (80) contradicts our assumption that $\|\widetilde{\boldsymbol{\delta}}\|_1 = r$, the reason for this contradiction is because we assume that $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 > r$, hence $\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq r$ and $\widetilde{\boldsymbol{\beta}}_j = \widehat{\boldsymbol{\beta}}_j^{(\ell)}$. This means that $\widehat{\boldsymbol{\beta}}_j^{(\ell)}$ stays in the ℓ_1-ball centered at $\boldsymbol{\beta}_j^*$ with radius r in each iteration.

Moreover, by (68) and (79), we obtain the following upper bound for $\|\boldsymbol{\delta}_I\|_2$:

$$\|\boldsymbol{\delta}\|_2 \leq 22\rho_*^{-1}\big(\big\|\nabla_{G^c}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \|\boldsymbol{\lambda}_S\|_2\big) \leq 24\rho_*^{-1}\sqrt{s^*}\lambda,$$

where we use the condition that $\lambda \geq 25\big\|\nabla L_j(\boldsymbol{\beta}_j^*)\big\|_\infty$. In addition, by(65) and (79) we obtain the following bound on $\|\boldsymbol{\delta}\|_1$

$$\|\boldsymbol{\delta}\|_1 \leq 2.2\|\boldsymbol{\delta}_{G^c}\|_1 \leq 22\sqrt{2s^*}\rho_*^{-1}\Big(\big\|\nabla_{G^c}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \|\boldsymbol{\lambda}_S\|_2\Big) \leq 33\rho_*^{-1}s^*\lambda, \tag{81}$$

Therefore going back to the original notations, note that $\kappa_2\geq 0.1$, we establish the following crude rates of convergence for $\ell\geq 1$:

$$\big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_2 \leq 24\rho_*^{-1}\sqrt{s^*}\lambda \;\text{ and }\; \big\|\widehat{\boldsymbol{\beta}}_j^{(\ell)} - \boldsymbol{\beta}_j^*\big\|_1 \leq 33\rho_*^{-1}s^*\lambda. \tag{82}$$

And (79) is equivalent to

$$\big\|\widehat{\boldsymbol{\beta}}_{I_j^\ell}^{(\ell)} - \boldsymbol{\beta}_{I_j^\ell}^*\big\|_2 \leq 10\rho_*^{-1}\Big(\big\|\nabla_{\widetilde{G}_j^\ell}L_j(\boldsymbol{\beta}_j^*)\big\|_2 + \big\|\boldsymbol{\lambda}_{S_j}^{(\ell-1)}\big\|_2\Big),\;\; \widetilde{G}_j^\ell := (G_j^\ell)^c. \tag{83}$$

Note that we use Lemmas 10 and 21, hence (83) and (83) hold with probability at least $1-d^{-1}$ for all $j\in[d]$. ■

Appendix D. Proof of Auxiliary Results for Asymptotic Inference

We prove the auxiliary results for asymptotic inference. More specifically, we first prove Lemma 14, which is pivotal for deriving the limiting distribution of the pairwise score statistic. Then we prove the lemmas presented in the proof of Theorem 8.

D.1. Proof of Lemma 14

Proof Before proving this lemma, we first let $\nabla^2 L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ be the Hessian of $L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ and define $\mathbf{H}^{jk} := \mathbb{E}\big[\nabla^2 L_{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)\big]$. We also define

$$\boldsymbol{\Sigma}^{jk} := \mathbb{E}\big[\mathbf{g}_{jk}(\boldsymbol{X}_i)\mathbf{g}_{jk}(\boldsymbol{X}_i)^T\big] \;\text{ and }\; \boldsymbol{\Theta}^{jk} := \mathbb{E}\big[\mathbf{h}_{ii'}^{jk}(\boldsymbol{\beta}^*)\mathbf{h}_{ii'}^{jk}(\boldsymbol{\beta}^*)^T\big].$$

Under Assumption 2, we first show that there exists a positive constant D such that for any $j,k\in d$, $j\neq k$, $\max\big\{\big\|\boldsymbol{\Sigma}^{jk}\big\|_\infty, \big\|\mathbf{H}^{jk}\big\|_\infty, \big\|\boldsymbol{\Theta}^{jk}\big\|_\infty\big\} \leq D$. The reason is as follows.

Note that Hölder's inequality imply

$$\big\|\mathbf{H}^{jk}\big\|_\infty \lesssim \max_{j\in[d]}\mathbb{E}|X_{ij}-X_{i'j}|^4 \lesssim \max_{j\in[d]}\mathbb{E}|X_j|^4 \;\text{ for any } j,k\in[d], j\neq k.$$

Similarly, for $\mathbf{\Theta}^{jk}$, we also have $\big\|\mathbf{\Theta}^{jk}\big\|_\infty \lesssim \max_{j\in[d]} \mathbb{E}|X_j|^4$. By (14) we have

$$\mathbb{E}|X_j|^4 = \int_0^\infty \mathbb{P}(|X_4|^4 > t)dt \le \int_0^\infty c\exp(-t^{1/4})dt = 24c, \quad c = 2\exp(\kappa_m + \kappa_h/2).$$

Moreover, note that by the law of total variance, the diagonal elements of $\mathbf{\Sigma}^{jk}$ are no larger than the corresponding diagonal elements of $\mathbf{\Theta}^{jk}$; then by Cauchy-Schwarz inequality, $\|\mathbf{\Sigma}^{jk}\|_\infty \le \|\mathbf{\Theta}^{jk}\|_\infty$. Therefore there exists a constant D that does not depend on (s^*, n, d) such that

$$\max\big\{\|\mathbf{H}^{jk}\|_\infty, \|\mathbf{\Sigma}^{jk}\|_\infty, \|\mathbf{\Theta}^{jk}\|_\infty\big\} \le D, \quad 1 \le j < k \le d. \tag{84}$$

Now we are ready to prove the lemma. Recall that $\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ is a U-statistic with kernel function $\mathbf{h}^{jk}_{ii'}(\boldsymbol{\beta}_{j\vee k})$. Because $\mathbf{h}^{jk}_{ii'}\big(\boldsymbol{\beta}^*_{j\vee k}\big)$ is centered, the law of total expectation implies that $\mathbb{E}\big[\mathbf{g}_{jk}(\boldsymbol{X}_i)\big] = \mathbf{0}$. Note that the left-hand side of (40) can be written as

$$\begin{aligned}\frac{\sqrt{n}}{2}\mathbf{b}^T\nabla L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big) &= \frac{\sqrt{n}}{2}\mathbf{b}^T\mathbf{U}_{jk} + \frac{\sqrt{n}}{2}\mathbf{b}^T\big[\nabla L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big) - \mathbf{U}_{jk}\big] \\ &= \underbrace{\frac{1}{\sqrt{n}}\sum_{i=1}^n \mathbf{b}^T\mathbf{g}_{jk}(\boldsymbol{X}_i)}_{I_1} + \underbrace{\frac{\sqrt{n}}{2}\mathbf{b}^T\big[\nabla L_{jk}\big(\boldsymbol{\beta}^*_{j\vee k}\big) - \mathbf{U}_{jk}\big]}_{I_2}.\end{aligned}$$

Notice that I_1 is a weighted sum of i.i.d. random variables with the mean and variance given by

$$\mathbb{E}\big[\mathbf{b}^T\mathbf{g}_{jk}(\boldsymbol{X}_i)\big] = \mathbf{0} \quad \text{and} \quad \mathrm{Var}\big[\mathbf{b}^T\mathbf{g}_{jk}(\boldsymbol{X}_i)\big] = \mathbf{b}^T\mathbf{\Sigma}^{jk}\mathbf{b}.$$

Central limit theorem implies that $I_1 \rightsquigarrow N(0, \mathbf{b}^T\mathbf{\Sigma}^{jk}\mathbf{b})$. In what follows we use $\mathbf{h}_{ii'}$ and $\mathbf{h}_{ii'|i}$ to denote $\mathbf{h}^{jk}_{ii'}\big(\boldsymbol{\beta}^*_{j\vee k}\big)$ and $\mathbb{E}\big[\mathbf{h}^{jk}_{ii'}\big(\boldsymbol{\beta}^*_{j\vee k}\big)\big|\boldsymbol{X}_i\big] = \mathbf{g}_{jk}(\boldsymbol{X}_i)$. Thus we can write I_2 as

$$I_2 = \frac{1}{\sqrt{n}(n-1)}\sum_{i<i'}\mathbf{b}^T\boldsymbol{\chi}_{ii'}, \quad \text{where } \boldsymbol{\chi}_{ii'} = (\mathbf{h}_{ii'} - \mathbf{h}_{ii'|i} - \mathbf{h}_{ii'|i'}).$$

Then $\mathbb{E}(I_2^2)$ can be expanded as

$$\mathbb{E}(I_2^2) = \frac{1}{n(n-1)^2}\sum_{i<i',s<s'}\mathbf{b}^T\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ss'}^T)\mathbf{b}. \tag{85}$$

By the definition of $\boldsymbol{\chi}_{ii'}$, we have

$$\begin{aligned}&\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ss'}^T) = \mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ss'}^T) - \mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ss'|s}^T) - \mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ss'|s'}^T) - \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ss'}^T) \\ &+ \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ss'|s}^T) + \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ss'|s'}^T) - \mathbb{E}(\mathbf{h}_{ii'|i'}\mathbf{h}_{ss'}^T) + \mathbb{E}(\mathbf{h}_{ii'|i'}\mathbf{h}_{ss'|s}^T) + \mathbb{E}(\mathbf{h}_{ii'|i'}\mathbf{h}_{ss'|s'}^T).\end{aligned} \tag{86}$$

Therefore, for $i \ne s, s'$ and $i' \ne s, s'$, law of total expectation implies that $\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ss'}^T) = \mathbf{0}$. Similarly, if exactly one of i, i' is identical to one of s, s', say $i = s$, then (86) becomes

$$\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ii''}^T) = \mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ii''}^T) - \mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ii''|i}^T) - \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ii''}^T) + \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ii''|i}^T), \ i \ne i' \ne i''.$$

Note that by the law of total expectation, for each term in (86) we have

$$\mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ii''}^T) = \mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ii''|i}^T) = \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ii''}^T) = \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ii''|i}^T).$$

Therefore, $\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ii''}^T) = \mathbf{0}$. Finally, if $i = s$ and $i' = s'$, by the law of total expectation, (86) can be further reduced to $\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ii'}^T) = \mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ii'}^T) - \mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ii'|i}^T) - \mathbb{E}(\mathbf{h}_{ii'|i'}\mathbf{h}_{ii'|i'}^T) = \mathbf{\Theta}^{jk} - 2\mathbf{\Sigma}^{jk}$. Thus by triangle inequality we have

$$\big\|\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ii'}^T)\big\|_\infty \le \big\|\mathbb{E}(\mathbf{h}_{ii'}\mathbf{h}_{ii'}^T)\big\|_\infty + \big\|\mathbb{E}(\mathbf{h}_{ii'|i}\mathbf{h}_{ii'|i}^T)\big\|_\infty + \big\|\mathbb{E}(\mathbf{h}_{ii'|j}\mathbf{h}_{ii'|j}^T)\big\|_\infty \le 3D,$$

where the last inequality follows from Assumption 6. Then equation (85) can be reduced to

$$\mathbb{E}(I_2^2) = \frac{1}{n(n-1)^2}\sum_{i<i',s<s'}\mathbf{b}^T\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ss}^T)\mathbf{b} = \frac{1}{n(n-1)^2}\sum_{i<i'}\mathbf{b}^T\mathbb{E}\big(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ii'}^T\big)\mathbf{b}.$$

By Hölder's inequality we obtain

$$\begin{aligned}\mathbb{E}(I_2^2) &\le \frac{1}{2(n-1)}\|\mathbf{b}\|_1\big\|\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ii'}^T)\mathbf{b}\big\|_\infty \\ &\le \frac{1}{2(n-1)}\|\mathbf{b}\|_1^2\big\|\mathbb{E}(\boldsymbol{\chi}_{ii'}\boldsymbol{\chi}_{ii'}^T)\big\|_\infty \le \frac{3D}{2(n-1)}\|\mathbf{b}\|_1^2.\end{aligned} \tag{87}$$

Since $\|\mathbf{b}\|_0 \le \widetilde{s}$, by the relationship between ℓ_1-norm and ℓ_2-norm, we can further bound the right-hand side of (87) by $\mathbb{E}(I_2^2) \le 1.5\widetilde{s}D/(n-1) \to 0$, where we use the condition that $\lim_{n\to\infty}\widetilde{s}/n = 0$. Therefore, we conclude the proof of Lemma 14. ■

D.2. Proof of Lemma 13

Proof By the definition of $\mathbf{w}^*_{j,k}$ we have $\mathbf{H}^j_{jk,j\backslash k} = \mathbf{w}^{*T}_{j,k}\mathbf{H}^j_{j\backslash k,j\backslash k}$. We let $\widehat{\boldsymbol{\beta}}'_j = (0, \widehat{\boldsymbol{\beta}}_{j\backslash k})$ and denote $\nabla^2 L_j(\widehat{\boldsymbol{\beta}}'_j)$ and $\nabla^2 L_j(\boldsymbol{\beta}^*_j)$ as $\mathbf{\Lambda}$ and $\mathbf{\Lambda}^*$ respectively. In addition, we write $\mathbf{H}^j, \mathbf{w}^*_{j,k}$ and $\widehat{\mathbf{w}}_{j,k}$ as $\mathbf{H}, \mathbf{w}^*$ and $\widehat{\mathbf{w}}$ respectively for notational simplicity. Triangle inequality implies that

$$\|\mathbf{\Lambda}_{jk,j\backslash k} - \mathbf{w}^{*T}\mathbf{\Lambda}_{j\backslash k,j\backslash k}\|_\infty \le \|\mathbf{H}_{jk,j\backslash k} - \mathbf{\Lambda}_{jk,j\backslash k}\|_\infty + \|\mathbf{w}^{*T}(\mathbf{H}_{j\backslash k,j\backslash k} - \mathbf{\Lambda}_{j\backslash k,j\backslash k})\|_\infty.$$

Hölder's inequality implies that

$$\|\mathbf{\Lambda}_{jk,j\backslash k} - \mathbf{w}^{*T}\mathbf{\Lambda}_{j\backslash k,j\backslash k}\|_\infty \le \|\mathbf{\Lambda} - \mathbf{H}\|_\infty(1 + \|\mathbf{w}^*\|_1). \tag{88}$$

Under null hypothesis, $\beta^*_{jk} = 0$. By Lemma 26, we have $\|\mathbf{\Lambda} - \mathbf{H}\|_\infty \lesssim s^*\lambda\log^2 d$. Then the right-hand side of (88) is bounded by

$$\|\mathbf{\Lambda}_{jk,j\backslash k} - \mathbf{w}^{*T}\mathbf{\Lambda}_{j\backslash k,j\backslash k}\|_\infty \lesssim (w_0 + 1)s^*\lambda\log^2 d.$$

Therefore, by the assumption that $\lambda_D \gtrsim \max\{1, w_0\}s^*\lambda\log^2 d$ we can ensure that $\mathbf{w}^*$ is in the feasible region of the Dantzig selector problem (11), hence we have $\|\widehat{\mathbf{w}}\|_1 \le \|\mathbf{w}^*\|_1 \le w_0$

by the optimality of $\widehat{\mathbf{w}}$. Let J be the support set of $\mathbf{w}^*$, that is, $J := \{(j,\ell)\colon [\mathbf{w}^*_{j,k}]_{j\ell} \neq 0, \ell \in [d], \ell \neq j\}$; the optimality of $\mathbf{w}^*$ is equivalent to $\|\widehat{\mathbf{w}}_{J^c}\|_1 + \|\widehat{\mathbf{w}}_J\|_1 \leq \|\mathbf{w}^*_J\|_1$. By triangle inequality, we have

$$\|\widehat{\mathbf{w}}_{J^c} - \mathbf{w}^*_{J^c}\|_1 = \|\widehat{\mathbf{w}}_{J^c}\|_1 \leq \|\mathbf{w}^*_J\|_1 - \|\widehat{\mathbf{w}}_J\|_1 \leq \|\widehat{\mathbf{w}}_J - \mathbf{w}^*_J\|_1, \tag{89}$$

where $J^c := \{(j,\ell)\colon (j,\ell) \notin J, j \text{ fixed}\}$. Letting $\widehat{\boldsymbol{\omega}} = \widehat{\mathbf{w}} - \mathbf{w}^*$, inequality (89) is equivalent to $\|\widehat{\boldsymbol{\omega}}_{J^c}\|_1 \leq \|\widehat{\boldsymbol{\omega}}_J\|_1$. Moreover, triangle inequality yields that

$$\|\boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\widehat{\boldsymbol{\omega}}\|_\infty \leq \|\boldsymbol{\Lambda}_{jk,j\setminus k} - \boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\widehat{\mathbf{w}}\|_\infty + \|\boldsymbol{\Lambda}_{jk,j\setminus k} - \boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\mathbf{w}^*\|_\infty \leq 2\lambda_D,$$

where the last inequality follows from that both $\mathbf{w}^*$ and $\widehat{\mathbf{w}}$ are feasible for the Dantzig selector problem (11). Then triangle inequality implies that

$$|\widehat{\boldsymbol{\omega}}^T \boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\widehat{\boldsymbol{\omega}}| \leq \underbrace{|\widehat{\boldsymbol{\omega}}_J^T \boldsymbol{\Lambda}_{J, j\setminus k}\widehat{\boldsymbol{\omega}}|}_{A_1} + \underbrace{|\boldsymbol{\omega}_{J^c}^T \boldsymbol{\Lambda}_{J^c, j\setminus k}\widehat{\boldsymbol{\omega}}|}_{A_2}.$$

By Hölder's inequality and inequality between ℓ_1-norm and ℓ_2-norms, we obtain that

$$A_1 \leq 2\lambda_D \|\widehat{\boldsymbol{\omega}}_J\|_1 \leq 2\sqrt{s_0^\star}\lambda_D \|\widehat{\boldsymbol{\omega}}_J\|_2 \quad \text{and} \quad A_2 \leq 2\lambda_D \|\widehat{\boldsymbol{\omega}}_{J^c}\|_1 \leq 2\lambda_D \|\widehat{\boldsymbol{\omega}}_J\|_1 \leq 2\sqrt{s_0^\star}\lambda_D \|\widehat{\boldsymbol{\omega}}_J\|_2.$$

Hence we conclude that $|\widehat{\boldsymbol{\omega}}^T \boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\widehat{\boldsymbol{\omega}}| \leq 4\sqrt{s_0^\star}\lambda_D \|\widehat{\boldsymbol{\omega}}_J\|_2$.

We let J_1 be the set of indices of the largest $k_0^\star$ component of $\widehat{\boldsymbol{\omega}}_{J^c}$ in absolute value and let $I = J_1 \cup J$, then $|I| \leq s_0^\star + k_0^\star$. Under the null hypothesis, $\|\widehat{\boldsymbol{\beta}}'_j - \boldsymbol{\beta}^*_j\|_1 = \|\widehat{\boldsymbol{\beta}}_{j\setminus k} - \boldsymbol{\beta}^*_{j\setminus k}\|_1 \leq 33\rho_*^{-1}s^*\lambda$. We denote the s-sparse eigenvalue of $\nabla^2_{j\setminus k, j\setminus k}L_j(\boldsymbol{\beta}_j)$ over the ℓ_1-ball centered at $\boldsymbol{\beta}^*_j$ with radius r as $\rho'_{j+}(s)$ and $\rho'_{j-}(s)$ respectively and denote the corresponding restricted correlation coefficients as $\pi'_j(s_1, s_2)$. And we denote these quantities of $\nabla^2 L_j(\boldsymbol{\beta}^*_j)$ as $\rho_{j-}(s), \rho_{j+}(s)$ and $\pi_j(s_1, s_2)$. By definition, we immediately have $\rho_{j-}(s) \leq \rho'_{j-}(s) \leq \rho'_{j+}(s) \leq \rho_{j+}(s)$.

By Lemma 22 we have

$$|\widehat{\boldsymbol{\omega}}^T \boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\widehat{\boldsymbol{\omega}}| \geq \rho'_{j-}\big(k^\star + s^\star\big)\big[\|\widehat{\boldsymbol{\omega}}_I\|_2 - 2\pi'_j(s^\star + k_0^\star, s_0^\star)\|\widehat{\boldsymbol{\omega}}_{J^c}\|_1 / k^\star\big]\|\widehat{\boldsymbol{\omega}}_I\|_2. \tag{90}$$

The following lemma relates the sparse eigenvalues of $\nabla^2 L_j(\boldsymbol{\beta}_j)$ to those of $\mathbb{E}\nabla^2 L_j(\boldsymbol{\beta}^*_j)$.

Lemma 24 *Under Assumptions 2, 4 and 7, if n is sufficiently large such that $\rho_* \gtrsim s^*\lambda \log^2 d$, with probability at least $1-(2d)^{-1}$, for all $j \in [d]$, there exists a constant $C_\rho \geq 33\rho_*^{-1}$ such that*

$$\rho^*_{j-}(2s_0^\star + 2k_0^\star) - 0.05\nu_* \leq \rho_{j-}(2s_0^\star + 2k_0^\star) < \rho_{j+}(k_0^\star) \leq \rho^*_{j+}(k_0^\star) + 0.05\nu_*, \quad \text{and}$$
$$\rho_{j+}(k_0^\star)/\rho_{j-}(2s_0^\star + 2k_0^\star) \leq 1 + 0.58k_0^\star/s_0^\star,$$

where we denote the local sparse eigenvalues $\rho_-\big(\nabla^2 L_j, \boldsymbol{\beta}^*_j; s, r\big)$ and $\rho_+\big(\nabla^2 L_j, \boldsymbol{\beta}^*_j; s, r\big)$ with $r = C_\rho\sqrt{\log d/n}$ as $\rho_{j-}(s)$ and $\rho_{j+}(s)$, respectively.

Proof The proof is similar to that of Lemma 3, hence is omitted here. ■

By $\|\widehat{\boldsymbol{\omega}}_{J^c}\|_1 \leq \|\widehat{\boldsymbol{\omega}}_J\|_1 \leq \sqrt{s_0^\star}\|\widehat{\boldsymbol{\omega}}_J\|_2$ and Lemma 24, the right-hand side of (90) can be reduced to

$$|\widehat{\boldsymbol{\omega}}^T \boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\widehat{\boldsymbol{\omega}}| \geq 0.95\nu_*\big(\|\widehat{\boldsymbol{\omega}}_I\|_2 - 2\pi'_j(s_0^\star + k_0^\star, s^\star)\|\widehat{\boldsymbol{\omega}}_J\|_2\sqrt{s_0^\star/k_0^\star})\|\widehat{\boldsymbol{\omega}}_I\|_2. \tag{91}$$

Using Lemma 20 we obtain

$$\begin{aligned} 2\pi'_j(s_0^\star + k_0^\star, k_0^\star)\sqrt{s_0^\star/k_0^\star} &\leq \sqrt{s_0^\star/k_0^\star}\sqrt{\rho'_{j+}(k_0^\star)/\rho'_{j-}(s_0^\star + 2k_0^\star) - 1} \\ &\leq \sqrt{s_0^\star/k_0^\star}\sqrt{\rho_{j+}(k_0^\star)/\rho_{j-}(s_0^\star + 2k_0^\star) - 1} \leq \sqrt{s_0^\star/k_0^\star}\sqrt{0.58k_0^\star/s_0^\star} \leq 0.76. \end{aligned}$$

Thus the right-hand side of (91) can be reduced to

$$|\widehat{\boldsymbol{\omega}}^T \boldsymbol{\Lambda}_{j\setminus k, j\setminus k}\widehat{\boldsymbol{\omega}}| \geq 0.95\nu_*(1 - 0.76\|\widehat{\boldsymbol{\omega}}_J\|_2/\|\widehat{\boldsymbol{\omega}}_I\|_2)\|\widehat{\boldsymbol{\omega}}_I\|_2^2 \geq \nu_*\kappa\|\widehat{\boldsymbol{\omega}}_I\|_2^2, \tag{92}$$

where $\kappa = 0.22$. This inequality holds because $J \subset I$. By (92) we have

$$\nu_*\kappa\|\widehat{\boldsymbol{\omega}}_I\|_2^2 \leq 4\sqrt{s_0^\star}\lambda_d\|\widehat{\boldsymbol{\omega}}_J\|_2 \leq 4\sqrt{s_0^\star}\lambda_d\|\widehat{\boldsymbol{\omega}}_I\|_2, \quad \text{which implies } \|\widehat{\boldsymbol{\omega}}_I\|_2 \leq 4\nu_*^{-1}\kappa^{-1}\sqrt{s_0^\star}\lambda_D.$$

Therefore the estimation error of $\widehat{\mathbf{w}}_{j,k}$ can be bounded by

$$\|\widehat{\boldsymbol{\omega}}\|_1 \leq 2\|\widehat{\boldsymbol{\omega}}_J\|_1 \leq 2\sqrt{s^\star}\|\widehat{\boldsymbol{\omega}}_J\|_2 \leq 8\nu_*^{-1}\kappa^{-1}s_0^\star\lambda_D \leq 37\nu_*^{-1}s_0^\star\lambda_D.$$

Returning to the original notations, we conclude that $\|\widehat{\mathbf{w}}_{j,k} - \mathbf{w}^*_{j,k}\|_1 \leq 37\nu_*^{-1}s_0^\star\lambda_D$ for all (j,k) such that $j, k \in [d]$, $j \neq k$. ■

D.3. Proof of Lemma 15

Proof We only need to show that $\widehat{\sigma}^2_{jk}$ is a consistent estimator of σ^2_{jk}, which is equivalent to showing that $\lim_{n\to\infty}|\widehat{\sigma}^2_{jk} - \sigma^2_{jk}| = 0$. To begin with, triangle inequality implies that

$$\begin{aligned} |\widehat{\sigma}^2_{jk} - \sigma^2_{jk}| \leq{}& \underbrace{\big|\widehat{\boldsymbol{\Sigma}}^{jk}_{jk,jk} - \boldsymbol{\Sigma}^{jk}_{jk,jk}\big|}_{I_1} + 2\underbrace{\big|\widehat{\mathbf{w}}^T_{j,k}\widehat{\boldsymbol{\Sigma}}^{jk}_{j\setminus k,jk} - \mathbf{w}^{*T}_{j,k}\boldsymbol{\Sigma}^{jk}_{j\setminus k,jk}\big|}_{I_{2j}} + \underbrace{\big|\widehat{\mathbf{w}}^T_{j,k}\widehat{\boldsymbol{\Sigma}}^{jk}_{j\setminus k,j\setminus k}\widehat{\mathbf{w}}_{j,k} - \mathbf{w}^{*T}_{j,k}\boldsymbol{\Sigma}^{jk}_{j\setminus k,j\setminus k}\mathbf{w}^*_{j,k}\big|}_{I_{3j}} \\ &+ 2\underbrace{\big|\widehat{\mathbf{w}}^T_{k,j}\widehat{\boldsymbol{\Sigma}}^{jk}_{k\setminus j,jk} - \mathbf{w}^{*T}_{k,j}\boldsymbol{\Sigma}^{jk}_{k\setminus j,jk}\big|}_{I_{2k}} + \underbrace{\big|\widehat{\mathbf{w}}^T_{k,j}\widehat{\boldsymbol{\Sigma}}^{jk}_{k\setminus j,k\setminus j}\widehat{\mathbf{w}}_{k,j} - \mathbf{w}^{*T}_{k,j}\boldsymbol{\Sigma}^{jk}_{k\setminus j,k\setminus j}\mathbf{w}^*_{k,j}\big|}_{I_{3k}}, \end{aligned}$$

where $\widehat{\boldsymbol{\Sigma}}^{jk} = \widehat{\boldsymbol{\Sigma}}^{jk}\big(\widehat{\boldsymbol{\beta}}'_{j\vee k}\big)$ and $\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ is defined as

$$\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}_{j\vee k}) = \frac{1}{n}\sum_{i=1}^n \Big\{\frac{1}{n-1}\sum_{i'\neq i}\mathbf{h}^{jk}_{ii'}(\boldsymbol{\beta}_{j\vee k})\Big\}^{\otimes 2}. \tag{93}$$

To prove the consistency of $\widehat{\sigma}^2_{jk}$, we need the following theorem to show that $\widehat{\boldsymbol{\Sigma}}^{jk}$ is a consistent estimator of $\boldsymbol{\Sigma}^{jk}$ in the sense that $\big\|\widehat{\boldsymbol{\Sigma}}^{jk} - \boldsymbol{\Sigma}^{jk}\big\|_\infty$ is negligible.

Lemma 25 *For $1\leq j<k\leq d$, let $\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ be defined as (93). Suppose $\widehat{\boldsymbol{\beta}}_j$ and $\widehat{\boldsymbol{\beta}}_k$ are the estimators of $\boldsymbol{\beta}_j^*$ and $\boldsymbol{\beta}_k^*$ obtained from Algorithm 1 and we denote $\widehat{\boldsymbol{\beta}}_{j\vee k}=(\widehat{\beta}_{jk},\widehat{\boldsymbol{\beta}}_{j\setminus k}^T,\widehat{\boldsymbol{\beta}}_{k\setminus j}^T)^T$. Then $\widehat{\boldsymbol{\Sigma}}^{jk}(\widehat{\boldsymbol{\beta}}_{j\vee k})$ is a consistent estimator of $\boldsymbol{\Sigma}^{jk}$. There exists a constant C_Σ that does not depend on (j,k) such that, with probability tending to one,*

$$\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\widehat{\boldsymbol{\beta}}_{j\vee k})-\boldsymbol{\Sigma}^{jk}\big\|_\infty\leq C_\Sigma s^*\lambda\log^2 d\quad \textit{for } 1\leq j<k\leq d.$$

Proof See §E.2.1 for a detailed proof. ∎

In the rest of the proof, we will omit the superscripts in both $\widehat{\boldsymbol{\Sigma}}^{jk}$ and $\boldsymbol{\Sigma}^{jk}$ for notational simplicity. By Lemma 25,

$$I_1\leq\|\widehat{\boldsymbol{\Sigma}}-\boldsymbol{\Sigma}\|_\infty\leq\mathcal{O}_{\mathbb{P}}\big(s^*\lambda\log^2 d\big).\tag{94}$$

By triangle inequality, we have the following inequality for I_2 :

$$I_{2j}\leq\underbrace{\big|(\widehat{\mathbf{w}}_{j,k}-\mathbf{w}_{j,k}^*)^T\big(\widehat{\boldsymbol{\Sigma}}_{j\setminus k,jk}-\boldsymbol{\Sigma}_{j\setminus k,jk}\big)\big|}_{I_{21}}+\underbrace{\big|(\widehat{\mathbf{w}}_{j,k}-\mathbf{w}_{j,k}^*)^T\boldsymbol{\Sigma}_{j\setminus k,jk}\big|}_{I_{22}}+\underbrace{\big|\mathbf{w}_{j,k}^{*T}\big(\widehat{\boldsymbol{\Sigma}}_{j\setminus k,jk}-\boldsymbol{\Sigma}_{j\setminus k,jk}\big)\big|}_{I_{23}}.$$

By Hölder's inequality, Lemma 25 and the estimation error of $\widehat{\mathbf{w}}_{j,k}$, we obtain an upper-bound for I_{21} as follows:

$$I_{21}\leq\|\widehat{\mathbf{w}}_{j,k}-\mathbf{w}_{j,k}^*\|_1\|\widehat{\boldsymbol{\Sigma}}-\boldsymbol{\Sigma}\|_\infty=\mathcal{O}_{\mathbb{P}}\big(s^*s_0^\star\lambda_D\lambda\log^2 d\big).\tag{95}$$

Similarly, for I_{22}, Hölder's inequality implies that

$$I_{22}\leq\|\widehat{\mathbf{w}}_{j,k}-\mathbf{w}_{j,k}^*\|_1\|\boldsymbol{\Sigma}\|_\infty=\mathcal{O}_{\mathbb{P}}\big(s_0^\star\lambda_D D\big),\tag{96}$$

where the constant D appears in (84). For I_{23}, by Hölder's inequality and 25 we obtain

$$I_{23}\leq\|\mathbf{w}_{j,k}^*\|_1\|\widehat{\boldsymbol{\Sigma}}-\boldsymbol{\Sigma}\|_\infty=\mathcal{O}_{\mathbb{P}}\big(w_0s^*\lambda\log^2 d\big).\tag{97}$$

Combining (95), (96) and (97) we have

$$I_{2j}\lesssim(w_0+s_0^\star\lambda_D)s^*\lambda\log^2 d+s_0^\star\lambda_D.\tag{98}$$

For I_{3j}, by triangle inequality we have

$$I_{3j}\leq\underbrace{\big|\widehat{\mathbf{w}}_{j,k}^T\big(\widehat{\boldsymbol{\Sigma}}_{j\setminus k,j\setminus k}-\boldsymbol{\Sigma}_{j\setminus k,j\setminus k}\big)\widehat{\mathbf{w}}_{j,k}\big|}_{I_{31}}+\underbrace{\big|\widehat{\mathbf{w}}_{j,k}^T\boldsymbol{\Sigma}_{j\setminus k,j\setminus k}\widehat{\mathbf{w}}_{j,k}-\mathbf{w}_{j,k}^{*T}\boldsymbol{\Sigma}_{j\setminus k,j\setminus k}\mathbf{w}_{j,k}^*\big|}_{I_{32}}.$$

For term I_{31}, Hölder's inequality and the optimality of $\widehat{\mathbf{w}}$ implies that

$$I_{31}\leq\|\widehat{\mathbf{w}}_{j,k}\|_1^2\|\widehat{\boldsymbol{\Sigma}}_{j\setminus k,j\setminus k}-\boldsymbol{\Sigma}_{j\setminus k,j\setminus k}\|_\infty\leq C_\Sigma w_0^2s^*\lambda\log^2 d.\tag{99}$$

For term I_{32}, Lemma 17 implies that

$$\begin{aligned}I_{32}&\leq\|\boldsymbol{\Sigma}_{j\setminus k,j\setminus k}\|_\infty\|\widehat{\mathbf{w}}_{j,k}-\mathbf{w}_{j,k}^*\|_1^2+\|\boldsymbol{\Sigma}_{j\setminus k,j\setminus k}\mathbf{w}_{j,k}^*\|_\infty\|\widehat{\mathbf{w}}_{j,k}-\mathbf{w}_{j,k}^*\|_1\\&\leq\big(D\omega_0s_0^\star\lambda_D+Ds_0^{\star2}\lambda_D^2\big),\end{aligned}\tag{100}$$

where we use Hölder's inequality $\|\boldsymbol{\Sigma}_{j\setminus k,j\setminus k}\mathbf{w}_{j,k}^*\|_\infty\leq\|\mathbf{w}_{j,k}^*\|_1\|\boldsymbol{\Sigma}\|_\infty\leq Dw_0$. By (99), (100) and $\lambda_D\gtrsim w_0s^*\lambda\log^2 d$, we obtain

$$I_{3j}\lesssim w_0^2s^*\lambda\log^2 d+\big(D\omega_0s_0^\star\lambda_D+Ds_0^{\star2}\lambda_D^2\big).\tag{101}$$

Therefore combining (94), (98) and (101) we obtain $I_1+I_{2j}+I_{3j}=o_{\mathbb{P}}(1)$. We can show similarly that $I_{2k}+I_{3k}=o_{\mathbb{P}}(1)$. Thus $\lim_{n\to\infty}\max_{j<k}\big|\widehat{\sigma}_{jk}^2-\sigma_{jk}^2\big|=0$ with probability converging to one. ∎

Appendix E. Proof of Technical Lemmas

Finally, we prove the technical lemmas in this appendix. Specifically, we prove the lemmas introduced to derive the auxiliary results.

E.1. Proof of Technical Lemmas in §C

In this subsection we prove the technical lemmas we use to prove the auxiliary results of estimation. These lemmas are standard for high-dimensional linear regression, but proving them for our logistic-type loss function needs nontrivial extensions.

E.1.1. Proof of Lemma 20

Proof Let I and J be two index sets with $I\cap J=\emptyset,|I|\leq s,|J|\leq k$, for any $\mathbf{u}\in\mathbb{R}^d$ with $\|\mathbf{u}-\mathbf{u}_0\|_2\leq r$ and any $\mathbf{v},\mathbf{w}\in\mathbb{R}^d$, let $\boldsymbol{\theta}=\mathbf{v}_I+\alpha\mathbf{w}_J$ with some $\alpha\in\mathbb{R}$, then by definition, $\|\boldsymbol{\theta}\|_0\leq s+k$. For notational simplicity, we denote s-sparse eigenvalues $\rho_+\big(\mathbf{M},\mathbf{u}_0;s,r\big)$ and $\rho_-\big(\mathbf{M},\mathbf{u}_0;s,r\big)$ as $\rho_-(s)$ and $\rho_+(s)$ respectively. By definition, we have

$$\rho_-(s+k)\|\boldsymbol{\theta}\|_2^2\leq\boldsymbol{\theta}^T\mathbf{M}(\mathbf{u})\boldsymbol{\theta}=\underbrace{\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I}_{A1}+2\alpha\underbrace{\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{w}_J}_{A2}+\alpha^2\underbrace{\mathbf{w}_J^T\mathbf{M}(\mathbf{u})\mathbf{w}_J}_{A3}.\tag{102}$$

Since $\|\boldsymbol{\theta}\|_2^2=\|\mathbf{v}_I\|_2^2+\alpha^2\|\mathbf{w}_J\|_2^2$. Rearranging the terms in (102) we have

$$\big[A_3-\rho_-(s+k)\|\mathbf{w}_J\|_2^2\big]\alpha^2+2A_2\alpha+\big[A_1-\rho_-(s+k)\|\mathbf{v}_I\|_2^2\big]\geq0\quad\text{for all }\alpha\in\mathbb{R}.\tag{103}$$

Note that the left-hand side (103) is a univariate quadratic function in α, thus (103) implies that

$$\big[A_1-\rho_-(s+k)\|\mathbf{v}_I\|_2^2\big]\big[A_3-\rho_-(s+k)\|\mathbf{w}_J\|_2^2\big]\geq A_2^2.\tag{104}$$

Therefore by multiplying $4\|\mathbf{v}_I\|_2^\infty/(A_1^2\|\mathbf{w}_J\|_2^2)$ to both sides of (104) we have

$$\frac{4A_2^2\|\mathbf{v}_I\|_2^2}{A_1^2\|\mathbf{w}_J\|_2^2}\leq\frac{4\|\mathbf{v}_I\|_2^2}{A_1\|\mathbf{w}_J\|_2^2}\bigg[\frac{A_1-\rho_-(s+k)\|\mathbf{v}_I\|_2^2}{A_1}\bigg]\big[A_3-\rho_-(s+k)\|\mathbf{w}_J\|_2^2\big].\tag{105}$$

By the inequality of arithmetic and geometric means, we have

$$\frac{\rho_-(s+k)\|\mathbf{v}_I\|_2^2}{A_1}\bigg[\frac{A_1-\rho_-(s+k)\|\mathbf{v}_I\|_2^2}{A_1}\bigg]\leq\frac{1}{4}.$$

Then the right-hand side of (104) can be bounded by

$$\frac{4A_2^2\|\mathbf{v}_I\|_2^2}{A_1^2\|\mathbf{w}_J\|_2^2} \le \frac{A_3-\rho_-(s+k)\|\mathbf{w}_J\|_2^2}{\rho_-(s+k)\|\mathbf{w}_J\|_2^2} \le \frac{\rho_+(k)}{\rho_-(s+k)} - 1,$$

where the last inequality follows from $A_3 \le \rho_+(k)\|\mathbf{w}_J\|_2^2$. Note that by the relationship between ℓ_2- and ℓ_∞ norm, we have $\|\mathbf{w}_J\|_2 \le \sqrt{k}\|\mathbf{w}_J\|_\infty$, which further implies that

$$\frac{\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{w}_J\|\mathbf{v}_I\|_2}{\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\|\mathbf{w}_J\|_\infty} \le \frac{\sqrt{k}\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{w}_J\|\mathbf{v}_I\|_2}{\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\|\mathbf{w}_J\|_2} = \frac{\sqrt{k}A_2\|\mathbf{v}_I\|_2}{A_1\|\mathbf{w}_J\|_2} \le \frac{\sqrt{k}}{2}\sqrt{\rho_+(k)/\rho_-(s+k)-1}.$$

Taking supremum over $\mathbf{v}, \mathbf{w} \in \mathbb{R}^d$ finally yields Lemma 20. ■

E.1.2. Proof of lemma 21

Proof Under Assumption 4, for any $\boldsymbol{\beta}_j \in \mathbb{R}^{d-1}$ such that $\|\boldsymbol{\beta}_j - \boldsymbol{\beta}_j^*\|_2 \le r$ and any $\mathbf{v} \in \mathbb{R}^{d-1}$ with $\|\mathbf{v}\|_0 \le 2s^* + 2k^*$, we denote $\nabla^2 L_j(\boldsymbol{\beta}_j) - \nabla^2 L_j(\boldsymbol{\beta}_j^*)$ and $\nabla^2 L_j(\boldsymbol{\beta}_j) - \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]$ as $\boldsymbol{\Lambda}_1$ and $\boldsymbol{\Lambda}_2$ respectively. Our goal is to show that both $|\mathbf{v}^T\boldsymbol{\Lambda}_1\mathbf{v}|$ and $|\mathbf{v}^T\boldsymbol{\Lambda}_2\mathbf{v}|$ are negligible. Hölder's inequality implies that $\big|\mathbf{v}^T\boldsymbol{\Lambda}_2\mathbf{v}\big| \le \|\mathbf{v}\|_1\|\boldsymbol{\Lambda}_2\mathbf{v}\|_\infty \le \|\mathbf{v}\|_1^2\|\boldsymbol{\Lambda}_2\|_\infty$. We use the following lemma to control $|\mathbf{v}^\top\boldsymbol{\Lambda}_1\mathbf{v}|$ and $\|\boldsymbol{\Lambda}_2\|_\infty$.

Lemma 26 *We denote $s^* = \max_{j\in[d]}\|\boldsymbol{\beta}_j^*\|_0$. Let $r_1(s^*,n,d) > 0$ be a real number depending on s^*, n, and d that satisfy $\lim_{n\to\infty} r_1(s^*,n,d)\log^2 d = 0$. We define $\mathbb{B}_j(r_1) \coloneqq \big\{\boldsymbol{\beta}_j \in \mathbb{R}^{d-1}\colon \big\|\boldsymbol{\beta}_j - \boldsymbol{\beta}_j^*\big\|_1 \le r_1(s^*,n,d)\big\}$ as the ℓ_1-ball centered at $\boldsymbol{\beta}_j^*$ with radius $r_1(s^*,n,d)$. Under Assumptions 2 and 4, there exist absolute constants $C_h, C_r > 0$ such that, with probability at least $1-(2d)^{-1}$, for all $j \in [d]$, $\boldsymbol{\beta}_j \in \mathbb{B}_j(r_1)$ and $\mathbf{v} \in \mathbb{R}^d$, it holds that,*

$$\big\|\nabla^2 L_j(\boldsymbol{\beta}_j^*) - \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]\big\|_\infty \le C_h\sqrt{\log d/n}, \tag{106}$$

$$\big\|\nabla^2 L_j(\boldsymbol{\beta}_j) - \nabla^2 L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \le C_r r_1(s^*,n,d)\cdot\log^2 d, \tag{107}$$

$$\big|\mathbf{v}^T\big[\nabla^2 L_j(\boldsymbol{\beta}_j) - \nabla^2 L_j(\boldsymbol{\beta}_j^*)\mathbf{v}\big]\big| \le C_r r_1(s^*,n,d)\cdot\|\mathbf{v}\|_2^2. \tag{108}$$

Proof See §E.3 for a detailed proof. ■

Lemma 26 implies that $\|\boldsymbol{\Lambda}_2\|_\infty \le C_h\sqrt{\log d/n}$ with probability at least $1-(2d)^{-1}$. By the relation between ℓ_1- and ℓ_2-norms, we have

$$\big|\mathbf{v}^T\boldsymbol{\Lambda}_2\mathbf{v}\big| \le (2s^*+2k^*)\|\mathbf{v}\|_2^2\|\boldsymbol{\Lambda}\|_\infty \le (2s^*+2k^*)C_h\sqrt{\log d/n}.$$

Moreover, setting $r = C_\rho s^*\sqrt{\log d/n}$ with $C_\rho \ge 33\rho_*^{-1}$, we have

$$|\mathbf{v}^T\boldsymbol{\Lambda}_1\mathbf{v}| \le C_r C_\rho\|\mathbf{v}\|_1^2 \le C_r C_\rho(2s^*+2k^*)\sqrt{\log d/n}.$$

By Assumption 4, if n is large enough such that $(2s^*+2k^*)(C_rC_\rho+C_h)\sqrt{\log d/n}\big] \le 0.05\rho_*$, then we have

$$0.95\rho_* \le \rho_{j-}^*(2s^*+2k^*) - 0.05\rho_* \le \rho_{j-}(2s^*+2k^*) < \rho_{j+}(k^*) \le \rho_{j+}^*(k^*) + 0.05\rho_*,$$

where we denote the s-sparse eigenvalues $\rho_-\big(\nabla^2 L_j, \boldsymbol{\beta}_j^*; s, r\big)$ and $\rho_+\big(\nabla^2 L_j, \boldsymbol{\beta}_j^*; s, r\big)$ as $\rho_{j-}(s)$ and $\rho_{j+}(s)$ respectively. Under Assumption 4, $\rho_{j+}^*(k^*)/\rho_{j-}^*(2s^*+2k^*) \le 1 + 0.2k^*/s^*$ and $k^* \ge 2s^*$, simple computation yields that

$$\frac{\rho_{j+}(k^*)}{\rho_{j-}(2s^*+2k^*)} \le \frac{\rho_{j+}^*(k^*)+0.05\rho_*}{\rho_{j-}^*(2s^*+2k^*)-0.05\rho_*} \le \frac{\rho_{j+}^*(k^*)+0.05\rho_{j-}^*(2s^*+2k^*)}{0.95\rho_{j-}^*(2s^*+2k^*)} \le 1 + 0.27k^*/s^*.$$

Thus, we conclude the proof of Lemma 26. ■

E.1.3. Proof of Lemma 22

Proof For $\mathbf{v} = (v_1,\ldots,v_d)^T \in \mathbb{R}^d$, without loss of generality, we assume that $F^c = [s_1]$ where $s_1 = |F^c| \le s$. In addition, we assume that when $j > s_1$, v_j is arranged in descending order of $|v_j|$. That is, we rearrange the components of $\mathbf{v}$ such that $|v_j| \ge |v_{j+1}|$ for all $j \ge s_1$. Let $J_0 = [s_1]$ and $J_i = \{s_1+(i-1)k+1,\ldots,\min(s_1+ik,d)\}$. By definition, we have $J = J_1$ and $I = J_0 \cup J_1$. Moreover, we have $\|\mathbf{v}_{J_i}\|_\infty \le \|\mathbf{v}_{J_{i-1}}\|_1/k$ when $i \ge 2$ because by the definition of J_i, we have $\sum_{i\ge2}\|\mathbf{v}_{J_i}\|_\infty \le \|\mathbf{v}_F\|_1/k$. Note that by the definition of index sets I and J_i, $|J_i| \le k$ and $|I| = k+s_1 \le k+s$. We denote the restricted correlation coefficients $\pi(\mathbf{M},\mathbf{u}_0;s,k,r)$ as $\pi(s,k)$, then by the definition of $\pi(s+k,k)$ we have

$$\big|\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_{J_i}\big| \le \pi(s+k,k)\big[\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\big]\|\mathbf{v}_{J_i}\|_\infty/\|\mathbf{v}_I\|_2.$$

Thus we have the following upper bound for $\big|\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_{I^c}\big|$:

$$\begin{aligned}\big|\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_{I^c}\big| &\le \sum_{i\ge2}\big|\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_{J_i}\big| \le \pi(s+k,k)\|\mathbf{v}_I\|_2^{-1}\big[\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\big]\sum_{i\ge2}\|\mathbf{v}_{J_i}\|_\infty \\ &\le \pi(s+k,k)\|\mathbf{v}_I\|_2^{-1}\big[\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\big]\|\mathbf{v}_F\|_1/k. \end{aligned} \tag{109}$$

Because $\mathbf{v}^T\mathbf{M}(\mathbf{u})\mathbf{v} \ge \mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I + 2\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_{I^c}$, by (109) we have

$$\begin{aligned}\mathbf{v}^T\mathbf{M}(\mathbf{u})\mathbf{v} &\ge \mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I - 2\pi(s+k,k)\|\mathbf{v}_I\|_2^{-1}\big[\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\big]\|\mathbf{v}_F\|_1/k \\ &= \big[\mathbf{v}_I^T\mathbf{M}(\mathbf{u})\mathbf{v}_I\big]\big[1 - 2\pi(s+k,k)\|\mathbf{v}_I\|_2^{-1}\|\mathbf{v}_F\|_1/k\big].\end{aligned}$$

Thus we can bound the right-hand side of the last formula using the sparse eigenvalue condition

$$\mathbf{v}^T\mathbf{M}(\mathbf{u})\mathbf{v} \ge \rho_-(s+k)\big[1 - 2\pi(s+k,k)k^{-1}\|\mathbf{v}_I\|_2^{-1}\|\mathbf{v}_F\|_1\big]\|\mathbf{v}_I\|_2^2, \tag{110}$$

where we denote s-sparse eigenvalue $\rho_-(\mathbf{M},\mathbf{u}_0;s,r)$ as $\rho_-(s+k)$ for the simplicity of notations. Inequality (110) concludes the proof of Lemma 22. ■

E.1.4. Proof of Lemma 23

Proof Let $F(t) = L_j\big(\boldsymbol{\beta}(t)\big) - L_j(\boldsymbol{\beta}_1) - \big\langle\nabla L_j(\boldsymbol{\beta}_1), \boldsymbol{\beta}(t) - \boldsymbol{\beta}_1\big\rangle$. Since the derivative of $L_j\big(\boldsymbol{\beta}(t)\big)$ with respect to t is $\big\langle\nabla L_j\big(\boldsymbol{\beta}(t)\big), \boldsymbol{\beta}_2 - \boldsymbol{\beta}_1\big\rangle$, the derivative of F is given by

$$F'(t) = \big\langle\nabla L_j\big(\boldsymbol{\beta}(t)\big) - \nabla L_j(\boldsymbol{\beta}_1), \boldsymbol{\beta}_2 - \boldsymbol{\beta}_1\big\rangle.$$

Therefore the Bregman divergence $D_j\big(\boldsymbol{\beta}(t),\boldsymbol{\beta}_1\big)$ can be written as

$$D_j\big(\boldsymbol{\beta}(t),\boldsymbol{\beta}_1\big)=\big\langle\nabla L_j[\boldsymbol{\beta}(t)]-\nabla L_j(\boldsymbol{\beta}_1),t(\boldsymbol{\beta}_2-\boldsymbol{\beta}_1)\big\rangle=tF'(t).$$

By definition, it is easy to see that $F'(1)=D_j(\boldsymbol{\beta}_2,\boldsymbol{\beta}_1)$. To derive Lemma 23, it suffices to show that $F(t)$ is convex, which implies that $F'(t)$ is non-decreasing and $D_j\big(\boldsymbol{\beta}(t),\boldsymbol{\beta}_1\big)=tF'(t)\le tF'(1)=tD_j(\boldsymbol{\beta}_2,\boldsymbol{\beta}_1)$.

For $\forall t_1,t_2\in\mathbb{R}_+,t_1+t_2=1,x,y\in(0,1)$, by the linearity of $\boldsymbol{\beta}(t)$, $\boldsymbol{\beta}(t_1x+t_2y)=t_1\boldsymbol{\beta}(x)+t_2\boldsymbol{\beta}(y)$. Then we have

$$\big\langle\nabla L_j(\boldsymbol{\beta}_1),\boldsymbol{\beta}(t_1x+t_2y)-\boldsymbol{\beta}_1\big\rangle=t_1\big\langle\nabla L_j(\boldsymbol{\beta}_1),\boldsymbol{\beta}(x)-\boldsymbol{\beta}_1\big\rangle+t_2\big\langle\nabla L_j(\boldsymbol{\beta}_1),\boldsymbol{\beta}(y)-\boldsymbol{\beta}_1\big\rangle.\quad(111)$$

In addition, by convexity of function $L_j(\cdot)$, we obtain

$$L_j\big(\boldsymbol{\beta}(t_1x+t_2y)\big)\le t_1L_j\big(\boldsymbol{\beta}(x)\big)+t_2L_j\big(\boldsymbol{\beta}(y)\big).\quad(112)$$

Adding (111) and (112) we obtain

$$F\big(t_1x+t_2y\big)\le t_1F(x)+t_2F(y).$$

Therefore $F(t)$ is convex, thus we have $D_j(\boldsymbol{\beta}(t),\boldsymbol{\beta}_1)\le tD_j(\boldsymbol{\beta}_2,\boldsymbol{\beta}_1)$. ■

E.2. Proof of Technical Lemmas in §D

Now we prove the lemmas that supports the auxiliary inferential results. We first prove Lemma 25, which implies that the $\widehat{\sigma}_{jk}^2$ is a consistent estimator of the asymptotic variance of σ_{jk}.

E.2.1. Proof of lemma 25

Proof Recall that we denote $\boldsymbol{\beta}_{j\vee k}=(\beta_{jk},\boldsymbol{\beta}_{j\setminus k},\boldsymbol{\beta}_{k\setminus j})$ and $L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)=L_j(\boldsymbol{\beta}_j)+L_k(\boldsymbol{\beta}_k)$. We denote the kernel function of the second-order U-statistic $\nabla L_{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ as $\mathbf{h}_{ii'}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)$ where the subscripts i,i' indicate that $\mathbf{h}_{ii'}^{jk}(\cdot)$ depends on $\boldsymbol{X}_i$ and $\boldsymbol{X}_{i'}$. We define $\mathbf{V}_{ii'i''}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big):=\mathbf{h}_{ii'}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)\mathbf{h}_{ii'}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)^T$. Then by definition, $\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\setminus k}\big)$can be written as

$$\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)=\frac{1}{n(n-1)^2}\sum_{i=1}^{n}\sum_{i'\neq i,i''\neq i}\mathbf{V}_{ii'i''}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big).$$

Note that $\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)-\boldsymbol{\Sigma}^{jk}=\underbrace{\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\vee k}\big)-\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)}_{I_1}+\underbrace{\widehat{\boldsymbol{\Sigma}}^{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)-\boldsymbol{\Sigma}^{jk}}_{I_2}$.

We first consider I_2. For notational simplicity, we use $\mathbf{h}_{ii'}$ and $\mathbf{h}_{ii'|i}$ to denote $\mathbf{h}_{ij}^{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)$ and $\mathbf{h}_{ii'|i}^{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big):=\mathbb{E}\big[\mathbf{h}_{ij}^{jk}\big(\boldsymbol{\beta}_{j\vee k}^*\big)\big|\boldsymbol{X}_i\big]$ respectively. As shown in §D.1, for $i\neq i'\neq i''$,

$$\mathbb{E}\big(\mathbf{h}_{ii'}\mathbf{h}_{ii''}^T\big)=\mathbb{E}\big(\mathbf{h}_{ii'}\mathbf{h}_{ii''}^T\big|\boldsymbol{X}_i\big)=\mathbb{E}\big(\mathbf{h}_{ii'|i}\mathbf{h}_{ii''|i}^T\big)=\boldsymbol{\Sigma}^{jk}\ \text{ and }\ \mathbb{E}\big(\mathbf{h}_{ij}\mathbf{h}_{ij}^T\big)=\boldsymbol{\Theta}^{jk},$$

we can write I_2 as

$$I_2=\frac{n-2}{n-1}\underbrace{\left\{\binom{n}{3}^{-1}\sum_{i<i'<i''}\big[\mathbf{V}_{ii'i''}-\mathbb{E}(\mathbf{V}_{ii'i''})\big]\right\}}_{I_{21}}+\frac{1}{n-1}\underbrace{\left\{\binom{n}{2}^{-1}\sum_{i<i'}\big[\mathbf{V}_{ii'i'}-\mathbb{E}(\mathbf{V}_{ii'i'})\big]\right\}}_{I_{22}}+\frac{1}{n-1}\big(\boldsymbol{\Theta}^{jk}-\boldsymbol{\Sigma}^{jk}\big),$$

where we use $\mathbf{V}_{ii'i''}$ to denote $\mathbf{V}_{ii'i''}^{jk}(\boldsymbol{\beta}_{j\vee k}^*)$. Observing that I_{21} is a centered third order U-statistic, for x large enough such that $x^4\ge\big\|\mathbb{E}\big[\mathbf{V}_{ijk}(\boldsymbol{\beta}_{j\vee k}^*)\big]\big\|_\infty$ and for any $(a,b),(c,d)\in\big\{(p,q)\colon p,q\in\{j,k\}\big\}$ we have

$$\begin{aligned}\mathbb{P}\big(\big[\mathbf{V}_{ii'i''}^{jk}(\boldsymbol{\beta}_{j\vee k})\big]_{ab,cd}>2x^4\big)&\le\mathbb{P}\big[(X_{ia}-X_{i'a})(X_{ib}-X_{i'b})(X_{ic}-X_{i''c})(X_{id}-X_{i''d})>x^4\big]\\&\le 8\exp(2\kappa_m+\kappa_h)\exp(-x).\end{aligned}$$

Thus there exist constants c_1 and C_1 that does not depend on n or d or (j,k) such that for any $x\in\mathbb{R}$, any $i,i',i''\in[n]$ and any $j,k\in[d]$,

$$\mathbb{P}\big([\mathbf{V}_{ii'i''}^{jk}(\boldsymbol{\beta}_{j\vee k}^*)]_{ab,cd}>x\big)\le C_1\exp(c_1x^{1/4}).\quad(113)$$

This implies that there exists some generic constant C such that $\|\mathbf{V}_{ii'i''}^{jk}(\boldsymbol{\beta}_{j\vee k}^*)\|_\infty\le C\log^4 d$ for all $j,k\in[d]$ and $i,i'\in[n]$ with probability tending to one. Similar to the method we use in §E.3, we define $\mathcal{E}:=\big\{\|\mathbf{V}_{ii'i''}^{jk}(\boldsymbol{\beta}_{j\vee k}^*)\|_\infty\le C\log^4 d,\forall i,i',i''\in[n],j,k\in[d]\big\}$. By Bernstein's inequality for U-statistics (Lemma 19) with $b=C\log^4 d$ in (56), for some generic constants C, it holds with high probability that

$$\binom{n}{2}^{-1}\sum_{i<i'}\big[\mathbf{V}_{ii'i'}-\mathbb{E}(\mathbf{V}_{ii'i'}|\mathcal{E})\big]\le C\sqrt{\log d/n},\quad\forall j,k\in[d],i,i',i''\in[n].\quad(114)$$

Moreover, by (113), we have

$$\begin{aligned}&\mathbb{E}\big\{[\mathbf{V}_{ii'i'}(\boldsymbol{\beta}_{j\vee k}^*)]_{ab,cd}|\mathcal{E}\big\}-\mathbb{E}\big\{[V_{ii'i''}(\boldsymbol{\beta}_{j\vee k}^*)]_{ab,cd}\big\}\\&\le\int_{C\log^4 d}^{\infty}\mathbb{P}\big\{\big|[\mathbf{V}_{ii'i''}^{jk}(\boldsymbol{\beta}_{j\vee k}^*)]_{ab,cd}\big|>x\big\}\le c_1\log^3 d\cdot\exp(-c_2\log d)\end{aligned}\quad(115)$$

for some absolute constant c_1 and c_2. Since (115) holds uniformly, we have

$$\binom{n}{2}^{-1}\sum_{i<i'}\big[\mathbb{E}(\mathbf{V}_{ii'i'}|\mathcal{E})-\mathbb{E}(\mathbf{V}_{ii'i''})\big]\le\log^3 d\cdot\exp(-c_2\log d)\lesssim\sqrt{\log d/n}.\quad(116)$$

Combining (114) and (116) we obtain that

$$\|I_{21}\|_\infty=\mathcal{O}_{\mathbb{P}}\big(\sqrt{\log d/n}\big)\ \text{ uniformly for } 1\le j<k\le n.\quad(117)$$

For the second part I_{22}, noting that it is a U-statistic of order 2, because (113) also holds for $\mathbf{V}_{ii'i''}(\boldsymbol{\beta}_{j\vee k}^*)$, applying the same technique, we have $\|I_{21}\|_\infty=\mathcal{O}_{\mathbb{P}}\big(\sqrt{\log d/n}\big)$ uniformly

for $1 \le j < k \le n$. Combining with (117), we conclude that, for some absolute constant C, we have

$$\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k}) - \boldsymbol{\Sigma}^{jk}\big\|_\infty \le C\sqrt{\log d/n}, \quad \forall 1 \le j < k \le n. \tag{118}$$

Now we turn to I_1. For any $\boldsymbol{\beta}_j, \boldsymbol{\beta}_k \in \mathbb{R}^{d-1}$ such that $\|\boldsymbol{\beta}_j - \boldsymbol{\beta}^*_j\|_1 \le r(s^*, n, d)$ and $\|\boldsymbol{\beta}_k - \boldsymbol{\beta}^*_k\|_1 \le r(s^*, n, d)$, we denote $\omega^j_{ii'} := \exp\big[-(X_{ij} - X_{i'j})(\boldsymbol{\beta}_j - \boldsymbol{\beta}^*_j)^T(\boldsymbol{X}_{i\setminus j} - \boldsymbol{X}_{i'\setminus j})\big]$ and denote $\omega^k_{ii'}$ similarly. Recall that we denote $R^j_{ii'}(\boldsymbol{\beta}_j) = \exp\big[-(x_{ij} - x_{i'j})\boldsymbol{\beta}_j{}^T(\boldsymbol{x}_{i\setminus j} - \boldsymbol{x}_{i'\setminus j})\big]$. Hence by definition we have $R^j_{ii'}(\boldsymbol{\beta}_j) = \omega^j_{ii'}R^j_{ii'}(\boldsymbol{\beta}^*_j)$. As shown in §E.3, we have

$$\min\{1, \omega^j_{ii'}, \omega^k_{ii'}\}\mathbf{h}^{jk}_{ii'}(\boldsymbol{\beta}^*_{j\vee k}) \le \mathbf{h}^{jk}_{ii'}(\boldsymbol{\beta}_{j\vee k}) \le \max\{1, \omega^j_{ii'}, \omega^k_{ii'}\}\mathbf{h}^{jk}_{ii'}(\boldsymbol{\beta}^*_{j\vee k}), \tag{119}$$

where the inequality is taken elementwisely. We denote $b := \max_{i,i'\in[n];j\in[d]} r(s^*, n, d)\big\|(X_{ij} - X_{i'j})(\boldsymbol{X}_{i\setminus j} - \boldsymbol{X}_{i'\setminus j})\big\|_\infty$. Note that when $\|\boldsymbol{\beta}_j - \boldsymbol{\beta}^*_j\|_1 \le r(s^*, n, d)$ and $\|\boldsymbol{\beta}_k - \boldsymbol{\beta}^*_k\|_1 \le r(s^*, n, d)$, we have $\omega^j_{ii'}, \omega^k_{ii'} \in [\exp(-b), \exp(b)]$. Therefore by (119) and the definition of $V^{jk}_{ii'i''}(\boldsymbol{\beta}_{j\setminus k})$, we obtain the following elementwise inequality

$$\exp(-2b)\mathbf{V}^{jk}_{ii'i''}(\boldsymbol{\beta}^*_{j\setminus k}) \le \mathbf{V}^{jk}_{ii'i''}(\boldsymbol{\beta}_{j\setminus k}) \le \exp(2b)\mathbf{V}^{jk}_{ii'i''}(\boldsymbol{\beta}^*_{j\setminus k}),$$

which implies that

$$\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}_{j\vee k}) - \widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k})\big\|_\infty \le \max\big\{1 - \exp(-2b), \exp(2b) - 1\big\}\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k})\big\|_\infty. \tag{120}$$

As we show in §E.3, $b \le Cr(s^*, n, d)\log^2 d$ with high probability for some absolute constant $C > 0$. Since $\lim_{n\to\infty} r(s^*, n, d)\log^2 d = 0$, by (120) we have

$$\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}_{j\vee k}) - \widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k})\big\|_\infty \lesssim b\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k})\big\|_\infty\big\|_\infty \le b\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k}) - \boldsymbol{\Sigma}^{jk}\big\|_\infty + b\|\boldsymbol{\Sigma}^{jk}\|_\infty.$$

Note that we show $\|I_2\|_\infty = \big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k}) - \boldsymbol{\Sigma}^{jk}\big\|_\infty = \mathcal{O}_{\mathbb{P}}\big(\sqrt{\log d/n}\big)$, which converges to zero asymptotically. Thus we conclude that

$$\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}_{j\vee k}) - \widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}^*_{j\vee k})\big\|_\infty = \mathcal{O}_{\mathbb{P}}\big(r(s^*, n, d)\log^2 d\big). \tag{121}$$

Combining (118) and (121), we have the following error bound for $\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}_{j\vee k})$:

$$\big\|\widehat{\boldsymbol{\Sigma}}^{jk}(\boldsymbol{\beta}_{j\vee k}) - \boldsymbol{\Sigma}^{jk}\big\|_\infty = \mathcal{O}_{\mathbb{P}}\Big(r(s^*, n, d)\log^2 d + \sqrt{\log d/n}\Big) \quad \text{for all } (j, k). \tag{122}$$

Finally, by the fact that $\max_{j\in[d]}\|\widehat{\boldsymbol{\beta}}_j - \boldsymbol{\beta}^*_j\|_1 \lesssim s^*\lambda$, we conclude the proof of Lemma 25 by setting $r = Cs^*\lambda$. ∎

E.3. Proof of Lemma 26

Now we turn to the last unproven result, namely Lemma 26, which characterizes the perturbation of $\nabla^2 L_j(\boldsymbol{\beta}_j)$.

Proof Note that $\nabla^2 L_j(\boldsymbol{\beta}_j)$ is a second-order U-statistic. Hence $\nabla^2 L_j(\boldsymbol{\beta}_j) - \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]$ is a centered U-statistic. We denote its kernel as $\mathbf{T}_{ii'}(\boldsymbol{\beta}_j)$, then

$$\nabla^2 L_j(\boldsymbol{\beta}_j) - \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big] = \frac{2}{n(n-1)}\sum_{i<i'}\mathbf{T}_{ii'}(\boldsymbol{\beta}_j).$$

Note that $\big\|\mathbb{E}[\mathbf{T}_{ii'}(\boldsymbol{\beta}_j)]\big\|_\infty$ is bounded for all $\boldsymbol{\beta}_j \in \mathbb{R}^{d-1}$ because

$$\max_{\mathbf{u}\in\mathbb{R}^{d-1}}\big\|\mathbb{E}[T_{ii'}(\boldsymbol{\beta}_j)]\big\|_\infty \lesssim \max_{j\in[d]}\mathbb{E}|X_{ij} - X_{i'j}|^4 \lesssim \max_{j\in[d],i\in[n]}\mathbb{E}|X_{ij}|^4 \le \int_0^\infty c\exp(-t^{1/4})dt = 24c,$$

where $c = 2\exp(\kappa_m + \kappa_h/2)$. Here the last inequality follows from (14). Let $\nabla^2_{jk,j\ell}L_j(\boldsymbol{\beta}_j) = \partial^2 L_j(\boldsymbol{\beta}_j)/\big(\partial\beta_{jk}\partial\beta_{j\ell}\big)$ and let $\big[\boldsymbol{T}_{ii'}(\boldsymbol{\beta}_j)\big]_{k\ell}$ be the corresponding kernel function. That is, $\nabla^2_{jk,j\ell}L_j(\boldsymbol{\beta}_j) = \binom{n}{2}^{-1}\sum_{i<i'}\big[\boldsymbol{T}_{ii'}(\boldsymbol{\beta}_j)\big]_{k\ell}$. For $x > 0$ such that $x^4 > 24c$ and $k, \ell \ne j$, we have

$$\begin{aligned}\mathbb{P}\big\{\big|[\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)]_{k\ell}\big| > 2x^4\big\} &\le \mathbb{P}\big[(X_{ij} - X_{i'j})^2(X_{ik} - X_{i'k})(X_{i\ell} - X_{i'\ell}) > x^4\big] \\ &\le \mathbb{P}\big(|X_{ij} - X_{i'j}| > x\big) + \mathbb{P}\big(|X_{ik} - X_{i'k}| > x\big) + \mathbb{P}\big(|X_{i\ell} - X_{i'\ell}| > x\big).\end{aligned} \tag{123}$$

As a direct implication of Assumption 2, we have $\mathbb{P}\big(|X_{ij} - X_{ij}| > x\big) \le 2\exp(2\kappa_m + \kappa_k)\exp(-x)$ for all $j \in [d]$. Then we can bound the right-hand side of (123) by

$$\mathbb{P}\big\{\big|[\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)]_{k\ell}\big| > 2x^4\big\} \le 6\exp(2\kappa_m + \kappa_h)\exp(-x) \quad \text{when } x^4 > 48\exp(\kappa_m + \kappa_h/2).$$

Letting $C_T = \max\Big\{6\exp(2\kappa_m + \kappa_h), \exp\big\{[48\exp(\kappa_m + \kappa_h/2)]^{1/4}\big\}\Big\}$, it holds that

$$\mathbb{P}\big\{\big|[\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)]_{k\ell}\big| > x\big\} \le C_T\exp(-2^{-1/4}x^{1/4}) \quad \text{for all } x > 0. \tag{124}$$

Thus by a union bound, we conclude that there exists some generic constant C such that $\|\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)\|_\infty \le C\log^4 d$ for all $j \in [d]$ and $i, i' \in [n]$ with probability at least $1 - (8d)^{-1}$. We define an event $\mathcal{E} := \big\{\|\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)\|_\infty \le C\log^4 d, \forall i, i' \in [n], j \in [d]\big\}$. By (124), it is easy to see that $\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)$ is ℓ_2-integrable. By Bernstein's inequality for U-statistics (Lemma 19) with $b = C\log^4 d$ in (56), for some generic constants C_1 and C_2, we obtain that

$$\mathbb{P}\Big(\nabla^2 L_j(\boldsymbol{\beta}_j) - \mathbb{E}_1\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big] > t\big|\mathcal{E}\Big) \le 4\exp\big[-nt^2/(C_1 + C_2\log^4 d\cdot t)\big], \quad \forall j \in [d]. \tag{125}$$

Here we use $\mathbb{E}_1\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]$ to denote $\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big|\mathcal{E}\big]$. Thus under Assumption 4 we obtain that, conditioning on event $\mathcal{E}$,

$$\big\|\nabla^2 L_j(\boldsymbol{\beta}_j) - \mathbb{E}_1\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]\big\|_\infty \le C\sqrt{\log d/n}, \quad \forall j \in [d] \tag{126}$$

with probability at least $1 - (8d)^{-1}$. Moreover, by (124) we obtain that

$$\mathbb{E}\big\{[\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)]_{k\ell}\big|\mathcal{E}\big\} - \mathbb{E}\big\{[\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)]_{k\ell}\big\} \le \int_{C\log^4 d}^\infty \mathbb{P}\big\{\big|[\mathbf{T}_{ii'}(\boldsymbol{\beta}^*_j)]_{k\ell}\big| > x\big\} \le c_1\log^3 d\cdot\exp(-c_2\log d)$$

for some absolute constant c_1 and c_2. Therefore we have

$$\big\|\mathbb{E}_1\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big] - \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j)\big]\big\|_\infty \lesssim \log^3 d\cdot\exp(-c_2\log d) \lesssim \sqrt{\log d/n}. \tag{127}$$

Combining (126) and (127) we show that, with probability at least $1-(4d)^{-1}$, $\big\|\nabla^2 L_j(\boldsymbol{\beta}_j^*) - \mathbb{E}[\nabla^2 L_j(\boldsymbol{\beta}_j^*)]\big\|_\infty \le C_h\sqrt{\log d/n}$ for all $j \in [d]$.

For the second argument (107), let $\boldsymbol{\Delta} = \boldsymbol{\beta}_j - \boldsymbol{\beta}_j^*$ where $\boldsymbol{\beta}_j \in \mathbb{R}^{d-1}$ lies in the ℓ_1-ball centered at $\boldsymbol{\beta}_j^*$ with radius $r_1(s^*,n,d)$, that is, $\big\|\boldsymbol{\beta}_j - \boldsymbol{\beta}_j^*\big\|_1 \le r_1(s^*,n,d)$. By the independence between $\boldsymbol{X}_i$ and $\boldsymbol{X}_{i'}$, Assumption 2 implies that

$$\max\Big\{\log\mathbb{E}\big[\exp(X_{ij}-X_{i'j})\big], \log\mathbb{E}\big[\exp(X_{i'j}-X_{ij})\big]\Big\} \le 2\kappa_m + \kappa_h,$$

which further implies that for any $x > 0$

$$\mathbb{P}\Big(\big|(X_{ij}-X_{i'j})\big| > x\Big) \le 2\exp(2\kappa_m+\kappa_h)\exp(-x), \quad \forall j \in [d].$$

Hence for any $x > 0$ and $j,k \in [d]$, a union bound implies that

$$\begin{aligned}\mathbb{P}\big[\big|(X_{ij}-X_{i'j})(X_{ik}-X_{i'k})\big| > x^2\big] &\le \mathbb{P}\big[\big|(X_{ij}-X_{i'j})\big| > x\big] + \mathbb{P}\big[\big|(X_{ik}-X_{i'k})\big| > x\big] \\ &\le 4\exp(2\kappa_m+\kappa_h)\exp(-x). \end{aligned} \tag{128}$$

Taking a union bound over $1 \le j < k \le d$ and $1 \le i < i' \le n$ we obtain that

$$\mathbb{P}\Big[\max_{i,i'\in[n];j\in[d]} \big\|(X_{ij}-X_{i'j})(\boldsymbol{X}_{i\setminus j}-\boldsymbol{X}_{i'\setminus j})\big\|_\infty > x^2\Big] \lesssim n^2d^2\exp(-x).$$

If we denote $b := \max_{i,i'\in[n];j\in[d]} r_1(s^*,n,d)\big\|(X_{ij}-X_{i'j})(\boldsymbol{X}_{i\setminus j}-\boldsymbol{X}_{i'\setminus j})\big\|_\infty$, then we obtain that $b \le Cr_1(s^*,n,d)\log^2 d$ with probability at least $1-(4d)^{-1}$ for some constant $C > 0$. Denoting $\omega_{ii'} := \exp\big\{-(X_{ij}-X_{i'j})\boldsymbol{\Delta}^T(\boldsymbol{X}_{i\setminus j}-\boldsymbol{X}_{i'\setminus j})\big\}$, by definition,

$$R_{ii'}^j(\boldsymbol{\beta}_j) = \exp\big\{-(X_{ij}-X_{i'j})(\boldsymbol{\Delta}+\boldsymbol{\beta}_j^*)^T(\boldsymbol{X}_{i\setminus j}-\boldsymbol{X}_{i'\setminus j})\big\} = \omega_{ii'}R_{ii'}^j(\boldsymbol{\beta}_j^*).$$

Thus we can write $\nabla^2 L_j(\boldsymbol{\beta}_j)$ as:

$$\nabla^2 L_j(\boldsymbol{\beta}_j) = \frac{2}{n(n-1)}\sum_{i<i'}\frac{R_{ii'}^j(\boldsymbol{\beta}^*)(X_{ij}-X_{i'j})^2(\boldsymbol{X}_{i\setminus j}-\boldsymbol{X}_{i'\setminus j})^{\otimes 2}}{\big(1+R_{ii'}^j(\boldsymbol{\beta}^*)\big)^2}\frac{\omega_{ii'}\big(1+R_{ii'}^j(\boldsymbol{\beta}^*)\big)^2}{\big(1+\omega_{ii'}R_{ii'}^j(\boldsymbol{\beta}^*)\big)^2}. \tag{129}$$

If $\omega_{ii'} \ge 1$, then $(\omega_{ii'})^{-2} \le \big(1+R_{ii'}^j(\boldsymbol{\beta}^*)\big)^2/\big(1+\omega_{ii'}R_{ii'}^j(\boldsymbol{\beta}^*)\big)^2 \le 1$; otherwise we have $1 \le \big(1+R_{ii'}^j(\boldsymbol{\beta})\big)^2/\big(1+\omega_{ii'}R_{ii'}^j(\boldsymbol{\beta}^*)\big)^2 \le (\omega_{ii'})^{-2}$. This observation implies

$$\min\big\{\omega_{ii'}, 1/\omega_{ii'}\big\} \le \frac{\omega_{ii'}\big(1+R_{ii'}^j(\boldsymbol{\beta})\big)^2}{\big(1+\omega_{ii'}R_{ii'}^j(\boldsymbol{\beta}^*)\big)^2} \le \max\big\{\omega_{ii'}, 1/\omega_{ii'}\big\}. \tag{130}$$

By the definition of $\omega_{ii'}$, Hölder's inequality implies that $\big|(X_{ij}-X_{i'j})\boldsymbol{\Delta}^T(\boldsymbol{X}_{i\setminus j}-\boldsymbol{X}_{i'\setminus j})\big| \le b$, thus we have

$$\exp(-b) \le \min\big\{\omega_{ii'}1/\omega_{ii'}\big\} \le \max\big\{\omega_{ii'}, 1/\omega_{ii'}\big\} \le \exp(b). \tag{131}$$

Combining (129),(130) and (131) we obtain

$$\exp(-b)\nabla^2 L_j(\boldsymbol{\beta}_j^*) \le \nabla^2 L_j(\boldsymbol{\beta}_j) \le \exp(b)\nabla^2 L_j(\boldsymbol{\beta}_j^*). \tag{132}$$

Then by (132), since $\lim_{n\to\infty} r_1(s^*,n,d)\log^2 d = 0$, we have

$$\big\|\nabla^2 L_j(\boldsymbol{\beta}_j) - \nabla^2 L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \le \max\big\{1-\exp(-b), \exp(b)-1\big\}\big\|\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \lesssim b\big\|\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big\|_\infty.$$

Notice that under Assumption 2, as shown in §D.1, we can assume that $\big\|\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]\big\|_\infty \le D$ where D appears in (84). By triangle inequality,

$$\big\|\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \le \big\|\nabla^2 L_j(\boldsymbol{\beta}_j^*) - \mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]\big\|_\infty + \big\|\mathbb{E}\big[\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]\big\|_\infty \le D + C_h\sqrt{\log d/n} \le 2D$$

with probability at least $1-(4d)^{-1}$, where the last inequality follows from the fact that $\big(\log^9 d/n\big)^{1/2}$ tends to zero as n goes to infinity. Then we obtain that

$$\big\|\nabla^2 L_j(\boldsymbol{\beta}_j) - \nabla^2 L_j(\boldsymbol{\beta}_j^*)\big\|_\infty \le C_r r_1(s^*,n,d)\log^2 d$$

holds for some absolute constant $C_r > 0$ and uniformly for all $j \in [d]$ and $\boldsymbol{\beta}_j \in \mathbb{B}_j(r_1)$ with probability at least $1-(2d)^{-1}$.

Finally, for the last argument (108), for any $\mathbf{v} \in \mathbb{R}^{d-1}$, by (132) we have

$$\exp(-b)\mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j^*)\mathbf{v} \le \mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j)\mathbf{v} \le \exp(b)\mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j^*)\mathbf{v}.$$

Thus we have

$$\big|\mathbf{v}^T\big[\nabla^2 L_j(\boldsymbol{\beta}_j) - \nabla^2 L_j(\boldsymbol{\beta}_j^*)\big]\mathbf{v}\big| \lesssim b\big|\mathbf{v}^T\nabla^2 L_j(\boldsymbol{\beta}_j^*)\mathbf{v}\big| \le b\|\mathbf{v}\|_1^2\big\|\nabla^2 L_j(\boldsymbol{\beta}_j^*)\big\|_\infty,$$

which implies (108). ∎

(a). The asymmetric score test based on $L_k(\boldsymbol{\beta}_k)$. (b). Inconsistent edges of the asymmetric score test

Figure 4: In (a) we plot estimated graph in the `CAL500` dataset inferred by the asymmetric score test based on the loss function $L_k(\boldsymbol{\beta}_k)$ for testing $H_0 \colon \beta^*_{jk} = 0$ for any $1 \le j < k \le d$. We plot the connected components of the estimated graph for illustration. Compared with Figure 3, we observe that the two asymmetric score tests yields different graphs. In (b) we plot the edges that appear in (a) and Figure 3-(a) but not in Figure 3-(b). In other words, we plot the inconsistent edges of these two asymmetric score tests that are discovered by the pairwise score test. Thus, by taking symmetry into consideration, the pairwise score test is able to correct such inconsistency.

Abstract

The present work aims at deriving theoretical guaranties on the behavior of some cross-validation procedures applied to the k-nearest neighbors (kNN) rule in the context of binary classification. Here we focus on the leave-p-out cross-validation (LpO) used to assess the performance of the kNN classifier. Remarkably this LpO estimator can be efficiently computed in this context using closed-form formulas derived by Celisse and Mary-Huard (2011).

We describe a general strategy to derive moment and exponential concentration inequalities for the LpO estimator applied to the kNN classifier. Such results are obtained first by exploiting the connection between the LpO estimator and U-statistics, and second by making an intensive use of the generalized Efron-Stein inequality applied to the L1O estimator. One other important contribution is made by deriving new quantifications of the discrepancy between the LpO estimator and the classification error/risk of the kNN classifier. The optimality of these bounds is discussed by means of several lower bounds as well as simulation experiments.

Keywords: Classification, Cross-validation, Risk estimation

1. Introduction

The k-nearest neighbor (kNN) algorithm (Fix and Hodges, 1951) in binary classification is a popular prediction algorithm based on the idea that the predicted value at a new point is based on a majority vote from the k nearest labeled neighbors of this point. Although quite simple, the kNN classifier has been successfully applied to many difficult classification tasks (Li et al., 2004; Simard et al., 1998; Scheirer and Slaney, 2003). Efficient implementations have been also developed to allow dealing with large datasets (Indyk and Motwani, 1998; Andoni and Indyk, 2006).

The theoretical performances of the kNN classifier have been already extensively investigated. In the context of binary classification preliminary theoretical results date back to Cover and Hart (1967); Cover (1968); Györfi (1981). The kNN classifier has been proved to be (weakly) universally consistent by Stone (1977) as long as $k = k_n \to +\infty$ and $k/n \to 0$ as $n \to +\infty$. For the 1NN classifier, an asymptotic expansion of the error rate has been derived by Psaltis et al. (1994). The same strategy has been successfully applied to the kNN classifier by Snapp and Venkatesh (1998). Hall et al. (2008) study the influence of the parameter k on the risk of the kNN classifier by means of an asymptotic expansion derived from a Poisson or binomial model for the training points. More recently, Cannings et al. (2017) pointed out some limitations suffered by the "classical" kNN classifier and deduced an improved version based on a local choice of k in the semi-supervised context. In contrast to the aforementioned results, the work by Chaudhuri and Dasgupta (2014) focuses on the finite-sample framework. They typically provide upper bounds with high probability on the risk of the kNN classifier where the bounds are not distribution-free. Alternatively in the regression setting, Kulkarni and Posner (1995) derived a strategy leading to a finite-sample bound on the performance of 1NN, which has been extended to the (weighted) kNN rule ($k \geq 1$) by Biau et al. (2010a,b) (see also Berrett et al., 2016, where a weighted kNN estimator is designed for estimating the entropy). We refer interested readers to Biau and Devroye (2016) for an almost thorough presentation of known results on the kNN algorithm in various contexts.

In numerous (if not all) practical applications, computing the cross-validation (CV) estimator (Stone, 1974, 1982) has been among the most popular strategies to evaluate the performance of the kNN classifier (Devroye et al., 1996, Section 24.3). All CV procedures share a common principle which consists in splitting a sample of n points into two disjoint subsets called *training* and *test* sets with respective cardinalities $n - p$ and p, for any $1 \leq p \leq n-1$. The $n-p$ training set data serve to compute a classifier, while its performance is evaluated from the p *left out* data of the test set. For a complete and comprehensive review on cross-validation procedures, we refer the interested reader to Arlot and Celisse (2010).

In the present work, we focus on the leave-p-out (LpO) cross-validation. Among CV procedures, it belongs to exhaustive strategies since it considers (and averages over) all the $\binom{n}{p}$ possible such splittings of $\{1, \ldots, n\}$ into training and test sets. Usually the induced computation time of the LpO is prohibitive, which gives rise to its surrogate called $V-$fold cross-validation (V-FCV) with $V \approx n/p$ (Geisser, 1975). However, Steele (2009); Celisse and Mary-Huard (2011) recently derived closed-form formulas respectively for the bootstrap and the LpO procedures applied to the kNN classifier. Such formulas allow for an efficient computation of the LpO estimator. Moreover since the V-FCV estimator suffers the same bias but a larger variance than the LpO one (Celisse and Robin, 2008; Arlot and Celisse, 2010), LpO (with $p = \lfloor n/V \rfloor$) strictly improves upon V-FCV in the present context.

Although being favored in practice for assessing the risk of the kNN classifier, the use of CV comes with very few theoretical guarantees regarding its performance. Moreover probably for technical reasons, most existing results apply to Hold-out and leave-one-out (L1O), that is LpO with $p = 1$ (Kearns and Ron, 1999). In this paper we rather consider the general LpO procedure (for $1 \leq p \leq n-1$) used to estimate the risk (alternatively the classification error rate) of the kNN classifier. Our main purpose is then to provide distribution-free theoretical guarantees on the behavior of LpO with respect to influential parameters such as p, n, and k. For instance we aim at answering questions such as: "Does

there exist any regime of $p = p(n)$ (with $p(n)$ some function of n) where the LpO estimator is a consistent estimate of the risk of the kNN classifier?", or "Is it possible to describe the convergence rate of the LpO estimator depending on p?"

Contributions. The main contribution of the present work is two-fold: (i) we describe a new general strategy to derive moment and exponential concentration inequalities for the LpO estimator applied to the kNN binary classifier, and (ii) these inequalities serve to derive the convergence rate of the LpO estimator towards the risk of the kNN classifier.

This new strategy relies on several steps. First exploiting the connection between the LpO estimator and U-statistics (Koroljuk and Borovskich, 1994) and the Rosenthal inequality (Ibragimov and Sharakhmetov, 2002), we prove that upper bounding the polynomial moments of the centered LpO estimator reduces to deriving such bounds for the simpler L1O estimator. Second, we derive new upper bounds on the moments of the L1O estimator using the generalized Efron-Stein inequality (Boucheron et al., 2005, 2013, Theorem 15.5). Third, combining the two previous steps provides some insight on the interplay between p/n and k in the concentration rates measured in terms of moments. This finally results in new exponential concentration inequalities for the LpO estimator applying whatever the value of the ratio $p/n \in (0,1)$. In particular while the upper bounds increase with $1 \leq p \leq n/2+1$, it is no longer the case if $p > n/2+1$. We also provide several lower bounds suggesting our upper bounds cannot be improved in some sense in a distribution-free setting.

The remainder of the paper is organized as follows. The connection between the LpO estimator and U-statistics is clarified in Section 2, where we also recall the closed-form formula of the LpO estimator applied to the kNN classifier (Celisse and Mary-Huard, 2011). Order-q moments ($q \geq 2$) of the LpO estimator are then upper bounded in terms of those of the L1O estimator. This step can be applied to any classification algorithm. Section 3 then specifies the previous upper bounds in the case of the kNN classifier, which leads to the main Theorem 3.2 characterizing the concentration behavior of the LpO estimator with respect to p, n, and k in terms of polynomial moments. Deriving exponential concentration inequalities for the LpO estimator is the main concern of Section 4 where we highlight the strength of our strategy by comparing our main inequalities with concentration inequalities derived with less sophisticated tools. Finally Section 5 exploits the previous results to bound the gap between the LpO estimator and the classification error of the kNN classifier. The optimality of these upper bounds is first proved in our distribution-free framework by establishing several new lower bounds matching the upper ones in some specific settings. Second, empirical experiments are also reported which support the above conclusions.

2. U-statistics and LpO estimator

2.1. Statistical framework

Classification We tackle the binary classification problem where the goal is to predict the unknown label $Y \in \{0,1\}$ of an observation $X \in \mathcal{X} \subset \mathbb{R}^d$. The random variable (X,Y) has an *unknown* joint distribution $P_{(X,Y)}$ defined by $P_{(X,Y)}(B) = \mathbb{P}[\,(X,Y) \in B\,]$ for any Borelian set $B \in \mathcal{X} \times \{0,1\}$, where $\mathbb{P}$ denotes a reference probability distribution. In what follows no particular distributional assumption is made regarding X. To predict the label, one aims at building a classifier $\hat{f} : \mathcal{X} \to \{0,1\}$ on the basis of a set of random variables

$\mathcal{D}_n = \{Z_1, \ldots, Z_n\}$ called the training sample, where $Z_i = (X_i, Y_i)$, $1 \leq i \leq n$ represent n copies of (X,Y) drawn independently from $P_{(X,Y)}$. In settings where no confusion is possible, we will replace $\mathcal{D}_n$ by $\mathcal{D}$.

Any strategy to build such a classifier is called a *classification algorithm*, and can be formally defined as a function $\mathcal{A} : \cup_{n \geq 1} \{\mathcal{X} \times \{0,1\}\}^n \to \mathcal{F}$ that maps a training sample $\mathcal{D}_n$ onto the corresponding classifier $\mathcal{A}^{\mathcal{D}_n}(\cdot) = \hat{f} \in \mathcal{F}$, where $\mathcal{F}$ is the set of all measurable functions from $\mathcal{X}$ to $\{0,1\}$. Numerous classifiers have been considered in the literature and it is out of the scope of the present paper to review all of them (see Devroye et al. (1996) for many instances). Here we focus on the k-nearest neighbor rule (kNN) initially proposed by Fix and Hodges (1951) and further studied for instance by Devroye and Wagner (1977); Rogers and Wagner (1978).

The kNN algorithm For $1 \leq k \leq n$, the kNN classification algorithm, denoted by $\mathcal{A}_k$, consists in classifying any new observation x using a *majority vote* decision rule based on the labels of the k closest points to x, denoted by $X_{(1)}(x), \ldots, X_{(k)}(x)$, among the training sample $X_1, \ldots, X_n$. In what follows these k *nearest neighbors* are chosen according to the distance associated with the usual Euclidean norm in $\mathbb{R}^d$. Note that other *adaptive metrics* have been also considered in the literature (see for instance Hastie et al., 2001, Chap. 14). But such examples are out of the scope of the present work, that is our reference distance does not depend on the training sample at hand. Let us also emphasize that possible ties are broken by using the *smallest index* among ties, which is one possible choice for the Stone lemma to hold true (Biau and Devroye, 2016, Lemma 10.6, p.125).

Formally, given $V_k(x) = \left\{1 \leq i \leq n,\ X_i \in \left\{X_{(1)}(x), \ldots, X_{(k)}(x)\right\}\right\}$ the set of indices of the k nearest neighbors of x among $X_1, \ldots, X_n$, the kNN classifier is defined by

$$\mathcal{A}_k(\mathcal{D}_n; x) = \widehat{f}_k(\mathcal{D}_n; x) := \begin{cases} 1 & \text{, if } \frac{1}{k}\sum_{i \in V_k(x)} Y_i = \frac{1}{k}\sum_{i=1}^k Y_{(i)}(x) > 0.5 \\ 0 & \text{, if } \frac{1}{k}\sum_{i=1}^k Y_{(i)}(x) < 0.5 \\ \mathcal{B}(0.5) & \text{, otherwise} \end{cases}, \quad (2.1)$$

where $Y_{(i)}(x)$ is the label of the i-th nearest neighbor of x for $1 \leq i \leq k$, and $\mathcal{B}(0.5)$ denotes a Bernoulli random variable with parameter $1/2$.

Leave-p-out cross-validation For a given sample $\mathcal{D}_n$, the performance of any classifier $\hat{f} = \mathcal{A}^{\mathcal{D}_n}(\cdot)$ (respectively of any classification algorithm $\mathcal{A}$) is assessed by the classification error $L(\hat{f})$ (respectively the risk $R(\hat{f})$) defined by

$$L(\hat{f}) = \mathbb{P}\left(\hat{f}(X) \neq Y \mid \mathcal{D}_n\right), \quad \text{and} \quad R(\hat{f}) = \mathbb{E}\left[\mathbb{P}\left(\hat{f}(X) \neq Y \mid \mathcal{D}_n\right)\right].$$

In this paper we focus on the estimation of $L(\hat{f})$ (and its expectation $R(\hat{f})$) by use of the *Leave-p-Out* (LpO) cross-validation for $1 \leq p \leq n-1$ (Zhang, 1993; Celisse and Robin, 2008). LpO successively considers all possible splits of $\mathcal{D}_n$ into a training set of cardinality $n-p$ and a test set of cardinality p. Denoting by $\mathcal{E}_{n-p}$ the set of all possible subsets of $\{1, \ldots, n\}$ with cardinality $n-p$, any $e \in \mathcal{E}_{n-p}$ defines a split of $\mathcal{D}_n$ into a training sample $\mathcal{D}^e = \{Z_i \mid i \in e\}$ and a test sample $\mathcal{D}^{\bar{e}}$, where $\bar{e} = \{1, \ldots, n\} \setminus e$. For a given classification algorithm $\mathcal{A}$, the final LpO estimator of the performance of $\mathcal{A}^{\mathcal{D}_n}(\cdot) = \widehat{f}$ is the average (over all possible splits) of the classification error estimated on each test set, that is

$$\widehat{R}_p(\mathcal{A}, \mathcal{D}_n) = \binom{n}{p}^{-1} \sum_{e \in \mathcal{E}_{n-p}} \left(\frac{1}{p}\sum_{i \in \bar{e}} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i\right\}}\right), \quad (2.2)$$

where $\mathcal{A}^{\mathcal{D}^e}(\cdot)$ is the classifier built from $\mathcal{D}^e$. We refer the reader to Arlot and Celisse (2010) for a detailed description of LpO and other cross-validation procedures. In the sequel, the lengthy notation $\widehat{R}_p(\mathcal{A}, \mathcal{D}_n)$ is replaced by $\widehat{R}_{p,n}$ in settings where no confusion can arise about the algorithm $\mathcal{A}$ or the training sample $\mathcal{D}_n$, and by $\widehat{R}_p(\mathcal{D}_n)$ if the training sample has to be kept in mind.

Exact LpO for the kNN classification algorithm Usually due to its seemingly prohibitive computational cost, LpO is not applied except with $p = 1$ where it reduces to the well known leave-one-out. However in several contexts such as density estimation (Celisse and Robin, 2008; Celisse, 2014) or regression (Celisse, 2008), closed-form formulas have been derived for the LpO estimator when applied with projection and kernel estimators. The kNN classifier is another instance of such estimators for which efficiently computing the LpO estimator is possible. Its computation requires a time complexity that is linear in p as previously established by Celisse and Mary-Huard (2011). Let us briefly recall the main steps leading to the closed-form formula.

1. From Eq. (2.2) the LpO estimator can be expressed as a sum (over the n observations of the complete sample) of probabilities:

$$\begin{aligned}\binom{n}{p}^{-1} \sum_{e \in \mathcal{E}_{n-p}} \frac{1}{p} \left(\sum_{i \notin e} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i\right\}} \right) &= \frac{1}{p} \sum_{i=1}^{n} \left[\binom{n}{p}^{-1} \sum_{e \in \mathcal{E}_{n-p}} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i\right\}} \mathbb{1}_{\{i \notin e\}} \right] \\ &= \frac{1}{p} \sum_{i=1}^{n} \mathbb{P}_e(\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i \mid i \notin e) \mathbb{P}_e(i \notin e).\end{aligned}$$

   Here $\mathbb{P}_e$ means that the integration is made with respect to the random variable $e \in \mathcal{E}_{n-p}$, which follows the uniform distribution over the $\binom{n}{p}$ possible subsets in $\mathcal{E}_{n-p}$ with cardinality $n-p$. For instance $\mathbb{P}_e(i \notin e) = p/n$ since it is the proportion of subsamples with cardinality $n-p$ which do not contain a given prescribed index i, which equals $\binom{n-1}{n-p}/\binom{n}{p}$. (See also Lemma D.4 for further examples of such calculations.)

2. For any X_i, let $X_{(1)}, ..., X_{(k+p-1)}, X_{(k+p)}, ..., X_{(n-1)}$ be the ordered sequence of neighbors of X_i. This list depends on X_i, that is $X_{(1)}$ should be noted $X_{(i,1)}$. But this dependency is skipped here for the sake of readability.

   The key in the derivation is to condition with respect to the random variable R_k^i which denotes the rank (in the whole sample $\mathcal{D}_n$) of the k-th neighbor of X_i in the $\mathcal{D}^e$. For instance $R_k^i = j$ means that $X_{(j)}$ is the k-th neighbor of X_i in $\mathcal{D}^e$. Then

$$\mathbb{P}_e(\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i | i \notin e) = \sum_{j=k}^{k+p-1} \mathbb{P}_e(\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i \mid R_k^i = j,\ i \notin e) \mathbb{P}_e(R_k^i = j \mid i \notin e),$$

   where the sum involves p terms since only $X_{(k)}, \ldots, X_{(k+p-1)}$ are candidates for being the k-th neighbor of X_i in at least one training subset e.

3. Observe that the resulting probabilities can be easily computed (see Lemma D.4):

   $\star$ $\mathbb{P}_e(i \notin e) = \frac{p}{n}$
   $\star$ $\mathbb{P}_e(R_k^i = j | i \notin e) = \frac{k}{j} P(U = j - k)$
   $\star$ $\mathbb{P}_e(\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i | V_k^i = j,\ i \notin e) = (1 - Y_j)\left[1 - F_H\left(\frac{k+1}{2}\right)\right] + Y_j\left[1 - F_{H'}\left(\frac{k-1}{2}\right)\right]$,

   with $U \sim \mathcal{H}(j, n-j-1, p-1)$, $H \sim \mathcal{H}(N_i^j, j - N_i^j - 1, k-1)$, and $H' \sim \mathcal{H}(N_i^j - 1, j - N_i^j, k-1)$, where F_H and $F_{H'}$ respectively denote the cumulative distribution functions of H and H', $\mathcal{H}$ denotes the hypergeometric distribution, and N_i^j is the number of 1's among the j nearest neighbors of X_i in $\mathcal{D}_n$.

The computational cost of LpO for the kNN classifier is the same as that of L1O for the $(k + p - 1)$NN classifier whatever p, that is $O(p\,n)$. This contrasts with the usual $\binom{n}{p}$ prohibitive computational complexity seemingly suffered by LpO.

2.2. U-statistics: General bounds on LpO moments

The purpose of the present section is to describe a general strategy allowing to derive new upper bounds on the polynomial moments of the LpO estimator. As a first step of this strategy, we establish the connection between the LpO risk estimator and U-statistics. Second, we exploit this connection to derive new upper bounds on the order-q moments of the LpO estimator for $q \geq 2$. Note that these upper bounds, which relate moments of the LpO estimator to those of the L1O estimator, hold true with any classifier.

Let us start by introducing U-statistics and recalling some of their basic properties that will serve our purposes. For a thorough presentation, we refer to the books by Serfling (1980); Koroljuk and Borovskich (1994). The first step is the definition of a U-statistic of order $m \in \mathbb{N}^*$ as an average over all m-tuples of distinct indices in $\{1, \ldots, n\}$.

Definition 2.1 (Koroljuk and Borovskich (1994)). *Let $h : \mathcal{X}^m \longrightarrow \mathbb{R}$ denote any measurable function where $m \geq 1$ is an integer. Let us further assume h is a symmetric function of its arguments. Then any function $U_n : \mathcal{X}^n \longrightarrow \mathbb{R}$ such that*

$$U_n(x_1, \ldots, x_n) = U_n(h)(x_1, \ldots, x_n) = \binom{n}{m}^{-1} \sum_{1 \leq i_1 < \ldots < i_m \leq n} h(x_{i_1}, \ldots, x_{i_m})$$

where $m \leq n$, is a U-statistic of order m and kernel h.

Before clarifying the connection between LpO and U-statistics, let us introduce the main property of U-statistics our strategy relies on. It consists in representing any U-statistic as an average, over all permutations, of sums of independent variables.

Proposition 2.1 (Eq. (5.5) in Hoeffding (1963)). *With the notation of Definition 2.1, let us define $W : \mathcal{X}^n \longrightarrow \mathbb{R}$ by*

$$W(x_1, \ldots, x_n) = \frac{1}{r} \sum_{j=1}^{r} h\left(x_{(j-1)m+1}, \ldots, x_{jm}\right), \tag{2.3}$$

where $r = \lfloor n/m \rfloor$ denotes the integer part of n/m. Then

$$U_n(x_1, \ldots, x_n) = \frac{1}{n!} \sum_{\sigma} W\left(x_{\sigma(1)}, \ldots, x_{\sigma(n)}\right),$$

where $\sum_\sigma$ denotes the summation over all permutations σ of $\{1, \ldots, n\}$.

We are now in position to state the key remark of the paper. All the developments further exposed in the following result from this connection between the LpO estimator defined by Eq. (2.2) and U-statistics.

Theorem 2.1. *For any classification algorithm $\mathcal{A}$ and any $1 \leq p \leq n-1$ such that a classifier can be computed from $\mathcal{A}$ on $n-p$ training points, the LpO estimator $\widehat{R}_{p,n}$ is a U-statistic of order $m = n-p+1$ with kernel $h_m \colon \mathcal{X}^m \longrightarrow \mathbb{R}$ defined by*

$$h_m(Z_1, \ldots, Z_m) = \frac{1}{m} \sum_{i=1}^{m} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}_m^{(i)}}(X_i) \neq Y_i\right\}},$$

where $\mathcal{D}_m^{(i)}$ denotes the sample $\mathcal{D}_m = (Z_1, \ldots, Z_m)$ with Z_i withdrawn.

Note for instance that when $\mathcal{A} = \mathcal{A}_k$ denotes the kNN algorithm, the cardinality of $\mathcal{D}_m^{(i)}$ has to satisfy $n-p \geq k$, which implies that $1 \leq p \leq n-k \leq n-1$.

Proof of Theorem 2.1.

From Eq. (2.2), the LpO estimator of the performance of any classification algorithm $\mathcal{A}$ computed from $\mathcal{D}_n$ satisfies

$$\begin{aligned}
\widehat{R}_p(\mathcal{A}, \mathcal{D}_n) = \widehat{R}_{p,n} &= \frac{1}{\binom{n}{p}} \sum_{e \in \mathcal{E}_{n-p}} \frac{1}{p} \sum_{i \in \bar{e}} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i\right\}} \\
&= \frac{1}{\binom{n}{p}} \sum_{e \in \mathcal{E}_{n-p}} \frac{1}{p} \sum_{i \in \bar{e}} \left(\sum_{v \in \mathcal{E}_{n-p+1}} \mathbb{1}_{\{v = e \cup \{i\}\}} \right) \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^e}(X_i) \neq Y_i\right\}},
\end{aligned}$$

since there is a unique set of indices v with cardinality $n-p+1$ such that $v = e \cup \{i\}$. Then

$$\widehat{R}_{p,n} = \frac{1}{\binom{n}{p}} \sum_{v \in \mathcal{E}_{n-p+1}} \frac{1}{p} \sum_{i=1}^{n} \left(\sum_{e \in \mathcal{E}_{n-p}} \mathbb{1}_{\{v = e \cup \{i\}\}} \mathbb{1}_{\{i \in \bar{e}\}} \right) \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^{v \setminus \{i\}}}(X_i) \neq Y_i\right\}}.$$

Furthermore for v and i fixed, $\sum_{e \in \mathcal{E}_{n-p}} \mathbb{1}_{\{v = e \cup \{i\}\}} \mathbb{1}_{\{i \in \bar{e}\}} = \mathbb{1}_{\{i \in v\}}$ since there is a unique set of indices e such that $e = v \setminus i$. One gets

$$\begin{aligned}
\widehat{R}_{p,n} &= \frac{1}{p} \frac{1}{\binom{n}{p}} \sum_{v \in \mathcal{E}_{n-p+1}} \sum_{i=1}^{n} \mathbb{1}_{\{i \in v\}} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^{v \setminus \{i\}}}(X_i) \neq Y_i\right\}} \\
&= \frac{1}{\binom{n}{n-p+1}} \sum_{v \in \mathcal{E}_{n-p+1}} \frac{1}{n-p+1} \sum_{i \in v} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}^{v \setminus \{i\}}}(X_i) \neq Y_i\right\}},
\end{aligned}$$

by noticing $p\binom{n}{p} = \frac{pn!}{p!n-p!} = \frac{n!}{p-1!n-p!} = (n-p+1)\binom{n}{n-p+1}$.

□

The kernel h_m is a deterministic and symmetric function of its arguments that does only depend on m. Let us also notice that $h_m(Z_1, \ldots, Z_m)$ reduces to the L1O estimator of the risk of the classifier $\mathcal{A}$ computed from $Z_1, \ldots, Z_m$, that is

$$h_m(Z_1, \ldots, Z_m) = \widehat{R}_1(\mathcal{A}, \mathcal{D}_m) = \widehat{R}_{1,n-p+1}. \tag{2.4}$$

In the context of testing whether two binary classifiers have different error rates, this fact has already been pointed out by Fuchs et al. (2013).

We now derive a general upper bound on the q-th moment ($q \geq 1$) of the LpO estimator that holds true for any classifier (as long as the following expectations are well defined).

Theorem 2.2. *For any classifier $\mathcal{A}$, let $\mathcal{A}^{\mathcal{D}_n}(\cdot)$ and $\mathcal{A}^{\mathcal{D}_m}(\cdot)$ be the corresponding classifiers built from respectively $\mathcal{D}_n$ and $\mathcal{D}_m$, where $m = n-p+1$. Then for every $1 \leq p \leq n-1$ such that a classifier can be computed from $\mathcal{A}$ on $n-p$ training points, and for any $q \geq 1$,*

$$\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^q\right] \leq \mathbb{E}\left[\left|\widehat{R}_{1,m} - \mathbb{E}\left[\widehat{R}_{1,m}\right]\right|^q\right]. \tag{2.5}$$

Furthermore as long as $p > n/2+1$, one also gets

- *for $q = 2$*

$$\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^2\right] \leq \frac{\mathbb{E}\left[\left|\widehat{R}_{1,m} - \mathbb{E}\left[\widehat{R}_{1,m}\right]\right|^2\right]}{\left\lfloor \frac{n}{m} \right\rfloor}. \tag{2.6}$$

- *for every $q > 2$*

$$\begin{aligned}
&\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^q\right] \leq B(q,\gamma) \times \\
&\max\left\{ 2^q \gamma \left\lfloor \frac{n}{m} \right\rfloor \mathbb{E}\left[\left| \frac{\widehat{R}_{1,m} - \mathbb{E}\left[\widehat{R}_{1,m}\right]}{\left\lfloor \frac{n}{m} \right\rfloor} \right|^q \right], \left(\sqrt{\frac{2\mathrm{Var}\left(\widehat{R}_{1,m}\right)}{\left\lfloor \frac{n}{m} \right\rfloor}} \right)^q \right\},
\end{aligned} \tag{2.7}$$

  where $\gamma > 0$ is a numeric constant and $B(q,\gamma)$ denotes the optimal constant defined in the Rosenthal inequality (Proposition D.2).

The proof is given in Appendix A.1. Eq. (2.5) and (2.6) straightforwardly result from the Jensen inequality applied to the average over all permutations provided in Proposition 2.1. If $p > n/2+1$, the integer part $\lfloor n/m \rfloor$ becomes larger than 1 and Eq. (2.6) becomes better than Eq. (2.5) for $q = 2$. As a consequence of our strategy of proof, the right-hand side of Eq. (2.6) is equal to the classical upper bound on the variance of U-statistics which suggests it cannot be improved without adding further assumptions.

Unlike the above ones, Eq. (2.7) is derived from the Rosenthal inequality, which enables us to upper bound a sum $\left\|\sum_{i=1}^r \xi_i\right\|_q$ of independent and identically centered random variables in terms of $\sum_{i=1}^r \|\xi_i\|_q$ and $\sum_{i=1}^r \mathrm{Var}(\xi_i)$. Let us remark that, for $q = 2$, both terms of the right-hand side of Eq. (2.7) are of the same order as Eq. (2.6) up to constants. Furthermore using the Rosenthal inequality allows taking advantage of the integer part $\lfloor n/m \rfloor$ when $p > n/2+1$ (unlike what we get by using Eq.(2.5) for $q > 2$). In particular it provides a new understanding of the behavior of the LpO estimator when $p/n \to 1$ as highlighted later by Proposition 4.2.

3. New bounds on LpO moments for the kNN classifier

Our goal is now to specify the general upper bounds provided by Theorem 2.2 in the case of the kNN algorithm $\mathcal{A}_k$ ($1 \leq k \leq n$) introduced by (2.1).

Since Theorem 2.2 expresses the moments of the LpO estimator in terms of those of the L1O estimator computed from $\mathcal{D}_m$ (with $m = n-p+1$), the next step consists in focusing on the L1O moments. Deriving upper bounds on the moments of the L1O is achieved using a generalization of the well-known Efron-Stein inequality (see Theorem D.1 for Efron-Stein's inequality and Theorem 15.5 in Boucheron et al. (2013) for its generalization). For the sake of completeness, we first recall a corollary of this generalization that is proved in Section D.1.4 (see Corollary D.1).

Proposition 3.1. *Let $\xi_1, \ldots, \xi_n$ denote n independent Ξ-valued random variables and $\zeta = f(\xi_1, \ldots, \xi_n)$, where $f : \Xi^n \to \mathbb{R}$ is any measurable function. With $\xi'_1, \ldots, \xi'_n$ independent copies of the ξ_is, there exists a universal constant $\kappa \leq 1.271$ such that for any $q \geq 2$,*

$$\|\zeta - \mathbb{E}\zeta\|_q \leq \sqrt{2\kappa q} \sqrt{\left\| \sum_{i=1}^{n} \left(f(\xi_1, \ldots, \xi_i, \ldots, \xi_n) - f(\xi_1, \ldots, \xi'_i, \ldots, \xi_n) \right)^2 \right\|_{q/2}} .$$

Then applying Proposition 3.1 with $\zeta = \widehat{R}_1(\mathcal{A}_k, \mathcal{D}_m) = \widehat{R}_{1,m}$ (L1O estimator computed from $\mathcal{D}_m$ with $m = n-p+1$) and $\Xi = \mathbb{R}^d \times \{0,1\}$ leads to the following Theorem 3.1. It controls the order-q moments of the L1O estimator applied to the kNN classifier.

Theorem 3.1. *For every $1 \leq k \leq n-1$, let $A_k^{\mathcal{D}_m}$ ($m = n-p+1$) denote the kNN classifier learnt from $\mathcal{D}_m$ and $\widehat{R}_{1,m}$ be the corresponding L1O estimator given by Eq. (2.2). Then*

- *for $q = 2$,*

$$\mathbb{E}\left[\left(\widehat{R}_{1,m} - \mathbb{E}\left[\widehat{R}_{1,m} \right] \right)^2 \right] \leq C_1 \frac{k^{3/2}}{m} \ ; \tag{3.1}$$

- *for every $q > 2$,*

$$\mathbb{E}\left[\left| \widehat{R}_{1,m} - \mathbb{E}\left[\widehat{R}_{1,m} \right] \right|^q \right] \ \leq (C_2 \cdot k)^q \left(\tfrac{q}{m} \right)^{q/2}, \tag{3.2}$$

with $C_1 = 2 + 16\gamma_d$ and $C_2 = 4\gamma_d\sqrt{2\kappa}$, where γ_d is a constant (arising from Stone's lemma, see Lemma D.5) that grows exponentially with dimension d, and κ is defined in Proposition 3.1.

Its proof (detailed in Section A.2) relies on Stone's lemma (Lemma D.5). For a given X_i, it proves that the number of points in $\mathcal{D}_n^{(i)}$ having X_i among their k nearest neighbors is not larger than $k\gamma_d$. The dependence of our upper bounds with respect to γ_d (see explicit constants C_1 and C_2) induces their strong deterioration as the dimension d grows since $\gamma_d \approx 4.8^d - 1$. Therefore the larger the dimension d, the larger the required sample size n for the upper bound to be small (at least smaller than 1). Note also that the tie breaking strategy (based on the smallest index in the present work) is chosen so that it ensures Stone's lemma to hold true.

In Eq. (3.1), the easier case $q = 2$ enables to exploit exact calculations of (rather than upper bounds on) the variance of the L1O estimator. Since $\mathbb{E}\left[\widehat{R}_{1,m} \right] = R\left(A_k^{\mathcal{D}_{n-p}} \right)$ (risk of the kNN classifier computed from $\mathcal{D}_{n-p}$), the resulting $k^{3/2}/m$ rate is a strict improvement upon the usual k^2/m that is derived from using the sub-Gaussian exponential concentration inequality proved by Theorem 24.4 in Devroye et al. (1996).

By contrast the larger k^q arising in Eq. (3.2) results from the difficulty to derive a tight upper bound for the expectation of $(\sum_{i=1}^n \mathbb{1}_{\left\{ A_k^{\mathcal{D}_m^{(i)}}(X_i) \neq A_k^{\mathcal{D}_m^{(i,j)}}(X_i) \right\}})^q$ with $q > 2$, where $\mathcal{D}_m^{(i)}$ (resp. $\mathcal{D}_m^{(i,j)}$) denotes the sample $\mathcal{D}_m$ where Z_i has been (resp. Z_i and Z_j have been) removed.

We are now in position to state the main result of this section. It follows from the combination of Theorem 2.2 (connecting moments of the LpO and L1O estimators) and Theorem 3.1 (providing an upper bound on the order-q moments of the L1O).

Theorem 3.2. *For every $p, k \geq 1$ such that $p+k \leq n$, let $\widehat{R}_{p,n}$ denote the LpO risk estimator (see (2.2)) of the kNN classifier $\mathcal{A}_k^{\mathcal{D}_n}(\cdot)$ defined by (2.1). Then there exist (known) constants $C_1, C_2 > 0$ such that for every $1 \leq p \leq n-k$,*

- *for $q = 2$,*

$$\mathbb{E}\left[\left(\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n} \right] \right)^2 \right] \leq C_1 \frac{k^{3/2}}{(n-p+1)} \ ; \tag{3.3}$$

- *for every $q > 2$,*

$$\mathbb{E}\left[\left| \widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n} \right] \right|^q \right] \leq (C_2 k)^q \left(\tfrac{q}{n-p+1} \right)^{q/2}, \tag{3.4}$$

with $C_1 = \frac{128\kappa\gamma_d}{\sqrt{2\pi}}$ and $C_2 = 4\gamma_d\sqrt{2\kappa}$, where γ_d denotes the constant arising from Stone's lemma (Lemma D.5). Furthermore in the particular setting where $n/2 + 1 < p \leq n-k$, then

- *for $q = 2$,*

$$\mathbb{E}\left[\left(\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n} \right] \right)^2 \right] \leq C_1 \frac{k^{3/2}}{(n-p+1)\left\lfloor \frac{n}{n-p+1} \right\rfloor} \ , \tag{3.5}$$

- *for every $q > 2$,*

$$\begin{aligned} &\mathbb{E}\left[\left| \widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n} \right] \right|^q \right] \\ &\leq \left\lfloor \frac{n}{n-p+1} \right\rfloor \Gamma^q \max\left(\frac{k^{3/2}}{(n-p+1)\left\lfloor \frac{n}{n-p+1} \right\rfloor} q, \frac{k^2}{(n-p+1)\left\lfloor \frac{n}{n-p+1} \right\rfloor^2} q^3 \right)^{q/2} \end{aligned} \tag{3.6}$$

where $\Gamma = 2\sqrt{2e}\max\left(\sqrt{2C_1}, 2C_2\right)$.

The straightforward proof is detailed in Section A.3. Let us start by noticing that both upper bounds in Eq. (3.3) and (3.4) deteriorate as p grows. This is no longer the case for Eq. (3.5) and (3.6), which are specifically designed to cover the setup where $p > n/2+1$, that is where $\lfloor n/m \rfloor$ is no longer equal to 1. Therefore unlike Eq. (3.3) and (3.4), these last two inequalities are particularly relevant in the setup where $p/n \to 1$, as $n \to +\infty$, which has been investigated by Shao (1993); Yang (2006, 2007); Celisse (2014). Eq. (3.5) and (3.6) lead to respective convergence rates at worse $k^{3/2}/n$ (for $q = 2$) and k^q/n^{q-1} (for $q > 2$). In particular this last rate becomes approximately equal to $(k/n)^q$ as q gets large.

One can also emphasize that, as a U-statistic of fixed order $m = n - p + 1$, the LpO estimator has a known Gaussian limiting distribution, that is (see Theorem A, Section 5.5.1 Serfling, 1980)

$$\frac{\sqrt{n}}{m}\left(\widehat{R}_{p,n} - \mathbb{E}\left[\,\widehat{R}_{p,n}\,\right]\right) \xrightarrow[n\to+\infty]{\mathcal{L}} \mathcal{N}\left(0, \sigma_1^2\right),$$

where $\sigma_1^2 = \mathrm{Var}\left[\, g(Z_1)\,\right]$, with $g(z) = E\left[\, h_m(z, Z_2, \ldots, Z_m)\,\right]$. Therefore the upper bound given by Eq. (3.5) is non-improvable in some sense with respect to the interplay between n and p since one recovers the right magnitude for the variance term as long as $m = n-p+1$ is assumed to be constant.

Finally Eq. (3.6) has been derived using a specific version of the Rosenthal inequality (Ibragimov and Sharakhmetov, 2002) stated with the optimal constant and involving a "balancing factor". In particular this balancing factor has allowed us to optimize the relative weight of the two terms between brackets in Eq. (3.6). This leads us to claim that the dependence of the upper bound with respect to q cannot be improved with this line of proof. However we cannot conclude that the term in q^3 cannot be improved using other technical arguments.

4. Exponential concentration inequalities

This section provides exponential concentration inequalities for the LpO estimator applied to the kNN classifier. Our main results heavily rely on the moment inequalities previously derived in Section 3, namely Theorem 3.2. In order to emphasize the gain allowed by this strategy of proof, we start this section by successively proving two exponential inequalities obtained with less sophisticated tools. We then discuss the strength and weakness of each of them to justify the additional refinements we introduce step by step along the section.

A first exponential concentration inequality for $\widehat{R}_p(\mathcal{A}_k, \mathcal{D}_n) = \widehat{R}_{p,n}$ can be derived by use of the bounded difference inequality following the line of proof of Devroye et al. (1996, Theorem 24.4) originally developed for the L1O estimator.

Proposition 4.1. *For any integers $p, k \geq 1$ such that $p + k \leq n$, let $\widehat{R}_{p,n}$ denote the LpO estimator (2.2) of the classification error of the kNN classifier $\mathcal{A}_k^{\mathcal{D}_n}(\cdot)$ defined by (2.1). Then for every $t > 0$,*

$$\mathbb{P}\left(\left|\widehat{R}_{p,n} - \mathbb{E}\left(\widehat{R}_{p,n}\right)\right| > t\right) \leq 2e^{-n\frac{t^2}{8(k+p-1)^2\gamma_d^2}}. \tag{4.1}$$

where γ_d denotes the constant introduced in Stone's lemma (Lemma D.5).

The proof is given in Appendix B.1.

The upper bound of Eq. (4.1) strongly exploits the facts that: (i) for X_j to be one of the k nearest neighbors of X_i in at least one subsample X^e, it requires X_j to be one of the $k+p-1$ nearest neighbors of X_i in the complete sample, and (ii) the number of points for which X_j may be one of the $k+p-1$ nearest neighbors cannot be larger than $(k+p-1)\gamma_d$ by Stone's Lemma (see Lemma D.5).

This reasoning results in a rough upper bound since the denominator in the exponent exhibits a $(k+p-1)^2$ factor where k and p play the same role. The reason is that we do not distinguish between points for which X_j is among or above the k nearest neighbors of X_i in the whole sample (although these two setups lead to highly different probabilities of being among the k nearest neighbors in the training sample). Consequently the dependence of the convergence rate on k and p in Proposition 4.1 can be improved, as confirmed by forthcoming Theorems 4.1 and 4.2.

Based on the previous comments, a sharper quantification of the influence of each neighbor among the $k+p-1$ ones leads to the next result.

Theorem 4.1. *For every $p, k \geq 1$ such that $p + k \leq n$, let $\widehat{R}_{p,n}$ denote the LpO estimator (2.2) of the classification error of the kNN classifier $\mathcal{A}_k^{\mathcal{D}_n}(\cdot)$ defined by (2.1). Then there exists a numeric constant $\square > 0$ such that for every $t > 0$,*

$$\max\left(\mathbb{P}\left(\widehat{R}_{p,n} - \mathbb{E}\left(\widehat{R}_{p,n}\right) > t\right), \mathbb{P}\left(\mathbb{E}\left(\widehat{R}_{p,n}\right) - \widehat{R}_{p,n} > t\right)\right) \leq \exp\left(-n\frac{t^2}{\square k^2\left[1 + (k+p)\frac{p-1}{n-1}\right]}\right),$$

with $\square = 1024e\kappa(1+\gamma_d)$, where γ_d is introduced in Lemma D.5 and $\kappa \leq 1.271$ is a universal constant.

The proof is given in Section B.2.

Unlike Proposition 4.1, taking into account the rank of each neighbor in the whole sample enables us to considerably reduce the weight of p (compared to that of k) in the denominator of the exponent. In particular, letting $p/n \to 0$ as $n \to +\infty$ (with k assumed to be fixed for instance) makes the influence of the $k+p$ factor asymptotically negligible. This would allow for recovering (up to numeric constants) a similar upper bound to that of Devroye et al. (1996, Theorem 24.4), achieved with $p = 1$.

However the upper bound of Theorem 4.1 does not reflect the right dependencies with respect to k and p compared with what has been proved for polynomial moments in Theorem 3.2. In particular it deteriorates as p increases unlike the upper bounds derived for $p > n/2+1$ in Theorem 3.2. This drawback is overcome by the following result, which is our main contribution in the present section.

Theorem 4.2. *For every $p, k \geq 1$ such that $p+k \leq n$, let $\widehat{R}_{p,n}$ denote the LpO estimator of the classification error of the kNN classifier $\hat{f}_k = \mathcal{A}_k^{\mathcal{D}_n}(\cdot)$ defined by (2.1). Then for every $t > 0$,*

$$\max\left(\mathbb{P}\left(\widehat{R}_{p,n} - \mathbb{E}\left[\,\widehat{R}_{p,n}\,\right] > t\right), \mathbb{P}\left(\mathbb{E}\left[\,\widehat{R}_{p,n}\,\right] - \widehat{R}_{p,n} > t\right)\right) \leq \exp\left(-(n-p+1)\frac{t^2}{\Delta^2 k^2}\right), \tag{4.2}$$

where $\Delta = 4\sqrt{e}\max\left(C_2, \sqrt{C_1}\right)$ *with* $C_1, C_2 > 0$ *defined in Theorem 3.1.*

Furthermore in the particular setting where $p > n/2+1$*, it comes*

$$\max\left(\mathbb{P}\left(\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right] > t\right), \mathbb{P}\left(\mathbb{E}\left[\widehat{R}_{p,n}\right] - \widehat{R}_{p,n} > t\right)\right) \leq e\left\lfloor\frac{n}{n-p+1}\right\rfloor \times$$
$$\exp\left[-\frac{1}{2e}\min\left\{(n-p+1)\left\lfloor\frac{n}{n-p+1}\right\rfloor\frac{t^2}{4\Gamma^2 k^{3/2}}, \left((n-p+1)\left\lfloor\frac{n}{n-p+1}\right\rfloor\right)^2\frac{t^2}{4\Gamma^2 k^2}\right)^{1/3}\right\}\right], \tag{4.3}$$

where Γ *arises in Eq.* (3.6) *and* γ_d *denotes the constant introduced in Stone's lemma (Lemma D.5).*

The proof has been postponed to Appendix B.3. It involves different arguments for deriving the two inequalities (4.2) and (4.3) depending on the range of values of p. Firstly for $p \leq n/2+1$, a simple argument is applied to derive Ineq. (4.2) from the two corresponding moment inequalities of Theorem 3.2 characterizing the sub-Gaussian behavior of the LpO estimator in terms of its even moments (see Lemma D.2). Secondly for $p > n/2+1$, we rather exploit: (i) the appropriate upper bounds on the moments of the LpO estimator given by Theorem 3.2, combined with (ii) Proposition D.1 which establishes exponential concentration inequalities from general moment upper bounds.

In accordance with the conclusions drawn about Theorem 3.2, the upper bound of Eq. (4.2) increases as p grows unlike that of Eq. (4.3). The best concentration rate in Eq. (4.3) is achieved as $p/n \to 1$, whereas Eq. (4.2) turns out to be useless in that setting. However Eq. (4.2) remains strictly better than Theorem 4.1 as long as $p/n \to \delta \in [0,1[$ as $n \to +\infty$. Note also that the constants Γ and γ_d are the same as in Theorem 3.1. Therefore the same comments regarding their dependence with respect to the dimension d apply here.

In order to facilitate the interpretation of the last Ineq. (4.3), we also derive the following proposition (proved in Appendix B.3) which focuses on the description of each deviation term in the particular case where $p > n/2+1$.

Proposition 4.2. *With the same notation as Theorem 4.2, for any* $p, k \geq 1$ *such that* $p+k \leq n$*,* $p > n/2+1$*, and for every* $t > 0$

$$\mathbb{P}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right| > \frac{\sqrt{2e}\Gamma}{\sqrt{n-p+1}}\left(\sqrt{\frac{k^{3/2}}{\left\lfloor\frac{n}{n-p+1}\right\rfloor}t} + 2e\frac{k}{\left\lfloor\frac{n}{n-p+1}\right\rfloor}t^{3/2}\right)\right] \leq \left\lfloor\frac{n}{n-p+1}\right\rfloor e\cdot e^{-t},$$

where $\Gamma > 0$ *is the constant arising from* (3.6).

The present inequality is very similar to the well-known Bernstein inequality (Boucheron et al., 2013, Theorem 2.10) except the second deviation term of order $t^{3/2}$ instead of t (for the Bernstein inequality).

With respect to n, the first deviation term is of order $\approx k^{3/2}/\sqrt{n}$, which is the same as with the Bernstein inequality. The second deviation term is of a somewhat different order, that is $\approx k\sqrt{n-p+1}/n$, as compared with the usual $1/n$ in the Bernstein inequality.

Nevertheless we almost recover the k/n rate by choosing for instance $p \approx n(1-\log n/n)$, which leads to $k\sqrt{\log n}/n$. Therefore varying p allows to interpolate between the $k/\sqrt{n}$ and the k/n rates.

Note also that the dependence of the first (sub-Gaussian) deviation term with respect to k is only $k^{3/2}$, which improves upon the usual k^2 resulting from Ineq. (4.2) in Theorem 4.2 for instance. However this $k^{3/2}$ remains certainly too large for being optimal even if this question remains widely open at this stage in the literature.

More generally one strength of our approach is its versatility. Indeed the two above deviation terms directly result from the two upper bounds on the moments of the L1O established in Theorem 3.1. Therefore any improvement of the latter upper bounds would immediately lead to enhance the present concentration inequality (without changing the proof).

5. Assessing the gap between LpO and classification error

5.1. Upper bounds

First, we derive new upper bounds on different measures of the discrepancy between $\widehat{R}_{p,n} = \widehat{R}_p\left(\mathcal{A}_k, \mathcal{D}_n\right)$ and the classification error $L(\hat{f}_k)$ or the risk $R(\hat{f}_k) = \mathbb{E}\left[L(\hat{f}_k)\right]$. These bounds on the L$p$O estimator are completely new for $p > 1$, some of them being extensions of former ones specifically derived for the L1O estimator applied to the kNN classifier.

Theorem 5.1. *For every* $p, k \geq 1$ *such that* $p \leq \sqrt{k}$ *and* $\sqrt{k}+k \leq n$*, let* $\widehat{R}_{p,n}$ *denote the LpO risk estimator (see* (2.2)*) of the kNN classifier* $\hat{f}_k = \mathcal{A}_k^{\mathcal{D}_n}(\cdot)$ *defined by* (2.1)*. Then,*

$$\left|\mathbb{E}\left[\widehat{R}_{p,n}\right] - R(\hat{f}_k)\right| \leq \frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n}\ , \tag{5.1}$$

and

$$\mathbb{E}\left[\left(\widehat{R}_{p,n} - R(\hat{f}_k)\right)^2\right] \leq \frac{128\kappa\gamma_d}{\sqrt{2\pi}}\frac{k^{3/2}}{n-p+1} + \frac{16}{2\pi}\frac{p^2 k}{n^2}\ . \tag{5.2}$$

Moreover,

$$\mathbb{E}\left[\left(\widehat{R}_{p,n} - L(\hat{f}_k)\right)^2\right] \leq \frac{2\sqrt{2}}{\sqrt{\pi}}\frac{(2p+3)\sqrt{k}}{n} + \frac{1}{n}\ . \tag{5.3}$$

In contrast to the results in the previous sections, a new restriction on p arises in Theorem 5.1, that is $p \leq \sqrt{k}$. This comes from the use of Lemma D.6 (proved by Devroye and Wagner (1979b)), which gives an upper bound on the L^1 stability of the kNN classifier when p observations are removed from the training sample $\mathcal{D}_n$. Actually this upper bound only remains meaningful as long as $1 \leq p \leq \sqrt{k}$.

Proof of Theorem 5.1.
Proof of (5.1)**:** With $\hat{f}_k^e = \mathcal{A}_k^{\mathcal{D}^e}$, Lemma D.6 immediately provides

$$\begin{aligned}\left|\mathbb{E}\left[\widehat{R}_{p,n} - L(\hat{f}_k)\right]\right| &= \left|\mathbb{E}\left[L(\hat{f}_k^e)\right] - \mathbb{E}\left[L(\hat{f}_k)\right]\right| \\ &\leq \mathbb{E}\left[\left|\mathbb{1}_{\{\mathcal{A}_k^{\mathcal{D}^e}(X)\neq Y\}} - \mathbb{1}_{\{\mathcal{A}_k^{\mathcal{D}_n}(X)\neq Y\}}\right|\right] \\ &= \mathbb{P}\left(\mathcal{A}_k^{\mathcal{D}^e}(X) \neq \mathcal{A}_k^{\mathcal{D}_n}(X)\right) \leq \frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n} \ .\end{aligned}$$

Proof of (5.2)**:** The proof combines the previous upper bound with the one established for the variance of the LpO estimator, that is Eq. (3.3).

$$\begin{aligned}\mathbb{E}\left[\left(\widehat{R}_{p,n} - \mathbb{E}\left[L(\hat{f}_k)\right]\right)^2\right] &= \mathbb{E}\left[\left(\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right)^2\right] + \left(\mathbb{E}\left[\widehat{R}_{p,n}\right] - \mathbb{E}\left[L(\hat{f}_k)\right]\right)^2 \\ &\leq \frac{128\kappa\gamma_d}{\sqrt{2\pi}}\frac{k^{3/2}}{n-p+1} + \left(\frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n}\right)^2 \ ,\end{aligned}$$

which concludes the proof.

The proof of Ineq. (5.3) is more intricate and has been postponed to Appendix C.1. □

Keeping in mind that $\mathbb{E}\left[\widehat{R}_{p,n}\right] = R(\mathcal{A}_k^{\mathcal{D}_{n-p}})$, the right-hand side of Ineq. (5.1) is an upper bound on the bias of the LpO estimator, that is on the difference between the risks of the classifiers built from respectively $n-p$ and n points. Therefore, the fact that this upper bound increases with p is reliable since the classifiers $\mathcal{A}_k^{\mathcal{D}_{n-p+1}}(\cdot)$ and $\mathcal{A}_k^{\mathcal{D}_n}(\cdot)$ can become more and more different from one another as p increases. More precisely, the upper bound in Ineq. (5.1) goes to 0 provided $p\sqrt{k}/n$ does. With the additional restriction $p \leq \sqrt{k}$, this reduces to the usual condition $k/n \to 0$ as $n \to +\infty$ (see Devroye et al., 1996, Chap. 6.6 for instance), which is used to prove the universal consistency of the kNN classifier (Stone, 1977). The monotonicity of this upper upper bound with respect to k can seem somewhat unexpected. One could think that the two classifiers would become more and more "similar" to each other as k increases enough. However it can be proved that, in some sense, this dependence cannot be improved in the present distribution-free framework (see Proposition 5.1 and Figure 1).

Note that an upper bound similar to that of Ineq. (5.2) can be easily derived for any order-q moment ($q \geq 2$) at the price of increasing the constants by using $(a+b)^q \leq 2^{q-1}(a^q + b^q)$, for every $a, b \geq 0$. We also emphasize that Ineq. (5.2) allows us to control the discrepancy between the LpO estimator and the risk of the kNN classifier, that is the expectation of its classification error. Ideally we would have liked to replace the risk $R(\hat{f}_k)$ by the prediction error $L(\hat{f}_k)$. But with our strategy of proof, this would require an additional distribution-free concentration inequality on the prediction error of the kNN classifier. To the best of our knowledge, such a concentration inequality is not available up to now.

Upper bounding the squared difference between the LpO estimator and the prediction error is precisely the purpose of Ineq. (5.3). Proving the latter inequality requires a completely different strategy which can be traced back to an earlier proof by Rogers and Wagner

(1978, see the proof of Theorem 2.1) applying to the L1O estimator. Let us mention that Ineq. (5.3) combined with the Jensen inequality lead to a less accurate upper bound than Ineq. (5.1).

Finally the apparent difference between the upper bounds in Ineq. (5.2) and (5.3) results from the completely different schemes of proof. The first one allows us to derive general upper bounds for all centered moments of the LpO estimator, but exhibits a worse dependence with respect to k. By contrast the second one is exclusively dedicated to upper bounding the mean squared difference between the prediction error and the LpO estimator and leads to a smaller $\sqrt{k}$. However (even if probably not optimal), the upper bound used in Ineq. (5.2) still enables to achieve minimax rates over some Hölder balls as proved by Proposition 5.3.

5.2. Lower bounds

5.2.1. Bias of the L1O estimator

The purpose of the next result is to provide a counter-example highlighting that the upper bound of Eq. (5.1) cannot be improved in some sense. We consider the following discrete setting where $\mathcal{X} = \{0,1\}$ with $\pi_0 = P[X=0]$, and we define $\eta_0 = \mathbb{P}[Y=1 \mid X=0]$ and $\eta_1 = \mathbb{P}[Y=1 \mid X=1]$. In what follows this two-class generative model will be referred to as the discrete setting **DS**.

Note that (i) the 3 parameters π_0, η_0 and η_1 fully describe the joint distribution $P_{(X,Y)}$, and (ii) the distribution of **DS** satisfies the strong margin assumption of Massart and Nédélec (2006) if both η_0 and η_1 are chosen away from $1/2$. However this favourable setting has no particular effect on the forthcoming lower bound except a few simplifications along the calculations.

Proposition 5.1. *Let us consider the **DS** setting with $\pi_0 = 1/2$, $\eta_0 = 0$ and $\eta_1 = 1$, and assume that k is odd. Then there exists a numeric constant $C > 1$ independent of n and k such that, for all $n/2 \leq k \leq n-1$, the kNN classifiers $\mathcal{A}_k^{\mathcal{D}_n}$ and $\mathcal{A}_k^{\mathcal{D}_{n-1}}$ satisfy*

$$\mathbb{E}\left[L\left(\mathcal{A}_k^{\mathcal{D}_n}\right) - L\left(\mathcal{A}_k^{\mathcal{D}_{n-1}}\right)\right] \geq C\frac{\sqrt{k}}{n} \ .$$

The proof of Proposition 5.1 is provided in Appendix C.2. The rate $\sqrt{k}/n$ in the right-hand side of Eq. (5.1) is then achieved under the generative model **DS** for any $k \geq n/2$. As a consequence this rate cannot be improved without any additional assumption, for instance on the distribution of the X_is. See also Figure 1 below and related comments.

Empirical illustration

To further illustrate the result of Proposition 5.1, we simulated data according to **DS**, for different values of n ranging from 100 to 500 and different values of k ranging from 5 to $n-1$.

Figure 1 (a) displays the evolution of the absolute bias $\left|\mathbb{E}\left[L\left(\mathcal{A}_k^{\mathcal{D}_n}\right) - L\left(\mathcal{A}_k^{\mathcal{D}_{n-1}}\right)\right]\right|$ as a function of k, for several values of n (plain curves). The absolute bias is a nondecreasing function of k, as suggested by the upper bound provided in Eq. (5.1) which is also plotted (dashed lines) to ease the comparison. The non-decreasing behavior of the absolute bias is not always restricted to high values of k (w.r.t. n), as illustrated in Figure 1 (b) which

corresponds to **DS** with parameter values $(\pi_0, \eta_0, \eta_1) = (0.2, 0.2, 0.9)$. In particular the non-decreasing behavior of the absolute bias now appears for a range of values of k that are smaller than $n/2$.

Note that a rough idea about the location of the peak, denoted by k_{peak}, can be deduced as follows in the simple case where $\eta_0 = 0$ and $\eta_1 = 1$.

- For the peak to arise, the two classifiers (based on n and respectively $n-1$ observations) have to disagree the most strongly.
- This requires one of the two classifiers – say the first one – to have ties among the k nearest neighbors of each label in at least one of the two cases $X = 0$ or $X = 1$.
- With $\pi_0 < 0.5$, then ties will most likely occur for the case $X = 0$. Therefore the discrepancy between the two classifiers will be the highest at any new observation $x_0 = 0$.
- For the tie situation to arise at x_0, half of its neighbors have to be 1. This only occurs if (i) $k > n_0$ (with n_0 the number of observations such that $X = 0$ in the training set), and (ii) $k_0\eta_0 + k_1\eta_1 = k/2$, where k_0 (resp. k_1) is the number of neighbors of x_0 such that $X = 0$ (resp. $X = 1$).
- Since $k > n_0$, one has $k_0 = n_0$ and the last expression boils down to $k = \dfrac{n_0(\eta_1 - \eta_0)}{\eta_1 - 1/2}$.
- For large values of n, one should have $n_0 \approx n\pi_0$, that is the peak should appear at $k_{peak} \approx \dfrac{n\pi_0(\eta_1 - \eta_0)}{\eta_1 - 1/2}$.

In the setting of Proposition 5.1, this reasoning remarkably yields $k_{peak} \approx n$, while it leads to $k_{peak} \approx 0.4n$ in the setting of Figure 1 (b), which is close to the location of the observed peaks. This also suggests that even smaller values of k_{peak} can arise by tuning the parameter π_0 close to 0. Let us mention that very similar curves have been obtained for a Gaussian mixture model with two disjoint classes (not reported here). On the one hand this empirically illustrates that the $\sqrt{k}/n$ rate is not limited to **DS** (discrete setting). On the other hand, all of this confirms that this rate cannot be improved in the present distribution-free framework.

Let us finally consider Figure 1 (c), which displays the absolute bias as a function of n where $k = \lfloor \text{Coef} \times n \rfloor$ for different values of Coef, where $\lfloor \cdot \rfloor$ denotes the integer part. With this choice of k, Proposition 5.1 implies that the absolute bias should decrease at a $1/\sqrt{n}$ rate, which is supported by the plotted curves. By contrast, panel (d) of Figure 1 illustrates that choosing smaller values of k, that is $k = \lfloor \text{Coef} \times \sqrt{n} \rfloor$, leads to a faster decreasing rate.

5.2.2. Mean squared error

Following an example described by Devroye and Wagner (1979a), we now provide a lower bound on the minimal convergence rate of the mean squared error (see also Devroye et al., 1996, Chap. 24.4, p.415 for a similar argument).

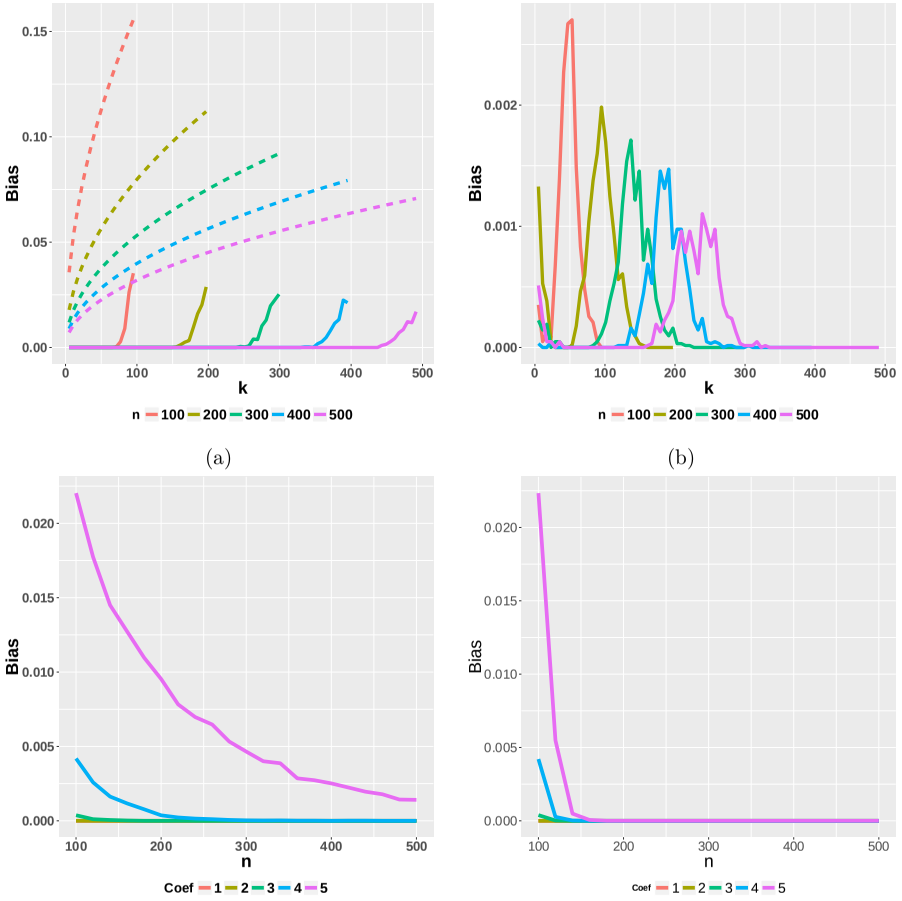

Figure 1: **(a)** Evolution of the absolute value of the bias as a function of k, for different values of n (plain lines). The dashed lines correspond to the upper bound obtained in (5.1). **(b)** Same as previous, except that data were generated according to the **DS** setting with parameters $(\pi_0, \eta_0, \eta_1) = (0.2, 0.2, 0.9)$. Upper bounds are not displayed in order to fit the scale of the absolute bias. **(c)** Evolution of the absolute value of the bias with respect to n, when k is chosen such that $k = \lfloor \text{Coef} \times n \rfloor$ ($\lfloor \cdot \rfloor$ denotes the integer part). The different colors correspond to different values of Coef. **(d)** Same as previous, except that k is chosen such that $k = \lfloor \text{Coef} \times \sqrt{n} \rfloor$.

Proposition 5.2. *Let us assume n is even, and that $P(Y=1 \mid X) = P(Y=1) = 1/2$ is independent of X. Then for $k = n-1$ (k odd), it results*

$$\mathbb{E}\left[\left(\widehat{R}_{1,n} - L(\hat{f}_k)\right)^2\right] = \int_0^1 2t \cdot \mathbb{P}\left[\left|\widehat{R}_{1,n} - L(\hat{f}_k)\right| > t\right] dt \geq \frac{1}{8\sqrt{\pi}} \cdot \frac{1}{\sqrt{n}} \ .$$

From the upper bound of order $\sqrt{k}/n$ provided by Ineq. (5.3) (with $p=1$), choosing $k = n-1$ leads to the same $1/\sqrt{n}$ rate as that of Proposition 5.2. This suggests that, at least for very large values of k, the $\sqrt{k}/n$ rate is of the right order and cannot be improved in the distribution-free framework.

5.3. Minimax rates

Let us conclude this section with a corollary, which provides a finite-sample bound on the gap between $\widehat{R}_{p,n}$ and $R(\hat{f}_k) = \mathbb{E}\left[L(\hat{f}_k)\right]$ with high probability. It is stated under the same restriction on p as the previous Theorem 5.1 it is based on, that is for $p \leq \sqrt{k}$.

Corollary 5.1. *With the notation of Theorems 4.2 and 5.1, let us assume $p, k \geq 1$ with $p \leq \sqrt{k}$, $\sqrt{k} + k \leq n$, and $p \leq n/2 + 1$. Then for every $x > 0$, there exists an event with probability at least $1 - 2e^{-x}$ such that*

$$\left|R(\hat{f}_k) - \widehat{R}_{p,n}\right| \leq \sqrt{\frac{\Delta^2 k^2}{n\left(1 - \frac{p-1}{n}\right)}x} + \frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n} \ , \tag{5.4}$$

where $\hat{f}_k = \mathcal{A}_k^{\mathcal{D}_n}(\cdot)$.

Proof of Corollary 5.1. Ineq. (5.4) results from combining the exponential concentration result derived for $\widehat{R}_{p,n}$, namely Ineq. (4.2) (from Theorem 4.2) and the upper bound on the bias, that is Ineq. (5.1).

$$\begin{aligned}\left|R(\hat{f}_k) - \widehat{R}_{p,n}\right| &\leq \left|R(\hat{f}_k) - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right| + \left|\mathbb{E}\left[\widehat{R}_{p,n}\right] - \widehat{R}_{p,n}\right| \\ &\leq \frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n} + \sqrt{\frac{\Delta^2 k^2}{n-p+1}x} \ .\end{aligned}$$

□

Note that the right-hand side of Ineq. (5.4) could be used to derive bounds on $R(\hat{f}_k)$ that seem similar to confidence bounds. However we do not recommend doing this in practice for several reasons. On the one hand, Ineq. (5.4) results from the repeated use of concentration inequalities where numeric constants are not optimized at all. This would lead to require a large sample size n for the deviation terms to be small in practice. On the other hand, explicit numeric constants such as Δ^2 in Corollary 5.1 exhibit a dependence on $\gamma_d \approx 4.8^d - 1$, which becomes exponentially large as d increases. Proving that this dependence can be weakened or not remains a completely open question at this stage. Nevertheless one can highlight that, for a given n, increasing d will quickly make the deviation term larger than 1, whereas both $R(\hat{f}_k)$ and $\widehat{R}_{p,n}$ belong to $[0,1]$.

The right-most term of order $\sqrt{k}/n$ in Ineq. (5.4) results from the bias. This is a necessary price to pay which cannot be improved in the present distribution-free framework according to Proposition 5.1. Besides combining the restriction $p \leq \sqrt{k}$ with the usual consistency constraint $k/n = o(1)$ leads to the conclusion that small values of p (w.r.t. n) have almost no effect on the convergence rate of the LpO estimator. Weakening the key restriction $p \leq \sqrt{k}$ would be necessary to potentially nuance this conclusion.

In order to highlight the interest of the above deviation inequality, let us deduce an optimality result in terms of minimax rate over Hölder balls $\mathcal{H}(\tau, \alpha)$ defined by

$$\mathcal{H}(\tau, \alpha) = \left\{g : \ \mathbb{R}^d \mapsto \mathbb{R}, \quad |g(x) - g(y)| \leq \tau \|x - y\|^\alpha\right\},$$

with $\alpha \in]0,1[$ and $\tau > 0$. In the following statement, Corollary 5.1 is used to prove that, uniformly with respect to k, the LpO estimator $\widehat{R}_{p,n}$ and the risk $R(\hat{f}_k)$ of the kNN classifier remain close to each other with high probability.

Proposition 5.3. *With the same notation as Corollary 5.1, for every $C > 1$ and $\theta > 0$, there exists an event of probability at least $1 - 2 \cdot n^{-(C-1)}$ on which, for any $p, k \geq 1$ such that $p \leq \sqrt{k}$, $k + \sqrt{k} \leq n$, and $p \leq n/2 + 1$, the LpO estimator of the kNN classifier satisfies*

$$\begin{aligned}&(1-\theta)\left[R(\hat{f}_k) - L^\star\right] - \frac{\theta^{-1}\Delta^2 C}{4}\frac{k^2\log(n)}{n\left(R(\hat{f}_k) - L^\star\right)} - \frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n} \\ &\leq \widehat{R}_p(\mathcal{A}_k, \mathcal{D}_n) - L^\star \leq (1+\theta)\left[R(\hat{f}_k) - L^\star\right] + \frac{\theta^{-1}\Delta^2 C}{4}\frac{k^2\log(n)}{n\left(R(\hat{f}_k) - L^\star\right)} + \frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n},\end{aligned} \tag{5.5}$$

where $L^\star$ denotes the classification error of the Bayes classifier.

Furthermore if one assumes the regression function η belongs to a Hölder ball $\mathcal{H}(\tau, \alpha)$ for some $\alpha \in]0, \min(d/4, 1)[$ (recall that $X_i \in \mathbb{R}^d$) and $\tau > 0$, then choosing $k = k^\star = k_0 \cdot n^{\frac{2\alpha}{2\alpha+d}}$ leads to

$$\widehat{R}_p(\mathcal{A}_{k^\star}, \mathcal{D}_n) - L^\star \sim_{n\to+\infty} R(\hat{f}_{k^\star}) - L^\star, \qquad a.s. \ . \tag{5.6}$$

Ineq. (5.5) gives a uniform control (over k) of the gap between the excess risk $R(\hat{f}_k) - L^\star$ and the corresponding LpO estimator $\widehat{R}_p(\hat{f}_k) - L^\star$ with high probability. The decreasing rate (in $n^{-(C-1)}$) of this probability is directly related to the $\log(n)$ factor in the lower and upper bounds. This decreasing rate could be made faster at the price of increasing the exponent of the $\log(n)$ factor. In a similar way the numeric constant θ has no precise meaning and can be chosen as close to 0 as we want, leading to increase one of the other deviation terms by a numeric factor θ^{-1}. For instance one could choose $\theta = 1/\log(n)$, which would replace the $\log(n)$ by a $(\log n)^2$.

The equivalence established by Eq. (5.6) results from knowing that this choice $k = k^\star$ makes the kNN classifier achieve the minimax rate $n^{-\frac{\alpha}{2\alpha+d}}$ over Hölder balls (Yang, 1999). This holds true for $\alpha \in]0,1[$ as long as $d \geq 4$. However if $d < 4$ the minimax rate is only achieved over $]0, d/4[$. This limitation results from the dependence of the deviation terms with respect to k^2 in Eq. (5.5), which is not optimal and should be further improved.

Proof of Proposition 5.3. Let us define $K \leq n$ as the maximum value of k and assume $x_k = C \cdot \log(n)$ (for some constant $C > 1$) for any $1 \leq k \leq K$. Let us also introduce the event

$$\Omega_n = \left\{ \forall 1 \leq k \leq K,\ \left| R(\hat{f}_k) - \widehat{R}_p(\mathcal{A}_k, \mathcal{D}_n) \right| \leq \sqrt{\Delta^2 \frac{k^2}{n} x_k} + \frac{4}{\sqrt{2\pi}} \frac{p\sqrt{k}}{n} \right\}.$$

Then $\mathbb{P}[\,\Omega_n^c\,] \leq \frac{1}{n^{C-1}} \to 0$, as $n \to +\infty$, since a union bound leads to

$$\sum_{k=1}^{K} e^{-x_k} = \sum_{k=1}^{K} e^{-C\cdot\log(n)} = K \cdot e^{-C\cdot\log(n)} \leq e^{-(C-1)\cdot\log(n)} = \frac{1}{n^{C-1}} \ .$$

Furthermore combining (for $a, b > 0$) the inequality $ab \leq a^2\theta^2 + b^2\theta^{-2}/4$ for every $\theta > 0$ with $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$, it results that

$$\begin{aligned}\sqrt{\Delta^2 \frac{k^2}{n} x_k} &\leq \theta \left(R(\hat{f}_k) - L^\star \right) + \frac{\theta^{-1}}{4} \Delta^2 \frac{k^2}{n \left(R(\hat{f}_k) - L^\star \right)} x_k \\ &\leq \theta \left(R(\hat{f}_k) - L^\star \right) + \frac{\theta^{-1}}{4} \Delta^2 \frac{k^2}{n \left(R(\hat{f}_k) - L^\star \right)} C \cdot \log(n),\end{aligned}$$

hence Ineq. (5.5).

Let us now prove the next equivalence, namely (5.6), by means of the Borel-Cantelli lemma.

First Yang (1999) combined with Theorem 7 in Chaudhuri and Dasgupta (2014) provide that the minimax rate over the Hölder ball $\mathcal{H}(\tau, \alpha)$ is achieved by the kNN classifier with $k = k^\star$), that is

$$\left(R(\hat{f}_{k^\star}) - L^\star \right) \asymp n^{-\frac{\alpha}{2\alpha+d}},$$

where $a \asymp b$ means there exist numeric constants $l, u > 0$ such that $l \cdot b \leq a \leq u \cdot b$. Moreover it is then easy to check that

- $D_1 := \frac{\theta^{-1}}{4} \Delta^2 \frac{k^{\star 2}}{n\left(R(\hat{f}_{k^\star}) - L^\star \right)} C \cdot \log(n) \asymp \frac{C\theta^{-1}\Delta^2 k_0}{4} \cdot \left(n^{-\frac{d-3\alpha}{2\alpha+d}} \log(n) \right) = o_{n\to+\infty}\left(R(\hat{f}_{k^\star}) - L^\star \right)$,
- $D_2 := \frac{p\sqrt{k^\star}}{n} \leq \frac{k^\star}{n} = k_0 \cdot n^{-\frac{d}{2\alpha+d}} = o_{n\to+\infty}\left(R(\hat{f}_{k^\star}) - L^\star \right)$.

Besides

$$\begin{aligned}\frac{1}{n^{C-1}} \geq \mathbb{P}[\,\Omega_n^c\,] &\geq \mathbb{P}\left[\left| \frac{\left(\widehat{R}_p(\mathcal{A}_{k^\star}, \mathcal{D}_n) - L^\star \right) - \left(R(\hat{f}_{k^\star}) - L^\star \right)}{R(\hat{f}_{k^\star}) - L^\star} \right| > \theta + \frac{D_1 + D_2}{R(\hat{f}_{k^\star}) - L^\star} \right] \\ &= \mathbb{P}\left[\left| \frac{\left(\widehat{R}_p(\mathcal{A}_{k^\star}, \mathcal{D}_n) - L^\star \right)}{R(\hat{f}_{k^\star}) - L^\star} - 1 \right| > \theta + \frac{D_1 + D_2}{R(\hat{f}_{k^\star}) - L^\star} \right].\end{aligned}$$

Let us now choose any $\epsilon > 0$ and introduce the sequence of events $\{A_n(\epsilon)\}_{n\geq 1}$ such that

$$A_n(\epsilon) = \left\{ \left| \frac{\left(\widehat{R}_p(\mathcal{A}_{k^\star}, \mathcal{D}_n) - L^\star \right)}{R(\hat{f}_{k^\star}) - L^\star} - 1 \right| > \epsilon \right\}.$$

Using that D_1 and D_2 are negligible with respect to $R(\hat{f}_{k^\star}) - L^\star$ as $n \to +\infty$, there exists an integer $n_0 = n_0(\epsilon) > 0$ such that, for all $n \geq n_0$ and with $\theta = \epsilon/2$,

$$\theta + \frac{D_1 + D_2}{R(\hat{f}_{k^\star}) - L^\star} \leq \epsilon.$$

Hence

$$\mathbb{P}[\,A_n(\epsilon)\,] \leq \mathbb{P}\left[\left\{ \left| \frac{\left(\widehat{R}_p(\mathcal{A}_{k^\star}, \mathcal{D}_n) - L^\star \right)}{R(\hat{f}_{k^\star}) - L^\star} - 1 \right| > \theta + \frac{D_1 + D_2}{R(\hat{f}_{k^\star}) - L^\star} \right\} \right] \leq \frac{1}{n^{C-1}} \ .$$

Finally, choosing any $C > 2$ leads to $\sum_{n=1}^{+\infty} \mathbb{P}[\,A_n(\epsilon)\,] < +\infty$, which provides the expected conclusion by means of the Borel-Cantelli lemma. □

6. Discussion

The present work provides several new results quantifying the performance of the LpO estimator applied to the kNN classifier. By exploiting the connexion between LpO and U-statistics (Section 2), the polynomial and exponential inequalities derived in Sections 3 and 4 give some new insight on the concentration of the LpO estimator around its expectation for different regimes of p/n. In Section 5, these results serve for instance to conclude to the consistency of the LpO estimator towards the risk (or the classification error rate) of the kNN classifier (Theorem 5.1). They also allow us to establish the asymptotic equivalence between the LpO estimator (shifted by the Bayes risk $L^\star$) and the excess risk over some Hölder class of regression functions (Proposition 5.3).

It is worth mentioning that the upper-bounds derived in Sections 4 and 5 — see for instance Theorem 5.1 — can be minimized by choosing $p = 1$, suggesting that the L1O estimator is optimal in terms of risk estimation when applied to the kNN classification algorithm. This observation corroborates the results of the simulation study presented in Celisse and Mary-Huard (2011), where it is empirically shown that small values of p (and in particular $p = 1$) lead to the best estimation of the risk for any fixed k, whatever the level of noise in the data. The suggested optimality of L1O (for risk estimation) is also consistent with results by Burman (1989) and Celisse (2014), where it is proved that L1O is asymptotically the best cross-validation procedure to perform risk estimation in the context of low-dimensional regression and density estimation respectively.

Alternatively, the LpO estimator can also be used as a data-dependent calibration procedure to tune k, by choosing the value $\hat{k}_p$ which minimizes the LpO estimate. For instance

in classification, LpO can be used to get the value of k leading to the best prediction performance. In this context the value of p (the splitting ratio) leading to the best kNN classifier can be very different from $p = 1$. This is illustrated by the simulation results summarized by Figure 2 in Celisse and Mary-Huard (2011) where p has to be larger than 1 as the noise level becomes strong. This phenomenon is not limited to the kNN classifier, but extends to various estimation/prediction problems (Breiman and Spector, 1992; Arlot and Lerasle, 2012; Celisse, 2014). If we turn now to the question of identifying the best predictor among several candidates, choosing $p = 1$ also leads to poor selection performances as proved by Shao (1993, Eq. (3.8)) with the linear regression model. For the LpO, Shao (1997, Theorem 5) proves the model selection consistency if $p/n \to 1$ and $n - p \to +\infty$ as $n \to +\infty$. For recovering the best predictor among two candidates, Yang (2006, 2007) proved the consistency of CV under conditions relating the optimal splitting ratio p to the convergence rates of the predictors to be compared, and further requiring that $\min(p, n - p) \to +\infty$ as $n \to +\infty$.

Although the focus of the present paper is different, it is worth mentioning that the concentration results established in Section 4 are a significant early step towards deriving theoretical guarantees on LpO as a model selection procedure. Indeed, exponential concentration inequalities have been a key ingredient to assess model selection consistency or model selection efficiency in various contexts (see for instance Celisse (2014) or Arlot and Lerasle (2012) in the density estimation framework). Still theoretically investigating the behavior of $\hat{k}_p$ requires some further dedicated developments. One first step towards such results is to derive a tighter upper bound on the bias between the LpO estimator and the risk. The best known upper bound currently available is derived from Devroye and Wagner (1980, see Lemma D.6 in the present paper). Unfortunately it does not fully capture the true behavior of the LpO estimator with respect to p (at least as p becomes large) and could be improved in particular for $p > \sqrt{k}$ as emphasized in the comments following Theorem 5.1. Another important direction for studying the model selection behavior of the LpO procedure is to prove a concentration inequality for the classification error rate of the kNN classifier around its expectation. While such concentration results have been established for the kNN algorithm in the (fixed-design) regression framework (Arlot and Bach, 2009), deriving similar results in the classification context remains a challenging problem to the best of our knowledge.

Appendix A. Proofs of polynomial moment upper bounds

A.1. Proof of Theorem 2.2

The proof relies on Proposition 2.1 that allows to relate the LpO estimator to a sum of independent random variables. In the following, we distinguish between the two settings $q = 2$ (where exact calculations can be carried out), and $q > 2$ where only upper bounds can be derived.

When $q > 2$, our proof deals separately with the cases $p \leq n/2 + 1$ and $p > n/2 + 1$. In the first one, a straightforward use of Jensen's inequality leads to the result. In the second setting, one has to be more cautious when deriving upper bounds. This is done by using the more sophisticated Rosenthal's inequality, namely Proposition D.2.

A.1.1. Exploiting Proposition 2.1

According to the proof of Proposition 2.1, it arises that the LpO estimator can be expressed as a U-statistic since

$$\widehat{R}_{p,n} = \frac{1}{n!} \sum_{\sigma} W\left(Z_{\sigma(1)}, \ldots, Z_{\sigma(n)}\right) \ ,$$

with

$$W\left(Z_1, \ldots, Z_n\right) = \left\lfloor \frac{n}{m} \right\rfloor^{-1} \sum_{a=1}^{\lfloor \frac{n}{m} \rfloor} h_m\left(Z_{(a-1)m+1}, \ldots, Z_{am}\right) \qquad (\text{with } m = n - p + 1)$$

$$\text{and} \quad h_m\left(Z_1, \ldots, Z_m\right) = \frac{1}{m} \sum_{i=1}^{m} \mathbb{1}_{\left\{\mathcal{A}^{\mathcal{D}_m^{(i)}}(X_i) \neq Y_i\right\}} = \widehat{R}_{1,n-p+1} \ ,$$

where $\mathcal{A}^{\mathcal{D}_m^{(i)}}(.)$ denotes the classifier based on sample $\mathcal{D}_m^{(i)} = (Z_1, \ldots, Z_{i-1}, Z_{i+1}, \ldots, Z_m)$. Further centering the LpO estimator, it comes

$$\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right] = \frac{1}{n!} \sum_{\sigma} \bar{W}\left(Z_{\sigma(1)}, \ldots, Z_{\sigma(n)}\right),$$

where $\bar{W}(Z_1, \ldots, Z_n) = W(Z_1, \ldots, Z_n) - \mathbb{E}\left[W(Z_1, \ldots, Z_n)\right]$.

Then with $\bar{h}_m(Z_1, \ldots, Z_m) = h_m(Z_1, \ldots, Z_m) - \mathbb{E}\left[h_m(Z_1, \ldots, Z_m)\right]$, one gets

$$\begin{aligned}
\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^q\right] &\leq \mathbb{E}\left[\left|\bar{W}\left(Z_1, \ldots, Z_n\right)\right|^q\right] \quad (\text{Jensen}'\text{s inequality}) \\
&= \mathbb{E}\left[\left|\left\lfloor \frac{n}{m} \right\rfloor^{-1} \sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \bar{h}_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right|^q\right] \qquad (A.1) \\
&= \left\lfloor \frac{n}{m} \right\rfloor^{-q} \mathbb{E}\left[\left|\sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \bar{h}_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right|^q\right] .
\end{aligned}$$

A.1.2. The setting $q = 2$

If $q = 2$, then by independence it comes

$$\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^q\right] \leq \left\lfloor \frac{n}{m} \right\rfloor^{-2} \mathrm{Var}\left(\sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} h_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right)$$
$$= \left\lfloor \frac{n}{m} \right\rfloor^{-2} \sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \mathrm{Var}\left[\, h_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right]$$
$$= \left\lfloor \frac{n}{m} \right\rfloor^{-1} \mathrm{Var}\left(\widehat{R}_1(\mathcal{A}, Z_{1,n-p+1})\right),$$

which leads to the result.

A.1.3. The setting $q > 2$

If $p \leq n/2 + 1$:

A straightforward use of Jensen's inequality from (A.1) provides

$$\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^q\right] \leq \left\lfloor \frac{n}{m} \right\rfloor^{-1} \sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \mathbb{E}\left[\left|\bar{h}_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right|^q\right]$$
$$= \mathbb{E}\left[\left|\widehat{R}_{1,n-p+1} - \mathbb{E}\left[\widehat{R}_{1,n-p+1}\right]\right|^q\right].$$

If $p > n/2 + 1$: Let us now use Rosenthal's inequality (Proposition D.2) by introducing symmetric random variables $\zeta_1, \ldots, \zeta_{\lfloor n/m \rfloor}$ such that

$$\forall 1 \leq i \leq \lfloor n/m \rfloor, \quad \zeta_i = h_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right) - h_m\left(Z'_{(i-1)m+1}, \ldots, Z'_{im}\right),$$

where $Z'_1, \ldots, Z'_n$ are *i.i.d.* copies of $Z_1, \ldots, Z_n$. Then it comes for every $\gamma > 0$

$$\mathbb{E}\left[\left|\sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \bar{h}_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right|^q\right] \leq \mathbb{E}\left[\left|\sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \zeta_i\right|^q\right],$$

which implies

$$\mathbb{E}\left[\left|\sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \bar{h}_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right|^q\right] \leq B(q,\gamma) \max\left\{\gamma \sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \mathbb{E}\left[\,|\zeta_i|^q\,\right], \left(\sqrt{\sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \mathbb{E}\left[\,\zeta_i^2\,\right]}\right)^q\right\}.$$

Then using for every i that

$$\mathbb{E}\left[\,|\zeta_i|^q\right] \leq 2^q \mathbb{E}\left[\,\left|\bar{h}_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right|^q\right],$$

it comes

$$\mathbb{E}\left[\left|\sum_{i=1}^{\lfloor \frac{n}{m} \rfloor} \bar{h}_m\left(Z_{(i-1)m+1}, \ldots, Z_{im}\right)\right|^q\right]$$
$$\leq B(q,\gamma) \max\left(2^q \gamma \left\lfloor \frac{n}{m} \right\rfloor \mathbb{E}\left[\left|\widehat{R}_{1,m} - \mathbb{E}\left[\,\widehat{R}_{1,m}\,\right]\right|^q\right], \left(\sqrt{\left\lfloor \frac{n}{m} \right\rfloor 2\mathrm{Var}\left(\widehat{R}_{1,m}\right)}\right)^q\right).$$

Hence, it results for every $q > 2$

$$\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^q\right]$$
$$\leq B(q,\gamma) \max\left(2^q \gamma \left\lfloor \frac{n}{m} \right\rfloor^{-q+1} \mathbb{E}\left[\left|\widehat{R}_{1,m} - \mathbb{E}\left[\,\widehat{R}_{1,m}\,\right]\right|^q\right], \left\lfloor \frac{n}{m} \right\rfloor^{-q/2} \left(\sqrt{2\mathrm{Var}\left(\widehat{R}_{1,m}\right)}\right)^q\right),$$

which concludes the proof.

A.2. Proof of Theorem 3.1

Our strategy of proof follows several ideas. The first one consists in using Proposition 3.1 which says that, for every $q \geq 2$,

$$\left\|\bar{h}_m(Z_1, \ldots, Z_m)\right\|_q \leq \sqrt{2\kappa q} \sqrt{\left\|\sum_{j=1}^{m} \left(h_m(Z_1, \ldots, Z_m) - h_m(Z_1, \ldots, Z'_j, \ldots, Z_m)\right)^2\right\|_{q/2}},$$

where $h_m(Z_1, \ldots, Z_m) = \widehat{R}_{1,m}$ by Eq. (2.4), and $\bar{h}_m(Z_1, \ldots, Z_m) = h_m(Z_1, \ldots, Z_m) - \mathbb{E}\left[\, h_m(Z_1, \ldots, Z_m)\,\right]$. The second idea consists in deriving upper bounds of

$$\Delta^j h_m = h_m(Z_1, \ldots, Z_j, \ldots, Z_m) - h_m(Z_1, \ldots, Z'_j, \ldots, Z_m)$$

by repeated uses of Stone's lemma, that is Lemma D.5 which upper bounds by $k\gamma_d$ the maximum number of X_is that can have a given X_j among their k nearest neighbors. Finally, for technical reasons we have to distinguish the case $q = 2$ (where we get tighter bounds) and $q > 2$.

A.2.1. Upper bounding $\Delta^j h_m$

For the sake of readability let us now use the notation $\mathcal{D}^{(i)} = \mathcal{D}_m^{(i)}$ (see Theorem 2.1), and let $\mathcal{D}_j^{(i)}$ denote the set $\left(Z_1, \ldots, Z'_j, \ldots, Z_n\right)$ where the i-th coordinate has been removed. Then, $\Delta^j h_m = h_m(Z_1, \ldots, Z_m) - h_m(Z_1, \ldots, Z'_j, \ldots, Z_m)$ is now upper bounded by

$$\left|\Delta^j h_m\right| \leq \frac{1}{m} + \frac{1}{m} \sum_{i \neq j} \left| \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq Y_i\right\}} - \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i) \neq Y_i\right\}} \right|$$
$$\leq \frac{1}{m} + \frac{1}{m} \sum_{i \neq j} \left| \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i)\right\}} \right|. \tag{A.2}$$

Furthermore, let us introduce for every $1 \leq j \leq n$,

$$A_j = \{1 \leq i \leq m,\ i \neq j,\ j \in V_k(X_i)\} \text{ and } A'_j = \left\{1 \leq i \leq m,\ i \neq j,\ j \in V'_k(X_i)\right\}$$

where $V_k(X_i)$ and $V'_k(X_i)$ denote the indices of the k nearest neighbors of X_i respectively among $X_1, \ldots, X_{j-1}, X_j, X_{j+1}, \ldots, X_m$ and $X_1, ..., X_{j-1}, X'_j, X_{j+1}, \ldots, X_m$. Setting $B_j = A_j \cup A'_j$, one obtains

$$\left|\Delta^j h_m\right| \leq \frac{1}{m} + \frac{1}{m} \sum_{i \in B_j} \left| \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i)\right\}} \right|. \tag{A.3}$$

From now on, we distinguish between $q = 2$ and $q > 2$ because we will be able to derive a tighter bound for $q = 2$ than for $q > 2$.

A.2.2. Case $q > 2$

From (A.3), Stone's lemma (Lemma D.5) provides

$$\left|\Delta^j h_m\right| \leq \frac{1}{m} + \frac{1}{m} \sum_{i \in B_j} \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i)\right\}} \leq \frac{1}{m} + \frac{2k\gamma_d}{m} \ .$$

Summing over $1 \leq j \leq n$ and applying $(a+b)^q \leq 2^{q-1}\left(a^q + b^q\right)$ $(a, b \geq 0$ and $q \geq 1)$, it comes

$$\sum_j \left(\Delta^j h_m\right)^2 \leq \frac{2}{m}\left(1 + (2k\gamma_d)^2\right) \leq \frac{4}{m}(2k\gamma_d)^2 \ ,$$

hence

$$\left\| \sum_{j=1}^m \left(h_m(Z_1, \ldots, Z_m) - h_m(Z_1, \ldots, Z'_j, \ldots, Z_m)\right)^2 \right\|_{q/2} \leq \frac{4}{m}(2k\gamma_d)^2.$$

This leads for every $q > 2$ to

$$\left\|\bar{h}_m(Z_1, \ldots, Z_m)\right\|_q \leq q^{1/2}\sqrt{2\kappa}\frac{4k\gamma_d}{\sqrt{m}} \ ,$$

which enables to conclude.

A.2.3. Case $q = 2$

It is possible to obtain a slightly better upper bound in the case $q = 2$ with the following reasoning. With the same notation as above and from (A.3), one has

$$\begin{aligned}
\mathbb{E}\left[\left(\Delta^j h_m\right)^2\right] &= \frac{2}{m^2} + \frac{2}{m^2}\mathbb{E}\left[\left(\sum_{i \in B_j} \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i)\right\}}\right)^2\right] \qquad \text{(using } \mathbb{1}_{\{\cdot\}} \leq 1\text{)} \\
&\leq \frac{2}{m^2} + \frac{2}{m^2}\mathbb{E}\left[|B_j| \sum_{i \in B_j} \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i)\right\}}\right].
\end{aligned}$$

Lemma D.5 implies $|B_j| \leq 2k\gamma_d$, which allows to conclude

$$\mathbb{E}\left[\left(\Delta^j h_m\right)^2\right] \leq \frac{2}{m^2} + \frac{4k\gamma_d}{m^2}\mathbb{E}\left[\sum_{i \in B_j} \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i)\right\}}\right].$$

Summing over j and introducing an independent copy of Z_1 denoted by Z_0, one derives

$$\begin{aligned}
&\sum_{j=1}^m \mathbb{E}\left[\left(h_m(Z_1, \ldots, Z_m) - h_m(Z_1, \ldots, Z'_j, \ldots, Z_m)\right)^2\right] \\
&\leq \frac{2}{m} + \frac{4k\gamma_d}{m}\sum_{i=1}^m \mathbb{E}\left[\mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)}}(X_i) \neq \mathcal{A}_k^{\mathcal{D}^{(i)} \cup Z_0}(X_i)\right\}} + \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^{(i)} \cup Z_0}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^{(i)}}(X_i)\right\}}\right] \\
&\leq \frac{2}{m} + 4k\gamma_d \times 2\frac{4\sqrt{k}}{\sqrt{2\pi}m} = \frac{2}{m} + \frac{32\gamma_d}{\sqrt{2\pi}}\frac{k\sqrt{k}}{m} \leq (2 + 16\gamma_d)\frac{k\sqrt{k}}{m} \ ,
\end{aligned} \tag{A.4}$$

where the last but one inequality results from Lemma D.6.

A.3. Proof of Theorem 3.2

The idea is to plug the upper bounds previously derived for the L1O estimator, namely Ineq. (2.5) and (2.6) from Theorem 2.2, in the inequalities proved for the moments of the LpO estimator in Theorem 2.2.

Proof of Ineq. (3.3), (3.4), and (3.5): These inequalities straightforwardly result from the combination of Theorem 2.2 and Ineq. (2.5) and (2.6) from Theorem 3.1.

Proof of Ineq. (3.6): It results from the upper bounds proved in Theorem 3.1 and plugged in Ineq. (2.7) (derived from Rosenthal's inequality with optimized constant γ, namely Proposition D.3).

Then it comes

$$\begin{aligned}
&\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n}\right]\right|^q\right] \leq \left(2\sqrt{2e}\right)^q \times \\
&\max\left\{(\sqrt{q})^q\left(\sqrt{\left\lfloor\frac{n}{n-p+1}\right\rfloor^{-1} 2C_1\sqrt{k}\left(\frac{\sqrt{k}}{\sqrt{n-p+1}}\right)^2}\right)^q, q^q\left\lfloor\frac{n}{n-p+1}\right\rfloor^{-q+1}(2C_2\sqrt{q})^q\left(\frac{k}{\sqrt{n-p+1}}\right)^q\right\} \\
&= \left(2\sqrt{2e}\right)^q \times \\
&\max\left\{(\sqrt{q})^q\left(\sqrt{2C_1\sqrt{k}}\sqrt{\frac{k}{(n-p+1)\left\lfloor\frac{n}{n-p+1}\right\rfloor}}\right)^q, \left(q^{3/2}\right)^q\left\lfloor\frac{n}{n-p+1}\right\rfloor\left(2C_2\frac{k}{\left\lfloor\frac{n}{n-p+1}\right\rfloor\sqrt{n-p+1}}\right)^q\right\} \\
&\leq \left\lfloor\frac{n}{n-p+1}\right\rfloor \max\left\{\left(\lambda_1 q^{1/2}\right)^q, \left(\lambda_2 q^{3/2}\right)^q\right\},
\end{aligned}$$

with

$$\lambda_1 = 2\sqrt{2e}\sqrt{2C_1\sqrt{k}}\sqrt{\frac{k}{(n-p+1)\left\lfloor \frac{n}{n-p+1}\right\rfloor}}, \quad \lambda_2 = 2\sqrt{2e}2C_2\frac{k}{\left\lfloor \frac{n}{n-p+1}\right\rfloor \sqrt{n-p+1}} \ .$$

Finally introducing $\Gamma = 2\sqrt{2e}\max\left(2C_2, \sqrt{2C1}\right)$ provides the result.

Appendix B. Proofs of exponential concentration inequalities

B.1. Proof of Proposition 4.1

The proof relies on two successive ingredients: McDiarmid's inequality (Theorem D.3), and Stone's lemma (Lemma D.5).

First with $\mathcal{D}_n = \mathcal{D}$ and $\mathcal{D}_j = (Z_1, \ldots, Z_{j-1}, Z'_j, Z_{j+1}, \ldots, Z_n)$, let us start by upper bounding $\left|\widehat{R}_p\left(\mathcal{D}_n\right) - \widehat{R}_p\left(\mathcal{D}_j\right)\right|$ for every $1 \leq j \leq n$.

Using Eq. (2.2), one has

$$\begin{aligned}
&\left|\widehat{R}_p\left(\mathcal{D}\right) - \widehat{R}_p\left(\mathcal{D}_j\right)\right| \\
&\leq \frac{1}{p}\sum_{i=1}^{n}\binom{n}{p}^{-1}\sum_{e}\left|\mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^e}(X_i)\neq Y_i\right\}} - \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}_j^e}(X_i)\neq Y_i\right\}}\right|\mathbb{1}_{\{i\notin e\}} \\
&\leq \frac{1}{p}\sum_{i=1}^{n}\binom{n}{p}^{-1}\sum_{e}\mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^e}(X_i)\neq \mathcal{A}_k^{\mathcal{D}_j^e}(X_i)\right\}}\mathbb{1}_{\{i\notin e\}} \\
&\leq \frac{1}{p}\sum_{i\neq j}^{n}\binom{n}{p}^{-1}\sum_{e}\left[\mathbb{1}_{\left\{j\in V_k^{\mathcal{D}^e}(X_i)\right\}} + \mathbb{1}_{\left\{j\in V_k^{\mathcal{D}_j^e}(X_i)\right\}}\right]\mathbb{1}_{\{i\notin e\}} + \frac{1}{p}\binom{n}{p}^{-1}\sum_{e}\mathbb{1}_{\{j\notin e\}},
\end{aligned}$$

where $\mathcal{D}_j^e$ denotes the set of random variables among $\mathcal{D}_j$ having indices in e, and $V_k^{\mathcal{D}^e}(X_i)$ (resp. $V_k^{\mathcal{D}_j^e}(X_i)$) denotes the set of indices of the k nearest neighbors of X_i among $\mathcal{D}^e$ (resp. $\mathcal{D}_j^e$).

Second, let us now introduce

$$B_j^{\mathcal{E}_{n-p}} = \bigcup_{e\in\mathcal{E}_{n-p}}\left\{1\leq i\leq n,\ i\notin e\cup\{j\},\ V_k^{\mathcal{D}_j^e}(X_i)\ni j \text{ or } V_k^{\mathcal{D}^e}(X_i)\ni j\right\}.$$

Then Lemma D.5 implies $\mathrm{Card}(B_j^{\mathcal{E}_{n-p}}) \leq 2(k+p-1)\gamma_d$, hence

$$\left|\widehat{R}_p\left(\mathcal{D}_n\right) - \widehat{R}_p\left(\mathcal{D}_j\right)\right| \leq \frac{1}{p}\sum_{i\in B_j^{\mathcal{E}_{n-p}}}\binom{n}{p}^{-1}\sum_{e}2\cdot\mathbb{1}_{\{i\notin e\}} + \frac{1}{n} \leq \frac{4(k+p-1)\gamma_d}{n} + \frac{1}{n} \ .$$

The conclusion results from McDiarmid's inequality (Section D.1.5).

B.2. Proof of Theorem 4.1

In this proof, we use the same notation as in that of Proposition 4.1.

The goal of the proof is to provide a refined version of previous Proposition 4.1 by taking into account the status of each X_j as one of the k nearest neighbors of a given X_i (or not).

To do so, our strategy is to prove a sub-Gaussian concentration inequality by use of Lemma D.2, which requires the control of the even moments of the LpO estimator $\widehat{R}_p$.

Such upper bounds are derived

- First, by using Ineq. (D.4) (generalized Efron-Stein inequality), which amounts to control the q-th moments of the differences

$$\widehat{R}_p(\mathcal{D}) - \widehat{R}_p\left(\mathcal{D}_j\right).$$

- Second, by precisely evaluating the contribution of each neighbor X_i of a given X_j, that is by computing quantities such as $\mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i)\right]$, where $\mathbb{P}_e[\cdot]$ denotes the probability measure with respect to the uniform random variable e over $\mathcal{E}_{n-p}$, and $V_k^{\mathcal{D}^e}(X_i)$ denotes the indices of the k nearest neighbors of X_i among $X^e = \{X_\ell, \ell \in e\}$.

B.2.1. Upper bounding $\widehat{R}_p(\mathcal{D}) - \widehat{R}_p(\mathcal{D}_j)$

For every $1 \le j \le n$, one gets

$$\widehat{R}_p(\mathcal{D}) - \widehat{R}_p(\mathcal{D}_j) = \binom{n}{p}^{-1} \sum_e \left\{ \mathbb{1}_{\{j\in\bar{e}\}} \frac{1}{p} \left(\mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^e}(X_j) \neq Y_j\right\}} - \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^e}(X'_j) \neq Y'_j\right\}} \right) \right.$$
$$\left. + \mathbb{1}_{\{j\in e\}} \frac{1}{p} \sum_{i\in\bar{e}} \left(\mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^e}(X_i) \neq Y_i\right\}} - \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}_j^e}(X_i) \neq Y_i\right\}} \right) \right\}.$$

Absolute values and Jensen's inequality then provide

$$\begin{aligned}
\left|\widehat{R}_p(\mathcal{D}) - \widehat{R}_p(\mathcal{D}_j)\right| &\le \binom{n}{p}^{-1} \sum_e \left\{ \mathbb{1}_{\{j\in\bar{e}\}} \frac{1}{p} + \mathbb{1}_{\{j\in e\}} \frac{1}{p} \sum_{i\in\bar{e}} \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^e}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^e}(X_i)\right\}} \right\} \\
&\le \frac{1}{n} + \binom{n}{p}^{-1} \sum_e \mathbb{1}_{\{j\in e\}} \frac{1}{p} \sum_{i\in\bar{e}} \mathbb{1}_{\left\{\mathcal{A}_k^{\mathcal{D}^e}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^e}(X_i)\right\}} \\
&= \frac{1}{n} + \frac{1}{p} \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ \mathcal{A}_k^{\mathcal{D}^e}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^e}(X_i) \right].
\end{aligned}$$

where the notation $\mathbb{P}_e$ means the integration is carried out with respect to the random variable $e \in \mathcal{E}_{n-p}$, which follows a discrete uniform distribution over the set $\mathcal{E}_{n-p}$ of all $n-p$ distinct indices among $\{1,\dots,n\}$.

Let us further notice that $\left\{\mathcal{A}_k^{\mathcal{D}^e}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^e}(X_i)\right\} \subset \left\{ j \in V_k^{\mathcal{D}^e}(X_i) \cup V_k^{\mathcal{D}_j^e}(X_i) \right\}$, where $V_k^{\mathcal{D}_j^e}(X_i)$ denotes the set of indices of the k nearest neighbors of X_i among $\mathcal{D}_j^e$ with the notation of the proof of Proposition 4.1. Then it results

$$\begin{aligned}
&\sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ \mathcal{A}_k^{\mathcal{D}^e}(X_i) \neq \mathcal{A}_k^{\mathcal{D}_j^e}(X_i) \right] \\
&\le \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \cup V_k^{\mathcal{D}_j^e}(X_i) \right] \\
&\le \sum_{i=1}^n \left(\mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] + \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \cup V_k^{\mathcal{D}_j^e}(X_i) \right] \right) \\
&\le 2 \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right],
\end{aligned}$$

which leads to

$$\left|\widehat{R}_p(\mathcal{D}) - \widehat{R}_p(\mathcal{D}_j)\right| \le \frac{1}{n} + \frac{2}{p} \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right].$$

Summing over $1 \le j \le n$ the square of the above quantity, it results

$$\begin{aligned}
\sum_{j=1}^n \left(\widehat{R}_p(\mathcal{D}) - \widehat{R}_p(\mathcal{D}_j)\right)^2 &\le \sum_{j=1}^n \left\{ \frac{1}{n} + \frac{2}{p} \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2 \\
&\le 2 \sum_{j=1}^n \frac{1}{n^2} + 2 \left\{ \frac{2}{p} \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2 \\
&\le \frac{2}{n} + 8 \sum_{j=1}^n \left\{ \frac{1}{p} \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2.
\end{aligned}$$

B.2.2. Evaluating the influence of each neighbor

Further using that

$$\begin{aligned}
&\sum_{j=1}^n \left(\frac{1}{p} \sum_{i=1}^n \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right)^2 \\
&= \sum_{j=1}^n \frac{1}{p^2} \sum_{i=1}^n \left(\mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right)^2 + \\
&\quad \sum_{j=1}^n \frac{1}{p^2} \sum_{1\le i\neq \ell\le n} \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_\ell) \right] \\
&= \quad T1 \quad + \quad T2\ ,
\end{aligned}$$

let us now successively deal with each of these two terms.

Upper bound on $T1$

First, we start by partitioning the sum over j depending on the rank of X_j as a neighbor of X_i in the whole sample $(X_1,\dots,X_n)$. It comes

$$\begin{aligned}
&= \sum_{j=1}^n \sum_{i=1}^n \left\{ \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2 \\
&= \sum_{i=1}^n \left(\sum_{j\in V_k(X_i)} \left\{ \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2 + \sum_{j\in V_{k+p}(X_i)\setminus V_k(X_i)} \left\{ \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2 \right).
\end{aligned}$$

Then Lemma D.4 leads to

$$\begin{aligned}
&\sum_{j\in V_k(X_i)} \left\{ \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2 + \sum_{j\in V_{k+p}(X_i)\setminus V_k(X_i)} \left\{ \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \right\}^2 \\
&\le \sum_{j\in V_k(X_i)} \left(\frac{p}{n} \frac{n-p}{n-1} \right)^2 + \sum_{j\in V_{k+p}(X_i)\setminus V_k(X_i)} \mathbb{P}_e\left[j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i) \right] \frac{p}{n} \frac{n-p}{n-1} \\
&= k \left(\frac{p}{n} \frac{n-p}{n-1} \right)^2 + \frac{kp}{n} \frac{p-1}{n-1} \frac{p}{n} \frac{n-p}{n-1} = k \left(\frac{p}{n} \right)^2 \frac{n-p}{n-1}\ ,
\end{aligned}$$

where the upper bound results from $\sum_j a_j^2 \leq (\max_j a_j)\sum_j a_j$, for $a_j \geq 0$. It results

$$T1 = \frac{1}{p^2}\sum_{j=1}^{n}\sum_{i=1}^{n}\left\{\mathbb{P}_e\left[\, j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i)\,\right]\right\}^2 \leq \frac{1}{p^2} n\left[k\left(\frac{p}{n}\right)^2 \frac{n-p}{n-1}\right] = \frac{k}{n}\frac{n-p}{n-1}\ .$$

Upper bound on $T2$

Let us now apply the same idea to the second sum, partitioning the sum over j depending on the rank of j as a neighbor of ℓ in the whole sample. Then,

$$\begin{aligned}
T2 &= \frac{1}{p^2}\sum_{j=1}^{n}\sum_{1\leq i\neq \ell\leq n}\mathbb{P}_e\left[\, j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i)\,\right]\mathbb{P}_e\left[\, j \in e,\ \ell \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_\ell)\,\right] \\
&\leq \frac{1}{p^2}\sum_{i=1}^{n}\sum_{\ell\neq i}\sum_{j\in V_k(X_\ell)}\mathbb{P}_e\left[\, j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i)\,\right]\frac{p}{n}\frac{n-p}{n-1} \\
&\quad + \frac{1}{p^2}\sum_{i=1}^{n}\sum_{\ell\neq i}\sum_{j\in V_{k+p}(X_\ell)\setminus V_k(X_\ell}\mathbb{P}_e\left[\, j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i)\,\right]\frac{kp}{n}\frac{p-1}{n-1}\ .
\end{aligned}$$

We then apply Stone's lemma (Lemma D.5) to get

$$\begin{aligned}
&T2 \\
&= \frac{1}{p^2}\sum_{i=1}^{n}\sum_{j=1}^{n}\mathbb{P}_e\left[\, j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i)\,\right]\left(\sum_{\ell\neq i}\mathbb{1}_{j\in V_k(X_\ell)}\frac{p}{n}\frac{n-p}{n-1} + \sum_{\ell\neq i}\mathbb{1}_{j\in V_{k+p}(X_\ell)\setminus V_k(X_\ell}\frac{kp}{n}\frac{p-1}{n-1}\right) \\
&\leq \frac{1}{p^2}\sum_{i=1}^{n}\frac{kp}{n}\left(k\gamma_d\frac{p}{n}\frac{n-p}{n-1} + (k+p)\gamma_d\frac{kp}{n}\frac{p-1}{n-1}\right) = \gamma_d\frac{k^2}{n}\left(\frac{n-p}{n-1} + (k+p)\frac{p-1}{n-1}\right) \\
&= \gamma_d\frac{k^2}{n}\left(1 + (k+p-1)\frac{p-1}{n-1}\right).
\end{aligned}$$

Gathering the upper bounds

The two previous bounds provide

$$\begin{aligned}
\sum_{j=1}^{n}\left\{\frac{1}{p}\sum_{i=1}^{n}\mathbb{P}_e\left[\, j \in e,\ i \in \bar{e},\ j \in V_k^{\mathcal{D}^e}(X_i)\,\right]\right\}^2 &= T1 + T2 \\
&\leq \frac{k}{n}\frac{n-p}{n-1} + \gamma_d\frac{k^2}{n}\left(1 + (k+p-1)\frac{p-1}{n-1}\right),
\end{aligned}$$

which enables to conclude

$$\begin{aligned}
&\sum_{j=1}^{n}\left(\widehat{R}_p(\mathcal{D}) - \widehat{R}_p(\mathcal{D}_j)\right)^2 \\
&\leq \frac{2}{n}\left(1 + 4k + 4k^2\gamma_d\left[1 + (k+p)\frac{p-1}{n-1}\right]\right) \leq \frac{8k^2(1+\gamma_d)}{n}\left[1 + (k+p)\frac{p-1}{n-1}\right].
\end{aligned}$$

B.2.3. Generalized Efron-Stein inequality

Then (D.4) provides for every $q \geq 1$

$$\left\|\widehat{R}_{p,n} - \mathbb{E}\left[\,\widehat{R}_{p,n}\,\right]\right\|_{2q} \leq 4\sqrt{\kappa q}\sqrt{\frac{8(1+\gamma_d)k^2}{n}\left[1 + (k+p)\frac{p-1}{n-1}\right]}.$$

Hence combined with $q! \geq q^q e^{-q}\sqrt{2\pi q}$, it comes

$$\begin{aligned}
\mathbb{E}\left[\left(\widehat{R}_{p,n} - \mathbb{E}\left[\,\widehat{R}_{p,n}\,\right]\right)^{2q}\right] &\leq (16\kappa q)^q\left(\frac{8(1+\gamma_d)k^2}{n}\left[1 + (k+p)\frac{p-1}{n-1}\right]\right)^q \\
&\leq q!\left(16e\kappa\frac{8(1+\gamma_d)k^2}{n}\left[1 + (k+p)\frac{p-1}{n-1}\right]\right)^q.
\end{aligned}$$

The conclusion follows from Lemma D.2 with $C = 16e\kappa\frac{8(1+\gamma_d)k^2}{n}\left[1 + (k+p)\frac{p-1}{n-1}\right]$. Then for every $t > 0$,

$$\mathbb{P}\left(\widehat{R}_{p,n} - \mathbb{E}\left(\widehat{R}_{p,n}\right) > t\right) \vee \mathbb{P}\left(\mathbb{E}\left(\widehat{R}_{p,n}\right) - \widehat{R}_{p,n} > t\right) \leq \exp\left(-\frac{nt^2}{1024e\kappa k^2(1+\gamma_d)\left[1 + (k+p)\frac{p-1}{n-1}\right]}\right).$$

B.3. Proof of Theorem 4.2 and Proposition 4.2

B.3.1. Proof of Theorem 4.2

If $p < n/2 + 1$:
In what follows, we exploit a characterization of sub-Gaussian random variables by their $2q$-th moments (Lemma D.2).

From (3.3) and (3.4) applied with $2q$, and further introducing a constant $\Delta = 4\sqrt{e}\max\left(\sqrt{C_1/2}, C_2\right) > 0$, it comes for every $q \geq 1$

$$\mathbb{E}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\,\widehat{R}_{p,n}\,\right]\right|^{2q}\right] \leq \left(\frac{\Delta^2}{16e}\frac{k^2}{n-p+1}\right)^q(2q)^q \leq \left(\frac{\Delta^2}{8}\frac{k^2}{n-p+1}\right)^q q!\ , \qquad \text{(B.1)}$$

with $q^q \leq q!e^q/\sqrt{2\pi q}$. Then Lemma D.2 provides for every $t > 0$

$$\mathbb{P}\left(\widehat{R}_{p,n} - \mathbb{E}\left[\,\widehat{R}_{p,n}\,\right] > t\right) \vee \mathbb{P}\left(\mathbb{E}\left[\,\widehat{R}_{p,n}\,\right] - \widehat{R}_{p,n} > t\right) \leq \exp\left(-(n-p+1)\frac{t^2}{\Delta^2 k^2}\right).$$

If $p \geq n/2 + 1$:
This part of the proof relies on Proposition D.1 which provides an exponential concentration inequality from upper bounds on the moments of a random variable.

Let us now use (3.3) and (3.6) combined with (D.1), where $C = \left\lfloor\frac{n}{n-p+1}\right\rfloor$, $q_0 = 2$, and $\min_j \alpha_j = 1/2$. This provides for every $t > 0$

$$\begin{aligned}
&\mathbb{P}\left[\left|\widehat{R}_{p,n} - \mathbb{E}\left[\,\widehat{R}_{p,n}\,\right]\right| > t\right] \leq \left\lfloor\frac{n}{n-p+1}\right\rfloor e\times \\
&\exp\left[-\frac{1}{2e}\min\left\{(n-p+1)\left\lfloor\frac{n}{n-p+1}\right\rfloor\frac{t^2}{4\Gamma^2 k\sqrt{k}},\ \left((n-p+1)\left\lfloor\frac{n}{n-p+1}\right\rfloor\right)^2\frac{t^2}{4\Gamma^2 k^2}\right)^{1/3}\right\}\right],
\end{aligned}$$

where Γ arises from Eq. (3.6).

B.3.2. Proof of Proposition 4.2

As in the previous proof, the derivation of the deviation terms results from Proposition D.1.

With the same notation and reasoning as in the previous proof, let us combine (3.3) and (3.6). From (D.2) of Proposition D.1 where $C = \left\lfloor \frac{n}{n-p+1} \right\rfloor$, $q_0 = 2$, and $\min_j \alpha_j = 1/2$, it results for every $t > 0$

$$\mathbb{P}\left[\left| \widehat{R}_{p,n} - \mathbb{E}\left[\widehat{R}_{p,n} \right] \right| > \Gamma \sqrt{\frac{2e}{(n-p+1)}} \left(\sqrt{\frac{k^{3/2}}{\left\lfloor \frac{n}{n-p+1} \right\rfloor} t} + 2e \frac{k}{\left\lfloor \frac{n}{n-p+1} \right\rfloor} t^{3/2} \right) \right] \leq \left\lfloor \frac{n}{n-p+1} \right\rfloor e \cdot e^{-t},$$

where $\Gamma > 0$ is given by Eq. (3.6).

Appendix C. Proofs of deviation upper bounds

C.1. Proof of Ineq. (5.3) in Theorem 5.1

The proof follows the same strategy as that of Theorem 2.1 in Rogers and Wagner (1978).

Along the proof, we will repeatedly use some notation that we briefly introduce here. First, let us define $Z_0 = (X_0, Y_0)$ and $Z_{n+1} = (X_{n+1}, Y_{n+1})$ that are independent copies of Z_1. Second to ease the reading of the proof, we also use several shortcuts: $\widehat{f}_k(X_0) = \mathcal{A}_k^{\mathcal{D}_n}(X_0)$, and $\widehat{f}_k^e(X_0) = \mathcal{A}_k^{\mathcal{D}^e}(X_0)$ for every set of indices $e \in \mathcal{E}_{n-p}$ (with cardinality $n-p$).

Finally along the proof, $e, e' \in \mathcal{E}_{n-p}$ denote two *random variables* which are sets of distinct indices *with discrete uniform distribution over* $\mathcal{E}_{n-p}$. The notation $\mathbb{P}_e$ (resp. $\mathbb{P}_{e,e'}$) means the integration is made with respect to the sample $\mathcal{D}$ and also the random variable e (resp. $\mathcal{D}$ and also the random variables e, e'). $\mathbb{E}_e[\cdot]$ and $\mathbb{E}_{e,e'}[\cdot]$ are teh corresponding expectations. Note that the sample $\mathcal{D}$ and the random variables e, e' are independent from each other, so that computing for instance $\mathbb{P}_e(i \notin e)$ amounts to integrating with respect to the random variable e only.

C.1.1. Main part of the proof

With the notation $L_n = L(\mathcal{A}_k^{\mathcal{D}_n})$, let us start from

$$\mathbb{E}\left[(\widehat{R}_{p,n} - L_n)^2 \right] = \mathbb{E}\left[\widehat{R}_p^2(\mathcal{A}_k^{\mathcal{D}_n}) \right] + \mathbb{E}\left[L_n^2 \right] - 2\mathbb{E}\left[\widehat{R}_{p,n} L_n \right],$$

let us notice that

$$\mathbb{E}\left[L_n^2 \right] = \mathbb{P}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k(X_{n+1}) \neq Y_{n+1} \right),$$

and

$$\mathbb{E}\left[\widehat{R}_{p,n} L_n \right] = \mathbb{P}_e\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_i) \neq Y_i | \ i \notin e \right) \mathbb{P}_e(i \notin e).$$

It immediately comes

$$\begin{aligned}
&\mathbb{E}\left[(\widehat{R}_{p,n} - L_n)^2 \right] \\
&= \mathbb{E}\left[\widehat{R}_p^2(\mathcal{A}_k^{\mathcal{D}_n}) \right] - \mathbb{P}_e\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_i) \neq Y_i \mid \ i \notin e \right) \mathbb{P}_e(i \notin e) \qquad \text{(C.1)} \\
&+ \left[\mathbb{P}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k(X_{n+1}) \neq Y_{n+1} \right) - \mathbb{P}_e\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_i) \neq Y_i | \ i \notin e \right) \mathbb{P}_e(i \notin e) \right]. \qquad \text{(C.2)}
\end{aligned}$$

The proof then consists in successively upper bounding the two terms (C.1) and (C.2) of the last equality.

Upper bound of (C.1)

First, we have

$$\begin{aligned}
p^2 \mathbb{E}\left[\widehat{R}_p^2(\mathcal{A}_k^{\mathcal{D}_n}) \right] &= \sum_{i,j} \mathbb{E}_{e,e'}\left[\mathbb{1}_{\left\{ \widehat{f}_k^e(X_i) \neq Y_i \right\}} \mathbb{1}_{\{i \notin e\}} \mathbb{1}_{\left\{ \widehat{f}_k^{e'}(X_j) \neq Y_j \right\}} \mathbb{1}_{\{j \notin e'\}} \right] \\
&= \sum_{i} \mathbb{E}_{e,e'}\left[\mathbb{1}_{\left\{ \widehat{f}_k^e(X_i) \neq Y_i \right\}} \mathbb{1}_{\{i \notin e\}} \mathbb{1}_{\left\{ \widehat{f}_k^{e'}(X_i) \neq Y_i \right\}} \mathbb{1}_{\{i \notin e'\}} \right] \\
&\quad + \sum_{i \neq j} \mathbb{E}_{e,e'}\left[\mathbb{1}_{\left\{ \widehat{f}_k^e(X_i) \neq Y_i \right\}} \mathbb{1}_{\{i \notin e\}} \mathbb{1}_{\left\{ \widehat{f}_k^{e'}(X_j) \neq Y_j \right\}} \mathbb{1}_{\{j \notin e'\}} \right].
\end{aligned}$$

Let us now introduce the five following events where we emphasize e and e' are random variables with the discrete uniform distribution over $\mathcal{E}_{n-p}$:

$$\begin{aligned} S_i^0 &= \{i \notin e,\ i \notin e'\}, \\ S_{i,j}^1 &= \{i \notin e,\ j \notin e',\ i \notin e',\ j \notin e\}, \qquad S_{i,j}^2 = \{i \notin e,\ j \notin e',\ i \notin e',\ j \in e\}, \\ S_{i,j}^3 &= \{i \notin e,\ j \notin e',\ i \in e',\ j \notin e\}, \qquad S_{i,j}^4 = \{i \notin e,\ j \notin e',\ i \in e',\ j \in e\}. \end{aligned}$$

Then,

$$\begin{aligned} p^2\mathbb{E}\left[\widehat{R}_p^2(\mathcal{A}_k^{\mathcal{D}_n})\right] &= \sum_i \mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_i) \neq Y_i,\ \widehat{f}_k^{e'}(X_i) \neq Y_i | S_i^0\right)\mathbb{P}_{e,e'}\left(S_i^0\right) \\ &\quad + \sum_{i\neq j}\sum_{\ell=1}^4 \mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_i) \neq Y_i,\ \widehat{f}_k^{e'}(X_i) \neq Y_i | S_{i,j}^\ell\right)\mathbb{P}_{e,e'}\left(S_{i,j}^\ell\right) \\ &= n\mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_1) \neq Y_1,\ \widehat{f}_k^{e'}(X_1) \neq Y_1 | S_1^0\right)\mathbb{P}_{e,e'}\left(S_1^0\right) \\ &\quad + n(n-1)\sum_{\ell=1}^4 \mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_1) \neq Y_1,\ \widehat{f}_k^{e'}(X_2) \neq Y_2 \mid S_{1,2}^\ell\right)\mathbb{P}_{e,e'}\left(S_{1,2}^\ell\right). \end{aligned}$$

Furthermore since

$$\frac{1}{p^2}\left[n\mathbb{P}_{e,e'}\left(S_1^0\right) + n(n-1)\sum_{\ell=1}^4 \mathbb{P}_{e,e'}\left(S_{1,2}^\ell\right)\right] = \frac{1}{p^2}\sum_{i,j}\mathbb{P}_{e,e'}\left(i \notin e,\ j \notin e'\right) = 1,$$

it comes

$$\mathbb{E}\left[\widehat{R}_p^2(\mathcal{A}_k^{\mathcal{D}_n})\right] - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_1) \neq Y_1\right) = \frac{n}{p^2}A + \frac{n(n-1)}{p^2}B, \quad \text{(C.3)}$$

where

$$\begin{aligned} A &= \left[\mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_1) \neq Y_1,\ \widehat{f}_k^{e'}(X_1) \neq Y_1 \mid S_1^0\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_1) \neq Y_1 \mid S_1^0\right)\right] \\ &\quad \times \mathbb{P}_{e,e'}\left(S_1^0\right), \end{aligned}$$

and

$$\begin{aligned} B &= \sum_{\ell=1}^4 \left[\mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_1) \neq Y_1,\ \widehat{f}_k^{e'}(X_2) \neq Y_2 \mid S_{1,2}^\ell\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_1) \neq Y_1 \mid S_{1,2}^\ell\right)\right] \\ &\quad \times \mathbb{P}_{e,e'}\left(S_{1,2}^\ell\right). \end{aligned}$$

• Upper bound for A:
To upper bound A, simply notice that:

$$A \leq \mathbb{P}_{e,e'}\left(S_i^0\right) \leq \mathbb{P}_{e,e'}\left(i \notin e,\ i \notin e'\right) \leq \left(\frac{p}{n}\right)^2.$$

• Upper bound for B:
To obtain an upper bound for B, one needs to upper bound

$$\mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_1) \neq Y_1,\ \widehat{f}_k^{e'}(X_2) \neq Y_2 \mid S_{1,2}^\ell\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_1) \neq Y_1 \mid S_{1,2}^\ell\right), \quad \text{(C.4)}$$

which depends on ℓ, i.e. on the fact that index 2 belongs or not to the training set e.

- If $2 \notin e$ (i.e. $\ell = 1$ or 3): Then, Lemma C.2 proves

$$\text{(C.4)} \leq \frac{4p\sqrt{k}}{\sqrt{2\pi}n}\ .$$

- If $2 \in e$ (i.e. $\ell = 2$ or 4): Then, Lemma C.3 settles

$$\text{(C.4)} \leq \frac{8\sqrt{k}}{\sqrt{2\pi}(n-p)} + \frac{4p\sqrt{k}}{\sqrt{2\pi}n}\ .$$

Combining the previous bounds and Lemma C.1 leads to

$$\begin{aligned} B &\leq \left(\frac{4p\sqrt{k}}{\sqrt{2\pi}n}\right)\left[\mathbb{P}_{e,e'}\left(S_{1,2}^1\right) + \mathbb{P}_{e,e'}\left(S_{1,2}^3\right)\right] + \left(\frac{8\sqrt{k}}{\sqrt{2\pi}(n-p)} + \frac{4p\sqrt{k}}{\sqrt{2\pi}n}\right)\left[\mathbb{P}_{e,e'}\left(S_{1,2}^2\right) + \mathbb{P}_{e,e'}\left(S_{1,2}^4\right)\right] \\ &\leq \frac{2\sqrt{2}}{\sqrt{\pi}}\sqrt{k}\left[\frac{p}{n}\left[\mathbb{P}_{e,e'}\left(S_{1,2}^1\right) + \mathbb{P}_{e,e'}\left(S_{1,2}^3\right)\right] + \left(\frac{2}{n-p} + \frac{p}{n}\right)\left[\mathbb{P}_{e,e'}\left(S_{1,2}^2\right) + \mathbb{P}_{e,e'}\left(S_{1,2}^4\right)\right]\right] \\ &\leq \frac{2\sqrt{2}}{\sqrt{\pi}}\sqrt{k}\left[\frac{p}{n}\mathbb{P}_{e,e'}\left(i \notin e,\ j \notin e'\right) + \frac{2}{n-p}\left(\mathbb{P}_{e,e'}\left(S_{1,2}^2\right) + \mathbb{P}_{e,e'}\left(S_{1,2}^4\right)\right)\right] \\ &\leq \frac{2\sqrt{2}}{\sqrt{\pi}}\sqrt{k}\left[\frac{p}{n}\left(\frac{p}{n}\right)^2 + \frac{2}{n-p}\left(\frac{(n-p)p^2(p-1)}{n^2(n-1)^2} + \frac{(n-p)^2p^2}{n^2(n-1)^2}\right)\right] \\ &\leq \frac{2\sqrt{2}}{\sqrt{\pi}}\sqrt{k}\left(\frac{p}{n}\right)^2\left[\frac{p}{n} + \frac{2}{n-1}\right]. \end{aligned}$$

Back to Eq. (C.3), one deduces

$$\begin{aligned} \mathbb{E}\left[\widehat{R}_p^2(\mathcal{A}_k^{\mathcal{D}_n})\right] - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_1) \neq Y_1\right) &= \frac{n}{p^2}A + \frac{n(n-1)}{p^2}B \\ &\leq \frac{1}{n} + \frac{2\sqrt{2}}{\sqrt{\pi}}\frac{(p+2)\sqrt{k}}{n}\ . \end{aligned}$$

Upper bound of (C.2) First observe that

$$\mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_i) \neq Y_i \mid i \notin e\right) = \mathbb{P}_{e,e'}\left(\widehat{f}_k^{(-1)}(X_0) \neq Y_0, \widehat{f}_k^e(X_{n+1}) \neq Y_{n+1}\right)$$

where $\widehat{f}_k^{(-1)}$ is built on sample $(X_2, Y_2), ..., (X_{n+1}, Y_{n+1})$. One has

$$\begin{aligned} &\mathbb{P}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k(X_{n+1}) \neq Y_{n+1}\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k^e(X_i) \neq Y_i \mid i \notin e\right) \\ =\ &\mathbb{P}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}_k(X_{n+1}) \neq Y_{n+1}\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k^{(-1)}(X_0) \neq Y_0, \widehat{f}_k^e(X_{n+1}) \neq Y_{n+1}\right) \\ \leq\ &\mathbb{P}\left(\widehat{f}_k(X_0) \neq \widehat{f}_k^{(-1)}(X_0)\right) + \mathbb{P}_{e,e'}\left(\widehat{f}_k^e(X_{n+1}) \neq \widehat{f}_k(X_{n+1})\right) \\ \leq\ &\frac{4\sqrt{k}}{\sqrt{2\pi}n} + \frac{4p\sqrt{k}}{\sqrt{2\pi}n}\ , \end{aligned}$$

where we used Lemma D.6 again to obtain the last inequality.

Conclusion:

The conclusion simply results from combining bonds (C.1) and (C.2), which leads to

$$\mathbb{E}\left[\left(\widehat{R}_{p,n} - L_n\right)^2\right] \leq \frac{2\sqrt{2}}{\sqrt{\pi}} \frac{(2p+3)\sqrt{k}}{n} + \frac{1}{n} \ .$$

C.1.2. Combinatorial lemmas

All the lemmas of the present section are proved with the notation introduced at the beginning of Section C.1.

Lemma C.1. *For any $1 \leq i \neq j \leq n$,*

$$\mathbb{P}_{e,e'}\left(S^1_{i,j}\right) = \frac{\binom{n-2}{n-p}}{\binom{n}{n-p}} \times \frac{\binom{n-2}{n-p}}{\binom{n}{n-p}}, \qquad \mathbb{P}_{e,e'}\left(S^2_{i,j}\right) = \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}} \times \frac{\binom{n-p}{n-2}}{\binom{n}{n-p}} \ ,$$
$$\mathbb{P}_{e,e'}\left(S^3_{i,j}\right) = \frac{\binom{n-p}{n-2}}{\binom{n}{n-p}} \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}}, \qquad \mathbb{P}_{e,e'}\left(S^4_{i,j}\right) = \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}} \times \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}} \ .$$

Proof of Lemma C.1. Along the proof, we repeatedly exploit the independence of the random variables e and e', which are set of $n-p$ distinct indices with the discrete uniform distribution over $\mathcal{E}_{n-p}$.

Note also that an important ingredient is that the probability of each one of the following events does not depend on the particular choice of the indices (i,j), but only on the fact that $i \neq j$.

$$\begin{aligned}
\mathbb{P}_{e,e'}\left(S^1_{i,j}\right) &= \mathbb{P}_{e,e'}\left(i \notin e,\ j \notin e',\ i \notin e',\ j \notin e\right) \\
&= \mathbb{P}_e\left(i \notin e,\ j \notin e\right)\mathbb{P}_{e'}\left(j \notin e',\ i \notin e'\right) = \frac{\binom{n-2}{n-p}}{\binom{n}{n-p}} \times \frac{\binom{n-2}{n-p}}{\binom{n}{n-p}} \ . \\
\mathbb{P}_{e,e'}\left(S^2_{i,j}\right) &= \mathbb{P}_{e,e'}\left(i \notin e,\ j \notin e',\ i \notin e',\ j \in e\right) \\
&= \mathbb{P}_e\left(i \notin e,\ j \in e\right)\mathbb{P}_{e'}\left(j \notin e',\ i \notin e'\right) = \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}} \times \frac{\binom{n-p}{n-2}}{\binom{n}{n-p}} \ . \\

&= \mathbb{P}_e\left(i \notin e,\ j \notin e\right)\mathbb{P}_{e'}\left(j \notin e',\ i \in e'\right) = \frac{\binom{n-p}{n-2}}{\binom{n}{n-p}} \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}} \ . \\
\mathbb{P}_{e,e'}\left(S^4_{i,j}\right) &= \mathbb{P}_{e,e'}\left(i \notin e,\ j \notin e',\ i \in e',\ j \in e\right) \\
&= \mathbb{P}_e\left(i \notin e,\ j \in e\right)\mathbb{P}_{e'}\left(j \notin e',\ i \in e'\right) = \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}} \times \frac{\binom{n-p-1}{n-2}}{\binom{n}{n-p}} \ .
\end{aligned}$$

□

Lemma C.2. *With the above notation, for $\ell \in \{1,3\}$, it comes*

$$\mathbb{P}_e\left(\widehat{f}^e_k(X_1) \neq Y_1,\ \widehat{f}^{e'}_k(X_2) \neq Y_2 \mid S^\ell_{1,2}\right) - \mathbb{P}_e\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \leq \frac{4p\sqrt{k}}{\sqrt{2\pi}n} \ .$$

Proof of Lemma C.2. First remind that as a test sample element Z_0 cannot belong to either e or e'. Consequently, an exhaustive formulation of

$$\mathbb{P}_e\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) = \mathbb{P}_e\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \ .$$

Then it results

$$\mathbb{P}_e\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \ = \ \mathbb{P}_e\left(\widehat{f}_k^{\,(2)}(X_2) \neq Y_2,\ \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right),$$

where $\widehat{f}_k^{\,(2)}$ is built on sample $(X_0,Y_0),(X_1,Y_1),(X_3,Y_3),...,(X_n,Y_n)$.

Hence Lemma D.6 implies

$$\begin{aligned}
&\mathbb{P}_{e,e'}\left(\widehat{f}^e_k(X_1) \neq Y_1,\ \widehat{f}^{e'}_k(X_2) \neq Y_2 \mid S^\ell_{1,2}\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \\
&= \mathbb{P}_{e,e'}\left(\widehat{f}^e_k(X_1) \neq Y_1,\ \widehat{f}^{e'}_k(X_2) \neq Y_2 \mid S^\ell_{1,2}\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k^{\,(2)}(X_2) \neq Y_2,\ \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \\
&\leq \mathbb{P}_{e,e'}\left(\left\{\widehat{f}^e_k(X_1) \neq Y_1\right\} \triangle \left\{\widehat{f}^e_k(X_1) \neq Y_1\right\} \mid S^\ell_{1,2}\right) + \mathbb{P}_{e,e'}\left(\left\{\widehat{f}_k^{\,(2)}(X_2) \neq Y_2\right\} \triangle \left\{\widehat{f}^{e'}_k(X_2) \neq Y_2\right\} \mid S^\ell_{1,2}\right) \\
&= \mathbb{P}_{e,e'}\left(\widehat{f}_k^{\,(2)}(X_2) \neq \widehat{f}^{e'}_k(X_2) \mid S^\ell_{1,2}\right) \leq \frac{4p\sqrt{k}}{\sqrt{2\pi}n} \ .
\end{aligned}$$

□

Lemma C.3. *With the above notation, for $\ell \in \{2,4\}$, it comes*

$$\begin{aligned}
&\mathbb{P}_{e,e'}\left(\widehat{f}^e_k(X_1) \neq Y_1,\ \widehat{f}^{e'}_k(X_2) \neq Y_2 \mid S^\ell_{1,2}\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \\
&\leq \frac{8\sqrt{k}}{\sqrt{2\pi}(n-p)} + \frac{4p\sqrt{k}}{\sqrt{2\pi}n} \ .
\end{aligned}$$

Proof of Lemma C.3. As for the previous lemma, first notice that

$$\mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) = \mathbb{P}_{e,e'}\left(\widehat{f}_k^{\,(2)}(X_2) \neq Y_2,\ \widehat{f}_k^{\,e_0}(X_1) \neq Y_1 \mid S^\ell_{1,2}\right),$$

where $\widehat{f}_k^{\,e_0}$ is built on sample e with observation (X_2,Y_2) replaced with (X_0,Y_0). Then

$$\begin{aligned}
&\mathbb{P}_{e,e'}\left(\widehat{f}^e_k(X_1) \neq Y_1,\ \widehat{f}^{e'}_k(X_2) \neq Y_2 \mid S^\ell_{1,2}\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k(X_0) \neq Y_0, \widehat{f}^e_k(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \\
&= \mathbb{P}_{e,e'}\left(\widehat{f}^e_k(X_1) \neq Y_1,\ \widehat{f}^{e'}_k(X_2) \neq Y_2 \mid S^\ell_{1,2}\right) - \mathbb{P}_{e,e'}\left(\widehat{f}_k^{\,(2)}(X_2) \neq Y_2,\ \widehat{f}_k^{\,e_0}(X_1) \neq Y_1 \mid S^\ell_{1,2}\right) \\
&\leq \mathbb{P}_{e,e'}\left(\left\{\widehat{f}^e_k(X_1) \neq Y_1\right\} \triangle \left\{\widehat{f}_k^{\,e_0}(X_1) \neq Y_1\right\} \mid S^\ell_{1,2}\right) + \mathbb{P}_{e,e'}\left(\left\{\widehat{f}_k^{\,(2)}(X_2) \neq Y_2\right\} \triangle \left\{\widehat{f}^{e'}_k(X_2) \neq Y_2\right\} \mid S^\ell_{1,2}\right) \\
&= \mathbb{P}_{e,e'}\left(\widehat{f}^e_k(X_1) \neq \widehat{f}_k^{\,e_0}(X_1) \mid S^\ell_{1,2}\right) + \mathbb{P}_{e,e'}\left(\widehat{f}_k^{\,(2)}(X_2) \neq \widehat{f}^{e'}_k(X_2) \mid S^\ell_{1,2}\right) \leq \frac{8\sqrt{k}}{\sqrt{2\pi}(n-p)} + \frac{4p\sqrt{k}}{\sqrt{2\pi}n} \ .
\end{aligned}$$

□

C.2. Proof of Proposition 5.1

The bias of the L1O estimator is equal to

$$
\begin{aligned}
&\mathbb{E}\left[L\left(\mathcal{A}_k^{\mathcal{D}_n}\right) - L\left(\mathcal{A}_k^{\mathcal{D}_{n-1}}\right)\right] \\
&= -2\mathbb{E}\left[(\eta(X)-1/2)\left(\mathbb{E}\left[\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(X) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(X) \mid X_{(k+1)}(X), X\right] \mid X\right]\right)\right] \\
&= -2\mathbb{E}\left[(\eta(X)-1/2)\left(\mathbb{E}\left[\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(X) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(X) \mid X_{(k+1)}(X), X\right] \mid X\right]\right)\right] \\
&= 1/2\left\{\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(0) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(0) \mid X_{(k+1)}(0)=0, X=0\right]\mathbb{P}\left[X_{(k+1)}(0)=0 \mid X=0\right]\right. \\
&\qquad\left. +\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(0) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(0) \mid X_{(k+1)}(0)=1, X=0\right]\mathbb{P}\left[X_{(k+1)}(0)=1 \mid X=0\right]\right\} \\
&- 1/2\left\{\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(1) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(1) \mid X_{(k+1)}(1)=0, X=1\right]\mathbb{P}\left[X_{(k+1)}(1)=0 \mid X=1\right]\right. \\
&\qquad\left. +\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(1) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(1) \mid X_{(k+1)}(1)=1, X=1\right]\mathbb{P}\left[X_{(k+1)}(1)=1 \mid X=1\right]\right\},
\end{aligned}
$$

where $X_{(k+1)}(x)$ denotes the $k+1$-th neighbor of x.

Then, a few remarks lead to simplify the above expression.

- On the one hand it is easy to check that

$$
\begin{aligned}
&\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(0) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(0) \mid X_{(k+1)}(0)=0, X=0\right] \\
&= \mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(1) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(1) \mid X_{(k+1)}(1)=1, X=1\right] = 0,
\end{aligned}
$$

  since all of the $k+1$ nearest neighbors share the same label.

- On the other hand, let us notice

$$
\begin{aligned}
&\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(0) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(0) \mid X_{(k+1)}(0)=1, X=0\right] \\
&= \mathbb{P}\left[\mathcal{A}_k^{\mathcal{D}_n}(0)=1, \mathcal{A}_k^{\mathcal{D}_{n-1}}(0)=0 \mid X_{(k+1)}(0)=1, X=0\right] \\
&- \mathbb{P}\left[\mathcal{A}_k^{\mathcal{D}_n}(0)=0, \mathcal{A}_k^{\mathcal{D}_{n-1}}(0)=1 \mid X_{(k+1)}(0)=1, X=0\right].
\end{aligned}
$$

  Then knowing $X_{(k+1)}(X)$ and X are not equal implies the only way for $\mathcal{A}_k^{\mathcal{D}_n}$ and $\mathcal{A}_k^{\mathcal{D}_{n-1}}$ to differ is that the numbers of k nearest neighbors of each label are almost equal, that is either equal to $(k-1)/2$ or to $(k+1)/2$ (k is odd by assumption).

  With N_0^1 (respectively $\tilde{N}_0^1$) denoting the number of 1s among th k nearest neighbors of $X=0$ among $X_1,\dots,X_n$ (resp. $X_1,\dots,X_{n-1}$), the proof of Theorem 3 in Chaudhuri and Dasgupta (2014) leads to

$$
\begin{aligned}
&\mathbb{P}\left[\mathcal{A}_k^{\mathcal{D}_n}(0)=1, \mathcal{A}_k^{\mathcal{D}_{n-1}}(0)=0 \mid X_{(k+1)}(0)=1, X=0\right] \\
&= \mathbb{P}\left[n \in V_k(0), N_0^1 = (k+1)/2, \tilde{N}_0^1 = (k-1)/2 \mid X_{(k+1)}(0)=1, X=0\right] \\
&= \frac{k}{n} \times \mathbb{P}\left[\tilde{N}_0^1 = (k-1)/2 \mid N_0^1 = (k+1)/2, X_{(k+1)}(0)=1, X=0\right] \\
&\times \mathbb{P}\left[N_0^1 = (k+1)/2 \mid X_{(k+1)}(0)=1, X=0\right] \\
&= \frac{k}{n} \times \mathbb{P}\left[\mathcal{H}\left(\frac{k+1}{2}, \frac{k-1}{2}; 1\right) = 1\right] \cdot \eta_1 \times \binom{k}{(k+1)/2} \bar{\eta}^{(k+1)/2}\left(1-\bar{\eta}\right)^{(k-1)/2} \\
&= \frac{k+1}{2n} \times \eta_1 \times \binom{k}{(k+1)/2} \bar{\eta}^{(k+1)/2}\left(1-\bar{\eta}\right)^{(k-1)/2},
\end{aligned}
$$

  where $\mathcal{H}(a,b;c)$ denotes a hypergeometric random variable with a successes in a population of cardinality $a+b$, and c draws, and $\bar{\eta} = \pi_0\eta_0 + (1-\pi_0)\eta_1 = 1/2$.

  Following the same reasoning for $\mathbb{P}\left[\mathcal{A}_k^{\mathcal{D}_n}(0)=0, \mathcal{A}_k^{\mathcal{D}_{n-1}}(0)=1 \mid X_{(k+1)}(0)=1, X=0\right]$ and recalling that $\eta_0 = 0$ and $\eta_1 = 1$ by assumption, it results

$$
\mathbb{E}\left[\mathcal{A}_k^{\mathcal{D}_n}(0) - \mathcal{A}_k^{\mathcal{D}_{n-1}}(0) \mid X_{(k+1)}(0)=1, X=0\right] = -\frac{k+1}{2n} \times \binom{k}{(k+1)/2}(1/2)^k.
$$

- Similar calculations applied to $X=1$ finally lead to

$$
\begin{aligned}
\mathbb{E}\left[L\left(\mathcal{A}_k^{\mathcal{D}_n}\right) - L\left(\mathcal{A}_k^{\mathcal{D}_{n-1}}\right)\right] &= \frac{k+1}{2n} \times \binom{k}{(k+1)/2}(1/2)^k \times \mathbb{P}\left[X_{(k+1)}(0)=1 \mid X=0\right] \\
&= \frac{k+1}{2n} \times \binom{k}{(k+1)/2}(1/2)^k \times \mathbb{P}\left[\mathcal{B}(n,1/2) \le k\right].
\end{aligned}
$$

- The conclusion then follows from considering $k \ge n/2$ which entails that $\mathbb{P}\left[\mathcal{B}(n,1/2) \le k\right] \ge 1/2$, and also by noticing that

$$
\frac{k+1}{2n} \times \binom{k}{(k+1)/2}(1/2)^k \ge C\frac{\sqrt{k}}{n},
$$

  where denotes a numeric constant independent of n and k.

Appendix D. Technical results

D.1. Main inequalities

D.1.1. From moment to exponential inequalities

Proposition D.1 (see also Arlot (2007), Lemma 8.10)**.** *Let X denote a real valued random variable, and assume there exist $C \geq 1$, $\lambda_1, \ldots, \lambda_N > 0$, and $\alpha_1, \ldots, \alpha_N > 0$ ($N \in \mathbb{N}^*$) such that for every $q \geq q_0$,*

$$\mathbb{E}\left[\,|X|^q\,\right] \leq C\left(\sum_{i=1}^{N} \lambda_i q^{\alpha_i}\right)^q.$$

Then for every $t > 0$,

$$\mathbb{P}\left[\,|X| > t\,\right] \leq Ce^{q_0 \min_j \alpha_j} e^{-(\min_i \alpha_i)e^{-1}\min_j\left\{\left(\frac{t}{N\lambda_j}\right)^{\frac{1}{\alpha_j}}\right\}}, \tag{D.1}$$

Furthermore for every $x > 0$, it results

$$\mathbb{P}\left[\,|X| > \sum_{i=1}^{N} \lambda_i \left(\frac{ex}{\min_j \alpha_j}\right)^{\alpha_i}\right] \leq Ce^{q_0 \min_j \alpha_j} \cdot e^{-x}. \tag{D.2}$$

Proof of Proposition D.1. By use of Markov's inequality applied to $|X|^q$ ($q > 0$), it comes for every $t > 0$

$$\mathbb{P}\left[\,|X| > t\,\right] \leq \mathbb{1}_{q \geq q_0} \frac{\mathbb{E}\left[\,|X|^q\,\right]}{t^q} + \mathbb{1}_{q < q_0} \leq \mathbb{1}_{q \geq q_0} C\left(\frac{\sum_{i=1}^{N} \lambda_i q^{\alpha_i}}{t}\right)^q + \mathbb{1}_{q < q_0}.$$

Now using the upper bound $\sum_{i=1}^{N} \lambda_i q^{\alpha_i} \leq N \max_i \left\{\lambda_i q^{\alpha_i}\right\}$ and choosing the particular value $\tilde{q} = \tilde{q}(t) = e^{-1}\min_j\left\{\left(\frac{t}{N\lambda_j}\right)^{\frac{1}{\alpha_j}}\right\}$, one gets

$$\begin{aligned}\mathbb{P}\left[\,|X| > t\,\right] &\leq \mathbb{1}_{\tilde{q} \geq q_0} C\left(\frac{\max_i\left\{N\lambda_i\left(e^{-\alpha_i}\min_j\left\{\left(\frac{t}{N\lambda_j}\right)^{\frac{1}{\alpha_j}}\right\}\right)^{\alpha_i}\right\}}{t}\right)^{\tilde{q}} + \mathbb{1}_{\tilde{q} < q_0} \\ &\leq \mathbb{1}_{\tilde{q} \geq q_0} Ce^{-(\min_i \alpha_i)\left[e^{-1}\min_j\left\{\left(\frac{t}{N\lambda_j}\right)^{\frac{1}{\alpha_j}}\right\}\right]} + \mathbb{1}_{\tilde{q} < q_0},\end{aligned}$$

which provides (D.1).

Let us now turn to the proof of (D.2). From $t^* = \sum_{i=1}^{N} \lambda_i \left(\frac{ex}{\min_j \alpha_j}\right)^{\alpha_i}$ combined with $q^* = \frac{x}{\min_j \alpha_j}$, it arises for every $x > 0$

$$\frac{\sum_{i=1}^{N} \lambda_i (q^*)^{\alpha_i}}{t^*} = \frac{\sum_{i=1}^{N} \lambda_i \left(e^{-1}\frac{ex}{\min_j \alpha_j}\right)^{\alpha_i}}{\sum_{i=1}^{N} \lambda_i \left(\frac{ex}{\min_j \alpha_j}\right)^{\alpha_i}} \leq \left(\max_k e^{-\alpha_k}\right) \frac{\sum_{i=1}^{N} \lambda_i \left(\frac{ex}{\min_j \alpha_j}\right)^{\alpha_i}}{\sum_{i=1}^{N} \lambda_i \left(\frac{ex}{\min_j \alpha_j}\right)^{\alpha_i}} = e^{-\min_k \alpha_k}.$$

Then,

$$C\left(\frac{\sum_{i=1}^{N} \lambda_i (q^*)^{\alpha_i}}{t^*}\right)^{q^*} \leq Ce^{-(\min_k \alpha_k)\frac{x}{\min_j \alpha_j}} = Ce^{-x}.$$

Hence,

$$\mathbb{P}\left[\,|X| > \sum_{i=1}^{N} \lambda_i \left(\frac{ex}{\min_j \alpha_j}\right)^{\alpha_i}\right] \leq Ce^{-x}\mathbb{1}_{q^* \geq q_0} + \mathbb{1}_{q^* < q_0} \leq Ce^{q_0 \min_j \alpha_j} \cdot e^{-x},$$

since $e^{q_0 \min_j \alpha_j} \geq 1$ and $-x + q_0 \min_j \alpha_j \geq 0$ if $q < q_0$.

□

D.1.2. Sub-Gaussian random variables

Lemma D.1 (Theorem 2.1 in Boucheron et al. (2013) first part)**.** *Any centered random variable X such that $\mathbb{P}(X > t) \vee \mathbb{P}(-X > t) \leq e^{-t^2/(2\nu)}$ satisfies*

$$\mathbb{E}\left[X^{2q}\right] \leq q!\,(4\nu)^q.$$

for all q in $\mathbb{N}_+$.

Lemma D.2 (Theorem 2.1 in Boucheron et al. (2013) second part)**.** *Any centered random variable X such that*

$$\mathbb{E}\left[X^{2q}\right] \leq q!C^q.$$

for some $C > 0$ and q in $\mathbb{N}_+$ satisfies $\mathbb{P}(X > t) \vee \mathbb{P}(-X > t) \leq e^{-t^2/(2\nu)}$ with $\nu = 4C$.

D.1.3. The Efron-Stein inequality

Theorem D.1 (Efron-Stein's inequality Boucheron et al. (2013), Theorem 3.1)**.** *Let $X_1, \ldots, X_n$ be independent random variables and let $Z = f(X_1, \ldots, X_n)$ be a square-integrable function. Then*

$$\mathrm{Var}(Z) \leq \sum_{i=1}^{n} \mathbb{E}\left[\left(Z - \mathbb{E}\left[Z \mid (X_j)_{j \neq i}\right]\right)^2\right] = \nu.$$

Moreover if $X_1', \ldots, X_n'$ denote independent copies of $X_1, \ldots, X_n$ and if we define for every $1 \leq i \leq n$

$$Z_i' = f\left(X_1, \ldots, X_i', \ldots, X_n\right),$$

then

$$\nu = \frac{1}{2}\sum_{i=1}^{n} \mathbb{E}\left[\left(Z - Z_i'\right)^2\right].$$

D.1.4. Generalized Efron-Stein's inequality

Theorem D.2 (Theorem 15.5 in Boucheron et al. (2013)). *Let $\xi_1, \dots, \xi_n$ be n independent Ξ-valued random variables, $f : \Xi^n \to \mathbb{R}$ denote a measurable function, and define $\zeta = f(\xi_1, \dots, \xi_n)$ and $\zeta_i' = f(\xi_1, \dots, \xi_i', \dots, \xi_n)$, with $\xi_1', \dots, \xi_n'$ independent copies of ξ_i. Furthermore let $V_+ = \mathbb{E}\left[\sum_{i=1}^n \left[(\zeta - \zeta_i')_+\right]^2 \mid \xi_1^n\right]$ and $V_- = \mathbb{E}\left[\sum_{i=1}^n \left[(\zeta - \zeta_i')_-\right]^2 \mid \xi_1^n\right]$. Then there exists a constant $\kappa \leq 1,271$ such that for all q in $[2, +\infty[$,*

$$\left\|(\zeta - \mathbb{E}\zeta)_+\right\|_q \leq \sqrt{2\kappa q \left\|V_+\right\|_{q/2}} \ , \qquad \text{and} \qquad \left\|(\zeta - \mathbb{E}\zeta)_-\right\|_q \leq \sqrt{2\kappa q \left\|V_-\right\|_{q/2}} \ .$$

Corollary D.1. *With the same notation, it comes*

$$\left\|\zeta - \mathbb{E}\zeta\right\|_q \leq \sqrt{2\kappa q}\sqrt{\left\|\sum_{i=1}^n (\zeta - \zeta_i')^2\right\|_{q/2}} \leq 2\sqrt{\kappa q}\sqrt{\left\|\sum_{i=1}^n (\zeta - \mathbb{E}\left[\zeta \mid (\xi_j)_{j\neq i}\right])^2\right\|_{q/2}} \ . \quad \text{(D.3)}$$

Moreover considering $\zeta^{(j)} = f(\xi_1, \dots, \xi_{j-1}, \xi_{j+1}, \dots, \xi_n)$ for every $1 \leq j \leq n$, it results

$$\left\|\zeta - \mathbb{E}\zeta\right\|_q \ \leq 2\sqrt{2\kappa q}\sqrt{\left\|\sum_{i=1}^n \left(\zeta - \zeta^{(j)}\right)^2\right\|_{q/2}} \ . \quad \text{(D.4)}$$

D.1.5. McDiarmid's inequality

Theorem D.3. *Let $X_1, ..., X_n$ be independent random variables taking values in a set A, and assume that $f : A^n \to \mathbb{R}$ satisfies*

$$\sup_{x_1,\dots,x_n,x_i'} \left|f(x_1, ..., x_i, ..., x_n) - f(x_1, ..., x_i', ..., x_n)\right| \leq c_i, \ 1 \leq i \leq n \ .$$

Then for all $\varepsilon > 0$, one has

$$\begin{aligned} \mathbb{P}\left(f(X_1, ..., X_n) - E\left[f(X_1, ..., X_n)\right] \geq \varepsilon\right) &\leq e^{-2\varepsilon^2/\sum_{i=1}^n c_i^2} \\ \mathbb{P}\left(E\left[f(X_1, ..., X_n)\right] - f(X_1, ..., X_n) \geq \varepsilon\right) &\leq e^{-2\varepsilon^2/\sum_{i=1}^n c_i^2} \end{aligned}$$

A proof can be found in Devroye et al. (1996) (see Theorem 9.2).

D.1.6. Rosenthal's inequality

Proposition D.2 (Eq. (20) in Ibragimov and Sharakhmetov (2002)). *Let $X_1, \dots, X_n$ denote independent real random variables with symmetric distributions. Then for every $q > 2$ and $\gamma > 0$,*

$$E\left[\left|\sum_{i=1}^n X_i\right|^q\right] \leq B(q,\gamma)\left\{\gamma \sum_{i=1}^n E\left[\left|X_i\right|^q\right] \vee \left(\sqrt{\sum_{i=1}^n E\left[X_i^2\right]}\right)^q\right\},$$

where $a \vee b = \max(a, b)$ $(a, b \in \mathbb{R})$, and $B(q,\gamma)$ denotes a positive constant only depending on q and γ. Furthermore, the optimal value of $B(q,\gamma)$ is given by

$$\begin{aligned} B^*(q,\gamma) &= 1 + \tfrac{E\left[|N|^q\right]}{\gamma} \qquad , \text{ if } \ 2 < q \leq 4, \\ &= \gamma^{-q/(q-1)} E\left[\left|Z - Z'\right|^q\right] \ , \text{ if } \ 4 < q, \end{aligned}$$

where N denotes a standard Gaussian variable, and Z, Z' are i.i.d. random variables with Poisson distribution $\mathcal{P}\left(\frac{\gamma^{1/(q-1)}}{2}\right)$.

Proposition D.3. *Let $X_1, \dots, X_n$ denote independent real random variables with symmetric distributions. Then for every $q > 2$,*

$$E\left[\left|\sum_{i=1}^n X_i\right|^q\right] \leq \left(2\sqrt{2e}\right)^q \max\left\{q^q \sum_{i=1}^n E\left[\left|X_i\right|^q\right], (\sqrt{q})^q \left(\sqrt{\sum_{i=1}^n E\left[X_i^2\right]}\right)^q\right\}.$$

Proof of Proposition D.3. From Lemma D.3, let us observe

- if $2 < q \leq 4$, choosing $\gamma = 1$ provides
$$B^*(q,\gamma) \leq \left(2\sqrt{2e}\sqrt{q}\right)^q.$$
- if $4 < q$, $\gamma = q^{(q-1)/2}$ leads to
$$B^*(q,\gamma) \leq q^{-q/2}\left(\sqrt{4eq\left(q^{1/2} + q\right)}\right)^q \leq q^{-q/2}\left(\sqrt{8eq}\right)^q = \left(2\sqrt{2e}\sqrt{q}\right)^q.$$

Plugging the previous upper bounds in Rosenthal's inequality (Proposition D.2), it results for every $q > 2$

$$E\left[\left|\sum_{i=1}^n X_i\right|^q\right] \leq \left(2\sqrt{2e}\sqrt{q}\right)^q \max\left\{(\sqrt{q})^q \sum_{i=1}^n E\left[\left|X_i\right|^q\right], \left(\sqrt{\sum_{i=1}^n E\left[X_i^2\right]}\right)^q\right\}.$$

□

Lemma D.3. *With the same notation as Proposition D.2 and for every $\gamma > 0$, it comes*

- *for every $2 < q \leq 4$,*
$$B^*(q,\gamma) \leq 1 + \frac{\left(\sqrt{2e}\sqrt{q}\right)^q}{\gamma},$$
- *for every $4 < q$,*
$$B^*(q,\gamma) \leq \gamma^{-q/(q-1)}\left(\sqrt{4eq\left(\gamma^{1/(q-1)} + q\right)}\right)^q.$$

Proof of Lemma D.3. If $2 < q \leq 4$,

$$B^*(q,\gamma) = 1 + \frac{E\left[\left|N\right|^q\right]}{\gamma} \leq 1 + \frac{\sqrt{2}e\sqrt{q}\left(\frac{q}{e}\right)^{\frac{q}{2}}}{\gamma} \leq 1 + \frac{\sqrt{2e}^q\sqrt{e}^q\left(\frac{q}{e}\right)^{\frac{q}{2}}}{\gamma} = 1 + \frac{\left(\sqrt{2e}\sqrt{q}\right)^q}{\gamma} \ ,$$

by use of Lemma D.9 and $\sqrt{q}^{1/q} \leq \sqrt{e}$ for every $q > 2$.

If $q > 4$,

$$\begin{aligned} B^*(q,\gamma) &= \gamma^{-q/(q-1)} E\left[\left|Z - Z'\right|^q\right] \\ &\leq \gamma^{-q/(q-1)} 2^{q/2+1} e\sqrt{q}\left[\frac{q}{e}\left(\gamma^{1/(q-1)}+q\right)\right]^{q/2} \\ &\leq \gamma^{-q/(q-1)} 2^{q/2}\sqrt{2e}^q\sqrt{e}^q\left[\frac{q}{e}\left(\gamma^{1/(q-1)}+q\right)\right]^{q/2} \\ &\leq \gamma^{-q/(q-1)}\left[4eq\left(\gamma^{1/(q-1)}+q\right)\right]^{q/2} = \gamma^{-q/(q-1)}\left(\sqrt{4eq\left(\gamma^{1/(q-1)}+q\right)}\right)^q , \end{aligned}$$

applying Lemma D.11 with $\lambda = 1/2\gamma^{1/(q-1)}$.

□

D.2. Technical lemmas

D.2.1. Basic computations for resampling applied to the kNN algorithm

Lemma D.4. *For every $1 \leq i \leq n$ and $1 \leq p \leq n$, one has*

$$\mathbb{P}_e\left(i \in \bar{e}\right) = \frac{p}{n}, \tag{D.5}$$

$$\sum_{j=1}^{n} \mathbb{P}_e\left[\, i \in \bar{e},\ j \in V_k^e(X_i)\,\right] = \frac{kp}{n}\ , \tag{D.6}$$

$$\sum_{k<\sigma_i(j)\leq k+p} \mathbb{P}_e\left[\, i \in \bar{e},\ j \in V_k^e(X_i)\,\right] = \frac{kp}{n}\frac{p-1}{n-1}\ . \tag{D.7}$$

Proof of Lemma D.4. The first equality is straightforward. The second one results from simple calculations as follows.

$$\begin{aligned} \sum_{j=1}^{n} \mathbb{P}_e\left[\, i \in \bar{e},\ j \in V_k^e(X_i)\,\right] &= \sum_{j=1}^{n}\binom{n}{p}^{-1}\sum_e \mathbb{1}_{i\in\bar{e}}\mathbb{1}_{j\in V_k^e(X_i)} = \binom{n}{p}^{-1}\sum_e \mathbb{1}_{i\in\bar{e}}\left(\sum_{j=1}^{n}\mathbb{1}_{j\in V_k^e(X_i)}\right) \\ &= \left(\binom{n}{p}^{-1}\sum_e \mathbb{1}_{i\in\bar{e}}\right)k = \frac{p}{n}\,k\ . \end{aligned}$$

For the last equality, let us notice every $j \in V_i$ satisfies

$$\mathbb{P}_e\left[\, i \in \bar{e},\ j \in V_k^e(X_i)\,\right] = \mathbb{P}_e\left[\, j \in V_k^e(X_i) \mid i \in \bar{e}\,\right]\mathbb{P}_e\left[\, i \in \bar{e}\,\right] = \frac{n-1}{n-p}\frac{p}{n}\ ,$$

hence

$$\begin{aligned} \sum_{k<\sigma_i(j)\leq k+p} \mathbb{P}_e\left[\, i \in \bar{e},\ j \in V_k^e(X_i)\,\right] &= \sum_{j=1}^{n}\mathbb{P}_e\left[\, i \in \bar{e},\ j \in V_k^e(X_i)\,\right] - \sum_{\sigma_i(j)\leq k}\mathbb{P}_e\left[\, i \in \bar{e},\ j \in V_k^e(X_i)\,\right] \\ &= k\frac{p}{n} - k\frac{n-1}{n-p}\frac{p}{n} = k\frac{p}{n}\frac{p-1}{n-1}\ . \end{aligned}$$

□

D.2.2. Stone's lemma

Lemma D.5 (Devroye et al. (1996), Corollary 11.1, p. 171)**.** *Given n points $(x_1, ..., x_n)$ in $\mathbb{R}^d$, any of these points belongs to the k nearest neighbors of at most $k\gamma_d$ of the other points, where γ_d increases on d.*

D.2.3. Stability of the kNN classifier when removing p observations

Lemma D.6 (Devroye and Wagner (1979b), Eq. (14))**.** *For every $1 \leq k \leq n$, let $\mathcal{A}_k$ denote k-NN classification algorithm defined by Eq. (2.1), and let $Z_1, \ldots, Z_n$ denote n i.i.d. random variables such that for every $1 \leq i \leq n$, $Z_i = (X_i, Y_i) \sim P$. Then for every $1 \leq p \leq n-k$,*

$$\mathbb{P}\left[\,\mathcal{A}_k(Z_{1,n}; X) \neq \mathcal{A}_k(Z_{1,n-p}; X)\,\right] \leq \frac{4}{\sqrt{2\pi}}\frac{p\sqrt{k}}{n}\ ,$$

where $Z_{1,i} = (Z_1, \ldots, Z_i)$ for every $1 \leq i \leq n$, and $(X, Y) \sim P$ is independent of $Z_{1,n}$.

D.2.4. Exponential concentration inequality for the L1O estimator

Lemma D.7 (Devroye et al. (1996), Theorem 24.4)**.** *For every $1 \leq k \leq n$, let $\mathcal{A}_k$ denote k-NN classification algorithm defined by Eq. (2.1). Let also $\widehat{R}_1(\cdot)$ denote the L1O estimator defined by Eq. (2.2) with $p = 1$. Then for every $\varepsilon > 0$,*

$$\mathbb{P}\left(\left|\widehat{R}_1(\mathcal{A}_k, Z_{1,n}) - \mathbb{E}\left[\,\widehat{R}_1(\mathcal{A}_k, Z_{1,n})\,\right]\right| > \varepsilon\right) \leq 2\exp\left\{-n\frac{\varepsilon^2}{\gamma_d^2 k^2}\right\}.$$

D.2.5. Moment upper bounds for the L1O estimator

Lemma D.8. *For every $1 \leq k \leq n$, let $\mathcal{A}_k$ denote k-NN classification algorithm defined by Eq. (2.1). Let also $\widehat{R}_1(\cdot)$ denote the L1O estimator defined by Eq. (2.2) with $p = 1$. Then for every $q \geq 1$,*

$$\mathbb{E}\left[\left|\widehat{R}_1\left(\mathcal{A}_k, Z_{1,n}\right) - \mathbb{E}\left[\,\widehat{R}_1\left(\mathcal{A}_k, Z_{1,n}\right)\,\right]\right|^{2q}\right] \leq q!\left(2\frac{(k\gamma_d)^2}{n}\right)^q. \tag{D.8}$$

The proof is straightforward from the combination of Lemmas D.1 and D.7.

D.2.6. Upper bound on the optimal constant in the Rosenthal's inequality

Lemma D.9. *Let N denote a real-valued standard Gaussian random variable. Then for every $q > 2$, one has*

$$\mathbb{E}\left[\,|N|^q\,\right] \leq \sqrt{2}e\sqrt{q}\left(\frac{q}{e}\right)^{\frac{q}{2}}.$$

Proof of Lemma D.9. If q is even ($q = 2k > 2$), then

$$\begin{aligned} \mathbb{E}\left[\,|N|^q\,\right] &= 2\int_0^{+\infty} x^q \frac{1}{\sqrt{2\pi}} e^{-\frac{x^2}{2}}dx = \sqrt{\frac{2}{\pi}}(q-1)\int_0^{+\infty} x^{q-2}e^{-\frac{x^2}{2}}dx \\ &= \sqrt{\frac{2}{\pi}}\frac{(q-1)!}{2^{k-1}(k-1)!} = \sqrt{\frac{2}{\pi}}\frac{q!}{2^{q/2}(q/2)!}\ . \end{aligned}$$

Then using for any positive integer a

$$\sqrt{2\pi a}\left(\frac{a}{e}\right)^a < a! < \sqrt{2e\pi a}\left(\frac{a}{e}\right)^a,$$

it results

$$\frac{q!}{2^{q/2}(q/2)!} < \sqrt{2e}\, e^{-q/2} q^{q/2},$$

which implies

$$\mathbb{E}\left[\,|N|^q\,\right] \leq 2\sqrt{\frac{e}{\pi}}\left(\frac{q}{e}\right)^{q/2} < \sqrt{2}e\sqrt{q}\left(\frac{q}{e}\right)^{\frac{q}{2}} \ .$$

If q is odd ($q = 2k+1 > 2$), then

$$\mathbb{E}\left[\,|N|^q\,\right] = \sqrt{\frac{2}{\pi}}\int_0^{+\infty} x^q e^{-\frac{x^2}{2}} dx = \sqrt{\frac{2}{\pi}}\int_0^{+\infty} \sqrt{2t}^q e^{-t}\frac{dt}{\sqrt{2t}},$$

by setting $x = \sqrt{2t}$. In particular, this implies

$$\mathbb{E}\left[\,|N|^q\,\right] \leq \sqrt{\frac{2}{\pi}}\int_0^{+\infty} (2t)^k\, e^{-t} dt = \sqrt{\frac{2}{\pi}} 2^k k! = \sqrt{\frac{2}{\pi}} 2^{\frac{q-1}{2}}\left(\frac{q-1}{2}\right)! < \sqrt{2}e\sqrt{q}\left(\frac{q}{e}\right)^{\frac{q}{2}}.$$

□

Lemma D.10. *Let S denote a binomial random variable such that $S \sim \mathcal{B}(k, 1/2)$ ($k \in \mathbb{N}^*$). Then for every $q > 3$, it comes*

$$\mathbb{E}\left[\,|S - \mathbb{E}\left[\,S\,\right]|^q\,\right] \leq 4\sqrt{e}\sqrt{q}\sqrt{\frac{qk}{2e}}^q \ .$$

Proof of Lemma D.10. Since $S - \mathbb{E}(S)$ is symmetric, it comes

$$\mathbb{E}\left[\,|S - \mathbb{E}\left[\,S\,\right]|^q\,\right] = 2\int_0^{+\infty} \mathbb{P}\left[\,S < \mathbb{E}\left[\,S\,\right] - t^{1/q}\,\right] dt = 2q\int_0^{+\infty} \mathbb{P}\left[\,S < \mathbb{E}\left[\,S\,\right] - u\,\right] u^{q-1} du.$$

Using Chernoff's inequality and setting $u = \sqrt{k/2}v$, it results

$$\mathbb{E}\left[\,|S - \mathbb{E}\left[\,S\,\right]|^q\,\right] \leq 2q\int_0^{+\infty} u^{q-1} e^{-\frac{u^2}{k}} du = 2q\sqrt{\frac{k}{2}}^q \int_0^{+\infty} v^{q-1} e^{-\frac{v^2}{2}} dv.$$

If q is even, then $q-1 > 2$ is odd and the same calculations as in the proof of Lemma D.9 apply, which leads to

$$\mathbb{E}\left[\,|S - \mathbb{E}\left[\,S\,\right]|^q\,\right] \leq 2\sqrt{\frac{k}{2}}^q 2^{q/2}\left(\frac{q}{2}\right)! \leq 2\sqrt{\frac{k}{2}}^q 2^{q/2}\sqrt{\pi e q}\left(\frac{q}{2e}\right)^{q/2} = 2\sqrt{\pi e}\sqrt{q}\sqrt{\frac{qk}{2e}}^q < 4\sqrt{e}\sqrt{q}\sqrt{\frac{qk}{2e}}^q \ .$$

If q is odd, then $q - 1 > 2$ is even and another use of the calculations in the proof of Lemma D.9 provides

$$\mathbb{E}\left[\,|S - \mathbb{E}\left[\,S\,\right]|^q\,\right] \leq 2q\sqrt{\frac{k}{2}}^q \frac{(q-1)!}{2^{(q-1)/2}\frac{q-1}{2}!} = 2\sqrt{\frac{k}{2}}^q \frac{q!}{2^{(q-1)/2}\frac{q-1}{2}!}.$$

Let us notice

$$\begin{aligned}\frac{q!}{2^{(q-1)/2}\frac{q-1}{2}!} &\leq \frac{\sqrt{2\pi e q}\left(\frac{q}{e}\right)^q}{2^{(q-1)/2}\sqrt{\pi(q-1)}\left(\frac{q-1}{2e}\right)^{(q-1)/2}} = \sqrt{2e}\sqrt{\frac{q}{q-1}}\frac{\left(\frac{q}{e}\right)^q}{\left(\frac{q-1}{e}\right)^{(q-1)/2}} \\ &= \sqrt{2e}\sqrt{\frac{q}{q-1}}\left(\frac{q}{e}\right)^{(q+1)/2}\left(\frac{q}{q-1}\right)^{(q-1)/2}\end{aligned}$$

and also that

$$\sqrt{\frac{q}{q-1}}\left(\frac{q}{q-1}\right)^{(q-1)/2} \leq \sqrt{2e}.$$

This implies

$$\frac{q!}{2^{(q-1)/2}\frac{q-1}{2}!} \leq 2e\left(\frac{q}{e}\right)^{(q+1)/2} = 2\sqrt{e}\sqrt{q}\left(\frac{q}{e}\right)^{q/2},$$

hence

$$\mathbb{E}\left[\,|S - \mathbb{E}\left[\,S\,\right]|^q\,\right] \leq 2\sqrt{\frac{k}{2}}^q 2\sqrt{e}\sqrt{q}\left(\frac{q}{e}\right)^{q/2} = 4\sqrt{e}\sqrt{q}\sqrt{\frac{qk}{2e}}^q \ .$$

□

Lemma D.11. *Let X, Y be two i.i.d. random variables with Poisson distribution $\mathcal{P}(\lambda)$ ($\lambda > 0$). Then for every $q > 3$, it comes*

$$\mathbb{E}\left[\,|X - Y|^q\,\right] \leq 2^{q/2+1} e\sqrt{q}\left[\,\frac{q}{e}\left(2\lambda + q\right)\,\right]^{q/2}.$$

Proof of Lemma D.11. Let us first remark that

$$\mathbb{E}\left[\,|X - Y|^q\,\right] = \mathbb{E}_N\left[\,\mathbb{E}\left[\,|X - Y|^q \mid N\,\right]\,\right] = 2^q \mathbb{E}_N\left[\,\mathbb{E}\left[\,|X - N/2|^q \mid N\,\right]\,\right],$$

where $N = X + Y$. Furthermore, the conditional distribution of X given $N = X + Y$ is a binomial distribution $\mathcal{B}(N, 1/2)$. Then Lemma D.10 provides that

$$\mathbb{E}\left[\,|X - N/2|^q \mid N\,\right] \leq 4\sqrt{e}\sqrt{q}\sqrt{\frac{qN}{2e}}^q \qquad a.s.,$$

which entails that

$$\mathbb{E}\left[\,|X - Y|^q\,\right] \leq 2^q \mathbb{E}_N\left[\,4\sqrt{e}\sqrt{q}\sqrt{\frac{qN}{2e}}^q\,\right] = 2^{q/2+2}\sqrt{e}\sqrt{q}\sqrt{\frac{q}{e}}^q \mathbb{E}_N\left[\,N^{q/2}\,\right].$$

It only remains to upper bound the last expectation where N is a Poisson random variable $\mathcal{P}(2\lambda)$ (since X, Y are *i.i.d.*):

$$\mathbb{E}_N\left[N^{q/2}\right] \leq \sqrt{\mathbb{E}_N\left[N^q\right]}$$

by Jensen's inequality. Further introducing Touchard polynomials and using a classical upper bound, it comes

$$\begin{aligned}\mathbb{E}_N\left[N^{q/2}\right] &\leq \sqrt{\sum_{i=1}^{q}(2\lambda)^i\frac{1}{2}\binom{q}{i}i^{q-i}} \leq \sqrt{\sum_{i=0}^{q}(2\lambda)^i\frac{1}{2}\binom{q}{i}q^{q-i}} \\ &= \sqrt{\frac{1}{2}\sum_{i=0}^{q}\binom{q}{i}(2\lambda)^i q^{q-i}} = \sqrt{\frac{1}{2}(2\lambda+q)^q} = 2^{\frac{-1}{2}}(2\lambda+q)^{q/2}.\end{aligned}$$

Finally, one concludes

$$\mathbb{E}\left[|X-Y|^q\right] \leq 2^{q/2+2}\sqrt{e}\sqrt{q}\sqrt{\frac{q}{e}}^q 2^{\frac{-1}{2}}(2\lambda+q)^{q/2} < 2^{q/2+1}e\sqrt{q}\left[\frac{q}{e}(2\lambda+q)\right]^{q/2}.$$

Abstract

We study maximum selection and sorting of n numbers using imperfect pairwise comparators. The imperfect comparator returns the larger of the two inputs if the inputs are more than a given threshold apart and an adversarially-chosen input otherwise. We consider two adversarial models: a non-adaptive adversary that decides on the outcomes in advance and an adaptive adversary that decides on the outcome of each comparison depending on the previous comparisons and outcomes.

Against the non-adaptive adversary, we derive a maximum-selection algorithm that uses at most $2n$ comparisons in expectation and a sorting algorithm that uses at most $2n \ln n$ comparisons in expectation. In the presence of the adaptive adversary, the proposed maximum-selection algorithm uses $\Theta(n \log(1/\epsilon))$ comparisons to output a correct answer with probability at least $1 - \epsilon$, resolving an open problem in Ajtai et al. (2015).

Our study is motivated by a density-estimation problem. Given samples from an unknown distribution, we would like to find a distribution among a known class of n candidate distributions that is close to the underlying distribution in ℓ_1 distance. Scheffe's algorithm, for example, in Devroye and Lugosi (2001) outputs a distribution at an ℓ_1 distance at most 9 times the minimum and runs in time $\Theta(n^2 \log n)$. Using our algorithm, the runtime reduces to $\Theta(n \log n)$.

Keywords: noisy sorting, adversarial comparators, density estimation, Scheffe estimator

1. Introduction

Maximum selection and sorting are fundamental operations with widespread applications in computing, investment, marketing (Aggarwal et al., 2009), decision making (Thurstone, 1927; David, 1963), and sports. These operations are often accomplished via pairwise comparisons between elements, and the goal is to minimize the number of comparisons.

For example, one may find the largest of n elements by first comparing two elements and then successively comparing the larger one to a new element. This simple algorithm takes $n-1$ comparisons, and it is easy to see that $n-1$ comparisons are necessary. Similarly, *merge sort* sorts n elements using less than $n \log n$ comparisons, close to the information theoretic lower bound of $\log n! = n \log n - o(n)$.

However, in many applications, the pairwise comparisons may be imprecise. For example, in comparing two random numbers, such as stock performances, or team strengths, the output of the comparison may vary due to chance. Consequently, a number of researchers have considered maximum selection and sorting with imperfect, or noisy, comparators. The comparators in these models mostly function correctly but occasionally may produce an inaccurate comparison result, where the form of inaccuracy is dictated by the application.

Based on the form of inaccuracy, models can be divided into two categories: probabilistic and adversarial. Probabilistic models can be parametric or non-parametric. One of the simplest parametric probabilistic models was considered in Feige et al. (1994), where the output of each comparator could be wrong with some known probability p. Algorithms applying this model for maximum selection were proposed in Adler et al. (1994) and for ranking in Karp and Kleinberg (2007); Ben-Or and Hassidim (2008); Braverman and Mossel (2008); Braverman et al. (2016).

Another parametric family of probabilistic models, the Bradley-Terry-Luce model (Bradley and Terry, 1952) assumes that if two values x and y are compared, then x is selected as the larger with probability $x/(x+y)$. Observe that the comparison is correct with probability $\max\{x,y\}/(x+y) \geq 1/2$. Algorithms for ranking and estimating values under this and another related model, the Plackett-Luce (Plackett, 1975; Luce, 2005), are proposed, for example, in Negahban et al. (2012); Szörényi et al. (2015). The Mallows model is yet another example of a parametric probabilistic model and is studied in Busa-Fekete et al. (2014).

Non-parametric probabilistic models assume some natural constraints on comparison probabilities, such as Strong Stochastic Transitivity or Stochastic Triangle Inequality. Algorithms for maximum selection and sorting under these models are studied in Falahatgar et al. (2017b,a, 2018); Yue and Joachims (2011) and algorithms for comparison-probability matrix estimation are considered in Shah et al. (2016). This model is also considered for the top-k sorting problem in Chen et al. (2017b,a).

We consider a model where, unlike the probabilistic models, the comparison outcome can be adversarial. If the numbers compared are more than a threshold Δ apart, the comparison is correct, while if they differ by at most Δ, the comparison outcome is arbitrary, and possibly even adversarial.

This model can be partially motivated by physical observations. Measurements are regularly quantized and often adulterated with some measurement noise. Quantities with the same quantized value may, therefore, be incorrectly compared. In psychophysics, the

Weber-Fechner law (Ekman, 1959) stipulates that humans can distinguish between two physical stimuli only when their difference exceeds some threshold (known as *just noticeable difference*). Additionally, in sports, a judge or a home-team advantage may, even adversarially, sway the outcome of a game between two teams of similar strength but not between teams of significantly different strengths. Our main motivation for the model derives from the important problem of density estimation and distribution learning.

1.1. Density estimation via pairwise comparisons

In a typical PAC-learning setup (Valiant, 1984; Kearns et al., 1994), we are given samples from an unknown distribution p_0 in a known distribution class $\mathcal{P}$ and would like to find, with high probability, a distribution $\hat{p} \in \mathcal{P}$ such that $\|\hat{p} - p_0\|_1 < \delta$.

One standard approach proceeds in two steps (Devroye and Lugosi, 2001):

1. Offline, construct a δ-*cover* of $\mathcal{P}$, a finite collection $\mathcal{P}_\delta \subseteq \mathcal{P}$ of distributions such that for any distribution $p \in \mathcal{P}$, there is a distribution $q \in \mathcal{P}_\delta$ such that $\|p - q\|_1 < \delta$.

2. Using the samples from p_0, find a distribution in $\mathcal{P}_\delta$ whose ℓ_1 distance to p_0 is close to the ℓ_1 distance of the distribution in $\mathcal{P}_\delta$ that is closest to p_0.

These two steps output a distribution whose ℓ_1 distance from p_0 is *close* to δ. Surprisingly, for several common distribution classes, such as Gaussian mixtures, the number of samples required by this generic approach matches the information theoretically optimal sample complexity, up to logarithmic factors (Daskalakis and Kamath, 2014; Suresh et al., 2014; Diakonikolas et al., 2016).

The Scheffe Algorithm (Scheffe, 1947; Devroye and Lugosi, 2001) is a popular method for implementing the second step, namely to find a distribution in $\mathcal{P}_\delta$ with a small ℓ_1 distance from p_0. It takes every pair of distributions in $\mathcal{P}_\delta$ and uses the samples from p_0 to decide which of the two distributions is closer to p_0. It then declares the distribution that "wins" the most pairwise closeness comparisons to be the nearly-closest to p_0. As shown in Devroye and Lugosi (2001), the Scheffe algorithm yields, with high probability, a distribution that is at most nine times further from p_0 than the distribution in $\mathcal{P}_\delta$ with the lowest ℓ_1 distance from p_0, plus a diminishing additive term; hence, a distribution that is roughly 9δ away from p_0 is found. Since this algorithm compares every pair of distributions in $\mathcal{P}_\delta$, it uses quadratic in $|\mathcal{P}_\delta|$ comparisons. In Section 6, we use maximum-selection results to derive an algorithm with the same approximation guarantee but linear in $|\mathcal{P}_\delta|$ comparisons.

1.2. Organization

This paper is organized as follows: in Section 2, we define the problem and introduce the notations; in Section 3, we summarize the results; in Section 4, we derive simple bounds and describe the performance of simple algorithms; and, in Section 5, we present our main maximum-selection algorithms. The relation between density estimation problem and our comparison model is discussed in Section 6, and, in Section 7, we discuss sorting with adversarial comparators.

2. Notations and preliminaries

Practical applications call for sorting or selecting the maximum of not just numbers, but, rather, of items with associated values—for example, finding the person with the highest salary, the product with the lowest price, or a sports team with the most *capability* of winning. Associate with each item i a real value x_i and let $\mathcal{X} \stackrel{\text{def}}{=} \{x_1, \ldots, x_n\}$ be the multiset of values. In maximum selection, we use noisy pairwise comparisons to find an index i such that x_i is close to the largest element $x^* \stackrel{\text{def}}{=} \max\{x_1, \ldots, x_n\}$.

Formally, a faulty comparator $\mathcal{C}$ takes two distinct indices i and j and, if $|x_i - x_j| > \Delta$, outputs the index associated with the higher value, while if $|x_i - x_j| \le \Delta$, outputs either i or j, possibly adversarially. Without loss of generality, we assume that $\Delta = 1$. Then,

$$\mathcal{C}(i,j) = \begin{cases} \arg\max\{x_i, x_j\} & \text{if} \quad |x_i - x_j| > 1, \\ i \text{ or } j \text{ (adversarially)} & \text{if} \quad |x_i - x_j| \le 1. \end{cases}$$

It is easier to think just of the numbers, rather than the indices. Therefore, informally we will simply view the comparators as taking two real inputs x_i and x_j, and outputting

$$\mathcal{C}(x_i,x_j) = \begin{cases} \max\{x_i, x_j\} & \text{if} \quad |x_i - x_j| > 1, \\ x_i \text{ or } x_j \text{ (adversarially)} & \text{if} \quad |x_i - x_j| \le 1. \end{cases} \tag{1}$$

We consider two types of adversarial comparators: *non-adaptive* and *adaptive*.

- A *non-adaptive adversarial comparator* has complete knowledge of $\mathcal{X}$ and the algorithm but must fix its outputs for every pair of inputs before the algorithm starts
- An *adaptive adversarial comparator* not only has access to the algorithm and the inputs but is also allowed to adaptively decide the outcomes of the queries taking into account all the previous comparisons made by the algorithm

A non-adaptive comparator can be naturally represented by a directed graph with n nodes representing the n indices. There is an edge from node i to node j if the comparator declares x_i to be larger than x_j, namely, $\mathcal{C}(x_i, x_j) = x_i$. Figure 1 is an example of such a comparator, where, for simplicity, we show only the values 0, 1, 1, 2, and not the indices. Note that, by definition, $\mathcal{C}(2,0) = 2$, but for all the other pairs, the outputs can be decided by the comparator. In this example, the comparator declares the node with value 2 as the "winner" against the right node with value 1 but as the "loser" against the left node, also with value 1. Among the two nodes with value 1, it arbitrarily declares the left one as the winner. An adaptive adversary reveals the edges one-by-one as the algorithm proceeds.

We refer to each comparison as a *query*. The number of queries an algorithm $\mathcal{A}$ makes for $\mathcal{X} = \{x_1, \ldots, x_n\}$ is its *query complexity*, denoted by $Q_n^{\mathcal{A}}$.[1] Our algorithms are randomized, and $Q_n^{\mathcal{A}}$ is a random variable. The *expected query complexity* of $\mathcal{A}$ for the input $\mathcal{X}$ is

$$q_n^{\mathcal{A}} \stackrel{\text{def}}{=} \mathbb{E}[Q_n^{\mathcal{A}}],$$

where the expectation is over the randomness of the algorithm. Note that the expected query complexity is defined for all runs of an algorithm, and it is independent of the success probability.

1. This is a slight abuse of notation suppressing $\mathcal{X}$.

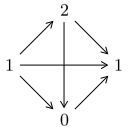

Figure 1: Comparator for four inputs with values $\{0, 1, 1, 2\}$

Let $\mathcal{C}_{\text{non}}(\mathcal{X})$, or simply $\mathcal{C}_{\text{non}}$, be the set of all non-adaptive adversarial comparators, and let $\mathcal{C}_{\text{adpt}}$ be the set of all adaptive adversarial comparators. The *maximum expected query complexity* of $\mathcal{A}$ against non-adaptive adversarial comparators is

$$q_n^{\mathcal{A},\text{non}} \stackrel{\text{def}}{=} \max_{\mathcal{C}\in\mathcal{C}_{\text{non}}} \max_{\mathcal{X}} q_n^{\mathcal{A}}. \tag{2}$$

Similarly, the maximum expected query complexity of $\mathcal{A}$ against adaptive adversarial comparators is

$$q_n^{\mathcal{A},\text{adpt}} \stackrel{\text{def}}{=} \max_{\mathcal{C}\in\mathcal{C}_{\text{adpt}}} \max_{\mathcal{X}} q_n^{\mathcal{A}}.$$

We evaluate an algorithm by how close its output is to x^* (the maximum of $\mathcal{X}$).

Definition 1 *A number x is a* t-approximation *of x^* if $x \geq x^* - t$.*

The *t-approximation error* of an algorithm $\mathcal{A}$ over n inputs is

$$\mathcal{E}_n^{\mathcal{A}}(t) \stackrel{\text{def}}{=} \Pr\left(Y_{\mathcal{A}}(\mathcal{X}) < x^* - t\right),$$

the probability that $\mathcal{A}$'s output $Y_{\mathcal{A}}(\mathcal{X})$ is *not* a t-approximation of x^*. For an algorithm $\mathcal{A}$, the maximum t-approximation error for the worst non-adaptive adversary is

$$\mathcal{E}_n^{\mathcal{A},\text{non}}(t) \stackrel{\text{def}}{=} \max_{\mathcal{C}\in\mathcal{C}_{\text{non}}} \max_{\mathcal{X}} \mathcal{E}_n^{\mathcal{A}}(t),$$

and, similarly, for the adaptive adversary,

$$\mathcal{E}_n^{\mathcal{A},\text{adpt}}(t) \stackrel{\text{def}}{=} \max_{\mathcal{C}\in\mathcal{C}_{\text{adpt}}} \max_{\mathcal{X}} \mathcal{E}_n^{\mathcal{A}}(t).$$

For the non-adaptive adversary, the minimum t-approximation error of any algorithm is

$$\mathcal{E}_n^{\text{non}}(t) \stackrel{\text{def}}{=} \min_{\mathcal{A}} \mathcal{E}_n^{\mathcal{A},\text{non}}(t),$$

and, similarly, for the adaptive adversary,

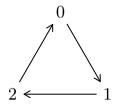
$$\mathcal{E}_n^{\text{adpt}}(t) \stackrel{\text{def}}{=} \min_{\mathcal{A}} \mathcal{E}_n^{\mathcal{A},\text{adpt}}(t).$$

Since adaptive adversarial comparators are stronger than non-adaptive, for all t,

$$\mathcal{E}_n^{\text{adpt}}(t) \geq \mathcal{E}_n^{\text{non}}(t).$$

Example 1 shows that $\mathcal{E}_3^{\text{non}}(t) \geq \frac{1}{3}$ for all $t < 2$.

Example 1 *$\mathcal{E}_3^{\text{non}}(t) \geq \frac{1}{3}$ for all $t < 2$. Consider $\mathcal{X} = \{0, 1, 2\}$ and the following comparators. .*



By symmetry, no algorithm can differentiate between the three inputs. Hence, any algorithm will output 0 with probability $1/3$.

3. Previous and new results

In Section 4.1 we lower bound $\mathcal{E}_n^{\text{non}}(t)$ as a function of t. In Lemma 2, we show that for all $t < 1$ and odd n, $\mathcal{E}_n^{\text{non}}(t) = 1 - 1/n$, namely for some $\mathcal{X}$, approximating the maximum to within less than one is equivalent to guessing a random x_i as the maximum. In Lemma 3, we modify Example 1 and show that for all $t < 2$ and odd n, any algorithm has t-approximation error close to $1/2$ for some input.

We propose a number of algorithms to approximate the maximum. These algorithms have different guarantees in terms of the probability of error, approximation factor, and query complexity.

We first consider two simple algorithms: the complete tournament, denoted COMPL, and the sequential selection, denoted SEQ. Algorithm COMPL compares all the possible input pairs and declares the input with the most wins as the maximum. We show the simple result that COMPL outputs a 2-approximation of x^*. We then consider the algorithm SEQ that compares a pair of inputs, discards the loser, and compares the winner with a new input. We show that even under random selection of the inputs, there exist inputs such that, with high probability, SEQ cannot provide a constant approximation to x^*.

We then consider more advanced algorithms. The knock-out algorithm, at each stage, pairs the inputs at random and keeps the winners of the comparisons for the next stage. We design a slight modification of this algorithm, denoted KO-MOD that achieves a 3-approximation with error probability at most ϵ, even against adaptive adversarial comparators. We note that Ajtai et al. (2015) proposed a different algorithm with similar performance guarantees.

Motivated by quick-sort, we propose a quick-select algorithm Q-SELECT that outputs a 2-approximation with zero error probability. It has an expected query complexity of at most $2n$ against the non-adaptive adversary. However, in Example 2, we see that this algorithm requires $\binom{n}{2}$ queries against the adaptive adversary.

This leaves the question of whether there is a randomized algorithm for 2-approximation of x^* with $\mathcal{O}(n)$ queries against the adaptive adversary. In fact, Ajtai et al. (2015) pose this as an open question. We resolve this problem by designing an algorithm COMB that combines quick-select and knock-out. We prove that COMB outputs a 2-approximation with probability of error, at most, ϵ, using $\mathcal{O}(n \log \frac{1}{\epsilon})$ queries. We summarize the results in Table 1.

We note that while we focus on randomized algorithms, Ajtai et al. (2015) also studied the best possible trade-offs for deterministic algorithms. They designed a deterministic

Algorithm	Notation	Approximation	$q_n^{\mathcal{A},\text{non}}$	$q_n^{\mathcal{A},\text{adpt}}$

Table 1: Maximum selection algorithms

algorithm for 2-approximation of the maximum using only $\mathcal{O}(n^{3/2})$ queries. Moreover, they prove that no deterministic algorithm with fewer than $\Omega(n^{4/3})$ queries can output a 2-approximation of x^* for the adaptive adversarial model.

4. Simple results

In Lemmas 2 and 3, we prove lower bounds on the error probability of any algorithm that provides a t-approximation of x^* for $t < 1$ and $t < 2$, respectively. We then consider two straightforward algorithms for finding the maximum. One is the complete tournament, where all pairs of inputs are compared, and the other is sequential, where inputs are compared sequentially, and the loser is discarded at each comparison.

4.1. Lower bounds

We show the following two results:

- $\mathcal{E}_n^{\text{non}}(t) = 1 - \frac{1}{n}$ for all $0 \le t < 1$ and odd n
- $\mathcal{E}_n^{\text{non}}(t) \ge \frac{1}{2} - \frac{1}{2n}$ for all $1 \le t < 2$ and odd n

These lower bounds can be applied to n, which is even, by adding an extra input that is smaller than all the other inputs and loses to them.

Lemma 2 *For all $0 \le t < 1$ and odd n,*

$$\mathcal{E}_n^{\text{non}}(t) = 1 - \frac{1}{n}.$$

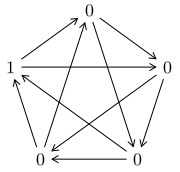

Figure 2: Tournament for Lemma 2 when $n = 5$

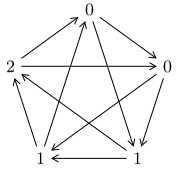

Figure 3: Tournament for Lemma 3 when $n = 5$

Proof Let $(x_1, x_2, \ldots, x_n)$ be an unknown permutation of $(1, \underbrace{0, \ldots, 0}_{n-1})$. Suppose we consider an adversary that ensures each input wins exactly $(n-1)/2$ times. An example is shown in Figure 2 for $n = 5$.

To get a lower bound on the performance of any randomized algorithm, we use Yao's principle. We consider only deterministic algorithms over a uniformly chosen permutation of the inputs, namely only one of the coordinates is 1, and the remaining are less than $1-t$. In this case, if we fix any comparison graph (as in Figure 2), and permute the inputs, the algorithm cannot distinguish between 1 and 0's, and outputs 0 with probability $1 - 1/n$; therefore, $\mathcal{E}_n^{\text{non}}(t) \ge 1 - \frac{1}{n}$. Also, an algorithm that randomly picks an element as the maximum achieves the error $1 - 1/n$; hence, the lemma. ■

Lemma 3 *For all $1 \le t < 2$ and odd n,*

$$\mathcal{E}_n^{\text{non}}(t) \ge \frac{1}{2} - \frac{1}{2n}.$$

Proof Let m be $(n-1)/2$. Let $(x_1, x_2, \ldots, x_n)$ be an unknown permutation of $(2, \underbrace{1, \ldots, 1}_{m}, \underbrace{0, \ldots, 0}_{m})$. Suppose the adversary ensures that 2 loses against all the 1's and, indeed, all inputs have exactly $(n-1)/2$ wins. An example is shown in Figure 3.

Similar to Lemma 2, the inputs are all identical to the algorithm, and, therefore, the algorithm outputs one of the 0's with probability $\frac{m}{n} = \frac{1}{2} - \frac{1}{2n}$. ■

4.2. Two elementary algorithms

In this section, we analyze two well-known maximum selection algorithms, the complete tournament and the sequential selection. We discuss their strengths and weaknesses and show that there is a trade-off between the query complexity and the approximation guarantees of these two algorithms. Another well-known algorithm for maximum selection is the knock-out algorithm, and we discuss a variant of it in Section 5.1.

4.2.1. Complete tournament (round-robin)

As its name evinces, a complete tournament involves a match between every pair of teams. Using this metaphor to competitions, we compare all the $\binom{n}{2}$ input pairs, and the input with maximum wins is declared as the output. If two or more inputs end up with the highest wins, any of them can be declared as the output. This algorithm is formally stated in COMPL.

input: $\mathcal{X}$
    compare all input pairs in $\mathcal{X}$, count the number of times each input wins
output: an input with the maximum number of wins

Algorithm COMPL - Complete tournament

Lemma 4 shows that COMPL gives a 2-approximation against both adversaries. The result, although weaker than the deterministic guarantees of Ajtai et al. (2015), is illustrative and useful in the algorithms proposed later.

Lemma 4 $q_n^{\text{COMPL,adpt}} = \binom{n}{2}$ *and* $\mathcal{E}_n^{\text{COMPL,adpt}}(2) = 0$.

Proof The number of queries is clearly $\binom{n}{2}$. To show $\mathcal{E}_n^{\text{COMPL,adpt}}(2) = 0$, note that if $y < x^* - 2$, then for all z that y wins over, $z \le y + 1 < x^* - 1$, and therefore x^* also beats them. Since x^* wins over y, it wins over more inputs than y, and y cannot be the output of the algorithm. It follows that the input with maximum wins is a 2-approximation of x^*. ■

COMPL is deterministic, and, after $\binom{n}{2}$ queries, it outputs a 2-approximation of x^*. If the comparators are noiseless, we can simply compare the inputs sequentially, discarding the loser at each step, and, thus, requiring only $n-1$ comparisons. This evokes the hope of finding a deterministic algorithm that requires a linear number of comparisons and outputs a 2-approximation of x^*. As mentioned earlier, however, Ajtai et al. (2015) showed it is not achievable, as they proved that any deterministic 2-approximation algorithm requires $\Omega(n^{4/3})$ queries. They also showed a strictly superlinear lower bound on any deterministic constant-approximation algorithm. They designed a deterministic 2-approximation algorithm using $\mathcal{O}(n^{3/2})$ queries.

4.2.2. Sequential selection

Sequential selection first compares a random pair of inputs and, at each successive step, compares the winner of the last comparison with a randomly chosen *new* input. It outputs the final remaining input. This algorithm uses $n-1$ queries.

input: $\mathcal{X}$
    choose a random $y \in \mathcal{X}$ and remove it from $\mathcal{X}$
    while $\mathcal{X}$ is not empty
        choose a random $x \in \mathcal{X}$ and remove it from $\mathcal{X}$
        $y \leftarrow \mathcal{C}(x, y)$
    end while
output: y

Algorithm SEQ - Sequential selection

Lemma 5 shows that even against the non-adaptive adversary, the algorithm cannot output a constant-approximation of x^*.

Lemma 5 *Let* $s = \frac{\log n}{\log\log n}$. *For all* $t < s$,

$$\mathcal{E}_n^{\text{SEQ,non}}(t) \ge 1 - \frac{1}{\log\log n}.$$

Proof Assume that s, $\log n$, and $\log\log n$ are integers and

$$x_i = \begin{cases} s & \text{for } i = 1, \\ s-1 & \text{for } i = 2, \dots, r, \\ s-2 & \text{for } i = r+1, \dots, r^2, \\ \vdots & \\ m & \text{for } i = r^{s-m-1}+1, \dots, r^{s-m}, \\ \vdots & \\ 0 & \text{for } i = r^{s-1}+1, \dots, r^s, \end{cases}$$

where $r = \log n$. Consider the following non-adaptive adversarial comparator:

$$\mathcal{C}(x_i, x_j) = \begin{cases} \max\{x_i, x_j\} & \text{if } |x_i - x_j| > 1, \\ \min\{x_i, x_j\} & \text{if } |x_i - x_j| \le 1. \end{cases} \tag{3}$$

The sequential algorithm takes a random permutation of the inputs. It then starts by comparing the first two elements and then sequentially compares the winner with the next element, and so on. Let L_j be the location in the permutation where input j appears for the last time. The next two observations follow from the construction of inputs and comparators respectively.

Observation 1 *Input* j *appears at least* $(\log n - 1)$ *times that of input* $j+1$.

Observation 2 *For the adversarial comparator defined in* (3), *if* $L_0 > L_1 > \ldots > L_s$, *then no input* j *can survive beyond location* L_{j-1}, *and, therefore,* SEQ *outputs* 0.

As a consequence of Observation 1, in the random permutation of inputs, $L_j > L_{j+1}$ with probability at least $1-\frac{1}{\log n}$. By the union bound, $L_0 > L_1 > \ldots > L_s$ with probability at least,

$$1 - \frac{s}{\log n} = 1 - \frac{1}{\log\log n}.$$

By applying Observation 2, SEQ outputs 0 with probability at least $1 - \frac{1}{\log\log n}$. ■

5. Algorithms

In the previous section, we saw that the complete tournament, COMPL, always outputs a 2-approximation but has quadratic query complexity, while the sequential selection, SEQ, has linear query complexity but a poor approximation guarantee. A natural question to ask is whether there exist algorithms with bounded error and linear query complexity. In this section, we propose algorithms with linear query complexity and approximation guarantees that compete with the best possible, namely, 2-approximation of x^*.

We propose three algorithms with different performance guarantees:

- **Modified knock-out**, described in Section 5.1, has linear query complexity, and, with high probability, outputs a 3-approximation of x^* against both adaptive and non-adaptive adversaries
- **Quick-select**, described in Section 5.2, outputs a 2-approximation to x^* (against both adversaries). It also has a linear expected query complexity against non-adaptive adversarial comparators
- **Knock-out and quick-select combination**, described in Section 5.3, has linear query complexity, and, with high probability, outputs a 2-approximation of x^* even against adaptive adversarial comparators

We now go over these algorithms in detail.

5.1. Modified knock-out

For simplification, in this section, we assume that $\log n$ is an integer. The knock-out algorithm derives its name from knock-out competitions where the tournament is divided into $\log n$ successive rounds. In each round, the inputs are paired at random, and the winners advance to the next round. Therefore, in round i, there are $\frac{n}{2^{i-1}}$ inputs. The winner at the end of $\log n$ rounds is declared as the maximum.

Under our adversarial model, at each round of the knock-out algorithm, the largest remaining input decreases by at most one. Therefore, the knock-out algorithm finds at least $\log n$-approximation of x^*. Analyzing the precise approximation error of knock-out algorithm appears to be difficult. However, simulations suggest that for any large n, for the set consisting of $0.2 \cdot n$ 0's, $\alpha \cdot n$ 1's, $(0.7-\alpha) \cdot n$ 2's, $0.1 \cdot n$ 3's, and a single 4, where $0 < \alpha < 0.7$ is an appropriately chosen parameter, the knock-out algorithm is not able to find a 3-approximation of x^* with positive constant probability. The problem with knock-out algorithm is that if at any of the $\log n$ rounds, many inputs are within 1 from the largest

input at that round, there is a fair chance that the largest input will be eliminated. If this elimination happens in several rounds, we will end up with a number significantly smaller than x^*.

To circumvent the problem of discarding large inputs, we select a specified number of inputs at each round and save them for the very end, thereby ensuring that at every round, if the largest input is eliminated, then an input within 1 from it has been saved. We then perform a complete tournament on these saved inputs. The algorithm is explained in KO-MOD.

input: $\mathcal{X}$
  pair the inputs of $\mathcal{X}$ randomly, let $\mathcal{X}'$ be the winners
output: $\mathcal{X}'$

Algorithm KO-SUB - Subroutine for KO-MOD and COMB

input: $\mathcal{X}, \epsilon$
  $\mathcal{Y} = \emptyset$, $n_1 = \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \cdot \log n \right\rceil$
  while $|\mathcal{X}| > n_1$
    randomly choose n_1 inputs from $\mathcal{X}$ and *copy* them to $\mathcal{Y}$
    $\mathcal{X} \leftarrow$ KO-SUB($\mathcal{X}$)
  end while
output: COMPL($\mathcal{X} \cup \mathcal{Y}$)

Algorithm KO-MOD - Modified knock-out algorithm

In Theorem 6, we show that KO-MOD has a 3-approximation error less than ϵ.

We first explain the algorithm and then state the result. Let $n_1 \stackrel{\text{def}}{=} \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \cdot \log n \right\rceil$. At each round, we add n_1 of the remaining inputs at random to the multiset $\mathcal{Y}$ and run the knock-out subroutine KO-SUB on the multiset $\mathcal{X}$. When $|\mathcal{X}| \le n_1$, we perform a complete tournament on $\mathcal{X} \cup \mathcal{Y}$ and declare the output as the winner. We show that, with probability at least $1-\epsilon$, the final set $\mathcal{Y}$ contains at least one input which is a 1-approximation of x^*. Since the complete tournament outputs a 2-approximation of its maximum input, KO-MOD outputs a 3-approximation of x^* with probability greater than $1-\epsilon$.

Theorem 6 *For $n_1 \ge 2$, we have $q_n^{\text{KO-MOD,adpt}} < n + \frac{1}{2}(\log^4 n) \cdot \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \right\rceil^2$ and $\mathcal{E}_n^{\text{KO-MOD,adpt}}(3) < \epsilon$.*

Proof The number of comparisons made by KO-SUB is at most $\frac{n}{2} + \frac{n}{4} + \frac{n}{8} + \ldots < n$. Observe that KO-SUB is called $m \stackrel{\text{def}}{=} \left\lceil \log \frac{n}{n_1} \right\rceil$ times. Let $\mathcal{X}_i$ be the multiset $\mathcal{X}$ at the start of the ith call to KO-SUB. Let $\mathcal{X}_{m+1}$ and $\mathcal{Y}_{m+1}$ be the multisets $\mathcal{X}$ and $\mathcal{Y}$ right before calling

compl. Then,

$$\begin{aligned}
|\mathcal{X}_{m+1} \cup \mathcal{Y}_{m+1}| &\le |\mathcal{X}_{m+1}| + |\mathcal{Y}_{m+1}| \\
&\le n_1 + \sum_{i=1}^{m} \left(|\mathcal{Y}_{i+1}| - |\mathcal{Y}_i|\right) \\
&\le n_1 + m n_1 \\
&= \left(\left\lceil \log \frac{n}{n_1} \right\rceil + 1\right) \cdot \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \cdot \log n \right\rceil \\
&\le \left(\left\lceil \log \frac{n}{n_1} \right\rceil + 1\right) \cdot \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \right\rceil \lceil \log n \rceil \\
&\le \log^2 n \cdot \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \right\rceil,
\end{aligned}$$

where the last inequality follows as $n_1 \ge 2$ and $\log n$ is an integer. Since the complete tournament is quadratic in the input size, the total number of queries is at most $n + \frac{1}{2}\log^4 n \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \right\rceil^2$.

Next, we bound the error of ko-mod. Let

$$\mathcal{X}^* \stackrel{\text{def}}{=} \{x \in \mathcal{X} : x \ge x^* - 1\}$$

be the multiset of all inputs that are at least $x^* - 1$. For $i \le m+1$, let $\mathcal{X}_i^* = \mathcal{X}_i \cap \mathcal{X}^*$ and $\mathcal{Y}_{m+1}^* = \mathcal{Y}_{m+1} \cap \mathcal{X}^*$. Let $\alpha_i \stackrel{\text{def}}{=} \frac{|\mathcal{X}_i^*|}{|\mathcal{X}_i|}$ and $\alpha = \max\{\alpha_1, \alpha_2, \ldots, \alpha_m\}$. We show that, with high probability, $|\mathcal{X}_{m+1}^* \cup \mathcal{Y}_{m+1}^*| \ge 1$, namely, some input in $\mathcal{X}_{m+1} \cup \mathcal{Y}_{m+1}$ belongs to $\mathcal{X}^*$. In particular, we show that, with probability $1-\epsilon$, for large α, $|\mathcal{Y}_{m+1}^*| > 0$, and for small α, $x^* \in \mathcal{X}_{m+1}$. Observe that

$$\begin{aligned}
\Pr(x^* \notin \mathcal{X}_{m+1}^*) &= \sum_{i=1}^{m} \Pr(x^* \notin \mathcal{X}_{i+1}^* | x^* \in \mathcal{X}_i) \cdot \Pr(x^* \in \mathcal{X}_i) \\
&\le \sum_{i=1}^{m} \Pr(x^* \notin \mathcal{X}_{i+1}^* | x^* \in \mathcal{X}_i) \\
&\stackrel{(a)}{\le} \sum_{i=1}^{m} \frac{|\mathcal{X}_i^*| - 1}{|\mathcal{X}_i| - 1} \\
&\le \sum_{i=1}^{m} \alpha_i \\
&\le \alpha m,
\end{aligned}$$

where (a) follows since at round i, ko-sub randomly pairs the inputs and only inputs in $\mathcal{X}_i^* \backslash \{x^*\}$ are able to eliminate x^*. Next we discuss $\Pr(|\mathcal{Y}_{m+1}^*| = 0)$. At round i, the probability that an input in $\mathcal{X}^*$ is not picked up in $\mathcal{Y}$ is

$$\frac{\binom{|\mathcal{X}_i| - |\mathcal{X}_i^*|}{n_1}}{\binom{|\mathcal{X}_i|}{n_1}} \le \left(1 - \frac{|\mathcal{X}_i^*|}{|\mathcal{X}_i|}\right)^{n_1} = (1-\alpha_i)^{n_1}.$$

Therefore,

$$\begin{aligned}
\Pr(|\mathcal{Y}_{m+1}^*| = 0) &\le \prod_{i=1}^{m} (1-\alpha_i)^{n_1} \\
&\le \min_i (1-\alpha_i)^{n_1} \\
&= (1-\alpha)^{n_1}.
\end{aligned}$$

As a result,

$$\begin{aligned}
\Pr(|\mathcal{X}_{m+1}^* \cup \mathcal{Y}_{m+1}^*| = 0) &= \Pr(|\mathcal{X}_{m+1}^*| = 0 \ \wedge \ |\mathcal{Y}_{m+1}^*| = 0) \\
&\le \Pr(x^* \notin \mathcal{X}_{m+1}^* \ \wedge \ |\mathcal{Y}_{m+1}^*| = 0) \\
&\le \max_\alpha \min\{\Pr(x^* \notin \mathcal{X}_{m+1}^*), \Pr(|\mathcal{Y}_{m+1}^*| = 0)\} \\
&\le \max_\alpha \min\left\{\alpha m, (1-\alpha)^{n_1}\right\} \\
&\stackrel{(a)}{\le} \max\left\{\alpha m, (1-\alpha)^{n_1}\right\}|_{\alpha = \frac{\epsilon}{\log n}} \\
&= \max\left\{\frac{\epsilon m}{\log n}, \left(1 - \frac{\epsilon}{\log n}\right)^{n_1}\right\} \\
&\stackrel{(b)}{<} \epsilon,
\end{aligned}$$

where (a) follows since the first argument of the min increases and the second argument decreases with α. Also, (b) follows since $m \le \log n$ and $n_1 = \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \log n \right\rceil$.

So far, we have shown that with probability $1-\epsilon$, there exists a 1-approximation of x^* in $\mathcal{X}_{m+1} \cup \mathcal{Y}_{m+1}$. From Lemma 4, compl gives a 2-approximation of the maximum input. Consequently, with probability $1-\epsilon$, ko-mod outputs a 3-approximation of x^*. ■

In Appendix A, we show that ko-mod cannot output better than 3-approximation of x^* with constant probability.

5.2. Quick-select

Motivated by quick-sort, we propose a quick-select algorithm q-select that at each round compares all the inputs with a random pivot to provide stronger performance guarantees against the non-adaptive adversary.

input: $\mathcal{X}$
pick a pivot $x_p \in \mathcal{X}$ at random
compare x_p with all other inputs in $\mathcal{X}$
let $\mathcal{Y} \subset \mathcal{X} \backslash \{x_p\}$ be the multiset of inputs that beat x_p
output: if $\mathcal{Y} \neq \emptyset$ output $\mathcal{Y}$ otherwise output $\{x_p\}$

Algorithm qs-sub - Subroutine for q-select and comb

We show that q-select provides a 2-approximation with no error against both the adaptive and non-adaptive adversaries. To show this result, observe that x^* will only be

input: $\mathcal{X}$
  while $|\mathcal{X}| > 1$
    $\mathcal{X} \leftarrow$ QS-SUB($\mathcal{X}$)
  end while
output: the unique input in $\mathcal{X}$

Algorithm Q-SELECT - Quick-select

eliminated if a 1-approximation of x^* is chosen as pivot, and, therefore, only inputs that are 2-approximation of x^* will survive.

Lemma 7 $\mathcal{E}_n^{\text{Q-SELECT,adpt}}(2) = 0$.

Proof If the output is x^*, the lemma holds. Otherwise, x^* is discarded when it was chosen as a pivot or compared with a pivot. Let x_p be the pivot when x^* is discarded; hence, $x_p \geq x^* - 1$. By the algorithm's definition, all the surviving inputs are at least $x_p - 1 \geq x^* - 2$. ■

We now show that the expected query complexity of Q-SELECT against a non-adaptive adversary is at most $2n$. This result follows from the observation that the non-adaptive adversary fixes the comparison graph at the beginning, and hence a random pivot wins against half of the inputs in expectation. This idea is made rigorous in the proof of Lemma 8.

In Example 2 we show an instance for which Q-SELECT requires $\binom{n}{2}$ queries against the adaptive adversary.

Lemma 8 $q_n^{\text{Q-SELECT,non}} < 2n$.

Proof Recall that the non-adaptive adversary can be modeled as a complete directed graph where each node is an input and there is an edge from x to y if $\mathcal{C}(x, y) = x$. Let $\text{in}(x)$ be the in-degree of x in such a graph.

At round i, the algorithm chooses a pivot x_p at random and compares it to all the remaining inputs. By keeping the winners, $\max\{\text{in}(x_p), 1\}$ inputs will remain for the next round. As a result, we have the following recursion for non-adaptive adversaries:

$$\begin{aligned} q_n^{\text{Q-SELECT}} &= \mathbb{E}\left[Q_n^{\text{Q-SELECT}}\right] \\ &= n - 1 + \frac{1}{n}\sum_{i=1}^{n} \mathbb{E}\left[Q_{\text{in}(x_i)}^{\text{Q-SELECT}}\right] \\ &= n - 1 + \frac{1}{n}\sum_{i=1}^{n} q_{\text{in}(x_i)}^{\text{Q-SELECT}}. \end{aligned}$$

By (2),

$$\begin{aligned} q_n^{\text{Q-SELECT,non}} &= \max_{\mathcal{C}\in\mathcal{C}_{\text{non}}} \max_{\mathcal{X}} q_n^{\text{Q-SELECT}} \\ &= \max_{\mathcal{C}\in\mathcal{C}_{\text{non}}} \max_{\mathcal{X}} \left[n - 1 + \frac{1}{n}\sum_{i=1}^{n} q_{\text{in}(x_i)}^{\text{Q-SELECT}}\right] \\ &\leq n - 1 + \frac{1}{n}\sum_{i=1}^{n} \max_{\mathcal{C}\in\mathcal{C}_{\text{non}}} \max_{\mathcal{X}} q_{\text{in}(x_i)}^{\text{Q-SELECT}} \\ &= n - 1 + \frac{1}{n}\sum_{i=1}^{n} q_{\text{in}(x_i)}^{\text{Q-SELECT,non}}, \end{aligned} \tag{4}$$

where the inequality follows as the maximum of sums is at most the sum of maxima. We prove by strong induction that $q_n^{\text{Q-SELECT,non}} \leq 2(n-1)$, which holds for $n = 1$. Suppose it holds for all $n' < n$, then,

$$\begin{aligned} q_n^{\text{Q-SELECT,non}} &\leq n - 1 + \frac{1}{n}\sum_{i=1}^{n} q_{\text{in}(x_i)}^{\text{Q-SELECT,non}} \\ &\leq n - 1 + \frac{1}{n}\sum_{i=1}^{n} 2 \cdot \text{in}(x_i) \\ &= n - 1 + \frac{n(n-1)}{n} \\ &\leq 2(n-1), \end{aligned}$$

where the equality follows since the in-degrees sum to $\frac{n(n-1)}{2}$. ■

Lemma 8 shows that $q_n^{\text{Q-SELECT,non}} < 2n$. Next, we show a naive concentration bound for the query complexity of Q-SELECT. By Markov's inequality, for a non-adaptive adversary,

$$\Pr(Q_n^{\text{Q-SELECT}} > 4n) \leq \frac{1}{2}.$$

Let k be an integer multiple of 4. Now suppose we run Q-SELECT, allowing kn queries. At each $4n$ queries, the Q-SELECT ends with probability $\geq \frac{1}{2}$. Therefore,

$$\Pr(Q_n^{\text{Q-SELECT}} > kn) \leq 2^{-\frac{k}{4}}.$$

This naive bound is exponential in k. The next lemma shows a tighter super-exponential concentration bound on the query complexity of the algorithm beyond its expectation. We defer the proof to appendix B.

Lemma 9 *Let $k' = \max\{e, k/2\}$. For a non-adaptive adversary, $Pr(Q_n^{\text{Q-SELECT}} > kn) \leq e^{-(k-k')\ln k'}$.*

While Q-SELECT has linear expected query complexity under the non-adaptive adversarial model, the following example suggested to us by Nelson (2015) shows that it has a quadratic query complexity against an adaptive adversary.

Example 2 *Let $\mathcal{X} = \{0, 0, \ldots, 0\}$. At each round, the adversary declares the pivot to be smaller than all the other inputs. Consequently, only the pivot is eliminated, and the query complexity is $\binom{n}{2}$.*

5.3. Knock-out and quick-select combination

KO-MOD has the benefit of reducing the number of inputs exponentially at each round and therefore maintaining a linear query-complexity while having only a 3-approximation guarantee. On the other side, Q-SELECT has a 2-approximation guarantee while it may require $\mathcal{O}(n^2)$ queries for some instances of inputs. In COMB we combine the benefits of these algorithms and avoid their shortcomings. By carefully repeating QS-SUB, we try to reduce the number of inputs by a fraction at each round and keep the largest element in the remaining set. If the number of inputs is not reduced by a fraction, most of them must be close to each other. Therefore, repeating the KO-SUB for a sufficient number of times and keeping the inputs with the higher number of wins will guarantee the reduction of the input size without making the approximation error worse. Our final algorithm COMB provides a 2-approximation of x^*, even against the adaptive-adversarial comparator and has linear query complexity. Therefore, an open question of Ajtai et al. (2015) is resolved.

input: $\mathcal{X}, \epsilon$
  $\beta_1 = 9$, $\beta_2 = 25$, $i = 0$
  while $|\mathcal{X}| > 1$
    $i = i + 1$ (i is the round)
    $n_i = |\mathcal{X}|$
    run $\mathcal{X} \leftarrow$ QS-SUB($\mathcal{X}$) for $\lfloor \beta_1 \log \frac{1}{\epsilon} \rfloor$ times
    $\mathcal{X}_i = \mathcal{X}$
    if $|\mathcal{X}_i| > \frac{2}{3} n_i$
      run KO-SUB on *fixed* $\mathcal{X}$ for $\left\lfloor \beta_2 \left(\frac{4}{3}\right)^i \log \frac{1}{\epsilon} \right\rfloor$ times
      if there exists an input with $> \frac{3}{4} \left\lfloor \beta_2 \left(\frac{4}{3}\right)^i \log \frac{1}{\epsilon} \right\rfloor$ wins
        let $\mathcal{X}$ be a multiset of inputs with $> \frac{3}{4} \left\lfloor \beta_2 \left(\frac{4}{3}\right)^i \log \frac{1}{\epsilon} \right\rfloor$ wins
      else
        let $\mathcal{X}$ be an input with highest number of wins
  end while
output: $\mathcal{X}$

Algorithm COMB - Knock-out and quick-select combination

We begin the algorithm's analysis with a few lemmas.

Lemma 10 *At each round $|\mathcal{X}|$ reduces by at least a third, namely, $n_{i+1} \le \frac{2}{3} n_i$.*

Proof If at any round $|\mathcal{X}_i| \le \frac{2}{3} n_i$, then the lemma holds, and the algorithm does not call KO-SUB. On the other hand, if KO-SUB is called, then by Markov's inequality at most two-thirds of the inputs win more than three-fourth of the queries. As a result, at round i, at least one-third of the inputs in $\mathcal{X}$ will be eliminated. ■

Recall that $\mathcal{X}^* = \{x \in \mathcal{X} : x \ge x^* - 1\}$. Lemma 11 shows that choosing inputs inside $\mathcal{X}^*$ as a pivot guarantees a 2-approximation of x^*. The proof is similar to Lemma 7 and is omitted.

Lemma 11 *If $x^* \in \mathcal{X}$, at a call to* QS-SUB *either x^* survives or a pivot from $\mathcal{X}^*$ is chosen where in the latter case, only inputs that are 2-approximation of x^* will survive.*

We showed that at each round, COMB reduces $|\mathcal{X}|$ by at least a third. As a result, the number of inputs decreases exponentially, and the total number of queries is linear in n. We also show that if x^* is eliminated at some round, then, with high probability, the pivot at that round is an input from $\mathcal{X}^*$. Using Lemma 11, this implies that COMB outputs a 2-approximation of x^* with high probability.

Theorem 12 $q_n^{\text{COMB,adpt}} = \mathcal{O}\left(n \log \frac{1}{\epsilon}\right)$ *and* $\mathcal{E}_n^{\text{COMB,adpt}}(2) < \epsilon$.

Proof We start by analyzing the query complexity of COMB. By Lemma 10,

$$n_i \le n \cdot \left(\tfrac{2}{3}\right)^{i-1}.$$

Therefore, the total number of queries at round i is at most

$$n \left(\tfrac{2}{3}\right)^{i-1} \beta_1 \log \tfrac{1}{\epsilon} + \tfrac{n}{2} \left(\tfrac{2}{3}\right)^{i-1} \beta_2 \left(\tfrac{4}{3}\right)^{i} \log \tfrac{1}{\epsilon},$$

where the first term is for calls to QS-SUB, and the second term is for calls to KO-SUB. Adding the query complexity of all the rounds,

$$\begin{aligned} q_n^{\text{COMB,adpt}} &\le n \log \tfrac{1}{\epsilon} \sum_{i=1}^{\infty} \left(\beta_1 \left(\tfrac{2}{3}\right)^{i-1} + \tfrac{2}{3} \beta_2 \left(\tfrac{8}{9}\right)^{i-1} \right) \\ &\le n(3\beta_1 + 6\beta_2) \log \tfrac{1}{\epsilon} \\ &= \mathcal{O}\left(n \log \tfrac{1}{\epsilon}\right). \end{aligned}$$

We now analyze the approximation guarantee of COMB. We show that at least one of the following events happens with probability greater than $1 - \epsilon$.

- COMB outputs x^*.
- An input inside $\mathcal{X}^*$ is chosen as a pivot at some round.

Let $\mathcal{X}_i^* \stackrel{\text{def}}{=} \mathcal{X}_i \cap \mathcal{X}^*$ and $\alpha_i \stackrel{\text{def}}{=} \frac{|\mathcal{X}_i^*|}{|\mathcal{X}_i|}$. We consider the following two cases separately.

- **Case 1** There exists an i such that $|\mathcal{X}_i| > \frac{2}{3} n_i$ and $\alpha_i > \frac{1}{8}$.
- **Case 2** For all i, either $|\mathcal{X}_i| \le \frac{2}{3} n_i$ or $\alpha_i \le \frac{1}{8}$.

First, we consider Case 1. We show that in this case a pivot from $\mathcal{X}^*$ is chosen with probability $> 1 - \epsilon$. Observe that at round i, $|\mathcal{X}|$ starts at $n_i < \frac{3}{2}|\mathcal{X}_i|$ and gradually decreases. On the other hand, in all the $\lfloor \beta_1 \log \frac{1}{\epsilon} \rfloor$ calls to QS-SUB, $|\mathcal{X} \cap \mathcal{X}^*|$ is at least $|\mathcal{X}_i^*| = \alpha_i |\mathcal{X}_i|$. Therefore, in all the calls to QS-SUB at round i,

$$\frac{|\mathcal{X} \cap \mathcal{X}^*|}{|\mathcal{X}|} \ge \frac{\alpha_i |\mathcal{X}_i|}{\frac{3}{2}|\mathcal{X}_i|} = \frac{2}{3} \alpha_i.$$

Let E be the event of not choosing a pivot from $\mathcal{X}^*$ at round i. As a result,

$$\begin{aligned}\Pr(E) &\leq \left(1-\tfrac{2}{3}\alpha_i\right)^{\left\lfloor \beta_1 \log \frac{1}{\epsilon}\right\rfloor} \\ &\leq \left(\tfrac{11}{12}\right)^{8\log\frac{1}{\epsilon}} \\ &< \epsilon.\end{aligned}$$

Therefore, in Case 1, with probability at least $1-\epsilon$, a pivot from $\mathcal{X}^*$ is chosen.

We now consider Case 2. By Lemma 11, during the calls to QS-SUB, either x^* survives or an input from $\mathcal{X}^*$ is chosen as a pivot. Therefore, we may only lose x^* without choosing a pivot from $\mathcal{X}^*$, if at some round i, $|\mathcal{X}_i| > \frac{2}{3}n_i$ and x^* wins less than three-fourth of its queries during the calls to KO-SUB.

Recall that in Case 2, if $|\mathcal{X}_i| > \frac{2}{3}n_i$ then $\alpha_i \leq \frac{1}{8}$. Observe that x^* wins against a random input in $\mathcal{X}_i$ with probability greater than $> 1-\alpha_i$, which is at least seven-eighths. Let E_i' be the event that x^* wins fewer than three-quarters of its queries at round i. By the Chernoff bound,

$$\begin{aligned}\Pr(E_i') &\leq \exp\left(-\left\lfloor \beta_2 \left(\tfrac{4}{3}\right)^i \log\tfrac{1}{\epsilon}\right\rfloor \cdot D\left(\tfrac{3}{4}\|\tfrac{7}{8}\right)\right) \\ &\leq \epsilon^{2\left(\frac{4}{3}\right)^i},\end{aligned}$$

where $D(p||q) \stackrel{\text{def}}{=} p\ln\frac{p}{q} + (1-p)\ln\frac{1-p}{1-q}$ is the Kullback-Leibler distance between Bernoulli distributed random variables with parameters p and q, respectively. Assuming $\epsilon < \frac{1}{2}$, the total probability of missing x^* without choosing a pivot form $\mathcal{X}^*$ is at most

$$\begin{aligned}\sum_{i=1}^{\infty}\Pr(E_i') &\leq \sum_{i=1}^{\infty}\epsilon^{2\left(\frac{4}{3}\right)^i} \\ &< \epsilon.\end{aligned}$$

This shows that with probability $> 1-\epsilon$, either x^* survives or an input inside $\mathcal{X}^*$ is chosen as a pivot. The theorem follows from Lemma 11. ■

6. Application to density estimation

Our study of maximum selection with adversarial comparators was motivated by the following density estimation problem:

Given a *known* set $\mathcal{P}_\delta = \{p_1, \ldots, p_n\}$ of n distributions and k samples from an *unknown* distribution p_0, output a distribution $\hat{p} \in \mathcal{P}_\delta$ such that for a small constant $C > 1$ and with high probability,

$$\|\hat{p} - p_0\|_1 \leq C \cdot \min_{p\in\mathcal{P}_\delta}\|p - p_0\|_1 + o_k(1).$$

This problem was studied in Devroye and Lugosi (2001) who showed that for $n = 2$, the SCHEFFE-TEST, described below in pseudocode, takes k samples and, with probability $1-\varepsilon$,

outputs a distribution $\hat{p} \in \mathcal{P}_\delta$ such that

$$||\hat{p} - p_0||_1 \leq 3 \cdot \min_{p\in\mathcal{P}_\delta}||p - p_0||_1 + \sqrt{\frac{10\log\frac{1}{\varepsilon}}{k}}. \tag{5}$$

input: distributions p_1 and p_2, k *i.i.d.* samples of unknown distribution p_0
let $\mathcal{S} = \{x : p_1(x) > p_2(x)\}$
let $p_1(\mathcal{S})$ and $p_2(\mathcal{S})$ be the probability mass that p_1 and p_2 assign to $\mathcal{S}$
let $\mu_{\mathcal{S}}$ be the frequency of samples in $\mathcal{S}$
output: if $|p_1(\mathcal{S}) - \mu_{\mathcal{S}}| \leq |p_2(\mathcal{S}) - \mu_{\mathcal{S}}|$ output p_1, otherwise output p_2

Algorithm SCHEFFE-TEST- Scheffe test for two distributions

SCHEFFE-TEST provides a factor-3 approximation with high probability. The algorithm, as stated in its pseudocode, requires computing $p_i(\mathcal{S})$ which can be hard since the distributions are not restricted. However, as noted in Suresh et al. (2014), the algorithm can be made to run in time linear in k. Devroye and Lugosi (2001) also extended SCHEFFE-TEST for $n > 2$. Their proposed algorithm for $n > 2$ runs SCHEFFE-TEST for each pair of distributions in $\mathcal{P}_\delta$ and outputs the distribution with the maximum wins, where a distribution is a winner if it is the output of SCHEFFE-TEST. This algorithm is referred to as the Scheffe tournament. They showed that this algorithm finds a distribution $\hat{p} \in \mathcal{P}_\delta$ such that

$$||\hat{p} - p_0||_1 \leq 9\min_{p\in\mathcal{P}_\delta}||p - p_0||_1 + o_k(1),$$

and the running time is clearly $\Theta(n^2k)$—quadratic in the number of distributions.

Mahalanabis and Stefankovic (2008) showed that the optimal coefficients for the Scheffe algorithms are indeed 3 and 9 for $n = 2$ and $n > 2$, respectively. They proposed an algorithm with an improved factor-3 approximation for $n > 2$—still running in time $\Theta(n^2)$, however. They also proposed a linear-time algorithm, but it requires a preprocessing step that runs in time exponential in n.

Scheffe's method has been used recently to obtain nearly sample optimal algorithms for learning Poisson Binomial distributions (Daskalakis et al., 2012), and Gaussian mixtures (Daskalakis and Kamath, 2014; Suresh et al., 2014).

We now describe how our noisy comparison model can be applied to this problem to yield a linear-time algorithm with the same estimation guarantee as the Scheffe tournament. Our algorithm uses the Scheffe test as a subroutine. Given a sufficient number of samples, $k = \Theta(\log n)$, the small term in the RHS of (5) vanishes, and SCHEFFE-TEST outputs

$$\begin{cases} p_i & \text{if } ||p_i - p_0||_1 < \frac{1}{3}||p_j - p_0||_1, \\ p_j & \text{if } ||p_j - p_0||_1 < \frac{1}{3}||p_i - p_0||_1, \\ \text{unknown} & \text{otherwise.}\end{cases}$$

Let $x_i = -\log_3||p_i - p_0||_1$, then analogously to the maximum selection with adversarial noise in (1), SCHEFFE-TEST outputs

$$\begin{cases} \max\{x_i, x_j\} & \text{if } |x_i - x_j| > 1, \\ \text{unknown} & \text{otherwise.}\end{cases}$$

Given a fixed multiset of samples the tournament results are fixed; hence, this setup is identical to the non-adaptive adversarial comparators. In particular, with probability $1-\varepsilon$, our quick-select algorithm can find $\hat{p} \in \mathcal{P}_\delta$ such that

$$||\hat{p} - p_0||_1 \leq 9 \cdot \min_{p \in \mathcal{P}_\delta} ||p - p_0||_1 ,$$

with running time $\Theta(nk)$. Next, we consider the combination of SCHEFFE-TEST and Q-SELECT in greater detail.

Theorem 13 *Combination of* SCHEFFE-TEST *and* Q-SELECT *algorithms, with probability* $1-\varepsilon$*, results in* $\hat{p}$ *such that*

$$||\hat{p} - p_0||_1 \leq 9 \cdot \min_{p \in \mathcal{P}_\delta} ||p - p_0||_1 + 4\sqrt{\frac{10 \log \frac{\binom{n}{2}}{\varepsilon}}{k}}.$$

Proof Let

$$p^* \stackrel{\text{def}}{=} \operatorname*{argmin}_{p \in \mathcal{P}_\delta} ||p - p_0||_1 .$$

Using (5), for each p_i and p_j in $\mathcal{P}_\delta$, with probability $1 - \varepsilon/\binom{n}{2}$, SCHEFFE-TEST outputs $\hat{p}$ such that

$$||\hat{p} - p_0||_1 \leq 3 \cdot \min_{p \in \{p_i, p_j\}} ||p - p_0||_1 + \sqrt{\frac{10 \log \frac{\binom{n}{2}}{\varepsilon}}{k}}. \tag{6}$$

By the union bound (6) holds for all p_i and p_j with probability at least $1-\varepsilon$. Similar to Lemma 7, if p^* is eliminated, then at some round, Q-SELECT has chosen p' as a pivot such that

$$\left|\left|p' - p_0\right|\right|_1 \leq 3 \cdot ||p^* - p_0||_1 + \sqrt{\frac{10 \log \frac{\binom{n}{2}}{\varepsilon}}{k}}.$$

Now after choosing p' as a pivot, for any distribution p'' that survives,

$$\begin{aligned}\left|\left|p'' - p_0\right|\right|_1 &\leq 3 \cdot \left|\left|p' - p_0\right|\right|_1 + \sqrt{\frac{10 \log \frac{\binom{n}{2}}{\varepsilon}}{k}} \\ &\leq 9 \cdot ||p^* - p_0||_1 + 4\sqrt{\frac{10 \log \frac{\binom{n}{2}}{\varepsilon}}{k}}.\end{aligned}$$

■

7. Noisy sorting

7.1. Problem statement

In this section, we consider sorting with noisy comparators. The comparator model is the same as before, and the goal is to approximately sort the inputs in decreasing order.

Consider an Algorithm $\mathcal{A}$ for sorting the inputs. The output of $\mathcal{A}$ is denoted by $\mathbf{Y}_{\mathcal{A}}(\mathcal{X}) \stackrel{\text{def}}{=} (Y_1, Y_2, \ldots, Y_n)$, a particular ordering of the inputs. Similar to the maximum-selection problem, a t-approximation error is

$$\mathcal{E}_n^{\mathcal{A}}(t) \stackrel{\text{def}}{=} \Pr\left(\max_{i,j:i>j} (Y_i - Y_j) > t\right),$$

namely, the probability of Y_i appearing after Y_j in $\mathbf{Y}_{\mathcal{A}}$ while $Y_i - Y_j > t$. Note that our definitions for $\mathcal{E}_n^{\mathcal{A},\text{non}}(t)$, $\mathcal{E}_n^{\mathcal{A},\text{adpt}}(t)$, $q_n^{\mathcal{A},\text{adpt}}$, and $q_n^{\mathcal{A},\text{non}}$ hold the same as before.

In the following, we first revisit the complete tournament with a small modification for the sake of the sorting problem, and we show that, under the adaptive adversarial model, it has zero 2-approximation error and query complexity of $\binom{n}{2}$. We then discuss the quick-sort algorithm Q-SORT and show that it has zero 2-approximation error but with improved query complexity for the non-adaptive adversary. We apply the known bounds for the running time of the general quick-sort algorithm with n distinct inputs to find the query complexity of Q-SORT.

7.2. Complete tournament

The algorithm is similar to COMPL in Section 4.2.1, and we refer to it as COMPL-SORT. The only difference is in the output of the algorithm.

input: $\mathcal{X}$
compare all input pairs in $\mathcal{X}$, count the number of times each input wins
output: output the inputs in the order of their number of wins, breaking the ties randomly

Algorithm COMPL-SORT - Complete tournament

The following lemma—and its proof—is similar to Lemma 4, and, therefore, we skip the proof.

Lemma 14 $q_n^{\text{COMPL-SORT},\text{adpt}} = \binom{n}{2}$ *and* $\mathcal{E}_n^{\text{COMPL-SORT},\text{adpt}}(2) = 0$.

Next, we discuss an algorithm with improved query complexity.

7.3. Quick-sort

Quick-sort is a well-known algorithm and, here, is denoted by Q-SORT. The expected query complexity of quick-sort with noiseless comparisons and distinct inputs is

$$f(n) \stackrel{\text{def}}{=} 2n \ln n - (4 - 2\gamma)n + 2 \ln n + \mathcal{O}(1), \tag{7}$$

where γ is Euler's constant (McDiarmid and Hayward, 1996). Note that $f(n)$ is a convex function of n.

In the rest of this section, we study the error guarantee of quick-sort and its query complexity in the presence of noise. In Lemma 15, we show that the error guarantee of quick-sort for our noise model is the same as the complete tournament, namely, it can sort

the inputs with zero 2-approximation error. Next, in Lemma 16, we show that the expected query complexity of quick-sort with non-adaptive adversarial noise is at most its expected query complexity in the noiseless model.

Lemma 15 $\mathcal{E}_n^{\text{Q-SORT,adpt}}(2) = 0$.

Proof The proof is by contradiction. Suppose $x_i > x_j + 2$, but x_j appears before x_i in the output of quick-sort algorithm. Then there must have been a pivot x_p such that $\mathcal{C}(x_i, x_p) = x_p$ while $\mathcal{C}(x_j, x_p) = x_j$. Since $x_i > x_j + 2$ no such a pivot exists. ■

The quick-sort algorithm chooses a pivot randomly to divide the set of inputs into smaller-size sets. The optimal pivot for noiseless quick-sort is known to be the median of the inputs to balance the size of the remained sets. In fact, it is easy to show that if we choose the median of the inputs as the pivot, the query complexity of quick-sort reduces to less than $n \log n$. Observe that in a non-adaptive adversarial model, the probability of having balanced sets after choosing pivot increases. As a result, in Lemma 16, we show that the expected query complexity of quick-sort in the presence of noise is upper bounded by $f(n)$.

Lemma 16 $q_n^{\text{Q-SORT,non}} = f(n)$ *and is achieved when the queries are noiseless and the inputs are distinct.*

Proof Let $\text{in}(x)$ and $\text{out}(x)$ be the in-degree and out-degree of node x in the complete tournament respectively. For the noiseless comparator with distinct inputs, the in-degrees and out-degrees of inputs are permutation of $(0, 1, \ldots, n-1)$. We show that

$$\operatorname*{argmax}_{\mathcal{C} \in \mathcal{C}_{\text{non}}} \max_{\mathcal{X}} q_n^{\text{Q-SORT}},$$

is a comparator whose complete tournament in-degrees and out-degrees are permutations of $(0, 1, \ldots, n-1)$. For notational simplicity let $q_n = q_n^{\text{Q-SORT,non}}$. We have the following recursion for quick-sort similar to (4):

$$q_n \le n - 1 + \frac{1}{n} \sum_{i=1}^{n} q_{\text{out}(x_i)} + q_{\text{in}(x_i)}. \tag{8}$$

By induction, we show that the solution to (8) is bounded above by $f(n)$, a convex function of n. The induction holds for $n = 0, 1$, and 2. Now suppose the induction holds for all $i < n$. Since $f(n)$ is a convex function of n and $\sum_i \text{in}(x_i) = \sum_i \text{out}(x_i) = \frac{n(n-1)}{2}$, the right hand side of (8) is maximized when the in-degrees and out-degrees take their extreme values, namely, when they are permutation of $(0, 1, \ldots, n-1)$. Plugging in these values, (8) is equivalent to,

$$\begin{aligned} q_n &\le n - 1 + \frac{1}{n} \sum_{i=1}^{n} f(\text{in}(x_i)) + f(\text{out}(x_i)) \\ &\le n - 1 + \frac{1}{n} \sum_{i=1}^{n} f(i-1) + f(n-i), \end{aligned}$$

where the solution to this recursion is $f(n)$, given in (7). Hence q_n is bounded above by $f(n)$, and the equality happens when the in-degrees and out-degrees are permutations of $(0, 1, \ldots, n-1)$. ■

Knuth (1998); Hennequin (1989); McDiarmid and Hayward (1992) show different concentration bounds for quick-sort. In particular, McDiarmid and Hayward (1992) show that the probability of the quick-sort algorithm requiring more comparisons than $(1+\epsilon)$ times its expected query complexity is $n^{-2\epsilon \ln \ln n + \mathcal{O}(\ln \ln \ln n)}$. Observe that for the non-adaptive adversarial model, the chance of a random pivot cutting the set of inputs into balanced sets increases. As a result, one can show that the analysis in McDiarmid and Hayward (1992) follows automatically. In particular, Lemmas 2.1 and 2.2 in McDiarmid and Hayward (1992), which are the basis of their analysis, are valid for our non-adaptive adversarial model. Therefore, their tight concentration bound for quick-sort algorithm can be applied to our non-adaptive adversarial model.

Acknowledgments

The authors would like to thank the editor and anonymous reviewers for their constructive comments, and Jelani Nelson for introducing the authors to the adaptive adversarial model. Appendix A. For all $t < 3$, ko-mod cannot output a t-approximation

Example 3 shows that the modified knock-out algorithm cannot achieve better than 3-approximation of x^*.

Example 3 *Suppose $n-2$ is multiple of 3 and n is a large number. Let $\mathcal{X}$ be a random permutation of*

$$\{3, \underbrace{2, 2, \ldots, 2}_{\frac{n-2}{3}}, \underbrace{1, 1, \ldots, 1}_{\frac{n-2}{3}}, \underbrace{0, 0, \ldots, 0}_{\frac{n-2}{3}}, 0^*\}.$$

This multiset consists of an input with value zero but specified with 0^* since this input is going to behave differently from other 0s. Let the adversarial comparator be such that all 0s, except 0^*, and all 2s lose to all 1s, and 3 loses to all 2s. If two inputs of the same value get paired, one of them wins randomly (except in the case of 0^*). By the properties of comparator, it is obvious that any 2 will defeat all zeros, including 0^*. In order to prove our main claim, we make the following arguments and show that each of them happens with high probability:

- *Pr(input with value 3 is not present in the final multiset)*$> \frac{3}{10}$
- *Pr(input 0^* is present in the final multiset)*$> \frac{1}{3}$
- *With high probability, the fraction of 1s in the final multiset is close to 1*

Before proving each argument, we show why satisfying all the above statements are sufficient to prove our claim. Consider the final multiset; with high probability, it mainly consists of 1s, and there are a small number of 0s and 2s. Moreover, with probability greater than $\frac{1}{3} \times \frac{3}{10}$, input with value 3 has been removed before reaching the final multiset, and 0^* has survived to reach the final multiset. Therefore, if we run algorithm COMPL *on the final multiset, the input 0^* will have the most wins and be declared as the output. Hence for all $t < 3$, we have $\mathcal{E}_n^{\text{KO-MOD,non}}(t) >$ constant. Note that we did not try to optimize this constant.*

Now we show why each of the arguments above is true. Note that the reasoning made here is in expectation and assuming n is sufficiently large. However, the concentration bounds for all these claims are straightforward and thus omitted.

Lemma 17 *With high probability, the fraction of 1s in the final multiset is close to 1, and the fraction of 0s and 2s are very small.*

Proof *We calculate the expected number of 0s, 1s, and 2s at each step. Let $f_i(j)$ be the fraction of j's at the end of step i. After each step, we lose an input with value 1 if and only if they are paired with each other. As a result, we have the following recursion:*

$$f_{i+1}(1) = 2 \cdot f_i(1) \left(\tfrac{f_i(1)}{2} + 1 - f_i(1) \right),$$

where the factor 2 on the RHS of the recursion above is due to the fact that at each step we are reducing the number of inputs to half. Starting with $f_0(1) = 1/3$, we get the set of values $\{1/3, 5/9, 65/81, 6305/6561 \sim 0.96, ...\}$ for $f_i(1)$s. We can see that the ratio is approaching 1 very fast. More precisely, the fraction of 0s is decreasing quadratically since their only chance of survival is to get paired among themselves. As a result, after a couple of steps, the fraction of zeros is extremely small, and, henceforth, the only chance of survival for 2s becomes getting paired among themselves. Additionally their fraction is going to decrease quadratically afterward. As a result, more samples of 1s will be in the final $\mathcal{Y}$ with high probability. ■

Lemma 18 *Pr(input with value 3 is not present in the final multiset)$> \frac{3}{10}$.*

Proof *The input with value 3 is going to be removed when it is compared against one of the 2s. There is a slight chance of it surviving if it is chosen randomly for being in the output. Thus, the probability of input 3 being removed from the multiset in the first round is*

$$Pr(\text{input 3 is being removed in the first round}) = \frac{n-2}{3n}\left(1 - \frac{n_1}{n}\right) > \frac{3}{10},$$

where $n_1 = \left\lceil \frac{1}{\epsilon} \ln \frac{1}{\epsilon} \log n \right\rceil$. ■

Lemma 19 *Pr(input 0^* is present in the final multiset)$> \frac{1}{3}$.*

Proof *Similar to the argument made in the proof of Lemma 17, we have the following recursion for $f_i(2)$.*

$$f_{i+1}(2) = 2 \cdot f_i(2) \left(\tfrac{f_i(2)}{2} + 1 - f_i(2) - f_i(1) \right)$$

Thus, we have $f_0(2) = 1/3$, $f_1(2) = 1/3$, $f_2(2) = 5/27$, $f_3(2) = 85/2187$. As we stated in the proof of Lemma 17, the expected fraction of 2s is decreasing quadratically and

$$Pr(0^* \text{surviving}) = (1 - \tfrac{1}{3})(1 - \tfrac{1}{3})(1 - \tfrac{5}{27})(1 - \tfrac{85}{2187}) \cdots > \frac{1}{3},$$

proving the lemma. ■

Appendix B. Proof of Lemma 9

Abbreviate $Q_n^{\text{Q-SELECT}}$ by Q_n. As in the Chernoff bound proof, for all $\lambda > 0$,

$$\Pr(Q_n > kn) \le \frac{\mathbb{E}[e^{\lambda Q_n}]}{e^{k\lambda n}}. \tag{9}$$

Let $\lambda = \frac{1}{n} \ln k'$ and $\Phi(i) \stackrel{\text{def}}{=} \mathbb{E}[e^{\lambda Q_i}]$. We prove by induction that $\Phi(i) \le e^{k'\lambda i}$. The induction holds for $i = 0$. Similar to (4), we have the following recursion for $\Phi(n)$:

$$\begin{aligned}\Phi(n) &\le \frac{e^{\lambda(n-1)}}{n} \sum_{j=1}^{n} \Phi(\text{in}(x_j)) \\ &\le \frac{e^{\lambda n}}{n} \sum_{j=1}^{n} \Phi(\text{in}(x_j)).\end{aligned}$$

Since $\text{in}(x_j) < n$, using induction,

$$\frac{e^{\lambda n}}{n} \sum_{j=1}^{n} \Phi(\text{in}(x_j)) \le \frac{e^{\lambda n}}{n} \sum_{j=1}^{n} e^{k'\lambda \text{in}(x_j)}. \tag{10}$$

Observe that $e^{k'\lambda \text{in}(x_j)}$ is a convex function of $\text{in}(x_j)$, and $\sum_{j=1}^{n} \text{in}(x_j) = \frac{n(n-1)}{2}$. As a result, the RHS of (10) is maximized when the in-degrees take their extreme values, namely, any permutation of $(0, 1, \ldots, n-1)$. Therefore,

$$\begin{aligned}\frac{e^{\lambda n}}{n} \sum_{j=1}^{n} e^{k'\lambda \text{in}(x_j)} &\le \frac{e^{\lambda n}}{n} \sum_{j=0}^{n-1} e^{k'\lambda j} \\ &= \frac{e^{\lambda n}}{n} \frac{e^{k'\lambda n} - 1}{e^{k'\lambda} - 1}.\end{aligned}$$

Combining the above equations,

$$\Phi(n) \le \frac{e^{\lambda n}}{n} \frac{e^{k'\lambda n} - 1}{e^{k'\lambda} - 1}.$$

Similarly, by induction on $1 \le i < n$,

$$\Phi(i) \le \frac{e^{\lambda i}}{i} \frac{e^{k'\lambda i} - 1}{e^{k'\lambda} - 1}.$$

In Lemma 20 we show that for $1 \le i \le n$,

$$\frac{e^{\lambda i}}{i}\frac{e^{k'\lambda i}-1}{e^{k'\lambda}-1} \le e^{k'\lambda i}. \tag{11}$$

Therefore, $\Phi(i) \le e^{k'\lambda i}$ for $1 \le i \le n$, and, in particular, $\Phi(n) \le e^{k'\lambda n}$. Substituting $\mathbb{E}[e^{\lambda Q_n}] = \Phi(n)$ in (9),

$$\begin{aligned}\Pr(Q_n > kn) &\le \frac{e^{k'\lambda n}}{e^{k\lambda n}} \\ &= \frac{e^{k'\ln k'}}{e^{k\ln k'}} \\ &= e^{-(k-k')\ln k'}.\end{aligned}$$

This proves the lemma.
We now prove (11). Let $k' = \max\{e, \frac{k}{2}\}$ and $\lambda = \frac{1}{n}\ln k'$.

Lemma 20 *For all* $1 \le i \le n$, $\frac{e^{\lambda i}}{i}\frac{e^{k'\lambda i}-1}{e^{k'\lambda}-1} \le e^{k'\lambda i}$.

Proof It suffices to show that for all $0 < t \le n$,

$$f(t) \stackrel{\text{def}}{=} \frac{e^{\lambda t}}{t}\frac{1-e^{-k'\lambda t}}{e^{k'\lambda}-1} < 1.$$

Observe that

$$\lim_{t\to 0} f(t) = \frac{k'\lambda}{e^{k'\lambda}-1} \le 1.$$

On the other hand,

$$\begin{aligned}f(n) &= \frac{e^{\lambda n}}{n}\frac{1-e^{-k'\lambda n}}{e^{k'\lambda}-1} \\ &\le \frac{k'}{n}\frac{1}{e^{k'\ln k'/n}-1} \\ &\le \frac{k'}{n}\frac{n}{k'\ln k'} \\ &\le 1.\end{aligned}$$

Next, we show that $f(t)$ is convex. One can show that,

$$\ln\frac{1-e^{-u}}{u},$$

is a convex function of u. As a result,

$$\ln\frac{1-e^{-k'\lambda t}}{t},$$

is a convex function of t. Observe that $\ln e^{\lambda t}$ is also convex. Therefore,

$$\ln\frac{1-e^{-k'\lambda t}}{t} + \ln e^{\lambda t},$$

is convex. As a result, logarithm of $f(t)$ is convex, and, therefore, $f(t)$ is convex.

We showed that $f(t)$ is convex, $f(t \to 0) \le 1$, and $f(n) \le 1$. Therefore, for all $0 < t \le n$, $f(t) \le 1$. ■

Abstract

We consider the situation where I items are ranked by paired comparisons. It is usually assumed that the probability that item i is preferred over item j is $p_{ij} = F(\mu_i - \mu_j)$ where F is a symmetric distribution function, which we refer to as the comparison function, and μ_i and μ_j are the merits or scores of the compared items. This modelling framework, which is ubiquitous in the paired comparison literature, strongly depends on the assumption that the comparison function F is known. In practice, however, this assumption is often unrealistic and may result in poor fit and erroneous inferences. This limitation has motivated us to relax the assumption that F is fully known and simultaneously estimate the merits of the objects and the underlying comparison function. Our formulation yields a flexible semi-definite programming problem that we use as a refinement step for estimating the paired comparison probability matrix. We provide a detailed sensitivity analysis and, as a result, we establish the consistency of the resulting estimators and provide bounds on the estimation and approximation errors. Some statistical properties of the resulting estimators as well as model selection criteria are investigated. Finally, using a large data-set of computer chess matches, we estimate the comparison function and find that the model used by the International Chess Federation does not seem to apply to computer chess.

Keywords: linear stochastic transitivity, statistical ranking, semi-definite programming, model selection, sensitivity analysis, chess

1. Introduction

There are many situations in which a preference or a ranking among a set of items is desired. Ranking methods are widely used in settings such as product testing (Cremonesi et al., 2010), the evaluation of political candidates (Saari, 1995; Pacuit, 2012), psychometrics (Regenwetter et al., 2011), machine learning (Ailon, 2012; Shah et al., 2015a) and sports (Herbrich et al., 2007; Govan, 2008). An ordering of a set of items can be inferred from different types of data including scores (Balinski and Laraki, 2010) and ranked lists (Marden, 1996). A ranked list may be complete, i.e., all items are compared and ranked, or partial or incomplete, when only a subset of items is compared and ranked. In particular, paired comparison data is obtained if all comparisons involve only two items (David, 1988). Here we focus on paired comparisons with a binary outcomes.

Given a set of I items, also called objects, or players, let Y_{ijk}, $1 \leq i, j \leq I$, be independent binary random variables where $Y_{ijk} = 1$ if item i is preferred over item j on their k^{th} comparison and $Y_{ijk} = 0$ otherwise. The probability of this event is denoted by p_{ij}, i.e., $p_{ij} = \mathbb{P}(Y_{ijk} = 1)$. We assume that m_{ij} comparisons were observed between each pair of items and we let $Y_{ij} = \sum_{k=1}^{m_{ij}} Y_{ijk}$ denote the number of times item i was preferred over item j. Further let $\boldsymbol{P} = [p_{ij}]$ denote the $I \times I$ underlying probability matrix.

Typically, it is assumed that

$$p_{ij} = F(\mu_i - \mu_j) \tag{1}$$

where $\mu_i, \mu_j \in \mathbb{R}$ are the merits (also called skills, scores or ratings) of items i and j respectively, and $F : \mathbb{R} \to [0, 1]$ is a known, strictly increasing, comparison function, i.e., a symmetric absolutely continuous distribution function. We assume that the merits are fixed and unknown. In some situations the merits may vary according to an "effort" (Jia et al., 2013), or depend on covariates (Herbrich et al., 2007; Allison and Christakis, 1994). Model (1) implies that $p_{ij} + p_{ji} = 1$ and imposes a form of stochastic transitivity (Morrison, 1963; Regenwetter et al., 2011) which is known as linear stochastic transitivity (LST). Models satisfying (1) will be referred to as LST models. Various LST models have been proposed, these differ in the choice of the comparison function F. In particular, two canonical LST models have been widely studied; the Thurstonian model (Thurstone, 1927) and the (Zarmelo) Bradley-Terry-Luce model (Zermelo, 1928; Bradley and Terry, 1952). The Bradley-Terry-Luce model (BTL, henceforth) assumes that F is a standard logistic distribution whereas Thurstone's model assumes F is a standard normal distribution. There are literally thousands of studies which employ these models and their variants. Other, albeit less popular, LST models are also studied in literature, e.g., the Threshold model which employs the Laplace distribution and is used for modelling animal behavior (Yellott, 1970), and the locally linear model (Batchelder et al., 1992) which employs a uniform on $[-1, 1]$ distribution.

The assumption that F is known has been recognized as rather unrealistic (Morrison, 1963; David, 1988; Regenwetter and Davis-Stober, 2008; Hwang, 2009; Shah et al., 2015b; Heckel et al., 2016). This has motivated several authors to resort to the use of less restrictive transitivity relations. A variety of stochastic transitivity relations have been explored in the literature (Morrison, 1963; Regenwetter et al., 2011; Oliveira et al., 2018), the weakest of which is known as weak stochastic transitivity. Under weak stochastic transitivity if $p_{ij} \geq 1/2$ and $p_{jk} \geq 1/2$ then $p_{ik} \geq 1/2$. A stronger form of stochastic transitivity, referred to as strong stochastic transitivity (SST), postulates that if $p_{ij} \geq 1/2$ and $p_{jk} \geq 1/2$ then $p_{ik} \geq \max\{p_{ij}, p_{jk}\}$. Of course model (1) satisfies both of the relations. Various authors have developed methods for analyzing data under these less restrictive assumptions (deCani, 1969; Regenwetter and Davis-Stober, 2008; Chatterjee and Mukherjee, 2016; Shah et al., 2015b). It turns out that the estimation procedures associated with these less restrictive

transitivity relations are in general, NP-hard. Since these models provide less structure, they may not be adequate when the comparison graph is sparse and most importantly may provide less predictive power. The SST model, for example, cannot guarantee that stronger players have higher chances than weaker players in knockout tournaments, whereas BTL can (Chung and Hwang, 1978; Israel, 1981; Adler et al., 2017; Baek et al., 2013). Thus we propose a different, potentially more powerful approach, within the LST framework, in which the assumption that the comparison function F is known is relaxed. The proposed methodology is flexible, tractable and retains the desirable computational and statistical characteristics of LST models.

A natural and widely used approach for estimating the model parameters in (1) is by least squares (LS). LS is often the method of choice due to its (relative) computational simplicity. Thus if (1) holds then the LS estimators solve the following optimization problem:

$$\hat{\boldsymbol{\mu}} \in \operatorname{argmin} \sum_{i \neq j} w_{ij} (\hat{\Delta}_{ij} - (\mu_i - \mu_j))^2, \tag{2}$$

where, typically, $\hat{\Delta}_{ij} \equiv F^{-1}(\hat{p}_{ij})$ and $\hat{p}_{ij}$ is an estimator of the probability p_{ij}. For now we assume that $\hat{p}_{ij}$ is bounded away from 0 and 1 and $\hat{p}_{ij} + \hat{p}_{ji} = 1$ so $\hat{\Delta}_{ij}$ is well defined. The weights w_{ij} are given and are either proportional to the variance of the estimated $\hat{\Delta}_{ij}$, or the number of comparisons between items i and j. Notice that (2) admits multiple solutions, for if $\boldsymbol{\mu}^*$ is a solution to problem (2) then so is $\boldsymbol{\mu}^* + v\mathbf{1}$ for any $v \in \mathbb{R}$. A unique solution exists if the comparison graph is connected and an additional linear constraint such as $\sum_i \mu_i = 0$ is enforced (Tsukida and Gupta, 2011).

When all w_{ij} in (2) are equal, then the solution is of the form $\mu_i^* = \kappa \sum_j \hat{\Delta}_{ij}$ for some $\kappa > 0$. For this reason the LS method is sometimes referred to as the row—sum procedure (Huber, 1963). There are other well known ranking methods which can be viewed as row—sum procedures with varying definitions of $\hat{\Delta}_{ij}$. For example, the Copland Method, popular within the voting literature (Levin and Nalebuff, 1995; Favardin et al., 2002), is a row sum procedure in which $\hat{p}_{ij}$ is defined as $\hat{p}_{ij} \equiv (\sum_k Y_{ijk})/I$ and $F(x) = 1/2 + x$ for $x \in [-1/2, 1/2]$ where Y_{ijk} equals one if the kth voter prefers candidate i above candidate j and zero otherwise. The Borda Count can be also shown to be a row—sum method. Another LS variant, known as Massey Ratings, is widely used in the rating of sport teams in college football, basketball, hockey, and baseball, see Chapter 4 of Massey (2017). For more on the LS literature, refer to Hodge rank in Jiang et al. (2010).

Our Contribution. We will weaken the assumption that the comparison function F is known and assume only that it belongs to, a new, large family of parametric functions. Our parametric set, can be understood as an interior approximation, with arbitrary precision, to the full set of comparison functions. We then simultaneously estimate the merits as well as the comparison function F by generalizing the LS approach. Estimating the probabilities p_{ij} is now an easy consequence. We show that this can be done efficiently both computationally and statistically. In particular, we develop a procedure that takes as input an estimate of the probability matrix and returns an estimate of the comparison function F, the merit vector $\boldsymbol{\mu}$ and a refinement of the original estimate of the probability matrix. Estimation reduces to a semi-definite programming problem with a tractable solution. We provide a thorough sensitivity analysis and derive statistical properties such as convergence and concentration bounds on the refined estimator and the estimated function. By applying our methodology to a large data-set of computer chess matches, we verify that the ubiquitous (Zarmelo) Bradley-Terry-Luce model may be inappropriate for computer chess.

2. Formulation and Estimation

Formulation: Least Squares Estimation Over Polynomial Families. First, we may generalize problem (2) by rewriting it in matrix notation in the following way

$$\hat{\boldsymbol{\mu}} \in \operatorname{argmin}_{\boldsymbol{\mu}} ||F^{-1}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}||_{\boldsymbol{W}}. \tag{3}$$

Here $\Delta\boldsymbol{\mu}$ is an $I \times I$ matrix whose ij^{th} element is $\mu_i - \mu_j$ and $F^{-1}(\hat{\boldsymbol{P}})$ is a matrix with the same dimensions whose ij^{th} element is $F^{-1}(\hat{p}_{ij})$, if $w_{ij} > 0$ and 0 otherwise. Unless specified otherwise, in this paper the norm $||\cdot||_{\boldsymbol{W}}$ will be the weighted Frobenius (semi-)norm, with pre-specified weights and $||\cdot||$ will be its unweighted counterpart. With a slight abuse of notation we will refer to the frobenius norm as the $\mathcal{L}_2$ norm. The minimization in (3) can also be formulated with respect to the sum of the absolute values of the elements, which we refer to as the $\mathcal{L}_1$ norm, or maximum value of the elements of a matrix, which we refer to as the $\mathcal{L}_\infty$ norm. The mechanics involved in solving (3) are norm dependent. If one views Δ as an operator from $\mathbb{R}^I \to \mathbb{R}^{I \times I}$ then $\Delta\hat{\boldsymbol{\mu}}$ is the projection of $F^{-1}(\hat{\boldsymbol{P}})$ on the image set of the operator Δ. Finally note that the least squares procedure takes an estimator $\hat{\boldsymbol{P}}$ and produces a refined estimator denoted by $\boldsymbol{P}^* = F(\Delta\hat{\boldsymbol{\mu}})$.

The assumption that the comparison function F is known is relaxed and instead it is assumed that $F \in \mathcal{F}$ where $\mathcal{F}$, where:

A$_1$ *(Parametric Assumption): The family $\mathcal{F}$ indexed by $\boldsymbol{\beta} \in \mathbb{R}^{D+1}$ consists of all distribution functions whose inverse, i.e., its quantile function, may be written as a polynomial, of the form*

$$F_{\boldsymbol{\beta}}^{-1}(p) = \beta_0 + \beta_1 p + ... + \beta_D p^D \text{ where } p \in [0, 1/2]. \tag{4}$$

Equation (4) defines a quantile regression model (Takeuchi et al., 2006; Su, 2015). By the LST condition $F_{\boldsymbol{\beta}}$ is symmetric, i.e., $F_{\boldsymbol{\beta}}(x) + F_{\boldsymbol{\beta}}(-x) = 1$ so $F_{\boldsymbol{\beta}}^{-1}(p) + F_{\boldsymbol{\beta}}^{-1}(1-p) = 0$. It immediately follows that $F_{\boldsymbol{\beta}}^{-1}(p)$ is also a polynomial when $p \in [1/2, 1]$. Also, (4) implies that the support of $F_{\boldsymbol{\beta}}$ is the finite interval $[\beta_0, -\beta_0]$, where $\beta_0 < 0$. It is further assumed that:

A$_2$ *(Lipschitz Assumption): For all $F_{\boldsymbol{\beta}} \in \mathcal{F}$, $F_{\boldsymbol{\beta}}$ is L-Lipschitz and $||\boldsymbol{\beta}||_\infty \leq U$* for some constants L and U.

We note that each fixed value of (D, U, L) generates a parametric family of distributions $\mathcal{F}(D, U, L)$; which we denote for convenience by $\mathcal{F}$. This is a new, non-standard, rich family of distributions, in which the quantile function, not the density, is parametrized. Figure 1 shows that the Bradley-Terry-Luce model can be can be approximated by a low degree polynomial over the interval $p \in [0.01, 0.99]$. Furthernote, that by increasing D, U and L we can approximate any quantile function with arbitrary precision.

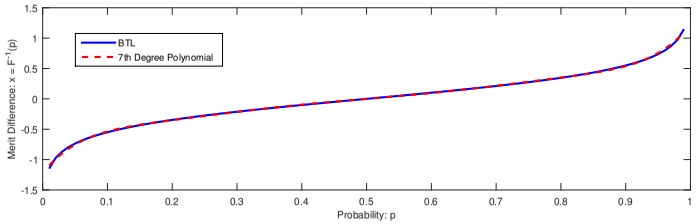

Figure 1: An approximation of the Bradley-Terry-Luce quantile function over the interval $p \in [0.01, 0.99]$ by a function $F \in \mathcal{F}$ for $D = 7$.

It is known that F and G are equivalent comparison functions iff $F(x) = G(\kappa x)$ for some positive κ, see Yellott (1977), and therefore F^{-1} is equivalent to G^{-1} iff $\kappa F^{-1}(p) = G^{-1}(p)$. A valid linear constraint on the coefficient vector $\boldsymbol{\beta}$ is thus imposed to ensure identifiability. For example, fixing the support of F, which amounts to fixing $\beta_0 < 0$, is sufficient. Another natural choice is to fix the derivative of F at 0, which amounts to fixing $\beta_1 > 0$. A rescaling argument shows that the resulting inferences do not depend on the chosen constraint. As noted earlier, identifiablity requires that the merits satisfy a constraint. Henceforth it will be assumed that:

A_3 *(Scaling Assumption): The merits and the comparison function are scaled to satisfy*

$$\sum_i \mu_i = 0 \quad \textit{and} \quad \beta_0 = -1. \tag{5}$$

Thus, if F belongs to $\mathcal{F}$ we may estimate $(\boldsymbol{\mu}, \boldsymbol{\beta})$ by solving the following optimization problem:

$$(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\beta}}) \in \operatorname{argmin}_{\boldsymbol{\mu} \in \mathbb{R}, F_{\boldsymbol{\beta}} \in \mathcal{F}} ||F_{\boldsymbol{\beta}}^{-1}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}||_{\boldsymbol{W}}. \tag{6}$$

Although (6) is a least squares problem it is non-standard as "both sides", i.e., the "predictor" and the "response" in the regression equation, are associated with unknown parameters which are estimated simultaneously. In the following subsection we will study problem (6) under assumptions A_1 to A_3.

Solution via Semidefinite Programming. Our first concern is to characterize the set of feasible solutions for $(\boldsymbol{\mu}, \boldsymbol{\beta})$. As noted earlier the quantile function (4) satisfies $F^{-1}(p) = -F^{-1}(1-p)$ so we need only consider constraints generated by values $p \in [0, 1/2]$. In this interval $F_{\boldsymbol{\beta}}^{-1}(p)$ is increasing hence its derivative, which is a polynomial of degree $D-1$, is non-negative. Furthermore, the Lipschitz continuity constraint on F implies that F^{-1} is strictly monotone with derivative greater or equal to $1/L$. Thus,

$$\beta_1 + ... + D\beta_D p^{(D-1)} - \frac{1}{L} \geq 0 \text{ for all } p \in [0, 1/2] \tag{7}$$

In addition $F(0) = 1/2$, so $F_{\boldsymbol{\beta}}^{-1}(1/2) = 0$ and $||\boldsymbol{\beta}||_\infty \leq U$ therefore

$$\sum_{i=0}^{D} \left(\frac{1}{2}\right)^i \beta_i = 0 \text{ and } -U \leq \beta_i \leq U \text{ for all } i. \tag{8}$$

Minimizing $||F^{-1}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}||_{\boldsymbol{W}}$ subject to (7) and (8) yields a semi-infinite programming problem (SIP) (Mutapcic and Boyd, 2009; Stein, 2012), i.e., an optimization problem with an infinite number of, in this case linear, constraints.

There are a number of methods for solving SIPs. One natural approach is discretization, which in our case means replacing (7) by N constraints of the form $\beta_1 + \beta_2 p_j ... + D\beta_D p_j^{(D-1)} - 1/L \geq 0$ where $0 < p_1 < p_2 < ... < p_N < 1/2$ for some finite N. This yields a simple quadratic programming problem. From a practitioner's point of view, discretization may be a method of choice due to its simplicity. This is specifically true when $||\cdot||_{\boldsymbol{W}}$ is either the weighted or unweighted $\mathcal{L}_1$ or $\mathcal{L}_\infty$ norms, since in these cases discretization results in a simple linear program. However, the resulting estimate of F is not guaranteed to be strictly monotone (although this can be overcome, see section 3.2 of Mutapcic and Boyd 2009) and more importantly in the worst case the solution may not be polynomially computable. These issues may be overcome by noting that the constraints in (7)-(8) are equivalent to a combination of linear constraints and positive semi-definite cone constraints, see Parrilo (2016) for further details. Thus our optimization problem is (also) a semi-definite optimization problem (SDP). There is a large literature on SDPs (Nemirovski and Todd, 2009) and in particular it is known that SDPs can be solved by interior point methods (Vandenberghe and Boyd, 1996) in polynomial time. Therefore we may formally rewrite (6) as:

Theorem 1 *Given $U, L \geq 0$, $D = 2d+1$ with $d \in \mathbb{N}$, a symmetric weight matrix $\boldsymbol{W}$ and an estimator $\hat{\boldsymbol{P}}$, then problem (6) is equivalent to:*

$$\begin{array}{ll} \textit{minimize} & \sum_{(i,j)\in\mathcal{S}} w_{ij}(\beta_0 + ... + \beta_D \hat{p}_{ij}^D + \mu_j - \mu_i)^2 \\ \textit{subject to} & \\ & \beta_i = \frac{1}{i}(\frac{1}{2}t_{i-2} - t_{i-3} + s_{i-1}) \textit{ for } i = 2, ..., D, \\ & \beta_1 = s_0 + \frac{1}{L}, \quad \sum_{k=0}^{D} \left(\frac{1}{2}\right)^k \beta_k = 0, \quad ||\boldsymbol{\beta}||_\infty \leq U, \\ & \\ & s_i = \sum_{j+k=i} Q_{jk}^0 \textit{ for } i = 0, ..., D-1, \quad \boldsymbol{Q^0} \in \mathbb{S}_+^{d+1}, \\ & t_i = \sum_{j+k=i} Q_{jk}^1 \textit{ for } i = 0, ..., D-3, \quad \boldsymbol{Q^1} \in \mathbb{S}_+^{d}. \end{array} \tag{9}$$

where $\mathcal{S} = \{(i,j) \mid p_{ij} \leq .5 \textit{ or } p_{ij} = .5 \textit{ and } i < j\}$, and $t_{D-1} = t_{D-2} = t_{-1} = t_{-2} = 0$, $\mathbb{S}_+^k$ is the set of $k \times k$ symmetric positive semi-definite matrices, and the rows and columns of $\boldsymbol{Q^0}$ and $\boldsymbol{Q^1}$ are indexed by 0 to d and 0 to $d-1$ respectively.

For brevity we present here only the case when D is odd, a similar characterization holds for D even. We note that analogues of Theorem 1 could also be formulated for the $\mathcal{L}_1$ and $\mathcal{L}_\infty$ norms and their weighted versions in which case the constraints in (9) would remain unaltered whereas the objective function would be as defined by the corresponding norm.

Note that (9) admits a unique solution when the objective function is positive definite. Lemma 2 below provides an example in a simple but important case. In large samples the solution to (9) is uniquely determined when the system of equations $\beta_1 p_{ij} + ... + \beta_D p_{ij}^D - (\mu_i - \mu_j) = -\beta_0$ for $(i,j) \in \mathcal{S}$ is of full rank. This condition is met when (i) there are at least $I + D - 1$ connected pairs $(i,j) \in \mathcal{S}$; which (ii) the coefficients appearing in the linear equations, which are derived from the comparison probabilities p_{ij}, are sufficiently diverse, otherwise the resulting equations would not be linearly independent. Thus we assume that:

A$_4$ *(Connectivity & Diversity Assumption): The comparison graph has at least $I + D - 1$ edges. These edges correspond to a set of linearly independent equations of the form $\beta_1 p_{ij} + ... + \beta_D p_{ij}^D - (\mu_i - \mu_j) = -\beta_0$.*

If we label these equations $(ij)_1, ..., (ij)_{D+I-1}$ then together with the constraint $\sum \mu_i = 0$ we may write the resulting system of equations (with a slight abuse of notation) as:

$$\boldsymbol{A} \begin{pmatrix} \boldsymbol{\beta} \\ \boldsymbol{\mu} \end{pmatrix} = \begin{pmatrix} -\boldsymbol{\beta_0} \\ 0 \end{pmatrix} \tag{10}$$

where the k'th row of $\boldsymbol{A}$ is $\boldsymbol{A}_k = (p_{(ij)_k} \quad ... \quad p_{(ij)_k}^D \quad -\boldsymbol{e}_{(ij)_k})$ for $k = 1, ..., I + D - 1$ and $\boldsymbol{A}_{I+D} = (\boldsymbol{0}^T \quad ... \quad \boldsymbol{1}^T)$ where $\boldsymbol{e}_{ij} \in \mathbb{R}^I$ is defined by $\boldsymbol{e}_{ij} \equiv \boldsymbol{e}_i - \boldsymbol{e}_j$, where $\boldsymbol{e}_i$ is the standard basis. The condition number of $\boldsymbol{A}$ plays a role in the quality of our estimators.

Define $\boldsymbol{p} = (1,\ p,\ ...\ ,\ p^D)^T$ and note that if all the weights are equal then

$$\mu_i = \frac{1}{I} \sum_k F_{\boldsymbol{\beta}}^{-1}(p_{ik}) = \frac{1}{I} \sum_{(i,k) \in \mathcal{S}} F_{\boldsymbol{\beta}}^{-1}(p_{ik}) - \frac{1}{I} \sum_{(i,k) \notin \mathcal{S}} F_{\boldsymbol{\beta}}^{-1}(p_{ki}) \tag{11}$$

and thus we may eliminate $\boldsymbol{\mu}$ from (9) by means of equation (11). This considerably reduces the size of the SDP at hand when the number of items I is larger than D. Algorithm PolyRank (displayed below) takes advantage of this. Furthermore:

Lemma 2 *When all weights w_{ij} are equal, then, the objective function of problem (9) is equivalent to minimizing $\boldsymbol{\beta}^T \boldsymbol{M} \boldsymbol{\beta}$, where*

$$\boldsymbol{M} \equiv \sum_{(ij) \in \mathcal{S}} \boldsymbol{v}_{(ij)} \boldsymbol{v}_{(ij)}^T \tag{12}$$

and $\boldsymbol{v}_{(ij)} \equiv -I \hat{\boldsymbol{p}}_{ij} + \sum_{(ik) \in \mathcal{S}} \hat{\boldsymbol{p}}_{ik} - \sum_{(ik) \notin \mathcal{S}} \hat{\boldsymbol{p}}_{ki} - \sum_{(jk) \in \mathcal{S}} \hat{\boldsymbol{p}}_{jk} + \sum_{(jk) \notin \mathcal{S}} \hat{\boldsymbol{p}}_{kj}$.

Hence the estimators can be efficiently calculated in three steps:

***Algorithm:* PolyRank**

Input: $\hat{\boldsymbol{P}} \in [0,1]^{I \times I}$ $D \in \mathbb{N}$ *an odd number and* $U, L \geq 0$.

1. *Preprocessing: Calculate* $\boldsymbol{M}$ *as in equation (12);*
2. *Functional Estimation:* $\hat{\boldsymbol{\beta}} \equiv$ *argmin* $\{\boldsymbol{\beta}^T \boldsymbol{M} \boldsymbol{\beta}$ *subject to* (9) *and* (5)$\}$;
3. *Merit Estimation:* $\hat{\mu}_i = \frac{1}{I} \sum_{(i,k) \in \mathcal{S}} F_{\hat{\boldsymbol{\beta}}}^{-1}(\hat{p}_{ik}) - \frac{1}{I} \sum_{(i,k) \notin \mathcal{S}} F_{\hat{\boldsymbol{\beta}}}^{-1}(\hat{p}_{ki})$;

Output: $\hat{\boldsymbol{\beta}} \in \mathbb{R}^{D+1}$, $\hat{\boldsymbol{\mu}} \in \mathbb{R}^n$ *and* $\boldsymbol{P}^* \equiv F_{\hat{\boldsymbol{\beta}}}(\Delta \hat{\boldsymbol{\mu}})$

Step 1 may be performed with no more than $O(I^3 D + I^2 D^2)$ operations, Step 2 with no more than $O(D^2 \sqrt{D})$ operations and Step 3 with no more than $O(I^2 D)$ operations. Thus, the overall computational complexity of solving problem (6) is no more than $O(I^3 D + I^2 D^2 + D^2 \sqrt{D})$. Notice also that Steps 1 and 3 can be done in a distributed fashion. When the weights are not all equal the merits cannot be written as in (11) and therefore Algorithm PolyRank as stated above cannot be used, in that case we solve (9) directly. Nevertheless we will refer to all versions of our estimation procedure as PolyRank. In our experience, problem (6) with any norm (weighted or unweighted) can be tackled successfully with a generic convex optimization solver on a desktop computer for problems of moderate size (e.g. with $D \leq 10$ and $I \leq 120$) in at most 2 or 3 seconds. Using the three step procedure (with the same generic solver) allows easy scaling up to problems where $D \leq 20$ and $I \leq 10000$. If (6) is treated as a SIP and solved via discretization, then significant reduction in computation time is observed at the cost of loosening the guarantee of optimality.

Remark 1 Notice that if the machine precision is ϵ and if D is such that $\epsilon > (1/2)^D$ then the last terms of the polynomial F^{-1} are rounded to zero. Therefore for standard 32 bit floating point arithmetic one should choose D at most 22, similarly for a 64 bit arithmetic D should not surpass 44. $O(V^2 \sqrt{V})$

Remark 2 In theory F can be recovered from F^{-1} exaclty via Lagrange Inversion Theorem. Numerically though, calculating $F_{\boldsymbol{\beta}}(\mu_i - \mu_j)$ reduces to a polynomial root-finding problem. Although root-finding is an ill-conditioned problem for general polynomials (Trefethen 2011), it may be solved via binary search (with linear convergence in the worst case) or via Newton steps (with possible quadratic convergence).

Remark 3 When the weights w_{ij} are not all equal, or $||\cdot||_{\boldsymbol{W}}$ represents the $\mathcal{L}_1$ or $\mathcal{L}_\infty$ norms, then a full SDP with $V = I + D$ variables must be solved. In these cases the simplifying row-sum structure is absent and the worst case bounds are well known, and of the order $O(V^2 \sqrt{V})$, see the general SDP literature (Vandenberghe and Boyd, 1996).

3. Sensitivity Analysis

The goal of this section is to investigate the sensitivity of PolyRank with respect to the input matrix $\hat{\boldsymbol{P}}$. There are several reasons for developing thorough, non-stochastic, sensitivity bounds. Firstly, the analysis serves to clarify the mechanics of PolyRank providing bounds that apply to any choice of $\hat{\boldsymbol{P}}$. Secondly, using the sensitivity bounds statistical properties such as consistency of the refined estimator are easily derived. A third motivation is that different estimators $\hat{\boldsymbol{P}}$ have been investigated in the literature, e.g., Rajkumar and Agarwal (2014); Chatterjee and Mukherjee (2016); Shah et al. (2015b), and since PolyRank may be applied to any of them, the respective bounds on the refined estimator are universal and apply to any $\hat{\boldsymbol{P}}$. Sensitivity analysis is carried out under three increasingly general settings. First, we provide a benchmark by studying the LS method with known F. Then, we consider PolyRank in the case where the model is correctly specified, i.e., $F \in \mathcal{F}$. This is also called the realizable case. Finally, we consider agnostic cases, that is, situations where the model may be misspecified in some way. Three examples of misspecifications are analyzed.

For simplicity we first focus on the unweighted $\mathcal{L}_2$ norm, extensions to the respective weighted versions are similarly obtained.

3.1. Known Comparison Function

Here the function F is assumed to be a known L-Lipschitz continuous function with a U-Lipschitz inverse, i.e., it is bilipschitz. A common assumption in the literature, cf. Shah et al. (2015a,b), is that the probabilities in (1) are bounded away from 0 and 1, i.e., $p_{ij} \in [\epsilon, 1-\epsilon]$, for some $\epsilon > 0$. Over this domain the Bradley-Terry-Luce, Thurstone, Threshold and Locally Linear models are all bilipschitz.

Theorem 3 *Let F be a known L-Lipschitz continuous function with a $4U$-Lipschitz continuous inverse (over their respective domains). Let $\hat{\boldsymbol{\mu}}$ be as in (2) and $\boldsymbol{P^*} = F(\Delta\hat{\boldsymbol{\mu}})$. Then,*

$$||\boldsymbol{P^*} - \boldsymbol{P}|| \leq 4LU||\hat{\boldsymbol{P}} - \boldsymbol{P}||, \tag{13}$$

and

$$||\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}|| \leq \frac{4U}{\sqrt{2I}}||\hat{\boldsymbol{P}} - \boldsymbol{P}||. \tag{14}$$

If, additionally, it is assumed that $\hat{\boldsymbol{P}}$ obeys strong stochastic transitivity, then the estimators are order preserving, i.e.,

$$\hat{\mu}_i < \hat{\mu}_j \iff \hat{p}_{ij} < \hat{p}_{ji}. \tag{15}$$

By construction the constant $4LU \geq 1$ and so (13) guarantees that $||\boldsymbol{P^*} - \boldsymbol{P}||$ will be at most a constant times $||\hat{\boldsymbol{P}} - \boldsymbol{P}||$. Although it may be possible to improve the constant in (13), its value can never be less than 1, for if not, one could generate a converging sequence $\boldsymbol{P_1}^*, \boldsymbol{P_2}^*, ...$ by recursively applying the LS refinement to any initial (blind) guess of $\hat{\boldsymbol{P}}$. This argument holds for any refinement procedure, including PolyRank. Also, by construction the LS refinement defines $\boldsymbol{P}^* = F(\Delta\hat{\boldsymbol{\mu}})$ and thus $\min_{\boldsymbol{\mu}} ||F^{-1}(\boldsymbol{P}^*) - \Delta\boldsymbol{\mu}|| = 0$ for $\boldsymbol{\mu} = \hat{\boldsymbol{\mu}}$ and so no improvement will be obtained via recursive LS type refinements. The bound in (13) is a "worst case" bound and on average we often observe that $||\boldsymbol{P^*} - \boldsymbol{P}||$ is indeed smaller that $||\hat{\boldsymbol{P}} - \boldsymbol{P}||$. For other norms refer to the appendix.

The benchmarks provided by Theorem 3 will be used for comparison with the more general cases tackled by PolyRank. As will be shown, inequality (13) also holds when F is unknown (with different constant factors); similarly, the order preservation is maintained in all the settings considered.

3.2. Realizable Case

Under the hypothesis of realizability, i.e., when the model is correctly specified, we have:

Theorem 4 *Let $\boldsymbol{P^*} = F_{\hat{\boldsymbol{\beta}}}(\Delta\hat{\boldsymbol{\mu}})$ where $\hat{\boldsymbol{\beta}}$ and $\hat{\boldsymbol{\mu}}$ are estimated using PolyRank. Then,*

$$||\boldsymbol{P^*} - \boldsymbol{P}|| \leq (1 + 4LU)||\hat{\boldsymbol{P}} - \boldsymbol{P}||, \tag{16}$$

and

$$\left|\left|\begin{pmatrix} \hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu} \end{pmatrix}\right|\right| \leq K_1||\hat{\boldsymbol{P}} - \boldsymbol{P}||, \tag{17}$$

as well as,

$$\max_{x\in[-1,1]} |F_{\hat{\boldsymbol{\beta}}}(x) - F_{\boldsymbol{\beta}}(x)| \leq K_2||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\infty, \tag{18}$$

where $K_1 \leq U(1+4LU)\sqrt{D(I+D)}||\boldsymbol{A}^{-1}||$ and $K_2 \leq 16LDU^2 \max_i \sum_j |A^{-1}_{ij}|$. If, additionally, it is assumed that $\hat{\boldsymbol{P}}$ obeys strong stochastic transitivity, then the estimators are order preserving.

Notice that the constants in (13) and (16) depend solely on the product of the Lipschitz constants of F and F^{-1}. Moreover the constant in (16) does not depend on D nor on the condition number of A . In contrast, the constants in inequalities (14) and (17) do depend on the dimensions of the problem. Equation (18) guarantees the convergence of $F_{\hat{\boldsymbol{\beta}}}$ to the true function F with respect to the Chebyshev distance, thus, one can eventually recover F with arbitrary precision.

3.3. Agnostic Cases

We will now investigate the properties of PolyRank under several types of misspecification. First, we investigate the effect of misspecifying the degree of the polynomial (4). Then, we provide results analogous to those provided by Theorem 4 by replacing the assumption that $F \in \mathcal{F}$ by the assumption that the true F is an analytic function. Finally, we drop the assumption that $\boldsymbol{P}$ satisfies the LST hypothesis all together and verify that we can still derive, albeit, weaker sensitivity bounds and rank consistency properties if strong stochastic transitivity is assumed.

Theorem 5 *Assume the true model satisfies (4), however the fitted model was of degree $D' \leq D-1$. Then for any $\boldsymbol{\beta'}$ of dimension $D' \leq D-1$, a lower bound on the approximation error, in the Chebyshev norm, is:*

$$\frac{1}{2U}\frac{|\beta_D|}{8^D} \leq \max_\alpha |F_{\boldsymbol{\beta'}}(\alpha) - F_{\boldsymbol{\beta}}(\alpha)| \tag{19}$$

The lower bound (19) shows that the Chebyshev distance between the true function and the estimated function cannot be arbitrarily minimized when the degree of the fitted polynomial is under-specified. The lower-bound, though, decreases with the value of D at an exponential rate.

Theorem 6 *Let $\boldsymbol{P}^* = F_{\hat{\boldsymbol{\beta}}}(\Delta\hat{\boldsymbol{\mu}})$ where $\hat{\boldsymbol{\beta}}$ and $\hat{\boldsymbol{\mu}}$ are estimated with* PolyRank. *Assume that the true probability matrix $\boldsymbol{P} = F(\Delta\boldsymbol{\mu})$ for some $\boldsymbol{\mu}$ and some unknown L-Lipschitz continuous function F with an analytic inverse function F^{-1} whose coefficients are upper-bounded by U. Then for the estimated probability matrix we have:*

$$||\boldsymbol{P}^* - \boldsymbol{P}|| \leq (1 + 4LU)||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + \frac{1}{2^D} LUI \tag{20}$$

If additionally it is assumed that $\hat{\boldsymbol{P}}$ obeys strong stochastic transitivity, then the estimators are order preserving.

Equation (20) shows that the error of $\boldsymbol{P}^*$ can be controlled under a broad class of analytic functions. The first term is controlled by increasing the precision of $\hat{\boldsymbol{P}}$ and the second term is controlled by choosing larger values for D.

In the following Theorem we will assume no particular structure on $\boldsymbol{P}$, i.e. the probability matrix $\boldsymbol{P}$ need not be consistent with any stochastic transitivity model.

Theorem 7 *Let $\boldsymbol{P}^* = F_{\hat{\boldsymbol{\beta}}}(\Delta\hat{\boldsymbol{\mu}})$ where $\hat{\boldsymbol{\beta}}$ and $\hat{\boldsymbol{\mu}}$ are estimated with* PolyRank. *Then for the estimated probability matrix we have:*

$$||\boldsymbol{P}^* - \boldsymbol{P}|| \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + L||F^{-1}_{\hat{\boldsymbol{\beta}}}(\hat{\boldsymbol{P}}) - \Delta\hat{\boldsymbol{\mu}}||, \tag{21}$$

If additionally it is assumed that $\hat{\boldsymbol{P}}$ obeys strong stochastic transitivity, then the estimators are order preserving.

An immediate consequence of order preservation is that if $\boldsymbol{P}$ is in the interior of the strong stochastic transitivity set then PolyRank is order-consistent for any consistent estimator $\hat{\boldsymbol{P}}$, i.e., when $\hat{\boldsymbol{P}} \to \boldsymbol{P}$ then the vector $\hat{\boldsymbol{\mu}}$ will correctly recover the underlying order among the items. The error bound in equation (21), though, cannot be controlled as in equation (20), this is so because the second term can be as big as κI^2 for some positive κ even when $\hat{\boldsymbol{P}}$ satisfies strong stochastic transitivity (Shah et al., 2015b).

4. Convergence and Concentration

In this subsection we assume that the model is correctly specified and investigate some properties of the estimators obtained by PolyRank. We start with the case where the comparisons graph is fixed and the number of comparisons per pair, i.e., the m_{ij}'s is allowed to increase. Similar conditions have been considered in literature (Rajkumar and Agarwal, 2014; Shah et al., 2015a).

It is well known that the topology of the comparison graph plays an important role in the quality of the estimators (Shah et al., 2015a; Massey, 2017; Colley, 2002). In particular Shah et al. (2015a) show that, the mean squared errors of the estimated merits from a

standard Bradley-Terry-Luce model are proportional to the second eigenvalue of the graph Laplacian. This eigenvalue, referred to as the algebraic connectivity of the graph, measures how "well" the graph is connected (Chung, 1994). In our concentration bounds the number of edges in the comparison graph and the condition number associated with (10) will play a similar role. Let $n = \sum_{i,j} m_{ij}$ be the number of paired comparisons.

Theorem 8 *Let $\hat{\boldsymbol{\beta}}_n$ and $\hat{\boldsymbol{\mu}}_n$ be estimated using* PolyRank *with $m_{ij} \equiv w_{ij}n$. Let $\hat{p}_{ij}$ be the usual MLEs. Then for large enough n there are constants K_1 and K_2 such that,*

$$\mathbb{P}\left(\left|\left|\begin{pmatrix} \hat{\boldsymbol{\beta}}_n - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}}_n - \boldsymbol{\mu} \end{pmatrix}\right|\right| \geq \epsilon\right) \leq K_1 \exp\left(-nK_2\epsilon^2\right), \tag{22}$$

where K_1 and K_2 are discussed bellow.

Theorem 8 shows that the estimators $\hat{\boldsymbol{\beta}}_n$ and $\hat{\boldsymbol{\mu}}_n$ converge at an exponential rate and are therefore strongly consistent. Theorem 8 also implies an exponential convergence of $\boldsymbol{P}^*$ to $\boldsymbol{P}$ as well as of $F_{\hat{\boldsymbol{\beta}}}(x)$ to $F_{\boldsymbol{\beta}}(x)$ in the Chebyschev distance. Theorem 8 is proved by first establishing sensitivity bounds for the weighted norm. These are analogues of Theorem 4 and are of the form

$$\left|\left|\begin{pmatrix} \hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu} \end{pmatrix}\right|\right| \leq K||\hat{\boldsymbol{P}} - \boldsymbol{P}||_{\boldsymbol{W}}. \tag{23}$$

The constants in (22) are $K_1 = 2|E|$ where $|E|$ is the number of edges in the comparison graph, and $K_2 = 2/(|E|(1+4LU)^2U^2D(I+D)||\boldsymbol{A}_{\boldsymbol{W}}^{-1}||^2)$, where $\boldsymbol{A}_{\boldsymbol{W}}^{-1}$ is defined as in equation (10) with the appropriate modifications for weights. Clearly, $I + D - 1 \leq |E| \leq (I^2 - I)/2$. Of course, smaller values of $|E|$ will provide tighter bounds in equation (22). The value of $||\boldsymbol{A}_{\boldsymbol{W}}^{-1}||$ is a function of, among other things, the topology of the comparison graph. Unfortunately, the condition number of $A_{\boldsymbol{W}}$ is difficult to analyze as it contains a $(I+D-1)\times D$ Vandermonde submatrix which can range from 1 (the best possible condition number) to exponential on the dimensions of the matrix (Pan, 2015). As a rule of thumb Vandermonde matrices are well conditioned when the points $p_{(ij)_1}, ..., p_{(ij)_{D+I-1}}$ are (approximately) spaced over Chebyshev points. Matrix $\boldsymbol{A}_{\boldsymbol{W}}$ also contains a standard $(I + D - 1) \times I$ submatrix of pairings and thus we conjecture that smaller values of the second eigenvalue of the graph Laplacian matrix should also provide tighter estimation bounds.

4.1. Round robin

We now turn our attention to round robin tournaments (Chatterjee and Mukherjee, 2016; Shah et al., 2015b; Simons and Yao, 1999), in which each pair of items is compared m times. If the number of items I is fixed and if $m \to \infty$ then we can use the results described above. A more interesting situations arises when $m = 1$ but the number of items $I \to \infty$. As pointed out earlier, in this setting if $\hat{p}_{ij} \propto Y_{ij}$ then the LS estimator $\hat{\mu}_i$ will be proportional to its Copeland Score (the number of times an item was preferred). Recent papers addressing this setting are by Chatterjee and Mukherjee (2016) and Shah et al. (2015b). In particular they assume strong stochastic transitivity and construct an estimator $\hat{\boldsymbol{P}}_{\text{ISO}}$ which is shown to satisfy:

$$\sup \frac{1}{I^2}\mathbb{E}||\hat{\boldsymbol{P}}_{\text{ISO}} - \boldsymbol{P}||_2^2 \leq C\sqrt{\frac{\log I}{I}}, \tag{24}$$

where the supremum is taken over all matrices that satisfy strong stochastic transitivity. They also show that if the true model was LST then, under some regularity conditions, the upper bound in (24) can be tightened to $O(1/I)$ up to log factors (Shah et al., 2015b). Their estimator is calculated in two steps: (i) first, they sort the items according to their Copeland Score; (ii) then, they perform a two dimensional isotonic regression on the matrix $\boldsymbol{Y}$ assuming the order obtained in (i).

The resulting estimator has two drawbacks when the true model is LST. First, the estimator may be infeasible, i.e., $\hat{\boldsymbol{P}}_{\text{ISO}}$ may not be LST. Our experience indicates that this is frequently the case. In addition the resulting estimator does not fully exploit the benefits of an LST model since the estimated probability matrix is not a Functional of a merit vector and the comparison function. These deficiencies, however, can be addressed by applying PolyRank to their estimator. A trivial consequence of equation (16) is that the refined estimator $\boldsymbol{P}^*$ retains the optimal risk bounds of $\hat{\boldsymbol{P}}_{\text{ISO}}$ and by construction is feasible. We state the full result for completeness:

Theorem 9 *Let $\boldsymbol{P}^*$ be the refinement of $\hat{\boldsymbol{P}}_{ISO}$ using* PolyRank*, where $\hat{\boldsymbol{P}}_{ISO}$ is the estimator of Chatterjee and Mukherjee (2016), then:*

$$\sup \frac{1}{I^2}\mathbb{E}||\boldsymbol{P}^* - \boldsymbol{P}||_2^2 \leq K\frac{\log^2 I}{I}, \tag{25}$$

for some constant K that does not depend on neither I nor D (nor the condition number of A) and the supremum is taken over the set of probability matrices consistent with functions $F \in \mathcal{F}$. This is optimal up to log factors.

5. Numerical Experiments and An Illustrative Example

In the following we describe four experiments performed to further test and investigate PolyRank. Each simulation is performed 1000 times and we report and discuss the average performance under the specified conditions.

Experiment 1: In this experiment we compare the empirical performance of the estimator of $\boldsymbol{P}$ when using PolyRank with a low degree polynomial with its performance given the correct comparison function. Specifically, this is done by generating $I = 20$ items with merits μ_i sampled uniformly from $[0, 10]$. A total of 50 pairs, selected randomly, were compared assuming a Bradley-Terry-Luce (BTL) model. We refine the estimator $\hat{p}_{ij} = (Y_{ij}+1)/(m_{ij}+2)$ with PolyRank using $D = 5$. We also compute the LS estimated with the known F. Figure 2 shows the average distance $||\boldsymbol{P}^* - \boldsymbol{P}||_2$. As expected, the LS method with the correct comparison function performs best, PolyRank performs almost as well and both substantially outperform the initial estimates. This is consistent with our expectations because the BTL model, despite not belonging to the class of functions $\mathcal{F}$, can be well approximated by this class within the range of choice probabilities generated.

Experiment 2 In this experiment we investigate the empirical performance of PolyRank in the round-robin setting when the number of items is increasing. Specifically, we generate a sequence of round-robin tournaments with an increasing number of items. The data is generated assuming model (4) with $D = 5$. The matrix $\boldsymbol{P}$ is estimated using the isotonic

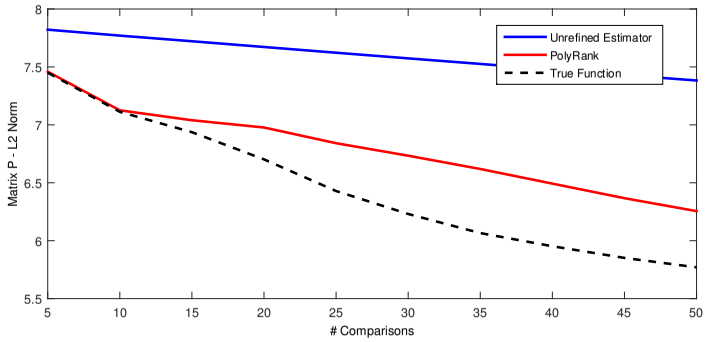

Figure 2: Comparison of refined estimators with low sampling.

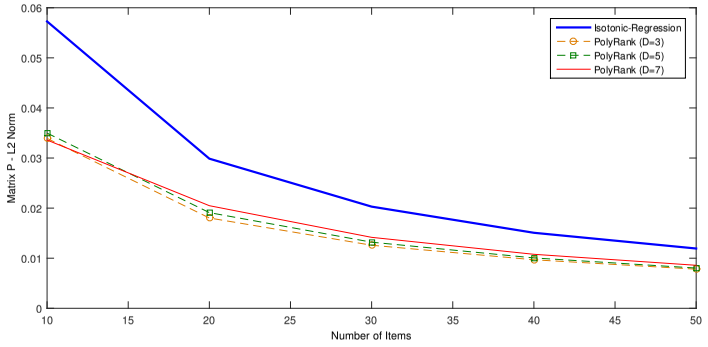

Figure 3: Refined estimators for round-robin tournaments.

regression estimator of Chatterjee and Mukherjee (2016) and refined using PolyRank with $D \in \{3, 5, 7\}$. Figures 3 and 4 display, respectively, the average of $||\boldsymbol{P}^* - \boldsymbol{P}||^2/I^2$ and the average of $||(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}, \hat{\boldsymbol{\mu}} - \boldsymbol{\mu})||^2/(I + D)$ for $I = 10, 20, 30, 40$ and 50.

Figure 3 shows four curves, all of which decrease with I. The top curve is the risk for the unrefined isotonic-regression based estimator. The estimators refined by PolyRank, which correspond to the lower 4 curves always do better. Notice that over-fitting, i.e., $D = 7$, which corresponds to the second curve from the top, usually results in higher estimation error with no change in the approximation error when compared to $D = 3, 5$. The second curve from the bottom corresponds to the true model. The bottom curve is obtained when $D = 3$, i.e., under under-fitting, and results in the lowest risk. Although this result is somewhat surprising it has been documented also in the context of other models (Claeskens

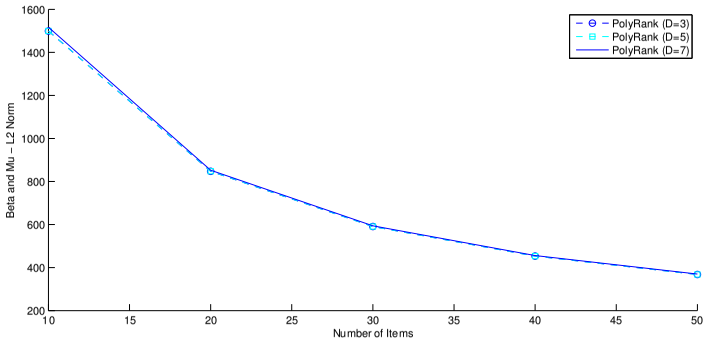

Figure 4: Estimated parameters for round-robin tournaments.

and Hjort, 2006, Chapter 5). This indicates that lower degree polynomial often perform well in practice. In Figure 4 we see that the average error of the estimated parameters decreases as a function of I.

Experiment 3: In this experiment we investigate the performance of PolyRank in the round-robin setting with a fixed number of items and a increasing number of comparisons. we generated a sequence of round-robin tournaments with $I = 10$ and an increasing number of matches. The data is generated assuming model (4) with $D = 3$. The matrix $\boldsymbol{P}$ is estimated using the standard frequency estimator for $\hat{p}_{ij}$ and is refined using PolyRank (with $D = 3$). Figure 5 displays the average of $||\boldsymbol{P}^* - \boldsymbol{P}||^2/I^2$, of $||\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}||^2/I$ and of $||\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}||^2$ for $m_{ij} = 1$ to 5 for all pairs (i, j) and Figure 6 shows the sequence of estimated functions.

The three decreasing curves of Figure 5 show that the variance of the estimators decreases with the amount of paired comparisons. Figure 6 shows that the estimated comparison function converges to its true value. These results and those of Experiment 2 are consistent with Theorems 8 and 9.

Experiment 4: In practice the degree D of the polynomial (4) may not be known in advance. If we choose D to be too small then we may not fully capture the geometry of F, while if D is too large there is a danger of over-fitting and possible numerical problems. In this experiment we investigate the use of some well known model selection criteria (Claeskens and Hjort, 2006) for choosing D. In particular, we test the empirical performance of the Bayesian Information Criterion (BIC) and two variants of the Akaike Information Criterion (AIC) and contrast these with the performance of (leave-one-out) cross-validation. The classical AIC criteria is

$$\mathcal{AIC}(D) \equiv 2(I + D) + n \log(l(D)) \tag{26}$$

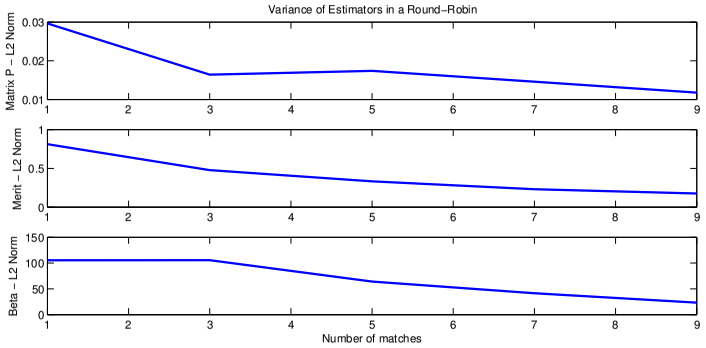

Figure 5: Variance of estimators in a round-robin with increasing number of matches between each pair.

	$m_{ij}=1$				$m_{ij}=3$			

Table 2: Model Selection ($I=12$, $D=5$)

where $l(D)$ is the least-squares loss function, given in (6) and evaluated at the estimated parameters, $I+D$ is the number of parameters in the model and n is the sample-size. The corrected AIC (AICc) is

$$\mathcal{AIC}_c(D) \equiv \mathcal{AIC}(D) + \frac{2(I+D+1)(I+D+2)}{n-I-D-2} \tag{27}$$

and is designed to correct for small sample-sizes. The BIC method penalizes more the number of parameters and is defined by

$$\mathcal{BIC}(D) \equiv (I+D)\log(n) + n\log(l(D)). \tag{28}$$

Tables 1 and 2 compares the AIC, the AICc and the BIC methods in a round-robin data generated with $I=6$ and $I=12$ objects and with $m_{ij}=1$ for all ij, as well as $m_{ij}=3$. The data was generated monotone polynomials of degree 5 randomly selected with uniform coefficients and projected to the monotone cone. We display the frequency in which the methods correctly identify the degree of the polynomial as opposed to overfit/underfit.

Tables 1 and 2 show the empirical performance of the model selection criteria as a function of number of items I and the number of paired comparisons m_{ij}. For low values of m_{ij} all criteria select the lowest degree polynomial, i.e., $D=1$. When the number of comparisons increases the procedures tend to select larger values of D. In general the performance of the procedures are comparable. However, AIC and Cross validation do seem to (slightly) outperform the other methods. Cross validation is significantly more demanding computationally than AIC and thus as a rule of thumb we recommend the use of the AIC method when no further information is available.

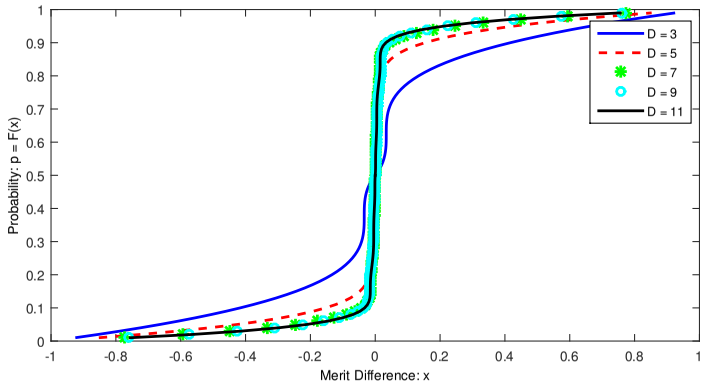

Figure 7: The effect of increasing the dimension D in estimating function F.

5.1. Illustrative Example

In this subsection we illustrate the use of PolyRank on a computer-chess data set[1]. The data set comprises of matches between 186 free single-CPU chess-engines. Each chess-engine played (roughly) 32 matches against 40 opponents. We use PolyRank to estimate model parameters from observed matches that resulted in a victory or defeat; ties are ignored. Figure 7 shows the estimated comparison function for various values of D when for the first 100 chess-engines. As is observed the estimated function $F_{\hat{\beta}}$ seems to stabilize for D greater than or equal to 7. Figure 8 shows the estimated function when the dimension $D=7$ is fixed and the number of chess-engines I is gradually increased. For I greater than or equal to 60 our estimated function seems to stabilize. Finally, Figure 9 compares the best fit function recovered by PolyRank to the family of BTL models described by $F_{\mathrm{BTL}}(x) = 1/(1+\exp(-\kappa x))$ for various values of $\kappa > 0$. Somewhat surprisingly, it seems that the family of BTL functions does not provide a good fit.

To illustrate this point consider three players i, j and k such that $p_{ij} = p_{jk} = \alpha > 0.5$ and $p_{ik} = \beta$, then, from (1) we have that $\beta = F(2F^{-1}(\alpha))$. For low values of α (say $\alpha = 0.55$) the BTL model and the polynomila model estimated by PolyRank virtually agree on the value of β (BTL: $\beta \approx 0.6$; Polynomial: $\beta \approx 0.59$); for intermediate values of α (say, $\alpha = 0.7$) the models begin to diverge $\beta \approx 0.84$; Polynomial: $\beta \approx 0.77$) and for large values of α (say $\alpha = 0.9$) this divergence is even more extreme (BTL: $\beta \approx 0.99$; Polynomial: $\beta \approx 0.92$). The estimated polynomial model seems to be more agreeable with the the data at hand since very few chess engines had a (near) perfect win against any opponent. It will be interesting to investigate whether our findings hold for human chess as well.

1. Publicly available at `http://kirill-kryukov.com/chess/kcec/games.html`.

6. Summary and Discussion

In this paper we propose a new method for analyzing paired comparison data. Our main contribution is to relax the assumption that the comparison function is known in advance. Instead, we assume that the inverse of the comparison function is a D'th degree polynomial and the comparison function has a bounded support. We show that estimation reduces to a tractable SDP that simultaneously recovers the merit vector and the underlying comparison function F from an initial estimator $\hat{\boldsymbol{P}}$. We refer to this new methodology as PolyRank. We provide non-stochastic as well as stochastic guarantees for our estimators. This includes a thorough sensitivity analysis and additionally convergence and concentration bounds. Our simulation study demonstrates that the method works well in practice. Finally, we investigate a large data set of computer chess matches and provide evidence that the comparison function used for calculating chess ratings for almost nine decades seems to be inadequate, at least for computer chess engines.

Our work shows that PolyRank can be used whenever the existing methods, which assume that the comparison function is known, are used. The only additional requirement is that the comparison graph must have at least $I+D-1$ edges, a condition which is almost always satisfied in practice. Thus, PolyRank provides a flexible and principled alternative to the existing methods for ranking and rating which are based on paired comparisons. Our analysis, however, is just a starting point and many open research problems remain. It is clear that PolyRank can be extended in various directions; these can be grouped into several domains including: (i) modelling issues; (ii) computational/numerical issues; (iii) statistical and inferential problems of varied types.

Modelling. We have assumed that F^{-1} is given by a polynomial. Many other models, in which the polynomial in (4) is replaced by some other set of basis functions, are possible. Monotone splines provide a class of such functions (Ramsay, 1988). One other interesting possibility, with more of a statistical flavor, is to write

$$F^{-1}(p) = \sum_{i=1}^{D} \beta_i K_i(p)$$

where $K_i(p)$ are themselves quantile functions of symmetric random variables. This equation can be viewed as a mixture model on the quantile scale. The family $\{K_i\}$ is then chosen by the investigator; the symmetrized beta family of distributions seems like a suitable family to explore. Another, important issue is the incorporation of covariates, such as time or a "home advantage", as well as many others in the model. This, again, can be done in several ways. The merits can be modeled as regression functions or alternatively one can incorporate the covariates directly into the comparison function. Other issues which deserve attention are the modelling of ties and the comparison of more than two items a time.

Computations and Numerics. Compared with traditional methods, where the comparison function is given, PolyRank has higher computational complexity and may suffer from numerical instability. In part, the numerical issues are related to our decision to model the inverse of the comparison function as a polynomial. This in turn entails that the normal equations are associated with Vandermonde matrices. A known way to circumvent

this problem is to use a different basis for solving equation (10), this amounts to choosing a different basis for the polynomial regression, such as Chebyshev Polynomials. Another possibility is the use of a different loss function which is less sensitive to numerical issues. Developing a method to uncouple the estimation of F and of $\boldsymbol{\mu}$ as we provided for the unweighted $\mathcal{L}_2$ norm might provide further insight in this direction. One other, future objective, is to extend the practical reach of PolyRank to larger values of D and I while at the same time increasing computational and numerical efficiency. There may be several ways of doing so. One approach is hand crafting a solver for the SDP at hand. Another possibility is developing an online distributed version of PolyRank in which the function and the merits are updated after each pairwise comparison is observed.

Statistics. The current paper leaves many statistical issues unresolved. For example, we did not provide any results on the asymptotic distributions of our estimated parameters. We believe, however, that normal limits are obtained provided $(\boldsymbol{\mu}, \boldsymbol{\beta})$ are in the interior of the parameter space. It is also clear that employing the one step method we can obtain a fully efficient estimator (Fan and Chen, 1999). Other issues of interest are limit theorems for the case where $I \to \infty$ and when paired comparisons are made adaptively. In the adaptive set up one may exploit the fact that function F can be recovered up to arbitrary precision by using a small subset of the items in order to reduce the overall query complexity of the paired comparison experiment.

Acknowledgments

This paper was written when the first author was a graduate student at the Israel Institute of Technology. The research leading to these results has received funding from the European Research Council under European Union's Horizon 2020 Program, ERC Grant agreement no. 682203 "SpeedInfTradeoff" and the research of Ori Davidov was partially supported by the Israeli Science Foundation Grants No. 1256/13 and 457/17.

Appendix A. Proof of Theorems

The following contains the proofs of our main results.

A.1. Proof of Theorem 1

Proof The constraint $F(0) = 1/2$ is equivalent to $F^{-1}(1/2) = \sum_{i=0}^{D} \beta_i (1/2)^i = 0$, which is the last equality constraint in (9). Also, F is increasing iff $F^{-1}(p)$ is increasing and for our set of polynomials this is equivalent to $(F^{-1}(p))' = \beta_1 + 2 \cdot \beta_2 p + ... + D \cdot \beta_D p^{D-1} \geq 0$ for every $p \in [0, 1/2]$. In addition, F is L-Lipschitz continuous and so $|F'(x)| \leq L$; which combined with the monotonicity constraint is equivalent to the constraint $(F^{-1}(p))' \geq 1/L$. By Theorem 6 of (Parrilo, 2016) we have that $(F^{-1}(p))' - 1/L = s(x) + x(1/2 - x)t(x)$ where $s(x)$ and $t(x)$ are sum of squares polynomial functions of degree at most $2d$ and $2d-2$ respectively. Now by Lemma 4 of Parrilo (2016) there exists $\boldsymbol{Q^0} \in \mathbb{S}_+^{d+1}$ and $\boldsymbol{Q^1} \in \mathbb{S}_+^{d}$ such that the coefficients of the polynomials $s(x)$ and $t(x)$ are $s_i = \sum_{j+k=i} Q^0_{jk}$ and $t_i = \sum_{j+k=i} Q^1_{jk}$. By combining these conditions on the polynomial $(F^{-1}(p))' - 1/L$ and the constraint $||\boldsymbol{\beta}||_\infty \leq U$ we obtain the desired result. ■

A.2. Proof of Theorem 3

Proof A little algebra show that

$$||\Delta\hat{\boldsymbol{\mu}} - \Delta\boldsymbol{\mu}||_2^2 = 2n||\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}||_2^2; \tag{29}$$

this is so because

$$||\Delta\hat{\boldsymbol{\mu}} - \Delta\boldsymbol{\mu}||_2^2 = \sum_{ij}(\hat{\mu}_i - \hat{\mu}_j - \mu_i + \mu_j)^2 = 2n||\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}||_2^2 - 2(\sum_i \hat{\mu}_i - \sum_i \mu_i)^2$$

where the last term is zero by construction. It follows that

$$||\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}||_2 = \frac{1}{\sqrt{2n}}||\Delta\hat{\boldsymbol{\mu}} - \Delta\boldsymbol{\mu}||_2 \leq \frac{1}{\sqrt{2n}}||F^{-1}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}||_2$$

$$= \frac{1}{\sqrt{2n}}||F^{-1}(\hat{\boldsymbol{P}}) - F^{-1}(\boldsymbol{P})||_2 \leq \frac{4U}{\sqrt{2n}}||\hat{\boldsymbol{P}} - \boldsymbol{P}||_2.$$

The first inequality is a conscequence of the convex projection theorem and the first equality follows from (29). Equation (13) is derived from

$$||\boldsymbol{P}^* - \boldsymbol{P}||_2^2 = ||F(\Delta\hat{\boldsymbol{\mu}}) - F(\Delta\boldsymbol{\mu})||_2^2 \leq L^2||\Delta\hat{\boldsymbol{\mu}} - \Delta\boldsymbol{\mu}||_2^2 = L^2 2n||\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}||_2^2 \leq L^2(4U)^2||\hat{\boldsymbol{P}} - \boldsymbol{P}||_2^2.$$

Where the last equality is an application of equation (29) and the last inequality an application of (14). If $\hat{\boldsymbol{P}}$ is assumed to obey strong stochastic transitivity, then $\hat{p}_{ij} < 1/2$ implies that $\hat{p}_{ik} \leq \hat{p}_{jk}$ for all k and $\hat{p}_{ik} < \hat{p}_{jk}$ for at least some k. Thus, the identity $\hat{\mu}_i - \hat{\mu}_j = (1/n)\sum_k (F^{-1}(\hat{p}_{ik}) - F^{-1}(\hat{p}_{jk})) < 0$ together with the fact that F^{-1} is strictly monotone assures that the strong stochastic transitivity order is the same as the order of the estimated merits. ■

Remark Theorem 3, applies to other norms with the proper modifications. Assume that the estimator $\boldsymbol{P}^*$ is obtained via (3) under the norm or semi-norm $||\cdot||_\#$. Let $L_\#$ and $4U_\#$ be the Lipschitz constants of F and F^{-1} associated with $||\cdot||_\#$, then

$$||\boldsymbol{P}^* - \boldsymbol{P}||_\# \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}^*||_\# + ||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# \leq L_\#||F^{-1}(\hat{\boldsymbol{P}}) - \Delta\hat{\boldsymbol{\mu}}||_\# + ||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# \leq$$

$$L_\#||F^{-1}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}||_\# + ||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# \leq 4L_\#U_\#||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# + ||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# = (1+4L_\#U_\#)||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\#,$$

as in (13).

A.3. Proof of Theorem 4

Proof Equation (16) is a conscequence of

$$||\boldsymbol{P}^* - \boldsymbol{P}|| \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}^*|| + ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| \leq L||F^{-1}_{\hat{\boldsymbol{\beta}}}(\hat{\boldsymbol{P}}) - \Delta\hat{\boldsymbol{\mu}}|| + ||\hat{\boldsymbol{P}} - \boldsymbol{P}||$$

$$\leq L||F^{-1}_{\boldsymbol{\beta}}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}|| + ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| \leq 4LU||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + ||\hat{\boldsymbol{P}} - \boldsymbol{P}||;$$

where the last inequality stems from the fact that $F^{-1}_{\boldsymbol{\beta}}(p)$ is $4U$-Lipschitz continuous for every $F_{\boldsymbol{\beta}}(p) \in \mathcal{F}$ and the previous inequality is a consequence of the optimality of PolyRank. In order to prove (17), consider a set of linear equations $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ and a perturbed version $(\boldsymbol{A}+\Delta\boldsymbol{A})(\boldsymbol{x}+\Delta\boldsymbol{x}) = b$ where both $\boldsymbol{A}$ and $\boldsymbol{A}+\Delta\boldsymbol{A}$ are non-singular square matrices. Under these conditions one can show that $\Delta\boldsymbol{x} = \boldsymbol{A}^{-1}\Delta\boldsymbol{A}(\boldsymbol{x}+\Delta\boldsymbol{x})$; thus:

$$\begin{pmatrix} \hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu} \end{pmatrix} = \boldsymbol{A}(\boldsymbol{P})^{-1}[\boldsymbol{A}(\boldsymbol{P}^*) - \boldsymbol{A}(\boldsymbol{P})] \begin{pmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\boldsymbol{\mu}} \end{pmatrix}. \tag{30}$$

Notice that $||\hat{\boldsymbol{\beta}}||_\infty \leq U$ and also $||\hat{\boldsymbol{\mu}}||_\infty \leq U$. The second claim is true for if $\hat{\mu}_j \geq U$ for some j then $|\hat{\mu}_i - \hat{\mu}_j| = |F^{-1}_{\hat{\boldsymbol{\beta}}}(\hat{p}^*_{ij})| \leq |F^{-1}_{\hat{\boldsymbol{\beta}}}(0)| = |\beta_0| \leq U$ which then implies that $\hat{\mu}_i \geq 0$ for every i and so $\sum_i \hat{\mu}_i \geq U > 0$ which violates the constraint $\sum_i \hat{\mu}_i = 0$; therefore we must have $\hat{\mu}_j < U$ for every j (the analogous argument is valid for $\hat{\mu}_j > -U$). Using the equivalence between norms find:

$$\left|\left|\begin{pmatrix} \hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu} \end{pmatrix}\right|\right| \leq U\sqrt{I+D}||\boldsymbol{A}(\boldsymbol{P})^{-1}||||\boldsymbol{A}(\boldsymbol{P}^*) - \boldsymbol{A}(\boldsymbol{P})||.$$

Now notice that

$$||\boldsymbol{A}(\boldsymbol{P}^*) - \boldsymbol{A}(\boldsymbol{P})||^2 = \sum_{k=1}^{D+I-1}\sum_{n=1}^{D}(p^{*n}_{(ij)_k} - p^n_{(ij)_k})^2 \leq \sum_{k=1}^{D+I-1} D(p^*_{(ij)_k} - p_{(ij)_k})^2 \leq D||\boldsymbol{P}^* - \boldsymbol{P}||^2$$

and therefore:

$$\left|\left|\begin{pmatrix} \hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu} \end{pmatrix}\right|\right| \leq U(4LU+1)\sqrt{D(I+D)}||\boldsymbol{A}(\boldsymbol{P})^{-1}||||\hat{\boldsymbol{P}} - \boldsymbol{P}||,$$

which completes the proof of (17). Now we will prove equation (18). A bit of algebra shows that for every $F_{\boldsymbol{\beta}} \in \mathcal{F}$ we have that $\max_{\alpha\in[0,1]}|F^{-1}_{\boldsymbol{\beta}}(\alpha) - F^{-1}_{\hat{\boldsymbol{\beta}}}(\alpha)| \leq 2||\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}||_\infty$; combining

this with (30), (17) and the lipschitz continuity of $F_{\boldsymbol{\beta}}$ we find the desired result. Finally, to prove order preservation, recognize that problem (9) can be solved by minimizing in $\boldsymbol{\mu}$ and in $\boldsymbol{\beta}$ separately. By minimizing on $\boldsymbol{\mu}$ we find the same closed form solution as the least squares refinement procedure, namely $\mu_i = (1/I)\sum_j F^{-1}_{\boldsymbol{\beta}}(\hat{p}_{ij})$. The proof follows by the same arguments as in Theorem 3. ■

A.4. Proof of Theorem 5

Proof We will first prove that $\max_{\alpha\in[0,1]}|F^{-1}_{\hat{\boldsymbol{\beta}}}(\alpha) - F^{-1}_{\boldsymbol{\beta}}(\alpha)| \geq 2|\beta_D|/8^D$. In the following proof $\mathcal{P}_{D-1}$ is the set of polynomials of degree less than or equal to $D-1$.

$$\max_{\alpha\in[0,1]}|F^{-1}_{\hat{\boldsymbol{\beta}}}(\alpha) - F^{-1}_{\boldsymbol{\beta}}(\alpha)| = \max_{\alpha\in[0,1/2]}|F^{-1}_{\hat{\boldsymbol{\beta}}}(\alpha) - F^{-1}_{\boldsymbol{\beta}}(\alpha)|$$

$$\geq \min_{G\in\mathcal{F}_{D'}}\max_{\alpha\in[0,1/2]}|G(\alpha) - F^{-1}_{\boldsymbol{\beta}}(\alpha)| \geq \min_{G^{-1}\in\mathcal{P}_{D-1}}\max_{\alpha\in[0,1/2]}|G^{-1}(\alpha) - F^{-1}_{\boldsymbol{\beta}}(\alpha)|$$

$$= \min_{F^{-1}_{\tilde{\boldsymbol{\beta}}}\in\mathcal{P}_{D-1}}\max_{\alpha\in[0,1/2]}|F^{-1}_{\tilde{\boldsymbol{\beta}}}(\alpha) + \beta_D\alpha^D|$$

$$= |\beta_D|\min_{F^{-1}_{\tilde{\boldsymbol{\beta}}}\in\mathcal{P}_{D-1}}\max_{\alpha\in[0,1/2]}|F^{-1}_{\tilde{\boldsymbol{\beta}}}(\alpha) + \alpha^D|$$

$$= |\beta_D|\min_{F^{-1}_{\tilde{\boldsymbol{\beta}}}\in\mathcal{P}_{D-1}}\max_{\alpha\in[-1,1]}|F^{-1}_{\tilde{\boldsymbol{\beta}}}((\alpha+1)/4) + ((\alpha+1)/4)^D|$$

$$\geq \frac{|\beta_D|}{4^D}\min_{F^{-1}_{\tilde{\boldsymbol{\beta}}}\in\mathcal{P}_{D-1}}\max_{\alpha\in[-1,1]}|F^{-1}_{\tilde{\boldsymbol{\beta}}}(\alpha) + \alpha^D|$$

$$= \frac{|\beta_D|}{4^D}\frac{1}{2^{D-1}}$$

The last equality is a defining property of Chebyshev polynomials (Mason and Handscomb, 2002). Now, notice that the $4U$-Lipschitz continuity of $F^{-1}_{\boldsymbol{\beta}}$ is equivalent to $|F_{\boldsymbol{\beta}}(y) - F_{\boldsymbol{\beta}}(x)| \geq (1/4U)|y-x|$; combining this with $\max_{\alpha\in[0,1]}|F^{-1}_{\hat{\boldsymbol{\beta}}}(\alpha) - F^{-1}_{\boldsymbol{\beta}}(\alpha)| \geq 2|\beta_D|/8^D$ we obtain equation (19). ■

A.5. Proof of Theorem 6

Proof Let $\hat{l}(D)$ be the empirical loss of a D dimensional fit provided by PolyRank, then:

$$\hat{l}(D) = \min_{\beta\in\mathbb{R}^D,\mu\in\mathbb{R}^I}\sqrt{\sum_{(ij)\in\mathcal{S}}(\beta_0 + ... + \beta_D\hat{p}^D_{ij} - \mu_i + \mu_j)^2}$$

where the minimum is taken over the sets specified by PolyRank for some triplet (D, U, L). It is also true that:

$$\hat{l}(D) = \min_{\beta \in \mathbb{R}^{D+1}, \mu \in \mathbb{R}^I} \sqrt{\sum_{(ij)\in\mathcal{S}} (\beta_0 + ... + \beta_D \hat{p}_{ij}^D - \mu_i + \mu_j)^2}$$

for the set specified by the triplet $(D+1, U, L)$, and so

$$\hat{l}(D) \leq \min_{\beta \in \mathbb{R}^{D+1}, \mu \in \mathbb{R}^I} \sqrt{\sum_{(ij)\in\mathcal{S}} (\beta_0 + ... + \beta_D \hat{p}_{ij}^D + \beta_{D+1}\hat{p}_{ij}^{D+1} - \mu_i + \mu_j)^2} + \sqrt{\sum_{(ij)\in\mathcal{S}} (\beta_{D+1}\hat{p}_{ij}^{D+1})^2}$$

$$\leq \min_{\beta \in \mathbb{R}^{D+1}, \mu \in \mathbb{R}^I} \sqrt{\sum_{(ij)\in\mathcal{S}} (\beta_0 + ... + \beta_D \hat{p}_{ij}^D + \beta_{D+1}\hat{p}_{ij}^{D+1} - \mu_i + \mu_j)^2} + U\sqrt{\sum_{(ij)\in\mathcal{S}} ((1/2)^{D+1})^2}$$

$$\leq \hat{l}(D+1) + U\,(1/2)^{D+1}\sqrt{|\mathcal{S}|}.$$

We have shown that $\hat{l}(D) \leq \hat{l}(D+1) + U\sqrt{|\mathcal{S}|}/2^{D+1}$ which implies that:

$$\hat{l}(D) \leq \hat{l}(D+K) + U\sqrt{|\mathcal{S}|}\sum_{i=D+1}^{D+K}\frac{1}{2^i} = \hat{l}(D+K) + \frac{U\sqrt{|\mathcal{S}|}}{2^D}\sum_{i=1}^{K}\frac{1}{2^i}.$$

Therefore taking the limit of $K \to \infty$ we find that $\hat{l}(D) \leq \hat{l}(\infty) + U\sqrt{|\mathcal{S}|}/2^D$; combining this with the optimality of the estimated parameters we obtain

$$||F_{\hat{\boldsymbol{\beta}}}^{-1}(\hat{\boldsymbol{P}}) - \Delta\hat{\boldsymbol{\mu}}|| \leq ||F^{-1}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}|| + \frac{U\sqrt{|\mathcal{S}|}}{2^D}. \tag{31}$$

To complete the proof of (20) notice that

$$||\boldsymbol{P}^* - \boldsymbol{P}|| \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + ||\hat{\boldsymbol{P}} - \boldsymbol{P}^*|| \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + L||F_{\hat{\boldsymbol{\beta}}}^{-1}(\hat{\boldsymbol{P}}) - \Delta\hat{\boldsymbol{\mu}}||$$

$$\leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + L||F^{-1}(\hat{\boldsymbol{P}}) - \Delta\boldsymbol{\mu}|| + \frac{LU\sqrt{|\mathcal{S}|}}{2^D} \leq (1+4LU)||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + \frac{1}{2^D}LUI.$$

■

Remark One could equivalently prove that PolyRank defined with the $\mathcal{L}_1$ norm satisfies $||\boldsymbol{P}^* - \boldsymbol{P}||_1 \leq (1+4LU)||\hat{\boldsymbol{P}} - \boldsymbol{P}||_1 + (1/2^D)LUI^2$ for analytic functions with bounded coefficients and with the $\mathcal{L}_\infty$ norm one finds that $||\boldsymbol{P}^* - \boldsymbol{P}||_\infty \leq (1+4LU)||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\infty + (1/2^D)LU$. We provide a sketch of the proof for a generic norm $||\cdot||_\#$. Again, we take $\mathcal{L}_\#$ to be the Lipschitz constant of F associated to $||\cdot||_\#$ and $4U_\#$ the Lipschitz constant of F^{-1} associated to $||\cdot||_\#$, then, we find that

$$||\boldsymbol{P}^* - \boldsymbol{P}||_\# \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# + ||\hat{\boldsymbol{P}} - \boldsymbol{P}^*||_\# \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# + L_\#||F_{\hat{\boldsymbol{\beta}}}^{-1}(\hat{\boldsymbol{P}}) - \Delta\hat{\boldsymbol{\mu}}||_\#;$$

then an inequality similar to (31) is obtained for the norm $||\cdot||_\#$. Norm equivalence guarantees that this can be done up to constant factors. Then, combining the two inequalities one finds that for some $k_1 \geq 1$ and some $k_2 \geq 0$ the following inequality holds:

$$||\boldsymbol{P}^* - \boldsymbol{P}||_\# \leq k_1||\hat{\boldsymbol{P}} - \boldsymbol{P}||_\# + \frac{k_2}{s^D}.$$

This completes the proof.

A.6. Proof of Theorem 7

Proof Equation (21) is a conscequence of the L-Lipschitz continuity of functions in $\mathcal{F}$:

$$||\boldsymbol{P}^* - \boldsymbol{P}|| \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + ||\hat{\boldsymbol{P}} - \boldsymbol{P}^*|| \leq ||\hat{\boldsymbol{P}} - \boldsymbol{P}|| + L||F_{\hat{\boldsymbol{\beta}}}^{-1}(\hat{\boldsymbol{P}}) - \Delta\hat{\boldsymbol{\mu}}||.$$

■

A.7. Proof of Theorem 8

We will use of the following lemma whose proof is virtually identical to that of Theorem 4:

Lemma 10 *Let $\hat{\boldsymbol{\beta}}$ and $\hat{\boldsymbol{\mu}}$ be estimated using* PolyRank. *Then,*

$$\left|\left|\begin{pmatrix}\hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\end{pmatrix}\right|\right| \leq K||\hat{\boldsymbol{P}} - \boldsymbol{P}||_{\boldsymbol{W}}, \tag{32}$$

where $K \leq U(1+4LU)\sqrt{D(I+D)}||\boldsymbol{A}_{\boldsymbol{W}}^{-1}||$ and $\boldsymbol{A}_{\boldsymbol{W}}$ is defined as in 10 with each line multiplied by its respective weight.

Proof Note that:

$$\mathbb{P}\left\{\left|\left|\begin{pmatrix}\hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\end{pmatrix}\right|\right| \geq \epsilon\right\} = \mathbb{P}\left\{\left|\left|\begin{pmatrix}\hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \\ \hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\end{pmatrix}\right|\right|^2 \geq \epsilon^2\right\} \leq \mathbb{P}\left\{K^2\sum w_{ij}|\hat{p}_{ij} - p_{ij}|^2 \geq \epsilon^2\right\}$$

$$\leq \mathbb{P}\left\{|E|\max_{ij}\{w_{ij}|\hat{p}_{ij} - p_{ij}|^2\} \geq \frac{\epsilon^2}{K^2}\right\} \leq \sum_{ij}\mathbb{P}\left\{w_{ij}|\hat{p}_{ij} - p_{ij}|^2 \geq \frac{\epsilon^2}{|E|K^2}\right\}$$

$$= \sum_{ij}\mathbb{P}\left\{|\hat{p}_{ij} - p_{ij}| \geq \frac{\epsilon}{K\sqrt{w_{ij}|E|}}\right\} \leq 2\sum_{ij}\exp\left\{-2m_{ij}\left(\frac{\epsilon}{K\sqrt{w_{ij}|E|}}\right)^2\right\}.$$

Where the last inequality follows from Hoeffding's bound; thus, taking $m_{ij} = nw_{ij}$ we have:

$$= 2\sum_{ij}\exp\left\{-2nw_{ij}\left(\frac{\epsilon}{K\sqrt{w_{ij}|E|}}\right)^2\right\} \leq 2|E|\exp\left\{-2n\frac{\epsilon^2}{K^2|E|}\right\},$$

which completes our proof. ■

Abstract

Binary, or one-bit, representations of data arise naturally in many applications, and are appealing in both hardware implementations and algorithm design. In this work, we study the problem of data classification from binary data obtained from the sign pattern of low-dimensional projections and propose a framework with low computation and resource costs. We illustrate the utility of the proposed approach through stylized and realistic numerical experiments, and provide a theoretical analysis for a simple case. We hope that our framework and analysis will serve as a foundation for studying similar types of approaches.

Keywords: binary measurements, one-bit representations, classification

1. Introduction

Our focus is on data classification problems in which only a *binary* representation of the data is available. Such binary representations may arise under a variety of circumstances. In some cases, they may arise naturally due to compressive acquisition. For example, distributed systems may have bandwidth and energy constraints that necessitate extremely coarse quantization of the measurements (Fang et al., 2014). A binary data representation can also be particularly appealing in hardware implementations because it is inexpensive to compute and promotes a fast hardware device (Jacques et al., 2013b; Laska et al., 2011); such benefits have contributed to the success, for example, of 1-bit Sigma-Delta converters (Aziz et al., 1996; Candy and Temes, 1962). Alternatively, binary, heavily quantized, or compressed representations may be part of the classification algorithm design in the interest of data compression and speed (Boufounos and Baraniuk, 2008; Hunter et al., 2010; Calderbank et al., 2009; Davenport et al., 2010; Gupta et al., 2010; Hahn et al., 2014). The goal of this paper is to present a framework for performing learning inferences, such as classification, from highly quantized data representations—we focus on the extreme case of 1-bit (binary) representations. Let us begin with the mathematical formulation of this problem.

Problem Formulation. Let $\{x_i\}_{i=1}^p \subset \mathbb{R}^n$ be a point cloud represented via a matrix

$$X = [x_1\ x_2\ \cdots\ x_p] \in \mathbb{R}^{n\times p}.$$

Moreover, let $A : \mathbb{R}^n \to \mathbb{R}^m$ be a linear map, and denote by $\text{sign} : \mathbb{R} \to \mathbb{R}$ the sign operator given by

$$\text{sign}(a) = \begin{cases} 1 & a \geq 0 \\ -1 & a < 0. \end{cases}$$

Without risk of confusion, we overload the above notation so the sign operator can apply to matrices (entrywise). In particular, for an m by p matrix M, and $(i,j) \in [m] \times [p]$, we define $\text{sign}(M)$ as the $m \times p$ matrix with entries

$$(\text{sign}(M))_{i,j} := \text{sign}(M_{i,j}).$$

We consider the setting where a classification algorithm has access to training data of the form $Q = \text{sign}(AX)$, along with a vector of associated labels $b = (b_1, \cdots, b_p) \in \{1, \ldots, G\}^p$, indicating the membership of each x_i to exactly one of G classes. Here, A is an m by n matrix. The rows of A define *hyperplanes* in $\mathbb{R}^n$ and the binary sign information tells us which side of the hyperplane each data point lies on. Throughout, we will primarily take A to have independent identically distributed standard Gaussian entries (though experimental results are also included for structured matrices). Given Q and b, we wish to train an algorithm that can be used to classify new signals, available only in a similar binary form via the matrix A, for which the label is unknown.

1.1. Contribution

Our contribution is a *framework* for classifying data into a given number of classes using only a binary representation (obtained as the sign pattern from low-dimensional projections, as described above) of the data. This framework serves several purposes: (i) it provides mathematical tools that can be used for classification in applications where data is already captured in a simple binary representation, (ii) demonstrates that for general problems, classification can be done effectively using low-dimensional measurements, (iii) suggests an approach to use these measurements for classification using low computation, (iv) provides a simple technique for classification that can be mathematically analyzed. We believe this framework can be extended and utilized to build novel algorithmic approaches for many types of learning problems. In this work, we present one method for classification using training data, illustrate its promise on synthetic and real data, and provide a theoretical analysis of the proposed approach in the simple setting of two-dimensional signals and two possible classes. Under mild assumptions, we derive an explicit lower bound on the probability that a new data point gets classified correctly. This analysis serves as a foundation for analyzing the method in more complicated settings, and a framework for studying similar types of approaches.

1.2. Organization

We proceed next in Section 1.3 with a brief overview of related work. Then, in Section 2 we propose a two-stage method for classifying data into a given number of classes using only a binary representation of the data. The first stage of the method performs training on data with known class membership, and the second stage is used for classifying new data points with a priori unknown class membership. Next, in Section 3 we demonstrate the potential of the proposed approach on both synthetically generated data as well as real datasets with application to handwritten digit recognition and facial recognition. Finally, in Section 4 we provide a theoretical analysis of the proposed approach in the simple setting of two-dimensional signals and two classes. We conclude in Section 5 with some discussion and future directions.

1.3. Prior Work

There is a large body of work on several areas related to the subject of this paper, ranging from classification to compressed sensing, hashing, quantization, and deep learning. Due to the popularity and impact of each of these research areas, any review of prior work that we provide here must necessarily be non-exhaustive. Thus, in what follows, we briefly discuss related prior work, highlighting connections to our work but also stressing the distinctions.

Support vector machines (SVM) (Christianini and Shawe-Taylor, 2000; Hearst et al., 1998; Joachims, 1998; Steinwart and Christmann, 2008) have become popular in machine learning, and are often used for classification. Provided a training set of data points and known labels, the SVM problem is to construct the optimal hyperplane (or hyperplanes) separating the data (if the data is linearly separable) or maximizing the geometric margin between the classes (if the data is not linearly separable). Although loosely related (in the sense that at a high level we utilize hyperplanes to separate the data), the approach taken in this paper is fundamentally different than in SVM. Instead of searching for the *optimal* separating hyperplane, our proposed algorithm uses many, randomly selected hyperplanes (via the rows of the matrix A), and uses the relationship between these hyperplanes and the training data to construct a classification procedure that operates on information between the same hyperplanes and the data to be classified.

The process of transforming high-dimensional data points into low-dimensional spaces has been studied extensively in related contexts. For example, the pioneering Johnson-Lindenstrauss Lemma states that any set of p points in high dimensional Euclidean space can be (linearly) embedded into $O(\epsilon^{-2}\log(p))$ dimensions, without distorting the distance between any two points by more than a small factor, namely ϵ (Johnson and Lindenstrauss, 1982). Since the original work of Johnson and Lindenstrauss, much work on Johnson-Lindenstrauss embeddings (often motivated by signal processing and data analysis applications) has focused on randomized embeddings where the matrix associated with the linear embedding is drawn from an appropriate random distribution. Such random embeddings include those based on Gaussian and other subgaussian random variables as well as those that admit fast implementations, usually based on the fast Fourier transform (Ailon and Chazelle, 2006; Achlioptas, 2003; Dasgupta and Gupta, 2003).

Another important line of related work is *compressed sensing*, in which it has been demonstrated that far fewer linear measurements than dictated by traditional Nyquist sampling can be used to represent high-dimensional data (Candès et al., 2006b,a; Donoho, 2006). For a signal $x \in \mathbb{R}^n$, one obtains $m < n$ measurements of the form $y = Ax$ (or noisy measurements $y = Ax + z$ for $z \in \mathbb{R}^m$), where $A \in \mathbb{R}^{m\times n}$, and the goal is to recover the signal x. By assuming the signal x is s-sparse, meaning that $\|x\|_0 = |\text{supp}(x)| = s \ll n$, the recovery problem becomes well-posed under certain conditions on A. Indeed, there is now a vast literature describing recovery results and algorithms when A, say, is a random matrix drawn from appropriate distributions (including those where the entries of A are independent Gaussian random variables). The relationship between Johnson-Lindenstrauss embeddings and compressed sensing is deep and bi-directional; matrices that yield Johnson-Lindenstrauss embeddings make excellent compressed sensing matrices (Baraniuk et al., 2006) and conversely, compressed sensing matrices (with minor modifications) yield Johnson-Lindenstrauss embeddings (Krahmer and Ward, 2011). Some initial work on performing inference tasks like classification from compressed sensing data shows promising results (Boufounos and Baraniuk, 2008; Hunter et al., 2010; Calderbank et al., 2009; Davenport et al., 2010; Gupta et al., 2010; Hahn et al., 2014).

To allow processing on digital computers, compressive measurements must often be *quantized*, or mapped to discrete values from some finite set. The extreme quantization setting where only the sign bit is acquired is known as *one-bit compressed sensing* and was introduced recently (Boufounos and Baraniuk, 2008). In this framework, the measurements now take the form $y = \text{sign}(Ax)$, and the objective is still to recover the signal x. Several methods have since been developed to recover the signal x (up to normalization) from such simple one-bit measurements (Plan and Vershynin, 2013a,b; Gopi et al., 2013; Jacques et al., 2013b; Yan et al., 2012; Jacques et al., 2013a). Although the data we consider in this paper takes a similar form, the overall goal is different; rather than signal *reconstruction*, our interest is data *classification*.

More recently, there has been growing interest in binary embeddings (embeddings into the binary cube (Plan and Vershynin, 2014; Yu et al., 2014; Gong et al., 2013; Yi et al., 2015; Choromanska et al., 2016; Dirksen and Stollenwerk, 2016), where it has been observed that using certain linear projections and then applying the sign operator as a nonlinear map largely preserves information about the angular distance between vectors provided one takes sufficiently many measurements. Indeed, the measurement operators used for binary embeddings are Johnson-Lindenstrauss embeddings and thus also similar to those used in compressed sensing, so they again range from random Gaussian and subgaussian matrices to those admitting fast linear transformations, such as random circulant matrices (Dirksen and Stollenwerk, 2016), although there are limitations to such embeddings for subgaussian but non-Gaussian matrices (Plan and Vershynin, 2014, 2013a). Although we consider a similar binary measurement process, we are not necessarily concerned with geometry preservation in the low-dimensional space, but rather the ability to still perform data classification.

Deep Learning is an area of machine learning based on learning data representations using multiple levels of abstraction, or layers. Each of these layers is essentially a function whose parameters are learned, and the full network is thus a composition of such functions. Algorithms for such deep neural networks have recently obtained state of the art results for classification. Their success has been due to the availability of large training data sets coupled with advancements in computing power and the development of new techniques (Krizhevsky et al., 2012; Simonyan and Zisserman, 2014; Szegedy et al., 2015; Russakovsky

et al., 2015). Randomization in neural networks has again been shown to give computational advantages and even so-called "shallow" networks with randomization and random initializations of deep neural networks have been shown to obtain results close to deep networks requiring heavy optimization (Rahimi and Recht, 2009; Giryes et al., 2016). Deep neural networks have also been extended to binary data, where the net represents a set of Boolean functions that maps all binary inputs to the outputs (Kim and Smaragdis, 2016; Courbariaux et al., 2015, 2016). Other types of quantizations have been proposed to reduce multiplications in both the input and hidden layers (Lin et al., 2015; Marchesi et al., 1993; Simard and Graf, 1994; Burge et al., 1999; Rastegari et al., 2016; Hubara et al., 2016). We will use randomized non-linear measurements but consider deep learning and neural networks as motivational to our multi-level algorithm design. Indeed, we are not tuning parameters nor doing any optimization as is typically done in deep learning, nor do our levels necessarily possess the structure typical in deep learning "architectures"; this makes our approach potentially simpler and easier to work with.

Using randomized non-linearities and simpler optimizations appears in several other works (Rahimi and Recht, 2009; Ozuysal et al., 2010). The latter work most closely resembles our approach in that the authors propose a "score function" using binary tests in the training phase, and then classifies new data based on the maximization of a class probability function. The perspective of this prior approach however is Bayesian rather than geometric, the score functions do not include any balancing terms as ours will below, the measurements are taken as "binary tests" using components of the data vectors (rather than our compressed sensing style projections), and the approach does not utilize a multi-level approach as ours does. We believe our geometric framework not only lends itself to easily obtained binary data but also a simpler method and analysis.

2. The Proposed Classification Algorithm

The training phase of our algorithm is detailed in Algorithm 1. Here, the method may take the binary data Q as input directly, or the training data $Q = \text{sign}(AX)$ may be computed as a one-time pre-processing step. For arbitrary matrices A, this step of course may incur a computational cost on the order of mnp. In Section 3, we also include experiments using structured matrices that have a fast multiply, reducing this cost to a logarithmic dependence on the dimension n. Then, the training algorithm proceeds in L "levels". In the ℓ-th level, m index sets $\Lambda_{\ell,i} \subset [m]$, $|\Lambda_{\ell,i}| = \ell$, $i = 1, ..., m$, are randomly selected, so that all elements of $\Lambda_{\ell,i}$ are unique, and $\Lambda_{\ell,i} \neq \Lambda_{\ell,j}$ for $i \neq j$. This is achieved by selecting the multi-set of $\Lambda_{\ell,i}$'s uniformly at random from a set of cardinality $\binom{\binom{m}{\ell}}{m}$. During the i-th "iteration" of the ℓ-th level, the rows of Q indexed by $\Lambda_{\ell,i}$ are used to form the $\ell \times p$ submatrix of Q, the columns of which define the sign patterns $\{\pm 1\}^\ell$ observed by the training data. For example, at the first level the possible sign patterns are 1 and -1, describing which side of the selected hyperplane the training data points lie on; at the second level the possible sign patters are $\begin{bmatrix}1\\1\end{bmatrix}$, $\begin{bmatrix}1\\-1\end{bmatrix}$, $\begin{bmatrix}-1\\1\end{bmatrix}$, $\begin{bmatrix}-1\\-1\end{bmatrix}$, describing which side of the two selected hyperplanes the training data points lie on, and so on for the subsequent levels. At each level, there are at most 2^ℓ possible sign patterns. Let $t = t(\ell) \in \{0, 1, 2, \dots\}$ denote the sign pattern *index* at level ℓ, where $0 \leq t \leq 2^\ell - 1$. Then, the binary (i.e., base 2) representation of each

$t = (t_\ell \dots t_2 t_1)_{\text{bin}} := \sum_{k=1}^{\ell} t_k 2^{k-1}$ is in one-to-one correspondence with the binary sign pattern it represents, up to the identification of $\{0, 1\}$ with the images $\{-1, 1\}$ of the sign operator. For example, at level $\ell = 2$ the sign pattern index $t = 2 = (10)_{\text{bin}}$ corresponds to the sign pattern $\begin{bmatrix}1\\-1\end{bmatrix}$.

For the t-th sign pattern and g-th class, a *membership index* parameter $r(\ell, i, t, g)$ that uses knowledge of the number of training points in class g having the t-th sign pattern, is calculated for every $\Lambda_{\ell,i}$. Larger values of $r(\ell, i, t, g)$ suggest that the t-th sign pattern is more heavily dominated by class g; thus, if a signal with unknown label corresponds to the t-th sign pattern, we will be more likely to classify it into the g-th class. In this paper, we use the following choice for the membership index parameter $r(\ell, i, t, g)$, which we found to work well experimentally. Below, $P_{g|t} = P_{g|t}(\Lambda_{\ell,i})$ denotes the number of training points from the g-th class with the t-th sign pattern at the i-th set selection in the ℓ-th level:

$$r(\ell, i, t, g) = \frac{P_{g|t}}{\sum_{j=1}^{G} P_{j|t}} \frac{\sum_{j=1}^{G} |P_{g|t} - P_{j|t}|}{\sum_{j=1}^{G} P_{j|t}}. \tag{1}$$

Let us briefly explain the intuition for this formula. The first fraction in (1) indicates the proportion of training points in class g out of all points with sign pattern t (at the ℓ-th level and i-th iteration). The second fraction in (1) is a balancing term that gives more weight to group g when that group is much different in size than the others with the same sign pattern. If $P_{j|t}$ is the same for all classes $j = 1, \dots, G$, then $r(\ell, i, t, g) = 0$ for all g, and thus no class is given extra weight for the given sign pattern, set selection, and level. If $P_{g|t}$ is nonzero and $P_{j|t} = 0$ for all other classes, then $r(\ell, i, t, g) = G - 1$ and $r(\ell, i, t, j) = 0$ for all $j \neq g$, so that class g receives the largest weight. It is certainly possible that a large number of the sign pattern indices t will have $P_{g|t} = 0$ for all groups (i.e., not all binary sign patterns are observed from the training data), in which case $r(\ell, i, t, g) = 0$.

Remark 1 *Note that in practice the membership index value need not be stored for all 2^ℓ possible sign pattern indices, but rather only for the unique sign patterns that are actually observed by the training data. In this case, the unique sign patterns at each level ℓ and iteration i must be input to the classification phase of the algorithm (Algorithm 2).*

Algorithm 1 Training

input: training labels b, number of classes G, number of levels L, binary training data Q (or raw training data X and fixed matrix A)
if raw data: Compute $Q = \text{sign}(AX)$
for ℓ from 1 to L, i from 1 to m **do**
  select: Randomly select $\Lambda_{\ell,i} \subset [m]$, $|\Lambda_{\ell,i}| = \ell$
  for t from 0 to $2^\ell - 1$, g from 1 to G **do**
    compute: Compute $r(\ell, i, t, g)$ by (1)
  end for
end for

Once the algorithm has been trained, we can use it to classify new signals. Suppose $x \in \mathbb{R}^n$ is a new signal for which the class is unknown, and we have available the quantized

measurements $q = \text{sign}(Ax)$. Then Algorithm 2 is used for the classification of x into one of the G classes. Notice that the number of levels L, the learned membership index values $r(\ell, i, t, g)$, and the set selections $\Lambda_{\ell,i}$ at each iteration of each level are all available from Algorithm 1. First, the decision vector $\tilde{r}$ is initialized to the zero vector in $\mathbb{R}^G$. Then for each level ℓ and set selection i, the sign pattern, and hence the binary base 2 representation, can be determined using q and $\Lambda_{\ell,i}$. Thus, the corresponding sign pattern index $t^\star = t^\star(\ell, i) \in \{0, 1, 2, \dots\}$ such that $0 \leq t^\star \leq 2^\ell - 1$ is identified. For each class g, $\tilde{r}(g)$ is updated via $\tilde{r}(g) \leftarrow \tilde{r}(g) + r(\ell, i, t^\star, g)$. Finally, after scaling $\tilde{r}$ with respect to the number of levels and measurements, the largest entry of $\tilde{r}$ identifies how the estimated label $\widehat{b}_x$ of x is set. This scaling of course does not actually affect the outcome of classification, we use it simply to ensure the quantity does not become unbounded for large problem sizes. We note here that especially for large m, the bulk of the classification will come from the higher levels (in fact the last level) due to the geometry of the algorithm. However, we choose to write the testing phase using all levels since the lower levels are cheap to compute with, may still contribute to classification accuracy especially for small m, and can be used naturally in other settings such as hierarchical classification and detection (see remarks in Section 5).

Algorithm 2 Classification

input: binary data q, number of classes G, number of levels L, learned parameters $r(\ell, i, t, g)$ and $\Lambda_{\ell,i}$ from Algorithm 1

initialize: $\tilde{r}(g) = 0$ for $g = 1, \dots, G$.
for ℓ from 1 to L, i from 1 to m **do**
  identify: Identify the sign pattern index $t^\star$ using q and $\Lambda_{\ell,i}$
  for g from 1 to G **do**
    update: $\tilde{r}(g) = \tilde{r}(g) + r(\ell, i, t^\star, g)$
  end for
end for
scale: Set $\tilde{r}(g) = \frac{\tilde{r}(g)}{Lm}$ for $g = 1, \dots, G$
classify: $\widehat{b}_x = \text{argmax}_{g \in \{1,\dots,G\}} \tilde{r}(g)$

3. Experimental Results

In this section, we provide experimental results of Algorithms 1 and 2 for synthetically generated datasets, handwritten digit recognition using the MNIST dataset, and facial recognition using the extended YaleB database. We note that for the synthetic data, we typically use Gaussian clouds, but note that since our algorithms use hyperplanes to classify data, the results on these type of datasets would be identical to any with the same radial distribution around the origin. We use Gaussian clouds simply because they are easy to visualize and allow for various geometries. Of course, our methods require no particular structure other than being centered around the origin, which can be done as a pre-processing step (and the framework could clearly be extended to remove this property in future work). The real data like the hand-written digits and faces clearly have more complicated geometries and

are harder to visualize. We include both types of data to fully characterize our method's performance.

We also remark here that we purposefully choose not to compare to other related methods like SVM for several reasons. First, if the data happens to be linearly separable it is clear that SVM will outperform or match our approach since it is designed precisely for such data. In the interesting case when the data is not linearly separable, our method will clearly outperform SVM since SVM will fail. To use SVM in this case, one needs an appropriate kernel, and identifying such a kernel is highly non-trivial without understanding the data's geometry, and precisely what our method avoids having to do.

Unless otherwise specified, the matrix A is taken to have i.i.d. standard Gaussian entries. Also, we assume the data is centered. To ensure this, a pre-processing step on the raw data is performed to account for the fact that the data may not be centered around the origin. That is, given the original training data matrix X, we calculate $\mu = \frac{1}{p}\sum_{i=1}^{p} x_i$. Then for each column x_i of X, we set $x_i \leftarrow x_i - \mu$. The testing data is adjusted similarly by μ. Note that this assumption can be overcome in future work by using *dithers*—that is, hyperplane dither values may be learned so that $Q = \text{sign}(AX + \tau)$, where $\tau \in \mathbb{R}^m$—or even with random dithers, as motivated by quantizer results (Baraniuk et al., 2017; Cambareri et al., 2017).

3.1. Classification of Synthetic Datasets

In our first stylized experiment, we consider three classes of Gaussian clouds in $\mathbb{R}^2$ (i.e., $n = 2$); see Figure 1 for an example training and testing data setup. For each choice of $m \in \{5, 7, 9, 11, 13, 15, 17, 19\}$ and $p \in \{75, 150, 225\}$ with equally sized training data sets for each class (that is, each class is tested with either 25, 50, or 75 training points), we execute Algorithms 1 and 2 with a single level and 30 trials of generating A. We perform classification of 50 test points per group, and report the average correct classification rate (ACCR) over all trials. Note that the ACCR is simply defined as the number of correctly classified testing points divided by the total number of testing points (where the correct class is known either from the generated distribution or the real label for real world data), and then averaged over the trials of generating A. We choose this metric since it captures both false negatives and positives, and since in all experiments we have access to the correct labels. The right plot of Figure 1 shows that $m \geq 15$ results in nearly perfect classification.

Next, we present a suite of experiments where we again construct the classes as Gaussian clouds in $\mathbb{R}^2$, but utilize various types of data geometries. In each case, we set the number of training data points for each class to be 25, 50, and 75. In Figure 2, we have two classes forming a total of six Gaussian clouds, and execute Algorithms 1 and 2 using four levels and $m \in \{10, 30, 50, 70, 90, 110, 130\}$. The classification accuracy increases for larger m, with nearly perfect classification for the largest values of m selected. A similar experiment is shown in Figure 3, where we have two classes forming a total of eight Gaussian clouds, and execute the proposed algorithm using five levels.

In the next two experiments, we display the classification results of Algorithms 1 and 2 when using $m \in \{10, 30, 50, 70, 90\}$ and one through four levels, and see that adding levels can be beneficial for more complicated data geometries. In Figure 4, we have three classes forming a total of eight Gaussian clouds. We see that from both $L = 1$ to $L = 2$ and $L = 2$

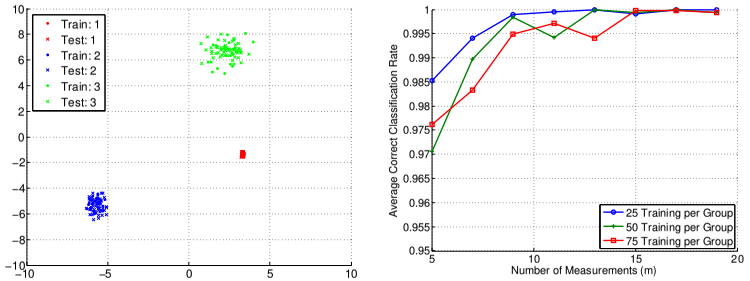

Figure 1: Synthetic classification experiment with three Gaussian clouds ($G = 3$), $L = 1$, $n = 2$, 50 test points per group, and 30 trials of randomly generating A. (Left) Example training and testing data setup. (Right) Average correct classification rate versus m and for the indicated number of training points per class.

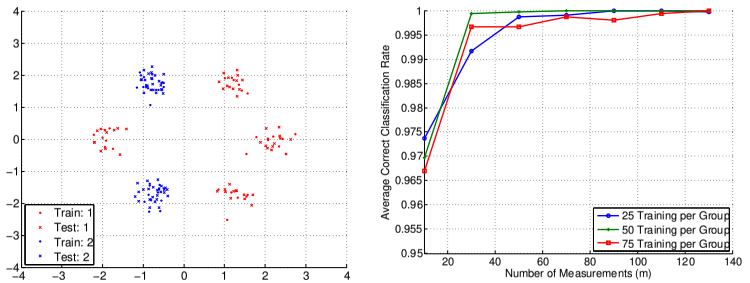

Figure 2: Synthetic classification experiment with six Gaussian clouds and two classes ($G = 2$), $L = 4$, $n = 2$, 50 test points per group, and 30 trials of randomly generating A. (Left) Example training and testing data setup. (Right) Average correct classification rate versus m and for the indicated number of training points per class.

to $L = 3$, there are huge gains in classification accuracy. In Figure 5, we have four classes forming a total of eight Gaussian clouds. Again, from both $L = 1$ to $L = 2$ and $L = 2$ to $L = 3$ we see large improvements in classification accuracy, yet still better classification with $L = 4$. We note here that in this case it also appears that more training data does not improve the performance (and perhaps even slightly decreases accuracy); this is of course unexpected in practice, but we believe this happens here only because of the construction of the Gaussian clouds—more training data leads to more outliers in each cloud, making the sets harder to separate.

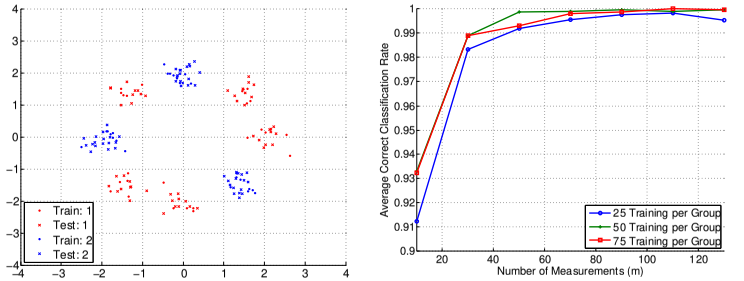

Figure 3: Synthetic classification experiment with eight Gaussian clouds and two classes ($G = 2$), $L = 5$, $n = 2$, 50 test points per group, and 30 trials of randomly generating A. (Left) Example training and testing data setup. (Right) Average correct classification rate versus m and for the indicated number of training points per class.

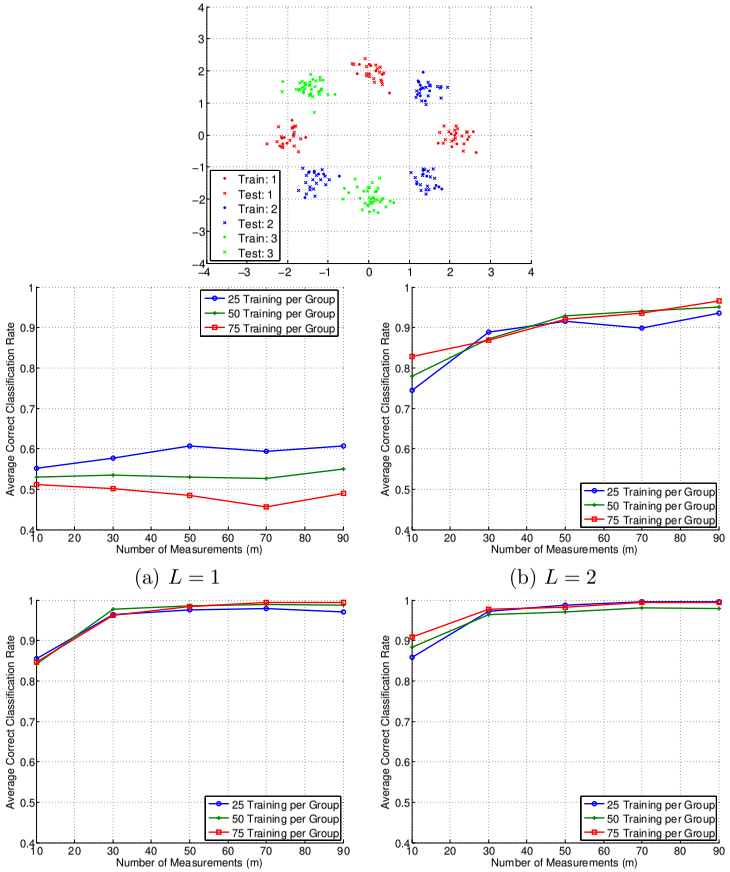
3.2. Handwritten Digit Classification

In this section, we apply Algorithms 1 and 2 to the MNIST (LeCun, 2018) dataset, which is a benchmark dataset of images of handwritten digits, each with 28×28 pixels. In total, the dataset has $60,000$ training examples and $10,000$ testing examples.

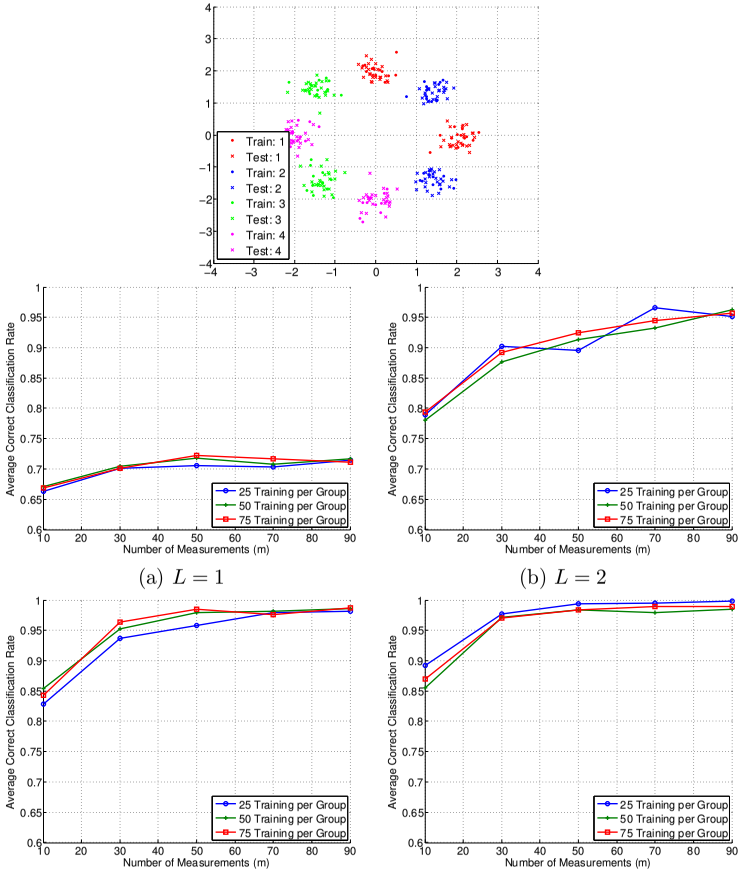
First, we apply Algorithms 1 and 2 when considering only two digit classes. Figure 6 shows the correct classification rate for the digits "0" versus "1". We set $m \in \{10, 30, 50, 70, 90, 110\}$, $p \in \{50, 100, 150\}$ with equally sized training data sets for each class, and classify 50 images per digit class. Notice that the algorithm is performing very well for small m in comparison to $n = 28 \times 28 = 784$ and only a single level. Figure 7 shows the results of a similar setup for the digits "0" and "5". In this experiment, we increased to four levels and achieve classification accuracy around 90% at the high end of m values tested. This indicates that the digits "0" and "5" are more likely to be mixed up than "0" and "1", which is understandable due to the more similar digit shape between "0" and "5". In Figure 7, we include the classification performance when the matrix A is constructed using the two-dimensional Discrete Cosine Transform (DCT) in addition to our typical Gaussian matrix A (note one could similarly use the Discrete Fourier Transform instead of the DCT but that requires re-defining the sign function on complex values). Specifically, to construct A from the $n \times n$ two-dimensional DCT, we select m rows uniformly at random



(a) $L = 1$ (b) $L = 2$

(c) $L = 3$ (d) $L = 4$

Figure 4: Synthetic classification experiment with eight Gaussian clouds and three classes ($G = 3$), $L = 1, \ldots, 4$, $n = 2$, 50 test points per group, and 30 trials of randomly generating A. (Top) Example training and testing data setup. Average correct classification rate versus m and for the indicated number of training points per class for: (middle left) $L = 1$, (middle right) $L = 2$, (bottom left) $L = 3$, (bottom right) $L = 4$.



(a) $L = 1$ (b) $L = 2$

(c) $L = 3$ (d) $L = 4$

Figure 5: Synthetic classification experiment with eight Gaussian clouds and four classes ($G = 4$), $L = 1, \ldots, 4$, $n = 2$, 50 test points per group, and 30 trials of randomly generating A. (Top) Example training and testing data setup. Average correct classification rate versus m and for the indicated number of training points per class for: (middle left) $L = 1$, (middle right) $L = 2$, (bottom left) $L = 3$, (bottom right) $L = 4$.

and then apply a random sign (i.e., multiply by +1 or -1) to the columns. We include these two results to illustrate that there is not much difference when using the DCT and Gaussian constructions of A, though we expect analyzing the DCT case to be more challenging and limit the theoretical analysis in this paper to the Gaussian setting. The advantage of using a structured matrix like the DCT is of course the reduction in computation cost in acquiring the measurements.

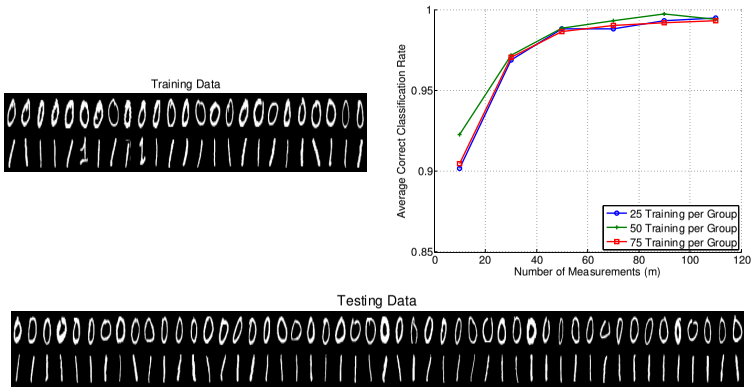


Figure 6: Classification experiment using the handwritten "0" and "1" digit images from the MNIST dataset, $L = 1$, $n = 28 \times 28 = 784$, 50 test points per group, and 30 trials of randomly generating A. (Top left) Training data images when $p = 50$. (Top right) Average correct classification rate versus m and for the indicated number of training points per class. (Bottom) Testing data images.

Next, we apply Algorithms 1 and 2 to the MNIST dataset with all ten digits. We utilize $1,000$, $3,000$, and $5,000$ training points per digit class, and perform classification with 800 test images per class. The classification results using 18 levels and $m \in \{100, 200, 400, 600, 800\}$ are shown in Figure 8, where it can be seen that with $5,000$ training points per class, above 90% classification accuracy is achieved for $m \geq 200$. We also see that larger training sets result in slightly improved classification.

3.3. Facial Recognition

Our last experiment considers facial recognition using the extended YaleB dataset (Cai et al., 2007b,a, 2006; He et al., 2005). This dataset includes 32×32 images of 38 individuals with roughly 64 near-frontal images under different illuminations per individual. We select four individuals from the dataset, and randomly select images with different illuminations to be included in the training and testing sets (note that the same illumination was included for *each* individual in the training and testing data). We execute Algorithms 1 and 2 using four levels with $m \in \{10, 50, 100, 150, 200, 250, 300\}$, $p \in \{20, 40, 60\}$ with equally sized training data sets for each class, and classify 30 images per class. The results are displayed

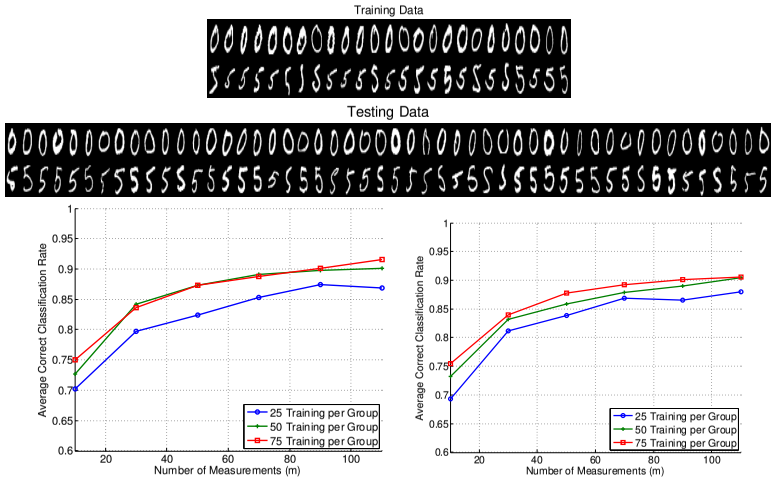

Figure 7: Classification experiment using the handwritten "0" and "5" digit images from the MNIST dataset, $L = 4$, $n = 28 \times 28 = 784$, 50 test points per group, and 30 trials of randomly generating A. (Top) Training data images when $p = 50$. (Middle) Testing data images. Average correct classification rate versus m and for the indicated number of training points per class (bottom left) when using a Gaussian matrix A and (bottom right) when using a DCT matrix A.

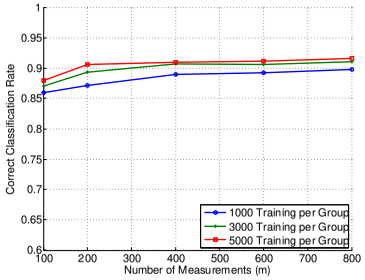

Figure 8: Correct classification rate versus m when using all ten (0-9) handwritten digits from the MNIST dataset, $L = 18$, $n = 28 \times 28 = 784$, 1,000, 3,000, and 5,000 training points per group, 800 test points per group (8,000 total), and a single instance of randomly generating A.

in Figure 9. Above 90% correct classification is achieved for $m \geq 150$ when using the largest training set.

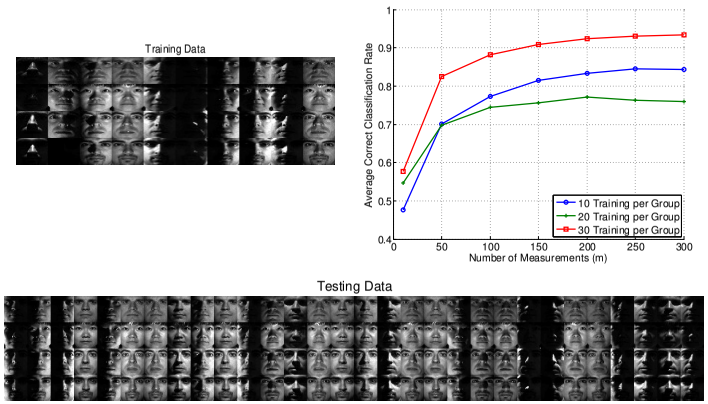

Figure 9: Classification experiment using four individuals from the extended YaleB dataset, $L = 4$, $n = 32 \times 32 = 1024$, 30 test points per group, and 30 trials of randomly generating A. (Top left) Training data images when $p = 20$. (Top right) Average correct classification rate versus m and for the indicated number of training points per class. (Bottom) Testing data images.

4. Theoretical Analysis for a Simple Case

4.1. Main Results

We now provide a theoretical analysis of Algorithms 1 and 2 in which we make a series of simplifying assumptions to make the development more tractable. We focus on the setting where the signals are two-dimensional, belonging to one of two classes, and consider a single level (i.e., $\ell = 1$, $n = 2$, and $G = 2$). Moreover, we assume the true classes G_1 and G_2 to be two disjoint *cones* in $\mathbb{R}^2$ and assume that regions of the same angular measure have the same number (or density) of training points. Of course, the problem of non-uniform densities relates to complicated geometries that may dictate the number of training points required for accurate classification (especially when many levels are needed) and is a great direction for future work. However, we believe analyzing this simpler setup will provide a foundation for a more generalized analysis in future work.

Let A_1 denote the angular measure of G_1, defined by

$$A_1 = \max_{x_1, x_2 \in G_1} \angle(x_1, x_2),$$

where $\angle(x_1, x_2)$ denotes the angle between the vectors x_1 and x_2; define A_2 similarly for G_2. Also, define

$$A_{12} = \min_{x_1 \in G_1, x_2 \in G_2} \angle(x_1, x_2)$$

as the angle between classes G_1 and G_2. Suppose that the test point $x \in G_1$, and that we classify x using m random hyperplanes. For simplicity, we assume that the hyperplanes can intersect the cones, but only intersect *one* cone at a time. This means we are imposing the condition $A_{12} + A_1 + A_2 \leq \pi$. See Figure 10 for a visualization of the setup for the analysis. Notice that A_1 is partitioned into two disjoint pieces, θ_1 and θ_2, where $A_1 = \theta_1 + \theta_2$. The angles θ_1 and θ_2 are determined by the location of x within G_1.

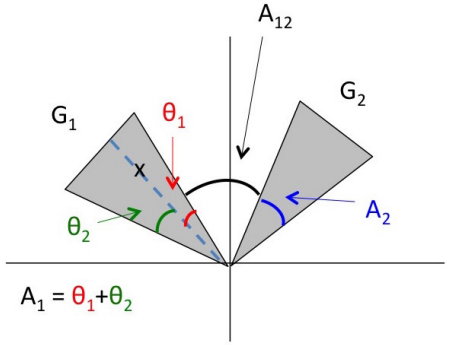

Figure 10: Visualization of the analysis setup for two classes of two dimensions. If a hyperplane intersects the θ_1 region of G_1, then x is not on the same side of the hyperplane as G_2. If a hyperplane intersects the θ_2 region of G_1, then x is on the same side of the hyperplane as G_2. That is, θ_1 and θ_2 are determined by the position of x within G_1, and $\theta_1 + \theta_2 = A_1$.

The membership index parameter (1) is still used; however, now we have angles instead of numbers of training points. That is,

$$r(\ell, i, t, g) = \frac{A_{g|t}}{\sum_{j=1}^{G} A_{j|t}} \frac{\sum_{j=1}^{G} |A_{g|t} - A_{j|t}|}{\sum_{j=1}^{G} A_{j|t}}, \tag{2}$$

where $A_{g|t} = A_{g|t}(\Lambda_{\ell,i})$ denotes the angle of the part of class g with the t-th sign pattern index at the i-th set selection in the ℓ-th level. Throughout, let $t_i^\star$ denote the sign pattern index of the test point x with the i-th hyperplane at the first level, $\ell = 1$; i.e. $t_i^\star = t_{\Lambda_{\ell,i}}^\star$ with the identification $\Lambda_{\ell,i} = \{i\}$ (since $\ell = 1$ implies a single hyperplane is used). Letting $\widehat{b}_x$ denote the classification label for x after running the proposed algorithm, Theorem 2 describes the probability that x gets classified correctly with $\widehat{b}_x = 1$. Note that for simplicity,

in Theorem 2 we assume the classes G_1 and G_2 are of the same size (i.e., $A_1 = A_2$) and the test point x lies in the middle of class G_1 (i.e., $\theta_1 = \theta_2$). These assumptions are for convenience and clarity of presentation only (note that (3) is already quite cumbersome), but the proof follows analogously (albeit without easy simplifications) for the general case; for convenience we leave the computations in Table 1 in general form and do not utilize the assumption $\theta_1 = \theta_2$ until the end of the proof. We first state a technical result in Theorem 2, and include two corollaries below that illustrate its usefulness.

Theorem 2 *Let the classes G_1 and G_2 be two cones in $\mathbb{R}^2$ defined by angular measures A_1 and A_2, respectively, and suppose regions of the same angular measure have the same density of training points. Suppose $A_1 = A_2$, $\theta_1 = \theta_2$, and $A_{12} + A_1 + A_2 \leq \pi$. Then, the probability that a data point $x \in G_1$ gets classified in class G_1 by Algorithms 1 and 2 using a single level and a measurement matrix $A \in \mathbb{R}^{m\times 2}$ with independent standard Gaussian entries is bounded as follows,*

$$\mathbb{P}[\widehat{b}_x = 1] \geq 1 - \sum_{\substack{j+k_{1,1}+k_{1,2}+k_2+k=m,\ k_{1,2}\geq 9(j+k_{1,1})}}^{m}\sum_{k_{1,1}=0}^{m}\sum_{k_{1,2}=0}^{m}\sum_{k_2=0}^{m}\sum_{k=0}^{m} \binom{m}{j,k_{1,1},k_{1,2},k_2,k} \left(\frac{A_{12}}{\pi}\right)^{j} \left(\frac{A_1}{2\pi}\right)^{k_{1,1}+k_{1,2}} \times \left(\frac{A_1}{\pi}\right)^{k_2} \left(\frac{\pi - 2A_1 - A_{12}}{\pi}\right)^{k}. \tag{3}$$

Figure 11 displays the classification probability bound of Theorem 2 compared to the (simulated) true value of $\mathbb{P}[\widehat{b}_x = 1]$. Here, $A_1 = A_2 = 15°$, $\theta_1 = \theta_2 = 7.5°$, and A_{12} and m are varied. Most importantly, notice that in all cases, the classification probability is approaching 1 with increasing m. Also, the result from Theorem 2 behaves similarly as the simulated true probability, especially as m and A_{12} increase.

The following two corollaries provide asymptotic results for situations where $\mathbb{P}[\widehat{b}_x = 1]$ tends to 1 when $m \to \infty$. Corollary 3 provides this result whenever A_{12} is at least as large as both A_1 and $\pi - 2A_1 - A_{12}$, and Corollary 4 provides this result for certain combinations of A_1 and A_{12}. These results of course should match intuition, since as m grows large, our hyperplanes essentially chop up the space into finer and finer wedges. Below, the dependence on the constants on A_1, A_{12} is explicit in the proofs.

Corollary 3 *Consider the setup of Theorem 2. Suppose $A_{12} \geq A_1$ and $2A_{12} \geq \pi - 2A_1$. Then $\mathbb{P}[\widehat{b}_x = 1] \to 1$ as $m \to \infty$. In fact, the probability converges to 1 exponentially, i.e. $\mathbb{P}[\widehat{b}_x = 1] \geq 1 - Ce^{-cm}$ for positive constants c and C that may depend on A_1, A_{12}.*

Corollary 4 *Consider the setup of Theorem 2. Suppose $A_1 + A_{12} > 0.58\pi$ and $A_{12} + \frac{3}{4}A_1 \leq \frac{\pi}{2}$. Then $\mathbb{P}[\widehat{b}_x = 1] \to 1$ as $m \to \infty$. In fact, the probability converges to 1 exponentially, i.e. $\mathbb{P}[\widehat{b}_x = 1] \geq 1 - Ce^{-cm}$ for positive constants c and C that may depend on A_1, A_{12}.*

4.2. Proof of Main Results

4.2.1. Proof of Theorem 2

Proof Using our setup, we have five possibilities for any given hyperplane: (i) the hyperplane completely separates the two classes, i.e., the cones associated with the two classes

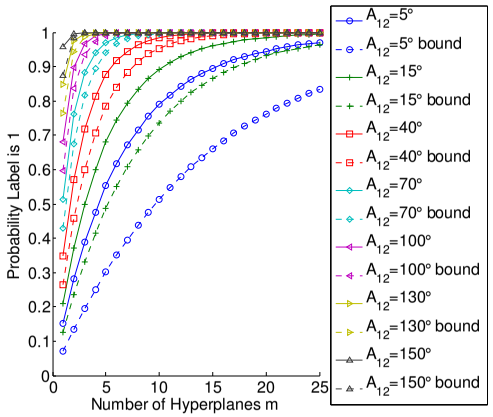

Figure 11: $\mathbb{P}[\widehat{b}_x = 1]$ versus the number of hyperplanes m when A_{12} is varied (see legend), $A_1 = A_2 = 15°$, and $\theta_1 = \theta_2 = 7.5°$. The solid lines indicate the probability (5) with the multinomial probability given by (6) and the conditional probability (9) simulated over 1000 trials of the uniform random variables. The dashed lines indicate the result (3) provided in Theorem 2.

fall on either side of the hyperplane, (ii) the hyperplane completely does not separate the two classes, i.e., the cones fall on the same side of the hyperplane, (iii) the hyperplane cuts through G_2, (iv) the hyperplane cuts through G_1 via θ_1, or (v) the hyperplane cuts through G_1 via θ_2. Using this observation, we can now define the event

$$E(j, k_{1,1}, k_{1,2}, k_2) \tag{4}$$

whereby from among the m total hyperplanes, j hyperplanes separate the cones, $k_{1,1}$ hyperplanes cut G_1 in θ_1, $k_{1,2}$ hyperplanes cut G_1 in θ_2, and k_2 hyperplanes cut G_2. See Table 1 for an easy reference of these quantities. Note that we must distinguish between hyperplanes that cut through θ_1 and those that cut through θ_2; $k_{1,1}$ hyperplanes cut G_1 and land within θ_1 so that x is *not* on the same side of the hyperplane as G_2 whereas $k_{1,2}$ hyperplanes cut G_1 and land within θ_2 so that x *is* on the same side of the hyperplane as G_2. These orientations will affect the computation of the membership index. Using the above definition of (4), we use the law of total probability to get a handle on $\mathbb{P}[\widehat{b}_x = 1]$, the probability that the test point x gets classified correctly, as follows,

$$\begin{aligned}\mathbb{P}[\widehat{b}_x = 1] &= \mathbb{P}\left[\sum_{i=1}^{m} r(\ell, i, t_i^\star, 1) > \sum_{i=1}^{m} r(\ell, i, t_i^\star, 2)\right] \\ &= \sum_{\substack{j,k_{1,1},k_{1,2},k_2 \\ j+k_{1,1}+k_{1,2}+k_2\leq m}} \mathbb{P}\left[\sum_{i=1}^{m} r(\ell, i, t_i^\star, 1) > \sum_{i=1}^{m} r(\ell, i, t_i^\star, 2)\,|E(j, k_{1,1}, k_{1,2}, k_2)\right]\end{aligned}$$

$$\times \mathbb{P}\left[E(j,k_{1,1},k_{1,2},k_2)\right]. \tag{5}$$

The latter probability in (5) is similar to the probability density of a multinomial random variable:

$$\begin{aligned}&\mathbb{P}\left[E(j,k_{1,1},k_{1,2},k_2)\right]\\ &= \binom{m}{j,k_{1,1},k_{1,2},k_2,m-j-k_{1,1}-k_{1,2}-k_2}\left(\frac{A_{12}}{\pi}\right)^j\left(\frac{\theta_1}{\pi}\right)^{k_{1,1}}\left(\frac{\theta_2}{\pi}\right)^{k_{1,2}}\\ &\quad\times\left(\frac{A_2}{\pi}\right)^{k_2}\left(\frac{\pi-A_1-A_2-A_{12}}{\pi}\right)^{m-j-k_{1,1}-k_{1,2}-k_2},\end{aligned} \tag{6}$$

where $\binom{n}{k_1,k_2,\ldots,k_m} = \frac{n!}{k_1!k_2!\cdots k_m!}$.

To evaluate the conditional probability in (5), we must determine the value of $r(\ell,i,t_i^\star,g)$, for $g=1,2$, given the hyperplane cutting pattern event. Table 1 summarizes the possible cases. In the cases where the hyperplane cuts through either G_1 or G_2, we model the location of the hyperplane within the class by a random variable defined on the interval $[0,1]$, with no assumed distribution. We let u, u', u_h, $u'_h \in [0,1]$ (for an index h) denote independent copies of such random variables.

Hyperplane Case	Number in event (4)	Class g	Value of $r(\ell,i,t_i^\star,g)$ (see (2))
(i) separates	j	1	1
		2	0
(ii) does not separate	$m-j-k_2-k_{1,1}-k_{1,2}$	1	$\frac{A_1\lvert A_1-A_2\rvert}{(A_1+A_2)^2}$
		2	$\frac{A_2\lvert A_1-A_2\rvert}{(A_1+A_2)^2}$
(iii) cuts G_2	k_2	1	$\frac{A_1\lvert A_1-A_2u'\rvert}{(A_1+A_2u')^2}$
		2	$\frac{A_2u'\lvert A_1-A_2u'\rvert}{(A_1+A_2u')^2}$
(iv) cuts G_1, θ_1	$k_{1,1}$	1	1
		2	0
(v) cuts G_1, θ_2	$k_{1,2}$	1	$\frac{(\theta_1+\theta_2u)\lvert\theta_1+\theta_2u-A_2\rvert}{(\theta_1+\theta_2u+A_2)^2}$
		2	$\frac{A_2\lvert\theta_1+\theta_2u-A_2\rvert}{(\theta_1+\theta_2u+A_2)^2}$

Table 1: Summary of (2) when up to one cone can be cut per hyperplane, where u,u' are independent random variables defined over the interval $[0,1]$.

Using the computations given in Table 1 and assuming j hyperplanes separate (i.e. condition (i) described above), $k_{1,1}$ hyperplanes cut G_1 in θ_1 (condition (iv) above), $k_{1,2}$ hyperplanes cut G_1 in θ_2 (condition (v) above), k_2 hyperplanes cut G_2 (condition (iii) above), and $m-j-k_{1,1}-k_{1,2}-k_2$ hyperplanes do not separate (condition (ii) above), we compute the membership index parameters defined in (2) as:

$$\sum_{i=1}^m r(\ell,i,t_i^\star,1) = j + (m-j-k_{1,1}-k_{1,2}-k_2)\frac{A_1|A_1-A_2|}{(A_1+A_2)^2} + k_{1,1}$$

$$\begin{aligned}&+\sum_{h=1}^{k_{1,2}}\frac{(\theta_1+\theta_2u_h)|\theta_1+\theta_2u_h-A_2|}{(\theta_1+\theta_2u_h+A_2)^2}+\sum_{h=1}^{k_2}\frac{A_1|A_1-A_2u'_h|}{(A_1+A_2u'_h)^2}\\ &= j+k_{1,1}+\sum_{h=1}^{k_{1,2}}\frac{(\theta_1+\theta_2u_h)|\theta_1+\theta_2u_h-A_1|}{(\theta_1+\theta_2u_h+A_1)^2}+\sum_{h=1}^{k_2}\frac{A_1|A_1-A_1u'_h|}{(A_1+A_1u'_h)^2}\end{aligned} \tag{7}$$

and

$$\begin{aligned}\sum_{i=1}^m r(\ell,i,t_i^\star,2) &= (m-j-k_{1,1}-k_{1,2}-k_2)\frac{A_2|A_1-A_2|}{(A_1+A_2)^2}\\ &\quad+\sum_{h=1}^{k_{1,2}}\frac{A_2|\theta_1+\theta_2u_h-A_2|}{(\theta_1+\theta_2u_h+A_2)^2}+\sum_{h=1}^{k_2}\frac{A_2u'_h|A_1-A_2u'_h|}{(A_1+A_2u'_h)^2}\\ &= \sum_{h=1}^{k_{1,2}}\frac{A_1|\theta_1+\theta_2u_h-A_1|}{(\theta_1+\theta_2u_h+A_1)^2}+\sum_{h=1}^{k_2}\frac{A_1u'_h|A_1-A_1u'_h|}{(A_1+A_1u'_h)^2},\end{aligned} \tag{8}$$

where in both cases we have simplified using the assumption $A_1=A_2$. Thus, the conditional probability in (5), can be expressed as:

$$\mathbb{P}\left[j+k_{1,1}+\sum_{h=1}^{k_{1,2}}\frac{|\theta_1+\theta_2u_h-A_1|(\theta_1+\theta_2u_h-A_1)}{(\theta_1+\theta_2u_h+A_1)^2}+\sum_{h=1}^{k_2}\frac{|A_1-A_1u'_h|(A_1-A_1u'_h)}{(A_1+A_1u'_h)^2}>0\right], \tag{9}$$

where it is implied that this probably is conditioned on the hyperplane configuration as in (5). Once the probability (9) is known, we can calculate the full classification probability (5).

Since by assumption, $\theta_1+\theta_2=A_1$, we have $\theta_1+\theta_2u-A_1\le 0$ and $A_1-A_1u'\ge 0$. Thus, (9) simplifies to

$$\mathbb{P}\left[j+k_{1,1}-\sum_{h=1}^{k_{1,2}}\frac{(\theta_1+\theta_2u_h-A_1)^2}{(\theta_1+\theta_2u_h+A_1)^2}+\sum_{h=1}^{k_2}\frac{(A_1-A_1u'_h)^2}{(A_1+A_1u'_h)^2}>0\right] \;\ge\; \mathbb{P}[\gamma>\beta] \tag{10}$$

where

$$\beta = k_{1,2}\left(\frac{\theta_2}{A_1+\theta_1}\right)^2 \quad\text{and}\quad \gamma = j+k_{1,1}.$$

To obtain the inequality in (10), we used the fact that

$$j+k_{1,1}-\sum_{h=1}^{k_{1,2}}\frac{(\theta_1-A_1)^2}{(\theta_1+\theta_2u_h+A_1)^2}+\sum_{h=1}^{k_2}\frac{(A_1-A_1u'_h)^2}{(A_1+A_1u'_h)^2}\ge j+k_{1,1}-\sum_{h=1}^{k_{1,2}}\frac{(\theta_1-A_1)^2}{(\theta_1+A_1)^2}+0=\gamma-\beta.$$

By conditioning on $\gamma>\beta$, the probability of interest (5) reduces to (note the bounds on the summation indices):

$$\mathbb{P}[\widehat{b}_x=1] = \sum_{\substack{j,k_{1,1},k_{1,2},k_2\\ j+k_{1,1}+k_{1,2}+k_2\le m}}\mathbb{P}\left[\sum_{i=1}^m r(\ell,i,t_i^\star,1)>\sum_{i=1}^m r(\ell,i,t_i^\star,2)\;|E(j,k_{1,1},k_{1,2},k_2)\right]$$

$$\times \mathbb{P}\left[E(j,k_{1,1},k_{1,2},k_2)\right] \tag{11}$$

$$\geq \sum_{\substack{j,k_{1,1},k_{1,2},k_2 \\ j+k_{1,1}+k_{1,2}+k_2\leq m, \\ \beta-\gamma<0}} \binom{m}{j,k_{1,1},k_{1,2},k_2,m-j-k_{1,1}-k_{1,2}-k_2} \left(\frac{A_{12}}{\pi}\right)^j \left(\frac{\theta_1}{\pi}\right)^{k_{1,1}} \times \left(\frac{\theta_2}{\pi}\right)^{k_{1,2}} \left(\frac{A_2}{\pi}\right)^{k_2} \left(\frac{\pi-A_1-A_2-A_{12}}{\pi}\right)^{m-j-k_{1,1}-k_{1,2}-k_2}. \tag{12}$$

The condition $\beta-\gamma<0$ is equivalent to $k_{1,2}(\frac{\theta_2}{A_1+\theta_1})^2-(j+k_{1,1})<0$, which implies $k_{1,2}(\frac{\theta_2}{A_1+\theta_1})^2<j+k_{1,1}$. Assuming $\theta_1=\theta_2$ simplifies this condition to depend *only* on the hyperplane configuration (and not A_1, θ_1, and θ_2) since $\frac{\theta_2}{A_1+\theta_1}=\frac{\theta_2}{3\theta_2}=\frac{1}{3}$. Thus, the condition $\beta-\gamma<0$ reduces to the condition $k_{1,2}<9(j+k_{1,1})$ and (12) then simplifies to

$$\sum_{\substack{j+k_{1,1}+k_{1,2}+k_2\leq m, \\ k_{1,2}<9(j+k_{1,1})}} \binom{m}{j,k_{1,1},k_{1,2},k_2,m-j-k_{1,1}-k_{1,2}-k_2} \left(\frac{A_{12}}{\pi}\right)^j \left(\frac{\theta_1}{\pi}\right)^{k_{1,1}+k_{1,2}} \times \left(\frac{A_2}{\pi}\right)^{k_2} \left(\frac{\pi-2A_1-A_{12}}{\pi}\right)^{m-j-k_{1,1}-k_{1,2}-k_2} \tag{13}$$

$$= \sum_{\substack{j+k_{1,1}+k_{1,2}+k_2+k=m, \\ k_{1,2}<9(j+k_{1,1})}} \binom{m}{j,k_{1,1},k_{1,2},k_2,k} \left(\frac{A_{12}}{\pi}\right)^j \left(\frac{\theta_1}{\pi}\right)^{k_{1,1}+k_{1,2}} \left(\frac{A_2}{\pi}\right)^{k_2} \left(\frac{\pi-2A_1-A_{12}}{\pi}\right)^{k}, \tag{14}$$

$$= \sum_{\substack{j+k_{1,1}+k_{1,2}+k_2+k=m, \\ k_{1,2}<9(j+k_{1,1})}} \binom{m}{j,k_{1,1},k_{1,2},k_2,k} \left(\frac{A_{12}}{\pi}\right)^j \left(\frac{A_1}{2\pi}\right)^{k_{1,1}+k_{1,2}} \left(\frac{A_1}{\pi}\right)^{k_2} \left(\frac{\pi-2A_1-A_{12}}{\pi}\right)^{k}, \tag{15}$$

where we have introduced k to denote the number of hyperplanes that do not separate nor cut through either of the groups, and simplified using the assumptions that $\theta_1=\frac{A_1}{2}$ and $A_1=A_2$.

Note that if we did not have the condition $k_{1,2}<9(j+k_{1,1})$ in the sum (15) (that is, if we summed over all terms), the quantity would sum to 1 (this can easily be seen by the Multinomial Theorem). Finally, this means (15) is equivalent to (3), thereby completing the proof. ■

4.2.2. Proof of Corollary 3

Proof We can bound (3) from below by bounding the excluded terms in the sum (i.e., those that satisfy $k_{1,2}\geq 9(j+k_{1,1})$) from above. One approach to this would be to count the number of terms satisfying $k_{1,2}\geq 9(j+k_{1,1})$ and bound them by their maximum. Using basic combinatorics (see the appendix, Section A.1), that the number of terms satisfying $k_{1,2}\geq 9(j+k_{1,1})$ is given by

$$W_1=\frac{1}{12}\left(\left\lfloor\frac{m}{10}\right\rfloor+1\right)\left(\left\lfloor\frac{m}{10}\right\rfloor+2\right)\left(150\left\lfloor\frac{m}{10}\right\rfloor^2-10(4m+1)\left\lfloor\frac{m}{10}\right\rfloor+3(m^2+3m+2)\right)\sim m^4. \tag{16}$$

Then, the quantity (3) can be bounded below by

$$1-W_1\max\left(\binom{m}{j,k_{1,1},k_{1,2},k_2,k}\left(\frac{A_{12}}{\pi}\right)^j\left(\frac{A_1}{2\pi}\right)^{k_{1,1}+k_{1,2}}\left(\frac{A_1}{\pi}\right)^{k_2}\left(\frac{\pi-2A_1-A_{12}}{\pi}\right)^k\right)=$$
$$1-W_1\max\left(\binom{m}{j,k_{1,1},k_{1,2},k_2,k}\left(\frac{1}{2}\right)^{k_{1,1}+k_{1,2}}\left(\frac{A_{12}}{\pi}\right)^j\left(\frac{A_1}{\pi}\right)^{k_{1,1}+k_{1,2}+k_2}\left(\frac{\pi-2A_1-A_{12}}{\pi}\right)^k\right), \tag{17}$$

where the maximum is taken over all $j,k_{1,1},k_{1,2},k_2,k=0,\ldots,m$ such that $k_{1,2}\geq 9(j+k_{1,1})$. Ignoring the constraint $k_{1,2}\geq 9(j+k_{1,1})$, we can upper bound the multinomial coefficient using the trivial upper bound of 5^m:

$$\binom{m}{j,k_{1,1},k_{1,2},k_2,k}\leq 5^m. \tag{18}$$

Since we are assuming A_{12} is larger than A_1 and $\pi-2A_1-A_{12}$ (from the assumption that $2A_{12}\geq\pi-2A_1$), the strategy is to take j to be as large as possible while satisfying $k_{1,2}\geq 9j$ and $j+k_{1,2}=m$. Since $k_{1,2}\geq 9j$, we have $j+9j\leq m$ which implies $j\leq\frac{m}{10}$. So, we take $j=\frac{m}{10}$, $k_{1,2}=\frac{9m}{10}$, and $k_{1,1}=k_2=k=0$. Then

$$\left(\frac{1}{2}\right)^{k_{1,1}+k_{1,2}}\left(\frac{A_{12}}{\pi}\right)^j\left(\frac{A_1}{\pi}\right)^{k_{1,1}+k_{1,2}+k_2}\left(\frac{\pi-2A_1-A_{12}}{\pi}\right)^k \tag{19}$$
$$\leq\left(\frac{1}{2}\right)^{9m/10}\left(\frac{A_{12}}{\pi}\right)^{m/10}\left(\frac{A_1}{\pi}\right)^{9m/10}$$
$$=\left(\frac{1}{2^9}\frac{A_{12}}{\pi}\left(\frac{A_1}{\pi}\right)^9\right)^{m/10}. \tag{20}$$

Combining (17) with the bounds given in (18) and (20), we have

$$\geq 1-W_1 5^m\left(\frac{1}{2^9}\frac{A_{12}}{\pi}\left(\frac{A_1}{\pi}\right)^9\right)^{m/10}$$
$$\sim 1-m^4 5^m\left(\frac{1}{2^9}\frac{A_{12}}{\pi}\left(\frac{A_1}{\pi}\right)^9\right)^{m/10}$$
$$=1-m^2\left(5^{10}\frac{1}{2^9}\frac{A_{12}}{\pi}\left(\frac{A_1}{\pi}\right)^9\right)^{m/10}. \tag{21}$$

For the above to tend to 1 as $m \to \infty$, we need $\frac{5^{10}}{2^9}\frac{A_{12}}{\pi}\left(\frac{A_1}{\pi}\right)^9 < 1$. This is equivalent to $A_{12}\left(\frac{A_1}{2}\right)^9 < \frac{\pi^{10}}{5^{10}}$, which implies $A_{12}\theta_1^9 < \left(\frac{\pi}{5}\right)^{10} = \frac{\pi}{5}\left(\frac{\pi}{5}\right)^9$. Note that if $\theta_1 = \frac{\pi}{5}$, then $A_1 = A_2 = 2\theta_1 = \frac{2\pi}{5}$. Then A_{12} could be at most $\frac{\pi}{5}$. But, this can't be because we have assumed $A_{12} \geq A_1$. Thus, we must have $\theta_1 < \frac{\pi}{5}$. In fact, $\theta_1 = \frac{\pi}{6}$ is the largest possible, in which case $A_{12} = A_1 = A_2 = \frac{\pi}{3}$. If $\theta_1 = \frac{\pi}{6}$, then $A_{12}\theta_1^9 < \frac{\pi}{5}\left(\frac{\pi}{5}\right)^9$ becomes $A_{12} < \frac{\pi}{5}\left(\frac{6}{5}\right)^9 \approx 3.24$. Therefore, since we are already assuming $A_{12} + 2A_1 \leq \pi$, this is essentially no further restriction on A_{12}, and the same would be true for all $\theta_1 \leq \frac{\pi}{6}$. This completes the proof. ■

4.2.3. Proof of Corollary 4

Proof Consider (3) and set $j' = j + k_{1,1}$ and $r = k_2 + k$. Then we view (3) as a probability equivalent to

$$1 - \sum_{\substack{j'=0}}^{2m} \sum_{k_{1,2}=0}^{m} \sum_{r=0}^{2m} \binom{m}{k_{1,2}, j', r} \left(\frac{A_{12} + \frac{A_1}{2}}{\pi}\right)^{j'} \left(\frac{A_1}{2\pi}\right)^{k_{1,2}} \left(\frac{\pi - A_1 - A_{12}}{\pi}\right)^{r}. \quad (22)$$
$$j'+k_{1,2}+r=m,\ k_{1,2}\geq 9j'$$

Note that multinomial coefficients are maximized when the parameters all attain the same value. Thus, the multinomial term above is maximized when $k_{1,2}$, j' and r are all as close to one another as possible. Thus, given the additional constraint that $k_{1,2} \geq 9j'$, the multinomial term is maximized when $k_{1,2} = \frac{9m}{19}$, $j' = \frac{m}{19}$, and $r = \frac{9m}{19}$ (possibly with ceilings/floors as necessary if m is not a multiple of 19), (see the appendix, Section A.2, for a quick explanation), which means

$$\binom{m}{k_{1,2}, j', r} \leq \frac{m!}{(\frac{9m}{19})!(\frac{m}{19})!(\frac{9m}{19})!} \quad (23)$$

$$\sim \frac{\sqrt{2\pi m}(\frac{m}{e})^m}{2\pi\frac{9m}{19}(\frac{9m}{19e})^{18m/19}\sqrt{2\pi\frac{m}{19}}(\frac{m}{19e})^{m/19}} \quad (24)$$

$$= \frac{19\sqrt{19}}{18\pi m}\left((\frac{19}{9})^{18/19}19^{1/19}\right)^m$$

$$\approx \frac{19\sqrt{19}}{18\pi m}2.37^m, \quad (25)$$

where (24) follows from Stirling's approximation for the factorial (and we use the notation $\sim$ to denote asymptotic equivalence, i.e. that two quantities have a ratio that tends to 1 as the parameter size grows).

Now assume $A_{12} + \frac{3}{4}A_1 \leq \frac{\pi}{2}$, which implies $\pi - A_1 - A_{12} \geq A_{12} + \frac{A_1}{2}$. Note also that $\pi - A_1 - A_{12} \geq A_1$ since it is assumed that $\pi - 2A_1 - A_{12} \geq 0$. Therefore, we can lower bound (22) by

$$1 - W_2\frac{19\sqrt{19}}{18\pi m}2.37^m\left(\frac{\pi - A_1 - A_{12}}{\pi}\right)^m, \quad (26)$$

where W_2 is the number of terms in the summation in (22), and is given by

$$W_2 = \frac{1}{6}\left(\left\lfloor\frac{m}{10}\right\rfloor + 1\right)\left(100\left\lfloor\frac{m}{10}\right\rfloor^2 + (5 - 30m)\left\lfloor\frac{m}{10}\right\rfloor + 3(m^2 + 3m + 2)\right) \sim m^3. \quad (27)$$

Thus, (26) goes to 1 as $m \to \infty$ when $2.37\left(\frac{\pi - A_1 - A_{12}}{\pi}\right) < 1$, which holds if $A_1 + A_{12} > 0.58\pi$. ■

5. Discussion and Conclusion

In this work, we have presented a supervised classification algorithm that operates on binary, or one-bit, data. Along with encouraging numerical experiments, we have also included a theoretical analysis for a simple case. We believe our framework and analysis approach is relevant to analyzing similar, multi-level-type algorithms. Future directions of this work include the use of dithers for more complicated data geometries, identifying settings where real-valued measurements may be worth the additional complexity, analyzing geometries with non-uniform densities of data, as well as a generalized theory for high dimensional data belonging to many classes and utilizing multiple levels within the algorithm. In addition, we believe the framework will extend nicely into other applications such as hierarchical clustering and classification as well as detection problems. In particular, the membership function scores themselves can provide information about the classes and/or data points that can then be utilized for detection, structured classification, false negative rates, and so on. We believe this framework will naturally extend to these types of settings and provide both simplistic algorithmic approaches as well as the ability for mathematical rigor.

Appendix A. Elementary Computations

A.1. Derivation of (16)

Suppose we have M objects that must be divided into 5 boxes (for us, the boxes are the 5 different types of hyperplanes). Let n_i denote the number of objects put into box i. Recall that in general, M objects can be divided into k boxes $\binom{M+k-1}{k-1}$ ways.

How many arrangements satisfy $n_1 \geq 9(n_2+n_3)$? To simplify, let n denote the total number of objects in boxes 2 and 3 (that is, $n = n_2 + n_3$). Then, we want to know how many arrangements satisfy $n_1 \geq 9n$?

If $n = 0$, then $n_1 \geq 9n$ is satisfied no matter how many objects are in box 1. So, this reduces to the number of ways to arrange M objects into 3 boxes, which is given by $\binom{M+2}{2}$.

Suppose $n = 1$. For $n_1 \geq 9n$ to be true, we must at least reserve 9 objects in box 1. Then $M-10$ objects remain to be placed in 3 boxes, which can be done in $\binom{(M-10)+2}{2}$ ways. But, there are 2 ways for $n = 1$, either $n_2 = 1$ or $n_3 = 1$, so we must multiply this by 2. Thus, $\binom{(M-10)+2}{2} \times 2$ arrangements satisfy $n_1 \geq 9n$.

Continuing in this way, in general for a given n, there are $\binom{M-10n+2}{2} \times (n+1)$ arrangements that satisfy $n_1 \geq 9n$. There are $n+1$ ways to arrange the objects in boxes 2 and 3, and $\binom{M-10n+2}{2}$ ways to arrange the remaining objects after $9n$ have been reserved in box 1.

Therefore, the total number of arrangements that satisfy $n_1 \geq 9n$ is given by

$$\sum_{n=0}^{\lfloor \frac{M}{10} \rfloor} \binom{M-10n+2}{2} \times (n+1). \tag{28}$$

To see the upper limit of the sum above, note that we must have $M - 10n + 2 \geq 2$, which means $n \leq \frac{M}{10}$. Since n must be an integer, we take $n \leq \lfloor \frac{M}{10} \rfloor$. After some heavy algebra (i.e. using software!), one can express this sum as:

$$W = \frac{1}{12}\left(\left\lfloor \frac{M}{10} \right\rfloor + 1\right)\left(\left\lfloor \frac{M}{10} \right\rfloor + 2\right)\left(150\left\lfloor \frac{M}{10} \right\rfloor^2 - 10(4M+1)\left\lfloor \frac{M}{10} \right\rfloor + 3(M^2+3M+2)\right) \tag{29}$$

$$\sim M^4. \tag{30}$$

A.2. Derivation of (23)

Suppose we want to maximize (over the choices of a, b, c) a trinomial $\frac{m!}{a!b!c!}$ subject to $a + b + c = m$ and $a > 9b$. Since m is fixed, this is equivalent to choosing a, b, c so as to minimize $a!b!c!$ subject to these constraints. First, fix c and consider optimizing a and b subject to $a + b = m - c =: k$ and $a > 9b$ in order to minimize $a!b!$. For convenience, suppose k is a multiple of 10. We claim the optimal choice is to set $a = 9b$ (i.e. $a = \frac{9}{10}k$ and $b = \frac{1}{10}k$). Write $a = 9b + x$ where x must be some non-negative integer in order to satisfy the constraint. We then wish to compare $(9b)!b!$ to $(9b+x)!(b-x)!$, since the sum of a and b must be fixed. One readily observes that:

$$(9b+x)!(b-x)! = \frac{(9b+x)(9b+x-1)\cdots(9b+1)}{b(b-1)\cdots(b-x+1)} \cdot (9b)!b! \geq \frac{9b \cdot 9b \cdots 9b}{b \cdot b \cdots b} \cdot (9b)!b! = 9^x \cdot (9b)!b!.$$

Thus, we only increase the product $a!b!$ when $a > 9b$, so the optimal choice is when $a = 9b$. This holds for any choice of c. A similar argument shows that optimizing b and c subject to $9b + b + c = m$ to minimize $(9b)!b!c!$ results in the choice that $c = 9b$. Therefore, one desires that $a = c = 9b$ and $a + b + c = m$, which means $a = c = \frac{9}{19}m$ and $b = \frac{1}{19}m$.

Abstract

In this work we consider non-linear classifiers that comprise intersections of hyperplanes. We learn these classifiers by minimizing the "minimax" bound over the negative training examples and the hinge type loss of the positive training examples. These classifiers fit typical real-life datasets that consist of a small number of positive data points and a large number of negative data points. Such an approach is computationally appealing since the majority of training examples (belonging to the negative class) are represented by the statistics of their distribution, which is used in a single constraint on the empirical risk, as opposed to SVM, in which the number of variables is equal to the size of the training set. We first focus on intersection of K hyperplanes, for which we provide empirical risk bounds. We show that these bounds are dimensionally independent and decay as $K/\sqrt{m}$ for m samples. We then extend the K-hyperplane mixed risk to the latent mixed risk for training a union of C K-hyperplane models, which can form an arbitrary complex, piecewise linear boundaries. We propose efficient algorithms for training the proposed models. Finally, we show how to combine hinge-minimax training with deep architectures and extend it to multi-class settings using transfer learning. The empirical evaluation of the proposed models shows their advantage over the existing methods in a small training labeled data regime.

Keywords: Minimiax, Imbalanced Classification, Intersection of K Hyperplanes, Transfer Learning

1. Introduction

Many real-life binary classification problems involve imbalanced classes, for example object detection in vision and fraud detection in security. In such problems it is easy to collect background data (the negative class), while data representing the target class (the positive class) is rare or hard (expensive) to obtain. The majority of existing classifiers (e.g., SVM, Neural Networks, including deep ones) assume balanced training sets and when trained on imbalanced sets show degraded classification performance or require a long and tedious bootstrapping process of mining negative examples (e.g. Malisiewicz et al. (2011); Girshick et al. (2014)) out of millions.

When there are (infinitely) many training examples, instead of minimizing the average sample loss, it is more computationally appealing to apply minimax setting (Lanckriet et al. (2003); Honorio and Jaakkola (2014)), which upper bounds the expected risk of a classifier assuming only the knowledge of mean and covariance of the data distribution. The "minimax" bound provides an upper bound for *every* distribution with a given mean and covariance. Applying the minimax learning (Lanckriet et al. (2003)) to the negative class (the majority class) allows to avoid bootstrapping procedure and makes learning more efficient, as it replaces loss evaluation on all negative samples with a single "minimax" bound.

Due to the assumption that the positive class is rare, we cannot apply the minimax learning to the positive class, as it completely relies on the mean and covariance of the data. Estimating the covariance matrix in high-dimensional space from a small number of positive training samples is problematic. Alternatively, we can use the hinge loss (Vapnik (2000); Zhang (2002); Bartlett and Mendelson (2003); Bousquet et al. (2004); Kakade et al. (2008)) for the positive class as it is computationally appealing when there are fairly small number of training samples.

We suggest to combine the hinge-like loss for the positive samples with the "minimax" bound applied to the statistics of the negative samples to enjoy the best of both worlds and we call these classifiers *Hinge-Minimax* classifiers.

The idea of combining "minimax" bound for the negative class and svm-like formulation for the positive samples was introduced in Osadchy et al. (2012, 2016) for computing linear and kernel classifiers. Kernel classifiers could be quite slow, as they require evaluating kernel on many support vectors. In this work we focus on more efficient non-linear classifiers – ensembles of hyperplanes. We first consider an intersection of hyperplanes and then extended it to more general ensembles of hyperplanes.

Previous algorithms for intersection of hyperplanes are computationally costly when considering large sets of negative data points (Klivans and Sherstov (2009); Daniely et al. (2014)). To deal with this computational difficulty we use the mixed risk. Namely, we extend the "minimax" bound to deal with intersection of hyperplanes over (infinitely many) negative examples. For the positive samples, we define a K-hyperplane hinge loss. We derive an empirical mixed-risk bound, that uses the Rademacher complexities to bound the risk of the positive class and vector Bernstein's inequalities to bound the risk associated with the negative class. Note that we treat the positive and negative samples differently because of the computational gain such separation provides.

Recently, Honorio and Jaakkola (2014) derived a generalization bound for the minimax setting using PAC-Bayesian approach, which bounds the expected loss with respect to a posterior distribution over all possible classifiers. Our work differs as we use stronger assumptions - that the norm of the data points is bounded by a constant, an assumption that is natural in many applications.[1] Thus we are able to avoid the PAC-Bayesian approach that considers generalization bounds over randomized predictors.

Intersection of positive half-spaces is a convex set. We generalize the mixed risk for a non-convex classifier. We learn an ensemble of K-hyperplane models, that can form arbitrary, piece-wise linear boundaries. We propose a training algorithm that minimizes this risk by simultaneously discovering the convex components in the positive class and building K-hyperplane models to separate

1. Input normalization is a standard procedure, applied for faster learning.

each component from the negative class. The learning is done by alternating between finding the best partition of the data into hidden components and updating the model over this partition. We call this novel classifier the *Latent Hinge Minimax* (LHM) classifier, as it discovers the latent structure in the data and employs the Hinge-Minimax paradigm.

We show that the LHM model has an equivalent Neural Networks (NN) architecture. This allows us 1) to use deep learning features via transfer learning and 2) to extend the proposed model to the multi-class setting. For the multi-class problems, we build one-against-all classifiers for all classes and combine them in a single model by mapping class specific LHM models to a multi-class NN with a matching architecture. We then use the cross-entropy loss to adjust the weights in the resulting *LHM-NN* combination.

We show that using LHM-NN in the transfer learning settings has significant benefits compared to NN (standard settings), in both classification accuracy and training efficiency. The improved accuracy stems from the ability of LHM model to learn from unlabeled data. The fast convergence of the LHM-NN (just a handful of epochs) is due to a very good initialization of the upper layers with class specific LHM classifiers. Note that class specific LHM models can be trained in parallel. Moreover, adding a new class to LHM-NN is fast and easy: train a classifier for the new class, map it to the corresponding LHM-NN architecture and run a very fast fine-tuning. Similarly to Kuzborskij et al. (2013), which considered the transfer learning for the $n+1$ category from a fully trained n-category classifier, we use only a handful of training samples for tuning it. In contrast to Kuzborskij et al. (2013), we do not restrict the new classifier to belong to the span of the previously learned n classifiers. This allows us greater flexibility in adding a new, non-related class to the multi-class model.

We performed empirical evaluation of the proposed models: the K-hyperplane, the LHM, and the multi-class models. In all cases, the proposed models outperformed their counterparts in small and imbalanced training data regime.

The rest of the paper is organized as follows. Section 2 introduces the K hyperplane Hinge-Minimax classifier (KHHM). Specifically, we extend the "minimax" bound for the intersection of K positive half-spaces in Section 2.1.1. Then in Section 2.2, we propose a novel training algorithm for the KHHM classifier. We prove the uniform generalization bounds for the KHHM model in Section 2.3. Section 3 focuses on a non-convex generalization of the KHHM model – LHM classifier. We introduce the latent mixed risk in Section 3.1, the training algorithm in Section 3.2, and we prove a uniform generalization bound for the LHM classifier with a fixed assignment of the positive labeled training set in Section 3.3. Section 4 discusses the mapping of the LHM classifier to a neural network. Section 5 reports the experiments with KHHM, LHM, and LHM-NN classifiers. Section 6 discusses the efficiency of the proposed models and Section 7 concludes the paper.

2. K-Hyperplane Hinge-Minimax Classifier

In the following, for simplicity we assume that for a linear classifier which predicts $y = sign(w^T x)$, $b = 0$ (or absorbed by w).

Definition 1 *Let w_i, $i = 1,..,K$ denote K hyperplanes. Let W be a matrix with w_i as its ith column. We define K-hyperplane classifier $f_W(x)$ as an intersection of these K half-spaces:*

$$f_W(x) = \begin{cases} 1 & \text{if } W^\top x \geq \vec{0} \\ -1 & \text{otherwise} \end{cases} \tag{1}$$

where $\vec{0}$ denotes a vector of zeros.

2.1. Mixed Risk for K-Hyperplane Model

We are interested in a classification problem in which the positive class corresponds to a single concept and the negative class is its complement and we refer to it as a *background*. We assume that the sample of the positive class is relatively small while the negative sample is very large (it can be represented by an unlabeled data as well, thus is easy to collect). Due to the specifics of the problem we propose a mixed risk for the non-linear classifier in eq. 1. We first define its parts in Definitions 2 and 3 and then define the mixed risk in Definition 4.

Definition 2 *Let $(x, y) \sim D$ be a joint distribution of samples $x \in \mathbb{R}^n$ and labels $y \in \{-1, 1\}$. We define the* hinge risk *of $f_W(x)$ as follows,*

$$L_D^H(W) = \mathbb{E}_D \left[\ell(W, x, y)\mathbb{1}[y = 1] + 0 \cdot \mathbb{1}[y = -1]\right] \tag{2}$$

where $\ell(W, x, y) = \max_{j\in\{1,..,K\}}\{\max\{0, 1 - yw_j^\top x\}\}$.

Definition 3 *Under the assumptions of Definition 2, let D_{neg} be a marginal distribution of samples from a ball of radius C over the negative labels with mean μ and covariance matrix Σ. Let $\Omega(\mu, \Sigma)$ be a family of all distributions with mean μ and covariance matrix Σ. We assume that $D_{neg} \in \Omega(\mu, \Sigma)$.*

We define the background risk[2] *of $f_W(x)$ as follows,*

$$L^B_{\mu,\Sigma}(W) = \left[\sup_{Z\in\Omega(\mu,\Sigma)} Pr_{z\sim Z}(W^\top z \geq \vec{0})\right] \mathbb{1}[y = -1] + 0 \cdot \mathbb{1}[y = 1] \tag{3}$$

We derive the expression for the background risk in the next section.

According to the Definitions 2 and 3, the hinge risk is defined over the samples of the positive class only and the background risk is defined over the distribution of the negative class only. Thus we can sum the two to form the mixed risk over D.

Definition 4 *Under the assumptions of Definitions 2 and 3, we define the mixed risk for the K-hyperplane classifier as:*

$$L_D^{HB}(W) = L_D^H(W) + L^B_{\mu,\Sigma}(W), \tag{4}$$

2.1.1. THE EXPECTED RISK OF THE NEGATIVE CLASS

The extension of Theorem 3.1 from Marshall and Olkin (1960) to a nonzero mean variable (as shown in Marshall and Olkin (1960) Eq. 7.7–7.8) states that for a random vector x with mean M and covariance Γ,

$$\sup_{x\sim(M,\Gamma)} \Pr(x \in S) = \frac{1}{1 + d^2},$$

with $d^2 = \inf_{x\in S}(x - M)^\top \Gamma^{-1}(x - M)$, where S is a given convex set.

The intersection of K hyperplanes is a convex set, thus we can bound the probability of a negative sample falling into the intersection of K hyperplanes using the above result and derive the expression for $L^B_{\mu,\Sigma}(W)$ as shown below in Theorem 1.

2. the name "background" is chosen to emphasize the fact that the negative class is the majority class, while the positive class is rare.

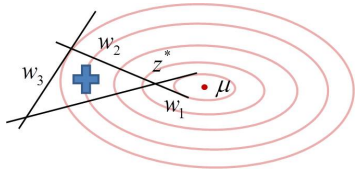

Figure 1: A 2D illustrative example of Theorem 1. z^* is the closest point to the mean of the negative distribution.

Theorem 1 *For any finite number of hyperplanes w_j,*

$$\sup_{Z\in\Omega(\mu,\Sigma)} Pr_{z\sim Z}(W^\top z \geq \vec{0}) = \frac{1}{1+d^2}$$

with $d^2 = \mu^\top U(U^\top\Sigma U)^{-1}U^\top\mu$, where U is a subset of columns of W that satisfy $w^\top z^* = 0$, where $z^* = \arg\min_z (z-\mu)^\top\Sigma^{-1}(z-\mu)$.

Before we proceed with the proof, let us consider the following 2D toy example to gain some intuition into Theorem 1 (see Figure 2.1.1). Assume that the positive class lies inside an intersection of three hyperplanes $W = [w_1, w_2, w_3]$ and the negative class is described by the normal distribution with mean μ and covariance Σ. d^2 is a square distance between the mean of the negative distribution and the point on the boundary of the positive region of the classifier, which is closest to μ. In the example, depicted in Figure 2.1.1, the closest point is denoted by z^* and it's an intersection of w_1 and w_2, thus $U = [w_1, w_2]$.

Proof Let $z \sim D_{neg} \in \Omega(\mu,\Sigma)$ be a sample from the negative class. $W^\top z \geq \vec{0}$ defines a convex set, thus we can apply the result due to Marshall and Olkin (1960) to obtain:

$$\sup_{Z\in\Omega(\mu,\Sigma)} Pr_{z\sim Z}(W^\top z \geq \vec{0}) = \frac{1}{1+d^2},$$

with $d^2 = \inf_{W^\top z\geq\vec{0}}(z-\mu)^\top\Sigma^{-1}(z-\mu)$, where the supremum is taken over all distributions in $\Omega(\mu,\Sigma)$.

Next, we want to derive a closed-form expression for d^2. We seek the solution for the primal problem

$$\min_z (z-\mu)^\top\Sigma^{-1}(z-\mu)$$

s.t. $w_i^\top z \geq 0$ for $i = 1,..,K$. We construct the Lagrangian:

$$L(z,\lambda_i) = (z-\mu)^\top\Sigma^{-1}(z-\mu) + \sum_i \lambda_i w_i^\top z, \quad \lambda_i \geq 0.$$

The optimality condition:

$$\frac{\partial L}{\partial z} = 2\Sigma^{-1}z - 2\Sigma^{-1}\mu + \sum_i \lambda_i w_i = 0,$$

gives us $z^* = \mu - \frac{1}{2}\sum_i \lambda_i\Sigma w_i$. The Lagrange dual function is as follows,

$$L(z^*,\lambda) = \left(\frac{1}{2}\sum_i \lambda_i\Sigma w_i\right)^\top \Sigma^{-1}\left(\frac{1}{2}\sum_j \lambda_j\Sigma w_j\right) + \sum_i \lambda_i w_i^\top\left(\mu - \frac{1}{2}\sum_j \lambda_j\Sigma w_j\right) \quad (5)$$

The optimality conditions are:

$$\frac{\partial L(z^*,\lambda)}{\partial\lambda_t} = -\frac{1}{2}\sum_i \lambda_i w_t^\top\Sigma w_i + w_t^\top\mu = 0$$

for t such that $\lambda_t > 0$.
The function is optimized at

$$\lambda^* = 2(U\Sigma U)^{-1}U^\top\mu, \quad (6)$$

where U is formed by a subset of columns of W for which $\lambda_t > 0$, and thus $w_t^\top z^* = 0$.

For the last step we substitute the optimal λ, given in eq. 6 into the dual function in eq. 5 and after simple algebraic manipulations we get:

$$d^2 = \max_{\lambda\geq 0}(L(z^*,\lambda^*)) = \mu^\top U(U^\top\Sigma U)^{-1}U^\top\mu$$

■

Given the result of Theorem 1, we can express the background part of the mixed risk of the K-hyperplane classifier as follows,

$$L^B_{\mu,\Sigma}(W) = \sup_{Z\in\Omega(\mu,\Sigma)} Pr_{z\sim Z}(W^\top z \geq \vec{0}) = \frac{1}{1+\mu^\top U(U^\top\Sigma U)^{-1}U^\top\mu}$$

2.2. K-Hyperplane Hinge-Minimax (KHHM) Training

We aim to minimize the mixed risk in eq. 4. To this end, we minimize the empirical risk

$$L^{HB}_S = L^B_S(W) + L^H_S(W) \quad (7)$$

regularized by the sum of L_2 norms of the K hyperplanes: $\frac{C}{2}\sum_i \|w_i\|^2 + L^{HB}_S$. This empirical risk is a non convex and non smooth function, hence a gradient based optimization of it is difficult. However, Osadchy et al. (2016) showed an algorithm for approximating this problem for a single hyperplane $\mathbf{w}$ using the following convex formulation:

$$\begin{aligned} &\underset{\mathbf{w}}{\text{minimize}} \quad \lambda\|\mathbf{w}\|^2 + \sum_i \max\{0, 1-\mathbf{w}^\top x_i\} \\ &\text{subject to} \quad \gamma\sqrt{\mathbf{w}^\top\Sigma\mathbf{w}} + \mathbf{w}^\top\mu \leq 0. \end{aligned} \quad (8)$$

where $\gamma = \sqrt{\frac{1-\delta}{\delta}}$. This formulation minimizes the regularized hinge loss on the positive samples while constraining the probability of "background" data misclassified by the classifier $\mathbf{w}$ to be less than a small threshold δ.

We approximate the solution to the problem in eq. 7 by finding K hyperplanes W, which minimize the regularized hinge loss $L_S^H(W)$ on the positive samples while constraining the probability of "background" data misclassified by the intersection of these hyperplanes to be less than a small threshold ϵ.

We propose an algorithm (Algorithm 1) that computes the hyperplane iteratively, each hyperplane at a time using Osadchy et al. (2016). Note that since the algorithm in Osadchy et al. (2016) constraints the supremum over all distributions with given μ and Σ, it constraints an upper bound on the true distribution of the negative class. However, for a Gaussian distribution the bound is tight.

The Algorithm 1 starts by training K hyperplanes in a greedy manner and then iteratively adjusts each hyperplane to further reduce the loss.

Algorithm 1 KHHM Training

Input: $\{x_i\}, i = 1,..,m^+$ a set of positive examples; $\{z_i\}, i = 1,..,m^-$ a set of negative examples.

Initialization:

Estimate μ and Σ using $\{z_i\}_i^{m^-}$. Find w_1 using Osadchy et al. (2016) with μ, Σ.
for t=2 to k **do**
Estimate μ_t and Σ_t using $\{z_i \mid w_j^\top z_i > 0, j = 1,..,t-1\}$
Find w_t using Osadchy et al. (2016) with μ_t and Σ_t.
end for

Training:

for t=$1, 2, 3...$ **do**
Let P_t be the probability $Pr(W^\top z > 0)$ in iteration t
if $(P_{t-1} - P_t > \epsilon)$
Estimate μ_t and Σ_t using $\{z_i \mid w_j^\top z_i > 0, j = 1,..,K; j \neq t\}$.
Find w_t using Osadchy et al. (2016) with μ_t and Σ_t.
else
Output W (K hyperplanes)
end if
end for

Lemma 2 *Algorithm 1 minimizes the regularized hinge loss $L_S^H(W)$ on the positive samples while keeping $Pr(W^\top z \geq \vec{0}) \leq \epsilon$ (for a small ϵ).*

Proof Let Z denote the distribution of the negative class and $z \sim Z$ denote a sample from this distribution. Let S^t denote the part of negative class that falls inside the intersection of $K-1$ hyperplanes (w_t is not included):

$$S^t = \{z | w_i^\top z \geq 0, \forall i \in \{1,...,K\} \setminus \{t\}\}.$$

In step i, Algorithm 1 finds w_{t_i} that minimizes the hinge loss (which is always positive) of w_{t_i} over positive labels and constrains $Pr(w_{t_i}^\top z \geq 0) | z \in S^{t_i}) \leq \delta$, while keeping the rest of the hyperplanes fixed.

The empirical risk of the intersection of K hyperplanes over positive labels is the maximum over K of hinge losses. Thus, the hinge loss of W is decreased at the iterations, in which the hyperplane with the maximal loss is updated, and it remains unchanged otherwise. Consequently, Algorithm 1 minimizes the hinge loss of W.

We can write

$$Pr(W^\top z \geq 0) = Pr(w_{t_i}^\top z \geq 0) | z \in S^{t_i}) Pr(z \in S^{t_i}) + 0 \cdot Pr(z \notin S^{t_i}).$$

$Pr(z \in S^{t_i}) = a$ which is constant (does not depend on w_{t_i}) and $Pr(w_{t_i}^\top z \geq 0) | z \in S^{t_i}) \leq \delta$. Thus, $Pr(W^\top z \geq 0) \leq a\delta$. Setting $\epsilon = a\delta$ concludes the proof. ■

2.3. Generalization Bound for KHHM Model

In the following we bound the mixed risk of the KHHM classifier by its finite sample. We show that the discrepancy between the risk $L_D^{HB}(W)$ and its empirical estimation $L_S^{HB}(W)$ decays at the rate of $O(K\sqrt{\frac{\log(1/\delta)}{m}})$ where δ is the confidence over the samples of the training data and m is the training data size. The main difficulty in deriving a generalization bound arises from mixing the hinge risk for the positive examples and the background risk for the negative examples. We approach this problem by deriving the uniform generalization bounds separately for the positive and negative classes.

2.3.1. UNIFORM GENERALIZATION BOUND FOR THE EMPIRICAL BACKGROUND RISK

Recall that D_{neg} is the distribution of the negative data points, and μ and Σ are its mean and covariance respectively. Let $\hat{\mu}$ and $\hat{\Sigma}$ be the mean and covariance estimates from the training data points that are associated with negative labels. We bound the background risk by its training sample estimation. The generalization bound is dominated by the discrepancy

$$\Delta = L_{\mu,\Sigma}^B(w) - L_{\hat{\mu},\hat{\Sigma}}^B(w)$$

To provide uniform generalization bound to the background risk, we show that the discrepancy Δ decreases when the size of the training sample increases. Therefore we represent the discrepancy with $\|\hat{\mu} - \mu\|$ and $\|\hat{\Sigma} - \Sigma\|$ that decrease as a function of the training sample.

Let U denote a subset of columns of W that satisfy $w^\top z^* = 0$, where $z^* = \arg\min_z (z-\mu)^\top \Sigma^{-1}(z-\mu)$. We make two additional assumptions on U: First, the number of hyperplanes K_U comprising U is smaller than the dimension of the features and second, the hyperplanes in U are linearly independent. Both assumptions hold in practice. The number of hypeplanes must be small to make the classifier computationally efficient and $K_U \leq K$ (while the dimension of the feature space is usually large). The same reason justifies the independence assumption, as linearly dependent hyperplanes are redundant and do not contribute to the classifier, thus should be removed/avoided.

Using the result of Theorem 1, we can write the discrepancy Δ as follows:

$$\Delta = \frac{1}{1 + \mu^\top U(U^\top \Sigma U)^{-1} U^\top \mu} - \frac{1}{1 + \hat{\mu}^\top U(U^\top \hat{\Sigma} U)^{-1} U^\top \hat{\mu}}$$

By noting that the denominator of both terms is greater than 1 we can upper bound Δ by omitting the denominator. Then,

$$\Delta \leq \hat{\mu}U(U^\top\hat{\Sigma}U)^{-1}U^\top\hat{\mu} - \mu^\top U(U^\top\Sigma U)^{-1}U^\top\mu$$

Next, we denote $A \triangleq U(U^\top\Sigma U)^{-1}U^\top$ and $\hat{A} \triangleq U(U^\top\hat{\Sigma}U)^{-1}U^\top$. By adding and subtracting $\mu^\top A\hat{\mu}$ and rearranging the terms, we obtain

$$\Delta \leq \mu^\top A(\hat{\mu}-\mu) + \hat{\mu}^\top(\hat{A}-A)\hat{\mu} + (\hat{\mu}-\mu)^\top A\hat{\mu}. \tag{9}$$

Denote

$$\Delta_1 \triangleq \mu^\top A(\hat{\mu}-\mu) + (\hat{\mu}-\mu)^\top A\hat{\mu}$$

and

$$\Delta_2 \triangleq \hat{\mu}^\top(\hat{A}-A)\hat{\mu}.$$

Going back to the original notations, we obtain

$$\Delta_1 = \mu^\top U(U^\top\Sigma U)^{-1}U^\top(\hat{\mu}-\mu) + (\hat{\mu}-\mu)^\top U(U^\top\Sigma U)^{-1}U^\top\hat{\mu} \tag{10}$$

$$\Delta_2 = \hat{\mu}^\top(U(U^\top\hat{\Sigma}U)^{-1}U^\top - U(U^\top\Sigma U)^{-1}U^\top)\hat{\mu} \tag{11}$$

In the following, let $\|\cdot\|_F$ denote the Frobenius norm of a matrix (the ℓ_2- norm of matrix vectorized form).

Lemma 3 *Assume $x \sim D_{neg}$ is a distribution over data points x with negative labels such that $\|x\| \leq C$ holds with probability 1. Denote by μ its mean and by Σ its covariance. Let S_1 denote a training sample of size m_1 and let $\hat{\mu} = \frac{1}{m_1}\sum_{x\in S_1} x$ be its sampled mean and $\hat{\Sigma} = \frac{1}{m_1}\sum_{x\in S_1}(x-\hat{\mu})(x-\hat{\mu})^\top$ be its sampled covariance. Define Δ_1 as in eq. 10, where matrix U has K_U linearly independent columns ($K_U \leq n$) . Assume that the minimal eigenvalues of $\Sigma, \hat{\Sigma}$ are lower bounded by $\alpha = \lambda_{min}(\Sigma), \hat{\alpha} = \lambda_{min}(\hat{\Sigma})$, respectively. Then, with probability at least $1-\delta$ over the draws of the training set S_1, the following holds uniformly for all W*

$$\Delta_1 \leq \frac{2C}{\alpha}\sqrt{\frac{32C^4(\log(1/\delta)+1/4)}{m_1}}$$

Proof First, we show the upper bound

$$\|U(U^\top\Sigma U)^{-1}U^\top\| \leq \frac{1}{\alpha} \tag{12}$$

Following the assumption that the columns of U are linearly independent and that their number is smaller than the dimension of the feature space, we can derive that $U = \sum_{i=1}^{K_U} s_i v_i t_i^\top$, where $v_1, ..., v_{K_U}$ are left singular vectors, $t_1, ..., t_{K_U}$ are right singular vectors, and $s_1, ..., s_{K_U}$ are singular values of U which are all non-zero. Let V be $n \times K_U$ matrix of left singular vectors $v_1, ..., v_{K_U}$, T be a $K_U \times K_U$ matrix of right singular vectors $t_1, ..., t_{K_U}$, and S be a $K_U \times K_U$ diagonal matrix of singular values $s_1, ..., s_{K_U}$, then

$$U(U^\top\Sigma U)^{-1}U^\top = VST^\top(TSV^\top\Sigma VST^\top)^{-1}TSV^\top = V(V^\top\Sigma V)^{-1}V^\top \tag{13}$$

$$\begin{aligned}\|V(V^\top\Sigma V)^{-1}V^\top\|^2 &= \max_{\|\beta\|\leq 1}\|V(V^\top\Sigma V)^{-1}V^\top\beta\|^2 \\ &= \max_{\|\beta\|\leq 1}(\beta^\top V(V^\top\Sigma V)^{-1}V^\top V(V^\top\Sigma V)^{-1}V^\top\beta) \\ &= \max_{\|\beta\|\leq 1}((V^\top\beta)^\top(V^\top\Sigma V)^{-2}(V^\top\beta)) \leq \|V^\top\Sigma V)^{-1}\|^2\end{aligned} \tag{14}$$

Since V is a projection operator, the last inequality in Eq. 14 is due to $\|V\beta\| \leq \|\beta\| \leq 1$.

$$\|V^\top\Sigma V)^{-1}\|^2 = \frac{1}{\lambda_{min}(V^\top\Sigma V)^2} \leq \frac{1}{\lambda_{min}(\Sigma)^2} \tag{15}$$

The last inequality in Eq. 15 follows from Poincaré Separation Theorem (Bellman (1970)).

Combining equations 13, 14, and 15, we obtain

$$\|U(U^\top\Sigma U)^{-1}U\| = \|V(V^\top\Sigma V)^{-1}V^\top\| \leq \|(V^\top\Sigma V)^{-1}\| \leq \frac{1}{\alpha}$$

Then applying the above upper bound and the Cauchy-Schwarz inequality, we obtain:

$$\Delta_1 \leq \frac{(\|\hat{\mu}\|+\|\mu\|)\|\hat{\mu}-\mu\|}{\alpha}.$$

Since $\|x\| \leq C$, then $\|\hat{\mu}\| + \|\mu\| \leq 2C$ and we get:

$$\Delta_1 \leq \frac{2C}{\alpha}\|\mu-\hat{\mu}\|.$$

Finally, we use the Bernstein inequality for vectors (cf. Candes and Plan (2011) Theorem 2.6) which states that for vectors $v_1, ..., v_{m_1}$ with $Ev_k = 0$ and $\|v_k\| \leq B$ and $\sum_k E\|v_k\|^2 \leq \sigma^2$ it holds that for all $0 \leq t \leq \sigma^2/B$ that $P[\|\sum_k v_k\| \geq t] \leq \exp(-\frac{t^2}{8\sigma^2}+\frac{1}{4})$. Here $\|v\|^2 = \sum_i v_i^2$.

To fit the Bernstein inequality for vectors to our setting, we set $v_k = \frac{1}{m_1}(x_k - E_{x\sim D_{neg}}x)$ for any $x_k \in S_1$. To see that the conditions of Candes and Plan (2011) Theorem 2.6 hold, we note that since $\|x\| \leq C$ then $\|v_k\| \leq 2C/m_1 \stackrel{def}{=} B$ and therefore $\|v_k\|^2 \leq \frac{4C^2}{m_1^2}$ and $\sum_{k=1}^{m_1} E\|v_k\|^2 \leq \frac{4C^2}{m_1} \stackrel{def}{=} \sigma^2$. Consequently it holds for $0 \leq t \leq 2C$ that

$$P[\|\hat{\mu}-\mu\| \geq t] \leq \exp\left(-\frac{m_1 t^2}{32C^2}+\frac{1}{4}\right).$$

The result follows when setting $\delta = \exp(-\frac{m_1 t^2}{32C^2}+\frac{1}{4})$, or equivalently $t = \sqrt{\frac{32C^2(\log(1/\delta)+1/4)}{m_1}}$. ■

We turn to handle the second term Δ_2 of the discrepancy.

Lemma 4 *Under the conditions of Lemma 3, define Δ_2 as in eq. 11. Then, with probability at least $1-\delta$ over the draws of the training set S_1, the following holds uniformly for all W*

$$\Delta_2 \leq \frac{C^2}{\alpha\hat{\alpha}}\left(2C\|\hat{\mu}-\mu\| + \sqrt{\frac{32C^4(\log(1/\delta)+1/4)}{m_1}}\right)$$

Proof

$$\begin{aligned}\Delta_2 &= \hat{\mu}^\top U\left((U^\top\hat{\Sigma}U)^{-1} - (U^\top\Sigma U)^{-1}\right)U^\top\hat{\mu} \\ &\leq \left|\hat{\mu}^\top U(U^\top\hat{\Sigma}U)^{-1}(U^\top\Sigma U - U^\top\hat{\Sigma}U)(U^\top\Sigma U)^{-1}U^\top\hat{\mu}\right| \\ &= \left|\hat{\mu}^\top U(U^\top\hat{\Sigma}U)^{-1}U^\top(\Sigma-\hat{\Sigma})U(U^\top\Sigma U)^{-1}U^\top\hat{\mu}\right|\end{aligned} \tag{16}$$

Applying the Cauchy-Schwarz inequality and the upper bound in eq. 12, we obtain:

$$\Delta_2 \leq \frac{\|\hat{\mu}\|^2\|\hat{\Sigma}-\Sigma\|}{\alpha\hat{\alpha}}.$$

We now consider $\|\Sigma-\hat{\Sigma}\|$:

$$\begin{aligned}\hat{\Sigma} &= \frac{1}{m_1}\sum_{k=1}^{m_1}(x_k-\hat{\mu})(x_k-\hat{\mu})^\top = \frac{1}{m_1}\sum_{k=1}^{m_1}x_k x_k - \hat{\mu}\hat{\mu}^\top \\ \Sigma &= E_{x\sim D_{neg}}(x-\mu)(x-\mu)^\top = E_{x\sim D_{neg}}xx^\top - \mu\mu^\top \\ \|\Sigma-\hat{\Sigma}\| \leq \|\hat{\Sigma}-\Sigma\|_F &\leq \|\frac{1}{m_1}\sum_{k=1}^{m_1}x_k x_k^\top - E_{x\sim D_{neg}}xx^\top\|_F + \|\hat{\mu}\hat{\mu}^\top - \mu\mu^\top\|_F\end{aligned}$$

For the second component in the bound: $\hat{\mu}\hat{\mu}^\top - \mu\mu^\top = \hat{\mu}(\hat{\mu}-\mu)^\top + (\hat{\mu}-\mu)\mu^\top$ therefore $\|\hat{\mu}\hat{\mu}^\top - \mu\mu^\top\|_F \leq \|\hat{\mu}(\hat{\mu}-\mu)^\top\|_F + \|(\hat{\mu}-\mu)\mu^\top\|_F \leq 2C\|\hat{\mu}-\mu\|$.

For the first component in the bound, we use the Bernstein inequality for vectors (Candes and Plan (2011) Theorem 2.6) in the same manner it is applied in Lemma 3. We set v_k to be the vectorization of $\frac{1}{m_1}x_k x_k^\top - E_{x\sim D_{neg}} xx^\top$ for any $x_k \in S_1$. To see that the conditions of Candes and Plan (2011) in Theorem 2.6 hold, we note that since $\|x\| \leq C$ then $\|v_k\| \leq \frac{2C^2}{m_1} \stackrel{def}{=} B$ and therefore $\|v_k\|^2 \leq \frac{4C^4}{m_1^2}$ and $\sum_{k=1}^{m_1} E\|v_k\|^2 \leq \frac{4C^4}{m_1} \stackrel{def}{=} \sigma^2$. Consequently it holds for $0 \leq t \leq 2C^2$ that

$$P\Big[\Big\|\frac{1}{m_1}\sum_{k=1}^{m_1} x_k x_k^\top - E_{x\sim D_{neg}} xx^\top\Big\| \geq t\Big] \leq \exp(-\frac{m_1 t^2}{32C^4} + \frac{1}{4})$$

The result follows when setting $\delta = \exp(-\frac{m_1 t^2}{32C^4} + \frac{1}{4})$ or equivalently $t = \sqrt{\frac{32C^4(\log(1/\delta)+1/4)}{m_1}}$. ■

The upper bound for Δ relies on the lower bound on the minimal eigenvalue of covariance $\Sigma = E_{x\sim D_{neg}}(x-\mu)(x-\mu)^\top$ and of the sampled covariance $\hat{\Sigma} = \frac{1}{m_1}\sum_{x\in S_1}(x-\hat{\mu})(x-\hat{\mu})^\top$. While the minimal eigenvalue of Σ, say $\alpha = \lambda_{min}(\Sigma)$, can be set to be away from zero, the minimal eigenvalue of the sampled covariance $\hat{\alpha} = \lambda_{min}(\hat{\Sigma})$ is a random variable. We show that $\hat{\alpha}$ is close to α with high probability:

Lemma 5 *Assume the conditions of Lemma 3 hold. Assume that the minimal eigenvalue of $\alpha = \lambda_{min}(\Sigma)$ is positive. Let $\hat{\alpha} = \lambda_{min}(\hat{\Sigma})$ be the minimal eigenvalue of the random covariance matrix $\hat{\Sigma}$. Then $\hat{\alpha} \geq \alpha/2$ with probability at least $1 - 2\exp(-\frac{m_1\alpha^2}{32\cdot 36C^4} + \frac{1}{4})$ over the draws of the training set S_1.*

Proof Using Cauchy-Schwartz inequality we obtain

$$\|U^\top\Sigma U\| - \|U^\top\hat{\Sigma}U\| \leq \Big|\|U^\top\Sigma U\| - \|U^\top\hat{\Sigma}U\|\Big| \leq \|U^\top\Sigma U - U^\top\hat{\Sigma}U\| \leq \|\Sigma-\hat{\Sigma}\|\|U\|^2.$$

Therefore,

$$\|U^\top\hat{\Sigma}U\| \geq \|U^\top\Sigma U\| - \|\Sigma-\hat{\Sigma}\|\|U\|^2.$$

Following Lemma 4 we note that

$$\|\hat{\Sigma}-\Sigma\| \leq \|\hat{\Sigma}-\Sigma\|_F \leq \|\frac{1}{m_1}\sum_{k=1}^{m_1} x_k x_k^\top - E_{x\sim D_{neg}} xx^\top\|_F + \|\hat{\mu}\hat{\mu}^\top - \mu\mu^\top\|_F$$

We use Bernstein inequality for vectors with $t = \alpha/6$ to bound

$$P[\|\frac{1}{m_1}\sum_{k=1}^{m_1} x_k x_k^\top - E_{x\sim D_{neg}} xx^\top\| \geq \alpha/6] \leq \exp(-m_1\alpha^2/(36\cdot 32) + 1/4)$$

for any $\alpha/6 \leq 4m_1$. We also use Bernstein inequality for vectors with $t = \alpha/(2C\cdot 3)$ to bound

$$P[\|\hat{\mu}-\mu\| \geq \alpha/(2C\cdot 3)] \leq \exp\left(-\frac{m_1\alpha^2}{36\cdot 32C^4} + \frac{1}{4}\right).$$

Thus with error probability of $2\exp\left(-\frac{m_1\alpha^2}{36\cdot 32C^4} + \frac{1}{4}\right)$ there hold $\|\frac{1}{m_1}\sum_{k=1}^{m_1} x_k x_k^\top - E_{x\sim D_{neg}} xx^\top\| \leq \alpha/6$ and $2C\|\hat{\mu}-\mu\| \leq \alpha/3$. In particular, the sum of both is upper bounded by $\alpha/2$, hence $\|\hat{\Sigma}-\Sigma\| \leq \alpha/2$, resulting in $\|U^\top\hat{\Sigma}U\| \geq (\alpha-\alpha/2)\|U\|^2$. Therefore $\hat{\alpha}\|U\|^2 \geq \alpha/2\|U\|^2$. ■

Bounds on the discrepancy between the expected and the empirical background risks that are uniform for any U guarantee generalization. The above lemmas suggest that the penalty of observing a finite sample space decreases as $1/m_1$. This is summarized in the following theorem.

Theorem 6 *Under the conditions of Lemma 3, for $\alpha \geq \sqrt{\frac{1152(\log(2/\delta)+1/4)}{m_1}}$ with probability at least $1-3\delta$ over m_1 the i.i.d. samples from D_{neg} the following holds uniformly for all W with K linearly independent hyperplanes:*

$$L^B_{\mu,\Sigma}(U) \leq L^B_{\hat{\mu},\hat{\Sigma}}(U) + \Big(\frac{2C^2}{\alpha} + \frac{6C^4}{\alpha^2}\Big)\sqrt{\frac{32(\log(1/\delta)+1/4)}{m_1}}.$$

Proof Following Eq. 9, we note that $L^B_{\mu,\Sigma}(U) - L^B_{\hat{\mu},\hat{\Sigma}}(U) \leq \Delta_1 + \Delta_2$, for Δ_1, Δ_2 defined in Lemmas 3, 4. The proof applies the bounds on Δ_1, Δ_2, where each of these bounds holds with an error probability at most δ. The proof is concluded by bounding $\hat{\alpha} \geq \alpha/2$ with an error probability at most δ. Formally, with error probability at most 3δ:

$$\begin{aligned}\Delta_1 &\leq \frac{2C^2}{\alpha}\sqrt{\frac{32\log(1/\delta)+1/4}{m_1}}\\ \Delta_2 &\leq \frac{3C^4}{\alpha\hat{\alpha}}\sqrt{\frac{32(\log(1/\delta)+1/4)}{m_1}} \leq \frac{6C^4}{\alpha^2}\sqrt{\frac{32(\log(1/\delta)+1/4)}{m_1}}\end{aligned}$$

■

The generalization guarantees of the background risk penalize a finite sample size m by $\sqrt{1/m_1}$. It decays to zero when the number of the negative labels in the training sample tends to infinity. In our setting, we assume that $m \approx m_1$, thus we get favorable guarantees with respect to the training size.

2.3.2. UNIFORM GENERALIZATION BOUND FOR THE EMPIRICAL RISK OF THE HINGE-LOSS

We derive a uniform generalization bound for the expected risk over the positive examples using Rademacher complexity. The Rademacher complexity of a bounded set $A \subset R^K$ is

$$R(A) = \frac{1}{m}E_\sigma\left[\max_{a\in A}\sum_{i=1}^{m}\sigma_i a_i\right],$$

while $\sigma_i \in \{-1,+1\}$ are i.i.d. and equally probable random variables.

Let $\mathcal{F}$ denote a family of functions:

$$\mathcal{F} \triangleq \{(x,y) \to \ell(W,x,y) : W = [w_1,...,w_k], w_j \in \mathbb{R}^d, \forall j\}.$$

Let $S = \{(x_1,y_1),...,(x_m,y_m)\}$ be a training sample. Let $\mathcal{F}\circ S$ be the set of all possible evaluations a function $f \in \mathcal{F}$ can achieve on a sample S:

$$\mathcal{F}\circ S = \{f(x_1,y_1),...,f(x_m,y_m)\}.$$

The Rademacher complexity of $\mathcal{F}$ with respect to S is defined as follows:

$$R(\mathcal{F}\circ S) \triangleq \frac{1}{m}\mathbb{E}_{\sigma\sim\{\pm1\}^m}\left[\sup_{f\in\mathcal{F}}\sum_{i=1}^{m}\sigma_i f(x_i,y_i)\right]$$

Since L_D^H is zero for $y=-1$, we consider only the positive subset of S, denoted as, $S_2 \triangleq \{(x_i,1),...(x_{m_2},1)\}$.

Theorem 7 [3] *Consider a $K-$hyperplanes loss function*

$$\ell(W,x,y) = \max_{j\in\{1,...,K\}}\{\max\{0,1-yw_j^\top x\}\}$$

3. Theorem 4 in the ICML'15 version of the paper had a typo. Here we present a corrected version of the theorem with a detailed proof.

for which each hyperplane satisfies $\|w_j\| \leq 1$ *and each data point satisfies* $\|x\| \leq 1$. *Then,*

$$R(\mathcal{F} \circ S_2) \leq \frac{K}{\sqrt{m_2}},$$

where m_2 *is the number of positive examples.*

Proof

$$m_2 R(\mathcal{F} \circ S_2) =$$

$$\mathbb{E}_{\sigma \sim \{\pm 1\}^m} \left[\max_{\substack{\|w_1\| \leq 1 \\ \ldots \\ \|w_k\| \leq 1}} \sum_{i=1}^{m} \sigma_i \max_{j \in \{1,\ldots,K\}} \{\max(0, 1 - w_j^\top x_i)\} \right] \leq$$

$$\mathbb{E}_{\sigma \sim \{\pm 1\}^m} \left[\max_{\substack{\|w_1\| \leq 1 \\ \ldots \\ \|w_k\| \leq 1}} \sum_{i=1}^{m} \sigma_i \sum_{j=1}^{K} \max(0, 1 - w_j^\top x_i) \right] \leq$$

$$\sum_{j=1}^{K} \mathbb{E}_{\sigma \sim \{\pm 1\}^m} \left[\sum_{i=1}^{m} \sigma_i \max(0, 1 - w_j^\top x_i) \right] \leq K\sqrt{m_2}$$

The bound follows from the Contraction Lemma (Ledoux and Talagrand, 1991), applied to $\max(0, 1 - w^\top x)$, which is 1-Lipschitz function.
Hence, $R(\mathcal{F} \circ S_2) \leq \frac{K}{\sqrt{m_2}}$. ■

Next we provide the uniform generalization bound for the empirical risk of the maximum over hinge losses.

Theorem 8 *Let* $L_D^H(W) = \mathbb{E}_D\left[\ell(W, x, y)\mathbb{1}[y = 1] + 0 \cdot \mathbb{1}[y = -1]\right]$ *be the expected risk, and let* $L_S^H(W) = \frac{1}{m_2}\sum_{i=1}^{m} \ell(W, x_i, 1)$ *be the empirical risk over a positive label training sample of size* m_2. *Then, for any* $\delta \in (0, 1]$ *with probability at least* $1 - \delta$ *over the i.i.d. sample of size* m_2 *it holds simultaneously for all* $\|w_1\|, ..., \|w_k\| \leq 1$ *that whenever* $\|x\| \leq 1$*:*

$$L_D^H(W) \leq L_S^H(W) + \frac{2K}{\sqrt{m_2}} + 8K\sqrt{\frac{2\log(2/\delta)}{m_2}}$$

Proof By noting that $|\ell(W, x, y)| \leq 2K$ and that a maximum over positive numbers is upper bounded by their sum, the result follows immediately, from Bartlett and Mendelson (2003). ■

3. Latent Hinge-Minimax Classifier

The intersection of K positive half-spaces forms a convex set. For non-convex sets, KHHM will produce many false positives (as show in Figure 2 left). To accommodate classes that form non-convex or disjoint sets, we propose a non-convex classifier, which is an ensemble of KHHM models that we call the Latent Hinge-Minimax (LHM) classifier. Specifically, we define the LHM classifier as a union of intersections of positive half-spaces. We assume that each intersection is composed of K hyperplanes: $W^i = [w_1^i, ..., w_K^i]$ and there are C components in the union (see Figure 2 right). Let $W_{LHM} \triangleq (W^1, \ldots, W^C)$ denote the LHM model.

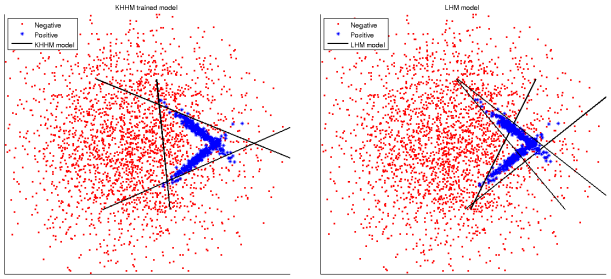

Figure 2: Schematic comparison of KHHM (left) and LHM (right) classifiers on a non-convex positive class. The LHM classifier iteratively discovers a partition of the positive set into convex components and builds KHHM model for each convex component.

3.1. Expected Latent Mixed Risk

Similarly to K-hyperplane model, the latent mixed risk is also composed of the hinge and background parts. However, we extend the risk in Eq. 4 to contain multiple components $Q^i \triangleq \{x \in R^n | {W^i}^T x \geq \vec{0}\}$ and a latent variable $\varphi(x) = i$ ($i \in \{1, \ldots, C\}$) which assigns each positive sample $x \in \mathbb{R}^n$ to one of the C components.

$$L_D(W_{LHM}; \varphi) = L^B_{\mu,\Sigma}(W_{LHM}) + L^H_D(W_{LHM}; \varphi), \tag{17}$$

The background part of the latent mixed risk bounds the probability of the negative class in all components Q^i:

$$L^B_{\mu,\Sigma}(W_{LHM}) = \sum_{i=1}^{C} L^B_{\mu,\Sigma}(W^i) = \sum_{i=1}^{C} \sup_{z \sim Z(\mu,\Sigma)} \Pr(z \in Q^i) \tag{18}$$

The hinge part of the latent mixed risk aggregates the K-hyperplane hinge risk over C components:

$$L^H_D(W_{LHM}; \varphi) = \mathbb{E}_{(x,y)\in D}\left[\sum_{i=1}^{C} \ell(W^i; x, y)\mathbb{1}\left[\varphi(x) = i\right]\right] \tag{19}$$

where

$$\ell(W; x, y) = \max_{j \in \{1..K\}} \{\max\{0, \alpha - y w_j^T x\}\}$$

is the modified K-hyperplane hinge loss (in Eq. 2). We replaced 1 with α to accommodate comparison between different norms of the hyperplanes.

3.2. Empirical Latent Mixed Risk

Recall that S is a training sample of size m, where $S_2 = \{(x, y) \in S : y = 1\}$, and $S_1 = \{(x, y) \in S : y = -1\}$ are the positive and negative training sets correspondingly, m_2 is the size of S_2 and m_1 be the size of S_1. We define the empirical risk over S as follows:

$$L^{HB}_S(W_{LHM}, \varphi) = L^H_{S_2}(W_{LHM}, \varphi) + L^B_{S_1}(W_{LHM}) \tag{20}$$

Both parts of the empirical latent mixed risk are aggregated over C latent components. Specifically, the background part of the risk is defined as a sum of background empirical risks of the model's components:

$$L^B_{S_1}(W_{LHM}) = \sum_{i=1}^{C} L^B_{\hat{\mu},\hat{\Sigma}}(W^i) \tag{21}$$

where $L^B_{\hat{\mu},\hat{\Sigma}}(W^i) = \sup_{Z\in\Omega(\hat{\mu},\hat{\Sigma})} Pr_{z\sim Z}(z \in Q^i)$ and $\hat{\mu}, \hat{\Sigma}$ are the empirical mean and covariance matrix, estimated from the negative training sample S_1.

Let $X^i \triangleq \{x : \varphi(x) = i\}$ define a subset of positive samples. The hinge part of the empirical risk is defined as the follows:

$$L^H_{S_2}(W_{LHM}, \varphi) = \sum_{i=1}^{C} L^H_{S_2}(W^i) \tag{22}$$

where $L^H_{S_2}(W^i) = \sum_{x\in X^i} \ell(W^i, x, 1)$.

Using the above notations, we can define a component empirical risk, as

$$L^{HB}(W^i) = L^H_{S_2}(W^i) + L^B_{\hat{\mu},\hat{\Sigma}}(W^i) \tag{23}$$

Next, we formalize the loss function for a positive sample which we use in the training algorithm in Section 3.3. Each sample with positive label encounters a loss only in a single latent component, specified by its latent variable $\varphi(x)$. The hinge part of this loss is $\ell(W^i, x, 1)$. The background empirical risk of a component $L^M_{\hat{\mu},\hat{\Sigma}}(W^i)$ depends on $\hat{\mu}, \hat{\Sigma}$ and W^i. W^i depends on the latent assignment of the positive samples. Thus the optimal assignment should minimize also the background part of the risk. We implement this by dividing the empirical risk $L^M_{\hat{\mu},\hat{\Sigma}}(W^i)$ equally among the positive samples with $\varphi(x) = i$. Hence the sample loss (for positive samples) is defined as follows:

$$L(W^{\varphi(x)}; x, 1, \varphi(x)) = \ell(W^{\varphi(x)}, x, 1) + \frac{1}{|S^i|} L^M_{\hat{\mu},\hat{\Sigma}}(W^{\varphi(x)}) \tag{24}$$

where $|S^i|$ is the number of samples with $\varphi(x) = i$.

3.3. LHM Training Algorithm

The training aims to minimize the empirical risk in Eq. 20 over the parameters W_{LHM} and the hidden variables φ. We propose an iterative algorithm, which reaches fast convergence and shows good results in practice. The algorithm iterates between two steps: First, given an assignment it produces a model W_{LHM}, second, it updates the latent variables $\varphi(x), \forall(x, y) \in S_2$ to better represent the latent structure of the data.

The **first** step updates the LHM model W^t_{LHM} in iteration t given the latent variables φ from iteration $t-1$. Namely, for each hidden component $i = 1, ..., C$, we find the hyperplanes W^i separating the training samples in S^i from D_{neg} by minimizing the empirical risk in Eq. 23. This risk is minimized by the training algorithm proposed in Algorithm 1.

The **second** step updates the latent variable assignment, given the current W^t_{LHM}. For each positive sample, it finds the best component w.r.t. the risk in Eq 20. Specifically, the hinge risk for x is simply $\ell(W^i, x, 1)$. The background part of the assignment function for $x \notin Q^i$ should consider the probability that this point adds when it is included in the component i (as shown in Figure 3, left). For $x \in Q^i$, the background part should consider the amount of probability released when the component shrinks as a result of change in the assignment of x (as shown in Figure 3, right). The optimal assignment should take both cases into consideration for all components. To define the assignment function we introduce the following notations.

W^{def} is a *deflated model* derived from W^i by parallel translation of the hyperplane closest to x such that $w^T_* x + b_* = 0$. W^{inf} is an *inflated model* derived from W^i by parallel translation of the hyperplanes for

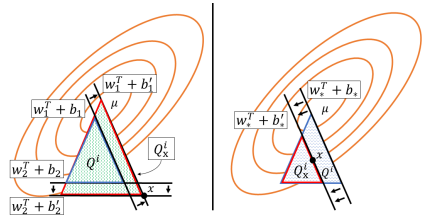

Figure 3: The orange ellipses represent the negative distribution $Z(\hat{\mu}, \hat{\Sigma})$, the red triangles corresponds to Q^i_x and the blue ones to Q^i. **Left**: w^i_1, w^i_2 are moved to pass through x, causing the probability Q^i to increase. **Right**:w^i_* is moved to pass through x, causing the probability Q^i to decrease.

which $w^T_k x + b_k < 0$, until they intersect in x, namely, $w^T_k x + b'_k = 0$. W^i_x is a surrogate model, defined as follows,

$$W^i_x \triangleq \begin{cases} W^{def} & \text{if } x \in Q^i \\ W^{inf} & \text{if } x \notin Q^i \end{cases}$$

and $Q^i_x \triangleq \{x : {W^i_x}^T x \geq \vec{0}\}$. Using the above notations, we define the assignment function as follows,

$$\varphi(x) = \underset{i\in\{1..C\}}{\operatorname{argmin}} Pr_{z\sim Z}(z \in Q^i_x) + \lambda\ell(W^i; x, 1) \tag{25}$$

where λ is a balancing parameter. The full training algorithm is summarized in Algorithm 2.

Lemma 9 *Algorithm 2 reduces the empirical risk $L^{HB}_S(W_{LHM}; \varphi)$ in each iteration.*

Proof Since latent mixed risk is a sum of risks over the latent components (Eq. 20), it is minimized by minimizing the empirical risk of each component. In step (5) of the Algorithm 2, we train $W^{i,t}$ model for each latent component $i = 1, ..., C$ using Algorithm 1 (Section 2.2). It is easy to see that $L^{HB}_S(W^i) = L^{HB}_S(W)$ (in Eq. 7), thus step (5) of the Algorithm 2 minimizes the component's risk in Eq. 23.

It is now left to show that the assignment φ^t in iteration t, will cause the reduction in the empirical risk in iteration $t+1$. Since the empirical risk is aggregated over positive samples, it is enough to prove the claim for a single sample. We consider two cases:

1. The assignment of sample x does not change, formally $\varphi^t(x) = \varphi^{t+1}(x)$.
In this case $L(W^{t+1}_{LHM}; \varphi^{t+1}(x))$ will only be affected by the $W^{i,t+1}$ training, thus

$$L\left(W^t_{LHM}; \varphi^t(x)\right) \geq L\left(W^{t+1}_{LHM}; \varphi^{t+1}(x)\right) \tag{26}$$

2. The assignment of sample x is changed. Formally, in iteration t: $\varphi^t(x) = i$ and in iteration $t+1$, exists $j \neq i$, such that

$$\varphi^{t+1}(x) = j = \underset{k\in\{1..C\}}{\operatorname{argmin}} L^B_{S_1}\left(W^{k,t}_x\right) + \lambda L^H_{S_2}\left(W^{k,t}; x\right). \tag{27}$$

Since $x \in Q^i$, reassigning it to a different component will cause the $Pr_{z\sim Z}(z \in Q^i_x)$ to decrease (or stay the same), thus

$$L^B_{S_1}(W^{i,t}_x) - L^B_{S_2}(W^{i,t}) \leq 0. \tag{28}$$

Algorithm 2 LHM Training. T is the threshold on the empirical risk change.

Input: C, K, S_1, S_2,T
Initialization:
$t \leftarrow 1$
$L(W_{LHM}^{t=0}; \varphi^{t=0}) \leftarrow \infty$
$\varphi^t \leftarrow Init(S_2, C)$

Training:
while $L(W_{LHM}^t; \varphi^t) - L(W_{LHM}^{t-1}; \varphi^{t-1}) \geq T$ **do**
{Model Step}
for i=1 to C do
$W^{i,t}$ =*KHHM-training*(S_1,X^i) {in Algorithm 1}
end for
{Assignment Step}
for$(x, y) \in S_2$
$\varphi^{t+1}(x)$ as defined in Eq. 25
end for
$t \leftarrow t + 1$
end while
Output: W_{LHM}, φ

Hence, the sample loss in component i is larger than the sample loss in the deflated component:

$$L\left(W^{i,t}; x\right) \geq L_{S_1}^B\left(W_x^{i,t}\right) + \lambda L_{S_2}^H\left(W^{i,t}; x\right). \tag{29}$$

At the same time, j is the optimal assignment, thus

$$L_{S_1}^B\left(W_x^{i,t}\right) + \lambda L_{S_2}^H\left(W^{i,t}; x\right) \geq L_{S_1}^B\left(W_x^{j,t}\right) + \lambda L_{S_2}^H\left(W^{j,t}; x\right). \tag{30}$$

Since $W_x^{j,t}$ is a naive inflation of $W^{j,t}$ to include x, the solution $W^{j,t+1}$, provided by KHHM training, would have lower (or same) empirical risk, thus

$$L_{S_1}^B\left(W_x^{j,t}\right) \geq L_{S_1}^B(W^{j,t+1}). \tag{31}$$

In iteration $t+1$, x is included in X^j for training the j'th latent component, consequently

$$L_{S_2}^H\left(W^{j,t}; x\right) \geq L_{S_2}^H(W^{j,t+1}; x). \tag{32}$$

(as we assume that $x \in X^j$ leads to $x \in Q^{j,t+1}$). Finally, by combining the inequalities in Eq. 29–32, we obtain:

$$L\left(W^{i,t}; x\right) \geq L\left(W^{j,t+1}; x\right). \tag{33}$$

■

3.4. Generalization Bound for LHM Model with Fixed Assignment

For a fixed $\varphi(x), \forall(x, y) \in S_2$, we can derive a uniform generalization bound for the union of the K-hyperplane models. Similarly to KHHM model (in Section 2.3), we derive the uniform generalization bounds separately for the positive and negative classes. We start with the positive class, for which we use the hinge part of the latent mixed risk.

Theorem 10 *Let φ^* denote a fixed assignment of the positive training samples to components. Let $L_D^H(W_{LHM}; \varphi^*) = \mathbb{E}_{(x,y)\in D}\left[\sum_{i=1}^C \ell(W^i; x, y)\mathbb{1}\left[\varphi^*(x) = i\right]\right]$ be the expected risk, and let $L_{S_2}^H(W_{LHM}, \varphi^*) = \sum_{i=1}^C L_{S_2}^H(W^i)$ be the empirical risk over a positive label training sample of size m_2 for a fixed assignment φ^* of the positive samples to C components. Then, for any $\delta \in (0, 1]$ with probability at least $1 - \delta$ over the i.i.d. sample of size m_2 it holds simultaneously for all $\|w_i\| \leq 1$ $(i = 1, ..., C \cdot K)$ that whenever $\|x\| \leq 1$:*

$$L_D^H(W_{LHM}; \varphi^*) \leq L_{S_2}^H(W_{LHM}, \varphi^*) + \sqrt{\frac{\log 1/\delta}{2m_2}} L_{S_2}^H(W_{LHM}, \varphi^*) + \max_{i\in\{1,...,C\}}\left(\frac{2K}{\sqrt{m^i}} + 8K\sqrt{\frac{2\log(2/\delta)}{m_2}}\right)$$

Proof Let $p_i = E_{(x,1)\sim D}\Big[\mathbb{1}[\varphi^*(x) = i]\Big]$, and let $\frac{m_i}{m^+}$ be its estimated mean. Then,

$$L_D^H(W_{LHM}; \varphi^*) - L_{S_2}^H(W_{LHM}, \varphi^*) = \sum_{i=1}^C\left(p_i L_D^H(W^i) - \frac{m_i}{m_2} L_{S^+}^H(W^i)\right)$$
$$= \sum_{i=1}^C\left[p_i\left(L_D^H(W^i) - L_{S_2}^H(W^i)\right)\right] + \sum_{i=1}^C\left[(p_i - \frac{m_i}{m^+})L_{S_2}^H(W^i)\right] \tag{34}$$

We can bound the discrepancy between the expected and empirical risks in a component using Theorem 8. Hence, the first term in Eq. 34 is upper bounded by $\max_{i\in\{1,...,C\}}\left(\frac{2K}{\sqrt{m^i}} + 8K\sqrt{\frac{2\log(2/\delta)}{m_2}}\right)$. We can upper bound $(p_i - \frac{m_i}{m_2})$ using the Hoeffding inequality. Rearranging the terms and noting that $\sum_{i=1}^C L_{S_2}^H(W^i) = L_{S_2}^H(W_{LHM}, \varphi^*)$ conclude the proof. ■

We formulate the uniform generalization bound for the negative class below.

Theorem 11 *Suppose that D is a distribution over $X \times Y$ such that $Y = \{-1, +1\}$ and $X = \{x : \|x\| \leq G\}$. Let $L_{\mu,\Sigma}^B(W_{LHM}; \varphi^*)$ be the background risk over the negative labels, where μ, Σ are the mean and covariance of the marginal distribution of x over the negative labels and the positive labeled samples have a fixed assignment φ^*. Consider a training sample S of size m, m_1 of which have negative label and let*

$$L_{\hat{\mu},\hat{\Sigma}}^B(W_{LHM}; \varphi^*) = \sum_{i=1}^C L_{\hat{\mu},\hat{\Sigma}}^B(W^i)$$

be the empirical background risk over the negative labels ($\hat{\mu}, \hat{\Sigma}$ are the empirical mean and covariance estimation of D_{neg}). With probability at least $1 - 3\delta$ over m_1 the i.i.d. samples from D_{neg} the following holds uniformly for all W including C components, each with K independent hyperplanes:

$$L_{\mu,\Sigma}^B(W_{LHM}; \varphi^*) \leq L_{\hat{\mu},\hat{\Sigma}}^B(W_{LHM}; \varphi^*) + C\Big(\frac{2G^2}{\alpha} + \frac{6G^4}{\alpha^2}\Big)\sqrt{\frac{32(\log(1/\delta) + 1/4)}{m_1}}.$$

The proof is straightforward as the assignment φ^* does not affect negative samples, and thus the bound is a simple summation of bounds for each component which is derived using Theorem 6.

4. Mapping LHM Classifier to a Neural Network

Deep Neural Networks and Convolutional Neural Networks (CNN) in particular have shown impressive results in a variety of domains, including images, speech, text, etc. CNN enables learning very good features for these domains, but requires a lot of labeled training samples. One way to reduce the number of examples

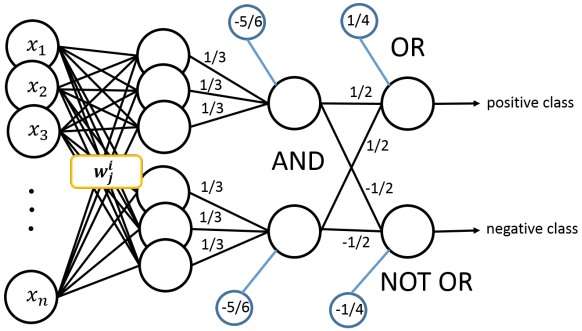

Figure 4: An example of NN equivalent to LHM for two components and three hyperplanes in each.

needed for training of a specific classification task is to pre-train a CNN on a different classification problem in a similar domain and then change the last layer of the CNN to fit the target classification problem and fine-tune the network on a smaller training set associated with the target problem. This approach is referred to as transfer learning.

When the target classification problem is less similar to that used to train CNN features, the classification accuracy of the fine-tuned network could be quite poor. This is because the high-level representation of the original and the target networks are different. One way to approach this problem is by employing a non-linear classifier, such as LHM classifier, on CNN features. In order to fine-tune the feature layers with the LHM classifier, we need to combine them in a single architecture. To this end we propose to map LHM Classifier to a Neural Network and stack it on top of the pre-trained convolutional layers. This enables end-to-end training of feature extraction and classifier. As we show below, mapping of LHM classifier to NN also allows extending it to multi-class problems.

4.1. Binary NN

A union of the intersections of positive half spaces can be implemented by a NN with three hidden layers. The first fully connected hidden layer has $K \times C$ neurons with a sigmoid activation, where K is the number of hyperplanes in an intersection and C is the number of components. The second hidden layer has C nodes with a sigmoid activation, connected only to the neurons associated with hyperplanes forming the corresponding intersection. The weights on these connections and the biases are fixed and mimic **AND** operation, namely, all weights of this layer are equal to $1/K$ and the biases are equal to $-1 + 1/(2K)$. The last hidden layer has two neurons, which are fully connected to the previous layer with the fixed weights and biases, one of which mimics **OR** operation, and the other **NOT OR**. Namely, the neuron, corresponding to OR has weights equal to $1/C$ and the bias of $-1/(2C)$. The neuron corresponding to NOT OR has weights equal to $-1/C$ and the bias of $1/(2C)$. The network has two outputs, one for the positive class (with label 1) and one for the negative class (with label 0). An example of such network for $C = 2$ and $K = 3$ is depicted in Figure 4.

4.2. Multi-Class NN

For a multi-class setting, we suggest to train LHM model for each class using an additional unlabeled data for estimating the statistics of the negative class. We then map these models to a multi-class NN with the following architecture. The first hidden layer is a fully connected layer with $C \times K$ neurons per class,

$C \times K \times G$ neurons in total, where G is the number of classes. These are equivalent to $C \times K \times G$ hyperplanes in the LHM model. For each hidden component, all hyperplanes in the intersection are connected to their corresponding node in the **AND** layer (as detailed in Section 4.1). The **AND** layer comprises $C \times G$ neurons. The next layer is a fully connected layer, comprising G nodes. The weights on the connections to the C components of the corresponding class are initialized with 1's, and the weights on the remaining connections are initialized with very small values from a Gaussian distribution. The network has G outputs and is trained using the cross-entropy loss.

To provide an end-to-end training, one can consider stacking the feature extraction layers of CNN (up to fully connected layers) with one of the above networks.

5. Experiments

We start by evaluating the simple K-hyperplane model (Section 5.1) and then move to a more general LHM model (Section 5.2). Both models are tested on synthetic and real data. Then we show how the hinge-minimax training can be combined with a CNN (Section 5.3) for approaching problems that require more powerful features but do not have large enough data to train a deep model from scratch. We demonstrate this for both binary and multi-class settings.

5.1. K-Hyperplane Hinge-Minimax Classifier

To test the proposed KHHM classifier, we ran experiments in three different scenarios: synthetic 2D data, letter recognition, and large scale scene classification.

During classification, the K-hyperplane classifier incurs only K times the computational complexity of a linear classifier (just K inner products), hence its "natural competitors" are linear classifiers, and we choose linear SVM for the benchmark. We have also compared the hinge-minimax classifiers to kernel SVM and ensemble-based methods, which incur far longer running times (this is especially true for kernel SVM). The classification rates of the hinge-minimax classifier in all our experiments were comparable to ensemble classifiers which required 100-170 basic classifiers in order to reach similar performance. In experiments with high-dimensional data, the KHHM classifiers preformed as well as kernel SVM.

The SVM classifiers were trained using C-SVC in LIBSVM [4]. We used the CVX optimization package [5] to find a single hyperplane in Algorithm 1. The ensemble classifiers were trained using the Matlab Statistic toolbox.

5.1.1. SYNTHETIC DATA EXAMPLE

We construct the KHHM classifier for 2D data to illustrate Algorithm 1. We samples 5000 data points from two highly overlapping Gaussians (see Figure 5) with varying ratio of positive (shown in red) and negative (shown in blue) examples. Each class was equally partitioned into training, validation, and test sets. We estimated the mean and covariance from the training data and tuned the parameters (C and γ) and the bias using the validation set. Table 1 shows the AUC for the different ratios of positive and negative examples using an intersection of 5 hyperplanes. These results demonstrate the robustness of the algorithm to imbalanced sets.

Positive fraction	0.01	0.1	0.2	0.3	0.4	0.5
AUC	94.68	94.91	95.07	94.96	94.89	95.83

Table 1: AUC for different size partitions of positive and negative classes

4. *http://www.csie.ntu.edu.tw/cjlin/libsvm/*
5. *http://cvxr.com/cvx/download/*

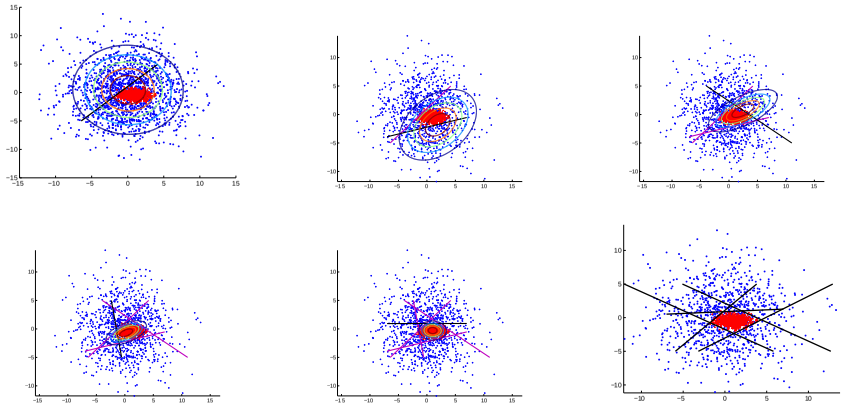

Figure 5: Illustration of KHHM classifier construction on a toy example.The first 5 figures show the greedy initial step. The last figure shows the final classifier after 25 iterations. The contour lines show the covariance matrix of the negative distribution inside the intersection of hyperplane, which is used to find the optimal hyperplane, depicted in black.

The first five plots in Figure 5 show the result of the initial greedy step for the first, second, third, forth, and fifth hyperplanes respectively. The contour lines in Figure 5 illustrate the covariance of the negative distribution inside the intersection, which is used to find the optimal separation hyperplane, depicted in black. The last plot in Figure 5 shows the final classifier after 25 iterations. It illustrates that the approximation algorithm succeeds in separating the positive set from the background, and that the refinement iterations improve the separation boundary.

5.1.2. LETTER RECOGNITION

The following tests were performed on a data set of letters from the UCI Machine Learning Repository (Murphy and Aha (1994)), which includes 16-dimensional feature vectors for the 26 letters in the English alphabet. The letter images were based on 20 different fonts and each letter within these 20 fonts was randomly distorted to produce 20,000 samples. For each letter, we used 100 samples for training, 250 for validation, and the rest for test (about 400 samples per letter). The parameters of all methods have been chosen using the validation set. Since the test set includes 25 times more negatives than positives, which leads to about 96% classification rate by just classifying all inputs as negative, we used EER as a more faithful measure of performance. Table 2 shows the classification rate at EER , averaged over 26 letters, and the average classification times of the tested classifiers.

The KHHM classifiers improve over the linear SVM for all K, and for $K > 1$ outperforms Adaboost with much shorter classification time. For this data set, kernel SVM outperform all methods. However, the KHHM classifier with $K = 4$ comes fairly close to the performance of the kernel SVM, while its classification time is three magnitudes faster.

Method	Classification rate at EER	Classification time
KHHM $K = 1$	89.32	5.6e-07
KHHM $K = 2$	92.98	1.4e-06
KHHM $K = 3$	93.93	1.5e-06
KHHM $K = 4$	94.48	1.7e-06
Linear SVM	84.87	4.6e-07
RBF kernel SVM	96.47	1.7e-03
AdaBoost	92.26	1.0e-03

Table 2: Letter experiments. K corresponds to the number of hyperplanes used in the hinge-minimax classifier. The times are in sec. AdaBoost uses 100 decision trees.

Method	AUC	classification time
KHHM $K = 1$	88.89	9.8e-05
KHHM $K = 2$	90.99	1.34e-04
Linear SVM	88.20	8.6e-05
RBF kernel SVM	90.77	23.97
RUSBoost	90.76	0.08

Table 3: Scene classification with 300 dim. features. The classification time of RBF kernel SVM is very high, since it chooses about 15,000 SVs from 19850 training examples. The RUSBoost uses 100 decision trees.

5.1.3. LARGE SCALE SCENE RECOGNITION

In this test we used 397 scene categories of the SUN data base, which have at least 100 images per category (Xiao et al. (2010)). We represent the images as BOW of dense HOG features with 300 words. We downloaded the features from the SUN web page[6], containing spatial pyramid of BOWs, and used the bottom layer (the details of the feature extraction can be found in Xiao et al. (2010)). The data is divided into 50 training and 50 test images in 10 folds. Training one-against-all classifiers for 397 categories with 50 training samples per category uses very unbalanced training sets. Thus we defined different weights for positive and negative samples in SVM training and we used RUSBoost (Seiffert et al. (2008)) as an ensemble method (it is designed for skewed data and performed significantly better than AdaBoost on this data set). Note that the KHHM classifier naturally handles imbalanced sets. KHHM classifier with more than two hyperplanes didn't improve the performance. Table 5.1.3 shows the average AUC of the tested methods and their running times.

Using a pyramid of BOWs with the histogram intersection kernel improves over the RBF kernel applied to the bottom layer of the pyramid, but then the dimension of the feature vector increases to 6300. The AUC of the KHHM classifier with $K = 2$ is 92.99% and of histogram kernel is 92.85%. Figure 6 shows the ROCs of the first three categories produced by the KHHM classifier and the histogram intersection kernel SVM classifiers.

6. $http://vision.cs.princeton.edu/projects/2010/SUN/$

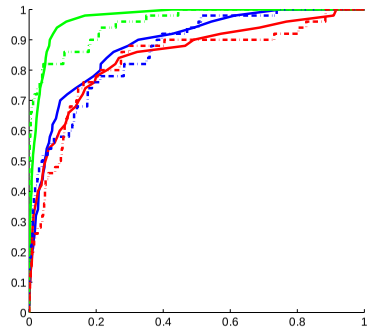

Figure 6: ROCs of the first three categories of the SUN data set, represented by a spatial pyramid of BOWs, obtained from dense HOG. The solid lines correspond to the hinge-minimax classifier, dotted lines correspond to the histogram intersection kernel SVM.

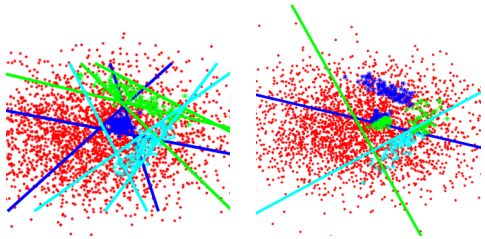

Figure 7: A qualitative comparison of the latent hinge minimax classifier (on the left) to the union of LDA classifiers (on the right).

5.2. Latent Hinge Minimax Classifier

We first show a 2D toy example (Section 5.2.1) to illustrate the ability of the LHM classifier to discover the hidden components in the positive class and to separate each of them from the negative class using a K-hyperplane model.

Then, we compare LHM model to alternative ensembles of hyperplanes (in shallow architectures) on the PASCAL-VOC 2007 dataset (Everingham et al. (2010)) (Section 5.2.2), and show its advantage over those methods and its robustness to the choice of the number of latent components.

5.2.1. SYNTHETIC DATA

A simpler alternative to the LHM model is a two-step algorithm which first finds the structure of the target class by applying some kind of unsupervised learning (e.g, k-means clustering) and then builds a model

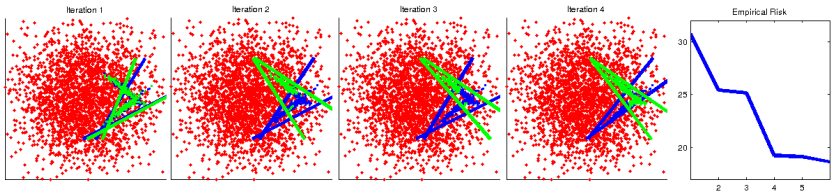

Figure 8: First four iterations of the LHM training on toy example and the corresponding loss convergence.

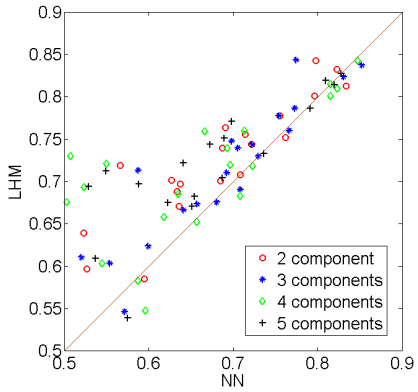

Figure 9: Comparison of the LHM classifier to the equivalent NN for a varying number of hidden components (from 2 to 5) on PASCAL VOC 2007. The points above the diagonal line show the advantage of LHM classifier.

for each component. Such a simple approach was employed in Hariharan et al. (2012) with LDA classifier (Hastie et al. (2001)) trained per cluster. Unless the clusters are very small[7], it relies heavily on the results of the clustering. If an initial clustering is incorrect (as in Figure 7, right), LDA (or any other convex classifier) cannot separate the resulting components from the background without including many false positives. The LHM training finds the underlying structure of the data and the model iteratively, improving both (Figure 7, left). Furthermore, LHM is quite robust to the initial assignment. Figure 8 shows a few iterations and the corresponding loss convergence when the initial assignment of the positive samples to components is chosen at random. Note the LHM training discovers the underlying structure in a 3-4 iterations.

7. as in time consuming exemplar-based approach(Malisiewicz et al. (2011))

LHM	Union of LDAs	NN	KHHM
71.48%	65.17%	67.19%	69.45%

Table 4: The table reports the accuracy at the EER point averaged over 20 classes and different hidden partitions (except for KHHM) on PASCAL VOC-2007 classification task using 80-dimensional HOG features.

5.2.2. ENSEMBLES OF HYPERPLANES

Next, we compared the LHM classifier to alternative ensembles of linear classifiers on PASCAL VOC 2007 dataset (Everingham et al. (2010)). To compare the raw performance of the classifiers we designed the experiment to separate the contribution of the classifier from that of features and the detection system (which usually involves various engineering steps that obscure the actual contribution of the classifier). To this end we used simple features, such as Dalal-Triggs variant of the HOG features (Dalal and Triggs (2005)) with a fixed number of cells (thus keeping the classification problem difficult), and we compared the classification accuracy on the bounding boxes of 20 VOC object categories in test images (instead of running a full detection system).

LDA Union (as a baseline model): We applied k-means clustering on whitened features to find the partition. We then learned an LDA classifier for each cluster in that partition. We varied the number of clusters from 2 to 5.

NN with an architecture equivalent to LHM: We used the model described in Section 4.1 with $K = 2$ and $H = 2, .., 5$, but the weights were initialized at random.

KHHM model This is essentially an LHM model with a single component, thus it is theoretically inferior to LHM. However, we ran this experiment to test the benefits of modeling the hidden structure of the positive class. We varied the number of hyperplanes from 2 to 5.

LHM model: We set the number of hyperplanes in each component to 2 and varied the number of components from 2 to 5. An initial assignment to the components was done using k-means with the Euclidian distance.

All ensembles were trained in one-against-all manner. Similarly to (Hariharan et al. (2012); Osadchy et al. (2012)), we learned the background mean and covariance using bounding boxes from all classes and used them to represent the negative class in LDA union, KHHM, and LHM training. We tested all ensemble classifiers on all bounding boxes from the test set. Table 4 summarizes the accuracy at the EER points of all ensembles averaged over classes and different parameters. It shows that LHM model outperforms all other classifiers. Figure 9 compares LHM to NN on 20 categories (as one-against-all binary classifiers) for varying number of hidden components. The plot shows that LHM outperforms NN independently of the number of components.

5.3. Hinge-Minimax Training in Deep Architecture

In the following experiments, we show that LHM classifier can be combined with CNN via transfer learning. Specifically, we test the LHM classifier on top of the pre-trained CNN feature extraction in imbalanced binary problems and in multi-class tasks with a small number of labeled examples.

We explore the following transfer learning settings. The first setting refers to the **best case** scenario in which the source and the target classification tasks operate on the *same* set of features but differ in the classification problem. The second setting refers to the **worst case** scenario for the transfer learning where the source and the target classification problems *share very little similarity*. The "worst case" scenario is very common in practice, as many classification tasks do not have a large, comprehensive training set (such as ImageNet (Deng et al. (2009)) in object recognition) to be used in transfer learning. No good solution currently exists for such problems.

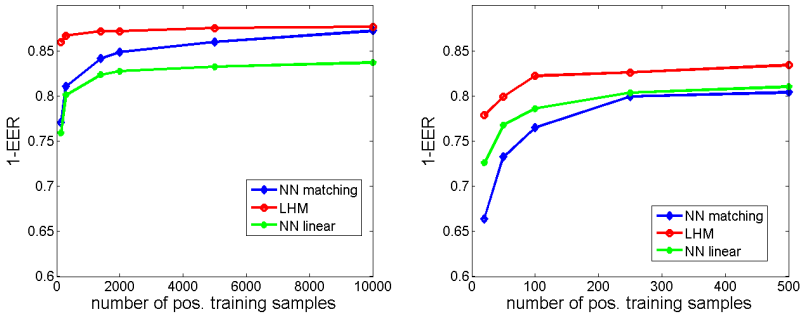

Figure 10: Binary imbalanced classification: left – the "best-case" transfer learning setting, right – the "worst-case" transfer learning setting.

We used the CIFAR-10, composed of 10 categories (airplane, automobile, bird, cat, deer, dog, frog, horse, ship, and truck) as the source problem. Specifically, we trained the LeNet model implemented in MatConvNet Vedaldi and Lenc (2015) on CIFAR-10. Then we removed the last fully-connected layer and the soft-max and used this trimmed network as a feature extractor which converts images to a 64-dimensional feature vectors.

For the best case transfer learning, we defined a new set of classes by coupling i and $i + 5$ indexes of CIFAR-10 classes. CNN trained on CIFAR-10 maps individual classes to linearly separable sub-spaces, thus using pairs of classes as a target classification problem makes it non-linear. Consequently, we get a new classification problem over the same space of features.

For the worst case transfer learning, we picked a subset of 5 classes (train, bottle, cattle, forest, and sweet peppers) from the CIFAR-100, which do not overlap (in their visual appearance) with the CIFAR-10 categories, to be the target classification task. CIFAR-10 data set is not rich enough to enable learning of features that can be used for an arbitrary category, thus we believe that such setting is especially difficult.

We tested the LHM binary and multi-class classifiers in the best and the worst case transfer learning scenarios and compared their performance to two baselines. One is an NN with a single fully connected layer and the cross-entropy loss (NN linear) and the other is the NN with the architecture matching the LHM model (NN matching). We repeated each experiment 50 times over different random subsets of training samples and random initialization of NN and averaged the results.

5.3.1. BINARY IMBALANCED SETTING

The "Best Case" Transfer Learning: We trained binary classifiers for pairs of classes from CIFAR-10 using imbalanced training sets, in which the negative class included all samples from all other classes (40,000 examples) and the positive class included a varying number of samples (140, 300, 600, 1400, 2000, 5000-all). This resulted in imbalance ratios from 1:256 to 1:4.

LHM model was trained with 2 hidden components and 3 hyperplanes per component. The matching NN mimicked the configuration of LHM model, but the weights were allowed to change in training. Figure 10-left shows the 1-EER (averaged over 5 classification problems) of the LHM classifier and the two NN baselines as a function of the positive training sample size.

The "Worst Case" Transfer Learning for Binary Imbalanced Problems: Since the number of samples per class in CIFAR-100 is significantly smaller, this experiment tests the robustness to imbalanced training data

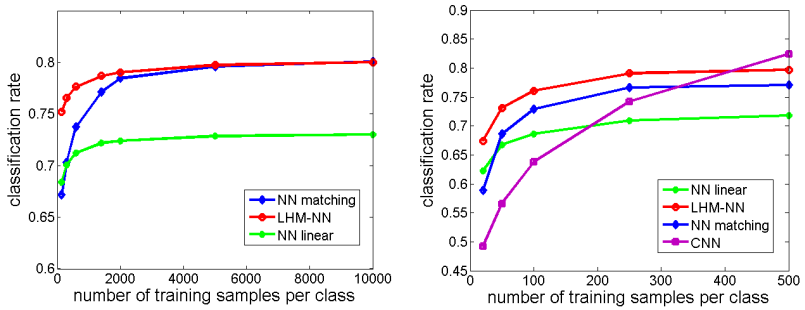

Figure 11: Multi-class classification: left – the "best-case" transfer learning setting, right – "worst-case" transfer learning setting.

and to a small number of examples. We varied the size of the positive training set between 20, 50, 100, 250, 500(all) samples and we used all 2,000 samples of other classes as the negative training set. We compared the LHM model trained with 2 hidden components and 2 hyperplanes per component to NN baselines. Figure 10-right shows the 1-EER of the classifiers averaged over 5 classification problems as a function of the positive training set size.

5.3.2. MULTI-CLASS SETTING

The "Best Case" Transfer Learning: We mapped the LHM binary classifiers trained for 5 pairs of categories to a multi-class NN as described in Section 4.2. We fine-tuned the weights with a very fast training (just a handful of epochs, while training from scratch requires two orders of magnitude more training epochs). Figure 11-left shows the accuracy of the LHM models mapped to a multi-class NN (LHM-NN) with the two baseline NNs as a function of the size of the training set.

The "Worst Case" Transfer Learning for Multi-Class Problems: We mapped the LHM binary classifiers trained for the 5 categories from CIFAR-100 (using CIFAR-10 features) to a multi-class NN and fine-tuned the weights with a small number of epochs.

To test the complexity of the transfer learning problem we also trained a CNN (LeNet model implemented in MatConvNet (Vedaldi and Lenc (2015))) on the target problem. We hoped that due to the small size of the target classification problem, 500 training examples per class would yield relatively good accuracy. Figure 11-right compares the accuracy of LHM-NN, two baseline NNs, and CNN (trained from scratch) as a function of the training sample size. It shows that CNN trained on the target problem is indeed the best as it succeeds to learn features specific for the task, but its accuracy drops very abruptly when the number of training samples becomes smaller. This suggests that when the number of training examples is small, using transfer learning even in a such difficult setting is a better solution than training a CNN from scratch.

The results in Figures 10 and 11 show that the NN models either heavily overfit when the number of training samples is small (NN matching) or they are not expressive enough when the number of training samples increases (NN linear). LHM classifiers are expressive enough to learn from a large set of examples and are more robust to overfitting when the number of examples is small.

6. Training Efficiency

Another advantage of LHM-NN is its training efficiency. A class-specific LHM model converges in 5-10 iterations. Its training time primarily depends on the number of positive samples and the dimension. The negative samples are used to estimate the mean and covariance of the background. The initial estimation (which involves a large number of samples) is done only once and used for all classes. Since the probability of the negative class is evaluated inside the positive region using false positives, the number of which drops very fast, the estimation time of the mean and covariance during the training is negligible. Training of a binary classifier per class is independent of other classes, thus their training can be done in parallel. Finally, the fine-tuning of the multi-class network after mapping is very fast, due to the initialization of all layers (using supervized learning): feature extraction layers with pre-trained CNN and classifier's layers with LHM models.

The LHM-NN is also beneficial for the problems in which classes are dynamically added or removed from the classification task. Adding a class requires training a single binary classifier and fast fine-tuning; removing a class requires only fine-tuning.

7. Conclusions and Future Work

We proposed an efficient method for learning an intersection of finite number of hyperplanes which combines the hinge-risk (for the small number of positive data) with the background risk, based on the "minimax bound" (for a large number of negative data points) and derived a generalization bound for the mixed risk. We showed that the proposed classifier yields results comparable to the popular non-linear classifiers, but at much lower (order of magnitude) computational cost of classification.

We generalized this model to a non-convex classifier (Latent Hinge-Minimax classifier), which discovers the hidden components in the positive class and separates them from the negative class with the intersections of positive half spaces. The main advantage of this classifier is its ability to incorporate unlabeled data in training which improves the robustness to imbalanced sets.

We showed that for multi-class tasks, class-specific LHM models can be mapped to a multi-class NN with matching architecture requiring only a few iterations of fine-tuning. Finally, the showed that LHM architecture can be integrated with CNN features via transfer learning. The entire training procedure is very efficient. Our experiments showed that such classifiers are much more robust to the number of labeled training samples than the equivalent NNs.

This work cay be extended in various directions. A lower Rademacher complexity was shown for the k-fold maxima of hyperplanes in Kontorovich (2018). We plan to extend this result to the maximum over hinge losses and improve the generalization bound for the positive sample. Structured output learning have had an impact on machine vision and can be applied to this framework while improving the multiclass procedure. Another direction is devising a unified probabilistic framework to include both the hinge-loss and background-loss. Also, extensions of Marshall-Olkin theorem to non-convex sets might have a significant impact on robust deep learning methods.

Abstract

We propose a short-term sparse portfolio optimization (SSPO) system based on alternating direction method of multipliers (ADMM). Although some existing strategies have also exploited sparsity, they either constrain the quantity of the portfolio change or aim at the long-term portfolio optimization. Very few of them are dedicated to constructing sparse portfolios for the short-term portfolio optimization, which will be complemented by the proposed SSPO. SSPO concentrates wealth on a small proportion of assets that have good increasing potential according to some empirical financial principles, so as to maximize the cumulative wealth for the whole investment. We also propose a solving algorithm based on ADMM to handle the ℓ^1-regularization term and the self-financing constraint simultaneously. As a significant improvement in the proposed ADMM, we have proven that its augmented Lagrangian has a saddle point, which is the foundation of the iterative formulae of ADMM but is seldom addressed by other sparsity strategies. Extensive experiments on 5 benchmark data sets from real-world stock markets show that SSPO outperforms other state-of-the-art systems in thorough evaluations, withstands reasonable transaction costs and runs fast. Thus it is suitable for real-world financial environments.

Keywords: short-term portfolio optimization, sparse portfolio, alternating direction method of multipliers

1. Introduction

Portfolio optimization (PO) via machine learning systems has been catching more and more attention recently (Li and Hoi, 2012; Huang et al., 2013; Li et al., 2015; Li and Hoi, 2014; He et al., 2015; Yang et al., 2015; Huang et al., 2016; Li et al., 2016; Mahdavi-Damghani et al., 2017). It aims to invest in a group of financial assets with instructions by the machine, based on some financial principles and optimization strategies. Since it requires a large amount of quantitative calculation, machine learning methods are in high demand to reduce mistakes and biases made by human in real-world investment.

PO originates from the mean-variance theory (Markowitz, 1952), which seeks to minimize the volatility of a portfolio given a certain expected return level. From then on, various theories based on such a framework are proposed in the language of probability and statistics (Sharpe, 1964; Fama, 1965; Lintner, 1965; Fama, 1970; Treynor and Black, 1973). The equally-weighted portfolio is a popular theory that can achieve good performance if the individual risks of the assets are similar, while the risk parity theory is efficient in diversifying the portfolio risk if the individual risks are significantly different (Maillard et al., 2010). Instead of treating PO as a static problem, the stochastic portfolio theory (Fernholz, 2002) further extends it to a dynamic problem under some strict statistical assumptions. Besides, some special objectives can be achieved by adding specific prior knowledge into the dynamic model, like the rank-dependent portfolios. However, all the above methods are rather theoretical and their conclusions are based on very strict statistical assumptions that are far from real-world situations. On the other hand, machine learning strategies do not require such strict assumptions, thus they are more productive and effective in a well-defined technical sense (Das et al., 2013; Shen et al., 2014; Ho et al., 2015).

The attempt to construct sparse portfolios via machine learning starts in the long-term PO. In general, a long-term PO changes its portfolio once for a week or a month (or even a year). It focuses on the choice of assets rather than the timing of trading (buying or selling). A kind of sparse and stable Markowitz portfolios (SSMP) is proposed by Brodie et al. (2009). It adds an ℓ^1-regularization (Candès and Plan, 2009) term of the portfolio vector to the traditional Markowitz model, which regulates the amount of short-position in the portfolio. The regularized symmetric tail average (STA) minimization is proposed by Still and Kondor (2010), which exploits the Karush-Kuhn-Tucker (KKT) conditions (Bertsekas, 1999) to make the portfolio sparse. Ho et al. (2015) also construct sparse mean-variance portfolios with weighted elastic net penalization (Zou and Hastie, 2005). Shen et al. (2014) propose the doubly regularized portfolio allocation to control the quantity of portfolio change. Empirical or simulated experiments indicate that they show some advantages in the long-term PO.

However, few systems construct sparse portfolios for the short-term and online PO, which changes its portfolio once for a day (or even shorter). Since the short-term PO is more general than the long-term PO (e.g., one can change the portfolio only on the first day of each month), the short-term PO considers both of the choice of assets and the timing of trading. While the objective of long-term PO is to minimize the quadratic risk (Markowitz, 1952; Brodie et al., 2009; Ho et al., 2015; Shen et al., 2014), the objective of short-term PO is to maximize the increasing factor on each day and ultimately the cumulative wealth (Cover, 1991; Agarwal et al., 2006; Li et al., 2011; Das et al., 2013; Li et al., 2015; Huang et al., 2016; Li et al., 2016).

Alternating direction method of multipliers (ADMM) (Boyd et al., 2010) is an efficient and reliable approach for solving ℓ^1-regularization problems in many applications (Yin et al., 2015; Fang et al., 2016). However, it is nontrivial to implement ADMM (and other approaches) on the short-term sparse PO especially when both the ℓ^1-regularization term and the self-financing constraint are present (Shen et al., 2014), thus there are few

public solving schemes. Shen et al. (2014) point out that this problem is difficult and turn to a commercial software for solution. Ho et al. (2015) include the ℓ^1-regularization term but exclude the self-financing constraint. Although Das et al. (2013) successfully set up an ADMM algorithm, they do not prove that its augmented Lagrangian has a saddle point, which is the foundation of the iterative formulae of ADMM. In fact, the saddle point proof is also absent in other applications (Mohsin et al., 2015; Zhan et al., 2016) than PO. Besides, not all designs of ADMM have saddle points.

To address the above-mentioned problems, we propose a novel Short-term Sparse PO (SSPO) system based on ADMM. It well fits the machine learning framework for the short-term PO and is free of the strict assumptions of the stochastic portfolio theory. Its novelty falls into several aspects.

- Most state-of-the-art short-term PO systems focus only on adopting empirical financial principles (like the mean reversion) (Li et al., 2012, 2013, 2015; Huang et al., 2016), but SSPO also exploits the intrinsic sparse structure of portfolio by using an ℓ^1-regularization term and a self-financing constraint simultaneously, which lacks public solving schemes.

- Most previous sparsity models minimize the square error (Brodie et al., 2009; Still and Kondor, 2010; Lai et al., 2015; Zhan et al., 2016) or the quadratic risk (Brodie et al., 2009; Ho et al., 2015), but SSPO maximizes an increasing factor, which is quite different from the former in formulation.

- Previous sparsity models for short-term PO constrain the quantity of the portfolio change to form "lazy updates" (Das et al., 2013; Shen et al., 2014), which are defensive strategies and not really sparse PO systems. But SSPO actively updates the sparse portfolio according to the changing increasing potential of different assets as time passes, which is an aggressive strategy.

- We prove that the augmented Lagrangian of SSPO has a saddle point, which is the foundation of the iterative formulae of ADMM but is seldom addressed by other sparsity models.

The rest of the paper is organized as follows. Section 2 presents some preliminaries and related works. Section 3 illustrates the whole SSPO system and its solving algorithm. Section 4 presents extensive experimental results to evaluate SSPO. Finally, Section 5 draws conclusions.

2. Preliminaries and Related Works

2.1. Problem Setting of Short-term Portfolio Optimization

We present the framework of short-term PO via machine learning, which is taken as baseline by many previous researches (Cover, 1991; Agarwal et al., 2006; Li et al., 2015; Huang et al., 2016; Li et al., 2016). Suppose there are d assets in a financial market, their prices are collected as a vector $\mathbf{p}_t \in \mathbb{R}^d_+, t = 0, 1, 2, \cdots$, where $\mathbb{R}^d_+$ represents the d-dimensional nonnegative real space. Note that $\mathbf{p}_t$ may change as time t goes, forming a

sequence. We can evaluate the performance of assets by the price relative $\mathbf{x}_t \triangleq \frac{\mathbf{p}_t}{\mathbf{p}_{t-1}}$, where the division is performed element-wise.

A portfolio is a vector lying on the d-dimensional simplex $\mathbf{b}_t \in \Delta_d := \{\mathbf{b} \in \mathbb{R}^d_+ : \sum_{i=1}^d \mathbf{b}^{(i)} = 1\}$ with assumptions of non-short-selling and self-financing (without borrowing money and full re-investment). It represents the proportion of the total wealth invested in different assets at the beginning of the t-th period.

At the end of the t-th period, the cumulative wealth S_t evolves by an increasing factor of $\mathbf{b}_t^\top \mathbf{x}_t$: $S_t = S_{t-1} \cdot (\mathbf{b}_t^\top \mathbf{x}_t)$. Suppose the whole investment lasts n periods and the initial wealth is $S_0 = 1$, then the final cumulative wealth is $S_n = \prod_{t=1}^n (\mathbf{b}_t^\top \mathbf{x}_t)$. The objective of short-term PO is to maximize S_n by maximizing $\mathbf{b}_t^\top \mathbf{x}_t$ on each period (Cover, 1991; Agarwal et al., 2006; Li et al., 2011; Das et al., 2013; Li et al., 2015; Huang et al., 2016; Li et al., 2016):

$$\hat{S}_n = \max_{\{\mathbf{b}_t \in \Delta_d\}_{t=1}^n} \prod_{t=1}^n (\mathbf{b}_t^\top \mathbf{x}_t). \tag{1}$$

Note that no statistical assumptions regarding the movement of asset prices are required in the framework.

2.2. Related Works on Short-term Portfolio Optimization

Different systems or strategies suggest different principles of optimizing $\mathbf{b}_t$ as time passes. In general, short-term PO systems need to flexibly react to the rapid change of financial environments, thus they have to exploit some principles of empirical financial studies (Jegadeesh, 1990, 1991; Li and Hoi, 2014; Li et al., 2016) and investing behaviors (Kahneman and Tversky, 1979; Bondt and Thaler, 1985; Jegadeesh and Titman, 1993) to make future price predictions, rather than follow strict statistical assumptions that may only take effect in the long run (Das et al., 2013). For example, some state-of-the-art short-term PO systems adopt the mean reversion principle in finance (Jegadeesh, 1990, 1991; Li et al., 2012, 2013, 2015; Huang et al., 2016), which indicates that the future price of an asset will reverse to some kind of its historical mean.

2.2.1. Two Trivial Systems

A simple but widely used system is the Uniformly Buy-And-Hold (UBAH) strategy (Li and Hoi, 2014), which disperses the wealth equally in all the assets at the very beginning and remains unchanged: $\hat{S}_n^{UBAH} = \frac{1}{d} \sum_{i=1}^d \prod_{t=1}^n \mathbf{x}_t^{(i)}$. It is taken by most financial markets as their market strategies.

On the contrary, the Beststock (BS) strategy (Li and Hoi, 2014) allocates all the wealth to the best performing asset in the whole investment: $\hat{S}_n^{BS} = \max_{\mathbf{b} \in \Delta_d} \mathbf{b}^\top (\bigotimes_{t=1}^n \mathbf{x}_t)$, where $\bigotimes$ is the element-wise product operator. It is a hindsight strategy that cannot be implemented in reality.

2.2.2. Systems Based on Correlation

Anticor (Borodin et al., 2004) is a mean-reversion system, selling previous good performing assets and buying the anti-correlated bad performing ones. It measures the similarity

of different assets by the cross-window correlation $cor_{i,j} = \frac{(\mathbf{lx}^{(i)} - \bar{lx}^{(i)})^\top (\mathbf{ly}^{(j)} - \bar{ly}^{(j)})}{\|\mathbf{lx}^{(i)} - \bar{lx}^{(i)}\| \|\mathbf{ly}^{(j)} - \bar{ly}^{(j)}\|}$ and an anti-correlation $A_i = |cor_{i,i}|$ if $cor_{i,i} < 0$; else $A_i = 0$, where $\|\cdot\|$ is the Euclidean norm, $\mathbf{lx}$ and $\mathbf{ly}$ are logarithmic returns in two successive windows.

CORN (Li et al., 2011) further combines correlation with pattern-matching (Györfi et al., 2006) and searches for historical correlation-similar patterns

$$\mathcal{C}_{t+1}(w, \rho) = \left\{ w < k < t : \frac{cov(\mathbf{X}_{k-w}^{k-1}, \mathbf{X}_{t-w+1}^{t})}{std(\mathbf{X}_{k-w}^{k-1}) std(\mathbf{X}_{t-w+1}^{t})} \geqslant \rho \right\},$$

where $\mathbf{X}_{k-w}^{k-1}$ denotes the price relative vectors in the time window $[k-w, k-1]$.

Mahdavi-Damghani et al. (2017) consider PO in the context of cointelated pairs, a typical model for pairs trading. It is designed to signify a hybrid method between the cointegration and the correlation models. There are two approaches to addressed this problem: Stochastic Differential Equation and Band-wise Gaussian Mixture, which give similar results but the latter keeps the methodology simpler and more adaptable to the regime change.

2.2.3. Systems Based on Average Indices

OLMAR (Li et al., 2015) exploits the popular financial tool of moving average (MA) to predict future asset prices. It is a defensive and moderate strategy with a neutral risk appetite, so as to avoid over-estimating or under-estimating:

$$\hat{\mathbf{x}}_{t+1}(w) = \frac{MA_t(w)}{\mathbf{p}_t} = \frac{\sum_{k=0}^{w-1} \mathbf{p}_{t-k}}{w \mathbf{p}_t} = \frac{1}{w} \left(\mathbf{1} + \frac{\mathbf{1}}{\mathbf{x}_t} + \cdots + \frac{\mathbf{1}}{\bigotimes_{k=0}^{w-2} \mathbf{x}_{t-k}} \right), \tag{2}$$

where $\mathbf{1}$ is a vector with elements of 1, whose dimension can be inferred from the context, and w is the window size. Its portfolio update scheme is the same as the below-mentioned RMR strategy (Huang et al., 2016).

RMR also makes moderate price predictions, but substitutes ℓ^1-median (Vardi and Zhang, 2000) for MA, since ℓ^1-median is more robust to noise and outliers:

$$\hat{\mathbf{p}}_{t+1} = \operatorname*{argmin}_{\mathbf{p} \in \mathbb{R}_+^d} \sum_{k=0}^{w-1} \|\mathbf{p}_{t-k} - \mathbf{p}\|, \quad \hat{\mathbf{x}}_{t+1} = \frac{\hat{\mathbf{p}}_{t+1}}{\mathbf{p}_t}. \tag{3}$$

Both RMR and OLMAR use the following optimization model to update portfolio:

$$\mathbf{b}_{t+1} = \operatorname*{argmin}_{\mathbf{b}} \frac{1}{2} \|\mathbf{b} - \hat{\mathbf{b}}_t\|^2 \quad \text{s.t. } \mathbf{b}^\top \hat{\mathbf{x}}_{t+1} \geqslant \epsilon > 0, \tag{4}$$

$$\hat{\mathbf{b}}_{t+1} = \operatorname*{argmin}_{\mathbf{b} \in \Delta_d} \|\mathbf{b} - \mathbf{b}_{t+1}\|^2. \tag{5}$$

(5) is a normalization to the simplex (Duchi et al., 2008). This optimization model does not impose sparsity constraints on the portfolio, and it tries to approach the current portfolio $\hat{\mathbf{b}}_t$ with a prospective growth $\mathbf{b}^\top \hat{\mathbf{x}}_{t+1} \geqslant \epsilon$.

2.3. Related Works on Sparsity Constraints

Although sparsity models have been proposed for PO, they either aim at the long-term PO or constrain the quantity of the portfolio change. Very few of them aim to construct sparse portfolios for the short-term PO.

2.3.1. Systems for Long-term Portfolio Optimization

Sparse and Stable Markowitz Portfolio (SSMP) (Brodie et al., 2009) uses the following regularization model

$$\mathbf{b}_{SSMP} = \operatorname*{argmin}_{\mathbf{b}} \|\epsilon \mathbf{1}_{(n)} - \mathcal{R}\mathbf{b}\|^2 + \tau \|\mathbf{b}\|_1 \quad \text{s.t. } \mathbf{b}^\top \boldsymbol{\mu} = \epsilon, \mathbf{b}^\top \mathbf{1} = 1, \tag{6}$$

where ϵ is a predefined prospective growth rate, $\mathbf{1}_{(n)}$ is an n-dimensional vector of 1, $\mathcal{R}$ is an $n \times d$-dimensional asset return matrix, $\boldsymbol{\mu}$ is the expectation of asset returns, $\|\cdot\|_1$ denotes the ℓ^1-Norm, and τ is the regularization strength. $\mathcal{R}\mathbf{b}$ contains the actual portfolio returns of n samples, while $\mathbf{b}^\top \boldsymbol{\mu}$ is the expectation of the portfolio return. (6) constrains $\mathbf{b}^\top \boldsymbol{\mu}$ to a predefined level ϵ, and tries to minimize the square error (i.e., the quadratic risk in the context of quantitative finance) of the actual portfolio returns to their expectation. Besides, it relaxes the nonnegativity constraint of $\mathbf{b}$ and retains the self-financing constraint $\mathbf{b}^\top \mathbf{1} = 1$. With ℓ^1-regularization, $\mathbf{b}$ is forced to be sparse and the short position is limited (Brodie et al., 2009).

Weighted Elastic Net Penalized Portfolio (WENPP) (Ho et al., 2015) adds an elastic net penalization (Zou and Hastie, 2005) but removes the self-financing constraint $\mathbf{b}^\top \mathbf{1} = 1$:

$$\mathbf{b}_{WENPP} = \operatorname*{argmin}_{\mathbf{b}} \mathbf{b}^\top \hat{\boldsymbol{\Sigma}} \mathbf{b} - \mathbf{b}^\top \hat{\boldsymbol{\mu}} + \sum_{i=1}^{d} \tau_i |\mathbf{b}^{(i)}| + \sum_{i=1}^{d} \iota_i |\mathbf{b}^{(i)}|^2, \tag{7}$$

where $\hat{\boldsymbol{\Sigma}}$ and $\hat{\boldsymbol{\mu}}$ are the estimated covariance and expectation of asset returns, respectively.

SSMP and WENPP reflect that the objective of long-term PO is to minimize the quadratic risk $\|\epsilon \mathbf{1}_{(n)} - \mathcal{R}\mathbf{b}\|^2$ or $\mathbf{b}^\top \hat{\boldsymbol{\Sigma}} \mathbf{b}$, which is quite different from the problem setting (1) of short-term PO. Besides, $\hat{\boldsymbol{\Sigma}}$ and $\hat{\boldsymbol{\mu}}$ have to be estimated in a single static period, which is not adaptive to the rapid changing financial environments in the short-term PO (Das et al., 2013).

2.3.2. Systems for Lazy Updates

Online Lazy Update (OLU) (Das et al., 2013) is a sparsity model for the short-term PO. However, the sparsity is on the change of portfolio, not on the portfolio itself:

$$\hat{\mathbf{b}}_{t+1} = \operatorname*{argmin}_{\mathbf{b} \in \Delta_d} -\eta \log(\mathbf{b}^\top \mathbf{x}_t) + \tau \|\mathbf{b} - \hat{\mathbf{b}}_t\|_1 + \frac{1}{2} \|\mathbf{b} - \hat{\mathbf{b}}_t\|^2. \tag{8}$$

Hence it is not really a sparse PO. Besides, it assumes that the current price relative $\mathbf{x}_t$ will be replicated in the next day, which may lack supports from empirical financial studies. Moreover, although it has established an ADMM solver, it has not given a saddle point proof for its augmented Lagrangian, which is the foundation of the iterative formulae of ADMM. Note that not all ADMM designs have saddle points.

Doubly Regularized Portfolio (DRP) (Shen et al., 2014) also employs the lazy update strategy in its model:

$$\hat{\mathbf{b}}_t = \operatorname*{argmin}_{\mathbf{b}} \mathbf{b}^\top \hat{\mathbf{\Sigma}}_t \mathbf{b} + \tau_1 \|\mathbf{b}\|_1 + \tau_2 \|\mathbf{b} - \hat{\mathbf{b}}_{t-}\|^2 \quad \text{s.t. } \mathbf{b}^\top \mathbf{1} = 1, \tag{9}$$

where $\hat{\mathbf{b}}_{t-}$ denotes the re-normalized portfolio before the rebalancing at time t, and $\hat{\mathbf{\Sigma}}_t$ denotes the estimated covariance at time t. DRP is also for the long-term PO in both model setting (minimizing the quadratic risk) and its experimental evaluation (weekly or monthly data). It updates the covariance $\hat{\mathbf{\Sigma}}_t$ based on the newest price information, instead of using a single static $\hat{\mathbf{\Sigma}}$ as in (7). The regularization term $\tau_2 \|\mathbf{b} - \hat{\mathbf{b}}_{t-}\|^2$ is introduced to control the change of portfolio. DRP does not propose a solver for its model, but turns to a commercial software toolbox (Shen et al., 2014).

3. Short-term Sparse Portfolio Optimization

To make a summary of Section 2, there are few sparse portfolio methods for the short-term PO that have reliable public solving schemes, especially when both the ℓ^1-regularization term and the self-financing constraint are present. Besides, most state-of-the-art short-term PO systems focus only on exploiting empirical financial principles and pay little attention to constructing sparse, concentrated and effective portfolios.

To fill this gap, we propose a novel Short-term Sparse PO (SSPO) system based on ADMM. We also prove that its augmented Lagrangian has a saddle point, which is the foundation of the iterative formulae of ADMM but is seldom addressed by other sparsity models. SSPO actively rebalances the sparse portfolio according to some empirical financial principles in order to maximize the cumulative wealth. To establish SSPO, we follow the 3 conventional steps of short-term PO system design (Borodin et al., 2004; Li et al., 2011; Li and Hoi, 2014; Li et al., 2015; Huang et al., 2016): price information processing, sparse portfolio model setup, and solving algorithm design.

3.1. Price Information

A sparse portfolio should concentrate on only a few assets that have good increasing potential, which is more adaptive to an aggressive strategy than a defensive one. Hence SSPO exploits the irrational investing behaviors indicated by some empirical financial studies on stock price overreactions (Bondt and Thaler, 1985; Kahneman and Tversky, 1979; Shiller, 2003), instead of the mean reversion principle (Jegadeesh, 1991). For example, investors are usually irrational to keep on buying the assets rising in value, which further pushes up the asset prices and postpones the reversion (Jegadeesh and Titman, 1993; Shiller, 2000).

To evaluate the increasing potential of an asset, the highest price in a recent time window with size w is observed:

$$\mathbf{p}_{MAX}^{(i)} = \max_{0 \leqslant k \leqslant w-1} \mathbf{p}_{t-k}^{(i)}, \quad i = 1, 2, \cdots, d. \tag{10}$$

$\mathbf{p}_{MAX}^{(i)}$ plays an important role in real-world investment and portfolio management, and it is an indispensable indicator in nearly every stock analysis software. Since most investors

gain profits by the growth of asset price, they consider $\mathbf{p}_{MAX}^{(i)}$ as a potential level that the future price can probably reach.

Next, the relative distance from the current price vector $\mathbf{p}_t$ to $\mathbf{p}_{MAX}$ implies the increasing potential of the assets. Thus we define a generalized logarithmic return as follows:

$$\mathbf{R}_t = 1.1 \log\left(\frac{\mathbf{p}_{MAX}}{\mathbf{p}_t}\right) + 1, \tag{11}$$

where $\log\left(\frac{\mathbf{p}_{MAX}}{\mathbf{p}_t}\right)$ is the logarithmic return (Borodin et al., 2004), $\mathbf{R}_t$ is a linear transform of $\log\left(\frac{\mathbf{p}_{MAX}}{\mathbf{p}_t}\right)$. $\frac{\mathbf{p}_{MAX}}{\mathbf{p}_t} \geqslant \mathbf{1}$ and the inequality dominates each element. If $\frac{\mathbf{p}_{MAX}^{(i)}}{\mathbf{p}_t^{(i)}} = 1$, then $\mathbf{R}_t^{(i)} = 1$. The coefficient 1.1 is a slight adjustment of the shape of linear transform. We use $\mathbf{R}_t$ as the price information input for the SSPO system.

3.2. Sparse Portfolio Model

We consider the following objective to set up a sparse portfolio model: first, we should maximize $\mathbf{b}^\top \mathbf{R}_t$, which is the increasing potential of the whole portfolio. Denote $\boldsymbol{\varphi}_t = -\mathbf{R}_t$, then we can change the maximization to a minimization. Second, we adopt an ℓ^1-regularization term and a self-financing constraint simultaneously to concentrate the portfolio on a few assets. It leads to the following model

$$\mathbf{b}_{t+1} = \min_{\mathbf{b}} \mathbf{b}^\top \boldsymbol{\varphi}_t + \lambda \|\mathbf{b}\|_1, \quad \text{s.t. } \mathbf{1}^\top \mathbf{b} = 1, \tag{12}$$

where $\lambda > 0$ controls the regularization strength.

Different from previous compressed sensing models (Brodie et al., 2009; Mohsin et al., 2015; Zhan et al., 2016) that minimize a square error, model (12) minimizes $\mathbf{b}^\top \boldsymbol{\varphi}_t$. It is also different from (7) and (9) which minimize a quadratic risk for the long-term PO. Besides, (12) has a self-financing constraint $\mathbf{1}^\top \mathbf{b} = 1$ which is absent in (7), and (9) is solved by a commercial software (Shen et al., 2014). Thus there are few existing public algorithms to solve (12) and we have to design a new algorithm. Last, $\mathbf{b}_{t+1}$ can be projected onto the simplex to form an eligible portfolio, as instructed by Duchi et al. (2008); Li et al. (2015); Huang et al. (2016).

Based on the ADMM criterion, we introduce an auxiliary vector $\mathbf{g} \in \mathbb{R}^d$ to approach $\mathbf{b}$, and turn to minimize $\lambda \|\mathbf{g}\|_1$. We also introduce a dual variable ρ for the constraint $\mathbf{1}^\top \mathbf{b} = 1$, and transform the constraint into a penalty function. By this way, the constrained model (12) is changed to the optimization of an unconstrained augmented Lagrangian

$$L(\mathbf{b}, \mathbf{g}, \rho) = \mathbf{b}^\top \boldsymbol{\varphi}_t + \frac{\lambda}{2\gamma} \|\mathbf{b} - \mathbf{g}\|^2 + \lambda \|\mathbf{g}\|_1 + \frac{\eta}{2} (\mathbf{1}^\top \mathbf{b} - 1)^2 + \rho (\mathbf{1}^\top \mathbf{b} - 1), \tag{13}$$

where $\gamma > 0$ controls the approximation of $\mathbf{g}$ to $\mathbf{b}$, and $\eta > 0$ controls the penalty strength when $\mathbf{1}^\top \mathbf{b} \neq 1$. Generally speaking, if $\gamma \to 0$, then the penalty $\frac{\lambda}{2\gamma} \|\mathbf{b} - \mathbf{g}\|^2$ forces $\mathbf{g} \to \mathbf{b}$. Further analysis of γ will be given later in the optimization steps.

Not all formulations of ADMM have saddle points. Few methods take the bother to figure out and prove the existence of saddle points (Das et al., 2013; Mohsin et al., 2015; Zhan et al., 2016). But we can prove that the augmented Lagrangian (13) has a saddle point, which makes the iterative formulae (25)$\sim$(27) of ADMM appropriate.

3.3. Solving Algorithm

3.3.1. The Existence of Saddle Point

Our algorithm originates from the existence of a saddle point $(\mathbf{b}^*, \mathbf{g}^*, \rho^*)$ for the Lagrangian (13) such that

$$L(\mathbf{b}^*, \mathbf{g}^*, \rho) \leqslant L(\mathbf{b}^*, \mathbf{g}^*, \rho^*) \leqslant L(\mathbf{b}, \mathbf{g}, \rho^*), \quad \forall\, \mathbf{b}, \mathbf{g}, \rho. \tag{14}$$

We now prove that this saddle point really exists. First, for any given ρ, the following equation holds:

$$\min_{\mathbf{b},\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho) = \min_{\mathbf{b}} \min_{\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho). \tag{15}$$

It can be seen that

$$\min_{\mathbf{b},\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho) \leqslant \min_{\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho) \leqslant L(\mathbf{b}, \mathbf{g}, \rho). \tag{16}$$

Taking $\min_{\mathbf{b},\mathbf{g}}$ in all 3 terms of the above inequalities, we find that they are restricted to equalities, since the first term equals the last term. Besides, $\min_{\mathbf{b},\mathbf{g}} \min_{\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho) = \min_{\mathbf{b}} \min_{\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho)$, thus we deduce equation (15).

Next, we examine the following functions

$$l(\mathbf{b}, \rho) = \min_{\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho) = \mathbf{b}^\top \boldsymbol{\varphi}_t + \lambda H(\mathbf{b}) + \frac{\eta}{2}(\mathbf{1}^\top \mathbf{b} - 1)^2 + \rho(\mathbf{1}^\top \mathbf{b} - 1), \tag{17}$$

$$H(\mathbf{b}) \triangleq \min_{\mathbf{g}} \frac{1}{2\gamma}\|\mathbf{b} - \mathbf{g}\|^2 + \|\mathbf{g}\|_1 = \sum_{i=1}^{d} h(\mathbf{b}^{(i)}), \tag{18}$$

where $h(\mathbf{b}^{(i)})$ is the Huber function (Boyd et al., 2010)

$$h(\mathbf{b}^{(i)}) = \min_{\mathbf{g}^{(i)}} \frac{1}{2\gamma}(\mathbf{b}^{(i)} - \mathbf{g}^{(i)})^2 + |\mathbf{g}^{(i)}| = \begin{cases} \frac{|\mathbf{b}^{(i)}|^2}{2\gamma} & \text{if } |\mathbf{b}^{(i)}| \leqslant \gamma \\ |\mathbf{b}^{(i)}| - \frac{\gamma}{2} & \text{if } |\mathbf{b}^{(i)}| > \gamma \end{cases}. \tag{19}$$

It is a continuous function, which only needs to be verified at $|\mathbf{b}^{(i)}| = \gamma$ and it is obvious. Moreover, it is decreasing when $\mathbf{b}^{(i)} \leqslant 0$ and increasing when $\mathbf{b}^{(i)} > 0$, indicating that it is also a strictly convex function.

Suppose we have 2 vectors $\mathbf{b} \neq \mathbf{c}$. For any $0 < \theta < 1$,

$$\begin{aligned} H(\theta\mathbf{b} + (1-\theta)\mathbf{c}) &= \sum_{i=1}^{d} h(\theta\mathbf{b}^{(i)} + (1-\theta)\mathbf{c}^{(i)}) \\ &< \theta \sum_{i=1}^{d} h(\mathbf{b}^{(i)}) + (1-\theta) \sum_{i=1}^{d} h(\mathbf{c}^{(i)}) = \theta H(\mathbf{b}) + (1-\theta) H(\mathbf{c}). \end{aligned}$$

Hence $H(\mathbf{b})$ is also a strictly convex function.

Looking back to (17), $l(\mathbf{b}, \rho)$ is the Lagrangian of the following problem

$$\min_{\mathbf{b}} \mathbf{b}^\top \boldsymbol{\varphi}_t + \lambda H(\mathbf{b}) + \frac{\eta}{2}(\mathbf{1}^\top \mathbf{b} - 1)^2, \text{ s.t. } \mathbf{1}^\top \mathbf{b} = 1. \tag{20}$$

We have proven that $H(\mathbf{b})$ is strictly convex. It is apparent that $\mathbf{b}^\top \boldsymbol{\varphi}_t$ and $\frac{\eta}{2}(\mathbf{1}^\top \mathbf{b} - 1)^2$ are also convex on $\mathbf{b}$. Hence the whole function to be minimized in (20) is strictly convex. By Slater's theorem (Boyd and Vandenberghe, 2004), strong duality holds and there exists a saddle point $(\mathbf{b}^*, \rho^*)$ such that

$$l(\mathbf{b}^*, \rho) \leqslant l(\mathbf{b}^*, \rho^*) \leqslant l(\mathbf{b}, \rho^*), \quad \forall\, \mathbf{b}, \rho. \tag{21}$$

The last step is to find $\mathbf{g}^*$. From (18) we know that $\mathbf{g}$ is determined by $\mathbf{b}$. Specifically, $\mathbf{g}^*$ is the minimizer of $H(\mathbf{b}^*)$ in (18), which is a soft shrinkage (Tibshirani, 1996)

$$\mathbf{g}^* = \text{sign}(\mathbf{b}^*) \otimes (\text{abs}(\mathbf{b}^*) - \gamma\mathbf{1})^+, \tag{22}$$

where $(\cdot)^+$ denotes the positive part of a vector, which maps all the negative elements to 0 and retains all the nonnegative ones. $\text{abs}(\cdot)$, $\text{sign}(\cdot)$ are the absolute value function and the sign function implemented on each element of a vector, respectively. The soft shrinkage operator shrinks each element of $\mathbf{b}^*$ towards 0 by a step size of γ.

Therefore, from the first inequality of (21) we have

$$L(\mathbf{b}^*, \mathbf{g}^*, \rho) = l(\mathbf{b}^*, \rho) \leqslant l(\mathbf{b}^*, \rho^*) = L(\mathbf{b}^*, \mathbf{g}^*, \rho^*). \tag{23}$$

Furthermore, by (15), (17) and the second inequality of (21) we have

$$L(\mathbf{b}^*, \mathbf{g}^*, \rho^*) = l(\mathbf{b}^*, \rho^*) = \min_{\mathbf{b}} l(\mathbf{b}, \rho^*) = \min_{\mathbf{b}} \min_{\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho^*) = \min_{\mathbf{b},\mathbf{g}} L(\mathbf{b}, \mathbf{g}, \rho^*). \tag{24}$$

Combining (23) and (24), we prove that $(\mathbf{b}^*, \mathbf{g}^*, \rho^*)$ is a saddle point satisfying (14).

3.3.2. The Algorithm Based on ADMM

Based on the saddle point inequalities (14) and the ADMM criterion, the Lagrangian (13) should be minimized by $\mathbf{b}$,$\mathbf{g}$ and maximized by ρ, which can be formulated in 3 iterative steps

$$\mathbf{b}_{(o+1)} = \operatorname*{argmin}_{\mathbf{b}} L(\mathbf{b}, \mathbf{g}_{(o)}, \rho_{(o)}), \tag{25}$$

$$\mathbf{g}_{(o+1)} = \operatorname*{argmin}_{\mathbf{g}} L(\mathbf{b}_{(o+1)}, \mathbf{g}, \rho_{(o)}), \tag{26}$$

$$\rho_{(o+1)} = \rho_{(o)} + \eta(\mathbf{1}^\top \mathbf{b}_{(o+1)} - 1). \tag{27}$$

To solve (25), we can leave out all the constant terms that do not include $\mathbf{b}$ in (13), which leads to

$$\begin{aligned} \mathbf{b}_{(o+1)} &= \operatorname*{argmin}_{\mathbf{b}} \mathbf{b}^\top \boldsymbol{\varphi}_t + \frac{\lambda}{2\gamma}\mathbf{b}^\top \mathbf{I}\mathbf{b} - \frac{\lambda}{\gamma}\mathbf{b}^\top \mathbf{g}_{(o)} + \frac{\eta}{2}\mathbf{b}^\top \mathbf{1}\mathbf{1}^\top \mathbf{b} - (\eta - \rho_{(o)})\mathbf{b}^\top \mathbf{1} \\ &= \operatorname*{argmin}_{\mathbf{b}} \frac{1}{2}\mathbf{b}^\top \left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)\mathbf{b} + \mathbf{b}^\top \left[\boldsymbol{\varphi}_t - \frac{\lambda}{\gamma}\mathbf{g}_{(o)} - (\eta - \rho_{(o)})\mathbf{1}\right], \end{aligned} \tag{28}$$

where $\mathbf{I}$ is an identity matrix whose dimension can be inferred from the context.

Proposition 1 *There is a unique minimum of (28):*

$$\mathbf{b}_{(o+1)} = \left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)^{-1}\left[\frac{\lambda}{\gamma}\mathbf{g}_{(o)} + (\eta - \rho_{(o)})\mathbf{1} - \boldsymbol{\varphi}_t\right]. \tag{29}$$

Proof We analyze the quadratic form $\left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)$ in (28). Apparently $\frac{\lambda}{\gamma}\mathbf{I}$ is positive definite. It can be shown that $\eta\mathbf{1}\mathbf{1}^\top$ is positive semidefinite:

$$\forall \mathbf{b},\ \eta\mathbf{b}^\top\mathbf{1}\mathbf{1}^\top\mathbf{b} = \eta(\mathbf{b}^\top\mathbf{1})(\mathbf{1}^\top\mathbf{b}) = \eta(\mathbf{b}^\top\mathbf{1})^2 \geqslant 0.$$

Thus the whole quadratic form $\left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)$ is positive definite.

We take the gradient of (28) with respect to $\mathbf{b}$ and let it be a zero vector

$$\left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)\mathbf{b} + \boldsymbol{\varphi}_t - \frac{\lambda}{\gamma}\mathbf{g}_{(o)} - (\eta - \rho_{(o)})\mathbf{1} = \mathbf{0}. \tag{30}$$

Since $\left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)$ is positive definite, the function of (28) is convex and the solution of (30) is the unique minimum

$$\mathbf{b}_{(o+1)} = \left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)^{-1}\left[\frac{\lambda}{\gamma}\mathbf{g}_{(o)} + (\eta - \rho_{(o)})\mathbf{1} - \boldsymbol{\varphi}_t\right].$$

■

Next, we turn to solve (26), which has already been addressed in Section 3.3.1. By excluding all the terms unrelated to $\mathbf{g}$ in (13), we have a Huber vector function

$$H(\mathbf{b}_{(o+1)}) \quad = \quad \min_{\mathbf{g}} \frac{1}{2\gamma}\|\mathbf{b}_{(o+1)} - \mathbf{g}\|^2 + \|\mathbf{g}\|_1. \tag{31}$$

Now we can see that γ balances between the approximation of $\mathbf{g}$ to $\mathbf{b}_{(o+1)}$ and the sparsity of $\mathbf{g}$. When $\gamma \to 0$, $\mathbf{g} \to \mathbf{b}_{(o+1)}$ and the sparse regularization $\|\mathbf{g}\|_1$ will be weaken, vice versa. The minimizer of (31) is a soft shrinkage:

$$\mathbf{g}_{(o+1)} \quad = \quad \text{sign}(\mathbf{b}_{(o+1)}) \otimes (\text{abs}(\mathbf{b}_{(o+1)}) - \gamma\mathbf{1})^+. \tag{32}$$

Next, we implement (27) as a dual ascent step for (13), and turn to the next iteration. We repeat (29)(32)(27) until the equality tolerance $|\mathbf{1}^\top\mathbf{b}_{(o)} - 1| < \epsilon$ or the maximum iteration is reached. Last, $\mathbf{b}_{(o)}$ should be normalized to be a real portfolio output for the next trading period (Duchi et al., 2008):

$$\hat{\mathbf{b}}_{t+1} \quad = \quad \underset{\mathbf{b}\in\Delta_d}{\text{argmin}} \|\mathbf{b} - \zeta\mathbf{b}_{(o)}\|^2, \tag{33}$$

where $\zeta > 0$ is a scale parameter.

We summarize the whole SSPO as Algorithm 1.

ALGORITHM 1: Short-term Sparse Portfolio Optimization (SSPO)

Input: Asset prices in the recent time window $\{\mathbf{p}_{t-k}\}_{k=0}^{w-1}$, the current portfolio $\hat{\mathbf{b}}_t$, parameters w, λ, γ, η, ζ. Set the equality tolerance $\epsilon = 10^{-4}$ and the maximum iteration$= 10^4$.

1. $\mathbf{p}_{MAX}^{(i)} = \max_{0\leqslant k\leqslant w-1} \mathbf{p}_{t-k}^{(i)}$, $i = 1, 2, \cdots, d$.
2. $\boldsymbol{\varphi}_t = -1.1\log\left(\frac{\mathbf{p}_{MAX}}{\mathbf{p}_t}\right) - 1$.
3. Initialize: $o = 1$, $\mathbf{b}_{(1)} = \mathbf{g}_{(1)} = \hat{\mathbf{b}}_t$, $\rho_{(1)} = 0$.

repeat

4. $\mathbf{b}_{(o+1)} = \left(\frac{\lambda}{\gamma}\mathbf{I} + \eta\mathbf{1}\mathbf{1}^\top\right)^{-1}\left[\frac{\lambda}{\gamma}\mathbf{g}_{(o)} + (\eta - \rho_{(o)})\mathbf{1} - \boldsymbol{\varphi}_t\right]$.
5. $\mathbf{g}_{(o+1)} = \text{sign}(\mathbf{b}_{(o+1)}) \otimes (\text{abs}(\mathbf{b}_{(o+1)}) - \gamma\mathbf{1})^+$.
6. $\rho_{(o+1)} = \rho_{(o)} + \eta(\mathbf{1}^\top\mathbf{b}_{(o+1)} - 1)$.
7. $o = o + 1$.

until $|\mathbf{1}^\top\mathbf{b}_{(o)} - 1| < \epsilon$ or $o > Max\_Iter$

8. Normalize: $\hat{\mathbf{b}}_{t+1} = \text{argmin}_{\mathbf{b}\in\Delta_d} \|\mathbf{b} - \zeta\mathbf{b}_{(o)}\|^2$.

Output: The next portfolio $\hat{\mathbf{b}}_{t+1}$.

3.3.3. Sparsity of the Portfolio

We show that our algorithm really produces sparse portfolios. We compute the corresponding portfolio $\mathbf{b}_{t+1}$ by Algorithm 1 without normalization in Step 8 (to verify that the core procedure of the algorithm produces sparse portfolios) and test its sparsity. For a portfolio, we consider the weights which are no larger than 10% of the maximum weight as small weights. Then the sparsity of a portfolio is the proportion of the small weights in all the non-maximum weights:

$$spar = \frac{\#\{small\ weights\}}{d - 1}. \tag{34}$$

We compute the average sparsity of the portfolios of SSPO on each of the 5 experimental data sets NYSE(O) (Cover, 1991), NYSE(N) (Li et al., 2013), DJIA (Borodin et al., 2004), SP500 (Borodin et al., 2004) and TSE (Borodin et al., 2004), and show the results in Table 1. The parameters of SSPO are set in Section 4.1. SSPO achieves high sparsities that are near to or greater than 90% on all the data sets. It indicates that SSPO can produce sparse portfolios. Moreover, these sparse portfolios also achieve good investing performance, which is supported by the experimental results in Section 4.

NYSE(O)	NYSE(N)	DJIA	SP500	TSE
92.91%	89.06%	91.91%	91.36%	94.50%

Table 1: Average sparsity of the portfolios of SSPO on 5 benchmark data sets.

To visualize the sparsity, we randomly choose 6 portfolios (the 2-nd,33-rd,450-th,276-th,127-th and 98-th investing days) of SSPO on the DJIA data set and show them in Figure 1. We can see that the portfolios are sparse and concentrate on only a few assets. For

example, in the first figure, the portfolio weight of the 29-th asset is much larger than other weights. In the second figure, the portfolio weights of the 18-th and the 26-th assets are much larger than other weights. Portfolios on other investing days are also sparse but we need not exhaustively show them all.

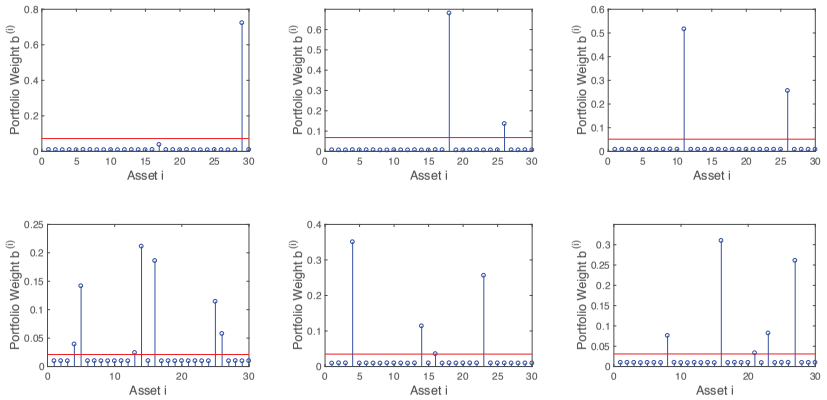

Figure 1: Portfolios produced by SSPO on 6 random investing days (2-nd,33-rd,450-th,276-th,127-th,98-th) of the DJIA data set. The red horizontal line separates small weights from large weights. The portfolios are sparse and concentrate on only a few assets. For example, in the first figure, the portfolio weight of the 29-th asset dominates others. In the second figure, the portfolio weights of the 18-th and the 26-th assets dominate others.

4. Experimental Results

We conduct extensive experiments on 5 benchmark data sets from real-world stock markets: NYSE(O) (Cover, 1991), NYSE(N) (Li et al., 2013), DJIA (Borodin et al., 2004), SP500 (Borodin et al., 2004), and TSE (Borodin et al., 2004). They consist of daily price relatives from New York Stock Exchange, Dow Jones Industrial Average, Standard & Pool 500 and Toronto Stock Exchange, covering a wide range of assets and time spans. Their information is shown in Table 2. To be consistent across the experiments, all the involved returns and increasing factors in this section are daily but not annualized.

We also show the box plots of asset price relatives on the 5 benchmark data sets in Figure 2. Note that if Asset i does not change in price at day (period) t, then $\mathbf{x}_t^{(i)} = \frac{\mathbf{p}_t^{(i)}}{\mathbf{p}_{t-1}^{(i)}} = 1$, which is the standard level of a price relative. The figure shows that all the benchmark data sets have a representative asset pool with diverse characteristics of return and volatility. Hence

Data Set	Region	Time	Days	Stocks
NYSE(O)	US	3/7/1962 ∼ 31/12/1984	5651	36
NYSE(N)	US	1/1/1985 ∼ 30/6/2010	6431	23
DJIA	US	14/1/2001 ∼ 14/1/2003	507	30
SP500	US	2/1/1998 ∼ 31/1/2003	1276	25
TSE	CA	4/1/1994 ∼ 31/12/1998	1259	88

Table 2: Information of 5 benchmark data sets from real-world stock markets.

they are reliable to test the performance of different PO systems in real-world financial environments.

For comparison, 7 state-of-the-art short-term PO systems are evaluated: ONS (Agarwal et al., 2006), CORN, Anticor, PAMR (Li et al., 2012), CWMR (Li et al., 2013), OLMAR and RMR, as well as 2 trivial ones: Beststock and Market. The parameters for these systems are set by the defaults in their original papers and previous experiments (Li and Hoi, 2014; Li et al., 2016, 2015; Huang et al., 2016): ONS: $\eta = 0, \beta = 1, \gamma = \frac{1}{8}$; CORN: $w = 5, P = 1, \rho = 0.1$; Anticor: $w = 5$; PAMR and CWMR: $\epsilon = 0.5$; OLMAR: $w = 5, \epsilon = 10$; RMR: $w = 5, \epsilon = 5$. The parameters for SSPO are set as: $w = 5, \lambda = 0.5, \gamma = 0.01, \eta = 0.005, \zeta = 500$. Note that the window size $w = 5$ is the same with all these systems, to be consistent.

Evaluation protocols mainly fall into 8 indicators: 1. Cumulative wealth (CW): the main score to evaluate investing performance; 2. Mean Excess Return (MER) (Jegadeesh, 1990): the average excess performance of a system compared with the market; 3. α Factor (Lintner, 1965): MER excluding the market risk; 4. Order statistics: the rank of a system return in all the asset returns; 5. Sharpe Ratio (Sharpe, 1966): risk-adjusted average return; 6. Information Ratio (Treynor and Black, 1973): risk-adjusted MER; 7. Transaction costs; 8. Running times. Indicators 1∼3 are investing performance measurements, Indicators 4∼6 are risk metrics, and Indicators 7,8 evaluate the applicability to real-world financial environments. SSPO achieves state-of-the-art results in all these indicators.

4.1. Parameter Setting

We first conduct experiments of the final cumulative wealth (CW) to empirically set the parameters for SSPO, which is similar to Borodin et al. (2004); Li et al. (2011, 2015); Huang et al. (2013, 2016). The final CW is the cumulative product of the actual increasing factors $\{\hat{\mathbf{b}}_t^\top \mathbf{x}_t\}_{t=1}^n$ with the initial wealth $S_0 = 1$.

First, $w = 5$ is a common window size in real-world stock trading, especially in short-term investment. It is also consistent with the compared state-of-the-art methods. Hence it is adopted for SSPO. Second, we fix $w = 5$, $\gamma = 0.01$, $\eta = 0.005$, $\zeta = 500$ and change λ in $0.4 \sim 0.65$. The results in Figure 3 show that $\lambda = 0.5$ leads to good performance in general and thus is set for SSPO. To better show the geometric scaling effect of the daily geometric increasing factor on the final CW, the power form is used to label the y-axis. The base is the daily geometric increasing factor while the exponent is the total number of trading days in the data set.

At each time, we change one parameter and fix other parameters, and the results are shown in Figure 4, Figure 5, and Figure 6. They indicate that $\gamma = 0.01$, $\eta = 0.005$, and $\zeta = 500$ are suitable parameters for SSPO.

of the daily geometric increasing factor on the final CW. The base is the daily geometric increasing factor while the exponent is the total number of trading days in the data set. SSPO achieves the best performance on all the data sets against other state-of-the-art systems. For instance, SSPO achieves a much higher CW (3.68) than OLMAR (2.54) and RMR (2.67) on DJIA which is difficult to handle (Huang et al., 2016). On NYSE(O), NYSE(N) and TSE, SSPO achieves CW= $1.06E{+}18$, $1.62E{+}9$ and 364.94, respectively,

which are much higher than OLMAR ($7.21E{+}16$, $4.14E{+}8$ and 58.51) and RMR ($1.64E{+}17$, $3.25E{+}8$ and 181.34). Therefore, SSPO is an efficient short-term PO system for diverse real-world stock markets. We also plot the CW evolution paths for different PO systems on DJIA in Figure 7. On most days, the SSPO plot is over other systems, and it climbs up significantly when there are good opportunities.

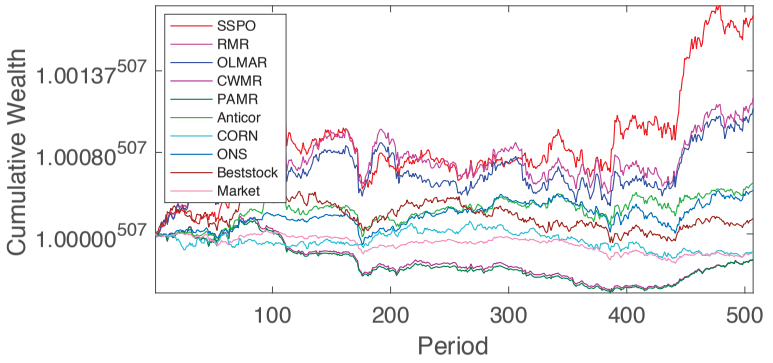

Figure 7: Cumulative wealth evolution paths of portfolio optimization systems on DJIA. The length of one period is one day.

4.3. Mean Excess Return

At the end of each day, we want to know what proportion of total wealth gained or lost on this day. This concept can be represented by the term "return": $r_t = \hat{\mathbf{b}}_t^\top \mathbf{x}_t - 1$.

Mean Excess Return (MER) (Jegadeesh, 1990) is the average daily excess return of a system compared with the market in the long run:

$$MER = \bar{r}_s - \bar{r}_m = \frac{1}{n}\sum_{t=1}^{n}(r_{s,t} - r_{m,t}), \tag{35}$$

where $r_{s,t}$ and $r_{m,t}$ are daily returns of a PO system and the market on the t-th day, respectively. It is more worthy of implementing a PO system with a higher MER. Even a small difference of MER leads to a large gap of CW in the long run, due to the geometric scaling effect.

We present the MERs for different PO systems in Table 4. SSPO outperforms other state-of-the-art systems on all the data sets. For instance, the MERs of SSPO (0.0036 and 0.0060) are much higher than those of OLMAR (0.0028 and 0.0045) and RMR (0.0029 and 0.0053) on DJIA and TSE, respectively. This is the reason why SSPO outperforms other systems in cumulative wealth in the long run.

System	NYSE(O)	NYSE(N)	DJIA	SP500	TSE

Table 4: Mean excess returns of portfolio optimization systems on 5 benchmark data sets.

4.4. α Factor

According to the Capital Asset Pricing Model (CAPM) (Sharpe, 1964), the expected return of a system can be decomposed into 2 parts: the market return component, and the intrinsic excess return usually called the α Factor in the finance industry (Lintner, 1965). The former is determined by the market environment, which cannot be improved by any active investing strategy or PO system, while the latter can be improved by a good PO system. The α Factor can be represented as follows:

$$E(r_s) = \beta E(r_m) + \alpha, \tag{36}$$

$$\hat{\beta} = \frac{\hat{c}(r_s, r_m)}{\hat{\sigma}^2(r_m)}, \quad \hat{\alpha} = \bar{r}_s - \hat{\beta}\bar{r}_m, \tag{37}$$

where $E(\cdot)$ denotes the mathematical expectation, $\hat{c}(\cdot,\cdot)$ and $\hat{\sigma}(\cdot)$ are the sample covariance and the sample standard deviation (STD) computed on n trading days, respectively. In finance, STD is a common tool to measure risk (volatility).

The α Factors of different PO systems are given in Table 5. SSPO outperforms other PO systems on all the data sets, indicating that SSPO achieves high intrinsic excess returns despite the market volatility. Particularly on DJIA data set which is difficult to handle, SSPO achieves $\alpha = 0.0037$, which is much higher than OLMAR (0.0029) and RMR (0.0030).

In the real-world portfolio management, it is common to perform a right-tailed t-test to see whether α is significantly > 0. If so, it indicates that the good performance of the system is not due to luck (Grinold and Kahn, 1999; Li et al., 2015; Huang et al., 2013, 2016). According to the results in Table 5, SSPO achieves significantly better performance than the market at a high confidence level of 99% (with all p-values < 0.01).

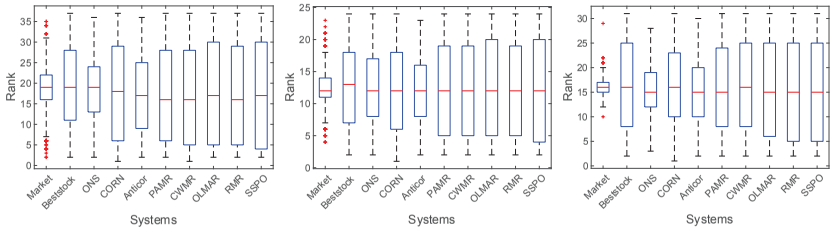
Table 5: α factors (with p-values of t-tests) of portfolio optimization systems on 5 benchmark data sets.

4.5. Order Statistics

One may worry about that a PO system just simply selects the lucky assets with the highest growth. To check this point, we can compare the system return $r_{s,t} = \hat{\mathbf{b}}_t^\top \mathbf{x}_t - 1$ with all the asset returns $r_t^{(i)} = \mathbf{x}_t^{(i)} - 1$, $i = 1, \cdots, d$ (d is the number of assets in a data set). By sorting the $(d+1)$ returns $\{r_{s,t}\} \bigcup \{r_t^{(i)}\}_{i=1}^d$ in the descending order, we can obtain the rank of $r_{s,t}$. If a PO system always chooses the lucky assets, then $r_{s,t}$ will always rank very high in the investment.

We give a summary description of the rank of $r_{s,t}$ in the whole investment (n days) on each data set for different PO systems, shown in Figure 8 and Table 6. It can be seen that the ranks for SSPO cover a wide range instead of concentrating on the highest ranks. Besides, the mean rank and the median rank of SSPO are close to the middle rank $(d+1)/2$ on each data set, indicating that SSPO is at the average return level of all the asset returns. Furthermore, the rank results of SSPO are similar to other state-of-the-art short-term PO systems, which means that SSPO has a similar return level to the related systems. To summarize, SSPO does not simply select the lucky assets with the highest growth and its returns are credible. Note that this rank test is different from the rank-dependent portfolio (Fernholz, 2002) that takes the rank information as prior knowledge and exploits it to formulate PO models.



(a) NYSE(O) (b) NYSE(N) (c) DJIA

SSPO	17	17.71	12	12.25	15	15.25	12	13.33	44	43.03

Table 6: Medians and means of the ranks for the system returns $r_{s,t}$ on 5 benchmark data sets. The value of $(d+1)$ is also given behind each data set name. The mean rank and the median rank of SSPO are close to the middle rank $(d+1)/2$ on each data set, which indicates that SSPO does not simply select the lucky assets with the highest growth.

4.6. Sharpe Ratio

In general, when an investor pursues high return, he/she should be ready to undertake high risk. Thus he/she has to balance between return and risk all the time. Sharpe Ratio (SR) (Sharpe, 1966) is such a measurement to meet this demand based on CAPM:

$$SR = \frac{\bar{r}_s - r_f}{\hat{\sigma}(r_s)}, \tag{38}$$

where r_f is the daily return of some risk-free asset, which is not considered in this paper. Hence we set $r_f = 0$ to make SR a daily risk-adjusted return.

We compute and present the daily SRs of different PO systems in Table 7. SSPO achieves the highest SR on NYSE(N) and DJIA, and is close to the best system on other data sets. Besides, SSPO is competitive to OLMAR and RMR. For example, SSPO achieves $SR = 0.0791$ on SP500 compared with RMR (0.0659), and achieves $SR = 0.1054$ on TSE compared with OLMAR (0.0820). It indicates that SSPO has a good ability in balancing between return and risk on the premise of good investing achievement with high CWs.

Table 7: Daily Sharpe Ratios (SR) and daily Information Ratios (IR) of portfolio optimization systems on 5 benchmark data sets.

4.7. Information Ratio

Different from SR, Information Ratio (IR) (Treynor and Black, 1973) directly measures the daily risk-adjusted excess return of a system compared with the market, which can be seen as a combination of MER and SR. It is also worth reference for the concern with risk.

$$IR = \frac{(\bar{r}_s - \bar{r}_m)}{\hat{\sigma}(r_s - r_m)}. \tag{39}$$

We compute the daily IRs of different PO systems in Table 7. SSPO achieves the highest IR on NYSE(N) and is close to the best system on other data sets. Moreover, SSPO is competitive to OLMAR and RMR. For example, SSPO achieves $IR = 0.0840, 0.1009$ on SP500 and TSE, respectively, while RMR achieves $IR = 0.0678$ on SP500 and OLMAR achieves $IR = 0.0769$ on TSE. It shows the robustness of SSPO to risk on the premise of good investing performance.

4.8. Transaction Costs

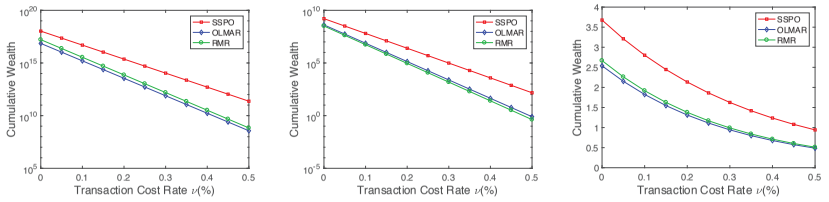
In practice, transaction cost is an important issue in PO. Suppose we have to pay at a transaction cost rate $\nu \in (0,1)$ to update the portfolio. Then according to the proportional transaction cost model (Blum and Kalai, 1999; Li et al., 2015; Huang et al., 2016), the cumulative wealth at the beginning of the t-th day is

$$S_n^\nu = S_0 \prod_{t=1}^{n} [(\hat{\mathbf{b}}_t^\top \mathbf{x}_t) \cdot (1 - \frac{\nu}{2} \sum_{i=1}^{d} |\hat{\mathbf{b}}_t^{(i)} - \tilde{\mathbf{b}}_{t-1}^{(i)}|)], \tag{40}$$

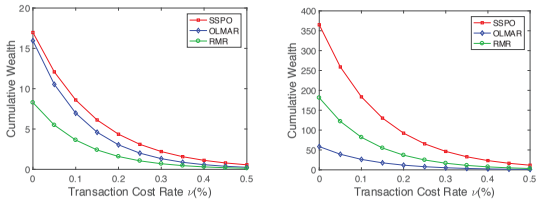
$$\tilde{\mathbf{b}}_{t-1}^{(i)} = \frac{\hat{\mathbf{b}}_{t-1}^{(i)} \cdot \mathbf{x}_{t-1}^{(i)}}{\hat{\mathbf{b}}_{t-1}^\top \mathbf{x}_{t-1}}, \tag{41}$$

where $\tilde{\mathbf{b}}_{t-1}^{(i)}$ denotes the adjusted portfolio of Asset i at the end of the $(t-1)$-th day and $\tilde{\mathbf{b}}_0$ is set as $[0, \cdots, 0]^\top$. $\frac{\nu}{2} \sum_{i=1}^{d} |\hat{\mathbf{b}}_t^{(i)} - \tilde{\mathbf{b}}_{t-1}^{(i)}|$ is the proportional transaction cost when we change the adjusted portfolio $\tilde{\mathbf{b}}_{t-1}$ to the next portfolio $\hat{\mathbf{b}}_t$.

To test the effectiveness of SSPO with consideration of transaction cost, we conduct experiments of cumulative wealth with $\nu = 0 \sim 0.5\%$, where $\nu = 0.5\%$ is a rather high cost rate for stock transactions. The results shown in Figure 9 indicate that SSPO outperforms the two state-of-the-art systems OLMAR and RMR on all the data sets and thus it is applicable to real-world financial environments.



(a) NYSE(O) (b) NYSE(N) (c) DJIA



(d) SP500 (e) TSE

Figure 9: Cumulative wealths of portfolio optimization systems with respect to the transaction cost rate ν on 5 benchmark data sets.

4.9. Running Times

We use a computer with an AMD A10-7800 CPU and an 8GB DDR3 1600MHz memory card to run SSPO in the experiments, which shows that it is sufficiently fast for large-scale and time-limited trading environments such as High-Frequency Trading (HFT) (Aldridge, 2013). The average running times (in seconds) of SSPO for one trade on different data sets are: NYSE(O) (0.0576s), NYSE(N) (0.0450s), DJIA (0.0455s), SP500 (0.0449s), and TSE (0.1190s). Hence SSPO has good computational efficiency besides significant investing advantage.

5. Conclusions

We present a novel short-term sparse portfolio optimization (SSPO) system to concentrate wealth on a few assets with good increasing potential according to some empirical financial principles. Few short-term PO systems construct sparse portfolios, and most existing sparsity systems are either lazy updates or for the long-term PO. These problems motivate the design of SSPO. We further propose an ADMM algorithm for SSPO, and prove that its augmented Lagrangian has a saddle point. This is the foundation of the iterative formulae of ADMM but is seldom addressed before.

We conduct extensive experiments on 5 benchmark data sets with diverse real-world stock data, which shows that SSPO outperforms other state-of-the-art short-term PO systems with all the investing performance measurements (cumulative wealth, mean excess return and α Factor) on all the benchmark data sets. The order statistics of the SSPO returns also indicate that SSPO does not simply select the lucky assets with the highest growth and its returns are credible. SSPO is also competitive to other systems on the risk metrics SR and IR, and shows robustness in balancing between return and risk. Furthermore, SSPO can withstand reasonable transaction costs and runs fast, thus it is applicable to real-world financial environments including High-Frequency Trading. Therefore, SSPO is an effective and robust system that is worth further investigations. In the future, we will continue to establish more complex SSPO systems, so as to improve the investing performance and the robustness to risk.

Abstract

There has been considerable interest in making Bayesian inference more scalable. In big data settings, most of the focus has been on reducing the computing time per iteration rather than reducing the number of iterations needed in Markov chain Monte Carlo (MCMC). This article considers data augmentation MCMC (DA-MCMC), a widely used technique. DA-MCMC samples tend to become highly autocorrelated in large samples, due to a mis-calibration problem in which conditional posterior distributions given augmented data are too concentrated. This makes it necessary to collect very long MCMC paths to obtain acceptably low MC error. To combat this inefficiency, we propose a family of calibrated data augmentation algorithms, which appropriately adjust the variance of conditional posterior distributions. A Metropolis-Hastings step is used to eliminate bias in the stationary distribution of the resulting sampler. Compared to existing alternatives, this approach can dramatically reduce MC error by reducing autocorrelation and increasing the effective number of DA-MCMC samples per unit of computing time. The approach is simple and applicable to a broad variety of existing data augmentation algorithms. We focus on three popular generalized linear models: probit, logistic and Poisson log-linear. Dramatic gains in computational efficiency are shown in applications.

Keywords: Bayesian Probit, Biased subsampling, Big n, Data augmentation, Log-linear model, Logistic regression, Maximal correlation, Polya-Gamma

1. Introduction

With the deluge of data in many modern application areas, there is pressing need for scalable computational algorithms for inference from such data, including uncertainty quantification (UQ). Somewhat surprisingly, even as the volume of data increases, uncertainty often remains sizable. Examples in which this phenomenon occurs include financial fraud detection (Ngai et al., 2011), disease mapping (Wakefield, 2007) and online click-through tracking (Wang et al., 2010). Bayesian approaches provide a useful paradigm for quantifying uncertainty in these and other settings.

The standard approach to Bayesian posterior computation is Markov chain Monte Carlo (MCMC) and related sampling algorithms. However, conventional MCMC algorithms often scale poorly in problem size and complexity. Due to its sequential nature, the computational cost of MCMC is the product of two factors: the evaluation cost at each sampling iteration and the total number of iterations needed to obtain an acceptably low Monte Carlo (MC) error. While a substantial literature has developed focusing on decreasing computational cost per iteration in "big data" (large sample) settings (Minsker et al. (2017); Maclaurin and Adams (2015); Srivastava et al. (2015); Conrad et al. (2016) among others), there has been less focus on reducing the required number of MCMC iterations. This contrasts with a historical focus in the statistics and probability literature on improving mixing and convergence of MCMC in more traditional small to moderate sample size problems, and suggests the opportunity for improved performance in big data settings through a renewed focus on improving mixing.

A major concern in applying MCMC algorithms in big data problems is that the level of autocorrelation in the MCMC path may increase with the size of the data. Markov chains with high autocorrelation have low *effective sample size (ESS)* per unit computational time, which we refer to informally as the *slow mixing* problem. The ESS compares the asymptotic variance of the MCMC time averaging estimate to a gold standard Monte Carlo algorithm that collects independent samples. For example, if the number of effective samples in 1,000 MCMC iterations is only 10, then the MCMC algorithm will need to be run 100 times as long as an ordinary MC algorithm to obtain the same MC error for time averages. Such a scenario is not unusual in big data problems, leading MCMC algorithms to face a *double burden*, with the time per iteration increasing and it becoming necessary to collect more iterations as sample size increases.

This double burden has led many members of the machine learning community to abandon MCMC in favor of more easily scalable alternatives, such as variational approximations. Unfortunately, these approaches typically lack theoretical guarantees and often badly underestimate posterior uncertainty. Hence, there has been substantial interest in recent years in designing scalable MCMC algorithms. The focus of this paper is a popular and broad class of Data Augmentation (DA)-MCMC algorithms. DA-MCMC algorithms are used routinely in many classes of models, with the algorithms of Albert and Chib (1993) for probit models and Polson et al. (2013) for logistic models being particularly popular. Our focus is on improving the performance of such algorithms in big data settings in which poor scalability occurs both because of high cost per iteration and deterioration of mixing as sample size increases. We focus here on the slow mixing problem.

Johndrow et al. (2018) demonstrate that popular DA-MCMC algorithms have small effective sample sizes in large data settings involving imbalanced data. For example, data may be binary with a high proportion of zeros. A key insight is that this problem results from a discrepancy in the rates at which Gibbs step sizes and the width of the high-probability region of the posterior converge to zero as n increases. In particular, the conditional posterior given the augmented data may simply be too concentrated relative to the marginal posterior, with this problem amplified as the data sample size increases. There is a rich literature on methods for accelerating mixing in DA-MCMC algorithms using tricks ranging from reparameterization to parameter-expansion (Liu and Wu, 1999; Meng and Van Dyk, 1999; Papaspiliopoulos et al., 2007). However, we find that such approaches fail to address the miscalibration problem and have no impact on the worsening mixing rate with increasing data sample size n.

This article proposes a general new class of algorithms that addresses the miscalibration of step sizes in DA. The idea underlying these *calibrated* DA (CDA) algorithms is to introduce auxiliary parameters that change the variance of full conditional distributions for one or more parameters. These auxiliary parameters can adapt with the data sample size n to correct the typical step sizes of the CDA algorithm to match the rate at which the high probability region of the posterior contracts as n increases. In general, the invariant measure of CDA-MCMC – which typically does exist and is unique – differs from the posterior of interest. Thus, CDA-MCMC is a computationally more efficient perturbation of the original Markov chain, and the bias can be eliminated using Metropolis-Hastings. Compared to other adaptive Metropolis-Hastings algorithms, which often require carefully chosen multivariate proposals and complicated adaptation with multiple chains (Tran et al., 2016), CDA-MCMC only requires a simple modification to Gibbs sampling steps to generate proposals. We show the auxiliary parameters can be efficiently adapted for each type of data augmentation via minimizing the difference between Fisher information of conditional and marginal distributions.

2. Calibrated Data Augmentation

Data augmentation Gibbs samplers alternate between sampling latent data z from their conditional posterior distribution given model parameters θ and observed data y, and sampling parameters θ given z and y; either of these steps can be further broken down into a series of full conditional sampling steps but we focus for simplicity on algorithms of the form:

$$\begin{aligned} z \mid \theta, y &\sim \pi(z; \theta, y) \\ \theta \mid z, y &\sim f(\theta; z, y), \end{aligned} \tag{1}$$

where f belongs to a location-scale family, such as the Gaussian. Popular data augmentation algorithms are designed so that both of these sampling steps can be conducted easily and efficiently; e.g., sampling the latent data for each subject independently and then drawing θ simultaneously (or at least in blocks) from a multivariate Gaussian or other standard distribution. This effectively avoids the need for tuning, which is a major issue for Metropolis-Hastings algorithms, particularly when θ is high-dimensional. Data augmentation algorithms are particularly common for generalized linear models (GLMs), with

$\mathbb{E}(y_i \mid x_i, \theta) = g^{-1}(x_i\theta)$ and a conditionally Gaussian prior distribution chosen for θ. We focus in particular on Poisson log-linear, binomial logistic, and binomial probit as motivating examples.

Consider a Markov kernel $K((\theta, z); \cdot)$ with invariant measure Π and update rule of the form (1), and a Markov chain (θ_t, z_t) on a state space $\Theta \times \mathcal{Z}$ evolving according to K. We will abuse notation in writing $\Pi(d\theta) = \int_{z\in\mathcal{Z}} \Pi(d\theta, dz)$. The lag-1 autocorrelation for a function $h : \Theta \to \mathbb{R}$ at stationarity can be expressed as the Bayesian fraction of missing information (Papaspiliopoulos et al. (2007), Rubin (2004), Liu (1994b))

$$\gamma_g = 1 - \frac{\mathbb{E}[\text{var}(h(\theta) \mid z)]}{\text{var}(h(\theta))}, \tag{2}$$

where the integrals in the numerator are with respect to $\Pi(d\theta, dz)$ and in the denominator with respect to $\Pi(d\theta)$. Let

$$L_2(\Pi) = \left\{ h : \Theta \to \mathbb{R}, \int_{\theta\in\Theta} \{h(\theta)\}^2 \Pi(d\theta) < \infty \right\}$$

be the set of real-valued, Π square-integrable functions. The *maximal autocorrelation*

$$\gamma = \sup_{h\in L_2(\Pi)} \gamma_h = 1 - \inf_{h\in L_2(\Pi)} \frac{\mathbb{E}[\text{var}(h(\theta) \mid z)]}{\text{var}(h(\theta))}$$

is equal to the geometric convergence rate of the data augmentation Gibbs sampler (Liu (1994b)). For $h(\theta) = \theta_j$ a coordinate projection, the numerator of the last term of (2) is, informally, the average squared step size for the augmentation algorithm at stationarity in direction j, while the denominator is the squared width of the bulk of the posterior in direction j. Consequently, γ will be close to 1 whenever the average step size at stationarity is small relative to the width of the bulk of the posterior.

The purpose of CDA is to introduce additional parameters that allow us to control the step size relative to the posterior width – roughly speaking, the ratio in (2) – with greater flexibility than reparametrization or parameter expansion. The flexibility gains are achieved by allowing the invariant measure to change as a result of the introduced parameters. The additional parameters, which we denote (r, b), correspond to a collection of reparametrizations, each of which defines a proper (but distinct) likelihood $L_{r,b}(\theta; y)$, and for which there exists a Gibbs update rule of the form (1). In general, r is a vector of scale parameters that are tuned to increase $\mathbb{E}[\text{var}(h(\theta) \mid z)]\{\text{var}(h(\theta))\}^{-1}$ – usually for coordinate projections $h(\theta) = \theta_j$ – although the exact way in which they enter the likelihood and corresponding Gibbs update depend on the application; b are location parameters that shift the high posterior region of $L_{r,b}(\theta; y)$ to better approximate $L(\theta; y)$. The reparametrization also has the property that $L_{1,0}(\theta; y) = L(\theta; y)$, the original likelihood. The resulting Gibbs sampler, which we refer to as CDA Gibbs, has θ-marginal invariant measure $\Pi_{r,b}(\theta; y) \propto L_{r,b}(\theta; y)\Pi^0(\theta)$, where $\Pi^0(\theta)$ is the prior. Ultimately, we are interested in $\Pi_{1,0}(\theta; y)$, so we use CDA Gibbs as an efficient proposal for Metropolis-Hastings. That is, we propose θ^* from $q(\theta^*; \theta)$ with

$$q(\theta^*; \theta) = \int_{z\in\mathcal{Z}} \pi_{r,b}(z; \theta, y) f_{r,b}(\theta^*; z, y) dz, \tag{3}$$

where $\pi_{r,b}$ and $f_{r,b}$ denote the conditional densities of z and θ in the Gibbs sampler with invariant measure $\Pi_{r,b}$. By tuning (r, b) during an adaptation phase to reduce the autocorrelations and increase the Metropolis-Hastings acceptance rate, we can obtain a computationally efficient algorithm. Tuning is facilitated by the fact that the MH acceptance ratios using this proposal kernel have a convenient form, which is a nice feature of using Gibbs to generate MH proposals.

Remark 1 *The CDA MH acceptance ratio is given by*

$$\begin{aligned}\alpha(\theta, \theta^*) &= \min\left\{1, \frac{L(\theta^*; y)\Pi^0(\theta^*)q(\theta; \theta^*)}{L(\theta; y)\Pi^0(\theta)q(\theta^*; \theta)}\right\} \\ &= \min\left\{1, \frac{L(\theta^*; y)L_{r,b}(\theta; y)}{L(\theta; y)L_{r,b}(\theta^*; y)}\right\}. \end{aligned} \tag{4}$$

A general strategy for tuning is given in Section 4.

We give a basic convergence guarantee that holds for CDA MH under weak assumptions on $L_{r,b}$, which is based on Roberts and Smith (1994). Basically, one needs $\Pi(\cdot) \ll \Pi_{r,b}(\cdot)$ for all r, b, where for two probability measures μ, ν, $\mu(\cdot) \ll \nu(\cdot)$ means μ is absolutely continuous with respect to ν.

Remark 2 (Ergodicity) *Assume that $\Pi(d\theta)$ and $\Pi_{r,b}(d\theta)$ have densities with respect to Lebesgue measure on $\mathbb{R}^p$, and that $K_{r,b}((\theta, z); (\theta', z')) > 0 \,\forall\, ((\theta, z), (\theta', z')) \in (\Theta \times \mathcal{Z}) \times (\Theta \times \mathcal{Z})$. Then,*

- *For fixed r, b, CDA Gibbs is ergodic with invariant measure $\Pi_{r,b}(d\theta, dz)$.*
- *A Metropolis-Hastings algorithm with proposal kernel $q_{r,b}(\theta'; \theta)$ as defined in (3) with fixed r, b is ergodic with invariant measure $\Pi(d\theta)$.*

Proofs are located in the Appendix.

2.1. Initial Example: Probit with Intercept Only

To illustrate the CDA algorithm, we first present a toy example of the probit regression with intercept only.

$$y_i \sim \text{Bernoulli}(p_i), \quad p_i = \Phi(\theta) \quad i = 1, \ldots, n$$

and improper prior $\Pi^0(\theta) \propto 1$. The data augmentation algorithm (Tanner and Wong, 1987; Albert and Chib, 1993) is based on the following integral

$$L(y_i; \theta) = \begin{cases} \int_0^\infty f(z_i; \theta, 1)dz_i & \text{if } y_i = 1 \\ \int_{-\infty}^0 f(z_i; \theta, 1)dz_i & \text{if } y_i = 0 \end{cases} \qquad i = 1, \ldots, n$$

where $f(z; \mu, \sigma^2)$ is the density for normal distribution $\text{No}(\mu, \sigma^2)$.

This leads to the update rule

$$z_i \mid \theta, y_i \sim \begin{cases} \text{No}_{[0,\infty)}(\theta, 1) & \text{if } y_i = 1 \\ \text{No}_{(-\infty,0]}(\theta, 1) & \text{if } y_i = 0 \end{cases} \qquad i = 1, \ldots, n$$

$$\theta \mid z, y \sim \text{No}\left(n^{-1}\sum_i z_i, n^{-1}\right),$$

where the subscript in $\text{No}_{[a,b]}(\mu, \sigma^2)$ denotes the truncation to the interval $[a, b]$. Johndrow et al. (2018) show that when $\sum_i y_i = 1$, $\text{var}(\theta_t \mid \theta_{t-1})$ is approximately $n^{-1}\log n$, while the width of the high probability region of the posterior is order $(\log n)^{-1}$, leading to slow mixing.

We introduce a scale parameter r_i in the update for z_i, and adjust the conditional mean by a location parameter b_i. This is equivalent to changing the scale of $z_i \mid \theta, y_i$ from 1 to r_i and the mean from θ to $\theta + b_i$. These adjustments yield

$$\begin{aligned}\Pr(y_i = 1|\theta, r_i, b_i) &= \int_0^\infty \frac{1}{\sqrt{2\pi r_i}} \exp\left(-\frac{(z_i - \theta - b_i)^2}{2r_i^2}\right) dz_i \\ &= \Phi\left(\frac{\theta + b_i}{\sqrt{r_i}}\right). \end{aligned} \tag{5}$$

In this simple example, we set the tuning parameters to be all the same: $r_i = r_0$ and $b_i = b_0$ over $i = 1, \ldots, n$, with r_0 and b_0 two scalars. This leads to the modified data augmentation algorithm

$$\begin{aligned} z_i \mid \theta, y_i &\sim \begin{cases} \text{No}_{[0,\infty)}(\theta + b_0, r_0) & \text{if } y_i = 1 \\ \text{No}_{(-\infty,0]}(\theta + b_0, r_0) & \text{if } y_i = 0 \end{cases} \qquad i = 1, \ldots, n \\ \theta \mid z, y &\sim \text{No}\left(n^{-1}\sum_i (z_i - b_0), n^{-1}r_0\right). \end{aligned} \tag{6}$$

To achieve step sizes consistent with the width of the high posterior probability region, we need $n^{-1}r_0 \approx (\log n)^{-1}$, so $r_0 \approx n/\log n$. To preserve the original target, we use (6) to generate an MH proposal θ^*. By Remark 1, the MH acceptance probability is given by (4) with $L_{r,b}(\theta; y_i) = \Phi\big((\theta + b_0){r_0}^{-1/2}\big)^{y_i}\Phi\big(-(\theta + b_0){r_0}^{-1/2}\big)^{(1-y_i)}$ and $L(\theta; y_i) = L_{1,0}(\theta; y_i)$. Setting $r_0 = 1$ and $b_0 = 0$ leads to acceptance rate of 1, which corresponds to the original Gibbs sampler.

To illustrate, we consider $\sum_i y_i = 1$ and $n = 10^4$. Letting $r_0 = n/\log n$, we then choose b_0 to increase the acceptance rate in the MH step. In this simple example, it is easy to compute a "good" value of b_0, since $b_0 = -3.7(\sqrt{r} - 1)$ results in $\Pr(y_i = 1) = \Phi(-3.7) = n^{-1}\sum_i y_i \approx 10^{-4}$ in the proposal distribution, centering the proposals near the MLE for p_i.

We perform computation for these data with different values of r_0 ranging from $r_0 = 1$ to $r_0 = 5,000$, with $r_0 = 1,000 \approx n/\log n$ corresponding to the theoretically optimal value. Figure 1(a) plots autocorrelation functions (ACFs) for these different samplers without MH adjustment. Autocorrelation is very high even at lag 40 for $r_0 = 1$, while increasing r_0 leads to dramatic improvements in mixing. There are no further gains in increasing r_0 from the theoretically optimal value of $r_0 = 1,000$ to $r_0 = 5,000$. Figure 1(b) shows kernel-smoothed density estimates of the posterior of θ without MH adjustment for different values of r_0 and based on long chains to minimize the impact of Monte Carlo error; the posteriors are all centered on the same values but with variance increasing somewhat with r_0. With MH adjustment such differences are removed; the MH step has acceptance probability close to one for $r_0 = 10$ and $r_0 = 100$, about 0.6 for $r_0 = 1,000$, and 0.2 for $r_0 = 5,000$.

We also study a common hierarchical Gaussian example in appendix C.

3. Specific Algorithms

In this section, we describe CDA algorithms for general probit and logistic regression.

3.1. Probit Regression

Consider the probit regression:

$$y_i \sim \text{Bernoulli}(p_i), \quad p_i = \Phi(x_i\theta) \quad i = 1, \ldots, n$$

with improper prior $\Pi^0(\theta) \propto 1$. The data augmentation sampler (Tanner and Wong, 1987; Albert and Chib, 1993) has the update rule

$$\begin{aligned} z_i \mid \theta, x_i, y_i &\sim \begin{cases} \text{No}_{[0,\infty)}(x_i\theta, 1) & \text{if } y_i = 1 \\ \text{No}_{(-\infty,0]}(x_i\theta, 1) & \text{if } y_i = 0 \end{cases} \quad i = 1, \ldots, n \\ \theta \mid z, x, y &\sim \text{No}((X'X)^{-1}X'z, (X'X)^{-1}). \end{aligned}$$

Liu and Wu (1999) and Meng and Van Dyk (1999), among others, previously studied this algorithm and proposed to rescale θ through parameter expansion. However, this modification does not impact the conditional variance of θ and thus does not directly increase typical step sizes.

Our approach is fundamentally different, since we directly adjust the conditional variance. Similar to the intercept only model, we modify $\text{var}(\theta|z)$ by changing the scale of each z_i. This yields the update rule

$$\begin{aligned} z_i \mid \theta, x_i, y_i &\sim \begin{cases} \text{No}_{[0,\infty)}(x_i\theta + b_i, r_i) & \text{if } y_i = 1 \\ \text{No}_{(-\infty,0]}(x_i\theta + b_i, r_i) & \text{if } y_i = 0 \end{cases} \quad i = 1, \ldots, n \\ \theta \mid z, X &\sim \text{No}((X'R^{-1}X)^{-1}X'R^{-1}(z-b), (X'R^{-1}X)^{-1}), \end{aligned} \tag{7}$$

where $R = \text{diag}(r_1, \ldots, r_n)$, $b = (b_1, \ldots, b_n)'$. Under the Bernoulli likelihood, we have

$$\Pr(y_i = 1|\theta, x_i, r_i, b_i) = \int_0^\infty \frac{1}{\sqrt{2\pi r_i}} \exp\left(-\frac{(z_i - x_i\theta - b_i)^2}{2r_i}\right) dz_i$$

$$= \Phi\left(\frac{x_i\theta + b_i}{\sqrt{r_i}}\right). \tag{8}$$

For fixed $r = (r_1, \ldots, r_n)$ and $b = (b_1, \ldots, b_n)$, (8) defines a proper Bernoulli likelihood for y_i conditional on parameters, and therefore the transition kernel $Q_{r,b}((\theta, z); \cdot)$ defined by the Gibbs update rule in (7) would have a unique invariant measure for fixed r, b, which we denote $\Pi_{r,b}(\theta, z \mid y)$.

For insight into the relationship between r and step size, consider the θ-marginal autocovariance in a Gibbs sampler evolving according to $K_{r,b}$

$$\begin{aligned} &\text{cov}_{r,b}(\theta_t \mid \theta_{t-1}, X, z, y) \\ =&(X'R^{-1}X)^{-1} + (X'R^{-1}X)^{-1}X'R^{-1}\text{cov}(z - b|R)R^{-1}X(X'R^{-1}X)^{-1} \\ \geq&(X'R^{-1}X)^{-1}. \end{aligned}$$

In the special case where $r_i = r_0$ for all i, we have

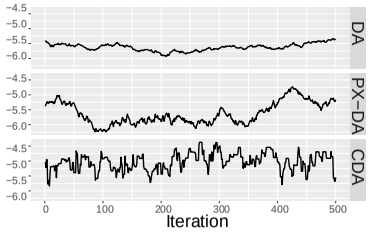
$$\text{cov}_{r,b}(\theta_t \mid \theta_{t-1}, X, z, y) \geq r_0(X'X)^{-1},$$

so that all of the conditional variances are increased by at least a factor of r_0. This holds uniformly over the entire state space, so it follows that

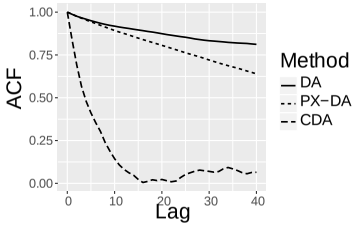
$$\mathbb{E}_{\Pi_{r,b}}[\text{var}(\theta_j \mid z)] \geq r_0\mathbb{E}_{\Pi}[\text{var}(\theta_j \mid z)].$$

The key to CDA is to choose r, b to make $\mathbb{E}_{\Pi_{r,b}}[\text{var}(\theta_j \mid z)]$ close to $\text{var}_{\Pi_{r,b}}(\theta_j \mid z)$, while additionally maximizing the MH acceptance probability. We defer the details of tuning algorithm for r, b to the next section.

For illustration, we consider a simulation study for probit regression with an intercept and two predictors $x_{i,1}, x_{i,2} \sim \text{No}(1, 1)$, with $\theta = (-5, 1, -1)'$, generating $\sum_i y_i \approx 20$ among $n = 10,000$. The Albert and Chib (1993) DA algorithm mixes slowly (Figure 2(a) and 2(b)). We also show the results of the parameter expansion algorithm (PX-DA) proposed by Liu and Wu (1999). PX-DA only mildly reduces the correlation, as it does not solve the small step size problem. After tuning, CDA reaches a satisfactory acceptance rate of 0.6 and leads to dramatically better mixing.



(a) Traceplot for the original DA, parameter expanded DA and CDA algorithms.



(b) ACF for original DA, parameter expanded DA and CDA algorithms.

Figure 2: Panel (a) demonstrates in traceplot and panel (b) in autocorrelation the substantial improvement in CDA by correcting the variance mis-match in probit regression with rare event data, compared with the original (Albert and Chib, 1993) and parameter-expanded methods (Liu and Wu, 1999).

3.2. Logistic Regression

In the second example, we focus on the logistic regression model with

$$y_i \sim \text{Bernoulli}(p_i), \quad p_i = \frac{\exp(x_i\theta)}{1+\exp(x_i\theta)} \quad i = 1, \ldots, n \tag{9}$$

and improper prior $\Pi^0(\theta) \propto 1$. For this model, Polson et al. (2013) proposed Polya-Gamma data augmentation:

$$\begin{aligned} z_i &\sim \text{PG}(1, |x_i\theta|) \quad i = 1, \ldots, n, \\ \theta &\sim \text{No}\left((X'ZX)^{-1}X'(y-0.5), (X'ZX)^{-1}\right), \end{aligned}$$

where $Z = \text{diag}(z_1, \ldots, z_n)$. This algorithm relies on expressing the logistic regression likelihood as

$$L(x_i\theta; y_i) = \int_0^\infty \exp\{x_i\theta(y_i - 1/2)\} \exp\left\{-\frac{z_i(x_i\theta)^2}{2}\right\} \text{PG}(z_i \mid 1, 0) dz_i,$$

where $\text{PG}(a_1, a_2)$ denotes the density of the Polya-Gamma distribution with parameters a_1, a_2, with $\mathbb{E}z_i = a_1/(2a_2)\tanh(a_2/2)$.

Since our goal is to increase the conditional variance $(X'ZX)^{-1}$, we can achieve this stochastically by reducing the mean $\mathbb{E}z_i$. We replace $\text{PG}(z_i \mid 1, 0)$ with $\text{PG}(z_i \mid r_i, 0)$ in the step for updating the latent data. Adding the location term b_i to the linear predictor $\eta_i = x_i\theta$ leads to

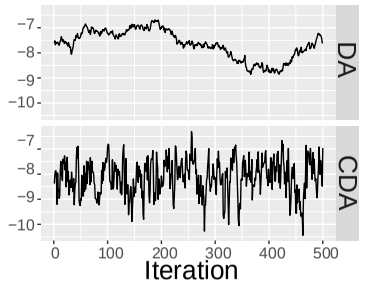
$$\begin{aligned} L_{r,b}(x_i\theta; y_i) &= \int_0^\infty \exp\{(x_i\theta + b_i)(y_i - r_i/2)\} \exp\left\{-\frac{z_i(x_i\theta+b_i)^2}{2}\right\} \text{PG}(z_i \mid r_i, 0) dz_i \\ &= \frac{\exp\{(x_i\theta + b_i)y_i\}}{\{1+\exp(x_i\theta+b_i)\}^{r_i}}, \end{aligned} \tag{10}$$

and the update rule for the CDA Gibbs sampler is then

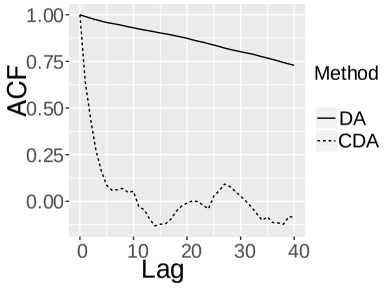
$$\begin{aligned} z_i &\sim \text{PG}(r_i, |x_i\theta + b_i|) \quad i = 1, \ldots, n, \\ \theta' &\sim \text{No}\left((X'ZX)^{-1}X'(y - r/2 - Zb), (X'ZX)^{-1}\right), \end{aligned}$$

where $r = (r_1, \ldots, r_n)'$ and $b = (b_1, \ldots, b_n)'$. We again defer the tuning details for r and b to the next section.

For illustration, we use a two-parameter intercept-slope model with $x_{i1} \overset{iid}{\sim} \text{No}(0, 1)$ and $\theta = (-8, 1)'$. With $n = 10^5$, we obtain rare outcome data with $\sum y_i \approx 50$. In CDA, after tuning, it reaches an acceptance rate of 0.8. Shown in Figure 3, DA mixes slowly, exhibiting strong autocorrelation even at lag 40, while CDA has dramatically better mixing.



(a) Traceplots for DA and CDA.



(b) ACF for DA and CDA.

Figure 3: Panel (a) demonstrates in traceplot and panel (b) in autocorrelation the substantial improvement of CDA in logistic regression with rare event data, compared with the original DA (Polson et al., 2013).

4. Automatic Tuning of Calibration Parameters

As illustrated in the previous subsection, efficiency of CDA is dependent on good choices of the calibration parameters r and b. We propose a simple and efficient algorithm for calculating "good" values of these parameters utilizing the Fisher information and empirical MH acceptance rate. Although our choice of calibration parameters relies on large sample approximations, we find that this calibration approach also works well for modest sample size.

Our goal is to adjust the conditional variance under calibration of (r, b) to approximately match the marginal variance under the exact target distribution, while maintaining a reasonable MH acceptance rate.

To approximate the marginal variance, we use the inverse of the observed Fisher information (Efron and Hinkley, 1978):

$$\begin{aligned}&\mathrm{var}(\theta \mid y) \approx \mathcal{I}^{-1}(\hat{\theta})\\ &\left(\mathcal{I}(\hat{\theta})\right)_{i,j} = \left(\frac{\partial}{\partial \theta_i} \log L(\theta; y)\right)\left(\frac{\partial}{\partial \theta_j} \log L(\theta; y)\right)\Big|_{\theta=\hat{\theta}}\end{aligned}$$

for $i = 1, \ldots, p$, $j = 1, \ldots, p$, where $\hat{\theta}$ is the Maximum a Posteriori (MAP) estimate of θ.

Recall that the CDA proposal has density

$$q(\theta^*; \theta) = \int f_{r,b}(\theta^*; z, y)\pi_{r,b}(z; \theta, y)dz,$$

and the conditional variance has lower bound $\mathrm{var}(\theta^* \mid \theta) \geq \mathbb{E}_{z|\theta}\mathrm{var}(\theta^* \mid z)$. We use the inverse of the observed Fisher information to approximate $\mathrm{var}(\theta^* \mid z)$ via

$$\begin{aligned}&\mathbb{E}_{z|\theta}\mathrm{var}(\theta^* \mid z) \approx \mathbb{E}_{z|\theta}\mathcal{I}^{-1}(\hat{\theta}; r, b, z) \approx \mathcal{I}^{-1}(\hat{\theta}; r, b, \tilde{z}(\hat{\theta}))\\ &\left(\mathcal{I}(\hat{\theta}; r, b, z)\right)_{i,j} = \left(\frac{\partial}{\partial \theta^*_i} \log f_{r,b}(\theta^*; y, z)\right)\left(\frac{\partial}{\partial \theta^*_j} \log f_{r,b}(\theta^*; y, z)\right)\Big|_{\theta^*=\hat{\theta}}.\end{aligned}$$

Since $\mathbb{E}_{z|\theta}\mathcal{I}^{-1}(\hat{\theta}; r, b, z)$ is often intractable or cumbersome to compute, we instead use the second approximation, the Fisher information evaluated at $\tilde{z}(\hat{\theta})$, the conditional mean or mode of $\pi_{r,b}(z; \hat{\theta}, y)$. The choice between mean and mode depends on which has a closed-form expression.

One can now adjust r, b to reduce the distance

$$d_1(r, b) = \mathrm{Dist}\left[\mathcal{I}^{-1}(\hat{\theta}), \mathcal{I}^{-1}(\hat{\theta}; r, b, \tilde{z}(\hat{\theta}))\right], \tag{11}$$

where $\mathrm{Dist}(M_1, M_2)$ is a distance between two matrices, such as $\|M_1 - M_2\|_F$ or $\|M_1^{-1} - M_2^{-1}\|_F$, the Frobenius norm of the difference.

However, the increase in proposal variance only results in an increase in the variance of the Metropolis-Hastings transition density so long as the acceptance probability is not substantially depressed (relative to the DA Gibbs sampler, which has acceptance probability one). Therefore, one also needs to adjust (r, b) both to optimize the acceptance rate $\alpha(\theta, \theta^*)$ and the proposal variance. Considering the average acceptance rate (on the negative-log scale), with expectation over proposal density $q(\theta^*; \theta)$ and posterior $\pi(\theta \mid y)$

$$\begin{aligned}&\mathbb{E}_{\theta|y}\mathbb{E}_{\theta^*|\theta}\big[-\log \alpha(\theta, \theta^*)\big]\\ =&\mathbb{E}_{\theta|y}\mathbb{E}_{\theta^*|z}\mathbb{E}_{z|\theta} \max\left[-\log \frac{L(\theta^*; y)}{L_{r,b}(\theta^*; y)} + \log \frac{L(\theta; y)}{L_{r,b}(\theta; y)}, 0\right].\end{aligned}$$

To provide tractable computation, we again use the functions evaluated at the conditional mean or mode to approximate the three expectations. This yields

$$d_2(r, b) = \max\left[-\log \frac{L(\tilde{\theta}^*(\tilde{z}(\hat{\theta})); y)}{L_{r,b}(\tilde{\theta}^*(\tilde{z}(\hat{\theta})); y)} + \log \frac{L(\hat{\theta}; y)}{L_{r,b}(\hat{\theta}; y)}, 0\right], \tag{12}$$

with $\hat{\theta}$ the MAP of θ, $\tilde{z}(\theta)$ the mean or mode of $\pi_{r,b}(z; \theta, y)$, $\tilde{\theta}^*$ the mean or mode of $f_{r,b}(\theta^*; z, y)$.

Combining (11) and (12), this yields the optimal tuning parameters under those two criteria:

$$(\hat{r}, \hat{b}) = \min_{r,b}\big[d_1(r, b) + \lambda d_2(r, b)\big]. \tag{13}$$

The optional parameter $\lambda > 0$ allows for differential weighting of the acceptance rate and variance, although the default $\lambda = 1$ works well for all of our applications.

To facilitate automatic tuning in generic cases, we exploit the automatic differentiation and optimization software, TensorFlow, to compute the Fisher information and optimize for $(\hat{r}, \hat{b})$. One only needs to provide the densities $L_{r,b}(\theta; y)$, $f_{r,b}(\theta^*; z, y)$, $\pi_{r,b}(z; \theta, y)$ and two conditional estimators $\tilde{z}(\theta)$ and $\tilde{\theta}^*(z)$.

We now provide the tuning details for probit and logistic regression. The likelihood and update densities $L_{r,b}(\theta; y)$, $f_{r,b}(\theta^*; z, y)$, $\pi_{r,b}(z; \theta, y)$ are already given, we present the conditional estimators. For probit regression, the two conditional modes for $\pi_{r,b}(z; \theta, y)$, $\tilde{\theta}^*$ and $f_{r,b}(\theta^*; z, y)$ are available in closed form, viz

$$\begin{aligned}\tilde{z}_i(\theta) =&\begin{cases} x_i\theta + b_i & \text{if } (y_i - 0.5)(x_i\theta + b_i) > 0\\ 0 & \text{otherwise}\end{cases} \quad \text{for } i = 1, \ldots, n,\\ \tilde{\theta}^*(z) =&(X'R^{-1}X)^{-1}X'R^{-1}(z - b).\end{aligned}$$

For logistic regression, the conditional means for $\pi_{r,b}(z; \theta, y)$, $\tilde{\theta}^*$ and $f_{r,b}(\theta^*; z, y)$ all have closed-form expressions given by

$$\begin{aligned}\tilde{z}_i(\theta) =&\frac{r_i}{2|x_i\theta_i + b_i|}\tanh(\frac{|x_i\theta_i + b_i|}{2}) \quad i = 1, \ldots, n,\\ \tilde{\theta}^*(z) =&(X'ZX)^{-1}X'(y - r/2 - Zb).\end{aligned}$$

5. Geometric convergence rates for CDA-MH and CDA-Gibbs

Although Remark 2 gives a basic guarantee of convergence of the usual time-averaging estimators commonly used in MCMC, the goal of CDA-MH is to improve upon the convergence rate of the usual DA Gibbs. Motivation for CDA is provided by the results of Johndrow et al. (2018), which studied the special case of intercept-only logistic and probit regression when $y = 1$ and $n \to \infty$ so that the data grow increasingly imbalanced as the sample size increases. Johndrow et al. (2018) showed that in this setting, the spectral gap of DA converges to zero at least as fast as $n^{-1/2}(\log n)^k$ for $k \leq 5.5$, while random-walk Metropolis has spectral gap order $(\log n)^3$ or larger. This suggests the superiority of Metropolis algorithms in the large sample imbalanced data setting. However, to implement Metropolis effectively with moderate to large numbers of covariates, one needs an efficient way to construct proposals, which is the goal of CDA.

We now give a result on the convergence rates of CDA and CDA-MH for imbalanced intercept-only logistic regression. The result shows that the spectral gap is larger than that for DA (as a function of n), and comparable to MH with optimally tuned proposals when y grows no faster than $\log n$. While this is a special case, we note that the result in Johndrow et al. (2018) is given only for fixed $y = 1$, and thus our result is more general. The difficulty

of obtaining quantitative estimates of the rate at which the spectral gap converges to zero as n grows is underscored by the length and complexity of the arguments in Johndrow et al. (2018).

Consider intercept-only logistic regression from (9) with $x_i = 1$ for $i = 1, \ldots, n$ and prior $\theta \sim \text{No}(0, \sigma^2)$. As all p_i's are the same, we use a single scalar $r_i = r$ and $b_i = b$ for all i. With r, b fixed, the update rule for CDA-Gibbs is

$$\pi_{r,b}(z \mid \theta) = \text{PG}(nr, |\theta + b|)$$
$$f_{r,b}(\theta' \mid z) = \text{No}(m, \Lambda)$$

where $\Lambda = (z + 1/\sigma^2)^{-1}$, $m = \Lambda a - b$ and $a = \sum_i y_i - nr/2 + b/\sigma^2$.

Theorem 3 *Consider intercept-only logistic regression with n observations. Then*

1. *CDA-Gibbs is uniformly ergodic*

2. *CDA-MH is uniformly ergodic*

3. *If $\sum_i y_i = o(\log n)$, there exist choices for r, b such that CDA-MH has spectral gap*

$$\kappa = \mathcal{O}(n^{-\frac{2.5+2\log 2}{\sigma^2}}).$$

Thus, for $\sigma^2 > 5 + 4\log 2 \approx 7.77$, the spectral gap of CDA-MH goes to zero more slowly with increasing n than DA-Gibbs. Moreover, if we choose the prior $\sigma^2 = \log n$, the spectral gap of CDA-MH is independent of n. It follows that CDA-MH mixes rapidly as $n \to \infty$ in the large-sample imbalanced setting, unlike DA-Gibbs, which has spectral gap converging to zero at rate $n^{-1/2}$ or faster (ignoring logarithmic factors).

To show that the result is borne out empirically, we conduct simulations as in Johndrow et al. (2018), with fixed $\sum_i y_i = 1$ and increasing n from 10^1 to a massive 10^{14}. Figure 4 compares the effective sample size per $1,000$ steps using DA and CDA. The deterioration of DA shows up as early as $n = 10^2$; its slow-down becomes critical at $n = 10^4$ with effective sample size close to 0. CDA performs exceptionally well, even at $n = 10^{14}$ (we stop at 10^{14} as $1/n$ reaches the limit of floating point accuracy).

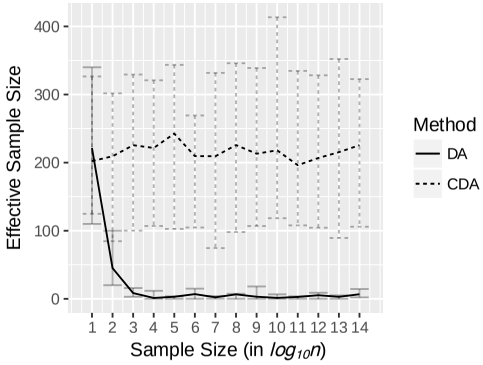


Figure 4: Effective sample size (with 95% pointwise confidence interval) per $1,000$ steps with different sample size n from 10 to 10^{14}, using logistic regression model with intercept.

6. Simulation Study

In this section, we compare the performance of CDA against popular alternative algorithms.

6.1. Comparison with Downsampling Algorithm

As motivated in the introduction, two factors are necessary for MCMC to be practically useful: a low computing cost in each iteration and a high effective sample size within a small number of iterations.

One potential issue for data augmentation in general is the large number of latent variables to sample in each iteration. A common strategy is to avoid sampling latent variables for every observation by approximating the Markov transition kernel using subsamples (Korattikara et al., 2014; Quiroz et al., 2018; Bardenet et al., 2017). Unlike other alternative algorithms we consider here, this changes the invariant measure. Finding a suitable subsample size while controlling the approximation error is challenging and usually problem-specific (Johndrow et al., 2017; Rudolf et al., 2018), and we do not consider it here. Instead, our goal is to show sub-sampling alone does not address the low ESS of DA; whereas one can trivially combine our proposed CDA strategy with subsampling to scale DA-MCMC up to enormous data sample sizes. We illustrate this strategy here.

We consider the same two-parameter intercept-slope model in logistic regression as described above, except we now vary data sample size from $n = 10^5$ to 10^8. We simulate Bernoulli outcomes $y_i \sim \text{Bernoulli}\big((1 + \exp(-x_i\theta))^{-1}\big)$ with $x_i = (1, w_i)$ for $w_i \overset{iid}{\sim} \text{No}(0, 1)$ and $\theta = (-\theta_0, 1)'$. We vary θ_0 to obtain $\sum y_i \approx 10$ for each n. We utilize the minibatch Polya-Gamma algorithm described by Johndrow et al. (2017), and apply CDA to calibrate

the variance discrepancy. Since y is highly imbalanced, we apply biased sampling by including all data with $y_i = 1$, while sub-sampling 1% of data with $y_i = 0$.

Denoting the set of all data with $y_i = 1$ as V_1 and a random subset with $y_i = 0$ as V_0, we adjust the likelihood contribution from $y_i = 0$ via a power of $(n - |V_1|)/|V_0|$ to compensate for the downsampling, leading to an approximate likelihood

$$L(\theta; y) = \prod_{i \in V_1} \frac{\exp(x_i\theta)}{1 + \exp(x_i\theta)} \left(\prod_{i \in V_0} \frac{1}{1 + \exp(x_i\theta)} \right)^{\frac{n-|V_1|}{|V_0|}}.$$

The number of latent variables is reduced to $n_0 \equiv |V_0| + |V_1|$; since n_0 is still large, slow mixing remains a problem and calibration is needed. The algorithmic details are presented in the appendix.

Figure 5 compares the performance of the two approximating algorithms, one combining CDA and sub-sampling, and one using sub-sampling alone. Clearly, sub-sampling alone still results in very small effective sample size, while using CDA and sub-sampling together can produce excellent computational performance.

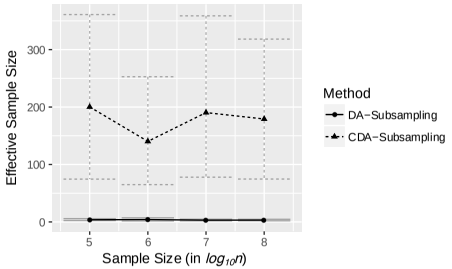

Figure 5: Comparing the performance of CDA and DA, coupled with sub-sampling approximation to reduce the number of sampled latent variables.

6.2. Comparison with Independence Metropolis-Hastings

In the CDA-MH algorithm, we utilize the marginal quantities $\hat{\theta}$ and $\mathcal{I}(\hat{\theta})$ to tune the (r, b) parameters. We compare the performance of the CDA proposal against alternative MH proposal with access to the same information. Specifically, we analyze MH using independent multivariate t proposals with mean $\hat{\theta}$ and variance $\mathcal{I}^{-1}(\hat{\theta})$. We show that this algorithm has very low acceptance rate relative to CDA-MH.

The general form of the MH acceptance rate is given by

$$\alpha(\theta, \theta^*) = \min\left\{1, \frac{L(\theta^*; y)q(\theta; \theta^*)}{q(\theta^*; \theta)L(\theta; y)} \frac{\Pi^0(\theta^*)}{\Pi^0(\theta)}\right\}.$$

Assuming the prior $\Pi^0(\theta)$ has negligible impact when n is large, the key to a high acceptance rate is to have $L(\theta; y)/q(\theta; \theta^*)$ close to a constant in the high posterior density region of the

parameter space. However, for computational convenience, one often has to use a proposal that is easy to sample. The density mis-match between $L(\theta; y)$ and $q(\theta; \theta^*)$ can cause the ratio to decrease rapidly moving away from the posterior mode of θ, resulting in a high rejection rate.

To illustrate, we consider the independent multivariate t-distribution proposal for logistic regression:

$$q(\theta^*, \theta) = q(\theta) = t_\nu\left\{\theta; \hat{\theta}, (\nu - 2)\nu^{-1}\mathcal{I}^{-1}(\hat{\theta})\right\},$$

where $\nu > 2$ and $\mathcal{I}(\hat{\theta}) = X^T \mathrm{diag}[\exp(x_i\hat{\theta})\{1 + \exp(x_i\hat{\theta})\}^{-2}]X$. The second parameter is set to have $\mathrm{var}(\theta) = \mathcal{I}^{-1}(\hat{\theta})$ exactly. We choose $\nu = 3$ to induce a tail heavier than the target likelihood, which is a necessary condition for geometric ergodicity of MH with independent proposals (Mengersen et al., 1996).

The density ratio is

$$\begin{aligned}\frac{L(\theta; y)}{q(\theta)} &= c_1 \left\{\prod_i \frac{\exp(y_i x_i \theta)}{1 + \exp(x_i\theta)}\right\} \left\{1 + \frac{1}{\nu - 2}(\theta - \hat{\theta})^{\mathrm{T}}\mathcal{I}(\hat{\theta})(\theta - \hat{\theta})\right\}^{(\nu+p)/2} \\ &= c_1 \frac{\exp(\sum_i y_i x_i \theta)}{\prod_i\{1 + \exp(x_i\theta)\}} \left[1 + \sum_i \frac{1}{\nu - 2}(x_i\theta - x_i\hat{\theta})^2 \exp(x_i\hat{\theta})\{1 + \exp(x_i\hat{\theta})\}^{-2}\right]^{(\nu+p)/2}, \end{aligned} \tag{14}$$

where c_1 denotes the constant part. We give an approximation of the acceptance ratio.

We focus on the case $\sum y_i \ll n$, where the mixing is slow for DA-Gibbs. This results in $\exp(x_i\hat{\theta}) \approx 0$ for most i. Assuming the high posterior density region is a neighborhood $\{\theta : |x_i\theta - x_i\hat{\theta}| < \eta \quad \text{for all } i\}$, where η is a bounded constant, the second term in (14) is close to a constant, while the first term is approximately equal to its numerator. The acceptance ratio is thus approximately

$$\frac{L(\theta^*; y)q(\theta)}{q(\theta^*)L(\theta; y)} \approx \exp\left\{\sum_i y_i x_i(\theta^* - \theta)\right\},$$

which decreases exponentially away from the current state.

In contrast, since the CDA proposal density is similar to the target, with calibration the density ratio can be made close to a constant in the neighborhood of the mode. Consider the density ratio in the logistic CDA proposal:

$$\frac{L(\theta; y)}{L_{r,b}(\theta; y)} = c_2 \prod_i \frac{\{1 + \exp(x_i\theta + b_i)\}^{r_i}}{1 + \exp(x_i\theta)},$$

where c_2 is a constant. Minimizing the Fisher information distance gives approximately $r_i \approx \exp(x_i\hat{\theta})$ and $b_i \approx -x_i\hat{\theta}$, so the density ratio is approximately c_2. Thus the acceptance ratio

$$\frac{L(\theta^*; y)L_{r,b}(\theta; y)}{L_{r,b}(\theta^*; y)L(\theta; y)} \approx 1.$$

We compare the performance of MH algorithms with t_3 and CDA proposals, using the two-parameter intercept-slope example described in Section 6.1. Figure 6 shows the acceptance ratio at different intercept values θ_0, which is approximately the average of $x_i\theta$.

The acceptance rate drops rapidly to 0 for the t_3 proposal, and is close to one for the CDA proposal.

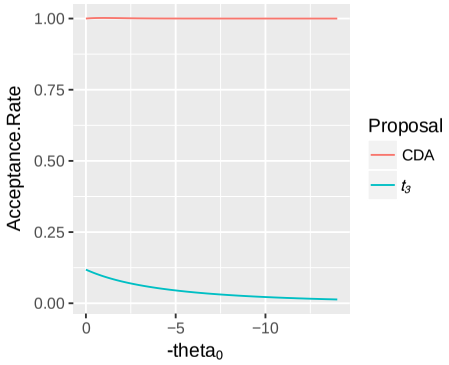

Figure 6: Comparing the acceptance ratios using the multivariate t-distribution and CDA proposals in logistic regression, with variance fixed at the inverse Fisher information. CDA has a much higher acceptance ratio than the multivariate t proposal.

7. Data Applications

7.1. Bernoulli Latent Factor Model with Group Intercepts for Network Modeling

We now apply CDA to accelerate estimation of group intercepts in a latent factor model. The dataset is a large sparse network from the Human Connectome Project (Marcus et al., 2011). The network data under consideration is an adjacency matrix representing the connectivity among $V = 1015$ macroscopic regions of one human brain. The matrix $\{A_{ij}\}_{(i,j)\in\{1\dots V\}^2}$ is binary and symmetric. For $i \neq j$, $A_{ij} = 1$ if regions i and j are connected, $A_{ij} = 0$ otherwise; A_{ii} are missing as self-connections are ignored. Therefore, there are effectively $n = V(V-1)/2 = 514,605$ observed binary outcomes.

There are 507 regions located in the left ($\mathcal{L}$) and 508 in the right hemisphere ($\mathcal{R}$). There are many more connections within each hemisphere ($\sum A_{i\in\mathcal{L},j\in\mathcal{L},i>j} = 2,280$, $\sum A_{i\in\mathcal{R},j\in\mathcal{R},i>j} = 2,443$), than across hemispheres ($\sum A_{i\in\mathcal{L},j\in\mathcal{R}} = 23$). To quantify this phenomenon, we use two intercepts β_0 and β_1 to represent the within- and across-hemisphere fixed effects

within the following Bernoulli probit latent factor model

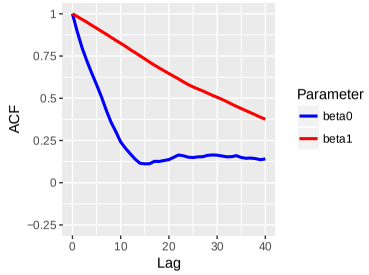
$$
\begin{aligned}
&A_{ij} \sim \text{Bernoulli}(p_{ij}), \qquad p_{ij} = \Phi(\psi_{ij}),\\
&\psi_{ij} = \sum_{r=1}^{d} u_{ir} v_r u_{jr} + \beta_0 w_{ij} + \beta_1 (1 - w_{ij}) \quad \text{for } i = 2\dots V, j < i,\\
&\pi(U) \propto 1, \qquad U^{\mathrm{T}} U = I_d,\\
&v_r \sim \text{No}_{(0,\infty)}(0, \sigma^2) \qquad \text{for } r = 1, \dots, d,\\
&\beta_0 \sim \text{No}(0, 100), \quad \beta_1 \sim \text{No}(0, 100), \quad \sigma^2 \sim \text{Inverse-Gamma}(2, 1),
\end{aligned}
$$

where $w_{ij} = 0$ if $i \in \mathcal{L}$ and $j \in \mathcal{R}$, otherwise $w_{ij} = 1$; $U = \{u_{ir}\}$ is a V-by-d matrix of latent factors. Following Hoff (2009), we assign U a uniform prior on Stiefel manifold $\mathbb{S}^{V\times d} = \{U : U^{\mathrm{T}}U = I_d\}$, and set the latent dimension at $d = 10$. The latent variable updates in the probit data augmentation algorithm are given by

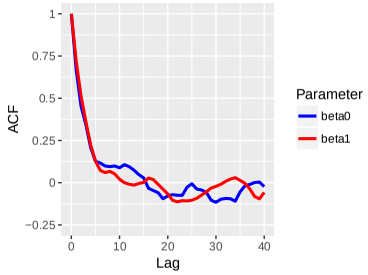
$$
\begin{aligned}
&z_{ij} \sim \begin{cases} \text{No}_{(0,\infty)}(\psi_{ij}, 1) & \text{if } A_{ij} = 1 \\ \text{No}_{(-\infty,0)}(\psi_{ij}, 1) & \text{if } A_{ij} = 0 \end{cases} \qquad \text{for } i = 2\dots V, j < i,\\
&z_{ji} = z_{ij}.
\end{aligned}
$$

Because the connection data are highly imbalanced – fewer than 5,000 connections out of a possible 514,605 – the intercepts β_0 and β_1 mix slowly in an ordinary DA Gibbs algorithm (Figure 7(a)). Without using DA, efficient MH proposals are difficult to develop due to the restriction that $U \in \mathbb{S}^{V\times d}$. The DA-Gibbs relies on the full conditional distribution

$$
U \mid \beta_0, \beta_1, Z \sim \text{Bingham}(\{z_{ij} - \beta_0 w_{ij} - \beta_1(1 - w_{ij})\}, \text{diag}\{v_r/2\}).
$$



(a) ACFs of the parameters β_0 and β_1 using DA.



(b) ACFs of the parameters β_0 and β_1 using CDA.

Figure 7: ACFs show the mixing performance of β_0 and β_1 in modeling average sparsity in network connectivity of a brain.

We use CDA to calibrate the updates of β_0 and β_1, while keeping the other Gibbs sampling steps unchanged, i.e.

$$z^*_{ij} \sim \begin{cases} \mathrm{No}_{(0,\infty)}(\psi_{ij} + b_{ij}, r_{ij}) & \text{if } A_{ij} = 1 \\ \mathrm{No}_{(-\infty,0)}(\psi_{ij} + b_{ij}, r_{ij}) & \text{if } A_{ij} = 0 \end{cases} \quad \text{for } i = 2 \dots V, j < i,$$

$$\beta^*_0 \sim \mathrm{No}\Big([\sum_{j<i} \frac{w_{ij}}{r_{ij}}]^{-1} \sum_{j<i} [\frac{w_{ij}}{r_{ij}} (z^*_{ij} - b_{ij} - \sum_{r=1}^{d} u_{ir} v_r u_{jr})], [\sum_{j<i} \frac{w_{ij}}{r_{ij}}]^{-1} \Big),$$

$$\beta^*_1 \sim \mathrm{No}\Big([\sum_{j<i} \frac{1-w_{ij}}{r_{ij}}]^{-1} \sum_{j<i} [\frac{1-w_{ij}}{r_{ij}} (z^*_{ij} - b_{ij} - \sum_{r=1}^{d} u_{ir} v_r u_{jr})], [\sum_{j<i} \frac{1-w_{ij}}{r_{ij}}]^{-1} \Big).$$

Then β^*_0 and β^*_1 are accepted via MH step with calibrated conditional density

$$L_{r,b}(\beta_0, \beta_1 \mid U, V, A) = \prod_{j<i} \Phi(\psi_{ij})^{A_{ij}} [1 - \Phi(\psi_{ij})]^{(1-A_{ij})}$$

$$\psi_{ij} = r_{ij}^{-1} [\sum_{r=1}^{d} u_{ir} v_r u_{jr} + \beta_0 w_{ij} + \beta_1 (1 - w_{ij}) + b_{ij}]$$

The tuning parameters are optimized using the approach described in Section 4, except with $x_i\theta$ replaced by $\sum_{r=1}^{d} u_{ir} v_r u_{jr} + \beta_0 w_{ij} + \beta_1 (1 - w_{ij})$.

	DA	CDA
β_0	-2.09 (-2.10, -2.08)	-2.09 (-2.10, -2.08)
β_1	-3.68 (-3.72, -3.64)	-3.75 (-3.86, -3.66)
Fitted AUC	90.5%	92.1%
T_{eff}/T	0.008	0.142
Avg Computing Time / T	2.0 sec	2.0 sec
Avg Computing Time / T_{eff}	251 sec	14.1 sec

Table 1: Parameter estimates and computing speed of DA and CDA in Bernoulli latent factor modeling of a brain network.

We run DA for 30,000 steps and CDA for 2,000 steps, so that they have approximately the same effective sample size (calculated with the `CODA` package in `R`). Both algorithms are initialized at the MAP estimates. CDA leads to significant reduction in autocorrelation (Figure 7(b)) and about 18 times lower computing time per effective sample size. We also compare the in-sample fitted AUCs, computed based on A_{ij} and the posterior mean of p_{ij}. The CDA estimates clearly have a better fit to the data.

7.2. Poisson Log-Normal Model for Web Traffic Prediction

As a second application, we apply CDA to an online browsing activity dataset obtained from a computational advertising company. The dataset contains a two-way table of visit count by users who browsed one of 96 websites belonging to clients of the computational advertising agency, and one of the $n = 59,792$ high-traffic sites during the same browsing

session. We refer to visiting more than one site during the same session as co-browsing. For each of the client websites, it is of commercial interest to identify the high-traffic sites with relatively high co-browsing rates, so that ads can be more effectively placed. In computational advertising, it is also valuable to understand the co-browsing behavior and predict the traffic pattern of users.

We consider a Poisson regression model for co-browsing. We use the co-browsing count of a single client website as the outcome y_i and the log of one plus the co-browsing count of the other 95 websites as the predictors, i.e. $x_{ij} = \log(x^*_{ij} + 1)$ for $i = 1, \dots, 59792$ and $j = 1, \dots, 95$, where x^* is the raw co-browsing count for high-traffic site i and client site j. A Gaussian random effect is included to account for over-dispersion relative to the Poisson distribution, leading to a Poisson log-normal regression model:

$$\begin{aligned} y_i \sim \text{Poisson}\left(\exp(x_i\beta + \tau_i)\right), \quad \tau_i \overset{iid}{\sim} \mathrm{No}(\tau_0, \nu^2), \quad i = 1 \dots n \\ \beta \sim \mathrm{No}(0, I\sigma^2_\beta), \quad \tau_0 \sim \mathrm{No}(0, \sigma^2_\tau) \quad \nu^2 \sim \pi(\nu^2). \end{aligned}$$

We assign a weakly informative prior for β and τ_0 with $\sigma^2_\beta = \sigma^2_\tau = 100$. For the over-dispersion parameter ν^2, we assign a non-informative flat prior on $(0, \infty)$.

When β and τ are sampled separately, the random effects $\tau = \{\tau_1, \dots, \tau_n\}$ mix slowly. Instead, we sample β and τ jointly. Letting $\tilde{X}$ be the $n \times (n+p)$ matrix given by $\tilde{X} = [I_n\, X]$, and $\eta_i = x_i\beta + \tau_i$ the linear predictor, $\theta = \{\tau, \beta\}'$ can be sampled jointly in a block. An explanation of improved mixing with blocked sampling can be found in Liu (1994a).

We now focus on the mixing behavior of data augmentation. We first review data augmentation for the Poisson log-normal model. Zhou et al. (2012) proposed to treat Poisson(η_i) as the limit of the negative binomial $\mathrm{NB}\big(\lambda, \eta_i/(\lambda + \eta_i)\big)$ with $\lambda \to \infty$, and used moderate $\lambda = 1,000$ for approximation. The limit relationship, omitting constants, is given by

$$L(\eta_i; y_i) = \frac{\exp(y_i\eta_i)}{\exp\{\exp(\eta_i)\}} = \lim_{\lambda\to\infty} \frac{\exp(y_i\eta_i)}{\{1 + \exp(\eta_i)/\lambda\}^\lambda}. \tag{15}$$

With finite λ approximation, the posterior can be sampled using Polya-Gamma data augmentation

$$\begin{aligned} z_i \mid \eta_i \sim \mathrm{PG}(\lambda, \eta_i - \log\lambda) \quad i = 1 \dots n \\ \theta \mid z, y \sim \mathrm{No}\Big(\Big(\tilde{X}' Z \tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma^2_\beta \cdot I_p \end{bmatrix} \Big)^{-1} \\ \Big\{ \tilde{X}'\big(y - \lambda/2 + Z\log\lambda\big) + \begin{bmatrix} \tau_0/\nu^2 1_n \\ 0_p \end{bmatrix} \Big\}, \\ \Big(\tilde{X}' Z \tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma^2_\beta \cdot I_p \end{bmatrix} \Big)^{-1} \Big), \end{aligned}$$

where $Z = \mathrm{diag}\{z_1, \dots, z_n\}$, $1_n = \{1, \dots, 1\}'$ and $0_p = \{0, \dots 0\}'$.

However, this approximation-based data augmentation is inherently problematic. For example, setting $\lambda = 1,000$ leads to large approximation error. As in (15), the approximating denominator has $(1 + \exp(\eta_i)/\lambda)^\lambda = \exp\{\exp(\eta_i) + \mathcal{O}(\exp(2\eta_i)/\lambda)\}$; for moderately large $\eta_i \approx 10$, λ needs to be at least 10^9 to make $\exp(2\eta_i)/\lambda$ close to 0. This large error

cannot be corrected with an additional MH step, since the acceptance rate would be too low. On the other hand, it is not practical to use a large λ in a Gibbs sampler, as it would create extremely large z_i (associated with small conditional covariance for θ), resulting in slow mixing.

We use CDA to circumvent this issue. We first choose a very large λ (10^9) to control the approximation error, then use a small fractional r_i multiplying to λ for calibration. This leads to a proposal likelihood similar to the logistic CDA:

$$L_{r,b}(x_i\theta; y_i) = \frac{\exp(\eta_i - \log\lambda + b_i)^{y_i}}{\{1+\exp(\eta_i - \log\lambda + b_i)\}^{r_i\lambda}},$$

with $r_i \geq (y_i - 1)/\lambda + \epsilon$ for proper likelihood, and proposal update rule:

$$\begin{aligned} z_i &\sim \mathrm{PG}(r_i\lambda, \eta_i - \log\lambda + b_i) \quad i = 1 \dots n \\ \theta^* &\sim \mathrm{No}\Big(\Big(\tilde{X}'Z\tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma_\beta^2 \cdot I_p \end{bmatrix}\Big)^{-1} \\ &\quad \Big\{\tilde{X}'\big(y - r\lambda/2 + Z\log(\lambda - b)\big) + \begin{bmatrix} \tau_0/\nu^2 1_n \\ 0_p \end{bmatrix}\Big\}, \\ &\quad \Big(\tilde{X}'Z\tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma_\beta^2 \cdot I_p \end{bmatrix}\Big)^{-1}\Big) \end{aligned}$$

Letting $\eta_i^* = \tilde{X}\theta^*$, the proposal is accepted with probability (based on the Poisson density and the approximation $L_{r,b}(x_i\theta; y_i)$):

$$\min\left\{1, \prod_i \frac{\exp\{\exp(\eta_i)\}}{\exp\{\exp(\eta_i^*)\}} \frac{\{1+\exp(\eta_i^* - \log\lambda + b_i)\}^{r_i\lambda}}{\{1+\exp(\eta_i - \log\lambda + b_i)\}^{r_i\lambda}}\right\}.$$

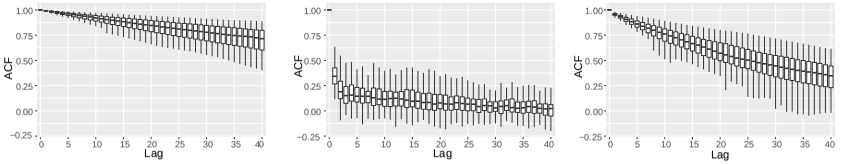
The tuning parameters are then optimized as described in Section 4, using

$$\begin{aligned} \tilde{z}_i(\theta) =& \frac{\lambda r_i}{2|\eta_i - \log\lambda + b_i|} \tanh\left(\frac{|\eta_i - \log\lambda + b_i|}{2}\right) \quad i = 1, \dots, n, \\ \tilde{\theta}^*(z) =& \Big(\tilde{X}'Z\tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma_\beta^2 \cdot I_p \end{bmatrix}\Big)^{-1} \\ & \Big\{\tilde{X}'\big(y - r\lambda/2 + Z\log(\lambda - b)\big) + \begin{bmatrix} \tau_0/\nu^2 1_n \\ 0_p \end{bmatrix}\Big\}. \end{aligned}$$

After θ is updated, the other parameters can be sampled via $\tau_0 \sim \mathrm{No}\big((n/\nu^2 + 1/\sigma_\tau^2)^{-1} \sum_i \tau_i/\nu^2, (n/\nu^2 + 1/\sigma_\tau^2)^{-1}\big)$ and $\nu^2 \sim \text{Inverse-Gamma}(n/2 - 1, \sum_i(\tau_i - \tau_0)^2/2)$.

We ran the ordinary DA algorithm with $\lambda = 1,000$, CDA with $\lambda = 10^9$ and Hamiltonian Monte Carlo with No-U-Turn sampler under the default tuning setting (as implemented in `STAN 2.17`). All algorithms are initialized at the MAP. We ran DA for $200,000$ steps, CDA for $2,000$ steps and HMC for $20,000$ steps so that they have approximately the same effective sample size. For CDA, we used the first $1,000$ steps for adapting r and b. Figure 8 shows empirical autocorrelations for DA, CDA and HMC. Even with small $\lambda = 1,000$ in DA, all of the parameters mix poorly; HMC seemed to be affected by the presence of random

effects, and most of parameters remain highly correlated within 40 lags; CDA substantially improves the mixing. Table 2 compares all three algorithms. CDA has the most efficient computing time per effective sample, and is about $30 - 300$ times more efficient than the other two algorithms.



(a) Autocorrelation of the parameters from DA.

(b) Autocorrelation of the parameters from CDA.

(c) Autocorrelation of the parameters from HMC.

Figure 8: CDA significantly improves the mixing of the parameters in the Poisson log-normal.

To evaluate predictive performance, we use another co-browsing count table for the same high traffic and client sites, collected during a different time period. We use the high traffic co-browsing count $x_{ij}^{\dagger *}$ and their log transform $x_{ij}^{\dagger} = \log(x_{ij}^{\dagger *} + 1)$ for the $j = 1, \dots, 95$ clients to predict the count for the client of interest $y_i^{\dagger}$, over the high traffic site $i = 1, \dots, 59792$. We predict using $\hat{y}_i^{\dagger} = \mathbb{E}_{\beta,\tau|y,x} y_i^{\dagger} = \mathbb{E}_{\beta,\tau|y,x} \exp(x_i^{\dagger}\beta + \tau_i)$ on the client site. The expectation is approximated using the MCMC sample path for $\beta, \tau \mid y, x$ obtained using training set $\{y, x\}$, as discussed above. Cross-validation root-mean-squared error $\big(\sum_i (\hat{y}_i^{\dagger} - y_i^{\dagger})^2/n\big)^{1/2}$ between the prediction and actual count $y_i^{\dagger}$'s is computed. As shown in Table 2, slow mixing in DA and HMC cause poor estimation of the parameters and high prediction error, while CDA has significantly lower error.

8. Discussion

Data augmentation (DA) is a technique routinely used to enable implementation of simple Gibbs samplers, avoiding the need for expensive and complex tuning of Metropolis-Hastings algorithms. Despite the convenience, DA mixes slowly when the conditional posterior variance given the augmented data is substantially smaller than the marginal variance. When the data sample size is massive, this problem arises when the rates of convergence of the augmented and marginal posterior differ. There is a rich literature on strategies for improving mixing rates of Gibbs samplers, with centered or non-centered re-parameterizations (Papaspiliopoulos et al., 2007) and parameter-expansion (Liu and Wu, 1999) leading to some improvements. However, existing approaches do not solve large sample mixing problems because they do not address the fundamental rate mismatch issue.

To tackle this problem, we propose to calibrate data augmentation by directly adjusting the conditional variance (which is associated with step size). CDA adds a small cost for likelihood evaluation, which is often negligible when compared to the random number generation required at each iteration of DA. In this article, we demonstrate that calibration is generally applicable when $\theta \mid z$ belongs to a location-scale family. We expect it to be also useful outside of location-scale families, but have not pursued that here.

As both CDA and HMC involve MH steps, we draw some further comparison between the two. Both methods rely on finding a good proposal by searching a region far from the current state. One key difference lies in the computing efficiency. Although HMC is more generally applicable beyond data augmentation, it is computationally intensive since Hamiltonian dynamics often requires multiple numeric steps. CDA only requires one step of calibrated Gibbs sampling, which is often much more efficient, leveraging on existing data augmentation algorithms. The idea of using an auxiliary Gibbs chain to generate MH proposals seems generally promising (Tran et al., 2016), yet has received little attention in the literature.

In this work, we focused on cases when the sample size n is large, with the parameter dimension p moderate. One limitation of CDA-MH is that when p grows, in order to maintain a reasonable acceptance rate, the range to increase the conditional variance has to decrease. This is a common problem for general MH algorithms. Therefore, solutions to high dimensionality require further study.

Appendix A. Proof of Remark 1

Proof Since $q_{r,b}(\theta;\theta')$ is the θ marginal of a Gibbs transition kernel, and Gibbs is reversible on its margins, we have

$$q(\theta;\theta^*)\Pi_{r,b}(\theta^*) = q(\theta^*;\theta)\Pi_{r,b}(\theta),$$

and so

$$\begin{aligned}\frac{L(\theta^*;y)\Pi^0(\theta^*)q(\theta;\theta^*)}{L(\theta;y)\Pi^0(\theta)q(\theta^*;\theta)} &= \frac{L(\theta^*;y)\Pi^0(\theta^*)L_{r,b}(\theta;y)\Pi^0(\theta)}{L(\theta;y)\Pi^0(\theta)L_{r,b}(\theta^*;y)\Pi^0(\theta^*)}\\ &= \frac{L(\theta^*;y)L_{r,b}(\theta;y)}{L(\theta;y)L_{r,b}(\theta^*;y)}.\end{aligned}$$

■

Appendix B. Proof of Remark 2

Proof For any r, b, the conditionals $\Pi_{r,b}(z \mid \theta)$ and $\Pi_{r,b}(\theta \mid z)$ are well-defined for all $z \in \mathcal{Z}, \theta \in \Theta$, and therefore the Gibbs transition kernel $K_{r,b}((\theta, z);\cdot)$ and corresponding marginal kernels $Q_{r,b}(\theta;\cdot)$ are well-defined. Moreover, for any $(z,\theta) \in \mathcal{Z} \times \Theta$, we have $\mathbb{P}[(\theta', z') \in A \mid (\theta, z)] > 0$ by assumption. Thus $K_{r,b}$ is aperiodic and $\Pi_{r,b}$-irreducible (see the discussion following Corollary 1 in Roberts and Smith (1994)).

$Q_{r,b}(\theta';\theta)$ is aperiodic and $\Pi_{r,b}(\theta)$-irreducible, since it is the θ marginal transition kernel induced by $K_{r,b}((\theta, z);\cdot)$. Thus, it is also $\Pi(\theta)$-irreducible so long as $\Pi \gg \Pi_{r,b}$, where for two measure μ, ν, $\mu \gg \nu$ indicates absolute continuity. Since $\Pi, \Pi_{r,b}$ have densities with respect to Lebesgue measure, $\Pi_{r,b}$-irreducibility implies Π irreducibility. Moreover, $q(\theta;\theta') > 0$ for all $\theta \in \Theta$. Thus, by Theorem 3 of Roberts and Smith (1994), CDA MH is Π-irreducible and aperiodic. ■

Appendix C. Toy example: Hierarchical Normal

To demonstrate the effects of r, b, we use a toy example commonly used in the data augmentation literature (Liu and Wu, 1999). Consider a marginal Normal model

$$y_i \sim \mathrm{No}(\theta, \sigma^2 + 1) \qquad i = 1, \ldots, n$$

with σ^2 known and improper prior $\pi(\theta) \propto 1$. This can be considered as a hierarchical model

$$y_i \sim \mathrm{No}(z_i, \sigma^2), \quad z_i \sim \mathrm{No}(\theta, 1), \qquad i = 1, \ldots, n, \tag{16}$$

where $z = \{z_1, \ldots, z_n\}$ are augmented data. The standard data augmentation algorithm has the update rule

$$\begin{aligned} z_i \mid y, \theta &\sim \mathrm{No}\left(\frac{y_i\sigma^{-2} + \theta}{\sigma^{-2} + 1}, \frac{1}{\sigma^{-2} + 1}\right) \qquad i = 1, \ldots, n\\ \theta \mid z &\sim \mathrm{No}(n^{-1}\sum_i z_i, n^{-1}).\end{aligned}$$

Thanks to the simple form, it is straightforward to compute the marginal variance of θ, $\mathrm{var}(\theta \mid y) = n^{-1}(1 + \sigma^2)$. Clearly, this is larger than the conditional variance $\mathbb{E}_z\mathrm{var}(\theta' \mid z) = n^{-1}$, when σ^2 is large.

To be able to adjust the conditional variance, we consider an alternative hierarchical model

$$y_i \sim \mathrm{No}(z_i, \sigma^2), \quad z_i \sim \mathrm{No}(\theta + b_0, r_0), \qquad i = 1, \ldots, n,$$

with update rule

$$\begin{aligned} z_i \mid y, \theta &\sim \text{No}\left(\frac{y_i\sigma^{-2} + (\theta + b_0)r_0^{-1}}{\sigma^{-2} + r_0^{-1}}, \frac{1}{\sigma^{-2} + r_0^{-1}}\right) \qquad i = 1, \ldots, n \\ \theta^* \mid z &\sim \text{No}(n^{-1}\sum_i z_i - b_0, n^{-1}r_0). \end{aligned} \tag{17}$$

To correct the deviation caused by the alternative model, we treat θ^* as a proposal to the target model (16), using M-H as in Remark 1 with $L_{r,b}(\theta; y) = (r_0 + \sigma^2)^{-1/2}\phi[(r_0 + \sigma^2)^{-1/2}(y_i - \theta - b_0)]$ and ϕ the standard normal density. We can choose r_0 so that the proposal variance equals to the target marginal variance $\text{var}_{r,b}(\theta' \mid z) = \text{var}(\theta \mid y)$; this yields

$$r_0 = 1 + \sigma^2.$$

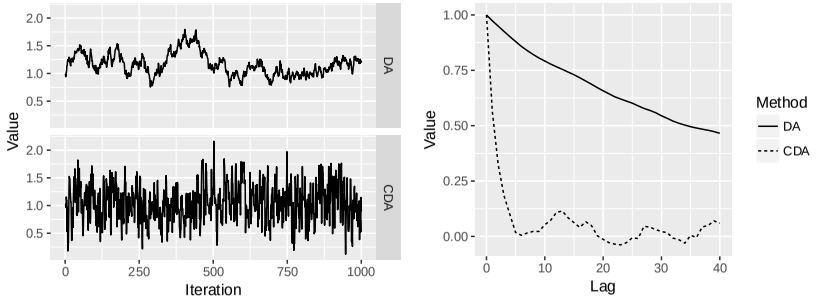
Note the proposal mean has

$$\mathbb{E}(\theta^* \mid \theta) = \mathbb{E}_{z|\theta}\mathbb{E}_{\theta^*|z}(\theta^* \mid z) = \theta + \frac{n^{-1}\sum_i y_i r_0}{\sigma^2 + r_0} - \frac{(b_0 + \theta)r_0}{\sigma^2 + r_0}$$

Intuitively, one way to improve the acceptance rate is to have the proposal centered at the current θ in the high posterior density region. That is, $\mathbb{E}(\theta^* \mid \theta) \approx \theta$ for θ near the MAP $\hat{\theta} = n^{-1}\sum_i y_i$. This yields one choice for b_0

$$\frac{n^{-1}\sum_i y_i r_0}{\sigma^2 + r_0} - \frac{(b_0 + \hat{\theta})r_0}{\sigma^2 + r_0} = 0 \qquad \Rightarrow b_0 = 0$$

We use $\sigma^2 = 100$, $\theta = 1$ to simulate $n = 1000$ data. Figure 9 compares the mixing performance, in terms of traceplots and autocorrelation plots (ACF) for the original DA and calibrated DA. Each algorithm was initiated at the MAP $\hat{\theta} = n^{-1}\sum_i y_i$. CDA significantly improves the mixing performance, with acceptance rate approximately 0.9.



(a) Traceplot for DA and CDA.

(b) ACF for DA and CDA.

Figure 9: Trace and autocorrelation plots for DA and CDA in hierarchical normal model.

Note in this special example, instead of relying on $\text{var}_{r,b}(\theta^* \mid z)$, one could directly adjust $\text{var}_{r,b}(\theta^* \mid \theta) = [r_0^2 + 2r_0\sigma^2]/[n(r_0 + \sigma_0^2)]$ to match $\text{var}(\theta \mid y)$. However, in general non-Gaussian cases, $\text{var}_{r,b}(\theta^* \mid \theta)$ is intractable, so we expect adjusting $\text{var}(\theta^* \mid z)$ to be more useful.

Appendix D. Calibrated Polya-Gamma Algorithm with Sub-sampling

Adapting based on Johndrow et al. (2017), we first randomly sample a subset of indices V of size $|V|$. This algorithm generates proposals from

$$\begin{aligned} &V = V_1 \cup V_0, \quad V_1 = \{i \in \{1, \ldots, n\} : y_i = 1\}, \quad V_0 \sim \text{Subset}(|V|, \{i \in \{1, \ldots, n\} : y_i = 0\}) \\ &z_i \sim \text{PG}(k_i r_i, |x_i\theta + b_i|) \quad i \in V, \\ &\theta^* \sim \text{No}\left((X_V' Z_V X_V)^{-1} X_V'(y_V - k_V r_V/2 - Z_V b_V), (X_V' Z_V X_V)^{-1}\right), \end{aligned}$$

where subscript $._V$ indicates the sub-matrix or sub-vector corresponding to the sub-sample; $k_i = 1$ if $y_i = 1$, and $k_i = (n - |V_1|)/|V_0|$. We accept θ^* in an MH step using calibrated likelihood

$$L_{r,b}(\theta; y) = \prod_{i \in V_1} \frac{\exp(x_i\theta + b_i)}{\{1 + \exp(x_i\theta + b_i)\}^{r_i}} \Big(\prod_{i \in V_0} \frac{1}{\{1 + \exp(x_i\theta + b_i)\}^{r_i}}\Big)^{\frac{n - |V_1|}{|V_0|}},$$

with target approximate likelihood $L_{1,0}(\theta; y)$.

Appendix E. Proof of Theorem 1

Proof Let Q be the proposal kernel for CDA-MH, which is identically the transition kernel for CDA-Gibbs, and let $\mathcal{P}$ be the Markov transition semigroup of CDA-MH.

Both have densities with respect to Lebesgue measure given by

$$\begin{aligned} q(\theta, \theta') &= \int_{\mathcal{Z}} f_{r,b}(\theta' \mid z, y)\pi_{r,b}(z \mid \theta, y)dz \\ p(\theta, \theta') &= \alpha(\theta, \theta')q(\theta, \theta') + \delta_\theta(\theta')\left(1 - \int \alpha(\theta, \tilde{\theta})q(\theta, \tilde{\theta})d\tilde{\theta}\right), \end{aligned}$$

respectively.

We seek a constant $c > 0$ and a density g such that

$$\inf_{\theta \in \Theta} p(\theta, \theta') > cg(\theta')$$

We proceed in the following steps:

1. Show that there exists a constant $c_1 > 0$ and a density g such that $\int_\Theta g(\theta)d\theta = 1$ for which

$$\inf_{\theta \in \Theta} q(\theta, \theta') \geq c_1 g(\theta');$$

conclude that CDA-Gibbs is uniformly ergodic.

2. Show that there exists $S \subset \Theta$ and a constant $c_2 > 0$ such that

$$\inf_{\theta\in\Theta,\theta'\in S} \alpha(\theta,\theta') > c_2.$$

3. Combine 1 and 2 to show $p(\theta,\theta') \geq \kappa g_S(\theta')$, where $\kappa = c_1c_2c_3$ with

$$c_3 = \int_S g(\theta)d\theta, \quad g_S(\theta) = c_3^{-1}g(\theta)\mathbf{1}\{\theta \in S\}$$

the restriction of g to S. Conclude that CDA-MH is uniformly ergodic with spectral gap κ.

4. Find values (r_0, b_0, S_0) of the tuning parameters r, b, S so that κ goes to zero slowly as $n \to \infty$.

1. Show that $q(\theta,\theta') \geq c_1 g(\theta')$. First we bound $\pi_{r,b}(\theta' \mid z)$ by a constant times a function depending on z

$$\begin{aligned}
\pi_{r,b}(\theta' \mid z) &= (2\pi)^{-1/2}(z+1/\sigma^2)^{1/2}\exp\left[-\frac{1}{2}(\theta'-m)(z+1/\sigma^2)(\theta'-m)\right]\\
&=(2\pi)^{-1/2}(z+1/\sigma^2)^{1/2}\exp\left[-\frac{1}{2}\left\{(\theta'+b)(z+1/\sigma^2)(\theta'+b)-2a(\theta'+b)+\frac{a^2}{z+1/\sigma^2}\right\}\right]\\
&>(2\pi)^{-1/2}(1/\sigma^2)^{1/2}\exp\left[-\frac{1}{2}\left\{(\theta'+b)(z+1/\sigma^2)(\theta'+b)-2a(\theta'+b)+\frac{a^2}{1/\sigma^2}\right\}\right]\\
&=(2\pi)^{-1/2}\sigma^{-1}\exp\left[-\frac{1}{2}\left\{(\theta'+b)^2/\sigma^2-2a(\theta'+b)+a^2\sigma^2\right\}\right]\exp\left[-\frac{1}{2}\left\{(\theta'+b)^2 z\right\}\right]
\end{aligned} \tag{18}$$

in which the inequality holds since $z > 0$.

Using the Laplace transform of $\omega \sim \mathrm{PG}(\alpha,\beta)$

$$\mathbb{E}[\exp(-\omega t)] = \frac{\cosh^\alpha(\beta/2)}{\cosh^\alpha(\sqrt{(\beta^2/2+t)/2})},$$

we proceed to bound the expectation of (18) with respect to z

$$\begin{aligned}
\int_0^\infty \exp\left[-\frac{1}{2}\left\{(\theta'+b)^2 z\right\}\right]\pi_{r,b}(z \mid \theta)dz &= \cosh^{nr}(\frac{|\theta+b|}{2})\cosh^{-nr}(\frac{\sqrt{((\theta+b)^2+(\theta'+b)^2)}}{2})\\
&\geq \cosh^{nr}(\frac{|\theta+b|}{2})\cosh^{-nr}(\frac{(|\theta+b|+|\theta'+b|)}{2})\\
&\geq 2^{-nr}\cosh^{nr}(\frac{|\theta+b|}{2})\cosh^{-nr}(\frac{|\theta+b|}{2})\cosh^{-nr}(\frac{|\theta'+b|}{2})\\
&= 2^{-nr}\cosh^{-nr}(\frac{|\theta'+b|}{2})\\
&\geq 2^{-nr}\exp\left[-\frac{nr|\theta'+b|}{2}\right]
\end{aligned}$$

$$\geq 2^{-nr}\exp\left[-\frac{nr[(\theta'+b)^2+1]}{4}\right]$$

where the first inequality uses $a^2+b^2 \leq (|a|+|b|)^2$; the second uses Lemma 3.2 of Choi and Hobert (2013); the third uses the property of cosh; and the fourth uses $|a| \leq (1+a^2)/2$. We combine to obtain $q(\theta,\theta') > c_1 g(\theta')$, viz

$$\begin{aligned}
q(\theta,\theta') &= \int_0^\infty \pi_{r,b}(\theta' \mid z, y_{1:n})\pi_{r,b}(z \mid \theta, y_{1:n})dz\\
&>(2\pi)^{-1/2}\sigma^{-1}\exp\left[-\frac{1}{2}\left\{(\theta'+b)^2/\sigma^2-2a(\theta'+b)+a^2\sigma^2\right\}\right]2^{-nr}\exp\left[-\frac{nr[(\theta'+b)^2+1]}{4}\right]\\
&=(2\pi)^{-1/2}\sigma^{-1}2^{-nr}\exp\left[-\frac{1}{2}\left\{(\theta'+b)^2(\frac{1}{\sigma^2}+\frac{nr}{2})-2a(\theta'+b)\right\}\right]\exp\left[-\frac{nr}{4}-\frac{a^2\sigma^2}{2}\right]\\
&=\sigma^{-1}2^{-nr}(\frac{1}{\sigma^2}+\frac{nr}{2})^{-1/2}\exp\left[-\frac{nr}{4}-\frac{a^2\sigma^2}{2}\right]\exp\left[\frac{1}{2}a^2(\frac{1}{\sigma^2}+\frac{nr}{2})^{-1}\right]\\
&\quad(2\pi)^{-1/2}(\frac{1}{\sigma^2}+\frac{nr}{2})^{1/2}\exp\left[-\frac{1}{2}\left(\theta'+b-(\frac{1}{\sigma^2}+\frac{nr}{2})^{-1}a\right)^2(\frac{1}{\sigma^2}+\frac{nr}{2})\right]\\
&=c_1 g(\theta')
\end{aligned}$$

where

$$\begin{aligned}
c_1 &= \sigma^{-1}2^{-nr}(\frac{1}{\sigma^2}+\frac{nr}{2})^{-1/2}\exp\left[-\frac{nr}{4}-\frac{a^2\sigma^2}{2}\right]\exp\left[\frac{1}{2}a^2(\frac{1}{\sigma^2}+\frac{nr}{2})^{-1}\right]\\
g(\theta') &= \mathrm{No}\left[\theta' \mid (\frac{1}{\sigma^2}+\frac{nr}{2})^{-1}a-b, (\frac{1}{\sigma^2}+\frac{nr}{2})^{-1}\right].
\end{aligned}$$

This completes the first part.

2. Show that $\inf_{\theta\in\Theta,\theta'\in S}\alpha(\theta,\theta') > c_2$ for some set S.

The acceptance ratio is

$$\alpha(\theta,\theta') = \min\left(\left[\frac{\alpha_0(\theta')}{\alpha_0(\theta)}\right]^n, 1\right), \qquad \alpha_0(x) = \frac{\{1+\exp(x+b)\}^r}{1+\exp(x)}$$

Differentiating with respect to x we obtain

$$\frac{\partial\alpha_0(x)}{\partial x} = \frac{e^x\left(e^{b+x}+1\right)^{r-1}\left((r-1)e^b e^x+e^b r-1\right)}{\left(e^x+1\right)^2},$$

Assuming that $r < 1$ and $e^b r > 1$, since

$$\frac{e^x\left(e^{b+x}+1\right)^{r-1}}{\left(e^x+1\right)^2} > 0$$

and there is only one root on $(-\infty,\infty)$ for

$$(r-1)e^b e^x + e^b r - 1 = 0 \quad\Longrightarrow\quad x = \log(\frac{e^b r-1}{1-r}) - b \equiv \hat{\theta}$$

$$(r-1)e^b e^x + e^b r - 1 < 0 \quad \Longrightarrow \quad x > \hat{\theta}$$
$$(r-1)e^b e^x + e^b r - 1 > 0 \quad \Longrightarrow \quad x < \hat{\theta}$$

Therefore, $\hat{\theta}$ is the unique mode of α_0, and α_0 is (1) monotonically increasing for $x < \hat{\theta}$ and monotonically decreasing for $x > \hat{\theta}$.

For convenience, we write $b = -\log(r) + \xi$ with $\xi > 0$, so that $1 + \exp(\hat{\theta} + b) = (e^\xi - r)/(1 - r)$. Now set $S = (s_1, s_2)$. We now show that $\alpha(\theta, \theta') > c_2$ for $\theta' \in S$. We proceed in two cases.

1. **Case 1**: $\theta \le \hat{\theta}$. We have three subcases

   (a) If $\theta < \theta' \le \hat{\theta}$, then $\alpha_0(\theta') \ge \alpha_0(\theta)$, $\alpha(\theta, \theta') = 1$.

   (b) If $s_1 < \theta' \le \theta \le \hat{\theta}$ then

$$\begin{aligned}\alpha(\theta,\theta') =& \left(\frac{1+\exp(\theta)}{1+\exp(\theta')}\right)^n \left(\frac{1+\exp(\theta'+b)}{1+\exp(\theta+b)}\right)^{rn} \\ \ge& 1 \times \quad \left(\frac{1}{1+\exp(\hat{\theta}+b)}\right)^{rn} = \left(\frac{1-r}{e^\xi - r}\right)^{rn}\end{aligned}$$

   (c) If $\theta \le \hat{\theta} < \theta' < s_2$,

$$\begin{aligned}\alpha(\theta,\theta') =& \left(\frac{1+\exp(\theta)}{1+\exp(\theta')}\right)^n \left(\frac{1+\exp(\theta'+b)}{1+\exp(\theta+b)}\right)^{rn} \\ \ge& \left(\frac{1}{1+\exp(\theta')}\right)^n \times 1 \ge \left(\frac{1}{1+\exp(s_2)}\right)^n\end{aligned}$$

   where we used that $\theta' > \theta$ so the second term is bounded below by 1, and that $1 + e^\theta > 1$. If $s_2 \le \hat{\theta}$, then $\theta' < \hat{\theta}$, we only need to consider the condition (a) and (b).

2. **Case 2:** $\theta > \hat{\theta}$,

   (a) If $\hat{\theta} < \theta' \le \theta$, then $\alpha_0(\theta') \ge \alpha_0(\theta)$, $\alpha(\theta, \theta') = 1$.

   (b) If $s_1 < \theta' \le \hat{\theta} < \theta$, because α_0 is monotone nondecreasing on $(-\infty, \hat{\theta})$, we have:

$$\alpha_0(\theta') = \frac{\{1+\exp(\theta'+b)\}^r}{1+\exp(\theta')} \ge \lim_{\theta' \to -\infty} \alpha_0(\theta') = 1,$$

   Further, because α_0 is monotone nonincreasing on $(\hat{\theta}, \infty)$ we have

$$\begin{aligned}\frac{1}{\alpha_0(\theta)} &= \frac{1+\exp(\theta)}{\{1+\exp(\theta+b)\}^r} \ge \frac{1}{\alpha_0(\hat{\theta})} \\ \alpha(\theta,\theta') &= \alpha_0(\theta')\frac{1}{\alpha_0(\theta)}\end{aligned}$$

$$\begin{aligned}&\ge 1 \times \frac{1}{\alpha_0(\hat{\theta})} = \frac{\{1+\exp(\hat{\theta})\}^n}{\{1+\exp(\hat{\theta}+b)\}^{rn}} \\ &\ge \frac{1}{\{1+\exp(\hat{\theta}+b)\}^{rn}} = \left(\frac{1-r}{e^\xi - r}\right)^{rn}\end{aligned}$$

   (c) If $\hat{\theta} < \theta < \theta' < s_2$,

$$\begin{aligned}\alpha(\theta,\theta') &= \left(\frac{1+\exp(\theta)}{1+\exp(\theta')}\right)^n \left(\frac{1+\exp(\theta'+b)}{1+\exp(\theta+b)}\right)^{rn} \\ &\ge \left(\frac{1}{1+\exp(\theta')}\right)^n \times 1 = \left(\frac{1}{1+\exp(s_2)}\right)^n\end{aligned}$$

If $s_2 \le \hat{\theta}$, then $\theta' < \hat{\theta}$ and we only need to consider the condition (b).

Combining (1) and (2), even when $s_2 \le \hat{\theta}$, the lower bound still has:

$$\left(\frac{1-r}{e^\xi - r}\right)^{rn} \ge \min\left\{\left(\frac{1-r}{e^\xi - r}\right)^{rn}, \left(\frac{1}{1+\exp(s_2)}\right)^n\right\}$$

Therefore we have the common lower bound:

$$\alpha(\theta,\theta') \ge c_2, \quad c_2 = \min\left\{\left(\frac{1-r}{e^\xi - r}\right)^{rn}, \left(\frac{1}{1+\exp(s_2)}\right)^n\right\}$$

for $\theta' \in (s_1, s_2)$. Since this does not depend on s_1, we take $s_1 = -\infty$.

3. Combine to show $p(\theta, \theta') \ge c_1 c_2 c_3 g_S(\theta')$

Since

$$\begin{aligned}p(\theta,\theta') &= \alpha(\theta,\theta')q(\theta,\theta') + \delta_\theta(\theta')\left(1 - \int \alpha(\theta,\tilde{\theta})q(\theta,\tilde{\theta})d\tilde{\theta}\right), \\ &\ge \alpha(\theta,\theta')q(\theta,\theta'),\end{aligned}$$

parts (1) and (2) establish the bound

$$\begin{aligned}\inf_{\theta\in\Theta} p(\theta,\theta') &\ge c_1 c_2 g(\theta')\mathbf{1}\{\theta' \in S\} \\ &= c_1 c_2 c_3 c_3^{-1} g(\theta')\mathbf{1}\{\theta' \in S\},\end{aligned}$$

where

$$c_3 = \int g(\theta')\mathbf{1}\{\theta' \in S\},$$

so that $g_S(\theta') = c_3^{-1} g(\theta')\mathbf{1}\{\theta' \in S\}$ is a density. Specifically we have

$$g_S(\theta') = c_3^{-1}\left(\frac{1}{\sigma^2} + \frac{nr}{2}\right)^{1/2} \phi\left(\frac{\theta' - \left((\frac{1}{\sigma^2} + \frac{nr}{2})^{-1}a - b\right)}{(\frac{1}{\sigma^2} + \frac{nr}{2})^{-1/2}}\right)\mathbf{1}\{\theta' \in S\}$$

for $\phi(\cdot)$ the standard Gaussian density, where

$$c_3 = \Phi\left\{\left(\frac{1}{\sigma^2}+\frac{nr}{2}\right)^{1/2}\left[s_2-(\frac{1}{\sigma^2}+\frac{nr}{2})^{-1}a+b\right]\right\}$$
$$= \Phi\left[\left(\frac{1}{\sigma^2}+\frac{rn}{2}\right)^{1/2}(s_2+b)-\left(\frac{1}{\sigma^2}+\frac{rn}{2}\right)^{-1/2}a\right].$$

It follows that $\mathcal{P}$ is uniformly ergodic with spectral gap at least $\kappa = c_1c_2c_3$.

4. Tune constants so that $\kappa \to 0$ slowly as $n \to \infty$

We now may choose r, b, S in such a way as to minimize the rate at which the spectal gap goes to zero, subject to the constraints on r, b from part (2) and

$$\begin{aligned}\kappa(r,b,S) &= c_1c_2c_3\\ &= \sigma^{-1}2^{-nr}(\frac{1}{\sigma^2}+\frac{nr}{2})^{-1/2}\exp\left[-\frac{nr}{4}-\frac{a^2\sigma^2}{2}\right]\exp\left[\frac{1}{2}a^2\left(\frac{1}{\sigma^2}+\frac{nr}{2}\right)^{-1}\right]\\ &\times\min\left\{\left(\frac{1-r}{e^\xi-r}\right)^{rn},\left(\frac{1}{1+\exp(s_2)}\right)^n\right\}\\ &\times\Phi\left[\left(\frac{1}{\sigma^2}+\frac{rn}{2}\right)^{1/2}(s_2+b)-\left(\frac{1}{\sigma^2}+\frac{rn}{2}\right)^{-1/2}a\right]\end{aligned}$$

First, we note that because $b = \xi - \log r$, tuning of r, ξ is equivalent to tuning of r, b, so we elect to do the former.

First, to reduce the effect of n, we set $r = w/n$, with $0 < w < n$. Noting $\exp(-a^2\sigma^2/2)$ decreases rapidly in a and recalling $a = \sum_i y_i - nr/2 + b/\sigma^2$ and $b = \xi - \log r$, we solve for w to make $a = 0$

$$\sum_i y_i - w/2 + (-\log(w)+\log(n)+\xi)/\sigma^2 = 0$$
$$\frac{\log w}{\sigma^2}+\frac{w}{2} = \sum_i y_i + \frac{\log n}{\sigma^2}+\frac{\xi}{\sigma^2}$$

assuming $\sum y_i + \xi/\sigma^2 = o(\log(n))$, we have

$$w = 2\log(n)/\sigma^2 + o(\log(n)).$$

Second, we make c_3 a constant independent of y, n, by choosing s_2 such that

$$(\frac{1}{\sigma^2}+\frac{rn}{2})^{1/2}(s_2+b)-(\frac{1}{\sigma^2}+\frac{rn}{2})^{-1/2}a = 0$$
$$(\frac{1}{\sigma^2}+\frac{rn}{2})^{1/2}(s_2+b) = 0$$
$$s_2 = -b = \log(w)-\log(n)-\xi.$$

which yields $c_3 = 0.5$.

Third, choose ξ so that

$$\xi \le \log\left\{\left(1-\frac{w}{n}\right)e+\frac{w}{n}\right\} \Longrightarrow \log\left(\frac{e^\xi - w/n}{1-w/n}\right) \le 1$$

meaning

$$\left(\frac{1-r}{e^\xi-r}\right)^{rn} = \left(\frac{1-w/n}{e^\xi-w/n}\right)^w = \exp\left(-w\log\left(\frac{e^\xi-w/n}{1-w/n}\right)\right) \ge e^{-w}$$

and

$$\left(\frac{1}{1+\exp(s_2)}\right)^n = \left(\frac{1}{1+we^{-\xi}/n}\right)^n \ge \exp(-we^{-\xi}) \ge e^{-w}$$

We have

$$c_2 = \min\left\{\left(\frac{1-r}{e^\xi-r}\right)^{rn},\left(\frac{1}{1+\exp(s_2)}\right)^n\right\} \ge \exp(-w).$$

Combining results and choosing $r = r_0 = w/n$, $b = b_0 = -\log(w)+\log(n)+\xi$, $S = S_0 = (-\infty, \log(w)-\log(n)-\xi)$, with $(w,\xi) : \sum_i y_i - w/2 + (-\log(w)+\log(n)+\xi)/\sigma^2 = 0, \xi \le \log[(1-w/n)e + w/n]$, we have

$$\begin{aligned}\kappa(r_0,b_0,S_0) =& \sigma^{-1}2^{-w-1}(\frac{1}{\sigma^2}+\frac{w}{2})^{-1/2}\exp\left[-\frac{w}{4}\right]\exp(-w)\\ =& \mathcal{O}\Big(\exp\big[-(\frac{5}{4}+\log 2)w\big]\Big)\\ =& \mathcal{O}\left(n^{-\frac{5/2+2\log 2}{\sigma^2}}\right).\end{aligned}$$

Abstract

The difficulty of multi-class classification generally increases with the number of classes. Using data for a small set of the classes, can we predict how well the classifier scales as the number of classes increases? We propose a framework for studying this question, assuming that classes in both sets are sampled from the same population and that the classifier is based on independently learned scoring functions. Under this framework, we can express the classification accuracy on a set of k classes as the $(k-1)$st moment of a discriminability function; the discriminability function itself does not depend on k. We leverage this result to develop a non-parametric regression estimator for the discriminability function, which can extrapolate accuracy results to larger unobserved sets. We also formalize an alternative approach that extrapolates accuracy separately for each class, and identify tradeoffs between the two methods. We show that both methods can accurately predict classifier performance on label sets up to ten times the size of the original set, both in simulations as well as in realistic face recognition or character recognition tasks.

Keywords: Multi-class problems, face recognition, object recognition, transfer learning, nonparametric models

1. Introduction

Many machine learning tasks are interested in recognizing or identifying an individual instance within a large set of possible candidates. These problems are usually modeled as multi-class classification problems, with a large and possibly complex label set. Leading examples include detecting the speaker from his voice patterns (Togneri and Pullella, 2011), identifying the author from her written text (Stamatatos et al., 2014), or labeling the object category from its image (Duygulu et al., 2002; Deng et al., 2010; Oquab et al., 2014). In all these examples, the algorithm observes an input x, and uses the classifier function h to guess the label y from a large label set $\mathcal{S}$.

There are multiple practical challenges in developing classifiers for large label sets. Collecting high quality training data is perhaps the main obstacle, as the costs scale with the number of classes. It can be more affordable to first collect data for a small set of classes, even if the long-term goal is to generalize to a larger set. Furthermore, classifier development can be accelerated by training first on fewer classes, as each training cycle may require substantially less resources. Indeed, due to interest in how small-set performance generalizes to larger sets, such comparisons can found in the literature (Oquab et al., 2014; Griffin et al., 2007). A natural question is: how does changing the size of the label set affect the classification accuracy?

We consider a pair of classification problems on finite label sets: a source task with label set $\mathcal{S}_{k_1}$ of size k_1, and a target task with a larger label set $\mathcal{S}_{k_2}$ of size $k_2 > k_1$. For each label set $\mathcal{S}_k$, one constructs the classification rule $h^{(k)} : \mathcal{X} \to \mathcal{S}_k$. Supposing that in each task, the test example (X^*, Y^*) has a joint distribution, define the generalization accuracy for label set $\mathcal{S}_k$ as

$$\mathrm{GA}_k = \Pr[h^{(k)}(X^*) = Y^*]. \tag{1}$$

The problem of *performance extrapolation* is the following: using data from only the source task $\mathcal{S}_{k_1}$, predict the accuracy for a target task with a larger unobserved label set $\mathcal{S}_{k_2}$.

A natural use case for performance extrapolation would be in the deployment of a facial recognition system. Suppose a system was developed in the lab on a database of k_1 individuals. Clients would like to deploy this system on a new larger set of k_2 individuals. Performance extrapolation could allow the lab to predict how well the algorithm will perform on the clients' problem, accounting for the difference in label set size.

Extrapolation should be possible when the source and target classifications belong to the same problem domain. In many cases, the set of categories $\mathcal{S}$ is to some degree a random or arbitrary selection out of a larger, perhaps infinite, set of potential categories $\mathcal{Y}$. Yet any specific experiment uses a fixed finite set. For example, categories in the classical Caltech-256 image recognition data set (Griffin et al., 2007) were assembled by aggregating keywords proposed by students and then collecting matching images from the web. The arbitrary nature of the label set is even more apparent in biometric applications (face recognition, authorship, fingerprint identification) where the labels correspond to human individuals (Togneri and Pullella, 2011; Stamatatos et al., 2014). In all these cases, the number of the labels used to define a concrete data set is therefore an experimental choice rather than a property of the domain. Despite the arbitrary nature of these choices, such data sets are viewed as representing the larger problem of recognition within the given domain, in the sense that success on such a data set should inform performance on similar problems.

In this paper, we assume that both $\mathcal{S}_{k_1}$ and $\mathcal{S}_{k_2}$ are samples consisting of independent and identically distributed (i.i.d.) labels from a population (or prior distribution) π, which is defined on the label space $\mathcal{Y}$. We have no constraints on the dependence between $\mathcal{S}_{k_1}$ and $\mathcal{S}_{k_2}$: for example, $\mathcal{S}_{k_1}$ may be independent of $\mathcal{S}_{k_2}$, or alternatively $\mathcal{S}_{k_1}$ may be a subsample of $\mathcal{S}_{k_2}$ (the latter case is used in our experiments in Section 5). The sampling assumption is an approximate characterization of the label selection process, which is often at least partially manual. Nevertheless, it provides the exact properties we need without having

to derive specialized metrics of how similar $\mathcal{S}_{k_2}$ is to $\mathcal{S}_{k_1}$. This simplifies the theory, and demonstrates that in a very general setting, extrapolation is possible. We also make the assumption that the classifiers train a model independently for each class. This convenient property allows us to characterize the accuracy of the classifier by selectively conditioning on one class at a time.

Since we assume the label set is random, the generalization accuracy of a given classifier becomes a random variable. Performance extrapolation then becomes the problem of estimating the average generalization accuracy AGA_k of an i.i.d. label set $\mathcal{S}_k$ of size k. Roughly speaking, the achievable accuracy of a classification problem depends on how well the labels can be 'separated' based on the training data– that is, how different the empirical distributions of the training data look at the points where new test instances are drawn. The condition of i.i.d. sampling of labels ensures that the separation of labels in a random set $\mathcal{S}_{k_2}$ can be inferred by looking at the empirical separation in $\mathcal{S}_{k_1}$, and therefore that some estimate of the average accuracy on $\mathcal{S}_{k_2}$ can be obtained.

Our paper presents several main contributions related to extrapolation within this framework. First, we present a theoretical formula describing how average accuracy for smaller k is linked to average accuracy for label set of size $K > k$. We show that accuracy at any size depends on a discriminability function D, which is determined by properties of the data distribution and the classifier but does not depend on k. Second, we propose an estimation procedure that allows extrapolation of the observed average accuracy curve from k_1-class data to a larger number of classes, based on the theoretical formula. Under certain conditions, the estimation method has the property of being an unbiased estimator of the average accuracy. Third, we formalize an alternative approach (proposed by Kay et al. (2008)) that extrapolates accuracy separately for each class, and discuss tradeoffs between the two methods.

The paper is organized as follows. In the rest of this section, we discuss related work. The framework of randomized classification is introduced in Section 2, and there we also introduce a toy example which is revisited throughout the paper. Section 3 develops our theory of extrapolation, and in Section 3.3 we suggest an estimation method. We evaluate our method using simulations in Section 4. In Section 5, we demonstrate our method on a facial recognition problem, as well as an optical character recognition problem. In Section 6 we discuss modeling choices and limitations of our theory, as well as potential extensions.

1.1. Related Work

Linking performance between two different but related classification tasks can be considered an instance of transfer learning (Pan and Yang, 2010). Under Pan and Yang's terminology, our setup is an example of multi-task learning, because the source task has labeled data, which is used to predict performance on a target task that also has labeled data. Applied examples of transfer learning from one label set to another include Oquab et al. (2014), Donahue et al. (2014), Sharif Razavian et al. (2014). However, there is little theory for predicting the behavior of the learned classifier on a new label set. Instead, most research of classification for large label sets deal with the computational challenges of jointly optimizing the many parameters required for these models for specific classification algorithms (Crammer and Singer, 2001; Lee et al., 2004; Weston and Watkins, 1999). Gupta et al. (2014) presents a method for estimating the accuracy of a classifier which can be used to improve performance for general classifiers, but doesn't apply for different set sizes.

The theoretical framework we adopt is one where there exists a family of classification problems with increasing number of classes. This framework can be traced back to Shannon (1948), who considered the error rate of a random codebook, which is a special case of randomized classification. More recently, a number of authors have considered the problem of high-dimensional feature selection for multi-class classification with a large number of classes (Pan et al., 2016; Abramovich and Pensky, 2015; Davis et al., 2011). All of these works assume specific distributional models for classification compared to our more general setup. However, we do not deal with the problem of feature selection.

Perhaps the most similar method that deals with extrapolation of classification error to a larger number of classes can be found in Kay et al. (2008). They trained a classifier for identifying the observed stimulus from a functional MRI scan of brain activity, and were interested in its performance on larger stimuli sets. They proposed an extrapolation algorithm, based on per-class kernel density estimation, as a heuristic with little theoretical discussion. In Section 3.5, we formalize their method within our framework, and implement two variations of their algorithm. We present simulation results and theoretical arguments to compare the algorithm to the regression approach we propose.

2. Randomized Classification

The randomized classification model we study has the following features. We assume that there exists an infinite, perhaps continuous, label space $\mathcal{Y}$ and an example space $\mathcal{X} \subseteq \mathbb{R}^p$. In the subsequent theory we assume that $\mathcal{Y}$ is continuous solely for the sake of mathematical convenience, so that we can discuss probability integrals on the space without the use of measure-theoretic notation. However, the theory would also approximately describe the case of $\mathcal{Y}$ is a sufficiently large discrete space, as long as the probability mass of the largest atom is suitably small.

We assume there exists a prior distribution π on the label space $\mathcal{Y}$, and that for each label $y \in \mathcal{Y}$, there exists a distribution of examples F_y. In other words, for an example-label pair (X, Y), the conditional distribution of X given $Y = y$ is given by F_y.

A random classification task can be generated as follows. The label set $\mathcal{S} = \{Y^{(1)}, \ldots, Y^{(k)}\}$ is generated by drawing labels $Y^{(1)}, \ldots, Y^{(k)}$ i.i.d. from π. Here we assume the number of labels k to be deterministic. For each label, we sample a training set and a test set. The test set is obtained by sampling r observations $X_\ell^{(i)}$ i.i.d. from $F_{Y^{(i)}}$ for $\ell = 1, \ldots, r$. For now, we can also assume that the training set is obtained by sampling r_{train} observations $X_{\ell,train}^{(i)}$ i.i.d. from $F_{Y^{(i)}}$ for $\ell = 1, \ldots, r_{train}$ and $i = 1, \ldots, k$. However, later we will relax these assumptions on the sampling of the training sets, so that we can accommodate classes have differing or stochastically determined number of instances, as long as the number of training instances for different labels are conditionally independent.

Recalling the face recognition example, $\mathcal{Y}$ is the space of all people, π is some distribution for sampling over people, X is a photo of a person's face, and F_Y is the conditional distribution of photos for person Y. The goal of classification is to label the photo X with the correct person Y.

We assume that the classifier $h(x)$ works by assigning a score to each label $y^{(i)} \in \mathcal{S}$, then choosing the label with the highest score. That is, there exist real-valued *score functions* $m_{y^{(i)}}(x)$ for each label $y^{(i)} \in \mathcal{S}$. Here we used the lower-case notation $y^{(i)}$ for the labels, treating them as fixed for now. Since the classifier is allowed to depend on the training data, it is convenient to view it (and its associated score functions) as random. We write $H(x)$ when we wish to work with the classifier as a random function, and likewise $M_y(x)$ to denote the score functions whenever they are considered as random. Since the classifier works by choosing the label with the highest score, the classifier is correct for a given test instance x^* with true label y^* whenever $m_{y^*}(x^*) = \max_j m_{y^{(j)}}(x^*)$, assuming that there are no ties.

For a fixed instance of the classification task with labels $\mathcal{S} = \{y^{(i)}\}_{i=1}^k$ and associated score functions $\{m_{y^{(i)}}\}_{i=1}^k$, recall the definition of the k-class generalization error (1). We will use the assumption that the test labels are uniformly distributed[1] over $\mathcal{S}$, which makes $\mathrm{GA}_k(h, \mathcal{S})$ a *balanced accuracy*, which equally weights the accuracies of the individual classes. Assuming that there are no ties, it can be written in terms of score functions as

$$\mathrm{GA}_k(h, \mathcal{S}) = \frac{1}{k} \sum_{i=1}^{k} \Pr[m_{y^{(i)}}(X^{(i)}) = \max_j m_{y^{(j)}}(X^{(i)})],$$

where $X^{(i)} \sim F_{y^{(i)}}$ for $i = 1, \ldots, k$.

However, it is often appropriate to model the labels $\{Y^{(i)}\}_{i=1}^k$ as a random sample from a distribution. Examples for such *randomized classification* problems include face recognition, where faces are drawn from a larger population, and large multi-class problems where only an arbitrary subset of labels have been collected.

Given our assumption that k is fixed, a natural target for prediction extrapolation is the expected value of the generalization accuracy $\mathrm{GA}_k(h, \mathcal{S})$ over the distribution of label sets. We call this the k-class *average generalization accuracy* of the classifier, denoted AGA_k, and formally defined as

$$\begin{aligned}
\mathrm{AGA}_k &= \mathbf{E}[\mathrm{GA}_k(H, \mathcal{S}_k)] \\
&= \frac{1}{k} \sum_{i=1}^{k} \Pr[M_{Y^{(i)}}(X^{(i)}) = \max_j M_{Y^{(j)}}(X^{(i)})] \\
&= \Pr[M_Y(X) > \max_{j=1}^{k-1} M_{Y^{(j)}}(X)]
\end{aligned}$$

where $Y^{(1)}, \ldots, Y^{(k)} \overset{iid}{\sim} \pi$, and where (X, Y) is an independent draw with the same joint distribution as its superscripted counterparts $(X^{(i)}, Y^{(i)})$. The last line follows from noting that all k summands in the previous line are identical, as each $Y^{(i)}$ is drawn from the same distribution π. The definition of average generalization accuracy is illustrated in Figure 1.

Note that in this framework, the role of the training and test sets is different than how they are usually used machine learning. Our goal is to predict the accuracy achieved on another (random) label set. Therefore, both the training and test data may be used

1. In Section 6, we discuss extensions of our framework that can accommodate the case that the test labels are not uniformly drawn from $\mathcal{S}$, i.e. that one has a non-uniform prior distribution over test labels.

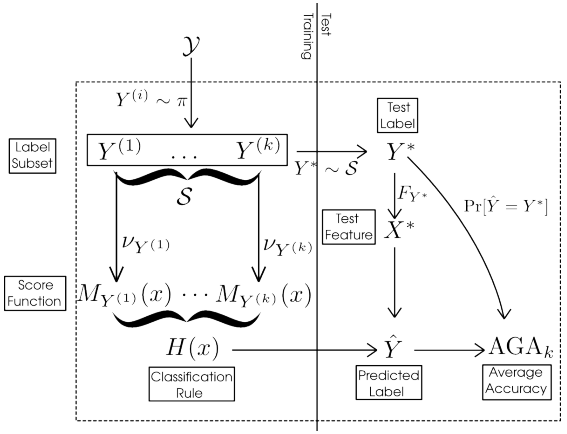

Figure 1: **Average generalization accuracy:** A diagram of the random quantities underlying the average generalization accuracy for k labels (AGA_k). At the training stage (left), a set of k labels $\mathcal{S}$ is sampled from the prior π, and score functions are trained from examples for these classes. At the test stage (right), one true class Y^* is sampled uniformly from $\mathcal{S}$, as well as a test example X^*. AGA_k measures the expected accuracy over these random variables.

in this estimation. Our approach, to be described in Section 2.3, uses the training data exclusively to construct classifiers on label subsets, and test data exclusively to estimate the distribution of favorability over test examples.

2.1. Marginal Classifier

The theoretical analysis of the average generalization accuracy is made much simpler if we can assume that the learning of the scoring functions $M_{Y^{(i)}}$ occurs independently for each labels–that is, there is no information shared between classes. For example, if there exists some function g such that

$$M_{y^{(i)}}(x) = g(x; y^{(i)}, (X^{(i)}_{1,train}, ..., X^{(i)}_{r_{train},train})),$$

the H is a marginal classifier since $M_{y^{(i)}}(x)$ only depends on the label $y^{(i)}$ and the class training set $X^{(i)}_{j,train}$.

In our analysis however, we shall relax the assumption that the classifier $H(x)$ is based on a training set[2]. Instead, it is sufficient that the score functions $\{M_{Y^{(i)}}\}_{i=1}^k$ associated

2. Due to this abstraction, our framework can accommodate scenarios where the classes have differing or stochastically determined number of instances, as long as the number of training instances for different labels are conditionally independent.

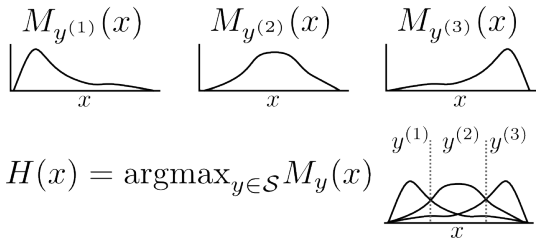

Figure 2: **Classification rule:** Top: Score functions for three classes in a one-dimensional example space. Bottom: The classification rule chooses between $y^{(1)}, y^{(2)}$ or $y^{(3)}$ by choosing the maximal score function.

with the random label set $\{Y^{(i)}\}_{i=1}^{k}$ are independent of the test instances. Under this formalism, we define a marginal classifier as follows.

Definition 1 *The classifier $H(x)$ is called a* marginal classifier *if and only if $M_{Y^{(i)}}$ are independent of both $Y^{(j)}$ and $M_{Y^{(j)}}$ for $j \neq i$.*

In marginal classifiers, classes "compete" only through selecting the highest score, but not in constructing the score functions. Therefore, each M_y can be considered to have been independently drawn from a distribution ν_y. The operation of a marginal classifier is illustrated in Figure 2.

For marginal classifiers, we can prove especially strong results about the accuracy of the classifier under i.i.d. sampling assumptions. And as we will see in the following section, many well-known types of classifiers satisfy the marginal property.

2.2. Examples of Marginal Classifiers

Estimated Bayes classifiers are primary examples of marginal classifiers. By this, we mean classifiers which output the class that maximizes the posterior probability for a class label according to Bayes' rule, but substituting in estimated distributions for the unknown true distributions. Let $\hat{f}_y$ be a density estimate of the example distribution under label y obtained from the empirical distribution $\hat{F}_y$, and let $\pi(y)$ be the prior distribution over labels. Then, we can use the estimated density to produce the score functions:

$$M_y^{EB}(x) = \log(\hat{f}_y(x)) + \log(\pi(y)).$$

The resulting empirical approximation for the Bayes classifier would be

$$H^{EB}(x) = \text{argmax}_{Y \in \mathcal{S}}(M_Y^{EB}(x)).$$

Both Quadratic Discriminant Analysis (QDA) and naïve Bayes classifiers can be seen as specific instances of an estimated Bayes classifier. For QDA, the score function is given by

$$m_y^{QDA}(x) = -(x - \mu(\hat{F}_y))^T \Sigma(\hat{F}_y)^{-1}(x - \mu(\hat{F}_y)) - \log\det(\Sigma(\hat{F}_y)),$$

where $\mu(F) = \int y dF(y)$ and $\Sigma(F) = \int (y - \mu(F))(y - \mu(F))^T dF(y)$. Hence, QDA is the special case of the estimated Bayes classifier when $\hat{f}_y$ is obtained as the multivariate Gaussian density with mean and covariance parameters estimated from the data.

In Naïve Bayes, the score function is

$$m_y^{NB}(x) = \sum_{j=1}^{p} \log \hat{f}_{y,j}(x),$$

where $\hat{f}_{y,j}$ is a density estimate for the j-th component of $\hat{F}_y$. Hence, Naïve Bayes is the estimated Bayes classifier when $\hat{f}_y$ is obtained as the product of estimated componentwise marginal distributions of $p(x_i|y)$.

For some classifiers, M_y is a deterministic function of y (and therefore ν_y is degenerate). A prime example is when there exist fixed or pre-trained embeddings $g, \tilde{g}$ that map both labels y and examples x into R^p. Then

$$M_y^{embed} = -\|g(y) - \tilde{g}(x)\|_2. \tag{2}$$

This would be the case when features from publicly available embeddings (e.g. word embedding vectors) are used for classification; see our example in Section 5. See also Pereira et al. (2018) for an example using word embedding vectors. Note that if the embeddings g or $\tilde{g}$ are informed by the specific set of classes in the experiment, this would no longer be a marginal classifier.

There are many classifiers which do not satisfy the marginal property, such as multinomial logistic regression, multilayer neural networks, decision trees, and k-nearest neighbors.

2.3. Estimation of Average Accuracy

Before tackling extrapolation, it will be useful for us to discuss the simpler task of generalizing accuracy results when the target set is *not* larger than the source set. This allows us to introduce several concepts and notations that are used in the harder problem of generalizing to a larger set. We will also illustrate all of these concept in a toy example following this section, which we shall revisit once more while tackling the problem of extrapolation.

Suppose we have training and test data for a classification task with k_1 classes. That is, we have a label set $\mathcal{S}_{k_1} = \{y^{(i)}\}_{i=1}^{k_1}$, and we assume that the training data has been used to obtain its associated set of score functions $M_{y^{(i)}}$. The test set, composed of $(x_1^{(i)}, \ldots, x_r^{(i)})$ for $i = 1, \ldots, k_1$ is also available to be used for this estimation task. What would be the predicted accuracy for a new randomly sampled set of $k_2 \leq k_1$ labels?

Note that AGA_{k_2} is the expected value of the accuracy on the new set of k_2 labels. Therefore, any unbiased estimator of AGA_{k_2} will be an unbiased predictor for the accuracy on the new set.

Let us start with the case $k_2 = k_1 = k$. For each test observation $x_\ell^{(i)}$, define the ranks of the candidate classes $j = 1, \ldots, k$ by

$$R_\ell^{i,j} = \sum_{s=1}^{k} I\{m_\ell^{(i,j)} \geq m_\ell^{(i,s)}\}.$$

where we have defined $m_\ell^{(i,j)} = m_{y^{(j)}}(x_\ell^{(i)})$. The test accuracy is the fraction of observations for which the correct class also has the highest rank

$$\mathrm{TA}_k = \frac{1}{rk}\sum_{i=1}^{k}\sum_{\ell=1}^{r} I\{R_\ell^{i,i} = k\}. \tag{3}$$

Taking expectations over both the test set and the random labels, the expected value of the test accuracy is AGA_k. Therefore, in this special case, TA_k provides an unbiased estimator for AGA_{k_2}.

Next, let us consider the case where $k_2 < k_1$. Consider label set $\mathcal{S}_{k_2}$ obtained by sampling k_2 labels uniformly without replacement from $\mathcal{S}_{k_1}$. Since $\mathcal{S}_{k_2}$ is unconditionally an i.i.d. sample from the population of labels π, the test accuracy of $\mathcal{S}_{k_2}$ is an unbiased estimator of AGA_{k_2}. However, we can get a better unbiased estimate of AGA_{k_2} by averaging over all the possible subsamples $\mathcal{S}_{k_2} \subset \mathcal{S}_{k_1}$. This defines the average test accuracy over subsampled tasks, ATA_{k_2}.

Remark. Naïvely, computing ATA_{k_2} requires us to train and evaluate $\binom{k_1}{k_2}$ classification rules. However, for marginal classifiers, retraining the classifier is not necessary. The rank $R_\ell^{i,i}$ of the correct label i for $x_\ell^{(i)}$, allows us to determine how many subsets $\mathcal{S}_2$ will result in a correct classification. Specifically, there are $R_\ell^{i,i} - 1 \le k_2$ labels with a lower score than the correct label i. Therefore, as long as one of the classes in $\mathcal{S}_2$ is i, and the other $k_2 - 1$ labels are from the set of $R_\ell^{i,i} - 1$ labels with lower score than i, the classification of $x_j^{(i)}$ will be correct. This implies that there are $\binom{R_\ell^{i,i}-1}{k_2-1}$ such subsets $\mathcal{S}_2$ where $x_\ell^{(i)}$ is classified correctly, and therefore the average test accuracy for all $\binom{k_1}{k_2}$ subsets $\mathcal{S}_2$ is

$$\mathrm{ATA}_{k_2} = \frac{1}{\binom{k_1}{k_2}}\frac{1}{rk_2}\sum_{i=1}^{k_1}\sum_{\ell=1}^{r}\binom{R_\ell^{i,i}-1}{k_2-1}. \tag{4}$$

2.4. Toy Example: Bivariate Normal

Let us illustrate these ideas using a toy example. Let (Y, X) have a bivariate normal joint distribution,

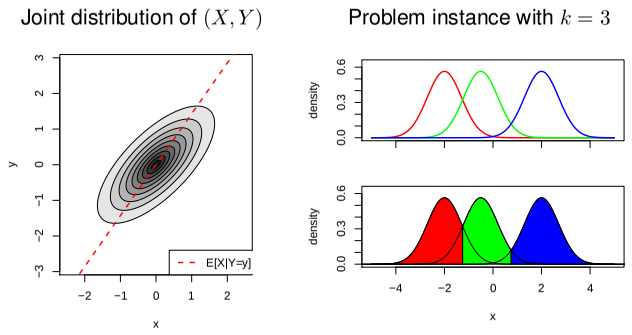
$$(Y, X) \sim N\left(\begin{pmatrix}0\\0\end{pmatrix}, \begin{pmatrix}1 & \rho\\ \rho & 1\end{pmatrix}\right),$$

as illustrated in Figure 3(a). Therefore, for a given randomly drawn label Y, the conditional distribution of X for that label is univariate normal with mean ρY and variance $1 - \rho^2$,

$$X|Y = y \sim N(\rho y, 1 - \rho^2).$$

Supposing we draw $k = 3$ labels $\{y^{(1)}, y^{(2)}, y^{(3)}\}$, the classification problem will be to assign a test instance X^* to the correct label. The test instance X^* would be drawn with equal probability from one of three conditional distributions $X|Y = y^{(i)}$, as illustrated in Figure 3(b, top). The Bayes rule assigns X^* to the class with the highest density $p(x|y^{(i)})$, as illustrated by Figure 3(b, bottom): it is therefore a marginal classifier, with score function

$$M_y(x) = \log(p(x|y)) = -\frac{(x-\rho y)^2}{2(1-\rho^2)} + \text{const.}$$



(a) (b)

Figure 3: **Toy example:** *Left:* The joint distribution of (X, Y) is bivariate normal with correlation $\rho = 0.7$. *Right:* A typical classification problem instance from the bivariate normal model with $k = 3$ classes. *(Top):* the conditional density of X given label Y, for $Y = \{y^{(1)}, y^{(2)}, y^{(3)}\}$. *(Bottom):* the Bayes classification regions for the three classes.

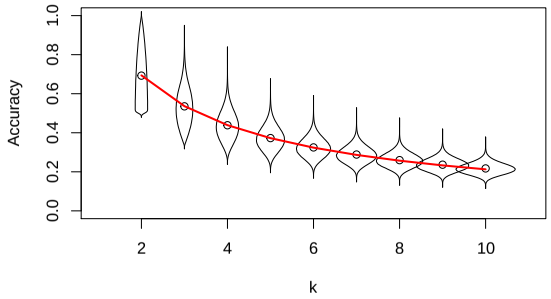


Figure 4: **Generalization accuracy for toy example:** The distribution of the generalization accuracy for $k = 2, 3, \ldots, 10$ for the bivariate normal model with $\rho = 0.7$. Circles indicate the average generalization accuracy AGA_k; the red curve is the theoretically computed average accuracy.

For this model, the generalization accuracy of the Bayes rule for any label set $\{y^{(1)}, \ldots, y^{(k)}\}$ is given by

$$\begin{aligned}\mathrm{GA}_k(h, \{y^{(1)}, \ldots, y^{(k)}\}) &= \frac{1}{k}\sum_{i=1}^{k} \Pr_{X\sim p(x|y^{(i)})}[p(X|y^{(i)}) = \max_{j=1}^{k} p(X|y^{(j)})] \\ &= \frac{1}{k}\sum_{i=1}^{k} \Phi\left(\frac{y^{[i+1]} - y^{[i]}}{2\sqrt{1-\rho^2}}\right) - \Phi\left(\frac{y^{[i-1]} - y^{[i]}}{2\sqrt{1-\rho^2}}\right),\end{aligned}$$

where Φ is the standard normal cdf, $y^{[1]} < \cdots < y^{[k]}$ are the sorted labels, $y^{[0]} = -\infty$ and $y^{[k+1]} = \infty$, and h is the maximum-margin classifier $h(x) = \mathrm{argmax}_{y\in\{y^{(1)},\ldots,y^{(k)}\}} m_y(x)$. We numerically computed $\mathrm{GA}_k(h, \{Y^{(1)}, \ldots, Y^{(k)}\})$ for randomly drawn labels $Y^{(1)}, \ldots, Y^{(k)} \overset{iid}{\sim} N(0,1)$, and the distributions of GA_k for $k = 2, \ldots, 10$ are illustrated in Figure 4. The mean of the distribution of GA_k is the k-class average accuracy, AGA_k. The theory presented in the next section deals with how to analyze the average accuracy AGA_k as a function of k.

3. Extrapolation

The section is organized as follows. We begin by introducing an explicit formula for the average accuracy AGA_k. The formula reveals that AGA_k is determined by moments of a one-dimensional function $D(u)$. Using this formula, we can estimate $D(u)$ using subsampled accuracies. These estimates allow us to extrapolate the average generalization accuracy to an arbitrary number of labels.

The result of our analysis is to expose the average accuracy AGA_k as the weighted average of a function $D(u)$, where $D(u)$ is independent of k, and where k only changes the weighting.

One of the assumptions we rely on is the *tie-breaking condition*, which allows us to neglect specifying the case when margins are tied.

Definition 2 Tie-breaking condition*: for all $x \in \mathcal{X}$, $M_Y(x) \neq M_{Y'}(x)$ with probability one for Y, Y' independently drawn from π.*

In practice, one can simply break ties randomly, which is mathematically equivalent to adding a small amount of random noise ϵ to the function M.

The result is stated as follows.

Theorem 3 *Suppose π, $\{F_y\}_{y\in\mathcal{Y}}$, and score functions M_y satisfy the tie-breaking condition. Then, there exists a cumulative distribution function $D(u)$ defined on the interval $[0,1]$ such that*

$$AGA_k = 1 - (k-1)\int_0^1 D(u)u^{k-2}du. \tag{5}$$

3.1. Analysis of Average Accuracy

Recall that for marginal classifiers, the model M_Y should be independent of the other labels and independent of the test instances. We often consider a random label (Y) with its

associated score function (M_Y) and an example vector (X) drawn from label Y. Explicitly, this sampling can be written:

$$Y \sim \pi, \quad M_Y|Y \sim \nu_Y, \quad X|Y \sim F_Y.$$

Similarly we use $(Y', M_{Y'}, X')$ and (Y^*, M_{Y^*}, X^*) for two more triplets with independent and identical distributions. Specifically, X^* will typically note the test example, and therefore Y^* the true label and M_{Y^*} its score function.

The function D is related to a favorability function. Favorability measures the probability that the score for the example x is going to be maximized by a particular score function m_y, compared to a random competitor $M_{Y'}$. Formally, we write

$$U_x(m_y) = \Pr[m_y(x) > M_{Y'}(x)]. \tag{6}$$

Note that for fixed example x, favorability is monotonically increasing in $m_y(x)$. If $m_y(x) > m_{y^\dagger}(x)$, then $U_x(y) > U_x(y^\dagger)$, because the event $\{m_y(x) > M_{Y'}(x)\}$ contains the event $\{m_{y^\dagger}(x) > M_{Y'}(x)\}$.

Therefore, given labels $y^{(1)}, \ldots, y^{(k)}$ and test instance x, we can think of the classifier as choosing the label with the greatest favorability:

$$\hat{y} = \mathrm{argmax}_{y^{(i)}\in\mathcal{S}} m_{y^{(i)}}(x) = \mathrm{argmax}_{y^{(i)}\in\mathcal{S}} U_x(m_{y^{(i)}}).$$

Furthermore, via a conditioning argument, we see that this is still the case even when the test instance and labels are random, as long as the random example X^* is independent of Y. (Recall that in our notation, X and Y are dependent, but $X^* \perp Y$.)

$$\hat{Y} = \mathrm{argmax}_{Y^{(i)}\in\mathcal{S}} M_{Y^{(i)}}(X^*) = \mathrm{argmax}_{Y^{(i)}\in\mathcal{S}} U_{X^*}(M_{Y^{(i)}}).$$

The favorability takes values between 0 and 1, and when any of its arguments are random, it becomes a random variable with a distribution supported on $[0,1]$. In particular, we consider the following two random variables:

a. the *incorrect-label* favorability $U_{x^*}(M_Y)$ between a given fixed test instance x^*, and the score function of a random incorrect label M_Y, and

b. the *correct-label* favorability $U_{X^*}(M_{Y^*})$ between a random test instance X^*, and the score function of the correct label, M_{Y^*}.

3.1.1. Incorrect-Label Favorability

The incorrect-label favorability can be written explicitly as

$$U_{x^*}(M_Y) = \Pr[M_Y(x^*) > M_{Y'}(x^*)|M_Y(x^*)]. \tag{7}$$

Note that M_Y and $M_{Y'}$ are identically distributed, and both are unrelated to x^* that is fixed. This leads to the following result:

Lemma 4 *Under the tie-breaking condition, the incorrect-label favorability $U_{x^*}(M_Y)$ is uniformly distributed for any $x^* \in \mathcal{X}$, meaning*

$$\Pr[U_{x^*}(M_Y) \leq u] = u \tag{8}$$

for all $u \in [0,1]$.

Proof Write $U_{x^*}(M_Y) = \Pr[Z > Z'|Z]$, where $Z = M_Y(x)$ and $Z' = M_{Y'}(x)$ for $Y, Y' \overset{i.i.d.}{\sim} \pi$. The tie-breaking condition implies that $\Pr[Z = Z'] = 0$. Now observe that for independent random variables Z, Z' with $Z \overset{D}{=} Z'$ and $\Pr[Z = Z'] = 0$, the conditional probability $\Pr[Z > Z'|Z]$ is uniformly distributed. ■

3.1.2. Correct-Label Favorability

The correct-label favorability is

$$U^* = U_{X^*}(M_{Y^*}) = \Pr[M_{Y^*}(X^*) > M_{Y'}(X^*)|Y^*, M_{Y^*}(X^*), X^*]. \tag{9}$$

The distribution of U^* will depend on π, $\{F_y\}_{y\in\mathcal{S}}$ and $\{\nu_y\}_{y\in\mathcal{S}}$, and generally cannot be written in a closed form. However, this distribution is central to our analysis–indeed, we will see that the function D appearing in theorem 3 is defined as the cumulative distribution function of U^*.

The special case of $k = 2$ shows the relation between the distribution of U^* and the average generalization accuracy, AGA_2. In the two-class case, the average generalization accuracy is the probability that a random correct label score function gives a larger value than a random distractor:

$$\mathrm{AGA}_2 = \Pr[M_{Y^*}(X^*) > M_{Y'}(X^*)].$$

where Y^* is the correct label, and Y' is a random incorrect label. If we condition on Y^*, M_{Y^*} and X^*, we get

$$\mathrm{AGA}_2 = \mathbf{E}[\Pr[M_{Y^*}(X^*) > M_{Y'}(X^*)|Y^*, M_{Y^*}, X^*]].$$

Here, the conditional probability inside the expectation is the correct-label favorability. Therefore,

$$\mathrm{AGA}_2 = \mathbf{E}[U^*] = \int D(u)du,$$

where $D(u)$ is the cumulative distribution function of U^*, $D(u) = \Pr[U^* \le u]$. Theorem 3 extends this to general k; we now give the proof.

Proof Without loss of generality, suppose that the true label is Y^* and the incorrect labels are $Y^{(1)}, \ldots, Y^{(k-1)}$. We have

$$\mathrm{AGA}_k = \Pr[M_{Y^*}(X^*) > \max_{i=1}^{k-1} M_{Y^{(i)}}(X^*)] = \Pr[U^* > \max_{i=1}^{k-1} U_{X^*}(M_{Y^{(i)}})],$$

recalling that $U^* = U_{X^*}(M_{Y^*})$. Now, if we condition on $X^* = x^*$, $Y^* = y^*$ and $M_{Y^*} = m_{y^*}$, then the random variable U^* becomes fixed, with value

$$u^* = U_{x^*}(m_{y^*}).$$

Therefore,

$$\begin{aligned}\mathrm{AGA}_k &= \mathbf{E}[\Pr[U^* > \max_{i=1}^{k-1} U_{X^*}(M_{Y^{(i)}})|X^* = x^*, Y^* = y^*, M_{Y^*} = m_{y^*}]] \\ &= \mathbf{E}[\Pr[U^* > \max_{i=1}^{k-1} U_{X^*}(M_{Y^{(i)}})|X^* = x^*, U^* = u^*]].\end{aligned}$$

Now define $U_{max,k-1} = \max_{i=1}^{k-1} U_{X^*}(M_{Y^{(i)}})$. Since by Lemma 4, $U_{X^*}(M_{Y^{(i)}})$ are i.i.d. uniform conditional on $X^* = x^*$, we know that

$$U_{max,k-1}|X^* = x^* \sim \mathrm{Beta}(k-1, 1). \tag{10}$$

Furthermore, $U_{max,k-1}$ is independent of U^* conditional on X^*. Therefore, the conditional probability can be computed as

$$\Pr[U^* > U_{max,k-1}|X^* = x^*, U^* = u^*] = \int_0^{u^*} (k-1)u^{k-2}du.$$

Consequently,

$$\mathrm{AGA}_k = \mathbf{E}[\Pr[U^* > \max_{i=1}^{k-1} U_{X^*}(M_{Y^{(i)}})|X^* = x^*, U^* = u^*]] \tag{11}$$

$$= \mathbf{E}[\int_0^{U^*} (k-1)u^{k-2}du|U^* = u^*] \tag{12}$$

$$= \mathbf{E}[\int_0^1 I\{u \le U^*\}(k-1)u^{k-2}du] \tag{13}$$

$$= (k-1)\int_0^1 \Pr[u \le U^*]u^{k-2}du \tag{14}$$

$$= 1 - (k-1)\int_0^1 \Pr[u \ge U^*]u^{k-2}du. \tag{15}$$

By defining $D(u)$ as the cumulative distribution function of U^* on $[0, 1]$,

$$D(u) = \Pr[U_{X^*}(M_{Y^*}) \le u], \tag{16}$$

and substituting this definition into (15), we obtain the identity (5). ■

Theorem 3 expresses the average accuracy as a weighted integral of the function $D(u)$. Essentially, this theoretical result allows us to reduce the problem of estimating AGA_k to one of estimating $D(u)$. But how shall we estimate $D(u)$ from data? We propose using non-parametric regression for this purpose in Section 3.3.

3.2. Favorability and Average Accuracy for the Toy Example

Recall that for the toy example from Section 2.4, the score function M_y was a non-random function of y that measures the distance between x and ρy

$$M_y(x^*) = \log(p(x^*|y)) = -\frac{(x^* - \rho y)^2}{2(1-\rho^2)}.$$

For this model, the favorability function $U_{x^*}(m_y)$ compares the distance between x^* and ρy to the distance between x^* and $\rho Y'$ for a randomly chosen distractor $Y' \sim N(0,1)$:

$$\begin{aligned} U_{x^*}(m_y) &= \Pr[|\rho y - x^*| < |\rho Y' - x^*|] \\ &= \Phi\left(\frac{x^* + |\rho y - x^*|}{\rho}\right) - \Phi\left(\frac{x^* - |\rho y - x^*|}{\rho}\right), \end{aligned}$$

where Φ is the standard normal cumulative distribution function. Figure 5(a) illustrates the level sets of the function $U_{x^*}(m_y)$. The highest values of $U_{x^*}(m_y)$ are near the line $x^* = \rho y$ corresponding to the conditional mean of $X|Y$, and as one moves farther from the line, $U_{x^*}(m_y)$ decays. Note, however, that large values of x^* and y (with the same sign) result in larger values of $U_{x^*}(m_y)$ since it becomes unlikely for $Y' \sim N(0,1)$ to exceed $Y = y$.

Using the formula above, we can calculate the correct-label favorability $U^* = U_{X^*}(M_{Y^*})$ and its cumulative distribution function $D(u)$. The function D is illustrated in Figure 5(b) for the current example with $\rho = 0.7$. The red curve in Figure 4 was computed using the formula

$$\mathrm{AGA}_k = 1 - (k-1)\int D(u)u^{k-2}du.$$

It is illuminating to consider how the average accuracy curves and the $D(u)$ functions vary as we change the parameter ρ. Higher correlations ρ lead to higher accuracy, as seen in Figure 6(a), where the accuracy curves are shifted upward as ρ increases from 0.3 to 0.9. The favorability $U_{x^*}(m_y)$ tends to be higher on average as well, which leads to lower values of the cumulative distribution function–as we see in Figure 6(b), where the function $D(u)$ decreases as ρ increases, and therefore accuracy increases.

3.3. Estimation

Next, we discuss how to use data from smaller classification tasks to extrapolate average accuracy. We are seeking an unbiased estimator $\widehat{\mathrm{AGA}_k}$ such that

$$\mathbf{E}[\widehat{\mathrm{AGA}_k}] = \mathrm{AGA}_k.$$

Assume that we have data from a k_1-class random classification task, and would like to estimate the average accuracy AGA_{k_2} for $k_2 > k_1$ classes. Our estimation method will use the k-class average test accuracies, $\mathrm{ATA}_2, ..., \mathrm{ATA}_{k_1}$ (see Eq 4), for its inputs.

The key to understanding the behavior of the average accuracy AGA_k is the function D. We adopt a linear model

$$D(u) = \sum_{\ell=1}^{m} \beta_\ell h_\ell(u), \tag{17}$$

where $h_\ell(u)$ are known basis functions, and β_ℓ are the linear coefficients to be estimated. The linearity assumption (17) means that linear regression can be used to estimate the average accuracy curve. This the the idea behind our proposed method ClassExReg, meaning *Classification Extrapolation using Regression.*

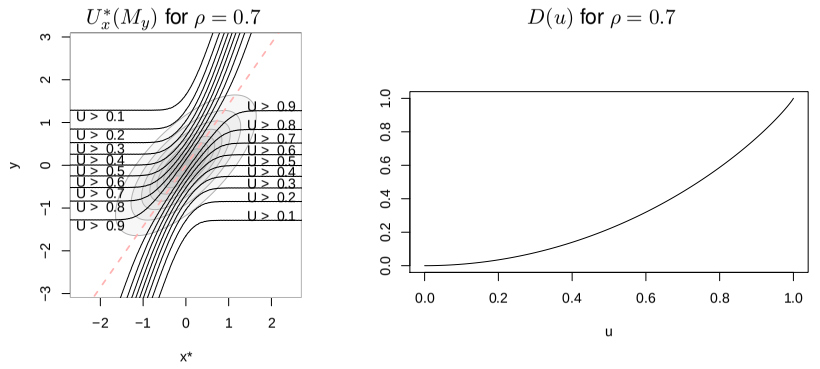

Figure 5: **Favorability for toy example:** *Left:* The level curves of the function $U_{x^*}(M_y)$ in the bivariate normal model with $\rho = 0.7$. *Right:* The function $D(u)$ gives the cumulative distribution function of the random variable $U_{X^*}(M_Y)$.

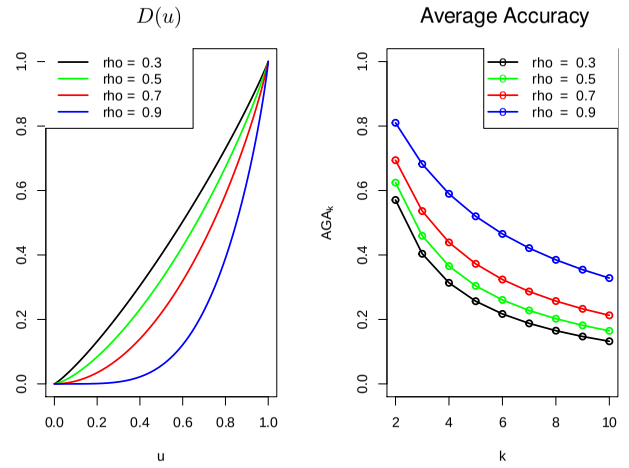

Figure 6: **Average accuracy with different ρ's:** *Left:* The average accuracy AGA_k. *Right:* $D(u)$ function for the bivariate normal model with $\rho \in \{0.3, 0.5, 0.7, 0.9\}$.

Conveniently, AGA_k can also be expressed in terms of the β_ℓ coefficients. If we plug in the assumed linear model (17) into the identity (5), then we get

$$1 - \mathrm{AGA}_k = (k-1)\int D(u)u^{k-2}du \tag{18}$$

$$= (k-1)\int_0^1 \sum_{\ell=1}^{m} \beta_\ell h_\ell(u)u^{k-2}du \tag{19}$$

$$= \sum_{\ell=1}^{m} \beta_\ell H_{\ell,k}, \tag{20}$$

where

$$H_{\ell,k} = (k-1)\int_0^1 h_\ell(u)u^{k-2}du. \tag{21}$$

The constants $H_{\ell,k}$ are moments of the basis function h_ℓ. Note that $H_{\ell,k}$ can be precomputed numerically for any $k \geq 2$.

Now, since the test accuracies ATA_k are unbiased estimates of AGA_k, this implies that the regression estimate

$$\hat{\beta} = \mathrm{argmin}_\beta \sum_{k=2}^{k_1} \left((1 - \mathrm{ATA}_k) - \sum_{\ell=1}^{m} \beta_\ell H_{\ell,k} \right)^2,$$

is unbiased for β. The estimate of AGA_{k_2} is similarly obtained from (20), via

$$\widehat{\mathrm{AGA}}_{k_2} = 1 - \sum_{\ell=1}^{m} \hat{\beta}_\ell H_{\ell,k_2}. \tag{22}$$

3.4. Model Selection

Accurate extrapolation using ClassExReg depends on a good fit between the linear model (17) and the true discriminability function $D(u)$. However, since the function $D(u)$ depends on the unknown joint distribution of the data, it makes sense to let the data help us choose a good basis $\{h_u\}$ from a set of candidate bases.

Let $B_1, \ldots, B_s$ be a set of candidate bases, with $B_i = \{h_u^{(i)}\}_{u=1}^{m_i}$. Ideally, we would like our model selection procedure to choose the B_i that obtains the best root-mean-squared error (RMSE) on the extrapolation from k_1 to k_2 classes. As an approximation, we estimate the RMSE of extrapolation from $\frac{k_1}{2}$ source classes to k_1 target classes, by means of the "bootstrap principle." This amounts to a resampling-based model selection approach, where we perform extrapolations from $k_0 = \lfloor \frac{k_1}{2} \rfloor$ classes to k_1 classes, and evaluate methods based on how closely the predicted $\widehat{\mathrm{AGA}}_{k_1}$ matches the test accuracy ATA_{k_1}. To elaborate, our model selection procedure is as follows.

1. For $\ell = 1, \ldots, L$ resampling steps:
   (a) Subsample $\mathcal{S}_{k_0}^{(\ell)}$ from $\mathcal{S}_{k_1}$ uniformly with replacement.
   (b) Compute average test accuracies $\mathrm{ATA}_2^{(\ell)}, \ldots, \mathrm{ATA}_{k_0}^{(\ell)}$ from the subsample $\mathcal{S}_{k_0}^{(\ell)}$.

   (c) For each candidate basis B_i, with $i = 1, \ldots, s$:
      i. Compute $\hat{\beta}^{(i,\ell)}$ by solving the least-squares problem

$$\hat{\beta}^{(i,\ell)} = \mathrm{argmin}_\beta \sum_{k=2}^{k_0} \left((1 - \mathrm{ATA}_k^{(\ell)}) - \sum_{j=1}^{m_i} \beta_j H_{j,k}^{(i)} \right)^2.$$

      ii. Estimate $\widehat{\mathrm{AGA}}_{k_1}^{(i,\ell)}$ by

$$\widehat{\mathrm{AGA}}_{k_1}^{(i,\ell)} = \sum_{\ell=1}^{m_i} \hat{\beta}_j^{(i,\ell)} H_{j,k_1}^{(i)}.$$

2. Select the basis B_{i^*} by

$$i^* = \mathrm{argmin}_{i=1}^{s} \sum_{\ell=1}^{L} (\widehat{\mathrm{AGA}}_{k_1}^{(i,\ell)} - \mathrm{ATA}_{k_1})^2.$$

3. Use the basis B_{i^*} to extrapolate from k_1 classes (the full data) to k_2 classes.

3.5. The Kay KDE-based estimator

In their paper,[3] Kay et al. (2008) proposed a method for extrapolating classification accuracy to a larger number of classes. The method depends on repeated kernel-density estimation (KDE) steps. Because the method is only briefly motivated in the original text, we present it in our notation.

The idea of the method is to estimate separately for each example $x_\ell^{(i)}$ associated with class $y^{(i)}$ the probability of outscoring a random competitor:

$$\mathrm{Acc}_2(x_\ell^{(i)}; m) := \Pr[m_\ell^{(i,i)} > m_Y(x_\ell^{(i)})],$$

recalling that we defined $m_\ell^{(i,j)} = m_{y^{(j)}}(x_\ell^{(i)})$. For a given example, accurate classification against $k-1$ independent (random) distractor classes is equivalent to $k-1$ independent accurate classifications of a single random competitor. Therefore,

$$\mathrm{Acc}_k(x_\ell^{(i)}; m_{y^{(i)}}) := \Pr[m_\ell^{(i,i)} > \max_{j \neq i} m_\ell^{(i,j)}] = \mathrm{Acc}_2(x_\ell^{(i)}; m_{y^{(i)}})^{k-1}.$$

Given estimated accuracy values $a_\ell^{(i)} = \widehat{\mathrm{Acc}}_2(x_\ell^{(i)})$, $\ell = 1, \ldots, r$, $i = 1, ..., k_1$, we can average the $k-1$ powers:

$$\widehat{\mathrm{AGA}}_k = \frac{1}{rk_1} \sum_{i=1}^{k_1} \sum_{\ell=1}^{r} (1 - (1 - a_\ell^{(i)})^{k-1})$$

Note that if we have noisy but unbiased estimates of $\mathrm{Acc}_2(x_\ell^{(i)}; m_{y^{(i)}})$, then the estimates for $\mathrm{Acc}_k(x_\ell^{(i)}; m_{y^{(i)}})$ and $\widehat{\mathrm{AGA}}_K$ will be upward biased because $\mathbf{E}[X^K] \geq \mathbf{E}[X]^K$.

Accuracy for each example $\mathrm{Acc}_2(x_\ell^{(i)})$ is estimated in two steps:

3. The KDE extrapolation method is described in page 29 of supplement to Kay et al. (2008). While the method is only described for a one-nearest neighbor classifier and for the setting where there is at most one test observation per class, we have taken the liberty of extending it to a generic multi-class classification problem.

1. The density of the wrong-class scores is estimated by smoothing the observed scores with a kernel function $K(\cdot,\cdot)$ and bandwidth h

$$\hat{f}_\ell^{(i)}(m) = \frac{1}{k_1 - 1}\sum_{j\neq i} K_h(m_\ell^{(i,j)}, m).$$

2. The density $\hat{f}_\ell^{(i)}(m)$ is integrated below the observed true value $m_\ell^{(i,i)}$:

$$a_\ell^{(i)} = \widehat{\mathrm{Acc}}_2(x_\ell^{(i)}) = \int_{-\infty}^{m_\ell^{(i,i)}} \hat{f}_\ell^{(i)}(m)dm.$$

The smoothed density usually over-estimates the size of the right-tail of wrong class distribution compared to the observed proportion of errors, biasing downward the accuracy of each individual example.

Briefly, let us point out several key differences between our regression method and Kay's KDE method:

i. The KDE method balances two biases: an upward bias in exponentiating the estimated accuracy, and a downward bias in smoothing the wrong-class densities. The upward bias occurs because even if $\widehat{\mathrm{Acc}}_2(x_\ell^{(i)})$ is unbiased, $\widehat{\mathrm{Acc}}_2(x_\ell^{(i)})^k$ will *not* be unbiased for $\mathrm{Acc}_2(x_\ell^{(i)})^k$, and will typically be larger. The bias becomes more prominent for larger k, but decreases as the true accuracy approaches 1. The result of the KDE method therefore depends non-trivially on the choice of smoothing bandwidth used in the density estimation step. (Without smoothing, however, any example that was correctly estimated in the smaller set would have $\widehat{\mathrm{Acc}}_K = 1$). The method relies on smoothing of each class to generate the tail density that exceeds $m_\ell^{(i,i)}$, and therefore it is highly dependent on the choice of kernel bandwidth.

ii. The KDE method estimates the accuracy separately for every class. When the source-set size k is small, this might lead to less stable estimation for each class and therefore a larger bias after extrapolating. The regression estimator, on the other hand, estimates the average accuracy pooling together information across classes. This might lead to higher variance.

iii. The regression method does not look at the scores directly, only at the rankings. It is therefore blind to monotone transformations on the score functions. The KDE method, on the other hand, is sensitive to the distribution of observed scores.

4. Simulation Study

We ran simulations to check how the proposed extrapolation method, ClassExReg, performs in different settings. The results are displayed in Figure 7. We varied the number of classes k_1 in the source data set, the difficulty of classification, and the basis functions. We generated data according to a mixture of isotropic multivariate Gaussian distributions: labels Y were sampled from $Y \sim N(0, I_{10})$, and the examples for each label sampled from $X|Y \sim N(Y, \sigma^2 I_{10})$. The noise-level parameter σ determines the difficulty of classification.

Similarly to the real-data example, we consider a 1-nearest neighbor classifier, which is given a single training instance per class.

For the estimation, we use the model selection procedure described in Section 3.4 to select the parameter h of the "radial basis"

$$h_\ell(u) = \Phi\left(\frac{\Phi^{-1}(u) - t_\ell}{h}\right).$$

where t_ℓ are a set of regularly spaced knots which are determined by h and the problem parameters. Additionally, we add a constant element to the basis, equivalent to adding an intercept to the linear model (17).

The rationale behind the radial basis is to model the density of $\Phi^{-1}(U^*)$ as a mixture of Gaussian kernels with variance h^2. To control overfitting, the knots are separated by at least a distance of $h/2$, and the largest knots have absolute value $\Phi^{-1}(1 - \frac{1}{rk_1^2})$. The size of the maximum knot is set this way since rk_1^2 is the number of ranks that are calculated and used by our method. Therefore, we do not expect the training data to contain enough information to allow our method to distinguish between more than rk_1^2 possible accuracies, and hence we set the maximum knot to prevent the inclusion of a basis element that has on average a higher mean value than $u = 1 - \frac{1}{rk_1^2}$. However, in simulations we find that the performance of the basis depends only weakly on the exact positioning and maximum size of the knots, as long as sufficiently large knots are included. As is the case throughout non-parametric statistics, the bandwidth h is the most crucial parameter. In the simulation, we use a grid $h = \{0.1, 0.2, \ldots, 1\}$ for bandwidth selection.

Meanwhile, for the KDE method, we used a Gaussian kernel, with the bandwidth chosen via pseudolikelihood cross-validation (Cao et al., 1994), as recommended by Kay et al. (2008). Specifically, we used the two methods for cross-validated KDE estimation provided in the `stats` package in the `R` statistical computing environment: biased cross-validation and unbiased cross-validation (Scott, 1992).

4.1. Simulation Results

We see in Figure 7 that ClassExReg and the KDE methods with unbiased and biased cross-validation (KDE-UCV, KDE-BCV) perform comparably in the Gaussian simulations. We studied how the difficulty of extrapolation relates to both the absolute size of the number of classes and the extrapolation factor $\frac{k_2}{k_1}$. Our simulation has two settings for $k_1 = \{500, 5000\}$, and within each setting we have extrapolations to 2 times, 4 times, 10 times, and 20 times the number of classes.

Within each problem setting defined by the number of source and target classes (k_1, k_2), we use the maximum RMSE across all signal-to-noise settings to quantify the overall performance of the method, as displayed in Table 1.

The results also indicate that more accurate extrapolation appears to be possible for smaller extrapolation ratios $\frac{k_2}{k_1}$ and larger k_1. ClassExReg improves in worst-case RMSE when moving from $k_1 = 500$ to $k_1 = 5000$ while keeping the extrapolation factor fixed, most dramatically in the case $\frac{k_2}{k_1} = 2$ when it improves from a maximum RMSE of 0.032 ± 0.001 ($k_1 = 500$) to 0.009 ± 0.000 ($k_1 = 5000$), which is 3.5-fold reduction in worst-case RMSE,

k_1	k_2	ClassExReg	KDE-BCV	KDE-UCV
500	1000	**0.032** (0.001)	0.090 (0.001)	0.067 (0.001)
500	2000	**0.044** (0.002)	0.088 (0.001)	0.059 (0.001)
500	5000	0.073 (0.004)	0.079 (0.001)	**0.051** (0.001)
500	10000	0.098 (0.004)	0.076 (0.001)	**0.045** (0.001)
5000	10000	**0.009** (0.000)	0.038 (0.000)	0.028 (0.000)
5000	20000	**0.015** (0.001)	0.028 (0.000)	0.019 (0.000)
5000	50000	**0.032** (0.002)	0.035 (0.000)	0.053 (0.000)
5000	100000	**0.054** (0.003)	0.065 (0.000)	0.086 (0.000)

Table 1: Maximum RMSE (se) across all signal-to-noise-levels in predicting TA_{k_2} from k_1 classes in multivariate Gaussian simulation. Standard errors were computed by nesting the maximum operation within the bootstrap, to properly account for the variance of a maximum of estimated means.

but also benefiting from at least a 1.8-fold reduction in RMSE when going from the smaller problem to the larger problem in the other three cases.

The kernel-density method produces comparable results, but is seen to depend strongly on the choice of bandwidth selection: KDE-UCV and KDE-BCV show very different performance profiles, although they differ only in the method used to choose the bandwidth. This matches our analysis in Section 3.5 (item i), where we noted the sensitivity of the tail densities to the bandwidth. Also, the KDE methods show significant estimation bias, as can be seen from Figure 8. As we discussed in 3.5 (item i), this is due to the fact that the KDE method ignores the bias introduced by exponentiation. Meanwhile, ClassExReg avoids this source of bias by estimating the $(k-1)$st moment of $D(u)$ directly. As we see in Figure 8, correcting for the bias of exponentiation helps greatly to reduce the overall bias. Indeed, while ClassExReg shows comparable bias for the 500 to 10000 extrapolation, the bias is very well-controlled in all of the $k_1 = 5000$ extrapolations.

5. Experimental Evaluation

We demonstrate the extrapolation of average accuracy in two data examples: (i) predicting the accuracy of a face recognition on a large set of labels from the system's accuracy on a smaller subset, and (ii) extrapolating the performance of various classifiers on an optical character recognition (OCR) problem in the Telugu script, which has over 400 glyphs.

The face-recognition example takes data from the "Labeled Faces in the Wild" data set (Huang et al. (2007)), where we selected the 1672 individuals with at least 2 face photos. We form a data set consisting of photo-label pairs $(x_j^{(i)}, y^{(i)})$ for $i = 1, \ldots, 1672$ and $j = 1, 2$ by randomly selecting 2 face photos for each individual. We used the OpenFace (Amos et al. (2016)) embedding for feature extraction.[4] In order to identify a new photo x^*, we obtain the feature vector $g(x^*)$ from the OpenFace network, and guess the label $\hat{y}$ with the

4. For each photo x, a 128-dimensional feature vector $g(x)$ is obtained as follows. The computer vision library DLLib is used to detect landmarks in x, and to apply a nonlinear transformation to align x to a template. The aligned photograph is then downsampled to a 96×96 image. The downsampled image

minimal Euclidean distance between $g(y^{(i)})$ and $g(x^*)$, which implies a score function

$$M_{y^{(i)}}(x^*) = -||g(x_1^{(i)}) - g(x^*)||^2.$$

In this way, we can compute the test accuracy on all 1672 classes, TA$_{1672}$, but we also subsample $k_1 = \{100, 200, 400\}$ classes in order to extrapolate from k_1 to 1672 classes.

In the Telugu optical character recognition example (Achanta and Hastie (2015)), we consider the use of three different classifiers: logistic regression, linear support-vector machine (SVM), and a deep convolutional neural network.[5] The full data consists of 400 classes with 50 training and 50 test observations for each class. We create a nested hierarchy of subsampled data sets consisting of (i) a subset of 100 classes uniformly sampled without replacement from the 400 classes, and (ii) a subset consisting of 20 classes uniformly sampled without replacement from the size-100 subsample. We therefore study three different prediction extrapolation problems:

1. Predicting the accuracy on $k_2 = 100$ classes from $k_1 = 20$ classes, comparing the predicted accuracy to the test accuracy of the classifier on the 100-class subsample as ground truth.

is fed into a pre-trained deep convolutional neural network to obtain the 128-dimensional feature vector $g(x)$. More details are found in Amos et al. (2016).

5. The network architecture is as follows: `48x48-4C3-MP2-6C3-8C3-MP2-32C3-50C3-MP2-200C3-SM`.

k_1	ClassExReg	KDE-BCV	KDE-UCV
100	0.113 (0.002)	**0.053** (0.001)	0.082 (0.001)
200	0.058 (0.002)	**0.037** (0.001)	0.057 (0.001)
400	0.050 (0.001)	**0.024** (0.001)	0.035 (0.001)

Table 2: **Face-recognition extrapolation RMSEs**: RMSE (se) on predicting TA_{1672} from k_1 classes

2. Same as (1), but setting $k_2 = 400$ and $k_1 = 20$, and using the full data set for the ground truth.

3. Same as (2), but setting $k_2 = 400$ and $k_1 = 100$.

Note that unlike in the case of the face recognition example, here the assumption of marginal classification is satisfied for none of the classifiers. We compare the result of our model to the ground truth obtained by using the full data set.

5.1. Results

The extrapolation results for the face recognition problem can be seen in Figure 10, which plots the extrapolated accuracy curves for each method for 100 different subsamples of size k_1. As can be seen, for all three methods, the variances decrease rapidly as k_1 increases.

The root-mean-square errors at $k_2 = 1672$ can be seen in Table 2. KDE-BCV achieves the best extrapolation for all three cases $k_1 = \{100, 200, 400\}$ with KDE-UCV consistently achieving second place. These results differ from the ranking of the RMSEs for the analagous simulation when predicting $k_2 = 2000$ from $k_1 = 500$ for accuracies around 0.45: in the first row and second column of Figure 7, where the true accuracy is 0.43 (from setting $\sigma^2 = 0.2$), the lowest RMSE belongs to KDE-UCV (RMSE=0.0361 ± 0.001), followed closely by ClassExReg (RMSE=0.0372 ± 0.002), and KDE-BCV (RMSE=0.0635 ± 0.001) having the highest RMSE. These discrepancies could be explained by differences between the data distributions between the simulation and the face recognition example, and also by the fact that we only have access to the $k_2 = 1672$-class ground truth for the real data example.

The results for Telugu OCR classification are displayed in Table 3. If we rank the three extrapolation methods in terms of distance to the ground truth accuracy, we see a consistent pattern of rankings between the 20-to-100 extrapolation and the 100-to-400 extrapolation. As we remarked in the simulation, the difficulty of extrapolation appears to be primarily sensitive to the extrapolation ratio $\frac{k_2}{k_1}$, which are similar (5 versus 4) in the 20-to-100 and 100-to-400 problems. In both settings, ClassExReg comes closest to the ground truth for the Deep CNN and the SVM, but KDE-BCV comes closest to ground truth for the Logistic regression. However, even for logistic regression, ClassExReg does better or comparably to KDE-UCV.

In the 20-to-400 extrapolation, which has the highest extrapolation ratio ($\frac{k_2}{k_1} = 20$), none of the three extrapolation methods performs consistently well for all three classifiers. It could be the case that the variability is a dominating effect given the small training

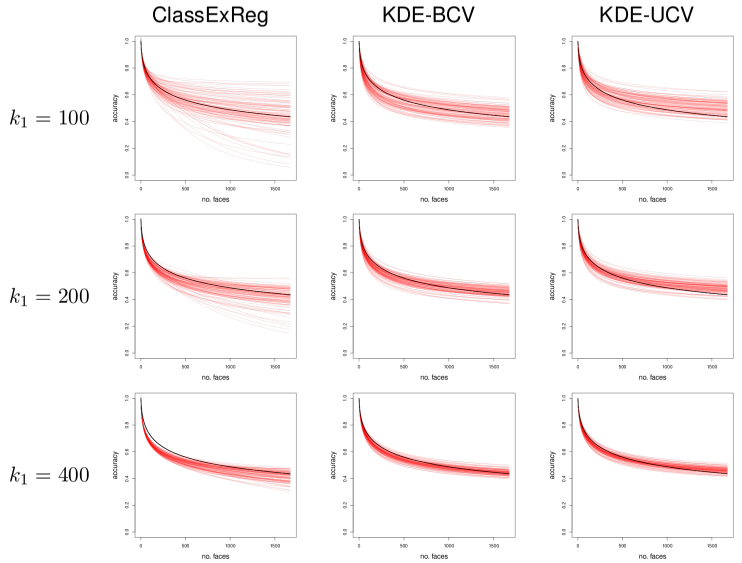

Figure 10: **Predicted accuracy curves for face-recognition example**: The plots show predicted accuracies. Each red curve represents the predicted accuracies using a single subsample of size k_1. The black curve shows the average test accuracy obtained from the full data set.

set, making it difficult to compare extrapolation methods using the 20-to-400 extrapolation task.

Unlike in the face recognition example, we did not resample training classes here, because that would require retraining all of the classifiers–which would be prohibitively time-consuming for the Deep CNN. Thus, we cannot comment on the robustness of the comparisons from this example, though it is likely that we would obtain different rankings under a new resampling of the training classes.

These empirical results indicate that in comparison to the KDE methods of Kay et al., ClassExReg has lower bias and better performance at small k (up to 500 classes), while the KDE methods start to achieve comparable results to ClassExReg when k is around 5,000 or more classes. This matches the theoretical intuition we developed in Section 3.5 (item ii): since the Kay et al. method works by estimating each the favorability of each example separately, that it requires more data (meaning more classes in the training set) to achieve robust estimation.

k_1	k_2	Classifier	True	ClassExReg	KDE-BCV	KDE-UCV
20	100	Deep CNN	0.9908	**0.9905**	0.7138	0.6507

6. Discussion

In this work, we suggest treating the class set in a classification task as random, in order to extrapolate classification performance on a small task to the expected performance on a larger unobserved task. We show that average generalized accuracy decreases with increased label set size like the $(k-1)$th moment of a distribution function. Furthermore, we introduce an algorithm for estimating this underlying distribution, that allows efficient computation of higher order moments. We additionally implement a kernel-density estimation based extrapolation, and discuss different regimes were the methods are useful. Code for the methods and the simulations can be found in `https://github.com/snarles/ClassEx`.

There are many choices and simplifying assumptions used in the description of the method. Here we discuss these decisions and map some alternative models or strategies for future work.

Two important practical aspects of real-world problems not currently handled by our analysis are (i) non-uniform prior distributions on the labels, and (ii) cost functions other than zero-one loss. In fact, a theory for arbitrary cost functions can double as a theory for non-uniform priors, because the risk incurred under non-uniform priors is equivalent to the risk incurred under a uniform prior but with a weighted cost function. Hence, we address both (i) and (ii) in forthcoming work that shows how performance extrapolation is possible under arbitrary cost functions.

Since our analysis is currently restricted to i.i.d. sampling of classes, one direction for future work is to generalize the sampling mechanism, such as to cluster sampling. More broadly, the assumption that the labels in $\mathcal{S}_k$ are a random sample from a homogeneous distribution π may be inappropriate. Many natural classification problems arise from hierarchically partitioning a space of instances into a set of labels. Therefore, rather than modeling $\mathcal{S}_k$ as a random sample, it may be more suitable to model it as a random hierarchical partition of $\mathcal{Y}$, such as one arising from an optional Pólya tree process (Wong and Ma, 2010). Finally, note that we assume no knowledge about the new class-set except for its size. Better accuracy might be achieved if some partial information is known.

A third direction of exploration is to impose additional modeling assumptions for specific problems. ClassExReg adopts a non-parametric model of the discriminability function $D(u)$, in the sense that $D(u)$ was defined via a spline expansion. However, an alternative approach is to assume a parametric family for $D(u)$ defined by a small number of parameters. In forthcoming work, we show that under certain limiting conditions, $D(u)$ is well-described by a two-parameter family. This substantially increases the efficiency of estimation in cases where the limiting conditions are well-approximated.

Acknowledgments

Abstract

We investigate the low-dimensional structure of deterministic transformations between random variables, i.e., transport maps between probability measures. In the context of statistics and machine learning, these transformations can be used to couple a tractable "reference" measure (e.g., a standard Gaussian) with a target measure of interest. Direct simulation from the desired measure can then be achieved by pushing forward reference samples through the map. Yet characterizing such a map—e.g., representing and evaluating it—grows challenging in high dimensions. The central contribution of this paper is to establish a link between the Markov properties of the target measure and the existence of low-dimensional couplings, induced by transport maps that are *sparse* and/or *decomposable*. Our analysis not only facilitates the construction of transformations in high-dimensional settings, but also suggests new inference methodologies for continuous non-Gaussian graphical models. For instance, in the context of nonlinear state-space models, we describe new variational algorithms for filtering, smoothing, and sequential parameter inference. These algorithms can be understood as the natural generalization—to the non-Gaussian case—of the square-root Rauch–Tung–Striebel Gaussian smoother.

Keywords: transport map, variational inference, graphical models, sparsity, state-space models, joint parameter and state estimation

1. Introduction

This paper studies the low-dimensional structure of transformations between random variables. Such transformations, which can be understood as transport maps between probability measures, are ubiquitous in statistics and machine learning. They can be used for posterior sampling (Moselhy and Marzouk, 2012), possibly via deep neural networks (Rezende and Mohamed, 2015); for accelerating Markov chain Monte Carlo or importance sampling algorithms (Parno and Marzouk, 2018; Han and Liu, 2017); or as the building blocks of implicit generative models (Kingma and Welling, 2013; Goodfellow et al., 2014) and flexible methods for density estimation (Tabak and Turner, 2013; Dinh et al., 2016).

In the context of variational inference (Blei et al., 2016), a transport map can be used to define a deterministic coupling between a tractable reference measure $\boldsymbol{\nu}_\eta$ that we can easily simulate (e.g., a standard Gaussian) and an arbitrary target measure $\boldsymbol{\nu}_\pi$ that we wish to characterize (e.g., a posterior distribution). Given i.i.d. samples $(\boldsymbol{X}_i)$ from the reference measure, we can evaluate the transport map to obtain i.i.d. samples $(T(\boldsymbol{X}_i))$ from the target. In other words, the map allows any expectation $\int g \, \mathrm{d}\boldsymbol{\nu}_\pi$ over the target measure to be rewritten as an integral over the reference measure,

$$\int g(\boldsymbol{x}) \, \mathrm{d}\boldsymbol{\nu}_\pi(\boldsymbol{x}) = \int g(T(\boldsymbol{x})) \, \mathrm{d}\boldsymbol{\nu}_\eta(\boldsymbol{x}) \,,$$

thus enabling the use of standard integration techniques for the tractable $\boldsymbol{\nu}_\eta$, including Monte Carlo sampling (Meng and Schilling, 2002) and deterministic quadratures.

We focus on absolutely continuous measures $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ on $\mathbb{R}^n$, for which the existence of a transport map $T : \mathbb{R}^n \to \mathbb{R}^n$ is guaranteed (Santambrogio, 2015). Such a map, however, is seldom unique. Identifying a particular map requires imposing additional structure on the problem. Optimal transport maps, for instance, define couplings that minimize a particular integrated *transport cost* expressing the effort required to rearrange samples (Villani, 2008). The analysis of such maps underpins a vast field that links geometry and partial differential equations, with applications in fluid dynamics, economics, statistics (Douglas, 1999; Kantorovich, 1965), and beyond. In recent years, several other couplings have been proposed for use in statistical problems, e.g., parametric approximations of the Knothe–Rosenblatt rearrangement (Moselhy and Marzouk, 2012), couplings induced by the flows of ODEs (Anderes and Coram, 2012; Heng et al., 2015), and couplings induced by the composition of many simple maps, including deep neural networks (Rezende and Mohamed, 2015; Liu and Wang, 2016). Yet the construction, representation, and evaluation of all these maps grows challenging in high dimensions. In the setting considered here, a transport map is a function from $\mathbb{R}^n$ onto itself; without specifying further structure, representing such a map or even realizing its action is often intractable as n increases.

The central contribution of this paper is to establish a link between the conditional independence structure of the reference-target pair—the so-called Markov properties (Lauritzen, 1996) of $\boldsymbol{\nu}_\eta$ and $\boldsymbol{\nu}_\pi$—and the existence of low-dimensional couplings. These couplings are induced by transport maps that are *sparse* and/or *decomposable*. A sparse map consists of scalar-valued component functions that each depend only on a few input variables, whereas a decomposable map factorizes as the *exact* composition of finitely many functions of low effective dimension (i.e., $T = T_1 \circ \cdots \circ T_\ell$, where each T_i differs from the identity map only along a subset of its components). These properties, and their combinations, dramatically reduce the complexity of representing a transport map and can be deduced *before* the map is explicitly computed.

The utility of these results is twofold. First, they make the construction of couplings—and hence the characterization of complex probability distributions—tractable for a large class of inference problems. In particular, these results can be exploited in state-of-the-art approaches for the numerical computation of transport maps, including normalizing flows or Stein variational algorithms (Rezende and Mohamed, 2015; Detommaso et al., 2018). Second, these results suggest new algorithmic approaches for important classes of statistical models. For instance, our analysis of sparse triangular maps provides a general framework for describing continuous and non-Gaussian Markov random fields, and for exploiting the conditional independence structure of these fields in computation. Our analysis of decomposable transport maps yields new variational algorithms for sequential inference in nonlinear and non-Gaussian state space models. These algorithms characterize the full Bayesian solution to the smoothing and joint state–parameter inference problems by means

of a decomposable transport map, which is constructed (recursively) in a *single* forward pass using local operations. These algorithms can be understood as the natural generalization, to the non-Gaussian case, of the square-root Rauch-Tung-Striebel Gaussian smoother. Moreover, the results presented in this paper underpin recent efforts in structure learning for non-Gaussian graphical models (Morrison et al., 2017), and novel approaches to the filtering of high-dimensional spatiotemporal processes (Spantini, 2017, Ch. 6). Overall, we propose a range of techniques to address problems of inference in continuous non-Gaussian graphical models.

The paper is organized as follows. Section 2 introduces some notation used throughout the paper. Section 3 reviews the Knothe-Rosenblatt rearrangement, a key coupling for our analysis, while Section 4 briefly recalls some standard terminology for Markov random fields and graphical models. The main results are in Sections 5–7: Section 5 addresses the sparsity of triangular transports, while Section 6 introduces and develops the concept of decomposable transport maps for general Markov networks. These two sections can be read independently. Section 7 specializes the theory of Section 6 to state-space models, introducing new variational algorithms for filtering, smoothing, and parameter inference. Section 8 illustrates aspects of the theory with numerical examples. A final discussion is presented in Section 9. Appendix A collects some technical details on the Knothe-Rosenblatt rearrangement and its generalizations. Appendix B contains the proofs of the main results. Appendix C provides pseudocode for our variational algorithms applied to state-space models, and additional numerical experiments are described in Appendix D. Code and all numerical examples are available online.[1]

2. Notation

Here, we collect some useful notation used throughout the paper.

Notation for functions, sets, and graphs. For a pair of functions f and g, we denote their composition by $f \circ g$. We denote by $\partial_k f$ the partial derivative of f with respect to its kth input variable. By $\partial_k f = 0$, we mean that the function f does not depend on its kth input variable. Depending on the context, we can identify a matrix Q with its corresponding linear map, given by $\boldsymbol{x} \mapsto Q\boldsymbol{x}$.

For all $n > 0$, we let $\mathbb{N}_n = \{1, \dots, n\}$ denote the set of the first n integers. For any pair of sets, $\mathcal{A} \subset \mathcal{B}$ means that $\mathcal{A}$ is a subset of $\mathcal{B}$ (including the possibility of $\mathcal{A} = \mathcal{B}$). We denote by $|\mathcal{A}|$ the cardinality of $\mathcal{A}$.

Given a graph $\boldsymbol{\mathcal{G}} = (\mathcal{V}, \mathcal{E})$ with vertices $\mathcal{V}$ and edges $\mathcal{E}$, we denote by $\mathrm{Nb}(k, \boldsymbol{\mathcal{G}})$ the neighborhood of a node k in $\boldsymbol{\mathcal{G}}$, while for any set $\mathcal{A} \subset \mathcal{V}$, we denote by $\boldsymbol{\mathcal{G}}_{\mathcal{A}} = (\mathcal{V}', \mathcal{E}')$ the subgraph given by $\mathcal{V}' = \mathcal{A}$ and $\mathcal{E}' = \mathcal{E} \cap (\mathcal{A} \times \mathcal{A})$.

Notation for measures and densities. In this paper, we mostly consider probability measures on $\mathbb{R}^n$ that are absolutely continuous with respect to the Lebesgue measure, $\boldsymbol{\lambda}$, and that are fully supported. We denote the set of such measures by $\mathscr{M}_+(\mathbb{R}^n)$. The *density* of a measure will always be intended with respect to $\boldsymbol{\lambda}$. For a pair of measures $\boldsymbol{\nu}_1, \boldsymbol{\nu}_2$, $\boldsymbol{\nu}_1 \ll \boldsymbol{\nu}_2$ means that $\boldsymbol{\nu}_1$ is absolutely continuous with respect to $\boldsymbol{\nu}_2$.

For any measure $\boldsymbol{\nu}$ and measurable map T, we denote by $T_\sharp \boldsymbol{\nu}$ the pushforward measure given by $\boldsymbol{\nu} \circ T^{-1}$, where for any set $\mathcal{B}$, $T^{-1}(\mathcal{B})$ is the set-valued preimage of $\mathcal{B}$ under T.

1. `http://transportmaps.mit.edu`

Similarly, we denote by $T^\sharp \boldsymbol{\nu}$ the pullback measure given by $\boldsymbol{\nu} \circ T$. Given a measure $\boldsymbol{\nu}$ with density π and a map T, we denote by $T_\sharp \pi$ the density of $T_\sharp \boldsymbol{\nu}$, provided it exists (depending on T). We call $T_\sharp \pi$ the *pushforward density* of π by T. Similarly, we define the pullback density $T^\sharp \pi$ as the density of $T^\sharp \boldsymbol{\nu}$, provided it exists. Whether the map T preserves the absolute continuity of the measure depends on the regularity of T. For instance, if $T : \mathbb{R}^n \to \mathbb{R}^n$ is a diffeomorphism—i.e., a differentiable bijection with differentiable inverse—then one has:

$$T_\sharp \pi(\boldsymbol{x}) = \pi(T^{-1}(\boldsymbol{x})) \, |\det \nabla T^{-1}(\boldsymbol{x})|, \qquad T^\sharp \pi(\boldsymbol{x}) = \pi(T(\boldsymbol{x})) \, |\det \nabla T(\boldsymbol{x})|, \tag{1}$$

where $\nabla T(\boldsymbol{x})$ denotes the Jacobian of T at $\boldsymbol{x}$. The regularity assumptions on T can be substantially weakened as long as one modifies (1) appropriately (Fremlin, 2000). We will give one such example shortly when dealing with triangular maps (see Section 3 or Appendix A). We denote by $\int f(\boldsymbol{x}) \, \boldsymbol{\nu}(\mathrm{d}\boldsymbol{x})$ the integration of a measurable function $f : \mathbb{R}^n \to \mathbb{R}$ with respect to a measure $\boldsymbol{\nu}$. For the Lebesgue measure, we simplify our notation as $\int f(\boldsymbol{x}) \, \boldsymbol{\lambda}(\mathrm{d}\boldsymbol{x}) = \int f(\boldsymbol{x}) \, \mathrm{d}\boldsymbol{x}$. Given a pair η, π of probability densities and a map $T : \mathbb{R}^n \to \mathbb{R}^n$, we say that T *pushes forward* η to π if and only if T couples the corresponding probability measures, i.e., $T_\sharp \boldsymbol{\nu}_\eta = \boldsymbol{\nu}_\pi$, with $\boldsymbol{\nu}_\eta(\mathcal{B}) = \int_{\mathcal{B}} \eta(\boldsymbol{x}) \, \mathrm{d}\boldsymbol{x}$ and $\boldsymbol{\nu}_\pi(\mathcal{B}) = \int_{\mathcal{B}} \pi(\boldsymbol{x}) \, \mathrm{d}\boldsymbol{x}$ for all measurable sets $\mathcal{B}$. (Notice that $T_\sharp \eta$ need not be given by (1) since we are not specifying any regularity on T.)

When it is clear from context, we will freely omit the qualifier a.e. to indicate a property that holds up to a set of measure zero.

Notation for random variables. We use boldface capital letters, e.g., $\boldsymbol{X}$, to denote random variables on $\mathbb{R}^n$ with $n > 1$, while we write scalar-valued random variables as X. The law of a random variable $\boldsymbol{X}$ defined on a probability space $(\Omega, \mathbb{P})$ is given by $\boldsymbol{X}_\sharp \mathbb{P}$. For a measure $\boldsymbol{\nu}$, $\boldsymbol{X} \sim \boldsymbol{\nu}$ means that $\boldsymbol{X}$ has law $\boldsymbol{\nu}$. If $\boldsymbol{X} = (\boldsymbol{X}_1, \dots, \boldsymbol{X}_p)$ is a collection of random variables and $\mathcal{A} \subset \mathbb{N}_p$, then $\boldsymbol{X}_{\mathcal{A}} = (\boldsymbol{X}_i, i \in \mathcal{A})$ denotes a subcollection of $\boldsymbol{X}$. In the same way, for $j < k$, $\boldsymbol{X}_{j:k} = (\boldsymbol{X}_j, \boldsymbol{X}_{j+1}, \dots, \boldsymbol{X}_k)$. If $\boldsymbol{X} = (\boldsymbol{X}_1, \dots, \boldsymbol{X}_p)$ has joint density π and $\mathcal{A} \subset \mathbb{N}_p$, we denote by $\pi_{\boldsymbol{X}_{\mathcal{A}}}$ the marginal of π along $\boldsymbol{X}_{\mathcal{A}}$, i.e., $\pi_{\boldsymbol{X}_{\mathcal{A}}}(\boldsymbol{x}_{\mathcal{A}}) = \int \pi(\boldsymbol{x}) \, \mathrm{d}\boldsymbol{x}_{\mathbb{N}_p \setminus \mathcal{A}}$. If π is the density of $\boldsymbol{Z} = (\boldsymbol{X}, \boldsymbol{Y})$, we denote by $\pi_{\boldsymbol{X}|\boldsymbol{Y}}$ the density of $\boldsymbol{X}$ given $\boldsymbol{Y}$, where

$$\pi_{\boldsymbol{X}|\boldsymbol{Y}}(\boldsymbol{x}|\boldsymbol{y}) = \begin{cases} \pi_{\boldsymbol{X},\boldsymbol{Y}}(\boldsymbol{x}, \boldsymbol{y}) / \pi_{\boldsymbol{Y}}(\boldsymbol{y}) & \text{if } \pi_{\boldsymbol{Y}}(\boldsymbol{y}) \neq 0 \\ 0 & \text{otherwise.} \end{cases} \tag{2}$$

We denote independence of a pair of random variables $\boldsymbol{X}, \boldsymbol{Y}$ by $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y}$. In the same way, $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} | \boldsymbol{R}$ means that $\boldsymbol{X}$ and $\boldsymbol{Y}$ are independent given a third random variable $\boldsymbol{R}$.

3. Triangular Transport Maps: a Building Block

An important transport for our analysis is the Knothe-Rosenblatt (KR) rearrangement on $\mathbb{R}^n$ (Rosenblatt, 1952). For a pair of measures $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$, with densities η and π, respectively, the KR rearrangement is the unique monotone increasing lower triangular measurable map that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$, i.e., $T_\sharp \boldsymbol{\nu}_\eta = \boldsymbol{\nu}_\pi$ (Carlier et al., 2010). Here, monotonicity is with respect to the lexicographic order on $\mathbb{R}^n$, while uniqueness is up to $\boldsymbol{\nu}_\eta$-null sets. A lower triangular map $T : \mathbb{R}^n \to \mathbb{R}^n$ is a multivariate function whose kth

component depends only on the first k input variables, i.e.,

$$T(\boldsymbol{x}) = \begin{bmatrix} T^1(x_1) \\ T^2(x_1, x_2) \\ \vdots \\ T^n(x_1, x_2, \dots x_n) \end{bmatrix}$$

for some collection of functions (T^k) and for all $\boldsymbol{x} = (x_1, \dots, x_n)$.

The distinction between lower, upper, or other more general forms of triangular map is a matter of convention. We will revisit this important point in Section 6. See Appendix A for a constructive definition of the KR rearrangement based on a sequence of one-dimensional transports. In our hypothesis, the KR rearrangement is always a bijection on $\mathbb{R}^n$, while each map

$$\xi \mapsto T^k(x_1, \dots, x_{k-1}, \xi) \tag{3}$$

is homeomorphic (continuous bijection with continuous inverse), strictly increasing, and differentiable a.e. (Santambrogio, 2015). Here, monotonicity with respect to the lexicographic order is equivalent to each function (3) being increasing. The resulting rearrangement T is far from being a diffeomorphism but is still regular enough to define a useful change of variables, as the following lemma proven in Bogachev et al. (2005) shows.

Lemma 1 *If T is a KR rearrangement pushing forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$, then $\boldsymbol{\nu}_\eta$-a.e.,*

$$T^\sharp \pi(\boldsymbol{x}) = \pi(T(\boldsymbol{x})) \det \nabla T(\boldsymbol{x}) = \eta(\boldsymbol{x}), \tag{4}$$

where $\det \nabla T \coloneqq \prod_{i=1}^n \partial_k T^k$ exists a.e., and where $T^\sharp \pi$ is the density of $T^\sharp \boldsymbol{\nu}_\pi$.

In general, $\det \nabla T$ in (4) is not the determinant of the Jacobian of T since the map may not be differentiable, in which case it would not be possible to define ∇T in the classical sense; this is why $\det \nabla T$ is *redefined* in the lemma. Nevertheless, it is known that T inherits the same regularity as η and π, but not more (Santambrogio, 2015). See Appendix A for additional remarks on the regularity of the map.

An essential feature of the triangular transport map is its *anisotropic* dependence on the input variables. That is, even though each component of the transport map does not depend on all n inputs, the map is still capable of coupling arbitrary probability distributions. Informally, we can think of the KR rearrangement as imposing the *sparsest* possible structure that preserves generality of the coupling—in that the rearrangement is guaranteed to exist for any $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$. In Section 6, we will show that the anisotropy of the KR rearrangement is crucial to proving that certain "complex" (and generally non-triangular) transports can be factorized into compositions of a few *lower-dimensional* triangular maps. Thus we can think of the KR rearrangement as the fundamental building block of a more general class of non-triangular transports.

The KR rearrangement also enjoys many attractive computational features. As shown in Marzouk et al. (2016), it can be characterized as the unique minimizer of the Kullback–Leibler (KL) divergence $\mathcal{D}_{\mathrm{KL}}(\, T_\sharp \boldsymbol{\nu}_\eta \,||\, \boldsymbol{\nu}_\pi \,)$ over the cone $\mathcal{T}_\triangle$ of monotone increasing triangular

maps. From the perspective of function approximation, parameterizing a monotone triangular map is straightforward: it suffices to write each component of the map as[2]

$$T^k(\boldsymbol{x}) = a_k(x_1, \dots, x_{k-1}) + \int_0^{x_k} \exp\left(b_k(x_1, \dots, x_{k-1}, t)\right) \, \mathrm{d}t, \tag{5}$$

for some arbitrary functions $a_k : \mathbb{R}^{k-1} \to \mathbb{R}$ and $b_k : \mathbb{R}^k \to \mathbb{R}$ (Ramsay, 1998). For example, one could parameterize each a_k, b_k using a linear expansion

$$a_k(\boldsymbol{x}) = \sum_i a_{k,i} \, \psi_i(\boldsymbol{x}), \qquad b_k(\boldsymbol{x}) = \sum_j b_{k,j} \, \psi_j(\boldsymbol{x})$$

in terms of multivariate Hermite polynomials (ψ_i) and unknown coefficients $\boldsymbol{c} = (a_{k,i}, b_{k,j})$; alternatively, one could use a neural network representation of a_k and b_k. The resulting transport map $T[\boldsymbol{c}]$—parameterized by the coefficients $\boldsymbol{c}$—is monotone and invertible for all choices of $\boldsymbol{c}$. (In contrast, parameterizing general classes of monotone *non-triangular* maps is a difficult task.) The minimization of $\mathcal{D}_{\mathrm{KL}}(\, T_\sharp \boldsymbol{\nu}_\eta \,||\, \boldsymbol{\nu}_\pi \,)$ for a map in $\mathcal{T}_\triangle$ and for a pair of nonvanishing target (π) and reference (η) densities can be rewritten as

$$\begin{aligned} \min_{T} \quad & -\mathbb{E}\left[\log \pi(T(\boldsymbol{X})) + \sum_k \log \partial_k T^k(\boldsymbol{X}) - \log \eta(\boldsymbol{X})\right] \\ \text{s.t.} \quad & T \in \mathcal{T}_\triangle, \end{aligned} \tag{6}$$

where the expectation is with respect to the reference measure—which is the law of $\boldsymbol{X}$.

Two aspects of (6) are particularly important. First, for the purpose of optimization, the target density can be replaced with its unnormalized version $\bar{\pi}$. (This replacement is essential in Bayesian inference, where the posterior normalizing constant is usually unknown.) Second, (6) can be treated as a stochastic program and solved by means of sample-average approximation (SAA) or stochastic approximation (Shapiro, 2013; Kushner and Yin, 2003). Recall that the reference measure is a degree of freedom of the problem and is chosen precisely to make the integration in (6) feasible using, for instance, quadrature, Monte Carlo, or quasi-Monte Carlo methods (Dick et al., 2013).

Assuming some additional regularity for π (e.g., at least differentiability) and using the monotone parameterization of (5), then (6) becomes an unconstrained and differentiable optimization problem. In particular, we can use the gradient of $\log \pi$ to obtain an unbiased estimator for the gradient of (6) (Asmussen and Glynn, 2007). Alternatively, if $\nabla \log \pi$ is unavailable, we can use the *score method* (Glynn, 1990) to produce an estimator that is still unbiased, but with higher variance. For concreteness, consider the realization of an i.i.d. sample $(\boldsymbol{x}_i)_{i=1}^M$ from $\boldsymbol{\nu}_\eta$. Then a SAA of (6) reads as:

$$\begin{aligned} \min_{T} \quad & -\sum_{i=1}^M \left(\log \bar{\pi}(T(\boldsymbol{x}_i)) + \sum_k \log \partial_k T^k(\boldsymbol{x}_i) - \log \eta(\boldsymbol{x}_i) \right) \\ \text{s.t.} \quad & T \in \mathcal{T}_\triangle, \end{aligned} \tag{7}$$

2. For computational efficiency, one may substitue the exponential function with any other strictly positive expression, like a positively shifted square function.

which is now amenable to deterministic optimization techniques. The numerical solution of (7) by means of an iterative method (e.g., BFGS, Wright and Nocedal, 1999) produces a sequence of maps $\widetilde{T}_1, \widetilde{T}_2, \ldots$ that are increasingly better approximations of the KR rearrangement, in the sense defined by (7). In particular, we can interpret $(\widetilde{T}_k)_k$ as a discrete time flow that pushes forward the collection of reference samples, $(\boldsymbol{x}_i)_{i=1}^M$, to the target distribution. See Figure 1 for a simple illustration. As shown by Moselhy and Marzouk (2012), the KL divergence $\mathcal{D}_{\mathrm{KL}}(\,\widetilde{T}_\sharp \boldsymbol{\nu}_\eta \,||\, \boldsymbol{\nu}_\pi\,)$ for an approximate map $\widetilde{T}$ can be estimated as:

$$\mathcal{D}_{\mathrm{KL}}(\,\widetilde{T}_\sharp \boldsymbol{\nu}_\eta \,||\, \boldsymbol{\nu}_\pi\,) \approx \frac{1}{2}\mathbb{V}\mathrm{ar}\left[\log \bar{\pi}(\widetilde{T}(\boldsymbol{X})) + \sum_k \log \partial_k \widetilde{T}^k(\boldsymbol{X}) - \log \eta(\boldsymbol{X})\right], \tag{8}$$

up to second-order terms, in the limit of $\mathcal{D}_{\mathrm{KL}}(\,\widetilde{T}_\sharp \boldsymbol{\nu}_\eta \,||\, \boldsymbol{\nu}_\pi\,) \to 0$, even if the normalizing constant of π is unknown. This convergence criterion is rather useful for *any* variational inference method, and is usually not available for techniques like MCMC. In the same way, one can construct effective estimators for the normalizing constant $\beta := \bar{\pi}/\pi$ as

$$\hat{\beta} = \exp \mathbb{E}\left[\log \bar{\pi}(\widetilde{T}(\boldsymbol{X})) + \sum_k \log \partial_k \widetilde{T}^k(\boldsymbol{X}) - \log \eta(\boldsymbol{X})\right]. \tag{9}$$

We refer the reader to (Parno, 2015; Parno and Marzouk, 2018) for an alternative construction of the transport map that is useful when only *samples from the target measure* are available. An interesting application of the latter construction is the problem of density estimation or Bayesian inference with intractable likelihoods (Tabak and Turner, 2013; Csilléry et al., 2010). In this case, it turns out that the *inverse* transport $S = T^{-1}$ can be easily computed via convex optimization. (Notice that S is just an ordinary triangular transport map that pushes forward $\boldsymbol{\nu}_\pi$ to $\boldsymbol{\nu}_\eta$. The "inverse" descriptor will help distinguish S from the map T that pushes forward the reference to the target distribution. We refer to T as the *direct* transport.) We can then invert S at $\boldsymbol{x} \in \mathbb{R}^n$ to obtain the evaluation of the direct transport $T(\boldsymbol{x})$. Inverting a monotone triangular function is a computationally trivial task since it requires the solution of a sequence of one-dimensional root finding problems. In practice, one just needs to invert (3) for $k = 1, \ldots, n$. It is also possible to compute the inverse transport from the unnormalized target density, rather than from samples; here, it suffices to minimize $\mathcal{D}_{\mathrm{KL}}(\,\boldsymbol{\nu}_\eta \,||\, S_\sharp \boldsymbol{\nu}_\pi\,)$ for $S \in \mathcal{T}_\triangle$. The resulting variational problem is equivalent to (6) with the identity $S = T^{-1}$. By symmetry of our formulation, S has the same regularity as T. In particular, Lemma 1 holds for S as well, and gives a formula for the pushforward density $T_\sharp \eta$ as:

$$T_\sharp \eta(\boldsymbol{z}) = \eta(S(\boldsymbol{z}))\, \det \nabla S(\boldsymbol{z}) = \pi(\boldsymbol{z}),$$

where $\det \nabla S := \prod_{i=1}^n \partial_k S^k$ exists a.e., and where $T_\sharp \eta$ is the density of $T_\sharp \boldsymbol{\nu}_\eta$.

There is a growing body of literature on the efficient numerical approximation of transport maps (e.g., Rezende and Mohamed, 2015; Bigoni et al., 2019; Mendoza et al., 2018). Essentially all of these approaches employ numerical optimization to construct or realize the action of a map, and thus harness *optimization* to enhance *integration*. Yet all these approaches face a fundamental challenge: the transport map is a function from $\mathbb{R}^n$ onto

itself, and in high dimensions (i.e., for large n) the representation and approximation of such functions becomes increasingly intractable. In the ensuing sections, on the other hand, we will show that a large class of transport maps are in fact only superficially high-dimensional; that is, they possess some *hidden* low-dimensional structure that can facilitate their fast and reliable computation. This low-dimensional structure is linked to the Markov properties of the target measure, which we briefly review in the next section.

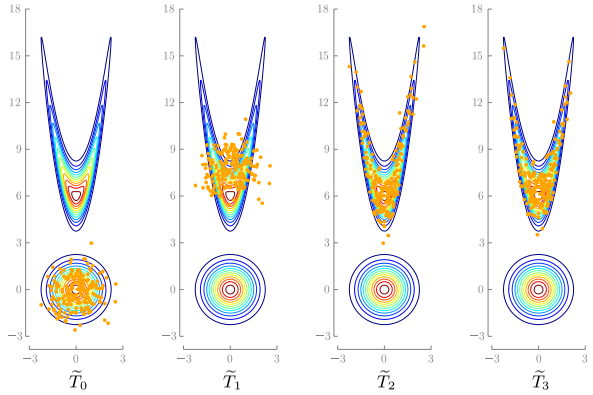

Figure 1: Computation of a simple transport map in two dimensions: The leftmost figure shows contours of the reference density η, which is a standard Gaussian, and of the target density π, which is a banana-shaped distribution in the tails of η. The target distribution has a nonlinear dependence structure. The orange dots in the leftmost figure correspond to 100 samples $(\boldsymbol{x}_i)$ from η and are used to make a sample-average approximation of (6). We adopt the triangular monotone parameterization of (5) for the candidate transport map, where the functions a_k, b_k are expanded in a multivariate Hermite polynomial basis of total degree two (Xiu, 2010). The resulting optimization problem is solved with a quasi-Newton method (BFGS). The kth figure from the left shows the pushforward of the original reference samples through the approximate transport map, $\widetilde{T}_k$, after k iterations of BFGS. The initial map $\widetilde{T}_0$ is chosen to be the identity. The reference samples flow *collectively* towards the target density and eventually settle on the support of π, capturing its structure after just a few iterations.

4. Markov Networks

Let $\boldsymbol{Z} = (Z_1, \ldots, Z_n)$ be a collection of random variables with law $\boldsymbol{\nu}_\pi$ and density π. We can represent a list of conditional independences satisfied by $\boldsymbol{Z}$—the so-called Markov properties—using a simple undirected graph $\boldsymbol{\mathcal{G}} = (\mathcal{V}, \mathcal{E})$, where each node $k \in \mathcal{V}$ is associated

with a distinct random variable, Z_k, and where the edges in $\mathcal{E}$ encode a specific notion of probabilistic interaction among these random variables (Koller and Friedman, 2009). In particular, we say that $\boldsymbol{Z}$ is a Markov network—or a Markov random field (MRF)—with respect to $\boldsymbol{\mathcal{G}}$ if for any triplet $\mathcal{A}, \mathcal{S}, \mathcal{B}$ of disjoint subsets of $\mathcal{V}$, where $\mathcal{S}$ is a separator set for $\mathcal{A}$ and $\mathcal{B}$,[3] the subcollections $\boldsymbol{Z}_\mathcal{A}$ and $\boldsymbol{Z}_\mathcal{B}$ are conditionally independent given $\boldsymbol{Z}_\mathcal{S}$, i.e.,

$$\boldsymbol{Z}_\mathcal{A} \perp\!\!\!\perp \boldsymbol{Z}_\mathcal{B} \,|\, \boldsymbol{Z}_\mathcal{S}. \tag{10}$$

The measure $\boldsymbol{\nu}_\pi$ is said to satisfy the global Markov property, relative to $\boldsymbol{\mathcal{G}}$, if (10) holds. We can also say that $\boldsymbol{\nu}_\pi$ is globally Markov with respect to $\boldsymbol{\mathcal{G}}$. The corresponding graph is then called an independence map (I-map) for $\boldsymbol{\nu}_\pi$.

Intuitively, a sparse graph represents a family of distributions that enjoy many conditional independence properties. I-maps are in general not unique. Of particular interest are *minimal* I-maps, i.e., the sparsest graphs compatible with the conditional independence structure of $\boldsymbol{\nu}_\pi$.

Conditional independence is associated with factorization properties of π. For instance, $\boldsymbol{Z}_\mathcal{A} \perp\!\!\!\perp \boldsymbol{Z}_\mathcal{B} \,|\, \boldsymbol{Z}_\mathcal{S}$ if and only if $\pi_{\boldsymbol{Z}_\mathcal{A}, \boldsymbol{Z}_\mathcal{B} | \boldsymbol{Z}_\mathcal{S}} = \pi_{\boldsymbol{Z}_\mathcal{A} | \boldsymbol{Z}_\mathcal{S}} \, \pi_{\boldsymbol{Z}_\mathcal{B} | \boldsymbol{Z}_\mathcal{S}}$ a.e. (Lauritzen, 1996). We then say that $\boldsymbol{\nu}_\pi$ *factorizes* according to some graph $\boldsymbol{\mathcal{G}}$ if there exists a version of the density of $\boldsymbol{\nu}_\pi$ such that

$$\pi(\boldsymbol{z}) = \frac{1}{\mathfrak{c}} \prod_{\mathcal{C} \in \boldsymbol{\mathcal{C}}} \psi_\mathcal{C}(\boldsymbol{z}_\mathcal{C}), \tag{11}$$

for some nonnegative functions $(\psi_\mathcal{C})$ called *potentials*, where $\boldsymbol{\mathcal{C}}$ is the set of maximal cliques[4] of $\boldsymbol{\mathcal{G}}$ and $\mathfrak{c}$ is a normalizing constant. It is immediate to show that if $\boldsymbol{\nu}_\pi$ factorizes according to $\boldsymbol{\mathcal{G}}$, then $\boldsymbol{\nu}_\pi$ satisfies the global Markov property relative to $\boldsymbol{\mathcal{G}}$ (Lauritzen, 1996, Prop. 3.8). The converse is true only under additional assumptions: for instance, if $\boldsymbol{\nu}_\pi$ admits a continuous and strictly positive density (see the Hammersley-Clifford theorem; Hammersley and Clifford, 1971; Lauritzen, 1996).

A critical question then is how to characterize a suitable I-map for a given measure. There are several answers. First of all, in many applications that involve probabilistic modeling, the target distribution is defined in terms of its potentials, as in (11), because this is just a more convenient way to specify a high-dimensional distribution and to perform inference (or general probabilistic reasoning) with it. Finding a graph for which $\boldsymbol{\nu}_\pi$ factorizes is then a trivial task. See Figure 4 (*left*) for an example. Applications where this commonly holds range from spatial statistics and image analysis to speech recognition (Koller and Friedman, 2009; Rue and Held, 2005). In Section 7, for example, we focus exclusively on discrete-time Markov processes, where the Markov structure of the problem is self-evident. More specifically, Section 7 tackles the problem of recursive smoothing and static parameter estimation for a state-space model. In this context, the target measure $\boldsymbol{\nu}_\pi$ could represent the joint distribution of state and parameters, conditioned on all the available observations (see Figures 4 and 8). The reader might want to consider this sequential inference problem

3. $\mathcal{S}$ is a separator set for $\mathcal{A}$ and $\mathcal{B}$ if (1) $\mathcal{S}$ is disjoint from $\mathcal{A}$ and $\mathcal{B}$, and if (2) every path from $\alpha \in \mathcal{A}$ to $\beta \in \mathcal{B}$ intersects $\mathcal{S}$. If $\mathcal{A}$ and $\mathcal{B}$ are disconnected components of $\boldsymbol{\mathcal{G}}$, then $\mathcal{S} = \emptyset$ is a separator set for $\mathcal{A}$ and $\mathcal{B}$.
4. A clique is a fully connected subset of the vertices, whereas a maximal clique is a clique that is not a strict subset of another clique.

as a guiding application while reading the forthcoming Sections 5 and 6. We emphasize, however, that our theory is far more general and by no means restricted to any specific Markov structure.

In other settings, the graph is unknown and must be estimated. When only samples from $\boldsymbol{\nu}_\pi$ are available, this is a question of model learning (Koller and Friedman, 2009, Part III)—a problem with various applications (Hyvärinen, 2005; Meinshausen and Bühlmann, 2006; Lin et al., 2015). In case of a known and smooth target density, we can characterize pairwise conditional independence in terms of mixed second-order partial derivatives, as shown by the following lemma.

Lemma 2 (Pairwise conditional independence) *If $\boldsymbol{Z} \sim \boldsymbol{\nu}_\pi$ for a measure $\boldsymbol{\nu}_\pi$ with smooth and strictly positive density π, we have:*

$$Z_i \perp\!\!\!\perp Z_j \,|\, \boldsymbol{Z}_{\mathcal{V}\setminus(i,j)} \quad \iff \quad \partial^2_{i,j} \log \pi = 0 \text{ on } \mathbb{R}^n.$$

Thus, if we can evaluate π and its derivatives (up to a normalizing constant), we can use Lemma 2 to assess pairwise conditional independence and to define a minimal I-map for $\boldsymbol{\nu}_\pi$ as follows: add an edge between every pair of distinct nodes unless the corresponding random variables are conditionally independent (Koller and Friedman, 2009, Thm. 4.5).

Regardless of the many ways to obtain an I-map, there is a fundamental connection between Markov properties of a distribution and the existence of low-dimensional transport maps. The rest of the paper will elaborate precisely on this connection.

5. Sparsity of Triangular Transport Maps

We begin our investigation of low dimensional structure by considering the notion of sparse transport map. A sparse map is a multivariate function where each component does not depend on all of its input variables. According to this definition, a triangular transport is already sparse. In this section, however, we show that the KR rearrangement can be even *sparser*, depending on the Markov structure of the target distribution.

5.1. Sparsity Bounds

Given a lower triangular function T, we define its sparsity pattern, $\mathfrak{I}_T$, as the set of all integer pairs (j,k), with $j < k$, such that the kth component of the map does not depend on the jth input variable, i.e., $\mathfrak{I}_T = \{(j,k) : j < k, \, \partial_j T^k = 0\}$. (We do not include pairs $j > k$ in the definition of $\mathfrak{I}_T$ since, for a lower triangular function, $\partial_j T^k = 0$ for $j > k$ by construction.)

Knowing the sparsity pattern of the KR rearrangement *before* computing the actual transport has important computational implications. For instance, in the variational characterization of the transport described in (6), we can restrict the feasible domain to the set of triangular maps with sparsity pattern given by $\mathfrak{I}_T$, and still recover the desired KR rearrangement. That is, if $(j,k) \in \mathfrak{I}_T$, we can parameterize any candidate transport map by removing the dependence on the jth input variable from the kth component of the map. Thus, analyzing the Markov structure of the target distribution enables the representation and computation of maps in possibly higher-dimensional settings.

The following theorem, which is the main result of this section, characterizes *bounds* on the sparsity patterns of triangular transport maps given an I-map for the target measure. In the statement of the theorem, we denote the direct transport by T and the inverse transport by $S = T^{-1}$ (see Section 3). The theorem suggests that S and T can have quite different sparsity patterns.[5]

Theorem 3 (Sparsity of Knothe–Rosenblatt rearrangements) *Let $\boldsymbol{X} \sim \boldsymbol{\nu}_\eta$, $\boldsymbol{Z} \sim \boldsymbol{\nu}_\pi$ with $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$ and $\boldsymbol{\nu}_\eta$ a product measure on $\times_{i=1}^n \mathbb{R}$. Moreover, assume that $\boldsymbol{\nu}_\pi$ is globally Markov with respect to $\boldsymbol{\mathcal{G}}$, and define, recursively, the sequence of graphs $(\boldsymbol{\mathcal{G}}^k)_{k=1}^n$ as: (1) $\boldsymbol{\mathcal{G}}^n \coloneqq \boldsymbol{\mathcal{G}}$ and (2) for all $1 \leq k < n$, $\boldsymbol{\mathcal{G}}^{k-1}$ is obtained from $\boldsymbol{\mathcal{G}}^k$ by removing node k and by turning its neighborhood $\mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$ into a clique. Then the following hold:*

1. *If $\mathfrak{I}_S$ is the sparsity pattern of the inverse transport map S, then*

$$\widehat{\mathfrak{I}}_S \subset \mathfrak{I}_S, \tag{12}$$

   where $\widehat{\mathfrak{I}}_S$ is the set of integer pairs (j,k) such that $j \notin \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$.

2. *If $\mathfrak{I}_T$ is the sparsity pattern of the direct transport map T, then*

$$\widehat{\mathfrak{I}}_T \subset \mathfrak{I}_T, \tag{13}$$

   where $\widehat{\mathfrak{I}}_T$ is defined recursively as follows: for $k = 2, \dots, n$ the pair $(j,k) \in \widehat{\mathfrak{I}}_T$ if and only if $(j,i) \in \widehat{\mathfrak{I}}_T$ for all $i \in \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$.

3. *The predicted sparsity pattern of S is always greater than or equal to that of T, i.e.,*

$$\widehat{\mathfrak{I}}_T \subset \widehat{\mathfrak{I}}_S. \tag{14}$$

Several remarks are in order. First, we emphasize the fact that Theorem 3 characterizes sparsity patterns using *only* an I-map for $\boldsymbol{\nu}_\pi$, without requiring any actual computation of the transports. One only needs to perform simple graph operations on $\boldsymbol{\mathcal{G}}$ to build the sequence of graphs $(\boldsymbol{\mathcal{G}}^k)$. See Figure 2 for an illustration of this procedure, with the corresponding sparsity patterns in Figure 3. We refer to $(\boldsymbol{\mathcal{G}}^k)$ as the *marginal* graphs. In fact, the sequence $(\boldsymbol{\mathcal{G}}^k)$ is precisely the set of intermediate graphs produced by the variable elimination algorithm (Koller and Friedman, 2009, Ch. 9), when marginalizing with elimination ordering $(n, n-1, \dots, 1)$. This should not be surprising as the KR rearrangement is essentially a sequence of ordered marginalizations (Villani, 2008). The hypothesis that $\boldsymbol{\nu}_\eta$ is a product measure is important for the theorem to hold. If we pick a reference measure with an arbitrary Markov structure, there need not exist a sparse transport map coupling $\boldsymbol{\nu}_\eta$ and $\boldsymbol{\nu}_\pi$, even if $\boldsymbol{\nu}_\pi$ has a sparse I-map. The role of a reference measure is somewhat peculiar to the world of couplings and is usually not addressed in classical treatments of graphical models. Nonetheless, this assumption on $\boldsymbol{\nu}_\eta$ is not restrictive in the present framework,

5. A note: as we already saw, the KR rearrangement is unique up to a set of measure zero. Theorem 3 characterizes the sparsity pattern of a particular *version* of the map, the one given by Definition 14 in Appendix A. We will implicitly make this assumption throughout the paper.

since the reference distribution is considered a degree of freedom of the problem. Theorem 3 gives sufficient but not necessary conditions on $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ for the existence of a sparse map. And it could not be otherwise: if $\boldsymbol{\nu}_\eta = \boldsymbol{\nu}_\pi$ then the identity map—the sparsest possible map—would be a valid coupling.

We also note that Theorem 3 does not provide the exact sparsity patterns of the triangular transport maps; instead, (12) and (13) provide *subsets* of $\mathfrak{I}_T$ and $\mathfrak{I}_S$. In other words, the actual transport maps might be sparser than predicted by the sets $\widehat{\mathfrak{I}}_S$ and $\widehat{\mathfrak{I}}_T$—but, crucially, they cannot be less sparse. Thus, we can think of Theorem 3 as providing *bounds* on the sparsity of triangular transports. An important fact is that, without additional information on $\boldsymbol{\nu}_\pi$, these bounds are sharp. That is, we can always find a pair of measures $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ satisfying the hypotheses of Theorem 3 and such that the predicted and actual sparsity patterns coincide, i.e., $\widehat{\mathfrak{I}}_T = \mathfrak{I}_T$ or $\widehat{\mathfrak{I}}_S = \mathfrak{I}_S$.

Part 3 of Theorem 3 shows that the predicted sparsity pattern of the inverse KR rearrangement is always larger than or equal to that of the direct transport, i.e., $\widehat{\mathfrak{I}}_T \subset \widehat{\mathfrak{I}}_S$. This does not mean that for every pair of measures $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$, the inverse triangular transport is always at least as sparse as the direct transport; in fact, it is possible to provide simple counterexamples. However, this result does imply that if we are only given an I-map for $\boldsymbol{\nu}_\pi$, then parameterizing candidate *inverse* triangular transports allows the imposition of more sparsity constraints than parameterizing candidate direct transports. In general, sparser transports are easier to represent. See Figure 4 (*right*) for a nontrivial example of sparsity patterns for a stochastic volatility model.

Indeed, (14) hints at a typical trend: inverse transport maps tend to be sparser (in many practical cases, *much* sparser) than their direct counterparts. Intuitively, the sparsity of a direct transport is associated with marginal independence in $\boldsymbol{Z}$, whereas the inverse transport inherits sparsity from the conditional independence structure of $\boldsymbol{Z}$. The latter is a weaker condition than mutual independence; for instance, the correlation length of a process modeled by a Markov random field may be much larger than the typical neighborhood size (Rue and Held, 2005). Thus, given a sparse I-map for the target measure, it can be computationally advantageous to characterize an inverse transport rather than a direct one, because the inverse transport can inherit a larger sparsity pattern. Given an inverse triangular transport S, we can then easily evaluate the direct transport $T = S^{-1}$ at any point $\boldsymbol{x} \in \mathbb{R}^n$ by inverting S pointwise, as described in Section 3. There is no need to have an explicit representation of the direct transport as long as it can be implicitly defined through its inverse.

5.2. Connection to Gaussian Markov Random Fields

The reader familiar with Gaussian Markov random fields (GMRFs), might see links between the preceding results and widespread approaches to the modeling of Gaussian fields. In this section, we clarify the extent of these connections.

Many applications (e.g., image analysis, spatial statistics, time series) involve modeling by means of high-dimensional Gaussian fields. Dealing with large and dense covariances, however, is often impractical; both storage and sampling of the Gaussian field are problematic. The usual workaround is to replace or approximate the Gaussian field with a *sparse* GMRF—i.e., a Gaussian Markov network that enforces locality in the probabilistic interac-

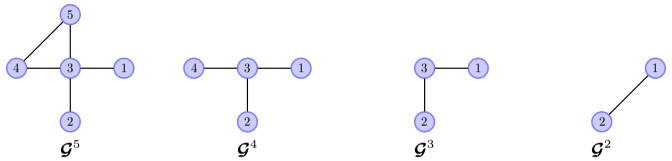

Figure 2: Sequence of graphs $(\mathcal{G}^k)$ described in Theorem 3 for a target measure in $\mathscr{M}_+(\mathbb{R}^5)$ with I-map illustrated by the leftmost graph, $\mathcal{G}^5$. Notice that to generate the graph $\mathcal{G}^2$, we remove node 3 from $\mathcal{G}^3$ and turn its neighborhood into a clique by adding the edge $(1, 2)$.

Figure 3: Sparsity patterns predicted by Theorem 3 for the target measure analyzed in Figure 2. We represent the sparsity patterns using a symbolic matrix notation: the (j, k)-th entry of the matrix is *not* colored if the kth component of the map (S or T) does not depend on the jth input variable, or, equivalently, if $(j, k) \in \widehat{\mathfrak{I}}_S$ (resp. $\widehat{\mathfrak{I}}_T$) (12). (Since we are considering lower triangular transports, all entries $j > k$ are uncolored. Note also that S^k and T^k are always functions of their kth input by strict monotonicity of the map.) The predicted sparsity pattern for the direct transport in this example is $\widehat{\mathfrak{I}}_T = \emptyset$.

tions among the underlying random variables. The minimal I-map for the GMRF is thus sparse, and so is the precision matrix Λ of the field (Rue and Held, 2005). The covariance matrix is still in general dense, but dealing with the sparse precision matrix is much easier. If $LL^\top$ is a (sparse) Cholesky decomposition of Λ, then $L^\top$ represents a linear triangular transport that pushes forward the joint distribution of the GMRF, $\boldsymbol{\nu}_\pi = \mathcal{N}(0, \Lambda^{-1})$, to a standard normal, $\boldsymbol{\nu}_\eta = \mathcal{N}(0, \mathbf{I})$. The key point is that for many Markov structures of interest, the Cholesky factor inherits sparsity from the underlying graph, so that sampling from $\boldsymbol{\nu}_\pi$ can be achieved at low cost as follows: if $\boldsymbol{X}$ is a sample from $\boldsymbol{\nu}_\eta$, then we can obtain a sample $\boldsymbol{Z}$ from $\boldsymbol{\nu}_\pi$ simply by solving the sparse triangular linear system $L^\top \boldsymbol{Z} = \boldsymbol{X}$. There is no need to explicitly represent or store the dense factor $L^{-\top}$, since we can implicitly represent its action by inverting a sparse triangular function.

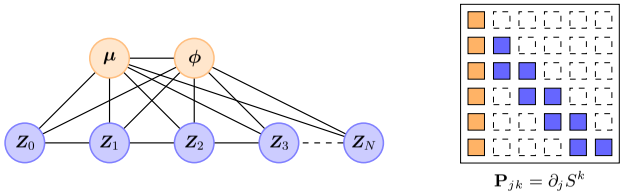

Figure 4: (*left*) Markov network for a stochastic volatility model (Kim et al., 1998). Blue nodes represent the discrete-time latent log-volatility process $(\boldsymbol{Z}_k)_{k=0}^N$, which obeys a simple autoregressive model with hyperparameters $\boldsymbol{\mu}, \boldsymbol{\phi}$. The graph above is a minimal I-map for the posterior density described in Section 8, $\pi_{\boldsymbol{\mu},\boldsymbol{\phi},\boldsymbol{Z}_{0:N}|\boldsymbol{y}_{0:N}}$, where $\boldsymbol{y}_{0:N}$ are some (fixed) observations. (*right*) The predicted sparsity pattern $\widehat{\mathfrak{I}}_S$ (only the top 6×6 block is shown) for the inverse transport corresponding to the model on the left: the first column/row of the matrix refer jointly to all of the hyperparameters. Each component S^k of the inverse transport can depend at most on four input variables, namely $\boldsymbol{\mu}, \boldsymbol{\phi}, \boldsymbol{Z}_{k-1}, \boldsymbol{Z}_k$, regardless of the overall dimension N of the problem. In order to apply the results of Theorem 3, we must select an ordering of the input variables; here, we used the ordering $(\boldsymbol{\mu}, \boldsymbol{\phi}, \boldsymbol{Z}_0, \ldots, \boldsymbol{Z}_N)$. Optimal orderings are further discussed in Section 5.3.

Now the connection with Section 5.1 is clear: $L^\top$ is an inverse triangular transport,[6] while $L^{-\top}$ is a direct one. Moreover, solving a triangular linear system is just a particular instance of inverting a nonlinear triangular function by performing a sequence of one-dimensional root-findings. Thus the developments of the previous section, which consider arbitrary *nonlinear* maps, are a natural generalization—to the *non-Gaussian* case—of modeling and sampling techniques for high-dimensional GMRFs (Rue and Held, 2005).

5.3. Ordering of Triangular Maps

The results of Theorem 3 suggest that the sparsity of a triangular transport map depends on the ordering of the input variables. See Figure 5 for a simple illustration. Indeed, the triangular transport itself depends anisotropically on the input variables and requires the definition of a proper ordering. A natural approach is then to seek the ordering that promotes the *sparsest* transport map possible.

Consider a pair of measures $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ that satisfies the hypotheses of Theorem 3. We associate an ordering of the input variables with a permutation σ on $\mathbb{N}_n = \{1, \ldots, n\}$, and define the *reordered* target measure $\boldsymbol{\nu}_\pi^\sigma$ as the pushforward of $\boldsymbol{\nu}_\pi$ by the matrix Q^σ that represents the permutation σ. In particular, $(Q^\sigma)_{ij} = (\boldsymbol{e}_{\sigma(i)})_j$, where $\boldsymbol{e}_i$ is the ith standard basis vector on $\mathbb{R}^n$. Moreover, if $\boldsymbol{\mathcal{G}}$ is an I-map for $\boldsymbol{\nu}_\pi$, then we denote an I-map for $\boldsymbol{\nu}_\pi^\sigma$ by

6. Actually, this transport is upper rather than lower triangular. This distinction plays no role in the following discussion, and the fact that a KR rearrangement is a lower triangular function is merely a matter of convention.

$\mathcal{G}^\sigma$. Notice that $\mathcal{G}^\sigma$ can be derived from $\mathcal{G}$ simply by relabeling its nodes according to the permutation σ. Then we can cast a variational problem for the *best* ordering σ^* as:

$$\begin{aligned} \sigma^* \in \arg\max_\sigma \quad & |\mathfrak{I}_S| \\ \text{s.t.} \quad & S_\sharp \boldsymbol{\nu}_\pi^\sigma = \boldsymbol{\nu}_\eta \\ & \sigma \in \mathfrak{P}(\mathbb{N}_n), \end{aligned} \tag{15}$$

where S is the KR rearrangement that pushes forward the reordered target $\boldsymbol{\nu}_\pi^\sigma$ to $\boldsymbol{\nu}_\eta$ and $\mathfrak{P}(\mathbb{N}_n)$ is the set of permutations of $\mathbb{N}_n$. The goal is to maximize the cardinality of the sparsity pattern of the inverse map, $|\mathfrak{I}_S|$. We restrict our attention to the sparsity of the inverse transport, since we know from Section 5.1 that the direct transport tends to be dense, even for the most trivial Markov structures.

Ideally, we would like to determine a good ordering for the map *before* computing the actual transport, and to use the resulting information about the sparsity pattern to simplify the optimization problem for S. However, evaluating the objective function of (15) requires computing a different inverse transport for each permutation σ. One possible way to relax (15) is to replace $\mathfrak{I}_S$ with the predicted sparsity pattern $\widehat{\mathfrak{I}}_S$ introduced in (12). The advantage of this approach is that the objective function of the relaxed problem can now be evaluated in closed form without computing any transport map, but rather by performing the simple sequence of graph operations on $\mathcal{G}^\sigma$ described by Theorem 3. The caveat is that, in general, $\widehat{\mathfrak{I}}_S \subset \mathfrak{I}_S$, and thus maximizing $|\widehat{\mathfrak{I}}_S|$ amounts to seeking the tightest lower bound on the sparsity pattern of the inverse transport. From the definition of $\widehat{\mathfrak{I}}_S$, it follows that the best ordering σ^* for the *relaxed* problem is one that introduces the fewest edges in the construction of the marginal graphs $\mathcal{G}^n, \dots, \mathcal{G}^1$, whenever $\mathcal{G}^n = \mathcal{G}^{\sigma^*}$. Thus, for a given I-map $\mathcal{G}$, we denote by $\mathfrak{F}(\sigma; \mathcal{G})$ the *fill-in* produced by the ordering σ. That is, $\mathfrak{F}(\sigma; \mathcal{G})$ is a set containing all the edges introduced in the construction of the marginal graphs $(\mathcal{G}^k)$ from $\mathcal{G}^\sigma$. A computationally feasible relaxation of (15) is then given by:

$$\begin{aligned} \sigma^* \in \arg\min_\sigma \quad & |\mathfrak{F}(\sigma; \mathcal{G})| \\ \text{s.t.} \quad & \sigma \in \mathfrak{P}(\mathbb{N}_n). \end{aligned} \tag{16}$$

(16) is a standard problem in graph theory; it arises in a variety of practical settings, including (most relatedly) finding the best elimination ordering for variable elimination in graphical models, or finding the permutation that minimizes the fill-in of the Cholesky factor of a positive definite matrix (George and Liu, 1989; Saad, 2003). From an algorithmic point of view, (16) is NP-complete (Yannakakis, 1981). This should not be surprising, as best–ordering problems are typically combinatorial in nature. Nevertheless, given its widespread applicability, a host of effective polynomial-time heuristics for (16) have been developed in past years (e.g., min-fill or weighted-min-fill, Koller and Friedman, 2009). Most importantly, (16) can be solved without ever touching the target measure (assuming, of course, that an I-map $\mathcal{G}$ for $\boldsymbol{\nu}_\pi$ is known). As a result, the cost of finding a good ordering is often negligible compared to the cost of characterizing a nonlinear transport map via optimization.

6. Decomposability of Transport Maps

Thus far, we have investigated the sparsity of triangular transport maps and found that inverse transports tend to inherit sparsity from the underlying Markov structure of the

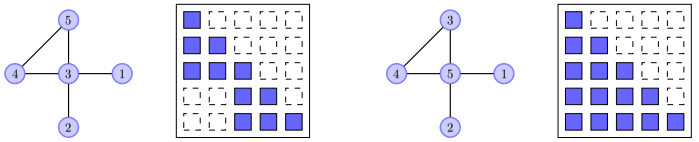

Figure 5: Illustration of how a simple re-ordering of the input variables can change the (predicted) sparsity pattern of the inverse map. On the left, $\mathcal{G}$ represents an I-map for the target measure considered in Figure 2, with ordering $(Z_1, Z_2, Z_3, Z_4, Z_5)$, together with its sparsity pattern $\widehat{\mathfrak{I}}_S$. (See Figure 3 for details on the "matrix" representation of sparsity patterns.) On the right, $\mathcal{G}'$ is an I-map for the same target measure but with the ordering $(Z_1, Z_2, Z_5, Z_4, Z_3)$. The corresponding sparsity pattern $\widehat{\mathfrak{I}}_{S'}$ is now the empty set.

target measure. Though direct triangular transports also inherit some sparsity according to Theorem 3, they tend to be more dense.

This section shows that direct transports enjoy a different form of low-dimensional structure: *decomposability*. A decomposable transport map is a function that can be written as the composition of a finite number of low-dimensional maps, e.g., $T = T_1 \circ \cdots \circ T_\ell$ for some integer $\ell \geq 2$. We use a very specific notion of low-dimensional map, as follows.

Definition 4 (Low-dimensional map with respect to a set) *A map $M : \mathbb{R}^n \to \mathbb{R}^n$ is low-dimensional with respect to a nonempty set $\mathcal{C} \subset \mathcal{V} \simeq \mathbb{N}_n$ if*

1. $M^k(\boldsymbol{x}) = x_k$ *for* $k \in \mathcal{C}$
2. $\partial_j M^k = 0$ *for* $j \in \mathcal{C}$ *and* $k \in \mathcal{V} \setminus \mathcal{C}$.

The effective dimension of M is the minimum cardinality $|\mathcal{V} \setminus \mathcal{C}|$ over all sets $\mathcal{C}$ with respect to which M is low-dimensional.

In particular, up to a permutation of its components, we can rewrite M as:

$$M(\boldsymbol{x}) = \begin{bmatrix} M^{\bar{\mathcal{C}}}(\boldsymbol{x}_{\bar{\mathcal{C}}}) \\ \boldsymbol{x}_{\mathcal{C}} \end{bmatrix},$$

where $\bar{\mathcal{C}} = \mathcal{V} \setminus \mathcal{C}$ denotes the complement of $\mathcal{C}$ in $\mathcal{V}$, and where for any map M and set $\mathcal{A} = \{a_1, \dots, a_k\}$, $M^{\mathcal{A}}$ denotes the multivariate function $\boldsymbol{x} \mapsto (M^{a_1}(\boldsymbol{x}), \dots, M^{a_k}(\boldsymbol{x}))$ obtained by stacking together the components of M with index in $\mathcal{A}$. Thus M is the trivial embedding of a $|\bar{\mathcal{C}}|$-dimensional function into the identity map and has *effective dimension* bounded by $|\bar{\mathcal{C}}| < n$. It is not surprising, then, that a decomposable transport $T = T_1 \circ \cdots \circ T_\ell$ should be easier to represent than an ordinary map. A perhaps less intuitive feature, however, is that the computation of a high-dimensional decomposable transport can be broken down into multiple simpler steps, each associated with the computation of a low-dimensional map T_j that accounts only for local features of the target measure.

The forthcoming analysis will consider *general*, and hence possibly non-triangular, transports. Thus its scope is much broader than that of Section 5, where we only focused on the sparsity of triangular transports. Yet, we will show that triangular maps are the building block of decomposable transports. The cornerstone of our analysis is Theorem 7, which characterizes the existence and structure of decomposable transports given only the Markov structure of the underlying target measure.

Our discussion will proceed in two stages: first, we show how to identify direct transports that decompose into two maps, i.e., $T = T_1 \circ T_2$, and then we explain how to apply this result recursively to obtain a general decomposition of the form $T = T_1 \circ \cdots \circ T_\ell$.

6.1. Preliminary Notions

Before addressing the decomposability of transport maps, we need to introduce two useful concepts: proper graph decompositions and generalized triangular functions. The decomposition of a graph is a standard notion (Lauritzen, 1996).

Definition 5 (Proper graph decomposition) *Given a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, a triple $(\mathcal{A}, \mathcal{S}, \mathcal{B})$ of disjoint subsets of the vertex set $\mathcal{V}$ forms a proper decomposition of $\mathcal{G}$ if (1) $\mathcal{V} = \mathcal{A} \cup \mathcal{S} \cup \mathcal{B}$, (2) $\mathcal{A}$ and $\mathcal{B}$ are nonempty, (3) $\mathcal{S}$ separates $\mathcal{A}$ from $\mathcal{B}$, and (4) $\mathcal{S}$ is a clique.*

See Figure 6 (*top left*) for an example of a decomposition. Clearly, not every graph admits a proper decomposition; for instance, a fully connected graph does not have a separator set for nonempty $\mathcal{A}$ and $\mathcal{B}$. The idea we will pursue here is that graph decompositions lead to the existence of decomposable transports.

The notion of a generalized triangular function is perhaps less standard, but still relatively straightforward:

Definition 6 (Generalized triangular function) *A function $T : \mathbb{R}^n \to \mathbb{R}^n$ is said to be generalized triangular, or simply σ-triangular, if there exists a permutation σ of $\mathbb{N}_n$ such that the $\sigma(k)$th component of T depends only on the variables $x_{\sigma(1)}, \dots, x_{\sigma(k)}$, i.e., $T^{\sigma(k)}(\boldsymbol{x}) = T^{\sigma(k)}(x_{\sigma(1)}, \dots, x_{\sigma(k)})$ for all $\boldsymbol{x} = (x_1, \dots, x_n)$ and for all $k = 1, \dots, n$.*

We can think of a generalized triangular function as a map that is lower triangular up to a permutation. In particular, if σ is the identity on $\mathbb{N}_n$, then a σ-triangular function is simply a lower triangular map (see Section 3). To represent the permutation σ, we use the notation $\sigma(\{i_1, \dots, i_k\}) = \{\sigma(i_1), \dots, \sigma(i_k)\}$ to denote an ordered set that collects the action of the permutation on the elements (i_j). For example, if $T : \mathbb{R}^4 \to \mathbb{R}^4$ is a σ-triangular map with σ defined as $\sigma(\mathbb{N}_4) = \{1, 4, 2, 3\}$, then T will be of the form:

$$T(\boldsymbol{x}) = \begin{bmatrix} T^1(x_1) \\ T^2(x_1, x_4, x_2) \\ T^3(x_1, x_4, x_2, x_3) \\ T^4(x_1, x_4) \end{bmatrix}$$

for some collection (T^k). We regard each component $T^{\sigma(k)}$ as a map $\mathbb{R}^k \to \mathbb{R}$. We say that a σ-triangular function T is monotone increasing if each component T^k is a monotone increasing function of the input x_k. Moreover, for any $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$ and for any

permutation σ of $\mathbb{N}_n$, there exists a ($\boldsymbol{\nu}_\eta$-unique) monotone increasing σ-triangular map—which we call a σ-generalized KR rearrangement—that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$. We give a constructive definition for a generalized KR rearrangement in Appendix A.

A key property of a σ-generalized KR rearrangement is that it allows different sparsity patterns to be engineered, depending on σ, in a map that is otherwise fully general—in the sense of being able to couple arbitrary measures in $\mathscr{M}_+(\mathbb{R}^n)$. This feature will be essential to characterizing decomposable transport maps.

6.2. Decomposition and Graph Sparsification

We now characterize transports that decompose into a pair of low-dimensional maps, as described in the following theorem. We formulate the theorem for a generic target measure $\boldsymbol{\nu}_i$. Later we will apply the theorem recursively to a sequence $(\boldsymbol{\nu}_i)$ of different targets.

Theorem 7 (Decomposition of transport maps) *Let $\boldsymbol{X} \sim \boldsymbol{\nu}_\eta$, $\boldsymbol{Z}^i \sim \boldsymbol{\nu}_i$, with $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_i \in \mathscr{M}_+(\mathbb{R}^n)$ and $\boldsymbol{\nu}_\eta$ tensor product measure. Denote by η, π_i a pair of nonvanishing densities for $\boldsymbol{\nu}_\eta$ and $\boldsymbol{\nu}_i$, respectively, and assume that $\boldsymbol{\nu}_i$ factorizes according to a graph $\boldsymbol{\mathcal{G}}^i$, which admits a proper decomposition $(\mathcal{A}, \mathcal{S}, \mathcal{B})$. Then the following hold:*

1. *There exists a factorization of π_i of the form*

$$\pi_i(\boldsymbol{z}) = \frac{1}{\mathfrak{c}} \, \psi_{\mathcal{A}\cup\mathcal{S}}(\boldsymbol{z}_{\mathcal{A}\cup\mathcal{S}}) \, \psi_{\mathcal{S}\cup\mathcal{B}}(\boldsymbol{z}_{\mathcal{S}\cup\mathcal{B}}), \tag{17}$$

   where $\psi_{\mathcal{A}\cup\mathcal{S}}$ is strictly positive and integrable, with $\mathfrak{c} = \int \psi_{\mathcal{A}\cup\mathcal{S}}$.

2. *For any factorization (17) and for any permutation σ of $\mathbb{N}_n$ with*

$$\sigma(k) \in \begin{cases} \mathcal{S} & \text{if } k = 1, \dots, |\mathcal{S}| \\ \mathcal{A} & \text{if } k = |\mathcal{S}| + 1, \dots, |\mathcal{A} \cup \mathcal{S}| \\ \mathcal{B} & \text{otherwise,} \end{cases} \tag{18}$$

   there exists a nonempty family, $\mathfrak{D}_i$, of decomposable transport maps $T = L_i \circ R$ parameterized by $R \in \mathfrak{R}_i$ such that each $T \in \mathfrak{D}_i$ pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_i$ and where:

   (a) *L_i is a σ-generalized KR rearrangement that pushes forward $\boldsymbol{\nu}_\eta$ to a measure with density $\psi_{\mathcal{A}\cup\mathcal{S}}(\boldsymbol{z}_{\mathcal{A}\cup\mathcal{S}}) \, \eta_{\boldsymbol{X}_{\mathcal{B}}}(\boldsymbol{z}_{\mathcal{B}})/\mathfrak{c}$ and is low-dimensional with respect to $\mathcal{B}$.*

   (b) *$\mathfrak{R}_i$ is the set of maps $\mathbb{R}^n \to \mathbb{R}^n$ that are low-dimensional with respect to $\mathcal{A}$ and that push forward $\boldsymbol{\nu}_\eta$ to the pullback $L_i^\sharp \, \boldsymbol{\nu}_i \in \mathscr{M}_+(\mathbb{R}^n)$.*

   (c) *If $\boldsymbol{Z}^{i+1} \sim L_i^\sharp \, \boldsymbol{\nu}_i$, then $\boldsymbol{Z}^{i+1}_{\mathcal{A}} \perp\!\!\!\perp \boldsymbol{Z}^{i+1}_{\mathcal{S}\cup\mathcal{B}}$ and $\boldsymbol{Z}^{i+1}_{\mathcal{A}} = \boldsymbol{X}_{\mathcal{A}}$ in distribution.*

   (d) *$L_i^\sharp \, \boldsymbol{\nu}_i$ factorizes according to a graph $\boldsymbol{\mathcal{G}}^{i+1}$ that can be derived from $\boldsymbol{\mathcal{G}}^i$ as follows:*

      – *Remove any edge from $\boldsymbol{\mathcal{G}}^i$ that is incident to any node in $\mathcal{A}$.*

      – *For any maximal clique $\mathcal{C} \subset \mathcal{S} \cup \mathcal{B}$ with nonempty intersection $\mathcal{C} \cap \mathcal{S}$, let $j_{\mathcal{C}}$ be the maximum integer j such that $\sigma(j) \in \mathcal{C} \cap \mathcal{S}$ and turn $\mathcal{C} \cup \{\sigma(1), \dots, \sigma(j_{\mathcal{C}})\}$ into a clique.*

We first look at the theorem for $i = 1$ and let $\boldsymbol{\nu}_1 \coloneqq \boldsymbol{\nu}_\pi$ and $\boldsymbol{\mathcal{G}}^1 \coloneqq \boldsymbol{\mathcal{G}}$, where $\boldsymbol{\nu}_\pi$ denotes our usual target measure with I-map $\boldsymbol{\mathcal{G}}$ and where $(\mathcal{A}, \mathcal{S}, \mathcal{B})$ denotes a decomposition of $\boldsymbol{\mathcal{G}}$.

Among the infinitely many transport maps from $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$, Theorem 7 identifies a family of decomposable ones. The existence of these maps relies exclusively on the Markov structure of $\boldsymbol{\nu}_\pi$: we just require $\boldsymbol{\mathcal{G}}$ to admit a (proper) decomposition.[7]

Each transport $T \in \mathfrak{D}_1$ pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$ and is the composition of two low-dimensional maps, i.e., $T = L_1 \circ R$ for a fixed L_1 defined in Theorem 7[Part 2a] and for some $R \in \mathfrak{R}_1$. (We also write $\mathfrak{D}_1 \coloneqq L_1 \circ \mathfrak{R}_1$.[8]) The structure of these low-dimensional maps is quite interesting. Up to a reordering of their components, Theorem 7[Parts 2a and 2b] show that L_1 and R have an intuitive complementary form:

$$L_1(\boldsymbol{x}) = \begin{bmatrix} L_1^{\mathcal{A}}(\boldsymbol{x}_{\mathcal{S}}, \boldsymbol{x}_{\mathcal{A}}) \\ L_1^{\mathcal{S}}(\boldsymbol{x}_{\mathcal{S}}) \\ \boldsymbol{x}_{\mathcal{B}} \end{bmatrix}, \qquad R(\boldsymbol{x}) = \begin{bmatrix} \boldsymbol{x}_{\mathcal{A}} \\ R^{\mathcal{S}}(\boldsymbol{x}_{\mathcal{S}}, \boldsymbol{x}_{\mathcal{B}}) \\ R^{\mathcal{B}}(\boldsymbol{x}_{\mathcal{S}}, \boldsymbol{x}_{\mathcal{B}}) \end{bmatrix}. \tag{19}$$

(If $\mathcal{S} = \emptyset$, one can just remove $L_1^{\mathcal{S}}$ and $R^{\mathcal{S}}$ from (19), and drop the dependence of the remaining components on $\boldsymbol{x}_{\mathcal{S}}$.) In particular, L_1 and R have effective dimensions bounded by $|\mathcal{A} \cup \mathcal{S}|$ and $|\mathcal{S} \cup \mathcal{B}| = |\mathcal{V} \setminus \mathcal{A}|$, respectively (see Definition 4). Even though L_1 and R are low-dimensional maps, their composition is quite dense—in the sense of Section 5—and is in general nontriangular:

$$T(\boldsymbol{x}) = (L_1 \circ R)(\boldsymbol{x}) = \begin{bmatrix} L_1^{\mathcal{A}}(\, R^{\mathcal{S}}(\boldsymbol{x}_{\mathcal{S}}, \boldsymbol{x}_{\mathcal{B}}),\, \boldsymbol{x}_{\mathcal{A}}) \\ L_1^{\mathcal{S}}(\, R^{\mathcal{S}}(\boldsymbol{x}_{\mathcal{S}}, \boldsymbol{x}_{\mathcal{B}})\,) \\ R^{\mathcal{B}}(\boldsymbol{x}_{\mathcal{S}}, \boldsymbol{x}_{\mathcal{B}}) \end{bmatrix},$$

and thus more difficult to represent and to work with. The key idea of decomposable transports is that they can be represented implicitly through the composition of their low-dimensional factors, similar to the way that direct transports can be represented implicitly through their sparse inverses (Section 5).

The sparsity patterns of L_1 and R in (19) are needed for the theorem to hold. In particular, L_1 must be a σ-triangular function with σ specified by (18). Notice that (18) does not prescribe an exact permutation, but just a few constraints on a feasible σ. Intuitively, these constraints say that L_1 should be a function whose components with indices in $\mathcal{S}$ depend only on the variables in $\mathcal{S}$ (whenever $\mathcal{S} \neq \emptyset$), and whose components with indices in $\mathcal{A}$ depend only on the variables in $\mathcal{A} \cup \mathcal{S}$. Thus, there is usually some freedom in the choice of σ. Different permutations lead to different families of decomposable transports, and can induce different sparsity patterns in an I-map, $\boldsymbol{\mathcal{G}}^2$, for $L_1^\sharp \boldsymbol{\nu}_\pi$ (Theorem 7[Part 2d]).

Part 2d of the theorem shows how to derive a possible I-map $\boldsymbol{\mathcal{G}}^2$—not necessarily minimal—by performing a sequence of graph operations on $\boldsymbol{\mathcal{G}}$. There are two steps: one that does not depend on σ and one that does. Let us focus first on the former: the idea is to remove from $\boldsymbol{\mathcal{G}}$ any edge that is incident to any node in $\mathcal{A}$, effectively disconnecting $\mathcal{A}$ from the rest of the graph. That is, if $\boldsymbol{Z}^2 \sim L_1^\sharp \boldsymbol{\nu}_\pi$, then, regardless of σ, L_1 makes $\boldsymbol{Z}^2_{\mathcal{A}}$ marginally

7. To obtain a proper decomposition of $\boldsymbol{\mathcal{G}}$, one is free to add edges to $\boldsymbol{\mathcal{G}}$ in order to turn the separator set $\mathcal{S}$ into a clique (see Definition 5); $\boldsymbol{\nu}_\pi$ still factorizes according to any less sparse version of $\boldsymbol{\mathcal{G}}$.
8. The notation here is intuitive: for a given $g : \mathbb{R}^n \to \mathbb{R}^n$ and for a given set of functions $\mathcal{F}$ from $\mathbb{R}^n$ to $\mathbb{R}^n$, $g \circ \mathcal{F}$ denotes the set of maps that can be written as $g \circ f$ for some $f \in \mathcal{F}$.

independent of $\boldsymbol{Z}^2_{\mathcal{S}\cup\mathcal{B}}$ by acting *locally* on $\boldsymbol{\mathcal{G}}$. And not only that: L_1 also ensures that the marginals of $\boldsymbol{\nu}_\eta$ and $L_1^\sharp \boldsymbol{\nu}_\pi$ agree along $\mathcal{A}$ (see Theorem 7[Part 2c]). Thus we should really interpret L_1 as the first step towards a progressive transport of $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$. L_1 is a local map: it can depend nontrivially only upon variables in $\boldsymbol{x}_{\mathcal{A}\cup\mathcal{S}}$. Indeed, in the most general case, $|\mathcal{A} \cup \mathcal{S}|$ is the minimum effective dimension of a low-dimensional map necessary to decouple $\mathcal{A}$ from the rest of the graph. The more edges incident to $\mathcal{A}$, the higher-dimensional a transport is needed. This type of *graph sparsification* requires a peculiar "block triangular" structure for L_1 as shown by (19): any σ-triangular function with σ given by (18) achieves this special structure. The second step of Part 2d shows that if $\mathcal{S} \neq \emptyset$, then it might be necessary to add edges to the subgraph $\boldsymbol{\mathcal{G}}_{\mathcal{S}\cup\mathcal{B}}$, depending on σ.[9] The relevant aspect of σ for this discussion is the definition of the permutation onto the first $|\mathcal{S}|$ integers. In general, there are $|\mathcal{S}|!$ different permutations that could induce different sparsity patterns in $\boldsymbol{\mathcal{G}}^2$. We shall see that permutations that add the fewest edges possible are of particular relevance.

6.3. Recursive Decompositions

The sparsity of $\boldsymbol{\mathcal{G}}^2$ is important because it affects the "complexity" of the maps in $\mathfrak{R}_1$: each $R \in \mathfrak{R}_1$ pushes forward $\boldsymbol{\nu}_\eta$ to $L_1^\sharp \boldsymbol{\nu}_\pi$. More specifically, by the previous discussion, we can see how the role of each $R \in \mathfrak{R}_1$ is really only that of matching the marginals of $\boldsymbol{\nu}_\eta$ and $L_1^\sharp \boldsymbol{\nu}_\pi$ along $\mathcal{V} \setminus \mathcal{A}$. A natural question then is whether we can break this matching step into simpler tasks, or, in the language of this section, whether $\mathfrak{R}_1$ contains transports that are further decomposable. Intuitively, we are seeking a finer-grained representation for some of the transports in $\mathfrak{R}_1$. The following lemma (for $i = 1$) provides a positive answer to this question as long as $\mathcal{V} \setminus \mathcal{A}$ is not fully connected in $\boldsymbol{\mathcal{G}}^2$. From now on, we denote $(\mathcal{A}, \mathcal{S}, \mathcal{B})$ by $(\mathcal{A}_1, \mathcal{S}_1, \mathcal{B}_1)$, since we will be dealing with a sequence of different graph decompositions.

Lemma 8 (Recursive decompositions) *Let $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_i, \boldsymbol{\mathcal{G}}^i$ be defined as in the assumptions of Theorem 7 for a proper decomposition $(\mathcal{A}_i, \mathcal{S}_i, \mathcal{B}_i)$ of $\boldsymbol{\mathcal{G}}^i$, while let $\boldsymbol{\mathcal{G}}^{i+1}$ and $\mathfrak{D}_i = L_i \circ \mathfrak{R}_i$ be the resulting graph (Part 2d) and family of decomposable transports,[10] respectively. Then there are two possibilities:*

1. *$\mathcal{S}_i \cup \mathcal{B}_i$ is not a clique in $\boldsymbol{\mathcal{G}}^{i+1}$. In this case, it is possible to identify a proper decomposition $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ of $\boldsymbol{\mathcal{G}}^{i+1}$ for some $\mathcal{A}_{i+1}$ that is a strict superset of $\mathcal{A}_i$ by (possibly) adding edges to $\boldsymbol{\mathcal{G}}^{i+1}$ in order to turn $\mathcal{S}_{i+1}$ into a clique. Let $\mathfrak{D}_{i+1} = L_{i+1} \circ \mathfrak{R}_{i+1}$ be defined as in Theorem 7 for the pair of measures $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_{i+1} \coloneqq L_i^\sharp \boldsymbol{\nu}_i$ and $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$. Then the following hold:*
   (a) *$\mathfrak{R}_i \supset \mathfrak{D}_{i+1}$ and $L_i \circ \mathfrak{R}_i \supset L_i \circ L_{i+1} \circ \mathfrak{R}_{i+1}$.*
   (b) *L_{i+1} is low-dimensional with respect to $\mathcal{A}_i \cup \mathcal{B}_{i+1}$ and has effective dimension bounded by $|(\mathcal{A}_{i+1} \setminus \mathcal{A}_i) \cup \mathcal{S}_{i+1}|$.*
   (c) *Each $R \in \mathfrak{R}_{i+1}$ has effective dimension bounded by $|\mathcal{V} \setminus \mathcal{A}_{i+1}|$.*

9. This is not always the case. For instance, if $\mathcal{S}$ is a subset of every maximal clique of $\boldsymbol{\mathcal{G}}$ in $\mathcal{S} \cup \mathcal{B}$ that has nonempty intersection with $\mathcal{S}$, then, by Theorem 7[Part 2d], no edges need to be added.
10. Whenever we do not specify a permutation σ_i or a factorization (17) in the definition of L_i, it means that the claim holds true for any feasible choice of these parameters.

2. $\mathcal{S}_i \cup \mathcal{B}_i$ is a clique in $\mathcal{G}^{i+1}$. In this case, the decomposition of Part 1 does not exist.

Lemma 8[Part 1] shows that if $\mathcal{S}_1 \cup \mathcal{B}_1$ is not fully connected in $\mathcal{G}^2$, then there exists a proper decomposition $(\mathcal{A}_2, \mathcal{S}_2, \mathcal{B}_2)$ of $\mathcal{G}^2$ (obtained, possibly, by adding edges to $\mathcal{G}^2$ in $\mathcal{V} \setminus \mathcal{A}_1$) for which $\mathcal{A}_2$ is a strict superset of $\mathcal{A}_1$. One can then apply Theorem 7 for the pair $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_2 = L_1^\sharp \boldsymbol{\nu}_1$ and the decomposition $(\mathcal{A}_2, \mathcal{S}_2, \mathcal{B}_2)$. As a result, Part 1a of the lemma shows that $\mathfrak{R}_1$ contains a subset $\mathfrak{D}_2 = L_2 \circ \mathfrak{R}_2$ of decomposable transport maps where both L_2 and each $R \in \mathfrak{R}_2$ are local transports on $\mathcal{V} \setminus \mathcal{A}_1$, i.e., they are both low-dimensional with respect to $\mathcal{A}_1$. In particular, L_2 is responsible for decoupling $\mathcal{A}_2 \setminus \mathcal{A}_1$ from the rest of the graph and for matching the marginals of $\boldsymbol{\nu}_\eta$ and $L_2^\sharp L_1^\sharp \boldsymbol{\nu}_\pi = (L_1 \circ L_2)^\sharp \boldsymbol{\nu}_\pi$ along $\mathcal{A}_2 \setminus \mathcal{A}_1$. The effective dimension of L_2 is bounded above by the size of the separator set $\mathcal{S}_2$ plus the number of nodes in $\mathcal{A}_2 \setminus \mathcal{A}_1$ (Part 1b of the lemma). The effective dimension of each $R \in \mathfrak{R}_2$ is bounded by the cardinality of $\mathcal{V} \setminus \mathcal{A}_2$ and is, in the most general case, lower than that of the maps in $\mathfrak{R}_1$ (Part 1c). Moreover, by Part 1a, $\mathfrak{D}_1 = L_1 \circ \mathfrak{R}_1 \supset L_1 \circ L_2 \circ \mathfrak{R}_2$, which means that among the infinitely many decomposable transports that push forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$, there exists at least one that factorizes as the composition of *three* low-dimensional maps as opposed to two, i.e., $T = L_1 \circ L_2 \circ R$ for some $R \in \mathfrak{R}_2$.

If, on the other hand, $\mathcal{S}_1 \cup \mathcal{B}_1$ is fully connected in $\mathcal{G}^2$, then by Lemma 8[Part 2] we know that the decomposition of Part 1 does not exist. As a result, we cannot use Theorem 7 to prove the existence of more finely decomposable transports in $\mathfrak{R}_1$. In other words, if we want to match the marginals of $\boldsymbol{\nu}_\eta$ and $L_1^\sharp \boldsymbol{\nu}_\pi$ along $\mathcal{V} \setminus \mathcal{A}_1 = \mathcal{S}_1 \cup \mathcal{B}_1$, then we must do so in one shot, using a *single* transport map.

The main idea, then, is to apply Lemma 8[Part 1], recursively, k times, where k is the first integer (possibly zero) for which $\mathcal{S}_{k+1} \cup \mathcal{B}_{k+1}$ is a clique in $\mathcal{G}^{k+2}$. After k iterations, the following inclusion must hold:

$$\mathfrak{D}_1 = L_1 \circ \mathfrak{R}_1 \supset L_1 \circ \cdots \circ L_{k+1} \circ \mathfrak{R}_{k+1}, \tag{20}$$

which shows that there exists a decomposable transport,

$$T = L_1 \circ \cdots \circ L_{k+1} \circ R, \tag{21}$$

for some $R \in \mathfrak{R}_{k+1}$, that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$. (Note that we can apply Lemma 8[Part 1] only finitely many times since $|\mathcal{V} \setminus \mathcal{A}_{i+1}|$ is an integer function strictly decreasing in i and bounded away from zero.) Each L_i in (20) is a σ_i-triangular map for some permutation σ_i that satisfies (21), and is low-dimensional with respect to $\mathcal{A}_{i-1} \cup \mathcal{B}_i$, i.e., for $i > 1$ and up to a permutation of its components,

$$L_i(\boldsymbol{x}) = \begin{bmatrix} \boldsymbol{x}_{\mathcal{A}_{i-1}} \\ L_i^{\mathcal{A}_i \setminus \mathcal{A}_{i-1}}(\boldsymbol{x}_{\mathcal{S}_i}, \boldsymbol{x}_{\mathcal{A}_i \setminus \mathcal{A}_{i-1}}) \\ L_i^{\mathcal{S}_i}(\boldsymbol{x}_{\mathcal{S}_i}) \\ \boldsymbol{x}_{\mathcal{B}_i} \end{bmatrix}.$$

The map R is low-dimensional with respect to $\mathcal{A}_{k+1}$ and can also be chosen as a generalized triangular function. Intuitively, we can think of L_i as decoupling nodes in $\mathcal{A}_i \setminus \mathcal{A}_{i-1}$ from the rest of the graph in an I-map for $(L_1 \circ \cdots \circ L_{i-1})^\sharp \boldsymbol{\nu}_\pi$. (Recall that by Lemma 8 all the

sets $(\mathcal{A}_i)$ are nested, i.e., $\mathcal{A}_1 \subset \cdots \subset \mathcal{A}_{k+1}$.) Figure 6 illustrates the mechanics underlying the recursive application of Lemma 8.

We emphasize that the existence and structure of (21) follow from simple graph operations on $\mathcal{G}$, and do not entail any actual computation with the target measure $\boldsymbol{\nu}_\pi$. Notice also that even if each map in the decomposition (20) is σ-triangular, the resulting transport map T need not be triangular at all. In other words, we obtain factorizations of general and possibly non-triangular transport maps in terms of low-dimensional generalized triangular functions. In this sense, we can regard triangular maps as a fundamental "building block" of a much larger class of transport maps.

Decomposable transports are clearly not unique. In particular, there are two factors that affect both the sparsity pattern and the number k of composed maps in the family $L_1 \circ \cdots \circ L_{k+1} \circ \mathfrak{R}_{k+1}$: the sequence of decompositions $(\mathcal{A}_i, \mathcal{S}_i, \mathcal{B}_i)$ and the sequence of permutations (σ_i). Usually, there is a certain freedom in the choice of these parameters, and each configuration might lead to a different family of decomposable transports. Of course some families might be more desirable than others: ideally, we would like the low-dimensional maps in the composition to have the smallest effective dimension possible. Recall that by Lemma 8 the effective dimension of each L_i can be bounded above by $|(\mathcal{A}_i \setminus \mathcal{A}_{i-1}) \cup \mathcal{S}_i|$ (with the convention $\mathcal{A}_0 = \emptyset$). Thus we should intuitively choose a decomposition $(\mathcal{A}_i, \mathcal{S}_i, \mathcal{B}_i)$ of $\mathcal{G}^i$ and a permutation σ_i for L_i that minimize the cardinality of $(\mathcal{A}_i \setminus \mathcal{A}_{i-1}) \cup \mathcal{S}_i$, and that, at the same time, minimize the number of edges added from $\mathcal{G}^i$ to $\mathcal{G}^{i+1}$. In principle, we should also account for the dimensions of all future maps in the recursion. In the most general case, this graph theoretic question could be addressed using dynamic programming (Bertsekas, 1995). In practice, however, we will often consider graphs for which a *good* sequence of decompositions and permutations is rather obvious (see Section 7). For instance, if the target distribution $\boldsymbol{\nu}_\pi$ factorizes according to a tree $\mathcal{G}$, then it is immediate to show the existence of a decomposable transport $T = T_1 \circ \cdots \circ T_{n-1}$ that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$ and that factorizes as the composition of $n-1$ low-dimensional maps $(T_i)_{i=1}^{n-1}$, each associated to an edge of $\mathcal{G}$: it suffices to consider a sequence of decompositions $(\mathcal{A}_i, \mathcal{S}_i, \mathcal{B}_i)$ with $\mathcal{A}_1 \subset \mathcal{A}_2 \subset \cdots$, where, for a given rooted version of $\mathcal{G}$, $\mathcal{A}_i \setminus \mathcal{A}_{i-1}$ consists of a single node a_i with the largest depth in $\mathcal{G}_{\mathcal{V} \setminus \mathcal{A}_{i-1}}$, and where $\mathcal{S}_i$ contains the unique parent of that node. Remarkably, each map T_i has effective dimension less than or equal to two, independent of n—the size of the tree.

At this point, it might be natural to consider a junction tree decomposition of a triangulation of $\mathcal{G}$ (Koller and Friedman, 2009) as a convenient graphical tool to schedule the sequence of decompositions $(\mathcal{A}_i, \mathcal{S}_i, \mathcal{B}_i)$ needed to apply Lemma 8 recursively. Decomposable graphs are in fact ultimately chordal (Lauritzen, 1996). However, the situation might not be as straightforward. The problem is that the clique structure of $\mathcal{G}^i$, an I-map for $\boldsymbol{\nu}_i$, can be *very* different than that of $\mathcal{G}^{i+1}$, an I-map for $L_i^\sharp \boldsymbol{\nu}_i$; Theorem 7[Part 2d] shows that $\mathcal{G}^{i+1}$ might contain larger maximal cliques than those in $\mathcal{G}^i$, even if $\mathcal{G}^i$ is chordal (see Figure 6 for an example). Thus, working with a junction tree might require a bit of extra care.

6.4. Computation of Decomposable Transports

Given the existence and structure of a decomposable transport like (21), what to do with it? There are at least two possible ways of exploiting this type of information. First, one could solve a variational problem like (6) and enforce an explicit parameterization of the transport map as the composition $T = L_1 \circ \cdots \circ L_{k+1} \circ R$. In this scenario, one need only parameterize the low-dimensional maps (L_i, R) and optimize, jointly, over their composition. The advantage of this approach is that it bypasses the parameterization of a single high-dimensional function, T, altogether. See the literature on normalizing flows (Rezende and Mohamed, 2015) for possible computational ideas in this direction.

An alternative—and perhaps more intriguing—possibility is to compute the maps (L_i) sequentially by solving *separate* low-dimensional optimization problems—one for each map L_i. By Theorem 7[Part 2a] and Lemma 8, there exists a factorization (17) of π_i—a density of $L_{i-1}^\sharp \boldsymbol{\nu}_{i-1}$—for which L_i is a σ_i-generalized KR rearrangement that pushes forward $\boldsymbol{\nu}_\eta$ to a measure with density proportional to $\psi_{\mathcal{A}_i \cup \mathcal{S}_i}\, \eta_{\boldsymbol{X}_{\mathcal{B}_i}}$, where $(\mathcal{A}_i, \mathcal{S}_i, \mathcal{B}_i)$ is a decomposition of $\boldsymbol{\mathcal{G}}^i$ and $\boldsymbol{\mathcal{G}}^i$ is an I-map for $\boldsymbol{\nu}_i$. In general $\psi_{\mathcal{A}_i \cup \mathcal{S}_i}$ depends on L_{i-1}, and so the maps (L_i) must be computed sequentially.[11] In essence, decomposable transports break the inference task into smaller and possibly easier steps.

Note that we could define L_i with respect to any factorization (17) with $\psi_{\mathcal{A}_i \cup \mathcal{S}_i}$ integrable: these different factorizations would lead to a family of decomposable transports with the same low-dimensional structure and sparsity patterns (as predicted by Theorem 7). Thus, as long as we have access to a sequence of integrable factors $(\psi_{\mathcal{A}_i \cup \mathcal{S}_i})$, we can compute each map L_i individually by solving a low-dimensional optimization problem. (See Appendix A for computational remarks on generalized triangular functions.) Intuitively, since by Lemma 8[Part 1b] L_i is low-dimensional with respect to $\mathcal{A}_{i-1} \cup \mathcal{B}_i$, we really only need to optimize for a portion of the map, namely $L_i^{\mathcal{C}}$ for $\mathcal{C} = (\mathcal{A}_i \setminus \mathcal{A}_{i-1}) \cup \mathcal{S}_i$, which can be regarded effectively as a multivariate map on $\mathbb{R}^{|\mathcal{C}|}$. In the same way, the map R can be computed as any transport (possibly triangular) that pushes forward $\boldsymbol{\nu}_\eta$ to $L_{k+1}^\sharp \boldsymbol{\nu}_{k+1}$. Theorem 7[Part 2b] tells us that once again we only need to optimize for a low-dimensional portion of the map, namely, $R^{\mathcal{S}_{k+1} \cup \mathcal{B}_{k+1}}$.

While it might be difficult to access a sequence of factorizations (17) for a general problem, there are important applications, such as Bayesian filtering, smoothing, and joint parameter/state estimation, where the sequential computation of the transports (L_i, R) is always possible by construction. We discuss these applications in the next section.

7. Sequential Inference on State-Space Models: Variational Algorithms

In this section, we consider the problem of sequential Bayesian inference (or discrete-time data assimilation; Reich and Cotter, 2015) for continuous, nonlinear, and non-Gaussian state-space models.

Our goal is to specialize the theory developed in Section 6 to the solution of Bayesian filtering and smoothing problems. The key result of this section is a new variational algorithm

11. This is not always the case. For instance, given a rooted version of $\boldsymbol{\mathcal{G}}$ and a pair of consecutive *depths* (see the discussion at the end of Section 6.3), all the maps (L_i) associated with edges connecting nodes at these two depths can be computed in parallel.

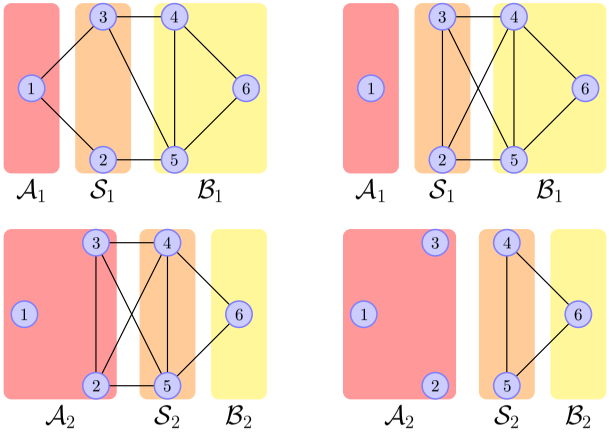

Figure 6: Sequence of graph decompositions associated with the recursive application of Lemma 8. On the *(top left)* there is an I-map, $\boldsymbol{\mathcal{G}}^1$, for $\boldsymbol{\nu}_\pi$, with $\boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^6)$. We first decompose this graph into $(\mathcal{A}_1, \mathcal{S}_1, \mathcal{B}_1)$ as indicated, and apply Theorem 7 to the pair $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi$. To do so, we first need to add edge $(2,3)$ to $\boldsymbol{\mathcal{G}}^1$ in order to turn $(\mathcal{A}_1, \mathcal{S}_1, \mathcal{B}_1)$ into a proper decomposition of $\boldsymbol{\mathcal{G}}^1$ with a fully connected $\mathcal{S}_1$. The resulting graph, $\boldsymbol{\mathcal{G}}^1_\star$, is now chordal (in fact, a triangulation of $\boldsymbol{\mathcal{G}}^1$, Lauritzen, 1996), but still an I-map for $\boldsymbol{\nu}_\pi$. The first map L_1 is σ_1-triangular with $\sigma_1(\mathbb{N}_6) = \{2,3,1,4,5,6\}$ and it is low-dimensional with respect to $\mathcal{B}_1$; The *(top right)* figure shows the I-map, $\boldsymbol{\mathcal{G}}^2$, for $L_1^\sharp \boldsymbol{\nu}_\pi$ as given by Theorem 7[Part 2d]: as expected, $\mathcal{A}_1$ is disconnected from $\mathcal{S}_1 \cup \mathcal{B}_1$; moreover, a new maximal clique $\{2,3,4,5\}$ appears in $\boldsymbol{\mathcal{G}}^2$. This new clique is larger than any of the maximal cliques in $\boldsymbol{\mathcal{G}}^1_\star$, even though $\boldsymbol{\mathcal{G}}^1_\star$ is chordal. (Notice that σ_1 is not the permutation that adds the fewest edges possible in $\boldsymbol{\mathcal{G}}^2$. An example of such "best" permutation would be $\sigma(\mathbb{N}_6) = \{3,2,1,4,5,6\}$.) Though Theorem 7 guarantees the existence of a low-dimensional map $R \in \mathfrak{R}_1$ that pushes forward $\boldsymbol{\nu}_\eta$ to $L_1^\sharp \boldsymbol{\nu}_\pi$, we instead proceed recursively by applying Lemma 8[Part 1] for a proper decomposition, $(\mathcal{A}_2, \mathcal{S}_2, \mathcal{B}_2)$, of $\boldsymbol{\mathcal{G}}^2$, where $\mathcal{A}_2$ is a strict superset of $\mathcal{A}_1$ *(bottom left)*. The lemma shows that $\mathfrak{R}_1 \supset L_2 \circ \mathfrak{R}_2$ for some σ_2-triangular map L_2, which is low-dimensional with respect to $\mathcal{A}_1 \cup \mathcal{B}_2$, and where each $R \in \mathfrak{R}_2$ pushes forward $\boldsymbol{\nu}_\eta$ to $(L_1 \circ L_2)^\sharp \boldsymbol{\nu}_\pi$. Can we apply Lemma 8 one more time to characterize decomposable transports in $\mathfrak{R}_2$? The answer is no, as the I-map for $(L_1 \circ L_2)^\sharp \boldsymbol{\nu}_\pi$ *(bottom right)* consists of a single clique in $\mathcal{S}_2 \cup \mathcal{B}_2$. Nevertheless, each $R \in \mathfrak{R}_2$ is still low-dimensional with respect to $\mathcal{A}_2$. Overall, we showed the existence of a transport map $T : \mathbb{R}^6 \to \mathbb{R}^6$ pushing forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$ that decomposes as $T = L_1 \circ L_2 \circ R$, where L_1, L_2, R are effectively $\{3,4,3\}$-dimensional maps, respectively.

for characterizing the full posterior distribution of the sequential inference problem—e.g., not just a few filtering or smoothing marginals—via recursive lag–1 smoothing with transport maps. The proposed algorithm builds a decomposable high-dimensional transport map in a *single forward pass* by solving a sequence of local low-dimensional problems, without resorting to any backward pass on the state space model (see Theorem 9). These results extend naturally to the case of joint parameter and state estimation (see Section 7.3 and Theorem 12). Pseudocode for the algorithm is given in Appendix C.

A state-space model consists of a pair of discrete-time stochastic processes $(\boldsymbol{Z}_k, \boldsymbol{Y}_k)_{k\geq 0}$ indexed by the time k, where $(\boldsymbol{Z}_k)$ is a latent Markov process of interest and where $(\boldsymbol{Y}_k)$ is the observed process. We can think of each $\boldsymbol{Y}_k$ as a noisy and perhaps indirect measurement of $\boldsymbol{Z}_k$. The Markov structure corresponding to the joint process $(\boldsymbol{Z}_k, \boldsymbol{Y}_k)$ is shown in Figure 7. The generalization of the results of this section to the case of missing observations is straightforward and will not be addressed here.

We assume that we are given the transition densities $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{Z}_k}$ for all $k \geq 0$, sometimes referred to as the "prior dynamic," together with the marginal density of the initial conditions $\pi_{\boldsymbol{Z}_0}$. (For instance, the prior dynamic could stem from the discretization of a continuous time stochastic differential equation; Oksendal, 2013.) We denote by $\pi_{\boldsymbol{Y}_k|\boldsymbol{Z}_k}$ the likelihood function, i.e., the density of $\boldsymbol{Y}_k$ given $\boldsymbol{Z}_k$, and assume that $\boldsymbol{Z}_k$ and $\boldsymbol{Y}_k$ are random variables taking values on $\mathbb{R}^n$ and $\mathbb{R}^d$, respectively. Moreover, we denote by $(\boldsymbol{y}_k)_{k\geq 0}$ a sequence of realizations of the observed process $(\boldsymbol{Y}_k)$ that will define the posterior distribution over the unobserved (hidden) states of the model, and make the following regularity assumption in our theorems: $\pi_{\boldsymbol{Z}_{0:k-1},\boldsymbol{Y}_{0:k-1}} > 0$ for all $k \geq 1$. (The existence of underlying fully supported measures will be left implicit throughout the section for notational convenience.)

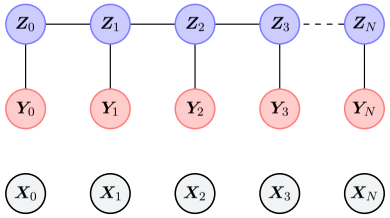

Figure 7: *(above)* I-map for the joint process $(\boldsymbol{Z}_k, \boldsymbol{Y}_k)_{k\geq 0}$ defining the state-space model. *(below)* I-map for the independent reference process $(\boldsymbol{X}_k)_{k\geq 0}$ used in Theorem 9.

7.1. Smoothing and Filtering: the Full Bayesian Solution

In typical applications of state-space modeling, the process $(\boldsymbol{Y}_k)$ is only observed sequentially, and thus the goal of inference is to characterize—sequentially in time and via a recursive algorithm—the joint distribution of the current and past states given currently available measurements, i.e.,

$$\pi_{\boldsymbol{Z}_{0:k}|\boldsymbol{y}_{0:k}}(\boldsymbol{z}_{0:k}) := \pi_{\boldsymbol{Z}_{0:k}|\boldsymbol{Y}_{0:k}}(\boldsymbol{z}_{0:k}|\boldsymbol{y}_{0:k}) \tag{22}$$

for all $k \geq 0$. That is, we wish to characterize $\pi_{\boldsymbol{Z}_{0:k}|\boldsymbol{y}_{0:k}}$ based on our knowledge of the posterior distribution at the previous timestep, $\pi_{\boldsymbol{Z}_{0:k-1}|\boldsymbol{y}_{0:k-1}}$, and with an effort that is constant over time. We regard (22) as the full Bayesian solution to the sequential inference problem (Särkkä, 2013).

Usually, the task of updating $\pi_{\boldsymbol{Z}_{0:k-1}|\boldsymbol{y}_{0:k-1}}$ to yield $\pi_{\boldsymbol{Z}_{0:k}|\boldsymbol{y}_{0:k}}$ becomes increasingly challenging over time due to the widening inference horizon, making characterization of the full Bayesian solution impractical for large k. Thus, two simplifications of the sequential inference problem are frequently considered: filtering and smoothing (Särkkä, 2013). In filtering, we characterize $\pi_{\boldsymbol{Z}_k|\boldsymbol{y}_{0:k}}$ for all $k \geq 0$, while in smoothing we recursively update $\pi_{\boldsymbol{Z}_j|\boldsymbol{y}_{0:k}}$ for increasing $k > j$, where $\boldsymbol{Z}_j$ is some past state of the unobserved process. Both filtering and smoothing deliver particular low-dimensional *marginals* of the full Bayesian solution to the inference problem, and hence are often considered good candidates for numerical approximation (Doucet and Johansen, 2009).

The following theorem shows that characterizing the full Bayesian solution to the sequential inference problem via a decomposable transport map is essentially no harder than performing lag–1 smoothing, which, in turn, amounts to characterizing $\pi_{\boldsymbol{Z}_{k-1},\boldsymbol{Z}_k|\boldsymbol{y}_{0:k}}$ for all $k \geq 0$ (an operation only slightly harder than regular filtering). This result relies on the recursive application of the decomposition theorem for couplings (Theorem 7) to the *tree* Markov structure of $\pi_{\boldsymbol{Z}_{0:k}|\boldsymbol{y}_{0:k}}$. In what follows, let $(\boldsymbol{X}_k)_{k\geq 0}$ be an independent (reference) process with nonvanishing marginal densities $(\eta_{\boldsymbol{X}_k})$, with each $\boldsymbol{X}_k$ taking values on $\mathbb{R}^n$. See Figure 7 for the corresponding Markov network.

Theorem 9 (Decomposition theorem for state-space models) *Let $(\mathfrak{M}_i)_{i\geq 0}$ be a sequence of (σ_i)-generalized KR rearrangements on $\mathbb{R}^n \times \mathbb{R}^n$, which are of the form*

$$\mathfrak{M}_i(\boldsymbol{x}_i, \boldsymbol{x}_{i+1}) = \begin{bmatrix} \mathfrak{M}_i^0(\boldsymbol{x}_i, \boldsymbol{x}_{i+1}) \\ \mathfrak{M}_i^1(\boldsymbol{x}_{i+1}) \end{bmatrix} \tag{23}$$

for some σ_i, $\mathfrak{M}_i^0 : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^n$, $\mathfrak{M}_i^1 : \mathbb{R}^n \to \mathbb{R}^n$, and that are defined by the recursion:

- *$\mathfrak{M}_0$ pushes forward $\eta_{\boldsymbol{X}_0,\boldsymbol{X}_1}$ to $\pi^0 = \widetilde{\pi}^0/\mathfrak{c}_0$,*
- *$\mathfrak{M}_i$ pushes forward $\eta_{\boldsymbol{X}_i,\boldsymbol{X}_{i+1}}$ to $\pi^i(\boldsymbol{z}_i, \boldsymbol{z}_{i+1}) = \eta_{\boldsymbol{X}_i}(\boldsymbol{z}_i)\, \widetilde{\pi}^i(\mathfrak{M}_{i-1}^1(\boldsymbol{z}_i), \boldsymbol{z}_{i+1})/\mathfrak{c}_i$,*

where $\mathfrak{c}_i$ is a normalizing constant and where $(\widetilde{\pi}^i)_{i\geq 0}$ are functions on $\mathbb{R}^n \times \mathbb{R}^n$ given by:

- *$\widetilde{\pi}^0(\boldsymbol{z}_0, \boldsymbol{z}_1) = \pi_{\boldsymbol{Z}_0,\boldsymbol{Z}_1}(\boldsymbol{z}_0, \boldsymbol{z}_1)\, \pi_{\boldsymbol{Y}_0|\boldsymbol{Z}_0}(\boldsymbol{y}_0|\boldsymbol{z}_0)\, \pi_{\boldsymbol{Y}_1|\boldsymbol{Z}_1}(\boldsymbol{y}_1|\boldsymbol{z}_1)$,*
- *$\widetilde{\pi}^i(\boldsymbol{z}_i, \boldsymbol{z}_{i+1}) = \pi_{\boldsymbol{Z}_{i+1}|\boldsymbol{Z}_i}(\boldsymbol{z}_{i+1}|\boldsymbol{z}_i)\, \pi_{\boldsymbol{Y}_{i+1}|\boldsymbol{Z}_{i+1}}(\boldsymbol{y}_{i+1}|\boldsymbol{z}_{i+1})$ for $i \geq 1$.*

Then, for all $k \geq 0$, the following hold:

1. *The map $\mathfrak{M}_k^1$ pushes forward $\eta_{\boldsymbol{X}_{k+1}}$ to $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$.* *[filtering]*
2. *The map $\overline{\mathfrak{M}}_k$, defined as ($\mathfrak{M}_{k-1}^1(\boldsymbol{x}) = \boldsymbol{x}$ for $k = 0$)*

$$\overline{\mathfrak{M}}_k(\boldsymbol{x}_k, \boldsymbol{x}_{k+1}) = \begin{bmatrix} \mathfrak{M}_{k-1}^1(\mathfrak{M}_k^0(\boldsymbol{x}_k, \boldsymbol{x}_{k+1})) \\ \mathfrak{M}_k^1(\boldsymbol{x}_{k+1}) \end{bmatrix}, \tag{24}$$

pushes forward $\eta_{\boldsymbol{X}_k,\boldsymbol{X}_{k+1}}$ to $\pi_{\boldsymbol{Z}_k,\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$. *[lag–1 smoothing]*

3. The composition of transport maps $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$, where each T_i is defined as

$$T_i(\boldsymbol{x}_0, \ldots, \boldsymbol{x}_{k+1}) = \begin{bmatrix} \boldsymbol{x}_0 \\ \vdots \\ \boldsymbol{x}_{i-1} \\ \mathfrak{M}_i^0(\boldsymbol{x}_i, \boldsymbol{x}_{i+1}) \\ \mathfrak{M}_i^1(\boldsymbol{x}_{i+1}) \\ \boldsymbol{x}_{i+2} \\ \vdots \\ \boldsymbol{x}_{k+1} \end{bmatrix}, \tag{25}$$

pushes forward $\eta_{\boldsymbol{X}_{0:k+1}}$ to $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$. *[full Bayesian solution]*

4. The model evidence (marginal likelihood) is given by

$$\pi_{\boldsymbol{Y}_{0:k+1}}(\boldsymbol{y}_{0:k+1}) = \prod_{i=0}^{k} \mathfrak{c}_i. \tag{26}$$

Theorem 9 suggests a variational algorithm for smoothing and filtering a continuous state-space model: compute the sequence of maps $(\mathfrak{M}_i)$, each of dimension $2n$; embed them into higher-dimensional identity maps to form (T_i) according to (25); then evaluate the composition $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$ to sample directly from $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ (i.e., the full Bayesian solution) and obtain information about any smoothing or filtering distribution of interest.

Successive transports in the composition $(\mathfrak{T}_k)_{k\geq 0}$ are *nested* and thus ideal for sequential assimilation: given $\mathfrak{T}_{k-1}$, we can obtain $\mathfrak{T}_k$ simply by computing an additional map $\mathfrak{M}_k$ of dimension $2n$—with no need to recompute $(\mathfrak{M}_i)_{i<k}$. This step converts a transport map that samples $\pi_{\boldsymbol{Z}_{0:k}|\boldsymbol{y}_{0:k}}$ into one that samples $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$. This feature is important since $\mathfrak{M}_k$ is always a $2n$-dimensional map, while $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ is a density on $\mathbb{R}^{n(k+2)}$—a space whose dimension increases with time k. In fact, from the perspective of Section 6, Theorem 9 simply shows that each $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ can be represented via a *decomposable* transport $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$. The sparsity pattern of each map $\mathfrak{M}_i$, specified in (23), is necessary for Theorem 9 to hold: $\mathfrak{M}_i$ cannot be *any* transport map; it must be block upper triangular.

The proposed algorithm consists of a forward pass on the state-space model—wherein the sequence of transport maps $(\mathfrak{M}_i)$ are computed and stored—followed by a backward pass where the composition $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$ is evaluated deterministically to sample $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$. This backward pass does not re-evaluate the potentials of the state-space model (e.g., transition kernels or likelihoods) at earlier times, nor does it perform any additional computation other than evaluating the maps $(\mathfrak{M}_i)$ in $\mathfrak{T}_k$.

Though each map T_j is usually trivial to evaluate—e.g., the map might be parameterized in terms of polynomials (Marzouk et al., 2016) and differ from the identity along only $2n$ components—it is true that the cost of evaluating $\mathfrak{T}_k$ grows linearly with k. This is hardly surprising since $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ is a density over spaces of increasing dimension. A direct approximation of $\mathfrak{T}_k$ is usually a bad idea since the map is high-dimensional and dense (in the sense defined by Section 6); it is better to store $\mathfrak{T}_k$ implicitly through the sequence of maps $(\mathfrak{M}_i)_{i\geq 0}^k$, and sample smoothed trajectories by evaluating $\mathfrak{T}_k$ only when it is needed. If

we are only interested in a particular smoothing marginal, e.g., $\pi_{\boldsymbol{Z}_0|\boldsymbol{y}_{0:k+1}}$ for all $k \geq 0$, then we can define a general forward recursion to sample $\pi_{\boldsymbol{Z}_0|\boldsymbol{y}_{0:k+1}}$ with a *single* transport map that is updated recursively over time, rather than with a growing composition of maps—and thus with a cost independent of k. This construction is given in Section 7.4.

Also, it is important to emphasize that in order to assimilate a new measurement, say $\boldsymbol{y}_{k+1}$, we do *not* need to evaluate the full composition $\mathfrak{T}_{k-1}$; we only need to compute a low-dimensional map $\mathfrak{M}_k$ whose target density π^k depends only on $\mathfrak{M}_{k-1}$. The previous maps $(\mathfrak{M}_i)_{i<k-1}$ are unnecessary at this stage. Thus the effort of assimilating a new piece of data is constant in time—modulo the complexity of each $\mathfrak{M}_k$.

The distribution $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ is not represented via a collection of particles as $k \geq 0$ increases, but rather via a growing composition of low-dimensional transport maps that yields *fully supported* approximations of $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$. These maps are computed via deterministic optimization: there are no importance sampling or resampling steps. Intuitively, the optimization step for $\mathfrak{M}_k$ *moves* the particles on which the map is evaluated, rather than reweighing them.

Part 1 of Theorem 9 shows that the lower subcomponent $\mathfrak{M}_k^1 : \mathbb{R}^n \to \mathbb{R}^n$ of the map $\mathfrak{M}_k$ characterizes the filtering distribution $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$ for all $k \geq 0$, while Part 2 shows that each $\mathfrak{M}_k$ also characterizes the lag–1 smoothing distribution $\pi_{\boldsymbol{Z}_k,\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$ up to an invertible transformation of the marginal over $\boldsymbol{Z}_k$. Thus, Theorem 9 implies a deterministic algorithm for lag–1 smoothing that in fact fully characterizes the posterior distribution of the nonlinear state-space model—much in the same spirit as the Rauch-Tung-Striebel (RTS) smoothing algorithm for Gaussian models. We clarify this connection in Section 7.2.

A related perspective on the proposed smoothing algorithm is that the composition of maps $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$ implements the following factorization of the full Bayesian solution,

$$\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}} = \pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}\, \pi_{\boldsymbol{Z}_k|\boldsymbol{Z}_{k+1},\boldsymbol{y}_{0:k}}\, \pi_{\boldsymbol{Z}_{k-1}|\boldsymbol{Z}_k,\boldsymbol{y}_{0:k-1}} \cdots \pi_{\boldsymbol{Z}_0|\boldsymbol{Z}_1,\boldsymbol{y}_0}, \tag{27}$$

wherein each map $\mathfrak{M}_i$, due to its block *upper* triangular structure, is associated with a specific factorization of the lag–1 smoothing density,

$$\pi_{\boldsymbol{Z}_{i+1},\boldsymbol{Z}_i|\boldsymbol{y}_{0:i+1}} = \pi_{\boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}\, \pi_{\boldsymbol{Z}_i|\boldsymbol{Z}_{i+1},\boldsymbol{y}_{0:i}}.$$

Evaluating $\mathfrak{T}_k$ on samples drawn from the reference process $\eta_{\boldsymbol{X}_{0:k+1}}$ amounts to sampling first from the final filtering marginal $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$ and then from the sequence of "backward" conditionals in (27). See also (Kitagawa, 1987; Doucet and Johansen, 2009; Godsill et al., 2004) for alternative approximations of the forward–filtering backward–smoothing formulas.

Note that the proposed approach does *not* reduce to the ensemble Kalman filter (EnKF) or to the ensemble Kalman smoother (EnKS) (Evensen, 2003; Evensen and Van Leeuwen, 2000), even if the maps $\{\mathfrak{M}_k\}$ are constrained to be linear. For one, the EnKF implements a two-step recursive approximation of each filtering marginal, which consists of (i) a particle approximation of the "forecast" distribution $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k}}$ obtained by *simulating* the transition kernel $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{Z}_k}$, followed by (ii) a *linear* approximation of the forecast-to-analysis update (i.e., the update from $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k}}$ to $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$). In contrast, our approach constructs a recursive *variational* approximation of each lag–1 smoothing distribution, essentially using numerical optimization to minimize the KL divergence between $\pi_{\boldsymbol{Z}_k,\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$ and its transport map approximation. We do not make a particle approximation of the forecast

distribution by integrating the model dynamics, but instead require explicit evaluations of the transition density $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{Z}_k}$. If, however, the dynamics of the state-space model are linear, with Gaussian transition/observational noise and Gaussian initial conditions, then the proposed algorithm is equivalent to filtering and smoothing via "exact" Kalman formulas; in this case, the EnKF and EnKS can be interpreted as Monte Carlo approximations of the recursions defined by the proposed algorithm (Raanes, 2016).

Numerical approximations. In general, the maps $(\mathfrak{M}_i)$ must be approximated numerically (see Section 3). As a result, Monte Carlo estimators associated with the evaluation of $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$ are *biased*, although possibly with negligible variance, since it is trivial to evaluate the map a large number of times. This bias is *only* due to the numerical approximation of $(\mathfrak{M}_i)$, and not to the particular factorization properties of $\mathfrak{T}_k$. In practice, one might either accept this bias or try to reduce it. The bias can be reduced in at least two ways: (1) by enriching the parameterization of some $(\mathfrak{M}_i)$, and thus increasing the accuracy of the variational approximation, or (2) by using the map-induced proposal density $(\mathfrak{T}_k)_\sharp \eta_{\boldsymbol{X}_{0:k+1}}$—i.e., the pushforward of a marginal of the reference process through $\mathfrak{T}_k$—within importance sampling or MCMC (see Section 8). For instance, the weight function

$$w^{k+1}(\boldsymbol{x}) = \frac{\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}(\boldsymbol{x})}{(\mathfrak{T}_k)_\sharp \eta_{\boldsymbol{X}_{0:k+1}}(\boldsymbol{x})}$$

is readily available, and can be used to yield consistent estimators with respect to the smoothing distribution. However, the resulting weights cannot be computed recursively in time, because even though the small dimensional maps $\mathfrak{M}_k$ are computed sequentially, the map-induced proposal $(\mathfrak{T}_k)_\sharp \eta_{\boldsymbol{X}_{0:k+1}}$ changes entirely at every step.

In particle filters, the complexity of approximating the underlying distribution is given by the number of particles N. In the proposed variational approach, the complexity of the approximation depends on the parameterization of each map $\mathfrak{M}_i$. There is no single parameter like N to describe the complexity of the latter—though, broadly, it should depend on the number of degrees of freedom in the parameterization. In some cases, one might think of using the total order of a multivariate polynomial expansion of each component of the map as a tuning parameter. But this is far from general or practical in high dimensions. The virtue of a functional representation of the transport map is the ability to carefully select the degrees of freedom of the parameterization. For instance, we might model local interactions between different groups of input variables using different approximation orders or even different sets of basis functions. This freedom should not be frightening, but rather embraced as a rich opportunity to exploit the structure of the particular problem at hand. Spantini (2017, Ch. 6) gives an example of this practice in the context of filtering high-dimensional spatiotemporal processes with chaotic dynamics.

In general, richer parameterizations of the maps are more costly to characterize because they lead to higher-dimensional optimization problems (7). Yet, richer parameterizations can yield arbitrarily accurate results. There is clearly a tradeoff between computational cost and statistical accuracy. We investigate this tradeoff numerically in Section 8, where we report the cost of computing a transport map under different parameterizations and inference scenarios.

Another important note: the *sequential* approximation of the individual maps $(\mathfrak{M}_i)$ might present additional challenges due to the accumulation of error, since the target density for the k-th map $\mathfrak{M}_k$ depends on the numerical approximation of the previous map, $\mathfrak{M}_{k-1}$. This is not an issue with the factorization of $\mathfrak{T}_k$ per se, but rather with sequentially computing each element of the factorization. The analysis of sequential Monte Carlo methods (e.g., Crisan and Doucet, 2002; Del Moral, 2004; Smith et al., 2013) addresses a similar accumulation of error, but has not yet been extended to sequential variational inference techniques. In Section 8, we empirically investigate the stability of variational transport map approximations for a problem of very long time smoothing (see Figure 17), showing excellent results—at least for the reconstruction of low-order smoothing marginals.

As shown in (9), the computation of each $\mathfrak{M}_i$ is also associated with an approximation of the normalizing constant $\mathfrak{c}_i$ of its own target density, which then leads to a one-pass approximation of the marginal likelihood using (26).

One last remark: the proof of Theorem 9 shows that the triangular structure hypothesis for each $\mathfrak{M}_i$ can be relaxed provided that the underlying densities are regular enough. The following corollary clarifies this point.

Corollary 10 *The results of Theorem 9 still hold if we replace every KR rearrangement $\mathfrak{M}_i$ with a "block triangular" diffeomorphism of the form* (23) *that couples the same distributions, provided that such regular transport maps exist.*

Filtering and smoothing are of course very rich problems, and in this section we have by no means attempted to be exhaustive. Rather, our goal was to highlight some implications of decomposable transports on problems of sequential Bayesian inference, in a general non-Gaussian setting.

7.2. The Linear Gaussian Case: Connection with the RTS Smoother

In this section, we specialize the results of Theorem 9 to linear Gaussian state-space models, and make explicit the connection with the RTS Gaussian smoother (Rauch et al., 1965).

Consider a linear Gaussian state-space model defined by

$$\begin{aligned} \boldsymbol{Z}_{k+1} &= \boldsymbol{F}_k \boldsymbol{Z}_k + \boldsymbol{\varepsilon}_k \\ \boldsymbol{Y}_k &= \boldsymbol{H}_k \boldsymbol{Z}_k + \boldsymbol{\xi}_k \end{aligned}$$

for all $k \geq 0$, where $\boldsymbol{\varepsilon}_k \sim \mathcal{N}(0, \boldsymbol{Q}_k)$, $\boldsymbol{\xi}_k \sim \mathcal{N}(0, \boldsymbol{R}_k)$, $\boldsymbol{F}_k \in \mathbb{R}^{n\times n}$, $\boldsymbol{H}_k \in \mathbb{R}^{d\times n}$, and $\boldsymbol{Z}_0 \sim \mathcal{N}(\mu_0, \boldsymbol{\Gamma}_0)$. Both $\boldsymbol{\varepsilon}_k$ and $\boldsymbol{\xi}_k$ are independent of $\boldsymbol{Z}_k$, while $\boldsymbol{Q}_k, \boldsymbol{R}_k$, and $\boldsymbol{\Gamma}_0$ are symmetric positive definite matrices for all $k \geq 0$.

If we choose an independent reference process $(\boldsymbol{X}_k)$ with standard normal marginals, i.e., $\eta_{\boldsymbol{X}_k} = \mathcal{N}(0, \mathbf{I})$, then the maps $(\mathfrak{M}_k)$ of Theorem 9 can be chosen to be linear:

$$\mathfrak{M}_k(\boldsymbol{z}_k, \boldsymbol{z}_{k+1}) = \begin{bmatrix} \boldsymbol{A}_k & \boldsymbol{B}_k \\ \mathbf{0} & \boldsymbol{C}_k \end{bmatrix} \begin{Bmatrix} \boldsymbol{z}_k \\ \boldsymbol{z}_{k+1} \end{Bmatrix} + \begin{Bmatrix} \boldsymbol{a}_k \\ \boldsymbol{c}_k \end{Bmatrix}, \tag{28}$$

for some matrices $\boldsymbol{A}_k, \boldsymbol{B}_k, \boldsymbol{C}_k \in \mathbb{R}^{n\times n}$ and $\boldsymbol{a}_k, \boldsymbol{c}_k \in \mathbb{R}^n$. (Notice that in this case Corollary 10 applies and the matrices $\boldsymbol{A}_k, \boldsymbol{B}_k$ can be full and not necessarily triangular.) The following lemma gives a closed form expression for the maps $(\mathfrak{M}_k)$ with $k \geq 1$. ($\mathfrak{M}_0$ can be derived analogously with simple algebra.)

Lemma 11 (The linear Gaussian case) *For $k \geq 1$, the map $\mathfrak{M}_k$ in (28) can be defined as follows: if $(\boldsymbol{c}_k, \boldsymbol{C}_k)$ is the output of a square-root Kalman filter at time k (Bierman, 2006), i.e., if $\boldsymbol{c}_k$ and $\boldsymbol{C}_k$ are, respectively, the mean and square root of the covariance of the filtering distribution $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$, then one can set:*

$$\begin{aligned} \boldsymbol{A}_k &= \boldsymbol{J}_k^{-1/2} \\ \boldsymbol{B}_k &= -\boldsymbol{J}_k^{-1}\,\boldsymbol{P}_k\,\boldsymbol{C}_k \\ \boldsymbol{a}_k &= \boldsymbol{J}_k^{-1}\,\boldsymbol{P}_k\,(\boldsymbol{F}_k\,\boldsymbol{c}_{k-1} - \boldsymbol{c}_k), \end{aligned} \tag{29}$$

for $\boldsymbol{J}_k \coloneqq \mathbf{I} + \boldsymbol{C}_{k-1}^\top\,\boldsymbol{F}_k^\top\,\boldsymbol{Q}_k^{-1}\,\boldsymbol{F}_k\,\boldsymbol{C}_{k-1}$ and $\boldsymbol{P}_k = -\boldsymbol{C}_{k-1}^\top\,\boldsymbol{F}_k^\top\,\boldsymbol{Q}_k^{-1}$.

The formulas in Lemma 11 can be interpreted as one possible implementation of a square-root RTS smoother for Gaussian models: at each step k of a forward pass, the filtering estimates $(\boldsymbol{c}_k, \boldsymbol{C}_k)$ are augmented with a collection $(\boldsymbol{a}_k, \boldsymbol{A}_k, \boldsymbol{B}_k)$ of stored quantities, which can then be reused to sample the full Bayesian solution (or particular smoothing marginals) whenever needed, and without ever touching the state-space model again. In this sense, the algorithm proposed in Section 7.1 can be understood as the natural generalization—to the non-Gaussian case—of the square-root RTS smoother.

7.3. Sequential Joint Parameter and State Estimation

In defining a state-space model, it is common to parameterize the transition densities of the unobserved process or the likelihoods of the observables in terms of some hyperparameters $\boldsymbol{\Theta}$. The Markov structure of the resulting Bayesian hierarchical model, conditioned on the data, is shown in Figure 8. The state-space model is now fully specified in terms of the conditional densities $(\pi_{\boldsymbol{Y}_k|\boldsymbol{Z}_k,\boldsymbol{\Theta}})_{k\geq 0}$, $(\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{Z}_k,\boldsymbol{\Theta}})_{k\geq 0}$, $\pi_{\boldsymbol{Z}_0|\boldsymbol{\Theta}}$, and the marginal $\pi_{\boldsymbol{\Theta}}$. We assume that the hyperparameters $\boldsymbol{\Theta}$ take values on $\mathbb{R}^p$, and that the following regularity conditions hold: $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k-1},\boldsymbol{Y}_{0:k-1}} > 0$ for all $k \geq 1$.

Given such a parameterization, one often wishes to *jointly* infer the hidden states and the hyperparameters of the model as observations of the process $(\boldsymbol{Y}_k)$ become available. That is, the goal of inference is to characterize, via a *recursive* algorithm, the sequence of posterior distributions given by

$$\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k}|\boldsymbol{y}_{0:k}}(\boldsymbol{z}_\theta, \boldsymbol{z}_{0:k}) \coloneqq \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k}|\boldsymbol{Y}_{0:k}}(\boldsymbol{z}_\theta, \boldsymbol{z}_{0:k}|\boldsymbol{y}_{0:k}) \tag{30}$$

for all $k \geq 0$ and for a sequence $(\boldsymbol{y}_k)_{k\geq 0}$ of observations. The following theorem shows that we can characterize (30) by computing a sequence of low-dimensional transport maps in the same spirit as Theorem 9. In what follows, let $(\boldsymbol{X}_k)$ be an independent process with marginals $(\eta_{\boldsymbol{X}_k})$ as defined in Theorem 9 and let $\boldsymbol{X}_{\boldsymbol{\Theta}}$ be a random variable on $\mathbb{R}^p$ that is independent of $(\boldsymbol{X}_k)$ and with nonvanishing density $\eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}}$.

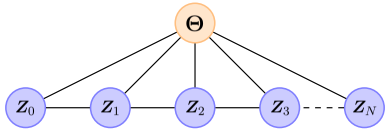

Figure 8: I-map for $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_0,\ldots,\boldsymbol{Z}_N|\boldsymbol{y}_0,\ldots,\boldsymbol{y}_N}$, for any $N > 0$.

Theorem 12 (Decomposition theorem for joint parameter and state estimation) *Let $(\mathfrak{M}_i)_{i\geq 0}$ be a sequence of (σ_i)-generalized KR rearrangements on $\mathbb{R}^p \times \mathbb{R}^n \times \mathbb{R}^n$, which are of the form*

$$\mathfrak{M}_i(\boldsymbol{x}_\theta, \boldsymbol{x}_i, \boldsymbol{x}_{i+1}) = \begin{bmatrix} \mathfrak{M}_i^{\boldsymbol{\Theta}}(\boldsymbol{x}_\theta) \\ \mathfrak{M}_i^0(\boldsymbol{x}_\theta, \boldsymbol{x}_i, \boldsymbol{x}_{i+1}) \\ \mathfrak{M}_i^1(\boldsymbol{x}_\theta, \boldsymbol{x}_{i+1}) \end{bmatrix} \tag{31}$$

for some σ_i, $\mathfrak{M}_i^{\boldsymbol{\Theta}} : \mathbb{R}^p \to \mathbb{R}^p$, $\mathfrak{M}_i^0 : \mathbb{R}^p \times \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^n$, $\mathfrak{M}_i^1 : \mathbb{R}^p \times \mathbb{R}^n \to \mathbb{R}^n$, and that are defined by the recursion:

- *$\mathfrak{M}_0$ pushes forward $\eta_{\boldsymbol{X}_{\boldsymbol{\Theta}},\boldsymbol{X}_0,\boldsymbol{X}_1}$ to*

$$\pi^0 = \widetilde{\pi}^0/\mathfrak{c}_0, \tag{32}$$

- *$\mathfrak{M}_i$ pushes forward $\eta_{\boldsymbol{X}_{\boldsymbol{\Theta}},\boldsymbol{X}_i,\boldsymbol{X}_{i+1}}$ to*

$$\pi^i(\boldsymbol{z}_\theta, \boldsymbol{z}_i, \boldsymbol{z}_{i+1}) = \eta_{\boldsymbol{X}_{\boldsymbol{\Theta}},\boldsymbol{X}_i}(\boldsymbol{z}_\theta, \boldsymbol{z}_i)\,\widetilde{\pi}^i(\mathfrak{T}_{i-1}^{\boldsymbol{\Theta}}(\boldsymbol{z}_\theta),\, \mathfrak{M}_{i-1}^1(\boldsymbol{z}_\theta, \boldsymbol{z}_i), \boldsymbol{z}_{i+1})/\mathfrak{c}_i, \tag{33}$$

where $\mathfrak{c}_i$ is a normalizing constant, the map $\mathfrak{T}_j^{\boldsymbol{\Theta}} \coloneqq \mathfrak{M}_0^{\boldsymbol{\Theta}} \circ \cdots \circ \mathfrak{M}_j^{\boldsymbol{\Theta}}$ for all $j \geq 0$, and where $(\widetilde{\pi}^i)_{i\geq 0}$ are functions on $\mathbb{R}^p \times \mathbb{R}^n \times \mathbb{R}^n$ given by:

- *$\widetilde{\pi}^0(\boldsymbol{z}_\theta, \boldsymbol{z}_0, \boldsymbol{z}_1) = \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_0,\boldsymbol{Z}_1}(\boldsymbol{z}_\theta, \boldsymbol{z}_0, \boldsymbol{z}_1)\,\pi_{\boldsymbol{Y}_0|\boldsymbol{Z}_0,\boldsymbol{\Theta}}(\boldsymbol{y}_0|\boldsymbol{z}_0, \boldsymbol{z}_\theta)\,\pi_{\boldsymbol{Y}_1|\boldsymbol{Z}_1,\boldsymbol{\Theta}}(\boldsymbol{y}_1|\boldsymbol{z}_1, \boldsymbol{z}_\theta)$,*
- *$\widetilde{\pi}^i(\boldsymbol{z}_\theta, \boldsymbol{z}_i, \boldsymbol{z}_{i+1}) = \pi_{\boldsymbol{Z}_{i+1}|\boldsymbol{Z}_i,\boldsymbol{\Theta}}(\boldsymbol{z}_{i+1}|\boldsymbol{z}_i, \boldsymbol{z}_\theta)\,\pi_{\boldsymbol{Y}_{i+1}|\boldsymbol{Z}_{i+1},\boldsymbol{\Theta}}(\boldsymbol{y}_{i+1}|\boldsymbol{z}_{i+1}, \boldsymbol{z}_\theta)$ for $i \geq 1$.*

Then, for all $k \geq 0$, the following hold:

1. *The map $\widetilde{\mathfrak{M}}_k$, defined as*

$$\widetilde{\mathfrak{M}}_k(\boldsymbol{x}_\theta, \boldsymbol{x}_{k+1}) = \begin{bmatrix} \mathfrak{T}_k^{\boldsymbol{\Theta}}(\boldsymbol{x}_\theta) \\ \mathfrak{M}_k^1(\boldsymbol{x}_\theta, \boldsymbol{x}_{k+1}) \end{bmatrix}, \tag{34}$$

   pushes forward $\eta_{\boldsymbol{X}_{\boldsymbol{\Theta}},\boldsymbol{X}_{k+1}}$ to $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{k+1}|\boldsymbol{y}_0,\ldots,\boldsymbol{y}_{k+1}}$. *[filtering]*

2. *The composition of transport maps $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$, where each T_i is defined as*

$$T_i(\boldsymbol{x}_\theta, \boldsymbol{x}_0, \ldots, \boldsymbol{x}_{k+1}) = \begin{bmatrix} \mathfrak{M}_i^{\boldsymbol{\Theta}}(\boldsymbol{x}_\theta) \\ \boldsymbol{x}_0 \\ \vdots \\ \boldsymbol{x}_{i-1} \\ \mathfrak{M}_i^0(\boldsymbol{x}_\theta, \boldsymbol{x}_i, \boldsymbol{x}_{i+1}) \\ \mathfrak{M}_i^1(\boldsymbol{x}_\theta, \boldsymbol{x}_{i+1}) \\ \boldsymbol{x}_{i+2} \\ \vdots \\ \boldsymbol{x}_{k+1} \end{bmatrix}, \tag{35}$$

   pushes forward $\eta_{\boldsymbol{X}_{\boldsymbol{\Theta}},\boldsymbol{X}_0,\ldots,\boldsymbol{X}_{k+1}}$ to $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_0,\ldots,\boldsymbol{Z}_{k+1}|\boldsymbol{y}_0,\ldots,\boldsymbol{y}_{k+1}}$. *[full Bayesian solution]*

3. The model evidence (marginal likelihood) is given by (26).

Theorem 12 suggests a variational algorithm for the joint parameter and state estimation problem that is similar to the one proposed in Theorem 9: compute the sequence of maps $(\mathfrak{M}_i)$, each of dimension $2n+p$; embed them into higher-dimensional identity maps to form (T_i) according to (35); then evaluate the composition $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$ to sample directly from $\pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ (i.e., the full Bayesian solution). See Appendix C for more details. Each map $\mathfrak{M}_i$ is now of dimension twice that of the model state plus the dimension of the hyperparameters. This dimension is slightly higher than that of the maps $(\mathfrak{M}_i)$ considered in Theorem 9, and should be regarded as the price to pay for introducing hyperparameters in the state-space model and having to deal with the Markov structure of Figure 8 as opposed to the tree structure of Figure 7. By Theorem 12[Part 1], the composition of maps $\mathfrak{T}_k^{\boldsymbol{\Theta}} = \mathfrak{M}_0^{\boldsymbol{\Theta}} \circ \cdots \circ \mathfrak{M}_k^{\boldsymbol{\Theta}}$ provides a recursive characterization of the posterior distribution over the static parameters, $\pi_{\boldsymbol{\Theta}|\boldsymbol{y}_{0:k+1}}$, for all $k \geq 0$. The latter is often the ultimate goal of inference (Andrieu et al., 2010). In order to have a sequential algorithm for parameter estimation, we also need to keep a running approximation of $\mathfrak{T}_k^{\boldsymbol{\Theta}}$ using the recursion $\mathfrak{T}_k^{\boldsymbol{\Theta}} = \mathfrak{T}_{k-1}^{\boldsymbol{\Theta}} \circ \mathfrak{M}_k^{\boldsymbol{\Theta}}$—e.g., via regression—so that the cost of evaluating $\mathfrak{T}_k^{\boldsymbol{\Theta}}$ does not grow with k.

Even in the joint parameter and state estimation case, only a single forward pass with local computations is necessary to gather all the information from the state-space model needed to sample the collection of posteriors $(\pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}})$. Notice that the accuracy of the variational procedure is only limited by the accuracy of each computed map, and that the proposed approach does not prescribe an artificial dynamic for the parameters (Kitagawa, 1998; Liu and West, 2001), or an *a priori* fixed-lag smoothing approximation (Polson et al., 2008). Yet there is no rigorous proof that the performance of the proposed sequential algorithm for parameter estimation does not deteriorate with time. Indeed, developing exact, sequential, and online algorithms for parameter estimation in general non-Gaussian state-space models is among the chief research challenges in SMC methods (Jacob, 2015). See (Chopin et al., 2013; Crisan and Miguez, 2013; Del Moral et al., 2017) for recent contributions in this direction and (Kantas et al., 2015) for a review of SMC approaches to Bayesian parameter inference. See also (Erol et al., 2017) for a hybrid approach that combines elements of variational inference with particle filters.

We refer the reader to Section 8 for a numerical illustration of parameter inference with transport maps involving a stochastic volatility model.

7.4. Fixed-Point Smoothing

Consider again the problem of sequential inference in a state-space model without static parameters (see Figure 7), and suppose that we are interested only in the smoothing marginal $\pi_{\boldsymbol{Z}_0|\boldsymbol{y}_{0:k}}$ for all $k \geq 0$; this is the fixed-point smoothing problem.

In Section 7.1 we showed that computing a sequence of maps $(\mathfrak{M}_i)$—each of dimension $2n$—is sufficient to sample the joint distribution $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ by evaluating the composition $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$, where each T_i is a trivial embedding of $\mathfrak{M}_i$ into an identity map. If we can sample $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$, then it is easy to obtain samples from the marginal $\pi_{\boldsymbol{Z}_0|\boldsymbol{y}_{0:k+1}}$: in fact, it suffices to evaluate only the first n components of $\mathfrak{T}_k$, which can be interpreted as a map from $\mathbb{R}^{n\times(k+2)}$ to $\mathbb{R}^n$. To do so, however, we need to evaluate k maps. A natural

question then is whether it is possible to characterize $\pi_{\boldsymbol{Z}_0|\boldsymbol{y}_{0:k+1}}$ via a *single* transport map that is updated recursively in time, as opposed to a growing composition of maps.

Here we propose a solution—certainly not the only possibility—based on the theory of Section 7.3. The idea is to treat $\boldsymbol{Z}_0$ as a static parameter, i.e., to set $\boldsymbol{\Theta} \coloneqq \boldsymbol{Z}_0$ and apply the results of Theorem 12 to the Markov structure of Figure 9. The resulting algorithm computes a sequence of maps $(\mathfrak{M}_i)$ of dimension $3n$, i.e., *three* times the state dimension, and keeps a running approximation of $\mathfrak{T}_k^{\boldsymbol{\Theta}}$ via the recursion $\mathfrak{T}_k^{\boldsymbol{\Theta}} = \mathfrak{T}_{k-1}^{\boldsymbol{\Theta}} \circ \mathfrak{M}_k^{\boldsymbol{\Theta}}$, where each $\mathfrak{M}_k^{\boldsymbol{\Theta}}$ is just a subcomponent of $\mathfrak{M}_k$. These maps $(\mathfrak{M}_i)$ are higher-dimensional than those considered in Section 7.1, but they do yield the desired result: each $\mathfrak{T}_k^{\boldsymbol{\Theta}} : \mathbb{R}^n \to \mathbb{R}^n$ characterizes the smoothing marginal $\pi_{\boldsymbol{Z}_0|\boldsymbol{y}_{0:k+1}}$, for all $k \geq 0$, via a single transport map that is updated recursively in time with just one forward pass (see Theorem 12[Part 1]).

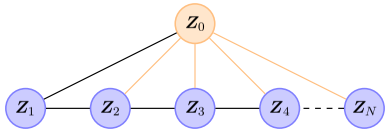

Figure 9: I-map (certainly not minimal) for $\pi_{\boldsymbol{Z}_0, \boldsymbol{Z}_{1:N}|\boldsymbol{y}_{0:N}}$, for any $N > 0$. Orange edges have been added compared to the tree structure of Figure 7.

8. Numerical Illustration

We illustrate some aspects of the preceding theory using a problem of sequential inference in a non-Gaussian state-space model. In particular, we show the application of decomposable transport maps (Sections 6 and 7) to joint state and parameter inference in a stochastic volatility model. This example is intended as a direct and simple illustration of the theory. The notion of decomposable transport maps is useful well beyond the sequential inference setting, and entails the general problem of inference in continuous non-Gaussian graphical models. We refer the reader to Morrison et al. (2017) for an application of the theory of sparse transports (Section 5) to the problem of learning the Markov structure of a non-Gaussian distribution, and we defer further numerical investigations to a dedicated paper (Bigoni et al., 2019).

Following (Kim et al., 1998; Rue et al., 2009), we model the scalar log-volatility $(\boldsymbol{Z}_k)$ of the return of a financial asset at time $k = 0, \dots, N$ using an autoregressive process of order one, which is fully specified by $\boldsymbol{Z}_{k+1} = \boldsymbol{\mu} + \boldsymbol{\phi}\,(\boldsymbol{Z}_k - \boldsymbol{\mu}) + \boldsymbol{\varepsilon}_k$, for all $k \geq 0$, where $\boldsymbol{\varepsilon}_k \sim \mathcal{N}(0, 1/16)$ is independent of $\boldsymbol{Z}_k$, $\boldsymbol{Z}_0|\boldsymbol{\mu}, \boldsymbol{\phi} \sim \mathcal{N}(\boldsymbol{\mu}, \frac{1}{1-\boldsymbol{\phi}^2})$, and where $\boldsymbol{\phi}$ and $\boldsymbol{\mu}$ represent scalar hyperparameters of the model. In particular, $\boldsymbol{\mu} \sim \mathcal{N}(0, 1)$ and $\boldsymbol{\phi} = 2\exp(\boldsymbol{\phi}^\star)/(1+\exp(\boldsymbol{\phi}^\star)) - 1$ with $\boldsymbol{\phi}^\star \sim \mathcal{N}(3, 1)$. We define $\boldsymbol{\Theta} \coloneqq (\boldsymbol{\mu}, \boldsymbol{\phi})$. The process $(\boldsymbol{Z}_k)$ and parameters $\boldsymbol{\Theta}$ are unobserved and must be estimated from an observed process $(\boldsymbol{Y}_k)$, which represents the mean return on holding the asset at time k, $\boldsymbol{Y}_k = \boldsymbol{\xi}_k \exp(\frac{1}{2}\boldsymbol{Z}_k)$, where $\boldsymbol{\xi}_k$ is a standard normal random variable independent of $\boldsymbol{Z}_k$. As a data set $(\boldsymbol{y}_k)_{k=0}^N$, we use the $N+1$ daily differences of the pound/dollar exchange rate starting on 1 October 1981, with $N = 944$ (Rue et al., 2009; Durbin and Koopman, 2000).

Our goal is to sequentially characterize $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k}|\boldsymbol{y}_{0:k}}$, for all $k = 0, \ldots, N$, as observations $(\boldsymbol{y}_k)$ become available. The Markov structure of $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:N}|\boldsymbol{y}_{0:N}}$ matches Figure 8. We solve the problem using the algorithm introduced in Section 7.3: we compute a sequence, $(\mathfrak{M}_j)_{j=0}^{N-1}$, of four-dimensional transport maps ($n = \dim(\boldsymbol{Z}_j) = 1$ and $p = \dim(\boldsymbol{\Theta}) = 2$) according to their definition in Theorem 12 and using the variational form (6). All reference densities are standard Gaussians. Then, by Theorem 12[part 1], for any $k < N$, we can easily sample the filtering marginal $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$ by pushing forward a standard normal through the subcomponent $\mathfrak{M}_k^1$ of $\mathfrak{M}_k$, and we can also sample the posterior distribution over the static parameters $\pi_{\boldsymbol{\Theta}|\boldsymbol{y}_{0:k+1}}$ by pushing forward a standard normal through the map $\mathfrak{T}_k^{\boldsymbol{\Theta}}$. The map $\mathfrak{T}_k^{\boldsymbol{\Theta}} = \mathfrak{M}_0^{\boldsymbol{\Theta}} \circ \cdots \circ \mathfrak{M}_k^{\boldsymbol{\Theta}}$ is updated sequentially over time (via regression) using the recursion $\mathfrak{T}_k^{\boldsymbol{\Theta}} = \mathfrak{T}_{k-1}^{\boldsymbol{\Theta}} \circ \mathfrak{M}_k^{\boldsymbol{\Theta}}$, so that the cost of evaluating $\mathfrak{T}_k^{\boldsymbol{\Theta}}$ does not increase with k. The resulting algorithm for parameter estimation is thus sequential. Moreover, if we want to sample $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+1}|\boldsymbol{Y}_{0:k+1}}$—the full Bayesian solution at time $k+1$—we simply need to embed each $\mathfrak{M}_j$ into an identity map to form the transport T_j, for $j = 0, \ldots, k$, and push forward reference samples through the composition $\mathfrak{T}_k = T_0 \circ \cdots \circ T_k$ (Theorem 12[part 2]). See Appendix C for pseudocode of the relevant algorithms.

Figures 10 and 11 show the resulting smoothing and filtering marginals of the states over time, respectively. Figures 12 and 13 collect the corresponding posterior marginals of the static parameters over time. Figure 14 illustrates marginals of the posterior predictive distribution of the data, together with the observed data $(\boldsymbol{y}_k)$, showing excellent coverage overall.

Our results rely on a numerical approximation of the desired transport maps. Each component of $\mathfrak{M}_k$ is parameterized via the monotone representation (5), with (a_k) and (b_k) chosen to be Hermite polynomials and functions, respectively, of total degree seven.The expectation in (6) is approximated using tensorized Gauss quadrature rules. The resulting minimization problems are solved sequentially using the Newton–CG method (Wright and Nocedal, 1999). This test case was run using the dedicated software package publicly available at `http://transportmaps.mit.edu`. The website contains details about additional possible parameterizations of the maps.

There are several ways to investigate the quality of these approximations. Figures 10, 12, and 13 compare the numerical approximation (via a decomposable transport map) of the smoothing marginals of the states and the posteriors of the static parameters to a "reference" solution obtained via MCMC. The MCMC chain is run until it yields 10^5 effectively independent samples. The two solutions agree remarkably well and are almost indistinguishable in most places. (Of course, MCMC in this context is not a data-sequential algorithm; it requires that all the data $(\boldsymbol{y}_k)_{k=0}^N$ be available simultaneously.) An important fact is that the MCMC chain is generated using an *independence* proposal (Robert and Casella, 2013) given by the pushforward of a standard Gaussian through the numerical approximation of $\mathfrak{T}_{N-1}$ (denoted as $\widetilde{\mathfrak{T}}_{N-1}$). The resulting MCMC chain has an acceptance rate slightly above 75%, confirming the overall quality of the variational approximation. We notice, however, a *slow* accumulation of error in the posterior marginal for the static parameter $\boldsymbol{\mu}$ (Figure 13). This is not surprising since we are performing *sequential* parameter inference (Jacob, 2015).

A second quality test can proceed as follows: since we use a standard Gaussian reference distribution $\boldsymbol{\nu}_\eta$, we expect the pullback of $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:N}|\boldsymbol{y}_{0:N}}$ through $\widetilde{\mathfrak{T}}_{N-1}$ to be close

to a standard Gaussian. Figure 15 supports this claim by showing a collection of random two-dimensional conditionals of the approximate pullback: these "slices" of the 947-dimensional (N+1 states plus two hyperparameters) pullback distribution are identical to a two-dimensional standard normal, as expected. The fact that we *can* evaluate the approximate pullback density is one of the key features of this variational approach to inference. Even more, we can use this approximate pullback density to estimate the KL divergence between our target $\boldsymbol{\nu}_\pi$ (the full Bayesian solution at time N) and the approximating measure $(\widetilde{\mathfrak{T}}_{N-1})_\sharp \boldsymbol{\nu}_\eta$, via the variance diagnostic in (8). A numerical realization of (8) yields $\mathcal{D}_{\mathrm{KL}}(\, (\widetilde{\mathfrak{T}}_{N-1})_\sharp \boldsymbol{\nu}_\eta \,\|\, \boldsymbol{\nu}_\pi \,) \approx 1.07 \times 10^{-1}$, which confirms the good numerical approximation of $\boldsymbol{\nu}_\pi$, a 947-dimensional target measure. For comparison, we note that the KL divergence from $\boldsymbol{\nu}_\pi$ to its Laplace approximation (a Gaussian approximation at the mode) is ≈ 5.68—considerably worse than what is achieved through optimization of a nonlinear transport map. Moreover, the Laplace approximation cannot be computed sequentially with a constant effort per time step.

While a slow accumulation of errors is expected for sequential parameter inference, we also wish to investigate the stability of our transport map approximation for recursive smoothing *without* static parameters. We try the following experiment: (1) compute the posterior medians of the static parameters after $N + 1 = 945$ days, i.e., $\boldsymbol{\theta}^* = \mathrm{med}[\Theta|\boldsymbol{y}_0, \ldots, \boldsymbol{y}_{944}]$; and then (2) use these parameters to characterize the smoothing distribution $\pi_{\boldsymbol{Z}_0,\ldots,\boldsymbol{Z}_{2500}|\boldsymbol{\theta}^*,\boldsymbol{y}_0,\ldots,\boldsymbol{y}_{2500}}$ of the log-volatility over (roughly) the next ten years worth of exchanges, using the sequential algorithm proposed in Section 7.1, which in this case amounts to computing only a sequence of two-dimensional maps $(\mathfrak{M}_k)$. The resulting smoothing marginals are shown in Figure 16 and compared to those of a reference MCMC simulation with 10^5 effectively independent samples; we observe excellent agreement despite the long assimilation window. We then repeat the same experiment for an even longer assimilation window, i.e., 9009 steps or roughly 35 years. Figure 17 shows the remarkable stability of the resulting smoothing approximation, at least for low-order marginals. In fact, even the approximation of the *joint* distribution of the states is quite good, as reported in the last column of Table 1. Understanding how errors propagate in this variational framework—and what could be potential mechanisms for the "dissipation" of errors—is an exciting avenue for future work.

The results presented so far are very accurate, but also expensive. Table 1 collects the computational times for the joint state-parameter inference problem (approximately two days) and for the long-time (9009 step) smoothing problem (approximately 40 minutes), using a degree-seven map. While there remains a tremendous opportunity to develop more performance-oriented versions of our transport map code, specialized to the problem of sequential inference, the present framework also offers a practical and powerful tradeoff between computational cost and accuracy. In Appendix D, we re-run all our test cases using linear, rather than degree seven, parameterizations of the maps $\{\mathfrak{M}_k\}$. Table 1 shows that the computational times are dramatically reduced: from two days to approximately one minute for the joint state-parameter inference problem, and from 40 minutes to 7 minutes for the long-time smoothing problem. The reduction in computational time comes, of course, at the price of accuracy; see last column of Table 1. This reduction in accuracy may or may not be acceptable. For instance, in Figure 24, it is difficult to distinguish the linear map approximation from the reference MCMC solution. Quantitatively, we know

from Table 1 that a linear map is worse at approximating the full Bayesian solution than a degree-7 transformation. Yet, as far as quantiles of low-order marginals are concerned, the two solutions are indistinguishable (Figure 24); in an applied setting, this accuracy may be more than sufficient. In other cases, however, a linear map might be inadequate. For example, the parameter marginals in Figures 20 and 22, estimated using linear maps, are much worse than their degree-7 counterparts (Figures 12 and 13). In these cases, we *need* nonlinear transformations.

Clearly, there is a rich spectrum of possibilities between a linear and a high-order transport map. Some parameterizations can scale with dimension (e.g., separable but nonlinear representations), while others cannot (e.g., total-degree polynomial expansions). Depending on the problem, some parameterizations will lead to accurate results, while others will not. Yet, the cost-accuracy tradeoff in the transport framework can be *controlled*, e.g., by estimating the quality of a given approximation using (8).

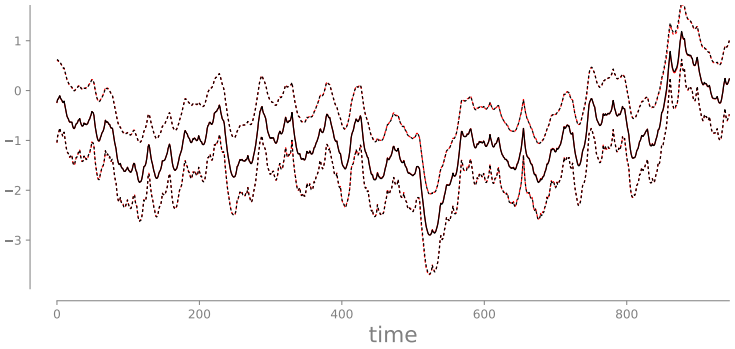

Figure 10: Comparison between the $\{5, 95\}$–percentiles (dashed lines) and the mean (solid line) of the numerical approximation of the smoothing marginals $\pi_{\boldsymbol{Z}_k|\boldsymbol{y}_{0:N}}$ via transport maps (red lines) versus a "reference" MCMC solution (black lines), for $k = 0, \ldots, N$. The two solutions are indistinguishable.

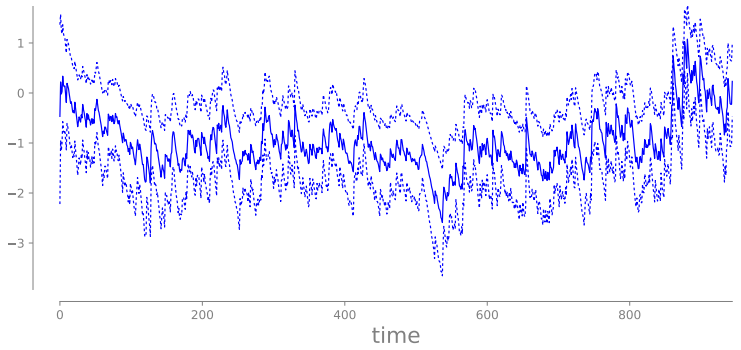

Figure 11: At each time k, we illustrate the $\{5, 95\}$–percentiles (dotted lines) and the mean (solid line) of the numerical approximation of the filtering distribution $\pi_{\boldsymbol{Z}_k|\boldsymbol{y}_{0:k}}$.

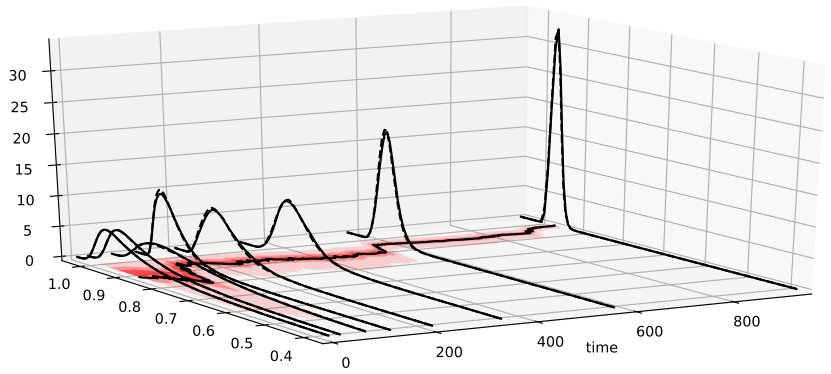

Figure 12: *(Horizontal plane)* At each time k, we illustrate the $\{5, 25, 40, 60, 75, 95\}$–percentiles (shaded regions) and the mean (solid line) of the numerical approximation of $\pi_{\boldsymbol{\phi}|\boldsymbol{y}_{0:k}}$, the posterior marginal of the static parameter $\boldsymbol{\phi}$. *(Vertical axis)* At several times k we also compare the transport map numerical approximation of $\pi_{\boldsymbol{\phi}|\boldsymbol{y}_{0:k}}$ (solid lines) with a reference MCMC solution (dashed lines). The two distributions agree remarkably well.

Type	**# steps**	**Order**	**Time [m : s]**	**# cores**	**Figures**	**Var. diag.** (8)
S/P	945	Laplace	00 : 04	1		5.68
		7	$\approx$ 2 days	64	10 – 15	1.07×10^{-1}
		linear	01 : 14	1	18 – 23	1.77
S	9009	Laplace	00 : 42	1		10.0
		7	42 : 50	1	17	1.19×10^{-1}
		linear	06 : 40	1	24	5.01

Table 1: Computational effort required to compute a decomposable transport map for different complexities of the transformations $\mathfrak{M}_k$—linear versus degree seven—and for different inference scenarios—smoothing and static parameter estimation *(top row)* or long-time smoothing without static parameters *(bottom row)*, for the stochastic volatility model of Section 8. The last column reports the variance diagnostic (8) for the corresponding *joint* posterior, not just a few marginals. It highlights a tradeoff between cost and accuracy, typical of the transport map approach to variational inference. For comparison, we also report the cost and accuracy of a simple Laplace approximation, which requires no formal optimization.

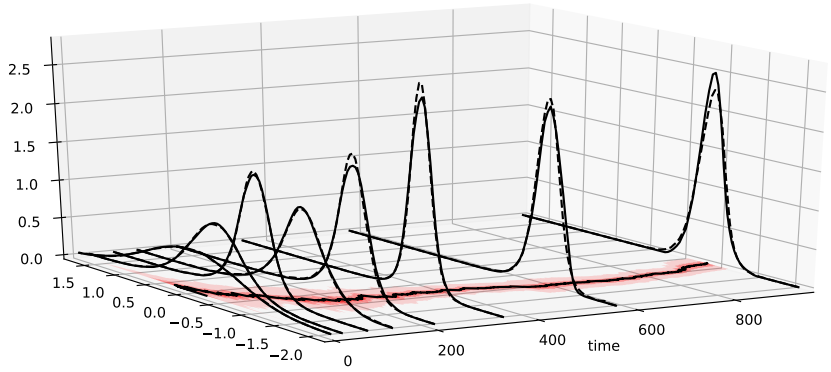

Figure 13: Same as Figure 12, but for the static parameter $\boldsymbol{\mu}$.

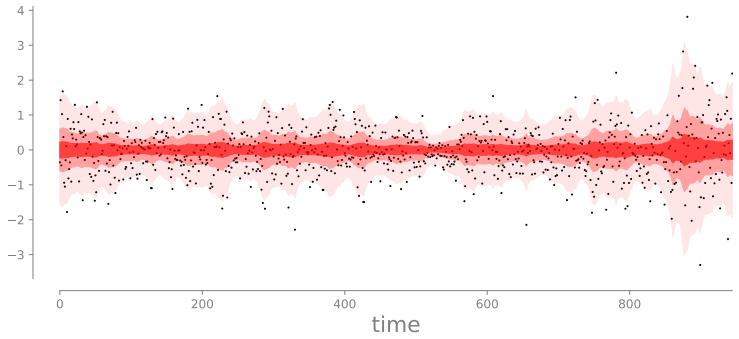

Figure 14: Shaded regions represent the $\{5, 25, 40, 60, 75, 95\}$–percentiles of the marginals of the posterior predictive distribution (conditioning on all the data), along with black dots that represent the observed data $(\boldsymbol{y}_k)_{k=0}^N$.

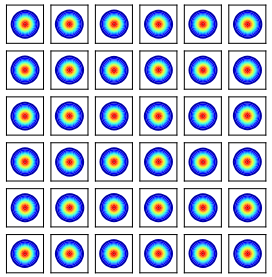

Figure 15: Randomly chosen two-dimensional conditionals of the pullback of $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:N}|\boldsymbol{y}_{0:N}}$ through the numerical approximation of $\mathfrak{T}_{N-1}$. Since we use a standard normal reference distribution, the numerical approximation of $\mathfrak{T}_{N-1}$ should be deemed satisfactory if the pullback density is close to a standard normal, as it is here.

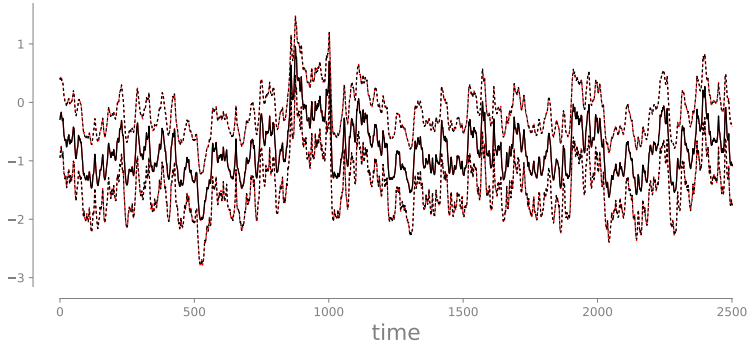

Figure 16: Comparison between the $\{5, 95\}$–percentiles (dashed lines) and the mean (solid line) of the transport map numerical approximation of the smoothing marginals $\pi_{\boldsymbol{Z}_k|\boldsymbol{\theta}^*,\boldsymbol{y}_{0:2500}}$, with $\boldsymbol{\theta}^* = \text{med}[\Theta|\boldsymbol{y}_0, \ldots, \boldsymbol{y}_N]$ (red lines), and a reference MCMC solution (black lines). The two solutions are indistinguishable.

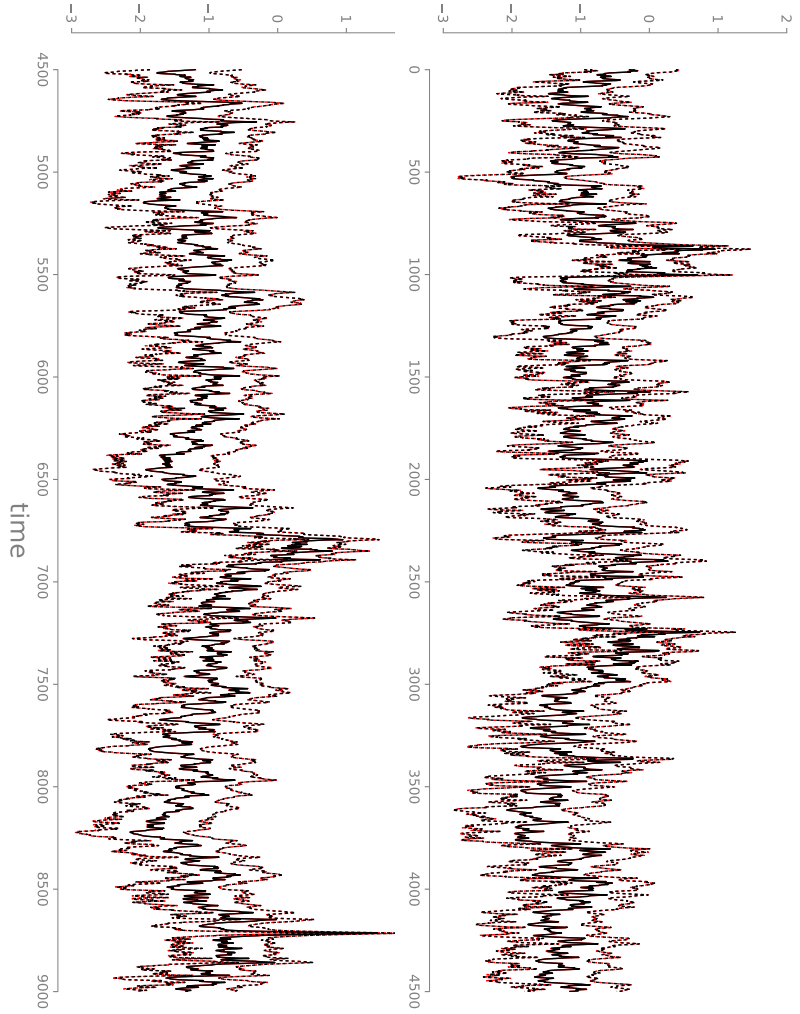

Figure 17: Same as Figure 16, but for a longer assimilation window, i.e., $\pi_{\boldsymbol{Z}_k|\boldsymbol{\theta}^*,\boldsymbol{y}_{0:9000}}$. The smoothing approximation remains excellent despite the widening inference horizon.

9. Discussion

This paper has focused on the problem of coupling a pair $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ of absolutely continuous measures on $\mathbb{R}^n$, for the purpose of sampling or integration. If $\boldsymbol{\nu}_\eta$ is a tractable measure (e.g., an isotropic Gaussian) and $\boldsymbol{\nu}_\pi$ is an intractable measure of interest (e.g., a posterior distribution), then a deterministic coupling enables principled approximations of integrals via the identity $\int g \, \mathrm{d}\boldsymbol{\nu}_\pi = \int g \circ T \, \mathrm{d}\boldsymbol{\nu}_\eta$. In other words, a deterministic coupling provides a simple way to simulate $\boldsymbol{\nu}_\pi$ by pushing forward samples from $\boldsymbol{\nu}_\eta$ through a transport map T. This idea, modulo some variations, has been exploited in a variety of statistical and machine learning applications—some old, some new—including random number generation (Marsaglia and Tsang, 2000), variational inference (Moselhy and Marzouk, 2012; Schillings and Schwab, 2016; Rezende and Mohamed, 2015), the computation of model evidence (Meng and Schilling, 2002), model learning and density estimation (Laparra et al., 2011; Anderes and Coram, 2012; Stavropoulou and Müller, 2015), non-Gaussian proposals for MCMC or importance sampling (Parno and Marzouk, 2018; Bardsley et al., 2014; Oliver, 2015), multiscale modeling (Parno et al., 2016), and filtering (Daum and Huang, 2008; Chorin and Tu, 2009; Reich, 2013), to name a few. Indeed there are infinitely many ways to transport one measure to another (Villani, 2008) and as many ways to compute one. Yet these maps are not equally easy to characterize.

This paper establishes an explicit link between the conditional independence structure of $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ and the existence of low-dimensional couplings induced by transport maps that are *sparse* and/or *decomposable*. These results can enhance a wide array of numerical approaches to the transportation of measures, including (Tabak and Turner, 2013; Rezende and Mohamed, 2015; Liu and Wang, 2016; Bigoni et al., 2019), and thus facilitate simulation with respect to complex distributions in high dimensions. We briefly discuss our main results below.

Sparse transports. A sparse transport is a map whose components do not depend on all input variables. Section 5 derives tight bounds on the sparsity pattern of the Knothe–Rosenblatt (KR) rearrangement (a triangular transport map) based solely on the Markov structure of $\boldsymbol{\nu}_\pi$, provided that $\boldsymbol{\nu}_\eta$ is a product measure (Theorem 3). This analysis shows that the inverse of the KR rearrangement is the natural generalization to the *non-Gaussian* case of the Cholesky factor of the precision matrix of a Gaussian MRF—in that both the inverse KR rearrangement (a potentially nonlinear map) and the Cholesky factor (a linear map) have the same sparsity pattern given target measures with the same Markov structure. Thus the KR rearrangement can be used to extend well-known modeling and sampling techniques for high-dimensional Gaussian MRFs (Rue and Held, 2005) to non-Gaussian fields (Section 5.2). These results are particularly useful when constructing a transport map from samples via convex optimization (Parno, 2015) and suggest novel approaches to model learning (Morrison et al., 2017) and high-dimensional filtering (Spantini, 2017, Ch. 6). Section 5 shows that sparsity is usually a feature of inverse transports, while direct transports tend to be dense, even for the most trivial Markov structures. In fact, the sparsity of direct transports stems from *marginal* (rather than conditional) independence—a property frequently exploited in localization schemes for high-dimensional covariance estimation (Gaspari and Cohn, 1999; Hamill et al., 2001).

Decomposable transports. A decomposable map is a function that can be written as the composition of *finitely* many low-dimensional maps that are triangular up to a permutation—i.e., $T = T_1 \circ \cdots \circ T_\ell$, where each T_i differs from the identity only along a small subset of its components and is a generalized triangular function as defined in Section 6. Theorem 7 shows that every target measure whose Markov network admits a graph decomposition can be coupled with a product (reference) measure via a decomposable map. Decomposable maps are important because they are much easier to represent than arbitrary multivariate functions on $\mathbb{R}^n$. In general, these maps are non-triangular, even though each map in the composition is generalized triangular.

The notion of a decomposable map is different from the composition-of-maps approaches advocated in the literature for the approximation of transport maps, e.g., consider normalizing flows (Rezende and Mohamed, 2015) or Stein variational algorithms (Anderes and Coram, 2012; Liu and Wang, 2016; Detommaso et al., 2018), but also (Tabak and Turner, 2013; Laparra et al., 2011). In these approaches, very simple maps $(M_i)_{i\geq 1}$ are composed in growing number to define a transport map of increasing complexity, $M = M_1 \circ \cdots \circ M_k$. The number of layers in M depends on the desired accuracy of the transport and can be arbitrarily large. On the other hand, a decomposable coupling is induced by a special transport map that can be written *exactly* as the composition of finitely many maps, $T = T_1 \circ \cdots \circ T_\ell$, where each T_i has a specific sparsity pattern that makes it low-dimensional. This definition does not specify a representation for T_i. In fact, each T_i could itself be approximated by the composition of simple maps using *any* of the aforementioned techniques. The advantage of targeting a decomposable transport is the fact that the (T_i) are *guaranteed* to be low-dimensional.

Approximate Markov properties. Sparsity and decomposability of certain transport maps are induced by the Markov properties of the target measure. A natural question is: what happens when $\boldsymbol{\nu}_\pi$ satisfies some Markov properties only *approximately*? In particular, let $\boldsymbol{\nu}_\pi$ be Markov with respect to $\boldsymbol{\mathcal{G}}$, and assume that there exists a measure $\hat{\boldsymbol{\nu}} \in \mathscr{M}_+(\mathbb{R}^n)$ which is Markov with respect to a graph $\hat{\boldsymbol{\mathcal{G}}}$ that is *sparser* than $\boldsymbol{\mathcal{G}}$ and such that $\mathcal{D}_{\mathrm{KL}}(\,\hat{\boldsymbol{\nu}}\,||\,\boldsymbol{\nu}_\pi\,) < \varepsilon$, for some $\varepsilon > 0$. For small ε, we would be tempted to use $\hat{\boldsymbol{\mathcal{G}}}$ to characterize couplings of $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ that are possibly sparser or more decomposable than those associated with $\boldsymbol{\mathcal{G}}$. Concretely, if we are interested in a triangular transport that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$, we could minimize $\mathcal{D}_{\mathrm{KL}}(\,T_\sharp\,\boldsymbol{\nu}_\eta\,||\,\boldsymbol{\nu}_\pi\,)$ over the set of maps whose *inverse* has the same sparsity pattern as the KR rearrangement between $\hat{\boldsymbol{\nu}}$ and $\boldsymbol{\nu}_\eta$. Bounds on this sparsity pattern are given by Theorem 3 using only graph operations on $\hat{\boldsymbol{\mathcal{G}}}$; no explicit knowledge of $\hat{\boldsymbol{\nu}}$ is required. Alternatively, if we are interested in decomposable transports that push forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$, we could minimize $\mathcal{D}_{\mathrm{KL}}(\,T_\sharp\,\boldsymbol{\nu}_\eta\,||\,\boldsymbol{\nu}_\pi\,)$ over the set of maps that factorize as any of the decomposable transports between $\boldsymbol{\nu}_\eta$ and $\hat{\boldsymbol{\nu}}$. The shapes of these low-dimensional factorizations are given by Theorem 7 using, once again, only graph operations on $\hat{\boldsymbol{\mathcal{G}}}$.

Now let $\hat{\mathcal{T}}$ denote the set of maps whose structure is constrained by $\hat{\boldsymbol{\mathcal{G}}}$ in terms of sparsity or decomposability. It is easy to show that

$$\min_{T\in\hat{\mathcal{T}}} \mathcal{D}_{\mathrm{KL}}(\,T_\sharp\,\boldsymbol{\nu}_\eta\,||\,\boldsymbol{\nu}_\pi\,) < \varepsilon,$$

which means that the price of assuming that the coupling is either sparser or more decomposable than it ought to be is just a small error in the approximation of $\boldsymbol{\nu}_\pi$.

Of course, the pending question is whether $\boldsymbol{\nu}_\pi$ can be well approximated by a measure that satisfies additional Markov properties. There is some work on this topic, e.g., Johnson and Willsky, 2008; Jog and Loh, 2015; Cheng et al., 2015—especially in the case of Gaussian measures—but a more thorough investigation of the problem remains an open and important direction for future work. Interestingly, the transport map framework also allows one to *adaptively* discover information about low-dimensional couplings. For instance, one might start with a very sparse transport map and then incrementally decrease the sparsity level of the map until the resulting approximation of $\boldsymbol{\nu}_\pi$ becomes satisfactory. The same can be done for decomposable transports. See Bigoni et al. (2019) for some details on this idea.

Filtering and smoothing. Section 6.4 shows how not only the representation, but also the *computation*, of a decomposable map, $T = T_1 \circ \cdots \circ T_\ell$, can be broken into a sequence of ℓ simpler steps, each associated with a low-dimensional optimization problem whose solution yields T_i. We give a concrete example of this idea for filtering, smoothing, and joint state–parameter inference in nonlinear and non-Gaussian state-space models (Section 7). In this context, Theorems 9 and 12 introduce variational approaches for characterizing the full posterior distribution of the sequential inference problem, essentially by performing only recursive lag–1 smoothing with transport maps. The proposed approaches consist of a *single* forward pass on the state-space model, and generalize the square-root Rauch-Tung-Striebel smoother to non-Gaussian models (see Section 7.2). In practice, we should think of Theorems 9 and 12 as providing "meta-algorithms" within which all kinds of approximations can be introduced, e.g., linearizations of the forward model, restriction to linear maps, and approximate flows (Daum and Huang, 2008; Liu and Wang, 2016), to name a few. These approximations are the workhorse of modern approaches to large-scale filtering, e.g., data assimilation in geophysical applications (Särkkä, 2013; Evensen, 2007), and may play a key role in further instantiations of the "meta-algorithms" proposed in Section 7. Of course, it would be desirable to complement such variational approximations with a rigorous error analysis, analogous to the analysis available for SMC methods (Crisan and Doucet, 2002; Del Moral, 2004; Smith et al., 2013). It is also important to note that one can always use functionals like (8) to estimate the quality of a given approximate map, or use the map itself to build sophisticated proposals for sampling techniques like MCMC (Parno and Marzouk, 2018).

A recent approach that constructs an approximation of the KR rearrangement for sequential inference is the "Gibbs flow" of Heng et al. (2015); here, the authors define a proposal for SMC (or MCMC) methods using the solution map of a discretized ordinary differential equation (ODE) whose drift term depends only on the full conditionals of the target distribution. Evaluating the solution map only requires the evaluation of one-dimensional integrals, and the action of this map implicitly defines a transport, without any explicit parameterization of the transformation. Several other filtering approaches in the literature, e.g., (Daum and Huang, 2012; Yang et al., 2013), rely on the solution of ODEs that are different from Heng et al. (2015), but also inspired by ideas from mass transportation. Implicit sampling for particle filters (Chorin and Tu, 2009) also implicitly constructs a transport map, from a standard Gaussian to a particular approximation of the filtering distribution; the action of this transport is realized by solving an optimization/root-finding problem for each sample (Morzfeld et al., 2012).

One of the first contributions to use *optimal* transport in filtering is due to Reich (2013), who constructs an optimal transport plan between an empirical approximation of the forecast distribution (given by simulating the prior dynamic) and a corresponding empirical approximation of the filtering distribution, obtained by reweighing the forecast ensemble according to the likelihood. Thus, Reich (2013) solves a *discrete* Kantorovich optimal transport problem instead of a continuous problem for a transport map (cf. Section 7.1). A linear transformation of the forecast ensemble is then derived from the optimal plan. In this approach, the explicit construction of couplings is used only to update the forecast distribution, instead of the previous filtering marginal.

Further extensions. We envision many additional ways to extend the present work. For instance, it would be interesting to investigate the low-dimensional structure of deterministic couplings between pair of measures $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$ that are not absolutely continuous and that need not be defined on the same space $\mathbb{R}^n$. Such couplings are usually induced by "random" maps and can be particularly effective for approximating multi-modal distributions; see the warp bridge transformations in (Meng and Schilling, 2002; Wang and Meng, 2016) for some examples.

Finally, we emphasize that this paper characterizes some classes of low-dimensional maps, but certainly not all. In particular, low dimensionality need not stem from the Markov properties of the underlying measures. In ongoing work we are exploring the notion of low-rank couplings: these are induced by transport maps that are low-dimensional up to a rotation of the space, i.e., maps whose action is nontrivial only along a low-dimensional subspace. This type of structure appears quite naturally in certain high-dimensional Bayesian inference problems—e.g., inverse problems (Stuart, 2010) and spatial statistics—where the data may be informative only about a few linear combinations of the latent parameters (Spantini et al., 2015; Cui et al., 2014; Spantini et al., 2017). Low-rank structure can be detected via certain average derivative functionals (Samarov, 1993; Constantine et al., 2014) but cannot be deduced, in general, from the Markov structure of $(\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi)$.

Acknowledgments

We would like to thank Ricardo Baptista, Chi Feng, Jeremy Heng, Pierre Jacob, Qiang Liu, Rebecca Morrison, Zheng Wang, Alan Willsky, Olivier Zahm, and Benjamin Zhang for many insightful discussions and for pointing us to key references in the literature. Appendix A. Generalized Knothe-Rosenblatt Rearrangement

In this section we first review the classical notion of KR rearrangement (Rosenblatt, 1952), and then give a formal definition for a *generalized* KR rearrangement, i.e., a transport map that is lower triangular up to a permutation. A disclaimer: these transports can also be defined under weaker conditions than those considered here, at the expense, however, of some useful regularity (Bogachev et al., 2005).

The following definition introduces the one-dimensional version of the KR-rearrangement, and it is key to extend the transport to higher dimensions.

Definition 13 (Increasing rearrangement on $\mathbb{R}$) *Let $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R})$, and let F, G be their respective cumulative distribution functions, i.e., $F(t) = \boldsymbol{\nu}_\eta((-\infty, t))$ and $G(t) = \boldsymbol{\nu}_\pi((-\infty, t))$. Then the increasing rearrangement on $\mathbb{R}$ is given by $T = G^{-1} \circ F$.*

Under the hypothesis of Definition 13, it is easy to see that both F and G are homeomorphisms, and that T is a strictly increasing map that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$ (Santambrogio, 2015).

Definition 14 (Knothe-Rosenblatt rearrangement) *Given $\boldsymbol{X} \sim \boldsymbol{\nu}_\eta$, $\boldsymbol{Z} \sim \boldsymbol{\nu}_\pi$, with $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$, and a pair η, π of strictly positive densities for $\boldsymbol{\nu}_\eta$ and $\boldsymbol{\nu}_\pi$, respectively, the corresponding KR rearrangement is a triangular map $T : \mathbb{R}^n \to \mathbb{R}^n$ defined, recursively, as follows. For all $\boldsymbol{x}_{1:k-1} \in \mathbb{R}^{k-1}$, the map $\xi \mapsto T^k(\boldsymbol{x}_{1:k-1}, \xi)$—the restriction of the kth component of T onto its first $k-1$ inputs—is defined as the increasing rearrangement on $\mathbb{R}$ that pushes forward $\xi \mapsto \eta_{X_k|\boldsymbol{X}_{1:k-1}}(\xi|\boldsymbol{x}_{1:k-1})$ to $\xi \mapsto \pi_{Z_k|\boldsymbol{Z}_{1:k-1}}(\xi|T^1(x_1), \dots, T^{k-1}(\boldsymbol{x}_{1:k-1}))$, where $\eta_{X_k|\boldsymbol{X}_{1:k-1}}$ and $\pi_{Z_k|\boldsymbol{Z}_{1:k-1}}$ are conditional densities defined as in (2).*

Notice that for any measure $\boldsymbol{\nu}$ in $\mathscr{M}_+(\mathbb{R}^n)$ there always exists a strictly positive *version* of its density. By considering such positive densities in Definition 14, we can define the KR rearrangement on the entire $\mathbb{R}^n$ (Bogachev et al., 2005). In fact, we should really think of Definition 14 as providing a possible *version* of the KR rearrangement (recall that the increasing triangular transport is unique up to sets of measure zero). Since in this case $\boldsymbol{\nu}_\pi$ is equivalent to the Lebesgue measure ($\boldsymbol{\nu}_\pi(\mathcal{A}) = \int_{\mathcal{A}} \pi(\boldsymbol{x})\, \boldsymbol{\lambda}(\mathrm{d}\boldsymbol{x}) = 0 \Rightarrow \boldsymbol{\lambda}(\mathcal{A}) = 0$ if $\pi > 0$ a.e.), the component (3) is also absolutely continuous on all compact intervals (Bogachev et al., 2005, Lemma 2.4). As a result, the rearrangement can be used to define general change of variables as well as pullbacks and pushforwards with respect to arbitrary densities, as shown by the following lemma adapted from Bogachev et al. (2005).

Lemma 15 *Let T be an increasing triangular bijection on $\mathbb{R}^n$ such that the functions*

$$\xi \mapsto T^k(x_1, \dots, x_{k-1}, \xi)$$

are absolutely continuous on all compact intervals for a.e. $(x_1, \dots, x_{k-1}) \in \mathbb{R}^{k-1}$. Then for any integrable function φ, it holds:

$$\int \varphi(\boldsymbol{y})\, \mathrm{d}\boldsymbol{y} = \int \varphi(T(\boldsymbol{x}))\, \det \nabla T(\boldsymbol{x})\, \mathrm{d}\boldsymbol{x},$$

where $\det \nabla T \coloneqq \prod_{k=1}^n \partial_k T^k$. In particular, if $\boldsymbol{\nu}_\rho$ is a measure on $\mathbb{R}^n$ with density ρ, then we also have $T^\sharp \boldsymbol{\nu}_\rho \ll \boldsymbol{\lambda}$ with density (a.e.):

$$T^\sharp \rho(\boldsymbol{x}) = \rho(T(\boldsymbol{x}))\, \det \nabla T(\boldsymbol{x}). \tag{36}$$

The lemma can also be applied to the inverse KR rearrangement T^{-1} to show that $T_\sharp \boldsymbol{\nu}_\rho \ll \boldsymbol{\lambda}$, where the form of the corresponding pushforward density $T_\sharp \rho$ is given by replacing T with T^{-1} in (36). We will use these results extensively in the proofs of Appendix B. Notice,

however, that Lemma 15 does not hold for a generic triangular function: the map must be somewhat regular, in the sense specified by the lemma. Bogachev et al. (2005) give an in depth discussion on this topic.

We now give a constructive definition for a generalized KR rearrangement.

Definition 16 (Generalized Knothe-Rosenblatt rearrangement) *Given $\boldsymbol{X} \sim \boldsymbol{\nu}_\eta$, $\boldsymbol{Z} \sim \boldsymbol{\nu}_\pi$, with $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$, a pair η, π of strictly positive densities for $\boldsymbol{\nu}_\eta$ and $\boldsymbol{\nu}_\pi$, respectively, and a permutation σ of $\mathbb{N}_n$, the corresponding σ-generalized KR rearrangement is a σ-triangular map[12] $T : \mathbb{R}^n \to \mathbb{R}^n$ defined at any $\boldsymbol{x} \in \mathbb{R}^n$ using the following recursion in k. The map $\xi \mapsto T^{\sigma(k)}(x_{\sigma(1)}, \dots, x_{\sigma(k-1)}, \xi)$ is defined as the increasing rearrangement on $\mathbb{R}$ that pushes forward $\xi \mapsto \eta_{X_{\sigma(k)}|\boldsymbol{X}_{\sigma(1:k-1)}}(\xi|\boldsymbol{x}_{\sigma(1:k-1)})$ to*

$$\xi \mapsto \pi_{Z_{\sigma(k)}|\boldsymbol{Z}_{\sigma(1:k-1)}}(\xi|T^{\sigma(1)}(x_{\sigma(1)}), \dots, T^{\sigma(k-1)}(\boldsymbol{x}_{\sigma(1:k-1)})),$$

where $\boldsymbol{x}_{\sigma(1:k-1)} = x_{\sigma(1)}, \dots, x_{\sigma(k-1)}$.

Existence of a generalized KR rearrangement follows trivially from its definition. Moreover, the transport map satisfies all the regularity properties discussed for the classic KR rearrangement, including Lemmas 1 and 15. Thus we will often cite these two results when dealing with generalized KR rearrangements in our proofs. The following lemma shows that the computation of a generalized KR rearrangement is also essentially no different than the computation of a lower triangular transport (and thus all the discussion of Section 3 readily applies).

Lemma 17 *Given $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$, let T be a σ-generalized KR rearrangement that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$ for some permutation σ. Then $T = Q_\sigma^\top \circ T_\ell \circ Q_\sigma$ a.e., where $Q_\sigma \in \mathbb{R}^{n \times n}$ is a matrix representing the permutation, i.e., $(Q^\sigma)_{ij} = (\boldsymbol{e}_{\sigma(i)})_j$, and where T_ℓ is a (lower triangular) KR rearrangement that pushes forward $(Q_\sigma)_\sharp \boldsymbol{\nu}_\eta$ to $(Q_\sigma)_\sharp \boldsymbol{\nu}_\pi$.*

Proof If T_ℓ pushes forward $(Q_\sigma)_\sharp \boldsymbol{\nu}_\eta$ to $(Q_\sigma)_\sharp \boldsymbol{\nu}_\pi$, then $\boldsymbol{\nu}_\eta \circ Q_\sigma^\top \circ T_\ell^{-1} = \boldsymbol{\nu}_\pi \circ Q_\sigma^\top$, and so $T = Q_\sigma^\top \circ T_\ell \circ Q_\sigma$ must push forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$. Moreover, notice that $T^{\sigma(k)}(\boldsymbol{x}) = T_\ell^k(\boldsymbol{x}^\top \boldsymbol{e}_{\sigma(1)}, \dots, \boldsymbol{x}^\top \boldsymbol{e}_{\sigma(k)})$, which shows that T is a monotone increasing σ-generalized triangular function (see Definition 6). The lemma then follows by $\boldsymbol{\nu}_\eta$-uniqueness of a KR rearrangement. ■

Appendix B. Proofs of the Main Results

In this section we collect the proofs of the main results and claims of the paper, together with useful additional lemmas to support the technical derivations.

Proof of Lemma 2 The general solution of $\partial^2_{i,j} \log \pi = 0$ on $\mathbb{R}^n$ is given by $\log \pi(\boldsymbol{z}) = g(\boldsymbol{z}_{1:i-1}, \boldsymbol{z}_{i+1:n}) + h(\boldsymbol{z}_{1:j-1}, \boldsymbol{z}_{j+1:n})$ for some functions $g, h : \mathbb{R}^{n-1} \to \mathbb{R}$. Hence $Z_i \perp\!\!\!\perp Z_j \,|\, \boldsymbol{Z}_{\mathcal{V}\setminus(i,j)}$ (Lauritzen, 1996). Conversely, if $Z_i \perp\!\!\!\perp Z_j \,|\, \boldsymbol{Z}_{\mathcal{V}\setminus(i,j)}$, then π—which is the

12. See Definition 6.

density of $\boldsymbol{\nu}_\pi$ with respect to a tensor product Lebesgue measure (Lauritzen, 1996)—must factor as

$$\pi = \pi_{Z_i|\boldsymbol{Z}_{\mathcal{V}\setminus(i,j)}} \pi_{Z_j|\boldsymbol{Z}_{\mathcal{V}\setminus(i,j)}} \pi_{\boldsymbol{Z}_{\mathcal{V}\setminus(i,j)}},$$

so that $\partial^2_{i,j} \log \pi = 0$ on $\mathbb{R}^n$. ■

Proof of Theorem 3 We begin with Part 1 of the theorem. Let η, π be a pair of strictly positive densities for $\boldsymbol{\nu}_\eta$ and $\boldsymbol{\nu}_\pi$, respectively (these positive densities exist since the measures are fully supported). Now consider a *version* of the KR rearrangement, S, that pushes forward $\boldsymbol{\nu}_\pi$ to $\boldsymbol{\nu}_\eta$ as given by Definition 14 for the pair η, π (Appendix A). By definition, and for all $\boldsymbol{z}_{1:k-1} \in \mathbb{R}^{k-1}$, the map $\xi \mapsto S^k(\boldsymbol{z}_{1:k-1}, \xi)$ is the monotone increasing rearrangement that pushes forward $\xi \mapsto \pi_{Z_k|\boldsymbol{Z}_{1:k-1}}(\xi|\boldsymbol{z}_{1:k-1})$ to the marginal η_{X_k} (recall that $\boldsymbol{\nu}_\eta$ is a tensor product measure). Moreover, it follows easily from (Lauritzen, 1996, Prop. 3.17), that each marginal $\pi_{\boldsymbol{Z}_{1:k}}$—or better yet, the corresponding measure—is globally Markov with respect to $\boldsymbol{\mathcal{G}}^k$, and that $\pi_{\boldsymbol{Z}_{1:k}}(\boldsymbol{z}_{1:k})\,\pi_{\mathcal{C}}(\boldsymbol{z}_{\mathcal{C}}) = \pi_{\boldsymbol{Z}_k,\boldsymbol{Z}_{\mathcal{C}}}(\boldsymbol{z}_k, \boldsymbol{z}_{\mathcal{C}})\,\pi_{\boldsymbol{Z}_{1:k-1}}(\boldsymbol{z}_{1:k-1})$, where $\mathcal{C} \coloneqq \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$, possibly empty. Thus, the conditional $\pi_{Z_k|\boldsymbol{Z}_{1:k-1}}(\boldsymbol{z}_k|\boldsymbol{z}_{1:k-1})$ is constant along any input $\boldsymbol{z}_j$ with $j \notin \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$. For any such j, S^k must be constant along its jth input, so that $(j,k) \in \widehat{\mathfrak{I}}_S$.

Part 2 of the theorem follows similarly. Consider the KR rearrangement, T, that pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_\pi$ as given by Definition 14. For all $\boldsymbol{x}_{1:k-1} \in \mathbb{R}^{k-1}$, the map $\xi \mapsto T^k(\boldsymbol{x}_{1:k-1}, \xi)$ is the monotone increasing rearrangement that pushes forward η_{X_k} to

$$\xi \mapsto \pi_{Z_k|\boldsymbol{Z}_{1:k-1}}(\xi|T^1(x_1), \ldots, T^{k-1}(\boldsymbol{x}_{1:k-1})).$$

We already know that $\pi_{Z_k|\boldsymbol{Z}_{1:k-1}}(\boldsymbol{z}_k|\boldsymbol{z}_{1:k-1})$ can only depend (nontrivially) on $\boldsymbol{z}_k$ and on $\boldsymbol{z}_j$ for $j \in \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$. Hence, if none of the components T^i, with $i \in \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$, depends on the jth input, then T^k is constant along its jth input as well, so that $(j,k) \in \widehat{\mathfrak{I}}_T$.

For Part 3, let $(j,k) \in \widehat{\mathfrak{I}}_T$. Then, by definition, $(j,i) \in \widehat{\mathfrak{I}}_T$ for all $i \in \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$, which also implies that $j \notin \mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k)$ since $j \neq i$ for all $(j,i) \in \widehat{\mathfrak{I}}_T$. Hence $(j,k) \in \widehat{\mathfrak{I}}_S$ and this shows the inclusion $\widehat{\mathfrak{I}}_T \subset \widehat{\mathfrak{I}}_S$.

These arguments show that there exists at least a *version* of the KR rearrangement that is exactly at least as sparse as predicted by the theorem. ■

The following lemma specializes the results of Theorem 3[Part 2] to the case of I-maps $\boldsymbol{\mathcal{G}}$ with a disconnected component, and will be useful in the proofs of Section 6.

Lemma 18 *Let $\boldsymbol{X} \sim \boldsymbol{\nu}_\eta$, $\boldsymbol{Z} \sim \boldsymbol{\nu}_\pi$ with $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_\pi \in \mathscr{M}_+(\mathbb{R}^n)$ and $\boldsymbol{\nu}_\eta$ tensor product measure, and let σ be any permutation of $\mathbb{N}_n$. Moreover, assume that $\boldsymbol{\nu}_\pi$ is globally Markov with respect to $\boldsymbol{\mathcal{G}} = (\mathcal{V}, \mathcal{E})$, and assume that there exists a nonempty set $\mathcal{A} \subset \mathcal{V} \simeq \mathbb{N}_n$ such that $\boldsymbol{Z}_\mathcal{A} \perp\!\!\!\perp \boldsymbol{Z}_{\mathcal{V}\setminus\mathcal{A}}$ and $\boldsymbol{Z}_\mathcal{A} = \boldsymbol{X}_\mathcal{A}$ in distribution. Then the σ-generalized KR rearrangement T given by Definition 16 (for a pair η, π of nonvanishing densities for $\boldsymbol{\nu}_\eta$ and $\boldsymbol{\nu}_\pi$, respectively) is low-dimensional with respect to $\mathcal{A}$, i.e.,*

1. *$T^k(\boldsymbol{x}) = x_k$ for $k \in \mathcal{A}$*
2. *$\partial_j T^k = 0$ for $j \in \mathcal{A}$ and $k \in \mathcal{V} \setminus \mathcal{A}$.*

Proof It suffices to prove the lemma for a lower triangular KR rearrangement; the result for an arbitrary σ then follows trivially. If $\mathcal{A} = \mathcal{V}$, then T is simply the identity map. Thus we assume that $\mathcal{V} \setminus \mathcal{A}$ is nonempty.

We begin with Part 1 of the lemma and use the results of Theorem 3[Part 2] to characterize the sparsity of the rearrangement. Let $k \in \mathcal{A}$ and notice that $\mathrm{Nb}(k, \boldsymbol{\mathcal{G}}^k) = \emptyset$, where $\boldsymbol{\mathcal{G}}^k$ is the marginal graph defined in Theorem 3. Thus $(j,k) \in \widehat{\mathfrak{I}}_T \subset \mathfrak{I}_T$ for all $j = 1, \ldots, k-1$, so that $T^k(\boldsymbol{x}) = x_k$ for all $k \in \mathcal{A}$.

Now let us focus on Part 2 and prove that $(j,k) \in \widehat{\mathfrak{I}}_T$ for all $j \in \mathcal{A}$ and $k \in \mathcal{V} \setminus \mathcal{A}$. We proceed by contradiction. Assume that there exists some pair $(j,k) \in \mathcal{A} \times (\mathcal{V} \setminus \mathcal{A})$ such that $(j,k) \notin \widehat{\mathfrak{I}}_T$. In particular, let $\boldsymbol{\mathcal{K}}$ be the set of $k \in \mathcal{V} \setminus \mathcal{A}$ for which there exists at least a $j \in \mathcal{A}$ such that $(j,k) \notin \widehat{\mathfrak{I}}_T$. Clearly $\boldsymbol{\mathcal{K}}$ is nonempty and finite. Let s be the minimum integer in $\boldsymbol{\mathcal{K}}$, and let $j \in \mathcal{A}$ be a corresponding index for which $(j,s) \notin \widehat{\mathfrak{I}}_T$. In this case, by Theorem 3[Part 2], there must exist an $i \in \mathrm{Nb}(s, \boldsymbol{\mathcal{G}}^s)$ such that $(j,i) \notin \widehat{\mathfrak{I}}_T$. Now there are two cases: either $i \in \mathcal{A}$ (for which we reach a contradiction by part 1 of the lemma) or $i \in \mathcal{V} \setminus \mathcal{A}$. In the latter case, we also reach a contradiction since $i < s$ and s was defined as the smallest index for which $(j,s) \notin \widehat{\mathfrak{I}}_T$ for some $j \in \mathcal{A}$. ■

Proof of Theorem 7 For notational convenience, we drop the subscript and superscript i from $\boldsymbol{\nu}_i$, π_i, $\boldsymbol{Z}^i$, and $\boldsymbol{\mathcal{G}}^i$. Consider a factorization of π of the form

$$\pi(\boldsymbol{z}) = \frac{1}{\mathfrak{c}}\, \psi_{\mathcal{A}\cup\mathcal{S}}(\boldsymbol{z}_{\mathcal{A}\cup\mathcal{S}})\, \psi_{\mathcal{S}\cup\mathcal{B}}(\boldsymbol{z}_{\mathcal{S}\cup\mathcal{B}}), \tag{37}$$

where $\psi_{\mathcal{A}\cup\mathcal{S}}$ is strictly positive and integrable, with $\mathfrak{c} = \int \psi_{\mathcal{A}\cup\mathcal{S}} < \infty$. A factorization like (37) always exist since $\boldsymbol{\nu}$ factorizes according to $\boldsymbol{\mathcal{G}}$—thus $\boldsymbol{\mathcal{G}}$ is an I-map for $\boldsymbol{\nu}$—and since $(\mathcal{A}, \mathcal{S}, \mathcal{B})$ is a proper decomposition of $\boldsymbol{\mathcal{G}}$. For instance, one can set $\psi_{\mathcal{A}\cup\mathcal{S}} = \pi_{\boldsymbol{Z}_{\mathcal{A}\cup\mathcal{S}}}$, $\mathfrak{c} = 1$, and $\psi_{\mathcal{S}\cup\mathcal{B}} = \pi_{\boldsymbol{Z}_\mathcal{B}|\boldsymbol{Z}_\mathcal{S}}$ since $\boldsymbol{Z}_\mathcal{A} \perp\!\!\!\perp \boldsymbol{Z}_\mathcal{B}|\boldsymbol{Z}_\mathcal{S}$ and since π is a nonvanishing density of $\boldsymbol{\nu}$. However, this is not the only possibility. See Section 7 for important examples where it is not convenient to assume that $\psi_{\mathcal{A}\cup\mathcal{S}}$ corresponds to a marginal of π. This proves Part 1 of the theorem.

By (Lauritzen, 1996, Prop. 3.16), we can rewrite $\psi_{\mathcal{S}\cup\mathcal{B}}$ as:

$$\psi_{\mathcal{S}\cup\mathcal{B}}(\boldsymbol{z}_{\mathcal{S}\cup\mathcal{B}}) = \prod_{\mathcal{C}\in\boldsymbol{\mathcal{C}}_{\mathcal{S}\cup\mathcal{B}}} \psi_\mathcal{C}(\boldsymbol{z}_\mathcal{C}) \tag{38}$$

for some nonvanishing functions $(\psi_\mathcal{C})$, where $\boldsymbol{\mathcal{C}}_{\mathcal{S}\cup\mathcal{B}}$ denotes the set of maximal cliques of the subgraph $\boldsymbol{\mathcal{G}}_{\mathcal{S}\cup\mathcal{B}}$. Since $\mathcal{S}$ is a fully connected separator set (possibly empty) for $\mathcal{A}$ and $\mathcal{B}$, the maximal cliques of $\boldsymbol{\mathcal{G}}_{\mathcal{S}\cup\mathcal{B}}$ are precisely the maximal cliques of $\boldsymbol{\mathcal{G}}$ that are a subset of $\mathcal{S}\cup\mathcal{B}$. We are going to use (38) shortly.

Define $\widetilde{\pi} : \mathbb{R}^n \to \mathbb{R}$ as $\widetilde{\pi}(\boldsymbol{z}) = \psi_{\mathcal{A}\cup\mathcal{S}}(\boldsymbol{z}_{\mathcal{A}\cup\mathcal{S}})\, \eta_{\boldsymbol{X}_\mathcal{B}}(\boldsymbol{z}_\mathcal{B})/\mathfrak{c}$, and notice that $\widetilde{\pi}$ is a nonvanishing probability density. Denote the corresponding measure by $\widetilde{\boldsymbol{\nu}} \in \mathscr{M}_+(\mathbb{R}^n)$. For an arbitrary permutation σ of $\mathbb{N}_n$ that satisfies (18), let L_i be the σ-generalized KR rearrangement that pushes forward $\boldsymbol{\nu}_\eta$ to $\widetilde{\boldsymbol{\nu}}$ as given by Definition 16 in Appendix A. By Lemma 18, L_i is low-dimensional with respect to $\mathcal{B}$ (Part 2a of the theorem). To see this, let $\widetilde{\boldsymbol{Z}} \sim \widetilde{\boldsymbol{\nu}}$, and notice that $\widetilde{\boldsymbol{Z}}_\mathcal{B} \perp\!\!\!\perp \widetilde{\boldsymbol{Z}}_{\mathcal{A}\cup\mathcal{S}}$ and $\widetilde{\boldsymbol{Z}}_\mathcal{B} = \boldsymbol{X}_\mathcal{B}$ in distribution. By Lemma 15, we can write a

density of the pullback measure $L_i^\sharp \boldsymbol{\nu}$ as:

$$\begin{aligned} L_i^\sharp \pi &= \pi \circ L_i \, |\det \nabla L_i| \\ &= \left(L_i^\sharp \widetilde{\pi}\right) \frac{\prod_{\mathcal{C}\in\boldsymbol{\mathcal{C}}_{\mathcal{S}\cup\mathcal{B}}} \psi_{\mathcal{C}} \circ L_i^{\mathcal{C}}}{\eta_{\boldsymbol{X}_{\mathcal{B}}}} \\ &= \eta_{\boldsymbol{X}_{\mathcal{A}\cup\mathcal{S}}} \prod_{\mathcal{C}\in\boldsymbol{\mathcal{C}}_{\mathcal{S}\cup\mathcal{B}}} \psi_{\mathcal{C}} \circ L_i^{\mathcal{C}}, \end{aligned} \tag{39}$$

where we used the identity $\pi = \widetilde{\pi}\, \psi_{\mathcal{S}\cup\mathcal{B}}/\eta_{\boldsymbol{X}_{\mathcal{B}}}$ together with (38) and the fact that $L_i^k(\boldsymbol{x}) = x_k$ for $k \in \mathcal{B}$ (Part 2a), and where, for any $\mathcal{C} = \{c_1, \dots, c_\ell\} \in \boldsymbol{\mathcal{C}}_{\mathcal{S}\cup\mathcal{B}}$ with $\psi_{\mathcal{C}}(\boldsymbol{z}_{\mathcal{C}}) = \psi_{\mathcal{C}}(z_{c_1}, \dots, z_{c_\ell})$, $L_i^{\mathcal{C}}$ is a map $\mathbb{R}^n \to \mathbb{R}^\ell$ given by $\boldsymbol{x} \mapsto (L_i^{c_1}(\boldsymbol{x}), \dots, L_i^{c_\ell}(\boldsymbol{x}))$.

If $\boldsymbol{Z}' \sim L_i^\sharp \boldsymbol{\nu}$, then (39) shows that $\boldsymbol{Z}'_{\mathcal{A}} \perp\!\!\!\perp \boldsymbol{Z}'_{\mathcal{S}\cup\mathcal{B}}$ and that $\boldsymbol{Z}'_{\mathcal{A}} = \boldsymbol{X}_{\mathcal{A}}$ in distribution (Part 2c of the theorem). Moreover, from the factorization in (39), we can easily construct a graph for which $L_i^\sharp \boldsymbol{\nu}$ factorizes: it suffices to consider the scope of the factors $(\psi_{\mathcal{C}} \circ L_i^{\mathcal{C}})$, i.e., the indices of the input variables that each $\psi_{\mathcal{C}} \circ L_i^{\mathcal{C}}$ can depend on. Recall that for a σ-triangular map, the $\sigma(k)$th component can only depend on the variables $x_{\sigma(1)}, \dots, x_{\sigma(k)}$. For each $\mathcal{C} \in \boldsymbol{\mathcal{C}}_{\mathcal{S}\cup\mathcal{B}}$ there are two possibilites: Either $\mathcal{C} \cap \mathcal{S} = \emptyset$, in which case the scope of $\psi_{\mathcal{C}} \circ L_i^{\mathcal{C}}$ is simply $\mathcal{C}$ since $L_i^k(\boldsymbol{x}) = x_k$ for $k \in \mathcal{B}$. Or $\mathcal{C} \cap \mathcal{S}$ is nonempty, in which case let $j_{\mathcal{C}}$ be the maximum integer j such that $\sigma(j) \in \mathcal{C} \cap \mathcal{S}$, and notice that the scope of $\psi_{\mathcal{C}} \circ L_i^{\mathcal{C}}$ is simply $\mathcal{C} \cup \{\sigma(1), \dots, \sigma(j_{\mathcal{C}})\}$. Thus, we can modify $\boldsymbol{\mathcal{G}}$ to obtain an I-map for $L_i^\sharp \boldsymbol{\nu}$ as follows: (1) Remove any edge that is incident to any node in $\mathcal{A}$ because of Part 2c. (2) For every maximal clique $\mathcal{C}$ in $\boldsymbol{\mathcal{G}}$ that is a subset of $\mathcal{S} \cup \mathcal{B}$ and that has nonempty intersection with $\mathcal{S}$, turn $\mathcal{C} \cup \{\sigma(1), \dots, \sigma(j_{\mathcal{C}})\}$ into a clique. This proves Part 2d of the theorem.

Now let $\mathfrak{R}_i$ be the set of maps $\mathbb{R}^n \to \mathbb{R}^n$ that are low-dimensional with respect to $\mathcal{A}$ and that push forward $\boldsymbol{\nu}_\eta$ to $L_i^\sharp \boldsymbol{\nu}$. $\mathfrak{R}_i$ is nonempty. To see this, let R be the σ-generalized KR rearrangement that pushes forward $\boldsymbol{\nu}_\eta$ to $L_i^\sharp \boldsymbol{\nu}$, for an arbitrary permutation σ, as given by Definition 16 (for the pair of nonvanishing densities η and $L_i^\sharp \pi$). By Part 2c and Lemma 18, R is low-dimensional with respect to $\mathcal{A}$. Thus $R \in \mathfrak{R}_i$ (Part 2b of the theorem).

Let $\mathfrak{D}_i \coloneqq L_i \circ \mathfrak{R}_i$ be the set of maps that can be written as $L_i \circ R$ for some $R \in \mathfrak{R}_i$. By construction, each $T \in \mathfrak{D}_i$ pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}$ (part 2 of the theorem). ■

In the following corollary every symbol should be interpreted as in Theorem 7.

Corollary 19 *Given the hypothesis of Theorem 7, assume that there exists $\mathcal{A}^\perp \subset \mathcal{A}$ such that $\boldsymbol{Z}^i_{\mathcal{A}^\perp} \perp\!\!\!\perp \boldsymbol{Z}^i_{\mathcal{V}\setminus\mathcal{A}^\perp}$ and $\boldsymbol{Z}^i_{\mathcal{A}^\perp} = \boldsymbol{X}_{\mathcal{A}^\perp}$ in distribution. Then L_i is low-dimensional with respect to $\mathcal{A}^\perp \cup \mathcal{B}$, while each $T \in \mathfrak{D}_i$ is low-dimensional with respect to $\mathcal{A}^\perp$.*

Proof By Theorem 7[Part 2a], L_i is low-dimensional with respect to $\mathcal{B}$, while Lemma 18 shows that L_i is also low-dimensional with respect to $\mathcal{A}^\perp$. Moreover, notice that if $\mathcal{A}^\perp$ is nonempty, then for all $T = L_i \circ R$ in $\mathfrak{D}_i$, we have $T^k(\boldsymbol{x}) = x_k$ for $k \in \mathcal{A}^\perp$ since $L_i^k(\boldsymbol{x}) = x_k$ and $R^k(\boldsymbol{x}) = x_k$ for $k \in \mathcal{A}^\perp$ (Theorem 7[Parts 2b]). Additionally, $\partial_j T^k = 0$ for $j \in \mathcal{A}^\perp$ and $k \in \mathcal{V} \setminus \mathcal{A}^\perp$. To see this, notice that $T^k(\boldsymbol{x}) = L_i^k(R(\boldsymbol{x}))$ and that the following two facts hold: (1) The component L_i^k, for $k \in \mathcal{V} \setminus \mathcal{A}^\perp$, does not depend on input variables whose index is in $\mathcal{A}^\perp$ since L_i is low-dimensional with respect to $\mathcal{A}^\perp$; (2) The ℓth component of

R with $\ell \notin \mathcal{A}^\perp$ also does not depend on $\boldsymbol{x}_{\mathcal{A}^\perp}$ since R is low-dimensional with respect to $\mathcal{A}$ (Theorem 7[Parts 2b]). Hence, T must be a low-dimensional map with respect to $\mathcal{A}^\perp$. ■

Proof of Lemma 8 Let $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_i, \pi_i, \boldsymbol{\mathcal{G}}^i, \mathfrak{D}_i, L_i, \mathfrak{R}_i$, and $\boldsymbol{\mathcal{G}}^{i+1}$ be defined as in Theorem 7 for a proper decomposition $(\mathcal{A}_i, \mathcal{S}_i, \mathcal{B}_i)$ of $\boldsymbol{\mathcal{G}}^i$, a permutation σ_i that satisfies (18), and for any factorization (17) of π_i.

We first want to prove that $\mathcal{S}_i \cup \mathcal{B}_i$ is fully connected in $\boldsymbol{\mathcal{G}}^{i+1}$ if and only if the decomposition $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ of Part 1 does not exist. Let us start with one direction. Assume that a decomposition like the one in Part 1 does not exist, despite the possibility to add edges to $\boldsymbol{\mathcal{G}}^{i+1}$ in $\mathcal{V} \setminus \mathcal{A}_i$. We want to show that in this case $\mathcal{S}_i \cup \mathcal{B}_i$ must be a clique in $\boldsymbol{\mathcal{G}}^{i+1}$. Since $\mathcal{B}_i$ is nonempty, there are two possibilities: either $|\mathcal{S}_i \cup \mathcal{B}_i| = 1$ or $|\mathcal{S}_i \cup \mathcal{B}_i| > 1$. If $|\mathcal{S}_i \cup \mathcal{B}_i| = 1$, then $\mathcal{S}_i \cup \mathcal{B}_i$ consists of a single node and thus it is a trivial clique. If $|\mathcal{S}_i \cup \mathcal{B}_i| > 1$, then $\mathcal{S}_i \cup \mathcal{B}_i$ contains at least two nodes. In this case, let us proceed by contradiction and assume that $\mathcal{S}_i \cup \mathcal{B}_i$ is not fully connected in $\boldsymbol{\mathcal{G}}^{i+1} = (\mathcal{V}, \mathcal{E}^{i+1})$, i.e., there exist a pair of nodes $\alpha, \beta \in \mathcal{S}_i \cup \mathcal{B}_i$ such that $(\alpha, \beta) \notin \mathcal{E}^{i+1}$. Let $\mathcal{A}_{i+1} = \mathcal{A}_i \cup \{\alpha\}$, $\mathcal{B}_{i+1} = \{\beta\}$, and $\mathcal{S}_{i+1} = (\mathcal{V} \setminus \mathcal{A}_{i+1}) \setminus \mathcal{B}_{i+1}$. Notice that $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ forms a partition of $\mathcal{V}$, with nonempty $\mathcal{A}_{i+1}, \mathcal{B}_{i+1}$ and with $\mathcal{A}_{i+1}$ strict superset of $\mathcal{A}_i$. Moreover $\mathcal{S}_{i+1}$ must be a separator set for $\mathcal{A}_{i+1}$ and $\mathcal{B}_{i+1}$ since $(\alpha, \beta) \notin \mathcal{E}^{i+1}$ and $\mathcal{A}_i$ is disconnected from $\mathcal{S}_i \cup \mathcal{B}_i$ in $\boldsymbol{\mathcal{G}}^{i+1}$ (Theorem 7[Part 2d]). Now there are two cases: If $\mathcal{S}_{i+1} = \emptyset$, then $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ is a decomposition that satisfies Part 1 of the lemma (contradiction). If $\mathcal{S}_{i+1} \neq \emptyset$, then we can always add enough edges to $\boldsymbol{\mathcal{G}}^{i+1}$ in $\mathcal{S}_i \cup \mathcal{B}_i \supset \mathcal{S}_{i+1}$ in order to make $\mathcal{S}_{i+1}$ fully connected. Also in this case, the resulting decomposition $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ satisfies Part 1 of the lemma and thus leads to a contradiction.

Now the reverse direction. Assume that $\mathcal{S}_i \cup \mathcal{B}_i$ is a clique in $\boldsymbol{\mathcal{G}}^{i+1}$. If $|\mathcal{S}_i \cup \mathcal{B}_i| = 1$, then the decomposition of Part 1 cannot exist since both $\mathcal{A}_{i+1} \setminus \mathcal{A}_i$ and $\mathcal{B}_{i+1}$ should be nonempty. Hence, let $|\mathcal{S}_i \cup \mathcal{B}_i| > 1$ and proceed by contradiction. That is, let $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ be a proper decomposition that satisfies Part 1 of the lemma. Notice that this decomposition must have been achieved without adding any edge to $\boldsymbol{\mathcal{G}}^{i+1}$ in $\mathcal{S}_i \cup \mathcal{B}_i$ since this set is already fully connected. By hypothesis, there must exist α, β such that $\alpha \in \mathcal{A}_{i+1} \setminus \mathcal{A}_i$ and $\beta \in \mathcal{B}_{i+1}$. However, both α and β are also in $\mathcal{S}_i \cup \mathcal{B}_i$, and so they must be connected by an edge in $\boldsymbol{\mathcal{G}}^{i+1}$. Hence, $\mathcal{S}_{i+1}$ is not a separator set for $\mathcal{A}_{i+1}$ and $\mathcal{B}_{i+1}$ (contradiction).

The latter result proves directly Part 2 of the lemma. Moreover, it shows that if $\mathcal{S}_i \cup \mathcal{B}_i$ is not a clique in $\boldsymbol{\mathcal{G}}^{i+1}$, then there exists a proper decomposition $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ of $\boldsymbol{\mathcal{G}}^{i+1}$, where $\mathcal{A}_{i+1}$ is a strict superset of $\mathcal{A}_i$, obtained, possibly, by adding edges to $\boldsymbol{\mathcal{G}}^{i+1}$ in order to turn $\mathcal{S}_{i+1}$ into a clique. Note that even if we add edges to $\boldsymbol{\mathcal{G}}^{i+1}$, $L_i^\sharp \boldsymbol{\nu}_i$ still factorizes according to the resulting graph, which is then an I-map for $L_i^\sharp \boldsymbol{\nu}_i$. Moreover we can really only add edges in $\mathcal{V} \setminus \mathcal{A}_i$ since $\mathcal{A}_i$ must be a strict subset of $\mathcal{A}_{i+1}$, and thus $\mathcal{A}_i$ remains disconnected from $\mathcal{S}_i \cup \mathcal{B}_i$ in $\boldsymbol{\mathcal{G}}^{i+1}$. Let $\mathfrak{D}_{i+1}, L_{i+1}, \mathfrak{R}_{i+1}$ be defined as in Theorem 7 for the pair of measures $\boldsymbol{\nu}_\eta, \boldsymbol{\nu}_{i+1} = L_i^\sharp \boldsymbol{\nu}_i$, the decomposition $(\mathcal{A}_{i+1}, \mathcal{S}_{i+1}, \mathcal{B}_{i+1})$ of $\boldsymbol{\mathcal{G}}^{i+1}$, a permutation σ_{i+1} that satisfies (18), and for any factorization (17) (note that $L_i^\sharp \boldsymbol{\nu}_i \in \mathscr{M}_+(\mathbb{R}^n)$ by Theorem 7[Part 2b]). Fix $T \in \mathfrak{D}_{i+1}$. By Theorem 7[Part 2], T pushes forward $\boldsymbol{\nu}_\eta$ to $\boldsymbol{\nu}_{i+1} = L_i^\sharp \boldsymbol{\nu}_i$. Moreover, if $\boldsymbol{Z}^{i+1} \sim L_i^\sharp \boldsymbol{\nu}_i$, then by Theorem 7[Part 2c] we have $\boldsymbol{Z}^{i+1}_{\mathcal{A}_i} \perp\!\!\!\perp \boldsymbol{Z}^{i+1}_{\mathcal{S}_i\cup\mathcal{B}_i}$ and $\boldsymbol{Z}^{i+1}_{\mathcal{A}_i} = \boldsymbol{X}_{\mathcal{A}_i}$ in distribution. Then by Corollary 19 it must also be that T is low-dimensional with respect to $\mathcal{A}_i$. Thus $T \in \mathfrak{R}_i$, and this proves the inclusion $\mathfrak{R}_i \supset \mathfrak{D}_{i+1}$.

Now fix any $T \in L_i \circ L_{i+1} \circ \mathfrak{R}_{i+1} = L_i \circ \mathfrak{D}_{i+1}$. It must be that $T = L_i \circ g$ for some $g \in \mathfrak{D}_{i+1} \subset \mathfrak{R}_i$, so that $T \in L_i \circ \mathfrak{R}_i$, which shows the inclusion $L_i \circ \mathfrak{R}_i \supset L_i \circ L_{i+1} \circ \mathfrak{R}_{i+1}$ (Part 1a of the lemma). By Corollary 19, we have that L_{i+1} is low-dimensional with respect to $\mathcal{A}_i \cup \mathcal{B}_{i+1}$, and so its effective dimension is bounded above by $|\mathcal{V} \setminus (\mathcal{A}_i \cup \mathcal{B}_{i+1})| = |(\mathcal{A}_{i+1} \setminus \mathcal{A}_i) \cup \mathcal{S}_{i+1}|$ (Part 1b). Finally, by Theorem 7[Part 2b], each $R \in \mathfrak{R}_{i+1}$ is low-dimensional with respect to $\mathcal{A}_{i+1}$, and so its effective dimension is bounded by $|\mathcal{V} \setminus \mathcal{A}_{i+1}|$ (Part 1c). ■

Proof of Theorem 9 For the sake of clarity, we divide the proof in two parts: First, we show that the maps $(\mathfrak{M}_i)_{i\geq 0}$ are well-defined. Then, we prove the remaining claims of the theorem.

The maps $(\mathfrak{M}_i)_{i\geq 0}$ are well-defined as long as, for instance, we show that π^i is a probability density for all $i \geq 0$, and as long as there exist permutations (σ_i) that guarantee the block upper triangular structure of (23). As for the permutations, it suffices to consider $\sigma = \sigma_1 = \sigma_2 = \cdots$ with $\sigma(\mathbb{N}_{2n}) = \{2n, 2n-1, \ldots, 1\}$, i.e., upper triangular maps. (If $n > 1$, then there is some freedom in the choice of σ.) As for the targets (π^i), we now show that π^i is a nonvanishing density and that the marginal $\int \pi^i(\boldsymbol{z}_i, \boldsymbol{z}_{i+1}) \,\mathrm{d}\boldsymbol{z}_i = \pi_{\boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$, for all $i \geq 0$, using an induction argument over i. For the base case ($i = 0$), just notice that

$$\mathfrak{c}_0 = \int \widetilde{\pi}^0(\boldsymbol{z}_0, \boldsymbol{z}_1) \,\mathrm{d}\boldsymbol{z}_{0:1} = \pi_{\boldsymbol{Y}_0,\boldsymbol{Y}_1}(\boldsymbol{y}_0, \boldsymbol{y}_1) < \infty, \tag{40}$$

so that $\pi^0 = \widetilde{\pi}^0/\mathfrak{c}_0 > 0$ is a valid density. Moreover, we have the desired marginal, i.e.,

$$\int \pi^0(\boldsymbol{z}_0, \boldsymbol{z}_1) \,\mathrm{d}\boldsymbol{z}_0 = \int \pi_{\boldsymbol{Z}_0,\boldsymbol{Z}_1|\boldsymbol{Y}_0,\boldsymbol{Y}_1}(\boldsymbol{z}_0, \boldsymbol{z}_1|\boldsymbol{y}_0, \boldsymbol{y}_1) \,\mathrm{d}\boldsymbol{z}_0 = \pi_{\boldsymbol{Z}_1|\boldsymbol{Y}_0,\boldsymbol{Y}_1}(\boldsymbol{z}_1|\boldsymbol{y}_0, \boldsymbol{y}_1).$$

Now assume that π^i is a nonvanishing density and that the marginal $\int \pi^i(\boldsymbol{z}_i, \boldsymbol{z}_{i+1}) \,\mathrm{d}\boldsymbol{z}_i = \pi_{\boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$ for some $i > 0$. The map $\mathfrak{M}_i$ is then well-defined. In particular, by definition of KR rearrangement, the submap $\mathfrak{M}_i^1$ pushes forward $\eta_{\boldsymbol{X}_{i+1}}$ to the marginal $\int \pi^i(\boldsymbol{z}_i, \boldsymbol{z}_{i+1}) \,\mathrm{d}\boldsymbol{z}_i$. Moreover, by Lemma 15, we have:

$$\begin{aligned}
\mathfrak{c}_{i+1} &= \int \eta_{\boldsymbol{X}_{i+1}}(\boldsymbol{z}_{i+1}) \, \widetilde{\pi}^{i+1}(\mathfrak{M}_i^1(\boldsymbol{z}_{i+1}), \boldsymbol{z}_{i+2}) \,\mathrm{d}\boldsymbol{z}_{i+1:i+2} \\
&= \int \pi_{\boldsymbol{Z}_{i+2},\boldsymbol{Y}_{i+2}|\boldsymbol{Y}_{0:i+1}}(\boldsymbol{z}_{i+2}, \boldsymbol{y}_{i+2}|\boldsymbol{y}_{0:i+1}) \,\mathrm{d}\boldsymbol{z}_{i+2} \\
&= \pi_{\boldsymbol{Y}_{i+2}|\boldsymbol{Y}_{0:i+1}}(\boldsymbol{y}_{i+2}|\boldsymbol{y}_{0:i+1}) < \infty,
\end{aligned} \tag{41}$$

where we used the change of variables $\boldsymbol{x}_{i+1} = \mathfrak{M}_i^1(\boldsymbol{z}_{i+1})$ and the fact that $(\mathfrak{M}_i^1)_\sharp \, \eta_{\boldsymbol{X}_{i+1}} = \pi_{\boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$ (induction hypothesis). Thus π^{i+1} is a nonvanishing density and by (41) we can easily verify that π^{i+1} has the desired marginal, i.e., $\int \pi^{i+1}(\boldsymbol{z}_{i+1}, \boldsymbol{z}_{i+2}) \,\mathrm{d}\boldsymbol{z}_{i+1} = \pi_{\boldsymbol{Z}_{i+2}|\boldsymbol{y}_{0:i+2}}$. This argument completes the induction step and shows that not only the maps $(\mathfrak{M}_i)_{i\geq 0}$ are well-defined—together with the maps $(T_i)_{i\geq 0}$ in (25)—but also that $(\mathfrak{M}_i^1)_\sharp \, \eta_{\boldsymbol{X}_{i+1}} = \pi_{\boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$ for all $i \geq 0$ (Part 1 of the theorem).

Now we move to Part 3 of the theorem and use another induction argument over $k \geq 0$. For the base case ($k = 0$), notice that $\mathfrak{T}_0 = T_0 = \mathfrak{M}_0$, and that, by definition, $\mathfrak{M}_0$ pushes forward $\eta_{\boldsymbol{X}_0,\boldsymbol{X}_1}$ to $\pi^0 = \pi_{\boldsymbol{Z}_0,\boldsymbol{Z}_1|\boldsymbol{y}_0,\boldsymbol{y}_1}$.

Assume that $\mathfrak{T}_k$ pushes forward $\eta_{\boldsymbol{X}_{0:k+1}}$ to $\pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ for some $k > 0$ ($\mathfrak{T}_k$ is well-defined for all k since the maps $(T_i)_{i\geq 0}$ in (25) are also well-defined), and notice that

$$\pi_{\boldsymbol{Z}_{0:k+2}|\boldsymbol{y}_{0:k+2}} = \pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}} \frac{\pi_{\boldsymbol{y}_{k+2}|\boldsymbol{Z}_{k+2}} \, \pi_{\boldsymbol{Z}_{k+2}|\boldsymbol{Z}_{k+1}}}{\pi_{\boldsymbol{y}_{k+2}|\boldsymbol{y}_{0:k+1}}} = \pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}} \frac{\widetilde{\pi}^{k+1}}{\mathfrak{c}_{k+1}},$$

where we used (41) and the definition of the collection $(\widetilde{\pi}^i)$. Let $\mathfrak{T}_{k+1} = T_0 \circ \cdots \circ T_{k+1}$ be defined as in Part 3 of the theorem, and observe that $\mathfrak{T}_{k+1} = A_{k+1} \circ T_{k+1}$ with

$$A_{k+1}(\boldsymbol{x}_{0:k+2}) = \begin{bmatrix} \mathfrak{T}_k(\boldsymbol{x}_{0:k+1}) \\ \boldsymbol{x}_{k+2} \end{bmatrix}, \quad T_{k+1}(\boldsymbol{x}_{0:k+2}) = \begin{bmatrix} \boldsymbol{x}_0 \\ \vdots \\ \boldsymbol{x}_k \\ \mathfrak{M}_{k+1}^0(\boldsymbol{x}_{k+1}, \boldsymbol{x}_{k+2}) \\ \mathfrak{M}_{k+1}^1(\boldsymbol{x}_{k+2}) \end{bmatrix}.$$

Thus the following hold:

$$\begin{aligned}
\mathfrak{T}_{k+1}^\sharp \, \pi_{\boldsymbol{Z}_{0:k+2}|\boldsymbol{Y}_{0:k+2}} &= T_{k+1}^\sharp \left(\left(\mathfrak{T}_k^\sharp \, \pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}} \right) \frac{\pi^{k+1}}{\eta_{\boldsymbol{X}_{k+1}}} \right) \\
&= T_{k+1}^\sharp \left(\eta_{\boldsymbol{X}_{0:k}} \, \pi^{k+1} \right) \\
&= \eta_{\boldsymbol{X}_{0:k}} \, \mathfrak{M}_{k+1}^\sharp \, \pi^{k+1} = \eta_{\boldsymbol{X}_{0:k+2}},
\end{aligned}$$

where we used the fact that by Lemma 15 (applied iteratively) it must be that $(A_{k+1} \circ T_{k+1})^\sharp \rho = T_{k+1}^\sharp A_{k+1}^\sharp \rho$ for all densities ρ. (Notice that A_{k+1} is the composition of functions which are trivial embeddings into the identity map of KR rearrangements that couple a pair of measures in $\mathscr{M}_+(\mathbb{R}^n \times \mathbb{R}^n)$, and thus each map in the composition satisfies the hypothesis of Lemma 15.) In particular, $(\mathfrak{T}_{k+1})_\sharp \, \eta_{\boldsymbol{X}_{0:k+2}} = \pi_{\boldsymbol{Z}_{0:k+2}|\boldsymbol{y}_{0:k+2}}$ (Part 3 of the theorem).

Now notice that each $\mathfrak{T}_k$ can also be written as

$$\mathfrak{T}_k(\boldsymbol{x}_{0:k+1}) = \begin{bmatrix} B_k(\boldsymbol{x}_{0:k+1}) \\ \overline{\mathfrak{M}}_k(\boldsymbol{x}_k, \boldsymbol{x}_{k+1}) \end{bmatrix}$$

for a multivariate function B_k—whose particular form is not relevant to this argument—and for a map, $\overline{\mathfrak{M}}_k$, defined in (24) as a function on $\mathbb{R}^n \times \mathbb{R}^n$. Since $(\mathfrak{T}_k)_\sharp \, \eta_{\boldsymbol{X}_{0:k+1}} = \pi_{\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$, the map $\overline{\mathfrak{M}}_k$ must also push forward $\eta_{\boldsymbol{X}_k,\boldsymbol{X}_{k+1}}$ to the lag-1 smoothing marginal $\pi_{\boldsymbol{Z}_k,\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$. This proves Part 2 of the theorem.

For Part 4, just notice that

$$\pi_{\boldsymbol{Y}_{0:k+1}}(\boldsymbol{y}_{0:k+1}) = \pi_{\boldsymbol{Y}_0,\boldsymbol{Y}_1}(\boldsymbol{y}_0, \boldsymbol{y}_1) \prod_{i=1}^{k} \pi_{\boldsymbol{Y}_{i+1}|\boldsymbol{Y}_{0:i}}(\boldsymbol{y}_{i+1}|\boldsymbol{y}_{0:i}) = \prod_{i=0}^{k} \mathfrak{c}_i, \tag{42}$$

where we used both (40) and (41). ■

Proof of Lemma 11 First a remark about notation: we denote by $\mathcal{N}(\boldsymbol{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma})$ the density (as a function of $\boldsymbol{x}$) of a Gaussian with mean $\boldsymbol{\mu}$ and covariance $\boldsymbol{\Sigma}$.

Now let $k > 0$ and notice that $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{Z}_k}(\boldsymbol{z}_{k+1}|\boldsymbol{z}_k) = \mathcal{N}(\boldsymbol{z}_{k+1}; \boldsymbol{F}_k\, \boldsymbol{z}_k, \boldsymbol{Q}_k)$, $\pi_{\boldsymbol{Y}_{k+1}|\boldsymbol{Z}_{k+1}}(\boldsymbol{y}_{k+1}|\boldsymbol{z}_{k+1}) = \mathcal{N}(\boldsymbol{y}_{k+1}; \boldsymbol{H}_{k+1}\, \boldsymbol{z}_{k+1}, \boldsymbol{R}_{k+1})$ and $\eta_{\boldsymbol{X}_k}(\boldsymbol{z}_k) = \mathcal{N}(\boldsymbol{z}_k; 0, \mathbf{I})$. By definition of the target π^k in Theorem 9, we have:

$$\begin{aligned}
\pi^k(\boldsymbol{z}_k, \boldsymbol{z}_{k+1}) &= \eta_{\boldsymbol{X}_k}(\boldsymbol{z}_k)\, \pi_{\boldsymbol{Y}_{k+1}|\boldsymbol{Z}_{k+1}}(\boldsymbol{y}_{k+1}|\boldsymbol{z}_{k+1})\, \pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{Z}_k}(\boldsymbol{z}_{k+1}|\mathfrak{M}^1_{k-1}(\boldsymbol{z}_k)) \\
&= \mathcal{N}(\boldsymbol{z}_k; 0, \mathbf{I})\, \mathcal{N}(\boldsymbol{y}_{k+1}; \boldsymbol{H}_{k+1}\, \boldsymbol{z}_{k+1}, \boldsymbol{R}_{k+1}) \\
&\quad \mathcal{N}(\boldsymbol{z}_{k+1}; \boldsymbol{F}_k\, (\boldsymbol{C}_{k-1}\, \boldsymbol{z}_k + \boldsymbol{c}_{k-1}), \boldsymbol{Q}_k) \\
&\propto \exp(-\frac{1}{2} \boldsymbol{z}^\top \boldsymbol{J}\, \boldsymbol{z} + \boldsymbol{z}^\top \boldsymbol{h}),
\end{aligned}$$

where $\boldsymbol{z} = (\boldsymbol{z}_k, \boldsymbol{z}_{k+1}) \in \mathbb{R}^{2n}$, and where $\boldsymbol{J} \in \mathbb{R}^{2n \times 2n}, \boldsymbol{h} \in \mathbb{R}^{2n}$ are defined as

$$\boldsymbol{J} = \begin{bmatrix} \boldsymbol{J}_{11} & \boldsymbol{J}_{12} \\ \boldsymbol{J}_{12}^\top & \boldsymbol{J}_{22} \end{bmatrix}, \quad \boldsymbol{h} = \begin{bmatrix} \boldsymbol{h}_1 \\ \boldsymbol{h}_2 \end{bmatrix},$$

with:

$$\begin{cases}
\boldsymbol{J}_{11} = \mathbf{I} + \boldsymbol{C}_{k-1}^\top\, \boldsymbol{F}_k^\top\, \boldsymbol{Q}_k^{-1}\, \boldsymbol{F}_k\, \boldsymbol{C}_{k-1} \\
\boldsymbol{J}_{12} = -\boldsymbol{C}_{k-1}^\top\, \boldsymbol{F}_k^\top\, \boldsymbol{Q}_k^{-1} \\
\boldsymbol{J}_{22} = \boldsymbol{Q}_k^{-1} + \boldsymbol{H}_{k+1}^\top\, \boldsymbol{R}_{k+1}^{-1}\, \boldsymbol{H}_{k+1} \\
\boldsymbol{h}_1 = \boldsymbol{J}_{12}\, \boldsymbol{F}_k\, \boldsymbol{c}_{k-1} \\
\boldsymbol{h}_2 = \boldsymbol{Q}_k^{-1}\, \boldsymbol{F}_k\, \boldsymbol{c}_{k-1} + \boldsymbol{H}_{k+1}^\top\, \boldsymbol{R}_{k+1}^{-1}\, \boldsymbol{y}_{k+1}.
\end{cases}$$

In particular, we can rewrite π^k in *information form* (Koller and Friedman, 2009) as $\pi^k(\boldsymbol{z}) = \mathcal{N}^{-1}(\boldsymbol{z}; \boldsymbol{h}, \boldsymbol{J})$. Moreover we know by Theorem 9[Part 1], that the submap $\mathfrak{M}^1_k(\boldsymbol{z}_{k+1}) = \boldsymbol{C}_k\, \boldsymbol{z}_{k+1} + \boldsymbol{c}_k$ pushes forward $\eta_{\boldsymbol{X}_{k+1}}$ to the filtering marginal $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$. Hence $(\boldsymbol{c}_k, \boldsymbol{C}_k)$ should be, respectively, the mean and a square root of the covariance of $\pi_{\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$ — thus the output of any square-root Kalman filter at time $k+1$. Now we just need to determine the submap $\mathfrak{M}^0_k(\boldsymbol{z}_k, \boldsymbol{z}_{k+1}) = \boldsymbol{A}_k\, \boldsymbol{z}_k + \boldsymbol{B}_k\, \boldsymbol{z}_{k+1} + \boldsymbol{a}_k$. Given that $\mathfrak{M}_k$ is a block upper triangular function, the map $\boldsymbol{z}_k \mapsto \mathfrak{M}^0_k(\boldsymbol{z}_k, \boldsymbol{z}_{k+1})$ should push forward $\eta_{\boldsymbol{X}_k}$ to $\boldsymbol{z}_k \mapsto \pi^k_{\boldsymbol{Z}_k|\boldsymbol{Z}_{k+1}}(\boldsymbol{z}_k|\mathfrak{M}^1_k(\boldsymbol{z}_{k+1}))$. Notice that $\pi^k_{\boldsymbol{Z}_k|\boldsymbol{Z}_{k+1}}(\boldsymbol{z}_k|\boldsymbol{z}_{k+1}) = \mathcal{N}^{-1}(\boldsymbol{z}_k; \boldsymbol{h}_1 - \boldsymbol{J}_{12}\, \boldsymbol{z}_{k+1}, \boldsymbol{J}_{11}) = \mathcal{N}(\boldsymbol{z}_k; \boldsymbol{J}_{11}^{-1}(\boldsymbol{h}_1 - \boldsymbol{J}_{12}\, \boldsymbol{z}_{k+1}), \boldsymbol{J}_{11}^{-1})$. Hence $\pi^k_{\boldsymbol{Z}_k|\boldsymbol{Z}_{k+1}}(\boldsymbol{z}_k|\mathfrak{M}^1_k(\boldsymbol{z}_{k+1})) = \mathcal{N}(\boldsymbol{z}_k; \boldsymbol{J}_{11}^{-1}\boldsymbol{J}_{12}(\boldsymbol{F}_k\, \boldsymbol{c}_{k-1} - \boldsymbol{C}_k\, \boldsymbol{z}_{k+1} - \boldsymbol{c}_k), \boldsymbol{J}_{11}^{-1})$, and so:

$$\mathfrak{M}^0_k(\boldsymbol{z}_k, \boldsymbol{z}_{k+1}) = \boldsymbol{J}_{11}^{-1}\boldsymbol{J}_{12}(\boldsymbol{F}_k\, \boldsymbol{c}_{k-1} - \boldsymbol{C}_k\, \boldsymbol{z}_{k+1} - \boldsymbol{c}_k) + \boldsymbol{J}_{11}^{-1/2}\boldsymbol{z}_k.$$

Simple algebra then leads to (29). ■

Proof of Theorem 12 We use a very similar argument to Theorem 9. We first show that the maps $(\mathfrak{M}_i)_{i \geq 0}$ are well-defined. These maps are well-defined as long as, for instance, we show that π^i is a probability density for all $i \geq 0$, and as long as there exist permutations (σ_i) that guarantee the generalized block triangular structure of (31). As for the permutations, it suffices to consider $\sigma = \sigma_1 = \sigma_2 = \cdots$ with $\sigma(\mathbb{N}_{p+2n}) = \{1, \ldots, p, p+2n, p+2n-1, \ldots, p+1\}$. As for the targets (π^i), we now use a (complete) induction argument over i to show that, for

all $i \geq 0$, π^i is a nonvanishing density and $\int \pi^i(\boldsymbol{z}_\theta, \boldsymbol{z}_i, \boldsymbol{z}_{i+1})\, \mathrm{d}\boldsymbol{z}_i = A_i^\sharp\, \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+1})$ for a map A_i defined on $\mathbb{R}^p \times \mathbb{R}^n$ as

$$A_i(\boldsymbol{x}_\theta, \boldsymbol{x}_{i+1}) = \begin{bmatrix} \mathfrak{T}^{\boldsymbol{\Theta}}_{i-1}(\boldsymbol{x}_\theta) \\ \boldsymbol{x}_{i+1} \end{bmatrix},$$

with $\mathfrak{T}^{\boldsymbol{\Theta}}_{i-1}(\boldsymbol{x}_\theta) = \boldsymbol{x}_\theta$ if $i = 0$.

For the base case ($i = 0$), just notice that $\mathfrak{c}_0 = \pi_{\boldsymbol{Y}_0, \boldsymbol{Y}_1}(\boldsymbol{y}_0, \boldsymbol{y}_1) < \infty$, so that $\pi^0 = \bar{\pi}^0/\mathfrak{c}_0 > 0$ is a valid density. Moreover, we have the desired marginal, i.e.,

$$\int \pi^0(\boldsymbol{z}_\theta, \boldsymbol{z}_0, \boldsymbol{z}_1)\, \mathrm{d}\boldsymbol{z}_0 = \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_1|\boldsymbol{Y}_0, \boldsymbol{Y}_1}(\boldsymbol{z}_\theta, \boldsymbol{z}_1|\boldsymbol{y}_0, \boldsymbol{y}_1) = A_0^\sharp\, \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_1|\boldsymbol{y}_0, \boldsymbol{y}_1}(\boldsymbol{z}_\theta, \boldsymbol{z}_1),$$

since A_0 is the identity map on $\mathbb{R}^p \times \mathbb{R}^n$. Now assume that π^j is a nonvanishing density for all $j \leq i$ (complete induction) with $i > 0$, and that the marginal $\int \pi^i(\boldsymbol{z}_\theta, \boldsymbol{z}_i, \boldsymbol{z}_{i+1})\, \mathrm{d}\boldsymbol{z}_i = A_i^\sharp\, \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+1})$. Under this hypothesis, the maps $(\mathfrak{M}_j)_{j \leq i}$ are well-defined, and so are A_i, A_{i+1} since $\mathfrak{T}^{\boldsymbol{\Theta}}_i = \mathfrak{M}^{\boldsymbol{\Theta}}_0 \circ \cdots \circ \mathfrak{M}^{\boldsymbol{\Theta}}_i$. Before checking the integrability of π^{i+1}, notice that by definition of $\mathfrak{M}_i$ (a KR rearrangement), the map B_i, given by

$$B_i(\boldsymbol{x}_\theta, \boldsymbol{x}_{i+1}) = \begin{bmatrix} \mathfrak{M}^{\boldsymbol{\Theta}}_i(\boldsymbol{x}_\theta) \\ \mathfrak{M}^1_i(\boldsymbol{x}_\theta, \boldsymbol{x}_{i+1}) \end{bmatrix},$$

pushes forward $\eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}, \boldsymbol{X}_{i+1}}$ to the marginal $\int \pi^i(\boldsymbol{z}_\theta, \boldsymbol{z}_i, \boldsymbol{z}_{i+1})\, \mathrm{d}\boldsymbol{z}_i$, which equals $A_i^\sharp\, \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$ (inductive hypothesis), i.e., $(B_i)_\sharp\, \eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}, \boldsymbol{X}_{i+1}} = A_i^\sharp\, \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$. In particular, it must also be that $(A_i \circ B_i)_\sharp\, \eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}, \boldsymbol{X}_{i+1}} = \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$, where $A_i \circ B_i$ corresponds precisely to the map $\widetilde{\mathfrak{M}}_i$ defined in (34), so that $(\widetilde{\mathfrak{M}}_i)_\sharp\, \eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}, \boldsymbol{X}_{i+1}} = \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$.

Now we can prove that $\mathfrak{c}_{i+1} < \infty$ using the following identities:

$$\begin{aligned}
\mathfrak{c}_{i+1} &= \int \eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}, \boldsymbol{X}_{i+1}}(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+1}) \\
&\quad \widetilde{\pi}^{i+1}(\mathfrak{T}^{\boldsymbol{\Theta}}_i(\boldsymbol{z}_\theta), \mathfrak{M}^1_i(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+1}), \boldsymbol{z}_{i+2})\, \mathrm{d}\boldsymbol{z}_\theta\, \mathrm{d}\boldsymbol{z}_{i+1:i+2} \\
&= \int (\widetilde{\mathfrak{M}}_i)_\sharp\, \eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}, \boldsymbol{X}_{i+1}}(\boldsymbol{x}_\theta, \boldsymbol{x}_{i+1})\, \pi_{\boldsymbol{Z}_{i+2}|\boldsymbol{Z}_{i+1}, \boldsymbol{\Theta}}(\boldsymbol{z}_{i+2}|\boldsymbol{x}_{i+1}, \boldsymbol{x}_\theta) \\
&\quad \pi_{\boldsymbol{Y}_{i+2}|\boldsymbol{Z}_{i+2}, \boldsymbol{\Theta}}(\boldsymbol{y}_{i+2}|\boldsymbol{z}_{i+2}, \boldsymbol{x}_\theta)\, \mathrm{d}\boldsymbol{x}_\theta\, \mathrm{d}\boldsymbol{x}_{i+1}\, \mathrm{d}\boldsymbol{z}_{i+2} \\
&= \int \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}(\boldsymbol{x}_\theta, \boldsymbol{x}_{i+1}) \\
&\quad \pi_{\boldsymbol{Z}_{i+2}, \boldsymbol{Y}_{i+2}|\boldsymbol{Z}_{i+1}, \boldsymbol{\Theta}}(\boldsymbol{z}_{i+2}, \boldsymbol{y}_{i+2}|\boldsymbol{x}_{i+1}, \boldsymbol{x}_\theta)\, \mathrm{d}\boldsymbol{x}_\theta\, \mathrm{d}\boldsymbol{x}_{i+1}\, \mathrm{d}\boldsymbol{z}_{i+2} \\
&= \pi_{\boldsymbol{Y}_{i+2}|\boldsymbol{Y}_{0:i+1}}(\boldsymbol{y}_{i+2}|\boldsymbol{y}_{0:i+1}) < \infty,
\end{aligned} \tag{43}$$

where we used the change of variables:

$$\begin{bmatrix} \boldsymbol{x}_\theta \\ \boldsymbol{x}_{i+1} \end{bmatrix} = \begin{bmatrix} \mathfrak{T}^{\boldsymbol{\Theta}}_i(\boldsymbol{z}_\theta) \\ \mathfrak{M}^1_i(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+1}) \end{bmatrix} = \widetilde{\mathfrak{M}}_i(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+1}), \tag{44}$$

and the fact that $(\widetilde{\mathfrak{M}}_i)_\sharp\, \eta_{\boldsymbol{X}_{\boldsymbol{\Theta}}, \boldsymbol{X}_{i+1}} = \pi_{\boldsymbol{\Theta}, \boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$ (induction hypothesis). (The change of variables in (44) is valid for the following reason: the map $\widetilde{\mathfrak{M}}_i$ can be factorized as the

composition of $i+1$ (generalized) triangular functions, all that fit the hypothesis of Lemma 15, so that (44) should really be interpreted as a sequence of $i+1$ change of variables—each associated with one map in the composition and justified by Lemma 15.) Therefore π^{i+1} is a nonvanishing density. Following the same derivations as in (43), it is not hard to show that π^{i+1} has also the desired marginal, i.e.,

$$\int \pi^{i+1}(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+1}, \boldsymbol{z}_{i+2})\,\mathrm{d}\boldsymbol{z}_{i+1} = A_{i+1}^\sharp\, \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{i+2}|\boldsymbol{y}_{0:i+2}}(\boldsymbol{z}_\theta, \boldsymbol{z}_{i+2}).$$

This argument completes the induction step and shows that not only the maps $(\mathfrak{M}_i)_{i\geq 0}$ are well-defined—together with the maps $(T_i)_{i\geq 0}$ in (35)—but also that $(\widetilde{\mathfrak{M}}_i^1)_\sharp\, \eta_{\boldsymbol{X}_\Theta,\boldsymbol{X}_{i+1}} = \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{i+1}|\boldsymbol{y}_{0:i+1}}$ for all $i \geq 0$ (Part 1 of the theorem).

Now we prove Part 2 of the theorem using another induction argument on $k \geq 0$. For the base case ($k = 0$), notice that $\mathfrak{T}_0 = T_0 = \mathfrak{M}_0$, and that, by definition, $\mathfrak{M}_0$ pushes forward $\eta_{\boldsymbol{X}_\Theta,\boldsymbol{X}_0,\boldsymbol{X}_1}$ to $\pi^0 = \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_0,\boldsymbol{Z}_1|\boldsymbol{y}_0,\boldsymbol{y}_1}$.

Assume that $\mathfrak{T}_k$ pushes forward $\eta_{\boldsymbol{X}_\Theta,\boldsymbol{X}_{0:k+1}}$ to $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$ for some $k > 0$ ($\mathfrak{T}_k$ is well-defined for all k since the maps $(T_i)_{i\geq 0}$ in (35) are also well-defined), and notice that

$$\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+2}|\boldsymbol{y}_{0:k+2}} = \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}\, \frac{\pi_{\boldsymbol{y}_{k+2}|\boldsymbol{Z}_{k+2},\boldsymbol{\Theta}}\, \pi_{\boldsymbol{Z}_{k+2}|\boldsymbol{Z}_{k+1},\boldsymbol{\Theta}}}{\pi_{\boldsymbol{y}_{k+2}|\boldsymbol{y}_{0:k+1}}} = \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}\, \frac{\widetilde{\pi}^{k+1}}{\mathfrak{c}_{k+1}},$$

where we used (43) and the definition of the collection $(\widetilde{\pi}^i)$. Let $\mathfrak{T}_{k+1} = T_0 \circ \cdots \circ T_{k+1}$ be defined as in Part 2 of the theorem, and observe that $\mathfrak{T}_{k+1} = C_{k+1} \circ T_{k+1}$ with

$$C_{k+1}(\boldsymbol{x}_\theta, \boldsymbol{x}_{0:k+2}) = \begin{bmatrix} \mathfrak{T}_k(\boldsymbol{x}_\theta, \boldsymbol{x}_{0:k+1}) \\ \boldsymbol{x}_{k+2} \end{bmatrix}, \quad T_{k+1}(\boldsymbol{x}_\theta, \boldsymbol{x}_{0:k+2}) = \begin{bmatrix} \mathfrak{M}_{k+1}^{\boldsymbol{\Theta}}(\boldsymbol{x}_\theta) \\ \boldsymbol{x}_0 \\ \vdots \\ \boldsymbol{x}_k \\ \mathfrak{M}_{k+1}^0(\boldsymbol{x}_\theta, \boldsymbol{x}_{k+1}, \boldsymbol{x}_{k+2}) \\ \mathfrak{M}_{k+1}^1(\boldsymbol{x}_\theta, \boldsymbol{x}_{k+2}) \end{bmatrix}.$$

Thus the following hold:

$$\begin{aligned} \mathfrak{T}_{k+1}^\sharp\, \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+2}|\boldsymbol{y}_{0:k+2}} &= T_{k+1}^\sharp \left(\left(\mathfrak{T}_k^\sharp\, \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}} \right) \frac{\pi^{k+1}}{\eta_{\boldsymbol{X}_\Theta,\boldsymbol{X}_{k+1}}} \right) \\ &= T_{k+1}^\sharp \left(\eta_{\boldsymbol{X}_{0:k}}\, \pi^{k+1} \right) \\ &= \eta_{\boldsymbol{X}_{0:k}}\, \mathfrak{M}_{k+1}^\sharp\, \pi^{k+1} = \eta_{\boldsymbol{X}_\Theta,\boldsymbol{X}_{0:k+2}}, \end{aligned}$$

where we used the fact that by Lemma 15 (applied iteratively) it must be that $(C_{k+1} \circ T_{k+1})^\sharp \rho = T_{k+1}^\sharp\, C_{k+1}^\sharp \rho$ for all densities ρ. (Notice that C_{k+1} is the composition of functions which are trivial embeddings into the identity map of KR rearrangements that couple a pair of measures in $\mathscr{M}_+(\mathbb{R}^p \times \mathbb{R}^n \times \mathbb{R}^n)$, and thus each map in the composition satisfies the hypothesis of Lemma 15.) Thus $(\mathfrak{T}_{k+1})_\sharp\, \eta_{\boldsymbol{X}_\Theta,\boldsymbol{X}_{0:k+2}} = \pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+2}|\boldsymbol{y}_{0:k+2}}$, and this concludes the induction argument and the proof of Part 2 of the theorem.

The proof of Part 3 follows from $\mathfrak{c}_0 = \pi_{\boldsymbol{Y}_0,\boldsymbol{Y}_1}(\boldsymbol{y}_0, \boldsymbol{y}_1)$, (43), and (42). ■

Appendix C. Algorithms for Inference on State-Space Models

Here we digest the smoothing and joint state-parameter inference methodologies discussed in Section 7 into a handful of algorithms, described with pseudocode. Algorithms 1 and 2 below are building blocks: they describe, respectively, how to approximate a transport map given an (unnormalized) target density, and how to project a given transport map onto a set of monotone transformations. Algorithm 3 shows how to build a recursive approximation of $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$—i.e., the full Bayesian solution to the problem of sequential inference in state-space models with static parameters—using a decomposable transport map. See details in Section 7.3. For simplicity, we always use a standard normal reference process $\eta_{\boldsymbol{X}}$, although more general choices are possible. Algorithm 4 shows how to sample from the resulting approximation of the joint distribution $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{0:k+1}|\boldsymbol{y}_{0:k+1}}$, whereas Algorithm 5 focuses on a particular "filtering" marginal, i.e., $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{k+1}|\boldsymbol{y}_{0:k+1}}$. The problem of sequential inference on state-space models *without* static parameters (see Section 7.1) can be tackled via a simplified version of Algorithm 3, wherein the formal dependence on $\boldsymbol{\Theta}$ is dropped. The actual implementation of these algorithms is available online at `http://transportmaps.mit.edu`.

Algorithm 1 (Computation of a monotone map)
Given an unnormalized target density $\bar{\pi}$ and a parametric triangular monotone map $T[\mathbf{c}]$ of the form (5), defined by an arbitrary set of coefficients $\mathbf{c} \in \mathbb{R}^N$, find the optimal coefficients $\mathbf{c}^\star$ according to (7).

procedure ComputeMap($\bar{\pi}$, $T[\mathbf{c}]$, m)
  Generate samples $(\boldsymbol{x}_i)_{i=1}^m \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \mathbf{I})$
  Solve (e.g., via a quasi-Newton or Newton method),

$$\mathbf{c}^\star = \operatorname*{argmin}_{\mathbf{c}\in\mathbb{R}^N} -\frac{1}{m}\sum_{i=1}^m \left(\log \bar{\pi}(T[\mathbf{c}](\boldsymbol{x}_i)) + \sum_k \log \partial_k T[\mathbf{c}]^k(\boldsymbol{x}_i) \right)$$

  return $T[\mathbf{c}^\star]$
end procedure

Algorithm 2 (Regression of a monotone map)
Given a map M and a parametric triangular monotone map $T[\mathbf{c}]$ of the form (5) , defined by an arbitrary set of coefficients $\mathbf{c} \in \mathbb{R}^N$, find the coefficients $\mathbf{c}^\star$ minimizing the discrete L^2 norm between the two maps.

procedure RegressionMap(M, $T[\mathbf{c}]$, m)
  Generate samples $(\boldsymbol{x}_i)_{i=1}^m \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \mathbf{I})$
  Solve

$$\mathbf{c}^\star = \operatorname*{argmin}_{\mathbf{c}\in\mathbb{R}^N} \frac{1}{m}\sum_{i=1}^m \left(M(\boldsymbol{x}_i) - T[\mathbf{c}](\boldsymbol{x}_i) \right)^2$$

  return $T[\mathbf{c}^\star]$
end procedure

Algorithm 3 (Joint parameter and state inference)
Given observations $(\boldsymbol{y}_i)_{i=0}^{k+1}$, construct a transport map approximation of the smoothing distribution $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_0,\ldots,\boldsymbol{Z}_{k+1}|\boldsymbol{y}_0,\ldots,\boldsymbol{y}_{k+1}}$ in terms of a list of maps $(\mathfrak{M}_j)_{j=0}^{k}$.

procedure AssimilATE($(\boldsymbol{y}_i)_{i=0}^{k+1}$, m)
  for $i \leftarrow 0$ to k **do** ▷ see Thm. 12
    if $i = 0$ **then**
      Define $\widetilde{\mathfrak{T}}_{i-1}^{\boldsymbol{\Theta}}$ to be the identity map
      Define π^i as in (32)
    else
      $\widetilde{\mathfrak{T}}_{i-1}^{\boldsymbol{\Theta}}[\mathbf{c}^\star] \leftarrow$ RegressionMap($\widetilde{\mathfrak{T}}_{i-2}^{\boldsymbol{\Theta}} \circ \mathfrak{M}_{i-1}^{\boldsymbol{\Theta}}$, $\widetilde{\mathfrak{T}}_{i-1}^{\boldsymbol{\Theta}}[\mathbf{c}]$, m)
      Define π^i as in (33)
    end if
    $\mathfrak{M}_i[\mathbf{c}^\star] \leftarrow$ ComputeMap(π^i, $\mathfrak{M}_i[\mathbf{c}]$, m)
    Append $\mathfrak{M}_i$ to the list $(\mathfrak{M}_j)_{j=0}^{i-1}$
  end for
  return $(\mathfrak{M}_j)_{j=0}^{k}, \widetilde{\mathfrak{T}}_{k-1}^{\boldsymbol{\Theta}}$
end procedure

Algorithm 4 (Sample the smoothing distribution)
Generate a sample from the smoothing distribution $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_0,\ldots,\boldsymbol{Z}_{k+1}|\boldsymbol{y}_0,\ldots,\boldsymbol{y}_{k+1}}$ using the maps computed in Algorithm 3.

procedure SampleSmoothing($(\mathfrak{M}_j)_{j=0}^{k}$)
  Generate $\boldsymbol{x} \sim \mathcal{N}(0, \mathbf{I})$, with $\mathbf{I}$ the identity in $d_\theta + k \cdot d_{\boldsymbol{z}}$ dimensions
  for $j \leftarrow k$ to 0 **do** ▷ see Thm. 12 Part. 2
    $\boldsymbol{x}_\theta \leftarrow \mathfrak{M}_j^{\boldsymbol{\Theta}}(\boldsymbol{x}_\theta)$
    $\boldsymbol{x}_j \leftarrow \mathfrak{M}_j^{0}(\boldsymbol{x}_\theta, \boldsymbol{x}_j, \boldsymbol{x}_{j+1})$
    $\boldsymbol{x}_{j+1} \leftarrow \mathfrak{M}_j^{1}(\boldsymbol{x}_\theta, \boldsymbol{x}_{j+1})$
  end for
  return $\boldsymbol{x}$
end procedure

Algorithm 5 (Sample the filtering distribution)
Generate a sample from the marginal distribution $\pi_{\boldsymbol{\Theta},\boldsymbol{Z}_{k+1}|\boldsymbol{y}_0,\ldots,\boldsymbol{y}_{k+1}}$ using the maps computed in Algorithm 3.

procedure SampleFiltering($\mathfrak{M}_k$, $\widetilde{\mathfrak{T}}_{k-1}^{\boldsymbol{\Theta}}$)
  Generate $\boldsymbol{x} \sim \mathcal{N}(0, \mathbf{I})$, with $\mathbf{I}$ the identity in $d_\theta + d_{\boldsymbol{z}}$ dimensions
  Define

$$\widetilde{\mathfrak{M}}_k(\boldsymbol{x}_\theta, \boldsymbol{x}_{k+1}) := \begin{bmatrix} \widetilde{\mathfrak{T}}_{k-1}^{\boldsymbol{\Theta}}(\mathfrak{M}_k^{\boldsymbol{\Theta}}(\boldsymbol{x}_\theta)) \\ \mathfrak{M}_k^{1}(\boldsymbol{x}_\theta, \boldsymbol{x}_{k+1}) \end{bmatrix}$$

  $\boldsymbol{y} \leftarrow \widetilde{\mathfrak{M}}_k(\boldsymbol{x}_\theta, \boldsymbol{x}_{k+1})$ ▷ see Thm. 12 Part. 1
  return $\boldsymbol{y}$
end procedure

Appendix D. Additional Results for the Stochastic Volatility Model

We revisit the numerical example of Section 8 and re-run both the joint state/parameter inference problem and the long-time smoothing problem with *linear* rather than nonlinear maps. The results are less accurate, but substantially faster; see Table 1 and the discussion of this comparison in Section 8.

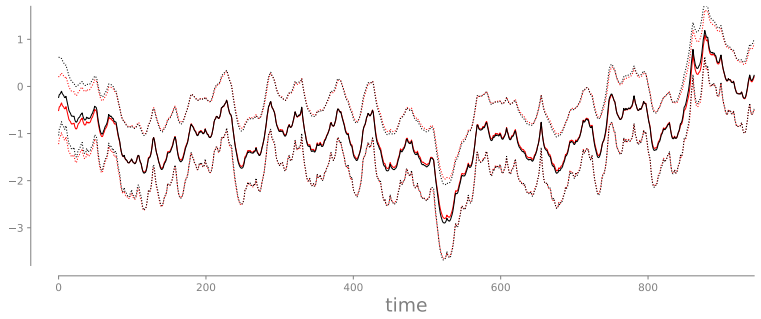

Figure 18: Same as Figure 10, but using linear maps. Compared to a high-order map, there seems to be only a minimal loss of accuracy, more prominent at earlier times.

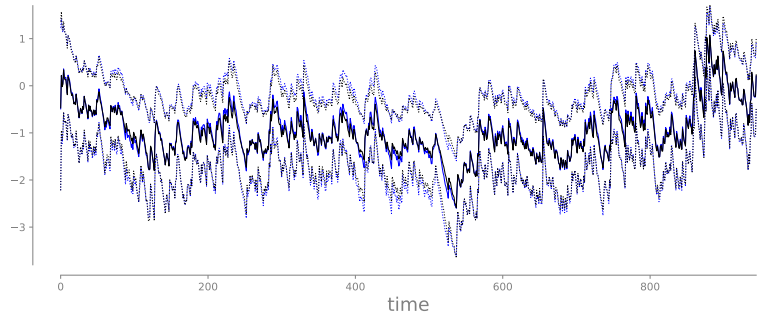

Figure 19: Comparison of the $\{5, 95\}$–percentiles (dashed lines) and the mean (solid line) of the numerical approximation of the filtering marginals using *linear* transport maps (blue lines) with those of a "reference" solution obtained via seventh-order maps (as shown in Figure 11). The two solutions look remarkably similar despite the enormous difference in computational cost (see Table 1).

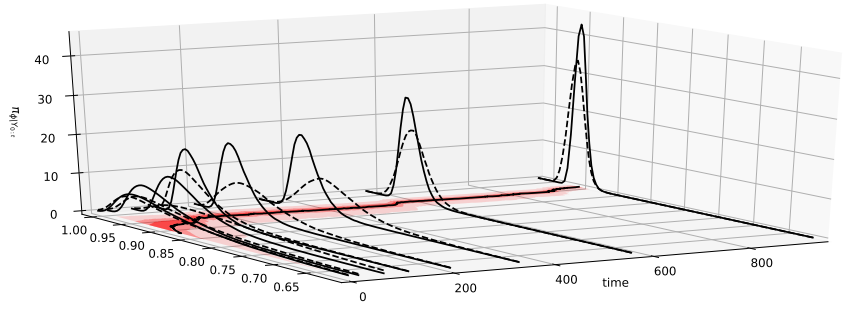

Figure 20: Same as Figure 12, but using linear maps. Here, the loss of accuracy is more dramatic than for the smoothing distribution of the state in Figure 18. Even though the approximate marginal captures the bulk of the true parameter marginals, for this specific problem of static parameter inference, a linear map is largely inadequate; hence the need for a higher-order nonlinear transformation.

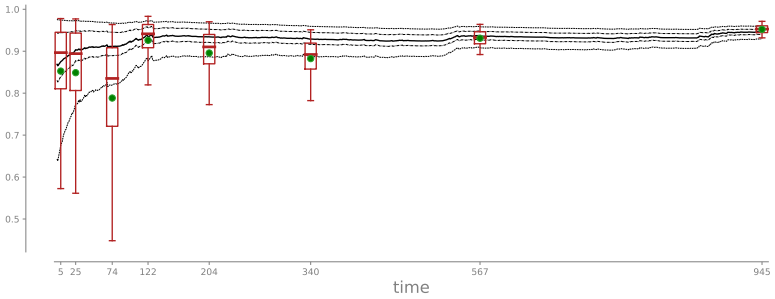

Figure 21: The horizontal plane of Figure 20 (*black lines*) overlaid with a selected number of box-and-whisker plots associated with the marginals of a "reference" MCMC solution. The ends of the whiskers represent the $\{5, 95\}$–percentiles, while the green dots correspond to the means of the reference distribution. Linear maps are insufficient to correctly characterize the parameter marginals, especially the transition at time 74 (cf. Figures 12 and 20)

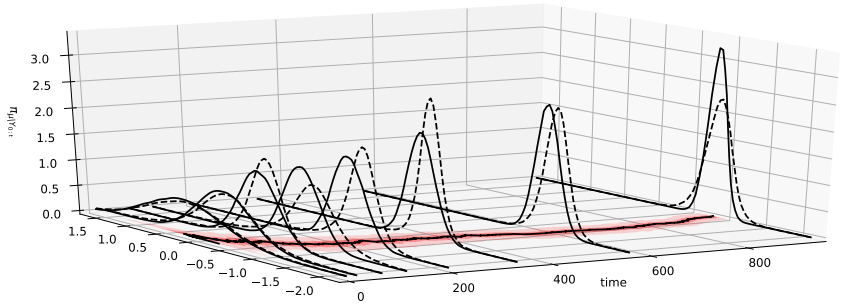

Figure 22: Same as Figure 13, but using linear maps. Once again, the linear map provides plausible, but somewhat inaccurate, results for sequential parameter inference. A nonlinear transformation is better suited for this problem.

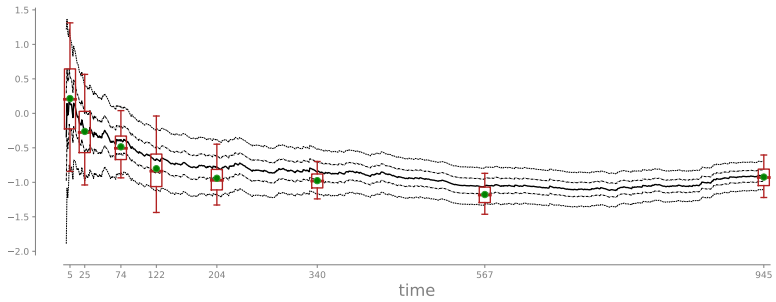

Figure 23: The horizontal plane of Figure 22 (*black lines*) overlaid with a selected number of box-and-whisker plots associated with the marginals of a "reference" MCMC solution. See Figure 21 caption for more details.

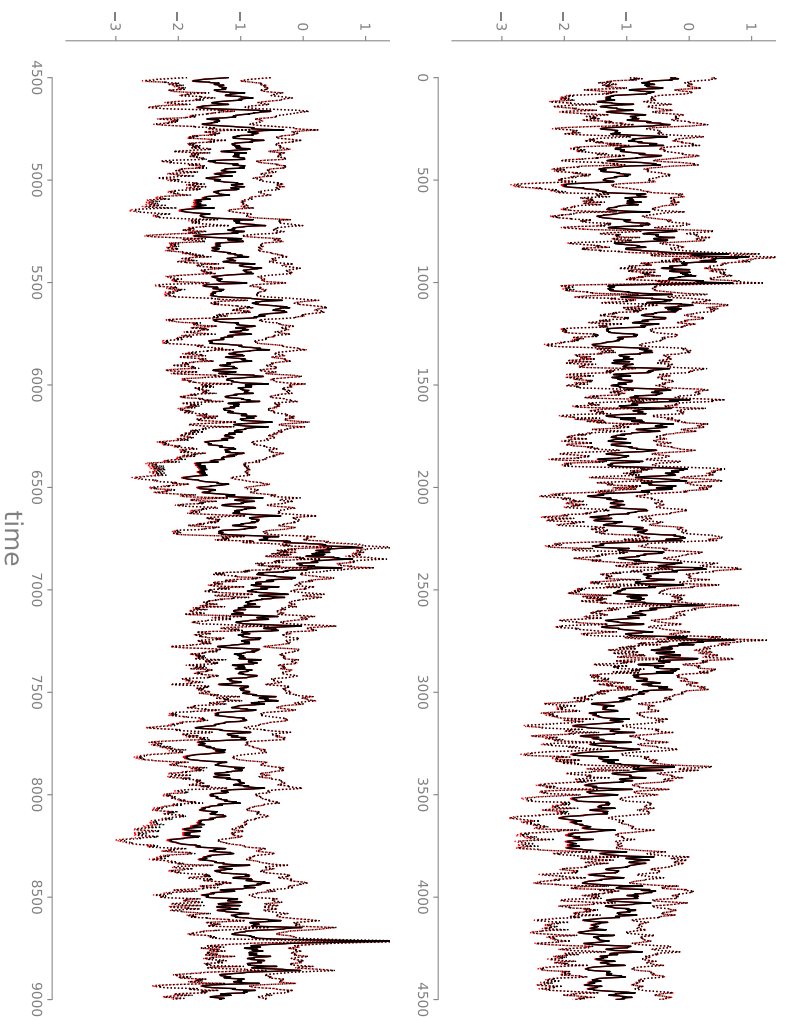

Figure 24: Same as Figure 17, but using linear maps. Long-time smoothing with no static parameters via linear maps yields accurate characterizations of the marginal distributions across all times, at a fraction of the cost of a high-order nonlinear transformation (see Table 1).
