We show that positivity of the stability statistic given in (12) with $0 < \gamma < \pi/2$ implies stability of L_* as a minimizer in the neighborhood $B(L_*, \gamma)$. Stability of L_* means that it is the only critical point and minimizer in $B(L_*, \gamma)$, and, at all other points in this neighborhood, there exists a direction in $G(D, d)$ such that the energy landscape looks like one of the two cases displayed in Figure 2; in other words, there is a direction of decrease.

Theorem 1 (Stability of L_*) *Suppose that a noiseless inlier-outlier dataset with an underlying subspace L_* satisfies $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$, for some $0 < \gamma < \pi/2$. Then, all points in*

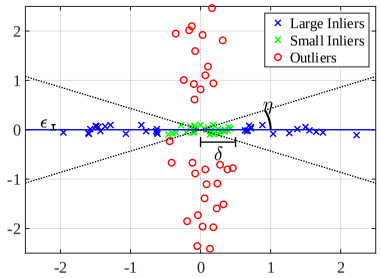

Figure 3: Demonstration of a noisy inlier-outlier dataset, where $d = 1$ and $D = 2$. The following parameters used in our analysis are also displayed: the small-projection cutoff δ, the noise bound ϵ, and the accuracy η. Note that, in this example, inliers within a δ-neighborhood of the origin are removed from the permeance calculation, and ϵ the maximum distance of the inliers to the X-axis. Our analysis guarantees recovery up to the accuracy η, which means that we would recover the x-axis within the acute angle formed by the dotted lines.

$B(L_*, \gamma) \setminus \{L_*\}$ have a subdifferential along a geodesic strictly less than $-\mathcal{S}(\mathcal{X}, L_*, \gamma)$, that is, it is a direction of decreasing energy. This implies that L_* is the only critical point and local minimizer in $B(L_*, \gamma)$.

Proof [Proof of Theorem 1] The main point behind the proof is the following statement. We show that, for any $L \in B(L_*, \gamma) \setminus \{L_*\}$, there is a geodesic $L(t)$ with $L(0) = L$, and an open interval around 0, $\mathcal{I} = (\theta_1(L, L_*) - \gamma, \delta(L))$, for some $\delta(L) > 0$, such that

$$\text{For } t \in \mathcal{I},\ \theta_1(L(t), L_*) \text{ is a strictly decreasing function;} \tag{17}$$

$$\text{For } t \in \mathcal{I},\ F(L(t); \mathcal{X}) \text{ is a strictly decreasing function.} \tag{18}$$

In simple words, the function $F(L(t); \mathcal{X})$ is decreasing as $L(t)$ moves closer to L_*. This implies that L_* is the only critical point and minimizer in $B(L_*, \gamma)$ by a perturbation argument, which we will explicitly state at the end of the proof.

Fix a subspace $L \in B(L_*, \gamma) \setminus \{L_*\}$, and let the principal angles between L and L_* be $\theta_1, \dots, \theta_d$. Also, choose a set of corresponding principal vectors $\boldsymbol{v}_1, \dots, \boldsymbol{v}_d$ and $\boldsymbol{y}_1, \dots, \boldsymbol{y}_d$ for L and L_*, respectively, and let $l \geq 1$ be the maximum index such that $\theta_1 = \cdots = \theta_l$. We let $\boldsymbol{u}_1, \dots, \boldsymbol{u}_l$ be complementary orthogonal vectors for $\boldsymbol{v}_1, \dots, \boldsymbol{v}_l$ and $\boldsymbol{y}_1, \dots, \boldsymbol{y}_l$. For $t \in [0, 1]$, we form the geodesic

$$L(t) = \mathrm{Sp}(\boldsymbol{v}_1 \cos(t) + \boldsymbol{u}_1 \sin(t), \dots, \boldsymbol{v}_l \cos(t) + \boldsymbol{u}_l \sin(t), \boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d). \tag{19}$$

Notice that this geodesic is parameterized by arclength in terms of the metric defined in Section 2.2. This geodesic moves only the l furthest directions of $L(0)$ towards L_* and fixes those directions that are closer than θ_1. This geodesic certainly satisfies (17). We

have also removed dependence on θ_1, since this unnecessarily impacts the magnitude of the geodesic subderivative (5). Following (5) with no dependence on $\theta_1, \dots, \theta_l$ and then using (6) and (8), we have

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}t} F(L(t); \mathcal{X})\Big|_{t=0} &= -\sum_{j=1}^{l} \sum_{\mathcal{X}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \\
&= -\sum_{j=1}^{l} \left(\sum_{\mathcal{X}_{\text{in}}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} + \sum_{\mathcal{X}_{\text{out}}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \right) \\
&\leq -\sum_{j=1}^{l} \left(\frac{\cos(\theta_1)\sin(\theta_1)}{\sin(\theta_1)} \sum_{\mathcal{X}_{\text{in}}} \frac{\boldsymbol{y}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{y}_j}{\|\boldsymbol{x}_i\|} - \sup_{\boldsymbol{V} \in B(L_*, \gamma)} \|\nabla F(\boldsymbol{V}; \mathcal{X}_{\text{out}})\|_2 \right) \\
&\leq -l\mathcal{S}(\mathcal{X}, L_*, \gamma) \leq -\mathcal{S}(\mathcal{X}, L_*, \gamma) < 0.
\end{aligned} \tag{20}$$

The third line is obtained by noting that the inliers and the vectors $\boldsymbol{y}_j$, $1 \leq j \leq l$, are contained L_*, the vectors $\boldsymbol{v}_j$, $1 \leq j \leq l$, are contained in L, and $\theta_1 = \ldots = \theta_l$. Therefore, for all $1 \leq j \leq l$ and all inliers $\boldsymbol{x}_i$, $\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j \geq \cos(\theta_1)\sin(\theta_1)(\boldsymbol{y}_j^T \boldsymbol{x}_i)^2$. In the third line we also used (6) and (8) for the outlier term and maximized it over $B(L_*, \gamma)$. Thus, (20) implies that every subspace in $\overline{B(L_*, \gamma)} \setminus \{L_*\}$ has a direction with negative local subderivative.

The argument above was for a special subderivative at $L(0)$. We now extend this argument to show that this implies that the subdifferential at every point is bounded above by $-\mathcal{S}(\mathcal{X}, L_*, \gamma)$. On the one hand, if $L(0)$ contains no points of $\mathcal{X}$, then the subderivative corresponds to the actual derivative, and we therefore have that $F(L(t); \mathcal{X})$ is decreasing, as desired.

On the other hand, assume that $L(0) \cap \mathcal{X}$ is non-empty. Since $\mathcal{X}$ is finite, there exists a neighborhood of 0, $(-\omega, \omega)$, for $0 < \omega < \pi/2$, such that $L(t)$ has empty intersection with $\mathcal{X} \setminus L(0)$, that is,

$$\{\boldsymbol{x} \in \mathcal{X} : \boldsymbol{x} \in L(t),\ \text{for some } t \in (-\omega, \omega)\} = L(0) \cap \mathcal{X}. \tag{21}$$

Notice that the changing directions in (19) form a geodesic along $G(D, l)$ while the other directions are fixed (i.e., $L(t) \supset \mathrm{Sp}(\boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d)$ for all t). Thus, derivatives of $F(L(t); \mathcal{X})$ over $G(D, d)$ are equivalent to derivatives of $F(\tilde{L}(t); \boldsymbol{Q}_{\boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d} \mathcal{X})$ over $G(D, l)$, where $\tilde{L}(t) = \mathrm{Sp}(\boldsymbol{v}_1 \cos(t) + \boldsymbol{u}_1 \sin(t), \dots, \boldsymbol{v}_l \cos(t) + \boldsymbol{u}_l \sin(t)))$. Here, $\boldsymbol{Q}_{\boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d}$ is the projection onto the orthogonal complement of $\mathrm{Sp}(\boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d)$, which is applied to all points of $\mathcal{X}$. By (21), this geodesic over $G(D, l)$ has the property

$$\tilde{L}(t) \cap \mathcal{X} = \emptyset,\ \forall\ t \in (-\omega, 0) \cup (0, \omega).$$

Consequently, $F(\tilde{L}(t); \boldsymbol{Q}_{\boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d} \mathcal{X})$ is continuously differentiable on $(-\omega, 0)$ and $(0, \omega)$ as a function over $G(D, l)$, and it is apparent that the bounds in (20) also hold for all of these derivatives. Putting these facts together, by the continuity of the derivatives of $F(\tilde{L}(t); \boldsymbol{Q}_{\boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d} \mathcal{X})$ for $t \in (-\omega, 0) \cup (0, \omega)$, the subdifferential of $F(L(t); \mathcal{X})$ at $t = 0$ is bounded above by $-\mathcal{S}(\mathcal{X}, L_*, \gamma)$, which in turn implies that (18) holds.

Finally, there are clearly no other critical points than L_* in $B(L_*, \gamma)$, because every point has a direction of decrease. To show that (17) and (18) imply that L_* is a local minimizer, consider a one-dimensional perturbation of L_*, L'. In other words, $\theta_1(L_*, L') > 0$

and $\theta_2(L_*, L') = 0$. Then, (17) and (18) imply that if $L(t)$ is the geodesic between L' and L_*, then $F(L(t); \mathcal{X})$ is decreasing for $t \in (\theta_1(L', L_*) - \gamma, \theta_1(L', L_*))$. The more general perturbation case is just an extension of this argument. Indeed, a d-dimensional perturbation may be written as a sequence of one-dimensional perturbations. ■

3.2.2. Stability with Small Noise

The following theorem generalizes Theorem 1 for the case of a noisy inlier-outlier dataset. The proof of this theorem is left to Appendix D.1, and it essentially follows that of the noiseless RSR setting with the altered stability statistic. Here, we only guarantee that there is a large region with no critical points up to a precision of $\eta = 2\arctan(\epsilon/\delta)$, which is determined by the noise level and inlier permeance.

Theorem 2 (Stability of $B(L_*, \eta)$ with Noise) *Assume a noisy inlier-outlier dataset, with an underlying subspace L_* and noise parameter $\epsilon > 0$, that satisfies for some $\delta > \epsilon > 0$ the stability condition $\mathcal{S}_n(\mathcal{X}, L_*, \epsilon, \delta, \gamma) > 0$. Let $\eta = 2\arctan(\epsilon/\delta)$ and assume further that $\eta < \gamma$. Then, all points in $B(L_*, \gamma) \setminus B(L_*, \eta)$ have a subdifferential along a geodesic strictly less than $-\mathcal{S}_n(\mathcal{X}, L_*, \epsilon, \delta, \gamma)$, that is, it is a direction of decreasing energy. This implies that the only local minimizers and saddle points in $B(L_*, \gamma)$ are in $B(L_*, \eta)$.*

4. A Geodesic Gradient Method for RSR and its Guarantees

In this section, we discuss a geodesic gradient descent method for minimizing (3). First, Section 4.1 gives the details of our algorithm. After laying out the algorithm, we discuss convergence to a local minimizer under deterministic conditions in Section 4.2. Then, Section 4.3 shows that the PCA d-subspace is a good initializer under a separate deterministic condition.

4.1. Minimization by Geodesic Gradient Descent

We use gradient descent to minimize (4). Denoting the singular value decomposition of the negative gradient by $-\nabla F(\boldsymbol{V}; \mathcal{X}) = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{W}^T$, Theorem 2.3 of Edelman et al. (1999) states that the geodesic starting at $\boldsymbol{V}(0) = \boldsymbol{V}$ with $\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{V}(t)|_{t=0} = -\nabla F(\boldsymbol{V}; \mathcal{X})$ is

$$\boldsymbol{V}(t) = \boldsymbol{V}\boldsymbol{W}\cos(\boldsymbol{\Sigma}t)\boldsymbol{W}^T + \boldsymbol{U}\sin(\boldsymbol{\Sigma}t)\boldsymbol{W}^T. \tag{22}$$

Here, sin and cos are the typical matrix sin and cos, defined by their corresponding power series.

We develop a geodesic gradient descent method using the construction in (22). At a point $\boldsymbol{V}^k$, we may choose a value of t and move along the geodesic to the next iterate. For a sequence of step-sizes $(t^k)_{k\in\mathbb{N}}$, the sequence of subspaces is defined recursively by $\boldsymbol{V}^{k+1} = \boldsymbol{V}^k(t^k)$. The full algorithm with a specific choice of step-size is given in Algorithm 1 and is referred to as GGD. The complexity of this algorithm is $O(TNDd)$, where T is the number of iterations. Note that we use a piecewise constant scheme for the step-sizes, which starts with step-size $t^1 = s$, and every K iterations the step-size is shrunk by a factor of $1/2$.

Algorithm 1 RSR by Geodesic Gradient Descent (GGD)

1: **Input:** dataset $\mathcal{X}$, subspace dimension d, initial step-size s, tolerance τ, constant step interval length K
2: **Output:** $\boldsymbol{V}^* \in O(D, d)$, whose columns span the robust subspace
3: $\boldsymbol{V}^1 = PCA(\boldsymbol{X}, d)$
4: $k = 1$, $s = 1$
5: **while** $\theta_1(\boldsymbol{V}^k, \boldsymbol{V}^{k-1}) > \tau$ or $k = 1$ **do**
6: Compute $\nabla F(\boldsymbol{V}^k; \mathcal{X})$ by (6) and (8)
7: Compute the SVD $\boldsymbol{U}^k\boldsymbol{\Sigma}^k\boldsymbol{W}^k = -\nabla F(\boldsymbol{V}^k; \mathcal{X})$
8: $s^k = s/2^{\lfloor k/K \rfloor}$
9: $\boldsymbol{V}^{k+1} = \boldsymbol{V}^k\boldsymbol{W}^k\cos(\boldsymbol{\Sigma}^k s^k)\boldsymbol{W}^{kT} + \boldsymbol{U}^k\sin(\boldsymbol{\Sigma}^k s^k)\boldsymbol{W}^{kT}$ ▷ (22)
10: $k = k + 1$
11: **end while**

The next section provides convergence guarantees for GGD with both the piecewise constant step-size of Algorithm 1 and with step-size $s/\sqrt{k}$. We later compare these two examples of step-size on a simulated dataset in Figure 6. The factor of $1/2$ in line 8 is called the shrink-factor and could be chosen to be any fraction. Later, in our experiments, we display the convergence properties of GGD with two choices of this factor.

4.2. Local Convergence of GGD Under Stability

In this section, we give convergence guarantees for GGD. Theorem 3 shows that the convergence is sublinear under the deterministic conditions of Theorem 1 for step-size $t^k = s/\sqrt{k}$. Then, Theorem 4 shows that the convergence of Algorithm 1 is linear under a slightly stronger assumption. These results are all for the noiseless RSR setting. However, all of these results can be extended to the noisy RSR setting in a simple fashion using the notions described in Section 3.1.2.

As a reminder, Theorem 1 implies that if $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ in the noiseless RSR setting then L_* is the only limit point in $B(L_*, \gamma)$ for GGD. In other words, there is no need to worry about saddle points or non-optimal critical points in this neighborhood of L_*. In the following theorem, we give a general sublinear convergence bound for GGD in the local neighborhood considered in Theorem 1. This implies that the algorithm can exactly recover the underlying subspace in the noiseless RSR problem. The step-size used in this theorem is $t^k = s/\sqrt{k}$ at iteration k instead of the piecewise constant scheme seen in Algorithm 1. The proof of this theorem is left to Appendix D.2.

Theorem 3 (Noiseless Sublinear Convergence) *Suppose that $\mathcal{X}$ is an inlier-outlier dataset with an underlying subspace L_*. Suppose also that there exists $0 < \gamma < \pi/2$ such that $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ and that the initial GGD iterate is $\boldsymbol{V}^1 \in B(L_*, \gamma)$. Then, for sufficiently small s as input (which may depend on $\mathcal{S}(\mathcal{X}, L_*, \gamma)$, d, D, N_{in}, and N_{out}), modified GGD with $t^k = s/\sqrt{k}$ converges to L_* with rate $\theta_1(L_k, L_*) < C/\sqrt{k}$, for some constant C.*

While the rate $O(1/\sqrt{k})$ matches typical results in non-smooth optimization, faster convergence is desirable. With the piecewise constant step-size given in Algorithm 1 and a further deterministic condition, GGD linearly converges to the underlying subspace L_*.

Theorem 4 (Noiseless Linear Convergence) *Suppose that $\mathcal{X}$ is an inlier-outlier dataset with an underlying subspace L_*. Suppose also that there exists $0 < \gamma < \pi/2$ such that $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ and that the initial GGD iterate is $\boldsymbol{V}^1 \in B(L_*, \gamma)$. Assume further that*

$$\inf_{L \in B(L_*,\gamma)\setminus\{L_*\}} \frac{1}{4}\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right| > \sup_{L\in B(L_*,\gamma)\setminus\{L_*\}} \sum_{\mathcal{X}\cap L} 2\|\boldsymbol{x}_i\|, \tag{23}$$

where $L(t)$ is a geodesic parameterized by arclength from L through L_*. Then, for sufficiently large K and sufficiently small s as input (which may depend on $\mathcal{S}(\mathcal{X}, L_*, \gamma)$, d, D, N_{in}, and N_{out}), the sequence generated by Algorithm 1 converges linearly to L_*.

Remark 5 *As mentioned earlier, Theorems 3 and 4 can also be extended to the noisy RSR setting with more complicated statements. Indeed, these extensions follow the same ideas as Theorem 2 (which extends Theorem 1 to the noisy RSR setting).*

We remark that the restriction in (23) can be weakened, although it results in a more complicated theorem statement: for clarity, we show the simpler version in the theorem statement. We refer to (23) as the strong gradient condition. In general, the sum in the right hand side of (23) only contains a few points when the inliers and outliers are not too linearly dependent. For example, consider the case of inliers lying in general position within the subspace and outliers lying in general position. This is the case if all D-subsets of $\mathcal{X}_{\text{out}}$ are linearly independent and all d-subsets of $\mathcal{X}_{\text{in}}$ are linearly independent. Under this assumption, the right hand side contains less than $2(d-1)$ points. On the other hand, the left hand side may be sufficiently large for a wide range of statistical models of data. For more interpretation of this condition for a specific model of data, we point the reader to Lemma 20, where we demonstrate a simple way in which the condition might hold.

We are not able to give an explicit bound on the rate of convergence factor, which depends on certain statistical characteristics of the data. While we do not currently have estimates of this factor and it may depend on N, D, and d, we expect this dependence to not be too bad, especially based on our numerical experiments.

Proof [Proof of Theorem 4] The proof of this theorem is a consequence of the following lemmas. The proof of these lemmas is deferred to Appendix D.3.

The first lemma locally bounds above the increase in cost around L_*.

Lemma 6 *If $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$, then*

$$F(L;\mathcal{X}) - F(L_*;\mathcal{X}) < 2\theta_1(L, L_*)\sum_{\mathcal{X}_{\text{in}}} \|\boldsymbol{x}_i\|, \ \forall L \in B(L_*, \gamma). \tag{24}$$

Notice that $\theta_1(L, L_*)$ is a measure of distance between L and L_*. The next lemma bounds the magnitude of the gradient in $B(L_*, \gamma) \setminus L_*$.

Lemma 7 *If $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$, then, for some $C_1 > 0$ (that depends on the data),*

$$\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right| > C_1 \sum_{\mathcal{X}_{\text{in}}} \|\boldsymbol{x}_i\|, \ \forall L \in B(L_*, \gamma) \setminus L_*, \tag{25}$$

where $L(t)$ is a geodesic parameterized by arclength from L through L_*.

Finally, the third lemma bounds the decrease in cost between consecutive iterates.

Lemma 8 *If $L_k \in B(L_*, \gamma)$ and (23) holds, then there exists $c_0 > 0$ such that for each step-size choice $t^k = c\theta_1(L_k, L_*)$ with $c < c_0$,*

$$F(L_k) - F(L_{k+1})) \geq \frac{c\theta_1(L_k, L_*)}{2}\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right|, \tag{26}$$

where $L(t)$ is a geodesic parameterized by arclength from L_k through L_*.

Choosing the step-size $t^k = c\theta_1(L_k, L_*)$, with c coming from Lemma 8, and combining the results of Lemmas 6, 7 and 8, we find that

$$\begin{aligned} F(L_{k+1};\mathcal{X}) - F(L_*;\mathcal{X}) &< F(L_k;\mathcal{X}) - F(L_*;\mathcal{X}) - \frac{c\theta_1(L_k, L_*)}{2}\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right| \\ &\leq F(L_k;\mathcal{X}) - F(L_*;\mathcal{X}) - \frac{C_1}{2}c\theta_1(L_k, L_*)\left(\sum_{\mathcal{X}_{\text{in}}}\|\boldsymbol{x}_i\|\right) \\ &\leq F(L_k;\mathcal{X}) - F(L_*;\mathcal{X}) - \frac{C_1 c}{4}\left(F(L_k;\mathcal{X}) - F(L_*;\mathcal{X})\right) \\ &\leq (1 - C_2)(F(L_k;\mathcal{X}) - F(L_*;\mathcal{X})), \end{aligned} \tag{27}$$

where $0 < C_2 < 1$. Here, $(1 - C_2)$ is the rate of convergence factor, which depends on d. Thus, if one could choose the step-size $t^k = c\theta_1(L_k, L_*)$, then the sequence of costs $F(L_k;\mathcal{X})$ would converge linearly to $F(L_*;\mathcal{X})$.

For all $L \in B(L_*, \gamma) \setminus \{L_*\}$, letting $a = \theta_1(L, L_*)$, we find that

$$\begin{aligned} F(L;\mathcal{X}) - F(L_*;\mathcal{X}) &= \int_{t=0}^{a} \frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})\mathrm{d}t \geq a \inf_{L'\in B(L_*,\gamma)}\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L'(t);\mathcal{X})\right| \\ &\geq a\mathcal{S}(\mathcal{X}, L_*, \gamma), \end{aligned} \tag{28}$$

where $L(t)$ is the geodesic parameterized by arclength from L_* through L and $L'(t)$ is the geodesic parameterized by arclength from L_* through L'. The last inequality follows from the argument in Theorem 1, and in particular from (20). Thus, for $C_3 = 1/\mathcal{S}(\mathcal{X}, L_*, \gamma)$, where $0 < C_3 < \infty$, (28) implies that

$$\theta_1(L_{k+1}, L_*) \leq C_3(F(L_{k+1};\mathcal{X}) - F(L_*;\mathcal{X})). \tag{29}$$

This means that linear convergence of the energy sequence, $(F(L_k;\mathcal{X}))_{k\in\mathbb{N}}$, gives linear convergence of the iterates, $(L_k)_{k\in\mathbb{N}}$.

So far, we have shown that there exists a c such that choosing step-size $t^k = c\theta_1(L_k, L_*)$ leads to linear convergence of L_k to L_*. However, this choice of step-size is purely theoretical, since in practice we would not know $\theta_1(L_k, L_*)$ at each iteration. We must now rectify this choice of step-size with that used in Algorithm 1.

Suppose a constant step-size s and a constant c satisfying the above argument. Then, the sequence $(L_k)_{k\in\mathbb{N}}$ at least converges linearly to an element of the set $B(L_*, s/c)$ because (27) holds as long as $t^k = s < c\theta_1(L_k, L_*)$. If instead the constant step-size is $s/2$, we will get

linear convergence to an element of the set $B(L_*, s/2c)$, albeit at a slower rate. Notice that, at each shrinking step (i.e., switching to step-size $s/2$ from s), if the sequence has already reached $B(L_*, s/c)$, we can bound the rate of convergence factor $(1 - C_2)$ by

$$\left(1 - \frac{s/2}{c\theta_1(L_k, L_*)}\frac{C_1 c}{4}\right) \leq \left(1 - \frac{C_1 c}{8}\right). \tag{30}$$

Further, for all subsequent steps where $s/2 < c\theta_1(L_k, L_*)$, we have that the rate of convergence factor is strictly less than $1 - C_1 c/(8\sqrt{d}(d+1))$. Thus, as long as the time between shrinking is large enough, we are guaranteed to have linear convergence. If the first step-size is allowed to run long enough, we find that the number of steps m between shrinking needs to be at most

$$\left(1 - \frac{C_1 c}{8}\right)^m < \frac{1}{2}.$$

■

4.3. Complete Guarantee with PCA Initialization

Notice that the previous section does not give a complete guarantee because the results are local. In other words, they assume that we first initialize in $B(L_*, \gamma)$ and then run GGD. To make these results practical, we will show that it is possible to initialize in this neighborhood under a simple deterministic condition. As before with Theorems 3 and 4, we consider only the noiseless RSR setting here. Extensions to the noisy case do not require much more effort.

The result of this section shows that PCA initializes in $B(L_*, \gamma)$ under a similar deterministic condition to $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$. This is quantified in the following lemma.

Lemma 9 *Suppose that, for a noiseless inlier-outlier dataset,*

$$\sqrt{2}\sin(\gamma)\lambda_d(\boldsymbol{X}_{\text{in}}\boldsymbol{X}_{\text{in}}^T) - \|\boldsymbol{X}_{\text{out}}\|_2^2 > 0. \tag{31}$$

Then, $L_{PCA} \in B(L_*, \gamma)$.

Proof The proof of this lemma is a direct consequence of the Davis-Kahan $\sin\theta$ Theorem (Davis and Kahan, 1970), which has a nice formulation in Vu et al. (2013). Let $L_* \in G(D, d)$ span the principal d-subspace of $\boldsymbol{X}_{\text{in}}\boldsymbol{X}_{\text{in}}^T$ and $L_{PCA} \in G(D, d)$ span the principal d-subspace of $\boldsymbol{X}_{\text{out}}\boldsymbol{X}_{\text{out}}^T + \boldsymbol{X}_{\text{in}}\boldsymbol{X}_{\text{in}}^T$. Then, applying Corollary 3.1 of Vu et al. (2013) to these matrices yields

$$|\sin(\theta_1(L_*, L_{PCA}))| \leq \sqrt{2}\frac{\|\boldsymbol{X}_{\text{out}}\|^2}{\lambda_d(\boldsymbol{X}_{\text{in}}\boldsymbol{X}_{\text{in}}^T)}. \tag{32}$$

Thus, if (31) holds, then we are guaranteed that

$$|\sin(\theta_1(L_*, L_{PCA}))| < |\sin(\gamma)|. \tag{33}$$

■

The condition required in (31) bears some nice similarity to the earlier condition of Theorems 1 and 3, $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$. Here the first term in (31) is like the inlier permeance and the second term is like the outlier alignment.

In summary, if both of the conditions $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ and (31) hold, then GGD with step-size $s/\sqrt{k}$ exactly recovers L_* with convergence rate $O(1/\sqrt{k})$. If we additionally have that (23) holds, then GGD with the step-size in Algorithm 1 linearly converges to L_*.

5. Guarantees for Specific Statistical Models

In this section, we discuss some statistical models of data and determine when they satisfy the assumptions of our theorems. These models are meant to illustrate that our conditions are satisfied in a wide range of RSR examples, and they begin to explore the recovery limits of our algorithm. These results should provide some useful context and lead to easier interpretation of the general conditions given in Section 3 and Section 4.

The main idea behind the study of statistical models of data is to compare the theoretical guarantees of various algorithms with a given choice of metric. A natural metric for this purpose is the signal to noise ratio (SNR). The SNR is the ratio of inliers to outliers, $N_{\text{in}}/N_{\text{out}}$, and we are interested in the minimal SNR that allows exact (or sufficiently near) recovery of an RSR algorithm under a given set of assumptions on the data. In other words, under further assumptions on the data generating model, we want to derive a more interpretable condition than $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$.

Due to the properties of these models, different SNR bounds may arise for different regimes of sample size. A first common small sample regime assumes that $N = O(D)$, where the SNR bounds are usually higher to account for the increased variation in the data. Another regime of slightly larger samples is obtained when $N = O(D^p)$ and $p > 1$ is sufficiently small. Under some special statistical models, the SNR may decrease as p increases. That is, a larger fraction of outliers can be tolerated with larger orders of sample size. A third regime uses very large, and possibly arbitrarily large, N. We refer to the SNR bound of this third case as the very large N regime. Under some very special models of data, the SNR bound can go to zero in this regime as the sample size increases. However, in this case, the sample size must depend on the SNR itself.

In the following, not only will we show almost state-of-the-art results for GGD on the Haystack Model of Lerman et al. (2015), but we will also demonstrate how our convergence theorem holds for other more general models of data. This is an important step towards understanding how RSR algorithms perform outside of the simple Haystack Model. The general statistical models considered below assume that the inliers and outliers are sampled from probability distributions that obey certain assumptions. These models are the following:

- Assumptions on the outliers:
  - Bounded support distributions
  - Sub-Gaussian distributions
- Assumptions on the inliers:

– Continuous, bounded support distributions
– Sub-Gaussian distributions

In each of these cases, the inliers and outliers will be assumed to be i.i.d. samples from the given distributions. The precise definition of each of these distributions will be given later.

In Section 5.1, we bound the alignment of outliers under the above outlier models. Then, in Section 5.2, we bound the permeance of inliers under the above inlier models. The goal of these first two subsections is to understand how each part of $\mathcal{S}(\mathcal{X}, L_*, \gamma)$ behaves on its own. After this, in Section 5.3 we prove that $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ under certain conditions on these models of inliers and outliers. Next, we show in Section 5.4 that PCA can initialize in $B(L_*, \gamma)$ in a wide range of cases. Then, Section 5.5 gives an in depth discussion of the Haystack Model, where we show that GGD with step-size $s/\sqrt{k}$ has almost state-of-the-art guarantees. The discussion considers the previously mentioned three regimes of sample size. Finally, Section 5.6 gives an idea of how statistical models can also ensure that the strong gradient condition in Theorem 4 holds, which gives more evidence that the method may converge linearly in practice.

5.1. Outlier Distributions with Restricted Alignment

We explain the two assumptions on outliers listed above, which lead to bounds on the alignment. We first discuss bounded distributions in Section 5.1.1 and then discuss sub-Gaussian distributions in Section 5.1.2.

5.1.1. Bounded Support Distributions

We consider the case of outliers drawn from a distribution with bounded support. This assumption is needed because our bound on the alignment scales like the spectral norm of $\boldsymbol{X}_{\text{out}}$, which can be very large for even a single large outlier. An outlier distribution of this type has the form

$$\mathcal{X}_{\text{out}} \sim \mu, \ \mu(\mathbb{R}^D \setminus B(\boldsymbol{0}, M)) = 0, \tag{34}$$

where μ represents the probability measure and M is a uniform bound on the magnitude of the outliers. In this case, we have the worst-case bound

$$\|\boldsymbol{X}_{\text{out}}\|_2 < M\sqrt{N_{\text{out}}}. \tag{35}$$

In the special case where $\mathcal{X}_{\text{out}} \sim \text{Unif}(B(\boldsymbol{0}, M))$, the following bound was provided in Lemma 8.4 of Lerman et al. (2015):

$$\|\boldsymbol{X}_{\text{out}}\|_2 \leq M\left(\sqrt{\frac{N_{\text{out}}}{D-0.5}} + \sqrt{2} + \frac{t}{\sqrt{D-0.5}}\right), \text{ w.p. at least } 1 - 1.5e^{-t^2}. \tag{36}$$

We remark that (35) holds under any sampling from a bounded distribution and (36) holds under i.i.d. sampling of a special distribution.

From these bounds and (11), we get a sense of how the alignment scales for different types of outliers. When outliers are more adversarial but still bounded, the alignment scales like $O(N_{\text{out}})$. On the other hand, when outliers have the special distribution $\text{Unif}(B(\boldsymbol{0}, M))$, we can bound the alignment by $N_{\text{out}}/\sqrt{D}$. Later, in Theorem 17, we show how to improve this to $O(N_{\text{out}}/\sqrt{D(D-d)})$, due to the fact that the bound in (11) is not tight.

5.1.2. Sub-Gaussian Distributions

Rather than assume that the outliers are bounded, we can instead assume they come from a sub-Gaussian distribution. In this case, we have the following lemma.

Lemma 10 *Suppose that the outliers follow a sub-Gaussian distribution with covariance $\boldsymbol{\Sigma}_{\text{out}}/D_{\text{out}}$, which has rank D_{out}. Then,*

$$\|\boldsymbol{X}_{\text{out}}\|_2 \leq \left\|\boldsymbol{\Sigma}_{\text{out}}^{1/2}\right\|_2 \left(2\frac{\sqrt{N_{\text{out}}}}{\sqrt{D_{\text{out}}}} + C\right), \tag{37}$$

with probability at least $1 - e^{-cN_{\text{out}}}$. Here, c and C depend on the sub-Gaussian norm of $\boldsymbol{\Sigma}_{\text{out}}^{-1/2}\boldsymbol{x}$, where $\boldsymbol{x}$ follows the outlier distribution.

Proof Note that the transformed data, $\boldsymbol{\Sigma}_{\text{out}}^{-1/2}\boldsymbol{X}_{\text{out}}$, is isometric. Therefore, we bound the spectral norm of the outliers by

$$\|\boldsymbol{X}_{\text{out}}\|_2 = \|\boldsymbol{\Sigma}_{\text{out}}^{1/2}\boldsymbol{\Sigma}_{\text{out}}^{-1/2}\boldsymbol{X}_{\text{out}}\|_2 \leq \|\boldsymbol{\Sigma}_{\text{out}}^{1/2}\|_2\|\boldsymbol{\Sigma}_{\text{out}}^{-1/2}\boldsymbol{X}_{\text{out}}\|_2.$$

We can apply Theorem 5.39 of Vershynin (2012b) to the last term in this inequality. This yields the bound in (37). ■

5.2. Permeating Inlier Distributions

We will look at two assumptions that yield permeance of inliers. First, Section 5.2.1 examines continuous distribution inliers, and then Section 5.2.2 looks at sub-Gaussian inliers.

5.2.1. Bounded Continuous Inlier Distributions

An i.i.d. sample from a distribution with a continuous density lies in general position with probability 1. In the case of a continuous distribution on a subspace L_*, this means that no d-subset of them lies on a $d-1$-dimensional subspace. Some slightly stronger assumptions are also needed to easily prove that the inlier permeance has a nontrivial lower bound, which includes the distribution having bounded support, although other assumptions could be used. We will refer to these distributions as bounded continuous distributions. The proof of this proposition is given in Appendix D.4.1.

Proposition 11 *Suppose that the inliers are sampled from a distribution that has a continuous density with respect to the uniform measure on L_*. Suppose further that this distribution has mean zero and has support contained in $B(\boldsymbol{0}, M) \cap L_*$, for some constant M. Then,*

$$\mathcal{P}(\mathcal{X}_{\text{in}}) \gtrsim \frac{N_{\text{in}}}{M} \min_{\boldsymbol{v} \in L_* \cap S^{D-1}} \text{Var}(\boldsymbol{v}^T\boldsymbol{x}), \ \textit{w.h.p.} \tag{38}$$

Here, the probability goes to 1 and the permeance goes to ∞ as $N_{\text{in}} \to \infty$.

5.2.2. Sub-Gaussian Inlier Distributions

We show how the assumption of a sub-Gaussian distribution provides a lower bound for the permeance of inliers. The proof of this theorem is given in Appendix D.4.2.

Proposition 12 *Suppose that inliers are sampled i.i.d. from a sub-Gaussian distribution with covariance $\mathbf{\Sigma}_{\text{in}}/d$, which has rank d. Then, for $0 < a < 1$ satisfying $(1-a)^2 N_{\text{in}} > C_1^2 d$,*

$$\mathcal{P}(\mathcal{X}_{\text{in}}) \geq \frac{\lambda_d(\mathbf{\Sigma}_{\text{in}})}{\lambda_1(\mathbf{\Sigma}_{\text{in}})^{1/2}}(1-a)^2\frac{N_{\text{in}}}{d} + O\left(\sqrt{\frac{N_{\text{in}}}{d}}\right), \text{ w.p. at least } 1 - 4e^{-c_1 a^2 N_{\text{in}}}. \tag{39}$$

Here, c_1 and C_1 are constants that depend on the sub-Gaussian norms of $\mathbf{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}$ and $\widehat{\mathbf{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}}$, where $\boldsymbol{x}$ is a random vector that follows the inlier distribution.

Notice that the choice of a here affects both the bound and the probability. One could, in principal, choose $a = N^{-1/2+\epsilon}$ for some constant $\epsilon > 0$ and still achieve an overwhelming probability bound.

5.3. Combining Statistical Models to Enforce $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$

In this section, we explicitly compare the permeance and alignment bounds for these statistical models of data to see when we can expect to have $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$, which is the essential assumption in Theorems 1 and 3. Together with the result of the next section on PCA initialization, this implies that GGD exactly recovers L_* provided that the SNR is appropriately bounded from below in these models. First, Section 5.3.1 will look at the case of bounded outliers and bounded continuous inliers. Then, Section 5.3.2 will discuss the case of sub-Gaussian inliers and outliers in what we call the Generalized Haystack Model.

5.3.1. Bounded Outliers and Bounded Continuous Inliers

Under the assumption of bounded outliers and bounded continuous inliers, we can guarantee $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ for large enough SNR and sample sizes. This results in the following proposition.

Proposition 13 (Stability with Bounded Outliers and Continuous Bounded Inliers) *Suppose that the outliers follow a bounded distribution and the inliers follow a mean zero, bounded distribution with continuous density on L_*. Then, for a fixed parameter $0 < \gamma < \pi/2$, $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ w.h.p. for sufficiently large SNR and N.*

Proof First, the result of Proposition 11 bounds the permeance of inliers. On the other hand, the outliers follow a bounded distribution. This implies that

$$\max_{L \in G(D,d)} \mathcal{A}(\mathcal{X}, L) \leq M N_{\text{out}}. \tag{40}$$

Thus, comparing (38) and (40), for both $N_{\text{in}}/N_{\text{out}}$ and N sufficiently large, $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ w.h.p. ■

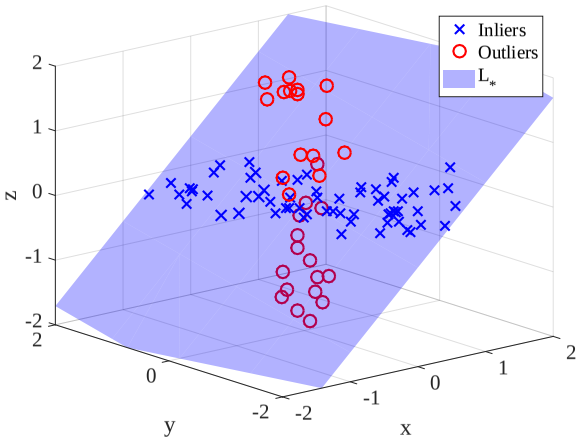

Figure 4: Example dataset drawn from a Generalized Haystack Model, where $d = 2$, $D = 3$, $N_{\text{in}} = 100$, and $N_{\text{out}} = 40$. Here, L_* is a random 2-dimensional subspace. Inliers are sampled i.i.d. from a normal distribution supported on L_* that has variance 4 and 0.09 in its principal directions. The outliers are sampled i.i.d. from a normal distribution with covariance $\mathbf{\Sigma}_{\text{out}} = \text{diag}(.04, .04, 2.25)$.

5.3.2. The Generalized Haystack Model: sub-Gaussian Inliers and Outliers

Next, we propose the Generalized Haystack Model as a special case of sub-Gaussian inliers and outliers. Fix a positive diagonal matrix $\mathbf{\Lambda}_{\text{in}} \in \mathbb{R}^{d\times d}$ and $\boldsymbol{V}^* \in O(D,d)$, which spans $L_* \in G(D,d)$. Letting $\mathbf{\Sigma}_{\text{in}} = \boldsymbol{V}^* \mathbf{\Lambda}_{\text{in}} \boldsymbol{V}^{*T}$, we assume that N_{in} inliers are i.i.d. sampled from a sub-Gaussian distribution with covariance $\mathbf{\Sigma}_{\text{in}}/d$. Fix a symmetric positive semi-definite matrix $\mathbf{\Sigma}_{\text{out}} \in \mathbb{R}^{D\times D}$ and assume N_{out} outliers are i.i.d. sampled from a sub-Gaussian distribution with covariance $\mathbf{\Sigma}_{\text{out}}/D_{\text{out}}$, where D_{out} is the rank of $\mathbf{\Sigma}_{\text{out}}$. This specifies a Generalized Haystack Model with parameters N_{in}, $\mathbf{\Sigma}_{\text{in}}$, N_{out}, $\mathbf{\Sigma}_{\text{out}}$, D_{out}, and d. An example dataset drawn from a Generalized Haystack Model is given in Figure 4. This model generalizes the Haystack Model, which was proposed by Lerman et al. (2015) as a simple model with spherically symmetric Gaussian distributions of inliers and outliers. In the latter model, inliers are distributed i.i.d. $\mathcal{N}(\mathbf{0}, \sigma_{\text{in}}^2 \boldsymbol{P}_{L_*}/d)$, and outliers are distributed i.i.d. $\mathcal{N}(\mathbf{0}, \sigma_{\text{out}}^2 \boldsymbol{I}/D)$. This defines the Haystack Model with parameters N_{in}, σ_{in}, N_{out}, σ_{out}, D and d.

We can combine the previous results on sub-Gaussian inliers and outliers to yield a theoretical guarantee. We show that, under certain conditions on the Generalized Haystack Model, $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ with overwhelming probability.

Theorem 14 (Stability of the Generalized Haystack Model) *Suppose that the dataset $\mathcal{X}$ follows the Generalized Haystack Model with parameters N_{in}, $\mathbf{\Sigma}_{\text{in}}$, N_{out}, $\mathbf{\Sigma}_{\text{out}}$, D_{out}, and*

d. Suppose also that $0 < \gamma < \pi/2$ *and*

$$\mathrm{SNR} > \frac{1}{\cos(\gamma)} \frac{\lambda_1(\mathbf{\Sigma}_{\mathrm{in}})^{1/2}}{\lambda_d(\mathbf{\Sigma}_{\mathrm{in}})} \lambda_1(\mathbf{\Sigma}_{\mathrm{out}}^{1/2}) \frac{2}{(1-a)^2} \frac{d}{\sqrt{D_{\mathrm{out}}}} + o(1). \tag{41}$$

Then $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ *with probability at least* $1 - 4e^{-c_1 a^2 N_{\mathrm{in}}} - 2e^{-c_2 N_{\mathrm{out}}}$*, provided that* $(1-a)^2 N_{\mathrm{in}} > C_1^2 d$*, where* c_1*,* c_2 *and* C_1 *are constants depending on the sub-Gaussian norms of the inliers and outliers.*

Proof It is left to compare the bounds derived earlier in Lemma 10 and Proposition 12. Notice that (41) can be obtained by requiring the right hand side of (37) to be less than $\cos(\gamma)$ times the right hand side of (39). This results in precisely the statement in the theorem. ■

Scaling the inlier and outlier covariance matrices by d and D_{out}, respectively, ensures that in the spherically symmetric case (where $\mathbf{\Sigma}_{\mathrm{in}}$ and $\mathbf{\Sigma}_{\mathrm{out}}$ are orthogonal projections onto subspaces of $\mathbb{R}^D$ of dimensions d and D_{out} respectively) the inliers and outliers have the same typical length. Thus, with this normalization, differences in the traces of $\mathbf{\Sigma}_{\mathrm{in}}$ and $\mathbf{\Sigma}_{\mathrm{out}}$ translate into differences in typical scale between inliers and outliers. We emphasize that it is important to prove results for general sub-Gaussian distributions rather than just spherically symmetric Gaussians. This is due to the fact that simpler strategies, like running PCA and then filtering points far from the PCA subspace, can be applied to the symmetric case with great success. The Generalized Haystack Model allows for certain adversarial outliers: for example, outliers can be contained in a low-dimensional subspace as well. Nevertheless, since the Haystack Model has been addressed by several previous works and since it is easy to improve our estimates for it, we address it in Section 5.5.

5.4. PCA Initialization

The discussed models can also guarantee good initialization by PCA. This is an essential ingredient to actually have a practical algorithm. We demonstrate this on the specific case of the Generalized Haystack Model. However, this sort of argument can be extended to the other types of models discussed above as well (such as bounded distributions of outliers and bounded continuous inliers).

We must have a lower bound on the SNR that depends on the parameters of the sub-Gaussian distributions in order for the following proposition to hold. A short proof for this proposition is given in Appendix D.5. It essentially states that Lemma 9 holds with high probability under certain conditions on the Generalized Haystack Model.

Proposition 15 (PCA Initialization with Sub-Gaussian Models) *Suppose that the dataset* $\mathcal{X}$ *follows the Generalized Haystack Model with parameters* N_{in}*,* $\mathbf{\Sigma}_{\mathrm{in}}$*,* N_{out}*,* $\mathbf{\Sigma}_{\mathrm{out}}$*,* D_{out}*, and* d*. Suppose also that, for some* $0 < \gamma < \pi/2$*,*

$$\mathrm{SNR} \geq \frac{\sqrt{2}}{\sin(\gamma)} \frac{d}{D_{\mathrm{out}}} \frac{\lambda_1(\mathbf{\Sigma}_{\mathrm{out}})}{\lambda_d(\mathbf{\Sigma}_{\mathrm{in}})} + o(1). \tag{42}$$

Then, for large enough $N = N_{\mathrm{out}} + N_{\mathrm{in}}$*, the PCA* d*-subspace is contained in* $B(L_*, \gamma)$ *w.h.p.*

5.5. Performance of GGD Under the Haystack Model

We assume here the simpler Haystack Model and show that GGD performs almost as well as state-of-the-art methods on datasets drawn from this model. We compute results for three different regimes of sample size. These are the small sample regime $N = O(D)$, the larger sample regime $N = O(D^p)$, for $p > 1$ sufficiently small, and the very large N regime, where N must depend on the SNR as well. In the larger sample regime, GGD requires at least $N = O(d(D-d)^2 \log(D))$, which is not more than $N = O(D^{3+\epsilon})$. In the very large N regime, in addition to dependence of N on a power of D, it also depends on a negative power of the SNR and thus is very large for small SNR. In our case, the very large N regime considers sample sizes of the order $N_{\mathrm{out}} = O(\max(d^3 D^3 \log^3(N_{\mathrm{out}}), (dN_{\mathrm{out}}/N_{\mathrm{in}})^6))$. The big O notation is slightly abused here, as we are really indicating results for finite N and D: the order is meant to illustrate the relation between these finite values. We compare all of these results together in Table 1.

5.5.1. Bounds for Sample Size $N = O(D)$

We first translate the bounds obtained previously in Theorem 14 to this special model. We choose $a = 1/2$ and thus obtain the following corollary:

Corollary 16 *Suppose that the dataset* $\mathcal{X}$ *follows the Haystack Model with parameters* N_{in}*,* σ_{in}*,* N_{out}*,* σ_{out}*,* D*, and* d*. Then, if* $N_{\mathrm{in}} > 4C_1^2 d$ *and*

$$\mathrm{SNR} \geq 8 \frac{1}{\cos(\gamma)} \frac{\sigma_{\mathrm{out}}}{\sigma_{\mathrm{in}}} \frac{d}{\sqrt{D}} + o(1), \tag{43}$$

$\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ *with probability at least* $1 - 4e^{-c_1 N_{\mathrm{in}}/4} - 2e^{-c_2 N_{\mathrm{out}}}$*, where* c_1*,* c_2 *and* C_1 *are absolute constants.*

Notice that in this case, we obtain strong probabilistic estimates for even small sample sizes of $N = O(D)$. For the full theoretical guarantee, we also need to consider (42), and we must choose a value for γ. To balance between the $\sin(\gamma)$ and $\cos(\gamma)$ in (42) and (43), respectively, we fix $\gamma = \pi/4$. From these equations, for this fixed γ, we conclude that our theoretical SNR for the Haystack Model in the small sample regime is

$$\mathrm{SNR} \geq \max\left(8\sqrt{2}\frac{\sigma_{\mathrm{out}}}{\sigma_{\mathrm{in}}}\frac{d}{\sqrt{D}}, 2\frac{\sigma_{\mathrm{out}}^2}{\sigma_{\mathrm{in}}^2}\frac{d}{D}\right). \tag{44}$$

On the other hand, previous works (Hardt and Moitra, 2013; Lerman et al., 2015; Zhang, 2016) obtained optimal bounds for this model when $N = O(D)$ and the SNR is on the order of

$$\mathrm{SNR} \gtrsim \frac{\sigma_{\mathrm{out}}}{\sigma_{\mathrm{in}}} \frac{d}{(D-d)}. \tag{45}$$

We remark that the bound of Lerman et al. (2015) for the REAPER algorithm requires the assumption $d < (D-1)/2$ and its constant is relatively large. This is in contrast to Hardt and Moitra (2013) and Zhang (2016), who do not have restrictions on d and do not have dependence on $\sigma_{\mathrm{out}}/\sigma_{\mathrm{in}}$. In this regime, we are unable to establish sharp results like the ones of REAPER, Tyler's M-estimator, or RandomizedFind. These estimates are

better by a factor of $\sqrt{D}/(D-d)$ than our current estimate. Nevertheless, in this regime the complexity of our algorithm is $O(NDd)$, whereas the complexity of the mentioned algorithms is $O(ND^2)$ or $O(D^3)$.

5.5.2. Bounds for Sample Size $N = O(d(D-d)^2 \log(D))$

Zhang and Lerman (2014) obtained the following sharper bound for the GMS algorithm under the Haystack Model and the larger sample regime of $N = O(D^2)$:

$$\text{SNR} \gtrsim \frac{\sigma_{\text{out}}}{\sigma_{\text{in}}} \frac{d}{\sqrt{D(D-d)}}. \tag{46}$$

We remark that this is the sharpest bound for any similar sample regime under this model when $\sigma_{\text{out}} \approx \sigma_{\text{in}}$. While the bounds mentioned above (Hardt and Moitra, 2013; Lerman et al., 2015; Zhang, 2016) hold for any regime of sample size, they are worse by a factor of $\sqrt{D/(D-d)}$. We show that a similar bound in a similar regime holds for the GGD algorithm. Indeed, the primary deficiency in Corollary 16 is that we use the loose bound on the alignment, $\sqrt{N_{\text{out}}}\|\boldsymbol{X}_{\text{out}}\|_2$. However, one could instead operate using the precursor to this bound,

$$\mathcal{A}(\mathcal{X}_{\text{out}}, L) \leq \|\widetilde{\boldsymbol{Q}_L \boldsymbol{X}_{\text{out}}}\|_2 \|\boldsymbol{X}_{\text{out}}\|_2. \tag{47}$$

Using this bound instead, we have the following theorem, which shows that GGD achieves the optimal SNR bound under the Haystack Model in the region $N = O(d\,(D-d)^2\,\log(D))$, which is at worst $O(D^3 \log D)$.

Theorem 17 (Stability of the Haystack Model) *Suppose that the dataset $\mathcal{X}$ follows the Haystack Model with parameters N_{in}, σ_{in}, N_{out}, σ_{out}, D, and d. If*

$$\text{SNR} \geq \frac{\sigma_{\text{in}}}{\sigma_{\text{out}}} \frac{1}{\cos(\gamma)} \frac{5}{(1-a)^2} \frac{d}{\sqrt{D(D-d)}} + o(1), \tag{48}$$

then $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ with probability at least

$$1 - 2e^{-N_{\text{out}}/16} - e^{-N_{\text{out}}/4} - C_1 \exp\left(-\frac{N_{\text{out}}}{4(D-d)} + \frac{d(D-d)}{2} \log\left(\frac{D}{D-d}\right)\right) - 4e^{-c_1 a^2 N_{\text{in}}}. \tag{49}$$

Here, we can take a close to 0 (e.g., we can take $a = o(N_{\text{in}}^{-1/2})$), and so we ignore the factor of $1/(1-a)^2$ in (48). The full theoretical guarantee, which also considers (42), is established similarly to (44). We conclude that our theoretical SNR bound for the Haystack Model in this regime is

$$\text{SNR} \geq \max\left(5\sqrt{2}\frac{\sigma_{\text{out}}}{\sigma_{\text{in}}} \frac{d}{\sqrt{D(D-d)}}, 2\frac{\sigma_{\text{out}}^2}{\sigma_{\text{in}}^2}\frac{d}{D}\right). \tag{50}$$

The final results for the two different regimes, that is, (44) and (50), are for $\gamma = \pi/4$ and initialization by PCA. As a side note, if the SNR grows, we see that larger values of γ may be tolerated for GGD. In particular, for large sample sizes and sufficiently large SNRs, γ can be sufficiently close to $\pi/2$. In this case, random initialization of GGD are expected

to work as well as the PCA initialization. We quantify this claim more rigorously in the special case where $d < D/2$ and $d, D \to \infty$. Based on the analysis of extreme singular values of random Gaussian matrices (Rudelson and Vershynin, 2008), it can be shown that with high probability, a random initialization lies in $B(L_*, \gamma) \setminus \{L_*\}$, where $\cos(\gamma) = O(1/\sqrt{Dd})$. Therefore, GGD with random initialization succeeds with high probability under the given assumptions on d and D when $N_{\text{in}}/N_{\text{out}} \geq O\left(d\sigma_{\text{out}}/\sigma_{\text{in}}\right)$.

5.5.3. Bounds for Very Large N

In the large sample regime, one can prove something much stronger. Indeed, for any fraction of outliers, it is obvious that PCA asymptotically recovers the underlying subspace L_* (Lerman and Maunu, 2018a). Further, it was shown that FMS can asymptotically recover L_* for any fraction of outliers with better dependence on the sample size than PCA (Lerman and Maunu, 2018a) (while the result given for FMS is for the spherized Haystack Model, the result can be extended to the non-spherized version as well). It would be very surprising if GGD could not do something similar.

In fact, this type of result can be extended to GGD as well, which means that, as $N \to \infty$, we can take SNR$\to 0$. However, while the PCA and FMS subspace estimators converge to the underlying subspace as $N \to \infty$, the probability of either exactly recovering the underlying subspace for any fixed N is zero. In contrast, GGD can exactly recover the underlying subspace with overwhelming probability for finite, yet large, N. This result is stated in the following theorem, which is proved in Appendix D.7.

Theorem 18 *Suppose that $\mathcal{X}$ follows the Haystack Model with parameters N_{in}, σ_{in}, N_{out}, σ_{out}, D, and d. For any* SNR *lower bound $\alpha > 0$ (i.e.,* SNR $> \alpha$*) and for any N_{out} at least $O(\max(d^3 D^3 \log^3(N_{\text{out}}), (dN_{\text{out}}/N_{\text{in}})^6))$, GGD recovers L_* w.o.p. In particular, N_{out} is at least $O(d/\alpha^6)$,*

For this theorem to hold, we see that N needs to be quite large, especially for low SNRs. However, note that we still obtain strong probabilistic bounds for large enough finite N. On the other hand, taking $\alpha \to 0$ in this theorem requires $N_{\text{out}} \to \infty$, which implies asymptotic recovery for GGD for any SNR in this model.

5.5.4. Comparison of all Haystack Model Results

We compare the lowest SNR guarantees for a variety of RSR algorithms under the Haystack Model. Table 1 replicates Table 1 of Lerman and Maunu (2018b) with updated estimates. It both compares lower bounds on SNR under the Haystack Model and also briefly describes the actual data model that each algorithm has guarantees for. The algorithms include geodesic gradient descent (GGD), FMS (Lerman and Maunu, 2018a), REAPER (Lerman et al., 2015), GMS (Zhang and Lerman, 2014), OP (Xu et al., 2012) and LLD (McCoy and Tropp, 2011), HR-PCA (Xu et al., 2013), Tyler's M-estimator (TME) (Zhang, 2016), TORP (Cherapanamjeri et al., 2017), CP (Rahmani and Atia, 2016), SSC (Soltanolkotabi and Candès, 2012), HOSC (Arias-Castro et al., 2011), RANSAC (Arias-Castro and Wang, 2017), and RF (Hardt and Moitra, 2013). For each SNR bound, we also give the associated sample size, N, for each result to begin holding with high probability. Again, we note that the big O notation is slightly abused here since the results are really for non-asymptotic N and D.

PCA	$N_{\text{in}}/N_{\text{out}}$ " $\gtrsim$ "0, when $N \to \infty$, D fixed *No exact recovery and poor estimates for finite N.*
GGD	$N_{\text{in}}/N_{\text{out}} \geq \max\left(8\sqrt{2}\frac{\sigma_{\text{out}}}{\sigma_{\text{in}}}\frac{d}{\sqrt{D}}, 2\frac{\sigma_{\text{out}}^2}{\sigma_{\text{in}}^2}\frac{d}{D}\right)$, when $N = O(D)$ $N_{\text{in}}/N_{\text{out}} \geq \max\left(5\sqrt{2}\frac{\sigma_{\text{out}}}{\sigma_{\text{in}}}\frac{d}{\sqrt{D(D-d)}}, 2\frac{\sigma_{\text{out}}^2}{\sigma_{\text{in}}^2}\frac{d}{D}\right)$, when $N = O(d(D-d)^2\log(D))$ Any $N_{\text{in}}/N_{\text{out}} > 0$, when $N_{\text{out}} \gtrsim \max(d^3D^3\log^3(N), (dN_{\text{out}}/N_{\text{in}})^6)$ $\implies N_{\text{in}}/N_{\text{out}} \gtrapprox 0$, when $N \to \infty$, D fixed *Deterministic condition, results for a variety of data models.*
FMS	$N_{\text{in}}/N_{\text{out}}$ " $\gtrsim$ "0, when $N \to \infty$, D fixed *Approximate recovery for large samples from spherized Haystack or from two one-dimensional subspaces on the sphere. Much better estimates for finite N than PCA.*
REAPER	$N_{\text{in}}/N_{\text{out}} \geq 16\frac{\sigma_{\text{out}}}{\sigma_{\text{in}}}\frac{d}{D}$, when $N = O(D)$, $1 \leq d \leq (D-1)/2$ *Deterministic condition, results for Haystack where $d < (D-1)/2$.*
GMS	$N_{\text{in}}/N_{\text{out}} \geq 4\frac{\sigma_{\text{out}}}{\sigma_{\text{in}}}\frac{d}{\sqrt{(D-d)D}}$, when $N = O(D^2)$ *Deterministic condition, results for Haystack that extends to elliptical outliers.*
OP	$N_{\text{in}}/N_{\text{out}} \geq \frac{121d}{9}O(\max(1, \log(N)/d))$, when $N = O(D)$ *Deterministic condition (formulated for arbitrary outliers) with last term in above formula replaced by an inlier incoherence parameter μ.*
HR-PCA	$N_{\text{in}}/N_{\text{out}} \to \infty$, when $N \to \infty$, D fixed *Weak lower bound on the expressed variance, requires fraction of outliers as input.*
TME/(D)RF	$N_{\text{in}}/N_{\text{out}} > \frac{d}{D-d}$, when $N = O(D)$ *Result for "general-position" data, but does not extend to noise.*
TORP	$N_{\text{in}}/N_{\text{out}} \geq 128d\max(1, \log(N)/d)^2$, when $N = O(D)$ *Deterministic condition (formulated for arbitrary outliers) with last term replaced by an inlier incoherence parameter μ, requires fraction of outliers as input.*
CP	$N_{\text{in}}/N_{\text{out}} \geq d/(D-d^2)$ $(N = O(D), d < \sqrt{D})$ $N_{\text{in}}/N_{\text{out}} \gtrapprox 0$, when $N \to \infty$, $d < \sqrt{D}$, D fixed *Exact recovery for the spherized Haystack model with a random inlier subspace and $d < \sqrt{D}$, and also for a special model of outliers around a line.*
SSC	$N_{\text{in}}/N_{\text{out}} \geq d/D \cdot ((\frac{N_{\text{in}}-1}{d})^{\frac{cD}{d}-1} - 1)^{-1}$, when $N < e^{c\sqrt{D}}/D$, w.h.p. in D *Exact recovery for the spherized Haystack model with a random inlier subspace.*
HOSC	$N_{\text{in}}/N_{\text{out}} \geq \log(N)N^{-2(D-d)/(2D-d)}$ $\implies N_{\text{in}}/N_{\text{out}} \gtrapprox 0$, where $N \to \infty$, D fixed *Result for outliers uniformly sampled from $[0,1]^D$ and inliers uniformly sampled from the intersection of a d-subspace with $(0,1)^d$. Also extends to a union of manifolds and to settings with small noise.*

Table 1: Updated table from Lerman and Maunu (2018b), which compares the lower bounds on SNR for many RSR methods under the Haystack Model. Included here are theoretical guarantees along with the corresponding sample size requirements for the result to hold with probability close to 1.

Here, the symbol $\gtrapprox 0$ is used for the SNR lower bound for recovery when a method can exactly recover an underlying subspace for any fixed SNR and large enough N. Similarly, the symbol " $\gtrsim$ "0 is used when a method can *approximate* L_* to any accuracy for any fixed

SNR and large enough N. However, methods with " $\gtrsim$ "0 instead of $\gtrapprox 0$ cannot exactly recover the underlying subspace.

Among all algorithms, only PCA, GGD, TORP, RANSAC, and FMS run in $O(NDd)$ time. Since the strong gradient condition can be shown to hold for the Haystack model (see Corollary 21 in Section 5.6), GGD also achieves linear convergence. This means that it is theoretically guaranteed to be the fastest out of these $O(NDd)$ algorithms (TORP has a guarantee for linear convergence, but under very restrictive assumptions on the SNR). Furthermore, among all algorithms, GGD is the only one with guarantees close to state-of-the-art for the small sample size regime. Among all algorithms it has the state-of-the-art result for the regime $N = O(d(D-d)^2\log(D))$, although GMS obtains such a result for the smaller regime $N = O(D^2)$. GGD is also the fastest algorithm with a result for the large sample regime as well. We note that algorithms with worse complexity, such as CP, SSC, and HOSC, have guarantees in this setting as well. We have found it too complicated to compare the exact theoretical results of these various methods, and so we have instead opted to just show that they are guaranteed to have exact recovery for any percentage of outliers for large enough N.

5.6. A Note on the Strong Gradient Condition in Theorem 4

While it may be hard to interpret the strong gradient condition in Theorem 4, it is possible to show that it holds for a variety of the data models in this section. The brief discussion here is just meant to illustrate that this condition is, in fact, practical. It is not hard to extend the arguments below to other cases discussed earlier as well. This lemma relies on the following definition.

Definition 19 *Sets of inliers and outliers, $\mathcal{X}_{\text{in}}$ and $\mathcal{X}_{\text{out}}$, within an inlier-outlier dataset are said to lie in general position with respect to each other if*

$$\max_{G(D,d)\setminus\{L_*\}} \#(\mathcal{X} \cap L) \leq d. \tag{51}$$

With this definition, we prove the following lemma.

Lemma 20 *Suppose that the inliers and outliers follow distributions that satisfy* (34) *and lie in general position with respect to each other. Assume further that the inliers are drawn from a distribution such that $\mathcal{P}(\mathcal{X}_{\text{in}}) \to \infty$ as $N \to \infty$, and that*

$$\max_{L\in G(D,d)} \mathcal{A}(\mathcal{X}_{\text{out}}, L) < c\cos(\gamma)\mathcal{P}(\mathcal{X}_{\text{in}}), \tag{52}$$

for some $0 < c < 1$ for all N. Then, (23) *holds for N sufficiently large.*

The general position assumption implies that the amount of data points in any d-subspace that is not L_* is at most d. This general position-type assumption is also satisfied with probability 1 by any sample drawn from the Haystack Model, or by inliers drawn uniformly from $L_* \cap B(\mathbf{0}, M)$ and outliers drawn uniformly from $B(\mathbf{0}, M)$.

Proof Under the assumptions of the lemma, (23) reduces to

$$\inf_{L\in B(L_*,\gamma)\setminus\{L_*\}} \left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right| > 2dM, \tag{53}$$

where $L(t)$ is a geodesic parameterized by arclength from L_k through L_*. Since we know that $\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right| \geq \mathcal{S}(\mathcal{X}, L_*, \gamma)$ (from the proof of Theorem 1), a sufficient condition for the strong gradient condition to hold is

$$\mathcal{S}(\mathcal{X}, L_*, \gamma) > 8dM. \tag{54}$$

The assumptions also imply that

$$\mathcal{S}(\mathcal{X}, L_*, \gamma) > \cos(\gamma)(1-c)\mathcal{P}(\mathcal{X}_{\text{in}}). \tag{55}$$

Therefore, the reduction of the strong gradient condition in (54) is satisfied for N sufficiently large, since $\mathcal{P}(\mathcal{X}_{\text{in}}) \to \infty$ as $N \to \infty$. ■

One can easily modify the proof of Theorem 18 and the proof of Lemma 20 to obtain linear convergence for the Haystack model. We state this result without proof in the following corollary.

Corollary 21 *Suppose that the inliers and outliers are distributed according to the Haystack Model with parameters N_{in}, σ_{in}, N_{out}, σ_{out}, D, and d. Then, (23) holds w.h.p. for N sufficiently large.*

6. Simulations

In this section, we run two simulations to verify the theory we proved earlier. All experiments are run using the Haystack Model. Some more comprehensive comparisons of the various RSR algorithms on synthetic and stylized datasets are contained in the review paper of Lerman and Maunu (2018b).

First, we attempt to demonstrate the stability condition $\mathcal{S}$ from (12). While we cannot explicitly evaluate the maximum within this expression, we can instead simulate the values achieved by

$$\cos(\gamma)\mathcal{P}(\mathcal{X}_{\text{in}}) - \mathcal{A}(\mathcal{X}_{\text{out}}, L), \tag{56}$$

for L in a small neighborhood of L_*.

The values achieved by (56) are simulated in Figure 5 for the noiseless RSR settings with the fixed value of $\gamma = \pi/4$. The dataset for this figure is generated according to the Haystack Model outlined in Section 5.5, with parameters $N_{\text{in}} = 200$, $\sigma_{\text{in}} = 1$, $N_{\text{out}} = 200$, $\sigma_{\text{out}} = 1$, $D = 200$, and $d = 10$. For this plot, the y-axis represents a distance from the underlying subspace L_* in terms of the maximum principal angle up to γ. The x-axis represents randomly generated subspaces at that distance from L_*. The color represents the value of (56). As we can see, the value of (56) is indeed positive within this large neighborhood of L_*.

We also simulate the convergence properties of the GGD method in Figure 6. The data was generated according to the Haystack Model with parameters $N_{\text{in}} = 200$, $\sigma_{\text{in}} = 1$, $N_{\text{out}} = 200$, $\sigma_{\text{out}} = 1$, $D = 100$, and $d = 5$. We compare different choices of step-size in accordance with the statements of Theorems 3 and 4. The green line denotes the convergence of the step-size $t^k = s/\sqrt{k}$ in GGD with $s = 1/D$, which is the modified GGD from Theorem 3. We also display three different types of piecewise constant step-size schemes

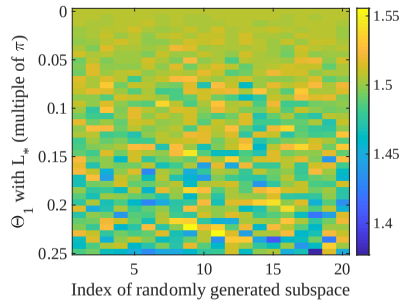

Figure 5: Simulation of the stability statistic. Data was generated for the Haystack Model with parameters $N_{\text{out}} = 200$, $\sigma_{\text{out}} = 1$, $D = 200$, and $d = 10$. The y-axis of each figure represents the maximum principal angle of a randomly generated subspace with L_*. For each value of the maximum principal angle, the x-axis represents the index in the set of 20 randomly generated subspaces with the specified maximum principal angle.

with initial step-size $1/D$. The blue and red lines represent Algorithm 1 with different choices of K and shrink-factors. In one case, we use $K = 20$ and a shrink-factor of $1/2$. In the other case, we use $K = 50$ and a shrink-factor of $1/10$. The pink line is a modification of this piecewise constant step-size scheme that decreases the cost monotonically. In this scheme, the algorithm only shrinks the step-size when the current constant step-size does not decrease the energy function. When this is the case, the step-size is shrunk by the largest factor $1/2^n$, for $n \in \mathbb{N}$, such that the energy decreases. While this set-up performs the best, we do not yet have a theoretical justification for this scheme. We see that all of the choices of piecewise constant step-size converge linearly to L_* (although the convergence is not monotonic). The small fluctuations around an error of 10^{-7} occur due to the machine precision limit in MATLAB.

7. Conclusion

We have presented a deterministic condition that ensures the landscape of (2) behaves nicely around an underlying subspace: if $\mathcal{S}(\gamma, 0, L_*) > 0$, the underlying subspace is the only minimizer and stationary point in $B(L_*, \gamma)$. The deterministic condition also ensures the convergence of a non-convex gradient method for RSR. The convergence of this method is linear under some slightly stronger assumptions on the data. We have shown that the condition $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ and the strong gradient condition in (23) hold for certain statistical models of data and have used these examples to understand the limits of recovery in various regimes. These models indicate the flexibility of the conditions to deal with a wide range of RSR datasets. GGD is even shown to have almost state-of-the-art SNR guarantees under the Haystack Model.

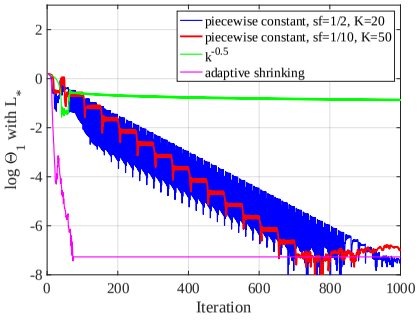

Figure 6: Convergence characteristics of the GGD algorithm with different step-size choices. Data was generated according to the Haystack Model with parameters $N_{\text{in}} = 200$, $\sigma_{\text{in}} = 1$, $N_{\text{out}} = 200$, $\sigma_{\text{out}} = 1$, $D = 100$, and $d = 5$.. The y-axis is the logarithm of the top principal angle with the underlying subspace L_*. For all algorithms, the initial step-size is $s = 1/D$. For the piecewise constant step-size scheme of Algorithm 1, we use two difference combinations of shrink-factor and time between shrinking, K. We also include an adaptive shrinking method, that only shrinks the constant step-size when the current step-size does not decrease the energy.

A main point of this work is to obtain exact recovery guarantees that are similar in spirit to the REAPER algorithm of Lerman et al. (2015) for a non-convex algorithm. We even manage to provide better estimates in large sample regimes. Indeed, the stability analysis of this work is inspired by the stability analysis of the REAPER algorithm, which is done with respect to a convex relaxation of the energy function considered here. Since we do not relax the non-convex problem, our stability is tighter than the REAPER stability when considering sufficiently small neighborhoods. However, for large enough neighborhoods, the REAPER stability might be tighter than ours. For example, a difference shows up in small sample regimes of the Haystack Model: the dependence on a neighborhood makes our result weaker in terms of the SNR regimes we can tolerate. Nevertheless, as far as we know, there is no non-convex RSR competitor for the types of estimates we have developed in this paper and no other competitor with computational complexity of order $O(NDd)$. Furthermore, in larger sample regimes we obtain a stronger result than REAPER's.

While there are many directions that future work can take, we only specify a couple here. One avenue for future work is to extend this result to other data models. For example, one may consider more adversarial models of corruption. This is pursued in a forthcoming work (Maunu and Lerman).

Another direction for future work involves study of subspace recovery in the presence of heavier noise. The only works that consider RSR in really noisy settings are Coudron and Lerman (2012), Minsker (2015), and Cherapanamjeri et al. (2017), although the area remains largely unexplored. The noise considered in our work involves small perturbations

from the underlying subspace. However, in general, more modern work in data science has focused on settings with heavier noise. For example, some have considered noise drawn from distributions with heavy tails (Minsker, 2015), while others have considered PCA in the spiked model (Johnstone, 2001; Baik et al., 2005). In the latter case, when the dimension is very large, the noisy inliers would most likely be very far from the underlying subspace. It is an interesting direction for future work to study RSR in both of these settings.

Future work may also consider proof of convergence for other methods, such as Newton's method and conjugate gradient (Edelman et al., 1999), or IRLS (Lerman and Maunu, 2018a), using the guarantees on the energy landscape of this paper. One could also consider using different frameworks for optimization over $G(D, d)$, such as a retraction based method like that specified in Absil et al. (2009). A quick heuristic argument indicates that the retraction formulation should agree with GGD up to first order, but we leave rigorous examination of this to future work.

Finally, one may also directly follow the ideas of Lim et al. (2016, 2018) and consider extensions to the affine Grassmannian, since in practice we cannot assume that the data is properly centered.

A supplementary web page with code will be made available at `https://twmaunu.github.io/WTL/`.

Appendix A. Landscape of the PCA energy

In this appendix, we discuss the landscape of the energy function described in (1). Let $\boldsymbol{X} \in \mathbb{R}^{D\times N}$ be a matrix with columns given by $\boldsymbol{x}_1, \boldsymbol{x}_2, \dots, \boldsymbol{x}_N$, and assume that its singular values and left singular vectors are $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_D$ and $\boldsymbol{v}_1, \dots, \boldsymbol{v}_D \in \mathbb{R}^D$, respectively. Under a generic scenario when $\sigma_d > \sigma_{d+1}$ and $\sigma_{D-d} > \sigma_{D-d+1}$, the landscape of the energy in (1) has the following properties:

- There exists a unique local minimum given by $L = \text{span}(\boldsymbol{v}_1, \dots, \boldsymbol{v}_d)$, which is also the global minimizer; and a unique local maximum given by $L = \text{span}(\boldsymbol{v}_{D-d+1}, \dots, \boldsymbol{v}_D)$, which is also the global maximizer.
- The set of saddle points are given by the set of L such that $L = \text{span}(\boldsymbol{v}_{i_1}, \dots, \boldsymbol{v}_{i_d})$ for any d distinct integers $(i_1, \dots, i_d)$ between 1 and D, and $(i_1, \dots, i_d)$ can not be $(1, \dots, d)$ or $(D-d+1, \dots, D)$ (which correspond to the minimizer and the maximizer).

These properties can be derived by casting the PCA problem as a constrained optimization problem and then examining the corresponding Lagrangian. Since the number of saddle points is finite and all saddle points are orthogonal to the minimizer, there exists a local neighborhood around the minimizer such that the minimizer is the unique critical point

inside this neighborhood, which is a property similar to Theorem 1. Using a strategy similar to this work, if an initialization is chosen appropriately such that the initialization lies in a neighborhood around the global minimizer, a gradient descent algorithm would converge to the global minimizer of (1).

One other case of interest involves $\sigma_d = \sigma_{d+1} = \cdots = \sigma_k$, for $d < k \leq D$. In this case, the singular vectors corresponding to $\sigma_d, \ldots, \sigma_k$ would span a subspace, and any orthonormal basis for $\mathrm{Sp}(\boldsymbol{v}_d, \ldots, \boldsymbol{v}_k)$ would result in a valid set of singular vectors corresponding to the singular values $\sigma_d, \ldots, \sigma_k$. As an example of what happens in this case, if $\sigma_1 > \sigma_2 > \cdots > \sigma_d = \cdots = \sigma_k$ then the d-subspace spanned by $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{d-1}$, $\boldsymbol{v}_i \in \mathrm{Sp}(\boldsymbol{v}_d, \ldots, \boldsymbol{v}_k) \cap S^{D-1}$ are minimizers. One can construct other sorts of continuums by also considering equality of singular values between σ_1 and σ_d. All cases constructed in these ways would yield a continuum of minimizers for the PCA d-subspace energy, which all achieve the same energy. Analogously, one can consider the cases where $\sigma_k = ... = \sigma_{D-d+1}$ for $1 \leq k < D-d+1$, and show a continuum of maximizers. Or, one can also consider the cases where $\sigma_k = ... = \sigma_l$ where $d < k < l < D - d + 1$, and show a continuum of saddle points.

In addition, while it is unrelated to the focus of this work, we remark that the landscape of PCA also has the "strict saddle point property" discussed in Ge et al. (2015): the Hessian of every saddle point has a negative eigenvalue. Ge et al. (2015) propose algorithms with theoretical guarantees to minimize such energy functions. This property can be seen by again examining the Lagrangian formulation of the PCA problem.

Appendix B. Grassmannian Geodesics

In this appendix, we describe some basic geometric notions on the Grassmannian manifold, $G(D,d)$. Given two subspaces $L_1, L_2 \in G(D,d)$, the principal angles between the two subspaces are defined sequentially. The smallest angle, θ_d, is given by

$$\theta_d = \min_{\substack{\boldsymbol{v} \in L_1, \boldsymbol{y} \in L_2 \\ \|\boldsymbol{v}\| = \|\boldsymbol{y}\| = 1}} \arccos(|\boldsymbol{v}^T \boldsymbol{y}|). \tag{57}$$

The vectors $\boldsymbol{v}_d$ and $\boldsymbol{y}_d$ which achieve the minimum are the principal vectors corresponding to θ_d. The d principal angles are defined sequentially by

$$\theta_k = \min_{\substack{\boldsymbol{v} \in L_1, \|\boldsymbol{v}\| = 1, \boldsymbol{v} \perp \boldsymbol{v}_{k+1}, \ldots, \boldsymbol{v}_d \\ \boldsymbol{y} \in L_2, \|\boldsymbol{y}\| = 1, \boldsymbol{y} \perp \boldsymbol{y}_{d+1}, \ldots, \boldsymbol{y}_d}} \arccos(|\boldsymbol{v}^T \boldsymbol{y}|), \tag{58}$$

and the corresponding principal vectors are found in the same way. The ordering defined in (57) and (58) is the reverse of what is usually used for principal angles: here, θ_1 is the largest principal angle, while most other works denote the smallest principal angle with θ_1. Notice that if two principal angles are equal, the choice of principal vectors is not unique. Principal angles and vectors can be efficiently calculated: if $\boldsymbol{W}_1 \in O(D,d)$ spans L_1 and $\boldsymbol{W}_2 \in O(D,d)$ spans L_2, then we write the singular value decomposition

$$\boldsymbol{W}_1^T \boldsymbol{W}_2 = \boldsymbol{V}_{12} \boldsymbol{\Sigma}_{12} \boldsymbol{Y}_{12}^T. \tag{59}$$

The principal angles are given in reverse order by $\arccos(\mathrm{diag}(\boldsymbol{\Sigma}_{12}))$, and the corresponding principal vectors are given by the columns of $\boldsymbol{V}_{12}$ and $\boldsymbol{Y}_{12}$ in reverse order. Now let two

subspaces L_1 and L_2 have principal angles $\theta_1, \ldots, \theta_d$ and principal vectors $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_d$ and $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_d$, respectively. Let k be the largest index such that $\theta_k > 0$, which is also known as the interaction dimension (Lerman and Zhang, 2014), where $d - k$ is the dimension of $L_1 \cap L_2$. Then, we can define a complementary orthogonal basis $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_k$ for L_2 with respect to L_1 as

$$\boldsymbol{u}_j \in \mathrm{Sp}(\boldsymbol{v}_j, \boldsymbol{y}_j),\ \boldsymbol{u}_j \perp \boldsymbol{v}_j,\ \boldsymbol{u}_j^T \boldsymbol{y}_j > 0. \tag{60}$$

As explained in Lerman and Zhang (2014), for any two subspaces L_1 and L_2 such that $\theta_1 = \arccos(|\boldsymbol{v}_1^T \boldsymbol{y}_1|) < \pi/2$, a unique geodesic on $G(D,d)$ with $L(0) = L_1$ and $L(1) = L_2$ can be parameterized by

$$L(t) = \mathrm{Sp}(\boldsymbol{v}_1 \cos(\theta_1 t) + \boldsymbol{u}_1 \sin(\theta_1 t), \ldots, \boldsymbol{v}_k \cos(\theta_k t) + \boldsymbol{u}_k \sin(\theta_k t), \boldsymbol{v}_{k+1}, \ldots, \boldsymbol{v}_d). \tag{61}$$

In the paper, we will frequently use a reparametrization of geodesics to prevent the angles from needlessly affecting the magnitude of the derivatives. In these cases, we reparametrize the geodesic in (62) by arclength (in terms of metric defined Section 2.2) by writing

$$\begin{aligned} L(t) = \mathrm{Sp}\Big(\boldsymbol{v}_1 \cos(t) + \boldsymbol{u}_1 \sin(t), \boldsymbol{v}_2 \cos\left(\frac{\theta_2}{\theta_1} t\right) + \boldsymbol{u}_2 \sin\left(\frac{\theta_2}{\theta_1} t\right), \ldots, \\ \boldsymbol{v}_k \cos\left(\frac{\theta_k}{\theta_1} t\right) + \boldsymbol{u}_k \sin\left(\frac{\theta_k}{\theta_1} t\right), \boldsymbol{v}_{k+1}, \ldots, \boldsymbol{v}_d\Big). \end{aligned} \tag{62}$$

Appendix C. Bound on the Alignment

Here we derive the simple bound on the alignment statistic seen in (11). Here, the $\widetilde{\cdot}$ notation denotes projection of the data points (columns of a data matrix) to the unit sphere, S^{D-1}. This bound is used to prove Theorem 17. The first step follows from (6), (8), and (10).

$$\begin{aligned} \mathcal{A}(\mathcal{X}_{\text{out}}, \boldsymbol{V}) &= \left\| \sum_{\boldsymbol{x}_i \in \mathcal{X}_{\text{out}}} \frac{\boldsymbol{Q}_{\boldsymbol{V}} \boldsymbol{x}_i}{\|\boldsymbol{Q}_{\boldsymbol{V}} \boldsymbol{x}_i\|} \boldsymbol{x}_i^T \boldsymbol{V} \right\|_2 = \left\| \widetilde{\boldsymbol{Q}_{\boldsymbol{V}} \boldsymbol{X}_{\text{out}}} \boldsymbol{X}_{\text{out}}^T \boldsymbol{V} \right\|_2 \\ &\leq \left\| \widetilde{\boldsymbol{Q}_{\boldsymbol{V}} \boldsymbol{X}_{\text{out}}} \right\|_2 \left\| \boldsymbol{X}_{\text{out}}^T \boldsymbol{V} \right\|_2 \leq \left\| \widetilde{\boldsymbol{Q}_{\boldsymbol{V}} \boldsymbol{X}_{\text{out}}} \right\|_F \|\boldsymbol{X}_{\text{out}}\|_2 \\ &\leq \sqrt{N_{\text{out}}} \|\boldsymbol{X}_{\text{out}}\|_2. \end{aligned} \tag{63}$$

Appendix D. Supplementary Proofs

In this appendix, we give the supplementary proofs for the various theorems, propositions, and lemmas given in the paper.

D.1. Proof of Theorem 2

The proof of this theorem proceeds much in the same way as the proof of Theorem 1.

We first define the following geodesic on $G(D,d)$: Fix a subspace $L \in B(L_*, \gamma) \setminus B(L_*, \eta)$, and let the principal angles between L and L_* be $\theta_1, \ldots, \theta_d$. Here, we define $\eta = 2 \arctan(\epsilon/\delta)$. Also, choose a set of corresponding principal vectors $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_d$

and $\boldsymbol{w}_1, \dots, \boldsymbol{w}_d$ for L and L_*, respectively, and let l be the maximum index such that $\theta_1 = \cdots = \theta_l$. We let $\boldsymbol{u}_1, \dots, \boldsymbol{u}_l$ be complementary orthogonal vectors for $\boldsymbol{v}_1, \dots, \boldsymbol{v}_l$ and $\boldsymbol{w}_1, \dots, \boldsymbol{w}_l$, which exist since $\theta_1(L, L_*) > 0$. For $t \in [0,1]$, we form the geodesic

$$L(t) = \mathrm{Sp}(\boldsymbol{v}_1 \cos(t) + \boldsymbol{u}_1 \sin(t), \dots, \boldsymbol{v}_l \cos(t) + \boldsymbol{u}_l \sin(t), \boldsymbol{v}_{l+1}, \dots, \boldsymbol{v}_d).$$

This geodesic moves only the furthest directions of $L(0)$ towards L_*, and we have removed dependence on θ_1, since this unnecessarily impacts the magnitude of the geodesic derivative (5).

We will first prove the inequality $\partial F(L(t); \mathcal{X}) < -\mathcal{S}_n(\mathcal{X}, L_*, \epsilon, \delta, \gamma)$. Using the derivative formula in (5), a subderivative of $F(L(t); \mathcal{X})$ at $t = 0$ is given by

$$\frac{\mathrm{d}}{\mathrm{d}t} F(L(t); \mathcal{X})\Big|_{t=0} = - \sum_{\substack{\boldsymbol{x}_i \in \mathcal{X} \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} \sum_{j=1}^{l} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \tag{64}$$

$$= - \sum_{j=1}^{l} \left(\sum_{\substack{\boldsymbol{x}_i \in \mathcal{F}_1(\mathcal{X}_{\mathrm{in}}, \boldsymbol{w}_j, \delta) \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} + \sum_{\substack{\boldsymbol{x}_i \in \mathcal{F}_0(\mathcal{X}_{\mathrm{in}}, \boldsymbol{w}_j, \delta) \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} + \sum_{\substack{\boldsymbol{x}_i \in \mathcal{X}_{\mathrm{out}} \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \right).$$

We examine the terms in (64) one by one. Using (6) and (8), we can bound the outlier term

$$- \sum_{\substack{\boldsymbol{x}_i \in \mathcal{X}_{\mathrm{out}} \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \leq \|\nabla F(L; \mathcal{X}_{\mathrm{out}})\|_2 . \tag{65}$$

We know that $|\boldsymbol{x}_i \cdot \boldsymbol{u}_j| \leq \|\boldsymbol{Q}_L \boldsymbol{x}_i\|$ for all i since $\boldsymbol{u}_j \in \mathrm{Sp}(\boldsymbol{Q}_L)$. We also know that, since $\theta_j > \eta$, $|\boldsymbol{v}_j^T \boldsymbol{x}_i| \leq |\boldsymbol{w}_j^T \boldsymbol{x}_i| \leq \sqrt{\delta^2 + \epsilon^2}$ for all $\boldsymbol{x}_i \in \mathcal{F}_0(\mathcal{X}_{\mathrm{in}}, \boldsymbol{w}_j, \delta)$. These two observations imply that

$$- \sum_{\substack{\boldsymbol{x}_i \in \mathcal{F}_0(\mathcal{X}_{\mathrm{in}}, \boldsymbol{w}_j, \delta) \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \leq \sqrt{\delta^2 + \epsilon^2} \max_{\boldsymbol{w} \in L_* \cap S^{D-1}} \#(\mathcal{F}_0(\mathcal{X}_{\mathrm{in}}, \boldsymbol{w}, \delta)). \tag{66}$$

Thus, we finally must deal with the inlier term. We have the inequalities

$$\boldsymbol{v}_j \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j \geq \cos(\theta_1 - \eta) \sin(\theta_1 - \eta), \tag{67}$$

$$\|\boldsymbol{Q}_L \boldsymbol{x}_i\| \leq \sin(\theta_1) \|\boldsymbol{P}_{L_*} \boldsymbol{x}_i\| + \epsilon. \tag{68}$$

Applying these to the inlier term, as long as $\theta_1 > \eta$, we find

$$\begin{aligned} - \sum_{\substack{\boldsymbol{x}_i \in \mathcal{F}_1(\mathcal{X}_{\mathrm{in}}, \boldsymbol{w}_j, \delta) \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} & \frac{\boldsymbol{v}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{u}_j}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \\ & \leq - \frac{\cos(\theta_1 - \eta) \sin(\theta_1 - \eta)}{\sin(\theta_1)} \sum_{\substack{\boldsymbol{x}_i \in \mathcal{F}_1(\mathcal{X}_{\mathrm{in}}, \boldsymbol{w}_j, \delta) \\ \|\boldsymbol{Q}_L \boldsymbol{x}_i\| > 0}} \frac{\boldsymbol{w}_j^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{w}_j}{\|\boldsymbol{P}_{L_*} \boldsymbol{x}_i\| + \epsilon / \sin(\theta_1)} \\ & \leq - \frac{\cos(\gamma - \eta)}{2} \lambda_d \left(\sum_i \frac{\boldsymbol{P}_{L_*} \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{P}_{L_*}}{\|\boldsymbol{P}_{L_*} \boldsymbol{x}_i\| + \sqrt{\delta^2 + \epsilon^2}} \right). \end{aligned} \tag{69}$$

Putting together (65), (66), and (69), we find that

$$\partial F(L(t); \mathcal{X})\Big|_{t=0} \leq -l \mathcal{S}_n(\mathcal{X}, L_*, \epsilon, \delta, \gamma) < 0. \tag{70}$$

Thus, (70) implies that every subspace in $B(L_*, \gamma) \backslash B(L_*, \eta)$ has a direction with negative local subderivative. From here, the proof is the same as that of Theorem 1.

D.2. Proof of Theorem 3

We will first show that

$$\theta_1(\boldsymbol{V}^{k+1}, L_*) < \theta_1(\boldsymbol{V}^k, L_*), \tag{71}$$

for sufficiently small t^k. Let $\boldsymbol{V}^* \in O(D, d)$ span L_*. We will establish (71) by showing

$$\sigma_d \left(\boldsymbol{V}^{*T} \boldsymbol{V}^{k+1} \right) > \sigma_d \left(\boldsymbol{V}^{*T} \boldsymbol{V}^k \right).$$

Using (22) and the fact that

$$\cos(\boldsymbol{\Sigma}^k t^k) = \boldsymbol{I} - O((t^k)^2), \qquad \sin(\boldsymbol{\Sigma}^k t^k) = \boldsymbol{\Sigma}^k t^k - O((t^k)^3),$$

we can write

$$\begin{aligned} \sigma_d \left(\boldsymbol{V}^{*T} \boldsymbol{V}^{k+1} \right) &= \sigma_d \left(\boldsymbol{V}^{*T} \left(\boldsymbol{V}^k \boldsymbol{W}^k \cos(\boldsymbol{\Sigma}^k t^k) \boldsymbol{W}^{kT} + \boldsymbol{U}^k \sin(\boldsymbol{\Sigma}^k t^k) \boldsymbol{W}^{kT} \right) \right) \\ &= \sigma_d \left(\boldsymbol{V}^{*T} \left(\boldsymbol{V}^k - t^k \nabla F(\boldsymbol{V}^k; \mathcal{X}) + O((t^k)^2) \right) \right). \end{aligned} \tag{72}$$

Let $\boldsymbol{v}_1^k \in \mathrm{Sp}(\boldsymbol{V}^k)$ be a unit vector corresponding to the maximum principal angle with L_*, and let $\boldsymbol{u}_1^k$ be its complementary orthogonal vector. Define the unit vector $\boldsymbol{y}_1^k \in L_* \cap \mathrm{Sp}(\boldsymbol{v}_1^k, \boldsymbol{u}_1^k)$, and write $\theta_1^k = \theta_1(\mathrm{Sp}(\boldsymbol{V}^k), L_*)$. Suppose that $\sigma_d^k = \sigma_d(\boldsymbol{V}^{*T} \boldsymbol{V}^k)$ has multiplicity r, and let $\boldsymbol{\beta}_1,\ \boldsymbol{\beta}_2 \in O(d, r)$ be such that

$$\boldsymbol{\beta}_1^T \boldsymbol{V}^{*T} \boldsymbol{V}^k \boldsymbol{\beta}_2 = \mathrm{diag}(\sigma_d^k, \dots, \sigma_d^k). \tag{73}$$

We now apply Result 4.1 in Söderström (1999), which states the following. Suppose a matrix $\boldsymbol{A}$ has a singular value σ with multiplicity r, with corresponding left and right

singular vectors $\boldsymbol{U}$ and $\boldsymbol{V}$. Suppose that we perturb $\boldsymbol{A}$ by $\epsilon\boldsymbol{B}$. Then, $\boldsymbol{A}+\epsilon\boldsymbol{B}$ has r singular values $\sigma_1(\boldsymbol{A}+\epsilon\boldsymbol{B}),\dots,\sigma_r(\boldsymbol{A}+\epsilon\boldsymbol{B})$ which satisfy

$$\sigma_j(\boldsymbol{A}+\epsilon\boldsymbol{B}) = \sigma_j(\boldsymbol{A}) + \frac{\epsilon}{2}\lambda_j\left(\boldsymbol{V}^T\boldsymbol{B}^T\boldsymbol{U} + \boldsymbol{U}^T\boldsymbol{B}\boldsymbol{V}\right) + O(\epsilon^2).$$

Applying this to (72) yields

$$\begin{aligned}
&\sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k+1}\right) \geq \sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k}\right) + \frac{t^k}{2}\lambda_d\left(\boldsymbol{\beta}_1^T\boldsymbol{V}^{*T}\sum_{\mathcal{X}}\frac{\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{V}^k}{\|\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\|}\boldsymbol{\beta}_2\right) + O((t^k)^2) \qquad (74)\\
&= \sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k}\right) + t^k\left(\boldsymbol{y}_1^{kT}\sum_{\mathcal{X}}\frac{\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\|}\boldsymbol{v}_1^k\right) + O((t^k)^2)\\
&= \sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k}\right) + t^k\sin(\theta_1^k)\left(\boldsymbol{u}_1^{kT}\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\|}\boldsymbol{v}_1^k + \boldsymbol{u}_1^{kT}\sum_{\mathcal{X}_{\text{out}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\|}\boldsymbol{v}_1^k\right) + O((t^k)^2).
\end{aligned}$$

Here, the $O((t^k)^2)$ term is bounded below by $-C_2(t^k)^2$, where C_2 does not depend on $\boldsymbol{V}^k$, which follows from compactness of $O(D,d)$.

Notice that the inlier term in (74) is positive and bounded below

$$\begin{aligned}
\boldsymbol{u}_1^{kT}\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\|}\boldsymbol{v}_1^k &\geq \frac{1}{\sin(\theta_1(\text{Sp}(\boldsymbol{V}^k),L_*))}\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{u}_1^{kT}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{v}_1^k}{\|\boldsymbol{x}_i\|} \qquad (75)\\
&\geq \cos(\theta_1(\text{Sp}(\boldsymbol{V}^k),L_*)))\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{y}_1^{kT}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{y}_1^k}{\|\boldsymbol{x}_i\|} \geq \cos(\gamma)\lambda_d\left(\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right).
\end{aligned}$$

Using the fact that $\boldsymbol{u}_1^k \in \text{Sp}(\boldsymbol{Q}_{\boldsymbol{V}^k})$ and $\boldsymbol{v}_1^k \in \text{Sp}(\boldsymbol{V}^k)$, we can bound the outlier term in (74)

$$\left|\boldsymbol{u}_1^{kT}\sum_{\mathcal{X}_{\text{out}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\|}\boldsymbol{v}_1^k\right| \leq \sigma_1\left(\sum_{\mathcal{X}_{\text{out}}}\frac{\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{Q}_{\boldsymbol{V}^k}\boldsymbol{x}_i\|}\boldsymbol{V}^k\right) = \sigma_1\left(\nabla F(\boldsymbol{V}^k;\mathcal{X}_{\text{out}})\right). \qquad (76)$$

Thus, from (75) and (76) we conclude

$$\begin{aligned}
&\sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k+1}\right) - \sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k}\right) \qquad (77)\\
&\geq t^k\sin(\theta_1^k)\left(\cos(\gamma)\lambda_d\left(\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right) - \sigma_1\left(\nabla F(\boldsymbol{V}^k;\mathcal{X}_{\text{out}})\right)\right) - C_2(t^k)^2\\
&\geq t^k\sin(\theta_1^k)\left(\cos(\gamma)\lambda_d\left(\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right) - \sup_{\boldsymbol{V}\in B(L_*,\gamma)}\sigma_1\left(\nabla F(\boldsymbol{V};\mathcal{X}_{\text{out}})\right)\right) - C_2(t^k)^2\\
&\geq t^k\sin(\theta_1^k)C_1 - C_2(t^k)^2 = t^k\left(\sin(\theta_1^k)C_1 - C_2t^k\right),
\end{aligned}$$

for positive constants C_1 and C_2 which do not depend on $\boldsymbol{V}^k$. Hence, for small enough t^k, we have that (71) holds.

It remains to show that the sequence with step-size $s/\sqrt{k}$ converges to L_* for sufficiently small s. Suppose that s satisfies

$$s < \min\left(\frac{C_1\sin(\gamma)}{2C_2}, \frac{1}{4\sqrt{C_2}}\right). \qquad (78)$$

Then, for any $\boldsymbol{V}^k$ with $\frac{\gamma}{2\sqrt{k}} \leq \theta_1(\boldsymbol{V}^k, L_*) \leq \gamma$, looking at (77) and the first term in (78), $s/\sqrt{k}$ decreases the principal angle by at least C_3/k, for some constant C_3. On the other hand, for any $\boldsymbol{V}^k$ such that $\theta_1(\boldsymbol{V}^k, L_*) < \frac{\gamma}{2\sqrt{k}}$, we have the bound

$$\sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k+1}\right) - \sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k}\right) > -C_2(t^k)^2. \qquad (79)$$

Note that (79) gives the inequality

$$\sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k+1}\right) > \sigma_d\left(\boldsymbol{V}^{*T}\boldsymbol{V}^{k}\right) - C_2(t^k)^2 \geq \cos\left(\frac{\gamma}{2\sqrt{k}}\right) - C_2(t^k)^2. \qquad (80)$$

It is straightforward to show that if

$$t^k < \frac{1}{4\sqrt{C_2}\sqrt{k}},$$

then the right hand side of (80) is greater than $\cos(\gamma/\sqrt{k})$. Thus, the second term in the minimum of (78) implies that if $\theta_1(\boldsymbol{V}^k, L_*) < \frac{\gamma}{2\sqrt{k}}$, then $\theta_1(\boldsymbol{V}^{k+1}, L_*) < \gamma/\sqrt{k}$.

We summarize this in the following way. For any k, either $\frac{\gamma}{2\sqrt{k}} \leq \theta_1(\boldsymbol{V}^k, L_*) \leq \gamma$ or $\theta_1(\boldsymbol{V}^k, L_*) < \frac{\gamma}{2\sqrt{k}}$. If the former holds, then $\theta_1(\boldsymbol{V}^{k+1}, L_*) < \theta_1(\boldsymbol{V}^k, L_*) - C_3/k$. If the latter holds, then we have the bound $\theta_1(\boldsymbol{V}^{k+1}, L_*) < \gamma/\sqrt{k}$. Thus, the maximum principal angle with L_* either decreases by C_3/k or the distance is bounded by $\gamma/\sqrt{k}$. Put together, these imply that $\boldsymbol{V}^k$ converges to L_* with $O(1/\sqrt{k})$ rate of convergence.

D.3. Proof of Lemmas in Theorem 4

This appendix contains proofs for the three lemmas in Theorem 4.

D.3.1. Proof of Lemma 6

For any fixed subspace $L \in B(L_*, \gamma)$, let the principle vectors and angles for L with respect to L_* be given by $\{\boldsymbol{v}_j\}_{j=1}^d$ and $\{\theta_j\}_{j=1}^d$. Then, writing $\boldsymbol{\Theta} = \text{diag}(\theta_1, \cdots, \theta_d)$, we know that $F(L_*; \mathcal{X}_{\text{in}}) = 0$ and

$$\begin{aligned}
F(L;\mathcal{X}_{\text{in}}) &= \sum_{\boldsymbol{x}\in\mathcal{X}_{\text{in}}}\|\sin(\theta)\boldsymbol{V}^T\boldsymbol{x}\| < \sum_{\boldsymbol{x}\in\mathcal{X}_{\text{in}}}\|\boldsymbol{\Theta}\boldsymbol{V}^T\boldsymbol{x}\| \leq \|\boldsymbol{\Theta}\|_2\max_{\boldsymbol{V}\in O(D,d)}\sum_{\mathcal{X}_{\text{in}}}\|\boldsymbol{V}^T\boldsymbol{x}_i\| \qquad (81)\\
&\leq \theta_1\sum_{\mathcal{X}_{\text{in}}}\|\boldsymbol{x}_i\|.
\end{aligned}$$

Let $L(t)$ be the geodesic from L_* to L parameterized by arclength, and let $s = \theta_1$. The difference in energies for the outliers is bounded by

$$|F(L;\mathcal{X}_{\text{out}}) - F(L_*;\mathcal{X}_{\text{out}})| = \left|\int_{t=0}^{s} \frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X}_{\text{out}})\mathrm{d}t\right| \tag{82}$$
$$\leq \theta_1 \sup_{L' \in B(L_*,\sin(\gamma)} (\sigma_1(\nabla F(L';\mathcal{X}_{\text{out}}))).$$

By the assumption $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$, we have by the definition in (12) that

$$\sup_{L' \in B(L_*,\sin(\gamma)} (\sigma_1(\nabla F(L';\mathcal{X}_{\text{out}}))) < \cos(\gamma)\lambda_d \left(\sum_{\mathcal{X}_{\text{in}}} \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right) \leq \max_{\boldsymbol{v}\in S^{D-1}} \left(\sum_{\mathcal{X}_{\text{in}}} \boldsymbol{v}^T \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\boldsymbol{v}\right) \tag{83}$$
$$< \max_{\boldsymbol{v}\in S^{D-1}} \sum_{\mathcal{X}_{\text{in}}} |\boldsymbol{v}^T \boldsymbol{x}| \leq \sum_{\mathcal{X}_{\text{in}}} \|\boldsymbol{x}_i\|_2.$$

Thus, combining (81)-(83) yields

$$|F(L;\mathcal{X}) - F(L_*;\mathcal{X})| = |F(L;\mathcal{X}_{\text{in}}) + F(L;\mathcal{X}_{\text{out}}) - (F(L_*;\mathcal{X}_{\text{in}}) + F(L;\mathcal{X}_{\text{out}}))| \tag{84}$$
$$\leq |F(L;\mathcal{X}_{\text{in}})| + |F(L;\mathcal{X}_{\text{out}}) - F(L;\mathcal{X}_{\text{out}})|$$
$$\leq 2\theta_1 \sum_{\mathcal{X}_{\text{in}}} \|\boldsymbol{x}_i\|.$$

As a result, the lemma is proved.

D.3.2. Proof of Lemma 7

For any $L \in B(L_*,\gamma) \setminus \{L_*\}$ and geodesic $L(t)$ parameterized by arclength from L through L_*,

$$\left|\frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X})|_{t=0}\right| = \left|\frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X}_{\text{in}})|_{t=0} + \frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X}_{\text{out}})|_{t=0}\right| \tag{85}$$
$$\geq \left|\frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X}_{\text{in}})|_{t=0}\right| - \left|\frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X}_{\text{out}})|_{t=0}\right|$$
$$\geq \cos(\gamma)\lambda_1 \left(\sum_{\mathcal{X}_{\text{in}}} \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right) - \sup_{L\in B(L_*,\gamma)} \sigma_1(\nabla F(L;\mathcal{X}_{\text{out}}))$$
$$\geq \mathcal{S}(\mathcal{X}, L_*, \gamma) \geq C_1 \sum_{\mathcal{X}_{\text{in}}} \|\boldsymbol{x}_i\|,$$

where, $C_1 = \mathcal{S}(\mathcal{X}, L_*, \gamma)/\sum_{\mathcal{X}_{\text{in}}} \|\boldsymbol{x}_i\|$.

D.3.3. Proof of Lemma 8

First, assume that c_0 is small enough such that

$$\inf_{L(0)\in B(L_*,\gamma)\setminus\{L_*\}} \frac{1}{4}\left|\frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X})|_{t=0}\right| > \sum_{\mathcal{X}} 3\sqrt{c_0}\|\boldsymbol{x}_i\|, \tag{86}$$

where $L(t)$ is a geodesic parameterized by arclength between $L(0)$ and L_*. We are guaranteed that such a c_0 exists by Lemma 6.

Fix $c < c_0$ and define a geodesic line $L(t)$ on $G(D,d)$ such that $L(0) = L_k$ and $L(c\theta_1(L_k, L_*)) = L_{k+1}$. We first investigate the derivatives of the function $\operatorname{dist}(\boldsymbol{x}, L(t))$. We will then show, under the given assumptions on the data, that $\sum_i \operatorname{dist}(\boldsymbol{x}_i, L(t))$ is close to being Lipschitz.

Applying Lerman and Zhang (2014, (23)-(24)), and assuming that $\sum_{j=1}^d \theta_j^2 = 1$, we have

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}\operatorname{dist}(\boldsymbol{x}, L(t)) \tag{87}$$
$$= \frac{\mathrm{d}}{\mathrm{d}t}\left[-\frac{\sum_{j=1}^d \theta_j((\cos(t\theta_j)\boldsymbol{v}_j + \sin(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})((-\sin(t\theta_j)\boldsymbol{v}_j + \cos(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})}{\operatorname{dist}(\boldsymbol{x}, L(t))}\right]$$
$$= -\frac{\left(\sum_{j=1}^d \theta_j((\cos(t\theta_j)\boldsymbol{v}_j + \sin(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})((-\sin(t\theta_j)\boldsymbol{v}_j + \cos(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})\right)^2}{\operatorname{dist}(\boldsymbol{x}, L(t))^3}$$
$$- \frac{\sum_{j=1}^d \theta_j^2((-\sin(t\theta_j)\boldsymbol{v}_j + \cos(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})((-\sin(t\theta_j)\boldsymbol{v}_j + \cos(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})}{\operatorname{dist}(\boldsymbol{x}, L(t))}$$
$$- \frac{\sum_{j=1}^d \theta_j^2((\cos(t\theta_j)\boldsymbol{v}_j + \sin(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})((-\cos(t\theta_j)\boldsymbol{v}_j - \sin(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})}{\operatorname{dist}(\boldsymbol{x}, L(t))}.$$

Using $|(\cos(t\theta_j)\boldsymbol{v}_j + \sin(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x}| \leq \|\boldsymbol{x}\|$ and the Cauchy-Schwarz inequality in this equation gives

$$\left(\sum_{j=1}^d \theta_j((\cos(t\theta_j)\boldsymbol{v}_j + \sin(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})((-\sin(t\theta_j)\boldsymbol{v}_j + \cos(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})\right)^2 \tag{88}$$
$$\leq \left(\sum_{j=1}^d \theta_j^2((\cos(t\theta_j)\boldsymbol{v}_j + \sin(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})^2\right)\left(\sum_{j=1}^d((-\sin(t\theta_j)\boldsymbol{v}_j + \cos(t\theta_j)\boldsymbol{u}_j)\cdot\boldsymbol{x})^2\right)$$
$$\leq \sum_{j=1}^d \theta_j^2\|\boldsymbol{x}\|^2 \operatorname{dist}(\boldsymbol{x}, L(t))^2 = \|\boldsymbol{x}\|^2 \operatorname{dist}(\boldsymbol{x}, L(t))^2.$$

Putting (87) and (88) together yields

$$\left|\frac{\mathrm{d}^2}{\mathrm{d}t^2}\operatorname{dist}(\boldsymbol{x}, L(t))\right| \leq \frac{\|\boldsymbol{x}\|^2 \operatorname{dist}(\boldsymbol{x}, L(t))^2}{\operatorname{dist}(\boldsymbol{x}, L(t))^3} + \frac{2\|\boldsymbol{x}\|^2 \sum_{j=1}^d \theta_j^2}{\operatorname{dist}(\boldsymbol{x}, L(t))} = \frac{3\|\boldsymbol{x}\|^2}{\operatorname{dist}(\boldsymbol{x}, L(t))}. \tag{89}$$

On the other hand, Lerman and Zhang (2014, Lemma 3.2) implies that

$$\left|\frac{\mathrm{d}}{\mathrm{d}t}\operatorname{dist}(\boldsymbol{x}, L(t))\right| \leq \|\boldsymbol{x}\|. \tag{90}$$

Then, define the set

$$\mathcal{G}(\mathcal{X}, L_*, L(t), c) = \left\{\boldsymbol{x} \in \mathcal{X} : \min_{t\in[0, c\theta_1(L, L_*)]} \frac{\operatorname{dist}(\boldsymbol{x}, L(t))}{\|\boldsymbol{x}\|} \leq \sqrt{c}\theta_1(L_k, L_*)\right\}. \tag{91}$$

Then, for all $0 \le s \le c\theta_1(L_k, L_*)$,

$$\begin{aligned}
&\left|\sum_{\boldsymbol{x}\in\mathcal{X}}\left(\frac{\mathrm{d}}{\mathrm{d}t}\operatorname{dist}(x, L(t))\Big|_{t=s} - \frac{\mathrm{d}}{\mathrm{d}t}\operatorname{dist}(x, L(t))\Big|_{t=0}\right)\right| \qquad (92)\\
&\quad\le \sum_{\boldsymbol{x}\in\mathcal{X}\setminus\mathcal{G}(\mathcal{X},L_*,L(t),c)}\int_{t=0}^{s}\left|\frac{\mathrm{d}^2}{\mathrm{d}t^2}\operatorname{dist}(\boldsymbol{x}, L(t))\right|\mathrm{d}t + \sum_{\boldsymbol{x}\in\mathcal{G}(\mathcal{X},L_*,L(t),c)} 2\|\boldsymbol{x}\|\\
&\quad\le \sum_{\boldsymbol{x}\in\mathcal{X}\setminus\mathcal{G}(\mathcal{X},L_*,L(t),c)} s\frac{3\|\boldsymbol{x}\|}{\sqrt{c}\theta_1(L_k, L_*)} + \sum_{\boldsymbol{x}\in\mathcal{G}(\mathcal{X},L_*,L(t),c)} 2\|\boldsymbol{x}\|\\
&\quad\le \sum_{\boldsymbol{x}\in\mathcal{X}\setminus\mathcal{G}(\mathcal{X},L_*,L(t),c))} 3\sqrt{c}\|\boldsymbol{x}\| + \sum_{\boldsymbol{x}\in\mathcal{G}(\mathcal{X},L_*,L(t),c)} 2\|\boldsymbol{x}\|.
\end{aligned}$$

In the last line of (92), the first term can be made as small as one would like by taking c_0 small enough. On the other hand, for c small enough, all points in $\mathcal{G}(\mathcal{X}, L_*, L(t), c)$ must be contained in a subspace $L \in B(L_*, \gamma) \setminus \{L_*\}$. Thus, for small enough c, the function $F(L(t); \mathcal{X})$ is approximately Lipschitz for $t \in [0, c\theta_1(L_k, L_*)]$.

As a result,

$$\begin{aligned}
F(L_k;\mathcal{X}) - F(L_{k+1};\mathcal{X})) &= F(L(0);\mathcal{X}) - F(L(c\theta_1(L_k,L_*));\mathcal{X})\\
&= -\int_{t=0}^{c\theta_1(L_k,L_*)}\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})\mathrm{d}t\\
&\ge -c\theta_1(L_k,L_*)\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\\
&\quad - c\theta_1(L_k,L_*)\left(\sum_{\boldsymbol{x}\in\mathcal{X}\setminus\mathcal{G}(L_k,L_{k+1})} 3\sqrt{c}\|\boldsymbol{x}\| + \sum_{\boldsymbol{x}\in\mathcal{G}(L_k,L_{k+1})} 2\|\boldsymbol{x}\|\right).
\end{aligned}$$

Finally, noting that $\frac{\mathrm{d}}{\mathrm{d}t}F(L(t))|_{t=0} < 0$, we use (86) and the assumption in (23) to find

$$\begin{aligned}
F(L_k) - F(L_{k+1})) &\ge \left|c\theta_1(L_k,L_*)\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right| - \frac{c\theta_1(L_k,L_*)}{2}\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right|\\
&\ge \frac{c\theta_1(L_k,L_*)}{2}\left|\frac{\mathrm{d}}{\mathrm{d}t}F(L(t);\mathcal{X})|_{t=0}\right|.
\end{aligned}$$

D.4. Proof of Inlier Permeance Bounds

D.4.1. Proof of Proposition 11

The continuous distribution assumption implies that all directions in $S^{D-1}\cap L_*$ have nonzero probability. Let $\boldsymbol{x}$ be a random variable following the inlier distribution. By the central limit theorem, we have that

$$\frac{1}{N_{\text{in}}}\sum_{\mathcal{X}_{\text{in}}}\left(\frac{|\boldsymbol{v}^T\boldsymbol{x}_i|^2}{\|\boldsymbol{x}_i\|} - \operatorname{Var}\left(\frac{\boldsymbol{v}^T\boldsymbol{x}}{\|\boldsymbol{x}\|^{1/2}}\right)\right) \xrightarrow{d} N(0,1).$$

We also have that $\max_i \|\boldsymbol{x}_i\| < M$ by the bounded-support assumption assumption. Thus, for large enough N_{in} and a covering argument, we have for some absolute constant C that

$$\min_{\boldsymbol{v}\in L_*\cap S^{D-1}}\sum_{\mathcal{X}_{\text{in}}}\frac{|\boldsymbol{v}^T\boldsymbol{x}_i|^2}{\|\boldsymbol{x}_i\|} \ge C\frac{N_{\text{in}}}{M}\min_{\boldsymbol{v}\in L_*\cap S^{D-1}}\operatorname{Var}\left(\frac{\boldsymbol{v}^T\boldsymbol{x}}{\|\boldsymbol{x}\|^{1/2}}\right), \text{ w.h.p.}$$

This can be done by using, e.g., Hoeffding's inequality on the bounded random variable $\boldsymbol{v}^T\boldsymbol{x}/\|\boldsymbol{x}\|^{1/2}$.

D.4.2. Proof of Proposition 12

For the inliers, we need to bound $\mathcal{P}(\mathcal{X}_{\text{in}})$. Using Theorem 3.1 in Lu and Pearce (2000) and letting $\widetilde{\cdot}$ denote the spherization operator,

$$\lambda_d\left(\sum_{\mathcal{X}_{\text{in}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right) = \sigma_d(\widetilde{\boldsymbol{X}_{\text{in}}}\boldsymbol{X}_{\text{in}}^T) \ge \sigma_d(\widetilde{\boldsymbol{X}_{\text{in}}})\sigma_d(\boldsymbol{X}_{\text{in}}). \qquad (93)$$

We proceed by bounding the last term in (93). Notice that $\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{X}_{\text{in}}$ has directional variance $1/d$ in all directions of L_* (i.e., these transformed inliers are isotropic with variance $1/d$). We again apply Theorem 3.1 in Lu and Pearce (2000) and then apply Theorem 5.39 in Vershynin (2012b) to $\sigma_d\left(\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{X}_{\text{in}}\right)$, where we scale by the standard deviation $1/\sqrt{d}$ and choose $t = a\sqrt{N_{\text{in}}}$:

$$\begin{aligned}
\sigma_d\left(\boldsymbol{X}_{\text{in}}\right) &= \sigma_d\left(\boldsymbol{\Sigma}_{\text{in}}^{1/2}\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{X}_{\text{in}}\right) \ge \sigma_d\left(\boldsymbol{\Sigma}_{\text{in}}^{1/2}\right)\sigma_d\left(\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{X}_{\text{in}}\right) \qquad (94)\\
&> \lambda_d\left(\boldsymbol{\Sigma}_{\text{in}}^{1/2}\right)\left((1-a)\sqrt{\frac{N_{\text{in}}}{d}} - C_1\right), \text{ w.p. at least } 1 - 2e^{-c_1a^2N_{\text{in}}}.
\end{aligned}$$

Here, c_1 and C_1 are constants that depend on the sub-Gaussian norm of $\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}$, where $\boldsymbol{x}$ follows the inlier distribution, and a must be chosen such that $(1-a)^2N_{\text{in}} > C_1^2d$. On the other hand, $\widetilde{\boldsymbol{X}}_{\text{in}}$ is still sub-Gaussian and $\widetilde{\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{X}_{\text{in}}}$ is isotropic sub-Gaussian. Therefore, by using (94) and applying Theorem 3.1 in Lu and Pearce (2000), we have

$$\begin{aligned}
\sigma_d\left(\widetilde{\boldsymbol{X}_{\text{in}}}\right) &= \sigma_d\left(\left[\frac{\boldsymbol{x}_1}{\|\boldsymbol{x}_1\|},\ldots,\frac{\boldsymbol{x}_{N_{\text{in}}}}{\|\boldsymbol{x}_{N_{\text{in}}}\|}\right]\right) \qquad (95)\\
&= \sigma_d\left(\boldsymbol{\Sigma}_{\text{in}}^{1/2}\left[\frac{\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_1}{\|\boldsymbol{\Sigma}_{\text{in}}^{1/2}\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_1\|},\ldots,\frac{\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_{N_{\text{in}}}}{\|\boldsymbol{\Sigma}_{\text{in}}^{1/2}\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_{N_{\text{in}}}\|}\right]\right)\\
&\ge \sigma_d\left(\frac{\boldsymbol{\Sigma}_{\text{in}}^{1/2}}{\|\boldsymbol{\Sigma}_{\text{in}}^{1/2}\|_2}\left[\frac{\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_1}{\|\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_1\|},\ldots,\frac{\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_{N_{\text{in}}}}{\|\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}_{N_{\text{in}}}\|}\right]\right)\\
&\ge \frac{\lambda_d(\boldsymbol{\Sigma}_{\text{in}}^{1/2})}{\lambda_1(\boldsymbol{\Sigma}_{\text{in}}^{1/2})}\sigma_d\left(\widetilde{\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{X}_{\text{in}}}\right)\\
&> \frac{\lambda_d(\boldsymbol{\Sigma}_{\text{in}}^{1/2})}{\lambda_1(\boldsymbol{\Sigma}_{\text{in}}^{1/2})}\left((1-a)\sqrt{\frac{N_{\text{in}}}{d}} - C_1'\right), \text{ w.p. at least } 1 - 2e^{-c_1'a^2N_{\text{in}}}.
\end{aligned}$$

Here, c_1' and C_1' are constants that depend on the sub-Gaussian norm of $\widetilde{\boldsymbol{\Sigma}_{\text{in}}^{-1/2}\boldsymbol{x}}$, where $\boldsymbol{x}$ is a random vector that follows the inlier distribution, and a must chosen such that $(1-a)^2 N_{\text{in}} > C_1'^2 d$. Therefore, for a to satisfy both requirements, we need $(1-a)^2 N_{\text{in}} > \max(C_1, C_1)'^2 d$. Abusing notation, we let c_1 be the minimum of c_1 and c_1', and we let C_1 be the maximum of C_1 and C_1'. Putting (94) and (95) together, we find

$$\lambda_d\left(\sum_{\mathcal{X}_{\text{in}}} \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right) > \frac{\lambda_d(\boldsymbol{\Sigma}_{\text{in}})}{\lambda_1(\boldsymbol{\Sigma}_{\text{in}})^{1/2}}\left((1-a)\sqrt{\frac{N_{\text{in}}}{d}} - C_1\right)^2, \text{ w.p. at least } 1 - 4e^{-c_1 a^2 N_{\text{in}}}. \quad (96)$$

D.5. Proof of Proposition 15

To prove this proposition, we only need to show that PCA initializes in $B(L_*, \gamma)$. Note that the covariance matrix for the data $\mathcal{X}$ is $\boldsymbol{\Sigma} = N_{\text{out}}\boldsymbol{\Sigma}_{\text{out}}/(ND_{\text{out}}) + N_{\text{in}}\boldsymbol{\Sigma}_{\text{in}}/(Nd)$. We want to see how close the sample covariance approximates $\boldsymbol{\Sigma}_{\text{in}}$, since the PCA subspace is spanned by the top d eigenvectors of the sample covariance. Denoting the sample covariance by $\boldsymbol{\Sigma}_N$, let $\boldsymbol{V}_{PCA}$ be its top d eigenvectors. Also, let $\boldsymbol{V}^*$ be the top d eigenvectors of $\boldsymbol{\Sigma}_{\text{in}}$ and let $\boldsymbol{V}$ be the top d eigenvectors of $\boldsymbol{\Sigma}$. We note that

$$|\sin(\theta_1(\boldsymbol{V}_{PCA}, \boldsymbol{V}^*))| \le |\sin(\theta_1(\boldsymbol{V}_{PCA}, \boldsymbol{V}))| + |\sin(\theta_1(\boldsymbol{V}, \boldsymbol{V}^*))|. \quad (97)$$

To deal with the last term in (97), the Davis-Kahan $\sin\theta$ Theorem (Davis and Kahan, 1970), or more precisely Corollary 3.1 of Vu et al. (2013), gives

$$|\sin(\theta_1(\boldsymbol{V}, \boldsymbol{V}^*)| \le \sqrt{2}\frac{\lambda_1(N_{\text{out}}\boldsymbol{\Sigma}_{\text{out}}/(ND_{\text{out}}))}{\lambda_d(N_{\text{in}}\boldsymbol{\Sigma}_{\text{in}}/(Nd))} = \sqrt{2}\frac{N_{\text{out}}}{N_{\text{in}}}\frac{d}{D_{\text{out}}}\frac{\lambda_1(\boldsymbol{\Sigma}_{\text{out}})}{\lambda_d(\boldsymbol{\Sigma}_{\text{in}})}.$$

Thus,

$$\sin(\gamma) > \sqrt{2}\frac{N_{\text{out}}}{N_{\text{in}}}\frac{d}{D_{\text{out}}}\frac{\lambda_1(\boldsymbol{\Sigma}_{\text{out}})}{\lambda_d(\boldsymbol{\Sigma}_{\text{in}})} \quad (98)$$

is a sufficient condition for $|\sin(\theta_1(\boldsymbol{V}, \boldsymbol{V}^*)| < \sin(\gamma)$.

On the other hand, similar to the derivation of (94), for the first term in the right hand side of (97), we must bound how close the sample covariance is to the true covariance. Proposition 2.1 of Vershynin (2012a) implies that, for every $\delta > 0$,

$$\|\boldsymbol{\Sigma} - \boldsymbol{\Sigma}_N\|_2 \le \epsilon(\delta, \boldsymbol{\Sigma}_{\text{in}}, \boldsymbol{\Sigma}_{\text{out}})\left(\frac{D_{\text{out}}}{N}\right)^{\frac{1}{2}}, \quad (99)$$

with probability at least $1-\delta$, where $\epsilon(\delta, \boldsymbol{\Sigma}_{\text{in}}, \boldsymbol{\Sigma}_{\text{out}})$ is a constant depending on δ, $\boldsymbol{\Sigma}_{\text{in}}$, and $\boldsymbol{\Sigma}_{\text{out}}$. By assumption, $\boldsymbol{\Sigma}$ has a positive dth eigengap. Thus, another application of the Davis-Kahan $\sin\theta$ Theorem yields

$$|\sin(\theta_1(\boldsymbol{V}_{PCA}, \boldsymbol{V}))| \le \frac{\|\boldsymbol{\Sigma} - \boldsymbol{\Sigma}_N\|_2}{\lambda_d(\boldsymbol{\Sigma}) - \lambda_{d+1}(\boldsymbol{\Sigma})} \le \epsilon_2(\delta, \boldsymbol{\Sigma}_{\text{in}}, \boldsymbol{\Sigma}_{\text{out}})\left(\frac{dD}{N}\right)^{\frac{1}{2}},$$

with probability $1-\delta$. For large enough N, we have

$$|\sin(\theta_1(\boldsymbol{V}_{PCA}, \boldsymbol{V})| \le \sin(\gamma) - |\sin(\theta_1(\boldsymbol{V}, \boldsymbol{V}^*)|. \quad (100)$$

Rearranging (100) and using the triangle inequality in (97) yields

$$|\sin(\theta_1(\boldsymbol{V}_{PCA}, \boldsymbol{V}^*))| \le \sin(\gamma),$$

with probability $1-\delta$.

D.6. Proof of Theorem 17

We begin by bounding the outlier term. The last term on the right hand side of (47) is optimally bounded in the proof of Theorem 14. On the other hand, in the following proposition, we obtain tighter bounds for the first term on the right hand side of this inequality.

Proposition 22 *Suppose that $\mathcal{X}$ is drawn from the Haystack Model with parameters N_{in}, σ_{in}, N_{out}, σ_{out}, D, and d. Then, for $D - d \ge 3$*

$$\max_{L\in G(D,d)} \left\|\widetilde{\boldsymbol{Q}_L \boldsymbol{X}_{\text{out}}}\right\|_2 \le \frac{7}{2}\sqrt{\frac{N_{\text{out}}}{D-d}} + \sqrt{2}, \quad (101)$$
$$\text{w.p. at least } 1 - \exp\left(-\frac{N_{\text{out}}}{4}\right) - C_1\exp\left(-\frac{N_{\text{out}}}{4(D-d)} + \frac{d(D-d)\log(D)}{2}\right),$$

where C_1 is an absolute constant.

Proof [Proof of Proposition 22] First, for a single L, Lemma 8.4 in Lerman et al. (2015) yields

$$\left\|\widetilde{\boldsymbol{Q}_L \boldsymbol{X}_{\text{out}}}\right\|_2 \le \left(\sqrt{\frac{N_{\text{out}}}{D-d-0.5}} + \sqrt{2} + \frac{t}{\sqrt{D-d-0.5}}\right), \text{ w.p. at least } 1 - 1.5e^{-t^2}. \quad (102)$$

We set $t = \sqrt{N_{\text{out}}}/2$ to obtain the desired bound for a single subspace L. However, in order to cover all of $G(D,d)$, we much use a more complicated argument.

Assume that we have two subspaces L_0 and L_1 such that $\theta_1(L_0, L_1) < 1/(2\sqrt{D})$. First, due to the triangle inequality,

$$\left\|\widetilde{\boldsymbol{Q}_{L_0}\boldsymbol{X}_{\text{out}}} - \widetilde{\boldsymbol{Q}_{L_1}\boldsymbol{X}_{\text{out}}}\right\|_2 < \left\|\widetilde{\boldsymbol{Q}_{L_0}\boldsymbol{X}^0_{\text{out}}} - \widetilde{\boldsymbol{Q}_{L_1}\boldsymbol{X}^0_{\text{out}}}\right\|_2 + \left\|\widetilde{\boldsymbol{Q}_{L_0}\boldsymbol{X}^1_{\text{out}}} - \widetilde{\boldsymbol{Q}_{L_1}\boldsymbol{X}^1_{\text{out}}}\right\|_2. \quad (103)$$

Here, we have partitioned the outliers into two parts. The following set-valued functions define these parts. Let $L(t)$ be the geodesic between L_0 and L_1 such that $L(0) = L_0$ and $L(1) = L_1$. Then, we define

$$\mathcal{X}^0_{\text{out}} = \left\{\boldsymbol{x} \in \mathcal{X}_{\text{out}} : \min_{t\in[0,1]} \angle(\boldsymbol{x}, L(t)) < \frac{1}{2\sqrt{D}}\right\}, \quad (104)$$

$$\mathcal{X}^1_{\text{out}} = \left\{\boldsymbol{x} \in \mathcal{X}_{\text{out}} : \min_{t\in[0,1]} \angle(\boldsymbol{x}, L(t)) \ge \frac{1}{2\sqrt{D}}\right\}. \quad (105)$$

Notice that

$$\mathcal{X}^0_{\text{out}} \subset \left\{\boldsymbol{x} \in \mathcal{X}_{\text{out}} : \angle(\boldsymbol{x}, L_0) < \frac{1}{\sqrt{D}}\right\}. \quad (106)$$

With these datasets, their data matrices are $\boldsymbol{X}^0_{\text{out}}$ and $\boldsymbol{X}^1_{\text{out}}$.

For the last term in (103), since $\theta_1(L_0, L_1) < 1/(2\sqrt{D})$, we have

$$\left\| \widetilde{\boldsymbol{Q}_{L_0} \boldsymbol{X}^1_{\text{out}}} - \widetilde{\boldsymbol{Q}_{L_1} \boldsymbol{X}^1_{\text{out}}} \right\|_2 < \frac{1}{2}\sqrt{\frac{N_{\text{out}}}{D}}. \tag{107}$$

On the other hand, we must look at the concentration of points around subspaces for the second to last term in (103). For any given L, we have the following concentration lemma.

Lemma 23 *If $\boldsymbol{x} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$, then*

$$\Pr\left(\angle(\boldsymbol{x}, L) < \frac{1}{2}\sqrt{\frac{D-d}{D}} \right) < \exp\left(-\frac{D-d}{2} \right).$$

Proof This is a direct consequence of Lemma 2.2 in Dasgupta and Gupta (2003). ■

For $D - d \geq 3$, we have

$$\Pr\left(\angle(\boldsymbol{x}, L) < \frac{1}{2}\sqrt{\frac{D-d}{D}} \right) \leq \exp\left(-\frac{D-d}{2} \right) \leq \frac{1}{D-d}. \tag{108}$$

Using (108) together with a loose Chernoff bound for the concentration of binomial random variables (Mitzenmacher and Upfal, 2005), we know that

$$\Pr\left(\#\left(\left\{ \boldsymbol{x} \in \mathcal{X}_{\text{out}} : \angle(\boldsymbol{x}, L) < \frac{1}{2}\sqrt{\frac{D-d}{D}} \right\} \right) > \frac{3}{2}\frac{N_{\text{out}}}{D-d} \right) < \exp\left(-\frac{N_{\text{out}}}{4(D-d)} \right). \tag{109}$$

Thus, we use (109) on the second to last term in (103) to find

$$\left\| \widetilde{\boldsymbol{Q}_{L_0} \boldsymbol{X}^0_{\text{out}}} - \widetilde{\boldsymbol{Q}_{L_1} \boldsymbol{X}^0_{\text{out}}} \right\|_2 < \sqrt{\#(\mathcal{X}^0_{\text{out}})} \leq \sqrt{\frac{3}{2}\frac{N_{\text{out}}}{D-d}}, \tag{110}$$
$$\text{w.p. at least } 1 - \exp\left(-\frac{N_{\text{out}}}{4(D-d)} \right).$$

Notice that also, by construction, this is true for all $L_0', L_1' \in B(L(t), \frac{1}{4}\sqrt{(D-d)/D})$.

We finish by completing the covering argument on $G(D, d)$. By remark 8.4 of (Szarek, 1983), $G(D, d)$ can be covered by $(C)^{d(D-d)}/(\gamma_1)^{d(D-d)}$ balls of radius γ_1. This means that, using a union bound and taking (102), (103), (107), and (110) together,

$$\Pr\left(\max_{L \in G(D,d)} \|\widetilde{\boldsymbol{Q}_L \boldsymbol{X}_{\text{out}}}\| < \frac{7}{2}\sqrt{\frac{N_{\text{out}}}{D-d-0.5}} + \sqrt{2} \right) > \tag{111}$$
$$1 - C_1 \exp\left(-\frac{N_{\text{out}}}{4(D-d)} + C_2 d(D-d)\log\left(\frac{D}{D-d} \right) \right) - \exp\left(-\frac{N_{\text{out}}}{4} \right),$$

where C_1 and C_2 are absolute constants. Thus, we see that N must be on the order $N = O(d(D-d)^2 \log(D))$, and we have have the desired statement. ■

We now continue with the proof of Theorem 17. In Proposition 22, We see that N needs to be on the order of $d(D-d)^2 \log(D)$, which is not the case of the small sample regime. On the other hand, Theorem 5.39 of Vershynin (2012b) states that

$$\|\boldsymbol{X}_{\text{out}}\|_2 \leq \sigma_{\text{out}} \left[\frac{5}{4}\sqrt{\frac{N_{\text{out}}}{D}} + 1 \right], \text{ w.p. at least } 1 - 2e^{-N_{\text{out}}/16}. \tag{112}$$

We combine the result of Proposition 22 with (112) to find that

$$\|\widetilde{\boldsymbol{Q}_L \boldsymbol{X}_{\text{out}}}\|_2 \|\boldsymbol{X}_{\text{out}}\|_2 \leq \frac{7}{2}\frac{N_{\text{out}}}{\sqrt{D(D-d)}} + O\left(\sigma_{\text{out}}\sqrt{\frac{N_{\text{out}}}{D}} \right), \tag{113}$$
$$\text{w.p. at least } 1 - 2e^{-N_{\text{out}}/16} - e^{-N_{\text{out}}/4} - C_1 \exp\left(-\frac{N_{\text{out}}}{4(D-d)} + C_2 d(D-d)\log\left(\frac{D}{D-d} \right) \right).$$

We can also improve the results for the inlier permeance bound since they are already isometric. In this case, we have that (94) still holds. On the other hand, $\widetilde{\boldsymbol{X}_{\text{in}}}$ is isotropic, which implies that

$$\sigma_d\left(\widetilde{\boldsymbol{X}_{\text{in}}} \right) > \left((1-a)\sqrt{\frac{N_{\text{in}}}{d}} - C_1' \right), \text{ w.p. at least } 1 - 2e^{-c_1' a^2 N_{\text{in}}}, \tag{114}$$

where as before we must have $(1-a)^2 N_{\text{in}}^2 > C_1'^2 d$. Abusing notation again (as we did in the proof of Proposition 12), we let c_1 be the minimum of c_1 and c_1' and C_1 be the max of C_1 and C_1' and we find that

$$\lambda_d\left(\sum_{\mathcal{X}_{\text{in}}} \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|} \right) > \sigma_{\text{in}}\left((1-a)\sqrt{\frac{N_{\text{in}}}{d}} - C_1 \right)^2, \text{ w.p. at least } 1 - 4e^{-c_1 a^2 N_{\text{in}}}. \tag{115}$$

This results in the following exact statement for the Haystack Model. We combine (113) with (115) to find that if (48) holds, then $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$ with probability at least (49).

D.7. Proof of Theorem 18

Here, we will show that GGD can recover the underlying subspace for any fixed fraction of outliers, provided that N_{out} is large enough. We denote the percentage of inliers by α_1 and the percentage of outliers by α_0. Then, the SNR is given by α_1/α_0.

Assume for simplicity that $\sigma_{\text{out}} = 1$, since the general case follows from the same logic. First, we will bound the maximum norm of the set of outlier points. Each $\boldsymbol{x}_i$ is i.i.d. $\mathcal{N}(\boldsymbol{0}, \boldsymbol{I}/D)$, we can bound its norm by

$$\Pr\left(\|\boldsymbol{x}_i\| \leq 1 + \frac{t}{\sqrt{D}} \right) \geq 1 - \exp\left(-ct^2 \right), \tag{116}$$

where c is just some universal constant. Thus, applying a union bound to (116) yields

$$\Pr\left(\max_i \|\boldsymbol{x}_i\| \leq 1 + \frac{t}{\sqrt{D}} \right) \geq 1 - N_{\text{out}} \exp\left(-ct^2 \right). \tag{117}$$

We can use a value of $t = \sqrt{D}N_{\text{out}}^{1/6}$ to find

$$\Pr\left(\max_i \|\boldsymbol{x}_i\| \leq 1 + N^{1/6}\right) \geq 1 - N_{\text{out}} \exp\left(-cDN_{\text{out}}^{1/3}\right). \tag{118}$$

Next, consider the alignment for a single fixed subspace $L \neq L_*$:

$$\mathcal{A}(\mathcal{X}_{\text{out}}, L) = \left\| \sum_{\mathcal{X}_{\text{out}}} \frac{\boldsymbol{Q}_L \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{P}_L}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} \right\|_2. \tag{119}$$

Taking an expectation within the norm in (119) yields

$$\mathbb{E} \sum_{\mathcal{X}_{\text{out}}} \frac{\boldsymbol{Q}_L \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{P}_L}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} = \boldsymbol{0}. \tag{120}$$

This follows by the symmetry of the outlier distribution, $\mathcal{N}(\boldsymbol{0}, \boldsymbol{I}/D)$. Fix arbitrary vectors $\boldsymbol{u} \in \text{Sp}(\boldsymbol{Q}_L) \cap S^{D-1}$ and $\boldsymbol{v} \in \text{Sp}(\boldsymbol{P}_L) \cap S^{D-1}$. Then, (120) implies that

$$\mathbb{E} \sum_{\mathcal{X}_{\text{out}}} \frac{\boldsymbol{u}^T \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{v}}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|} = 0. \tag{121}$$

In the following, we will continue to use $\boldsymbol{u}$ and $\boldsymbol{v}$ defined in this way.

To this end, define the following random variable

$$J(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{v}) = \frac{\boldsymbol{u}^T \boldsymbol{x} \boldsymbol{x}^T \boldsymbol{v}}{\|\boldsymbol{Q}_L \boldsymbol{x}\|}, \tag{122}$$

where $\boldsymbol{x}$ is distributed $\mathcal{N}(\boldsymbol{0}, \boldsymbol{I}/D)$ (i.e., it is an outlier in the Haystack model). We will first give a concentration bound for $\sum_{\mathcal{X}_{\text{out}}} J(\boldsymbol{x}_i, \boldsymbol{u}, \boldsymbol{v})$, which appears in (121). Notice that $J(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{v})$ is a mean zero random variable and is bounded by

$$|J(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{v})| \leq |\boldsymbol{x}^T \boldsymbol{v}|. \tag{123}$$

Here, $\boldsymbol{x}^T \boldsymbol{v}$ is Gaussian with variance $1/D$. Thus, $J(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{v})$ is sub-Gaussian with variance proxy $1/D$. This implies that

$$\Pr\left(\left|\sum_{\mathcal{X}_{\text{out}}} J(\boldsymbol{x}_i, \boldsymbol{u}, \boldsymbol{v})\right| > N_{\text{out}} t\right) \leq 2 \exp\left(-\frac{t^2 D N_{\text{out}}}{2}\right). \tag{124}$$

Letting $t = N_{\text{out}}^{-1/3}$ we find that

$$\Pr\left(\left|\sum_{\mathcal{X}_{\text{out}}} J(\boldsymbol{x}_i, \boldsymbol{u}, \boldsymbol{v})\right| > N_{\text{out}}^{2/3}\right) \leq 2 \exp\left(-\frac{D N_{\text{out}}^{1/3}}{2}\right). \tag{125}$$

Notice that $J(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{v})$ is continuous as a function of $\boldsymbol{u}$ and $\boldsymbol{v}$. Using (123), between two points $\boldsymbol{v}_1, \boldsymbol{v}_2 \in S^{D-1}$, we can bound the deviation in $\sum_{\mathcal{X}_{\text{out}}} J(\boldsymbol{x}_i, \boldsymbol{u}, \cdot)$ by

$$\left|\sum_{\mathcal{X}_{\text{out}}} J(\boldsymbol{x}_i, \boldsymbol{u}, \boldsymbol{v}_1) - \sum_{\mathcal{X}_{\text{out}}} J(\boldsymbol{x}_i, \boldsymbol{u}, \boldsymbol{v}_2)\right| \leq \sum_{\mathcal{X}_{\text{out}}} |(\boldsymbol{v}_1 - \boldsymbol{v}_2)^T \boldsymbol{x}_i| \leq \|\boldsymbol{v}_1 - \boldsymbol{v}_2\| N_{\text{out}} \max_i \|\boldsymbol{x}_i\|. \tag{126}$$

Combining (118), (125) and (126) with $\|\boldsymbol{v}_1 - \boldsymbol{v}_2\| < N_{\text{out}}^{-1/3}$ yields

$$\Pr\left(\max_{\boldsymbol{v}_2 : \|\boldsymbol{v}_2 - \boldsymbol{v}_1\| \leq N_{\text{out}}^{-1/3}} \left|\sum_i J(\boldsymbol{x}_i, \boldsymbol{u}, \boldsymbol{v}_2)\right| \leq 3N_{\text{out}}^{5/6}\right) \geq 1 - N_{\text{out}} \exp\left(-cDN_{\text{out}}^{1/3}\right) - 2\exp\left(-\frac{DN_{\text{out}}^{1/3}}{2}\right). \tag{127}$$

Since $L \cap S^{D-1}$ can be covered by $\left(2N_{\text{out}}^{1/3} + 1\right)^d$ balls of radius $N_{\text{out}}^{-1/3}$, we use a covering argument with (127) to find

$$\Pr\left(\max_{\boldsymbol{v} \in L \cap S^{D-1}} \left|\sum_{\mathcal{X}_{\text{out}}} J(\boldsymbol{x}_i, \boldsymbol{u}, \boldsymbol{v})\right| \leq 3N_{\text{out}}^{5/6}\right) \geq 1 - N_{\text{out}} \exp\left(-cDN_{\text{out}}^{1/3}\right) - 2\left(2N_{\text{out}}^{1/3} + 1\right)^d \exp\left(-\frac{DN_{\text{out}}^{1/3}}{2}\right). \tag{128}$$

Notice that we do not include the probability from (118) in the covering, since this probability holds independently of the choice of $\boldsymbol{v} \in L \cap S^{D-1}$.

The previous argument was actually independent of choice of $\boldsymbol{u} \in L^\perp \cap S^{D-1}$. Thus, we finally have

$$\Pr\left(\left\|\sum_{\mathcal{X}_{\text{out}}} \frac{\boldsymbol{Q}_L \boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{P}_L}{\|\boldsymbol{Q}_L \boldsymbol{x}_i\|}\right\|_2 \leq 3N_{\text{out}}^{5/6}\right) \geq 1 - N_{\text{out}} \exp\left(-cDN_{\text{out}}^{1/3}\right) - 2\left(2N_{\text{out}}^{1/3} + 1\right)^d \exp\left(-\frac{DN_{\text{out}}^{1/3}}{2}\right). \tag{129}$$

Now that we have covered a single $L \in G(D, d)$, we must extend this to all of $G(D, d)$ by another covering argument. From Lemma 2.2 of Dasgupta and Gupta (2003), we have, for each $\boldsymbol{x}_i \in \mathcal{X}_{\text{out}}$

$$\Pr\left(\angle(\boldsymbol{x}_i, L) < \frac{\pi}{2}\sqrt{\frac{\beta(D-d)}{D}}\right) \leq \exp\left(\frac{D-d}{2}(1 + \log(\beta))\right). \tag{130}$$

If we choose $\beta < N_{\text{out}}^{-2/3}$, then it is not hard to show that

$$\Pr\left(\angle(\boldsymbol{x}_i, L) < \frac{\pi}{2}\sqrt{\frac{\beta(D-d)}{D}}\right) \leq N_{\text{out}}^{-1/3}. \tag{131}$$

Define the cone around a subspace L as

$$\mathcal{C}(L, \xi) = \{\boldsymbol{x} \in \mathbb{R}^D : \angle(\boldsymbol{x}, L) < \xi\}. \tag{132}$$

Using a loose Chernoff bound for the concentration of binomial random variables (Mitzenmacher and Upfal, 2005), we have

$$\Pr\left(\left|\#\left(\mathcal{X}_{\text{out}}\cap\mathcal{C}\left(L,N_{\text{out}}^{-1/3}\frac{\pi}{2}\sqrt{\frac{(D-d)}{D}}\right)\right)-\delta N_{\text{out}}^{2/3}\right|\geq N_{\text{out}}^{2/3}\right)\leq\exp\left(-\frac{N_{\text{out}}^{2/3}\delta^2}{3}\right). \tag{133}$$

Choosing $\delta = N_{\text{out}}^{-1/6}$ yields

$$\Pr\left(\left|\#\left(\mathcal{X}_{\text{out}}\cap\mathcal{C}\left(L,N_{\text{out}}^{-1/3}\frac{\pi}{2}\sqrt{\frac{(D-d)}{D}}\right)\right)-N_{\text{out}}^{1/2}\right|\geq N_{\text{out}}^{2/3}\right)\leq\exp\left(-\frac{N_{\text{out}}^{1/3}}{3}\right). \tag{134}$$

For any $L_0 \in G(D,d)$, and $L_1 \in B(L_0,\xi)$, we can separate the alignment term into two parts: those $\boldsymbol{x}_i$ that are close to L_0 and L_1 and those that lie further away. The idea behind this is that points that are far away from L_0 and L_1 will contribute similar amounts to the alignment. On the other hand, those that are very close can contribute at most 2 times their norm to the alignment.

Rigorously, we write

$$\begin{aligned}
&\left\|\sum_{\mathcal{X}_{\text{out}}}\frac{\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_0}}{\|\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\|_2}-\frac{\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_1}}{\|\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\|_2}\right\|_2 \\
&\qquad\leq\left\|\sum_{\boldsymbol{x}_i\in\mathcal{X}_{\text{out}}\cap\mathcal{C}(L_0,\xi)}\frac{\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_0}}{\|\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\|_2}-\frac{\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_1}}{\|\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\|_2}\right\|_2+ \\
&\qquad\qquad\left\|\sum_{\boldsymbol{x}_i\in\mathcal{X}_{\text{out}}\cap\mathcal{C}(L_0,\xi)^C}\frac{\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_0}}{\|\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\|_2}-\frac{\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_1}}{\|\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\|_2}\right\|_2 \\
&\qquad\leq\sum_{\boldsymbol{x}_i\in\mathcal{X}_{\text{out}}\cap\mathcal{C}(L_0,\xi)}2\|\boldsymbol{x}_i\|+2\xi\sum_{\boldsymbol{x}_i\in\mathcal{X}_{\text{out}}\cap\mathcal{C}(L_0,\xi)^C}\|\boldsymbol{x}_i\|_2.
\end{aligned} \tag{135}$$

We will examining (135) term by term. For the first term, if we choose $\xi = N_{\text{out}}^{-1/3}$ and combine (118) and (134), we find that

$$\sum_{\boldsymbol{x}_i\in\mathcal{X}_{\text{out}}\cap\mathcal{C}(L_0,\xi)}2\|\boldsymbol{x}_i\|\leq 2\#(\mathcal{X}_{\text{out}}\cap\mathcal{C}(L_0,\xi))\max_{\mathcal{X}_{\text{out}}}\|\boldsymbol{x}_i\|\leq 2\left(1+N_{\text{out}}^{1/6}\right)N_{\text{out}}^{2/3}, \tag{136}$$

$$\text{w.p. at least } 1-N_{\text{out}}\exp\left(-cDN_{\text{out}}^{1/3}\right)-\exp\left(-\frac{N_{\text{out}}^{1/3}}{3}\right).$$

For the second term, choosing $\xi = N_{\text{out}}^{-1/3}$ and again using (118) yields

$$2\xi\sum_{\boldsymbol{x}_i\in\mathcal{X}_{\text{out}}\cap\mathcal{C}(L_0,\xi)^C}\|\boldsymbol{x}_i\|_2\leq 2\left(1+N_{\text{out}}^{1/6}\right)N_{\text{out}}^{2/3}+o(1), \tag{137}$$

$$\text{w.p. at least } 1-N_{\text{out}}\exp\left(-cDN_{\text{out}}^{1/3}\right).$$

Putting (136) and (137) yields

$$\left\|\sum_{\mathcal{X}_{\text{out}}}\frac{\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_0}}{\|\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\|_2}-\frac{\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_1}}{\|\boldsymbol{Q}_{L_1}\boldsymbol{x}_i\|_2}\right\|_2\leq 8N_{\text{out}}^{5/6}, \tag{138}$$

$$\text{w.p. at least } 1-N_{\text{out}}\exp\left(-cDN_{\text{out}}^{1/3}\right)-\exp\left(-\frac{N_{\text{out}}^{1/3}}{3}\right).$$

As already mentioned in Appendix D.6 (following Szarek (1983)), $G(D,d)$ can be covered by $(C_1)^{d(D-d)}/(\gamma_1)^{d(D-d)}$ balls of radius γ_1. Thus, by a union bound with (129) and (138),

$$\left\|\sum_{\mathcal{X}_{\text{out}}}\frac{\boldsymbol{Q}_L\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_L}{\|\boldsymbol{Q}_L\boldsymbol{x}_i\|}\right\|_2\leq 11N_{\text{out}}^{5/6},\ \forall\ L\in G(D,d), \tag{139}$$

$$\text{w.p. at least } 1-N_{\text{out}}\exp\left(-cDN_{\text{out}}^{1/3}\right)-2\left((C_1)^{d(D-d)}(N_{\text{out}}^{1/3})^{d(D-d)}\right)\cdot$$
$$\left(\left(2N_{\text{out}}^{1/3}+1\right)^d\exp\left(-\frac{DN_{\text{out}}^{1/3}}{2}\right)+\exp\left(-\frac{N_{\text{out}}^{1/3}}{3}\right)\right).$$

As $N_{\text{out}}\to\infty$, we see that this probability goes to 1.

On the other hand, we recall the bound on the permeance of inliers from (115). Combining this with (139) and adding back in the scale factor σ_{out}, we have that if

$$\cos(\gamma)\sigma_{\text{in}}\left((1-a)\sqrt{\frac{N_{\text{in}}}{d}}-C_1\right)^2\geq 11\sigma_{\text{out}}N_{\text{out}}^{5/6}, \tag{140}$$

then $\mathcal{S}(\mathcal{X},L_*,\gamma)>0$ w.o.p. This equates to

$$\text{SNR}\geq\frac{11d\sigma_{\text{out}}}{\cos(\gamma)N_{\text{out}}^{1/6}\sigma_{\text{in}}(1-a)^2}+O\left(\frac{\sqrt{N_{\text{in}}}}{N_{\text{out}}}\right), \tag{141}$$

which goes to 0 as $N\to\infty$ for any fixed fraction of outliers. We see, in terms of dependence on parameters in (139) and (141), N_{out} must be at least on the order of $O(\max(d^3D^3\log^3(N_{\text{out}}),(dN_{\text{out}}/N_{\text{in}})^6))$. This is due to the fact that (141) must hold and the limiting probability in (139) is

$$2\left((C_1)^{d(D-d)}(N_{\text{out}}^{1/3})^{d(D-d)}\right)\exp\left(-\frac{N_{\text{out}}^{1/3}}{3}\right),$$

which is only close to zero when the number of outliers is more than the specified regime.

Abstract

In this paper, we consider three typical optimization problems with a convex loss function and a nonconvex sparse penalty or constraint. For the sparse penalized problem, we prove that finding an $\mathcal{O}(n^{c_1}d^{c_2})$-optimal solution to an $n \times d$ problem is strongly NP-hard for any $c_1, c_2 \in [0, 1)$ such that $c_1 + c_2 < 1$. For two constrained versions of the sparse optimization problem, we show that it is intractable to approximately compute a solution path associated with increasing values of some tuning parameter. The hardness results apply to a broad class of loss functions and sparse penalties. They suggest that one cannot even approximately solve these three problems in polynomial time, unless P = NP.

Keywords: nonconvex optimization, computational complexity, variable selection, NP-hardness, sparsity

1. Introduction

Sparsity is a prominent modeling tool for extracting useful information from high-dimensional data. A practical goal is to minimize the empirical loss using as few variables/features as possible. In this paper, we consider three typical optimization problems arising from sparse machine learning. The first problem takes the form of empirical risk minimization with an additive sparse penalty.

Problem 1 Given the loss function $\ell : \mathbb{R} \times \mathbb{R} \mapsto \mathbb{R}^+$, penalty function $p : \mathbb{R} \mapsto \mathbb{R}^+$, and regularization parameter $\lambda > 0$, consider the problem

$$\min_{x \in \mathbb{R}^d} \sum_{i=1}^{n} \ell\left(a_i^T x, b_i\right) + \lambda \sum_{j=1}^{d} p\left(|x_j|\right),$$

where $A = (a_1, \ldots, a_n)^T \in \mathbb{R}^{n \times d}$, $b = (b_1, \ldots, b_n)^T \in \mathbb{R}^n$ are input data.

License: CC-BY 4.0, see https://creativecommons.org/licenses/by/4.0/. Attribution requirements are provided at http://jmlr.org/papers/v20/17-373.html.

We also consider two constrained versions of sparse optimization, which are given by Problems 2 and 3. Such problems arise from sparse estimation (Shen et al., 2012) and sparse recovery (Natarajan, 1995; Bruckstein et al., 2009).

Problem 2 Given the loss function $\ell : \mathbb{R} \times \mathbb{R} \mapsto \mathbb{R}^+$, penalty function $p : \mathbb{R} \mapsto \mathbb{R}^+$, consider the problem

$$\min_{x \in \mathbb{R}^d} \sum_{i=1}^{n} \ell\left(a_i^T x, b_i\right) \quad \text{s.t.} \sum_{j=1}^{d} p\left(|x_j|\right) \leq K,$$

where $A = (a_1, \ldots, a_n)^T \in \mathbb{R}^{n \times d}$, $b = (b_1, \ldots, b_n)^T \in \mathbb{R}^n$ and the sparsity parameter K are input data.

Problem 3 Given the loss function $\ell : \mathbb{R} \times \mathbb{R} \mapsto \mathbb{R}^+$, penalty function $p : \mathbb{R} \mapsto \mathbb{R}^+$, consider the problem

$$\min_{x \in \mathbb{R}^d} \sum_{j=1}^{d} p\left(|x_j|\right) \quad \text{s.t.} \sum_{i=1}^{n} \ell\left(a_i^T x, b_i\right) \leq \eta,$$

where $A = (a_1, \ldots, a_n)^T \in \mathbb{R}^{n \times d}$, $b = (b_1, \ldots, b_n)^T \in \mathbb{R}^n$ and the error tolerance parameter $\eta \geq 0$ are input data.

For a given sparsity level K, the optimal solution to Problem 2 is the best K-sparse solution that fits the data set (A, b). To select the best sparsity level that fits the data, one usually needs to solve a sequence of instances of Problem 2, corresponding to different values of K. Similarly for Problem 3, one often needs to compute the solution path that is associated with a sequence of values of η.

We are interested in the computational complexity of Problems 1, 2 and 3 under general conditions of the loss function ℓ and the sparse penalty p. In particular, we focus on the case where ℓ is a convex loss function and p is a nonconvex function with a unique minimizer at 0. These problems naturally arise from feature selection, compressive sensing, and sparse approximation. For some special cases of Problem 1, it has been shown that finding an *exact solution* is strongly NP-hard (Huo and Chen, 2010; Chen et al., 2014). However, these results have not excluded the possibility of the existence of polynomial-time algorithms with small approximation error. The technical note by Chen and Wang (2016) established the hardness of approximately solving Problems 1, 2 for the special case where p is the L_0 norm.

In this paper, we prove that it is strongly NP-hard to approximately solve Problems 1, 2 and 3 within certain levels of suboptimality. For Problem 1, we show that there exists a worst-case lower bound on the suboptimality error that can be achieved by any tractable deterministic algorithm. For Problems 2 and 3, we show that there does not exist any pseudo polynomial-time algorithm that can approximately compute a solution path where K or η increases at a certain speed. Our results apply to a variety of optimization problems in estimation and machine learning. Examples include sparse classification, sparse logistic regression and many more. The strong NP-hardness of approximation is one of the strongest forms of complexity result for continuous optimization. To our best knowledge, this is the first work that gives the proof of the approximation hardness for sparse optimization under general conditions on ℓ and p. A preliminary conference version of this paper (Chen et al.,

2017) focused solely on Problem 1. The current journal version extends the analysis to sparse constrained optimization and establishes hardness results for Problems 2 and 3.

Our results on optimization complexity provide new insights into the complexity of sparse feature selection (Zhang et al., 2014; Foster et al., 2015). In the case of sparse regression for linear models, our result on Problem 1 shows that the lower bound of approximation error is significantly larger than the desired small statistical error (although our lower bound is worst-case). In the case where practitioners wish to choose the best sparsity level, our result on Problem 2 shows that it is impossible to know how much the loss function would improve when increasing the sparsity level. These observations provide strong evidences for the hardness of variable selection.

Our main contributions are four-folded.

1. We prove the strong NP-hardness for Problems 1, 2 and 3 with a general loss function $\ell(\cdot)$, which are no longer limited to L_2 or L_p functions. These are the first results that apply to the broad class of problems including but not limited to: least square regression, linear model with Laplacian noise, robust regression, Poisson regression, logistic regression, inverse Gaussian models and the generalized linear model under the exponential distributions.

2. We present a general condition on the penalty function $p(\cdot)$ such that Problems 1, 2 and 3 are strongly NP-hard. Our condition is a slightly weaker version of strict concavity. It only requires the penalty function be concave while ruling out the possibility of linear penalty function (i.e., the LASSO) which is concave but also convex. It is satisfied by typical penalty functions such as the L_p norm ($p \in [0, 1)$), clipped L_1 norm, smoothly clipped absolute deviation, etc. To the best of our knowledge, this is the most general condition on the penalty function in the literature.

3. We prove that finding an $\mathcal{O}\left(\lambda n^{c_1} d^{c_2}\right)$-optimal solution to Problem 1 is strongly NP-hard, for any $c_1, c_2 \in [0, 1)$ such that $c_1 + c_2 < 1$. Here the $\mathcal{O}(\cdot)$ hides parameters that depend on the penalty function p, which is to be specified later. Our proof provides a first unified analysis that deals with a broad class of problems taking the form of Problem 1.

4. We prove that it is strongly NP-hard to distinguish the optimal values of instances of Problem 2 (or Problem 3) that are associated with increasing values of the sparsity parameter K (or the error tolerance parameter η). This is the first hardness result for sparsity-constrained optimization with general loss and penalty functions. It implies that it is hard to approximately compute a solution path for the purpose of parameter tuning.

Section 2 reviews the background of sparse optimization and related literatures in the complexity theory. Section 3 presents the key assumptions and illustrates examples of loss and penalty functions that satisfy the assumptions. Section 4 gives the main results. Section 5 discusses the implications of our hardness results. The full proofs are given in Section 6.

2. Background and Related Works

Sparse optimization problems are common in machine learning, estimation, and signal processing. The sparse penalty p plays the important role of variable/feature selection. A common technique of imposing sparsity is to penalize the objective with a penalty function, leading to Problem 1. A well known example is the LASSO where p is the L_1 norm penalty and ℓ is the regression objective (Tibshirani, 1996). Nonconvex choices of p have been extensively studied in order to provide stronger statistical guarantee to the optimal soluion. Fan and Li (2001) proposed the smoothly clipped absolute deviation (SCAD) penalty which forces the solution of Problem 1 to be unbiased, sparse and stable in certain statistical sense. Frank and Friedman (1993) proposed the bridge estimator which use the L_p norm ($0 < p < 1$) as its penalty function. Other related works include exact reconstruction of sparse signals by Candes et al. (2008) and Chartrand (2007), high-dimensional variable selection by Fan and Lv (2010), sparse Ising model by Xue et al. (2012) and regularized M-estimators by Loh and Wainwright (2013), etc.

Problem 2 finds applications in sparse estimation and feature selection. The work by Shen et al. (2012) proposed a statistically optimal estimator as the solution to the maximimum likelihood problem with L_0 sparsity constraint

$$\min_{x \in \mathbb{R}^d} -\sum_{i=1}^{n} \log g(x; a_i, b_i) \quad \text{s.t.} \sum_{i=1}^{d} \|x_i\|_0 \leq K.$$

This is a special case of Problem 2. The work by Fang et al. (2015) proposed an L_0 constrained optimization problem for sparse estimation of large-scale graphical models, which is also a special case of Problem 2. Another related problem is sparse recovery, which is to find the sparsest solution to a system of equations within an error tolerance. For example, Natarajan (1995) considered the problem

$$\min_{x \in \mathbb{R}^d} \sum_{i=1}^{d} \|x_i\|_0 \quad \text{s.t.} \sum_{i=1}^{n} (a_i^T x - b_i)^2 \leq \delta,$$

which is a special case of Problem 3. See the work by Bruckstein et al. (2009) for more examples of Problem 3.

Within the mathematical programming community, the complexity of Problem 1 has been considered in a few works. Huo and Chen (2010) first proved the hardness result for problems with a relaxed family of penalty functions $\min_{x \in \mathbb{R}^d} \|Ax - b\|_2^2 + \lambda \sum_{i=1}^{d} p(|x_i|)$. They show that for the penalties in ℓ_0, hard-thresholded (Antoniadis and Fan, 2001) and SCAD (Fan and Li, 2001), the above optimization problem is NP-hard. Our result (Theorem 1) requires weaker conditions on $p(\cdot)$ than theirs. In particular, our results applies to the $L_p (0 < p < 1)$ penalization and the clipped L_1 penalty function specified in Section 3.1 which do not satisfy the conditions in their paper. Moreover, our result applies to a broad class of ℓ functions and obtains *strong NP-hardness*. A problem is *strongly NP-hard* if every problem in NP can be polynomially reduced to it in a way such that input in the reduced instance are written in unary (Vazirani, 2001). It is a stronger notion than NP-hardness where NP-hard problems might still be fast to solve in practice using pseudo-polynomial algorithms if the coding size is small (Garey and Johnson, 1978). On the contrary, a

strongly NP-hard problem doesn't have such a pseudo-polynomial algorithm. Chen et al. (2014) showed that the L_2-L_p minimization $\min_{x\in\mathbb{R}^d} \|Ax-b\|_2^2 + \lambda\sum_{i=1}^d |x_i|^p$ is strongly NP-hard when $p \in (0,1)$. At the same time, Bian and Chen (2014) proved the strong NP-hardness for another class of penalty functions. Their result requires $p(t)$ to be at least locally strictly concave, while ours does not. In particular, among the examples listed in Section 3.1, their results do not apply to L_0 penalization and clipped L_1 penalty function. To the best of our knowledge, our results are the most general ones up to today, which contains as special cases a broad class of penalty functions including ℓ_0, hard-thresholded, SCAD, L_p penalization ($p \in (0,1)$), folded concave penalty family (Fan et al., 2014) etc.

Within the theoretical computer science community, there have been several early works on the complexity of sparse recovery, beginning with the work by Arora et al. (1993). Amaldi and Kann (1998) proved that the problem $\min\{\|x\|_0 \mid Ax = b\}$ is not approximable within a factor $2^{\log^{1-\epsilon} d}$ for any $\epsilon > 0$. Natarajan (1995) showed that, given $\epsilon > 0, A$ and b, the problem $\min\{\|x\|_0 \mid \|Ax-b\|_2 \le \epsilon\}$ is NP-hard. Davis et al. (1997) proved a similar result that for some given $\epsilon > 0$ and $M > 0$, it is NP-complete to find a solution x such that $\|x\|_0 \le M$ and $\|Ax-b\| \le \epsilon$. More recently, Foster et al. (2015) studied sparse linear recovery and sparse linear regression with *subgaussian noises*. Assuming that the true solution is K-sparse, it showed that no polynomial-time (randomized) algorithm can find a $K \cdot 2^{\log^{1-\delta} d}$-sparse solution x with $\|Ax-b\|_2^2 \le d^{C_1} n^{1-C_2}$ *with high probability*, where δ, C_1, C_2 are arbitrary positive scalars. Another work (Zhang et al., 2014) showed that under the Gaussian linear model, there exists a gap between the mean square loss that can be achieved by polynomial-time algorithms and the statistically optimal mean squared error. These two works focus on the estimation of linear models and impose distributional assumptions regarding the input data. For comparison with our results, theirs are stronger in the sense that they exclude the existence of any tractable randomized algorithm that succeds with high probability, while ours apply to deterministic algorithms. In the mean time, their results are less general than ours in the sense that they assume specific data distributions and specific loss functions, while ours are concerned with a much more general setting. In short, existing complexity results on sparse recovery are different in nature with our results on sparse computational optimization.

There remain several open questions. First, existing results do not apply to general loss functions ℓ or sparse penalties p. Existing analyses rely on specific properties of the L_q loss functions, such as the linear shift property $\|ax\|^q = a^q\|x\|^q$ and the property that L_q has sufficiently large second-order derivative around its minimum. However, these nice properties are lost in a majority of estimation problems, such as logistic regression and poisson regression. Second, the existing results from mathematical programming community apply only to the unconstrained Problem 1. The computational complexity of Problems 2 and 3 remain under-investigated in the community of optimization. Third, the results from computer science community apply to Problem 2 when the penalty function is L_0. These results work for specific loss functions and some of them impose distributional assumption about the input (Foster et al., 2015). In this paper, we focus on the worst-case complexity without making any distributional assumption regarding the input data. In this setting, the complexity of Problems 2 and 3 with penalty functions other than L_0 is yet to be established.

3. Assumptions

In this section, we state the two critical assumptions that lead to the strong NP-hardness results: one for the penalty function p, the other one for the loss function ℓ. We argue that these assumptions are essential and very general. They apply to a broad class of loss functions and penalty functions that are commonly used.

3.1. Assumption On The Sparse Penalty

Throughout this paper, we make the following assumption regarding the sparse penalty function $p(\cdot)$.

Assumption 1 *The penalty function $p(\cdot)$ satisfies the following conditions:*

(i) (Monotonicity) $p(\cdot)$ is non-decreasing on $[0,+\infty)$.

(ii) (Concavity) There exists $\tau > 0$ such that $p(\cdot)$ is concave but not linear on $[0,\tau]$.

In words, condition (ii) means that the concave penalty $p(\cdot)$ is nonlinear. Assumption 1 is the most general condition on penalty functions in the existing literature of sparse optimization. Below we present a few such examples.

1. In variable selection problems, the L_0 penalization $p(t) = I_{\{t\neq 0\}}$ arises naturally as a penalty for the number of factors selected.

2. A natural generalization of the L_0 penalization is the L_p penalization $p(t) = t^p$ where $(0 < p < 1)$. The corresponding minimization problem is called the bridge regression problem (Frank and Friedman, 1993).

3. To obtain a hard-thresholding estimator, Antoniadis and Fan (2001) use the penalty functions $p_\gamma(t) = \gamma^2 - ((\gamma - t)^+)^2$ with $\gamma > 0$, where $(x)^+ := \max\{x, 0\}$ denotes the positive part of x.

4. Any penalty function that belongs to the folded concave penalty family (Fan et al., 2014) satisfies the conditions in Assumption 1. Examples include the SCAD (Fan and Li, 2001) and the MCP (Zhang, 2010a), whose derivatives on $(0,+\infty)$ are $p'_\gamma(t) = \gamma I_{\{t\le\gamma\}} + \frac{(a\gamma-t)^+}{a-1} I_{\{t>\gamma\}}$ and $p'_\gamma(t) = (\gamma - \frac{t}{b})^+$, respectively, where $\gamma > 0$, $a > 2$ and $b > 1$.

5. The conditions in Assumption 1 are also satisfied by the clipped L_1 penalty function (Antoniadis and Fan, 2001; Zhang, 2010b) $p_\gamma(t) = \gamma \cdot \min(t, \gamma)$ with $\gamma > 0$. This is a special case of the piecewise linear penalty function:

$$p(t) = \begin{cases} k_1 t & \text{if } 0 \le t \le a \\ k_2 t + (k_1 - k_2)a & \text{if } t > a \end{cases}$$

where $0 \le k_2 < k_1$ and $a > 0$.

6. Another family of penalty functions which bridges the L_0 and L_1 penalties are the fraction penalty functions $p_\gamma(t) = \dfrac{(\gamma+1)t}{\gamma + t}$ with $\gamma > 0$ (Lv and Fan, 2009).

7. The family of log-penalty functions:

$$p_\gamma(t) = \frac{1}{\log(1+\gamma)} \log(1+\gamma t)$$

with $\gamma > 0$, also bridges the L_0 and L_1 penalties (Candes et al., 2008).

3.2. Assumption On The Loss Function

We state our assumption about the loss function ℓ.

Assumption 2 *Let M be an arbitrary constant. For any interval $[\tau_1, \tau_2]$ where $0 < \tau_1 < \tau_2 < M$, there exists $k \in \mathbb{Z}^+$ and $b \in \mathbb{Q}^k$ such that $h(y) := \sum_{i=1}^k \ell(y, b_i)$ has the following properties:*

(i) $h(y)$ is convex and Lipschitz continuous on $[\tau_1, \tau_2]$.

(ii) $h(y)$ has a unique minimizer y^* in (τ_1, τ_2).

(iii) There exists $N \in \mathbb{Z}^+, \bar{\delta} \in \mathbb{Q}^+$ and $C \in \mathbb{Q}^+$ such that when $\delta \in (0, \bar{\delta})$, we have

$$\frac{h(y^* \pm \delta) - h(y^*)}{\delta^N} \geq C.$$

(iv) $h(y^*)$, $\{b_i\}_{i=1}^k$ can be represented in $\mathcal{O}(\log \frac{1}{\tau_2 - \tau_1})$ bits.

Assumption 2 is a critical, but very general, assumption regarding the loss function $\ell(y, b)$. Condition (i) requires convexity and Lipschitz continuity within a neighborhood. Conditions (ii), (iii) essentially require that, given an interval $[\tau_1, \tau_2]$, one can artificially pick $b_1, \ldots, b_k$ to construct a function $h(y) := \sum_{i=1}^k \ell(y, b_i)$ such that h has its unique minimizer in $[\tau_1, \tau_2]$ and has enough curvature near the minimizer. This property ensures that a bound on the minimal value of $h(y)$ can be translated to a meaningful bound on the distance to the minimizer y^*. The conditions (i), (ii), (iii) are typical properties that a loss function usually satisfies. Condition (iv) is a technical condition that is used to avoid dealing with infinitely-long irrational numbers. It can be easily verified for almost all common loss functions.

We will show that Assumptions 2 is satisfied by a variety of loss functions. An (incomplete) list is given below.

1. In the least squares regression, the loss function has the form

$$\sum_{i=1}^n \left(a_i^T x - b_i\right)^2.$$

Using our notation, the corresponding loss function is $\ell(y, b) = (y - b)^2$. For all τ_1, τ_2, we choose an arbitrary $b' \in [\tau_1, \tau_2]$. We can verify that $h(y) = \ell(y, b')$ satisfies all the conditions in Assumption 2.

2. In the linear model with Laplacian noise, the negative log-likelihood function is

$$\sum_{i=1}^n \left|a_i^T x - b_i\right|.$$

So the loss function is $\ell(y, b) = |y - b|$. As in the case of least squares regression, the loss function satisfy Assumption 2. Similar argument also holds when we consider the L_q loss $|\cdot|^q$ with $q \geq 1$.

3. In robust regression, we consider the Huber loss (Huber, 1964) which is a mixture of L_1 and L_2 norms. The loss function takes the form

$$L_\delta(y, b) = \begin{cases} \frac{1}{2}|y - b|^2 & \text{for } |y - b| \leq \delta, \\ \delta(|y - b| - \frac{1}{2}\delta) & \text{otherwise.} \end{cases}$$

for some $\delta > 0$ where $y = a^T x$. We then verify that Assumption 2 is satisfied. For any interval $[\tau_1, \tau_2]$, we pick an arbitrary $b \in [\tau_1, \tau_2]$ and let $h(y) = \ell(y, b)$. We can see that $h(y)$ satisfies all the conditions in Assumption 2.

4. In Poisson regression (Cameron and Trivedi, 2013), the negative log-likelihood minimization is

$$\min_{x \in \mathbb{R}^d} -\log L(x; A, b) = \min_{x \in \mathbb{R}^d} \sum_{i=1}^n (\exp(a_i^T x) - b_i \cdot a_i^T x).$$

We now show that $\ell(y, b) = e^y - b \cdot y$ satisfies Assumption 2. For any interval $[\tau_1, \tau_2]$, we choose q and r such that $q/r \in [e^{\tau_1}, e^{\tau_2}]$. Note that $e^{\tau_2} - e^{\tau_1} = e^{\tau_1 + \tau_2 - \tau_1} - e^{\tau_1} \geq \tau_2 - \tau_1$. Also, e^{τ_2} is bounded by e^M. Thus, q, r can be chosen to be polynomial in $\lceil 1/(\tau_2 - \tau_1) \rceil$ by letting $r = \lceil 1/(\tau_2 - \tau_1) \rceil$ and q be some number less than $r \cdot e^M$. Then, we choose $k = r$ and $b \in \mathbb{Z}^k$ such that $h(y) = \sum_{i=1}^k \ell(y, b_i) = r \cdot e^y - q \cdot y$. Let us verify Assumption 2. (i), (iv) are straightforward by our construction. For (ii), note that $h(y)$ take its minimum at $\ln(q/r)$ which is inside $[\tau_1, \tau_2]$ by our construction. To verify (iii), consider the second order Taylor expansion of $h(y)$ at $\ln(q/r)$,

$$h(y + \delta) - h(y) = \frac{r \cdot e^y}{2} \cdot \delta^2 + o(\delta^2) \geq \frac{\delta^2}{2} + o(\delta^2),$$

We can see that (iii) is satisfied. Therefore, Assumption 2 is satisfied.

5. In logistic regression, the negative log-likelihood function minimization is

$$\min_{x \in \mathbb{R}^d} \sum_{i=1}^n \log(1 + \exp(a_i^T x)) - \sum_{i=1}^n b_i \cdot a_i^T x.$$

We claim that the loss function $\ell(y, b) = \log(1 + \exp(y)) - b \cdot y$ satisfies Assumption 2. By a similar argument as the one in Poisson regression, we can verify that $h(y) = \sum_{i=1}^r \ell(y, b_i) = r \log(1 + \exp(y)) - qy$ where $q/r \in [\frac{e^{\tau_1}}{1+e^{\tau_1}}, \frac{e^{\tau_2}}{1+e^{\tau_2}}]$ and q, r are polynomial in $\lceil 1/(\tau_2 - \tau_1) \rceil$ satisfies all the conditions in Assumption 2. For (ii), observe that $\ell(y, b)$

take its minimum at $y = \ln \frac{q/r}{1-q/r}$. To verify (iii), we consider the second order Taylor expansion at $y = \ln \frac{q/r}{1-q/r}$, which is

$$h(y+\delta) - h(y) = \frac{q}{2(1+e^y)}\delta^2 + o(\delta^2)$$

where $y \in [\tau_1, \tau_2]$. Note that e^y is bounded by e^M, which can be computed beforehand. As a result, (iii) holds as well.

6. In the mean estimation of inverse Gaussian models (McCullagh, 1984), the negative log-likelihood function minimization is

$$\min_{x\in\mathbb{R}^d} \sum_{i=1}^n \frac{(b_i \cdot \sqrt{a_i^T x} - 1)^2}{b_i}.$$

Now we show that the loss function $\ell(y,b) = \frac{(b\cdot\sqrt{y}-1)^2}{b}$ satisfies Assumption 2. By setting the derivative to be zero with regard to y, we can see that y take its minimum at $y = 1/b^2$. Thus for any $[\tau_1, \tau_2]$, we choose $b' = q/r \in [1/\sqrt{\tau_2}, 1/\sqrt{\tau_1}]$. We can see that $h(y) = \ell(y, b')$ satisfies all the conditions in Assumption 2.

7. In the estimation of generalized linear model under the exponential distribution (McCullagh, 1984), the negative log-likelihood function minimization is

$$\min_{x\in\mathbb{R}^d} -\log L(x; A, b) = \min_{x\in\mathbb{R}^d} \frac{b_i}{a_i^T x} + \log(a_i^T x).$$

By setting the derivative to 0 with regard to y, we can see that $\ell(y,b) = \frac{b}{y} + \log y$ has a unique minimizer at $y = b$. Thus by choosing $b' \in [\tau_1, \tau_2]$ appropriately, we can readily show that $h(y) = \ell(y, b')$ satisfies all the conditions in Assumption 2.

To sum up, the combination of *any* loss function given in Section 3.1 and *any* penalty function given in Section 3.2 results in a strongly NP-hard sparse optimization problem. We will provide formal statements and proof of these results in subsequent sections.

4. Main Results

In this paper, we aim to clarify the complexity for a broader class of sparse optimization problems taking the form of Problems 1, 2 and 3. Given an optimization problem $\min_{x\in X} f(x)$, we say that a solution $\bar{x}$ is ϵ-optimal if $\bar{x} \in X$ and $f(\bar{x}) \le \inf_{x\in X} f(x) + \epsilon$.

Theorem 1 (Strong NP-Hardness of Problem 1) *Let Assumptions 1 and 2 hold, and let $c_1, c_2 \in [0,1)$ be arbitrary such that $c_1 + c_2 < 1$. Then it is strongly NP-hard to find a $\lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$-optimal solution of Problem 1, where d is the dimension of variable space and $\kappa = \min_{t\in[\tau/2,\tau]}\{\frac{2p(t/2)-p(t)}{t}\}$.*

The non-approximable error in Theorem 1 involves the constant κ which is determined by the sparse penalty function p. In the case where p is the L_0 norm function, we can take $\kappa = 1$. In the case of piecewise linear L_1 penalty, we have $\kappa = (k_1 - k_2)/4$. In the case of SCAD penalty, we have $\kappa = \Theta(\gamma^2)$.

According to Theorem 1, the non-approximable error $\lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$ is determined by three factors: (i) properties of the regularization penalty $\lambda \cdot \kappa$; (ii) data size n; and (iii) dimension or number of variables d. This result illustrates a fundamental gap that can not be closed by any polynomial-time deterministic algorithm. This gap scales up when either the data size or the number of variables increases. In Section 5.1, we will see that this gap is substantially larger than the desired estimation precision in a special case of sparse linear regression.

Next we study the complexity of the sparsity-constrained Problem 2. We denote by $\ell_n(x)$ the normalized loss function:

$$\ell_n(x) = \frac{1}{n}\sum_{i=1}^n \ell\left(a_i^T x, b_i\right),$$

and denote by x_K^* the best K-sparse solution:

$$x_K^* \in \operatorname{argmin}\left\{ \ell_n(x) \,\middle|\, \sum_{j=1}^d p(|x_j|) \le K \right\}.$$

We obtain the following result.

Theorem 2 (Strong NP-Hardness of Problem 2) *Let Assumptions 1 and 2 hold, and let $c_1, c_2 \in [0,1)$ be arbitrary such that $c_1 + c_2 < 1$. Let $\hat{x}_K$ be the approximate solution to Problem 2 with sparsity parameter K. Then there does not exist a pseudo polynomial-time algorithm that takes the input of Problem 2 and outputs a sequence of approximate solutions satisfying*

$$\ell_n(\hat{x}_{K+\kappa n^{c_1} d^{c_2}}) \le \ell_n(x_K^*),$$

for all $K = 0, \kappa n^{c_1} d^{c_2}, 2\kappa n^{c_1} d^{c_2}, \ldots,$ unless P=NP, where $\kappa = \min_{t\in[\tau/2,\tau]}\{\frac{2p(t/2)-p(t)}{t}\}$.

Let us interpret the results of Theorem 2 in a practical setting. Suppose that we want to solve a sequence of sparsity-constrained problems with different values of the sparsity parameter K. The aim is to compare the corresponding empirical losses $\{\ell_n(x_K^*)\}$ and tune the parameter K.

Theorem 2 suggests that we cannot decide whether and how much the objective value will change by increasing the sparsity level from K to $K + \kappa n^{c_1} d^{c_2}$. Even if $\ell_n(x_K^*)$ is known as a benchmark, we can not find a better approximation of $\ell_n(x^*_{K+\kappa n^{c_1} d^{c_2}})$ in polynomial time. In short, Theorem 2 tells us that it is computationally intractable to differentiate the minimal empirical losses that correspond to different values of K, unless P=NP. This implies that tuning the parameter K is computationally intractable.

Our last result concerns the error-constrained Problem 3.

Theorem 3 *Let Assumptions 1 and 2 hold, and let $c \in [0,1)$ be arbitrary. Let $\hat{x}_\eta$ be the approximate solution to Problem 3 with error tolerance η and let x^*_η be the corresponding optimal solution. There does not exist a pseudo polynomial-time algorithm that takes the input of Problem 3 and outputs a sequence of approximate solutions satisfying*

$$\sum_{j=1}^{d} p\left(\left(\hat{x}_{\eta+\kappa n^{c_1} d^{c_2}}\right)_j\right) \leq \sum_{j=1}^{d} p\left(\left(x^*_\eta\right)_j\right),$$

for all $\eta = 0, \kappa n^{c_1} d^{c_2}, 2\kappa n^{c_1} d^{c_2}, \ldots,$ unless P=NP. Here, $(x)_j$ is the j-th component of vector x and $\kappa = \min_{t\in[\tau/2,\tau]}\{\frac{2p(t/2)-p(t)}{t}\}$.

Theorems 1, 2 and 3 are closely related to one another. Recall that the goal of sparse optimization is to make both the loss function and sparsity level small. Theorem 2 and Theorem 3 suggest that it is not possible to approximate the solution path, where either the loss tolerance or the sparsity level varies, in polynomial time. In contrast, Theorem 1 proves the approximation hardness for the sum between the loss tolerance and the sparsity level, when a fixed λ is used.

Theorems 1, 2 and 3 validate the long-lasting belief that optimization involving nonconvex penalty is hard. They provide worst-case lower bounds for the optimization error that can be achieved by any polynomial-time algorithm. This is one of the strongest forms of hardness result for continuous optimization.

5. Implications of The Hardness Results

In this section, we interpret the strong NP-hardness results in the contexts of linear regression with SCAD penalty (which is a special case of Problem 1) and sparsity parameter tuning (which is related to Problem 2). We give a few remarks on the implication of our hardness results.

5.1. Hardness of Regression with SCAD Penalty

Let us try to understand how significant is the non-approximable error of Problem 1. We consider the special case of linear models with SCAD penalty. Let the input data (A, b) be generated by the linear model $A\bar{x} + \varepsilon = b$, where $\bar{x}$ is the unknown *true* sparse coefficients and ε is a zero-mean multivariate subgaussian noise. Given the data size n and variable dimension d, we follow the work by Fan and Li (2001) and obtain a special case of Problem 1, given by

$$\min_x \frac{1}{2}\|Ax - b\|_2^2 + n\sum_{j=1}^{d} p_\gamma(|x_j|), \tag{1}$$

where $\gamma = \sqrt{\log d/n}$. Fan and Li (2001) showed that the optimal solution x^* of problem (1) has a small statistical error, i.e., $\|\bar{x} - x^*\|_2^2 = \mathcal{O}\left(n^{-1/2} + a_n\right)$, where $a_n = \max\{p'_\lambda(|x^*_j|) : x^*_j \neq 0\}$. Fan et al. (2015) further showed that we only need to find a $\sqrt{n\log d}$-optimal solution to (1) to achieve such a small estimation error.

However, Theorem 2 tells us that it is not possible to compute an $\epsilon_{d,n}$-optimal solution for problem (1) in polynomial time, where $\epsilon_{d,n} = \lambda\kappa n^{1/2} d^{1/3}$ (by letting $c_1 = 1/2, c_2 = 1/3$).

In the special case of problem (1), we can verify that $\lambda = n$ and $\kappa = \Omega(\gamma^2) = \Omega(\log d/n)$. As a result, we see that

$$\epsilon_{d,n} = \Omega(n^{1/2} d^{1/3}) \gg \sqrt{n\log d},$$

for high values of the dimension d. According to Theorem 2, it is strongly NP-hard to approximately solve problem (1) within the required statistical precision $\sqrt{n\log d}$, where there is no distributional assumption on the data.

This gap is due to that the positive statistical properties of SCAD rely on strong distributional assumptions, while our hardness result does not. This illustrates a sharp contrast between the desirable statistical properties of sparse optimization under distributional assumptions and the worst-case computational complexity. In short, there does not exist a general-purpose polynomial algorithm.

5.2. Hardness of Tuning the Sparsity Level with L_0 Penalty

Suppose that we are given the input data set (A, b) with d variables/features and n samples. Now we want to find a sparse solution x that approximately minimize the empirical loss $L_n(x) = \frac{1}{n}\sum_{i=1}^{n} \ell(a_i^T x, b_i)$. A practical problem is to find the right sparsity level for the approximate solution. This is essentially a model selection problem.

Finding the sparsity level requires computing the K-sparse solutions

$$x^*_K \in \operatorname{argmin}\left\{L_n(x) \mid \|x\|_0 \leq K\right\},$$

for a range of values of K. This can be translated into solving a sequence of L_0 constrained problems (of the form Problem 2) with K ranging from 1 to d. Regardless of the specific model selection procedure, it is inevitable to compute x^*_K for many values of K's, and to compare their empirical losses such as $L_n(x^*_K)$ and $L_n(x^*_{K+1})$.

Now let us interpret the results of Theorem 3 in the setting of tuning parameter K. Theorem 3 can be translated as follows. There exists some sparsity level K such that: even if the exact K-sparse solution x^*_K is known, the non-approximable optimization error for the $(K+1)$-sparse problem is at least

$$L_n(x^*_K) - L_n(x^*_{K+1}) > 0.$$

The minimal empirical loss using K features is the best possible approximation to the minimal loss using $K+1$ features. In other words, we cannot decide whether and how much the objective value will change by increasing the sparsity level from K to $K+1$. Even if $L_n(x^*_K)$ is known as a benchmark, we can not find a better approximation of $L_n(x^*_{K+1})$ in polynomial-time. In summary, Theorem 2 tells us that it is computationally intractable to differentiate between the sparsity levels K and $K+1$, unless P=NP. This implies that selection of the sparsity level is computationally intractable.

5.3. Remarks on the NP-Hardness Results

As illustrated by the preceding analysis, the non-approximibility of Problems 1, 2 and 3 suggests that computing the sparse estimator and tuning the sparsity parameter are hard *in the worst case*. Although the results seem negative, they should not discourage researchers from studying computational perspectives of sparse optimization. We make the following remarks:

1. Theorems 1, 2 and 3 are *worst-case* complexity results. They suggest that one cannot find a tractable solution to the sparse optimization problems, without making any additional assumption to rule out the worst-case instances. It is possible that the worst-case instances are highly unlikely to occur in practical situations.

2. Our results do not exclude the possibility that, under more stringent modeling and distributional assumptions, the problem would be tractable with high probability or on average.

In short, the sparse optimization Problems 1, 2 and 3 are fundamentally hard from a purely computational perspective. This paper together with the prior related works provide a complete answer to the computational complexity of sparse optimization.

6. Technical Proofs

In this section, we prove the hardness of approximation of Problem 1, 2 and 3 for general loss function ℓ and penalty function p. We develop the reduction proof through a series of preliminary lemmas.

6.1. Preliminary Lemmas

Our first lemma gives us a key fact about the nonconvex penalty function p. We use $B(\theta, \delta)$ to denote the interval $(\theta - \delta, \theta + \delta)$.

Lemma 4 *For any penalty function p that satisfies Assumption 1, we have*

(i) *$p(t)$ is continuous on $(0, \tau]$.*

(ii) *For any $t_1, ..., t_l \geq 0$, if $\sum_{i=1}^n t_i \leq \tau$, then $\sum_{i=1}^l p(t_i) \geq p(\sum_{i=1}^l t_i)$.*

(iii) *There exists $a \in [1/2, 1)$ such that when $\sum_{i=1}^l t_i \in [a\tau, \tau]$, the above inequality holds as equality if and only if $t_i = t^*$ for some i while $t_j = 0$ for $j \neq i$.*

(iv) *Denote $\kappa = \min_{t \in [a\tau, \tau]} \{\frac{2p(t/2) - p(t)}{t}\}$. For the constant a given in (iii), we have that $\forall \delta > 0, t_1, \cdots, t_l \in \mathbb{R}, \forall \epsilon \leq \kappa\delta$: if $\sum_{i=1}^l t_i = t^* \in [a\tau, \tau]$ and $p(\sum_{i=1}^l t_i) + \epsilon \geq \sum_{i=1}^l p(t_i)$, then there is at most one i such that $t_i \notin B(0, \delta)$.*

Proof As (i), (ii) and (iii) are proved by Ge et al. (2015), we prove (iv) here. We first prove the lemma when $t_1, \cdots, t_l \geq 0$. We start by proving the case when $l = 2$. By (iii), there exists a such that when $t^* \in [a\tau, \tau]$ and $p(t^*) \geq p(t_1) + p(t_2)$, we have $t_1 = 0$ or $t_2 = 0$. It follow that when $t_1 \neq 0, t_2 \neq 0$ and $t^* \in [a\tau, \tau]$, we have $p(t_1 + t_2) < p(t_1) + p(t_2)$. Without loss of genearlity, we assume that $t_1 \leq t_2$. Then, we have

$$\frac{p(t^*) - p(t^* - t_1)}{t_1} < \frac{p(t_1)}{t_1}.$$

Notice that the right term is non-increasing with the increment of t_1 as p is a concave function and the left term is non-decreasing with the increment of t_1 when t^* is fixed. As

$t_1 \leq t^*/2$, we have $\frac{p(t_1)}{t_1} \geq k_1(t^*) \coloneqq \frac{p(t^*/2)}{t^*/2}$ and $\frac{p(t^*) - p(t^* - t_1)}{t_1} \leq k_2(t^*) \coloneqq \frac{p(t^*) - p(t^*/2)}{t^*/2}$. As p is not linear on $[0, t^*]$, we have $k_1(t^*) > k_2(t^*)$.

On the other hand, we can see that when $p(t_1 + t_2) + \epsilon \geq p(t_1) + p(t_2)$,

$$\frac{p(t_1 + t_2) - p(t_2)}{t_1} + \frac{\epsilon}{t_1} \geq \frac{p(t_1)}{t_1}.$$

Assume $t_1 < t_2$, we have $k_2(t^*) + \epsilon/t_1 \geq k_1(t^*)$ [1]. As a result $t_1 \leq \frac{\epsilon}{k_1(t^*) - k_2(t^*)}$. Note that k_1 and k_2 are defined on a closed interval $[a\tau, \tau]$ by (iii), giving us that $\min_{t \in [a\tau, \tau]}(k_1(t) - k_2(t)) > 0$. Therefore, $\exists a \in (0, 1), \forall \delta > 0, \exists \epsilon_0 = \min_{t \in [a\tau, \tau]}(k_1(t) - k_2(t)) \cdot \delta, \forall \epsilon < \epsilon_0$, if $t_1 + t_2 = t^* \in [a\tau, \tau]$ and $p(t_1 + t_2) + \epsilon \geq p(t_1) + p(t_2)$, then $t_1 \leq \frac{\epsilon}{k_1(t^*) - k_2(t^*)} \leq \delta$. Therefore, there is at most one i such that $t_i \notin B(0, \delta)$.

Now consider the case when $l > 2$ and $t_1, \ldots, t_l \geq 0$. If there are more than one i such that $t_i \notin B(0, \delta)$, assume t_1 and t_2 are two of them. By (ii), we have

$$\sum_{i=1}^l p(t_i) \geq p(t_1) + p\left(\sum_{i=2}^l t_i\right).$$

If $t_1 + \sum_{i=2}^n t_i \in [a\tau, \tau]$ and $p(t_1 + \sum_{i=2}^l t_i) + \epsilon \geq \sum_{i=1}^l p(t_i) \geq p(t_1) + p(\sum_{i=2}^l t_i)$, either t_1 or $\sum_{i=2}^n t_i$ should be inside $B(0, \delta)$. This is contradictory to our assumption that both t_1 and t_2 are outside $B(0, \delta)$. To this point, we prove (iv) when $t_1, \cdots, t_l \geq 0$.

Next, we prove the lemma when $t_1, \cdots, t_l$ could be smaller than 0. Suppose $t^* = \sum_{i=1}^l t_i \in [a\tau, \tau]$ and $p(t^*) + \epsilon \geq \sum_{i=1}^l p(t_i)$. We consider two cases separately. In the first case, assume that there is one $t_i \leq -\delta$. Without loss of generality, we assume that $t^* > 0$. Then we can choose $\alpha = \delta, \beta = t^* - \alpha$ and get

$$p(\alpha + \beta) + \epsilon = p(t^*) + \epsilon \geq \sum_{i \in \{j : t_j < 0\}} p(t_i) + \sum_{i \in \{j : t_j > 0\}} p(t_i) \geq p(\alpha) + p(\beta),$$

which is a contradiction to the previous proof that only one of α, β could be outside of $B(0, \delta)$ as δ is smaller than $t^*/2$ by our choice and $\sum_{i \in \{j : t_j > 0\}} t_i > t^* > t^* - \alpha$. We then proceed to the case when there is one $t_i \geq \delta$ and one $t_j \geq \delta$. Suppose that $\alpha = t_i \geq t_j = \beta$. If $\alpha + \beta > t^*$, we set $\alpha' = \delta + \frac{t^* - 2\delta}{\alpha + \beta - 2\delta} \cdot (\alpha - \delta)$ and $\beta' = \delta + \frac{t^* - 2\delta}{\alpha + \beta - 2\delta} \cdot (\beta - \delta)$. It is easy to verify that

$$p(\alpha' + \beta') + \epsilon = p(t^*) + \epsilon \geq \sum_{i=1}^l p(t_i) \geq p(\alpha) + p(\beta) \geq p(\alpha') + p(\beta'),$$

which is a contradiction. If $\alpha + \beta < t^*$, we can verify that

$$p(\alpha + \beta + t^* - \alpha - \beta) + \epsilon = p(t^*) + \epsilon \geq \sum_{i=1}^l p(t_i) \geq p(\alpha) + p(\beta) + p(t^* - \alpha - \beta),$$

which is also a contradiction. To this point, we prove the case that $t_1, \cdots, t_l$ could be smaller than 0, which completes the proof of the lemma.

1. For the case when $t_1 = 0$, (iv) holds trivially.

Remark. In the proof of (iv), our choice of ϵ is linear to δ given δ. However, in the case of L_0, ϵ could be any constant smaller than 1 no matter what δ is. This property of L_0 has wide applications in statistical problems. Actually, suppose that penalty function is indexed by δ and p_δ satisfies

$$p_\delta(\delta) - p_\delta(a\tau) + p_\delta(a\tau - \delta) \geq C$$

for some constant C, then $\forall \delta > 0$ and $\epsilon \leq C$, the proposition stated in (iv) holds. To prove this, just note that if $p(t_1+t_2)-p(t_2)+\epsilon > p(t_1)$ and $t_1 > \delta$, then $p(t_1)-p(t_1+t_2)+p(t_2) > p(\delta)-p(a\tau)+p(a\tau-\delta) \geq C$ which is a contradiction to that ϵ should be smaller than C. ■

Lemma 4 states the key properties of the penalty function p. Property (iv) is of special interest. It indicates that if we can manipulate the sum of non-negative variables to let it lie within $[a\tau, \tau]$ while minimizing the penalty function, we can be sure that only one variable has large absolute value.

Our second lemma explores the relationship between the penalty function p and the loss function ℓ.

Lemma 5 *Let Assumption 1 hold. Let $f(\cdot)$ be a convex function with a unique minimizer $\hat{\tau} \in (a\tau, \tau)$ and $\frac{f(\hat{\tau}\pm x)-f(\hat{\tau})}{x^N} \geq C (0 < x < \bar{\delta})$ for some $N \in \mathbb{Z}^+, \bar{\delta} \in \mathbb{R}^+, C \in \mathbb{R}^+$. Define*

$$g_\mu(t) = p(|t|) + \mu \cdot f(t),$$

where $\mu > 0$. Let $h(\mu)$ be the minimum value of $g_\mu(\cdot)$. We have $\forall \delta < \bar{\delta}, \mu_\delta > \frac{p(|\hat{\tau}|)2^N}{C\delta^N}, \exists \epsilon_0 = \mu_\delta \cdot C \cdot \left(\frac{\delta}{2}\right)^N - p(|\hat{\tau}|)$: if t satisfies $h(\mu_\delta) + \epsilon_0 \geq g_{\mu_\delta}(t) \geq h(\mu_\delta)$, then $t \in [\hat{\tau} - \delta/2, \hat{\tau} + \delta/2]$.

Proof First, we can see that when $t > \hat{\tau} + \delta/2$, we have

$$\begin{aligned} g_{\mu_\delta}(t) &\geq p(|\hat{\tau}|) + \mu_\delta \cdot f(t) > p(|\hat{\tau}|) + \mu_\delta \cdot f(\hat{\tau} + \delta/2) \geq p(|\hat{\tau}|) + \mu_\delta \cdot f(\hat{\tau}) + \mu_\delta \cdot C \cdot \left(\frac{\delta}{2}\right)^N \\ &= g_{\mu_\delta}(\hat{\tau}) + \mu_\delta \cdot C \cdot \left(\frac{\delta}{2}\right)^N \geq h(\mu_\delta) + \mu_\delta \cdot C \cdot \left(\frac{\delta}{2}\right)^N \geq h(\mu_\delta) + \epsilon_0, \end{aligned}$$

by the definition of $f(\cdot)$. When $t < \hat{\tau} - \delta/2$, we have

$$\begin{aligned} g_{\mu_\delta}(t) &\geq \mu_\delta \cdot f(t) > \mu_\delta \cdot f(\hat{\tau} - \delta/2) \geq \mu_\delta \cdot f(\hat{\tau}) + \mu_\delta \cdot C \cdot \left(\frac{\delta}{2}\right)^N \\ &= \mu_\delta \cdot f(\hat{\tau}) + \frac{p(|\hat{\tau}|)2^N}{C\delta^N} \cdot C \cdot \left(\frac{\delta}{2}\right)^N + \left(\mu_\delta - \frac{p(|\hat{\tau}|)2^N}{C\delta^N}\right) \cdot C \cdot \left(\frac{\delta}{2}\right)^N \\ &\geq h(\mu_\delta) + \mu_\delta \cdot C \cdot \left(\frac{\delta}{2}\right)^N - p(|\hat{\tau}|). \end{aligned}$$

Therefore, when we choose $\epsilon_0 = \mu_\delta \cdot C \cdot \left(\frac{\delta}{2}\right)^N - p(|\hat{\tau}|)$, point t satisfying $h(\mu_\delta) + \epsilon_0 \geq g_{\mu_\delta}(t) \geq h(\mu_\delta)$ must lie in $[\hat{\tau} - \delta/2, \hat{\tau} + \delta/2]$. ■

Lemma 6 *Let Assumption 1 hold and let $f(\cdot)$ be a convex function with a unique minimizer $\hat{\tau} \in (a\tau, \tau)$ and $\frac{f(\hat{\tau}\pm x)-f(\hat{\tau})}{x^N} \geq C_1 (0 < x < \bar{\delta})$ for some $N \in \mathbb{Z}^+, \bar{\delta} \in \mathbb{R}^+, C_1 \in \mathbb{R}^+$. Let $h(\mu)$ be the minimum value of $g_\mu(x) = p(|x|) + \mu \cdot f(x)$, then we have*

(i) $\forall \mu \in \mathbb{Z}^+, t_1, ..., t_n \in \mathbb{R} : \sum_{j=1}^n p(|t_j|) + \mu \cdot f\left(\sum_{j=1}^n t_j\right) \geq h(\mu)$.

(ii) $\exists \kappa = \min_{t \in [a\tau, \tau]} \{\frac{2p(t/2)-p(t)}{t}\}, \forall \delta \leq \min\{\bar{\delta}, 4\tau - 4\hat{\tau}, 4\hat{\tau} - 4a\tau\}, \exists \mu = \frac{p(|\hat{\tau}|)4^{N+1}}{C_1\delta^N}, \epsilon_0 = \kappa \cdot \frac{\delta}{n}, \forall \theta \in [\hat{\tau} - \delta/4, \hat{\tau} + \delta/4]$: *if $t_1, ..., t_n \in \mathbb{R}$ satisfy*

$$h(\mu) + \epsilon_0 \geq \sum_{j=1}^n p(|t_j|) + \mu \cdot f\left(\sum_{j=1}^n t_j\right) \geq h(\mu), \tag{2}$$

then $t_i \in B(\theta, \delta)$ for one i and $t_j \in B(0, \delta)$ for all $j \neq i$.

Proof

We first prove (i). We consider two cases separately. In the first case, we suppose that $|\sum_{j=1}^n t_j| > \tau$. Then we have

$$\sum_{j=1}^n p(|t_j|) \geq \sum_{j=1}^n p\left(\frac{\tau}{\sum_{k=1}^n |t_k|} \cdot |t_j|\right) \geq p\left(\sum_{j=1}^n \frac{\tau}{\sum_{k=1}^n |t_k|} \cdot |t_j|\right) \geq p(\tau),$$

where the first inequality is inferred by the monotonicity of p and the second inequality is due to (ii) of Lemma 4. Thus, we have

$$\sum_{j=1}^n p(|t_j|) + \mu \cdot f\left(\sum_{j=1}^n t_j\right) > \min\{p(\tau) + \mu \cdot f(\tau), p(\tau) + \mu \cdot f(-\tau)\} \geq h(\mu).$$

As a result, we can see that (i) holds when $|\sum_{j=1}^n t_j| > \tau$. In the second case, we suppose $|\sum_{j=1}^n t_j| \leq \tau$ and obtain

$$\sum_{j=1}^n p(|t_j|) \geq \sum_{j=1}^n p\left(\frac{|\sum_{k=1}^n t_k|}{\sum_{k=1}^n |t_k|} |t_j|\right) \geq p\left(\sum_{j=1}^n \frac{|\sum_{k=1}^n t_k|}{\sum_{k=1}^n |t_k|} |t_j|\right) \geq p\left(\left|\sum_{j=1}^n t_j\right|\right),$$

where the second inequality is due to (ii) of Lemma 4. It follows that

$$\sum_{j=1}^n p(|t_j|) + \mu \cdot f\left(\sum_{j=1}^n t_j\right) \geq p\left(\left|\sum_{j=1}^n t_j\right|\right) + \mu \cdot f\left(\sum_{j=1}^n t_j\right) = g_\mu\left(\sum_{j=1}^n t_j\right) \geq h(\mu). \tag{3}$$

which completes our proof of (i).

We then prove (ii). Assume equation (2) holds. If $\sum_{j=1}^n t_j > \tau$, we can see that by choosing $\epsilon_0 \leq g_\mu(\tau) - g_\mu(\hat{\tau})$, we have

$$\sum_{j=1}^n p(|t_j|) + \mu \cdot f\left(\sum_{j=1}^n t_j\right) > g_\mu(\tau) = g_\mu(\hat{\tau}) + g_\mu(\tau) - g_\mu(\hat{\tau}) \geq h(\mu) + \epsilon_0.$$

We will show later that our choice of ϵ_0 is indeed smaller than $g_\mu(\tau) - g_\mu(\hat{\tau})$. We will also show later that equation (2) cannot hold when $\sum_{j=1}^n t_j < -\tau$ under our choice of parameters. Thus, if equation (2) holds, then $|\sum_{j=1}^n t_j| \leq \tau$, which implies that

$$p\left(\left|\sum_{j=1}^n t_j\right|\right) + \mu \cdot f\left(\sum_{j=1}^n t_j\right) \leq h(\mu) + \epsilon_0, \tag{4}$$

by equation (2) and the first inequality of (3), and

$$\sum_{j=1}^n p(|t_j|) \leq p\left(\left|\sum_{j=1}^n t_j\right|\right) + \epsilon_0, \tag{5}$$

due to equation (2) and equation (3). Note that we just need to prove the case when δ is sufficiently small. Thus, we assume in the following paper that δ is smaller than $\bar{\delta}, 4\tau - 4\hat{\tau}, 4\hat{\tau} - 4a\tau$.

Consider the case when equation (4) holds. By Lemma 6, if we choose $\mu = \frac{p(|\hat{\tau}|)4^{N+1}}{C\delta^N}$ and $\epsilon_1 = 3p(|\hat{\tau}|)$, then all of the points t such that $h(\mu)+\epsilon_1 \geq g_\mu(t) \geq h(\mu)$ lie in $[\hat{\tau}-\delta/4, \hat{\tau}+\delta/4]$. Thus, we have $\sum_{j=1}^n t_j \in [a\tau, \tau]$ and $\sum_{j=1}^n t_j \in B(\theta, \frac{\delta}{2})$ for all $\theta \in [\hat{\tau} - \delta/4, \hat{\tau} + \delta/4]$. Note that $g_\mu(t)$ is non-increasing when $t < 0$, meaning that equation (2) cannot hold under our choice of ϵ_1 when $\sum_{j=1}^n t_j \leq -\tau$.

On the other hand, if equation (2) holds, equation (5) should also hold. By (iv) of Lemma 4, for the same δ, $\exists \epsilon_2 = \min_{t\in[a\tau,\tau]}(k_1(t) - k_2(t)) \cdot \frac{\delta}{2n-2}$, there is at most one i such that $t_i \notin B(0, \frac{\delta}{2n-2})$. As $\sum_{j=1}^n t_j \in B(\theta, \frac{\delta}{2})$, we have $t_i \in B(\theta, \delta)$ for all $i = 1, \cdots, n$. Observe that $g_\mu(\tau) - g_\mu(\hat{\tau})$ is always larger than ϵ_1. Also, $\epsilon_1 > \epsilon_2$ if δ is sufficiently small. Therefore, $\exists \kappa = \min_{t\in[a\tau,\tau]}(k_1(t) - k_2(t))/2$, $\forall \delta \leq \min\{\bar{\delta}, 4\tau - 4\hat{\tau}, 4\hat{\tau} - 4a\tau\}, \exists \mu = \frac{p(|\hat{\tau}|)4^{N+1}}{C\delta^N}, \epsilon = \kappa \cdot \frac{\delta}{n}, \forall \theta \in [\hat{\tau} - \delta/4, \hat{\tau} + \delta/4]$: if $h(\mu) + \epsilon \geq g_\mu(\sum_{j=1}^n t_i)$, then $t_i \in B(\theta, \delta)$ for some i while $t_j \in B(0, \delta)$ for all $j \neq i$. ■

6.2. Proof of Theorem 1

Now we are ready to prove Theorem 1.

Proof Suppose that we are given the input to the 3-partition problem, i.e., $3m$ positive integers $s_1, ..., s_{3m}$. Assume *without loss of generality* that all s_i's are upper bounded by some polynomial function $M(m)$. This restriction on the input space does not weaken our result, because the 3-partition problem is strongly NP-hard.

In what follows, we construct a reduction from the 3-partition problem to Problem 1. We assume without loss of generality that $\frac{1}{4m}\sum_{j=1}^{3m} s_j < s_i < \frac{1}{2m}\sum_{j=1}^{3m} s_j$ for all $i = 1, \ldots, n$. Such condition can always be satisfied by adding a sufficiently large integer to all s_i's.

Step 1: The Reduction. The reduction is developed through the following steps.

1. For the interval $[a\tau, \tau]$, we choose $\{b_{1i}\}_{i=1}^{k_1}$ such that $\ell_1(y) = \frac{1}{\lambda}\sum_{i=1}^{k_1} \ell(y, b_{1i})$ satisfies Assumption 1 with constants $C, N, \bar{\delta}$ and has a unique minimizer $\hat{\tau}$ inside the interval $(a\tau, \tau)$. Let $\kappa = \min_{t\in[a\tau,\tau]}\{\frac{2p(t/2)-p(t)}{t}\}$. Let $\delta \leq \{\frac{a\tau}{9m\cdot M(m)}, \bar{\delta}, 4\tau - 4\hat{\tau}, 4\hat{\tau} - 4a\tau\}$, $\mu \geq \frac{p(|\hat{\tau}|)4^{N+1}}{C_1\delta^N}$ and $\epsilon = \kappa \cdot \frac{\delta}{3m}$ such that Lemma 6 is satisfied. Note that $\epsilon \geq \frac{C_3}{m^2\cdot M(m)}$ for some constant C_3 by our construction.

2. For the μ and ϵ chosen in the previous step, all the minimizers of $g_\mu(x) = p(|x|) + \mu \cdot \ell_1(x)$ lie in $[\hat{\tau}-\delta/4, \hat{\tau}+\delta/4]$ by Lemma 6. By the Lipschitz continuity of $p(|x|), f(x)$ and thus $g_\mu(x)$ on $[a\tau, \tau]$, there exists $\delta_\epsilon = \frac{\epsilon}{6mK}$ (K is the Lipschitz constant) such that we can find in polynomial time an interval $[\theta_1, \theta_2]$ where $\theta_2 - \theta_1 = \delta_\epsilon$ and $g_\mu(x) - g_\mu(t^*) < \frac{\epsilon}{6m}$ for $x \in [\theta_1, \theta_2]$. This interval can be find in polynomial time as $g_\mu(x)$ is Lipschitz continuous.

3. By Assumption 2, for the interval $[\theta_1, \theta_2]$, we choose $\{b_{2i}\}_{i=1}^{k_2}$ to construct a loss function $\ell_2 : \mathbb{R} \mapsto \mathbb{R}$ in polynomial time with regard to $1/\delta_\epsilon$ such that $\ell_2(y) = \frac{1}{\lambda}\sum_{i=1}^{k_2} \ell(y, b_{2i})$ has a unique minimizer at $\tilde{t} \in [\theta_1, \theta_2]$. We choose

$$\nu = \left\lceil \epsilon / \max\left(\ell_2(\tilde{t} + 2\delta m) - \ell_2(\tilde{t}), \ell_2(\tilde{t} - 2\delta m) - \ell_2(\tilde{t})\right)\right\rceil + 1,$$

and construct function $f : \mathbb{R}^{3m\times m} \mapsto \mathbb{R}$ where

$$f(x) = \lambda \cdot \sum_{i=1}^{3m}\sum_{j=1}^{m} p\left(|x_{ij}|\right) + \lambda\mu \cdot \sum_{i=1}^{3m} \ell_1\left(\sum_{j=1}^{m} x_{ij}\right) + \lambda\nu \cdot \sum_{j=1}^{m} \ell_2\left(\sum_{i}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} x_{ij}\right). \tag{6}$$

Note that by (iii) of Assumption 2, ν is polynomial in $\max(\lceil \frac{1}{\delta_\epsilon} \rceil, \lceil \theta_2 \rceil)$. In the rest of the paper, we ignore the $\lceil \theta_2 \rceil$ term in the bound as it can be upperbounded by τ, which can be taken as a constant in the reduction.

4. Let $\Phi_1 = 3m \cdot p(|\tilde{t}|) + \mu \cdot 3m \cdot \ell_1(\tilde{t}) - \frac{\epsilon}{2}$ and $\Phi_2 = \nu \cdot m \cdot \ell_2(\tilde{t})$. We claim that

   (i) If there exists z such that

   $$\Phi_1 + \Phi_2 + \epsilon \geq \frac{1}{\lambda} f(z) \geq \Phi_1 + \Phi_2,$$

   then we obtain a feasible assignment for the 3-partition problem as follows: If $z_{ij} \in B(\tilde{t}, \delta)$, we assign number i to subset j.

   (ii) If the 3-partition problem has a solution, we have $\frac{1}{\lambda}\min_x f(x) \leq \Phi_1 + \Phi_2 + \frac{\epsilon}{2}$.

5. Choose $r = \left\lceil \left(\frac{2(3m\cdot\lambda\cdot\mu\cdot k_1 + m\cdot\lambda\cdot\nu\cdot k_2)^{c_1}(3m^2)^{c_2}}{\epsilon/\kappa}\right)^{1/(1-c_1-c_2)} \right\rceil$ where c_1 and c_2 are two arbitrary constants that $c_1 + c_2 < 1$. Construct the following instance of Problem 1:

$$\begin{aligned}\min_{x^{(1)},\cdots,x^{(r)}\in\mathbb{R}^{3m\times m}} \sum_{q=1}^{r} f(x^{(q)}) = \min_{x^{(1)},\cdots,x^{(r)}\in\mathbb{R}^{3m\times m}} \lambda \cdot \sum_{q=1}^{r}\sum_{i=1}^{3m}\sum_{j=1}^{m} p(|x_{ij}^{(q)}|) + \\ \lambda\mu \sum_{q=1}^{r}\sum_{i=1}^{3m}\sum_{t=1}^{k_1} \ell\left(\sum_{j=1}^{m} x_{ij}^{(q)}, b_{1t}\right) + \lambda\nu \sum_{q=1}^{r}\sum_{j=1}^{m}\sum_{t=1}^{k_2} \ell\left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} x_{ij}^{(q)}, b_{2t}\right),\end{aligned} \tag{7}$$

where the input data are coefficients of x and the values $b_{11}, \ldots, b_{1t}, b_{21}, \ldots, b_{2t}$. The variable dimension d is $r \cdot 3m^2$ and the sample size n is $\lambda \cdot \mu \cdot r \cdot 3m \cdot k_1 + \lambda \cdot \nu \cdot r \cdot m \cdot k_2$. The input size is polynomial with respect to m. Our choice of r is the solution to $\epsilon r = 2\kappa n^{c_1} d^{c_2}$ where $\kappa = \min_{t \in [a\tau, \tau]} \{\frac{2p(t/2) - p(t)}{t}\}$.

The parameters μ, ν, δ, r, d are bounded by polynomial functions of m. Computing their values also takes polynomial time. The parameter k_1 and k_2 is a constant determined by the loss function ℓ and is not related to m. As a result, the reduction is polynomial.

6. Let $z^{(1)}, \cdots z^{(r)} \in \mathbb{R}^{3m \times m}$ be a $\lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$-optimal solution to problem (13) such that $\sum_{i=1}^r f(z^{(i)}) \le \min_{x^{(1)}, \cdots, x^{(r)}} \sum_{i=1}^r f(x^{(i)}) + \lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$. We claim that

   (iii) If the approximate solution $z^{(1)}, \cdots z^{(r)}$ satisfies

   $$\frac{1}{\lambda} \sum_{i=1}^{r} f(z^{(i)}) \le r\Phi_1 + r\Phi_2 + 2\kappa n^{c_1} d^{c_2}, \tag{8}$$

   we can choose one $z^{(i)}$ such that $\Phi_1 + \Phi_2 + \epsilon \ge \frac{1}{\lambda} f(z^{(i)}) \ge \Phi_1 + \Phi_2$ and obtain a feasible assignment: If $z_{ij}^{(i)} \in B(\tilde{t}, \delta)$, we assign number i to subset j. If the $\lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$-optimal solution $z^{(1)}, \cdots z^{(r)}$ does not satisfy (8), the 3-partition problem has no feasible solution.

We have constructed a polynomial reduction from the 3-partition problem to finding an $\lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$-optimal solution to problem (13). In what follows, we prove that the reduction works.

Step 2: Proof of Claim (i). We begin with the proof (i). By our choice of μ and Lemma 6(i), we can see that for all $x \in \mathbb{R}^{3m \times m}$,

$$\sum_{i=1}^{3m} \sum_{j=1}^{m} p(|x_{ij}|) + \mu \cdot \sum_{i=1}^{3m} \ell_1 \left(\sum_{j=1}^{m} x_{ij} \right) \ge 3m \cdot p(|t^*|) + \mu \cdot 3m \cdot \ell_1(t^*) \ge \Phi_1,$$

where the last inequality is due to that $g_\mu(\tilde{t}) - g_\mu(t^*) < \frac{\epsilon}{6m}$. By the fact $\tilde{t} = \operatorname{argmin}_t \ell_2(t)$, we have for all $x \in \mathbb{R}^{3m \times m}$ that

$$\nu \cdot \sum_{j=1}^{m} h \left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} x_{ij} \right) \ge \nu \cdot m \cdot \ell_2(\tilde{t}) = \Phi_2.$$

Thus we always have $\min_z \frac{1}{\lambda} f(z) \ge \Phi_1 + \Phi_2$. Now if there exists z such that $\Phi_1 + \Phi_2 + \epsilon \ge \frac{1}{\lambda} f(z) \ge \Phi_1 + \Phi_2$, we must have

$$\Phi_1 + \epsilon \ge \sum_{i=1}^{3m} \sum_{j=1}^{m} p(|z_{ij}|) + \mu \cdot \sum_{i=1}^{3m} h \left(\sum_{j=1}^{m} z_{ij} \right) \ge \Phi_1, \tag{9}$$

and

$$\Phi_2 + \epsilon \ge \nu \cdot \sum_{j=1}^{m} h \left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} z_{ij} \right) \ge \Phi_2. \tag{10}$$

In order for equation (9) to hold, we have that for all i,

$$p(|\tilde{t}|) + \mu \cdot \ell_1(\tilde{t}) + \frac{\epsilon}{2} \ge \sum_{j=1}^{m} p(|z_{ij}|) + \mu \cdot \ell_1 \left(\sum_{j=1}^{m} z_{ij} \right) \ge p(|t^*|) + \mu \cdot \ell_1(t^*).$$

Consider an arbitrary i. By Lemma 6(ii) and $g_\mu(\tilde{t}) - g_\mu(t^*) < \frac{\epsilon}{6m}$, we have $z_{ij} \in B(\tilde{t}, \delta)$ for one j while $z_{ik} = 0$ for all $k \ne j$. If $z_{ij} \in B(\tilde{t}, \delta)$, we assign number i to subset j. As $\delta < a\tau/2 \le \tilde{t}/2$, $B(\tilde{t}, \delta)$ and $B(0, \delta)$ are not overlapping. Thus each number index i is assigned to exactly one subset index j. Therefore the assignment is feasible.

We claim that every subset sum must equal to $\sum_{i=1}^{3m} s_i/m$. Assume that the jth subset sum is greater than or equal to $\sum_{i=1}^{3m} s_i/m + 1$. Let $I_j = \{i \mid z_{ij} \in B(\tilde{t}, \delta)\}$. Thus, $\sum_{i \in I_j} s_i \ge \sum_{i=1}^{3m} s_i/m + 1$. As a result, we have

$$\begin{aligned} \sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} z_{ij} &\ge \sum_{i \in I_1} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} (\tilde{t} - \delta) + \sum_{i \in I_2} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} (-\delta) \\ &\ge \frac{\sum_{i=1}^{3m} s_i/m + 1}{\sum_{i=1}^{3m} s_i/m} \tilde{t} - \delta m = \tilde{t} + \frac{\tilde{t}}{\sum_{i=1}^{3m} s_i/m} - \delta m. \end{aligned}$$

Because $s_i \le M(m)$ for all i and $\delta = \frac{a\tau}{9m \cdot M(m)}$, we have

$$\frac{\tilde{t}}{\sum_{i=1}^{3m} s_i/m} - \delta m \ge \frac{a\tau}{3m \cdot M(n)} m - \delta m = 2\delta m > 0.$$

Since h is a convex function with minimizer y^*, we apply the preceding inequalities and further obtain

$$\ell_2 \left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} z_{ij} \right) \ge \ell_2(\tilde{t} + 2\delta m).$$

By our construction of ν and Assumption 1(iii), we further have

$$\nu \cdot \left(\ell_2 \left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} z_{ij} \right) - \ell_2(\tilde{t}) \right) \ge \nu \cdot \big(\ell_2(\tilde{t} + 2\delta m) - \ell_2(\tilde{t}) \big) > \epsilon. \tag{11}$$

However, in order for equation (10) to hold, we have that for all j,

$$\nu \cdot \ell_2(\tilde{t}) + \epsilon \ge \nu \cdot \ell_2 \left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} z_{ij} \right) \ge \nu \cdot \ell_2(\tilde{t}),$$

yielding a contradiction to (11). We could prove similarly that it is not possible for any subset sum to be strictly smaller than $\frac{1}{m} \sum_{i=1}^{3m} s_i$. Therefore, the sum of every subset equals to $\sum_{i=1}^{3m} s_i/m$. Finally, using the assumption that $\frac{1}{4m} \sum_{i=1}^{3m} s_i < s_i < \frac{1}{2m} \sum_{i=1}^{3m} s_i$, each subset has exactly three components. Therefore the assignment is indeed a solution to the 3-partition problem.

Step 3: Proof of Claim (ii). Suppose we have a solution to the 3-partition problem. Now we construct z to the optimization problem such that $f(z) \le \Phi_1 + \Phi_2 + \frac{\epsilon}{2}$. For all

$1 \le i \le 3m$, if number i is assigned to subset j, let $z_{ij} = \tilde{t}$ and $z_{ik} = 0$ for all $k \neq j$. We can easily verify that

$$\sum_{i=1}^{3m}\sum_{j=1}^{m} p\left(|z_{ij}|\right) + \mu \cdot \sum_{i=1}^{3m} \ell_1\left(\sum_{j=1}^{m} z_{ij}\right) = 3m \cdot \left(p(\tilde{t}) + \mu \cdot \ell_1(\tilde{t})\right) = \Phi_1 + \frac{\epsilon}{2},$$

Also, we have

$$\nu \cdot \sum_{j=1}^{m} \ell_2\left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} z_{ij}\right) = \nu \cdot m \cdot \ell_2(\tilde{t}) = \Phi_2.$$

Therefore,

$$\frac{1}{\lambda} f(z) \le \Phi_1 + \Phi_2 + \frac{\epsilon}{2}. \tag{12}$$

which completes the proof of (ii).

Step 4: Proof of Claim (iii). Suppose that the $\lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$-optimal solution satisfies (8), i.e., $\frac{1}{\lambda}\sum_{i=1}^{r} f(z^{(i)}) \le r\Phi_1 + r\Phi_2 + 2\kappa n^{c_1} d^{c_2}$. It follows that there exists at least one term $z^{(i)}$ such that

$$\frac{1}{\lambda} f(z^{(i)}) \le \Phi_1 + \Phi_2 + \frac{2\kappa n^{c_1} d^{c_2}}{r} \le \Phi_1 + \Phi_2 + \epsilon.$$

where the second inequality equality uses $\epsilon r = 2\kappa n^{c_1} d^{c_2}$. Therefore, by claim (ii), we can find a solution to the 3-partition problem.

Suppose that the 3-partition problem has a solution. By claim (ii), there exists z such that $\frac{1}{\lambda} f(z) \le \Phi_1 + \Phi_2 + \frac{\epsilon}{2}$. Thus we have

$$\min_{x^{(1)},\cdots,x^{(r)}} \frac{1}{\lambda}\sum_{i=1}^{r} f(x^{(i)}) \le \frac{r}{\lambda} f(z) \le r\Phi_1 + r\Phi_2 + \kappa n^{c_1} d^{c_2}.$$

Thus if $z^{(1)}, \cdots z^{(r)}$ is a $\lambda \cdot \kappa \cdot n^{c_1} d^{c_2}$-optimal solution to (13), we have

$$\frac{1}{\lambda}\sum_{i=1}^{r} f(z^{(i)}) \le \min_{x^{(1)},\cdots,x^{(r)}} \frac{1}{\lambda}\sum_{i=1}^{r} f(x^{(i)}) + \kappa n^{c_1} d^{c_2} \le r\Phi_1 + r\Phi_2 + 2\kappa n^{c_1} d^{c_2}$$

implying that the relation (8) must hold. If (8) is not satisfied, the 3-partition problem has no solution. ■

Remark. When the loss function is L_2 loss, we can move $\lambda\mu$ and $\lambda\nu$ of equation (13) into the loss. Specifically, we have

$$\begin{aligned}
&\min_{x^{(1)},\cdots,x^{(r)}\in\mathbb{R}^{3m\times m}} \sum_{q=1}^{r} f(x^{(q)}) = \min_{x^{(1)},\cdots,x^{(r)}\in\mathbb{R}^{3m\times m}} \lambda \cdot \sum_{q=1}^{r}\sum_{i=1}^{3m}\sum_{j=1}^{m} p(|x_{ij}^{(q)}|) + \\
&\sum_{q=1}^{r}\sum_{i=1}^{3m}\left(\sum_{j=1}^{m}\sqrt{\lambda\mu}x_{ij}^{(q)} - \sqrt{\lambda\mu}b_1\right)^2 + \sum_{q=1}^{r}\sum_{j=1}^{m}\left(\sum_{i=1}^{3m}\frac{\sqrt{\lambda\nu}s_i}{\sum_{i'=1}^{3m} s_{i'}/m}x_{ij}^{(q)} - \sqrt{\lambda\nu}b_2\right)^2,
\end{aligned} \tag{13}$$

where μ, ν is chosen such that $\sqrt{\lambda\mu}, \sqrt{\lambda\nu}$ are rational numbers. In this case, the variable dimension is $r \cdot 3m^2$ and the sample size n is $4r \cdot m$. Our choice of r is the solution to $\epsilon r = 2\kappa n^{c_1} d^{c_2}$ which is $r = \left\lceil \left(\frac{2(4m)^{c_1}(3m^2)^{c_2}}{\epsilon/\kappa}\right)^{1/(1-c_1-c_2)} \right\rceil$. The value of r doesn't depend on λ and p, which means that we can plug in any λ, p and the reduction is still polynomial in m. It means that for any choice of λ and p, it is strongly NP hard to find a $\lambda\kappa n^{c_1} d^{c_2}$-optimal solution.

6.3. Proof of Theorem 2

Next we study the complexity of Problem 2. The proof uses a basic duality between Problem 1 and Problem 2.

Proof We will use a reduction from the 3-partition problem to prove the theorem. The reduction is developed through the following steps. We first constructed a polynomial reduction from the 3-partition problem to finding an approximate solution to Problem 2. We then prove that the reduction works.

1. Given the input to the 3-partition problem, we conduct the first three steps of the reduction in Theorem 1 to compute $\mu, \nu, \tilde{t}$ and ϵ with $\lambda = 1$. The nuance is that we pick $\delta_\epsilon = \frac{\epsilon}{12mK}$ in step 2 so that $g_\mu(\tilde{t}) - g_\mu(t^*) \le \frac{\epsilon}{12m}$ where $g_\mu(x) = p(|x|) + \mu \cdot \ell_1(x)$. Denote $f(x) = \mu \cdot \sum_{i=1}^{3m}\sum_{t=1}^{k_1} \ell\left(\sum_{j=1}^{m} x_{ij}, b_{1t}\right) + \nu \cdot \sum_{j=1}^{m}\sum_{t=1}^{k_2} \ell\left(\sum_{i=1}^{3m} \frac{s_i}{\sum_{i'=1}^{3m} s_{i'}/m} x_{ij}, b_{2t}\right)$ and $q(x) = \sum_{i=1}^{3m}\sum_{j=1}^{m} p\left(|x_{ij}|\right)$.

2. Choose $r = \left\lceil \left(\frac{4(3m\cdot\mu\cdot k_1 + m\cdot\nu\cdot k_2)^{c_1}(3m^2)^{c_2}}{\epsilon/\kappa}\right)^{1/(1-c_1-c_2)} \right\rceil$ where c_1 and c_2 are two arbitrary constants that $c_1 + c_2 < 1$. Note that $\kappa n^{c_1} d^{c_2} = \frac{\epsilon r}{4}$ by our choice of r. Construct the following instance of Problem 2:

$$\min_{x^{(1)},x^{(2)},\ldots,x^{(r)}\in\mathbb{R}^{3m\times m}} \sum_{i=1}^{r} f(x^{(i)}) \quad \text{s.t.} \quad \sum_{i=1}^{r} q(x^{(i)}) \le \bar{K}, \tag{14}$$

   where $\bar{K} \in [3m \cdot r \cdot p(\tilde{t}), 3m \cdot r \cdot p(\tilde{t}) + \epsilon r/4)$. The coding size of $\bar{K}$ is bounded by a polynomial function of m because $\epsilon r/4$ and $3m \cdot r \cdot p(\tilde{t})$ are both bounded by a polynomial functions of n. Denote the minimizer of the minimization problem (14) to be $x_{\bar{K}}^{(1)}, \cdots x_{\bar{K}}^{(r)}$.

3. Let $\Phi_1 = 3m \cdot p(|\tilde{t}|) + \mu \cdot 3m \cdot \ell_1(\tilde{t}) - \frac{\epsilon}{4}$ and $\Phi_2 = \nu \cdot m \cdot \ell_2(\tilde{t})$. We claim that if the 3-partition problem has a solution, then

   (i) $\sum_{i=1}^{r} f(x_{\bar{K}}^{(i)}) + \sum_{i=1}^{r} q(x_{\bar{K}}^{(i)}) \le r\Phi_1 + r\Phi_2 + \frac{\epsilon r}{2}$.

   (ii) $\sum_{i=1}^{r} q(x_{\bar{K}}^{(i)}) \ge 3m \cdot r \cdot p(\tilde{t}) - \epsilon r/4$.

4. Suppose we have approximate solutions satisfying $\sum_{i=1}^{r} f(\hat{x}_{\bar{K}+\kappa n^{c_1} d^{c_2}}^{(i)}) \le \sum_{i=1}^{r} f(x_{\bar{K}}^{(i)})$, we claim that

(iii) If the approximate solutions satisfy

$$\sum_{i=1}^{r} f(\hat{x}^{(i)}_{\bar{K}+\kappa n^{c_1}d^{c_2}}) + \sum_{i=1}^{r} q(\hat{x}^{(i)}_{\bar{K}+\kappa n^{c_1}d^{c_2}}) \le r\Phi_1 + r\Phi_2 + 4\kappa n^{c_1}d^{c_2}, \tag{15}$$

we can choose one index k such that $\Phi_1+\Phi_2+\epsilon \ge f(\hat{x}^{(k)}_{\bar{K}+\kappa n^{c_1}d^{c_2}}) \ge \Phi_1+\Phi_2$ and obtain a feasible assignment: If $\left(\hat{x}^{(k)}_{\bar{K}+\kappa n^{c_1}d^{c_2}}\right)_{ij} \in B(\tilde{t},\delta)$, we assign number i to subset j. If the approximate solutions do not satisfy (15), the 3-partition problem has no feasible solution.

We begin with the proof of (i). By the condition that the 3-partition problem has a solution, we construct $x^* \in \mathbb{R}^{3m\times m}$ as follows. If number i is assigned to subset j, let $x^*_{ij} = \tilde{t}$ and $x^*_{ik} = 0$ otherwise. We can see that $x^{(1)} = \cdots = x^{(r)} = x^*$ satisfy the constraint of (14) with sparsity level $\bar{K}$ and $\sum_{i=1}^r q(x^{(i)}_{\bar{K}}) \le 3m\cdot r\cdot p(\tilde{t}) + \epsilon r/4$. Thus,

$$\begin{aligned}\sum_{i=1}^{r} f(x^{(i)}_{\bar{K}}) + \sum_{i=1}^{r} q(x^{(i)}_{\bar{K}}) &\le r\cdot f(x^*) + 3m\cdot r\cdot p(\tilde{t}) + \frac{\epsilon r}{4} = r\cdot 3m\cdot g_\mu(\tilde{t}) + r\Phi_2 + \frac{\epsilon r}{4}\\ &= r\cdot 3m\cdot\left(g_\mu(\tilde{t}) - \frac{\epsilon}{12m}\right) + r\Phi_2 + \frac{\epsilon r}{2} = r\Phi_1 + r\Phi_2 + \frac{\epsilon r}{2},\end{aligned} \tag{16}$$

where $g_\mu(x) = p(|x|) + \mu\cdot\ell_1(x)$. To prove (ii), we just need to notice that if $\sum_{i=1}^r q(x^{(i)}_{\bar{K}}) < 3m\cdot r\cdot p(\tilde{t}) - \epsilon r/4$, we would have $\sum_{i=1}^r f(x^{(i)}_{\bar{K}}) + \sum_{i=1}^r q(x^{(i)}_{\bar{K}}) < r\Phi_1 + r\Phi_2$ by the same reasoning of equation (16), yielding a contradiction as $\sum_{i=1}^r f(x^{(i)}_{\bar{K}}) + \sum_{i=1}^r q(x^{(i)}_{\bar{K}})$ will always be greater than or equal to $r\Phi_1 + r\Phi_2$.

Now we prove (iii). To prove the first half of the claim, we only need to use $4\kappa n^{c_1}d^{c_2} = r\epsilon$ and apply the proof of Theorem 1 to get the result. To prove the second half of the claim, assume that we have an algorithm that outputs $\hat{x}_{\bar{K}+\kappa n^{c_1}d^{c_2}}$ satisfying $\sum_{i=1}^r f(\hat{x}^{(i)}_{\bar{K}+\kappa n^{c_1}d^{c_2}}) \le \sum_{i=1}^r f(x^{(i)}_{\bar{K}})$. Suppose that the 3-partition problem has a solution. Then we have

$$\sum_{i=1}^{r} f(\hat{x}^{(i)}_{\bar{K}+\kappa n^{c_1}d^{c_2}}) + \sum_{i=1}^{r} q(\hat{x}^{(i)}_{\bar{K}+\kappa n^{c_1}d^{c_2}}) \le \sum_{i=1}^{r} f(x^{(i)}_{\bar{K}}) + \sum_{i=1}^{r} q(x^{(i)}_{\bar{K}}) + \frac{\epsilon r}{2} \le r\Phi_1 + r\Phi_2 + \epsilon r,$$

where the first inequality is due to (ii) and the second inequality is due to (i). It means that the approximate solutions satisfy (15). To this point, we have finished the proof of Theorem 2. ■

Remark. Note that K is the input of Problem 2, which means that for all ℓ and p, we only need to find a K that makes Problem 2 hard to solve. A natural question to ask is whether or not K could be the parameter of Problem 2 such that the hardness result still holds. Unfortunately, we have the following counterexample. Assume p is L_0 norm and $K = 1$. Then the constraint is $\sum_{j=1}^d L_0(x_j) \le 1$, which means that there is at most one component of x that is not equal to 0. In this case, we could solve the optimization problem in polynomial time by searching for the nonzero component of x.

6.4. Proof of Theorem 3

Using a similar argument, we can prove the last part of our main result.

Proof The proof is analogous to the proof of Theorem 2. We will use a reduction from the 3-partition problem to prove the theorem. The reduction is developed through the following steps.

1. Given the input to the 3-partition problem, we conduct the first reduction step of Theorem 2 to compute $\mu, \nu, \tilde{t}$ and ϵ with $\lambda = 1$. Let $f(x) = \mu\cdot\sum_{i=1}^{3m}\sum_{t=1}^{k_1}\ell\left(\sum_{j=1}^m x_{ij}, b_{1t}\right) + \nu\cdot\sum_{j=1}^m\sum_{t=1}^{k_2}\ell\left(\sum_{i=1}^{3m}\frac{s_i}{\sum_{i'=1}^{3m}s_{i'}/m}x_{ij}, b_{2t}\right)$ and $q(x) = \sum_{i=1}^{3m}\sum_{j=1}^m p(|x_{ij}|)$.

2. Choose $r = \left\lceil\left(\frac{4(3m\cdot\mu\cdot k_1 + m\cdot\nu\cdot k_2)^{c_1}(3m^2)^{c_2}}{\epsilon/\kappa}\right)^{1/(1-c_1-c_2)}\right\rceil$ where c_1 and c_2 are two arbitrary constants that $c_1 + c_2 < 1$. Note that $\kappa n^{c_1}d^{c_2} = \frac{\epsilon r}{4}$ by our choice of r. Construct the following instance of Problem 3:

$$\min_{x^{(1)},x^{(2)},\ldots,x^{(r)}\in\mathbb{R}^{3m\times m}} \sum_{i=1}^{r} q(x^{(i)}) \quad \text{s.t.} \quad \sum_{i=1}^{r} f(x^{(i)}) \le \bar{\eta}, \tag{17}$$

where $\bar{\eta} \in [\mu\cdot 3m\cdot\ell_1(\tilde{t}) + \nu\cdot m\cdot\ell_2(\tilde{t}), \mu\cdot 3m\cdot\ell_1(\tilde{t}) + \nu\cdot m\cdot\ell_2(\tilde{t}) + \epsilon r/4)$. Note that the parameters $\mu, \nu, \delta, m, r, d$ and $\bar{\eta}$ are bounded by polynomial functions of n. Computing their values also takes polynomial time. Given the sparsity level $\bar{\eta}$, denote the minimizer of (17) to be $x^{(1)}_{\bar{\eta}}, \cdots x^{(r)}_{\bar{\eta}}$.

3. Let $\Phi_1 = 3m\cdot p(|\tilde{t}|) + \mu\cdot 3m\cdot\ell_1(\tilde{t}) - \frac{\epsilon}{4}$ and $\Phi_2 = \nu\cdot m\cdot\ell_2(\tilde{t})$. We claim that if the 3-partition problem has a solution, then

   (i) $\sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) + \sum_{i=1}^r q(x^{(i)}_{\bar{\eta}}) \le r\Phi_1 + r\Phi_2 + \frac{\epsilon r}{2}$.

   (ii) $\sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) \ge \mu\cdot 3m\cdot\ell_1(\tilde{t}) + \nu\cdot m\cdot\ell_2(\tilde{t}) - \epsilon r/4$.

4. Suppose we have an approximate solution satisfying $\sum_{i=1}^r f(\hat{x}^{(i)}_{\bar{\eta}+\kappa n^{c_1}d^{c_2}}) \le \sum_{i=1}^r f(x^{(i)}_{\bar{\eta}})$, we claim that

   (iii) If the approximate solution satisfies

$$\sum_{i=1}^{r} f(\hat{x}^{(i)}_{\bar{\eta}+\kappa n^{c_1}d^{c_2}}) + \sum_{i=1}^{r} q(\hat{x}^{(i)}_{\bar{\eta}+\kappa n^{c_1}d^{c_2}}) \le r\Phi_1 + r\Phi_2 + 4\kappa n^{c_1}d^{c_2}, \tag{18}$$

   we can choose the index k such that $\Phi_1+\Phi_2+\epsilon \ge f(\hat{x}^{(k)}_{\bar{\eta}+\kappa n^{c_1}d^{c_2}}) \ge \Phi_1+\Phi_2$ and obtain a feasible assignment: If $\left(\hat{x}^{(k)}_{\bar{\eta}+\kappa n^{c_1}d^{c_2}}\right)_{ij} \in B(\tilde{t},\delta)$, we assign number i to subset j. If the approximate solutions do not satisfy (18), the 3-partition problem has no feasible solution.

We have constructed a polynomial reduction from the 3-partition problem to finding an approximate solution to Problem 3. We then prove that the reduction works. We begin

with the proof of (i). By the condition that the 3-partition problem has a solution, we construct $x^* \in \mathbb{R}^{3m\times m}$ as follows. If number i is assigned to subset j, let $x^*_{ij} = \tilde{t}$ and $x^*_{ik} = 0$ otherwise. We can see that $x^{(1)} = \cdots = x^{(r)} = x^*$ satisfy the constraint of (14) with error tolerance $\bar{\eta}$ and $\sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) \le \mu \cdot 3m \cdot \ell_1(\tilde{t}) + \nu \cdot m \cdot \ell_2(\tilde{t}) + \epsilon r/4$. Thus,

$$\begin{aligned}\sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) + \sum_{i=1}^r q(x^{(i)}_{\bar{\eta}}) &\le r \cdot q(x^*) + \mu \cdot 3m \cdot \ell_1(\tilde{t}) + \nu \cdot m \cdot \ell_2(\tilde{t}) + \epsilon r/4 \\ &\le r \cdot 3m \cdot \Big(g_\mu(t^*) - \frac{\epsilon}{12m}\Big) + r\Phi_2 + \frac{\epsilon r}{2} = r\Phi_1 + r\Phi_2 + \frac{\epsilon r}{2},\end{aligned} \tag{19}$$

where $g_\mu(x) = p(|x|) + \mu \cdot \ell_1(x)$ and the last inequality is due to the choice of $\tilde{t}$ in step 1 of the reduction.

To prove (ii), we just need to notice that if $\sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) \le \mu\cdot 3m\cdot\ell_1(\tilde{t}) + \nu\cdot m\cdot\ell_2(\tilde{t}) - \epsilon r/4$, we would have $\sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) + \sum_{i=1}^r q(x^{(i)}_{\bar{\eta}}) < r\Phi_1 + r\Phi_2$ by the same reasoning of equation (16), yielding a contradiction as $\sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) + \sum_{i=1}^r q(x^{(i)}_{\bar{\eta}})$ will always be greater than or equal to $r\Phi_1 + r\Phi_2$.

Now we prove (iii). To prove the first half of the claim, we only need to use $4\kappa n^{c_1} d^{c_2} = r\epsilon$ and apply the proof of Theorem 1 to get the result. To prove the second half of the claim, assume that we have an algorithm that outputs $\hat{x}_\eta$ satisfying $\sum_{i=1}^r f(\hat{x}^{(i)}_{\eta+\kappa n^{c_1} d^{c_2}}) \le \sum_{i=1}^r f(x^{(i)}_\eta)$. Suppose that the 3-partition problem has a solution. Replacing η by $\bar{\eta}$ gives us

$$\sum_{i=1}^r f(\hat{x}^{(i)}_{\bar{\eta}+\kappa n^{c_1} d^{c_2}}) + \sum_{i=1}^r q(\hat{x}^{(i)}_{\bar{\eta}+\kappa n^{c_1} d^{c_2}}) \le \sum_{i=1}^r f(x^{(i)}_{\bar{\eta}}) + \sum_{i=1}^r q(x^{(i)}_{\bar{\eta}}) + \frac{\epsilon r}{2} \le r\Phi_1 + r\Phi_2 + \epsilon r,$$

where the first inequality is due to (ii) and the second inequality is due to (i). It means that the approximate solutions satisfy (18). To this point, we have finished the proof of Theorem 3. ■

Abstract

In recent years, randomized methods for numerical linear algebra have received growing interest as a general approach to large-scale problems. Typically, the essential ingredient of these methods is some form of randomized dimension reduction, which accelerates computations, but also creates random approximation error. In this way, the dimension reduction step encodes a tradeoff between cost and accuracy. However, the exact numerical relationship between cost and accuracy is typically unknown, and consequently, it may be difficult for the user to precisely know (1) how accurate a given solution is, or (2) how much computation is needed to achieve a given level of accuracy. In the current paper, we study randomized matrix multiplication (sketching) as a prototype setting for addressing these general problems. As a solution, we develop a bootstrap method for *directly estimating* the accuracy as a function of the reduced dimension (as opposed to deriving worst-case bounds on the accuracy in terms of the reduced dimension). From a computational standpoint, the proposed method does not substantially increase the cost of standard sketching methods, and this is made possible by an "extrapolation" technique. In addition, we provide both theoretical and empirical results to demonstrate the effectiveness of the proposed method.

Keywords: matrix sketching, randomized matrix multiplication, bootstrap methods

1. Introduction

The development of randomized numerical linear algebra (RNLA or RandNLA) has led to a variety of efficient methods for solving large-scale matrix problems, such as matrix multiplication, least-squares approximation, and low-rank matrix factorization, among others (Halko et al., 2011; Mahoney, 2011; Woodruff, 2014; Drineas and Mahoney, 2016). A general feature of these methods is that they apply some form of randomized dimension reduction to an input matrix, which reduces the cost of subsequent computations. In exchange for the reduced cost, the randomization leads to some error in the resulting solution, and consequently, there is a tradeoff between cost and accuracy.

For many canonical matrix problems, the relationship between cost and accuracy has been the focus of a growing body of theoretical work, and the literature provides many performance guarantees for RNLA methods. In general, these guarantees offer a good qualitative description of how the accuracy depends on factors such as problem size, number of iterations, condition numbers, and so on. Yet, it is also the case that such guarantees tend to be overly pessimistic for any particular problem instance — often because the guarantees are formulated to hold in the worst case among a large class of possible inputs. Likewise, it is often impractical to use such guarantees to determine precisely how accurate a given solution is, or precisely how much computation is needed to achieve a desired level of accuracy.

In light of this situation, it is of interest to develop efficient methods for estimating the exact relationship between the cost and accuracy of RNLA methods on a *problem-specific basis*. Since the literature has been somewhat quiet on this general question, the aim of this paper is to analyze randomized matrix multiplication as a prototype setting, and propose an approach that may be pursued more broadly. (Extensions are discussed at the end of the paper in Section 6.)

1.1. Randomized matrix multiplication

To describe our problem setting, we briefly review the rudiments of randomized matrix multiplication, which is often known as matrix sketching (Drineas et al., 2006a; Mahoney, 2011; Woodruff, 2014). If $\mathbf{A} \in \mathbb{R}^{n\times d}$ and $\mathbf{B} \in \mathbb{R}^{n\times d'}$ are fixed input matrices, then sketching methods are commonly used to approximate $\mathbf{A}^T\mathbf{B}$ in the the regime where $\max\{d, d'\} \ll n$. For instance, this regime corresponds to "big data" applications where $\mathbf{A}$ and $\mathbf{B}$ are data matrices with very large numbers of observations.

As a way of reducing the cost of ordinary matrix multiplication, the main idea of sketching is to compute the product $\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}$ of smaller matrices $\tilde{\mathbf{A}} \in \mathbb{R}^{t\times d}$ and $\tilde{\mathbf{B}} \in \mathbb{R}^{t\times d'}$, for some choice of $t \ll n$. These smaller matrices are referred to as "sketches", and they are generated randomly according to

$$\tilde{\mathbf{A}} := \mathbf{S}\mathbf{A} \quad \text{and} \quad \tilde{\mathbf{B}} := \mathbf{S}\mathbf{B}, \tag{1}$$

where $\mathbf{S} \in \mathbb{R}^{t\times n}$ is a random "sketching matrix" satisfying the condition

$$\mathbb{E}[\mathbf{S}^T\mathbf{S}] = \mathbf{I}_n, \tag{2}$$

with $\mathbf{I}_n$ being the identity matrix. In particular, the relation (2) implies that the sketched product is an unbiased estimate, $\mathbb{E}[\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}] = \mathbf{A}^T\mathbf{B}$. Most commonly, the matrix $\mathbf{S}$ can be interpreted as acting on $\mathbf{A}$ and $\mathbf{B}$ by sampling their rows, or by randomly projecting their columns. In Section 2, we describe some popular examples of sketching matrices to be considered in our analysis.

1.2. Problem formulation

When sketching is implemented, the choice of the sketch size t plays a central role, since it directly controls the relationship between cost and accuracy. If t is small, then the sketched

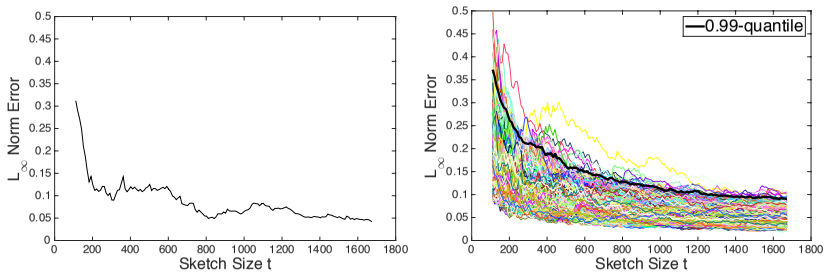

Figure 1: **Left panel:** The curve shows how ε_t fluctuates with varying sketch size t, as rows are added to $\mathbf{S}$, with $\mathbf{A}$ and $\mathbf{B}$ held fixed. (Each row of $\mathbf{A} \in \mathbb{R}^{8,124\times 112}$ is a feature vector of the Mushroom dataset (Frank and Asuncion, 2010), and we set $\mathbf{B} = \mathbf{A}$.) The rows of $\mathbf{S}$ were generated randomly from a Gaussian distribution (see Section 2), and the matrix $\mathbf{A}$ was scaled so that $\|\mathbf{A}^T\mathbf{A}\|_\infty = 1$. **Right panel:** There are 1,000 colored curves, each arising from a repetition of the simulation in the left panel. The thick black curve represents $q_{0.99}(t)$.

product $\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}$ may be computed quickly, but it is unlikely to be a good approximation to $\mathbf{A}^T\mathbf{B}$. Conversely, if t is large, then the sketched product is more expensive to compute, but it is more likely to be accurate. For this reason, we will parameterize the relationship between cost and accuracy in terms of t.

Conventionally, the error of an approximate matrix product is measured with a norm, and in particular, we will consider error as measured by the ℓ_∞-norm,

$$\varepsilon_t \;:=\; \left\|\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B} - \mathbf{A}^T\mathbf{B}\right\|_\infty, \tag{3}$$

where $\|\mathbf{C}\|_\infty := \max_{i,j}|c_{ij}|$ for a matrix $\mathbf{C} = [c_{ij}]$. (Further background on analysis of ℓ_∞-norm or entry-wise error for matrix multiplication may be found in (Higham, 2002; Drineas et al., 2006a; Demmel et al., 2007; Pagh, 2013), among others.) In the context of sketching, it is crucial to note that ε_t is a random variable, due to the randomness in $\mathbf{S}$. Consequently, it is natural to study the quantiles of ε_t, because they specify the *tightest possible bounds* on ε_t that hold with a prescribed probability. More specifically, for any $\alpha \in (0,1)$, the $(1-\alpha)$-quantile of ε_t is defined as

$$q_{1-\alpha}(t) \;:=\; \inf\left\{q \in [0,\infty) \,\middle|\, \mathbb{P}\big(\varepsilon_t \le q\big) \;\ge\; 1-\alpha\right\}. \tag{4}$$

For example, the quantity $q_{0.99}(t)$ is the tightest upper bound on ε_t that holds with probability at least 0.99. Hence, for any fixed α, the function $q_{1-\alpha}(t)$ represents a precise *tradeoff curve* for relating cost and accuracy. Moreover, the function $q_{1-\alpha}(t)$ is specific to the input matrices $\mathbf{A}$ and $\mathbf{B}$.

To clarify the interpretation of $q_{1-\alpha}(t)$, it is helpful to plot the fluctuations of ε_t. In the left panel of Figure 1, we illustrate a simulation where randomly generated rows are incrementally added to a sketching matrix $\mathbf{S}$, with $\mathbf{A}$ and $\mathbf{B}$ held fixed. Each time a row is added to $\mathbf{S}$, the sketch size t increases by 1, and we plot the corresponding value of ε_t as t ranges from 100 to 1,700. (Note that the user is typically unable to observe such a curve in practice.) In the right panel, we display 1,000 repetitions of the simulation, with each colored curve corresponding to one repetition. (The variation is due only to the different draws of $\mathbf{S}$.) In particular, the function $q_{0.99}(t)$ is represented by the thick black curve, delineating the top 1% of the colored curves at each value of t.

In essence, the right panel of Figure 1 shows that if the user had knowledge of the (unknown) function $q_{1-\alpha}(t)$, then two important purposes could be served. First, for any fixed value t, the user would have a sharp problem-specific bound on ε_t. Second, for any fixed error tolerance ϵ, the user could select t so that that "just enough" computation is spent in order to achieve $\varepsilon_t \le \epsilon$ with probability at least $1-\alpha$.

The estimation problem. The challenge we face is that a naive computation of $q_{1-\alpha}(t)$ by generating samples of ε_t would defeat the purpose of sketching. Indeed, generating samples of ε_t by brute force would require running the sketching method many times, and it would also require computing the entire product $\mathbf{A}^T\mathbf{B}$. Consequently, the technical problem of interest is to develop an efficient way to estimate $q_{1-\alpha}(t)$, without adding much cost to a *single run* of the sketching method.

1.3. Contributions

From a conceptual standpoint, the main novelty of our work is that it bridges two sets of ideas that are ordinarily studied in distinct communities. Namely, we apply the statistical technique of bootstrapping to enhance algorithms for numerical linear algebra. To some extent, this pairing of ideas might seem counterintuitive, since bootstrap methods are sometimes labeled as "computationally intensive", but it will turn out that the cost of bootstrapping can be managed in our context. Another reason our approach is novel is that we use the bootstrap to quantify error in the output of a randomized algorithm, rather than for the usual purpose of quantifying uncertainty arising from data. In this way, our approach harnesses the versatility of bootstrap methods, and we hope that our results in the "use case" of matrix multiplication will encourage broader applications of bootstrap methods in randomized computations. (See also Section 6, and note that in concurrent work, we have pursued similar approaches in the contexts of randomized least-squares and classification algorithms (Lopes et al., 2018b; Lopes, 2019).)

From a technical standpoint, our main contributions are a method for estimating the function $q_{1-\alpha}(t)$, as well as theoretical performance guarantees. Computationally, the proposed method is efficient in the sense that its cost is comparable to a single run of standard sketching methods (see Section 2). This efficiency is made possible by an "extrapolation" technique, which allows us to bootstrap small "initial" sketches with t_0 rows, and inexpensively estimate $q_{1-\alpha}(t)$ at larger values $t \gg t_0$. The empirical performance of the extrapolation technique is also quite encouraging, as discussed in Section 5. Lastly, with regard to theoretical analysis, our proofs circumvent some technical restrictions occurring in the analysis of related bootstrap methods in the statistics literature.

1.4. Related work

Several works have considered the problem of error estimation for randomized matrix computations—mostly in the context of low-rank approximation (Woolfe et al., 2008; Liberty et al., 2007; Halko et al., 2011), least squares (Lopes et al., 2018b), or matrix multiplication (Ar et al., 1993; Sarlós, 2006). With attention to matrix multiplication, the latter two papers offer methods for estimating high-probability bounds on the error $\eta_t := \|\tilde{\mathbf{A}}^T\tilde{\mathbf{B}} - \mathbf{A}^T\mathbf{B}\|$, where $\|\cdot\|$ is either the maximum absolute row sum norm, or the Frobenius norm. At a high level, all of the mentioned papers rely on a common technique, which is to randomly generate a sequence of "test-vectors", say $\mathbf{v}_1, \mathbf{v}_2, \ldots$, and then use the matrix-vector products $\mathbf{w}_i := \tilde{\mathbf{A}}^T\tilde{\mathbf{B}}\mathbf{v}_i - \mathbf{A}^T(\mathbf{B}\mathbf{v}_i)$ to derive an estimated bound, say $\hat{\eta}_t$, for η_t. The origin of this technique may be traced to the classical works (Dixon, 1983; Freivalds, 1979).

Our approach differs from the "test-vector approach" in some essential ways. One difference arises because the bounds on $\hat{\eta}_t$ are generally constructed from the vectors $\{\mathbf{w}_i\}$ using conservative inequalities. By contrast, our approach avoids this conservativeness by *directly estimating* $q_{1-\alpha}(t)$, which is an optimal bound on ε_t in the sense of equation (4).

A second difference deals with computational demands. For example, in order to compute the vectors $\{\mathbf{w}_i\}$ in the test-vector approach, it is necessary to access the full matrices $\mathbf{A}$ and $\mathbf{B}$. On the other hand, our method does not encounter this difficulty, because it only requires access to the much smaller sketches $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$. Also, in the test-vector approach, the cost to compute each vector $\mathbf{w}_i$ is proportional to the large dimension n, while the cost to compute $\hat{q}_{1-\alpha}(t)$ with our method is *independent* of n. Finally, the test-vector approach can only be used to check if the product $\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}$ is accurate after it has been computed, whereas our approach can be used to dynamically "predict" an appropriate sketch size t from a small "initial" sketching matrix (see Section 3.3).

With regard to the statistics literature, our work builds upon a line of research dealing with "multiplier bootstrap methods" in high-dimensional problems (Chernozhukov et al., 2013, 2014, 2017). Such methods are well-suited to approximating the distributions of statistics such as $\|\bar{\mathbf{x}}\|_\infty$, where $\bar{\mathbf{x}} \in \mathbb{R}^p$ denotes the sample average of n independent mean-zero vectors, with $n \ll p$. More recently, this approach has been substantially extended to other "max type" statistics arising from sample covariance matrices (Chang et al., 2016; Chen, 2018). Nevertheless, the strong results in these works do not readily translate to our context, either because the statistics are substantially different from the ℓ_∞-norm (Chang et al., 2016), or because of technical assumptions (Chen, 2018). For instance, if the results in the latter work are applied to a sample covariance matrix of the form $\frac{1}{n}\sum_{i=1}^n(\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})^\top$, where $\mathbf{x}_1, \ldots, \mathbf{x}_n \in \mathbb{R}^p$ are mean-zero i.i.d. vectors, with $\mathbf{x}_1 = (X_{11}, \ldots, X_{1p})$, then it is necessary to make assumptions such as $\min_{j,k} \mathsf{var}(X_{1j}X_{1k}) \geq c$, for some constant $c > 0$. As this relates to the sketching context, note that the sketched product may be written as $\tilde{\mathbf{A}}^T\tilde{\mathbf{B}} = \frac{1}{t}\sum_{i=1}^t \mathbf{A}^T\mathbf{s}_i\mathbf{s}_i^T\mathbf{B}$, where $\mathbf{s}_1, \ldots, \mathbf{s}_n \in \mathbb{R}^t$ are the rows of $\sqrt{t}\mathbf{S}$. It follows that analogous variance assumptions would lead to conditions on the matrices $\mathbf{A}$ and $\mathbf{B}$ that could be violated if any column of $\mathbf{A}$ or $\mathbf{B}$ has many small entries, or is sparse. By contrast, our results do not rely on such variance assumptions, and we allow the matrices $\mathbf{A}$ and $\mathbf{B}$ to be unrestricted.

At a more technical level, the ability to avoid restrictions on $\mathbf{A}$ and $\mathbf{B}$ comes from our use of the Lévy-Prohorov metric for distributional approximations — which differs from the Kolmogorov metric that has been predominantly used in previous works on multiplier bootstrap methods. More specifically, analyses based on the Kolmogorov metric typically rely on "anti-concentration inequalities" (Chernozhukov et al., 2013, 2015), which ultimately lead to the mentioned variance assumptions. On the other hand, our approach based on the Lévy-Prohorov metric does not require the use of anti-concentration inequalities. Finally it should be mentioned that the techniques used to control the LP metric are related to those that have been developed for bootstrap approximations via coupling inequalities as in Chernozhukov et al. (2016).

Outline. This paper is organized as follows. Section 2 introduces some technical background. Section 3 describes the proposed bootstrap algorithm. Section 4 establishes the main theoretical results, and then numerical performance is illustrated in Section 5. Lastly, conclusions and extensions of the method are presented in Section 6, and all proofs are given in the appendices.

2. Preliminaries

Notation and terminology. The set $\{1, \ldots, n\}$ is denoted as $[n]$. The ith standard basis vector is denoted as $\mathbf{e}_i$. If $\mathbf{C} = [c_{ij}]$ is a real matrix, then $\|\mathbf{C}\|_F = (\sum_{i,j} c_{ij}^2)^{1/2}$ is the Frobenius norm, and $\|\mathbf{C}\|_2$ is the spectral norm (maximum singular value). If X is a random variable and $p \geq 1$, we write $\|X\|_p = (\mathbb{E}[|X|^p])^{1/p}$ for the usual L_p norm. If $\psi : [0, \infty) \to [0, \infty)$ is a non-decreasing convex function with $\psi(0) = 0$, then the ψ-Orlicz norm of X is defined as $\|X\|_\psi := \inf\{r > 0 \mid \mathbb{E}[\psi(|X|/r)] \leq 1\}$. In particular, we define $\psi_p(x) := \exp(x^p) - 1$ for $p \geq 1$, and we say that X is sub-Gaussian when $\|X\|_{\psi_2} < \infty$, or sub-exponential when $\|X\|_{\psi_1} < \infty$. In Appendix F, Lemma 9 summarizes the facts about Orlicz norms that will be used.

We will use c to denote a positive absolute constant that may change from line to line. The matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{S}$ are viewed as lying in a sequence of matrices indexed by the tuple (d, d', t, n). For a pair of generic functions f and g, we write $f(d, d', t, n) \lesssim g(d, d', t, n)$ when there is a positive absolute constant c so that $f(d, d', t, n) \leq c\, g(d, d', t, n)$ holds for all large values of d, d', t, and n. Furthermore, if a and b are two quantities that satisfy both $a \lesssim b$ and $b \lesssim a$, then we write $a \asymp b$. Lastly, we do not use the symbols $\lesssim$ or $\asymp$ when relating random variables.

Examples of sketching matrices. Our theoretical results will deal with three common types of sketching matrices, reviewed below.

- *Row sampling.* If $(p_1, \ldots, p_n)$ is a probability vector, then $\mathbf{S} \in \mathbb{R}^{t\times n}$ can be constructed by sampling its rows i.i.d. from the set $\{\frac{1}{\sqrt{tp_1}}\mathbf{e}_1, \ldots, \frac{1}{\sqrt{tp_n}}\mathbf{e}_n\} \subset \mathbb{R}^n$, where the vector $\frac{1}{\sqrt{tp_i}}\mathbf{e}_i$ is selected with probability p_i. Some of the most well known choices for the sampling probabilities include *uniform sampling*, with $p_i \equiv 1/n$, *length sampling* (Drineas et al., 2006a; Magen and Zouzias, 2011), with

$$p_i = \frac{\|\mathbf{e}_i^T\mathbf{A}\|_2\|\mathbf{e}_i^T\mathbf{B}\|_2}{\sum_{j=1}^n \|\mathbf{e}_j^T\mathbf{A}\|_2\|\mathbf{e}_j^T\mathbf{B}\|_2}, \tag{5}$$

and *leverage score sampling*, for which further background may be found in the papers (Drineas et al., 2006b, 2008, 2012).

- *Sub-Gaussian projection.* Gaussian projection is the most well-known random projection method, and is sometimes referred to as the Johnson-Lindenstrauss (JL) transform (Johnson and Lindenstrauss, 1984). In detail, if $\mathbf{G} \in \mathbb{R}^{t\times n}$ is a standard Gaussian matrix, with entries that are i.i.d. samples from $\mathcal{N}(0,1)$, then $\mathbf{S} = \frac{1}{\sqrt{t}}\mathbf{G}$ is a Gaussian projection matrix. More generally, the entries of $\mathbf{G}$ can be drawn i.i.d. from a zero-mean sub-Gaussian distribution, which often leads to similar performance characteristics in RNLA applications.

- *Subsampled randomized Hadamard transform (SRHT).* Let n be a power of 2, and define the Walsh-Hadamard matrix $\mathbf{H}_n$ recursively*

$$\mathbf{H}_n := \begin{pmatrix} \mathbf{H}_{n/2} & \mathbf{H}_{n/2} \\ \mathbf{H}_{n/2} & -\mathbf{H}_{n/2} \end{pmatrix} \quad \text{with} \quad \mathbf{H}_2 := \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

  Next, let $\mathbf{D}_n^\circ \in \mathbb{R}^{n\times n}$ be random diagonal matrix with independent ± 1 Rademacher variables along the diagonal, and let $\mathbf{P} \in \mathbb{R}^{t\times n}$ have rows uniformly sampled from $\{\frac{1}{\sqrt{t/n}}\mathbf{e}_1, \ldots, \frac{1}{\sqrt{t/n}}\mathbf{e}_n\}$. Then, the $t \times n$ matrix

$$\mathbf{S} = \mathbf{P}(\tfrac{1}{\sqrt{n}}\mathbf{H}_n)\mathbf{D}_n^\circ \tag{6}$$

  is called an SRHT matrix. This type of sketching matrix was introduced in the seminal paper (Ailon and Chazelle, 2006), and additional details regarding implementation may be found in the papers (Drineas et al., 2011; Wang, 2015). (The factor $\frac{1}{\sqrt{n}}$ is used so that $\frac{1}{\sqrt{n}}\mathbf{H}_n$ is an orthogonal matrix.) An important property of SRHT matrices is that they can be multiplied with any $n \times d$ matrix in $\mathcal{O}(n \cdot d \cdot \log t)$ time (Ailon and Liberty, 2009), which is faster than the $\mathcal{O}(n \cdot d \cdot t)$ time usually required for a dense sketching matrix.

3. Methodology

Before presenting our method in algorithmic form, we first explain the underlying intuition.

3.1. Intuition for multiplier bootstrap method

If the row vectors of $\sqrt{t}\mathbf{S}$ are denoted $\mathbf{s}_1, \ldots, \mathbf{s}_t \in \mathbb{R}^n$, then $\mathbf{S}^T\mathbf{S}$ may be conveniently expressed as a sample average

$$\mathbf{S}^T\mathbf{S} = \tfrac{1}{t}\textstyle\sum_{i=1}^t \mathbf{s}_i\mathbf{s}_i^T. \tag{7}$$

For row sampling, Gaussian projection, and SRHT, these row vectors satisfy $\mathbb{E}[\mathbf{s}_i\mathbf{s}_i^T] = \mathbf{I}_n$. Consequently, if we define the random $d \times d'$ rank-1 (dyad) matrix

$$\mathbf{D}_i \;=\; \mathbf{A}^T\mathbf{s}_i\mathbf{s}_i^T\mathbf{B}, \tag{8}$$

*The restriction that n is a power of 2 can be relaxed with variants of SRHT matrices (Avron et al., 2010; Boutsidis and Gittens, 2013).

then $\mathbb{E}[\mathbf{D}_i] = \mathbf{A}^T\mathbf{B}$, and it follows that the difference between the sketched and unsketched products can be viewed as a sample average of zero-mean random matrices

$$\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B} - \mathbf{A}^T\mathbf{B} \;=\; \tfrac{1}{t}\textstyle\sum_{i=1}^t(\mathbf{D}_i - \mathbf{A}^T\mathbf{B}). \tag{9}$$

Furthermore, in the cases of length sampling and Gaussian projection, the matrices $\mathbf{D}_1, \ldots, \mathbf{D}_t$ are independent, and in the case of SRHT sketches, these matrices are "nearly" independent. So, in light of the central limit theorem, it is natural to suspect that the random matrix (9) will be well-approximated (in distribution) by a matrix with Gaussian entries. In particular, if we examine the (j_1, j_2) entry, then we may expect that $\mathbf{e}_{j_1}^T(\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B} - \mathbf{A}^T\mathbf{B})\mathbf{e}_{j_2}$ will approximately follow the distribution $\mathcal{N}(0, \frac{1}{t}\sigma_{j_1,j_2}^2)$, where the unknown parameter σ_{j_1,j_2}^2 can be estimated with

$$\hat{\sigma}_{j_1,j_2}^2 \;:=\; \tfrac{1}{t}\textstyle\sum_{i=1}^t \big(\mathbf{e}_{j_1}^T(\mathbf{D}_i - \mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B})\mathbf{e}_{j_2}\big)^2.$$

Based on these considerations, the idea of the proposed bootstrap method is to generate a random matrix whose (j_1, j_2) entry is sampled from $\mathcal{N}(0, \frac{1}{t}\hat{\sigma}_{j_1,j_2}^2)$. It turns out that an efficient way of generating such a matrix is to sample i.i.d. random variables $\xi_1, \ldots, \xi_t \sim \mathcal{N}(0,1)$, independent of $\mathbf{S}$, and then compute

$$\tfrac{1}{t}\textstyle\sum_{i=1}^t \xi_i(\mathbf{D}_i - \mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B}). \tag{10}$$

In other words, if $\mathbf{S}$ is conditioned upon, then the distribution of the (j_1, j_2) entry of the above matrix is exactly $\mathcal{N}(0, \frac{1}{t}\hat{\sigma}_{j_1,j_2}^2)$.† Hence, if the matrix (10) is viewed as an "approximate sample" of $\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B} - \mathbf{A}^T\mathbf{B}$, then it is natural to use the ℓ_∞-norm of the matrix (10) as an approximate sample of $\varepsilon_t = \|\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B} - \mathbf{A}^T\mathbf{B}\|_\infty$. Likewise, if we define the bootstrap sample

$$\varepsilon_t^\star \;:=\; \Big\|\tfrac{1}{t}\textstyle\sum_{i=1}^t \xi_i\Big(\mathbf{D}_i - \mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B}\Big)\Big\|_\infty, \tag{11}$$

then the bootstrap algorithm will generate i.i.d. samples of $\varepsilon_t^\star$, conditionally on $\mathbf{S}$. In turn, the $(1-\alpha)$-quantile of the bootstrap samples, say $\hat{q}_{1-\alpha}(t)$, can be used to estimate $q_{1-\alpha}(t)$.

3.2. Multiplier bootstrap algorithm

We now explain how proposed method can be implemented in just a few lines. This description also reveals the important fact that the algorithm only requires access to the sketches $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$ (rather than the full matrices $\mathbf{A}$ and $\mathbf{B}$). Although the formula for generating samples of $\varepsilon_t^\star$ given below may appear different from equation (11), it is straightforward to check that these are equivalent. Lastly, the choice of the number of bootstrap samples B will be discussed at the end of subsection 3.3.

†It is also possible to show that the *joint* distribution of the entries in the matrix (10) mimics that of $\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B} - \mathbf{A}^T\mathbf{B}$, but we omit such details to simplify the discussion.

Algorithm 1 (Multiplier bootstrap for ε_t).
Input: *the number of bootstrap samples B, and the sketches $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$.*
For $b = 1, \ldots, B$ **do**

1. *Draw an i.i.d. sample $\xi_1, \ldots, \xi_t$ from $\mathcal{N}(0,1)$, independent of $\mathbf{S}$;*
2. *Compute the bootstrap sample $\varepsilon^\star_{t,b} := \left\| \bar{\xi} \cdot (\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}) - \tilde{\mathbf{A}}^T \mathbf{\Xi} \tilde{\mathbf{B}} \right\|_\infty$, where $\bar{\xi} := \frac{1}{t}\sum_{i=1}^t \xi_i$ and $\mathbf{\Xi} := \mathsf{diag}(\xi_1, \ldots, \xi_t)$.*

Return: $\hat{q}_{1-\alpha}(t) \longleftarrow$ *the $(1-\alpha)$-quantile of the values $\varepsilon^\star_{t,1}, \ldots, \varepsilon^\star_{t,B}$.*

3.3. Saving on computation with extrapolation

In its basic form, the cost of Algorithm 1 is $\mathcal{O}(B \cdot t \cdot d \cdot d')$, which has the favorable property of being independent of the large dimension n. Also, the computation of the samples $\varepsilon^\star_{t,1}, \ldots, \varepsilon^\star_{t,B}$ is embarrassingly parallel, with the cost of each sample being $\mathcal{O}(t \cdot d \cdot d')$. Moreover, due to the way that the quantile $q_{1-\alpha}(t)$ scales with t, it is possible to reduce the cost of Algorithm 1 even further — via the technique of extrapolation (also called Richardson extrapolation) (Sidi, 2003; Brezinski and Zaglia, 2013).

The essential idea of extrapolation is to carry out Algorithm 1 for a modest "initial" sketch size t_0, and then use an initial estimate $\hat{q}_{1-\alpha}(t_0)$ to "look ahead" and predict a larger value t for which $q_{1-\alpha}(t)$ is small enough to satisfy the user's desired level of accuracy. The immediate benefit of this approach is that Algorithm 1 only needs to applied to small "initial versions" of $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$, each with t_0 rows, which reduces the cost of the algorithm to $\mathcal{O}(B \cdot t_0 \cdot d \cdot d')$. Furthermore, this means that if Algorithm 1 is run in parallel, then it is only necessary to communicate copies of the small initial sketching matrices. (To illustrate the small size of the initial sketching matrices, our experiments include several examples where the ratio t_0/n is approximately 1/100 or less.)

From a theoretical viewpoint, our use of extrapolation is based on the approximation $q_{1-\alpha}(t) \approx \frac{\kappa}{\sqrt{t}}$, where t is sufficiently large, and $\kappa = \kappa(\mathbf{A}, \mathbf{B}, \alpha)$ is an unknown number. A formal justification for this approximation can be made using Proposition 3 in Appendix A, but it is simpler to give an intuitive explanation here. Recall from Section 3.1 that as t becomes large, the (j_1, j_2) entry $[\tilde{\mathbf{A}}^T\tilde{\mathbf{B}} - \mathbf{A}^T\mathbf{B}]_{j_1,j_2}$ should be well-approximated in distribution by a Gaussian random variable of the form $\frac{1}{\sqrt{t}} G_{j_1,j_2}$. In turn, this suggests that ε_t should be well-approximated in distribution by $\frac{1}{\sqrt{t}} \max_{j_1,j_2} |G_{j_1,j_2}|$, which has quantiles that are proportional to $\frac{1}{\sqrt{t}}$.

In order to take advantage of the theoretical scaling $q_{1-\alpha}(t) \approx \frac{\kappa}{\sqrt{t}}$, we may use Algorithm 1 to compute $\hat{q}_{1-\alpha}(t_0)$ with an initial sketch size t_0, and then approximate the value $q_{1-\alpha}(t)$ for $t \gg t_0$ with the following extrapolated estimator

$$\hat{q}^{\,\mathrm{ext}}_{1-\alpha}(t) := \tfrac{\sqrt{t_0}}{\sqrt{t}} \hat{q}_{1-\alpha}(t_0). \tag{12}$$

Hence, if the user would like to determine a sketch size t so that $q_{1-\alpha}(t) \leq \epsilon$, for some tolerance ϵ, then t should be selected so that $\hat{q}^{\,\mathrm{ext}}_{1-\alpha}(t) \leq \epsilon$, which is equivalent to

$$t \geq \left(\tfrac{\sqrt{t_0}}{\epsilon}\, \hat{q}_{1-\alpha}(t_0) \right)^2. \tag{13}$$

In our experiments in Section 5, we illustrate some examples where an accurate estimate of $q_{1-\alpha}(t)$ at $t = 10{,}000$ can be obtained from the rule (13) using an initial sketch size $t_0 \approx 500$, yielding a roughly 20-fold speedup on the basic version of Algorithm 1.

Comparison with the cost of sketching. Given that the purpose of Algorithm 1 is to enhance sketching methods, it is important to understand how the added cost of the bootstrap compares to the cost of running sketching methods in the standard way. As a point of reference, we compare with the cost of computing $\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B}$ when $\mathbf{S}$ is chosen to be an SRHT matrix, since this is one of the most efficient sketching methods. If we temporarily assume for simplicity that $\mathbf{A}$ and $\mathbf{B}$ are both of size $n \times d$, then it follows from Section 2 that computing $\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B}$ has a cost of order $\mathcal{O}(t \cdot d^2 + n \cdot d \cdot \log(t))$. Meanwhile, the cost of running Algorithm 1 with the extrapolation speedup based on an initial sketch size t_0 is $\mathcal{O}(B \cdot t_0 \cdot d^2)$. Consequently, the extra cost of the bootstrap does not exceed the stated cost of sketching when the number of bootstrap samples satisfies

$$B = \mathcal{O}(\tfrac{t}{t_0} + \tfrac{n \log(t)}{d\, t_0}), \tag{14}$$

and in fact, this could be improved further if parallelization of Algorithm 1 is taken into account. It is also important to note that rather small values of B are shown to work well in our experiments, such as $B = 20$. Hence, as long t_0 remains fairly small compared to t, then the condition (14) may be expected to hold, and this is borne out in our experiments. The same reasoning also applies when $n \log(t) \gg d \cdot t_0$, which conforms with the fact that sketching methods are intended to handle situations where n is very large.

3.4. Relation with the non-parametric bootstrap

For readers who are more familiar with the "non-parametric bootstrap" (based on sampling with replacement), the purpose of this short subsection is to explain the relationship with the multiplier bootstrap in Algorithm 1. Indeed, an understanding of this relationship may be helpful, since the non-parametric bootstrap might be viewed as more intuitive, and perhaps easier to generalize to more complex situations. However, it turns out that Algorithm 1 is technically more convenient to analyze, and that is why the paper focuses primarily on Algorithm 1. Meanwhile, from a practical point of view, there is little difference between the two approaches, since both have the same order of computational cost, and in our experience, we have observed essentially the same performance in simulations. Also, the extrapolation technique can be applied to both algorithms in the same way.

To spell out the connection, the only place where Algorithm 1 needs to be changed is in step 1. Rather than choosing the multiplier variables $\xi_1, \ldots, \xi_t$ to be i.i.d. $\mathcal{N}(0,1)$ as in Algorithm 1, the non-parametric bootstrap chooses $\xi_i = \zeta_i - 1$, where $(\zeta_1, \ldots, \zeta_t)$ is a sample from a multinomial distribution, based on tossing t balls into t equally likely bins, where ζ_i is the number of balls in bin i. Hence, the mean and variance of each ξ_i are nearly the same as before, with $\mathbb{E}[\xi_i] = 0$ and $\mathsf{var}(\xi_i) = 1 - 1/t$, but the variables $\xi_1, \ldots, \xi_t$ are no longer independent.

From a more algorithmic viewpoint, it is simple to check that the choice of $\xi_1, \ldots, \xi_t$ based on the multinomial distribution is equivalent to sampling with replacement from the rows of $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$. The underlying intuition for this approach is based on the fact that for many types of sketching matrices, the rows of $\mathbf{S}$ are i.i.d., which makes the rows of $\tilde{\mathbf{A}}$ i.i.d.,

and likewise for $\tilde{\mathbf{B}}$. Hence, if $\mathbf{S}$ is conditioned upon, then sampling with replacement from the rows of $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$ imitates the random mechanism that originally generated $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$.

Algorithm 2 (Non-parametric bootstrap for ε_t).

Input: *the number of samples B, and the sketches $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$.*

For $b = 1, \ldots, B$ **do**

1. *Draw a vector $(i_1, \ldots, i_t)$ by sampling t numbers with replacement from $\{1, \ldots, t\}$.*
2. *Form matrices $\tilde{\mathbf{A}}^* \in \mathbb{R}^{t \times d}$ and $\tilde{\mathbf{B}}^* \in \mathbb{R}^{t \times d'}$ by selecting (respectively) the rows from $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$ that are indexed by $(i_1, \ldots, i_t)$.*
3. *Compute the bootstrap sample $\varepsilon^*_{t,b} := \big\|(\tilde{\mathbf{A}}^*)^T(\tilde{\mathbf{B}}^*) - \tilde{\mathbf{A}}^T\tilde{\mathbf{B}}\big\|_\infty$.*

Return: $\hat{q}_{1-\alpha}(t) \longleftarrow$ *the $(1-\alpha)$-quantile of the values $\varepsilon^*_{t,1}, \ldots, \varepsilon^*_{t,B}$.*

4. Main results

Our main results quantify how well the estimate $\hat{q}_{1-\alpha}(t)$ from Algorithm 1 approximates the true value $q_{1-\alpha}(t)$, and this will be done by analyzing how well the distribution of a bootstrap sample $\varepsilon^\star_{t,1}$ approximates the distribution of ε_t. For the purposes of comparing distributions, we will use the Lévy-Prohorov metric, defined below.

Lévy-Prohorov (LP) metric. Let $\mathcal{L}(U)$ denote the distribution of a random variable U, and let $\mathscr{B}$ denote the collection of Borel subsets of $\mathbb{R}$. For any $A \in \mathscr{B}$, and $\delta > 0$, define the δ-neighborhood $A^\delta := \big\{x \in \mathbb{R} \,\big|\, \inf_{y \in A} |x - y| \le \delta\big\}$. Then, for any two random variables U and V, the d_{LP} metric between their distributions is given by

$$d_{\mathrm{LP}}(\mathcal{L}(U), \mathcal{L}(V)) \;:=\; \inf\Big\{\delta > 0 \,\Big|\, \mathbb{P}(U \in A) \le \mathbb{P}(V \in A^\delta) + \delta \;\text{ for all }\; A \in \mathscr{B}\Big\}.$$

The d_{LP} metric is a standard tool for comparing distributions, due to the fact that convergence with respect to d_{LP} is equivalent to convergence in distribution (Huber and Ronchetti, 2009, Theorem 2.9).

Approximating quantiles. An important property of the d_{LP} metric is that if two distributions are close in this metric, then their quantiles are close in the following sense. Recall that if F_U is the distribution function of a random variable U, then the $(1-\alpha)$-quantile of U is the same as the generalized inverse $F_U^{-1}(1-\alpha) := \inf\{q \in [0, \infty) \,|\, F_U(q) \ge 1 - \alpha\}$. Next, suppose that two random variables U and V satisfy

$$d_{\mathrm{LP}}\big(\mathcal{L}(U),\, \mathcal{L}(V)\big) \;\le\; \epsilon,$$

for some $\epsilon \in (0, \alpha)$ with $\alpha \in (0, 1/2)$. Then, the quantiles of U and V are close in the sense that

$$\big|F_U^{-1}(1-\alpha) - F_V^{-1}(1-\alpha)\big| \;\le\; \psi_\alpha(\epsilon), \tag{15}$$

where the function $\psi_\alpha(\epsilon) := F_U^{-1}(1-\alpha+\epsilon) - F_U^{-1}(1-\alpha-\epsilon) + \epsilon$ is strictly monotone, and satisfies $\psi_\alpha(0) = 0$. (For a proof, see Lemma 15 of Appendix F.) In light of this fact, it will be more convenient to express our results for approximating $q_{1-\alpha}(t)$ in terms of the d_{LP} metric.

4.1. Statements of results

Our main assumption involves three separate cases, corresponding to different choices of the sketching matrix $\mathbf{S}$.

Assumption 1 *The dimensions d and d' satisfy $d \asymp d'$. Also, there is a positive absolute constant $\kappa \ge 1$ such that $d^{1/\kappa} \lesssim t \lesssim d^\kappa$, which is to say that neither d nor t grows exponentially with the other. In addition, one of the following sets of conditions holds, involving the parameter $\nu(\mathbf{A}, \mathbf{B}) := \sqrt{\|\mathbf{A}^T\mathbf{A}\|_\infty \|\mathbf{B}^T\mathbf{B}\|_\infty}$.*

(a) (Sub-Gaussian case). The entries of the matrix $\mathbf{S} = [S_{i,j}]$ are zero-mean i.i.d. sub-Gaussian random variables, with $\mathbb{E}[S_{i,j}^2] = \frac{1}{t}$, and $\max_{i,j} \|\sqrt{t} S_{i,j}\|_{\psi_2} \lesssim 1$. Furthermore, $t \gtrsim \nu(\mathbf{A}, \mathbf{B})^{2/3} (\log d)^5$.

(b) (Length sampling case). The matrix $\mathbf{S}$ is generated by length sampling, with the probabilities in equation (5), and also, $t \gtrsim (\|\mathbf{A}\|_F \|\mathbf{B}\|_F)^{2/3} (\log d)^5$.

(c) (SRHT case). The matrix $\mathbf{S}$ is an SRHT matrix as defined in equation (6), and also, $t \gtrsim \nu(\mathbf{A}, \mathbf{B})^{2/3} (\log n)^2 (\log d)^5$.

Clarifications on bootstrap approximation. Before stating our main results below, it is worth clarifying a few technical items. First, since our analysis involves central limit type approximations of $\tilde{\mathbf{A}}^T\tilde{\mathbf{B}} - \mathbf{A}^T\mathbf{B}$ as a sum of t independent matrices, we will rescale the error variables by a factor of $\sqrt{t}$, obtaining

$$Z_t := \sqrt{t}\varepsilon_t, \tag{16}$$

as well as its bootstrap analogue,

$$Z_t^\star := \sqrt{t}\varepsilon_t^\star. \tag{17}$$

With regard to the original problem of estimating the quantile $q_{1-\alpha}(t)$ for ε_t, this rescaling makes no essential difference, since quantiles are homogenous with respect to scaling, and in particular, the $(1-\alpha)$-quantile of Z_t is simply $\sqrt{t} q_{1-\alpha}(t)$.

As a second clarification, recall that the bootstrap method generates samples $\varepsilon_t^\star$ based upon a particular realization of $\mathbf{S}$. For this reason, the bootstrap approximation to $\mathcal{L}(Z_t)$ is the conditional distribution $\mathcal{L}(Z_t^\star|\mathbf{S})$. Consequently, it should be noted that $\mathcal{L}(Z_t^\star|\mathbf{S})$ is a random probability measure, and $d_{\mathrm{LP}}(\mathcal{L}(Z_t)\,,\, \mathcal{L}(Z_t^\star|\mathbf{S}))$ is a random variable, since they both depend on the random matrix $\mathbf{S}$.

Theorem 1 *Let $h(x) = x^{1/2} + x^{3/4}$ for $x \geq 0$. If Assumption 1 (a) holds, then there is an absolute constant $c > 0$ such that the following bound holds with probability at least $1 - \frac{1}{t} - \frac{1}{dd'}$,*

$$d_{\mathrm{LP}}\Big(\mathcal{L}(Z_t)\,,\,\mathcal{L}(Z_t^\star|\mathbf{S})\Big) \;\leq\; \frac{c\cdot h(\nu(\mathbf{A},\mathbf{B}))\cdot\sqrt{\log(d)}}{t^{1/8}}.$$

If Assumption 1 (b) holds, then there is an absolute constant $c > 0$ such that the following bound holds with probability at least $1 - \frac{1}{t} - \frac{1}{dd'}$,

$$d_{\mathrm{LP}}\Big(\mathcal{L}(Z_t)\,,\,\mathcal{L}(Z_t^\star|\mathbf{S})\Big) \;\leq\; \frac{c\cdot h(\|\mathbf{A}\|_F\|\mathbf{B}\|_F)\cdot\sqrt{\log(d)}}{t^{1/8}}.$$

Remarks. A noteworthy property of the bounds is that they are *dimension-free* with respect to the large dimension n. Also, they have a very mild logarithmic dependence on d. With regard to the dependence on t, there are two other important factors to keep in mind. First, the practical performance of the bootstrap method (shown in Section 5) is much better than what the $t^{-1/8}$ rate suggests. Second, the problem of finding the optimal rates of approximation for multiplier bootstrap methods is a largely open problem — even in the simpler setting of bootstrapping the coordinate-wise maximum of vectors (rather than matrices). In the vector context, the literature has focused primarily on the Kolmogorov metric (rather than the LP metric), and some quite recent improvements beyond the $t^{-1/8}$ rate have been developed in Chernozhukov et al. (2017) and Lopes et al. (2018a). However, these works also rely on model assumptions that would lead to additional restrictions on the matrices $\mathbf{A}$ and $\mathbf{B}$ in our setup. Likewise, the problem of extending our results to achieve faster rates or handle other metrics is a natural direction for future work.

The SRHT case. For the case of SRHT matrices, the analogue of Theorem 1 needs to be stated in a slightly different way for technical reasons. From a qualitative standpoint, the results for SRHT and sub-Gaussian matrices turn out to be similar.

The technical issue to be handled is that the rows of an SRHT matrix are not independent, due to their common dependence on the matrix $\mathbf{D}_n^\circ$. Fortunately, this inconvenience can be addressed by conditioning on $\mathbf{D}_n^\circ$. Theoretically, this simplifies the analysis of the bootstrap, since it "decouples" the rows of the SRHT matrix. Meanwhile, if we let $\tilde{q}_{1-\alpha}(t)$ denote the $(1-\alpha)$-quantile of the distribution $\mathcal{L}(\varepsilon_t|\mathbf{D}_n^\circ)$,

$$\tilde{q}_{1-\alpha}(t) \;:=\; \inf\Big\{q\in[0,\infty)\Big|\;\mathbb{P}(\varepsilon_t\leq q\big|\mathbf{D}_n^\circ)\geq 1-\alpha\Big\},$$

then it is simple to check that $\tilde{q}_{1-\alpha}(t)$ acts as a "surrogate" for $q_{1-\alpha}(t)$, since[‡]

$$\begin{aligned}\mathbb{P}(\varepsilon_t\leq\tilde{q}_{1-\alpha}(t)) &= \mathbb{E}\big[\mathbb{P}\big(\varepsilon_t\leq\tilde{q}_{1-\alpha}(t)\big|\mathbf{D}_n^\circ\big)\big]\\ &\geq \mathbb{E}[1-\alpha]\\ &= 1-\alpha.\end{aligned}\tag{18}$$

[‡]It is also possible to show that $\tilde{q}_{1-\alpha}(t)$ fluctuates around $q_{1-\alpha}(t)$. Indeed, if we define the random variable $V := \mathbb{P}(\varepsilon_t \leq q_{1-\alpha}(t)|\mathbf{D}_n^\circ)$, it can be checked that the event $V \geq 1-\alpha$ is equivalent to the event $\tilde{q}_{1-\alpha}(t) \leq q_{1-\alpha}(t)$. Furthermore, if we suppose that $1-\alpha$ lies in the range of the c.d.f. of ε_t, then $\mathbb{E}[V] = 1-\alpha$. In turn, it follows that the event $\tilde{q}_{1-\alpha}(t) \leq q_{1-\alpha}(t)$ occurs when $V \geq \mathbb{E}[V]$, and conversely, the event $\tilde{q}_{1-\alpha}(t) > q_{1-\alpha}(t)$ occurs when $V < \mathbb{E}[V]$.

For this reason, we will view $\tilde{q}_{1-\alpha}(t)$ as the new parameter to estimate (instead of $q_{1-\alpha}(t)$), and accordingly, the aim of the following result is to quantify how well the bootstrap distribution $\mathcal{L}(Z_t^\star|\mathbf{S})$ approximates the conditional distribution $\mathcal{L}(Z_t|\mathbf{D}_n^\circ)$.

Theorem 2 *Let $h(x) = x^{1/2} + x^{3/4}$ for $x \geq 0$. If Assumption 1 (c) holds, then there is an absolute constant $c > 0$ such that the following bound holds with probability at least $1 - \frac{1}{t} - \frac{1}{dd'} - \frac{c}{n}$,*

$$d_{\mathrm{LP}}\Big(\mathcal{L}(Z_t|\mathbf{D}_n^\circ)\,,\,\mathcal{L}(Z_t^\star|\mathbf{S})\Big) \;\leq\; \frac{c\cdot h(\nu(\mathbf{A},\mathbf{B})\log(n))\cdot\sqrt{\log(d)}}{t^{1/8}}.$$

Remarks. Up to a factor involving $\log(n)$, the bound for SRHT matrices matches that for sub-Gaussian matrices. Meanwhile, from a more practical standpoint, our empirical results will show that the bootstrap's performance for SRHT matrices is generally similar to that for both sub-Gaussian and length-sampling matrices.

Further discussion of results. To comment on the role of $\nu(\mathbf{A},\mathbf{B})$ and $\|\mathbf{A}\|_F\|\mathbf{B}\|_F$ in Theorems 1 and 2, it is possible to interpret them as problem-specific "scale parameters". Indeed, it is natural that the bounds on d_{LP} should increase with the scale of $\mathbf{A}$ and $\mathbf{B}$ for the following reason. Namely, if $\mathbf{A}$ or $\mathbf{B}$ is multiplied by a scale factor $\kappa > 0$, then it can be checked that the quantile error $|\hat{q}_{1-\alpha}(t) - q_{1-\alpha}(t)|$ will also change by a factor of κ, and furthermore, the inequality (15) demonstrates a monotone relationship between the sizes of the quantile error and the d_{LP} error. For this reason, the bootstrap may still perform well in relation to the scale of the problem when the magnitudes of the parameters $\nu(\mathbf{A},\mathbf{B})$ and $\|\mathbf{A}\|_F\|\mathbf{B}\|_F$ are large. Alternatively, this idea can be seen by noting that the d_{LP} bounds can be made arbitrarily small by simply changing the units used to measure the entries of $\mathbf{A}$ and $\mathbf{B}$.

Beyond these considerations, it is still of interest to compare the results for different sketching matrices once a particular scaling has been fixed. For concreteness, consider a scaling where the spectral norms of $\mathbf{A}$ and $\mathbf{B}$ satisfy $\|\mathbf{A}\|_2 \asymp \|\mathbf{B}\|_2 \asymp 1$. (As an example, if we view $\mathbf{A}^\top\mathbf{A}$ as a sample covariance matrix, then the condition $\|\mathbf{A}\|_2 \asymp 1$ simply means that the largest principal component score is of order 1.) Under this scaling, it is simple to check that $\nu(\mathbf{A},\mathbf{B}) = \mathcal{O}(1)$, and $\|\mathbf{A}\|_F\|\mathbf{B}\|_F = \mathcal{O}(\sqrt{\mathsf{r}(\mathbf{A})\mathsf{r}(\mathbf{B})})$, where $\mathsf{r}(\mathbf{A}) := \|\mathbf{A}\|_F^2/\|\mathbf{A}\|_2^2$ is the "stable rank". In particular, note that if $\mathbf{A}$ and $\mathbf{B}$ are approximately low rank, as is common in applications, then $\mathsf{r}(\mathbf{A}) \ll d$, and $\mathsf{r}(\mathbf{B}) \ll d'$. Accordingly, we may conclude that if the conditions of Theorems 1 and 2 hold, then bootstrap consistency occurs under the following limits

$$\sqrt{\log(d)}/t^{1/8} = o(1) \quad \text{in the sub-Gaussian case,} \tag{19}$$

$$(\mathsf{r}(\mathbf{A})\mathsf{r}(\mathbf{B}))^{3/8}\sqrt{\log(d)}/t^{1/8} = o(1) \quad \text{in the length-sampling case,} \tag{20}$$

$$\log(n)^{3/4}\sqrt{\log(d)}/t^{1/8} = o(1) \quad \text{in the SRHT case,} \tag{21}$$

where we have used the simplifying assumption that $d \asymp d'$.

5. Experiments

This section outlines a set of experiments for evaluating the performance of Algorithm 1 with the extrapolation speed-up described in Section 3.3. The experiments involved both synthetic and natural matrices, as described below.

Synthetic matrices. In order to generate the matrix $\mathbf{A} \in \mathbb{R}^{n\times d}$ synthetically, we selected the factors of its singular value decomposition $\mathbf{A} = \mathbf{U}\mathsf{diag}(\boldsymbol{\sigma})\mathbf{V}^T$ in the following ways, fixing $n = 30,000$ and $d = 1,000$. In previous work, a number of other experiments in randomized matrix computations have been designed along these lines (Ma et al., 2014; Yang et al., 2016).

The factor $\mathbf{U} \in \mathbb{R}^{n\times d}$ was selected as the Q factor from the reduced QR factorization of a random matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$. The rows of $\mathbf{X}$ were sampled i.i.d. from a multivariate t-distribution, $\boldsymbol{t}_2(\boldsymbol{\mu}, \mathbf{C})$, with 2 degrees of freedom, mean $\boldsymbol{\mu} = \mathbf{0}$, and covariance $c_{ij} = 2 \times 0.5^{|i-j|}$ where $\mathbf{C} = [c_{ij}]$. (This choice causes the matrix $\mathbf{A}$ to have high row-coherence, which is of interest, since this is a challenging case for sampling-based sketching matrices.) Next, the factor $\mathbf{V} \in \mathbb{R}^{d\times d}$ was selected as the Q factor from a QR factorization of a $d \times d$ matrix with i.i.d. $\mathcal{N}(0, 1)$ entries. For the singular values $\boldsymbol{\sigma} \in \mathbb{R}^d_+$, we chose two options, leading to either a low or high stable rank $\mathsf{r}(\mathbf{A}) = \frac{\|\mathbf{A}\|_F^2}{\|\mathbf{A}\|_2^2}$. In the low stable rank case, we put $\sigma_i = 10^{\kappa_i}$ for a set of equally spaced values κ_i between 0 and -6, yielding $\mathsf{r}(\mathbf{A}) = 36.7$. Alternatively, in the high stable rank case, the entries of $\boldsymbol{\sigma}$ were equally spaced between 0.1 and 1, yielding $\mathsf{r}(\mathbf{A}) = 370.1$. Finally, to make all numerical comparisons on a common scale, we normalized $\mathbf{A}$ so that $\|\mathbf{A}^T\mathbf{A}\|_\infty = 1$.

Natural matrices. We also conducted experiments on five natural data matrices $\mathbf{A}$ from the LIBSVM repository Chang and Lin (2011), named 'Connect', 'DNA', 'MNIST', 'Mushrooms', and 'Protein', with the same normalization that was used for the synthetic matrices. These datasets are briefly summarized in Table 1.

Table 1: A summary of the natural datasets.

Dataset	Connect	DNA	MNIST	Mushrooms	Protein
n	67,557	2,000	60,000	8,124	17,766
d	126	180	780	112	356

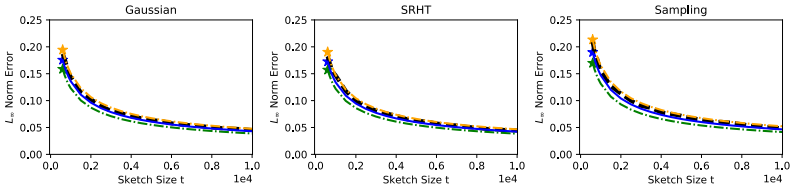
5.1. Design of experiments

For each matrix $\mathbf{A}$, natural or synthetic, we considered the task of estimating the quantile $q_{0.99}(t)$ for the random sketching error $\varepsilon_t = \left\|\mathbf{A}^T\mathbf{A} - \mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{A}\right\|_\infty$. The sketching matrix $\mathbf{S} \in \mathbb{R}^{t\times n}$ was allowed to be one of three types: Gaussian projection, length-sampling, and SRHT, as described in Section 2.

Ground truth values. The ground truth values for $q_{0.99}(t)$ were constructed in the following way. For each matrix $\mathbf{A}$, a grid of t values was specified, ranging from $d/2$ up to a larger number as high as $10d$ or $20d$, depending on $\mathbf{A}$. Next, for each t value, and for each type of sketching matrix, we used 1,000 realizations of $\mathbf{S} \in \mathbb{R}^{t\times n}$, yielding 1,000 realizations of the random variable ε_t. In turn, the 0.99 sample quantile of the 1,000 realizations of ε_t was treated as the true value of $q_{0.99}(t)$, and this appears as the black curve in all plots.

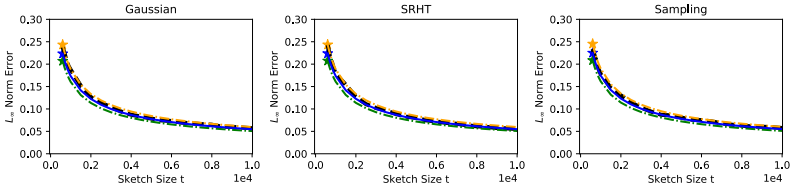
Extrapolated estimates. With regard to the bootstrap extrapolation method in Section 3.3, we fixed the value $t_0 = d/2$ as the initial sketch size to extrapolate from. For each $\mathbf{A}$, and each type of sketching matrix, we applied Algorithm 1 to each of the 1,000 realizations of $\tilde{\mathbf{A}} = \mathbf{S}\mathbf{A} \in \mathbb{R}^{t_0\times d}$ generated previously. Each time Algorithm 1 was run, we used the modest choice of $B = 20$ for the number of bootstrap samples. From each set of 20 bootstrap samples, we used the 0.99 sample quantile as the estimate $\hat{q}_{0.99}(t_0)$.[§] Hence, there were 1,000 realizations of $\hat{q}_{0.99}(t_0)$ altogether. Next, we used the scaling rule in equation (12) to obtain 1,000 realizations of the extrapolated estimate $\hat{q}^{\text{ext}}_{0.99}(t)$ for values $t \geq t_0$.

In order to illustrate the variability of the estimate $\hat{q}^{\text{ext}}_{0.99}(t)$ over the 1,000 realizations, we plot three different curves as a function of t. The blue curve represents the average value of $\hat{q}^{\text{ext}}_{0.99}(t)$, while the green and yellow curves respectively correspond to the estimates ranking 100th an 900th out of the 1,000 realizations.



5.2. Comments on numerical results

Overall, the numerical results for the bootstrap extrapolation method are quite encouraging, and to a large extent, the method is accurate across many choices of $\mathbf{A}$ and $\mathbf{S}$. Given that the blue curves representing $\mathbb{E}[\hat{q}^{\text{ext}}_{0.99}(t)]$ are closely aligned with the black curves for $q_{0.99}(t)$, we see that the extrapolated estimate is essentially unbiased. Moreover, the variance of the estimate is fairly low, as indicated by the small gap between the green and yellow curves. The low variance is also notable when considered in light of the fact that only $B = 20$ bootstrap samples are used to construct $\hat{q}^{\text{ext}}_{0.99}(t)$, since the variance should decrease as B becomes larger.

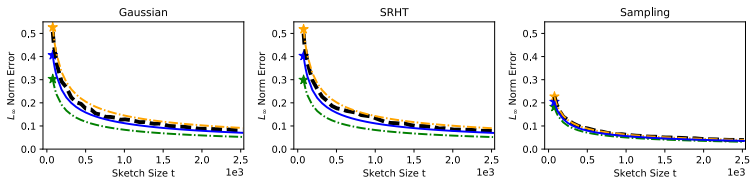


With attention to the extrapolation rule (12), there are two main points to note. First, the plots show that the extrapolation may be initiated at fairly low values of t_0, which are much less than the sketch sizes needed to achieve a small sketching error ε_t. Second, we see that $\hat{q}^{\text{ext}}_{0.99}(t)$ remains accurate for t much larger than t_0, well up to $t = 10,000$ and perhaps even farther. Consequently, the results show that the extrapolation technique is capable of saving quite a bit of computation without much detriment to statistical performance.

To consider the relationship between theory and practice, one basic observation is that all three types of sketching matrices obey roughly similar bounds in Theorems 1 and 2, and indeed, we also see generally similar numerical performance among the three types. At a more fine-grained level however, the Gaussian and SRHT sketching matrices tend to produce estimates $\hat{q}^{\text{ext}}_{0.99}(t)$ with somewhat higher variance than in the case of length sampling. Another difference between theory and simulation, is that the actual performance of the method seems to be better than what the theory suggests — since the estimates are accurate at values of t_0 that are much smaller than what would be expected from the rates in Theorems 1 and 2.

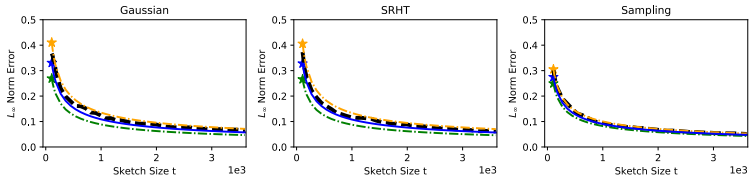
[§]Note that since $19/20 = 0.95$ and $20/20 = 1$, the 0.99 quantile was obtained by an interpolation rule.

(a) Low stable rank data.



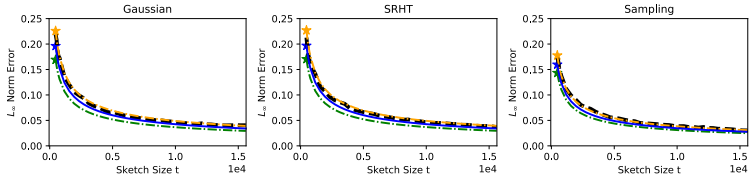
(b) High stable rank data.

Figure 2: **Results for synthetic matrices.** The black line represents $q_{0.99}(t)$ as a function of t. The blue star is the average bootstrap estimate at the initial sketch size $t_0 = d/2 = 500$, and the blue line represents the average extrapolated estimate $\mathbb{E}[\hat{q}^{\text{ext}}_{0.99}(t)]$ derived from the starting value t_0. To display the variability of the estimates, the green and yellow curves correspond to the 100th and 900th largest among the 1,000 realizations of $\hat{q}^{\text{ext}}_{0.99}(t)$ at each t.

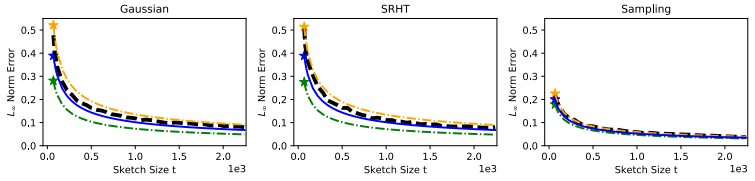


6. Conclusions and extensions

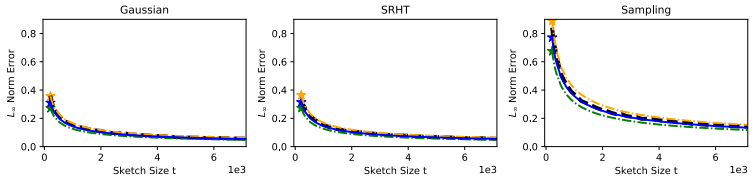
In this paper, we have focused on estimating the quantile $q_{1-\alpha}(t)$ as a way of addressing two fundamental issues in randomized matrix multiplication: (1) knowing how accurate a given sketched product is, and (2) knowing how much computation is needed to achieve a specified degree of accuracy. With regard to methodology, our approach is relatively novel in that it uses the statistical technique of bootstrapping to serve a computational purpose — by quantifying the error of a randomized sketching algorithm. A second important component of our method is the extrapolation technique, which ensures that the cost of estimating $q_{1-\alpha}(t)$ does not substantially increase the overall cost of standard sketching methods. Furthermore, our numerical results show that the extrapolated estimate is quite accurate in a variety of different situations, suggesting that our method may offer a general way to enhance sketching algorithms in practice.



Extensions. More generally, the problems we have addressed for randomized matrix multiplication arise for many other large-scale matrix computations. Hence, it is natural to consider extensions of our approach to more complex settings, and in the remainder of this section, we briefly mention a few possibilities for future study.



(a) Connect ($n = 67,557$ and $d = 126$).



(b) DNA ($n = 2,000$ and $d = 180$).

(c) MNIST ($n = 60,000$ and $d = 780$).

(d) Mushrooms ($n = 8,124$ and $d = 112$).

(e) Protein ($n = 17,766$ and $d = 356$).

Figure 3: **Results for natural matrices.** The results for the natural matrices are plotted in the same way as described in the caption for the results on the synthetic matrices.

At a high level, each of the applications below deals with an object, say Θ, that is difficult to compute, as well as a randomized approximation, say $\widetilde{\Theta}$, that is built from a sketching matrix $\mathbf{S}$ with t rows. Next, if we consider the random error variable

$$\varepsilon_t = \|\widetilde{\Theta} - \Theta\|,$$

for an unspecified norm $\|\cdot\|$, then the problem of estimating the relationship between accuracy and computation can again be viewed as the problem of estimating the quantile function $q_{1-\alpha}(t)$ associated with ε_t. In turn, this leads to the question of how to develop a new bootstrap procedure that can generate approximate samples of ε_t, yielding an estimate $\hat{q}_{1-\alpha}(t)$. However, instead of starting from the multiplier bootstrap (Algorithm 1) as before, it may be conceptually easier to extend the non-parametric bootstrap (Algorithm 2) — because the latter bootstrap can viewed as a "plug-in" procedure that replaces $\mathbf{A}^T\mathbf{B}$ with $\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}$, and replaces $\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}$ with $(\tilde{\mathbf{A}}^*)^T(\tilde{\mathbf{B}}^*)$.

- *Linear regression.* Consider a multi-response linear regression problem, where the rows of $\mathbf{B} \in \mathbb{R}^{n\times d'}$ are response vectors, and the rows of $\mathbf{A} \in \mathbb{R}^{n\times d}$ are input observations. The optimal solution to ℓ_2-regression is given by

$$\mathbf{W}_{\text{opt}} \;=\; \underset{\mathbf{W}\in\mathbb{R}^{d\times d'}}{\text{argmin}} \; \|\mathbf{AW} - \mathbf{B}\|_F^2 \;=\; (\mathbf{A}^T\mathbf{A})^\dagger\mathbf{A}^T\mathbf{B},$$

  which has $\mathcal{O}(nd^2 + ndd')$ cost. In the case where $\max\{d, d'\} \ll n$, the matrix multiplications are a computational bottleneck, and an approximate solution can be obtained via

$$\widetilde{\mathbf{W}}_{\text{opt}} = (\tilde{\mathbf{A}}^T\tilde{\mathbf{A}})^\dagger(\tilde{\mathbf{A}}^T\tilde{\mathbf{B}}),$$

  which has a cost $\mathcal{O}(td^2 + tdd') + C_{\text{sketch}}$, where C_{sketch} is cost of matrix sketching (Drineas et al., 2006b, 2011, 2012; Clarkson and Woodruff, 2013). In order to estimate the quantile function associated with the error variable $\varepsilon_t = \|\widetilde{\mathbf{W}}_{\text{opt}} - \mathbf{W}_{\text{opt}}\|$, we could consider generating bootstrap samples of the form $\varepsilon_t^* = \|\widetilde{\mathbf{W}}^*_{\text{opt}} - \widetilde{\mathbf{W}}_{\text{opt}}\|$, where $\widetilde{\mathbf{W}}^*_{\text{opt}} = ((\tilde{\mathbf{A}}^*)^T(\tilde{\mathbf{A}}^*))^\dagger(\tilde{\mathbf{A}}^*)^T(\tilde{\mathbf{B}}^*)$. For recent results in the case where $\mathbf{W}$ is a vector, we refer to the paper (Lopes et al., 2018b).

- *Functions of covariance matrices.* If the rows of the matrix $\mathbf{A}$ are viewed as a sample of observations, then inferences on the population covariance structure are often based on functions of the form $\psi(\mathbf{A}^T\mathbf{A})$. For instance, the function $\psi(\mathbf{A}^T\mathbf{A})$ could be the top eigenvector, a set of eigenvalues, the condition number, or a test statistic. In any of these cases, if $\psi(\tilde{\mathbf{A}}^T\tilde{\mathbf{A}})$ is used as a fast approximation (Dasarathy et al., 2015), then the sketching error $\varepsilon_t = \|\psi(\tilde{\mathbf{A}}^T\tilde{\mathbf{A}}) - \psi(\mathbf{A}^T\mathbf{A})\|$ might be bootstrapped using $\varepsilon_t^* = \|\psi((\tilde{\mathbf{A}}^*)^T(\tilde{\mathbf{A}}^*)) - \psi(\tilde{\mathbf{A}}^T\tilde{\mathbf{A}})\|$.

- *Approximate Newton methods.* In large-scale applications, Newton's method is often impractical, since it involves the costly processing of a Hessian matrix. As an example, consider an optimization problem arising in binary classification, where the rows of $\mathbf{X} \in \mathbb{R}^{n\times d}$ are observations $\mathbf{x}_1, \ldots, \mathbf{x}_n \in \mathbb{R}^d$, and $y_1, \ldots, y_n \in \{0, 1\}$ are labels. If an ℓ_2-regularized logistic classifier is used, this leads to minimizing the objective function $f(\mathbf{w}) = \sum_{i=1}^n \log\left(1 + e^{-y_i\mathbf{w}^T\mathbf{x}_i}\right) + \frac{\gamma}{2}\|\mathbf{w}\|_2^2$ over coefficient vectors $\mathbf{w}$ in $\mathbb{R}^d$. The associated Newton step, with step size κ, is

$$\mathbf{w} \leftarrow \mathbf{w} - \kappa\,\mathbf{H}^{-1}\nabla f,$$

  involving the Hessian

$$\mathbf{H} = \mathbf{A}^T\mathbf{A} + \gamma\mathbf{I}_d, \quad \text{where} \quad \mathbf{A} = \mathsf{diag}\big(1 + e^{y_1\mathbf{w}^T\mathbf{x}_1}, \ldots, 1 + e^{y_n\mathbf{w}^T\mathbf{x}_n}\big)^{-1}\mathbf{X}.$$

  If $d \ll n$, the cost of Newton's method is dominated by the formation of $\mathbf{H}$ at each iteration, and the Hessian matrix can be approximated by the sketched version $\tilde{\mathbf{H}} = \tilde{\mathbf{A}}^T\tilde{\mathbf{A}} + \gamma\mathbf{I}_d$, which reduces the per-iteration cost from $\mathcal{O}(nd^2)$ to $\mathcal{O}(td^2 + nd) + C_{\text{sketch}}$ (Pilanci and Wainwright, 2017; Roosta-Khorasani and Mahoney, 2016; Xu et al., 2016). In this context, the quality of the approximate Newton step could be assessed in terms of the error

$$\varepsilon_t = \|\tilde{\mathbf{H}}^{-1}\nabla f \;-\; \mathbf{H}^{-1}\nabla f\|,$$

  and in turn, this might be bootstrapped using $\varepsilon_t^* = \|(\tilde{\mathbf{H}}^*)^{-1}\nabla f \;-\; \tilde{\mathbf{H}}^{-1}\nabla f\|$, where $\tilde{\mathbf{H}}^* = (\tilde{\mathbf{A}}^*)^T(\tilde{\mathbf{A}}^*) + \gamma\mathbf{I}_d$.

Acknowledgments

We thank the anonymous reviewers for their helpful suggestions. MEL thanks the National Science Foundation for partial support under grant DMS-1613218. MWM would like to thank the National Science Foundation, the Army Research Office, and the Defense Advanced Research Projects Agency for providing partial support of this work.

Appendices

Outline of appendices. Appendix A explains the main conceptual ideas underlying the proofs of Theorems 1 and 2. In particular, the proofs of these theorems will be decomposed into two main results: Propositions 3 and 4, which are given in Appendix A.

Appendix B will prove the sub-Gaussian case of Proposition 3, and Appendix C will prove the sub-Gaussian case of Proposition 4. Later on, Appendices D and E, will explain how the arguments can be changed to handle the length-sampling and SRHT cases.

Conventions used in proofs. If either of the matrices $\mathbf{A}$ or $\mathbf{B}$ are $\mathbf{0}$, then ε_t has a trivial point-mass distribution at 0. In this degenerate case, it is simple to check that the bootstrap produces an exact approximation. So, without loss of generality, all proofs are written under the assumption that $\mathbf{A}$ and $\mathbf{B}$ are non-zero. Next, since Assumption 1 is formulated using the $\lesssim$ notation, there is no loss of generality in carrying out calculations under the assumption that all the numbers t, n, d, d' are at least 8, which will ensure that quantities such as $\log(d)$ are greater than 2. Lastly, if a numbered lemma is invoked in the middle of a proof, the lemma may be found in Appendix F.

Appendix A. Gaussian and bootstrap approximations

Section A.1 introduces some notation that helps us to analyze the rescaled sketching error Z_t from the viewpoint of empirical processes. Next, in Section A.2, Theorem 1 will be decomposed into two propositions that compare Z_t and $Z_t^\star$ with the maximum of a suitable Gaussian process. The proofs of these propositions may be found in Appendices B and C.

A.1. Making a link between empirical processes and sketching error

The main idea of our analysis is to view Z_t as the maximum of an empirical process, which we now define. Recall the notation

$$\mathbf{D}_i = \mathbf{A}^T\mathbf{s}_i\mathbf{s}_i^T\mathbf{B} \quad \text{and} \quad \mathbf{M}_i \;=\; \mathbf{A}^T(\mathbf{s}_i\mathbf{s}_i^T - \mathbf{I}_n)\mathbf{B}.$$

Let $\mathbb{G}_t(\cdot)$ be the empirical process that acts on *linear* functions $f : \mathbb{R}^{d\times d'} \to \mathbb{R}$, according to

$$\mathbb{G}_t(f) \;:=\; \frac{1}{\sqrt{t}}\sum_{i=1}^{t}\Big(f(\mathbf{D}_i) - f(\mathbf{A}^T\mathbf{B})\Big) \;=\; \frac{1}{\sqrt{t}}\sum_{i=1}^{t} f(\mathbf{M}_i).$$

For future reference, we also define the corresponding bootstrap process

$$\mathbb{G}_t^\star(f) \;:=\; \frac{1}{\sqrt{t}}\sum_{i=1}^{t}\xi_i\cdot\Big(f(\mathbf{D}_i) - f\big(\mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B}\big)\Big),$$

where $\xi_1,\ldots,\xi_t$ are i.i.d. $\mathcal{N}(0,1)$ and independent of $\mathbf{S}$.

Next, we define a certain collection $\mathscr{F}$ of linear functions from $\mathbb{R}^{d\times d'}$ to $\mathbb{R}$. Let $j_1 \in [d]$, $j_2 \in [d']$, $s \in \{-1,1\}$, and $\mathbf{j} := (j_1, j_2, s)$. Then, for any matrix $\mathbf{W} \in \mathbb{R}^{d\times d'}$, we put

$$f_{\mathbf{j}}(\mathbf{W}) \;:=\; s\cdot\mathrm{tr}\big(\mathbf{C}_{\mathbf{j}}^T\mathbf{W}\big),$$

where $\mathbf{C}_{\mathbf{j}} := s\,\mathbf{e}_{j_1}\mathbf{e}_{j_2}^T \in \mathbb{R}^{d\times d'}$ and $\mathbf{e}_{j_1} \in \mathbb{R}^d$, $\mathbf{e}_{j_2} \in \mathbb{R}^{d'}$ are standard basis vectors. In words, the function $f_{\mathbf{j}}$ merely picks out the (j_1, j_2) entry of $\mathbf{W}$, and multiplies by a sign s. Likewise, let $\mathscr{J}$ be the collection of all the triples $\mathbf{j}$, and define the class of linear functions

$$\mathscr{F} \;:=\; \big\{f_{\mathbf{j}} \mid \mathbf{j}\in\mathscr{J}\big\}.$$

Clearly, $\mathsf{card}(\mathscr{F}) = 2dd'$. Under this definition, it is simple to check that Z_t and $Z_t^\star$, defined in equations (16) and (17), can be expressed as

$$Z_t \;=\; \max_{f_{\mathbf{j}}\in\mathscr{F}} \mathbb{G}_t(f_{\mathbf{j}}), \qquad \text{and} \qquad Z_t^\star \;=\; \max_{f_{\mathbf{j}}\in\mathscr{F}} \mathbb{G}_t^\star(f_{\mathbf{j}}).$$

A.2. Statements of the approximation results

Theorems 1 and 2 are obtained by combining the following two results (Propositions 3 and 4) via the triangle inequality. In essence, these results are based on a comparison with the maximum of a certain Gaussian process. More specifically, let $\mathbb{G} : \mathscr{F} \to \mathbb{R}$ be a zero-mean Gaussian process whose covariance structure is defined according to

$$\begin{aligned}\mathbb{E}\big[\mathbb{G}(f_{\mathbf{j}})\,\mathbb{G}(f_{\mathbf{k}})\big] \;&=\; \mathrm{cov}\big(f_{\mathbf{j}}(\mathbf{D}_1),\, f_{\mathbf{k}}(\mathbf{D}_1)\big)\\ &=\; \mathbb{E}\Big[f_{\mathbf{j}}(\mathbf{D}_1)\,f_{\mathbf{k}}(\mathbf{D}_1)\Big] - f_{\mathbf{j}}(\mathbf{A}^T\mathbf{B})\,f_{\mathbf{k}}(\mathbf{A}^T\mathbf{B}),\end{aligned} \tag{22}$$

for all $\mathbf{j},\mathbf{k} \in \mathscr{J}$. In turn, define the following random variable as the the maximum of this Gaussian process,

$$Z \;:=\; \max_{f_{\mathbf{j}}\in\mathscr{F}} \mathbb{G}(f_{\mathbf{j}}).$$

In order to handle the case of SRHT matrices, define another zero-mean Gaussian process $\tilde{\mathbb{G}} : \mathscr{F} \to \mathbb{R}$ (conditionally on a fixed realization of $\mathbf{D}_n^\circ$) to have its covariance structure given by

$$\begin{aligned}\mathbb{E}\big[\tilde{\mathbb{G}}(f_{\mathbf{j}})\,\tilde{\mathbb{G}}(f_{\mathbf{k}})\big|\mathbf{D}_n^\circ\big] \;&=\; \mathrm{cov}\big(f_{\mathbf{j}}(\mathbf{D}_1),\, f_{\mathbf{k}}(\mathbf{D}_1)\big|\mathbf{D}_n^\circ\big)\\ &=\; \mathbb{E}\Big[f_{\mathbf{j}}(\mathbf{D}_1)\,f_{\mathbf{k}}(\mathbf{D}_1)\Big|\mathbf{D}_n^\circ\Big] - f_{\mathbf{j}}(\mathbf{A}^T\mathbf{B})\,f_{\mathbf{k}}(\mathbf{A}^T\mathbf{B}),\end{aligned} \tag{23}$$

and let $\tilde{Z}$ denote the maximum of the process $\tilde{\mathbb{G}}$,

$$\tilde{Z} \;:=\; \max_{f_{\mathbf{j}}\in\mathscr{F}} \tilde{\mathbb{G}}(f_{\mathbf{j}}).$$

We are now in position to state the approximation results.

Proposition 3 (Gaussian approximation) *Under Assumption 1 (a), the following bound holds,*

$$d_{\mathrm{LP}}\big(\mathcal{L}(Z_t)\,,\,\mathcal{L}(Z)\big) \;\le\; \frac{c\cdot\nu(\mathbf{A},\mathbf{B})^{3/4}\cdot\sqrt{\log(d)}}{t^{1/8}}.$$

Under Assumption 1 (b), the following bound holds,

$$d_{\mathrm{LP}}\big(\mathcal{L}(Z_t)\,,\,\mathcal{L}(Z)\big) \;\le\; \frac{c\cdot(\|\mathbf{A}\|_F\|\mathbf{B}\|_F)^{3/4}\cdot\sqrt{\log(d)}}{t^{1/8}}.$$

Under Assumption 1 (c), the following bound holds with probability at least $1 - c/n$

$$d_{\mathrm{LP}}\big(\mathcal{L}(Z_t)\,,\,\mathcal{L}(\tilde{Z}|\mathbf{D}_n^\circ)\big) \;\le\; \frac{c\cdot\nu(\mathbf{A},\mathbf{B})^{3/4}\cdot(\log(n))^{3/4}\cdot\sqrt{\log(d)}}{t^{1/8}}.$$

Proposition 4 (Bootstrap approximation) *If Assumption 1 (a) holds, then the following bound holds with probability at least $1 - \frac{1}{t} - \frac{1}{dd'}$,*

$$d_{\mathrm{LP}}\big(\mathcal{L}(Z)\,,\,\mathcal{L}(Z_t^\star|\mathbf{S})\big) \;\le\; \frac{c\cdot\nu(\mathbf{A},\mathbf{B})^{1/2}\sqrt{\log(d)}}{t^{1/8}}.$$

If Assumption 1 (b) holds, then the following bound holds with probability at least $1-\frac{1}{t}-\frac{1}{dd'}$,

$$d_{\mathrm{LP}}\big(\mathcal{L}(Z)\,,\,\mathcal{L}(Z_t^\star|\mathbf{S})\big) \;\le\; \frac{c\cdot(\|\mathbf{A}\|_F\|\mathbf{B}\|_F)^{1/2}\sqrt{\log(d)}}{t^{1/8}}.$$

If Assumption 1 (c) holds, then the following bound holds with probability at least $1-\frac{1}{t}-\frac{1}{dd'}-\frac{c}{n}$,

$$d_{\mathrm{LP}}\big(\mathcal{L}(\tilde{Z}|\mathbf{D}_n^\circ)\,,\,\mathcal{L}(Z_t^\star|\mathbf{S})\big) \;\le\; \frac{c\cdot\nu(\mathbf{A},\mathbf{B})^{1/2}\cdot\log(n)^{1/2}\cdot\sqrt{\log(d)}}{t^{1/8}}.$$

Appendix B. Proof of Proposition 3, part (a)

Let $A \subset \mathbb{R}$ be a Borel set. Due to Theorem 3.1 from the paper Chernozhukov et al. (2016), we have for any $\delta > 0$,

$$\mathbb{P}(Z_t \in A) \leq \mathbb{P}(Z \in A^{c\delta}) + \tfrac{c\log^2(d)}{\delta^3\sqrt{t}}\Big(L_t + K_t(\delta) + J_t(\delta))\Big), \tag{24}$$

where we define the following non-random quantities

$$L_t := \max_{f_{\mathbf{j}} \in \mathscr{F}} \frac{1}{t}\sum_{i=1}^{t} \mathbb{E}\Big[\big|f_{\mathbf{j}}(\mathbf{M}_i)\big|^3\Big], \tag{25}$$

$$K_t(\delta) := \mathbb{E}\Bigg[\max_{f_{\mathbf{j}} \in \mathscr{F}} |f_{\mathbf{j}}(\mathbf{M}_1)|^3 \cdot 1\Big\{\max_{f_{\mathbf{j}} \in \mathscr{F}} |f_{\mathbf{j}}(\mathbf{M}_1)| > \tfrac{\delta\sqrt{t}}{\log(\mathrm{card}(\mathscr{F}))}\Big\}\Bigg], \tag{26}$$

$$J_t(\delta) := \mathbb{E}\Bigg[\max_{f_{\mathbf{j}} \in \mathscr{F}} |\mathbb{G}(f_{\mathbf{j}})|^3 \cdot 1\Big\{\max_{f_{\mathbf{j}} \in \mathscr{F}} |\mathbb{G}(f_{\mathbf{j}})| > \tfrac{\delta\sqrt{t}}{\log(\mathrm{card}(\mathscr{F}))}\Big\}\Bigg]. \tag{27}$$

The remainder of the proof consists in bounding each of these quantities, and we will establish the following two bounds for all $\delta > 0$,

$$L_t \leq c\,\nu(\mathbf{A},\mathbf{B})^3, \tag{28}$$

$$K_t(\delta) + J_t(\delta) \leq c\Big(\tfrac{\delta\sqrt{t}}{\log(d)} + \log(d)\,\nu(\mathbf{A},\mathbf{B})\Big)^3 \cdot \exp\Big(-\tfrac{\delta\sqrt{t}}{c\;\nu(\mathbf{A},\mathbf{B})\log^2(d)}\Big). \tag{29}$$

Recall also that $\mathrm{card}(\mathscr{F}) = 2dd'$, and $d \asymp d'$ under Assumption 1.

For the moment, we set aside the task of proving these bounds, and consider the choice of δ. There are two constraints that we would like δ to satisfy. First, we would like to choose δ so that the bounds on L_t and $(K_t(\delta) + J_t(\delta))$ are of the same order. In particular, we desire

$$K_t(\delta) + J_t(\delta) \;\leq\; c\,\nu(\mathbf{A},\mathbf{B})^3. \tag{30}$$

Second, with regard to line (24) we would like δ to solve the equation

$$\delta \;=\; \tfrac{1}{\delta^3}\tfrac{\log^2(d)\,\nu(\mathbf{A},\mathbf{B})^3}{\sqrt{t}}, \tag{31}$$

so that the second term in line (24) is of order δ. The idea is that if δ satisfies both of the conditions (30) and (31), then the definition of the d_{LP} metric and line (24) imply

$$d_{\mathrm{LP}}(\mathcal{L}(Z), \mathcal{L}(Z_t)) \;\leq\; c\,\delta.$$

To proceed, consider the choice

$$\delta_0 \;:=\; \tfrac{\log^{1/2}(d)\,\nu(\mathbf{A},\mathbf{B})^{3/4}}{t^{1/8}},$$

which clearly satisfies line (31). Futhermore, it can be checked that δ_0 also satisfies the constraint (30) under Assumption 1 (a). (The details of verifying this are somewhat tedious and are given in Lemma 16 in Appendix F.)

To finish the proof, it remains to establish the bounds (28) and (29). To handle L_t, note that[¶]

$$\begin{aligned}
\mathbb{E}[|f_{\mathbf{j}}(\mathbf{M}_i)|^3] &= \|f_{\mathbf{j}}(\mathbf{M}_1)\|_3^3 \\
&\leq c\|f_{\mathbf{j}}(\mathbf{M}_1)\|_{\psi_1}^3, && \text{(Lemma 9)} \qquad (32)\\
&\leq c\Big(\tfrac{\|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_F^2}{\|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_2}\Big)^3, && \text{(Lemma 14)} \\
&= c\Big(\|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_F\Big)^3 && \text{(since } \|\mathbf{H}\|_2 = \|\mathbf{H}\|_F \text{ when } \mathbf{H} \text{ is rank-1)} \\
&= c\Big(\mathrm{tr}\big(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\mathbf{A}\mathbf{C}_{\mathbf{j}}\mathbf{B}^T\big)\Big)^{3/2} \\
&= c\Big(\mathbf{e}_{j_1}^T\mathbf{A}^T\mathbf{A}\mathbf{e}_{j_1} \cdot \mathbf{e}_{j_2}^T\mathbf{B}^T\mathbf{B}\mathbf{e}_{j_2}\Big)^{3/2} \\
&\leq c\;\nu(\mathbf{A},\mathbf{B})^3, && (33)
\end{aligned}$$

which proves the claimed bound in line (28).

Next, regarding $K_t(\delta)$, let us consider the random variable

$$\eta := \max_{f_{\mathbf{j}} \in \mathscr{F}} |f_{\mathbf{j}}(\mathbf{M}_1)|.$$

It follows from Lemma 9 (part 4) and Lemma 13 in Appendix F that $K_t(\delta)$ can be bounded in terms of the Orlicz norm $\|\eta\|_{\psi_1}$,

$$K_t(\delta) \leq c\Big(\tfrac{\delta\sqrt{t}}{\log(\mathsf{card}(\mathscr{F}))} + \|\eta\|_{\psi_1}\Big)^3 \cdot \exp(-\tfrac{\delta\sqrt{t}}{\|\eta\|_{\psi_1}\log(\mathsf{card}(\mathscr{F})}).$$

To handle $\|\eta\|_{\psi_1}$, it follows from Lemma 9 (part 3), that

$$\|\eta\|_{\psi_1} \leq c\log(\mathsf{card}(\mathscr{F})) \cdot \max_{f_{\mathbf{j}} \in \mathscr{F}} \|f_{\mathbf{j}}(\mathbf{M}_1)\|_{\psi_1}. \tag{34}$$

Furthermore, due to the earlier calculation starting at line (32) above,

$$\|f_{\mathbf{j}}(\mathbf{M}_1)\|_{\psi_1} \leq c\;\nu(\mathbf{A},\mathbf{B}). \tag{35}$$

Combining the last few steps, we conclude that

$$K_t(\delta) \leq c\Big(\tfrac{\delta\sqrt{t}}{\log(\mathrm{card}(\mathscr{F}))} + \log(\mathrm{card}(\mathscr{F}))\nu(\mathbf{A},\mathbf{B})\Big)^3 \cdot \exp\Big(-\tfrac{\delta\sqrt{t}}{c\nu(\mathbf{A},\mathbf{B})\log^2(\mathrm{card}(\mathscr{F}))}\Big). \tag{36}$$

Lastly, we turn to bounding $J_t(\delta)$. Fortunately, much of the argument for bounding $K_t(\delta)$ can be carried over. Specifically, consider the random variable

$$\zeta := \max_{f_{\mathbf{j}} \in \mathscr{F}} |\mathbb{G}(f_{\mathbf{j}})|.$$

[¶]In this step, we use the assumption that $\|\sqrt{t}S_{i,j}\|_{\psi_2} \leq c$ for all i and j.

Lemma 13 in Appendix F shows that $J_t(\delta)$ can be bounded in terms of $\|\zeta\|_{\psi_1}$,

$$J_t(\delta) \leq c\Big(\tfrac{\delta\sqrt{t}}{\log(\mathsf{card}(\mathscr{F}))} + \|\zeta\|_{\psi_1}\Big)^3 \cdot \exp\Big(-\tfrac{\delta\sqrt{t}}{\|\zeta\|_{\psi_1}\,\log(\mathsf{card}(\mathscr{F}))}\Big).$$

Proceeding in a way that is similar to the bound for $K_t(\delta)$, it follows from part (3) of Lemma 9 that

$$\|\zeta\|_{\psi_1} \leq c\log(\mathsf{card}(\mathscr{F})) \cdot \max_{f_{\mathbf{j}}\in\mathscr{F}} \|\mathbb{G}(f_{\mathbf{j}})\|_{\psi_1}.$$

Furthermore, for every $f_{\mathbf{j}} \in \mathscr{F}$, the facts in Lemma 9 imply

$$\begin{aligned}
\|\mathbb{G}(f_{\mathbf{j}})\|_{\psi_1} &\leq c\,\|\mathbb{G}(f_{\mathbf{j}})\|_{\psi_2} \\
&\leq c\sqrt{\mathsf{var}(\mathbb{G}(f_{\mathbf{j}}))} \\
&= c\sqrt{\mathsf{var}(f_{\mathbf{j}}(\mathbf{D}_1))} \quad \text{(by definition of } \mathbb{G}) \\
&\leq c\|f_{\mathbf{j}}(\mathbf{D}_1)\|_2 \\
&\leq c\|f_{\mathbf{j}}(\mathbf{D}_1)\|_{\psi_1} \qquad (37) \\
&\leq c\,\|f_{\mathbf{j}}(\mathbf{D}_1) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)\|_{\psi_1} + c\,|\mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]| \\
&= c\|f_{\mathbf{j}}(\mathbf{M}_1)\|_{\psi_1} + c\,|\mathrm{tr}(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A})| \\
&\leq c\,\nu(\mathbf{A},\mathbf{B}), \qquad (38)
\end{aligned}$$

where the last step follows from the bounds (32) through (33), and the fact that $|\mathrm{tr}(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A})| \leq \nu(\mathbf{A},\mathbf{B})$. Consequently, up to a constant factor, $J_t(\delta)$ satisfies the same bound as $K_t(\delta)$ given in line (36), and this proves the claim in line (29).

■

Appendix C. Proof of Proposition 4, part (a)

We will show there is a set of "good" sketching matrices $\mathscr{S} \subset \mathbb{R}^{t\times n}$ with the following two properties. First, a randomly drawn sketching matrix $\mathbf{S}$ is likely to fall in $\mathscr{S}$. Namely,

$$\mathbb{P}(\mathbf{S} \in \mathscr{S}) \geq 1 - \tfrac{1}{t}. \qquad (39)$$

Second, whenever the event $\{\mathbf{S} \in \mathscr{S}\}$ occurs, we have the following bound for any $\delta > 0$ and any Borel set $A \subset \mathbb{R}$,

$$\mathbb{P}\Big(\max_{f_{\mathbf{j}}\in\mathscr{F}} \mathbb{G}_t^\star(f_{\mathbf{j}}) \in A \Big| \mathbf{S}\Big) \;\leq\; \mathbb{P}\Big(\max_{f_{\mathbf{j}}\in\mathscr{F}} \mathbb{G}(f_{\mathbf{j}}) \in A^\delta\Big) + \tfrac{c\,\nu(\mathbf{A},\mathbf{B})\cdot\log(\mathsf{card}(\mathscr{F}))}{\delta\, t^{1/4}}. \qquad (40)$$

If we set δ to the particular choice $\delta_0 := t^{-1/8}\sqrt{\nu(\mathbf{A},\mathbf{B})\cdot\log(\mathsf{card}(\mathscr{F}))}$, then δ_0 solves the equation

$$\delta_0 \;=\; \tfrac{\nu(\mathbf{A},\mathbf{B})\cdot\log(\mathsf{card}(\mathscr{F}))}{\delta_0\, t^{1/4}}.$$

Consequently, by the definition of the d_{LP} metric, this implies that whenever the event $\{\mathbf{S} \in \mathscr{S}\}$ occurs, we have

$$d_{\mathrm{LP}}\big(\mathcal{L}(Z_t^\star|\mathbf{S})\,,\,\mathcal{L}(Z)\big) \;\leq\; c\,t^{-1/8}\,\sqrt{\nu(\mathbf{A},\mathbf{B})\cdot\log(\mathsf{card}(\mathscr{F}))}, \qquad (41)$$

and this implies the statement of Proposition 4.

To proceed with the main argument of constructing $\mathscr{S}$ and demonstrating the two properties (39) and (40), it is helpful to think of $\mathbb{G}_t^\star$ (conditionally on $\mathbf{S}$) and $\mathbb{G}$ as Gaussian vectors of dimension $\mathsf{card}(\mathscr{F}) = 2dd'$. From this point of view, we can compare the maxima of these vectors using a result due to Chernozhukov et al. (2016, Theorem 3.2). Under our assumptions, this result implies that for any realization of $\mathbf{S}$, any number $\delta > 0$, and any Borel set $A \subset \mathbb{R}$, we have

$$\mathbb{P}\Big(\max_{f_{\mathbf{j}}\in\mathscr{F}} \mathbb{G}_t^\star(f_{\mathbf{j}}) \in A \Big| \mathbf{S}\Big) \;\leq\; \mathbb{P}\Big(\max_{f_{\mathbf{j}}\in\mathscr{F}} \mathbb{G}(f_{\mathbf{j}}) \in A^\delta\Big) + \tfrac{c\sqrt{\Delta_t(\mathbf{S})\log(\mathsf{card}(\mathscr{F}))}}{\delta},$$

where we define the following function of $\mathbf{S}$,

$$\Delta_t(\mathbf{S}) \;:=\; \max_{(f_{\mathbf{j}},f_{\mathbf{k}})\in\mathscr{F}\times\mathscr{F}} \Big|\mathbb{E}\big[\mathbb{G}_t^\star(f_{\mathbf{j}})\mathbb{G}_t^\star(f_{\mathbf{k}})\big|\mathbf{S}\big] - \mathbb{E}\big[\mathbb{G}(f_{\mathbf{j}})\mathbb{G}(f_{\mathbf{k}})\big]\Big|. \qquad (42)$$

When referencing Theorem 3.2 from the paper Chernozhukov et al. (2016), note that $\mathbb{E}[\mathbb{G}(f_{\mathbf{j}})] = 0$ and $\mathbb{E}[\mathbb{G}_t^\star(f_{\mathbf{j}})|\mathbf{S}] = 0$ for all $f_{\mathbf{j}} \in \mathscr{F}$. To interpret $\Delta_t(\mathbf{S})$, it may be viewed as the ℓ_∞-distance between the covariance matrices associated with $\mathbb{G}_t^\star$ (conditionally on $\mathbf{S}$) and $\mathbb{G}$.

Using the above notation, we define the set of sketching matrices $\mathscr{S} \subset \mathbb{R}^{n\times t}$ according to

$$\mathbf{S} \in \mathscr{S} \qquad \text{if and only if} \qquad \Delta_t(\mathbf{S}) \leq \tfrac{c}{\sqrt{t}}\cdot\nu(\mathbf{A},\mathbf{B})^2\cdot\log(\mathsf{card}(\mathscr{F})). \qquad (43)$$

Based on this definition, it is simple to check that the proof is reduced to showing that the event $\{\mathbf{S} \in \mathscr{S}\}$ occurs with probability at least $1 - \frac{1}{t} - \frac{1}{dd'}$. This is guaranteed by the lemma below.

■

Lemma 5 *Suppose Assumption 1 (a) holds. Then, the event*

$$\Delta_t(\mathbf{S}) \;\leq\; \frac{c}{\sqrt{t}}\cdot\nu(\mathbf{A},\mathbf{B})^2\cdot\log\big(\mathsf{card}(\mathscr{F})\big)$$

occurs with probability at least $1 - \frac{1}{t} - \frac{1}{dd'}$.

Proof We begin by bounding $\Delta_t(\mathbf{S})$ with two other quantities (to be denoted $\Delta_t'(\mathbf{S})$, $\Delta_t''(\mathbf{S})$) that are easier to bound. Using the fact that $\frac{1}{t}\sum_{i=1}^t \mathbf{D}_i = \mathbf{A}^T\mathbf{S}^T\mathbf{S}\mathbf{B}$ it can be checked that

$$\mathbb{E}\big[\mathbb{G}_t^\star(f_{\mathbf{j}})\mathbb{G}_t^\star(f_{\mathbf{k}})\big|\mathbf{S}\big] \;=\; \Big(\tfrac{1}{t}\textstyle\sum_{i=1}^t f_{\mathbf{j}}(\mathbf{D}_i)f_{\mathbf{k}}(\mathbf{D}_i)\Big) - \Big(\tfrac{1}{t}\textstyle\sum_{i=1}^t f_{\mathbf{j}}(\mathbf{D}_i)\Big)\cdot\Big(\tfrac{1}{t}\textstyle\sum_{i=1}^t f_{\mathbf{k}}(\mathbf{D}_i)\Big).$$

Similarly, recall from line (22) that

$$\mathbb{E}[\mathbb{G}(f_{\mathbf{j}})\mathbb{G}(f_{\mathbf{k}})] \;=\; \mathbb{E}\Big[f_{\mathbf{j}}(\mathbf{D}_1)f_{\mathbf{k}}(\mathbf{D}_1)\Big] - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]\cdot\mathbb{E}[f_{\mathbf{k}}(\mathbf{D}_1)].$$

From looking at the last two lines, it is natural to define the following *zero-mean* random variables for any triple $i, \mathbf{j}, \mathbf{k}$,[‖]

$$Q_{i\,\mathbf{j},\mathbf{k}} := f_{\mathbf{j}}(\mathbf{D}_i) f_{\mathbf{k}}(\mathbf{D}_i) - \mathbb{E}\Big[f_{\mathbf{j}}(\mathbf{D}_i) f_{\mathbf{k}}(\mathbf{D}_i)\Big],$$

and

$$R_{t,\mathbf{j}} := \tfrac{1}{t}\textstyle\sum_{i=1}^{t}\big(f_{\mathbf{j}}(\mathbf{D}_i) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_i)]\big).$$

Then, some algebra shows that

$$\begin{aligned}\mathbb{E}\big[\mathbb{G}_t^*(f_{\mathbf{j}})\,\mathbb{G}_t^*(f_{\mathbf{k}})\,\big|\,\mathbf{S}\big] - \mathbb{E}\big[\mathbb{G}(f_{\mathbf{j}})\,\mathbb{G}(f_{\mathbf{k}})\big] = \Big(\tfrac{1}{t}\textstyle\sum_{i=1}^{t} Q_{i\,\mathbf{j},\mathbf{k}}\Big) - R_{t,\mathbf{j}}\cdot R_{t,\mathbf{k}} \\ - \mathbb{E}\big[f_{\mathbf{j}}(\mathbf{D}_1)\big]\cdot R_{t,\mathbf{k}} - \mathbb{E}\big[f_{\mathbf{k}}(\mathbf{D}_1)\big]\cdot R_{t,\mathbf{j}}.\end{aligned}$$

So, if we define the quantities

$$\Delta_t'(\mathbf{S}) \;:=\; \max_{(\mathbf{j},\mathbf{k})\in\mathscr{J}\times\mathscr{J}}\Big|\tfrac{1}{t}\sum_{i=1}^{t} Q_{i,\mathbf{j},\mathbf{k}}\Big|,$$

$$\Delta_t''(\mathbf{S}) \;:=\; \max_{\mathbf{j}\in\mathscr{J}}\big|R_{t,\mathbf{j}}\big|,$$

then

$$\Delta_t(\mathbf{S}) \;\le\; \Delta_t'(\mathbf{S}) + \Delta_t''(\mathbf{S})^2 + 2\nu(\mathbf{A},\mathbf{B})\cdot\Delta_t''(\mathbf{S}),$$

where we have made use of the simple bound $|\mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]| \le \|\mathbf{A}^T\mathbf{B}\|_\infty \le \nu(\mathbf{A},\mathbf{B})$. The following lemma establishes tail bounds for $\Delta_t'(\mathbf{S})$ and $\Delta_t''(\mathbf{S})$, which lead to the statement of Proposition 4. ■

Lemma 6 *Suppose Assumption 1 (a) holds. Then, the event*

$$\Delta_t'(\mathbf{S}) \;\le\; \frac{c}{\sqrt{t}}\cdot\nu(\mathbf{A},\mathbf{B})^2\cdot\log\big(\mathsf{card}(\mathscr{F})\big) \qquad \text{(i)}$$

occurs with probability at least $1-\frac{1}{t}$*, and the event*

$$\Delta_t''(\mathbf{S}) \;\le\; \frac{c}{\sqrt{t}}\cdot\nu(\mathbf{A},\mathbf{B})\cdot\sqrt{\log\big(\mathsf{card}(\mathscr{F})\big)} \qquad \text{(ii)}$$

occurs with probability at least $1-\frac{1}{dd'}$.

[‖] Note that $Q_{i,\mathbf{j},\mathbf{k}}$ is a multivariate polynomial of degree-4 in the variables $S_{i,j}$, and so techniques based on moment generating functions, like Chernoff bounds, are not generally applicable to controlling $Q_{i\,\mathbf{j},\mathbf{k}}$. For instance, if $X\sim\mathcal{N}(0,1)$, then the variable X^4 does not have a moment generating function. Handling this obstacle is a notable aspect of our analysis.

Proof of Lemma 6 (i). Let $p>2$. Due to part (3) of Lemma 9 in Appendix F, we have

$$\|\Delta_t'(\mathbf{S})\|_p \;\le\; \big(\mathsf{card}(\mathscr{F})^2\big)^{1/p}\cdot\max_{(\mathbf{j},\mathbf{k})\in\mathscr{J}\times\mathscr{J}}\Big\|\tfrac{1}{t}\textstyle\sum_{i=1}^{t} Q_{i,\mathbf{j},\mathbf{k}}\Big\|_p. \qquad (44)$$

Note that each variable $Q_{i,\mathbf{j},\mathbf{k}}$ has moments of all orders, and when $\mathbf{j}$ and $\mathbf{k}$ are held fixed, the sequence $\{Q_{i,\mathbf{j},\mathbf{k}}\}_{1\le i\le t}$ is i.i.d. For this reason, it is natural to use Rosenthal's inequality to bound the L_p norm of the right side of the previous line. Specifically, the version of Rosenthal's inequality[**] stated in Lemma 10 in Appendix F leads to

$$\Big\|\tfrac{1}{t}\textstyle\sum_{i=1}^{t} Q_{i,\mathbf{j},\mathbf{k}}\Big\|_p \le c\cdot\frac{p/\log(p)}{t}\cdot\max\Big\{\Big\|\textstyle\sum_{i=1}^{t} Q_{i,\mathbf{j},\mathbf{k}}\Big\|_2,\,\big(\textstyle\sum_{i=1}^{t}\|Q_{i,\mathbf{j},\mathbf{k}}\|_p^p\big)^{1/p}\Big\}. \qquad (45)$$

The L_2 norm on the right side of Rosenthal's inequality (45) satisfies the bound

$$\begin{aligned}\Big\|\textstyle\sum_{i=1}^{t} Q_{i,\mathbf{j},\mathbf{k}}\Big\|_2 &= \sqrt{\mathsf{var}\big(\textstyle\sum_{i=1}^{t} Q_{i,\mathbf{j},\mathbf{k}}\big)} \\ &= \sqrt{t}\sqrt{\mathsf{var}(Q_{1,\mathbf{j},\mathbf{k}})} \\ &= \sqrt{t}\sqrt{\mathsf{var}\big(f_{\mathbf{j}}(\mathbf{D}_1)\,f_{\mathbf{k}}(\mathbf{D}_1)\big)} \\ &\le \sqrt{t}\Big\|f_{\mathbf{j}}(\mathbf{D}_1)\,f_{\mathbf{k}}(\mathbf{D}_1)\Big\|_2 \\ &\le \sqrt{t}\big\|f_{\mathbf{j}}(\mathbf{D}_1)\big\|_4\cdot\big\|f_{\mathbf{k}}(\mathbf{D}_1)\big\|_4 \qquad \text{(Cauchy-Schwarz)} \\ &\le c\sqrt{t}\big\|f_{\mathbf{j}}(\mathbf{D}_1)\big\|_{\psi_1}\cdot\big\|f_{\mathbf{k}}(\mathbf{D}_1)\big\|_{\psi_1} \qquad \text{(Lemma 9)} \\ &\le c\,\sqrt{t}\nu(\mathbf{A},\mathbf{B})^2,\end{aligned}$$

where the last step follows from the fact

$$\|f_{\mathbf{j}}(\mathbf{D}_1)\|_{\psi_1} \le c\,\nu(\mathbf{A},\mathbf{B}), \qquad (46)$$

obtained in the bounds (32) through (33).

Next, to handle the L_p norms in the bound (45), observe that

$$\begin{aligned}\|Q_{1,\mathbf{j},\mathbf{k}}\|_p &\le \big\|f_{\mathbf{j}}(\mathbf{D}_1)f_{\mathbf{k}}(\mathbf{D}_1)\big\|_p + \big|\mathbb{E}\big[f_{\mathbf{j}}(\mathbf{D}_1)f_{\mathbf{k}}(\mathbf{D}_1)\big]\big| \\ &\le 2\big\|f_{\mathbf{j}}(\mathbf{D}_1)\big\|_{2p}\cdot\big\|f_{\mathbf{k}}(\mathbf{D}_1)\big\|_{2p} \qquad \text{(Cauchy-Schwarz)} \\ &\le c p^2\big\|f_{\mathbf{j}}(\mathbf{D}_1)\big\|_{\psi_1}\cdot\big\|f_{\mathbf{k}}(\mathbf{D}_1)\big\|_{\psi_1} \qquad \text{(Lemma 9 in Appendix F)} \\ &\le c p^2\,\nu(\mathbf{A},\mathbf{B})^2 \qquad \text{(inequality (46))}.\end{aligned}$$

Hence, the second term in the Rosenthal bound (45) satisfies

$$\big(\textstyle\sum_{i=1}^{t}\|Q_{i,\mathbf{j},\mathbf{k}}\|_p^p\big)^{1/p} \;\le\; c\cdot p^2\cdot t^{1/p}\cdot\nu(\mathbf{A},\mathbf{B})^2,$$

[**] Here we are using the version of Rosenthal's inequality with the optimal dependence on p. It is a notable aspect of our argument that it makes essential use of this scaling in p.

and as long as the first term in the Rosenthal bound dominates[††], i.e.

$$p^2\, t^{1/p} \lesssim t^{1/2} \tag{47}$$

then we conclude that for any $\mathbf{j}$ and $\mathbf{k}$,

$$\Big\| \tfrac{1}{t} \textstyle\sum_{i=1}^t Q_{i,\mathbf{j},\mathbf{k}} \Big\|_p \;\leq\; \tfrac{c\cdot(p/\log(p))\cdot \nu(\mathbf{A},\mathbf{B})^2}{\sqrt{t}}.$$

Since the previous bound does not depend on $\mathbf{j}$ or $\mathbf{k}$, combining it with the first step in line (44) leads to

$$\big\|\Delta_t'(\mathbf{S})\big\|_p \;\leq\; c\cdot(p/\log(p))\cdot \mathsf{card}(\mathscr{F})^{2/p}\cdot \tfrac{\nu(\mathbf{A},\mathbf{B})^2}{\sqrt{t}}.$$

Next, we convert this norm bound into a tail bound. Specifically, if we consider the value

$$x_p \;:=\; c\cdot(p/\log(p))\cdot \mathsf{card}(\mathscr{F})^{2/p}\cdot \tfrac{\nu(\mathbf{A},\mathbf{B})^2}{\sqrt{t}}\cdot t^{1/p}$$

then Markov's inequality gives

$$\mathbb{P}\big(\Delta_t'(\mathbf{S}) \;\geq\; x_p\big) \;\leq\; \tfrac{\|\Delta_t'(\mathbf{S})\|_p^p}{x_p^p} \leq \tfrac{1}{t}.$$

Considering the choice of p given by

$$p = \log(\mathsf{card}(\mathscr{F})),$$

and noting that $\mathsf{card}(\mathscr{F})^{1/p} = e$, it follows that under this choice of p,

$$x_p \;\leq\; \Big(\tfrac{c\cdot\nu(\mathbf{A},\mathbf{B})^2\cdot\log(\mathsf{card}(\mathscr{F}))}{\sqrt{t}}\Big)\cdot\Big(\tfrac{t^{1/p}}{\log(p)}\Big).$$

Moreover, as long as $t \lesssim \mathsf{card}(\mathscr{F})^\kappa$ for some absolute constant $\kappa \geq 1$ (which holds under Assumption 1), then the last factor on the right satisfies

$$\big(\tfrac{t^{1/p}}{\log(p)}\big) \leq \tfrac{(\mathsf{card}(\mathscr{F})^{1/p})^\kappa}{\log(p)} = \tfrac{e^\kappa}{\log(\log(\mathsf{card}(\mathscr{F}))} \lesssim 1.$$

So, combining the last few steps, there is an absolute constant c such that

$$\mathbb{P}\Big(\Delta_t'(\mathbf{S}) \;\geq\; \tfrac{c\cdot\nu(\mathbf{A},\mathbf{B})^2\cdot\log(\mathsf{card}(\mathscr{F}))}{\sqrt{t}}\Big) \;\leq\; \tfrac{1}{t},$$

as needed. ■

[††]Under the choice of $p = \log(\mathsf{card}(\mathscr{F})) = \log(2dd')$ that will be made at the end of this argument, it is straightforward to check that the condition (47) holds under Assumption 1.

Proof of Lemma 6 (ii). Note that for each $i \in [t]$ and $\mathbf{j} \in \mathscr{J}$, we have

$$f_{\mathbf{j}}(\mathbf{D}_i) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_i)] \;=\; f_{\mathbf{j}}(\mathbf{M}_i) \;=\; \mathbf{s}_i^T(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)\mathbf{s}_i - \mathrm{tr}(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T), \tag{48}$$

which is a centered sub-Gaussian quadratic form. Due to the bound (35), we have

$$\Big\| f_{\mathbf{j}}(\mathbf{D}_i) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_i)] \Big\|_{\psi_1} \;\leq\; c\,\nu(\mathbf{A},\mathbf{B}). \tag{49}$$

Furthermore, this can be combined with a standard concentration bound for sums of independent sub-exponential random variables (Lemma 12) to show that for any $r \geq 0$,

$$\mathbb{P}\Big(\Big|\tfrac{1}{t}\textstyle\sum_{i=1}^t f_{\mathbf{j}}(\mathbf{D}_i) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_i)]\Big| \;\geq\; r\,\nu(\mathbf{A},\mathbf{B})\Big) \;\leq\; 2\exp\Big(-c\cdot t\cdot\min(r^2,r)\Big). \tag{50}$$

Hence, taking a union bound over all $\mathbf{j}$ gives

$$\mathbb{P}\Big(\Delta_t''(\mathbf{S}) \geq\; r\,\nu(\mathbf{A},\mathbf{B})\Big) \;\leq\; 2\exp\Big(\log(\mathsf{card}(\mathscr{F})) - c\cdot t\cdot\min(r^2,r)\Big). \tag{51}$$

Regarding the choice of r, note that by Assumption 1, we have $\frac{1}{\sqrt{t}}\sqrt{\log(\mathsf{card}(\mathscr{F}))} \lesssim 1$. It follows that there is a sufficiently large absolute constant $c_1 > 0$ such that if we put

$$r = \tfrac{c_1}{\sqrt{t}}\sqrt{\log(\mathsf{card}(\mathscr{F}))},$$

then

$$c\,t\,\min(r^2,r) \geq 2\log(\mathsf{card}(\mathscr{F})),$$

where c is the same as in the bound (51). In turn, this implies

$$\mathbb{P}\Big(\Delta_t''(\mathbf{S}) \;\geq\; \tfrac{c_1}{\sqrt{t}}\sqrt{\log(\mathsf{card}(\mathscr{F}))}\cdot\nu(\mathbf{A},\mathbf{B})\Big) \;\leq\; 2\exp(-\log(\mathsf{card}(\mathscr{F})) \;=\; \frac{1}{dd'}, \tag{52}$$

as desired. ■

Appendix D. Proof of Propositions 3 and 4 in case (b) (length sampling)

In order to carry out the proof Propositions 3 and 4 in the case of length sampling (Assumption 1 (b)), there are only two bounds that need to be updated. Namely, we must derive new bounds on $\|f_{\mathbf{j}}(\mathbf{D}_1) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]\|_{\psi_1}$ and $\|f_{\mathbf{j}}(\mathbf{D}_1)\|_{\psi_1}$ in order to account for the new distributional assumptions in case (b). Both of the new bounds will turn out to be of order $\|\mathbf{A}\|_F\|\mathbf{B}\|_F$, and consequently, the result of the propositions in case (b) will have the same form as in case (a), but with $\|\mathbf{A}\|_F\|\mathbf{B}\|_F$ replacing $\nu(\mathbf{A},\mathbf{B})$.

To derive the bound on $\|f_{\mathbf{j}}(\mathbf{D}_1) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]\|_{\psi_1}$, first note that

$$\begin{aligned}|\mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]| &= |\mathrm{tr}(\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\mathbf{B})| \\ &\leq \|\mathbf{A}\|_F\|\mathbf{B}\|_F.\end{aligned}$$

Consequently,

$$\begin{aligned}\|f_{\mathbf{j}}(\mathbf{D}_1) - \mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]\|_{\psi_1} &\leq \|f_{\mathbf{j}}(\mathbf{D}_1)\|_{\psi_1} + \|\mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)]\|_{\psi_1} \\ &\leq \|f_{\mathbf{j}}(\mathbf{D}_1)\|_{\psi_1} + c\|\mathbf{A}\|_F\|\mathbf{B}\|_F.\end{aligned} \tag{53}$$

Hence, it remains to show that $\|f_{\mathbf{j}}(\mathbf{D}_1)\|_{\psi_1} \leq c\|\mathbf{A}\|_F\|\mathbf{B}\|_F$, which is the content of Lemma 7 below. ■

Lemma 7 *If* $\mathbf{S}$ *is generated by length sampling with the probabilities in line* (5)*, then for any* $\mathbf{j} \in \mathscr{J}$*, we have the bound*

$$\big\|f_{\mathbf{j}}(\mathbf{D}_1)\big\|_{\psi_1} \leq 2\|\mathbf{A}\|_F\|\mathbf{B}\|_F. \tag{54}$$

Proof By the definition of the ψ_1-Orlicz norm, it suffices to find a value of $r > 0$ so that $\mathbb{E}\big[\exp\big(|f_{\mathbf{j}}(\mathbf{D}_1)|/r\big)\big]$ is at most 2. Due to the Cauchy-Schwarz inequality, the non-zero length-sampling probabilities p_l satisfy

$$\frac{1}{p_l} \leq \frac{\sqrt{\sum_{j=1}^n \|\mathbf{e}_j^T\mathbf{A}\|_2^2}\sqrt{\sum_{j=1}^n \|\mathbf{e}_j^T\mathbf{B}\|_2^2}}{\|\mathbf{e}_l^T\mathbf{A}\|_2\|\mathbf{e}_l^T\mathbf{B}\|_2} = \frac{\|\mathbf{A}\|_F\|\mathbf{B}\|_F}{\|\mathbf{e}_l^T\mathbf{A}\|_2\|\mathbf{e}_l^T\mathbf{B}\|_2}.$$

Consequently, for each $r > 0$ we have

$$\begin{aligned}\mathbb{E}\Big[\exp\Big(\tfrac{|f_{\mathbf{j}}(\mathbf{D}_1)|}{r}\Big)\Big] &= \sum_{l\in[n]:\, p_l>0} p_l \cdot \exp\Big(\tfrac{1}{r}\big|f_{\mathbf{j}}(\tfrac{1}{p_l}\mathbf{A}^T\mathbf{e}_l\mathbf{e}_l^T\mathbf{B})\big|\Big) \\ &\leq \max_{l\in[n]:\, p_l>0} \exp\Big(\tfrac{1}{r}\tfrac{1}{p_l}\big|f_{\mathbf{j}}(\mathbf{A}^T\mathbf{e}_l\mathbf{e}_l^T\mathbf{B})\big|\Big) \\ &\leq \max_{l\in[n]} \exp\Big(\tfrac{1}{r}\|\mathbf{A}\|_F\|\mathbf{B}\|_F\big|\tfrac{\mathbf{e}_l^T\mathbf{B}}{\|\mathbf{e}_l^T\mathbf{B}\|_2}\mathbf{C}_{\mathbf{j}}^T\tfrac{\mathbf{A}^T\mathbf{e}_l}{\|\mathbf{A}^T\mathbf{e}_l\|_2}\big|\Big) \\ &\leq \exp\Big(\tfrac{1}{r}\|\mathbf{A}\|_F\|\mathbf{B}\|_F\ \|\mathbf{C}_{\mathbf{j}}\|_2\Big) \\ &= \exp\Big(\tfrac{1}{r}\|\mathbf{A}\|_F\|\mathbf{B}\|_F\Big).\end{aligned}$$

Hence, if we take $r = 2\|\mathbf{A}\|_F\|\mathbf{B}\|_F$, then the right hand side is at most $e^{1/2} \leq 2$. ■

Appendix E. Proof of Propositions 3 and 4 in case (c) (SRHT)

The steps needed to extend the propositions in the case of SRHT matrices follows the same pattern as in case (b). However, there is a small subtlety insofar as all of the analysis is done conditionally on the matrix of signs $\mathbf{D}_n^\circ$ in the product $\mathbf{S} = \mathbf{P}_n(\frac{1}{\sqrt{n}}\mathbf{H}_n)\mathbf{D}_n^\circ$. Hence, it suffices to bound the ψ_1 Orlicz norm of $f_{\mathbf{j}}(\mathbf{D}_1)$ conditionally on $\mathbf{D}_n^\circ$, as well as the conditional expectation $|\mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)|\mathbf{D}_n^\circ]$. Regarding the conditional expectation, it can be checked that $\mathbb{E}[\mathbf{S}^T\mathbf{S}|\mathbf{D}_n^\circ] = \mathbf{I}_n$, and it follows that

$$|\mathbb{E}[f_{\mathbf{j}}(\mathbf{D}_1)|\mathbf{D}_n^\circ]| = |\mathrm{tr}(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)| \leq \nu(\mathbf{A},\mathbf{B}).$$

Since we are not aware of a standard notation for a conditional Orlicz norm, we define

$$\big\|f_{\mathbf{j}}(\mathbf{D}_1)\big|\mathbf{D}_n^\circ\big\|_{\psi_1} := \inf\Big\{r > 0 \;\Big|\; \mathbb{E}\big[\psi_1\big(|f_{\mathbf{j}}(\mathbf{D}_1)|/r\big)\big|\mathbf{D}_n^\circ\big] \leq 1\Big\},$$

which is a random variable, since it is a function of $\mathbf{D}_n^\circ$. The following lemma provides a bound on this quantity, which turns out to be of order $\log(n)\,\nu(\mathbf{A},\mathbf{B})$. For this reason, the SRHT case (c) of Propositions 3 and 4 will have the same form as case (a), but with $\log(n)\,\nu(\mathbf{A},\mathbf{B})$ replacing $\nu(\mathbf{A},\mathbf{B})$. ■

Lemma 8 *If* $\mathbf{S}$ *is an SRHT matrix, then the following bound holds with probability at least* $1 - c/n$*,*

$$\big\|f_{\mathbf{j}}(\mathbf{D}_1)\big|\mathbf{D}_n^\circ\big\|_{\psi_1} \leq c \cdot \log(n) \cdot \nu(\mathbf{A},\mathbf{B}). \tag{55}$$

Proof By the definition of the conditional ψ_1-Orlicz norm, it suffices to find a value of $r > 0$ so that $\mathbb{E}\big[\exp\big(|f_{\mathbf{j}}(\mathbf{D}_1)|/r\big)\big|\mathbf{D}_n^\circ\big]$ is at most 2 (with the stated probability).

For an SRHT matrix $\mathbf{S} = \mathbf{P}\frac{1}{\sqrt{n}}\mathbf{H}_n\mathbf{D}_n^\circ$, recall that the rows of $\sqrt{t}\mathbf{P}$ are sampled uniformly at random from the set $\{\frac{1}{\sqrt{1/n}}\mathbf{e}_1, \ldots, \frac{1}{\sqrt{1/n}}\mathbf{e}_n\}$. It follows that

$$\begin{aligned}\mathbb{E}\Big[\exp\Big(\tfrac{|f_{\mathbf{j}}(\mathbf{D}_1)|}{r}\Big)\Big|\mathbf{D}_n^\circ\Big] &= \mathbb{E}\Big[\exp\Big(\tfrac{1}{r}\big|\mathrm{tr}(\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\mathbf{s}_1\mathbf{s}_1^T\mathbf{B})\big|\Big)\Big|\mathbf{D}_n^\circ\Big] \\ &= \frac{1}{n}\sum_{l=1}^n \exp\Big(\tfrac{1}{r}\big|\mathbf{e}_l^T(\mathbf{H}_n\mathbf{D}_n^\circ)\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T(\mathbf{D}_n^\circ\mathbf{H}_n^T)\mathbf{e}_l\big|\Big).\end{aligned}$$

Next, let $\boldsymbol{\varepsilon}_l \in \mathbb{R}^n$ be the lth row of $\mathbf{H}_n\mathbf{D}_n^\circ$, which gives

$$\begin{aligned}\mathbb{E}\Big[\exp\Big(\tfrac{|f_{\mathbf{j}}(\mathbf{D}_1)|}{r}\Big)\Big|\mathbf{D}_n^\circ\Big] &= \frac{1}{n}\sum_{l=1}^n \exp\Big(\big|\tfrac{\boldsymbol{\varepsilon}_l^T(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)\boldsymbol{\varepsilon}_l}{r}\big|\Big) \\ &\leq \exp\Big(\max_{l\in[n]}\big|\tfrac{\boldsymbol{\varepsilon}_l^T(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)\boldsymbol{\varepsilon}_l}{r}\big|\Big).\end{aligned} \tag{56}$$

Recalling that $\mathbf{D}_n^\circ = \mathsf{diag}(\boldsymbol{\varepsilon})$ where $\boldsymbol{\varepsilon} \in \mathbb{R}^n$ is a vector of i.i.d. Rademacher variables, and that all entries of $\mathbf{H}_n$ are ± 1, it follows that $\boldsymbol{\varepsilon}_l$ has the same distribution as $\boldsymbol{\varepsilon}$ for each $l \in [n]$. Consequently, each quadratic form $\boldsymbol{\varepsilon}_l^T(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)\boldsymbol{\varepsilon}_l$ concentrates around $\mathrm{tr}(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)$, and we can use a union bound to control the maximum of these quadratic forms. Note also that the matrix $\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T$ is rank-1, and so $\|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_2^2 = \|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_F^2$, Hence, by choosing the parameter u to be proportional to $\log(n)\cdot\|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_F$ in the Hanson-Wright inequality (Lemma 11), and using a union bound, there is an absolute constant $c > 0$ such that

$$\mathbb{P}\Big(\max_{l\in[n]}\ \big|\boldsymbol{\varepsilon}_l^T(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)\boldsymbol{\varepsilon}_l\big| \ \geq\ \mathrm{tr}(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T) + c\log(n)\|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_F\Big) \ \leq\ \tfrac{c}{n}. \tag{57}$$

Furthermore, noting that $\mathrm{tr}(\mathbf{B}\mathbf{C}_j^T\mathbf{A}^T)$ and $\|\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T\|_F$ are both at most $\nu(\mathbf{A},\mathbf{B})$, we have

$$\mathbb{P}\Big(\max_{l\in[n]}\ \big|\boldsymbol{\varepsilon}_l^T(\mathbf{B}\mathbf{C}_{\mathbf{j}}^T\mathbf{A}^T)\boldsymbol{\varepsilon}_l\big| \ \geq\ 2c\log(n)\nu(\mathbf{A},\mathbf{B})\Big) \ \leq\ \tfrac{c}{n}. \tag{58}$$

Finally, this means that if we take $r = 4c\log(n)\nu(\mathbf{A},\mathbf{B})$ in the bound (56), then the event

$$\mathbb{E}\big[\exp\big(|f_{\mathbf{j}}(\mathbf{D}_1)|/r\big)\big|\mathbf{D}_n^{\circ}\big] \leq e^{1/2}$$

holds with probability at least $1-\frac{c}{n}$, which completes the proof, since $e^{1/2} \leq 2$. ■

Appendix F. Technical Lemmas

Lemma 9 (Facts about Orlicz norms) *Orlicz norms have the following properties, where c, c_1, and c_2 are positive absolute constants.*

1. *For any random variable X, and any $p \geq 1$,*

$$\|X\|_p \leq cp\|X\|_{\psi_1} \tag{59}$$

$$\|X\|_p \leq c\sqrt{p}\|X\|_{\psi_2} \tag{60}$$

$$\|X\|_{\psi_1} \leq c\|X\|_{\psi_2}. \tag{61}$$

2. *If $X \sim \mathcal{N}(0,\sigma^2)$, then $\|X\|_{\psi_2} \leq c\,\sigma$.*

3. *Let $p \geq 1$. For any sequence of random variables $X_1,\ldots,X_d$,*

$$\Big\|\max_{1\leq j\leq d} X_j\Big\|_p \leq d^{1/p}\max_{1\leq j\leq d}\|X_j\|_p$$

and

$$\Big\|\max_{1\leq j\leq d} X_j\Big\|_{\psi_1} \leq c\log(d)\max_{1\leq j\leq d}\|X_j\|_{\psi_1}$$

4. *Let X be any random variable. Then, for any $x>0$ and $p\geq 1$, we have*

$$\mathbb{P}\big(|X|\geq x\big) \leq \Big(\tfrac{\|X\|_p}{x}\Big)^p.$$

and

$$\mathbb{P}\big(|X|\geq x\big) \leq c_1 e^{-c_2 x/\|X\|_{\psi_1}}.$$

Proof In part 1, line (59) follows from line 5.11 of Vershynin (2012), line (60) follows from definition 5.13 of Vershynin (2012), and line (61) follows from p.94 of van der Vaart and Wellner (1996). Next, part 2 follows from the definition of the ψ_2-Orlicz norm and the moment generating function for $\mathcal{N}(0,\sigma^2)$. Part 3 is due to Lemma 2.2.2 of van der Vaart and Wellner (1996). Lastly, part 4 follows from Markov's inequality and line 5.14 of Vershynin (2012). ■

Lemma 10 (Rosenthal's inequality with best constants) *Fix any number $p>2$. Let $Y_1,\ldots,Y_t$ be independent random variables with $\mathbb{E}[Y_i]=0$ and $\mathbb{E}\big[|Y_i|^p\big]<\infty$ for all $1\leq i\leq t$. Then,*

$$\big\|\textstyle\sum_{i=1}^t Y_i\big\|_p \leq c\big(\frac{p}{\log(p)}\big)\cdot\max\Big\{\big\|\textstyle\sum_{i=1}^t Y_i\big\|_2,\ \big(\textstyle\sum_{i=1}^t \big\|Y_i\|_p^p\big)^{1/p}\Big\}. \tag{62}$$

Proof See the paper Johnson et al. (1985). The statement above differs slightly from the Theorem 4.1 in the paper Johnson et al. (1985), which requires symmetric random variables, but the remark on p.247 of that paper explains why the variables $Y_1,\ldots,Y_t$ need not be symmetric as long as they have mean 0. ■

Lemma 11 (Hanson-Wright inequality) *Let $\mathbf{x}=(X_1,\ldots,X_n)$ be a vector of independent sub-Gaussian random variables with $\mathbb{E}[X_j]=0$, and $\|X_j\|_{\psi_2}\leq\kappa$ for all $1\leq j\leq n$. Also, let $\mathbf{H}\in\mathbb{R}^{n\times n}$ be any fixed non-zero matrix. Then, there is an absolute constant $c>0$ such that for any $u\geq 0$,*

$$\mathbb{P}\Big(\big|\mathbf{x}^T\mathbf{H}\mathbf{x}-\mathbb{E}[\mathbf{x}^T\mathbf{H}\mathbf{x}]\big| \ \geq\ u\Big) \ \leq\ 2\exp\Big(-c\cdot\min\Big\{\tfrac{u^2}{\kappa^2\|\mathbf{H}\|_F^2},\tfrac{u}{\kappa\|\mathbf{H}\|_2}\Big\}\Big). \tag{63}$$

Proof See the paper Rudelson and Vershynin (2013). ■

Lemma 12 (Bernstein inequality for sub-exponential variables) *Let $Y_1,\ldots,Y_t$ be independent random variables with $\mathbb{E}[Y_i]=0$ and $\|Y_i\|_{\psi_1}\leq\kappa$ for all $1\leq i\leq t$. Then, there is an absolute constant $c>0$, such that for any $u\geq 0$,*

$$\mathbb{P}\Big(\Big|\tfrac{1}{t}\textstyle\sum_{i=1}^t Y_i\Big|\geq\kappa\cdot u\Big) \ \leq\ 2\exp\Big(-c\cdot t\cdot\min(u^2,u)\Big). \tag{64}$$

Proof See Proposition 16 in Vershynin (2012). ■

Lemma 13 ((Chernozhukov et al., 2016)) *If η is a non-negative random variable, and there are numbers $a,b>0$ such that*

$$\mathbb{P}(\eta>x)\leq ae^{-x/b},$$

for all $x>0$, then the following bound holds for all $r>0$,

$$\mathbb{E}[\eta^3\cdot 1\{\eta>r\}]\leq 6a(r+b)^3e^{-r/b}.$$

Proof See Lemma 6.6 in Chernozhukov et al. (2016). ■

Remark. The following lemma may be of independent interest, since it provides an explicit bound on the ψ_1-Orlicz norm of a centered sub-Gaussian quadratic form. Although this bound follows from the Hanson-Wright inequality, we have not seen it stated in the literature.

Lemma 14 *Let $\mathbf{x} = (X_1, \ldots, X_n)$, be independent random variables satisfying $\mathbb{E}[X_j] = 0$ and $\|X_j\|_{\psi_2} \leq \kappa$ for all $1 \leq j \leq n$. Also, let $\mathbf{H} \in \mathbb{R}^{n \times n}$ be a non-zero fixed matrix. Then, there is an absolute constant $c > 0$ such that*

$$\Big\| \mathbf{x}^T\mathbf{H}\mathbf{x} - \mathbb{E}[\mathbf{x}^T\mathbf{H}\mathbf{x}] \Big\|_{\psi_1} \;\leq\; c\kappa^2 \tfrac{\|\mathbf{H}\|_F^2}{\|\mathbf{H}\|_2}.$$

Proof Define the random variable $Q := \mathbf{x}^T\mathbf{H}\mathbf{x} - \mathbb{E}[\mathbf{x}^T\mathbf{H}\mathbf{x}]$. By the definition of the ψ_1-Orlicz norm, it suffices to find a value $r > 0$ such that $\mathbb{E}\big[\exp(|Q|/r)\big] \leq 2$. Using the tail-sum formula, and the change of variable $v = e^{u/r}$, we have

$$\begin{aligned}\mathbb{E}\big[\exp(|Q|/r)\big] &\leq 1 + \int_1^\infty \mathbb{P}(\exp(|Q|/r) > v) dv \\ &= 1 + \tfrac{1}{r}\int_0^\infty \mathbb{P}(|Q| > u) \cdot e^{u/r} du.\end{aligned}$$

Next, we employ the Hanson-Wright inequality (Lemma 11). By considering the "threshold" $u^* := \kappa^2 \frac{\|\mathbf{H}\|_F^2}{\|\mathbf{H}\|_2}$, it is helpful to note that the quantities in the exponent of the Hanson-Wright inequality satisfy $\frac{u^2}{\kappa^4\|\mathbf{H}\|_F^2} \leq \frac{u}{\kappa^2\|\mathbf{H}\|_2}$ if and only if $u \leq u^*$. Hence,

$$\begin{aligned}\mathbb{E}\big[\exp(|Q|/r)\big] &\leq 1 + \tfrac{1}{r}\int_0^\infty \exp\Big\{ - c\min\big(\tfrac{u^2}{\kappa^4\|\mathbf{H}\|_F^2}, \tfrac{u}{\kappa^2\|\mathbf{H}\|_2}\big)\Big\} \cdot e^{u/r} du \\ &\leq 1 + \tfrac{1}{r}\int_0^{u^*} e^{u/r} du + \tfrac{1}{r}\int_{u^*}^\infty \exp\Big\{ - u\big(\tfrac{c}{\kappa^2\|\mathbf{H}\|_2} - \tfrac{1}{r}\big)\Big\} du.\end{aligned}$$

Evaluating the last two integrals directly, if we let $C' := \frac{c}{\kappa^2\|\mathbf{H}\|_2} - \frac{1}{r}$ and choose r so that $C' > 0$, then

$$\begin{aligned}\mathbb{E}\big[\exp(|Q|/r)\big] &\leq e^{u^*/r} + \tfrac{1}{rC'} e^{-u^*C'}, \\ &\leq e^{u^*/r} + \tfrac{1}{\frac{cr}{\kappa^2\|\mathbf{H}\|_2} - 1}.\end{aligned}$$

Note that the condition $C' > 0$ means that it is necessary to have $r > \frac{1}{c}\kappa^2\|\mathbf{H}\|_2$. To finish the argument, we further require that r is large enough so that (say)

$$\tfrac{u^*}{r} \leq \tfrac{1}{4} \quad \text{and} \quad \tfrac{cr}{\kappa^2\|\mathbf{H}\|_2} \geq 3, \tag{65}$$

which ensures

$$\mathbb{E}\big[\exp(|Q|/r)\big] \leq e^{1/4} + \tfrac{1}{2} < 2,$$

as desired. Note that the constraints (65) are the same as

$$r \geq 4\kappa^2 \tfrac{\|\mathbf{H}\|_F^2}{\|\mathbf{H}\|_2} \quad \text{and} \quad r \geq \tfrac{3}{c}\kappa^2\|\mathbf{H}\|_2.$$

Due to the basic fact that $\|\mathbf{H}\|_2 \leq \|\mathbf{H}\|_F$ for all matrices $\mathbf{H}$, it follows that whenever $r \geq \max(4, \frac{3}{c})\kappa^2 \frac{\|\mathbf{H}\|_F^2}{\|\mathbf{H}\|_2}$, we have $\mathbb{E}\big[\exp(|Q|/r)\big] < 2$. ■

Remark. The following lemma is a basic fact about the d_{LP} metric, but may not be widely known, and so we give a proof. Recall also that we use the generalized inverse $F_V^{-1}(\alpha) := \inf\{z \in \mathbb{R} \,|\, F_V(z) \geq \alpha\}$, where F_V denotes the c.d.f. of V.

Lemma 15 *Fix $\alpha \in (0, 1/2)$ and suppose there is some $\epsilon \in (0, \alpha)$ such that random variables U and V satisfy*

$$d_{\text{LP}}(\mathcal{L}(U), \mathcal{L}(V)) \leq \epsilon.$$

Then, the quantiles of U and V satisfy

$$\big|F_U^{-1}(1-\alpha) - F_V^{-1}(1-\alpha)\big| \;\leq\; \psi_\alpha(\epsilon), \tag{66}$$

where the right side is defined as

$$\psi_\alpha(\epsilon) := F_U^{-1}(1-\alpha+\epsilon) - F_U^{-1}(1-\alpha-\epsilon) + \epsilon.$$

Proof Consider the Lévy metric, defined as

$$d_{\text{L}}(\mathcal{L}(U), \mathcal{L}(V)) := \inf\Big\{\epsilon > 0 \,\Big|\, F_U(x-\epsilon) - \epsilon \leq F_V(x) \leq F_U(x+\epsilon) + \epsilon \text{ for all } x \in \mathbb{R}\Big\}.$$

It is a fact that this metric is always dominated by the d_{LP} metric in the sense that

$$d_{\text{L}}(\mathcal{L}(U), \mathcal{L}(V)) \;\leq\; d_{\text{LP}}(\mathcal{L}(U), \mathcal{L}(V)),$$

for all scalar random variables U and V (Huber and Ronchetti, 2009, p.36). Based on the definition of the d_{L} metric, it is straightforward to check that the following inequalities hold under the assumption of the lemma,

$$F_U^{-1}(1-\alpha-\epsilon) - \epsilon \;\leq\; F_V^{-1}(1-\alpha) \;\leq\; F_U^{-1}(1-\alpha+\epsilon) + \epsilon.$$

(Specifically, consider the choices $x = F_V^{-1}(1-\alpha)$ and $x = F_U^{-1}(1-\alpha+\epsilon) + \epsilon$.) Next, if we subtract $F_U^{-1}(1-\alpha)$ from each side of the inequalities above, and note that $F_U^{-1}(\cdot)$ is non-decreasing, it follows that if we put $a = F_U^{-1}(1-\alpha+\epsilon) - F_U^{-1}(1-\alpha) + \epsilon$ and $b = F_U^{-1}(1-\alpha) - F_U^{-1}(1-\alpha-\epsilon) + \epsilon$, then

$$|F_V^{-1}(\alpha) - F_U^{-1}(\alpha)| \;\leq\; \max\{a, b\} \;\leq\; \psi_\alpha(\epsilon),$$

as needed. ■

Lemma 16 *Under Assumption 1 (a), the quantity*

$$\delta_0 = t^{-1/8}\log^{1/2}(d)\nu(\mathbf{A}, \mathbf{B})^{3/4}$$

satisfies conditions (30) *and* (31).

Proof Consider the number

$$\delta_1(r) := \tfrac{\log^2(d)\nu(\mathbf{A},\mathbf{B})}{\sqrt{t}} \cdot r,$$

where $r \geq 1$ is a free parameter to be adjusted. Based on the bound (29), it is easy to check that plugging $\delta_1(r)$ into $K_t(\cdot)$ and $J_t(\cdot)$ leads to

$$K_t(\delta_1(r)) + J_t(\delta_1(r)) \leq c \cdot \nu(\mathbf{A},\mathbf{B})^3 \cdot \log(d)^3 \cdot r^3 \cdot \exp(-r/c)$$

and if we take $r \geq c\log(\log(d)^4)$, then

$$K_t(\delta_1(r)) + J_t(\delta_1(r)) \leq c\,\nu(\mathbf{A},\mathbf{B})^3,$$

as desired in (30). Hence, as long as there is a choice of r satisfying

$$r \geq c\log(\log(d)^4) \qquad \text{and} \qquad \delta_1(r) = \delta_0,$$

then $\delta_1(r)$ will satisfy both of the desired constraints (30) and (31). Solving the equation $\delta_1(r) = \delta_0$ gives

$$r = t^{3/8} \cdot \log^{-3/2}(d) \cdot \nu(\mathbf{A},\mathbf{B})^{-1/4},$$

and then the condition $r \geq c\log(\log(d)^4)$ is the same as

$$\begin{aligned} t &\geq \Big(c\,\nu(\mathbf{A},\mathbf{B})^{1/4}\log(d)^{3/2} \cdot \log(\log(d)^4)\Big)^{8/3} \\ &= c\,\nu(\mathbf{A},\mathbf{B})^{2/3}\log(d)^4 \cdot \log(\log(d)^4)^{8/3}, \end{aligned} \tag{67}$$

which holds under Assumption 1 (a). ■

Abstract

We develop the mathematical foundations of the stochastic modified equations (SME) framework for analyzing the dynamics of stochastic gradient algorithms, where the latter is approximated by a class of stochastic differential equations with small noise parameters. We prove that this approximation can be understood mathematically as an weak approximation, which leads to a number of precise and useful results on the approximations of stochastic gradient descent (SGD), momentum SGD and stochastic Nesterov's accelerated gradient method in the general setting of stochastic objectives. We also demonstrate through explicit calculations that this continuous-time approach can uncover important analytical insights into the stochastic gradient algorithms under consideration that may not be easy to obtain in a purely discrete-time setting.

Keywords: stochastic gradient algorithms, modified equations, stochastic differential equations, momentum, Nesterov's accelerated gradient

1. Introduction

Stochastic gradient algorithms are often used to solve optimization problems of the form

$$\min_{x\in\mathbb{R}^d} \quad f(x) := \mathbb{E}f_\gamma(x) \tag{1.1}$$

where $\{f_r : r \in \Gamma\}$ is a family of functions from $\mathbb{R}^d$ to $\mathbb{R}$ and γ is a Γ-valued random variable, with respect to which the expectation is taken (these notions will be made precise in the following sections). For empirical loss minimization in supervised learning applications, γ is usually a uniform random variable taking values in $\Gamma = \{1, 2, \ldots, n\}$. In this case, f is the total empirical loss function and f_r, $r \in \Gamma$ are the loss function due to the r^{th} training sample. In this paper, we shall consider the general situation of a expectation over arbitrary index sets and distributions.

Solving (1.1) using the standard gradient descent (GD) on x gives the iteration scheme

$$x_{k+1} = x_k - \eta\nabla\mathbb{E}f_\gamma(x_k), \tag{1.2}$$

for $k \geq 0$ and η is a small positive step-size known as the learning rate. Note that this requires the evaluation of the gradient of an expectation, which can be costly (in this empirical risk minimization case, this happens when n is large). In its simplest form, the stochastic gradient descent (SGD) algorithm replaces the expectation of the gradient with a sampled gradient, i.e.

$$x_{k+1} = x_k - \eta\nabla f_{\gamma_k}(x_k), \tag{1.3}$$

where each γ_k is an independent and identically distributed (i.i.d.) random variable with the same distribution as γ. Under mild conditions, we then have $\mathbb{E}[\nabla f_{\gamma_k}(x_k)|x_k] = \nabla\mathbb{E}f(x_k)$. In other words, (1.3) is a sampled version of (1.2).

In the literature, many convergence results are available for SGD and its variants (Shamir and Zhang, 2013; Moulines and Bach, 2011; Needell et al., 2014; Xiao and Zhang, 2014; Shalev-Shwartz and Zhang, 2014; Bach and Moulines, 2013; Défossez and Bach, 2015). However, it is often the case that different analysis techniques must be adopted for different variants of the algorithms and there generally lacked a systematic approach to study their precise dynamical properties. In Li et al. (2015), a general approach was introduced to address this problem, in which discrete-time stochastic gradient algorithms are approximated by continuous-time stochastic differential equations with the noise term depending on a small parameter (the learning rate). This can be viewed as a generalization of the method of modified equations (Hirt, 1968; Noh and Protter, 1960; Daly, 1963; Warming and Hyett, 1974) to the stochastic setting, and allows one to employ tools from stochastic calculus to systematically analyze the dynamics of stochastic gradient algorithms. The stochastic modified equations (SME) approach was further developed in Li et al. (2017), where a weak approximation result for the SGD was proved in a finite-sum-objective setting.

The present series of papers builds on the earlier work of Li et al. (2015, 2017) and aims to establish the framework of stochastic modified equations and their applications in greater generality and depth, and highlight the advantages of this systematic framework for studying stochastic gradient algorithms using continuous-time methods. As the first in the series, this paper will focus on mathematical aspects, namely the main approximation theorems relating stochastic gradient algorithms to stochastic modified equations in the form of weak approximations. These generalize the approximation results in Li et al. (2017) in various aspects. In a subsequent paper in the series, we will discuss the application of this formalism to adaptive stochastic gradient algorithms and related problems.

The organization of this paper is as follows. We first discuss related work in Sec. 2, especially in the context of continuous-time approximations. Next, we motivate the SME approach and set up the precise mathematical framework in Sec. 3.2. We then prove in Sec. 4 a central result relating discrete stochastic algorithms and continuous stochastic processes, which allows us to derive SMEs for stochastic gradient descent and variants. In Sec. 5, the SME approach is used to analyze the dynamics of stochastic gradient algorithms when applied to optimize a simple yet non-trivial objective. Lastly, we conclude with some discussion

of our results in Sec. 6. The longer proofs of the results used in the paper are organized in the appendix. These are essentially self-contained, but basic knowledge of stochastic calculus and probability theory are assumed. Unfamiliar readers may refer to standard introductory texts, such as Durrett (2010) and Oksendal (2013).

1.1. Notation

In this paper, we adhere wherever possible to the following notation. Dimensional indices are written as subscripts with a bracket to avoid confusion with other sequential indices (e.g. time, iteration number), which do not have brackets. When more than one indices are present, we separate them with a comma, e.g. $x_{k,(i)}$ is the i-th coordinate of the vector x_k, the k^{th} member of a sequence. We adopt the Einstein's summation convention, where repeated (spatial) indices are summed, i.e. $x_{(i)}x_{(i)} := \sum_{i=1}^{d} x_{(i)}x_{(i)}$. For a matrix A, we denote by $\lambda(A) = \{\lambda_1(A), \lambda_2(A), \dots\}$ the set of eigenvalues of A. If A is Hermitian, then the eigenvalues are ordered so that $\lambda_1(A)$ denotes a maximum eigenvalue. We denote the usual Euclidean norm by $|\cdot|$ and for higher rank tensors, we use the same notation to denote the flattened vector norms (e.g. for matrices it will be the Frobenius norm). The $\wedge$ symbols denotes the minimum operator, i.e. $a \wedge b := \min(a, b)$.

For a probability space (or generally, a measure space) $(\Omega, \mathcal{F}, \mathbb{P})$, the symbol $\mathcal{L}(\Omega, \mathcal{F}, \mathbb{P})$, $p \in (1, \infty)$ denotes the usual Lebesgue spaces, i.e. $u \in \mathcal{L}^p(\Omega, \mathcal{F}, \mathbb{P})$ if

$$\|u\|^p_{\mathcal{L}^p(\Omega,\mathcal{F},\mathbb{P})} := \int_\Omega |u(\omega)|^p d\mathbb{P}(\omega) \equiv \mathbb{E}|u|^p < \infty.$$

When the underlying probability space is obvious, we use the shorthand $\mathcal{L}^p(\Omega) \equiv \mathcal{L}(\Omega, \mathcal{F}, \mathbb{P})$. In addition, when $\Omega = \mathbb{R}^d$, we also write the local $\mathcal{L}^p$ spaces as $\mathcal{L}^p_{\text{loc}}(\mathbb{R}^d)$, which contains u for which $|u|^p$ is integrable on compact subsets of $\mathbb{R}^d$.

Finally, we note that in the proofs of various results, we typically use the letter C (whose value may change across results) to denote a generic positive constant. This is usually independent of the learning rate η, but if not explicitly stated otherwise, it may depend on e.g. Lipschitz constants, ambient dimensions, etc.

2. Related work

In this section, we discuss several related works on analyzing discrete-time algorithms using continuous-time approaches. The idea of approximating discrete-time stochastic algorithms by continuous equations dates back to the large body of work known as stochastic approximation theory (Kushner and Yin, 2003; Ljung et al., 2012). These typically establish law of large numbers type results where the limiting equation is an ODE, which can then be used to prove powerful convergence results for the stochastic algorithms under consideration. A notion of convergence in distribution, similar to a central limit theorem, was also studied for the purpose of estimating the rate of convergence of the ODE methods (Kushner, 1978; Kushner and Shwartz, 1984; Kushner and Clark, 2012), where connections between leading order perturbations and Ornstein-Uhlenbeck (OU) processes are established. However, these estimates are not used to systematically study the dynamics of stochastic gradient descent and their variants, beyond convergence analysis for the discrete-time algorithms.

As far as the authors are aware, the first work on using stochastic differential equations to study the precise dynamical properties of stochastic gradient descent are the independent works of Li et al. (2015) and Mandt et al. (2015). In Li et al. (2015), a systematic framework of SDE approximation of SGD and SGD with momentum are derived and applied to study dynamical properties of the stochastic algorithms as well as adaptive parameter tuning schemes. These go beyond OU process approximations and this distinction is important since the OU process is not always the appropriate stochastic approximation in general settings (See Sec. 4.2 of this paper). In Mandt et al. (2015), a similar procedure is employed to derive a SDE approximation for the SGD, from which issues such as choice of learning rates are studied. Although the concrete analysis in Mandt et al. (2015) is on the restricted case of constant diffusion matrices leading to OU processes, the essential ideas on the general leading order approximation are also discussed. We also mention the work of Raginsky and Bouvrie (2012) and Mertikopoulos and Staudigl (2017), where the authors considered a continuous-time variant of mirror descent in the form of a coupled SDE and studied its convergence properties. In Krichene and Bartlett (2017), a SDE approximation of a general class of accelerated mirror descent algorithms is introduced. Under appropriate choices of the mirror map, the approximations considered there can be linked with the order-1 approximations derived in this paper. In contrast with the present paper which studies the precise sense in which these approximations hold, these works are primarily concerned with investigating the convergence of the optimization algorithms themselves using the approximate continuous-time equations.

It is important to note that the approximation arguments in the aforementioned works, including both Li et al. (2015) and Mandt et al. (2015), are heuristic from a mathematical point of view. In Li et al. (2017), the SME approximation is rigorously proved in the finite-sum-objective case with strong regularity conditions, and further asymptotic analysis and tuning algorithms are studied. The SME approach has subsequently been utilized to study variants of stochastic gradient algorithms, including those in the distributed optimization setting (An et al., 2018). The work of Mandt et al. (2015) is further developed in Mandt et al. (2016, 2017), with applications such as the development scalable MCMC algorithms.

The present paper builds on the earlier work of Li et al. (2015, 2017), but focuses on extending and solidifying the mathematical aspects. In particular, we present an entirely rigorous and self-contained mathematical formulation of the SME framework that applies to more general algorithms (including momentum SGD and stochastic Nesterov's accelerated gradient method) and more general objectives (expectation over random functions, instead of just a finite-sum). Moreover, various regularity conditions in Li et al. (2017) have been relaxed. The main approximation procedure is inspired by the seminal works of Milstein (1986, 1975) in numerical analysis of stochastic differential equations, but lower regularity conditions are required in our case due to the presence of the small noise parameter, which allows for better truncation of Itô-Taylor expansions. The mathematical analysis of the SME-type approximation for the SGD was also performed in Feng et al. (2017); Hu et al. (2017) using semi-group approaches, although the smoothness requirements presented there are greater than those established using the current methods. Lastly, the Nesterov's accelerated gradient SME we derive in Sec. 4.4 can be viewed as a generalization of the ODE approach in Su et al. (2014) to stochastic gradients, and we show that the presence of noise gives additional features to the dynamics. Finally, we note that continuous-time approx-

imations that establish links between optimization, calculus of variations and symplectic integration has been studied in Wibisono et al. (2016); Betancourt et al. (2018).

3. Stochastic modified equations

We now introduce the stochastic modified equations framework. The starting motivation is the observation that GD iterations is a (Euler) discretization of the continuous-time, ordinary differential equation

$$\frac{dx}{dt} = -\nabla f(x), \tag{3.1}$$

and studying (3.1) can give us important insights to the dynamics of the discrete-time algorithm for small enough learning rates. The natural question when extending this to SGD is, what is the right continuous-time equation to consider? Below, we begin with some heuristic considerations.

3.1. Heuristic motivations

we rewrite the SGD iteration (1.3) as

$$x_{k+1} = x_k - \eta \nabla f(x_k) + \sqrt{\eta} V_k(x_k, \gamma_k), \tag{3.2}$$

where $V_k(x_k, \gamma_k) = \sqrt{\eta}(\nabla f(x_k) - \nabla f_{\gamma_k}(x_k))$ is a d-dimensional random vector. A straightforward calculation shows that

$$\begin{aligned} &\mathbb{E}[V_k|x_k] = 0 \\ &\mathrm{cov}[V_k, V_k|x_k] = \eta \Sigma(x_k), \\ &\Sigma(x_k) := \mathbb{E}[(\nabla f_{\gamma_k}(x_k) - \nabla f(x_k))(f_{\gamma_k}(x_k) - \nabla f(x_k))^T|x_k], \end{aligned} \tag{3.3}$$

i.e. conditional on x_k, $V_k(x_k)$ has 0 mean and covariance $\eta\Sigma(x_k)$. Here, Σ is simply the conditional covariance of the stochastic gradient approximation ∇f_γ of ∇f.

Now, consider a time-homogeneous Itô stochastic differential equation (SDE) of the form

$$dX_t = b(X_t)dt + \sqrt{\eta}\sigma(X_t)dW_t, \tag{3.4}$$

where $X_t \in \mathbb{R}^d$ for $t \geq 0$ and W_t is a standard d-dimensional Wiener process. The function $b : \mathbb{R}^d \to \mathbb{R}^d$ is known as the drift and $\sigma : \mathbb{R}^d \to \mathbb{R}^{d\times d}$ is the diffusion matrix. The key observation is that if we apply the Euler discretization with step-size η to (3.4), approximating $X_{k\eta}$ by $\hat{X}_k$, we obtain the following discrete iteration for the latter:

$$\hat{X}_{k+1} = \hat{X}_k + \eta b(\hat{X}_k) + \eta\sigma(\hat{X}_k)Z_k, \tag{3.5}$$

where $Z_k := W_{(k+1)\eta} - W_{k\eta}$ are d-dimensional i.i.d. standard normal random variables. Comparing with (3.2), if we set $b = -\nabla f$, $\sigma(x) = \Sigma(x)^{1/2}$ and identify t with $k\eta$, we then have matching first and second conditional moments. Hence, this motivates the approximating equation

$$dX_t = -\nabla f(X_t)dt + (\eta\Sigma(X_t))^{1/2}dW_t. \tag{3.6}$$

Note that as this heuristic argument shows, the presence of the small parameter $\sqrt{\eta}$ on the diffusion term is necessary to model the fact that when learning rate decreases, the fluctuations to the SGA iterates must also decrease.

The immediate mathematical question is then: in what sense is an SDE like (3.6) an approximation of (1.3)? Let us now establish the precise mathematical framework in which we can answer this question.

3.2. The mathematical framework

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a sufficiently rich probability space and $(\Gamma, \mathcal{F}_\Gamma)$ be a measure space representing the index space for our random objectives. Let $\gamma : \Omega \to \Gamma$ be a random variable and $(r, x) \mapsto f_r(x)$ a measurable mapping from $\Gamma \times \mathbb{R}^d$ to $\mathbb{R}$. Hence, for each x, $f_\gamma(x)$ is a random variable. Throughout this paper, we assume the follow facts about $f_\gamma(x)$:

Assumption 3.1 *The random variable $f_\gamma(x)$ satisfies*

(i) $f_\gamma(x) \in \mathcal{L}^1(\Omega)$ *for all* $x \in \mathbb{R}^d$

(ii) $f_\gamma(x)$ *is continuously differentiable in* x *almost surely and for each* $R > 0$*, there exists a random variable* $M_{R,\gamma}$ *such that* $\max_{|x|\leq R} |\nabla f_\gamma(x)| \leq M_{R,\gamma}$ *almost surely, with* $\mathbb{E}|M_{R,\gamma}| < \infty$

(iii) $\nabla f_\gamma(x) \in \mathcal{L}^2(\Omega)$ *for all* $x \in \mathbb{R}^d$

Note that in the empirical risk minimization case where Γ is finite, the conditions above are often trivially satisfied. Condition (i) in Assumption 3.1 allows us to define the total objective function we would like to minimize as the expectation

$$f(x) := \mathbb{E}f_\gamma(x) \equiv \int_\Omega f_{\gamma(\omega)}(x)d\mathbb{P}(\omega). \tag{3.7}$$

Moreover, Assumption 3.1 (ii) implies via the dominated convergence theorem that $\mathbb{E}\nabla f_\gamma = \nabla\mathbb{E}f_\gamma \equiv \nabla f$. Now, let $\{\gamma_k : k = 0, 1, \dots\}$ be a sequence of i.i.d. Γ-valued random variables with the same distribution as γ. Let $x_0 \in \mathbb{R}^d$ be fixed and define the generalized stochastic gradient iteration as the stochastic process

$$x_{k+1} = x_k + \eta h(x_k, \gamma_k, \eta) \tag{3.8}$$

for $k \geq 0$, where $h : \mathbb{R}^d \times \Gamma \times \mathbb{R} \to \mathbb{R}^d$ is a measurable function and $\eta > 0$ is the learning rate. In the simple case of SGD, we have $h(x, r, \eta) = -\nabla f_r(x)$, but we shall consider the generalized version above so that modified equations for SGD variants can also be derived from our approximation theorems.

Next, let us define the class of approximating continuous stochastic processes, which we call stochastic modified equations. Consider the time-homogeneous Itô diffusion process $\{X_t : t \geq 0\}$ represented by the following stochastic differential equation (SDE)

$$dX_t = b(X_t, \eta)dt + \sqrt{\eta}\sigma(X_t, \eta)dW_t, \qquad X_0 = x_0 \tag{3.9}$$

where $\{W_t : t \geq 0\}$ is a standard d-dimensional Wiener process independent of $\{\gamma_k\}$, $b : \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^d$ is the approximating drift vector and $\sigma : \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^{d\times d}$ is the approximating

diffusion matrix. In the following, we will need to pick b, σ appropriately so that (3.8) is approximated by (3.9), the sense of which we now describe.

First, notice that the stochastic process $\{x_k\}$ induces a probability measure on the product space $\mathbb{R}^d \times \mathbb{R}^d \times \cdots$, whereas $\{X_t\}$ induces a probability measure on $\mathcal{C}^0([0,\infty), \mathbb{R}^d)$. To compare them, one can form a piece-wise linear interpolation of the former. Alternatively, as we do in this work, we sample a discrete number of points from the latter. Second, the process $\{x_k\}$ is adapted to the filtration generated by $\{\gamma_k\}$ (e.g. in the case of SGD, this is the random sampling of functions in $\{f_r\}$), whereas the process $\{X_t\}$ is adapted to an independent, Wiener filtration. Hence, it is not appropriate to compare individual sample paths. Rather, we define below a sense of weak approximations by comparing the distributions of the two processes.

Definition 1 *Let G denote the set of continuous functions $\mathbb{R}^d \to \mathbb{R}$ of at most polynomial growth, i.e. $g \in G$ if there exists positive integers $\kappa_1, \kappa_2 > 0$ such that*

$$|g(x)| \leq \kappa_1(1 + |x|^{2\kappa_2}),$$

for all $x \in \mathbb{R}^d$. Moreover, for each integer $\alpha \geq 1$ we denote by G^α the set of α-times continuously differentiable functions $\mathbb{R}^d \to \mathbb{R}$ which, together with its partial derivatives up to and including order α, belong to G. Note that each G^α is a subspace of $\mathcal{C}^\alpha$, the usual space of α-times continuously differentiable functions. Moreover, if g depends on additional parameters, we say $g \in G^\alpha$ if the constants κ_1, κ_2 are independent of these parameters, i.e. $g \in G^\alpha$ uniformly. Finally, the definition generalizes to vector-valued functions coordinate-wise in the co-domain.

Definition 2 *Let $T > 0$, $\eta \in (0, 1 \wedge T)$, and $\alpha \geq 1$ be an integer. Set $N = \lfloor T/\eta \rfloor$. We say that a continuous-time stochastic process $\{X_t : t \in [0,T]\}$ is an order α weak approximation of a discrete stochastic process $\{x_k : k = 0, \ldots, N\}$ if for every $g \in G^{\alpha+1}$, there exists a positive constant C, independent of η, such that*

$$\max_{k=0,..,N} |\mathbb{E}g(x_k) - \mathbb{E}g(X_{k\eta})| \leq C\eta^\alpha. \tag{3.10}$$

Let us discuss briefly the notion of *weak approximation* as introduced above. These are approximations of the distribution of sample paths, instead of the sample paths themselves. This is enforced by requiring that the expectations of the two processes $\{X_t\}$ and $\{x_k\}$ over a sufficiently large class of test functions to be close. In our definition, the test function class $G^{\alpha+1}$ is quite large, and in particular it includes all polynomials. Thus, Eq. (3.10) implies in particular that all moments of the two processes become close at the rate of η^α, and hence so must their distributions. The notion of weak approximation must be contrasted with that of *strong approximations*, where one would for example require (in the case of *mean-square approximations*)

$$\left[\mathbb{E}|x_k - X_{k\eta}|^2\right]^{1/2} \leq C\eta^\alpha.$$

The above forces the actual sample-paths of the two processes to be close, per realization of the random process, which severely limits its application. In fact, one important advantage of

weak approximations is that the continuous-time process X_t can in fact approximate discrete stochastic processes whose step-wise driving noise is not Gaussian, as long as appropriate moments are matched (see e.g. the content of Theorem 3). This additional flexibility is useful as it allows the treatment of more general classes of stochastic gradient iterations.

4. The approximation theorems

We now present the main approximation theorems. The derivation is based on the following two-step process:

1. We establish a connection between one-step approximation and approximation on a finite time interval.
2. We construct a one-step approximation that is of order $\alpha+1$, and so the approximation on a finite interval is of order α.

4.1. Relating one-step to N-step approximations

Let us consider generally the question of the relationship between one-step approximations and approximations on a finite interval. Let $T > 0$, $\eta \in (0, 1 \wedge T)$ and $N = \lfloor T/\eta \rfloor$ and recall the general SGA iterations

$$x_{k+1} = x_k + \eta h(x_k, \gamma_k, \eta), \quad x_0 \in \mathbb{R}^d, \quad k = 0, \ldots, N. \tag{4.1}$$

and the general candidate family of approximating SDEs

$$dX_t^{\eta,\epsilon} = b(X_t^{\eta,\epsilon}, \eta, \epsilon)dt + \sqrt{\eta}\sigma(X_t^{\eta,\epsilon}, \eta, \epsilon)dW_t, \quad X_0 = x_0, \quad t \in [0,T], \tag{4.2}$$

where $\epsilon \in (0,1)$ is a mollification parameter, whose role will become apparent later. To reduce notational clutter and improve readability, unless some limiting procedure is considered, we shall not explicitly write the dependence of $X_t^{\eta,\epsilon}$ on η, ϵ and simply denote by X_t the solution of the above SDE. Let us also denote for convenience $\widetilde{X}_k := X_{k\eta}$. Further, let $\{X_t^{x,s} : t \geq s\}$ denote the stochastic process obeying the same equation (4.2), but with the initial condition $X_s^{x,s} = x$. We similarly write $\widetilde{X}_k^{x,l} := X_{k\eta}^{x,l\eta}$ and denote by $\{x_k^{x,l} : k \geq l\}$ the stochastic process satisfying (4.1) but with $x_l = x$.

Throughout this section, we assume the following conditions:

Assumption 4.1 *The functions $b : \mathbb{R}^d \times (0, 1 \wedge T) \times (0,1) \to \mathbb{R}^d$ and $\sigma : \mathbb{R}^d \times (0, 1 \wedge T) \times (0,1) \to \mathbb{R}^{d\times d}$ satisfy:*

1. *Uniform linear growth condition*

$$|b(x,\eta,\epsilon)|^2 + |\sigma(x,\eta,\epsilon)|^2 \leq L^2(1 + |x|^2)$$

for all $x, y \in \mathbb{R}^d$, $\eta \in (0, 1 \wedge T)$, $\epsilon \in (0,1)$.

2. *Uniform Lipschitz condition*

$$|b(x,\eta,\epsilon) - b(y,\eta,\epsilon)| + |\sigma(x,\eta,\epsilon) - \sigma(y,\eta,\epsilon)| \leq L|x - y|$$

for all $x, y \in \mathbb{R}^d$, $\eta \in (0, 1 \wedge T)$, $\epsilon \in (0,1)$.

Note that 2 implies 1 if there is at least one x where the supremum of b, σ over η, ϵ is finite. In particular, these conditions imply via Thm. 18 that there exists a unique solution to Eq. 4.2.

Now, let us denote the one-step changes

$$\Delta(x) := x_1^{x,0} - x, \qquad \widetilde{\Delta}(x) := \widetilde{X}_1^{x,0} - x. \tag{4.3}$$

We prove the following result which relates one-step approximations with approximations on a finite time interval.

Theorem 3 *Let $T > 0$, $\eta \in (0, 1 \wedge T)$, $\epsilon \in (0,1)$ and $N = \lfloor T/\eta \rfloor$. Let $\alpha \geq 1$ be an integer. Suppose further that the following conditions hold:*

(i) There exists a function $\rho : (0,1) \to \mathbb{R}_+$ and $K_1 \in G$ independent of η, ϵ such that

$$\left| \mathbb{E} \prod_{j=1}^{s} \Delta_{(i_j)}(x) - \mathbb{E} \prod_{j=1}^{s} \widetilde{\Delta}_{(i_j)}(x) \right| \leq K_1(x)(\eta\rho(\epsilon) + \eta^{\alpha+1}),$$

for $s = 1, 2, \ldots, \alpha$ and

$$\mathbb{E} \prod_{j=1}^{\alpha+1} \left| \Delta_{(i_j)}(x) \right| \leq K_1(x)\eta^{\alpha+1},$$

for all $i_j \in \{1, \ldots, d\}$.

(ii) For each $m \geq 1$, the $2m$-moment of $x_k^{x,0}$ is uniformly bounded with respect to k and η, i.e. there exists a $K_2 \in G$, independent of η, k, such that

$$\mathbb{E}|x_k^{x,0}|^{2m} \leq K_2(x),$$

for all $k = 0, \ldots, N \equiv \lfloor T/\eta \rfloor$.

Then, for each $g \in G^{\alpha+1}$, there exists a constant $C > 0$, independent of η, ϵ, such that

$$\max_{k=0,\ldots,N} |\mathbb{E}g(x_k) - \mathbb{E}g(X_{k\eta})| \leq C(\eta^\alpha + \rho(\epsilon))$$

The proof of Thm. 3 requires a number of technical results that we defer to the appendix. Below, we demonstrate the main ingredients of the proof and refer to the appendix where the proofs of the auxiliary results are fully presented.

Proof In this proof, since there are many conditioning on the initial condition, to prevent nested superscripts we shall introduce the alternative notation $X_t(x,s) \equiv X_t^{x,s}$, and similarly for $\tilde{X}_k$ and x_k. Fix $g \in G^{\alpha+1}$ and $1 \leq k \leq N$. We have

$$\mathbb{E}g(X_{k\eta}) = \mathbb{E}g(\widetilde{X}_k) = \mathbb{E}g(\widetilde{X}_k(\widetilde{X}_1, 1)) - \mathbb{E}g(\widetilde{X}_k(x_1, 1)) + \mathbb{E}g(\widetilde{X}_k(x_1, 1)).$$

If $k > 1$, by noting that $\widetilde{X}_k(x_1, 1) = \widetilde{X}_k(\widetilde{X}_2(x_1, 1), 2)$, we get

$$\mathbb{E}g(\widetilde{X}_k(x_1, 1)) = \mathbb{E}g(\widetilde{X}_k(\widetilde{X}_2(x_1, 1), 2)) - \mathbb{E}g(\widetilde{X}_k(x_2, 2)) + \mathbb{E}g(\widetilde{X}_k(x_2, 2))$$

Continuing this process, we then have

$$\begin{aligned}\mathbb{E}g(\widetilde{X}_k) =& \sum_{l=1}^{k-1} \mathbb{E}g(\widetilde{X}_k(\widetilde{X}_l(x_{l-1}, l-1), l)) - \mathbb{E}g(\widetilde{X}_k(x_l, l)) \\ &+ \mathbb{E}g(\widetilde{X}_k(x_{k-1}, k-1))\end{aligned}$$

and hence by subtracting $\mathbb{E}g(x_k) \equiv \mathbb{E}g(x_k(x_{k-1}, k-1))$ we get

$$\begin{aligned}\mathbb{E}g(\widetilde{X}_k) - \mathbb{E}g(x_k) =& \sum_{l=1}^{k-1} \mathbb{E}g(\widetilde{X}_k(\widetilde{X}_l(x_{l-1}, l-1), l)) - \mathbb{E}g(\widetilde{X}_k(x_l, l)) \\ &+ \mathbb{E}g(\widetilde{X}_k(x_{k-1}, k-1)) - \mathbb{E}g(x_k(x_{k-1}, k-1))\end{aligned}$$

and so

$$\mathbb{E}g(\widetilde{X}_k) - \mathbb{E}g(x_k) = \sum_{l=1}^{k-1} \mathbb{E}\mathbb{E}\left[g(\widetilde{X}_k(\widetilde{X}_l(x_{l-1}, l-1), l)) \middle| \widetilde{X}_l(x_{l-1}, l-1) \right] - \mathbb{E}\mathbb{E}\left[g(\widetilde{X}_k(x_l, l)) \middle| x_l \right]$$

$$+ \mathbb{E}g(\widetilde{X}_k(x_{k-1}, k-1)) - \mathbb{E}g(x_k(x_{k-1}, k-1)),$$

Now, let $u(x,s) = \mathbb{E}g(X_{k\eta}(x,s))$. Then, we have

$$\begin{aligned}|\mathbb{E}g(\widetilde{X}_k) - \mathbb{E}g(x_k)| \leq& \sum_{l=1}^{k-1} |\mathbb{E}u(\widetilde{X}_l(x_{l-1}, l-1), l\eta) - \mathbb{E}u(x_l(x_{l-1}, l-1), l\eta)| \\ &+ |\mathbb{E}g(\widetilde{X}_k(x_{k-1}, k-1)) - \mathbb{E}g(x_k(x_{k-1}, k-1))| \\ \leq& \sum_{l=1}^{k-1} \mathbb{E}|\mathbb{E}[u(\widetilde{X}_l(x_{l-1}, l-1), l\eta)|x_{l-1}] - \mathbb{E}[u(x_l(x_{l-1}, l-1), l\eta)|x_{l-1}]| \\ &+ \mathbb{E}|\mathbb{E}[g(\widetilde{X}_k(x_{k-1}, k-1))|x_{k-1}] - \mathbb{E}[g(x_k(x_{k-1}, k-1))|x_{k-1}]|.\end{aligned}$$

Using Prop. 25, $u(\cdot, s) \in G^{\alpha+1}$ uniformly in s, t, η and ϵ. Thus, by Assumption (i) and Lem. 27,

$$\begin{aligned}|\mathbb{E}g(x_k) - \mathbb{E}g(\widetilde{X}_k)| \leq& (\eta\rho(\epsilon) + \eta^{\alpha+1}) \left(\sum_{l=1}^{k-1} \mathbb{E}K_{l-1}(x_{l-1}) + \mathbb{E}K_{k-1}(x_{k-1}) \right) \\ \leq& (\eta\rho(\epsilon) + \eta^{\alpha+1}) \sum_{l=0}^{N} \kappa_{l,1}(1 + \mathbb{E}|x_l|^{2\kappa_{l,2}}),\end{aligned}$$

where in the last line we used moment estimates from Thm. 19. Finally, using Assumption (ii) and the fact that $N \leq T/\eta$, we have

$$|\mathbb{E}g(x_k) - \mathbb{E}g(X_{k\eta})| = |\mathbb{E}g(x_k) - \mathbb{E}g(\widetilde{X}_k)| \leq C(\rho(\epsilon) + \eta^\alpha).$$

■

4.2. SME for stochastic gradient descent

Thm. 3 allows us to prove the main approximation results for the current paper. In particular, in this section we derive a second-order accurate weak approximation for the simple SGD iterations (1.3), from which a simpler, first-order accurate approximation also follows. As seen in Thm. 3, we need only verify the conditions (i)-(ii) in order to prove the weak approximation result. These conditions mostly involve moment estimates, which we now perform. To simplify presentation, we introduce the following shorthand. Whenever we write

$$\psi(x) = \psi_0(x) + \eta\psi_1(x) + \mathcal{O}(r(\eta,\epsilon)),$$

for some remainder term $r(\eta,\epsilon)$, we mean: there exists $K \in G$ independent of η, ϵ such that

$$|\psi(x) - \psi_0(x) - \eta\psi_1(x)| \leq K(x)r(\eta,\epsilon).$$

Now, let us set in (4.2)

$$\begin{aligned} b(x,\eta,\epsilon) &= b_0(x,\epsilon) + \eta b_1(x,\epsilon) \\ \sigma(x,\eta,\epsilon) &= \sigma_0(x,\epsilon), \end{aligned}$$

where b_0, b_1, σ_0 are functions to be determined. We have the following moment estimate.

Lemma 4 *Let $\widetilde{\Delta}(x)$ be defined as in (4.3). Suppose further that with $b_0, b_1, \sigma_0 \in G^3$. Then we have*

(i) $\mathbb{E}\widetilde{\Delta}_{(i)}(x) = b_0(x,\epsilon)_{(i)}\eta + [\frac{1}{2}b_0(x,\epsilon)_{(j)}\partial_{(j)}b_0(x,\epsilon)_{(i)} + b_1(x,\epsilon)_{(i)}]\eta^2 + \mathcal{O}(\eta^3)$,

(ii) $\mathbb{E}\widetilde{\Delta}_{(i)}(x)\widetilde{\Delta}_{(j)}(x) = [b_0(x,\epsilon)_{(i)}b_0(x,\epsilon)_{(j)} + \sigma_0(x,\epsilon)_{(i,k)}\sigma_0(x,\epsilon)_{(j,k)}]\eta^2 + \mathcal{O}(\eta^3)$,

(iii) $\mathbb{E}\prod_{j=1}^3 |\widetilde{\Delta}_{(i_j)}(x)| = \mathcal{O}(\eta^3)$.

Proof To obtain (i)-(iii), we simply apply Lem. 28 with $\psi(z) = \prod_{j=1}^s (z_{(i_j)} - x_{(i_j)})$ for $s = 1, 2, 3$ respectively. ■

Next, we estimate the moments of the SGA iterations below.

Lemma 5 *Let $\Delta(x)$ be defined as in (4.3) with the SGD iterations, i.e. $h(x,r,\eta) = -\nabla f_r(x)$. Suppose that for each $x \in \mathbb{R}^d$, $f \in G^1$. Then,*

(i) $\mathbb{E}\Delta_{(i)}(x) = -\partial_{(i)}f(x)\eta$,

(ii) $\mathbb{E}\Delta_{(i)}(x)\Delta_{(j)}(x) = \partial_{(i)}f(x)\partial_{(j)}f(x)\eta^2 + \Sigma(x)_{(i,j)}\eta^2$,

(iii) $\mathbb{E}\prod_{j=1}^3 |\Delta_{(i_j)}(x)| = \mathcal{O}(\eta^3)$,

where $\Sigma(x) := \mathbb{E}(\nabla f_\gamma(x) - \nabla f(x))(\nabla f_\gamma(x) - \nabla f(x))^T$.

Proof We have $\Delta(x) = -\eta\nabla f_{\gamma_0}(x)$. Taking expectations, the results then follow. ■

We now prove the main approximation theorem for the simple SGD. Before presenting the statement and proof, we shall note a few technical issues that prevents the direct application of Thm. 3 with the moment estimates in Lem.4 and 5. The latter suggest ignoring ϵ and setting

$$b_0(x,\epsilon) = -\nabla f(x), \quad b_1(x,\epsilon) = --\tfrac{1}{4}\nabla|\nabla f(x)|^2, \quad \sigma_0(x,\epsilon) = \Sigma(x)^{\frac{1}{2}}.$$

Then, we would see from Lem.4 and 5 that the SGD and the SDE have matching moments up to $\mathcal{O}(\eta^3)$. The first issue with this approach is that even if $\Sigma(x)$ is sufficiently smooth (which may follow from the regularity of ∇f_γ), the smoothness of $\Sigma(x)^{1/2}$ cannot be guaranteed unless $\Sigma(x)$ is positive-definite, which is often too strong an assumption in practice and excludes interesting cases where $\Sigma(x)$ is a singular diffusion matrix. However, the results in Sec. 4.1 require smoothness. Second, we would like to consider functions f_γ that may not have higher strong derivatives required by the Lemmas, beyond those required to define the modified equation itself. To fix both of these issues, we will use a simple mollifying technique. This is the reason for the inclusion of the ϵ parameter in the results in Sec. 4.1.

Definition 6 *Let us denote by $\nu : \mathbb{R}^d \to \mathbb{R}$, $\nu \in \mathcal{C}_c^\infty(\mathbb{R}^d)$ the standard mollifier*

$$\nu(x) := \begin{cases} C\exp(-\frac{1}{1-|x|^2}) & |x| < 1 \\ 0 & |x| \geq 1, \end{cases}$$

where $C := (\int_{\mathbb{R}^d}\nu(y)dy)^{-1}$ is chosen so that the integral of ν is 1. Further, define $\nu^\epsilon(x) = \epsilon^{-d}\nu(x/\epsilon)$. Let $\psi \in \mathcal{L}^1_{loc}(\mathbb{R}^d)$ be locally integrable, then we may define its mollification by

$$\psi^\epsilon(x) := (\nu^\epsilon * \psi)(x) = \int_{\mathbb{R}^d}\nu^\epsilon(x-y)\psi(y)dy = \int_{\mathcal{B}(0,\epsilon)}\nu^\epsilon(y)\psi(x-y)dy,$$

where $\mathcal{B}(z,\epsilon)$ is the d-dimensional ball of radius ϵ centered at z. The mollification of vector (or matrix) valued functions are defined element-wise.

The mollifier has very useful properties. In particular, we will use the following well-known facts (see e.g. Evans (2010) for proof)

(i) If $\psi \in \mathcal{L}^1_{\text{loc}}(\mathbb{R}^d)$, then $\psi^\epsilon \in \mathcal{C}^\infty(\mathbb{R}^d)$

(ii) $\psi^\epsilon(x) \to \psi(x)$ as $\epsilon \to 0$ for almost every $x \in \mathbb{R}^d$ (with respect to the Lebesgue measure)

(iii) If ψ is continuous, then $\psi^\epsilon(x) \to \psi(x)$ as $\epsilon \to 0$ uniformly on compact subsets of $\mathbb{R}^d$

Next, we make use of the idea of weak derivatives.

Definition 7 *Let $\Psi \in \mathcal{L}^1_{loc}(\mathbb{R}^d)$ and J be a multi-index of order $|J|$. Suppose that there exists a $\psi \in \mathcal{L}^1_{loc}(\mathbb{R}^d)$ such that*

$$\int_{\mathbb{R}^d}\Psi(x)\nabla^J\phi(x)dx = (-1)^{|J|}\int_{\mathbb{R}^d}\psi(x)\phi(x)dx$$

for all $\phi \in \mathcal{C}_c^\infty$. Then, we call ψ the order J weak derivative of Ψ and write $D^J\Psi = \psi$. Note that when it exists, the weak derivative is unique almost everywhere and if Ψ is differentiable, $\nabla^J\Psi = D^J\Psi$ almost everywhere (Evans, 2010).

The introduction of weak derivatives motivates the definition of the weak version of the function spaces G^α.

Definition 8 *For $\alpha \geq 1$, we define the space G_w^α to be the subspace of $\mathcal{L}^1_{loc}(\mathbb{R}^d)$ such that if $g \in G_w^\alpha$, then g has weak derivatives up to order α and for each multi-index J with $|J| \leq \alpha$, there exists positive integers κ_1, κ_2 such that*

$$|D^J g(x)| \leq \kappa_1(1 + |x|^{2\kappa_2}) \text{ for a.e. } x \in \mathbb{R}^d.$$

As in Def. 1, if g depends on additional parameters, we say that $g \in G_w^\alpha$ if the above constants do not depend on the additional parameters. Also, vector-valued g are defined as above element-wise in the co-domain. Note that G_w^α is a subspace of the Sobolev space $W^{\alpha,1}_{loc}$.

Theorem 9 *Let, $T > 0$, $\eta \in (0, 1 \wedge T)$ and set $N = \lfloor T/\eta \rfloor$. Let $\{x_k : k \geq 0\}$ be the SGD iterations defined in (1.3). Suppose the following conditions are met:*

(i) $f \equiv \mathbb{E}f_\gamma$ is twice continuously differentiable, $\nabla|\nabla f|^2$ is Lipschitz, and $f \in G_w^4$.

(ii) ∇f_γ satisfies a Lipschitz condition:

$$|\nabla f_\gamma(x) - \nabla f_\gamma(y)| \leq L_\gamma|x - y| \quad a.s.$$

for all $x, y \in \mathbb{R}^d$, where L_γ is a random variable which is positive a.s. and $\mathbb{E}L_\gamma^m < \infty$ for each $m \geq 1$.

Define $\{X_t : t \in [0, T]\}$ as the stochastic process satisfying the SDE

$$dX_t = -\nabla(f(X_t) + \tfrac{1}{4}\eta|\nabla f(X_t)|^2)dt + \sqrt{\eta}\Sigma(X_t)^{1/2}dW_t \qquad X_0 = x_0, \tag{4.4}$$

with $\Sigma(x) = \mathbb{E}(\nabla f_\gamma(x) - \nabla f(x))(\nabla f_\gamma(x) - \nabla f(x))^T$. Then, $\{X_t : t \in [0, T]\}$ is an order-2 weak approximation of the SGD, i.e. for each $g \in G^3$, there exists a constant $C > 0$ independent of η such that

$$\max_{k=0,..,N} |\mathbb{E}g(x_k) - \mathbb{E}g(X_{k\eta})| \leq C\eta^2.$$

Proof First, we check that Eq. (4.4) admits a unique solution, which amounts to checking the conditions in Thm. 18. Note that the Lipschitz condition (ii) implies ∇f is Lipschitz with constant $\mathbb{E}L_\gamma$. To see that $\Sigma(x)^{1/2}$ is also Lipschitz, observe that $u(x) := \nabla f_\gamma(x) - \nabla f(x)$ is Lipschitz (in the sense of (ii), with constant at most $L_\gamma + \mathbb{E}L_\gamma$), and

$$\begin{aligned}|\Sigma(x)^{1/2} - \Sigma(y)^{1/2}| &= \left| \|[u(x)u(x)^T]^{1/2}\|_{\mathcal{L}^2(\Omega)} - \|[u(y)u(y)^T]^{1/2}\|_{\mathcal{L}^2(\Omega)} \right| \\ &\leq \|[u(x)u(x)^T]^{1/2} - [u(y)u(y)^T]^{1/2}\|_{\mathcal{L}^2(\Omega)}.\end{aligned}$$

Moreover, observe that for vectors $u \in \mathbb{R}^d$ the mapping $u \mapsto (uu^T)^{1/2} = uu^T/|u|$ is Lipschitz, which implies

$$|\Sigma(x)^{1/2} - \Sigma(y)^{1/2}| \leq L'\|u(x) - u(y)\|_{\mathcal{L}^2(\Omega)} \leq L''|x - y|.$$

The Lipschitz conditions on the drift and the diffusion matrix imply uniform linear growth, so by Thm. 18, Eq. (4.4) admits a unique solution.

For each $\epsilon \in (0, 1)$, define the mollified functions

$$b_0(x, \epsilon) = -\nu^\epsilon * \nabla f(x), \quad b_1(x, \epsilon) = -\tfrac{1}{4}\nu^\epsilon * (\nabla|\nabla f(x)|^2), \quad \sigma_0(x, \epsilon) = \nu^\epsilon * \Sigma(x)^{1/2}.$$

Observe that $b_0 + \eta b_1, \sigma_0$ satisfies a Lipschitz condition in x uniformly in η, ϵ. To see this, note that for any Lipschitz function ψ with constant L, we have

$$|\nu^\epsilon * \psi(x) - \nu^\epsilon * \psi(y)| \leq \int_{\mathcal{B}(0,\epsilon)} \nu^\epsilon(z)|\psi(x - z) - \psi(y - z)|dz \leq L|x - y|,$$

which proves $b_0 + \eta b_1$ and σ_0 are uniformly Lipschitz. Similarly, the linear growth condition follows. Hence, we may define a family of stochastic processes $\{X_t^\epsilon : \epsilon \in (0, 1)\}$ satisfying

$$dX_t^\epsilon = b_0(X_t^\epsilon, \epsilon) + \eta b_1(X_t^\epsilon, \epsilon) + \sqrt{\eta}\sigma_0(X_t^\epsilon, \epsilon)dW_t \qquad X_0^\epsilon = x_0,$$

which each admits a unique solution by Thm. 18. Now, we claim that $b_0(\cdot, \epsilon), b_1(\cdot, \epsilon), \sigma_0(\cdot, \epsilon) \in G^3$ uniformly in ϵ. To see this, simply observe that mollifications are smooth, and moreover, the polynomial growth is satisfied since $\nu^\epsilon * D^J\psi = \nabla^J(\nu^\epsilon * \psi)$ and furthermore, if $\psi \in G$, then we have

$$\begin{aligned}|\psi^\epsilon(x)| \leq& \int_{\mathcal{B}(0,\epsilon)} \nu^\epsilon(y)|\psi(x - y)|dy \\ \leq& \kappa_1\left(1 + 2^{2\kappa_2 - 1}|x|^{2\kappa_2} + 2^{2\kappa_2 - 1}\tfrac{1}{\epsilon^d}\int_{\mathcal{B}(0,\epsilon)} |y|^{2\kappa_2}dy\right)\end{aligned}$$

But $\int_{\mathcal{B}(0,\epsilon)} |y|^{2\kappa_2}dy \leq \text{Vol}(\mathcal{B}(0, \epsilon)) = C\epsilon^d$, where C is independent of ϵ. This shows that $\psi^\epsilon \in G$ uniformly in ϵ. This immediately implies that $b_0(\cdot, \epsilon), b_1(\cdot, \epsilon), \sigma_0(\cdot, \epsilon) \in G^3$.

Now, since $b_0(x, \epsilon) \to b_0(x, 0)$ (and similarly for b_1, σ_0), and the limits are continuous, by Lem. 4, 5, 29, 30,, all conditions of Thm. 3 are satisfied, and hence we conclude that for each $g \in G^3$, we have,

$$\max_{k=0,..,N} |\mathbb{E}g(X_{k\eta}^\epsilon) - \mathbb{E}g(x_k)| \leq C(\eta^2 + \rho(\epsilon)),$$

where C is independent of η and ϵ and $\rho(\epsilon) \to 0$ as $\epsilon \to 0$. Moreover, since $b_0(x, \epsilon) \to b_0(x, 0)$ (and similarly for b_1, σ_0) uniformly on compact sets, we may apply Thm. 20 to conclude that

$$\sup_{t \in [0,T]} \mathbb{E}|X_t^\epsilon - X_t|^2 \to 0 \text{ as } \epsilon \to 0.$$

Thus, we have

$$\begin{aligned}&|\mathbb{E}g(X_{k\eta}) - \mathbb{E}g(x_k)|\\ \leq&|\mathbb{E}g(X^\epsilon_{k\eta}) - \mathbb{E}g(x_k)| + |\mathbb{E}g(X^\epsilon_{k\eta}) - \mathbb{E}g(X_{k\eta})|\\ \leq& C(\eta^2 + \rho(\epsilon)) + \left(\mathbb{E}|X^\epsilon_{k\eta} - X_{k\eta}|^2\right)^{1/2}\\ &\times\left(\int_0^1 \mathbb{E}|\nabla^2 g(\lambda X^\epsilon_{k\eta} + (1-\lambda)X_{k\eta})|^2 d\lambda\right)^{1/2}\end{aligned}$$

Using Thm. 19 and assumption that $\nabla^2 g \in G$, the last expectation is finite and hence taking the limit $\epsilon \to 0$ yields our result. ■

By going for a lower order approximation, we of course have the following:

Corollary 10 *Assume the same conditions as in Thm. 9, except that we replace (i) with*

(i)' $f \equiv \mathbb{E}f_\gamma$ is continuously differentiable, and $f \in G^3_w$.

Define $\{X_t : t \in [0,T]\}$ as the stochastic process satisfying the SDE

$$dX_t = -\nabla f(X_t)dt + \sqrt{\eta}\Sigma(X_t)^{1/2}dW_t \qquad X_0 = x_0, \tag{4.5}$$

with $\Sigma(x) = \mathbb{E}(\nabla f_\gamma(x) - \nabla f(x))(\nabla f_\gamma(x) - \nabla f(x))^T$. Then, $\{X_t : t \in [0,T]\}$ is an order-1 weak approximation of the SGD, i.e. for each $g \in G^2$, there exists a constant $C > 0$ independent of η such that

$$\max_{k=0,\ldots,N} |\mathbb{E}g(X_{k\eta}) - \mathbb{E}g(x_k)| \leq C\eta.$$

Remark 11 *In the above results, the most restrictive condition is probably the Lipschitz condition on ∇f_γ. Such Lipschitz conditions are important to ensure that the SMEs admit unique strong solutions and the SGA having uniformly bounded moments. Note that following similar techniques in SDE analysis (e.g. Kloeden and Platen (2011)), these global conditions may be relaxed to their respective local versions if we assume in addition a uniform global linear growth condition on ∇f_γ. Finally, for applications, typical loss functions have inward pointing gradients for all sufficiently large x, meaning that the SGD iterates will be uniformly bounded almost surely. Thus, we may simply modify the loss functions for large x (without affecting the SGA iterates) to satisfy the conditions above.*

Remark 12 *The constant C does not depend on η, but as evidenced in the proof of the theorem, it generally depends on g, T, d and the various Lipschitz constants. For the fairly general situation we are consider, we do not derive tight estimates of these dependencies.*

4.3. SME for stochastic gradient descent with momentum

Let us discuss the corresponding SME for a popular variant of the SGD called the *momentum SGD* (MSGD). The momentum SGD augments the usual SGD iterations with a "memory" term. In the usual form, we have the iterations

$$\begin{aligned}\hat{v}_{k+1} &= \hat{\mu}\hat{v}_k - \hat{\eta}\nabla f_{\gamma_k}(x_k)\\ x_{k+1} &= x_k + \hat{v}_{k+1}\end{aligned}$$

where $\hat{\mu} \in (0,1)$ (typically close to 1) is called the *momentum parameter* and $\hat{\eta}$ is the learning rate. Let us consider a rescaled version of the above that is easier to analyze via continuous-time approximations. We redefine

$$\eta := \sqrt{\hat{\eta}}, \qquad v_k := \hat{v}_k/\sqrt{\hat{\eta}}, \qquad \mu := (1-\hat{\mu})/\sqrt{\hat{\eta}} \tag{4.6}$$

to obtain

$$\begin{aligned}v_{k+1} &= v_k - \mu\eta v_k - \eta\nabla f_{\gamma_k}(x_k)\\ x_{k+1} &= x_k + \eta v_{k+1}.\end{aligned} \tag{4.7}$$

In view of the rescaling, the range of momentum parameters we consider becomes $\mu \in (0, \eta^{-1/2})$, which we may replace by $(0,\infty)$ for simplicity.

Let us now derive the SME satisfied by the iterations (4.7). Observe that this is again a special case of (4.1) with x now replaced by (v,x) and

$$h(v,x,\gamma,\eta) = (-\mu v - \nabla f_\gamma(x), v - \eta\mu v - \eta\nabla f_\gamma(x))$$

In view of Thm. 14 and the results in Sec. 4.2, in order to derive the SMEs we simply match moments up to order 3. As in Sec. 4.2, let us define the one step difference

$$\Delta(v,x) := (v_1^{v,x,0} - v, x_1^{v,x,0} - x). \tag{4.8}$$

The following moment expansions are immediate.

Lemma 13 *Let $\Delta(x,v)$ be defined as in (4.8). We have*

(i) $\mathbb{E}\Delta_{(i)}(v,x) = \eta(-\mu v_{(i)} - \partial_{(i)}f(x), v) + \eta^2(0, -\mu v_{(i)} - \partial_{(i)}f(x)),$

(ii) $\mathbb{E}\Delta_{(i)}(v,x)\Delta_{(j)}(v,x) =$

$$\eta^2\begin{pmatrix}\mu^2 v_{(i)}v_{(j)} + \mu v_{(i)}\partial_{(j)}f(x) + \mu v_{(j)}\partial_{(i)}f(x)\\ \quad +\Sigma(x)_{(i,j)} + \partial_{(i)}\partial_{(j)}f(x) & -\mu v_{(i)}v_{(j)} - v_{(i)}\partial_{(j)}f(x)\\ -\mu v_{(i)}v_{(j)} - v_{(j)}\partial_{(i)}f(x) & v_{(i)}v_{(j)}\end{pmatrix}$$
$$+\mathcal{O}(\eta^3),$$

(iii) $\mathbb{E}\prod_{j=1}^3 |\Delta_{(i_j)}(v,x)| = \mathcal{O}(\eta^3),$

where $\Sigma(x) := \mathbb{E}(\nabla f_\gamma(x) - \nabla f(x))(\nabla f_\gamma(x) - \nabla f(x))^T$.

Proof The proof follows from direct calculation of the moments. ■

Hence, proceeding exactly as in Sec. 4.2 and using Lem.4, 13, we see that we may set

$$\begin{aligned}b_0(v,x) &= (-\mu v - \nabla f(x), v)\\ b_1(v,x) &= -\tfrac{1}{2}\left(\mu[\mu v + \nabla f(x)] - \nabla^2 f(x)v, \mu v + \nabla f(x)\right)\\ \sigma_0(v,x) &= \begin{pmatrix}\Sigma(x)^{1/2} & 0\\ 0 & 0\end{pmatrix}\end{aligned}$$

in order to match the moments. By similar mollification and limiting arguments as in Thm. 9, we arrive at the following approximation theorem, where we can see that the SME for MSGD takes the form of a Langevin equation.

Theorem 14 *Assume the same conditions as in Thm. 9 and that the drift terms in the following SDE are Lipschitz. Let $\mu > 0$ be fixed and define $\{V_t, X_t : t \in [0,T]\}$ as the stochastic process satisfying the SDE*

$$\begin{aligned} dV_t &= -[(\mu I + \tfrac{1}{2}\eta[\mu^2 I - \nabla^2 f(X_t)])V_t + (1+\tfrac{1}{2}\eta\mu)\nabla f(X_t)]dt + \sqrt{\eta}\Sigma(X_t)^{1/2}dW_t \quad V_0 = v_0, \\ dX_t &= [(1-\tfrac{1}{2}\eta\mu)V_t - \tfrac{1}{2}\eta\nabla f(X_t)]dt \quad X_0 = x_0, \end{aligned} \tag{4.9}$$

with $\Sigma(x)$ as defined in Thm. 9. Then, $\{(V_t, X_t) : t \in [0,T]\}$ is an order-2 weak approximation of the MSGD.

Moreover, if we relax the assumptions to Cor. 10, we have the order-1 weak approximation

$$\begin{aligned} dV_t &= -[\mu V_t + \nabla f(X_t)]dt + \sqrt{\eta}\Sigma(X_t)^{1/2}dW_t \quad V_0 = v_0, \\ dX_t &= V_t dt \quad X_0 = x_0. \end{aligned} \tag{4.10}$$

Note that by inverting the scaling (4.6), the order-1 SME (4.10) is the formal equation derived in Li et al. (2015). As discussed in Remark 11, using standard techniques the restrictive global Lipschitz conditions can be relaxed to a local Lipschitz condition together with a linear growth condition.

4.4. SME for a momentum variant: Nesterov accelerated gradient

It follows from the calculation above that we can also obtain the SME for the stochastic gradient version of the Nesterov accelerated gradient (NAG) method (Nesterov, 1983), which we refer to as SNAG. In the non-stochastic case, the NAG method has been analyzed using the ODE approach (Su et al., 2014). Therefore, the derivations in this section can be viewed as a stochastic parallel. The NAG method is sometimes used with stochastic gradients, and hence it is useful to analyze its properties in this setting and compare it to MSGD.

The unscaled NAG iterations are

$$\begin{aligned} \hat{v}_{k+1} &= \hat{\mu}_k \hat{v}_k - \hat{\eta}\nabla f_{\gamma_k}(x_k + \hat{\mu}_k \hat{v}_k) \\ x_{k+1} &= x_k + \hat{v}_{k+1} \end{aligned}$$

with $\hat{v}_0 = 0$, which differs from the momentum iterations as the gradient is now evaluated at a "predicted" position $x_k + \hat{\mu}_k\hat{v}_k$, instead of the original position x_k. Moreover, the momentum parameter $\hat{\mu}_k$ is now allowed to vary as k increases, and in fact, the usual choice of

$$\hat{\mu}_k = \tfrac{k-1}{k+2} \tag{4.11}$$

this has important links to stability and acceleration in the deterministic case (Nesterov, 1983; Su et al., 2014). In particular, it achieves $\mathcal{O}(1/k^2)$ convergence rate for general convex functions. On the other hand, a constant $\hat{\mu}_k$ is suggested for strongly convex functions (Nesterov, 2013). In the following, we shall first consider the case of constant momentum parameter with $\hat{\mu}_k \equiv \hat{\mu}$, and then the choice (4.11) subsequently.

Constant momentum. Using the same rescaling in (4.6), we have

$$\begin{aligned} v_{k+1} &= v_k - \mu\eta v_k - \eta\nabla f_{\gamma_k}(x_k + \eta(1-\mu\eta)v_k) \\ x_{k+1} &= x_k + \eta v_{k+1}. \end{aligned} \tag{4.12}$$

which is again (4.1) with

$$h(v,x,\gamma,\eta) = (-\mu v - \nabla f_\gamma(x+\eta(1-\mu\eta)v), v - \eta\mu v - \eta\nabla f_\gamma(x+\eta(1-\mu\eta)v))$$

Hence, we have the following moment expansion.

Lemma 15 *Let $\Delta(x,v) := (v_1^{v,x,0} - v, x_1^{v,x,0} - x)$. We have*

(i) $\mathbb{E}\Delta_{(i)}(v,x) = \eta(-\mu v_{(i)} - \partial_{(i)}f(x), v)$
$+ \eta^2(\partial_{(i)}\partial_{(j)}f(x)v_{(j)}, -\mu v_{(i)} - \partial_{(i)}f(x+v)) + \mathcal{O}(\eta^3)$,

(ii) $\mathbb{E}\Delta_{(i)}(v,x)\Delta_{(j)}(v,x) =$
$$\eta^2\begin{pmatrix} \mu^2 v_{(i)}v_{(j)} + \mu v_{(i)}\partial_{(j)}f(x+v) + \mu v_{(j)}\partial_{(i)}f(x+v) & \\ \quad +\Sigma(x+v)_{(i,j)} + \partial_{(i)}\partial_{(j)}f(x+v) & -\mu v_{(i)}v_{(j)} - v_{(i)}\partial_{(j)}f(x+v) \\ -\mu v_{(i)}v_{(j)} - v_{(j)}\partial_{(i)}f(x+v) & v_{(i)}v_{(j)} \end{pmatrix}$$
$+ \mathcal{O}(\eta^3)$,

(iii) $\mathbb{E}\prod_{j=1}^3 |\Delta_{(i_j)}(v,x)| = \mathcal{O}(\eta^3)$,

where $\Sigma(x) := \mathbb{E}(\nabla f_\gamma(x) - \nabla f(x))(\nabla f_\gamma(x) - \nabla f(x))^T$.

Proof The proof follows from direct calculation of the moments and Taylor's expansion. ■

Hence, we may match moments by setting

$$\begin{aligned} b_0(v,x) &= (-\mu v - \nabla f(x), v) \\ b_1(v,x) &= -\tfrac{1}{2}\left(\mu[\mu v + \nabla f(x)] + \nabla^2 f(x)v, \mu v + \nabla f(x)\right) \\ \sigma_0(v,x) &= \begin{pmatrix} \Sigma(x)^{\frac{1}{2}} & 0 \\ 0 & 0 \end{pmatrix} \end{aligned}$$

from which we obtain the following approximation theorem for SNAG.

Theorem 16 *Assume the same conditions as in Thm. 14. Define $\{V_t, X_t : t \in [0,T]\}$ as the stochastic process satisfying the SDE*

$$\begin{aligned} dV_t &= -[(\mu I + \tfrac{1}{2}\eta[\mu^2 I + \nabla^2 f(X_t)])V_t + (1+\tfrac{1}{2}\eta\mu)\nabla f(X_t)]dt + \sqrt{\eta}\Sigma(X_t)^{1/2}dW_t \quad V_0 = v_0, \\ dX_t &= [(1-\tfrac{1}{2}\eta\mu)V_t - \tfrac{1}{2}\eta\nabla f(X_t)]dt \quad X_0 = x_0, \end{aligned} \tag{4.13}$$

with Σ as defined in Thm. 14. Then, $\{(V_t, X_t) : t \in [0,T]\}$ is an order-2 weak approximation of SNAG. Moreover, the same order-1 weak approximation of MSGD in (4.10) holds for the SNAG.

The result above shows that for constant momentum parameters, the modified equations for MSGD and the SNAG are equivalent at leading order, but differ when we consider the second order modified equation. Let us now discuss the case where the momentum parameter is allowed to vary.

Varying momentum. Now let us take $\hat{\mu}$ as in (4.11). Then, using the same rescaling arguments, we arrive at

$$\begin{aligned} v_{k+1} &= v_k - \mu_k \eta v_k - \eta \nabla f_{\gamma_k}(x_k + \eta(1-\mu_k\eta)v_k) \\ x_{k+1} &= x_k + \eta v_{k+1}. \end{aligned} \tag{4.14}$$

with $\mu_k = 3/(2\eta + k\eta)$. Now, in order to apply our theoretical results to deduce the SME, simply notice that we may introduce an auxiliary scalar variable

$$z_{k+1} = z_k + \eta, \qquad z_0 = 0.$$

Then, $\mu_k = 3/(2\eta + z_k)$, and hence all terms are now not explicitly k-independent, thus we may proceed formally as in the previous sections to arrive at the order-1 SME for SNAG with varying momentum

$$\begin{aligned} dV_t &= -[\tfrac{3}{t}V_t + \nabla f(X_t)]dt + \sqrt{\eta}\Sigma(X_t)^{1/2}dW_t \quad V_0 = 0, \\ dX_t &= V_t dt \quad X_0 = x_0. \end{aligned} \tag{4.15}$$

This result is formal because the term $3/t$ does not satisfy our global Lipschitz conditions, unless we restrict our interval to some $[t_0, T]$ with $t_0 > 0$, in which case the above result becomes rigorous. Alternatively, some limiting arguments have to be used to establish well-posedness of the equation on $[0, T]$ individually. We shall omit these analyses in the current paper, and only consider (4.15) on some interval $[t_0, T]$, where initial conditions are then replaced by (v_{t_0}, x_{t_0}). As a point of comparison, (4.15) reduces to the ODE derived in Su et al. (2014) if $\Sigma(x) \equiv 0$ (i.e. the gradients are non-stochastic).

5. Applications of the SMEs to the analysis of SGA

In this section, we apply the SME framework developed to analyze the dynamics of the three stochastic gradient algorithm variants discussed above, namely SGD, MSGD and SNAG. We shall focus on simple but non-trivial models where to a large extent, analytical computations using SME are tractable, giving us key insights into the algorithms that are otherwise difficult to obtain without appealing to the continuous formalism presented in this paper. We consider primarily the following model:

Model: Let $H \in \mathbb{R}^{d\times d}$ be a symmetric, positive definite matrix. Define the sample objective

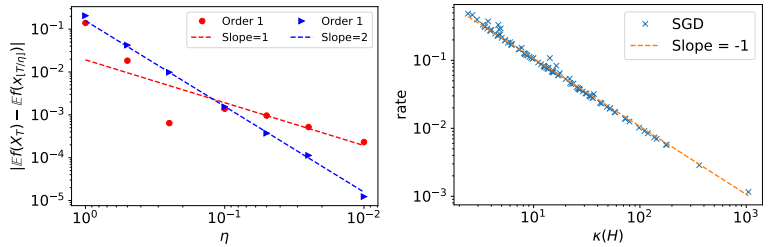
$$\begin{aligned} f_\gamma(x) &:= \tfrac{1}{2}(x-\gamma)^T H(x-\gamma) - \tfrac{1}{2}\mathrm{Tr}(H) \\ \gamma &\sim \mathcal{N}(0, I) \end{aligned} \tag{5.1}$$

which gives the total objective $f(x) \equiv \mathbb{E} f_\gamma(x) = \frac{1}{2}x^T H x$.

5.1. SME analysis of SGD

We first derive the SME associated with (5.1). For simplicity, we will only consider the order-1 SME (4.5). A direct computation shows that $\Sigma(x) = H^2$ and so the SME for SGD applied to model (5.1) is

$$dX_t = -HX_t dt + \sqrt{\eta} H dW_t,$$



This is a multi-dimensional Ornstein-Uhlenbeck (OU) process and admits the explicit solution

$$X_t = e^{-tH}\left(x_0 + \sqrt{\eta}\int_0^t e^{sH} H dW_s\right).$$

Observe that for each $t \geq 0$, the distribution of X_t is Gaussian. Using Itô's isometry, we then deduce the dynamics of the objective function

$$\begin{aligned} \mathbb{E} f(X_t) =& \tfrac{1}{2}x_0^T H e^{-2tH} x_0 + \tfrac{1}{2}\eta \int_0^t \mathrm{Tr}(H^3 e^{-2(t-s)H}) ds \\ =& \tfrac{1}{2}x_0^T H e^{-2tH} x_0 + \tfrac{1}{4}\eta \sum_{i=1}^n \lambda_i^2(H)(1 - e^{-2t\lambda_i(H)}). \end{aligned} \tag{5.2}$$

The first term decays linearly with asymptotic rate $2\lambda_d(H)$, and the second term is induced by noise, and its asymptotic value is proportional to the learning rate η. This is the well-known two-phase behavior of SGD under constant learning rates: an initial descent phase induced by the deterministic gradient flow and an eventual fluctuation phase dominated by the variance of the stochastic gradients. In this sense, the SME makes the same predictions, and in fact we can see that it approximates the SGD iterations well as η decreases (Fig. 5.1(a)), according to the rates we derived in Thm. 9 and Cor. 10.

(a) (b)

Figure 5.1: SME prediction vs SGD dynamics. (a) SME as a weak approximation of the SGD. We compute the weak error with test function g equal to f (see Thm. 9). As predicted by our analysis, the order-2 SME (4.4) (order-1 SME (4.5)) should give a slope $= 2$ (1) decrease in error as η decreases (note that the x-axis is flipped). The SME solution is computed using an exact formula derived by the application of Itô isometry and the SGD expectation is averaged over 1e6 runs. We took $T = 2.0$. We see that the predictions of Thm. 9 and Cor.10 hold. (b) Descent rate vs condition number. H is generated with different condition numbers, and the resulting descent rate of SGD is approximately $\propto \kappa(H)^{-1}$, as predicted by the SME.

Moreover, notice that by the identification $t = k\eta$ (k is the SGD iteration number), the SME analysis tells us that the asymptotic linear convergence rate (in k, i.e. rate $\sim$

$-\log[\mathbb{E}f(x_k)]/k)$ in the descent phase of the SGD is $2\lambda_d(H)\eta$. For numerical stability (even in the non-stochastic case), we usually require $\eta \propto 1/\lambda_1(H)$, thus the maximal descent rate is inversely proportional to the condition number $\kappa(H) = \lambda_1(H)/\lambda_d(H)$. We validate this observation by generating a collection of H's with varying condition numbers and applying SGD with $\eta \propto 1/\lambda_1(H)$. In Fig 5.1(b), we plot the initial descent rates versus the condition number of H and we observe that we indeed have rate $\propto \kappa(H)^{-1}$.

Alternate model. Now, we consider a slight variation of the model (5.1). The goal is show that the dynamics of SGD (and the corresponding SME) is not always Gaussian-like and thus using the OU process to model the SGD is not always valid. Given the same positive-definite matrix H, we diagonalize it in the form $H = QDQ^T$ where Q is an orthogonal matrix and D is a diagonal matrix of eigenvalues. We then define the sample objective

$$\begin{aligned} &f_\gamma(x) := \tfrac{1}{2}(Q^T x)^T[D + \operatorname{diag}(\gamma)](Q^T x) \\ &\gamma \sim \mathcal{N}(0, I) \end{aligned} \tag{5.3}$$

which gives the same total objective $f(x) \equiv \mathbb{E}f_\gamma(x) = \frac{1}{2}x^T H x$. However, we have a different expression for $\Sigma(x)$

$$\Sigma(x) = Q\operatorname{diag}(Qx)^2 Q^T,$$

which gives the SME

$$\begin{aligned} dX_t &= -HX_t dt + \sqrt{\eta}Q|\operatorname{diag}(Q^T X_t)|Q^T dW_t \\ &\overset{\text{in distribution}}{=} -HX_t dt + \sqrt{\eta}Q\operatorname{diag}(Q^T x)Q^T dW_t. \end{aligned}$$

We can rewrite the above as

$$dX_t = -HX_t dt + \sqrt{\eta}\sum_{l=1}^{d} Q^{(l)} X_t dW_{(l),t},$$

where $Q^{(l)} = Q\operatorname{diag}(Q_{(l,\cdot)})Q^T$ and $Q_{(l,\cdot)}$ denotes the l^{th} row of Q. By observing that every pair of $\{H, Q^{(1)}, \ldots, Q^{(d)}\}$ commute, we have the explicit solution

$$X_t = e^{-\frac{1}{2}\eta t + \sqrt{\eta}\sum_{l=1}^{d} Q^{(l)} W_{(l),t}} e^{-Ht} x_0.$$

which is a multi-dimensional Black-Scholes (Black and Scholes, 1973) type of stochastic process. In particular, the distribution is not Gaussian of any $t > 0$. Nevertheless, we may take expectation to obtain

$$\mathbb{E}f(X_t) = \tfrac{1}{2}e^{\eta t}x_0^T H e^{-2Ht}x_0.$$

This immediately implies the following interesting behavior: if $\eta < 2\lambda_d(H)$, then $2H - \eta I$ is positive definite and so $\mathbb{E}f(X_t) \to 0$ exponentially at constant, non-zero η; Otherwise, depending on initial condition x_0, the objective may not converge to 0. In particular, if $\eta > 2\lambda_d(H)$ (which happens quite often if the condition number of H is large) and x_0

is in general position, then we have asymptotic exponential divergence. This is a variance-induced divergence typically observed in Black-Scholes and geometric Brownian motion type of stochastic processes. The term "variance-induced" is important here since the deterministic part of the evolution equation is mean-reverting and in fact is identical to the stable OU process studied earlier. In Fig. 5.2(a), (b), we show the correspondence of the SME findings with the actual dynamics of the SGD iterations. In particular, we see in Fig. 5.2(c) that for small η, we have exponential convergence of the SGD at constant learning rates, whereas for $\eta > 2\lambda_d(H)$, the SGD iterates start to oscillate wildly and its mean value is dominated by few large values and diverges approximately at the rate predicted by the SME. Note that this divergence is predicted to be at a finite η, and from the theory developed so far we cannot conclude that the SME approximation always holds accurately at this regime (but the approximation is guaranteed for η sufficiently small). Nevertheless, we observe at least in this model that the variance-induced divergence of the SGD happens as predicted by the SME.

5.2. SME analysis of MSGD

Let us now use the SME to analyze MSGD applied to model (5.1). We have shown earlier that $\Sigma(x) = H$. Thus, according to Thm. 14, the order-1 SME for MSGD is

$$\begin{aligned} dV_t &= -[\mu V_t + HX_t]dt + \sqrt{\eta}H dW_t, \\ dX_t &= V_t dt, \end{aligned} \tag{5.4}$$

with $X_0 = x_0$ and $V_0 = 0$. If we set $Y_t := (V_t, X_t) \in \mathbb{R}^{2d}$, U_t a $2d$-dimensional Brownian motion with first d coordinates equal to W_t, and define block matrices

$$A := \begin{pmatrix} \mu I & H \\ -I & 0 \end{pmatrix}, \qquad B := \begin{pmatrix} H & 0 \\ 0 & 0 \end{pmatrix}, \tag{5.5}$$

we can then write (5.4) as

$$dY_t = -AY_t + \sqrt{\eta}B dU_t, \qquad Y_0 = (0, x_0),$$

which admits the explicit solution

$$Y_t = e^{-At}\left(Y_0 + \sqrt{\eta}\int_0^t e^{As}B dU_s.\right).$$

By Itô's isometry, we have

$$\mathbb{E}f(X_t) = \tfrac{1}{2}\left[|\operatorname{diag}(0,H)^{1/2}e^{-At}Y_0|^2 + \eta\int_0^t |\operatorname{diag}(0,H)^{1/2}e^{-(t-s)A}B|^2 ds\right], \tag{5.6}$$

One can see immediately that a similar two-phase behavior is present, but the property of the descent phase now hinges on the spectral properties of the matrix A (instead of H). Before proceeding, we first observe that the eigenvalues of A can be written as

$$\lambda(A) := \{\Lambda_+, \Lambda_-\}, \qquad \Lambda_{\pm,i} = \tfrac{1}{2}\left(\mu \pm \sqrt{\mu^2 - 4\lambda_i(H)}\right), \qquad i = 1, 2, \ldots, d. \tag{5.7}$$

In particular, $\Re\lambda_i(A) > 0$ for all i as long as $\mu > 0$. We also need the following simple result concerning the decay of the norm of e^{-tA} if all eigenvalues of A have positive real part.

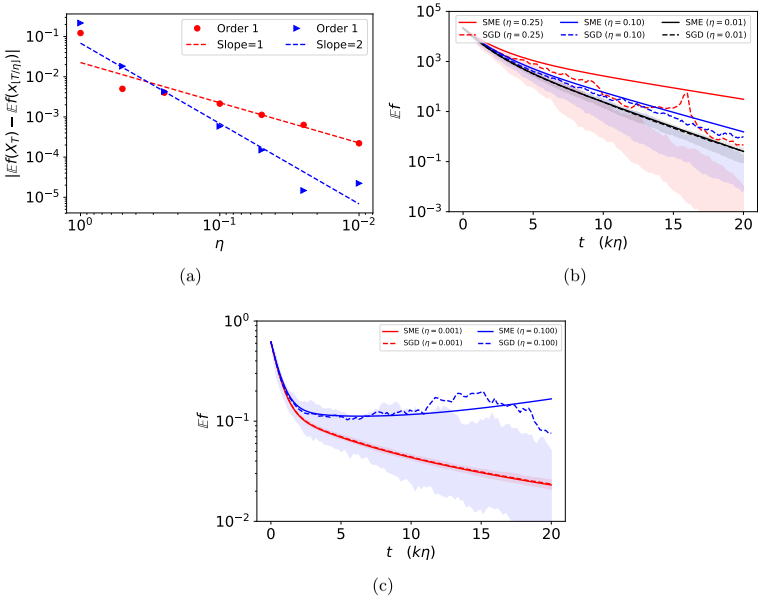


Figure 5.2: SME prediction vs SGD dynamics for the model variant (5.3). (a) Order of convergence of the SME to the SGD. We use the same setup as in Fig. 5.1(a). Observe that our analysis again predicts the correct rate of weak error decay as η decreases. (b) SGD paths vs order-1 SME prediction. Solid lines are SME exact solutions and dotted lines are means of SGD paths over 500 runs, and the 25-75 percentiles are shaded. We observe convergence of $\mathbb{E}f$ at constant η, and that the sample mean is dominated by few large values, as observed by the deviation of the percentiles from the mean. (b) Variance-induced explosion. As predicted by the SME analysis, if $\eta > 2\lambda_d(H)$ (Here, $\lambda_d(H) = 0.01$), variance-induced instability sets in.

Lemma 17 *Let A be a real square matrix such that all eigenvalues have positive real part. Then,*

(i) For each $\epsilon > 0$, there exists a constant $C_\epsilon > 0$ independent of t but depends on ϵ, such that

$$|e^{-tA}| \leq C_\epsilon e^{-t(\min_i \Re\lambda_i(A) - \epsilon)}$$

(ii) If in addition A is diagonalizable, then there exists a constant $C > 0$ independent of t such that

$$|e^{-tA}| \leq Ce^{-t\min_i \Re\lambda_i(A)}$$

Proof See Appendix E. ■

With the above results, we can now characterize the decay of the objective under momentum SGD. From expression (5.7), we see that as long as $\mu^2 \neq 4\lambda_i$ for any $i = 1, \ldots, d$, A has $2d$ distinct eigenvalues and is hence diagonalizable. We shall hereafter assume that μ is in general position such that this is the case. Using Lem. 17 and expression (5.6), we arrive at the estimate

$$\mathbb{E}f(X_t) \leq \tfrac{1}{2}C^2|x_0|^2\lambda_1(H)e^{-2t\min_i \Re\lambda_i(A)} + \tfrac{1}{2}\frac{\eta C^2\lambda_1(H)^3}{\min_i \Re\lambda_i(A)}(1 - e^{-2t\min_i \Re\lambda_i(A)}). \tag{5.8}$$

This result tells us that the convergence rate of the descent phase is now controlled by the minimum real part of the eigenvalues of A, instead of the minimum eigenvalue of H. In particular, we achieve the best linear convergence rate by maximizing the smallest real part of the eigenvalues of A. This leads to the following optimization problem for the optimal convergence rate:

$$\sup_{\mu\in(0,\infty)} \min_{i=1,\ldots,d} \min_{s\in\{+1,-1\}} \left\{\Re\left[\mu + s\sqrt{\mu^2 - 4\lambda_i(H)}\right]\right\}$$

Since H is positive definite, the supremum is attained at $\mu^* = 2\sqrt{\lambda_d(H)}$ with the rate also equal to $2\sqrt{\lambda_d(H)}$. However, note that if we take $\mu = \mu^*$ exactly, one can check that A is no longer diagonalizable and by Lem. 17, the rate is slightly diminished, thus technically we can take μ as close to μ^* as we like (i.e. the rate is as close to $2\sqrt{\lambda_d(H)}$ as we like), but exact equality is not technically deducible from current results. In Fig. 5.3(c), we demonstrate the optimal choice of μ and its effect on the convergence rate. Moreover, observe that as μ increases, the number of complex eigenvalues start to decrease, and the magnitudes of the imaginary parts of the complex eigenvalues also decrease. This signifies that increasing μ causes oscillations to decreases in magnitude and frequency. This is again corroborated by numerical experiments (Fig. 5.3(c)).

Another interesting observation is that by the identification $t = \eta k$, the descent rate (in terms of k) is $2\sqrt{\lambda_d(H)}\eta$. As before, if we choose the maximal stable learning rate we would have $\hat{\eta} \propto 1/\lambda_1(H)$ ($\hat{\eta} = \eta^2$ according to the scaling introduced in (4.6)). Thus, for the MSGD iterates we have its descent rate $\propto \kappa(H)^{-1/2}$, which is a huge improvement over SGD, whose rate is $\propto \kappa(H)^{-1}$, especially for badly conditioned matrices where $\kappa(H) \gg 1$. In Fig. 5.3(d), we plot the MSGD initial descent rates for varying condition numbers of H. Again, we observe that the SME analysis gives the correct characterization of the precise dynamics and recovers the square-root relationship with condition number.

Finally, let us discuss the effect of adding momentum to the asymptotic fluctuations due to noisy gradients. Note that it is not correct to conclude, using Eq. (5.8), that taking $\mu \approx \mu^*$ also gives the lowest fluctuations. This is because the constant C depends on μ as well, as is evidenced in the proof of Lem. 17, which shows that C depends on the conditioning of the

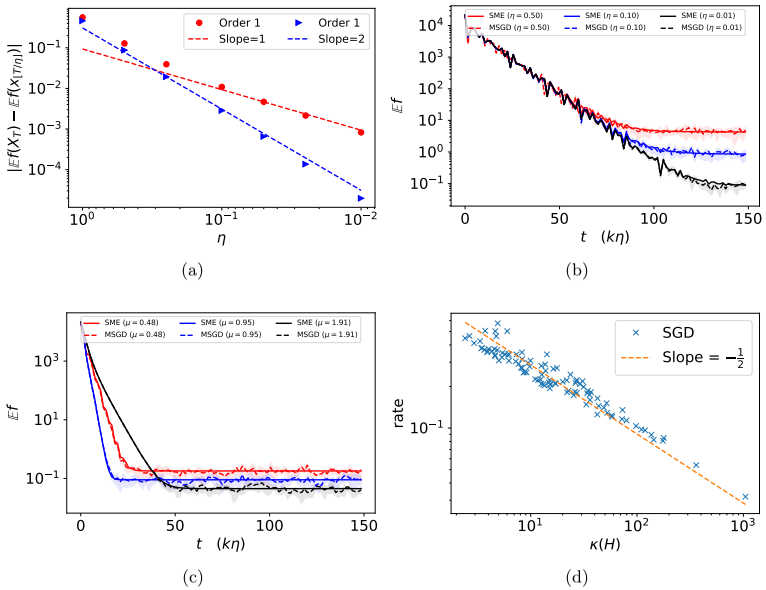

Figure 5.3: SME prediction vs MSGD dynamics. (a) and (b) SME vs MSGD dynamics at $\mu = 0.1$ for different learning rates η. As before, the SME prediction gets better as η decreases according to the predicted order. Notice also the presence of oscillations, due to the complex eigenvalues of A. (c) Optimal descent rate of the SGD is achieved by the SME prediction $\mu = \mu^*$, which is 0.95 in this case. Notice that exactly as predicted by the SME, increasing μ decreases the oscillation frequency and magnitude (due to having fewer complex eigenvalues and smaller imaginary parts), as well as the asymptotic fluctuations (due to formula (5.9)). (d) Descent rate vs condition number. H is generated with different condition numbers, and the descent rate of MSGD is $\propto \kappa(H)^{-1/2}$, as predicted by the SME, which for badly conditioned H gives a large improvement.

eigenvector matrix of A. To proceed, we do not use the bounds (5.8). Instead, we explicitly diagonalize A and after some computations, we arrive at the exact expression for $\mathbb{E}f(X_t)$

$$\mathbb{E}f(X_t) = \tfrac{1}{2}|\operatorname{diag}(0,H)^{1/2}e^{-At}Y_0|^2 \tag{5.9}$$

$$+ \tfrac{1}{2}\eta\sum_{i=1}^{d}\frac{\lambda_i^3}{|\mu^2-4\lambda_i|}\left[\frac{1-e^{-2t\Re\Lambda_{+,i}}}{2\Re\Lambda_{+,i}} + \frac{1-e^{-2t\Re\Lambda_{-,i}}}{2\Re\Lambda_{-,i}} - 2R(t,\mu,\lambda_i(H))\right] \tag{5.10}$$

where

$$R(t,\mu,\lambda) = \begin{cases} \frac{1-e^{-t\mu}}{\mu} & \mu \geq 2\sqrt{\lambda} \\ \frac{\mu+\sqrt{4\lambda-\mu^2}e^{-\mu t}\sin(t\sqrt{4\lambda-\mu^2})-\mu e^{-\mu t}\cos(t\sqrt{4\lambda-\mu^2})}{4\lambda} & \mu < 2\sqrt{\lambda} \end{cases}. \tag{5.11}$$

In particular, the asymptotic loss value induced by noise is

$$\lim_{t\to\infty}\mathbb{E}f(X_t) = \tfrac{1}{2}\eta\sum_{i=1}^{d}\frac{\lambda_i(H)^3}{|\mu^2-4\lambda_i(H)|}\left[\frac{1}{2\Re\Lambda_{+,i}} + \frac{1}{2\Re\Lambda_{-,i}} - 2\min\left\{\frac{\mu}{4\lambda_i(H)}, \frac{1}{\mu}\right\}\right] \tag{5.12}$$

Observe that this function (in fact, each term in the sum) is monotone-decreasing in μ, and for $\mu \ll 1$ it scales like μ^{-1}, and for $\mu \gg 1$ it scales like μ^{-3}. Thus, increasing the momentum parameter decreases the asymptotic noise in the iterates, i.e. decreases the asymptotic value of $\mathbb{E}f$, which should be 0 in the absence of noise. This again agrees with the actual MSGD dynamics (Fig. 5.3(b)). Consequently, to obtain "optimal" tradeoff between descent and noise, we would like a momentum schedule that equals μ^* in the descent phase and increases to infinity (in the original scaling this corresponds to $\hat{\mu} \to 0$) as we approach the optimum. Finding this optimal schedule can be cast as an optimal control problem (Li et al., 2017), and a rigorous investigation of these approaches will be considered in subsequent work.

5.3. SME analysis of SNAG

Finally, let us see what we can say, using the SME approach, about the difference between MSGD and SNAG in this stochastic setting. Let us first consider the case of constant momentum. From Thm. 16, we know that the order-1 SMEs are identical, so we must consider higher order SMEs. A straightforward computation yields the following order-2 SMEs for MSGD and SNAG (again we let $Y_t = (V_t, X_t)$)

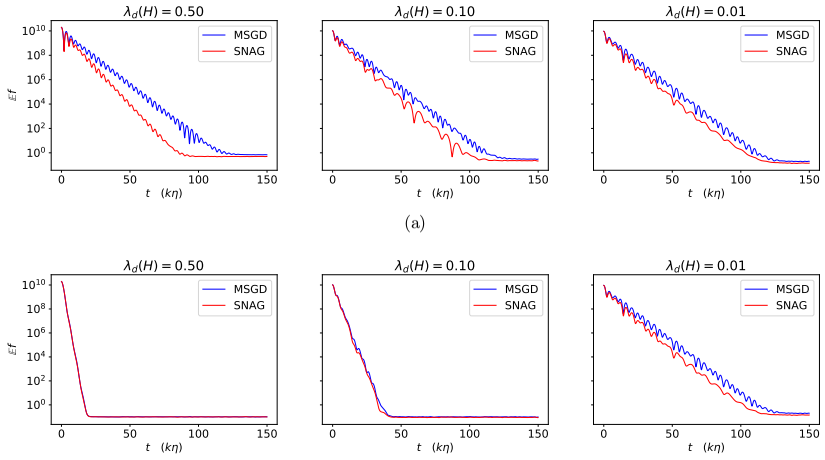
$$\begin{aligned} &\text{MSGD:} && dY_t = -A_1 Y_t + \sqrt{\eta}B dU_t, && Y_0 = (0, x_0), \\ &\text{SNAG:} && dY_t = -A_2 Y_t + \sqrt{\eta}B dU_t, && Y_0 = (0, x_0), \end{aligned}$$

where $A_i = A + \frac{1}{2}\eta E_i$ with A, B as defined in (5.5) and

$$E_1 := \begin{pmatrix} \mu^2 I - H & \mu H \\ \mu I & H \end{pmatrix}, \qquad E_2 := \begin{pmatrix} \mu^2 I + H & \mu H \\ \mu I & H \end{pmatrix}.$$

From the analysis in Sec. 4.3, the descent rate is dominated by the minimal real parts of the eigenvalues of A_i, which are respectively

$$\lambda(A_1) = \left\{\tfrac{1}{4}\left(\mu(\eta\mu+2) \pm \sqrt{\mu^2(\eta\mu+2)^2 + 4\eta^2\lambda_i(H)^2 - 8\lambda_i(H)(\eta\mu+2)}\right), \quad i = 1,\dots,d\right\}$$



$$\lambda(A_2) = \left\{\tfrac{1}{4}\left(\mu(\eta\mu+2) + 2\eta\lambda_i(H) \pm \sqrt{\eta\mu+2}\sqrt{\mu^2(\eta\mu+2) + 4\lambda_i(H)(\eta\mu-2)}\right), \quad i = 1,\dots,d\right\}$$

We observe that for small μ (i.e. $\hat{\mu} \approx 1$ in the usual MSGD scaling), the terms in square-roots are negative and hence for the same small μ, the convergence rate of SNAG (in terms of initial descent rate) is $\frac{1}{2}\eta\lambda_d(H)$ larger than that of MSGD. This says in particular that

for H with larger $\lambda_d(H)$, the acceleration is more pronounced. Moreover, recall that the asymptotic fluctuations is given by

$$\eta \lim_{t\to\infty} \int_0^t |\operatorname{diag}(0,H)^{1/2} e^{-(t-s)(A+\frac{1}{2}\eta E_i)} B|^2 ds.$$

Without performing tedious computations, we can see that since $E_2 - E_1$ is positive definite, the exponential for the SNAG case decays more rapidly, and hence the eventual fluctuations are expected to be lower. These observations from the SME are again consistent with the behavior of their SGA counter-parts, as shown in Fig. 5.4(a). On the other hand, if we pick μ for each case by separately maximizing the smallest real part of the eigenvalues (as in Sec. 4.3), we obtain similar convergence rates up to η^2. In other words, if we tune μ well, there would be no difference between MSGD and SNAG in terms of descent rate (Fig. 5.4(b)).

(a)

(b)

Figure 5.4: MSGD vs SNAG (with constant momentum) dynamics for $\eta = 0.1$ and different $\lambda_d(H)$. (a) Dynamics at fixed $\mu = 0.2$. We observe that as predicted by the SME analysis, SNAG enjoys a faster linear convergence rate in the descent phase, as well as lower asymptotic fluctuations. The acceleration is indeed more pronounced for larger $\lambda_d(H)$. (b) When, μ for each case is chosen optimally for the descent (by maximizing the minimal real part of the eigenvalues of A_1, A_2 respectively), the dynamics becomes similar.

Now, let us discuss the varying momentum case. According to (4.15), for some small $t_0 > 0$ we have the order-1 SME for $t \in [t_0, T]$

$$dY_t = -A_t Y_t + \sqrt{\eta} B dU_t, \qquad Y_{t_0} = (v_{t_0}, x_{t_0}) \qquad A_t := \begin{pmatrix} \frac{3}{t} I & H \\ -I & 0 \end{pmatrix},$$

and B is defined as in (5.5). This admits the explicit solution

$$Y_t = e^{-(t-t_0)\tilde{A}_t} \left(Y_{t_0} + \sqrt{\eta} \int_{t_0}^t e^{s\tilde{A}_s} B dU_s. \right), \qquad \tilde{A}_t := \begin{pmatrix} 3\frac{\log(t/t_0)}{t-t_0} I & H \\ -I & 0 \end{pmatrix}.$$

The eigenvalues of $\tilde{A}_t$ are

$$\lambda(\tilde{A}_t) = \left\{ \frac{1}{2} \left(3\frac{\log(t/t_0)}{t-t_0} \pm \sqrt{9[\frac{\log(t/t_0)}{t-t_0}]^2 - 4\lambda_i(H)} \right), \qquad i = 1, \dots, d \right\}.$$

Since there is no lower-bound on the minimal real part, the descent rate before the onset of fluctuations is sub-linear. This is expected because the $\mathcal{O}(1/t)$ momentum schedule is suited for non-strongly-convex functions, whereas constant momentum is more appropriate for strong-convex functions (Nesterov, 2013). Furthermore, we observe that since the real parts of all eigenvalues of $\tilde{A}_t$ converge to 0 as $t \to \infty$, according to the analysis in Sec. 4.3, the asymptotic fluctuations due to noise should be large. Fig. 5.5 confirms these observations and further suggests that in the case of stochastic gradient methods, more careful momentum schedules must be derived in order to balance descent and fluctuations, e.g. using the optimal control framework presented in Li et al. (2017).

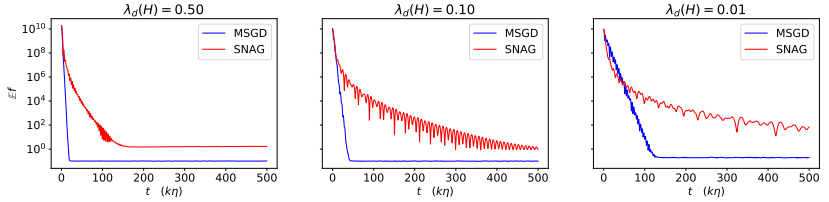


Figure 5.5: MSGD vs SNAG (with dynamic momentum according to Nesterov's choice (4.11)) dynamics for $\eta = 0.1$ and different $\lambda_d(H)$. We see that the convergence is indeed sub-linear, and moreover, the asymptotic fluctuations are large compared with MSGD, in which case μ here is picked to achieve optimal descent rate.

6. Conclusion

In this paper, we developed the general mathematical foundation of the stochastic modified equations framework for analyzing stochastic gradient algorithms. In particular, we demonstrate that this approach is (1) rigorous, (2) flexible and (3) useful. Indeed, the technique of weak approximations provides a precise mathematical framework for analyzing the relationship between stochastic gradient algorithms and stochastic differential equations. This should be contrasted with strong approximations in the numerical analysis of SDEs, where approximations are required to hold path-wise, say in the mean-square sense (Kloeden and Platen, 2011). The weak formulation greatly increases the flexibility of modelling different

type of stochastic gradient algorithms, as we have demonstrated in Sec. 4. In fact, the main result relating discrete-time algorithms and continuous-time SDEs (Thm. 3) is proved in a fairly general setting that allows one to derive a variety of SMEs for different variations of the SGAs (Sec. 4). Finally, in Sec. 5, we demonstrated the usefulness of the SME approach through explicit calculations. This is enabled by the precise approximation nature of the SMEs and the application of stochastic calculus tools. In particular, we uncovered interesting behaviors of SGAs when applied to a simple yet non-trivial setting, including the tradeoff of descent and fluctuations, the relationship with condition numbers and the subtle differences of MSGD and SNAG in the stochastic setting. In the subsequent work in the series, we will focus on applications, where we extend the SME formalism to study adaptive algorithms and related topics.

Appendix A. General existence, uniqueness and moment estimates for SDEs

In this section, we establish general existence, uniqueness and moment estimates for the stochastic differential equations that we encounter in this paper. The results here will be used throughout the subsequent proofs. We note that although similar well-posedness results are well-known, here we require a slightly more general version (where the drift and diffusion terms are themselves random functions) in order to deal with the analysis in Appendix B. Moreover, we need uniform estimates with respect to parameters (η, ϵ), which warrants the following standard but necessary analysis.

Let $T > 0$ and Q be a subset of a Euclidean space. For $(x, t, q) \in \mathbb{R}^d \times [0, T] \times Q$, let $B(x, t, q)$ be a d-dimensional random vector and $S(x, t, q)$ be a $d \times d$-dimensional random matrix. Throughout this section we assume:

Assumption A.1 *The random functions B, S satisfy the following:*

(i) B, S are W_t-adapted and continuous in $(x, t) \in \mathbb{R}^d \times [0, T]$ almost surely

(ii) B, S satisfy a uniform linear growth condition, i.e. there exists a non-random constant $L > 0$ such that

$$|B(x,t,q)|^2 + |S(x,t,q)|^2 \le L^2(1+|x|^2) \quad a.s.$$

for all $x, y \in \mathbb{R}^d$, $t \in [s, T]$, $q \in Q$.

(iii) B, S satisfy a uniform Lipschitz condition in x, i.e.

$$|B(x,t,q) - B(y,t,q)| + |S(x,t,q) - S(y,t,q)| \le L|x-y| \quad a.s.$$

for all $t \in [s, T]$, $q \in Q$.

Theorem 18 *Let $s \in [0, T)$ and for each $q \in Q$, let $\{\phi_t^q : t \in [s, T]\}$ be a $\mathbb{R}^d$-valued, W_t-adapted random process that is continuous in $t \in [s, T]$ almost surely, with*

$$\sup_{q\in Q} \mathbb{E} \sup_{t\in[s,T]} |\phi_t^q|^2 < \infty. \tag{A.1}$$

Then, for each $q \in Q$ the stochastic differential equation

$$\xi_t^q = \phi_t^q + \int_s^t B(\xi_v^q, v, q)dv + \int_s^t S(\xi_v^q, v, q)dW_v \tag{A.2}$$

admits a unique solution $\{\xi_t^q : t \in [s, T]\}$ which is continuous for $t \in [s, T]$ a.s. and satisfies

$$\sup_{q\in Q} \mathbb{E} \sup_{t\in[s,T]} |\xi_t^q|^2 \le C\left(1 + \sup_{q\in Q} \mathbb{E} \sup_{t\in[s,T]} |\phi_t^q|^2\right) \tag{A.3}$$

for some constant $C > 0$ that depends only on L, T.

Proof For each $q \in Q$, let us define the recursion

$$\xi_t^{q,0} = \phi_t^q$$
$$\xi_t^{q,m+1} = \phi_t^q + \int_s^t B(\xi_v^{q,m}, v, \eta)dv + \int_s^t S(\xi_v^{q,m}, v, \eta)dW_v, \quad m \geq 0.$$

Note that Assumption A.1 implies each $\xi_t^{q,m}$ is well-defined. Now, let $m \geq 1$. By Itô's isometry, we have

$$|\xi_t^{q,m+1} - \xi_t^{q,m}|^2 \leq 2\left|\int_s^t B(\xi_v^{q,m}, v, q) - B(\xi_v^{q,m-1}, v, q)dv\right|^2 \tag{A.4}$$
$$+ 2\left|\int_s^t S(\xi_v^{q,m}, v, q) - S(\xi_v^{q,m-1}, v, q)dW_v\right|^2 \tag{A.5}$$
$$\leq 2T\int_s^t |B(\xi_v^{q,m}, v, q) - B(\xi_v^{q,m-1}, v, q)|^2 dv \tag{A.6}$$
$$+ 2\int_s^t |S(\xi_v^{q,m}, v, q) - S(\xi_v^{q,m-1}, v, q)|^2 dv. \tag{A.7}$$

Thus, applying the Lipschitz assumption A.1 (iii) and taking expectations, we get

$$\mathbb{E}|\xi_t^{q,m+1} - \xi_t^{q,m}|^2 \leq 2L^2(1+T)\int_s^t \mathbb{E}|\xi_v^{q,m} - \xi_v^{q,m-1}|^2 dv. \tag{A.8}$$

Now, for $m = 0$, Assumption A.1 (ii) together with (A.1) gives

$$\mathbb{E}|\xi_t^{q,1} - \xi_t^{q,0}|^2 \leq C\int_s^t \left(1 + \sup_{q\in Q}\mathbb{E}|\phi_v^q|^2\right)dv \leq C'(t-s). \tag{A.9}$$

Combining (A.8) and (A.9), we have

$$\mathbb{E}|\xi_t^{q,m+1} - \xi_t^{q,m}|^2 \leq \tfrac{[C(t-s)]^{m+1}}{(m+1)!}, \qquad m \geq 0 \tag{A.10}$$

for some $C > 0$ that only depends on T, L and $C_\phi := \sup_{q\in Q}\mathbb{E}\sup_{t\in[s,T]}|\phi_t^q|^2$. Moreover, Eq. (A.4) implies

$$\mathbb{E}\sup_{t\in[s,T]}|\xi_t^{q,m+1} - \xi_t^{q,m}|^2 \leq 2L^2T\int_s^T \mathbb{E}|\xi_t^{q,m} - \xi_t^{q,m-1}|^2 dt$$
$$+ 2\mathbb{E}\sup_{t\in[s,T]}\left|\int_s^t S(\xi_v^{q,m}, v, q) - S(\xi_v^{q,m-1}, v, q)dW_v\right|^2.$$

Estimate (A.10) implies the last stochastic integral is a martingale, and hence using Doob's maximal inequality and Itô's isometry, we have

$$\mathbb{E}\sup_{t\in[s,T]}|\xi_t^{q,m+1} - \xi_t^{q,m}|^2 \leq 2L^2T\int_s^T \mathbb{E}|\xi_t^{q,m} - \xi_t^{q,m-1}|^2 dt + 8L^2\int_s^T \mathbb{E}|\xi_t^{q,m} - \xi_t^{q,m-1}|^2 dt$$
$$\leq 2L^2(T+4)\tfrac{C^m T^{m+1}}{(m+1)!} = 2L^2(T+4)\tfrac{C^m T^{m+1}}{(m+1)!}$$

Applying Markov's inequality,

$$\sum_{m\geq 0}\mathbb{P}\left[\sup_{t\in[s,T]}|\xi_t^{q,m+1} - \xi_t^{q,m}| > 2^{-m}\right] \leq 2L^2(T+4)\sum_{m\geq 0}2^{2m}\tfrac{C^m T^{m+1}}{(m+1)!} < \infty.$$

Thus, by the Borel-Cantelli lemma,

$$\mathbb{P}\left[\sup_{t\in[s,T]}|\xi_t^{q,m+1} - \xi_t^{q,m}| > 2^{-m} \text{ infinitely often}\right] = 0,$$

which immediately implies

$$\xi_t^{q,k} = \xi_t^{q,0} + \sum_{m=0}^{k-1}(\xi_t^{q,m+1} - \xi_t^{q,m}) \to \xi_t^q \quad a.s.$$

uniformly in $t \in [s,T]$, for some limiting process ξ_t^q which is necessarily continuous almost surely and W_t-adapted. Moreover, we also have convergence in $\mathcal{L}^2(\Omega)$ uniformly in t. To see this, for each $k > l$ we observe that

$$\sup_{t\in[s,T]}\left(\mathbb{E}|\xi_t^k - \xi_t^l|^2\right)^{1/2} \leq \sup_{t\in[s,T]}\sum_{m=l}^{k-1}\left(\mathbb{E}|\xi_t^{q,m+1} - \xi_t^{q,m}|^2\right)^{1/2}$$
$$\leq \sum_{m=l}^{\infty}\sqrt{2L^2(T+4)\tfrac{C^m T^{m+1}}{(m+1)!}} \xrightarrow{l\to\infty} 0.$$

And hence $\xi_t^{q,k}$ converges uniformly in $\mathcal{L}^2(\Omega)$ to ξ_t^q as $k \to \infty$ (the limit is the same as the a.s. limit since a sub-sequence of it must converge a.s.). This immediately implies via the Lipschitz condition and Itô's isometry that

$$\mathbb{E}\left|\int_s^T B(\xi_t^{q,k}, t, \eta) - B(\xi_t^q, t, \eta)dt\right|^2 \leq T^2L^2\sup_{t\in[s,T]}\mathbb{E}\left|\xi_t^{q,k} - \xi_t^q\right|^2 \to 0,$$
$$\mathbb{E}\left|\int_s^T S(\xi_t^{q,k}, t, \eta) - S(\xi_t^q, t, \eta)dW_t\right|^2 \leq TL^2\sup_{t\in[s,T]}\left|\xi_t^{q,k} - \xi_t^q\right|^2 \to 0.$$

Thus, ξ_t^q satisfies (A.2).

We now show the estimate (A.3). From Eq. (A.2), we have by Itô's isometry,

$$\mathbb{E}|\xi_t^q|^2 \leq 3\mathbb{E}|\phi_t^q|^2 + 3\mathbb{E}\left|\int_s^T B(\xi_v^q, v, q)dv\right|^2 + 3\mathbb{E}\left|\int_s^t S(\xi_v^q, v, q)dW_v\right|^2$$
$$\leq 3C_\phi + 3T^2L^2\int_s^T \mathbb{E}(1 + |\xi_v^q|^2)dv + 3TL^2\int_s^T \mathbb{E}(1 + |\xi_v^q|^2)dv$$

Thus, by Gronwall's lemma, we have

$$\mathbb{E}|\xi_t^q|^2 \leq C(1 + C_\phi) \tag{A.11}$$

for some $C > 0$ depending only on T, L. Consequently, we have

$$\mathbb{E} \sup_{t\in[s,T]} |\xi_t^q|^2 \leq 3C_\phi + 3T^2L^2\mathbb{E}\int_s^T 1 + |\xi_s^q|^2 dt \tag{A.12}$$

$$+ 3\mathbb{E} \sup_{t\in[s,T]} \left|\int_s^t S(\xi_t^q, t, q)dW_t\right|^2. \tag{A.13}$$

Assumption A.1 (ii) and (A.11) implies the last stochastic integral is a martingale, and so by Doob's maximal inequality,

$$\left(\mathbb{E} \sup_{t\in[s,T]} \left|\int_s^t S(\xi_t, t, \eta)dW_t\right|\right)^2 \leq \int_s^T 4L^2(1 + \mathbb{E}|\xi_t|^2)dt. \tag{A.14}$$

Combining (A.12) and (A.14), we arrive at (A.3).

Finally, we show uniqueness. Suppose that ξ_t, ξ_t' are two solutions to (A.2). The same calculation as before shows that

$$\mathbb{E}|\xi_t - \xi_t'|^2 \leq 2L^2T(1+T)\int_s^t \mathbb{E}|\xi_v - \xi_v'|^2 dv.$$

and Gronwall's lemma implies

$$\mathbb{E}|\xi_t - \xi_t'|^2 \leq e^{2L^2T(1+T)}\mathbb{E}|\xi_s - \xi_s'|^2 = 0.$$

■

Theorem 19 *Let us assume the same conditions as in Thm. 18 and for each $q \in Q$, let ξ_t^q be the unique solution of* (A.2)*. Let $m \geq 1$ and suppose $\sup_{q\in Q}\mathbb{E}\sup_{t\in[s,T]}|\phi_t^q|^{2m} < \infty$. Then, there exists a constant $C > 0$ depending only on L, T, m such that*

$$\sup_{q\in Q}\mathbb{E} \sup_{t\in[s,T]} |\xi_t^q|^{2m} \leq C\left(1 + \sup_{q\in Q}\mathbb{E} \sup_{t\in[s,T]} |\phi_t^q|^{2m}\right).$$

Proof We have

$$|\xi_t^q|^{2m} \leq 3^{2m-1}|\phi_t^q|^{2m} + (3(t-s))^{2m-1}\int_s^t |B(\xi_v^q, v, q)|^{2m}dv$$
$$+ 3^{2m-1}\left|\int_s^t S(\xi_v^q, v, q)dW_v\right|^{2m}$$

Taking expectations, using Itô's isometry (inequality version) and Gronwall's inequality, we obtain

$$\mathbb{E}|\xi_t^q|^{2m} \leq 3^{2m-1}\sup_{q\in Q}\mathbb{E} \sup_{t\in[s,T]} |\phi_t^q|^{2m} + (3(t-s))^{2m-1}L^{2m}\int_s^t (1 + \mathbb{E}|\xi_v^q|^{2m})dv$$
$$+ 3^{2m-1}(m(2m-1))^m(t-s)^{m-1}L^{2m}\int_s^t (1 + \mathbb{E}|\xi_v^q|^{2m})dv$$
$$\leq C\left(1 + \sup_{q\in Q}\mathbb{E} \sup_{t\in[s,T]} |\phi_t^q|^{2m}\right) < \infty,$$

with C depending only on L, T, m. Next,

$$\mathbb{E} \sup_{t\in[s,T]} |\xi_t^q|^{2m} \leq 3^{2m-1}\sup_{q\in Q}\mathbb{E} \sup_{t\in[s,T]} |\phi_t^q|^{2m}$$
$$+ 3T^{2m-1}\mathbb{E}\int_s^T |B(\xi_v^q, v, q)|^{2m}dv$$
$$+ 3^{2m-1}\mathbb{E} \sup_{t\in[s,T]} \left|\int_s^t S(\xi_v^q, v, q)dW_v\right|^{2m}$$

Now, in the last term, the stochastic integral is a local martingale and so its absolute value is a submartingale, and hence the last term is bounded by

$$\mathbb{E} \sup_{t\in[s,T]} \left|\int_s^t S(\xi_v^q, v, q)dW_v\right|^{2m} \leq \left|\int_s^T S(\xi_v^q, v, q)dW_v\right|^{2m}$$
$$\leq C\int_s^T |S(\xi_v^q, v, q)|^{2m}dv.$$

Thus, using Thm. 19 and the linear growth condition, we conclude that

$$\sup_{q\in Q}\mathbb{E} \sup_{t\in[s,T]} |\xi_t^q|^{2m} \leq C\left(1 + \sup_{q\in Q}\mathbb{E} \sup_{t\in[s,T]} |\phi_t^q|^{2m}\right)$$

■

Finally, we examine some limiting behavior of solutions ξ_t^q as $q \to q^*$ for some $q^* \in Q$.

Theorem 20 *Let us assume the same conditions as in Thm. 18 and let $q^* \in Q$ be fixed. Suppose further that the following holds for any $t \in [s,T]$, $R > 0$ and $\epsilon > 0$:*

(i) $\lim_{q\to q^*}\mathbb{P}\left[\sup_{|x|\leq R}|B(x,t,q) - B(x,t,q^*)| > \epsilon\right] = 0$

(ii) $\lim_{q\to q^*}\mathbb{P}\left[\sup_{|x|\leq R}|S(x,t,q) - S(x,t,q^*)| > \epsilon\right] = 0$

(iii) $\lim_{q\to q^*}\sup_{t\in[s,T]}\mathbb{E}|\phi_t^q - \phi_t^{q^*}|^2 = 0$

Then, the solutions ξ_t^q of (A.2) *satisfy*

$$\lim_{q\to q^*}\sup_{t\in[s,T]}\mathbb{E}|\xi_t^q - \xi_t^{q^*}|^2 = 0,$$

i.e. $\xi_t^q \to \xi_t^{q^*}$ in $\mathcal{L}^2(\Omega)$ uniformly in $t \in [s,T]$.

Proof We have

$$\xi_t^q - \xi_t^{q^*} = \zeta_t^q + \int_s^t B(\xi_v^q, v, q) - B(\xi_v^{q^*}, v, q)dv$$
$$+ \int_s^t S(\xi_v^q, v, q) - S(\xi_v^{q^*}, v, q)dW_v,$$

where

$$\zeta_t^q := \phi_t^q - \phi_t^{q^*} + \int_s^t B(\xi_v^{q^*}, v, q) - B(\xi_v^{q^*}, v, q^*)dv + \int_s^t S(\xi_v^{q^*}, v, q) - S(\xi_v^{q^*}, v, q^*)dW_v.$$

Using the Lipschitz conditions,

$$\mathbb{E}|\xi_t^q - \xi_t^{q^*}|^2 \le 3\mathbb{E}|\zeta_t^q|^2 + 6L^2 \int_s^t \mathbb{E}|\xi_v^q - \xi_v^{q^*}|^2 dv,$$

which by Gronwall's lemma implies

$$\sup_{t\in[s,T]} \mathbb{E}|\xi_t^q - \xi_t^{q^*}|^2 \le 3e^{6L^2T} \sup_{t\in[s,T]} \mathbb{E}|\zeta_t^q|^2.$$

Thus, it remains to show that $\sup_{t\in[s,T]} \mathbb{E}|\zeta_t^q|^2 \to 0$ as $h \to 0$. Now,

$$\sup_{t\in[s,T]} \mathbb{E}|\zeta_t^q|^2 \le 3 \sup_{t\in[s,T]} \mathbb{E}|\phi_t^q - \phi_t^{q^*}|^2 + 3T \int_s^T \mathbb{E}|B(\xi_v^{q^*}, v, q) - B(\xi_v^{q^*}, v, q^*)|^2 dv + 3\int_s^T \mathbb{E}|S(\xi_v^{q^*}, v, q) - S(\xi_v^{q^*}, v, q^*)|^2 dv.$$

For each $v \in [s,T]$, the assumption (i) together with the a.s. continuity of B implies $B(\xi_v^{q^*}, v, q) \to B(\xi_v^{q^*}, v, q^*)$ in probability. Moreover, by Assumption A.1 (ii) the last integrand is bounded by $2L^2(1+\sup_{v\in[s,T]}|\xi_v^{q^*}|^2)$, which is integrable. By the dominated convergence theorem, the integral vanishes in the limit $h \to 0$. A similar calculation shows the last integral also vanishes in the same limit. Together with (iii), we arrive at our assertion. ■

Appendix B. Derivatives with respect to initial condition

Let us denote by $\{X_t^{x,s,q} : t \ge 0\}$ the stochastic process defined by the SDE

$$dX_t^{x,s,q} = b(X_t^{x,s,q}, q)dt + \sigma(X_t^{x,s,q}, q)dW_t, \quad t \in [s,T], \qquad X_s^{x,s,q} = x. \tag{B.1}$$

As in the previous section, $q \in Q$ where Q is a subset of a Euclidean space. Throughout this section, we assume the following:

Assumption B.1 *The (non-random) functions b, σ satisfy*

1. *Uniform linear growth condition*

$$|b(x,q)|^2 + |\sigma(x,q)|^2 \le L^2(1+|x|^2)$$

for all $x \in \mathbb{R}^d$, $q \in Q$.

2. *Uniform Lipschitz condition*

$$|b(x,q) - b(y,q)| + |\sigma(x,q) - \sigma(y,q)| \le L|x-y|$$

for all $x, y \in \mathbb{R}^d$, $q \in Q$.

With the above assumptions, by Thm. 18 the SDE (B.1) admits a unique solution. The focus of this section is to derive the SDEs that characterize the derivatives of $X_t^{x,s,q}$ with respect to x, the initial condition. In doing so, we will make use the results proved in Sec. A.

Definition 21 *Let $\Psi : \mathbb{R}^d \to \mathbb{R}$ and $\psi : \mathbb{R}^d \to \mathbb{R}^d$ be random functions and suppose for each $i = 1, \dots, d$,*

$$\lim_{h\to 0} \mathbb{E}\left|\tfrac{1}{h}[\Psi(x_{(1)}, \dots, x_{(i-1)}, x_{(i)} + h, x_{(i+1)}, \dots, x_{(d)}) - \psi_i(x_{(1)}, \dots, x_{(d)})] - \psi_{(i)}(x)\right|^2 = 0.$$

Then, we call ψ the derivative (in the $\mathcal{L}^2(\Omega)$ sense) of Ψ and write $\partial_{(i)}\Psi = \psi_{(i)}$, or $\nabla\Psi = \psi$. For multidimensional Ψ, we similarly define the derivative element-wise. Note that the derivative is almost surely unique, if it exists.

Lemma 22 *Let $s \in [0,T)$, $q \in Q$ and suppose that b and σ are continuously differentiable with respect to x. Then, $\nabla X_t^{x,s,q}$ exists and if we write $\xi_{(i,j),t}^{x,s,q} := \partial_{(j)} X_{(i),t}^{x,s,q}$, then it satisfies the linear random-coefficient stochastic differential equation*

$$\xi_{(i,j),t}^{x,s,q} = \delta_{(i,j)} + \int_s^t \xi_{(k,j),v}^{x,s,q} \partial_{(k)} b(X_v^{x,s,q}, v, q)_{(i)} dv + \int_s^t \xi_{(k,j),v}^{x,s,q} \partial_{(k)} \sigma(X_v^{x,s,q}, v, q)_{(i,l)} dW_{(l),v}, \tag{B.2}$$

where δ is the usual Kronecker delta. Moreover, we have

$$\sup_{q\in Q} \mathbb{E} \sup_{t\in[s,T]} |\xi_t^{x,s,q}|^{2m} < \infty$$

for all $m \ge 1$.

Proof Let j be fixed and h^j be a d-dimensional vector of 0's except the j^{th} coordinate where it is equal $h_{(j)}^j = h \ne 0$. Then, we have

$$\tfrac{1}{h}(X_{(i),t}^{x+h^j,s,q} - X_{(i),t}^{x,s,q}) = \delta_{(i,j)} + \tfrac{1}{h}\int_s^t b(X_v^{x+h^j,s,q}, q)_{(i)} - b(X_v^{x,s,q}, q)_{(i)} dv + \tfrac{1}{h}\int_s^t \sigma(X_v^{x+h^j,s,q}, q)_{(i,l)} - \sigma(X_v^{x,s,q}, q)_{(i,l)} dW_{(l),v}.$$

But,

$$\tfrac{1}{h}\int_s^t b(X_v^{x+h^j,(i),s}, q)_{(i)} - b(X_v^{x,s,q}, q)_{(i)} dv = \int_0^1 \int_s^t \tfrac{1}{h}(X_{(k),v}^{x+h^j,s,q} - X_{(k),v}^{x,s,q}) \partial_{(k)} b(\lambda X_v^{x+h^j,s,q} + (1-\lambda)X_v^{x,s,q})_{(i)} dv d\lambda,$$

and similarly,

$$\begin{aligned}&\frac{1}{h}\int_s^t \sigma(X_v^{x+h^j,s,q},q)_{(i,l)} - \sigma(X_v^{x,s,q},q)_{(i,l)}dW_{(l),v}\\ =&\int_0^1\int_s^t \frac{1}{h}(X_{(k),v}^{x+h^j,s,q} - X_{(k),v}^{x,s,q})\partial_{(k)}\sigma(\lambda X_v^{x+h^j,s,q} + (1-\lambda)X_v^{x,s,q})_{(i,l)}dW_{(l),v}d\lambda.\end{aligned}$$

Therefore, $\xi_t^{x,s,q,h} := \frac{1}{h}(X_t^{x+h^j,s,q} - X_t^{x,s,q})$ satisfies (A.2) with $Q\times[0,1]$ in place of Q, $\phi_{t,(i,j)}^{q,h} = \delta_{(i,j)}$ and

$$\begin{aligned}B(z,t,q,h)_{(i)} &= z_{(k)}\int_0^1\int_s^t \partial_{(k)}b(\lambda X_v^{x+h^j,s,q} + (1-\lambda)X_v^{x+h^j,s,q},q)_{(i)}dvd\lambda,\\ S(z,t,q,h)_{(i)} &= z_{(k)}\int_0^1\int_s^t \partial_{(k)}\sigma(\lambda X_v^{x+h^j,s,q} + (1-\lambda)X_v^{x+h^j,s,q},q)_{(i,l)}dW_{(l),v}d\lambda,\end{aligned}$$

if $h>0$. If $h<0$ we simply consider $-h$ on the left hand side instead and the proof is identical. Furthermore, the uniform Lipschitz conditions on b,σ implies bounded derivatives and so we may apply Thm. 18 to conclude that there is a process $\xi_t^{0,q}$ satisfying (A.2) with $h=0$, i.e. satisfies (B.2).

It remains to show $\xi_t^{q,h}\to\xi_t^{q,0}$ in $\mathcal{L}^2(\Omega)$ uniformly in $t\in[s,T]$, which amounts to checking conditions (i)-(iii) in Thm. 20, with $q^*=(q,0)$. The last condition (iii) is trivially satisfied. As for the first two, it is enough to show that $X_t^{x+h^j,s,q}\to X_t^{x,s,q}$ in $\mathcal{L}^2(\Omega)$ as $h\to 0$, uniformly in x, which follows from the straightforward estimate

$$\begin{aligned}\mathbb{E}|X_t^{x,s,q} - X_t^{x+h^j,s,q}|^2 \le& 3h^2 + C\int_s^t \mathbb{E}|X_v^{x,s,q} - X_v^{x+h^j,s,q}|^2dv\\ \le& C'h^2.\end{aligned}$$

Now, we may apply Thm. 20 to deduce the satisfaction of the SDE. Finally, the last moment estimate follows from Thm. 19. ∎

Let us now extend the above result to higher order derivatives. As before, we denote the order α partial derivative of Ψ in the $\mathcal{L}^2(\Omega)$ sense by

$$\partial_{(J)}^{\alpha}\Psi \equiv \partial_{(j_1,\dots,j_\alpha)}^{\alpha}\Psi$$

where J is an order α multi-index.

Lemma 23 *Suppose that $b,\sigma\in G^2$. Then, for each $i,j_1,j_2\in\{1,\dots,d\}$, the derivative $\xi_{(i,j_1,j_2),t}^{2,x,s,q} := \partial_{(j_1,j_2)}^2 X_{(i),t}^{x,s,q}$ exists and is the unique solution of the linear random-coefficient*

stochastic differential equation

$$\xi_{(i,j_1,j_2),t}^{2,x,s,q} = \int_s^t \partial_{(k_1,k_2)}^2 b(X_v^{x,s,q},q)_{(i)}\xi_{(k_1,j_1),v}^{1,x,s,q}\xi_{(k_2,j_2),v}^{1,x,s,q}dv \tag{B.3}$$

$$+\int_s^t \partial_{(k_1,k_2)}^2\sigma(X_v^{x,s,q},q)_{(i,l)}\xi_{(k_1,j_1),v}^{1,x,s,q}\xi_{(k_2,j_2),v}^{1,x,s,q}dW_{(l),v} \tag{B.4}$$

$$+\int_s^t \partial_{(k)}b(X_v^{x,s,q},q)_{(i)}\xi_{(k,j_1,j_2),v}^{2,x,s,q}dv \tag{B.5}$$

$$+\int_s^t \partial_{(k)}\sigma(X_v^{x,s,q},q)_{(i,l)}\xi_{(k,j_1,j_2),v}^{2,x,s,q}dW_{(l),v} \tag{B.6}$$

where $\xi_{(i,j),t}^{1,x,s,q} := \partial_{(j)}X_{(i),t}^{x,s,q}$ is the first derivative. Moreover, for each $m\ge 1$, we have $\mathbb{E}\sup_{t\in[s,T]}|\xi_t^{2,x,s,q}|^{2m}\in G$, i.e.

$$\sup_{q\in Q,s\in[0,T]}\mathbb{E}\sup_{t\in[s,T]}|\xi_t^{2,x,s,q}|^{2m}\le\kappa_1(1+|x|^{2\kappa_2}) \tag{B.7}$$

Proof Let us denote

$$\begin{aligned}\phi_{(i,j_1,j_2),t}^{x,s,q} =& \int_s^t \partial_{(k_1,k_2)}^2 b(X_v^{x,s,q},q)_{(i)}\xi_{(k_1,j_1),v}^{1,x,s,q}\xi_{(k_2,j_2),v}^{1,x,s,q}dv\\ &+\int_s^t \partial_{(k_1,k_2)}^2\sigma(X_v^{x,s,q},q)_{(i,l)}\xi_{(k_1,j_1),v}^{1,x,s,q}\xi_{(k_2,j_2),v}^{1,x,s,q}dW_{(l),v}.\end{aligned}$$

Note that by Lem. 22, $\mathbb{E}\sup_{t\in[s,T]}|\xi_t^{1,x,s,q}|^{2m}$ is finite for any $m\ge1$. Then, proceeding as in the proof of Lem. 22, we have

$$\begin{aligned}&\mathbb{E}\sup_{t\in[s,T]}|\phi_t^{x,s,q}|^2\\ \le& C\mathbb{E}\sup_{t\in[s,T]}\left(|\nabla^2 b(X_t^{x,s,q},q)|^2 + |\nabla^2\sigma(X_t^{x,s,q},q)|^2\right)|\xi_t^{1,x,s,q}|^4\\ \le& C\left[\mathbb{E}\sup_{t\in[s,T]}\left(|\nabla^2 b(X_t^{x,s,q},q)|^2 + |\nabla^2\sigma(X_t^{x,s,q},q)|^2\right)^2\right]^{1/2}\left[\mathbb{E}\sup_{t\in[s,T]}|\xi_t^{1,x,s,q}|^8\right]^{1/2}\end{aligned}$$

Here, C is independent of q and s. From the above, using the assumption that $b,\sigma\in G^2$, and the moment estimate in Thm. 19 on $X_t^{x,s,q}$, we conclude that

$$\sup_{q\in Q,s\in[0,T]}\mathbb{E}\sup_{t\in[s,T]}|\phi_t^{x,s,q}|^2\le\kappa_1(1+|x|^{2\kappa})$$

thus (B.3) admits a unique solution by Thm. 18, and the solution $\xi_t^{2,x,s,q}$ satisfies the same estimate. Moreover, the estimate above holds for any $2m$ power for $m\ge1$ by a similar calculation, which shows that $\mathbb{E}\sup_{t\in[s,T]}|\xi_t^{2,x,s,q}|^{2m}\in G$.

Finally, To show that $\xi_t^{2,x,s,q}$ is the second derivative of $X_t^{x,s,q}$ with respect to x, we proceed analogously as in the proof of 22, thanks to estimate (B.7) and polynomial growth

conditions, all the estimates required for interchanging the derivative and the integral signs are satisfied, so the equation for $\xi_t^{2,x,s,q}$ is obtained by formally differentiating under the integral sign with respect to x, which is precisely (B.3). ■

Lemma 24 *For each $\alpha \geq 1$, suppose that $b, \sigma \in G^{\alpha+1}$, then, the derivative $\nabla^{\alpha+1} X_t^{x,s,q}$ exists and is the unique a.s. continuous solution of the linear random-coefficient SDE*

$$\xi_{(i,J),t}^{\alpha+1,x,s,q} = \phi_{(i,J),t}^{x,s,q} + \int_s^t \partial_{(k)} b(X_v^{x,s,q}, q)_{(i)} \xi_{(k,J),t}^{\alpha+1,x,s,q} dv \tag{B.8}$$

$$+ \int_s^t \partial_{(k)} \sigma(X_v^{x,s,q}, q)_{(i,l)} \xi_{(k,J),t}^{\alpha+1,x,s,q} dW_{(l),v}, \tag{B.9}$$

where J is a multi-index of order $\alpha+1$ and $\phi_t^{x,s,q}$ is an a.s. continuous stochastic process satisfying $\mathbb{E}\sup_{t\in[s,T]} |\phi_t^{x,s,q}|^{2m} \in G$ for all $m \geq 1$. In fact, (B.8) *is obtained by formally differentiating* (B.2) *under the integral sign α times. Moreover, we have $\mathbb{E}\sup_{t\in[s,T]} |\xi_t^{\alpha+1,x,s,q}|^{2m} \in G$ for all $m \geq 1$.*

Proof The proof is identical to the $\alpha = 1$ case in Lem. 23. We omit writing out the whole proof here. ■

We now prove the following useful result, which imparts polynomial growth conditions onto expectations functionals.

Proposition 25 *Let $s \in [0,T]$ and $g \in G^{\alpha+1}$ for some $\alpha \geq 1$. For $t \in [s,T]$, define*

$$u(x,s,q,t) := \mathbb{E} g(X_t^{x,s,q})$$

Then, $u(\cdot, s, q, t) \in G^{\alpha+1}$ uniformly in s, q, t.

Proof Consider first the case $\alpha = 1$. We shall use the results in Lem. 22-24 to show that

$$\partial_{(i)} u(x,s,q,t) = \mathbb{E} \partial_{(k)} g(X_t^{x,s,q}) \partial_{(i)} X_{(k),t}^{x,s,q}$$

and that $\partial_{(i)} u(x,s,q,t) \in G$. Let h^j be defined as in the proof of 22, we have

$$\begin{aligned}
&\tfrac{u(x+h^j,s,q,t)-u(x,s,q,t)}{h} \\
=&\mathbb{E} \int_0^1 \tfrac{1}{h} \tfrac{d}{d\lambda} g(\lambda X_t^{x+h^j,s,q} + (1-\lambda) X_t^{x,s,q}) d\lambda \\
=&\mathbb{E} \int_0^1 \partial_{(k)} g(\lambda X_t^{x+h^j,s,q} + (1-\lambda) X_t^{x,s,q}) d\lambda \tfrac{X_{(k),t}^{x+h^j,s,q} - X_{(k),t}^{x,s,q}}{h}.
\end{aligned}$$

Now, $\frac{1}{h}(X_t^{x+h^j,s} - X_t^{x,s,q}) \to \partial_{(j)} X_t^{x,s,q}$ in $\mathcal{L}^2(\Omega)$. Moreover, set

$$I_h := \int_0^1 \partial_{(k)} g(\lambda X_t^{x+h^j,s,q} + (1-\lambda) X_t^{x,s,q}) d\lambda.$$

Since ∇g is continuous, $|I_h - \partial_{(k)} g(X_t^{x,s,q})|^2 \to 0$ in probability. Moreover,

$$\mathbb{E}|I_h - \partial_{(k)} g(X_t^{x,s,q})|^4 < \infty$$

by the assumption that $g \in G^1$. Thus, $\{|I_h - \partial_{(k)} g(X_t^{x,s,q})|^2 : h \in [0,1]\}$ is uniformly integrable and so $I_h \to \partial_{(k)} g(X_t^{x,s,q})$ in $\mathcal{L}^2(\Omega)$. We have thus arrived at

$$\partial_{(i)} u(x,s,q,t) = \mathbb{E} \partial_{(k)} g(X_t^{x,s,q}) \partial_{(i)} X_{(k),t}^{x,s,q},$$

and in particular,

$$|\nabla u(x,s,q,t)|^2 \leq \mathbb{E}|\nabla g(X_t^{x,s,q})|^2 \mathbb{E}|\nabla X_t^{x,s,q}|^2 \in G,$$

where we have used Thm. 19 and 22. The proof for higher order derivatives follow accordingly by the above procedure, using Lem. 24. ■

Appendix C. Auxiliary results for the proof of Thm. 3

Lemma 26 *Let $\alpha \geq 1$ and suppose b, σ satisfy Assumption B.1. Then, there exists a $K \in G$, independent of η and ϵ, such that*

$$\mathbb{E} \prod_{j=1}^{\alpha+1} \left| \widetilde{\Delta}_{(i_j)} \right| \leq K(x) \eta^{\alpha+1}.$$

where $i_j \in \{1, \ldots, d\}$ and $C > 0$ is independent of η.

Proof We have

$$\begin{aligned}
\mathbb{E}|\widetilde{\Delta}(x)|^{\alpha+1} \leq& 2^\alpha \mathbb{E} \left| \int_0^\eta b(X_s^{x,0}, \eta, \epsilon) ds \right|^{\alpha+1} + 2^\alpha \eta^{\frac{\alpha+1}{2}} \mathbb{E} \left| \int_0^\eta \sigma(X_s^{x,0}, \eta, \epsilon) dW_s \right|^{\alpha+1} \\
\leq& 2^\alpha \eta^\alpha \int_0^\eta \mathbb{E}|b(X_s^{x,0}, \eta, \epsilon)|^{\alpha+1} ds + 2^\alpha \eta^{\frac{\alpha+1}{2}} \left| \int_0^\eta \sigma(X_s^{x,0}, \eta, \epsilon) dW_s \right|^{\alpha+1}
\end{aligned}$$

Using Cauchy-Schwarz inequality, Itô's isometry, we get

$$\begin{aligned}
\mathbb{E} \left| \int_0^\eta \sigma(X_s^{x,0}, \eta, \epsilon) dW_s \right|^{\alpha+1} \leq& \left(\mathbb{E} \left| \int_0^\eta \sigma(X_s^{x,0}, \eta, \epsilon) dW_s \right|^{2\alpha+2} \right)^{1/2} \\
\leq& C \eta^{\alpha/2} \left(\int_0^\eta \mathbb{E}|\sigma(X_s^{x,0}, \eta, \epsilon)|^{2\alpha+2} ds \right)^{1/2}
\end{aligned}$$

where C depends only on α. Now, using the linear growth condition (B.1 (i)) and the moment estimates in Thm. 19, we obtain the result. ■

Lemma 27 *Suppose $u \in G^{(\alpha+1)}$ for some $\alpha \geq 1$. Let assumption (i) in Thm. 3 hold. Then, there exists some $K \in G$, independent of η, ϵ, such that*

$$\left|\mathbb{E}u(x_1^{x,0}) - \mathbb{E}u(\widetilde{X}_1^{x,0})\right| \leq K(x)(\eta\rho(\epsilon) + \eta^{\alpha+1})$$

Proof Using Taylor's theorem with the Lagrange form of the remainder, we have

$$\begin{aligned}
u(x_1^{x,0}) - u(\widetilde{X}_1^{x,0}) =& \sum_{s=1}^{\alpha} \tfrac{1}{s!} \sum_{i_1,\ldots,i_j=1}^{d} \prod_{j=1}^{s} [\Delta_{(i_j)}(x) - \widetilde{\Delta}_{(i_j)}(x)] \tfrac{\partial^s u}{\partial x_{(i_1)},\ldots x_{(i_j)}}(x) \\
&+ \tfrac{1}{(\alpha+1)!} \sum_{i_1,\ldots,i_j=1}^{d} \prod_{j=1}^{\alpha+1} [\Delta_{(i_j)}(x) - \widetilde{\Delta}_{(i_j)}(x)] \\
&\times \left[\tfrac{\partial^{(\alpha+1)} u}{\partial x_{(i_1)},\ldots x_{(i_j)}}(x + a\Delta(x)) - \tfrac{\partial^{(\alpha+1)} u}{\partial x_{(i_1)},\ldots x_{(i_j)}}(x + \widetilde{a}\widetilde{\Delta}(x)) \right],
\end{aligned}$$

where $a, \widetilde{a} \in [0,1]$. Taking expectations, using assumption (i) of Thm. 4.1 and Lem. 26, we get

$$|\mathbb{E}u(x_1^{x,0}) - \mathbb{E}u(\widetilde{X}_1^{x,0})| \leq K(x)(\eta\rho(\epsilon) + \eta^{\alpha+1}).$$

■

Appendix D. Auxiliary results for the proof of Thm. 9

Set in (4.2)

$$\begin{aligned}
b(x,\eta,\epsilon) &= b_0(x,\epsilon) + \eta b_1(x,\epsilon) \\
\sigma(x,\eta,\epsilon) &= \sigma_0(x,\epsilon),
\end{aligned}$$

We prove the following Itô-Taylor expansion.

Lemma 28 *Let $\psi : \mathbb{R}^d \to \mathbb{R}$ be a sufficiently smooth function and define the operators*

$$\begin{aligned}
A_{\epsilon,0}\psi(x) :=& b_0(x,\epsilon)_{(i)} \partial_{(i)} \psi(x) \\
A_{\epsilon,1}\psi(x) :=& b_1(x,\epsilon)_{(i)} \partial_{(i)} \psi(x) + \tfrac{1}{2} \sigma_0(x,\epsilon)_{(i,k)} \sigma_0(x,\epsilon)_{(j,k)} \partial^2_{(i,j)} \psi(x) \\
[\Lambda_{\epsilon,0} g(x)]_{(l)} :=& \sigma_0(x,\epsilon)_{(i,l)} \partial_{(i)} \psi(x), \qquad l = 1,\ldots,d.
\end{aligned}$$

Suppose further that $b_0, b_1, \sigma_0 \in G^3$. Then, we have

$$\mathbb{E}\psi(X_\eta^{x,0}) = \psi(x) + \eta A_{\epsilon,0}\psi(x) + \eta^2(\tfrac{1}{2}A^2_{\epsilon,0} + A_{\epsilon,1})\psi(x) + \mathcal{O}(\eta^3).$$

Proof Using Itô's formula, we have

$$\begin{aligned}
\psi(X_\eta^{x,0}) =& \psi(x) + \int_0^\eta A_{\epsilon,0}\psi(X_s^{x,0})ds + \eta \int_0^\eta A_{\epsilon,1}\psi(X_s^{x,0})ds \\
&+ \sqrt{\eta} \int_0^\eta \Lambda_{\epsilon,0}\psi(X_s^{x,0}) dW_s
\end{aligned}$$

By further application of the above formula to $A_{\epsilon,0}\psi$ and $A_{\epsilon,1}\psi$, we have

$$\begin{aligned}
\psi(X_\eta^{x,0}) =& \psi(x) + \eta A_{\epsilon,0}\psi(x) + \eta^2(\tfrac{1}{2}A^2_{\epsilon,0} + A_{\epsilon,1})\psi(x) \\
&+ \eta \int_0^\eta \int_0^s (A_{\epsilon,1}A_{\epsilon,0} + A_{\epsilon,0}A_{\epsilon,1})\psi(X_v^{x,0}) dv ds \\
&+ \int_0^\eta \int_0^s \int_0^v A^3_{\epsilon,0}\psi(X_r^{x,0}) dr dv ds \\
&+ \eta^2 \int_0^\eta \int_0^s A^2_{\epsilon,1}\psi(X_v^{x,0}) dv ds \\
&+ \eta \int_0^\eta \int_0^s \int_0^v A_{\epsilon,1}A^2_{\epsilon,0}\psi(X_r^{x,0}) dr dv ds \\
&+ \sqrt{\eta} \int_0^\eta \Lambda_{\epsilon,0}\psi(X_s^{x,0}) dW_s \\
&+ \sqrt{\eta} \int_0^\eta \int_0^s \Lambda_{\epsilon,0}A_{\epsilon,0}\psi(X_v^{x,0}) dW_v ds \\
&+ \sqrt{\eta} \int_0^\eta \int_0^s \int_0^v \Lambda_{\epsilon,0}A^2_{\epsilon,0}\psi(X_r^{x,0}) dW_r dv ds \\
&+ \eta^{3/2} \int_0^\eta \int_0^s \Lambda_{\epsilon,0}A_{\epsilon,1}\psi(X_v^{x,0}) dW_v ds
\end{aligned}$$

Taking expectations of the above, it remains to show that each of the terms in the integral either vanishes, or is $\mathcal{O}(\eta^3)$. This follows immediately from the assumption that $b_0, b_1, \sigma_0 \in G^3$ and $\psi \in G^4$. Indeed, observe that all the integrands have at most 3 derivatives in b_0, b_1, σ_0 and 4 derivatives in ψ, which by our assumptions all belong to G. Thus, the expectation of each integrand is bounded by $\kappa_1(1 + \sup_{t\in[0,\eta]} \mathbb{E}|X_t^{x,0}|^{2\kappa_2})$ for some κ_1, κ_2, which by Thm. 19 must be finite. Thus, the last 3 stochastic integrals are martingales and their expectation vanish, and the expectations of the other integrals are $\mathcal{O}(\eta^3)$ by the polynomial growth assumption and moment estimates in Thm. 19. ■

We also prove a general moment estimate for the generalized SGA iterations 4.1.

Lemma 29 *Let $\{x_k : k \geq 0\}$ be the generalized SGA iterations defined in 4.1. Suppose*

$$|h(x,\gamma,\eta)| \leq L_\gamma(1 + |x|)$$

for some random variable $L_\gamma > 0$ a.s. and $\mathbb{E}{L_\gamma}^m < \infty$ for all $m \geq 1$. Then, for fixed $T > 0$ and any $m \geq 1$, $\mathbb{E}|x_k|^m$ exists and is uniformly bounded in η and $k = 0,\ldots,N \equiv \lfloor T/\eta \rfloor$.

Proof For each $k \geq 0$, we have

$$|x_{k+1}|^m \leq |x_k|^l + \sum_{l=1}^{m} \binom{m}{l} |x_k|^{m-l} \eta^l |h(x_k,\gamma_k,\eta)|^{m-l}$$

Now, for $1 \leq l \leq m$,

$$\begin{aligned}
\mathbb{E}|x_k|^{m-l}|h(x_k,\gamma_k,\eta)|^l =& \mathbb{E}|x_k|^{m-l}\mathbb{E}(|h(x_k,\gamma_k,\eta)|^l|x_k) \\
\leq& \mathbb{E}(L_\gamma^l)\mathbb{E}|x_k|^{m-l}(1 + |x_k|^l) \\
\leq& 2\mathbb{E}(L_\gamma^l)(1 + \mathbb{E}|x_k|^m).
\end{aligned}$$

Hence, if we let $a_k := \mathbb{E}|x_k|^m$, we have

$$a_{k+1} \le (1 + C\eta)a_k + C'\eta$$

where $C, C' > 0$ are independent of η and k, which immediately implies

$$\begin{aligned} a_k \le & (a_0 + C'/C)(1 + C\eta)^k - C'/C \\ \le & (|x_0|^m + C'/C)e^{(T/\eta)\log(1+C\eta)} - C'/C \\ \le & (|x_0|^m + C'/C)e^{CT} - C'/C. \end{aligned}$$

■

We also need the following result concerning mollified functions.

Lemma 30 *Let $\epsilon \in (0, 1)$ and ψ be continuous with its weak derivative $D\psi$ belonging to G_w. Denote by $\psi^\epsilon = \nu^\epsilon * \psi$ the mollification of ψ. Then, there exists a $K \in G$ independent of ϵ such that*

$$|\psi^\epsilon(x) - \psi(x)| \le \epsilon K(x)$$

Proof We have for almost every x,

$$\begin{aligned} |\psi^\epsilon(x) - \psi(x)| \le & \int_{\mathcal{B}(0,\epsilon)} \nu^\epsilon(y)|\psi(x - y) - \psi(x)|dy \\ = & \int_{\mathcal{B}(0,\epsilon)} \nu^\epsilon(y) \left| \int_0^1 D\psi(x - \lambda y) \cdot y d\lambda \right| dy \\ \le & \epsilon \int_{\mathcal{B}(0,\epsilon)} \int_0^1 \nu^\epsilon(y)|D\psi(x - \lambda y)|d\lambda dy \\ \le & \epsilon \int_{\mathcal{B}(0,\epsilon)} \nu^\epsilon(y)\kappa_1[1 + \kappa_2(|x| + |y|)]dy \\ \le & \epsilon K(x). \end{aligned}$$

Since ψ is continuous, the above equality holds for all $x \in \mathbb{R}^d$. ■

Appendix E. Auxiliary results for computations in Sec. 5

Lemma 31 *Let A be a real square matrix such that all eigenvalues have positive real part. Then,*

(i) For each $\epsilon > 0$, there exists a constant $C_\epsilon > 0$ independent of t but depends on ϵ, such that

$$|e^{-tA}| \le C_\epsilon e^{-t(\min_i \Re\lambda_i(A) - \epsilon)}$$

(ii) If in addition A is diagonalizable, then there exists a constant $C > 0$ independent of t such that

$$|e^{-tA}| \le Ce^{-t \min_i \Re\lambda_i(A)}$$

Proof (i) We know that A is similar to a Jordan block matrix J so that $e^{-At} = Pe^{-Jt}P^{-1}$. Hence, $|e^{-At}| \le |P||P^{-1}||e^{-Jt}|$. For each Jordan block J_k, we have $J_k = \lambda_k I + N_k$ where N_k is nilpotent ($N_k^k = 0$). Hence,

$$\begin{aligned} e^{-J_k t} = & e^{-\lambda_k I t}e^{-N_k t} = e^{-\lambda_k t} \sum_{m=0}^{k-1} \frac{N_k^m}{m!}(-t)^m \\ = & e^{-(\lambda_k - \epsilon)t} \left[\sum_{m=0}^{k-1} \frac{N_k^m}{m!}(-t)^m e^{-\epsilon t} \right]. \end{aligned}$$

For each $\epsilon > 0$ the norm of the last term is uniformly bounded in t, and hence we obtain the result.

(ii) We denote the similarity transformation $A = PDP^{-1}$ where D is the diagonal matrix of eigenvalues of A. Defining $Q := P^\dagger P$ ($\dagger$ denotes conjugate transpose), we have

$$|e^{-tA}| = \mathrm{Tr}(e^{-tA^T}e^{-tA}) = \mathrm{Tr}(Q^{-1}e^{-tD^\dagger}Qe^{-tD})$$

Abstract

Many machine learning problems can be characterized by *mutual contamination models*. In these problems, one observes several random samples from different convex combinations of a set of unknown base distributions and the goal is to infer these base distributions. This paper considers the general setting where the base distributions are defined on arbitrary probability spaces. We examine three popular machine learning problems that arise in this general setting: multiclass classification with label noise, demixing of mixed membership models, and classification with partial labels. In each case, we give sufficient conditions for identifiability and present algorithms for the infinite and finite sample settings, with associated performance guarantees.

Keywords: multiclass classification with label noise, classification with partial labels, mixed membership models, topic modeling, mutual contamination models

1. Introduction

In many machine learning problems, the learner observes several random samples from different mixtures of unknown base distributions, with unknown mixing weights, and the goal is to infer these base distributions. Examples include binary classification with label noise, multiclass classification with label noise, classification with partial labels, and topic modeling. The goal of this paper is to develop a unified framework and set of tools to study statistical properties of these problems in a very general setting.

To this end, we use the general framework of mutual contamination models (Blanchard and Scott, 2014). In a mutual contamination model, there are L distributions $P_1, \ldots, P_L$ called *base distributions*. The learner observes M random samples

$$X_1^i, \ldots, X_{n_i}^i \overset{i.i.d.}{\sim} \tilde{P}_i = \sum_{j=1}^{L} \pi_{i,j} P_j \tag{1}$$

where $i = 1, \ldots, M$, $\pi_{i,j} \geqslant 0$, and $\sum_j \pi_{i,j} = 1$. Here $\pi_{i,j}$ is the probability that an instance of the *contaminated distribution* $\tilde{P}_i$ is a realization of P_j. The $\pi_{i,j}$s and P_js are unknown and the $\tilde{P}_i$s are observed through data. In this work, we avoid parametric models and assume that the sample space is arbitrary. The model can be stated concisely as

$$\tilde{\boldsymbol{P}} = \boldsymbol{\Pi} \boldsymbol{P} \tag{2}$$

where $\boldsymbol{P} = (P_1, \ldots, P_L)^T$, $\tilde{\boldsymbol{P}} = (\tilde{P}_1, \ldots, \tilde{P}_M)^T$, and $\boldsymbol{\Pi} = \left(\pi_{i,j}\right)$ is an $M \times L$ matrix that we call the *mixing matrix*.

In this paper we study *decontamination* of mutual contamination models, which is the problem of recovering, or estimating, the base distributions $\boldsymbol{P}$ from the contaminated distributions $\tilde{\boldsymbol{P}}$ from which data are observed, without knowledge of the mixing matrix $\boldsymbol{\Pi}$. We focus our attention on three specific types of mutual contamination models, all of which describe modern problems in machine learning: multiclass classification with label noise, demixing of mixed membership models and classification with partial labels. We will demonstrate that these three decontamination problems can be addressed using a common set of concepts and techniques. Before elaborating our contributions in detail, we first offer an overview of the three specific mutual contamination models, and associated decontamination problems, that we study.

Multiclass Classification with Label Noise: In multiclass classification with label noise, $M = L$ and the goal is to recover $\boldsymbol{P}$. Each P_i represents the distribution of a class of examples. The learner observes training examples with noisy labels, that is, realizations from the $\tilde{P}_j$s. This problem arises in nuclear particle classification (Scott et al., 2013). When one draws samples of a specific particle, it is impossible to remove other types of particles from the background. Thus, each example is drawn from a mixture of the different types of particles.

Demixing of Mixed Membership Models: We consider the following decontamination problem in mixed membership models: given a sample from each $\tilde{P}_i$, recover $\boldsymbol{P}$ up to a permutation. We refer to this decontamination problem as *demixing of mixed membership models*. This problem arises in the task of automatically uncovering the thematic topics of a corpus of documents. Under the mixed membership model approach, the words of each document are thought of as being drawn from a document-specific mixture of topics. Specifically, documents correspond to the $\tilde{P}_i$s and the topics to the P_is. This approach is also referred to as topic modeling. As we discuss in the next section, our theory significantly generalizes existing topic modeling theoretical guarantees.

Classification with Partial Labels:[1] In classification with partial labels, each data point is labeled with a *partial label* $Y \subset \{1, \ldots, L\}$; the true label is in Y, but it is not known which label is the true one. In our setup, we view the ith random sample as having partial label $Y_i \coloneqq \{j : \boldsymbol{\pi}_{i,j} > 0\}$ and being distributed according to $\tilde{P}_i = \sum_{j \in Y_i} \pi_{i,j} P_j$. Thus, the learner observes training examples from the contaminated distributions $\tilde{\boldsymbol{P}}$ and the *partial label matrix* $\boldsymbol{\Pi}^+ = (\mathbf{1}_{\{\boldsymbol{\Pi}_{i,j} > 0\}})$, and the goal is to recover $\boldsymbol{P}$.

There are many applications of classification with partial labels because often abundant sources of data are naturally associated with information that can be interpreted as partial

1. Classification with partial labels has also been referred to as the "superset learning problem" or the "multiple label problem" (Liu and Dietterich, 2014).

labels. For example, consider the task of face recognition. On the internet, there are many images with captions that indicate who is in the picture but do not indicate which face belongs to which person. A partial label could be formed by associating each face with the names of the individuals appearing in the same image (Cour et al., 2011).

Although our work emphasizes recovery of $\boldsymbol{P}$, it is also possible to think of decontamination of mutual contamination models as concerned with estimation of the mixing matrix $\boldsymbol{\Pi}$. This estimate of $\boldsymbol{\Pi}$ could be used as a plug-in for recently developed debiased losses for multiclass classification with label noise and classification with partial labels, which require knowledge of $\boldsymbol{\Pi}$ (Cid-Sueiro, 2012; Menon et al., 2015b; van Rooyen and Williamson, 2015; Patrini et al., 2017).

In this paper, we make the following contributions: (i) We give sufficient conditions on $\boldsymbol{P}$, $\boldsymbol{\Pi}$, and $\boldsymbol{\Pi}^+$ for identifiability of the three problems. (ii) We establish necessary conditions that in some cases match or are similar to the sufficient conditions. (iii) We introduce novel algorithms for the infinite and finite sample settings. These algorithms are nonparametric in the sense that they do not model P_i as a probability vector or other parametric model. Our algorithmic contributions show that while all three problems can be described in a unified way, the special structure of multiclass classification with label noise allows for a substantially simpler algorithm. (iv) We develop novel estimators for distributions obtained by iteratively applying the κ^* operator (defined below). (v) Finally, our framework gives rise to several novel geometric insights about each of these three problems and leverages concepts from affine geometry, multilinear algebra, and probability.

1.1. Notation

Let $\mathbb{Z}^+$ denote the positive integers. For $n \in \mathbb{Z}^+$, let $[n] = \{1, \ldots, n\}$. If $\boldsymbol{x} \in \mathbb{R}^K$, let x_i denote the ith entry of $\boldsymbol{x}$. If $\boldsymbol{x}_j \in \mathbb{R}^K$, then $x_{j,i}$ denotes the ith entry of $\boldsymbol{x}_j$. Let $\boldsymbol{e}_i$ denote the length L vector with 1 in the ith position and zeros elsewhere. Let $\boldsymbol{\pi}_i \in \Delta_L \subset \mathbb{R}^L$ be the transpose of the ith row of $\boldsymbol{\Pi}$ where Δ_L denotes the $(L-1)$-dimensional simplex, i.e., $\Delta_L = \{\boldsymbol{\mu} = (\mu_1, \ldots, \mu_L)^T \in \mathbb{R}^L \,|\, \sum_{i=1}^L \mu_i = 1 \text{ and } \forall i : \mu_i \geqslant 0\}$. Let Δ_L^M denote the product of M $(L-1)$-dimensional simplices, viewed as the space of $M \times L$ row-stochastic matrices. Let $\mathcal{P}$ denote the space of probability distributions on a measurable space $(\mathcal{X}, \mathcal{C})$. Let $\text{supp}(F)$ denote the support of a distribution F on a Borel space.

2. Related Work

Our work makes various contributions to the statistical understanding of multiclass classification with label noise, demixing of mixed membership models, and classification with partial labels. In the following subsections, we discuss how our results improve upon and relate to previous results in the literature.

2.1. Multiclass Classification with Label Noise

There has not been much work on classification with multiclass label noise. By contrast, label noise in the binary setting has received a fair amount of attention. For a review of work prior to 2013, see Scott et al. (2013). More recently, Natarajan et al. (2013) considered the binary label noise case where the label noise rates are known (in our case, the label noise

rates are unknown). van Rooyen and Williamson (2015) generalized the work of Natarajan et al. (2013) to the multiclass case, but again assumed that the mixing proportions are known. Recent work has proposed various algorithms for the binary setting where the label noise rates are unknown (Scott, 2015; van Rooyen et al., 2015; Menon et al., 2015a), but these algorithms have not been generalized to the multiclass case. Menon et al. (2016) consider the binary setting with instance-dependent corruption, but they assume that the class probability functions take the form of a single-index model, whereas we make no parametric assumptions on the P_is. Ghosh et al. (2017) consider multiclass label noise, but they make two restrictive assumptions: *(i)* in the infinite sample setting, they assume that there exists some function belonging to the chosen hypothesis class that attains 0 risk and *(ii)* in the finite sample setting, they assume that the label noise is symmetric, i.e., there exists a constant $c \in (0, 1)$ such that $\pi_{i,j} = \frac{c}{L-1}$ for all $i \neq j$. Patrini et al. (2017) also study the multiclass setting, but they assume that if their neural network has access to sufficiently many samples, it can perfectly model $\Pr(\tilde{Y} = k \,|\, \boldsymbol{x})$ where $\boldsymbol{x}$ is a given feature vector and $\tilde{Y}$ is a corrupted label. Unlike most previous work that aims to learn a classifier, our focus is on estimating the base distributions. Given these estimates, one could then design a classifier to optimize some performance measure. See, for example, Section 4.3 of our initial work on this subject (Blanchard and Scott, 2014).

Another approach for modeling random label noise, in addition to the mutual contamination model, is the label flipping model. Indeed, several of the above-cited papers adopt this setting. In this model, the label Y of a data point is flipped independently of its features X and

$$\mu_{l,k} \coloneqq \Pr(\tilde{Y} = k \,|\, Y = l)$$

gives the probability that a data point with true label $Y = l$ is corrupted to have an observed label $\tilde{Y} = k$. Under the assumption that Y and X are jointly distributed, the $\mu_{l,k}$s can be related to the $\pi_{i,j}s$ via Bayes' rule. We choose to study the mutual contamination model because we find it more convenient to study the question of identifiability.

In this paper, we extend Scott et al. (2013), which examined binary classification with label noise (the case where $M = L = 2$). The multiclass setting is significantly more challenging and, as such, requires novel sufficient conditions and mathematical notions. In particular, Scott et al. (2013) use the notion of *irreducibility* of distributions as one of their sufficient conditions.

Definition 1 *For distributions G and H, we say that G is* irreducible *with respect to H if it is not possible to write $G = \gamma H + (1-\gamma)F$ where F is a distribution and $0 < \gamma \leqslant 1$.*

Definition 2 *For distributions G and H, we say that G and H are* mutually irreducible *if G is irreducible with respect to H and H is irreducible with respect to G. We denote*

$$IR = \{(G, H) : G \text{ and } H \text{ are mutually irreducible distributions}\}.$$

Scott et al. (2013) require that P_1 and P_2 are mutually irreducible. To treat the multiclass setting, we introduce a generalization of mutual irreducibility, namely *joint irreducibility*.

The work presented below on multiclass label noise originally appeared in a conference paper (Blanchard and Scott, 2014). The purpose of the present paper is to demonstrate that

the framework developed in that paper can be extended to the other two decontamination problems, and to provide a unified presentation of the three settings. In particular, the joint irreducibility assumption plays a pivotal role in all three settings, as does the task of mixture proportion estimation. However, the decontamination procedures for the latter two problems are substantially more complicated than for multiclass classification with label noise.

2.2. Demixing Mixed Membership Models

Mixed membership models have become a powerful modeling tool for data where data points are associated with multiple distributions. Applications have appeared in a wide range of fields including image processing (Li and Perona, 2005), population genetics (Pritchard et al., 2000), document analysis (Blei et al., 2003), and surveys (Berkman et al., 1989). One particularly popular application is topic modeling on a corpus of documents, such as the articles published in the journal Science. Topic modeling is closely related to demixing of mixed membership models and our work may be viewed as studying topic modeling on general domains.

In topic modeling, the base distributions P_i correspond to topics and the contaminated distributions $\tilde{P}_i$ to documents, which are regarded as mixtures of topics. In most cases, the P_is are assumed to have a finite sample space. A variety of approaches have been proposed for topic modeling. The most common approach assumes a generative model for a corpus of documents and determines the maximum likelihood fit of the model given data. However, because maximum likelihood is NP-hard, these approaches must rely on heuristics that can get stuck in local minima (Arora et al., 2012).

Recently, a trend towards algorithms for topic modeling with provable guarantees has emerged. Most of these methods rely on the separability assumption **(SEP)** and its variants (Donoho and Stodden, 2003; Arora et al., 2012, 2013; Ding et al., 2013, 2014; Recht et al., 2012; Huang et al., 2016). According to **(SEP)**, $P_1, \ldots, P_L$ are distributions on a finite sample space and for every $i \in \{1, \ldots, L\}$, there exists a word $x \in \text{supp}(P_i)$ such that $x \notin \cup_{j \neq i} \text{supp}(P_j)$. Our requirement that $P_1, \ldots, P_L$ are jointly irreducible is a natural generalization of separability of $P_1, \ldots, P_L$, as we will argue below. Specifically, if $P_1, \ldots, P_L$ have discrete sample spaces, separability and joint irreducibility coincide; however, if $P_1, \ldots, P_L$ are continuous, under joint irreducibility, $P_1, \ldots, P_L$ can have the same support.

A key ingredient in these algorithms is to use the assumption of a finite sample space to view the distributions as probability vectors in Euclidean space; this leads to approaches based on non-negative matrix factorization (NMF), linear programs, and random projections (Donoho and Stodden, 2003; Arora et al., 2012, 2013; Ding et al., 2013, 2014; Recht et al., 2012; Huang et al., 2016). However, more general distributions cannot be viewed as finite-dimensional vectors. Therefore, topic modeling on general domains requires new techniques. Our work seeks to provide such techniques.

Topic modeling on general domains has several applications, including in high-energy physics (Metodiev and Thaler, 2018a,b). In collider data, quantum chromodynamics causes data samples to be a mixture of different types of particles, where the underlying fraction of the particle type is unknown. In this setting, it is of interest to recover information about

each of the particles. Recently, Metodiev and Thaler (2018b) applied the Demix algorithm, Algorithm 4 in the current paper, to this problem in the case $M = L = 2$.

Topic modeling on general domains is also relevant to recent empirical research on topic modeling with word embeddings, e.g., (Das et al., 2015; Li et al., 2016b,a; Xun et al., 2017; Zhao et al., 2018). Word embeddings map words to vectors in $\mathbb{R}^d$ in a semantically and syntactically meaningful way. Their use has been pivotal to the state-of-art performance of many algorithms in NLP (Luong et al., 2013). Several algorithms for topic modeling with word embeddings model the topics as multivariate Gaussian distributions in order to handle words that do not belong to the vocabulary of the training dataset (Das et al., 2015; Xun et al., 2017). Whereas current topic modeling algorithms with theoretical guarantees do not cover such a modeling approach, the generality of our algorithms does.

2.3. Classification with Partial Labels

Classification with partial labels has had two main formulations in previous work (Liu and Dietterich, 2014). In one formulation **(PL-1)**, instances from each class are drawn independently and the partial label for each instance is drawn independently from a set-valued distribution. In another formulation **(PL-2)**, training data are in the form of bags where each bag is a set of instances and the bag has a set of labels. Each instance belongs to a single class, and the set of labels associated with the bag is given by the union of the labels of the instances in the bag. Our framework is similar to **(PL-2)**, although it does not assume a joint distribution on the features of instances and the partial labels.

Most work takes an empirical risk minimization approach to classification with partial labels (Jin and Ghahramani, 2002; Nyugen and Caruana, 2008; Cour et al., 2011; Liu and Dietterich, 2012). Typically, these algorithms aim to pick a classifier that minimizes the *partial label error*: the probability that a given classifier assigns a label to a training instance that is not contained in the partial label associated with the training instance. By contrast, our approach is to estimate the base distributions. One could then use these estimates to train a classifier under some performance measure.

There has not been much theoretical work on developing a statistical understanding of classification with partial labels. Cid-Sueiro (2012) and van Rooyen and Williamson (2015) develop methods for classification with partial labels that require knowledge of the mixing proportions, e.g., the probability that a label is in a partial label, given the true label. In this work, we make the more realistic assumption that the mixing proportions are unknown.

Liu and Dietterich (2014) consider the question of learnability where the mixing proportions are unknown. They consider two main sufficient conditions for learnability of a partial label problem. First, they require that for every label $l \in [L]$, the probability that l occurs with any particular distinct label l' is less than 1. Our condition on the partial label (described in the next Section) is considerably weaker. For example, it permits the case where there are two labels $l \neq l'$ such that whenever l occurs in a partial label, l' also occurs.

The second sufficient condition of Liu and Dietterich (2014) is based on the class distributions, partial label distributions *and* the hypothesis class of choice. It requires that every hypothesis that attains zero partial label error also attains zero true error. While this condition may be useful for the selection of a suitable hypothesis class for an ERM

approach, it is important to develop interpretable sufficient conditions that only depend on the characteristics of a partial label problem. Our work provides such conditions.

We also note that Liu and Dietterich (2014) consider the realizable case, that is, the case where the supports of $P_1, \ldots, P_L$ do not overlap. By contrast, we make the significantly weaker assumption that $P_1, \ldots, P_L$ are jointly irreducible, which allows $P_1, \ldots, P_L$ to have the same support. Thus, our work addresses the agnostic case in classification with partial labels.

3. Sufficient Conditions for Identifiability

We can think of each problem as requiring a specific factorization of $\tilde{\boldsymbol{P}}$ in terms of $\boldsymbol{P}$ and $\boldsymbol{\Pi}$. We say $\tilde{\boldsymbol{P}}$ is *factorizable* if there exists $(\boldsymbol{\Pi}, \boldsymbol{P}) \in \Delta_L^M \times \mathcal{P}^L$ such that $\tilde{\boldsymbol{P}} = \boldsymbol{\Pi}\boldsymbol{P}$; we call $(\boldsymbol{\Pi}, \boldsymbol{P})$ a *factorization* of $\tilde{\boldsymbol{P}}$. Multiclass classification with label noise requires a specific ordering of the elements of $\boldsymbol{P}$; classification with partial labels requires that $\boldsymbol{\Pi}$ is consistent with $\boldsymbol{\Pi}^+$ and a specific ordering of the elements of $\boldsymbol{P}$.

A factorization is not guaranteed to exist. For example, there is no factorization in the case where $M = 3$, $L = 2$, and $\tilde{P}_1, \tilde{P}_2, \tilde{P}_3$ are linearly independent. When a factorization exists, in general it is not unique. For instance, consider the case where $L = M$, $(\boldsymbol{\Pi}, \boldsymbol{P})$ solves (2), and $\boldsymbol{\Pi}$ is not a permutation matrix. Then, another solution is $\tilde{\boldsymbol{P}} = \boldsymbol{I}\tilde{\boldsymbol{P}}$. Furthermore, there are infinitely many solutions in the following general case.

Proposition 1 *Suppose that $\tilde{\boldsymbol{P}}$ has at least two distinct $\tilde{P}_j$s and has a factorization $(\boldsymbol{\Pi}, \boldsymbol{P})$. If there is some $\tilde{P}_i$ in the interior of* $\mathrm{conv}(P_1, \ldots, P_L)$*, then there are infinitely many distinct non-trivial factorizations of $\tilde{\boldsymbol{P}}$.*

Proof Without loss of generality, suppose that $i = 1$ and $\tilde{P}_1 \neq \tilde{P}_2$. Then, since $\tilde{P}_1$ is in the interior of $\mathrm{conv}(P_1, \ldots, P_L)$, there is some $\delta > 0$ such that for any $\alpha \in (1, 1+\delta)$, $Q_\alpha = \alpha\tilde{P}_1 + (1-\alpha)\tilde{P}_2$ is a distribution. Then, $\mathrm{conv}(\tilde{P}_1, \ldots, \tilde{P}_L) \subseteq \mathrm{conv}(Q_\alpha, \tilde{P}_2, \ldots, \tilde{P}_L)$ and, consequently, there is some $\boldsymbol{\Pi}' \in \Delta_L^L$ such that $(\boldsymbol{\Pi}', (Q_\alpha, \tilde{P}_2, \ldots, \tilde{P}_L)^T)$ solves (2). Clearly, by varying α, there are infinitely many solutions to (2). ■

Identifiability of each problem is equivalent to the existence of a unique factorization for that problem. Therefore, to establish identifiability for the three problems, we must impose conditions on $(\boldsymbol{\Pi}, \boldsymbol{P})$ and $\boldsymbol{\Pi}^+$. To this end, we use the notion of joint irreducibility of distributions.

Definition 3 *The distributions $\{P_i\}_{1 \leqslant i \leqslant L}$ are* jointly irreducible *iff the following equivalent conditions hold*

(a) For all $I \subset [L]$ such that $1 \leqslant |I| < L$, and ϵ_i such that $\epsilon_i \geqslant 0$ and $\sum_{i \in I} \epsilon_i = \sum_{i \notin I} \epsilon_i = 1$,

$$(\sum_{i \in I} \epsilon_i P_i, \sum_{i \notin I} \epsilon_i P_i) \in IR.$$

(b) $\sum_{i=1}^L \gamma_i P_i$ is a distribution implies that $\gamma_i \geqslant 0 \, \forall i$.

Conditions *(a)* and *(b)*, whose equivalence was established by Blanchard and Scott (2014), give two ways to think about joint irreducibility. Condition *(a)* says that every convex combination of a subset of the P_is is irreducible (see Section 2.1) with respect to every convex combination of the other P_is. Condition *(b)* says that if a distribution is in the span of $P_1, \ldots, P_L$, it is in their convex hull. Joint irreducibility holds when each P_i has a region of positive probability that does not belong to the support of any of the other P_is; thus, separability (see Section 2.2) of the P_is entails joint irreducibility of $P_1, \ldots, P_L$. However, the converse is not true: the P_is can have the same support and still be jointly irreducible (e.g., P_is Gaussian with a common variance and distinct means (Scott et al., 2013)).

For all three problems, we assume that

(A) $P_1, \ldots, P_L$ are jointly irreducible.

Henceforth, unless we say otherwise, $P_1, \ldots, P_L$ are assumed to be jointly irreducible. In Appendix G, we provide experiments on real-world datasets that suggest that this assumption is reasonable.

We make different assumptions on $\boldsymbol{\Pi}$ for each of the three problems. For multiclass classification with label noise, we assume that

(B1) $\boldsymbol{\Pi}$ is invertible and $\boldsymbol{\Pi}^{-1}$ is a matrix with strictly positive diagonal entries and non-positive off-diagonal entries.

According to Lemma 1 below, this assumption essentially says that the problem has low noise in the sense that for each i, $\tilde{P}_i$ mostly comes from P_i. In particular, each P_i can be recovered by subtracting small multiples of $\tilde{P}_j$, $j \neq i$ from $\tilde{P}_i$. For example, consider the following case where $\boldsymbol{\Pi}$ satisfies **(B1)**. Suppose that there is a "common background noise" $\boldsymbol{c} \in \Delta_L$ that appears in different proportions in each of the distributions; formally, we have $\boldsymbol{\pi}_i = \gamma_i \boldsymbol{c} + (1-\gamma_i)\boldsymbol{e}_i$ with $\gamma_i \in [0, 1)$. In other words, we shift each of the vertices $\boldsymbol{e}_i$ towards a common point $\boldsymbol{c}$ (see panel (iii) of Figure 1). See Blanchard and Scott (2014) for a proof that this setup satisfies **(B1)**. In the binary case where $M = L = 2$, **(B1)** is equivalent to the simple condition that $\pi_{1,1} + \pi_{2,2} < 1$. This assumption roughly says that in expectation the majority of labels are correct. In Section 4.3, we present Lemma 1, which gives a geometric interpretation of **(B1)**.

For the demixing problem, we assume that

(B2) $\boldsymbol{\Pi}$ has full column rank.

We note that **(B2)** is considerably weaker than **(B1)**, e.g., it allows $M > L$. Of course, it is natural to demand a weaker sufficient condition for demixing the mixed membership problem than muliticlass classification with label noise because the goal of the former problem is to recover any permutation of $\boldsymbol{P}$ while the goal of the latter is to recover $\boldsymbol{P}$ exactly. Nevertheless, the identifiability analysis to establish **(B2)** as a sufficient condition is also significantly more involved than the analysis of **(B1)**.

For classification with partial labels, we assume that

(B3) $\boldsymbol{\Pi}$ has full column rank and the columns of $\boldsymbol{\Pi}^+$ are unique.

The assumption that the columns of $\boldsymbol{\Pi}^+$ are unique says that there are no two classes that always appear together in the partial labels. In Appendix C, we argue that several of the above conditions are also necessary, or are not much stronger than what is necessary.

4. Algorithms for the Population Case

In this section, to establish that the above conditions are indeed sufficient for identifiability, we give a population case analysis of the three problems. The results on multiclass classification with label noise appeared in a conference paper (Blanchard and Scott, 2014); we refer the reader to that paper for the proofs.

4.1. Background

This paper relies on the following quantity from Blanchard et al. (2010).

Definition 4 *Given probability distributions F_0, F_1, define*

$$\kappa^*(F_0 \,|\, F_1) = \max\{\kappa \in [0,1] | \, \exists \text{ a distribution } G \text{ s.t. } F_0 = (1-\kappa)G + \kappa F_1\}.$$

The following Proposition from Blanchard et al. (2010) establishes some useful properties of κ^*.

Proposition 2 *Given probability distributions F_0, F_1 on a measurable space $(\mathcal{X}, \mathcal{C})$, if $F_0 \neq F_1$, then $\kappa^*(F_0 \,|\, F_1) < 1$ and the above maximum is attained for a unique distribution G (which we refer to as the* residue of F_0 wrt. F_1*). Furthermore, the following equivalent characterization holds:*

$$\kappa^*(F_0 \,|\, F_1) = \inf_{C \in \mathcal{C}, F_1(C) > 0} \frac{F_0(C)}{F_1(C)}.$$

Note that $\kappa^*(F_0 \,|\, F_1) = 0$ iff F_0 is irreducible wrt F_1. $\kappa^*(F_0 \,|\, F_1)$ can be thought of as the maximum possible proportion of F_1 in F_0. We can think of $1 - \kappa^*(F_0 \,|\, F_1)$ as a statistical distance since it is non-negative and equal to zero if and only if $F_0 = F_1$. We refer to κ^* as the two-sample κ^* operator. To obtain the residue of F_0 wrt F_1, one computes Residue$(F_0 \,|\, F_1)$ (see Algorithm 1); this is well-defined under Proposition 2 when $F_0 \neq F_1$.

In order to gain intuition about κ^*, we briefly discuss how it can be used to recover $\mathbf{\Pi}^{-1}$ in the case $L = 2$. Under conditions discussed above (Scott et al., 2013), it holds that

$$\tilde{P}_1 = (1-\kappa_1)P_1 + \kappa_1 \tilde{P}_2, \text{ and}$$
$$\tilde{P}_2 = (1-\kappa_2)P_2 + \kappa_2 \tilde{P}_1.$$

and $\kappa_1 = \kappa^*(\tilde{P}_1 \,|\, \tilde{P}_2)$ and $\kappa_2 = \kappa^*(\tilde{P}_2 \,|\, \tilde{P}_1)$. By rearranging this system of equations, we can write

$$\boldsymbol{P} = \mathbf{\Pi}^{-1}\tilde{\boldsymbol{P}} = \begin{pmatrix} \frac{1}{1-\kappa_1} & -\frac{\kappa_1}{1-\kappa_1} \\ -\frac{\kappa_2}{1-\kappa_2} & \frac{1}{1-\kappa_2} \end{pmatrix} \tilde{\boldsymbol{P}}.$$

Next, we turn to the multi-sample generalization of κ^*, which we call the multi-sample κ^* operator.

Definition 5 *Given distributions $F_0, \ldots, F_K$, define*

$$\kappa^*(F_0 \,|\, F_1, \ldots, F_K) = \max_{\boldsymbol{\mu} \in \Delta_K} \kappa^*(F_0 \,|\, \sum_{i=1}^K \mu_i F_i)$$
$$= \max\Big(\sum_{i=1}^K \nu_i : \nu_i \geqslant 0, \sum_{i=1}^K \nu_i \leqslant 1, \exists \text{ distribution } G \text{ s.t. } F_0 = (1 - \sum_{i=1}^K \nu_i)G + \sum_{i=1}^K \nu_i F_i\Big). \quad (3)$$

Algorithm 1 Residue$(F_0 \,|\, F_1)$

1: $\kappa \longleftarrow \kappa^*(F_0 \,|\, F_1)$
2: **return** $\frac{F_0 - \kappa F_1}{1-\kappa}$

Algorithm 2 MultiResidue$(F_0 \,|\, \{F_1, \ldots, F_K\})$

1: $(\nu_1, \ldots, \nu_K)^T \longleftarrow (\nu'_1, \ldots, \nu'_K)^T$ achieving the maximum in $\kappa^*(F_0 \,|\, F_1, \ldots, F_K)$
2: **return** $\frac{F_0 - \sum_{i=1}^K \nu_i F_i}{1 - \sum_{i=1}^K \nu_i}$

Blanchard and Scott (2014) establish the equivalence in line (3), as well as Lemma 15, which shows that the outer maximum is always attained at some $\boldsymbol{\mu} \in \Delta_K$, i.e., κ^* is well-defined. Although there is always a G achieving the max, it is not necessarily unique. Any G attaining the maximum is called a *maximizer* of $\kappa^*(F_0 \,|\, F_1, \ldots, F_K)$. The algorithm MultiResidue$(F_0 \,|\, \{F_1, \ldots, F_K\})$ returns one of these G (see Algorithm 2). If G is unique, we call G the *multi-sample residue of F_0 with respect to $\{F_1, \ldots, F_K\}$*. Under our proposed sufficient conditions, certain residues are shown to exist, and our decontamination methods compute such residues via Algorithm 2. In Section 4.3, we discuss Lemma 1, which establishes useful conditions under which a multi-sample residue exists and is equal to one of the vertices of Δ_L.

In general, one cannot express the multi-sample version of κ^* in terms of the two-sample version. However, it is possible in some special cases. For example, if one had access to feasible $\nu_1, \ldots, \nu_K$ that attain the optimum in (3), then it holds that $\kappa^*(F_0 \,|\, F_1, \ldots, F_K) = \kappa^*(F_0 \,|\, \frac{\sum_{i=1}^K \nu_i F_i}{\sum_{i=1}^K \nu_i})$. Further, it is possible to replace the multi-sample κ^* with several calls of the two-sample κ^* when $K = L-1$, $F_i = P_i$ for all $i \neq 0$ and $F_0 = \sum_{i=1}^L \alpha_i P_i$ where $\sum_i \alpha_i = 1$ and $\forall i \ \alpha_i > 0$ (see Lemmas 6 and 13).

We remark that in previous work that assumes P_i are probability vectors, distributions are compared using l_p distances. By contrast, in our setting of general probability spaces, we use κ^* to compare different distributions.

4.2. Mixture Proportions

Recall that we assume that $P_1, \ldots, P_L$ are jointly irreducible. If $\boldsymbol{\eta} \in \mathbb{R}^L$ and $Q = \boldsymbol{\eta}^T \boldsymbol{P}$, we say that $\boldsymbol{\eta}$ is the *mixture proportion* of Q. Since by Lemma 16, joint irreducibility of $P_1, \ldots, P_L$ implies linear independence of $P_1, \ldots, P_L$, mixture proportions are well-defined, i.e., the mixture proportions are unique.

An important feature of our decontamination strategy is recovering various mixture proportions in the simplex Δ_L. To make this precise, we introduce the following definitions. If $i \in [L]$, we say that conv$(\{\boldsymbol{e}_j : j \neq i\})$ is a *face* of the simplex Δ_L; if $A \subset [L]$ and $|A| = k$, we also say that conv$(\{\boldsymbol{e}_j : j \in A\})$ is a *k-face* of Δ_L. If $\boldsymbol{\eta} \in \mathbb{R}^L$, Q is a distribution, and $Q = \boldsymbol{\eta}^T \boldsymbol{P}$, we say that $\mathcal{N}(Q) = \mathcal{N}(\boldsymbol{\eta}) = \{j : \eta_j > 0\}$ is the *support set* of $\boldsymbol{\eta}$ or the support set of Q. Note that by joint irreducibity, $\mathcal{N}(\boldsymbol{\eta})$ consists of the indices of all the nonzero entries in the mixture proportion $\boldsymbol{\eta}$. Finally, for $\boldsymbol{\eta}_i \in \Delta_L$, and $Q_i = \boldsymbol{\eta}_i^T \boldsymbol{P}$ for $i = 1, 2$, we

Algorithm 3 Multiclass($\tilde{P}_1, \ldots, \tilde{P}_L$)

1: **for** $i = 1, \ldots, L$ **do**
2: $\quad Q_i \longleftarrow \text{MultiResidue}(\tilde{P}_i \,|\, \{\tilde{P}_j : j \neq i\})$
3: **end for**
4: **return** $(Q_1, \ldots, Q_L)^T$

say that the distributions Q_1 and Q_2 (or the mixture proportions $\boldsymbol{\eta}_1$ and $\boldsymbol{\eta}_2$) are *on the same face* of the simplex Δ_L if there exists $j \in [L]$ such that $\boldsymbol{\eta}_1, \boldsymbol{\eta}_2 \in \text{conv}(\{\boldsymbol{e}_k : k \neq j\})$.

The heart of our approach is that under joint irreducibility, one can interchange distributions $Q_1, \ldots, Q_K$ and their mixture proportions $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_K$, as indicated by the following Proposition. We note that it is valid to to apply the κ^* operator to $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_K$ since they can be viewed as discrete probability distributions over $[L]$.

Proposition 3 *Let $Q_i = \boldsymbol{\eta}_i^T \boldsymbol{P}$ for $i \in [L]$ and $\boldsymbol{\eta}_i \in \Delta_L$. Suppose $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_L$ are linearly independent and $P_1, \ldots, P_L$ are jointly irreducible. Then,*

1. *for any $i \in [L]$ and $A \subseteq [L] \backslash \{i\}$, $\kappa^*(Q_i \,|\, \{Q_j : j \in A\}) = \kappa^*(\boldsymbol{\eta}_i \,|\, \{\boldsymbol{\eta}_j : j \in A\}) < 1$,*
2. *for any $i \in [L]$ and $A \subseteq [L] \backslash \{i\}$, a maximizer of $\kappa^*(Q_i \,|\, \{Q_j : j \in A\})$ exists, and*
3. *$\boldsymbol{\gamma} \in \Delta_L$ is a maximizer to $\kappa^*(\boldsymbol{\eta}_i \,|\, \{\boldsymbol{\eta}_j : j \in A\})$ if and only if $G = \boldsymbol{\gamma}^T \boldsymbol{P}$ is a maximizer to $\kappa^*(Q_i \,|\, \{Q_j : j \in A\})$.*

In words, this proposition says that the optimization problem given by $\kappa^*(Q_i \,|\, \{Q_j : j \in A\})$ is equivalent to the optimization problem given by $\kappa^*(\boldsymbol{\eta}_i \,|\, \{\boldsymbol{\eta}_j : j \in A\})$. *Thus, joint irreducibility of $P_1, \ldots, P_L$ and linear independence of the mixture proportions enable a reduction of each of the three problems to a geometric problem where the goal is to recover the vertices of a simplex by applying κ^* to points (i.e., the mixture proportions) in the simplex.* This makes the figures below valid for general distributions (see Figures 1, 2, 3, and 4).

4.3. Multiclass Classification with Label Noise

Our algorithm for multiclass classification with label noise is by far the simplest of the three. It simply computes a maximizer of $\kappa^*(\tilde{P}_i \,|\, \{\tilde{P}_j : j \neq i\})$ for every $i \in [L]$.

Theorem 1 *Let $P_1, \ldots, P_L$ be jointly irreducible and $\boldsymbol{\Pi}$ satisfy **(B1)**. Then, Multiclass($\tilde{P}_1, \ldots, \tilde{P}_L$) returns $\boldsymbol{Q} \in \mathcal{P}^L$ such that $\boldsymbol{Q} = \boldsymbol{P}$.*

The proof of this result has two main ideas. First, it applies the one-to-one correspondence established in Proposition 3 between the maximizers of $\kappa^*(\tilde{P}_i \,|\, \{\tilde{P}_j : j \neq i\})$ and the maximizers of $\kappa^*(\boldsymbol{\pi}_i \,|\, \{\boldsymbol{\pi}_j : j \neq i\})$.

Second, the proof shows that $\kappa^*(\boldsymbol{\pi}_i \,|\, \{\boldsymbol{\pi}_j : j \neq i\})$ is well-behaved in the sense that the residue of $\boldsymbol{\pi}_i$ wrt $\{\boldsymbol{\pi}_j : j \neq i\}$ is $\boldsymbol{e}_i$. The key idea is encapsulated in the following Lemma from Blanchard and Scott (2014).

Lemma 1 (Blanchard and Scott, 2014) *The following conditions on $\boldsymbol{\pi}_1, \ldots, \boldsymbol{\pi}_L$ are equivalent:*

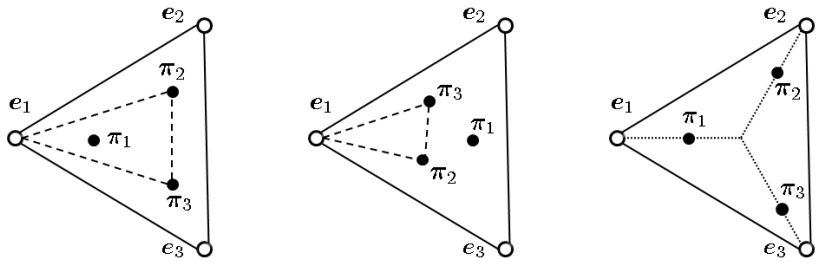

Figure 1: Illustration of the **(B1)** when there are $L = 3$ classes where $\boldsymbol{e}_i$ denotes the ith unit vector. Panel (i): Low noise, $\boldsymbol{\Pi}$ recoverable. Each $\boldsymbol{\pi}_l$ can be written as a convex combination of $\boldsymbol{e}_l$ and the other two $\boldsymbol{\pi}_j$ (with a positive weight on $\boldsymbol{e}_l$), depicted here for $l = 1$. Panel (ii): High noise, $\boldsymbol{\Pi}$ not recoverable. Panel (iii): The setting of "common background noise" described in the text.

1. *For each i, the residue of $\boldsymbol{\pi}_i$ with respect to $\{\boldsymbol{\pi}_j, j \neq i\}$ is $\boldsymbol{e}_i$.*
2. *For every i there exists a decomposition $\boldsymbol{\pi}_i = \kappa_i \boldsymbol{e}_i + (1 - \kappa_i)\boldsymbol{\pi}_i'$ where $\kappa_i > 0$ and $\boldsymbol{\pi}_i'$ is a convex combination of $\boldsymbol{\pi}_j$ for $j \neq i$.*
3. *$\boldsymbol{\Pi}$ is invertible and $\boldsymbol{\Pi}^{-1}$ is a matrix with strictly positive diagonal entries and non-positive off-diagonal entries.*

This lemma establishes that under **(B1)**, for each i, the residue of $\boldsymbol{\pi}_i$ with respect to $\{\boldsymbol{\pi}_j, j \neq i\}$ is $\boldsymbol{e}_i$. The main step in the proof of this Lemma is establishing that *3* implies *1*. The argument identifies the residue of $\boldsymbol{\pi}_i$ with respect to $\{\boldsymbol{\pi}_j\}_{j \neq i}$ by reformulating the linear program in $\kappa^*(\boldsymbol{\pi}_i \,|\, \{\boldsymbol{\pi}_j\}_{j \neq i})$ such that the objective is to maximize $\boldsymbol{e}_i^t \boldsymbol{\Pi}^{-1} \gamma$ subject to some appropriately defined constraint. By the structure of $\boldsymbol{\Pi}^{-1}$ assumed in **(B1)**, it follows that the $\gamma \in \Delta_L$ that maximizes this objective is $\boldsymbol{e}_i$, and it can further be shown that this maximizer satisfies the other constraints.

Thus, combining the above two ideas yields the result. In addition, Lemma 1 provides geometric intuition as to when **(B1)** is satisfied through condition *2*. Figure 1 illustrates the case $L = 3$. See Panel (i) for an example where condition (b) is satisfied and Panel (ii) for an example where (b) is not satisfied.

4.4. Demixing Mixed Membership Models

In this section, we assume that $M = L$; we consider the nonsquare case in the appendix. For certain simple cases of mixture proportions, a straightforward resampling strategy can be used to reduce the problem of demixing mixed membership models to multiclass classi-

fication with label noise. For example, suppose that there are $L = 3$ classes and

$$\mathbf{\Pi} = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} & 0 \\ \frac{1}{2} & 0 & \frac{1}{2} \\ 0 & \frac{1}{2} & \frac{1}{2} \end{pmatrix}. \tag{4}$$

Inspection shows that the inverse of $\mathbf{\Pi}$ does not satisfy the condition in **(B1)** and, therefore, one cannot simply apply Algorithm 3. A simple procedure to circumvent this issue is to resample from the contaminated distributions to obtain the following distributions:

$$\tilde{Q}_1 = \frac{1}{2}\tilde{P}_1 + \frac{1}{2}\tilde{P}_2,\ \tilde{Q}_2 = \frac{1}{2}\tilde{P}_1 + \frac{1}{2}\tilde{P}_3,\ \text{and}\ \tilde{Q}_3 = \frac{1}{2}\tilde{P}_2 + \frac{1}{2}\tilde{P}_3.$$

Then, it can be shown that the resulting mixing matrix

$$\tilde{\mathbf{\Pi}} = \begin{pmatrix} \frac{1}{2} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{2} \end{pmatrix}$$

associated with the $\tilde{Q}_i$s satisfies the conditions of Lemma 1 so that $\text{Multiclass}(\tilde{Q}_1, \tilde{Q}_2, \tilde{Q}_3)$ gives the desired solution. However, this approach breaks down for most possible mixing matrices. Thus, the challenge is to develop an algorithm that works for a large class of mixture proportions and does not rely on knowledge of the mixture proportions. To meet this challenge, we propose the Demix algorithm.

The Demix algorithm is recursive. Let $S_1, \ldots, S_K$ denote K contaminated distributions. In the base case, the algorithm takes as its input two contaminated distributions S_1 and S_2. It returns $\text{Residue}(S_1 \,|\, S_2)$ and $\text{Residue}(S_2 \,|\, S_1)$, which are a permutation of the two base distributions (see Figure 2). When $K > 2$, Demix uses a subroutine FindFace (see Algorithm 5) to find $K-1$ distributions $R_2, \ldots, R_K$ on the same $(K-1)$-face. FindFace iteratively generates candidates for distributions on the same $(K-1)$-face, which it tests using FaceTest (see Algorithm 6). $\text{FaceTest}(S_1, \ldots, S_{K-1})$ determines whether a set of distributions $S_1, \ldots, S_{K-1}$ are on the interior of the same face by using the two-sample κ^* operator; equivalently, it tests whether there exists a pair of distributions S_i and S_j such that S_i is irreducible with respect to S_j. Once Demix finds $K-1$ distributions $R_2, \ldots, R_K$ on the same $(K-1)$-face, it recursively applies Demix to $R_2, \ldots, R_K$ to obtain distributions $Q_1, \ldots, Q_{K-1}$ that are a permutation of $K-1$ of the base distributions. Subsequently, the algorithm computes a maximizer Q_K of $\kappa^*(\frac{1}{K}\sum_{i=1}^K S_i \,|\, Q_1, \ldots, Q_{K-1})$. Since $Q_1, \ldots, Q_{K-1}$ are a permutation of $K-1$ of the base distributions, the maximizer Q_K is guaranteed to be unique and to be the remaining base distribution (see Figure 3 for an execution of the algorithm).

A number of remarks are in order regarding the Demix algorithm. First, although we compute the residue of $\frac{1}{n}S_i + \frac{n-1}{n}Q$ wrt S_1 for each $i \neq 1$, there is nothing special about the distribution S_1. We could replace S_1 with any S_j where $j \in [K]$, provided that we adjust the rest of the algorithm accordingly. Second, we can replace the sequence $\{\frac{n-1}{n}\}_{n=1}^{\infty}$ with any sequence $\alpha_n \nearrow 1$. Finally, we could replace line 7 with the following sequence of steps: for $i = 1, \ldots, K-1$, compute $Q_K \longleftarrow \text{Residue}(Q_K \,|\, Q_i)$ (see Lemma 13). Then, the algorithm would only use the two-sample κ^* operator. We use such an algorithm in the finite-sample setting.

Algorithm 4 $\text{Demix}(S_1, \ldots, S_K)$

Input: $S_1, \ldots, S_K$ are distributions

1: **if** $K = 2$ **then**
2: **return** $(\text{Residue}(S_1 \,|\, S_2), \text{Residue}(S_2 \,|\, S_1))^T$
3: **else**
4: $(R_2, \ldots, R_K)^T \longleftarrow \text{FindFace}(S_1, \ldots, S_K)$
5: $(Q_1, \ldots, Q_{K-1})^T \longleftarrow \text{Demix}(R_2, \ldots, R_K)$
6: $Q_K \longleftarrow \frac{1}{K}\sum_{i=1}^K S_i$
7: $Q_K \longleftarrow \text{MultiResidue}(Q_K \,|\, Q_1, \ldots, Q_{K-1})$
8: **return** $(Q_1, \ldots, Q_K)^T$
9: **end if**

Algorithm 5 $\text{FindFace}(S_1, \ldots, S_K)$

Input: $S_1, \ldots, S_K$ are distributions

1: $Q \longleftarrow$ uniformly distributed element in $\text{conv}(S_2, \ldots, S_K)$
2: **for** $n = 1, 2, \ldots$ **do**
3: Set $R_i \longleftarrow \text{Residue}(\frac{1}{n}S_i + \frac{n-1}{n}Q \,|\, S_1)$ for all $i \in \{2, \ldots, K\}$
4: **if** $\text{FaceTest}(R_2, \ldots, R_K)$ **then**
5: **return** $(R_2, \ldots, R_K)^T$
6: **end if**
7: **end for**

We also remark that a simplified version of Demix solves the demixing mixed membership models problem if we assume **(B1)** from the multiclass label noise setting. In that case, finding $L-1$ distributions on the same face can be accomplished by simply computing $Q_i \longleftarrow \text{MultiResidue}(\tilde{P}_i \,|\, \{\tilde{P}_j\}_{j \neq i})$ for $i = 2, \ldots, L$. Indeed, then, each Q_i is equal to P_i and P_1 can be obtained by computing $\text{MultiResidue}(\tilde{P}_1 \,|\, \{Q_j\}_{j=2,\ldots,L})$.

We establish the following theorem.

Theorem 2 *Let $P_1, \ldots, P_L$ be jointly irreducible and $\mathbf{\Pi}$ have full column rank. Then, with probability 1, Demix$(\tilde{\boldsymbol{P}})$ returns a permutation of $\boldsymbol{P}$.*

We briefly sketch three key aspects of the proof. First, in the FindFace subroutine, sampling Q uniformly at random from $\text{conv}(S_2, \ldots, S_K)$ ensures that w.p. 1 $\text{Residue}(Q \,|\, S_1)$ is on the interior of a face of the simplex. Then, conditional on this event, we show that by a continuity property of $\text{Residue}(\cdot \,|\, S_1)$ there is a large enough n such that $R_2, \ldots, R_K$ are on the same face of the simplex Δ_{K-1} (see panels (c) and (d) of Figure 3). Second, Proposition 8 in Appendix D establishes that the subroutine $\text{FaceTest}(R_2, \ldots, R_K)$ returns 1 if and only if $R_2, \ldots, R_K$ are on the same face of the simplex. Combining the above two observations implies that eventually $\text{FindFace}(S_1, \ldots, S_K)$ terminates at which point $\{R_k\}_{k \in [K]\setminus\{1\}} \subset \{P_k\}_{k \in [K]\setminus\{l\}}$ for some $l \in [K]$. The final key observation is that $\{R_k\}_{k \in [K]\setminus\{1\}}$ and $\{P_k\}_{k \in [K]\setminus\{l\}}$ form an instance of the demixing problem that satisfies the sufficient conditions **(A)** and **(B2)** (see Figure 2). Therefore, this instance can be solved recursively.

Algorithm 6 FaceTest$(S_1, \ldots, S_K)$

1: Set $\boldsymbol{Z}_{i,j} \coloneqq \mathbf{1}\{\kappa^*(S_i \,|\, S_j) > 0\}$ for all i and j
2: **if** $\boldsymbol{Z}$ has a zero off-diagonal entry **then**
3: **return** 0
4: **else**
5: **return** 1
6: **end if**

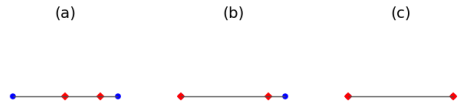

Figure 2: In (a), we consider a demixing problem where there are two classes and $M = L$ (the base case of Algorithm 4). The diamonds represent the mixture proportions of $\tilde{P}_1$ and $\tilde{P}_2$. The circles represent the base distributions. In (b), the residue of a contaminated distribution wrt the other contaminated distribution is computed (line 3), yielding a base distribution. In (c), the residue is computed again switching the roles of the contaminated distributions (line 4); this yields the remaining base distribution.

4.5. Classification with Partial Labels

As in the case of demixing mixed membership models, a simple resampling strategy works in certain nice settings of classification with partial labels. For example, consider an instance of classification with partial labels with the mixing matrix from equation (4). The resampling procedure that yields $\tilde{Q}_1, \tilde{Q}_2, \tilde{Q}_3$ (described in Section 4.4) also works here. Nevertheless, as in demixing mixed membership models, this approach does not meet our goal of an algorithm that solves a broad class of mixing matrices and partial labels.

Indeed, we observe that the partial labels do not provide enough information for choosing the resampling weights. Consider another instance of the problem with the same partial label matrix:

$$\boldsymbol{\Pi} = \begin{pmatrix} \frac{1}{10} & \frac{9}{10} & 0 \\ \frac{9}{10} & 0 & \frac{1}{10} \\ 0 & \frac{1}{10} & \frac{9}{10} \end{pmatrix}. \tag{5}$$

Applying the resampling approach to (5) can be shown to fail by observing that the inverse of the resampled mixing matrix does not satisfy condition *3* of Lemma 1. Thus, although the

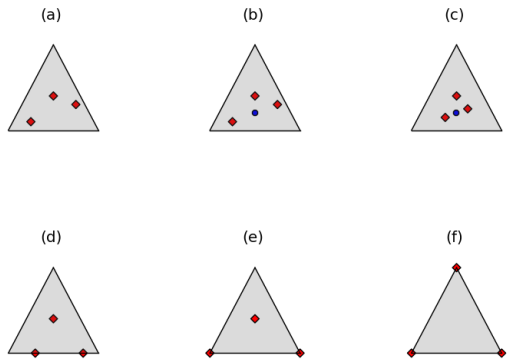

Figure 3: In (a), we consider a demixing problem where there are three classes and $M = L$. The diamonds represent the mixture proportions of $\tilde{P}_1$, $\tilde{P}_2$ and $\tilde{P}_3$. In (b), the blue circle is a random distribution chosen in the convex hull of two of the distributions (line 7). In (c), two of the distributions are resampled so that their residues wrt the other distribution are on the same face of the simplex (lines 12-15). In (d), these particular residues are computed (lines 12-15). In (e), two of the distributions are demixed (lines 3-5). In (f), the residue of the final distribution wrt the final two demixed distributions is computed to obtain the final demixing (line 18-21).

Algorithm 7 PartialLabel$(\boldsymbol{\Pi}^+, (\tilde{P}_1, \ldots, \tilde{P}_M)^T)$

1: **for** $i = 1, \ldots, L$ **do**
2: $Q_i \longleftarrow$ uniformly random distribution in $\text{conv}(\tilde{P}_1, \ldots, \tilde{P}_M)$
3: **end for**
4: **for** $k = 2, 3, \ldots$ **do**
5: $(W_1, \ldots, W_L)^T \longleftarrow$ GenerateCandidates$(k, (Q_1, \ldots, Q_L)^T)$
6: (FoundVertices, $\boldsymbol{C}$) $\longleftarrow$ VertexTest$(\boldsymbol{\Pi}^+, \tilde{P}_1, \ldots, \tilde{P}_M, W_1, \ldots, W_L)$
7: **if** FoundVertices **then**
8: **return** $\boldsymbol{C}(W_1, \ldots, W_L)^T$
9: **end if**
10: **end for**

problem instances (4) and (5) have the same partial label matrix, the resampling procedure only works for one of these.

Next, we turn to presenting an algorithm that solves classification with partial labels for a wide class of mixing matrices and partial labels. We propose the PartialLabel algorithm

Algorithm 8 GenerateCandidates($k, (Q_1, \ldots, Q_L)^T$)

1: Set $W_i \longleftarrow Q_i$ for all $i \in [K]$
2: **for** $i = 1, \ldots, L$ **do**
3: $\quad \bar{Q}_i \longleftarrow \frac{1}{L-1}[\sum_{j>i} Q_j + \sum_{j<i} W_j]$
4: $\quad W_i \longleftarrow \text{MultiResidue}(\frac{1}{k}Q_i + (1-\frac{1}{k})\bar{Q}_i \,|\, \{Q_j\}_{j>i} \cup \{W_j\}_{j<i})$
5: **end for**
6: **return** $(W_1, \ldots, W_L)^T$

Algorithm 9 VertexTest($\boldsymbol{\Pi}^+, (\tilde{P}_1, \ldots, \tilde{P}_M)^T, (Q_1, \ldots, Q_L)^T$)

1: Form the matrix $Y_{i,j} \coloneqq \mathbf{1}\{\kappa^*(Q_i \,|\, Q_j) > 0\}$
2: **if** $\boldsymbol{Y}$ has a non-zero off-diagonal entry **then**
3: $\quad$ **return** $(0, \mathbf{0})$
4: **end if**
5: Form the matrix $Z_{i,j} \coloneqq \mathbf{1}\{\kappa^*(\tilde{P}_i \,|\, Q_j) > 0\}$
6: Use any algorithm that finds a permutation matrix $\boldsymbol{C}$ such that $\boldsymbol{ZC} = \boldsymbol{\Pi}^+$ (if it exists)
7: **if** such a permutation matrix $\boldsymbol{C}$ exists **then**
8: $\quad$ **return** $(1, \boldsymbol{C}^T)$
9: **else**
10: $\quad$ **return** $(0, \mathbf{0})$
11: **end if**

(see Algorithm 7). PartialLabel proceeds by iteratively creating sets of candidate distributions $\boldsymbol{W} \coloneqq (W_1, \ldots, W_L)^T$ via the subroutine CreateCandidates (see Algorithm 8). Given each $\boldsymbol{W}$, it runs an algorithm VertexTest (see Algorithm 9) that uses $\tilde{\boldsymbol{P}}$ and the partial label matrix $\boldsymbol{\Pi}^+$ to determine whether $\boldsymbol{W}$ is a permutation of the base distributions $\boldsymbol{P}$. If $\boldsymbol{W}$ is a permutation of $\boldsymbol{P}$, VertexTest constructs the corresponding permutation matrix for relating these distributions. If not, it reports failure and the PartialLabel algorithm increments k and finds another set of candidate distributions.

The VertexTest algorithm proceeds as follows on a vector of candidate distributions $\boldsymbol{Q} \coloneqq (Q_1, \ldots, Q_L)^T$. First, it determines whether there are two distinct distributions Q_i, Q_j such that Q_i is not irreducible wrt Q_j, in which case $\boldsymbol{Q}$ cannot be a permutation of $\boldsymbol{P}$. If there is such a pair, it reports failure. Otherwise, it forms the matrix $Z_{i,j} \coloneqq \mathbf{1}\{\kappa^*(\tilde{P}_i \,|\, Q_j) > 0\}$ and uses any algorithm that finds a permutation $\boldsymbol{C}$ (if it exists) of the columns of $\boldsymbol{Z}$ to match the columns of $\boldsymbol{\Pi}^+$. If such a permutation $\boldsymbol{C}$ exists, it returns $\boldsymbol{C}^T$ and, as we show in Lemma 7, $\boldsymbol{C}^T\boldsymbol{Q} = \boldsymbol{P}$; otherwise, VertexTest reports failure.

We remark that finding the permutation in line 6 of Algorithm 9 is not NP-hard. One algorithm (but most likely not the most efficient) proceeds as follows: define a total ordering on the columns of binary matrices. Sort the columns of $\boldsymbol{Z}$ and $\boldsymbol{\Pi}^+$ according to this total ordering. Check whether the resulting matrices are equal.

The following theorem gives our identification result for classification with partial labels.

Theorem 3 *Suppose that $P_1, \ldots, P_L$ are jointly irreducible, $\boldsymbol{\Pi}$ has full column rank, and the columns of $\boldsymbol{\Pi}^+$ are unique. Then, PartialLabel($\boldsymbol{\Pi}^+, (\tilde{\boldsymbol{P}})^T$) returns $\boldsymbol{R} \in \mathcal{P}^L$ such that $\boldsymbol{R} = \boldsymbol{P}$.*

There are two key ideas to the proof of Theorem 3. First, the randomization in line 2 of Algorithm 7 ensures through a linear independence argument that with probability 1, the operation MultiResidue($\frac{1}{k}Q_i + (1-\frac{1}{k})\bar{Q}_i \,|\, \{Q_j\}_{j>i} \cup \{W_j\}_{j<i}$) in line 4 of Algorithm 8 is well-defined. Second, in the GenerateCandidates algorithm, let $Q_j = \boldsymbol{\tau}_j^T\boldsymbol{P}$ and $W_j = \boldsymbol{\gamma}_j^T P$. We make the simple observation that the affine hyperplane given by $\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_{i-1}, \boldsymbol{\tau}_{i+1}, \ldots, \boldsymbol{\tau}_L$ bisects Δ_L such that $\boldsymbol{\tau}_i$ and a nonempty subset of $\{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_L\} \backslash \{\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_{i-1}\}$ are in the same halfspace. Using this observation, we show that for large enough k, W_i is one of the base distributions and is distinct from all W_j with $j < i$.

The VertexTest algorithm connects the demixing problem and classification with partial labels by showing that any algorithm that solves the demixing problem can be used as a subroutine to solve classification with partial labels. For example, consider the following algorithm for classification with partial labels. First, use the Demix algorithm to obtain a permutation $\boldsymbol{Q}$ of the base distributions $\boldsymbol{P}$. Second, use VertexTest to find the permutation matrix relating $\boldsymbol{Q}$ and $\boldsymbol{P}$. This alternate algorithm is the basis of our finite sample algorithm for classification with partial labels (see Section 5.3 for a more thorough discussion).

5. Estimators for the Finite Sample Setting

In this section, we develop the estimation theory to treat the three problems in the finite sample setting. Let $\mathcal{X} = \mathbb{R}^d$ be equipped with the standard Borel σ-algebra $\mathcal{C}$ and $\tilde{P}_1, \ldots, \tilde{P}_L$ be probability distributions on this space. Suppose that we observe for $i = 1, \ldots, L$,

$$X_1^i, \ldots, X_{n_i}^i \overset{i.i.d.}{\sim} \tilde{P}_i.$$

Let $\mathcal{E}$ be any Vapnik-Chervonenkis (VC) class with VC-dimension $V < \infty$, containing the set of all open balls, all open rectangles, or some other collection of sets that generates the Borel σ-algebra $\mathcal{C}$. For example, $\mathcal{E}$ could be the set of all open balls wrt the Euclidean distance, in which case $V = d + 1$. Define $\epsilon_i(\delta_i) \equiv 3\sqrt{\frac{V\log(n_i+1) - \log(\delta_i/2)}{n_i}}$ for $i = 1, \ldots, L$. Our estimators are based on the VC inequality (Devroye et al., 1996). This inequality says that for each $i \in [L]$, and $\delta > 0$, the following holds with probability at least $1 - \delta$:

$$\sup_{E \in \mathcal{E}} |\tilde{P}_i(E) - \tilde{P}_i^\dagger(E)| \leqslant \epsilon_i(\delta)$$

where the *empirical distribution* is given by $\tilde{P}_i^\dagger(E) = \frac{1}{n_i}\sum_{j=1}^{n_i} \mathbf{1}_{\{X_j^i \in E\}}$.

5.1. Multiclass Classification with Label Noise

Let $F_0^\dagger, \ldots, F_M^\dagger$ denote the empirical distributions based on i.i.d. random samples from respective distributions $F_0, \ldots, F_M$. We introduce the following estimator of the multi-sample κ^*:

$$\widehat{\kappa}(F_0^\dagger \,|\, F_1^\dagger, \ldots, F_M^\dagger) = \max_{\boldsymbol{\mu} \in \Delta_M} \inf_{E \in \mathcal{E}} \frac{F_0^\dagger(E) + \epsilon_0(\frac{1}{n_0})}{(\sum_{i=1}^M \mu_i F_i^\dagger(E) - \sum_i \mu_i \epsilon_i(\frac{1}{n_i}))_+} \tag{6}$$

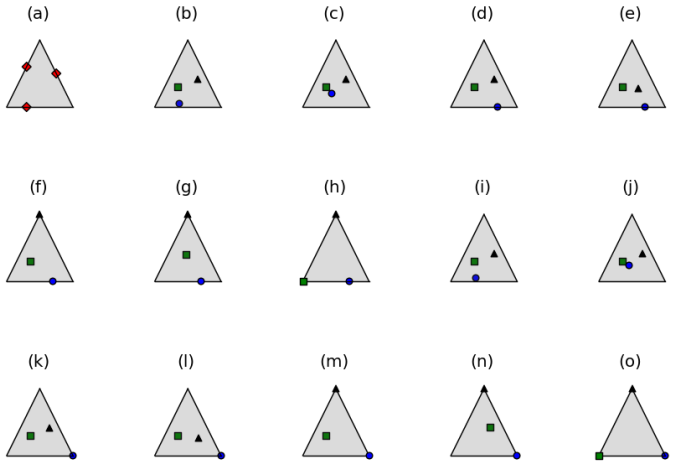

Figure 4: (a) depicts an instance of the partial label problem where there are $L = 3$ classes, $M = 3$ partial labels, and each partial label only contains two of the classes. In (a), the red diamonds represent the mixture proportions of the distributions $\tilde{P}_1, \tilde{P}_2, \tilde{P}_3$. In (b), three distributions Q_1, Q_2, Q_3 are sampled uniformly randomly from the convex hull of $\tilde{P}_1, \tilde{P}_2, \tilde{P}_3$; the blue circle, black triangle, and green square represent their mixture proportions. Figures (c)-(h) show how the algorithm generates a set of candidate distributions $(W_1^{(2)}, W_2^{(2)}, W_3^{(2)})^T$ with $k = 2$. In (h), PartialLabel runs VertexTest on $(W_1^{(2)}, W_2^{(2)}, W_3^{(2)})^T$ and determines that $(W_1^{(2)}, W_2^{(2)}, W_3^{(2)})^T$ is not a permutation of $(P_1, P_2, P_3)^T$. In (i)-(o), PartialLabel begins again with Q_1, Q_2, Q_3 and executes the same series of steps with $k = 3$, generating $(W_1^{(3)}, W_2^{(3)}, W_3^{(3)})^T$. In (o), it runs VertexTest on $(W_1^{(3)}, W_2^{(3)}, W_3^{(3)})^T$ and determines that $(W_1^{(3)}, W_2^{(3)}, W_3^{(3)})^T$ is a permutation of $(P_1, P_2, P_3)^T$.

where the ratio is defined to be ∞ when the denominator is zero. This estimator arises from applying the VC inequality to the following expression:

$$\kappa^*(F_0 \,|\, F_1, \ldots, F_M) = \max_{\boldsymbol{\mu} \in \Delta_M} \kappa^*(F_0 \,|\, \sum_{i=1}^{M} \mu_i F_i) = \max_{\boldsymbol{\mu} \in \Delta_M} \inf_{E \in \mathcal{E}, \sum_{i=1}^{M} \mu_i F_i(E) > 0} \frac{F_0(E)}{\sum_{i=1}^{M} \mu_i F_i(E)},$$

where the last equality uses Proposition 2. Let $\widehat{\boldsymbol{\mu}}$ denote a point where the maximum is achieved in (6). Then, $\widehat{\boldsymbol{\nu}} \coloneqq \widehat{\kappa}\widehat{\boldsymbol{\mu}}$ estimates the vector $(\nu_1, \ldots, \nu_M)$ attaining the maximum

in (3). See Proposition 2 of Blanchard and Scott (2014) to find a proof that the proposed estimator is consistent.

Based on this estimator, we introduce estimators that under the assumptions of Theorem 1 converge to the base distributions uniformly in probability. Let $\boldsymbol{n} \equiv (n_1, \ldots, n_L)$; we write $\boldsymbol{n} \longrightarrow \infty$ to indicate that $\min_i n_i \longrightarrow \infty$.

Theorem 4 *Let $(\widehat{\nu}_{i,j})_{j \neq i}$ be a vector attaining the maximum in the definition of $\widehat{\kappa}_i \coloneqq \widehat{\kappa}(\tilde{P}_i^\dagger \,|\, \{\tilde{P}_j^\dagger : j \neq i\})$ and*

$$\widehat{Q}_i = \frac{\tilde{P}_i^\dagger - \sum_{j \neq i} \widehat{\nu}_{i,j} \tilde{P}_j^\dagger}{1 - \widehat{\kappa}_i}.$$

Then, under the assumptions of Theorem 1, $\forall i = 1, \ldots, L$, $\sup_{E \in \mathcal{E}} |\widehat{Q}_i(E) - P_i(E)| \xrightarrow{i.p.} 0$ as $\boldsymbol{n} \longrightarrow \infty$.

5.2. Demixing Mixed Membership Models

In this section, we develop a novel estimator that can be used to extend the Demix algorithm to the finite sample case. Uniform convergence results typically assume access to i.i.d. samples. The challenge of developing an estimator for Demix is that because of the recursive nature of the Demix algorithm, we cannot assume access to i.i.d. samples to estimate every distribution that arises. Nonetheless, we show that uniform convergence of distributions propagates through the algorithm if we employ an estimator of κ^* with a known rate of convergence.

Let $\widehat{F}$ and $\widehat{H}$ be estimates of distributions F and H, respectively. We introduce the following estimator:

$$\widehat{\kappa}(\widehat{F} \,|\, \widehat{H}) = \inf_{E \in \mathcal{E}} \frac{\widehat{F}(E) + \gamma_{\boldsymbol{n}}}{(\widehat{H}(E) - \gamma_{\boldsymbol{n}})_+}$$

where $\gamma_{\boldsymbol{n}} = \sum_{i=1}^{L} \epsilon_i(\frac{1}{n_i})$. Our estimator is closely related to the estimator from Blanchard et al. (2010): if $\widehat{F}$ and $\widehat{H}$ are empirical distributions, e.g., $\widehat{F} = \tilde{P}_i^\dagger$ and $\widehat{H} = \tilde{P}_j^\dagger$, then their estimator for $\kappa^*(F \,|\, H)$ is $\inf_{E \in \mathcal{E}} \frac{\widehat{F}(E) + \epsilon_i(\frac{1}{n_i})}{(\widehat{H}(E) - \epsilon_j(\frac{1}{n_j}))_+}$. Note that our proofs only require that $\gamma_{\boldsymbol{n}}$ include the terms $\epsilon_i(\frac{1}{n_i})$ corresponding to $\tilde{P}_i$ that the estimators $\widehat{F}$ and $\widehat{H}$ use samples from; to simplify presentation, however, we include all the terms, which leads to bounds that are looser by only a constant factor.

Based on the estimator $\widehat{\kappa}$, we introduce the following estimator of the residue of F wrt H.

Definition 6 *Let $\widehat{F}$ and $\widehat{H}$ be estimators of F and H, respectively, where $F \neq H$ and let $G \longleftarrow$ Residue$(F \,|\, H)$ and $\widehat{G} \longleftarrow$ ResidueHat$(\widehat{F} \,|\, \widehat{H})$. We call $\widehat{G}$ a* ResidueHat estimator *of order $k \geqslant 1$ if (i) $F, H \in \mathrm{conv}(P_1, \ldots, P_L)$, and (ii) at least one of $\widehat{F}$ and $\widehat{H}$ is a ResidueHat estimator of order $k-1$ and the other is either an empirical distribution or a ResidueHat estimator of order less than or equal to $k-1$. We call $\widehat{G}$ a* ResidueHat estimator *of order 0 if (i) holds, and $\widehat{F}$ and $\widehat{H}$ are empirical distributions.*

Algorithm 10 ResidueHat($\widehat{F} \,|\, \widehat{H}$)

Input: $\widehat{F}, \widehat{H}$ are estimates of F, H

$\widehat{\kappa} \longleftarrow \widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$

return $\frac{\widehat{F} - \widehat{\kappa}(1-\widehat{H})}{1-\widehat{\kappa}}$

Algorithm 11 DemixHat($\widehat{S}_1, \ldots, \widehat{S}_K \,|\, \epsilon$)

Input: $\widehat{S}_1, \ldots, \widehat{S}_K$ are ResidueHat estimates

if $K = 2$ **then**
  return $(\text{ResidueHat}(\widehat{S}_1 \,|\, \widehat{S}_2), \text{ResidueHat}(\widehat{S}_2 \,|\, \widehat{S}_1))^T$
else
  $(R_2, \ldots, R_K)^T \longleftarrow \text{FindFaceHat}(\widehat{S}_1, \ldots, \widehat{S}_K \,|\, \epsilon)$
  $(\widehat{Q}_1, \cdots, \widehat{Q}_{K-1})^T \longleftarrow \text{DemixHat}(\widehat{R}_2, \cdots, \widehat{R}_K)$
  $\widehat{Q}_K \longleftarrow \frac{1}{K}\sum_{i=1}^{K} \widehat{S}_i$
  for $i = 1, \ldots, K-1$ **do**
    $\widehat{Q}_K \longleftarrow \text{ResidueHat}(\widehat{Q}_K \,|\, \widehat{Q}_i)$
  end for
  return $(\widehat{Q}_1, \cdots, \widehat{Q}_K)^T$
end if

Note that the above definition is recursive and matches the recursive structure of the Demix algorithm. We suppress the qualifier "of order k" when it is not relevant.

To use ResidueHat estimators to estimate the P_is, we build on the rate of convergence result from Scott (2015). In Scott (2015), a rate of convergence was established for an estimator of κ^* using empirical distributions; we extend these results to our setting of recursive estimators and achieve the same rate of convergence. To ensure that this rate of convergence holds for every estimate in our algorithm, we introduce the following condition.

(A″) $P_1, \ldots, P_L$ are such that $\forall i \ \text{supp}(P_i) \nsubseteq \cup_{j \neq i} \text{supp}(P_j)$.

Note that this assumption implies joint irreducibility and is a natural generalization of the separability assumption.

The following result establishes sufficient conditions under which ResidueHat estimates converge uniformly.

Proposition 4 *If $P_1, \ldots, P_L$ satisfy **(A″)** and $\widehat{G}$ is a ResidueHat estimator of a distribution $G \in \text{conv}(P_1, \ldots, P_L)$, then $\sup_{E \in \mathcal{E}} |\widehat{G}(E) - G(E)| \xrightarrow{i.p.} 0$ as $\boldsymbol{n} \longrightarrow \infty$.*

Based on the ResidueHat estimators, we introduce an empirical version of the Demix algorithm—DemixHat (see Algorithm 11). The main differences are that *(i)* we replace the Residue function with the ResidueHat function, *(ii)* we replace line 7 in the Demix algorithm with a sequence of applications of the two-sample κ^* operator, as mentioned just before Theorem 2, and *(iii)* DemixHat requires specification of a hyperparameter $\epsilon \in (0, 1)$. We replace the multi-sample κ^* with the two-sample κ^* because there is no known estimator with a rate of convergence for the multi-sample κ^*, and the rate of convergence is

Algorithm 12 FindFaceHat($\widehat{S}_1, \ldots, \widehat{S}_K \,|\, \epsilon$)

Input: $\widehat{S}_1, \ldots, \widehat{S}_K$ are ResidueHat estimates

$\widehat{Q} \longleftarrow$ uniformly distributed random element from $\text{conv}(\widehat{S}_2, \ldots, \widehat{S}_K)$
for $n = 2, 3, \ldots$ **do**
  Set $\widehat{R}_i \longleftarrow \text{ResidueHat}(\frac{1}{n}\widehat{S}_i + \frac{n-1}{n}\widehat{Q}) \,|\, \widehat{S}_1)$ for all $i \in \{2, \ldots, K\}$
  if $\text{FaceTestHat}(\widehat{R}_2, \cdots, \widehat{R}_K \,|\, \epsilon)$ **then**
    return $(\widehat{R}_2, \cdots, \widehat{Q}_K)^T$
  end if
end for

Algorithm 13 FaceTestHat($\widehat{Q}_1, \cdots, \widehat{Q}_K \,|\, \epsilon$)

Set $\boldsymbol{Z}_{i,j} \coloneqq \mathbf{1}\{\widehat{\kappa}(\widehat{Q}_i \,|\, \widehat{Q}_j) > \epsilon\}$ for $i \neq j$
if $\boldsymbol{Z}$ has a zero off-diagonal entry **then**
  return 0
else
  return 1
end if

essential to our consistency proof. The hyperparameter ϵ gives a tradeoff between runtime and accuracy. The runtime increases with increasing ϵ, but the amount of uncertainty about whether DemixHat executes successfully decreases with increasing ϵ.

We now state our main estimation result.

Theorem 5 *Let $\delta > 0$ and $\epsilon \in (0, 1)$. Suppose that $P_1, \ldots, P_L$ satisfy **(A″)** and $\boldsymbol{\Pi}$ has full rank. Then, with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$, DemixHat($\tilde{P}_1^\dagger, \ldots, \tilde{P}_L^\dagger \,|\, \epsilon$) returns $(\widehat{Q}_1, \ldots, \widehat{Q}_L)$ for which there exists a permutation $\sigma : [L] \longrightarrow [L]$ such that for every $i \in [L]$,*

$$\sup_{E \in \mathcal{E}} |\widehat{Q}_i(E) - P_{\sigma(i)}(E)| < \delta.$$

5.3. Classification with Partial Labels

In this section, we present a finite sample algorithm for the decontamination of a partial label model (see Algorithm 14). This algorithm is based on a different approach from PartialLabel (Algorithm 7): it combines DemixHat with an empirical version of the VertexTest algorithm (see Algorithm 17). The reason for this is that we have an estimator with a rate of convergence for the two-sample κ^*, whereas there is no known estimator with a rate of convergence for the multi-sample κ^*. We leverage this rate of convergence to prove the consistency of our algorithm.

We make an assumption that simplifies our algorithm: $\boldsymbol{\Pi}^+$ satisfies

(D) there does not exist $i, j \in [L]$ such that $\boldsymbol{\Pi}^+_{i,:} = \boldsymbol{e}_j^T$.

In words, this says that there is no contaminated distribution $\tilde{P}_i$ and base distribution P_j such that $\tilde{P}_i = P_j$. We emphasize that we make this assumption only to simplify the

Algorithm 14 PartialLabelHat($\mathbf{\Pi}^+, (\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger)^T \,|\, \epsilon$)

1: $(\widehat{Q}_1, \ldots, \widehat{Q}_L)^T \longleftarrow$ DemixHat$(\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger \,|\, \epsilon)$
2: (FoundVertices, $\boldsymbol{C}$) $\longleftarrow$ VertexTestHat$(\mathbf{\Pi}^+, (\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger)^T, (\widehat{Q}_1, \ldots, \widehat{Q}_L)^T)$
3: **return** $\boldsymbol{C}(\widehat{Q}_1, \ldots, \widehat{Q}_L)^T$

presentation and development of the algorithm; one can reduce any instance of a partial label model satisfying **(B3)** and **(A)** to an instance of a partial label model that also satisfies **(D)**. We defer the sketch of this reduction to Section E.3.

We now state our main estimation result for classification with partial labels.

Theorem 6 *Let $\delta > 0$ and $\epsilon \in (0,1)$. Suppose that $P_1, \ldots, P_L$ satisfy **(A″)**, $\mathbf{\Pi}$ has full rank, the columns of $\mathbf{\Pi}^+$ are unique and $\mathbf{\Pi}^+$ satisfies **(D)**. Then, with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$, PartialLabelHat($\mathbf{\Pi}^+, (\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger)^T \,|\, \epsilon$) returns $(\widehat{Q}_1, \ldots, \widehat{Q}_L)^T$ such that for every $i \in [L]$,*

$$\sup_{E \in \mathcal{E}} |\widehat{Q}_i(E) - P_i(E)| < \delta.$$

5.4. Sieve Estimators

In the preceding, we have assumed a fixed VC class to simplify the presentation. However, these results easily extend to the setting where $\mathcal{E} = \mathcal{E}_k$ and $k \longrightarrow \infty$ at a suitable rate depending on the growth of the VC dimensions V_k. This allows for the P_is to be estimated uniformly on arbitrarily complex events, e.g., $\mathcal{E}_k$ is the set of unions of k open balls.

6. Discussion

In this paper, we have studied the problem of how to recover the base distributions $\boldsymbol{P}$ from the contaminated distributions $\tilde{\boldsymbol{P}}$ without knowledge of the mixing matrix $\mathbf{\Pi}$. We used a common set of concepts and techniques to solve three popular machine learning problems that arise in this setting: multiclass classification with label noise, demixing of mixed membership models, and classification with partial labels. Our technical contributions include: (i) We provide sufficient and sometimes necessary conditions for identifiability for all three problems. (ii) We give nonparametric algorithms for the infinite and finite sample settings. (iii) We provide a new estimator for iterative applications of κ^* that is of independent interest. (iv) Finally, our work provides a novel geometric perspective on each of the three problems.

Our results improve on what was previously known for all three problems. For multiclass classification with label noise and unknown $\mathbf{\Pi}$, previous work had only considered the case $M = L = 2$. Our work achieves a generalization to arbitrarily many distributions. For demixing of mixed membership models, previous algorithms with theoretical guarantees required a finite sample space. Our work allows for a much more general set of distributions. Finally, for classification with partial labels, previous work on learnability assumed the realizable case (non-overlapping $P_1, \ldots, P_L$) and assumed strong conditions on label co-occurence in partial labels. Our analysis covers the agnostic case and a much wider set of partial labels.

Our work has also highlighted the advantages and disadvantages associated with the two-sample κ^* operator and multi-sample κ^* operator, respectively. Algorithms that only use the two-sample κ^* operator have the following two advantages: (i) the geometry of the two-sample κ^* operator is simpler than the geometry of the multi-sample κ^* operator and, as such, can be more tractable. Indeed, in recent years, several practical algorithms for estimating the two-sample κ^* have been developed (see Jain et al. (2016) and references therein). (ii) We have estimators with established rates of convergence for the two-sample κ^* operator, but not for the multi-sample κ^* operator. On the other hand, algorithms that use the multi-sample κ^* operator have fewer steps.

The aims of this work are mainly theoretical, but we believe that our work can inform practical algorithms. First, we note that while we have emphasized recovery of $\boldsymbol{P}$, another interpretation is that our work deals with estimating $\mathbf{\Pi}$. One can then plug our estimate of $\mathbf{\Pi}$ into corrected losses for multiclass classification with label noise and classification with partial labels that require knowledge of $\mathbf{\Pi}$ (Cid-Sueiro, 2012; Menon et al., 2015b; van Rooyen and Williamson, 2015; Patrini et al., 2017). Thus, in general, our work can be applied in this two-stage approach. Second, when L or M are small, the Demix algorithm is practical. For example, Metodiev and Thaler (2018b) apply the Demix algorithm to a high-energy physics application where $L = M = 2$. It is of interest to examine more generally whether variants of Demix work when M or L are small. Third, we conjecture that our analysis suggests novel principles for designing algorithms. For example, an alternative approach to the three problems in question is to embed the contaminated distributions in a reproducing kernel Hilbert Space and to estimate the $\mathbf{\Pi}$ matrix by setting up an optimization problem (e.g., see Ramaswamy et al. (2016) for the setting where there are two distributions). One of our necessary conditions, maximality (see Appendix C), suggests formulating the optimization problem to search for base distributions that *(i)* explain the observed contaminated distributions and *(ii)* whose convex hull is as large as possible. In this way, we believe that our general treatment of these three problems that arise in mutual contamination models provides intuitions that could be useful for designing new algorithms.

Although our experiments in Appendix G suggest that joint irreducibility of the base distributions is a reasonable assumption, it is nevertheless worthwhile to consider what questions arise if the base distributions are not exactly jointly irreducible. We see two possible research directions. First, one could perform a stability analysis: when the base distributions are not jointly irreducible, but are nearly jointly irreducible (in some sense that would need to be defined precisely), does the estimate of $\mathbf{\Pi}$ remain close to the true $\mathbf{\Pi}$? A second research question is to reinterpret the problem of demixing of mixed membership models as a dimensionality reduction problem. That is, given a large set of distributions, one could seek to represent them as convex combinations of a small set of irreducible base distributions. Then, the challenge would be to define an appropriate measure of approximation quality and to determine whether our approach could be useful for designing a consistent algorithm for the best approximation.

Appendix A. Outline of Appendices

To begin, we introduce additional notation for the appendices. In Section C, we discuss how strong our sufficient conditions are and present factorization results that suggest that they are reasonable. In Section D, we give our identifiability analysis of demixing mixed membership models and classification with partial labels. In Section E, we prove our results on the ResidueHat estimator, as well as the finite sample algorithms for demixing mixed membership models and classification with partial labels. In Section F, we state some lemmas from related papers that we use in our arguments.

Appendix B. Notation for Appendices

Let $A \subset \mathbb{R}^d$ be a set. Let $\operatorname{aff} A$ denote the affine hull of A, i.e., $\operatorname{aff} A = \{\sum_{i=1}^K \theta_i \boldsymbol{x}_i | \boldsymbol{x}_1, \ldots, \boldsymbol{x}_K \in A, \sum_{i=1}^K \theta_i = 1\}$. A° denotes the relative interior of A, i.e., $A^\circ = \{x \in A | B(x, r) \cap \operatorname{aff} A \subseteq A \text{ for some } r > 0\}$. Then, ∂A denotes the relative boundary of A, i.e., $\partial A = A \backslash A^\circ$. In addition, let $\|\cdot\|$ denote an arbitrary finite-dimensional norm on $\mathbb{R}^L$. For two vectors, $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^K$, define

$$\min(\boldsymbol{x}^T, \boldsymbol{y}^T) = (\min(x_1, y_1), \ldots, \min(x_K, y_K)).$$

$\boldsymbol{x} \geqslant \boldsymbol{y}$ means $x_i \geqslant y_i \; \forall i \in [K]$.

For distributions $Q_1, \ldots, Q_k$, we use $\operatorname{conv}(Q_1, \ldots, Q_K)^\circ$ to denote the relative interior of their convex hull and have that

$$\operatorname{conv}(Q_1, \ldots, Q_K)^\circ = \{\sum_{i=1}^K \alpha_i Q_i : \alpha_i > 0, \sum_{i=1}^K \alpha_i = 1\}.$$

Note that when $Q_1, \ldots, Q_K$ are discrete distributions, this definition coincides with the definition of the relative interior of a set of Euclidean vectors.

We use the following affine mapping throughout the paper: $m_\nu(\boldsymbol{x}, \boldsymbol{y}) = (1 - \nu)\boldsymbol{x} + \nu \boldsymbol{y}$ where $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^L$ and $\nu \in [0, 1]$. Overloading notation, when Q_1 and Q_2 are distributions, we define $m_\nu(Q_1, Q_2) = (1 - \nu)Q_1 + \nu Q_2$. Note that if $\boldsymbol{\eta}_1, \boldsymbol{\eta}_2 \in \Delta_L$ and $Q_1 = \boldsymbol{\eta}_1^T \boldsymbol{P}$ and $Q_2 = \boldsymbol{\eta}_2^T \boldsymbol{P}$, then $m_\nu(\boldsymbol{\eta}_1, \boldsymbol{\eta}_2)$ is the mixture proportion for the distribution $m_\nu(Q_1, Q_2)$.

Appendix C. Factorization Results

In this section, we discuss whether our sufficient conditions are necessary. For the problems of demixing mixed membership models and classification with partial labels, we provide factorization results that suggest that our sufficient conditions are not much stronger than what is necessary.

C.1. Multiclass Classification with Label Noise

Our sufficient condition **(B1)** for multiclass classification with label noise is not necessary. Rather, **(B1)** is one of several possible sufficient conditions, and one that reflects a low noise assumption as illustrated in Figure 1. Consider the case $L = M = 2$ where **(B1)** is equivalent to $\pi_{1,2} + \pi_{2,1} < 1$. Recovery is still possible if $\pi_{1,2} + \pi_{2,1} > 1$ since one can simply swap $\tilde{P}_1$ and $\tilde{P}_2$ in a decontamination procedure. $\pi_{1,2} + \pi_{2,1} < 1$ is only necessary if one assumes that most of the training labels are correct, which is what $\pi_{1,2} + \pi_{2,1} < 1$ essentially says. For larger $L = M$, **(B1)** says in a sense that most of the data from $\tilde{P}_i$ come from P_i for every i. Other sufficient conditions are possible (as in the binary case), but these would require at least one $\tilde{P}_i$ to contain a significant portion of some P_j, $j \neq i$. Regarding **(A)**, Blanchard et al. (2016) study the question of necessity for joint irreducibility in the case $L = M = 2$ and show that under mild assumptions on the decontamination procedure, joint irreducibility is necesssary.

C.2. Demixing Mixed Membership Models

Recall the definition of a factorization: $\tilde{\boldsymbol{P}}$ is factorizable if there exists $(\boldsymbol{\Pi}, \boldsymbol{P}) \in \Delta_L^M \times \mathcal{P}^L$ such that $\tilde{\boldsymbol{P}} = \boldsymbol{\Pi}\boldsymbol{P}$; we call $(\boldsymbol{\Pi}, \boldsymbol{P})$ a factorization of $\tilde{\boldsymbol{P}}$.

Our sufficient conditions are not much stronger than what is required by factorizations that satisfy the two forthcoming desirable properties.

Definition 7 *We say a factorization $(\boldsymbol{\Pi}, \boldsymbol{P})$ of $\tilde{\boldsymbol{P}}$ is* maximal ***(M)*** *iff for all factorizations $(\boldsymbol{\Pi}', \boldsymbol{P}')$ of $\tilde{\boldsymbol{P}}$ with $\boldsymbol{P}' = (P_1', \ldots, P_L')^T \in \mathcal{P}^L$, it holds that $\{P_1', \ldots, P_L'\} \subseteq \operatorname{conv}(P_1, \ldots, P_L)$.*

In words, $\boldsymbol{P} = (P_1, \ldots, P_L)^T$ is a maximal collection of base distributions if it is not possible to move any of the P_is outside of $\operatorname{conv}(P_1, \ldots, P_L)$ and represent $\tilde{\boldsymbol{P}}$.

Definition 8 *We say a factorization $(\boldsymbol{\Pi}, \boldsymbol{P})$ of $\tilde{\boldsymbol{P}}$ is* linear ***(L)*** *iff $\{P_1, \ldots, P_L\} \subseteq \operatorname{span}(\tilde{P}_1, \ldots, \tilde{P}_M)$.*

We believe that **(L)** is a reasonable requirement because it holds in the common situation in which there exist $\boldsymbol{\pi}_{i_1}, \ldots, \boldsymbol{\pi}_{i_L}$ that are linearly independent. Then for $I = \{i_1, \ldots, i_L\}$, we can write $\tilde{\boldsymbol{P}}_I = \boldsymbol{\Pi}_I \boldsymbol{P}$ where $\boldsymbol{\Pi}_I$ is the submatrix of $\boldsymbol{\Pi}$ containing only the rows indexed by I and $\tilde{\boldsymbol{P}}_I$ is similarly defined. Then, $\boldsymbol{\Pi}_I$ is invertible and $\boldsymbol{P} = \boldsymbol{\Pi}_I^{-1} \tilde{\boldsymbol{P}}_I$.

Factorizations that satisfy **(A)** and **(B2)** are maximal and linear.

Proposition 5 *Let $(\boldsymbol{\Pi}, \boldsymbol{P})$ be a factorization of $\tilde{\boldsymbol{P}}$. If $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(A)** and **(B2)**, then $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(M)** and **(L)**.*

Proof We first show that $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(L)**. By hypothesis, $P_1, \ldots, P_L$ are jointly irreducible. By Lemma 16, $P_1, \ldots, P_L$ are linearly independent. Since by hypothesis $\boldsymbol{\Pi}$ has full rank, there exist L rows in $\boldsymbol{\Pi}$, $\boldsymbol{\pi}_{i_1}, \ldots, \boldsymbol{\pi}_{i_L}$, that are linearly independent. By Lemma 16, $\tilde{P}_{i_1}, \ldots, \tilde{P}_{i_L}$ are linearly independent. Since $\boldsymbol{\Pi}\boldsymbol{P} = \tilde{\boldsymbol{P}}$, $\operatorname{span}(\tilde{P}_1, \ldots, \tilde{P}_M) \subseteq \operatorname{span}(P_1, \ldots, P_L)$. Since $\dim \operatorname{span}(\tilde{P}_1, \ldots, \tilde{P}_M) \geqslant L$, we have $\operatorname{span}(\tilde{P}_1, \ldots, \tilde{P}_M) = \operatorname{span}(P_1, \ldots, P_L)$. Therefore, $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(L)**.

Now, we show that $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(M)**. Suppose that there is another solution $(\boldsymbol{\Pi}', \boldsymbol{P}')$ with $\boldsymbol{P}' = (P_1', \ldots, P_L')^T$ such that $\boldsymbol{\Pi}'\boldsymbol{P}' = \tilde{\boldsymbol{P}}$ and with some P_i' such that

$P_i' \notin \text{conv}(P_1, \ldots, P_L)$. We claim that $P_i' \notin \text{span}(P_1, \ldots, P_L)$. Towards a contradiction, suppose that $P_i' \in \text{span}(P_1, \ldots, P_L)$ so that we can write $P_i' = \sum_{i=1}^{L} a_i P_i$. Then, at least one of the a_i is negative since, by assumption, $P_i' \notin \text{conv}(P_1, \ldots, P_L)$. But, by joint irreducibility of $P_1, \ldots, P_L$, P_i' is not a distribution, which is a contradiction. So, the claim follows. But, then, since $\text{span}(P_1, \ldots, P_L) = \text{span}(\tilde{P}_1, \ldots, \tilde{P}_M)$, we must have that $\text{span}(\tilde{P}_1, \ldots, \tilde{P}_M) \subseteq \text{span}(P_1', \ldots, P_{i-1}', P_{i+1}', \ldots, P_L)$, which is impossible since $\dim \text{span}(\tilde{P}_1, \ldots, \tilde{P}_M) = L$. ■

Maximal and linear factorizations imply conditions that are not much weaker than our sufficient conditions.

Theorem 7 *Let $(\boldsymbol{\Pi}, \boldsymbol{P})$ be a factorization of $\tilde{\boldsymbol{P}}$. If $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(M)**, then*

(A′) *$\forall i$, P_i is irreducible with respect to every distribution in $\text{conv}(\{P_j : j \neq i\})$.*

*If $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(L)**, then*

(B′) $\text{rank}(\boldsymbol{\Pi}) \geqslant \dim \text{span}(P_1, \ldots, P_L)$.

Proof

(A′) We prove the contrapositive. Suppose that there is some P_i and $Q \in \text{conv}(\{P_j : j \neq i\})$ with $Q = \sum_{j \neq i} \beta_j P_j$ such that P_i is not irreducible wrt Q. Then, there is some distribution G and $\gamma \in (0, 1]$ such that $P_i = \gamma Q + (1 - \gamma) G$.

Suppose $\gamma = 1$. Then, $P_i = Q \in \text{conv}(\{P_k : k \neq i\})$. But, then $\tilde{P}_1, \ldots, \tilde{P}_M \in \text{conv}(\{P_j : j \neq i\} \cup \{R\})$ for any distribution $R \notin \text{conv}(P_1, \ldots, P_L)$. This shows that $(\boldsymbol{\Pi}, \boldsymbol{P})$ does not satisfy **(M)**.

Therefore, assume that $\gamma \in (0, 1)$. Either $G \in \text{conv}(P_1, \ldots, P_L)$ or $G \notin \text{conv}(P_1, \ldots, P_L)$. Suppose that $G \in \text{conv}(P_1, \ldots, P_L)$. Then, there exist $\alpha_1, \ldots, \alpha_L$ all nonnegative and summing to 1 such that

$$P_i = \gamma Q + (1 - \gamma)(\alpha_1 P_1 + \ldots + \alpha_L P_L).$$

Therefore, $P_i \in \text{conv}(\{P_k : k \neq i\})$. Then, by the argument in the previous paragraph, $(\boldsymbol{\Pi}, \boldsymbol{P})$ does not satisfy **(M)**.

Now, suppose that $G \notin \text{conv}(P_1, \ldots, P_L)$. Since $P_i \in \text{conv}(G, Q)$ and $Q \in \text{conv}(\{P_j : j \neq i\})$, we have that $\text{conv}(\{P_j : j \neq i\} \cup \{G\}) \supset \text{conv}(P_1, \ldots, P_L)$. Then, $\tilde{P}_1, \ldots, \tilde{P}_M \in \text{conv}(\{P_j : j \neq i\} \cup \{G\})$. This shows that $(\boldsymbol{\Pi}, \boldsymbol{P})$ does not satisfy **(M)**. The result follows.

(B′) Clearly, $\dim \text{span}(\tilde{P}_1, \ldots, \tilde{P}_M) \leqslant \dim \text{span}(P_1, \ldots, P_L)$ since $\tilde{P}_i = \boldsymbol{\pi}_i^T \boldsymbol{P}$ for all $i \in [M]$. Since $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(L)**, $\text{span}(P_1, \ldots, P_L) \subset \text{span}(\tilde{P}_1, \ldots, \tilde{P}_L)$, which implies that

$$\dim \text{span}(P_1, \ldots, P_L) \leqslant \dim \text{span}(\tilde{P}_1, \ldots, \tilde{P}_M).$$

Therefore, $\dim \text{span}(\tilde{P}_1, \ldots, \tilde{P}_M) = \dim \text{span}(P_1, \ldots, P_L)$. Then, since $\tilde{P}_1, \ldots, \tilde{P}_M \in \text{range}(\boldsymbol{\Pi})$, $\dim \text{span}(P_1, \ldots, P_L) \leqslant \dim \text{range}\, \boldsymbol{\Pi}$. By Result 3.117 of Axler (2015),

$$\text{rank}(\boldsymbol{\Pi}) = \dim \text{range}\, \boldsymbol{\Pi} \geqslant \dim \text{span}(P_1, \ldots, P_L).$$

■

As a corollary, Theorem 7 implies that if there is a linear factorization $(\boldsymbol{\Pi}, \boldsymbol{P})$ of $\tilde{P}$ and $P_1, \ldots, P_L$ are linearly independent, then there must be at least as many contaminated distributions as base distributions, i.e., $M \geqslant L$. Also, note that **(A′)** appears as a sufficient condition in Sanderson and Scott (2014).

By comparing **(A)** with **(A′)** and **(B2)** with **(B′)**, we see that the proposed sufficient conditions are not much stronger than **(M)** and **(L)** require. Since joint irreducibility of $P_1, \ldots, P_L$ entails their linear independence by Lemma 16, under **(A)**, **(B2)** and **(B′)** are the same. **(A)** differs from **(A′)** in that it requires that a slightly larger set of distributions are irreducible with respect to convex combinations of the remaining distributions. Specifically, under **(A)**, *every convex combination* of a subset of the P_is is irreducible with respect to every convex combination of the other P_is whereas **(A′)** only requires that every P_i be irreducible with respect to every convex combination of the other P_is.

C.3. Classification with Partial Labels

Most of our definitions and results for classification with partial labels parallel those of demixing mixed membership models. We say that $\tilde{\boldsymbol{P}}$ is $\boldsymbol{\Pi}^+$-factorizable if there exists a pair $(\boldsymbol{\Pi}, \boldsymbol{P}) \in \Delta_L^M \times \mathcal{P}^L$ that solves (2) such that $\boldsymbol{\Pi}$ is consistent with $\boldsymbol{\Pi}^+$; we call $(\boldsymbol{\Pi}, \boldsymbol{P})$ an $\boldsymbol{\Pi}^+$-factorization of $\tilde{\boldsymbol{P}}$. We say a partial label model is identifiable if given $(\tilde{\boldsymbol{P}}, \boldsymbol{\Pi}^+)$, $\tilde{\boldsymbol{P}}$ has a unique $\boldsymbol{\Pi}^+$-factorization $(\boldsymbol{\Pi}, \boldsymbol{P})$.

Our definitions of maximal and linear $\boldsymbol{\Pi}^+$-factorizations resemble definitions 7 and 8.

Definition 9 *We say a $\boldsymbol{\Pi}^+$-factorization $(\boldsymbol{\Pi}, \boldsymbol{P})$ of $\tilde{\boldsymbol{P}}$ is* maximal **(M)** *iff for all $\boldsymbol{\Pi}^+$-factorizations $(\boldsymbol{\Pi}', \boldsymbol{P}')$ of $\tilde{\boldsymbol{P}}$ with $\boldsymbol{P}' = (P_1', \ldots, P_L')^T \in \mathcal{P}^L$, it holds that $\{P_1', \ldots, P_L'\} \subseteq \text{conv}(P_1, \ldots, P_L)$.*

Definition 10 *We say a $\boldsymbol{\Pi}^+$-factorization $(\boldsymbol{\Pi}, \boldsymbol{P})$ of $\tilde{\boldsymbol{P}}$ is* linear **(L)** *iff $\{P_1, \ldots, P_L\} \subseteq \text{span}(\tilde{P}_1, \ldots, \tilde{P}_M)$.*

Similarly, $\boldsymbol{\Pi}^+$-factorizations that satisfy **(A)** and **(B3)** are maximal and linear. The proof is identical and, accordingly, omitted.

Proposition 6 *Let $(\boldsymbol{\Pi}, \boldsymbol{P})$ be a $\boldsymbol{\Pi}^+$-factorization of $\tilde{\boldsymbol{P}}$. If $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(A)** and **(B3)**, then $(\boldsymbol{\Pi}, \boldsymbol{P})$ satisfies **(M)** and **(L)**.*

Linear $\boldsymbol{\Pi}^+$-factorizations must satisfy **(B′)**; indeed, the proof is identical to the proof for linear factorizations. However, maximal $\boldsymbol{\Pi}^+$-factorizations need not satisfy **(A′)**. Consider the following counterexample. Let $Q_1 \sim \text{unif}(0, 2)$ and $Q_2 \sim \text{unif}(1, 3)$. Let $P_1 = \frac{2}{3}Q_1 + \frac{1}{3}Q_2$, $P_2 = \frac{1}{3}Q_1 + \frac{2}{3}Q_2$, $\tilde{P}_1 = P_1$, and $\tilde{P}_2 = P_2$. Then, $\boldsymbol{\Pi}^+ = \boldsymbol{I}_2$—the identity matrix. Then, any $(\boldsymbol{\Pi}', \boldsymbol{P}')$ that satisfies (2) and is consistent with $\boldsymbol{\Pi}^+$ must be such that $(P_1, P_2)^T = \boldsymbol{P}'$. Therefore, **(M′)** is satisfied. But, clearly, **(A′)** is not satisfied.

In summary, we are unable to offer a necessary condition that is close to **(A)**. On the other hand, **(B3)** is necessary.

Proposition 7 *Let $(\boldsymbol{\Pi}, \boldsymbol{P})$ be an $\boldsymbol{\Pi}^+$-factorization of $\tilde{\boldsymbol{P}}$. If $(\tilde{\boldsymbol{P}}, \boldsymbol{\Pi}^+)$ is identifiable, then the columns of $\boldsymbol{\Pi}^+$ are distinct.*

Proof First, suppose $(\tilde{\boldsymbol{P}}, \boldsymbol{\Pi}^+)$ is identifiable. Then, we can write $\tilde{\boldsymbol{P}} = \boldsymbol{\Pi}\boldsymbol{P}$ where $\boldsymbol{\Pi}$ is consistent with $\boldsymbol{\Pi}^+$. We claim that for all $i \neq j$, $P_i \neq P_j$. To the contrary, suppose that there exists $i \neq j$ such that $P_i = P_j$. Without loss of generality, suppose $i = 1, j = 2$. Then, we can write

$$\tilde{\boldsymbol{P}} = \begin{pmatrix} 2\boldsymbol{\Pi}_{:,1} & \boldsymbol{\Pi}_{:,3} & \dots & \boldsymbol{\Pi}_{:,L} \end{pmatrix} \begin{pmatrix} P_1 \\ P_3 \\ \vdots \\ P_L \end{pmatrix},$$

which contradicts the uniqueness of $\boldsymbol{P}$ and $\boldsymbol{\Pi}$.

Next, we give a proof by contraposition. Suppose that there exists $i \neq j$ such that $\boldsymbol{\Pi}^+_{:,i} = \boldsymbol{\Pi}^+_{:,j}$. Without loss of generality, let $i = 1$ and $j = 2$. Suppose that $(\boldsymbol{\Pi}, \boldsymbol{P})$ is consistent with $\boldsymbol{\Pi}^+$ and solves $\tilde{\boldsymbol{P}} = \boldsymbol{\Pi}\boldsymbol{P}$. Then, the pair $(\boldsymbol{\Pi}', \boldsymbol{P}')$ given by

$$\boldsymbol{\Pi}' = \begin{pmatrix} \boldsymbol{\Pi}_{:,2} & \boldsymbol{\Pi}_{:,1} & \boldsymbol{\Pi}_{:,3} & \dots & \boldsymbol{\Pi}_{:,L} \end{pmatrix}$$

$$\boldsymbol{P}' = \begin{pmatrix} P_2 \\ P_1 \\ P_3 \\ \vdots \\ P_L \end{pmatrix}$$

solves $\tilde{\boldsymbol{P}} = \boldsymbol{\Pi}'\boldsymbol{P}'$ and is consistent with $\boldsymbol{\Pi}^+$. If $P_1 = P_2$, then $(\tilde{\boldsymbol{P}}, \boldsymbol{\Pi}^+)$ is not identifiable, so we may rule out this case. Therefore, $\boldsymbol{P}' \neq \boldsymbol{P}$, yielding the result. ■

Appendix D. Identification

In this section, we establish our identification results, i.e., Theorems 2 and 3. We begin by proving Proposition 3. Second, we prove a set of useful lemmas in Section D.2. Third, we present our results on demixing mixed membership models in Section D.3. Finally, we present our results on classification with partial labels in Section D.4.

D.1. Proof of Proposition 3

Proof We prove the claims in order.

1. Without loss of generality, suppose $i = 1$ and let $A = [L]\backslash\{1\}$. There is at least one point attaining the maximum in the optimization problem $\kappa^*(\boldsymbol{\eta}_1 \,|\, \{\boldsymbol{\eta}_j : j \neq 1\})$ by Lemma 15. Take a G that achieves the maximum in $\kappa^*(Q_1 \,|\, \{Q_j : j \neq 1\})$, which exists also by Lemma 15. Then, we can write:

$$Q_1 = (1 - \sum_{j \geqslant 2} \mu_j)G + \sum_{j \geqslant 2} \mu_j Q_j. \tag{7}$$

Note that since $\boldsymbol{\eta}_1, \dots, \boldsymbol{\eta}_L$ are linearly independent and $P_1, \dots, P_L$ are jointly irreducible, $Q_1, \dots, Q_L$ are linearly independent by Lemma 16. Therefore, $\kappa^*(Q_1 \,|\, \{Q_j : j \neq 1\}) = \sum_{j \geqslant 2} \mu_j < 1$ because, if not, $Q_1 = \sum_{j \geqslant 2} \mu_j Q_j$.

Further, any G that satisfies (7) has the form $\sum_{i=1}^L \gamma_i P_i$ because (7) implies that $G \in \text{span}(Q_1, \dots, Q_L)$ and each $Q_i \in \text{conv}(P_1, \dots, P_L)$ by hypothesis. The γ_i must sum to one, and we have that they are nonnegative by joint irreducibility. That is, $\boldsymbol{\gamma} \equiv (\gamma_1, \dots, \gamma_L)^T$ is a discrete distribution. Then, the above equation is equivalent to

$$\boldsymbol{\eta}_1^T \boldsymbol{P} = (1 - \sum_{j \geqslant 2} \mu_j)\boldsymbol{\gamma}^T \boldsymbol{P} + \sum_{j \geqslant 2} \mu_j \boldsymbol{\eta}_j^T \boldsymbol{P}. \tag{8}$$

Since $P_1, \dots, P_L$ are jointly irreducible, $P_1, \dots, P_L$ are linearly independent by Lemma 16. By linear independence of $P_1, \dots, P_L$, we obtain

$$\boldsymbol{\eta}_1 = (1 - \sum_{j \geqslant 2} \mu_j)\boldsymbol{\gamma} + \sum_{j \geqslant 2} \mu_j \boldsymbol{\eta}_j. \tag{9}$$

Consequently, $\kappa^*(Q_1 \,|\, \{Q_j : j \neq 1\}) = \kappa^*(\boldsymbol{\eta}_1 \,|\, \{\boldsymbol{\eta}_j : j \neq 1\}) < 1$. This completes the proof of statement 1.

2. This result follows immediately from Lemma 15.

3. By equations (8) and (9), there is a one-to-one correspondence between the maximizer G to $\kappa^*(Q_1 \,|\, \{Q_j : j \neq 1\})$ and the maximizer $\boldsymbol{\gamma}$ to $\kappa^*(\boldsymbol{\eta}_1 \,|\, \{\boldsymbol{\eta}_j : j \neq 1\})$. The one-to-one correspondence is given by $G = \boldsymbol{\gamma}^T \boldsymbol{P}$.

■

D.2. Lemmas for Identification

We present some technical results that are used repeatedly for our identification results. Lemma 2 gives us some useful properties of the two-sample κ^* that we exploit in the PartialLabel and Demix algorithms. Statement *1* gives an alternative form of κ^*. Statement *2* gives the intuitive result that the residues lie on the boundary of the simplex. Statement *3* gives a useful relation for determining whether two mixture proportions are on the same face; we use this relation extensively in our algorithms.

Lemma 2 *Let $F_1, \dots, F_K$ be jointly irreducible distributions with $\boldsymbol{F} = (F_1, \dots, F_K)^T$, Q_1, Q_2 be two distributions such that $Q_i = \boldsymbol{\eta}_i^T \boldsymbol{F}$ where $\boldsymbol{\eta}_i \in \Delta_K$ for $i = 1, 2$ and $\boldsymbol{\eta}_1 \neq \boldsymbol{\eta}_2$. Let R be the residue of Q_1 wrt Q_2 and $R = \boldsymbol{\mu}^T \boldsymbol{F}$.*

1. *There is a one-to-one correspondence between the optimization problem in $\kappa^*(Q_1 \,|\, Q_2)$ and the optimization problem*

$$\max(\alpha \geqslant 1 | \exists \text{ a distribution } G \text{ s.t } G = Q_2 + \alpha(Q_1 - Q_2))$$

via $\alpha = (1 - \kappa)^{-1}$.

2. *$\boldsymbol{\mu} \in \partial\Delta_K$.*

3. *$\mathcal{N}(\boldsymbol{\eta}_2) \nsubseteq \mathcal{N}(\boldsymbol{\eta}_1)$ if and only if $R = Q_1$ if and only if $\kappa^*(Q_1 \,|\, Q_2) = 0$.*

Proof We note that we may assume that $R = \boldsymbol{\mu}^T \boldsymbol{F}$ since by definition of the residue, $R \in \text{span}(Q_1, Q_2)$ and $Q_1, Q_2 \in \text{conv}(F_1, \ldots, F_K)$.

1. Consider the linear relation: $Q_1 = (1-\kappa)G + \kappa Q_2$ where $\kappa \in [0,1]$. Since $F_1, \ldots, F_K$ are jointly irreducible and $\boldsymbol{\eta}_1$ and $\boldsymbol{\eta}_2$ are linearly independent, Q_1 and Q_2 are linearly independent by Lemma 16. Therefore, $\kappa < 1$. We can rewrite the relation as

$$G = \frac{1}{1-\kappa} Q_1 - \frac{\kappa}{1-\kappa} Q_2 = \alpha Q_1 + (1-\alpha) Q_2$$

where $\alpha = \frac{1}{1-\kappa}$. The equivalence follows.

2. Since R is the residue of Q_1 wrt Q_2, by Proposition 3, $\boldsymbol{\mu}$ is the residue of $\boldsymbol{\eta}_1$ wrt $\boldsymbol{\eta}_2$ and $\boldsymbol{\mu} \in \Delta_K$. Therefore, by statement *1* in Lemma 2, $\boldsymbol{\mu}$ is such that α^* is maximized subject to the following constraints:

$$\begin{aligned} \boldsymbol{\mu} &= (1-\alpha^*)\boldsymbol{\eta}_2 + \alpha^* \boldsymbol{\eta}_1 \\ \alpha^* &\geqslant 1 \\ \boldsymbol{\mu} &\in \Delta_K. \end{aligned}$$

Suppose that $\min_i \mu_i > 0$. Then,

$$\boldsymbol{\mu} = (1-\alpha^*)\boldsymbol{\eta}_2 + \alpha^* \boldsymbol{\eta}_1 = \boldsymbol{\eta}_2 + \alpha(\boldsymbol{\eta}_1 - \boldsymbol{\eta}_2) > 0$$

so that there is some $\epsilon > 0$ such that

$$\begin{aligned} \boldsymbol{\mu}' &= (1-\alpha^*-\epsilon)\boldsymbol{\eta}_2 + (\alpha^*+\epsilon)\boldsymbol{\eta}_1 \\ \alpha^* + \epsilon &\geqslant 1 \\ \boldsymbol{\mu}' &\in \Delta_K. \end{aligned}$$

But, this contradicts the definition of α^* and $\boldsymbol{\mu}$. Therefore, $\min_i \mu_i = 0$. Consequently, $\boldsymbol{\mu} \in \partial \Delta_K$.

3. By definition of κ^*, it is clear that $R = Q_1$ if and only if $\kappa^*(Q_1 \,|\, Q_2) = 0$. Therefore, it suffices to show that $\mathcal{N}(\boldsymbol{\eta}_2) \nsubseteq \mathcal{N}(\boldsymbol{\eta}_1)$ if and only if $\kappa^*(Q_1 \,|\, Q_2) = 0$. Suppose $\mathcal{N}(\boldsymbol{\eta}_2) \nsubseteq \mathcal{N}(\boldsymbol{\eta}_1)$. Then, there must be $i \in [K]$ such that $\eta_{2,i} > 0$ and $\eta_{1,i} = 0$. For any $\alpha > 1$,

$$\min_{i \in [K]} (1-\alpha)\eta_{2,i} + \alpha \eta_{1,i} < 0;$$

but, this violates the constraint of the optimization problem. Therefore, $\alpha = 1$. By statement *1* in Lemma 2, $\kappa^*(\boldsymbol{\eta}_1 \,|\, \boldsymbol{\eta}_2) = 0$. By statement *1* of Proposition 3, $\kappa^*(Q_1 \,|\, Q_2) = \kappa^*(\boldsymbol{\eta}_1 \,|\, \boldsymbol{\eta}_2) = 0$.

Now, suppose $\mathcal{N}(\boldsymbol{\eta}_2) \subseteq \mathcal{N}(\boldsymbol{\eta}_1)$. Then, for any $i \in [K]$, if $\eta_{2,i} > 0$, then $\eta_{1,i} > 0$. Then, there is $\alpha > 1$ sufficiently close to 1 such that

$$\min_{i \in [K]} \eta_{2,i} + \alpha(\eta_{1,i} - \eta_{2,i}) \geqslant 0.$$

By statement *1* in this Lemma, $\kappa^*(\boldsymbol{\eta}_1 \,|\, \boldsymbol{\eta}_2) > 0$. By statement *1* of proposition 3, $\kappa^*(Q_1 \,|\, Q_2) = \kappa^*(\boldsymbol{\eta}_1 \,|\, \boldsymbol{\eta}_2) > 0$.

■

Lemma 3 *Let $0 \leqslant k < L$. If $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k \in \Delta_L$ are linearly independent and $\boldsymbol{w}_{k+1}, \ldots, \boldsymbol{w}_L \in \Delta_L$ are random vectors drawn independently from the uniform distribution on a set $A \subset \Delta_L$ with positive $(L-1)$-dimensional Lebesgue measure, then $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k, \boldsymbol{w}_{k+1}, \ldots, \boldsymbol{w}_L$ are linearly independent with probability* 1.

Proof We prove the result inductively. To begin, we prove the base case, i.e. $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k, \boldsymbol{w}_{k+1}$ are linearly independent w.p. 1. It suffices to show that $\boldsymbol{w}_{k+1} \notin \text{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$ w.p. 1. Thus, it is enough to show that $\text{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k) \cap A$ has $(L-1)$-dimensional Lebesgue measure 0. Since

$$\text{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k) \cap A \subset \text{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k) \cap \Delta_L,$$

it suffices to show that $\text{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k) \cap \Delta_L$ has $(L-1)$-dimensional Lebesgue measure 0.

Next, we claim that $\text{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k) \cap \Delta_L \subseteq \text{aff}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$. Let $\sum_{i=1}^k \alpha_i \boldsymbol{v}_i \in \Delta_L$. Since $\boldsymbol{v}_i \in \Delta_L$ for all $i \in [k]$, we can write $\boldsymbol{v}_i = \sum_{j=1}^L \beta_{i,j} \boldsymbol{e}_i$ where $\beta_{i,j} \geqslant 0$ and $\sum_{j=1}^L \beta_{i,j} = 1$. Then, since $\sum_{i=1}^k \alpha_i \boldsymbol{v}_i = \sum_{i=1}^k \alpha_i \sum_{j=1}^L \beta_{i,j} \boldsymbol{e}_j \in \Delta_L$, it holds that

$$1 = \sum_{i=1}^k \alpha_i \sum_{j=1}^L \beta_{i,j} = \sum_{i=1}^k \alpha_i.$$

Thus, $\sum_{i=1}^k \alpha_i \boldsymbol{v}_i \in \text{aff}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$, establishing the claim.

Thus, it suffices to show that $\text{aff}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$ has $(L-1)$-dimensional Lebesgue measure 0. $\text{aff}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$ has affine dimension at most $k-1$. Since it is not possible to fit a $(L-1)$ dimensional ball in an affine subspace of affine dimension $k-1 < L-1$, $\text{aff}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$ has $(L-1)$-dimensional Lebesgue measure 0. Thus, with probability 1, $\boldsymbol{w}_{k+1} \notin \text{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$. This establishes the base case.

The inductive step follows by a union bound and a similar argument to the base case. Thus, the result follows. ■

D.3. Demixing Mixed Membership Models

In this section, we prove our identification result for demixing mixed membership models, i.e., Theorem 2. First, we present technical lemmas in Section D.3.1. Second, in Section D.3.2, we present the key subroutine FaceTest and prove that it behaves as desired. Third, we prove Theorem 2 in Section D.3.3. Finally, in Section D.3.4, we extend our results to the nonsquare case (where $M > L$).

D.3.1. Lemmas

Lemma 4 establishes an intuitive continuity property of the two-sample version of κ^* and the residue. Recall that $\|\cdot\|$ denotes an arbitrary finite-dimensional norm on $\mathbb{R}^L$.

Lemma 4 *Let $\boldsymbol{\eta}_1, \boldsymbol{\eta}_2 \in \Delta_L$ be distinct vectors and let $\boldsymbol{\mu}$ be the residue of $\boldsymbol{\eta}_2$ wrt $\boldsymbol{\eta}_1$. Let $\boldsymbol{\gamma}_n \in \Delta_L$ be a sequence such that $\|\boldsymbol{\gamma}_n - \boldsymbol{\eta}_2\| \longrightarrow 0$ as $n \longrightarrow \infty$, and let $\boldsymbol{\tau}_n$ be the residue of $\boldsymbol{\gamma}_n$ wrt $\boldsymbol{\eta}_1$. Then,*

1. $\lim_{n\longrightarrow\infty} \kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\eta}_1) = \kappa^*(\boldsymbol{\eta}_2 \,|\, \boldsymbol{\eta}_1)$, *and*
2. $\lim_{n\longrightarrow\infty} \|\boldsymbol{\tau}_n - \boldsymbol{\mu}\| = 0$.
3. *If, in addition, $\boldsymbol{\rho}_n \in \Delta_L$ is a sequence such that $\|\boldsymbol{\rho}_n - \boldsymbol{\eta}_2\| \longrightarrow 0$ as $n \longrightarrow \infty$ and $\mathcal{N}(\boldsymbol{\eta}_2) = \mathcal{N}(\boldsymbol{\gamma}_n) = \mathcal{N}(\boldsymbol{\rho}_n)$ for all n. Then, $\lim_{n\longrightarrow\infty} \kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\rho}_n) = 1$.*

Proof

1. In order to apply the residue operator κ^* to $\boldsymbol{\eta}_1, \boldsymbol{\eta}_2, \boldsymbol{\gamma}_n$ we think of $\boldsymbol{\eta}_1, \boldsymbol{\eta}_2, \boldsymbol{\gamma}_n$ as discrete probability distributions. By Proposition 2,

$$\kappa^*(\boldsymbol{\eta}_2 \,|\, \boldsymbol{\eta}_1) = \min_{i,\, \eta_{1,i}>0} \frac{\eta_{2,i}}{\eta_{1,i}}.$$

   Clearly, there is a constant $\delta > 0$ such that $\min_{i,\, \boldsymbol{\eta}_{1,i}>0} \boldsymbol{\eta}_{1,i} > \delta$. Let $\epsilon > 0$. By the equivalence of norms on finite-dimensional vector spaces, there exists a constant $C > 0$ such that $\|\cdot\|_\infty \leqslant C\,\|\cdot\|$ where $\|\cdot\|_\infty$ denotes the supremum norm. Thus, since $\|\boldsymbol{\gamma}_n - \boldsymbol{\eta}_2\| \longrightarrow 0$ as $n \longrightarrow \infty$, we can let n large enough such that $|\boldsymbol{\gamma}_{n,i} - \boldsymbol{\eta}_{2,i}| \leqslant \epsilon$ for all $i \in [L]$. Then,

$$\begin{aligned}\kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\eta}_1) = \min_{i,\eta_{1,i}>0} \frac{\gamma_{n,i}}{\eta_{1,i}} &\leqslant \min_{i,\eta_{1,i}>0} \frac{\eta_{2,i}+\epsilon}{\eta_{1,i}} \\ &\leqslant \kappa^*(\boldsymbol{\eta}_2 \,|\, \boldsymbol{\eta}_1) + \frac{\epsilon}{\delta}.\end{aligned}$$

   Similarly,

$$\begin{aligned}\kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\eta}_1) &= \min_{i,\eta_{1,i}>0} \frac{\gamma_{n,i}}{\eta_{1,i}} \\ &\geqslant \frac{\eta_{2,i}-\epsilon}{\eta_{1,i}} \\ &\geqslant \kappa^*(\boldsymbol{\eta}_2 \,|\, \boldsymbol{\eta}_1) - \frac{\epsilon}{\delta}.\end{aligned}$$

   Since $\epsilon > 0$ was arbitrary, statement *1* follows.

2. Write $\boldsymbol{\mu} = \kappa\boldsymbol{\eta}_2 + (1-\kappa)\boldsymbol{\eta}_1$ and $\boldsymbol{\tau}_n = \kappa_n\boldsymbol{\gamma}_n + (1-\kappa_n)\boldsymbol{\eta}_1$ where $\kappa = \kappa^*(\boldsymbol{\eta}_2 \,|\, \boldsymbol{\eta}_1)$ and $\kappa_n = \kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\eta}_1)$. Then, by the triangle inequality,

$$\begin{aligned}\|\boldsymbol{\mu} - \boldsymbol{\tau}_n\| &\leqslant \|\kappa\boldsymbol{\eta}_2 - \kappa_n\boldsymbol{\gamma}_n\| + \|(1-\kappa)\boldsymbol{\eta}_1 - (1-\kappa_n)\boldsymbol{\eta}_1\| \\ &\leqslant |\kappa - \kappa_n|\,\|\boldsymbol{\eta}_2\| + |\kappa_n|\,\|\boldsymbol{\eta}_2 - \boldsymbol{\gamma}_n\| + |\kappa - \kappa_n|\,\|\boldsymbol{\eta}_1\| \longrightarrow 0\end{aligned}$$

   as $n \longrightarrow \infty$.

3. W.l.o.g., suppose that $[K] = \mathcal{N}(\boldsymbol{\eta}_2) = \mathcal{N}(\boldsymbol{\gamma}_n) = \mathcal{N}(\boldsymbol{\rho}_n)$ where $K \leqslant L$. Observe that

$$\kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\rho}_n) = \min_{i,\, \rho_{n,i}>0} \frac{\gamma_{n,i}}{\rho_{n,i}} = \min_{i\in[K]} \frac{\gamma_{n,i}}{\rho_{n,i}}$$

   There exists a constant $\delta > 0$ such that $\min_{i\in[K]} \eta_{2,i} \geqslant \delta$. Let $\delta > \epsilon > 0$. By the equivalence of norms on finite-dimensional vector spaces, we can let n large enough such that $|\gamma_{n,i} - \eta_{2,i}| \leqslant \epsilon$ and $|\rho_{n,i} - \eta_{2,i}| \leqslant \epsilon$ for all $i \in [L]$. Then,

$$\begin{aligned}\kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\rho}_n) &= \min_{i\in[K]} \frac{\gamma_{n,i}}{\rho_{n,i}} \\ &\leqslant \min_{i\in[K]} \frac{\eta_{2,i}+\epsilon}{\eta_{2,i}-\epsilon} \\ &\leqslant \frac{\eta_{2,i}+\epsilon}{\eta_{2,i}-\epsilon}\end{aligned}$$

   for any $i \in [K]$, which goes to 1 as $\epsilon \longrightarrow 0$. Similarly,

$$\begin{aligned}\kappa^*(\boldsymbol{\gamma}_n \,|\, \boldsymbol{\rho}_n) &= \min_{i\in[K]} \frac{\gamma_{n,i}}{\rho_{n,i}} \\ &\geqslant \min_{i\in[K]} \frac{\eta_{2,i}-\epsilon}{\eta_{2,i}+\epsilon}\end{aligned}$$

   Since for any $i \in [K]$,

$$\frac{\eta_{2,i}-\epsilon}{\eta_{2,i}+\epsilon} \longrightarrow 1$$

   as $\epsilon \longrightarrow 0$, the above lower bound goes to 1 as $\epsilon \longrightarrow 0$. Thus, statement *3* follows.

■

Lemma 5 guarantees that certain operations in the Demix algorithm preserve linear independence of the mixture proportions. The proof uses tools from multilinear algebra.

Lemma 5 *Let $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_K \in \Delta_K$ be linearly independent and $P_1, \ldots, P_K$ be jointly irreducible. Let $Q_i = \boldsymbol{\tau}_i^T \boldsymbol{P}$ for $i \in [K]$. Then for any $i, j \in [K]$ such that $i \neq j$,*

1. *If $\boldsymbol{\eta} = \sum_{k=1}^K a_k \boldsymbol{\tau}_k$ with $a_j \neq 0$, then $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_{j-1}, \boldsymbol{\eta}, \boldsymbol{\tau}_{j+1}, \ldots, \boldsymbol{\tau}_K$ are linearly independent.*
2. *Let R_k be the residue of Q_k with respect to Q_j for all $k \in [K]\backslash\{j\}$. Then, $R_k = \boldsymbol{\eta}_k^T \boldsymbol{P}$ where $\boldsymbol{\eta}_k \in \Delta_L$ and $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_{j-1}, \boldsymbol{\tau}_j, \boldsymbol{\eta}_{j+1}, \ldots, \boldsymbol{\eta}_K$ are linearly independent.*
3. *Let $\boldsymbol{\tau}^* \in \operatorname{conv}(\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_k)^\circ$ and $\boldsymbol{\eta}_i \in \operatorname{conv}(\boldsymbol{\tau}_i, \boldsymbol{\tau}^*)^\circ$ for $i \in [k]$ where $k \leqslant K$. Then,*

$$\boldsymbol{\eta}_1, \boldsymbol{\eta}_2, \ldots, \boldsymbol{\eta}_k, \boldsymbol{\tau}_{k+1}, \ldots, \boldsymbol{\tau}_K$$

   are linearly independent.

Proof We use the multilinear expansion and usual properties of determinants.

1. Viewing each $\boldsymbol{\tau}_i$ as a column vector,
$$\det(\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_{j-1}, \sum_k a_k \boldsymbol{\tau}_k, \boldsymbol{\tau}_{j+1}, \ldots, \boldsymbol{\tau}_K) = a_j \det(\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_K) \neq 0.$$

2. Linear independence of $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_K$ implies that the $Q_1, \ldots, Q_K$ are distinct. Hence, by Proposition 2, we can write $\boldsymbol{\eta}_k = (1-\alpha_k)\boldsymbol{\tau}_j + \alpha_k \boldsymbol{\tau}_k$ where $\alpha_k \neq 0 \, \forall k \neq j$. Then, it holds that
$$\det(\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_{j-1}, \boldsymbol{\tau}_j, \boldsymbol{\eta}_{j+1}, \ldots, \boldsymbol{\eta}_K) = \left(\prod_{i \neq j} \alpha_i\right) \det(\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_K) \neq 0.$$

3. Since $\boldsymbol{\eta}_j = (1-\alpha_j)\boldsymbol{\tau}^* + \alpha_j \boldsymbol{\tau}_j$ where $\alpha_j \in (0,1)$ for all $j \leqslant k$, and $\boldsymbol{\tau}^* = \sum_i \beta_i \boldsymbol{\tau}_i$, it holds
$$\det(\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_{k-1}, \boldsymbol{\tau}_k, \ldots, \boldsymbol{\tau}_K) = \left(1 + \sum_{j=1}^{k} \frac{(1-\alpha_j)}{\alpha_j} \beta_j\right) \left(\prod_{i=1}^{k} \alpha_i\right) \det(\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_K) \neq 0.$$

■

Lemma 6 gives a condition on the mixture proportions under which the multi-sample residue is unique. Lemma 2 in Blanchard and Scott (2014) is very similar and is proved in a very similar way. We give a useful generalization here that reproduces many of the same details.

Lemma 6 *Let $l, k \in [L]$. Let $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_L \in \Delta_L$ be linearly independent. We have that condition 1 implies condition 2 and condition 2 implies condition 3.*

1. *There exists a decomposition*
$$\boldsymbol{\tau}_l = \kappa \boldsymbol{e}_k + (1-\kappa)\boldsymbol{\tau}_l'$$
where $\kappa > 0$ and $\boldsymbol{\tau}_l' \in \mathrm{conv}(\{\boldsymbol{\tau}_j : j \neq l\})$. Further, for every $\boldsymbol{e}_i$ such that $i \neq k$, there exists a decomposition
$$\boldsymbol{e}_i = \sum_{j=1}^{L} a_j \boldsymbol{\tau}_j$$
such that $a_l < \frac{1}{\kappa}$.

2. *Let*
$$\boldsymbol{T} = \begin{pmatrix} \boldsymbol{\tau}_1^T \\ \vdots \\ \boldsymbol{\tau}_L^T \end{pmatrix};$$
the matrix $\boldsymbol{T}$ is invertible and $\boldsymbol{T}^{-1}$ is such that $(\boldsymbol{T}^{-1})_{l,k} > 0$ and $(\boldsymbol{T}^{-1})_{l,i} \leqslant 0$ for $i \neq k$ and $(\boldsymbol{T}^{-1})_{l,k} > (\boldsymbol{T}^{-1})_{j,k}$ for $j \neq l$. In words, the (l,k)th entry in $\boldsymbol{T}^{-1}$ is positive, every other entry in the lth row of $\boldsymbol{T}^{-1}$ is nonpositive and every other entry in the kth column of $\boldsymbol{T}^{-1}$ is strictly less than the (l,k)th entry. [2]

2. $(\boldsymbol{T}^{-1})_{i,j}$ is the $i \times j$ entry in the matrix $\boldsymbol{T}^{-1}$.

3. *The residue of $\boldsymbol{\tau}_l$ with respect to $\{\boldsymbol{\tau}_j, j \neq l\}$ is $\boldsymbol{e}_k$.*

Proof Without loss of generality, let $l = 1$ and $k = 2$. By relabeling the vectors $\boldsymbol{e}_1, \ldots, \boldsymbol{e}_L$, we can assume without loss of generality that $k = 1$. First, we show that condition *1* implies condition *2*. Suppose that condition *1* holds. Then, there exists $\kappa > 0$ such that
$$\boldsymbol{\tau}_1 = \kappa \boldsymbol{e}_1 + (1-\kappa) \sum_{i=2}^{L} \mu_i \boldsymbol{\tau}_i$$
with $\mu_i \geqslant 0$ for $i \in [L] \backslash \{1\}$. Then,
$$\boldsymbol{e}_1 = \frac{1}{\kappa}(\boldsymbol{\tau}_1 - \sum_{i \geqslant 2} (1-\kappa)\mu_i \boldsymbol{\tau}_i).$$
Hence, the first row of $\boldsymbol{T}^{-1}$ is given by $\frac{1}{\kappa}(1, -(1-\kappa)\mu_2, \cdots, -(1-\kappa)\mu_L)$. This shows that the first row is such that $(\boldsymbol{T}^{-1})_{1,1} > 0$ and $(\boldsymbol{T}^{-1})_{1,i} \leqslant 0$ for $i \neq 1$.

Consider $\boldsymbol{e}_i$ such that $i \neq 1$. Then, we have the relation: $\boldsymbol{e}_i = \sum_{j=1}^{L} a_j \boldsymbol{\tau}_j$, which gives the ith row of $\boldsymbol{T}^{-1}$. By assumption, $a_1 < \frac{1}{\kappa}$, so the $(i,1)$th entry is strictly less than the $(1,1)$th entry. Hence, *2* follows.

Now, we prove that condition *2* implies condition *3*. Suppose condition *2* is true. Consider the optimization problem
$$\max_{\boldsymbol{\nu}, \boldsymbol{\gamma}} \sum_{i=2}^{L} \nu_i \ s.t. \ \boldsymbol{\tau}_1 = (1 - \sum_{i \geqslant 2} \nu_i)\boldsymbol{\gamma} + \sum_{i=2}^{L} \nu_i \boldsymbol{\tau}_i$$
over $\boldsymbol{\gamma} \in \Delta_L$ and $\boldsymbol{\nu} = (\nu_2, \cdots, \nu_L) \in C_{L-1} = \{(\nu_2, \cdots, \nu_L) : \nu_i \geqslant 0; \sum_{i=2}^{L} \nu \leqslant 1\}$.

By the same argument given in the proof of Lemma 2 of Blanchard and Scott (2014), this optimization problem is equivalent to the program
$$\max_{\boldsymbol{\gamma} \in \Delta_L} \boldsymbol{e}_1^T (\boldsymbol{T}^T)^{-1} \boldsymbol{\gamma} \ s.t. \ \boldsymbol{\nu}((\boldsymbol{T}^T)^{-1}\boldsymbol{\gamma}) \in C_{L-1}$$
where $\boldsymbol{\nu}(\boldsymbol{\eta}) \coloneqq \eta_1^{-1}(-\eta_2, \cdots, -\eta_L)$. The above objective is of the form $\boldsymbol{a}^T \boldsymbol{\gamma}$ where $\boldsymbol{a}$ is the first column of $\boldsymbol{T}^{-1}$. Since $l = 1$, by assumption, for every $i \neq 1$, $\boldsymbol{T}_{1,1}^{-1} > \boldsymbol{T}_{i,1}^{-1}$. Therefore, the unconstrained maximum over $\boldsymbol{\gamma} \in \Delta_L$ is attained uniquely by $\boldsymbol{\gamma} = \boldsymbol{e}_1$. Notice that $(\boldsymbol{T}^T)^{-1}\boldsymbol{e}_1$ is the first row of $\boldsymbol{T}^{-1}$. Denote this vector $\boldsymbol{b} = (b_1, \cdots, b_L)$. We show that $\boldsymbol{\nu}(\boldsymbol{b}) = b_1^{-1}(-b_2, \cdots, -b_L) \in C_{L-1}$. By assumption, $\boldsymbol{b}$ has its first coordinate positive and the other coordinates are nonpositive. Therefore, all of the components of $\boldsymbol{\nu}(\boldsymbol{b})$ are nonnegative. Furthermore, the sum of the components of $\boldsymbol{\nu}(\boldsymbol{b})$ is
$$\sum_{i=2}^{L} \frac{-b_i}{b_1} = 1 - \frac{\sum_{i=1}^{L} b_i}{b_1} = 1 - \frac{1}{b_1} \leqslant 1.$$
The last equality follows because the rows of $\boldsymbol{T}^{-1}$ sum to 1 since $\boldsymbol{T}$ is a stochastic matrix. Then, we have $\boldsymbol{\nu}((\boldsymbol{T}^T)^{-1}\boldsymbol{e}_1) \in C_{L-1}$. Consequently, the unique maximum of the optimization problem is attained for $\boldsymbol{\gamma} = \boldsymbol{e}_1$. This establishes *3*. ■

D.3.2. The FaceTest Algorithm

Next, we consider the main subroutine in the Demix algorithm: the FaceTest algorithm (see Algorithm 6). Proposition 8 establishes that FaceTest$(Q_1, \ldots, Q_K)$ returns 1 if and only if $Q_1, \ldots, Q_K$ are in the relative interior of the same face of the simplex.

Proposition 8 *Let $Q_j = \boldsymbol{\eta}_j^T \boldsymbol{P}$ for $\boldsymbol{\eta}_j \in \Delta_K$ and all $j \in [K]$. Let $P_1, \ldots, P_K$ be jointly irreducible, $Q_1, \ldots, Q_K \in \mathrm{conv}(P_1, \ldots, P_K)$ be distinct, and for each $i \in [K]$, let $\boldsymbol{\eta}_i$ lie in the relative interior of one of the faces of Δ_K. FaceTest$(Q_1, \ldots, Q_K)$ returns 1 if and only if $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_K$ lie in the relative interior of the same face of Δ_K.*

Proof Suppose that $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_K$ lie on the relative interior of the same face of Δ_K. Then, $\mathcal{N}(Q_1) = \ldots = \mathcal{N}(Q_K)$. By statement 3 of Lemma 2, $\kappa^*(Q_i \,|\, Q_j) > 0$ for all $i \neq j$. Hence, FaceTest$(Q_1, \ldots, Q_K)$ returns 1.

Suppose that $Q_1, \ldots, Q_K$ do not all lie on the relative interior of the same face. Then, there exists Q_i, Q_j $(i \neq j)$ that do not lie on the relative interior of the same face. Without loss of generality, suppose that $\mathcal{N}(Q_j) \nsubseteq \mathcal{N}(Q_i)$. Then, by statement 3 of Lemma 2, $\kappa^*(Q_i \,|\, Q_j) = 0$. Hence, FaceTest$(Q_1, \ldots, Q_K)$ returns 0. ■

D.3.3. The Demix Algorithm

Proof [Proof of Theorem 2]

Let $K \leqslant L$, $\boldsymbol{\gamma}_i \in \Delta_L$ for all $i \in [K]$, $S_i = \boldsymbol{\gamma}_i^T \boldsymbol{P}$ for all $i \in [K]$, and

$$\boldsymbol{\Gamma} = \begin{pmatrix} \boldsymbol{\gamma}_1^T \\ \vdots \\ \boldsymbol{\gamma}_K^T \end{pmatrix}.$$

We claim that for any $\{i_1, \ldots, i_K\} \subset [L]$ and $\{S_1, \ldots, S_K\} \subset \mathrm{conv}(P_{i_1}, \ldots, P_{i_K})$, if $P_1, \ldots, P_L$ are jointly irreducible, and $\boldsymbol{\Gamma}$ has full row rank, then w.p. 1 Demix$(S_1, \ldots, S_K)$ returns a permutation of $(P_{i_1}, \ldots, P_{i_K})$. If the claim holds, then setting $K = L$ and putting $\tilde{P}_i = S_i$ yields the result. We prove the claim by induction on K.

Consider the base case: $K = 2$. Suppose that $\{S_1, S_2\} \subset \mathrm{conv}(P_1, P_2)$ (the other cases are similar). Note that $\boldsymbol{\gamma}_1 \neq \boldsymbol{\gamma}_2$ by linear independence of $\boldsymbol{\gamma}_1$ and $\boldsymbol{\gamma}_2$. Either $\boldsymbol{\gamma}_1 \in \mathrm{conv}(\boldsymbol{e}_1, \boldsymbol{\gamma}_2)$ or $\boldsymbol{\gamma}_1 \in \mathrm{conv}(\boldsymbol{e}_2, \boldsymbol{\gamma}_2)$. Suppose $\boldsymbol{\gamma}_1 \in \mathrm{conv}(\boldsymbol{e}_1, \boldsymbol{\gamma}_2)$. Condition *2* of Lemma 1 is satisfied so that $\boldsymbol{e}_1$ is the residue of $\boldsymbol{\gamma}_1$ with respect to $\boldsymbol{\gamma}_2$ and $\boldsymbol{e}_2$ is the residue of $\boldsymbol{\gamma}_2$ with respect to $\boldsymbol{\gamma}_1$. Thus, by statement *3* of Proposition 3, P_1 is the residue of S_1 with respect to S_2 and P_2 is the residue of S_2 with respect to S_1. If $\boldsymbol{\gamma}_1 \in \mathrm{conv}(\boldsymbol{e}_2, \boldsymbol{\gamma}_2)$, then similar reasoning establishes that P_2 is the residue of S_1 with respect to S_2 and P_1 is the residue of S_2 with respect to S_1. Thus, the base case follows.

Suppose $L \geqslant K > 2$. The inductive hypothesis is:

Inductive Hypothesis: for any $\{i_1, \ldots, i_{K-1}\} \subset [L]$ and $\{S_1, \ldots, S_{K-1}\} \subset \mathrm{conv}(P_{i_1}, \ldots, P_{i_{K-1}})$, if $P_1, \ldots, P_L$ are jointly irreducible and $\boldsymbol{\Gamma}$ has full row rank, then w.p. 1 Demix$(S_1, \ldots, S_{K-1})$ returns a permutation of $(P_{i_1}, \ldots, P_{i_{K-1}})$.

Suppose that $\{S_1, \ldots, S_K\} \subset \mathrm{conv}(P_1, \ldots, P_K)$ (the other cases are similar). Set $\Xi = \mathrm{conv}(\boldsymbol{e}_1, \ldots, \boldsymbol{e}_K)$. With probability 1, $Q \in \mathrm{conv}(S_2, \ldots, S_K)^\circ$. We can write $Q = \boldsymbol{\eta}^T \boldsymbol{P}$ where $\boldsymbol{\eta}$ is a uniformly distributed random vector in $\mathrm{conv}(\boldsymbol{\gamma}_2, \ldots, \boldsymbol{\gamma}_K)$. Let R be the residue of Q with respect to S_1. By statement *3* of Proposition 3, we can write $R = \boldsymbol{\lambda}^T \boldsymbol{P}$ where $\boldsymbol{\lambda}$ is the residue of $\boldsymbol{\eta}$ with respect to $\boldsymbol{\gamma}_1$. By statement *2* of Lemma 2, $\boldsymbol{\lambda} \in \partial\Xi$.

Step 1: We claim that with probability 1, there is $l \in [K]$ such that $\boldsymbol{\lambda} \in \mathrm{conv}(\{\boldsymbol{e}_j : j \in [K]\backslash\{l\}\})^\circ$. Let $B_{i,j} = \mathrm{conv}(\{\boldsymbol{\gamma}_1\} \cup \{\boldsymbol{e}_k : k \in [K]\backslash\{i,j\}\})$ where $i, j \in [K]$ and $i \neq j$ and let $C = \mathrm{conv}(\boldsymbol{\gamma}_2, \ldots, \boldsymbol{\gamma}_K)$. First, we argue that $C \cap B_{i,j}$ has affine dimension at most $K - 3$.[3] Since $\boldsymbol{\gamma}_2, \ldots, \boldsymbol{\gamma}_K$ are linearly independent, C has affine dimension $K - 2$. Since $\{\boldsymbol{e}_k : k \in [K]\backslash\{i,j\}\}$ are linearly independent, $B_{i,j}$ has affine dimension $K - 2$ or $K - 3$. If $B_{i,j}$ has affine dimension $K - 3$, then $C \cap B_{i,j}$ has affine dimension at most $K - 3$. So, suppose that $B_{i,j}$ has affine dimension $K - 2$. If $C \cap B_{i,j}$ has affine dimension $K - 2$, then $\mathrm{aff}\, C = \mathrm{aff}\, B_{i,j}$. Then, in particular, $\boldsymbol{\gamma}_1 \in \mathrm{aff} C$. But, this contradicts the linear independence of $\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_K$. Therefore, $C \cap B_{i,j}$ has affine dimension at most $K - 3$.

Because C has affine dimension $K - 2$ and $\boldsymbol{\eta}$ is a uniformly distributed random vector in C, with probability 1, $\boldsymbol{\eta} \notin \cup_{i,j \in [K], i \neq j} B_{i,j}$. Since $\boldsymbol{\gamma}_1 \in B_{i,j}$ for all $i, j \in [K]$ and $\boldsymbol{\eta} \in \mathrm{conv}(\boldsymbol{\lambda}, \boldsymbol{\gamma}_1)$ by definition, the convexity of $B_{i,j}$ implies that $\boldsymbol{\lambda} \notin \cup_{i,j \in [K], i \neq j} B_{i,j}$. Since $\boldsymbol{\lambda} \in \partial\Xi$, the claim follows.

Step 2: Let $R_i^{(n)}$ be the residue of $m_{\frac{n-1}{n}}(S_i, Q)$ with respect to S_1. We claim that there is some finite integer $N \geqslant 2$ such that for all $n \geqslant N$,

$$\text{FaceTest}(R_2^{(n)}, \ldots, R_K^{(n)})$$

returns 1. By Proposition 8, this is equivalent to the statement that there exists $N \geqslant 2$ such that for all $n \geqslant N$, the mixture proportions of $R_2^{(n)}, \ldots, R_K^{(n)}$ are on the relative interior of the same face. Let $m_{\frac{n-1}{n}}(S_i, Q) = (\boldsymbol{\tau}_i^{(n)})^T \boldsymbol{P}$ for $i \in [K]\backslash\{1\}$; note that $\boldsymbol{\tau}_i^{(n)} = \frac{1}{n}\boldsymbol{\gamma}_i + \frac{n-1}{n}\boldsymbol{\eta}$ and, consequently, $\boldsymbol{\tau}_i^{(n)} \in \Xi$. Since $\boldsymbol{\eta} \in \mathrm{conv}(\boldsymbol{\gamma}_2, \ldots, \boldsymbol{\gamma}_K)^\circ$ with probability 1, $\boldsymbol{\tau}_i^{(n)} \in \mathrm{conv}(\boldsymbol{\gamma}_i, \boldsymbol{\eta})^\circ$ for all $i \in [K]\backslash\{1\}$ and $n \in \mathbb{N}$, and $\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_K$ are linearly independent, it follows that for all $n \in \mathbb{N}$ with probability 1, $\boldsymbol{\gamma}_1, \boldsymbol{\tau}_2^{(n)}, \ldots, \boldsymbol{\tau}_K^{(n)}$ are linearly independent by statement *3* in Lemma 5. Fix $i \in [K]\backslash\{1\}$. It suffices to show that there is large enough N such that for $n \geqslant N$, Residue$(m_{\frac{n-1}{n}}(S_i, Q) \,|\, S_1) = R_i^{(n)}$ is on the same face as R. Let $R_i^{(n)} = (\boldsymbol{\mu}_i^{(n)})^T \boldsymbol{P}$; by statement *3* of Proposition 3, $\boldsymbol{\mu}_i^{(n)}$ is the residue of $\boldsymbol{\tau}_i^{(n)}$ with respect to $\boldsymbol{\gamma}_1$ and by statement 2 of Lemma 2 $\boldsymbol{\mu}_i^{(n)} \in \Xi$. It suffices to show that $\mathcal{N}(\boldsymbol{\mu}_i^{(n)}) = \mathcal{N}(\boldsymbol{\lambda})$, i.e., every $\boldsymbol{\mu}_i^{(n)}$ is on the same face as $\boldsymbol{\lambda}$. As $n \longrightarrow \infty$, $\boldsymbol{\tau}_i^{(n)} = (1 - \frac{n-1}{n})\boldsymbol{\gamma}_i + \frac{n-1}{n}\boldsymbol{\eta} \longrightarrow \boldsymbol{\eta}$, hence by statement *2* in Lemma 4, $\left\|\boldsymbol{\mu}_i^{(n)} - \boldsymbol{\lambda}\right\| \longrightarrow 0$. Since with probability 1, $\boldsymbol{\lambda} \in \mathrm{conv}(\{\boldsymbol{e}_j : j \in [K]\backslash\{l\}\})^\circ$ for some l (step 1), it follows that for large enough n, $\boldsymbol{\mu}_i^{(n)} \in \mathrm{conv}(\{\boldsymbol{e}_j : j \in [K]\backslash\{l\}\})^\circ$.

3. Note that if $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_n \in \mathbb{R}^L$ are linearly independent and $n \leqslant L$, then $\mathrm{aff}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_n)$ has affine dimension $n - 1$.

Algorithm 15 NonSquareDemix($\tilde{P}_1, \ldots, \tilde{P}_M$)

1: $R_1, \ldots, R_L \longleftarrow$ independently uniformly distributed elements in $\mathrm{conv}(\tilde{P}_1, \ldots, \tilde{P}_M)$
2: $(Q_1, \ldots, Q_L)^T \longleftarrow \mathrm{Demix}(R_1, \ldots, R_L)$
3: **return** $(Q_1, \ldots, Q_L)^T$

Step 3: Assume that n is sufficiently large such that $R_2^{(n)}, \ldots, R_K^{(n)}$ are on the same face. The algorithm recurses on $R_2^{(n)}, \ldots, R_K^{(n)}$. Since $\boldsymbol{\gamma}_1, \boldsymbol{\tau}_2^{(n)}, \ldots, \boldsymbol{\tau}_K^{(n)}$ are linearly independent, it follows by statement *2* in Lemma 5 that $\boldsymbol{\mu}_2^{(n)}, \ldots, \boldsymbol{\mu}_K^{(n)}$ are linearly independent. Suppose wlog that $\{R_2^{(n)}, \ldots, R_K^{(n)}\} \subset \{P_1, \ldots, P_{K-1}\}$. Then, by the inductive hypothesis, if $(Q_1, \ldots, Q_{K-1}) \longleftarrow \mathrm{Demix}(R_2^{(n)}, \ldots, R_K^{(n)})$, then $(Q_1, \ldots, Q_{K-1})$ is a permutation of $(P_1, \ldots, P_{K-1})$. Note that $\frac{1}{K}\sum_{i=1}^K S_i \in \mathrm{conv}(P_1, \ldots, P_K)^\circ$ since $\boldsymbol{\Gamma}$ has full rank by assumption.

Write $Q_i = \boldsymbol{\rho}_i^T \boldsymbol{P}$ for $i \in [K]$. Then, there exists of a permutation $\sigma : [K-1] \longrightarrow [K-1]$ such that $\boldsymbol{\rho}_i = \boldsymbol{e}_{\sigma(i)}$. Since $\boldsymbol{\rho}_K \in \Xi^\circ$ and $\boldsymbol{\rho}_i = \boldsymbol{e}_{\sigma(i)}$ for $i \leqslant K-1$, the conditions in statement *1* of Lemma 6 are satisfied. Therefore, by Lemma 6, the residue of $\boldsymbol{\rho}_K$ with respect to $\{\boldsymbol{\rho}_1, \ldots, \boldsymbol{\rho}_{K-1}\}$ is $\boldsymbol{e}_K$. Then, by statement *3* of Proposition 3, the residue of Q_K with respect to $\{Q_1, \ldots, Q_{K-1}\}$ is P_K. This completes the inductive step.

■

D.3.4. The Non-Square Demix Algorithm

Now, we examine the non-square case of the demixing problem ($M > L$). Note that knowledge of L is needed since one must resample exactly L distributions in order to run the square Demix algorithm.

Corollary 1 *Suppose $M > L$. Let $P_1, \ldots, P_L$ be jointly irreducible and $\boldsymbol{\Pi}$ have full rank. Then, with probability 1, NonSquareDemix($\tilde{P}_1, \ldots, \tilde{P}_M$) returns $(Q_1, \ldots, Q_L)$ such that $(Q_1, \ldots, Q_L)$ is a permutation of $(P_1, \ldots, P_L)$.*

Proof We can write $R_i = \boldsymbol{\tau}_i^T \boldsymbol{P}$ where $\boldsymbol{\tau}_i \in \Delta_L$ and $i = 1, \ldots, L$. $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_L$ are drawn uniformly independently from a set with positive $(L-1)$-dimensional Lebesgue measure since $\boldsymbol{\Pi}$ has full rank by hypothesis. By Lemma 3, $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_L$ are linearly independent with probability 1. Then, by Theorem 2, with probability 1, Demix($R_1, \ldots, R_L$) returns a permutation of $(P_1, \ldots, P_L)$. ■

D.4. Classification with Partial Labels

In this section, we present our identification result for classification with partial labels, i.e., Theorem 3. To begin, in Section D.4.1, we prove an important lemma for the main subroutine of the algorithm PartialLabel: VertexTest (algorithm 9). Second, in Section D.4.2, we present the proof of Theorem 3.

D.4.1. VertexTest Algorithm

Lemma 7 establishes that the VertexTest algorithm determines whether one vector of distributions is a permutation of another vector of distributions.

Lemma 7 *Let $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_L \in \Delta_L$ and $Q_i = \boldsymbol{\eta}_i^T \boldsymbol{P}$ for $i \in [L]$ and $\boldsymbol{Q} = (Q_1, \ldots, Q_L)^T$. Suppose that $P_1, \ldots, P_L$ are jointly irreducible, $\boldsymbol{\Pi}$ has full column rank, and the columns of $\boldsymbol{\Pi}^+$ are unique. Then, VertexTest($\boldsymbol{\Pi}^+, \tilde{\boldsymbol{P}}, \boldsymbol{Q}$) returns $(1, \boldsymbol{C}^T)$ with $\boldsymbol{C}$ a permutation matrix if and only if $\boldsymbol{Q}$ is a permutation of $\boldsymbol{P}$. Further, if VertexTest($\boldsymbol{\Pi}^+, \tilde{\boldsymbol{P}}, \boldsymbol{Q}$) returns $(1, \boldsymbol{C}^T)$, then $\boldsymbol{C}^T \boldsymbol{Q} = \boldsymbol{P}$.*

Proof If $\boldsymbol{Q} = (Q_1, \ldots, Q_L)^T$ is such that $\boldsymbol{D}^T \boldsymbol{Q} = \boldsymbol{P}$ where $\boldsymbol{D}$ is a permutation matrix, then it is clear that VertexTest($\boldsymbol{\Pi}^+, (\tilde{P}_1, \ldots, \tilde{P}_M)^T, (Q_1, \ldots, Q_L)^T$) returns $(1, \boldsymbol{C}^T)$ for some permutation matrix $\boldsymbol{C}$ since the entries of $\boldsymbol{\Pi}^+$ are $\boldsymbol{\Pi}^+_{i,j} = \mathbf{1}_{\{\kappa^*(\tilde{P}_i \,|\, P_j) > 0\}}$. Since $\boldsymbol{D}^T \boldsymbol{Q} = \boldsymbol{P}$, clearly, $\boldsymbol{Z}\boldsymbol{D} = \boldsymbol{\Pi}^+$. But since the columns of $\boldsymbol{\Pi}^+$ are unique, there is a unique permutation of the columns of $\boldsymbol{Z}$ to obtain the columns of $\boldsymbol{\Pi}^+$. Therefore, $\boldsymbol{D} = \boldsymbol{C}$.

Consider the "only if" direction. We use the notation from Algorithm 9. Suppose Algorithm 9 has returned $(1, \boldsymbol{C}^T)$ where $\boldsymbol{C}$ is a permutation matrix. W.l.o.g. (reordering the Q_i) we can assume that $\boldsymbol{C}$ is the identity and thus $\boldsymbol{Z} = \boldsymbol{\Pi}^+$.

In the sequel denote $\phi(x) := \mathbf{1}_{\{x>0\}}$ and $\phi(\boldsymbol{M})$ the entry-wise application of ϕ to the matrix or vector $\boldsymbol{M}$. We denote $\boldsymbol{v} \preceq \boldsymbol{w}$ when all entries of $\boldsymbol{v}$ are less than or equal to the corresponding entries of $\boldsymbol{w}$ (where $\boldsymbol{v}$ and $\boldsymbol{w}$ are vectors). This is a partial order, which will be used only for $0-1$ vectors below (essentially to denote support inclusion). W.l.o.g. (reordering the P_i) we can assume that the columns of $\boldsymbol{\Pi}^+$ are reordered in some sequence compatible with $\preceq$ in decreasing order, i.e. such that if $\boldsymbol{\Pi}^+_{:,j} \preceq \boldsymbol{\Pi}^+_{:,i}$, then $i \leqslant j$.

Introduce the following additional notation: let $\boldsymbol{\Lambda}$ be the matrix with rows $\boldsymbol{\Lambda}_{i,:} = \phi(\boldsymbol{\eta}_i^T)$. Observe that by statement 3 of Lemma 2, for any i, j, k, $\kappa^*(\tilde{P}_i | Q_j) > 0$ and $\kappa^*(Q_j | P_k) > 0$ implies $\kappa^*(\tilde{P}_i | P_k) > 0$. Note that we can write $\boldsymbol{\Lambda}_{j,k} = \mathbf{1}_{\{\kappa^*(Q_j \,|\, P_k) > 0\}}$ and $\boldsymbol{\Pi}^+_{j,k} = \mathbf{1}_{\{\kappa^*(\tilde{P}_j \,|\, P_k) > 0\}}$. Thus, we must have $\phi(\boldsymbol{Z}\boldsymbol{\Lambda}) \preceq \boldsymbol{\Pi}^+$.

We now argue that this implies that $\boldsymbol{\Lambda}$ is sub-diagonal, i.e., $\boldsymbol{\Lambda}_{ij} = 0$ for $i < j$. Let $i < j$. If $\boldsymbol{\Lambda}_{ij} > 0$, then $\boldsymbol{Z}_{:,i} \preceq \boldsymbol{\Pi}^+_{:,j}$ by the above relation. Since $\boldsymbol{Z} = \boldsymbol{\Pi}^+$, this implies $\boldsymbol{\Pi}^+_{:,i} \preceq \boldsymbol{\Pi}^+_{:,j}$, which implies $j \leqslant i$ by the assumed ordering of the columns of $\boldsymbol{\Pi}^+$, a contradiction. Hence $\boldsymbol{\Lambda}_{ij} = 0$ for $i < j$.

Now, since the matrix $\boldsymbol{Y}$ (line 1 of Algorithm 9) is diagonal, Statement 3 of Lemma 1 gives that for any $i \neq j$ we have $\boldsymbol{\Lambda}_{i,:} \not\preceq \boldsymbol{\Lambda}_{j,:}$. One can conclude by a straightforward recursion that since $\boldsymbol{\Lambda}$ is sub-diagonal, this implies that $\boldsymbol{\Lambda}$ is in fact diagonal. Start with the first row $\boldsymbol{\Lambda}_{1,:}$ which must be $(1, 0, \ldots, 0)^T$ (by sub-diagonality). Since $\boldsymbol{\Lambda}_{1,:} \not\preceq \boldsymbol{\Lambda}_{j,:}$ for $j > 1$, this implies the first column $\boldsymbol{\Lambda}_{:,1}$ is also $(1, 0, \ldots, 0)$. The subsequent columns/rows are handled in the same way.

Hence $\boldsymbol{\Lambda}$ is the identity, which implies that $\boldsymbol{Q} = \boldsymbol{P}$. ■

D.4.2. Proof of Theorem 3

Proof We adopt the notation from the description of Algorithm 7 with the exception that we make explicit the dependence on k by writing $W_i^{(k)}$ instead of W_i and $\bar{Q}_i^{(k)}$ instead of

$\bar{Q}_i$. We show that there is a K such that for all $k \geqslant K$, $(W_1^{(k)}, \ldots, W_L^{(k)})^T$ is a permutation of $(P_1, \ldots, P_L)^T$. Then, the result will follow from Lemma 7.

Let $Q_i = \boldsymbol{\tau}_i^T \boldsymbol{P}$, $\bar{Q}_i^{(k)} = \bar{\boldsymbol{\tau}}_i^{(k)^T} \boldsymbol{P}$, and $W_i^{(k)} = \boldsymbol{\gamma}_i^{(k)^T} \boldsymbol{P}$. Further, let $0 \leqslant n < L$, $\{i_1, \ldots, i_n\} \subset [L]$, $l \neq j \in [L]$, and define the following events wrt the randomness of $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_L$:

$$
\begin{aligned}
E_{i_1,\ldots,i_n} &= \{\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_n}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L \text{ are linearly independent}\} \\
E &= \cap_{\{i_1,\ldots,i_n\} \subset [L], 0 \leqslant n < L} E_{i_1,\ldots,i_n} \\
F_{l,j} &= \{\boldsymbol{e}_l - \boldsymbol{e}_j, \boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L \text{ are linearly independent}\} \\
F &= \cap_{l \neq j \in [L]} F_{l,j} \\
G^{l,j}_{i_1,\ldots,i_{n-1}} &= \{\boldsymbol{e}_l - \boldsymbol{e}_j, \boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L \text{ are linearly independent}\} \\
G &= \cap_{\{i_1,\ldots,i_{n-1}\} \subset [L], 0 \leqslant n < L, l \neq j \in [L] \setminus \{i_1,\ldots,i_{n-1}\}} G^{l,j}_{i_1,\ldots,i_{n-1}}.
\end{aligned}
$$

By Lemma 3, for any $0 \leqslant n < L$, $\{i_1, \ldots, i_n\} \subset [L]$, the event $E_{i_1,\ldots,i_n}$ occurs with probability 1. Similarly, by Lemma 3, for any $l \neq j \in [L]$, the event $F_{l,j}$ occurs with probability 1. Finally, by Lemma 3, for any $0 \leqslant n < L$, $\{i_1, \ldots, i_{n-1}\} \subset [L]$ and any $l \neq j \in [L] \setminus \{i_1, \ldots, i_{n-1}\}$, the event $G^{l,j}_{i_1,\ldots,i_{n-1}}$ occurs with probability 1. Hence, the event $E \cap F \cap G$ occurs with probability 1. For the remainder of the proof, assume event $E \cap F \cap G$ occurs.

We prove the claim inductively. We show that for all $n \leqslant L$ there exists K_n such that if $k \geqslant K_n$, then $W_1^{(k)}, \ldots, W_n^{(k)}$ are distinct base distributions.

Base Case: $n = 1$. We will apply Lemma 6. By event E, $\boldsymbol{\tau}_1, \ldots, \boldsymbol{\tau}_L$ are linearly independent. Therefore, $\text{aff}(\boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L)$ gives a hyperplane with an associated open halfspace $\boldsymbol{H}$ that contains $\boldsymbol{\tau}_1$ and at least one $\boldsymbol{e}_j$. Inspection of Line 3 of Algorithm 8 shows that $\bar{\boldsymbol{\tau}}_1^{(k)}$ is simply the average of $\boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L$ and does not depend on k. Thus, there exists K_1 such that for all $k \geqslant K_1$, if $\boldsymbol{e}_j \in \boldsymbol{H}$, then $\boldsymbol{\lambda}_k \coloneqq \frac{1}{k}\boldsymbol{\tau}_1 + \frac{k-1}{k}\bar{\boldsymbol{\tau}}_1^{(k)} \in \text{conv}(\boldsymbol{e}_j, \boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L)^\circ$. Fix $k \geqslant K_1$. Then, by event E, for all $\boldsymbol{e}_j \in \boldsymbol{H}$, there exists a unique $\kappa_j > 0$ and unique $a_{j,2}, \ldots, a_{j,L}$ such that

$$
\begin{aligned}
\boldsymbol{\lambda}_k &= \kappa_j \boldsymbol{e}_j + \sum_{i=2}^{L} a_{j,i} \boldsymbol{\tau}_i \\
&= \kappa_j \boldsymbol{e}_j + (1 - \kappa_j) \tilde{\boldsymbol{\tau}}_j
\end{aligned}
$$

where $\tilde{\boldsymbol{\tau}}_j \in \text{conv}(\boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L)$ is unique. We claim that for all $i \neq j$ and $\{\boldsymbol{e}_i, \boldsymbol{e}_j\} \subset \boldsymbol{H}$, $\kappa_i \neq \kappa_j$. Suppose to the contrary that there is $i \neq j$ such that $\{\boldsymbol{e}_i, \boldsymbol{e}_j\} \subset \boldsymbol{H}$ and $\kappa_i = \kappa_j = \kappa$. Then,

$$
\begin{aligned}
\boldsymbol{\lambda}_k &= \kappa \boldsymbol{e}_i + (1 - \kappa) \tilde{\boldsymbol{\tau}}_i \\
\boldsymbol{\lambda}_k &= \kappa \boldsymbol{e}_j + (1 - \kappa) \tilde{\boldsymbol{\tau}}_j.
\end{aligned}
$$

Then, $(1-\kappa)(\tilde{\boldsymbol{\tau}}_j - \tilde{\boldsymbol{\tau}}_i) - \kappa(\boldsymbol{e}_i - \boldsymbol{e}_j) = 0$, from which it follows that $\boldsymbol{e}_i - \boldsymbol{e}_j \in \text{span}(\boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L)$. But, by event F, $\boldsymbol{e}_i - \boldsymbol{e}_j, \boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L$ are linearly independent and, hence, we have a contradiction. Thus, the claim follows.

Consequently, there is a unique j that minimizes κ_j. Note that for all $\boldsymbol{e}_i \notin \boldsymbol{H}$, if we write $\boldsymbol{e}_i = \sum_{l \geqslant 2} a_l \boldsymbol{\tau}_l + a_1 \boldsymbol{\lambda}_k$, then $a_1 \leqslant 0$. Then, by Lemma 6, $\boldsymbol{e}_j$ is the residue of $\boldsymbol{\lambda}_k$ with

respect to $\boldsymbol{\tau}_2, \ldots, \boldsymbol{\tau}_L$. Therefore, by Proposition 3, $\text{MultiResidue}(\frac{1}{k}Q_1 + (1-\frac{1}{k})\bar{Q}_1 \,|\, \{Q_j\}_{j>1})$ is well-defined and if $W_1^{(k)} \longleftarrow \text{MultiResidue}(\frac{1}{k}Q_1 + (1-\frac{1}{k})\bar{Q}_1 \,|\, \{Q_j\}_{j>1})$, $W_1^{(k)}$ is one of the base distributions. This establishes the base case.

The Inductive Step: The proof is similar to the base case. Suppose that there exists K_{n-1} such that for all $k \geqslant K_{n-1}$, $W_1^{(k)}, \ldots, W_{n-1}^{(k)}$ are distinct base distributions. Let $\{i_1, \ldots, i_{n-1}\} \subset [L]$ denote the indices of the base distributions that are equal to $W_1^{(k)}, \ldots, W_{n-1}^{(k)}$ under the inductive hypothesis. By the event E, $\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_n, \ldots, \boldsymbol{\tau}_L$ are linearly independent. Hence, $\text{aff}(\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L)$ gives a hyperplane with an associated open halfspace $\boldsymbol{H}_{i_1,\ldots,i_{n-1}}$ such that $\boldsymbol{\tau}_n \in \boldsymbol{H}_{i_1,\ldots,i_{n-1}}$. We claim that there is $\boldsymbol{e}_j \notin \{\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}\}$ such that $\boldsymbol{e}_j \in \boldsymbol{H}_{i_1,\ldots,i_{n-1}}$. Suppose not. Then, $\boldsymbol{e}_1, \ldots, \boldsymbol{e}_L \in \boldsymbol{H}^c_{i_1,\ldots,i_{n-1}}$ and $\boldsymbol{\tau}_n \in \boldsymbol{H}_{i_1,\ldots,i_{n-1}}$, which implies that $\boldsymbol{\tau}_n \notin \Delta_{L-1}$. This is a contradiction, so the claim follows.

Define

$$
\boldsymbol{\lambda}_k^{(i_1,\ldots,i_{n-1})} \coloneqq \frac{1}{k}\boldsymbol{\tau}_n + [\frac{k-1}{k}]\frac{1}{L-1}(\sum_{s>n} \boldsymbol{\tau}_s + \sum_{s<n} \boldsymbol{e}_{i_s}).
$$

There exists an integer $K_n^{(i_1,\ldots,i_{n-1})}$ such that if $k \geqslant K_n^{(i_1,\ldots,i_{n-1})}$, then for all $\boldsymbol{e}_j \in \boldsymbol{H}_{i_1,\ldots,i_{n-1}}$, $\boldsymbol{\lambda}_k^{(i_1,\ldots,i_{n-1})} \in \text{conv}(\boldsymbol{e}_j, \boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L)^\circ$. Set

$$
K_n \coloneqq \max(\max_{\{i_1,\ldots,i_{n-1}\} \subset [L]} (K_n^{(i_1,\ldots,i_{n-1})}), K_{n-1}).
$$

Fix $k \geqslant K_n$. Define

$$
\begin{aligned}
\boldsymbol{\lambda}_k &\coloneqq \frac{1}{k}\boldsymbol{\tau}_n + [\frac{k-1}{k}]\bar{\boldsymbol{\tau}}_n^{(k)} \\
&= \frac{1}{k}\boldsymbol{\tau}_n + [\frac{k-1}{k}]\frac{1}{L-1}(\sum_{s>n} \boldsymbol{\tau}_s + \sum_{s<n} \boldsymbol{\gamma}_s^{(k)}).
\end{aligned}
$$

By the inductive hypothesis, $k \geqslant K_{n-1}$, and Proposition 3, there exists $\{i_1, \ldots, i_{n-1}\} \subset [L]$ such that $\boldsymbol{\gamma}_j^{(k)} = \boldsymbol{e}_{i_j}$ for all $j \in [n-1]$. For the sake of abbreviation, let $\boldsymbol{H} = \boldsymbol{H}_{i_1,\ldots,i_{n-1}}$. Thus, $\boldsymbol{\tau}_n \in \boldsymbol{H}$ and there exists $\boldsymbol{e}_j \in \boldsymbol{H}$ such that $\boldsymbol{e}_j \notin \{\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}\}$. Hence, by our choice of K_n, for every $\boldsymbol{e}_j \in \boldsymbol{H}$

$$
\boldsymbol{\lambda}_k = \boldsymbol{\lambda}_k^{(i_1,\ldots,i_{n-1})} \in \text{conv}(\boldsymbol{e}_j, \boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L)^\circ.
$$

By event E for all $\boldsymbol{e}_j \in \boldsymbol{H}$, there is a unique $\kappa_j > 0$ and unique $a_{j,1}, \ldots, a_{j,n-1}, a_{j,n+1}, \ldots, a_{j,L} > 0$ such that

$$
\begin{aligned}
\boldsymbol{\lambda}_k &= \kappa_j \boldsymbol{e}_j + \sum_{l<n} a_{j,i} \boldsymbol{e}_{i_l} + \sum_{l>n} a_{j,l} \boldsymbol{\tau}_l \\
&= \kappa_j \boldsymbol{e}_j + (1 - \kappa_j) \tilde{\boldsymbol{\tau}}_j
\end{aligned}
$$

where $\tilde{\boldsymbol{\tau}}_j \in \text{conv}(\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L)$ is unique.

We claim that for all $l \neq j$ such that $\{\boldsymbol{e}_l, \boldsymbol{e}_j\} \subset \boldsymbol{H}$, $\kappa_l \neq \kappa_j$. Suppose to the contrary that there exists $l \neq j$ such that $\{\boldsymbol{e}_l, \boldsymbol{e}_j\} \subset \boldsymbol{H}$ and $\kappa_l = \kappa_j = \kappa$. Then,

$$\boldsymbol{\lambda}_k = \kappa \boldsymbol{e}_l + (1-\kappa)\tilde{\boldsymbol{\tau}}_i = \kappa \boldsymbol{e}_j + (1-\kappa)\tilde{\boldsymbol{\tau}}_j.$$

This implies that $\boldsymbol{e}_l - \boldsymbol{e}_j \in \text{span}(\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L)$. Observe that $\{\boldsymbol{e}_l, \boldsymbol{e}_j\} \subset \boldsymbol{H}$ implies that $\boldsymbol{e}_l \notin \{\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}\}$ and $\boldsymbol{e}_j \notin \{\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}\}$. Thus, event G implies that $\boldsymbol{e}_l - \boldsymbol{e}_j, \boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L$ are linearly independent. Therefore, we have a contradiction, establishing the claim.

Consequently, there is a unique j that minimizes κ_j. Note that for all $\boldsymbol{e}_l \notin \boldsymbol{H}$, if we write $\boldsymbol{e}_l = \sum_{m<n} a_m \boldsymbol{e}_{i_m} + \sum_{m>n} a_m \boldsymbol{\tau}_m + a_n \boldsymbol{\lambda}_k$, then $\boldsymbol{a}_n \leqslant 0$. Then, by Lemma 6, $\boldsymbol{e}_j$ is the residue of $\boldsymbol{\lambda}_k$ with respect to $\boldsymbol{\gamma}_1^{(k)}, \ldots, \boldsymbol{\gamma}_{n-1}^{(k)}, \boldsymbol{\tau}_{n+1}, \ldots, \boldsymbol{\tau}_L$. Therefore, by Proposition 3, $\text{MultiResidue}(\frac{1}{k}Q_n + (1-\frac{1}{k})\bar{Q}_n \,|\, \{Q_j\}_{j>n} \cup \{W_j^{(k)}\}_{j<n})$ is well-defined and if $W_n \longleftarrow \text{MultiResidue}(\frac{1}{k}Q_n + (1-\frac{1}{k})\bar{Q}_n \,|\, \{Q_j\}_{j>n} \cup \{W_j^{(k)}\}_{j<n})$, $W_n^{(k)}$ is one of the base distributions. Since $\boldsymbol{e}_j \in \boldsymbol{H}$ implies that $\boldsymbol{e}_j \notin \{\boldsymbol{e}_{i_1}, \ldots, \boldsymbol{e}_{i_{n-1}}\}$, it follows that $W_1^{(k)}, \ldots, W_n^{(k)}$ are distinct base distributions. This establishes the inductive step.

The result follows from applying Lemma 7. ■

Appendix E. Estimation

In this section, we present the estimation results of our paper. To begin, in Section E.1, we present the proof of sufficient conditions under which ResidueHat estimators converge uniformly in probability (Proposition 4). Second, in Section E.2, we prove our main estimation result for demixing mixed membership models (Theorem 5). Finally, in Section E.3, we prove our main estimation result for classification with partial labels (Theorem 6).

E.1. ResidueHat Results

Let $A_1, A_2, \ldots$ denote positive constants whose values may change from line to line. We introduce the following definitions.

Definition 11 *Let $\widehat{F}$ and $\widehat{H}$ be ResidueHat estimators of F and H, respectively, where $F \neq H$ and let $G \longleftarrow$ Residue$(F \,|\, H)$ and $\widehat{G} \longleftarrow$ ResidueHat$(\widehat{F} \,|\, \widehat{H})$. If $\widehat{G}$ is a ResidueHat estimator of order 0, we say its* distributional ancestors *are $\{F, H\}$ and define ancestors$(\widehat{G}) \coloneqq \{F, H\}$. If $\widehat{G}$ is a ResidueHat estimator of the kth order, we define its distributional ancestors to be ancestors$(\widehat{G})$ = ancestors$(\widehat{F}) \cup$ ancestors$(\widehat{H})$.*

The constants in our bounds depend on the distributional ancestors.

Definition 12 *We say that the distribution F satisfies the* support condition ***(SC)*** *with respect to H if there exists a distribution G and $\gamma \in [0, 1)$ such that $\text{supp}(H) \nsubseteq \text{supp}(G)$ and $F = (1-\gamma)G + \gamma H$.*

Definition 13 *If*

$$\sup_{E \in \mathcal{E}} |\widehat{F}(E) - F(E)| \xrightarrow{i.p.} 0$$

as $\boldsymbol{n} \longrightarrow \infty$, we say that $\widehat{F} \longrightarrow F$ uniformly (or $\widehat{F}$ converges uniformly to F) with respect to $\mathcal{E}$.

Definition 14 *Let $\widehat{F}$ be a ResidueHat estimator of a distribution F. We say that $\widehat{F}$ satisfies a Uniform Deviation Inequality* ***(UDI)*** *with respect to $\mathcal{E}$ if for all $\epsilon > 0$, there exist constants $A_{1,\epsilon}, A_{2,\epsilon} > 0$ and $\boldsymbol{N}$ depending on ancestors$(\widehat{F})$ such that if $\boldsymbol{n} \geqslant \boldsymbol{N}$, then for all $E \in \mathcal{E}$*

$$|\widehat{F}(E) - F(E)| < A_{1,\epsilon}\gamma_{\boldsymbol{n}} + \epsilon$$

with probability at least $1 - A_{2,\epsilon}\sum_{i \in [L]} \frac{1}{n_i}$

Henceforth, for the purposes of abbreviation, we will only say that a ResidueHat estimator satisfies a Uniform Deviation Inequality **(UDI)** and omit "with respect to $\mathcal{E}$" because the context makes this clear.

Definition 15 *Let $\widehat{F}$ and $\widehat{H}$ be ResidueHat estimators. We say that $\widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$ satisfies a Rate of Convergence* ***(RC)*** *with respect to $\mathcal{E}$ if for all $\epsilon > 0$, there exists constants $A_{1,\epsilon}, A_{2,\epsilon} > 0$ and $\boldsymbol{N}$ depending on ancestors$(\widehat{F}) \cup$ ancestors$(\widehat{H})$ such that for $\boldsymbol{n} \geqslant \boldsymbol{N}$,*

$$|\widehat{\kappa}(\widehat{F} \,|\, \widehat{H}) - \kappa^*(F \,|\, H)| \leqslant A_{1,\epsilon}\gamma_{\boldsymbol{n}} + \epsilon$$

with probability at least $1 - A_{2,\epsilon}\sum_{i \in [L]} \frac{1}{n_i}$.

Lemma 8 gives sufficient conditions under which F satisfies **(SC)** with respect to H.

Lemma 8 *Let $P_1, \ldots, P_L$ satisfy* ***(A″)*** *and let $F, H \in \text{conv}(P_1, \ldots, P_L)$ such that $F \neq H$. Then, F satisfies* ***(SC)*** *with respect to H.*

Proof Let $A = \arg\min(|B| : B \subseteq \{P_1, \ldots, P_L\}, F, H \in \text{conv}(B))$. Without loss of generality, suppose that $A = \{P_1, \ldots, P_K\}$. F either lies on the boundary of $\text{conv}(P_1, \ldots, P_K)$ or doesn't. If F lies on the boundary of $\text{conv}(P_1, \ldots, P_K)$, then $H \in \text{conv}(P_1, \ldots, P_K)^\circ$ by minimality of A. Then, we pick $G = F$ and $\gamma = 0$ to obtain $F = (1-\gamma)F + \gamma H$. Since $P_1, \ldots, P_L$ satisfy **(A″)**, $\text{supp}(H) \nsubseteq \text{supp}(F)$.

Now, suppose that $F \in \text{conv}(P_1, \ldots, P_K)^\circ$. Let $G \longleftarrow \text{Residue}(F \,|\, H)$; we can write $F = (1-\gamma)G + \gamma H$ for $\gamma \in [0, 1)$ since $F \neq H$. Then, by Statement *2* of Lemma 2 and statement *3* of Proposition 3, G is on the boundary of $\text{conv}(P_1, \ldots, P_K)$. Without loss of generality, suppose that $G \in \text{conv}(P_1, \ldots, P_{K-1})$. Since $F = (1-\gamma)G + \gamma H \in \text{conv}(P_1, \ldots, P_K)^\circ$, and $G \in \text{conv}(P_1, \ldots, P_{K-1})$, $H \notin \text{conv}(P_1, \ldots, P_{K-1})$. Since $P_1, \ldots, P_L$ satisfy **(A″)**, $\text{supp}(H) \nsubseteq \text{supp}(G)$. This completes the proof. ■

Lemma 9 gives sufficient conditions under which an estimator $\widehat{G}$ satisfies a **(UDI)**.

Lemma 9 *Let*

1. *F and H be distributions such that $F \neq H$,*
2. *$G \longleftarrow$ Residue$(F \,|\, H)$, and*
3. *$\widehat{G} \longleftarrow$ ResidueHat$(\widehat{F} \,|\, \widehat{H})$.*

*If $\widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$ satisfies a **(RC)**, $\widehat{H}$ satisfies a **(UDI)**, and $\widehat{F}$ satisfies a **(UDI)**, then $\widehat{G}$ satisfies a **(UDI)**.*

Proof For the sake of abbreviation, let $\widehat{\kappa} = \widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$, $\kappa^* = \kappa^*(F \,|\, H)$, $\widehat{\alpha} = \frac{1}{1-\widehat{\kappa}}$ and $\alpha^* = \frac{1}{1-\kappa^*}$. Let $\epsilon > 0$. We claim that there are constants $A_{1,\epsilon}, A_{2,\epsilon} > 0$ such that for sufficiently large $\boldsymbol{n}$,

$$\Pr(|\widehat{\alpha} - \alpha^*| < A_{1,\epsilon}\gamma_{\boldsymbol{n}} + \epsilon) \geqslant 1 - A_{2,\epsilon} \sum_{i \in [L]} \frac{1}{n_i}. \tag{10}$$

Let $\delta = \frac{\epsilon(1-\kappa^*)^2}{2}$. Since $\widehat{\kappa}$ satisfies a **(RC)**, there exists constants $A_{1,\delta}, A_{2,\delta} > 0$ such that for large enough $\boldsymbol{n}$,

$$|\widehat{\kappa} - \kappa^*| \leqslant A_{1,\delta}\gamma_{\boldsymbol{n}} + \delta$$

with probability at least $1 - A_{2,\delta} \sum_{i \in [L]} \frac{1}{n_i}$. Since $F \neq H$, $\kappa^* < 1$ by Proposition 2, so we can let $\boldsymbol{n}$ large enough so that

$$\frac{1}{(1-\kappa^*)(1-\widehat{\kappa})} \leqslant 2\frac{1}{(1-\kappa^*)^2}$$

with high probability. Then, on this same event, for large enough $\boldsymbol{n}$,

$$\begin{aligned}
|\frac{1}{1-\kappa^*} - \frac{1}{1-\widehat{\kappa}}| &\leqslant \frac{A_{1,\delta}\gamma_{\boldsymbol{n}} + \delta}{(1-\kappa^*)(1-\widehat{\kappa})} \\
&\leqslant 2\frac{A_{1,\delta}\gamma_{\boldsymbol{n}} + \delta}{(1-\kappa^*)^2} \\
&\leqslant 2\frac{A_{1,\delta}\gamma_{\boldsymbol{n}}}{(1-\kappa^*)^2} + \epsilon.
\end{aligned}$$

Thus, we obtain the claim.

We can write $G = \alpha F + (1-\alpha)H$ with $\alpha \geqslant 1$. Then, by the triangle inequality,

$$\begin{aligned}
|\widehat{G} - G| &= |\widehat{\alpha}\widehat{F} + (1-\widehat{\alpha})\widehat{H} - \alpha F - (1-\alpha)H| \\
&\leqslant |\widehat{\alpha}\widehat{F} - \alpha F| + |(1-\widehat{\alpha})\widehat{H} - (1-\alpha)H| \\
&= |\widehat{\alpha}\widehat{F} - \widehat{\alpha}F + \widehat{\alpha}F - \alpha F| + |(1-\widehat{\alpha})\widehat{H} - (1-\widehat{\alpha})H + (1-\widehat{\alpha})H - (1-\alpha)H| \\
&\leqslant |\widehat{\alpha}||\widehat{F} - F| + |\widehat{\alpha} - \alpha| + |1-\widehat{\alpha}||\widehat{H} - H| + |\widehat{\alpha} - \alpha|.
\end{aligned}$$

Since $\widehat{F}$ satisfies a **(UDI)**, $\widehat{H}$ satisfies a **(UDI)**, inequality (10) holds, and $|\widehat{\alpha}|$ and $|1-\widehat{\alpha}|$ are bounded in probability, the result follows by an application of a union bound and picking the ϵs in the uniform deviation inequalities appropriately for each term. ■

Lemma 10 gives sufficient conditions under which $\widehat{\kappa}$ satisfies **(RC)**.

Lemma 10 *Let F and H be distributions such that $F \neq H$. If*

- *F satisfies **(SC)** with respect to H,*

- *$\widehat{F}$ satisfies **(UDI)**, and*
- *$\widehat{H}$ satisfies **(UDI)**,*

*then $\widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$ satisfies **(RC)**.*

Proof For abbreviation, let $\kappa^* = \kappa(F \,|\, H)$ and $\widehat{\kappa} = \widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$.

We first prove the upper bound. F satisfies **(SC)** with respect to H, so there exists a distribution G such that $F = (1-\gamma)G + \gamma H$ for some $\gamma \in [0,1)$ and $\text{supp}(H) \nsubseteq \text{supp}(G)$. Therefore, we have that G is irreducible with respect to H and, by Proposition 2, $\kappa^* = \gamma$.

Let $\delta > 0$ (to be chosen later). Since by hypothesis $\widehat{F}$ and $\widehat{H}$ satisfy **(UDI)**, there exist constants $A_{1,\delta}, A_{2,\delta} > 0$ such that for large enough $\boldsymbol{n}$, with probability at least $1 - A_{1,\delta}[\sum_{i \in [L]} \frac{1}{n_i}]$, for all $E \in \mathcal{E}$,

$$|\widehat{F}(E) - F(E)| < A_{2,\delta}\gamma_{\boldsymbol{n}} + \delta \tag{11}$$

$$|\widehat{H}(E) - H(E)| < A_{2,\delta}\gamma_{\boldsymbol{n}} + \delta. \tag{12}$$

Without loss of generality, let $A_{1,\delta}, A_{2,\delta} > 1$.

Pick $R \in \mathcal{E}$ such that $H(R) > 0$. By inequality (12), there exists $\boldsymbol{N}_1$ such that $\boldsymbol{n} \geqslant \boldsymbol{N}_1$ implies that $\widehat{H}(R) - \gamma_{\boldsymbol{n}} > 0$ with high probability. This implies that for $\boldsymbol{n} \geqslant \boldsymbol{N}_1$, $\widehat{\kappa}$ is finite. Let $\epsilon > 0$. By definition of $\widehat{\kappa}$, there exists $E \in \mathcal{E}$ such that

$$\frac{\epsilon}{2} + \widehat{\kappa} \geqslant \frac{\widehat{F}(E) + \gamma_{\boldsymbol{n}}}{(\widehat{H}(E) - \gamma_{\boldsymbol{n}})_+}.$$

Since $\widehat{\kappa}$ is finite, we have that $\widehat{H}(E) > \gamma_{\boldsymbol{n}}$ and $H(E) > 0$. Then,

$$\begin{aligned}
\frac{\epsilon}{2} + \widehat{\kappa} &\geqslant \frac{\widehat{F}(E) + \gamma_{\boldsymbol{n}}}{\widehat{H}(E) - \gamma_{\boldsymbol{n}}} \\
&\geqslant \frac{F(E) - (A_{2,\delta}-1)\gamma_{\boldsymbol{n}} - \delta}{H(E) + (A_{2,\delta}-1)\gamma_{\boldsymbol{n}} + \delta} \\
&\geqslant \frac{\gamma H(E)}{H(E) + (A_{2,\delta}-1)\gamma_{\boldsymbol{n}} + \delta} - \frac{(A_{2,\delta}-1)\gamma_{\boldsymbol{n}}}{H(E) + (A_{2,\delta}-1)\gamma_{\boldsymbol{n}} + \delta} - \frac{\delta}{H(E) + (A_{2,\delta}-1)\gamma_{\boldsymbol{n}} + \delta} \\
&\geqslant \frac{\gamma H(E)}{H(E)} - \frac{(A_{2,\delta}-1)\gamma_{\boldsymbol{n}} + \delta}{H(E)} - \frac{(A_{2,\delta}-1)\gamma_{\boldsymbol{n}}}{H(E) + (A_{2,\delta}-1)\gamma_{\boldsymbol{n}} + \delta} - \frac{\delta}{H(E) + (A_{2,\delta}-1)\gamma_{\boldsymbol{n}} + \delta} \\
&\geqslant \kappa^* - 2\frac{(A_{2,\delta}-1)\gamma_{\boldsymbol{n}}}{H(E)} - 2\frac{\delta}{H(E)}
\end{aligned}$$

where in the second to last inequality we used the elementary fact that if $a, b, c > 0$ and $a \leqslant b$, then $\frac{a}{b+c} \geqslant \frac{a}{b} - \frac{c}{b}$. Picking $\delta = \frac{H(E)\epsilon}{4}$, we obtain the upper bound.

The proof of the other direction of the inequality is very similar to the proof of Theorem 2 in Scott (2015). By hypothesis, F satisfies **(SC)** with respect to H, so there exists a distribution G such that $F = (1-\gamma)G + \gamma H$ for some $\gamma \in [0,1)$ and $\text{supp}(H) \nsubseteq \text{supp}(G)$. Therefore, we have that G is irreducible with respect to H and, by Proposition 2, $\kappa^*(F \,|\, H) = \gamma$. For

abbreviation, let $\kappa^* = \kappa^*(F \,|\, H)$ and $\widehat{\kappa} = \widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$. Since $\text{supp}(H) \nsubseteq \text{supp}(G)$, there exists an open set O such that

$$\frac{F(O)}{H(O)} = (1-\gamma)\frac{G(O)}{H(O)} + \gamma = \kappa^*.$$

Then, since $\mathcal{E}$ contains a generating set for the standard topology on $\mathbb{R}^d$, there exists $E \in \mathcal{E}$ such that

$$\frac{F(E)}{H(E)} = \kappa^*.$$

Let $\delta > 0$ such that $\delta \leqslant \frac{1}{4}H(E)$. Since by hypothesis $\widehat{F}$ and $\widehat{H}$ satisfy **(UDI)**, there exist constants $A_{3,\delta}, A_{4,\delta} > 0$ such that for large enough $\boldsymbol{n}$, with probability at least $1 - A_{3,\delta}[\sum_{i\in[L]} \frac{1}{n_i}]$,

$$\begin{aligned}\widehat{\kappa} &\leqslant \frac{F(E) + A_{4,\delta}\gamma_{\boldsymbol{n}} + \delta}{(H(E) - A_{4,\delta}\gamma_{\boldsymbol{n}} - \delta)_+} \\ &\leqslant \frac{F(E) + \epsilon}{(H(E) - \epsilon)_+}\end{aligned}$$

where $\epsilon = 2A_{4,\delta}\gamma_{\boldsymbol{n}} + \delta$. The rest of the proof is identical to the proof of Theorem 2 from Scott (2015) and, therefore, we omit it. ■

The following theorem gives sufficient conditions under which a ResidueHat estimator satisfies **(UDI)**. It is the basis of Proposition 4.

Lemma 11 *If $P_1, \ldots, P_L$ satisfy **(A″)** and $\widehat{G}$ is a ResidueHat estimator of order k of a distribution $G \in \text{conv}(P_1, \ldots, P_L)$, then $\widehat{G}$ satisfies **(UDI)**.*

Proof Let $\widehat{G} \longleftarrow \text{ResidueHat}(\widehat{F} \,|\, \widehat{H})$ where $G \longleftarrow \text{ResidueHat}(F \,|\, H)$, $F \neq H$, $F, H \in \text{conv}(P_1, \ldots, P_L)$ and $\widehat{F}, \widehat{H}$ are ResidueHat estimators of F and H respectively. We use induction on k. Suppose $k = 0$. Then, $\widehat{F}$ and $\widehat{H}$ are empirical distributions. Therefore, the VC inequality applies to $\widehat{F}$ and $\widehat{H}$. Consequently, $\widehat{F}$ and $\widehat{H}$ satisfy **(UDI)**. Since $P_1, \ldots, P_L$ satisfy **(A″)**, $F, H \in \text{conv}(P_1, \ldots, P_L)$ and $F \neq H$, by Lemma 8, F satisfies **(SC)** with respect to H. Then, by Lemma 10, $\widehat{\kappa}(\widehat{F} \,|\, \widehat{H})$ satisfies **(RC)**. Then, all of the assumptions of Lemma 9 are satisfied, so $\widehat{G}$ satisfies **(UDI)**. Note that $G \in \text{conv}(P_1, \ldots, P_L)$ by Proposition 3.

The inductive step ($k > 0$) follows by similar reasoning. The difference is that instead of applying the VC inequality to $\widehat{F}$ and $\widehat{H}$, we use the fact that $\widehat{F}$ and $\widehat{H}$ are ResidueHat estimators of order $k-1$ and, therefore, satisfy **(UDI)** by the inductive hypothesis. ■

Proof [Proof of Proposition 4] Let $0 < \delta < \epsilon$. By Lemma 11, $\widehat{G}$ satisfies **(UDI)**. Consequently, there exist constants $A_{1,\delta}, A_{2,\delta} > 0$ such that for large enough $\boldsymbol{n}$ with probability at least $1 - A_{1,\delta}\sum_{i\in[L]} \frac{1}{n_i}$, $\widehat{G}$ satisfies for every $E \in \mathcal{E}$,

$$|\widehat{G}(E) - G(E)| \leqslant A_{2,\delta}\gamma_{\boldsymbol{n}} + \delta = A_{2,\delta}\sum_{i\in[L]} \epsilon_i(\frac{1}{n_i}) + \delta \longrightarrow \delta < \epsilon.$$

■

E.2. Demixing Mixed Membership Models

In this section, we prove our main estimation result for demixing mixed membership models, i.e., Theorem 5. First, in Section E.2.1, we present an important lemma for FaceTestHat. Second, in Section E.2.2, we present an empirical version of Demix and prove Theorem 5.

E.2.1. The FaceTestHat Algorithm

The following establishes that FaceTestHat behaves as desired.

Lemma 12 *Let $\epsilon \in (0,1)$. For all $j \in [K]$, let $Q_j = \boldsymbol{\eta}_j^T \boldsymbol{P}$ and $\boldsymbol{\eta}_j \in \Delta_K$ such that every $\boldsymbol{\eta}_j$ lies in the relative interior of the same face of Δ_K. Let $P_1, \ldots, P_K$ satisfy **(A″)**, and $Q_1, \ldots, Q_K \in \text{conv}(P_1, \ldots, P_K)$ be distinct. Let $\widehat{Q}_i$ be a ResidueHat estimate of Q_i $\forall i \in [K]$.*

1. *With probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$, if FaceTestHat$(\widehat{Q}_1, \cdots, \widehat{Q}_K \,|\, \epsilon)$ returns 1, then $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_K$ are in the relative interior of the same face.*
2. *Let $\kappa^*_{i,j} = \kappa^*(Q_i \,|\, Q_j)$. If $\boldsymbol{\eta}_1, \ldots, \boldsymbol{\eta}_K$ are in the relative interior of the same face and $\min_{i,j} \kappa^*_{i,j} > \epsilon$, then with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$, FaceTestHat$(\widehat{Q}_1, \cdots, \widehat{Q}_K \,|\, \epsilon)$ returns 1.*

Proof Let $\epsilon > 0$, $\kappa^*_{i,j} = \kappa^*(Q_i \,|\, Q_j)$ and $\widehat{\kappa}_{i,j} = \widehat{\kappa}(\widehat{Q}_i \,|\, \widehat{Q}_j)$. Since $P_1, \ldots, P_K$ satisfy **(A″)** and $Q_i \neq Q_j$, by Lemma 8, Q_i satisfies **(SC)** wrt Q_j. Since $\widehat{Q}_i$ and $\widehat{Q_j}$ are ResidueHat estimators, $\widehat{Q}_i$ and $\widehat{Q}_j$ satisfy **(UDI)** (Lemma 11). Then, by Lemma 10 $\widehat{\kappa}_{i,j}$ satisfies **(RC)**.

1. We prove the contrapositive. Suppose that $Q_1, \ldots, Q_K$ are not in the relative interior of the same face. Then, by Proposition 8, FaceTest$(Q_1, \ldots, Q_K)$ returns 0, which occurs if and only if there exist $i \neq j$ such that $\kappa^*_{i,j} = 0$. Since $\widehat{\kappa}_{i,j}$ satisfies **(RC)**, as $\boldsymbol{n} \longrightarrow \infty$, with probability tending to 1, $\widehat{\kappa}_{i,j} \longrightarrow 0$. This completes the proof.
2. If $\min_{i,j} \kappa^*_{i,j} > \epsilon$, then as $\boldsymbol{n} \longrightarrow \infty$, with probability tending to 1, $\min_{i,j} \widehat{\kappa}_{i,j} > \epsilon$.

■

E.2.2. The DemixHat Algorithm

The DemixHat algorithm (see Algorithm 11) differs from the Demix algorithm in that *(i)* it requires the specification of a constant $\epsilon \in (0,1)$ and *(ii)* it only uses the two-sample κ^* operator. In the interest of clarity, we state the population version of the algorithm DemixHat, which we call Demix2. The only difference between Demix and Demix2 is that line 7 in Demix has been replaced with lines 6-8 in Demix2.

Lemma 13 establishes that it is possible to replace line 7 of the Algorithm 4 with the sequence of applications of the two-sample κ^* in lines 6-8 of Algorithm 16, without changing the conclusion of Theorem 2.

Lemma 13 *Let $\{i_1, \ldots, i_K\} \subset [L]$ be distinct indices. Let $P_1, \ldots, P_L$ be jointly irreducible, $(Q_1, \ldots, Q_{K-1})$ be a permutation of $(P_{i_1}, \ldots, P_{i_{K-1}})$ and $Q^1_K \in \text{conv}(P_{i_1}, \ldots, P_{i_K})^\circ$. Define*

Algorithm 16 Demix2($S_1, \ldots, S_K$)

Input: $S_1, \ldots, S_K$ are distributions

1: **if** $K = 2$ **then**
2: **return** $(\text{Residue}(S_1 \,|\, S_2), \text{Residue}(S_2 \,|\, S_1))^T$
3: **else**
4: $(R_2, \ldots, R_K)^T \longleftarrow \text{FindFace}(S_1, \ldots, S_K)$
5: $(Q_1, \ldots, Q_{K-1})^T \longleftarrow \text{Demix2}(R_2, \ldots, R_K)$
6: **for** $i = 1, \ldots, K-1$ **do**
7: $Q_K \longleftarrow \text{Residue}(Q_K \,|\, Q_i)$
8: **end for**
9: **return** $(Q_1, \ldots, Q_K)^T$
10: **end if**

the sequence

$$Q_K^i \longleftarrow \mathit{Residue}(Q_K^{i-1} \,|\, Q_{i-1});$$

then, $Q_K^K = P_{i_K}$.

Proof Relabel the distributions so that $Q_j = P_j$. Let $\boldsymbol{\mu}_i$ denote the mixture proportion of Q_K^i and $\boldsymbol{e}_j$ the mixture proportion of P_j. Write $\boldsymbol{\mu}_1 = \sum_{i=1}^K \alpha_i \boldsymbol{e}_i$. We claim that $\boldsymbol{\mu}_k = \frac{\sum_{i \geqslant k} \alpha_i \boldsymbol{e}_i}{\sum_{i \geqslant k} \alpha_i}$ for all $k \leqslant K$. We prove this inductively. The base case $k = 1$ follows since $\sum_{i \geqslant 1} \alpha_i = 1$. Next, we prove the inductive step. Suppose that $\boldsymbol{\mu}_{k-1} = \frac{\sum_{i \geqslant k-1} \alpha_i \boldsymbol{e}_i}{\sum_{i \geqslant k-1} \alpha_i}$. By Proposition 3, the mixture proportion of Q_K^k, $\boldsymbol{\mu}_k$, is the residue of $\boldsymbol{\mu}_{k-1}$ with respect to $\boldsymbol{e}_{k-1}$. By statement 1 of Lemma 2, we can write

$$\begin{aligned}\boldsymbol{\mu}_k &= \boldsymbol{e}_{k-1} + \alpha^*(\boldsymbol{\mu}_{k-1} - \boldsymbol{e}_{k-1}) \\ &= \frac{[\sum_{i \geqslant k-1} \alpha_i (1 - \alpha^*) + \alpha^* \alpha_{k-1}] \boldsymbol{e}_{k-1} + \alpha^* \sum_{i \geqslant k} \alpha_i \boldsymbol{e}_i}{\sum_{i \geqslant k-1} \alpha_i}\end{aligned}$$

where

$$\alpha^* = \frac{1}{1 - \kappa^*(\boldsymbol{\mu}_{k-1} \,|\, \boldsymbol{e}_{k-1})}$$

and we have used the inductive hypothesis $\boldsymbol{\mu}_{k-1} = \frac{\sum_{i \geqslant k-1} \alpha_i \boldsymbol{e}_i}{\sum_{i \geqslant k-1} \alpha_i}$. α^* is the value of the following optimization problem (in statement 1 of Lemma 2):

$$\max(\alpha \geqslant 1 \,|\, \exists G, G = \boldsymbol{\mu}_{k-1} + \alpha(\boldsymbol{e}_{k-1} - \boldsymbol{\mu}_{k-1})).$$

Inspection of the above optimization problem reveals that $\alpha^* = \frac{\sum_{i \geqslant k-1} \alpha_i}{\sum_{i \geqslant k} \alpha_i}$. Plugging this into the above equation gives $\boldsymbol{\mu}_k = \frac{\sum_{i \geqslant k} \alpha_i \boldsymbol{e}_i}{\sum_{i \geqslant k} \alpha_i}$. This establishes the claim.

Setting $k = K$, it follows that $\mu_K = \frac{\alpha_K \boldsymbol{e}_K}{\alpha_K} = \boldsymbol{e}_K$. ■

Corollary 2 *Let* $P_1, \ldots, P_L$ *be jointly irreducible and* $\boldsymbol{\Pi}$ *have full column rank. Then, with probability* 1*, Demix2*($\tilde{\boldsymbol{P}}$) *returns a permutation of* $\boldsymbol{P}$.

Proof [Proof of Theorem 5] Note that every estimator of a distribution in the DemixHat algorithm is a ResidueHat estimator since *(i)* the Demix2 algorithm 16 only considers distributions that are in $\text{conv}(P_1, \ldots, P_L)$ and *(ii)* only computes $\text{Residue}(F \,|\, H)$ if $F \neq H$. To see why *(ii)* is true, consider: the Demix2 algorithm computes $\text{Residue}(\cdot \,|\, \cdot)$ at lines 2 and 7 in Demix2 and line 3 in FindFace. In the proof of Theorem 2, we showed that $S_1, \ldots, S_K$ are always linearly independent and therefore distinct. This implies that in lines 2 and 7 in Demix2 and line 3 in FindFace, the residue function is called on distinct distributions. Thus, every estimator of a distribution of the DemixHat algorithm satisfies the assumptions of Lemma 11.

First, we argue that the order of the ResidueHat estimators is bounded; this implies that the constants in the uniform deviation inequalities associated with the ResidueHat estimators are bounded. We give a very loose bound. DemixHat calls itself at most $L-1$ times and in each call recurses on at most $L-1$ ResidueHat estimators and calculates at most $L-1$ more ResidueHat estimators. Therefore, each ResidueHat estimator has order at most $(L-1)^3$.

Second, let A_i denote the event that DemixHat recurses on i distributions lying in the relative interior of an i-face in the $(L-i)$th recursive call. We show that the event $\cap_{i=2}^{L-1} A_i$ occurs with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$. Consider A_{L-1}. Let $\widehat{R}_i^{(n)}$ denote the estimate of the ith distribution in line 3 in the nth iteration of the for loop in Algorithm 12 and let $R_i^{(n)}$ denote the corresponding distribution. Let $\kappa_{i,j,n}^* = \kappa^*(R_i^{(n)} \,|\, R_j^{(n)})$. From the proof of Theorem 2, there exists an integer $N_1 \geqslant 0$ such that for $n \geqslant N_1$, $R_i^{(n)}$ lies in the relative interior of the same face for all $i = 2, \ldots, L$. Further, using the notation from the proof of Theorem 2, we have that the mixture proportions of the $R_i^{(n)}$s, i.e., the $\boldsymbol{\mu}_i^{(n)}$s, converge to a common $\boldsymbol{\lambda}$ on this face, i.e., for all $i = 2, \ldots, L$, $\left\| \boldsymbol{\mu}_i^{(n)} - \boldsymbol{\lambda} \right\| \longrightarrow 0$. Thus, by statement 3 of Lemma 4, for all $i \neq j \in [L] \backslash \{1\}$ $\kappa^*(\boldsymbol{\mu}_i^{(n)} \,|\, \boldsymbol{\mu}_j^{(n)}) \longrightarrow 1$. Hence, there exists $N_2 \geqslant N_1$ such that $\kappa^*(\boldsymbol{\mu}_i^{(N_2)} \,|\, \boldsymbol{\mu}_j^{(N_2)}) > \epsilon$ for all $i \neq j$. By statement 1 of Lemma 12 and a union bound argument, with probability increasing to 1, $\text{FaceTestHat}(\widehat{R}_2^{(n)}, \ldots, \widehat{R}_L^{(n)} \,|\, \epsilon)$ returns 0 for all $n < N_1$ since $R_2^{(n)}, \ldots, R_L^{(n)}$ are not on the relative interior of the same face. Thus, with probability tending to 1, FaceTest does not make the mistake to return 1 before the distributions $R_2^{(n)}, \ldots, R_L^{(n)}$ are on the relative interior of the same face. By statement 2 of Lemma 12, with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$, $\text{FaceTestHat}(\widehat{R}_2^{(N_2)}, \ldots, \widehat{R}_L^{(N_2)} \,|\, \epsilon)$ returns 1. Hence, with probability increasing to 1, the event A_{L-1} occurs. Applying the same argument to A_i for $i < L-1$ and taking the union bound shows that $\cap_{i=2}^{L-1} A_i$ occurs with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$.

Now, we can complete the proof. Under the assumptions of Theorem 2, there is a permutation σ such that for each distribution Q_i estimated by $\widehat{Q}_i$, $P_{\sigma(i)} = Q_i$. By Proposition 4, as $\boldsymbol{n} \longrightarrow \infty$, $\widehat{Q}_i$ converges uniformly to Q_i. The result follows. ■

Algorithm 17 VertexTestHat($\mathbf{\Pi}^+, (\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger)^T, (\widehat{Q}_1, \ldots, \widehat{Q}_L)^T$)

Form the matrix $\widehat{\boldsymbol{M}}_{i,j} \coloneqq \widehat{\kappa}(\tilde{P}_i^\dagger \,|\, \widehat{Q}_j)$
Let $|\mathbf{\Pi}^+|$ denote the number of nonzero entries in $\mathbf{\Pi}^+$
Form the matrix $\widehat{\boldsymbol{Z}}$ by making the $|\mathbf{\Pi}^+|$ largest entries of $\widehat{\boldsymbol{M}}$ equal to 1 and the rest of its entries equal to 0
Use any algorithm that finds a permutation matrix $\boldsymbol{C}$ such that $\widehat{\boldsymbol{Z}}\boldsymbol{C} = \mathbf{\Pi}^+$ (if it exists)

if such a permutation matrix $\boldsymbol{C}$ exists **then**
  return $(1, \boldsymbol{C}^T)$
else
  return $(0, \mathbf{0})$
end if

E.3. Classification with Partial Labels

In this section, we prove Theorem 6. To begin, we briefly sketch an argument that one can reduce any instance of a partial label model satisfying **(B3)** and **(A)** to an instance of a partial label model that also satisfies **(D)**. Let $J = \{i : \mathbf{\Pi}^+_{i,:} = \boldsymbol{e}_j^T \text{ for some } j \in [L]\} = \{j_1, \ldots, j_k\}$, the set of indices of contaminated distributions that are equal to some base distribution. Compute Residue($\tilde{P}_i \,|\, \tilde{P}_{j_1}$) for $i \in [L] \backslash J$ if there is l such that $\mathbf{\Pi}^+_{i,l} = \mathbf{\Pi}^+_{j_1,l} = 1$. Replace $\tilde{P}_i$ with Residue($\tilde{P}_i \,|\, \tilde{P}_{j_1}$) (and call it $\tilde{P}_i$ for simplicity of presentation). Update $\mathbf{\Pi}^+$ and remove j_1 from J. Repeat this procedure until J is empty. Then, there will be $(L - |J|)$ $\tilde{P}_i$ lying in a $(L - |J|)$-face of Δ_L that are not equal to any of the base distributions and the other contaminated distributions will be equal to base distributions. Then, it suffices to solve the instance of the partial label model on the $(L - |J|)$-face, which satisfies **(D)**.

Next, we introduce VertexTestHat (Algorithm 17), an empirical version of VertexTest, and prove that it satisfies a useful consistency property.

Lemma 14 *Suppose that $P_1, \ldots, P_L$ satisfy **(A″)**, $\mathbf{\Pi}$ has full column rank, the columns of $\mathbf{\Pi}^+$ are unique and $\mathbf{\Pi}^+$ satisfies **(D)**. Let $\widehat{Q}_1, \ldots, \widehat{Q}_L$ be ResidueHat estimators of $Q_1, \ldots, Q_L$, respectively. Suppose that $(Q_1, \ldots, Q_L)$ is a permutation of $(P_1, \ldots, P_L)$. Then, with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$, VertexTestHat($\mathbf{\Pi}^+, (\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger)^T, (\widehat{Q}_1, \ldots, \widehat{Q}_L)^T$) returns a permutation matrix $\boldsymbol{C}$ such that $\forall i$, $\boldsymbol{C}_{i,:}(\widehat{Q}_1, \ldots, \widehat{Q}_L)^T$ is a ResidueHat estimator of P_i.*

Proof Define $\widehat{\kappa}_{i,j} \coloneqq \widehat{\kappa}(\tilde{P}_i^\dagger \,|\, \widehat{Q}_j)$ and $\kappa^*_{i,j} \coloneqq \kappa^*(\tilde{P}_i \,|Q_j)$. We claim that $\widehat{\kappa}_{i,j}$ satisfies a **(RC)**. Since $P_1, \ldots, P_L$ satisfy **(A″)** and by assumption **(D)** $Q_j \neq \tilde{P}_i$, by Lemma 8, $\tilde{P}_i$ satisfies **(SC)** wrt Q_j. Since $\tilde{P}_i^\dagger$ is an empirical distribution, $\tilde{P}_i^\dagger$ satisfies a **(UDI)**. Since $\widehat{Q}_j$ is a ResidueHat estimator, $\widehat{Q}_j$ satisfies a **(UDI)** by Lemma 11. Therefore, the hypotheses of Lemma 10 are satisfied and $\widehat{\kappa}_{i,j}$ satisfies a **(RC)**.

Form the matrix $Z_{i,j} = \mathbf{1}_{\{\kappa^*(\tilde{P}_i \,|\, Q_j) > 0\}}$ as in Algorithm 9. Since $Q_1, \ldots, Q_L$ are a permutation of $P_1, \ldots, P_L$, $\boldsymbol{Z}$ is formed by permuting the columns of $\mathbf{\Pi}^+$ appropriately. Thus, there are $|\mathbf{\Pi}^+|$ (i, j) pairs such that $\kappa_{i,j} > 0$ and the rest are such that $\kappa_{i,j} = 0$. Then, using Lemma 10 and a union bound, with probability tending to 1 as $\boldsymbol{n} \longrightarrow \infty$, $\widehat{\kappa}_{i,j}$ is among the $|S|$ largest values in the matrix $\widehat{M}$ if and only if $\kappa_{i,j} > 0$. On this event, VertexTestHat($\mathbf{\Pi}^+, (\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger)^T, (\widehat{Q}_1, \ldots, \widehat{Q}_L)^T$) and VertexTest($\mathbf{\Pi}^+, (\tilde{P}_1, \ldots, \tilde{P}_M)^T, (Q_1, \ldots, Q_L)^T$) return the same output. Since $(Q_1, \ldots, Q_L)$ is a permutation of $(P_1, \ldots, P_L)$ by hypothesis, by Lemma 7 VertexTest($\mathbf{\Pi}^+, (\tilde{P}_1, \ldots, \tilde{P}_M)^T, (Q_1, \ldots, Q_L)^T$) returns $(1, \boldsymbol{C}^T)$ such that $\boldsymbol{C}^T(Q_1, \ldots, Q_L)^T = \boldsymbol{P}$. The result follows. ■

Proof [Proof of Theorem 6] Let $(\widehat{Q}_1, \ldots, \widehat{Q}_L) \longleftarrow$ DemixHat($\tilde{P}_1^\dagger, \ldots, \tilde{P}_M^\dagger \,|\, \epsilon$). By Theorem 5, w.p. tending towards 1 as $\boldsymbol{n} \longrightarrow \infty$, there exists a permutation $\sigma : [L] \longrightarrow [L]$ such that for every $i \in [L]$,

$$\sup_{E \in \mathcal{E}} |\widehat{Q}_i(E) - P_{\sigma(i)}(E)| < \delta.$$

From the proof of Theorem 5, each $\widehat{Q}_i$ is a ResidueHat estimator. The assumptions of Lemma 14 are satisfied. The result follows immediately from Lemma 14. ■

Appendix F. Previous Results

Lemma 15 (Lemma A.1 (Blanchard and Scott, 2014)) *The maximum operation in the definition of κ^* and $\widehat{\kappa}$ (lines (3) and (6), respectively) is well-defined, that is, the outside supremum is attained at at least one point.*

Lemma 16 (Lemma B.1 (Blanchard and Scott, 2014)) *If Π satisfies **(B1)**, then $\boldsymbol{\pi}_1, \ldots, \boldsymbol{\pi}_L$ are linearly independent. If $P_1, \ldots, P_L$ are jointly irreducible, then they are linearly independent. If $\boldsymbol{\pi}_1, \ldots, \boldsymbol{\pi}_L$ are linearly independent and $P_1, \ldots, P_L$ are linearly independent, then $\tilde{P}_1, \ldots, \tilde{P}_L$ are linearly independent.*

Appendix G. Experiments

In this Section, we perform experiments that suggest that joint irreducibility of $P_1, \ldots, P_L$ is a reasonable assumption. In particular, our experiments suggest that on the datasets in question, **(A″)** holds (which is a strictly stronger condition than joint irreducibility). We consider three datasets: classes 1, 2, and 3 of MNIST (LeCun et al., 1998), the Iris dataset (Fisher, 1936), and the Breast Cancer Wisconsin (Diagnostic) Data Set (Dheeru and K. Taniskidou, 2017). We use the Spectral Support Estimation algorithm (De Vito et al., 2010; Rudi et al., 2014) to estimate the support of each class in each dataset. We split each dataset into training, validation, and test sets, applying the algorithm to the training set, using the validation set to pick the hyperparameters, and evaluating the performance on the test set. We average our results over 60 trials where in each trial we randomly permute the dataset, thus altering the training, validation, and test sets. Let $\widehat{S}_i$ denote an estimate of the support of class i. Tables 1, 3, and 5 display an estimate of the probability that a point sampled from P_i belongs to the estimate of the support $\widehat{S}_i$. They indicate that the Spectral Support Estimation has reasonably good performance in producing $\widehat{S}_i$s containing the support of the associated class. Tables 2, 4, and 6 use the $\widehat{S}_i$ to estimate the quantity

$\Pr_{\boldsymbol{x}\sim P_i}(\boldsymbol{x} \in \cup_{j\neq i} \mathrm{supp}(P_j))$, which must be strictly less than 1 for **(A″)** to hold. We find that our estimates are considerably less than 1, which suggests that joint irreducibility holds on these datasets.

Abstract

We present a novel minibatch stochastic optimization method for empirical risk minimization of linear predictors. The method efficiently leverages both sub-sampled first-order and higher-order information, by incorporating variance-reduction and acceleration techniques. We prove improved iteration complexity over state-of-the-art methods under suitable conditions. In particular, the approach enjoys global fast convergence for quadratic convex objectives and local fast convergence for general convex objectives. Experiments are provided to demonstrate the empirical advantage of the proposed method over existing approaches in the literature.

1. Introduction

We consider the following optimization problem of finite-sums:

$$\min_w f(w) := \frac{1}{n}\sum_{i=1}^n f_i(w), \tag{1}$$

which arises in many machine learning applications. In this paper, we focus on regularized loss minimization of linear predictors, where $f_i(w) = \ell(w^\top x_i; b_i) + \frac{\lambda}{2}\|w\|^2$. Let $x_1, x_2, ..., x_n \in \mathbb{R}^d$ be feature vectors of n data samples, and $b_1, ..., b_n \in \mathbb{R}$ or $\{-1, 1\}$ be the corresponding target variables of interest. We note that (1) covers many popular models used in machine learning: for example when $\ell(w^\top x_i; b_i) = \frac{1}{2}(b_i - w^\top x_i)^2$ we obtain ridge regression; when $\ell(w^\top x_i; b_i) = \log(1 + \exp(-b_i w^\top x_i))$ we obtain ℓ_2 regularized logistic regression. Other examples such as SVMs can also be obtained by setting different loss functions $\ell(w^\top x_i; b_i)$. The ubiquitousness of such finite-sum optimization problems and the massive scale of modern datasets motivate significant research effort on efficient optimization algorithms to solve (1).

We denote $w^* = \arg\min_w f(w)$ to be the optimum of (1). For any approximate solution w, we say that it achieves ϵ-objective suboptimality if $f(w) - f(w^*) \le \epsilon$. For any $\epsilon > 0$, the runtime cost of optimization algorithms to find an ϵ-suboptimal minimizer typically depends on the target accuracy ϵ, as well as the conditions of the problem (1). Throughout the paper, we use the following notion of strong convexity and smoothness to discuss the iteration complexity of various optimization algorithms.

Definition 1 *A function $f_i(w)$ is L-smooth with respect to w if $f_i(w)$ is differentiable and its gradient is L-Lipschitz continuous, i.e. we have*

$$\left\|\nabla f_i(w) - \nabla f_i(w')\right\| \le L\left\|w - w'\right\|, \quad \forall w, w' \in \mathbb{R}^d.$$

A function $f_i(w)$ is λ-strongly convex with respect to w, if we have

$$f_i(w) \ge f_i(w') + \langle \nabla f_i(w'), w - w'\rangle + \frac{\lambda}{2}\left\|w - w'\right\|^2, \quad \forall w, w' \in \mathbb{R}^d.$$

It is well-known that a consequence of L-smoothness is the following quadratic upper bound for $f_i(w)$:

$$f_i(w) \le f_i(w') + \langle \nabla f_i(w'), w - w'\rangle + \frac{L}{2}\left\|w - w'\right\|^2, \quad \forall w, w' \in \mathbb{R}^d.$$

In recent years there have been significant advances in developing fast optimization algorithms for (1), and we refer the readers to (Bottou et al., 2016) for a comprehensive survey of these developments. For large-scale problems in the form of (1), randomized methods are particularly efficient because of their low per iteration computation. Below we briefly review two lines of research: i) randomized variance reduced first-order methods; ii) randomized methods leveraging second-order information. Through out this section we focus on problems where each function $f_i(w), \forall i \in [n]$ is λ-strongly convex and L-smooth. For non-strongly convex or non-smooth objectives, we can use regularization or smoothing technique to reduce it to strongly convex and smooth objectives (Allen-Zhu and Hazan, 2016).

1.1 Variance Reduced First-order Methods

The key technique for developing fast stochastic first-order methods is variance reduction, which makes the variance of the randomized update direction approching zero when the iterate gets closer to the optimum. Representative methods of this category include SAG (Roux et al., 2012), SVRG (Johnson and Zhang, 2013), SDCA (Shalev-Shwartz and Zhang, 2013) and SAGA (Defazio et al., 2014), etc. In order to find a solution that reaches ϵ-suboptimality, these methods requires

$$\mathcal{O}\left(\left(n + \frac{L}{\lambda}\right)\log\left(\frac{1}{\epsilon}\right)\right) \tag{2}$$

calls to the first-order oracle to compute the gradient of an individual function. In the large condition number regime (e.g. $\frac{L}{\lambda} > n$), by using an acceleration technique (such as Catalyst (Shalev-Shwartz and Zhang, 2016; Frostig et al., 2015; Lin et al., 2015a), APCG (Lin et al., 2015b), SPDC (Zhang and Xiao, 2015), Katyusha (Allen-Zhu, 2016), etc), one can further improve the iteration complexity to

$$\mathcal{O}\left(\left(n + \sqrt{n\cdot\frac{L}{\lambda}}\right)\log\left(\frac{1}{\epsilon}\right)\right). \tag{3}$$

License: CC-BY 4.0, see https://creativecommons.org/licenses/by/4.0/. Attribution requirements are provided at http://jmlr.org/papers/v20/17-594.html.

Recently, Woodworth and Srebro (2016) provided a first-order oracle lower bound for (1) which has the same iteration complexity as (3). This means that (3) is not improvable for general (high dimensional) problems, if the optimization procedure only uses the first order and proximal oracles of individual functions.

1.2 Leveraging Second-order Information

Second-order information is often useful in improving the convergence of optimization algorithms. However for large-scale problems, obtaining and inverting the exact Hessian matrix is often computational expensive, making vanilla Newton methods not well suited in solving (1). Therefore, there have been emerging studies in designing randomized algorithms that effectively utilize the *approximated* Hessian information. One line of such research is the sub-sampled Newton method which approximates the Hessian matrix based on a sub-sampled minibatch of data. Several work, such as (Byrd et al., 2011; Erdogdu and Montanari, 2015; Roosta-Khorasani and Mahoney, 2016a,b; Bollapragada et al., 2016), established local linear convergence rates for different variants of sub-sampled Newton methods, when the size of the sub-sampled data is large enough. (Xu et al., 2016) considered non-uniform sampling in constructing the stochastic Hessian matrix, and showed that weighted sampling according to individual smoothness or leverage score can help constructing better approximation of Hessian, which improves the convergence. (Pilanci and Wainwright, 2017) discussed how to use sketching instead of sub-sampling to approximate the Hessian matrix. All of the aforementioned methods employ the full first-order gradient, and require calling the second-order oracle to compute the Hessian and solving a resulting linear system at every iteration. Therefore the computational complexity (as compared in Table 2 of (Xu et al., 2016)) are often worse than stochastic algorithms such as SVRG.

Another line of research is to consider randomness in both first and second-order information to design lower per-iteration cost algorithms. In particular, (Byrd et al., 2016) considered combining minibatch SGD with Limited-memory BFGS (L-BFGS) (Liu and Nocedal, 1989) type update. Inspired by this, (Moritz et al., 2016; Gower et al., 2016; Wang et al., 2017b) proposed to combine variance reduced stochastic gradient with L-BFGS, and proved linear convergence for strongly convex and smooth objectives. Moreover, experiments in (Moritz et al., 2016; Gower et al., 2016; Wang et al., 2017b) also demonstrated superior empirical performance of this type of methods. However, theoretically it is hard to guarantee the quality of approximated Hessian using L-BFGS update, and thus the iteration complexity obtained by (Moritz et al., 2016; Gower et al., 2016; Wang et al., 2017b) can be pessimistic, and can be much worse than vanilla SVRG. Moreover, (Qu et al., 2015) proposed to incorporate curvature information in minibatch SDCA methods, and showed improved convergence over SDCA, but the method proposed in (Qu et al., 2015) involves solving a much more expensive subproblem than minibatch SDCA. Therefore the overall runtime benefit is still unclear. (Gonen et al., 2016) considered ridge regression problems specifically, and proposed to use sketching to compute the rank-k approximation of the Hessian matrix, based on which SVRG is ran with preconditioning. (Yang et al., 2016) suggested to use preconditioning as a preprocessing step for general stochastic optimization problems. (Agarwal et al., 2016) proposed to approximate the inverse Hessian matrix directly by sampling from its Taylor expansion. In terms of lower bound, (Arjevani and Shamir, 2016) showed under

some mild algorithmic assumptions, second-order oracle generally cannot improve the oracle complexity over first-order methods, for very high-dimensional problems.

Though lower bound have been established showing that the iteration complexity of accelerated SVRG methods cannot be improved in general, the establishments of these lower bounds are based on constructing very high-dimensional hard problems where dimension d can be much larger than sample size n. Such pessimistic situations are not consistent with practice, where second-order information is observed to be very helpful in improving the convergence speed. Therefore it is still interesting to analyze theoretically how second-order information can be helpful under suitable conditions, and more importantly, how to design more efficient methods that make use of possibly noisy second-order information. In this paper, we make effort in solving empirical risk minimization problems with linear predictors more efficiently, and make the following contributions:

- We propose a novel approach that combines the advantages of variance-reduced first-order methods and sub-sampled Newton methods, in a efficient way that does not require expensive Hessian matrix computation and inversion. The method can be naturally extended to solve composite optimization problems with non-smooth regularization.

- We theoretically show under certain conditions the proposed approach can improve state-of-the-art iteration complexity, and empirically demonstrate it can substantially improve the convergence of existing methods. Note that though we only establish theoretical guarantees for empirical risk minimization of linear predictors, the methods it self can be applied to general finite-sum problems.

1.3 Notations

We use $[n]$ to denote the set $1, ..., n$. For a vector $w \in \mathbb{R}^d$, we use $\|w\|$ to denote its ℓ_2 norm and $\|w\|_1$ to denote its ℓ_1 norm. For a matrix X, we use $\|X\|_2$ to denote its spectral norm and $\|X\|_F$ to denote its Frobenius norm, and $\lambda_{\min}(X)$ to denote its minimum singular value, and $\mathrm{tr}(X)$ to denote the trace of X. We use I to denote an identity matrix. For two symmetric matrices A and B, we denote $A \succeq B$ if $A - B$ is positive semi-definite. For two sequences of numbers $\{a_n\}$ and $\{b_n\}$, we say $a_n = \mathcal{O}(b_n)$ if $a_n \leq Cb_n$ for n large enough, with some positive constant C. We use the notation $\widetilde{\mathcal{O}}(\cdot)$ to hide poly-log factors. We also use $a_n \lesssim b_n$ to denote $a_n = \mathcal{O}(b_n)$, $a_n \gtrsim b_n$ to denote $b_n = \mathcal{O}(a_n)$, $a_n \asymp b_n$ to denote $a_n = \mathcal{O}(b_n)$ and $b_n = \mathcal{O}(a_n)$.

1.4 Organization

The rest of the paper is organized as follows: we introduce the proposed method in Section 2, and present the main theoretical results in Section 3. In Section 4 we present the convergence analysis of inexact minibatch accelerated SVRG update as a key step in proving the main results, and this analysis might be of independent interest. We provide some empirical comparisons over existing approaches in Section 5, and conclusions in Section 6. Some detailed proofs are deferred to the Appendices.

2. Minibatch Stochastic Variance Reduced Proximal Iterations

In this section we present the proposed approach for minimizing (1), which naturally integrate both noisy first-order and higher-order information in an efficient way.

2.1 Algorithm Description

The high-level description is given in Algorithm 1, which consists of two main innovations:

- simultaneous incorporation of first-order and higher-order information via sub-sampling;
- allowing larger minibatch sizes through acceleration with inexact minimization.

We explain these features in the remaining of this section.

2.1.1 Sampling both First-order and Higher-order Information

We first discuss the main building block of the algorithm. Suppose at iteration t, given the previous iterate w_{t-1}, we consider the following update rule:

$$w_t = \arg\min_w \frac{1}{b}\sum_{i\in\bar{B}} f_i(w) - \left\langle \frac{1}{b}\sum_{i\in\bar{B}} \nabla f_i(w_{t-1}), w \right\rangle + \left\langle \frac{\eta}{b}\sum_{i\in B_t} \nabla f_i(w_{t-1}) + \eta\nabla f(\widetilde{w}) - \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}), w \right\rangle + \frac{\bar{\lambda}}{2}\|w - w_{t-1}\|^2, \quad (6)$$

where $\bar{B}, B_t$ are some randomly sampled minibatch from $1, ..., n$, both with minibatch size b; η and $\bar{\lambda}$ are stepsize parameters, and $\widetilde{w}$ is a "reference" predictor used for reducing variance. The main feature of updating rule (6) is it considered both noisy first-order and higher-order information via minibatch sampling. In particular, the term $\left\langle \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \eta\nabla f(\widetilde{w}) - \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}), w\right\rangle$ and $\frac{1}{b}\sum_{i\in\bar{B}} f_i(w) - \left\langle \frac{1}{b}\sum_{i\in\bar{B}}\nabla f_i(w_{t-1}), w\right\rangle$ in (6) incorporates variance-reduced first-order and noisy higher-order information of the objective function, respectively. To see this, second-order methods (e.g. Newton methods) often use the following second-order Taylor approximation of the function:

$$\frac{1}{b}\sum_{i\in\bar{B}} f_i(w) \approx \frac{1}{b}\sum_{i\in\bar{B}} f_i(w_{t-1}) + \left\langle \frac{1}{b}\sum_{i\in\bar{B}}\nabla f_i(w_{t-1}), w - w_{t-1}\right\rangle + \frac{1}{2}(w - w_{t-1})^\top \left(\frac{1}{b}\sum_{i\in\bar{B}}\nabla^2 f_i(w_{t-1})\right)(w - w_{t-1}). \quad (7)$$

Algorithm 1 MB-SVRP: Minibatch Stochastic Variance Reduced Proximal Iterations.

Parameters η, b, $\bar{\lambda}$, ν, ε.
Initialize $\widetilde{w}_0 = 0$.
Sampling Sampling b items from $[n]$ to form a minibatch $\bar{B}$.
for $s = 1, 2, \ldots, S$ **do**
  Calculate $\widetilde{v} = \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}_{s-1})$.
  Initialize $y_0 = w_0 = \widetilde{w}_s$.
  for $t = 1, 2, \ldots, T$ **do**
    Sampling b items from $[n]$ to form a minibatch B_t.
    Find w_t **that approximately solve** (4) (**Option-I**) or (5) (**Option-II**) such that $\widetilde{f}_t(w_t) - \min_w \widetilde{f}_t(w) \le \varepsilon$.

$$\textbf{Option-I}: \widetilde{f}_t(w) \coloneqq \frac{1}{b}\sum_{i\in\bar{B}} f_i(w) - \left\langle \frac{1}{b}\sum_{i\in\bar{B}}\nabla f_i(y_{t-1}), w\right\rangle + \left\langle \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(y_{t-1}) + \eta\widetilde{v} - \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}_{s-1}), w\right\rangle + \frac{\bar{\lambda}}{2}\|w - y_{t-1}\|^2, \quad (4)$$

$$\textbf{Option-II}: \widetilde{f}_t(w) \coloneqq \frac{1}{2}(w - y_{t-1})^\top \left(\frac{1}{b}\sum_{i\in\bar{B}}\nabla^2 f_i(y_{t-1})\right)(w - y_{t-1}) + \left\langle \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(y_{t-1}) + \eta\widetilde{v} - \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}_{s-1}), w\right\rangle + \frac{\bar{\lambda}}{2}\|w - y_{t-1}\|^2. \quad (5)$$

    Update:
$$y_t = w_t + \nu(w_t - w_{t-1}).$$
  end for
  Update $\widetilde{w}_s = w_m$.
end for
Return $\widetilde{w}_s$

If we plug the second-order approximation (7) into (6), we get the update rule as

$$w_t \approx \arg\min_w \frac{1}{2}(w - w_{t-1})^\top \left(\frac{1}{b}\sum_{i\in\bar{B}}\nabla^2 f_i(w_{t-1})\right)(w - w_{t-1}) + \frac{\bar{\lambda}}{2}\|w - w_{t-1}\|^2 + \left\langle \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \eta\nabla f(\widetilde{w}) - \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}), w\right\rangle \quad (8)$$

$$= w_{t-1} - \eta\left(\frac{1}{b}\sum_{i\in\bar{B}}\nabla^2 f_i(w_{t-1}) + \bar{\lambda}I\right)^{-1}\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \nabla f(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})\right), \quad (9)$$

which can be treated as a variant of sub-sampled Newton method, combined with the minibatch stochastic gradient with variance reduction. Moreover, when $f_i(w)$ is a quadratic function of w, the approximation (7) is exact (thus Option-I and Option-II in Algorithm 1 are coincident). Therefore the update rule (6) can be treated as a preconditioned minibatch SVRG update rule, with $\left(\frac{1}{b}\sum_{i\in\bar{B}}\nabla^2 f_i(w_{t-1})+\bar{\lambda}I\right)^{-1}$ as a precondition matrix. This is formalized in the proposition below.

Proposition 2 *When $f_i(w), \forall i$ is a quadratic function of w, then the update rule of* (4) *and* (5) *is equivalent to the following preconditioned minibatch SVRG update rule:*

$$w_t \leftarrow w_{t-1} - \eta\left(\bar{H}+\bar{\lambda}I\right)^{-1}\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \nabla f(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})\right),$$

where

$$\bar{H} = \frac{1}{b}\sum_{i\in\bar{B}}\nabla^2 f_i(w)$$

is the sub-sampled Hessian matrix.

2.1.2 Connection to Existing Methods

Depending on the choice of these parameters, we observe that the update rule of (6) can be viewed as a generalization of several update rules proposed recently:

- When $b=1$, $\bar{\lambda}\to\infty$ and $\eta=\frac{\bar{\lambda}}{L}$, the term $\frac{1}{b}\sum_{i\in\bar{B}} f_i(w) - \left\langle\frac{1}{b}\sum_{i\in\bar{B}}\nabla f_i(w_{t-1}), w\right\rangle$ is negligible, thus (6) reduced to standard SVRG update (Johnson and Zhang, 2013):

$$w_t \leftarrow w_{t-1} - \frac{1}{L}\left(\nabla f_i(w_{t-1}) + \frac{1}{n}\sum_{i=1}^n\nabla f_i(\widetilde{w}) - \nabla f_i(\widetilde{w})\right).$$

- When $b>1$, $\bar{\lambda},\eta\to\infty$, then the term $\frac{1}{b}\sum_{i\in\bar{B}} f_i(w) - \left\langle\frac{1}{b}\sum_{i\in\bar{B}}\nabla f_i(w_{t-1}), w\right\rangle$ in (6) is negligible as well, (6) reduces to the following update:

$$w_t \leftarrow w_{t-1} - \frac{\eta}{\bar{\lambda}}\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \frac{1}{n}\sum_{i=1}^n\nabla f_i(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})\right),$$

  which recovers the update rule of minibatch semi-stochastic gradient methods (a.k.a minibatch SVRG) (Konečnỳ et al., 2016).

- When $\bar{B}=B_t$, $b=1$, $\eta=1$, (6) reduced to stochastic variance reduced proximal iterations. More specifically, (6) will be reduced to:

$$w_t = \arg\min_w f_i(w) + \left\langle\frac{1}{n}\sum_{i=1}^n\nabla f_i(\widetilde{w}) - \nabla f_i(\widetilde{w}), w\right\rangle + \frac{\bar{\lambda}}{2}\|w-w_{t-1}\|^2, \tag{10}$$

  by checking the first order optimality condition it is easy to verify that (10) is performing the following update:

$$w_t \leftarrow w_{t-1} - \frac{1}{\bar{\lambda}}\left(\nabla f_i(w_t) + \frac{1}{n}\sum_{i=1}^n\nabla f_i(\widetilde{w}) - \nabla f_i(\widetilde{w})\right),$$

compared with standard SVRG update with stepsize $\frac{1}{\bar{\lambda}}$, we see the only difference is the gradient evaluation on f_i is based on "future" iterate w_t rather than the current iterate w_{t-1} in SVRG. Stochastic proximal iterations based on SAGA method has been proposed and analyzed in (Defazio, 2016) recently.

- When $B_t=\bar{B}$, $b>1$, $\eta=1$, and $\widetilde{w}=w_{t-1}$, (6) will be reduced to:

$$w_t = \arg\min_w \frac{1}{b}\sum_{i\in\bar{B}} f_i(w) + \left\langle\frac{1}{n}\sum_{i=1}^n\nabla f_i(w_{t-1}) - \frac{1}{b}\sum_{i\in\bar{B}}\nabla f_i(w_{t-1}), w\right\rangle + \frac{\bar{\lambda}}{2}\|w-w_{t-1}\|^2, \tag{11}$$

  (11) covers the update rule of DANE algorithm (Shamir et al., 2014), which is a communication-efficient distributed optimization algorithm. DANE uses the data on local machine to form the minibatch $\bar{B}$ and every round machines communicate the gradient vector based on their local data. As shown in (Shamir et al., 2014), DANE is provably communication more efficient than the first-order methods in certain scenarios.

- When $\bar{B}=B_t$, and we ignore the linear term $-\left\langle\frac{1}{b}\sum_{i\in\bar{B}}\nabla f_i(w_{t-1}), w\right\rangle + \left\langle\frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \eta\nabla f(\widetilde{w}) - \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}), w\right\rangle$, then (6) reduces to the minibatch proximal iterations (Li et al., 2014; Wang et al., 2017a):

$$w_t = \arg\min_w \frac{1}{b}\sum_{i\in B_t} f_i(w) + \frac{\bar{\lambda}}{2}\|w-w_{t-1}\|^2.$$

  Such an update allows larger minibatch size than standard minibatch SGD, but without the linear correction term as we considered in (6). For such methods only sublinear convergence can be established for finite-sum problems.

2.1.3 Large Minibatch Size via Acceleration with Inexact Minimization

Using (6) as the building block, we propose the MB-SVRP (minibatch stochastic variance reduced proximal iterations) method, which is detailed in Algorithm 1. At the beginning of the algorithm, we form a minibatch $\bar{B}$ by sampling from $1,...,n$ and fix it for the whole optimization process[1]. Then following the SVRG method (Johnson and Zhang, 2013), the algorithm is divided to multiple stages, indexed by s. At each stage, we iteratively solve a minimization problem of the form (4) (Option I) or (5) (Option II) based on the randomly sampled minibatch B_t.

Compared with the simple update rule in (6), the major difference in Algorithm 1 is that we consider a momentum scheme by maintaining two sequences $\{w_t, y_t\}$, which is inspired by Nesterov's acceleration technique (Nesterov, 2004) and its recent SVRG variant (Nitanda, 2014). The main theoretical advantage over minibatch SVRG without momentum (Konečnỳ et al., 2016) is that such an acceleration allows us to use a much larger minibatch

1. We can also consider the varying $\bar{B}$ option by simply setting $\bar{B}=B_t$, which makes the algorithm simpler to implement. In practice, we observe no significant difference between this option and the pre-fixed $\bar{B}$. Here we consider fixed $\bar{B}$ mainly for the sake of simplicity in our theoretical analysis.

size (up to a size of $\mathcal{O}(\sqrt{n})$) without slowing down the convergence. In comparison the iteration complexity of standard minibatch SVRG will become worse when the minibatch size (Konečnỳ et al., 2016) increases. The advantage of allowing larger minibatch size using acceleration in SVRG type algorithms is in analogy to the situation of stochastic gradient descent (without variance reduction) type algorithms (Dekel et al., 2012; Cotter et al., 2011; Lan, 2012).

Since it is often expensive to find the exact minimizer of (4), we consider an approximate minimizer with objective suboptimality ε. When we choose the appropriate $\bar{\lambda}$ for $\widetilde{f}_t(w)$ to obtain enough strong convexity, the subproblems defined in Option-I and Option-II can be both be solved to high accuracy efficiently. For example, using SVRG-type algorithms (Johnson and Zhang, 2013) to solve (4) or (5) allows us to find an approximate solution with a small suboptimality ε with a constant number of passes over the data in the minibatch $\bar{B} \cup B_t$, if $\bar{\lambda}$ is set appropriately (discussed in details in our theoretical analysis). This approach avoids Hessian matrix construction and inversion operations, which are often computationally expensive for large-scale problems. Allowing error in gradient oracle has been analyzed in several first-order methods (Schmidt et al., 2011; Devolder et al., 2014) in the batch setting, but has been largely unexplored in stochastic gradient methods. The recent work of (Wang et al., 2017a) analyzed inexact minibatch proximal updates, which can be treated as an implicit minibatch stochastic gradient with errors. In Section 4, we establish convergence rate of *inexact*, *minibatched*, *accelerated* SVRG method, which might be of independent interest.

2.2 Extension to Composite Minimization

For many methods that try to incorporate second-order information such as sub-sampled Newton and L-BFGS type algorithms, it is not clear how to extend them to solving non-smooth composite problems. In contrast, the proposed approach can be easily extended to handle non-smooth composite minimization problems. Consider the minimization of:

$$F(w) := \frac{1}{n}\sum_{i=1}^{n} f_i(w) + g(w), \tag{12}$$

where the component functions $f_i(w), \forall i \in [n]$ are smooth and strongly convex, and $g(w)$ is a non-smooth regularizer. For example when $g(w) = \mu \|w\|_1$ and $f_i(w) = \frac{1}{2}(b_i - w^\top x_i)^2$, we get the Lasso objective (Tibshirani, 1996); when $g(w) = \mu \|w\|_1 + \frac{\lambda}{2}\|w\|^2$ and $f_i(w) = \log(1+\exp(-b_i w^\top x_i))$, we get the elastic net regularized logistic regression (Zou and Hastie, 2005).

We can easily modify Algorithm 1 to solve (12). The idea is rather straightforward: at each inner iteration, rather than (4), we simply solve the following minibatch composite minimization problem:

$$\begin{aligned} w_t \approx \arg\min_w \widetilde{F}_t(w) := &\frac{1}{\eta b}\sum_{i\in\bar{B}} f_i(w) - \left\langle \frac{1}{\eta b}\sum_{i\in\bar{B}} \nabla f_i(y_{t-1}), w \right\rangle \\ &+ \left\langle \frac{1}{b}\sum_{i\in B_t} \nabla f_i(y_{t-1}) + \widetilde{v} - \frac{1}{b}\sum_{i\in B_t} \nabla f_i(\widetilde{w}_{s-1}), w \right\rangle + \frac{\bar{\lambda}}{2\eta}\|w - y_{t-1}\|^2 + g(w). \end{aligned} \tag{13}$$

We slightly re-scale the approximated loss term to make sure that the relative weight between the approximated loss and the regularization term is correct. Since (13) is a standard finite-sum composite minimization problem, we could apply prox-SVRG or prox-SAGA to solve (13) efficiently when the term $\frac{\bar{\lambda}}{2\eta}\|w - y_{t-1}\|^2$ has sufficient strong convexity.

3. Convergence Analysis

In this section we present theoretical results for the proposed approach. As declared in the introduction, we focus on establishing convergence analysis on linear model empirical risk minimization problems because the Hessian structure is easier to interpret. However, the algorithms itself can be implemented for solving general finite-sum problems, and the theory can also be extended to handle such case. For non-qudratic convex objectives, our convergence analysis is local, i.e. we assume the initial and subsequent solutions are within a bounded region near the optimum, which is common in the analysis of second-order methods in optimization (Nesterov, 2004; Boyd and Vandenberghe, 2004). As will be discussed in the sequel, the size of the region depends on the condition number of the problem, as well as the Lipschitz parameter of the Hessian. For quadratic objectives, the radius of the region can be infinite, which implies global fast convergence.

In this section, for simplicity, we focus on the analysis of Option-II in Algorithm 1 which uses second-order approximation to construct each sub-problem (5). Similar results hold for Option-I because locally around the optimal solution, the two methods are equivalent. Note that for linear predictors $f_i(w)$ admits the form $f_i(w) = \ell(w^\top x_i; b_i) + \frac{\lambda}{2}\|w\|$, where the Hessian can be computed as $\nabla^2 f_i(y_{t-1}) = \ell''(y_{t-1}^\top x_i; b_i) x_i x_i^\top + \lambda I$. Moreover, we do not need to explicitly maintain the Hessian matrix: when calculating the stochastic gradient of equation (5), especially the gradient of $(1/2)(w - y_{t-1})^\top \nabla^2 f_i(y_{t-1})(w - y_{t-1})$, we get $\nabla^2 f_i(y_{t-1})(w - y_{t-1}) = \ell''(y_{t-1}^\top x_i; b_i)(x_i^\top (w - y_{t-1}))x_i + \lambda(w - y_{t-1})$, which can be computed in time $\mathcal{O}(d)$. Thus approximately solving objective equation (5) would only requires a few stochastic gradients calculation (or equivalent operations in $\mathcal{O}(d)$), we count total number of such gradient computation operations as a measure of Algorithms 1's efficiency in optimization.

Besides the strong convexity and smoothness, we also need the following Hessian Lipschitz condition.

Condition 1 *For each loss function $\ell(w^\top x_i; b_i), \forall i \in [n]$, its second derivative is $\bar{M}$-Lipschitz, i.e.*

$$|\ell''(w_1^\top x_i; b_i) - \ell''(w_2^\top x_i; b_i)| \le \bar{M}\|w_1 - w_2\|, \forall w_1, w_2 \in \mathbb{R}^d, \forall i \in [n].$$

Conditions of Lipschitz Hessians are typically not required for first-order methods such as SVRG and SAGA, but are typically required for second-order methods, such as Newton methods and sub-sampled Newton methods. Moreover, Lipschitz Hessians condition is often satisfied for popular loss functions used in machine learning such as logistic loss and square loss. We consider the component function in form of convex loss function of linear predictor: $f_i(w) = \ell(w^\top x_i; b_i) + \frac{\lambda}{2}\|w\|_2^2$. By Condition 1, combined with the condition that

maximum norm of data points are bounded: $\max_i \|x_i\|^2 \leq D$, we know Hessian matrix of each component loss function $f_i(w)$ is $M = \bar{M}D + \lambda$-Lipschitz, i.e.

$$\left\|\nabla^2 f_i(w_1) - \nabla^2 f_i(w_2)\right\| \leq M \|w_1 - w_2\|, \forall w_1, w_2 \in \mathbb{R}^d, \forall i \in [n].$$

For $f(w) = (1/n)\sum_i f_i(w)$, we have the following formula of Hessian matrix:

$$H_\lambda(w) = \frac{1}{n}\sum_{i=1}^n \nabla^2 f_i(w) = \frac{1}{n}\sum_{i=1}^n \ell''(w^\top x_i; b_i) x_i x_i^\top + \lambda I.$$

Let $H_\lambda(w_{t-1})$ be the Hessian matrix at w_{t-1}, and suppose we have an approximated Hessian

$$\bar{H}_{\widetilde{\lambda}}(w_{t-1}) = \frac{1}{b}\sum_{i\in\bar{B}} \ell''(w_{t-1}^\top x_i; b_i) x_i x_i^\top + \widetilde{\lambda} I,$$

the following proposition states that performing the preconditioned minibatch SVRG update is equivalent to the standard minibatch SVRG in a linear transformed (preconditioned) space:

Proposition 3 *Considering the following minibatch SVRG type update when solving* $\min_w f(w)$*:*

$$w_t \leftarrow w_{t-1} - \eta \bar{H}_{\widetilde{\lambda}}(w_{t-1})^{-1}\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})\right), \quad (14)$$

which is equivalent to solving a minimization problem with respect to z*:*

$$\min_z f(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*) z)$$

via the variable transform $z = \bar{H}_{\widetilde{\lambda}}^{1/2}(w^*)w$*. Moreover, the update rule* (14) *is equivalent to the following update on* z*:*

$$\begin{aligned} z_t \leftarrow & z_{t-1} - \eta\left(\frac{1}{b}\sum_{i\in B_t}\nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z}) - \frac{1}{b}\sum_{i\in B_t}\nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z})\right) \\ & + \eta \bar{H}_{\widetilde{\lambda}}^{1/2}(w^*)\left(\bar{H}_{\widetilde{\lambda}}(w^*)^{-1} - \bar{H}_{\widetilde{\lambda}}(w_{t-1})^{-1}\right)\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})\right). \end{aligned} \quad (15)$$

With the above proposition, and Proposition 2, we can see that the proposed updates (4) and (5) are implicitly performing inexact minibatch SVRG update on the following transformed problem:

$$\min_z f(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z) := \frac{1}{n}\sum_{i=1}^n \ell(z^\top \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)x_i; b_i) + \lambda\left\|\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z\right\|^2, \quad (16)$$

by choosing $\bar{\lambda} = \widetilde{\lambda} - \lambda$. In the following, we focus on discussing the choice of $\widetilde{\lambda}$, and $\bar{\lambda}$ can be settled accordingly. As a straightforward extension, it is also easy to see that using the acceleration technique as Algorithm 1 is equivalent to performing inexact *accelerated* minibatch SVRG update, similar to the exact update analyzed in (Nitanda, 2014). The analysis of inexact algorithms are presented in Section 4.

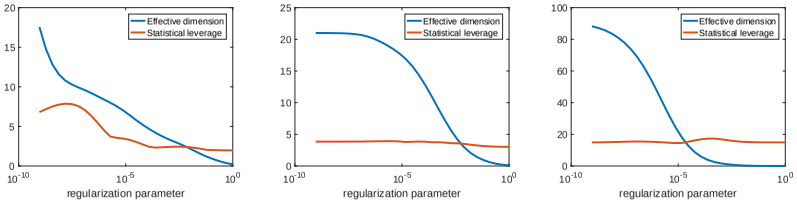
The benefit of the transformed problem is that when $\bar{H}_{\widetilde{\lambda}}(w^*) \approx H_\lambda(w^*)$, the condition number of the new problem (16) becomes smaller than that of the original problem. As a consequence, when the computational cost of update (14) is cheap, we expect improved convergence and runtime guarantees for solving the original problem. Before analyzing the condition number, we state the following lemma, which connects the inexactness in w space when performing the update (8) (and (14)) to the inexactness in z space when performing the update (15).

Lemma 4 *Let* $\widetilde{f}_t(w)$ *be the function to be minimized in* (8)*, and* $w_t^* = \arg\min_w \widetilde{f}_t(w)$ *to be its exact minimizer. Let*

$$\bar{z}_t = z_{t-1} - \eta\left(\frac{1}{b}\sum_{i\in B_t}\nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z}) - \frac{1}{b}\sum_{i\in B_t}\nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z})\right),$$

be the exact minibatch SVRG update solution in the preconditioned space, and $z_t = \bar{H}_{\widetilde{\lambda}}^{1/2}(w^*)w_t$ *be the actual update in precondition space by approximately solving* (8)*. Let* $\vartheta_t = \frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})$*, We have the following upper bound on* $\|z_t - \bar{z}_t\|$*:*

$$\|z_t - \bar{z}_t\| \leq \sqrt{\frac{2(\widetilde{f}_t(w_t) - \widetilde{f}_t(w_t^*))(L + \widetilde{\lambda})}{\lambda + \widetilde{\lambda}}} + \frac{\eta M \|w_{t-1} - w^*\| \|\vartheta_t\|}{\widetilde{\lambda}^{3/2}}.$$



Remark 5 *Lemma 4 states that the inexactness in the minibatch SVRG update in the* z *space can be decomposed to two sources, the first source is the fact that we solve the minimization problem of objective* $\widetilde{f}_t(w)$ *inexactly, and the second source is the fact that the Hessian matrix is changing at different locations. Nevertheless, we can fix the* z *space that use Hessian matrix at optimum* $\bar{H}_{\widetilde{\lambda}}(w^*)$ *as the preconditioner. For quadratic objectives where* $M = 0$*, the second error term becomes zero.*

3.1 Improved Condition Number

In this section we analyze the condition number in the "preconditioned" space (16), where $\bar{B}$ is sampled uniformly from $1, ..., n$. For the analysis, we introduce two notions which describes the global and local properties of data. The following definitions of effective dimension and bounded statistical leverage extend the ones defined in (Hsu et al., 2014) which were used to analyzing the generalization performance of ridge regression.

Definition 6 ***(Effective dimension)*** *Let the* $\lambda_1, ..., \lambda_d$ *be the top-d eigenvalues of* $H_0(w^*) = (1/n)\sum_{i=1}^n \ell''(w^{*\top}x_i; b_i)x_i x_i^\top$*, define the effective dimension* $d_{\widetilde{\lambda}}$ *(for some* $\widetilde{\lambda} \geq 0$*) of* $H_0(w^*)$ *being*

$$d_{\widetilde{\lambda}} = \sum_{j=1}^d \frac{\lambda_j}{\lambda_j + \widetilde{\lambda}}.$$

covtype
$n = 581,012,\ d = 54$

svmguide3
$n = 1,243,\ d = 21$

year
$n = 463,715,\ d = 91$

Figure 1: Effective dimension and maximum statistical leverage with different regularization parameters $\widetilde{\lambda}$ on some empirical datasets for ridge regression problems.

We see $d_{\widetilde{\lambda}}$ is a decreasing function of $\widetilde{\lambda}$, and $d_0 = d$ when $\widetilde{\lambda} = 0$. When the spectrum of $\frac{1}{n}\sum_{i=1}^n \ell''(w^{*\top}x_i; b_i)x_i x_i^\top$ is decaying very fast, the effective dimension $d_{\widetilde{\lambda}}$ can be significantly smaller than d for moderate $\widetilde{\lambda}$. The following lemma demonstrated this for Hessian matrices with fast decaying spectrum, which can be well approximated by low-rank matrices.

Lemma 7 *We have the following upper bound for $d_{\widetilde{\lambda}}$:*

$$d_{\widetilde{\lambda}} \leq \min_k \left\{ k + \frac{\sum_{j>k} \lambda_j}{\widetilde{\lambda}} \right\}.$$

As an example of data with fast decaying spectrum, consider generalized linear predictors in a Hilbert space induced by a Gaussian kernel $K(x_i, x_i') = \exp(-\|x - x_i'\|^2/(2\sigma^2))$ where σ is a bandwidth parameter. The covariance matrix of the induced feature space has exponentially decaying eigenvalues with $\lambda_j \leq c_1 \exp(-c_2 j^2)$, where c_1 and c_2 are constants (Zhang et al., 2015). With exponentially decaying eigenvalues, it is shown in Corollary 5 (Zhang et al., 2015) that $d_{\widetilde{\lambda}} \leq \mathcal{O}(\sqrt{\log(1/\widetilde{\lambda})})$ even though the Gaussian kernel maps the original data to an infinite dimensional space.

The following notion of statistical leverage have been used in regression analysis (Chatterjee and Hadi, 2009; Hsu et al., 2014) and matrix approximation (Mahoney et al., 2011).

Definition 8 ***(Statistical leverage at $\widetilde{\lambda}$)*** *Let $H_{\widetilde{\lambda}}(w^*) = \frac{1}{n}\sum_{i=1}^n \ell''(w^{*\top}x_i; b_i)x_i x_i^\top + \widetilde{\lambda} I$, we say the statistical leverage of data matrix X is bounded by $\rho_{\widetilde{\lambda}}$ at $\widetilde{\lambda}$ if*

$$\max_{i\in[n]} \frac{\left\| H_{\widetilde{\lambda}}^{-1/2}(w^*)\ell'(w^{*\top}x_i; b_i)^{1/2} x_i \right\|}{\sqrt{(1/n)\sum_{j=1}^n \left\| H_{\widetilde{\lambda}}^{-1/2}(w^*)\ell''(w^{*\top}x_j; b_j)^{1/2} x_j \right\|^2}} \leq \rho_{\widetilde{\lambda}}. \tag{17}$$

For ridge regression problems, the above definition is slightly different from the one used in (Hsu et al., 2014) in the sense that the empirical Hessian matrix $H_{\widetilde{\lambda}}$ in (17) is replaced by the population Hessian matrix $\mathbb{E}\left[x_i^\top x_i\right] + \widetilde{\lambda} I$ in (Hsu et al., 2014). When the sample size n is large, the differences in these two definitions are minor. As argued in (Hsu et al., 2014), when x_i is i.i.d. randomly drawn from sub-Gaussian distributions, $\left(\mathbb{E}\left[x_i^\top x_i\right]\right)^{-1/2} x_i$ is isotropic. In this case the statistical leverage only grows logarithmically with dimension. For the empirical statistical leverage considered in (17), if we consider the un-regularized form (when $\widetilde{\lambda} = 0$), then Definition 8 is closely related to the leverage score used in (Mahoney et al., 2011; Drineas and Mahoney, 2017), where the leverage score for x_i is defined as $x_i^\top \left((1/n)\sum_{j=1} x_j x_j^\top\right)^{-1} x_i$, and thus statistical leverage is just the ratio between "maximum leverage score" and "average leverage score". Though the in worse case $\rho_{\widetilde{\lambda}}$ can be as large as $\sqrt{n}$, in many situations it is small. For instance, if the data is generated by random Gaussian distributions, or when we apply certain random projections on the data, the (projected) data matrix is known to have almost uniform leverage scores (i.e. the statistical leverage parameter in (17) can be upper bounded by $\mathcal{O}(\log d)$, see Lemma 70 in (Drineas and Mahoney, 2017) for example).

Our theoretical analysis relies on the condition that the two quantities defined above are not too large. This condition often holds in practice, as shown in Figure 1, which plots the effective dimension and the statistical leverage for several real world datasets with varying regularization parameters.

The convergence of stochastic gradient based algorithms for minimizing the objective (16) depends on two important quantities: strong convexity and smoothness. The strong convexity for problem (16) (with respect to z) is

$$\min_z \lambda_{\min}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*) \left(\frac{1}{n}\sum_{i=1}^n \ell''(z^\top \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)x_i; b_i)x_i x_i^\top + \lambda I \right) \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*) \right), \tag{18}$$

which is a property of the overall objective function rather than individual component. However, we must consider the smoothness parameter for individual function $f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z)$ (with respect to z), which in our context, is

$$\max_i \max_z \lambda_{\max}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*) \left(\ell''(z^\top \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)x_i; b_i)x_i x_i^\top + \lambda I \right) \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*) \right). \tag{19}$$

By the variable transformation $w = \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z$, we get $\ell''(z^\top \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)x_i; b_i) = \ell''(w^\top x_i; b_i)$. Moreover, we consider a local region where w is close to w^* measured by diameter R: $\|w - w^*\| \leq R$, and study the local strong convexity and smoothness quantities((18) and (19)).

Both of these quantities are related to how close is the constructed Hessian approximation $\bar{H}_{\widetilde{\lambda}}(w^*)$ to the true Hessian $H_{\widetilde{\lambda}}(w^*)$ in spectral norm. The following lemma bound this quantity using matrix concentration.

Lemma 9 *If $\bar{B}$ is formed by uniform sampling with replacement from $[n]$, then we have the following concentration bound, with probability at least $1 - \delta$,*

$$\left\| H_{\widetilde{\lambda}}^{-1}(w^*) \left(\frac{1}{b}\sum_{i\in\bar{B}} \ell''(w^{*\top}x_i; b_i)x_i x_i^\top - \frac{1}{n}\sum_{i=1}^n \ell''(w^{*\top}x_i; b_i)x_i x_i^\top \right) \right\|_2 \leq 2\log\left(\frac{d}{\delta}\right) \cdot \sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}}.$$

3.1.1 Strong Convexity

Based on above lemma, we have the following lower bound of the strong convexity for (16), specified in the following lemma.

Lemma 10 *If we set $\widetilde{\lambda}$ such that $\widetilde{\lambda} \geq \lambda$, then with probability at least $1-\delta$ over the random choice of $\bar{B}$ to form $\bar{H}_{\widetilde{\lambda}}$, we have*

$$\min_{\|w-w^*\|\leq R} \lambda_{\min}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_\lambda(w)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right) \geq \frac{\lambda}{\widetilde{\lambda}} \frac{1}{1+2\log(d/\delta)\sqrt{(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}})/b}(1+MR/\widetilde{\lambda})+MR/\widetilde{\lambda}}.$$

3.1.2 Smoothness

Next we explore the local smoothness parameter of (16). Using the variable transform $w = \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z$, if we consider the individual smoothness parameter (with respect to z) around the neighborhood of w^* with diameter R, it can be upper bounded by

$$\max_{i\in[n]} \max_{\|w-w^*\|\leq R} \lambda_{\max}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\ell''(w^\top x_i;b_i)x_i x_i^\top + \lambda I\right)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right).$$

Since

$$\begin{aligned}
&\lambda_{\max}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\ell''(w^\top x_i;b_i)x_i x_i^\top + \lambda I\right)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right)\\
&\leq \lambda_{\max}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\ell''(w^\top x_i;b_i)x_i x_i^\top\right)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right) + \lambda_{\max}\left(\lambda\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)\right)\\
&\leq \ell''(w^\top x_i;b_i)x_i^\top \bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i + \frac{\lambda}{\widetilde{\lambda}} \qquad (20)
\end{aligned}$$

The most straightforward way to upper bound $\ell''(w^\top x_i;b_i)x_i^\top \bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i$ is

$$\begin{aligned}
&\max_{i\in[n]} \max_{\|w-w^*\|\leq R} \ell''(w^\top x_i;b_i)x_i^\top \bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i\\
&\leq \max_{i\in[n]} \max_{\|w-w^*\|\leq R} \ell''(w^\top x_i;b_i)\|x_i\|^2 \lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1}(w^*))\\
&= \max_{i\in[n]} \max_{\|w-w^*\|\leq R} \frac{\ell''(w^\top x_i;b_i)\|x_i\|^2}{\widetilde{\lambda}} = \frac{L}{\widetilde{\lambda}}.
\end{aligned}$$

In this way, the condition number after preconditioning becomes

$$\mathcal{O}\left(\frac{4\widetilde{\lambda}}{\lambda}\cdot\frac{L}{\widetilde{\lambda}}\right) = \mathcal{O}\left(\frac{L}{\lambda}\right),$$

which didn't show any advantage of using preconditioning. This is not surprising because it is known that for high dimensional problems, the worse case behavior of second order methods is no better than that of the first order methods.

In the lemma below, we provide an improved analysis of smoothness which is based on the notion of effective dimension (Definition 6) and statistical leverage (Definition 8).

Lemma 11 *If we choose $\widetilde{\lambda} \geq \lambda$ and $b \geq 16\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\log^2(d/\delta)$, then with probability at least $1-\delta$ over the random choice of $\bar{B}$ to form $\bar{H}_{\widetilde{\lambda}}(w^*)$, we have*

$$\max_{i\in[n]} \max_{\|w-w^*\|\leq R} \ell''(w^\top x_i;b_i)x_i^\top \bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i \leq 2\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} + \frac{MR}{\widetilde{\lambda}}.$$

Based on above analysis, we have the following corollary states the local individual smoothness parameter of (16).

Corollary 12 *If we choose $\widetilde{\lambda} \geq \lambda$ and $b \geq 16\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\log^2(d/\delta)$, and $R \leq \frac{\widetilde{\lambda}}{M}$. Then with probability at least $1-\delta$ over the random choice of $\bar{B}$ to form $\bar{H}_{\widetilde{\lambda}}(w^*)$, we have the following upper bound hold for the local smoothness parameter*

$$\max_{i\in[n]} \max_{\|w-w^*\|\leq R} \lambda_{\max}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\ell''(w^\top x_i;b_i)x_i x_i^\top + \lambda I\right)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right) \leq 2\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} + 2.$$

Proof Combining (20) and Lemma 11, as well as the conditions of $\widetilde{\lambda}$ and R stated in the corollary we get the desired results. ■

Combining Lemma 10 and Corollary 12 we get the following result about the condition number for (16). If we choose $\widetilde{\lambda}$ and b that satisfy

$$\widetilde{\lambda} \geq \max\left\{\lambda, \frac{L}{b}\right\}, \quad b \geq 16\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\log^2\left(\frac{d}{\delta}\right), \quad R \leq \min\left\{\frac{1}{4ML}, \frac{\widetilde{\lambda}}{4M}\right\},$$

then with probability at least $1-\delta$, the condition number for stochastic gradient algorithms after preconditioning scales as $\frac{4\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\widetilde{\lambda}}{\lambda}$, more specifically when $\widetilde{\lambda} = \max\{\lambda, \frac{L}{b}\}$, then the condition number of (16) can be upper bounded by:

$$\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \max\left\{4, \frac{4L}{\lambda b}\right\},$$

which improves the original condition number L/λ by a factor of at least $\widetilde{\mathcal{O}}(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}/b)$.

3.2 Improved Runtime Guarantee

Based on the above analysis, we have the following main results stating the iteration complexity of MB-SVRP algorithms on general convex objectives (1).

Theorem 13 *Consider Algorithm 1 on problems with L-smooth and λ-strongly convex functions that satisfied Condition 1 with Hessian Lipschitz parameter M. Suppose we sample minibatch $\bar{B}$ uniformly from $1,...,n$, and set the tuning parameters as*

$$\widetilde{\lambda} = \max\left\{\lambda, \frac{L}{b}\right\}, \quad b \asymp \min\left\{n, \rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\left(\frac{L}{\lambda}\right)^{1/3}\right\}, \quad \eta \asymp \min\left\{\frac{b^3\lambda}{(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}})^2 L}, \frac{1}{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}\right\},$$

and suppose we start from the initialization point that is sufficiently close to the optimum:

$$\|w_0 - w^*\| \leq R = \mathcal{O}\left(\frac{\lambda^4}{L^2 M}\right). \tag{21}$$

Given $\epsilon > 0$, and let

$$\varepsilon \leq \frac{1}{10^5} \cdot \left(\frac{\lambda}{L}\right)^7 \epsilon. \tag{22}$$

Then for the MB-SVRP algorithm to find the approximate solution $\widetilde{w}_s$ of (1) that reaches the expected ϵ-objective suboptimality

$$\mathbb{E} f(\widetilde{w}_s) - \min_w f(w) \leq \epsilon,$$

we can set

$$T \leq \mathcal{O}\left(\max\left\{\left(\frac{L}{\lambda}\right)^{1/3}, \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{\lambda n^2}\right\}\right),$$

and uses $S \leq \mathcal{O}(\log(1/\epsilon))$ total stages in Algorithm 1. Thus the total number of oracle calls to solve (8) is no more than

$$\mathcal{O}\left(\max\left\{\left(\frac{L}{\lambda}\right)^{1/3}, \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{\lambda n^2}\right\} \cdot \log\left(\frac{1}{\epsilon}\right)\right).$$

Remark 14 *There are two source of randomness in Algorithm 1: i) sampling $\bar{B}$ to form the precondition minibatch before the iterations begins; ii) sampling B_t during the iterations. In particular, sampling $\bar{B}$ affects the new condition number as Section 3.1 analyzed, while sampling B_t affects the precondition SVRG convergence. We state the results about the randomness in $\bar{B}$ in high-probability form as Lemma 10 and Corollary 12; while state the randomness in B_t in expectation results, it is also possible to obtain high-probability results for randomness in B_t by using Markov's inequality, for example as Corollary 1 in (Xiao and Zhang, 2014).*

Note that in Algorithm 1, we can use SVRG to solve each subproblem in (8). This leads to the following result.

Corollary 15 *Assume that the conditions of Theorem 13 hold. Moreover, if we use SVRG to solve each subproblem in (8) up to the suboptimality ε, then the total number of gradient evaluations used in the whole MB-SVRP algorithm can be upper bounded by*

$$\mathcal{O}\left(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \max\left\{\left(\frac{L}{\lambda}\right)^{2/3}, \frac{L}{\lambda n}\right\} \cdot \log\left(\frac{L}{\lambda}\right) \cdot \log^2\left(\frac{1}{\epsilon}\right) + n \cdot \log\left(\frac{1}{\epsilon}\right)\right).$$

We make the following remarks about Theorem 13 and Corollary 15.

Remark 16 *The solution accuracy requirement in (22) (in practice we can monitoring ε via $\|\nabla \widetilde{f}_t(w)\|$ since $\widetilde{f}_t(w)$ is $\widetilde{\lambda}$-strongly convex) is conservative, but does not affect the overall iteration complexity because solving (4) and (5) to high precision only introduces an additional logarithmic factor using SVRG. In practice, we observe that using only one pass SVRG warm started from previous iterate performs well (please refer to the experiments).*

Remark 17 *For quadratic objectives, where $M = 0$, the local fast region defined in (21) is the whole space, implying global fast convergence for quadratic objectives. Moreover, in experiments, we observe that even for the general non-quadratic objectives, the proposed MB-SVRP method also converges fast globally. Therefore the size of the local fast convergence region (21) established here might be too conservative. We leave the investigation on improving the size of the local fast convergence region to future work.*

Remark 18 *Corollary 15 states that the iteration complexity of Algorithm 1 is*

$$\widetilde{\mathcal{O}}\left(n + \rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \max\left\{\left(\frac{L}{\lambda}\right)^{2/3}, \frac{L}{\lambda n}\right\}\right),$$

where $\widetilde{\mathcal{O}}(\cdot)$ hides the minor poly logarithmic factors. When $\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}$ is small so that it can be treated as a constant, then the iteration complexity of MB-SVRP improves over standard SVRG by a factor of $\min\left\{n, \left(\frac{L}{\lambda}\right)^{1/3}\right\}$ when the condition number $\frac{L}{\lambda}$ is much larger than n. Even compared with accelerated methods (such as SVRG equipped with catalyst acceleration (Shalev-Shwartz and Zhang, 2016; Frostig et al., 2015; Lin et al., 2015a)), it can sometimes be better (when $n < L/\lambda < n^2$, see Table 1 for details).

Remark 19 *Though the optimal parameter choice stated in Theorem 13 might depend on the property of the Hessian matrix at w^*, the algorithm actually works for a wide range of parameters without the knowledge of w^* because i) for quadratic objectives the Hessian matrix does not change with w so the optimal parameter choice will not depend on w^*; ii) we only requires some constants $\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}$ to bound certain quantities of the Hessian matrix at w^*, but do not need exactly where w^* is; iii) if we are uncertain about the data we can choose some conservative parameters (as discussed in Section 3.1) to ensure the method converges at least as fast as vanilla SVRG.*

Remark 20 *When $\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}$ is small such that can be treated as constant, then the optimal choice of b according to our theory is often smaller than n, except the case where the condition number is extremely large: $L/\lambda \gtrsim (n/(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}))^3$. Moreover, when combine the proposed approach with Catalyst acceleration as in Section 3.3, the condition number in each proximal point problem can always be controlled to be not too large, in which case the optimal batch size b is smaller than n.*

Remark 21 *MB-SVRP method is able to improve the iteration complexity over SVRG when $\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}$ is small, thus it is also possible to use MB-SVRP itself to solve the minibatch subproblem (4). Such a nested approach allows us to choose a even smaller $\widetilde{\lambda}$, thus can further reduce the dependency on condition number in the iteration complexity. However, this is at the cost of increasing the dependency on $\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}$ and more complicated implementation. We will leave such investigation to future research.*

3.3 With Catalyst Acceleration

Algorithm 2 Acc-MB-SVRP: Accelerated MB-SVRP method.

Initialize $w_0 = z_0 = 0$.
for $r = 1, 2, \ldots$ **do**
Call MB-SVRP algorithm 1 to approximately solve

$$w_r \approx \arg\min_w f(w) + \frac{\gamma}{2}\|w - z_{r-1}\|^2. \tag{23}$$

Update

$$z_r = w_r + \nu_r(w_r - w_{r-1}).$$

end for
Return w_r.

Table 1: Comparison of iteration complexity of various finite-sum quadratic optimization algorithms when effective dimension and statistical leverage are bounded, where we compare the different relative scale of condition number $\kappa = L/\lambda$ and sample size n, ignoring logarithmic factors.

	$\kappa \le n$	$\kappa = n^{4/3}$	$\kappa = n^{3/2}$	$\kappa = n^2$	$\kappa = n^3$
SVRG	n	$n^{4/3}$	$n^{3/2}$	n^2	n^3
MB-SVRP	n	$\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \cdot n$	$\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \cdot n$	$\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \cdot n^{3/2}$	$\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \cdot n^{5/2}$
Acc-SVRG	n	$n^{7/6}$	$n^{5/4}$	$n^{3/2}$	n^2
Acc-MB-SVRP	n	$\left(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\right)^{1/2} \cdot n$	$\left(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\right)^{1/2} \cdot n$	$\left(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\right)^{1/2} \cdot n^{5/4}$	$\left(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\right)^{1/2} \cdot n^{7/4}$

Corollary 15 stated that if the condition number is not too large: $\frac{L}{\lambda} \le n^{5/4}$, then MB-SVRP only requires logarithmic passes over data to find a solution with high accuracy. When the condition number is large, MB-SVRP can still be slow. By using the accelerated proximal point framework proposed in (Shalev-Shwartz and Zhang, 2016; Frostig et al., 2015; Lin et al., 2015a), it is possible to obtain an accelerated convergence rate which has milder dependence on condition number, the algorithm is outlined in Algorithm 2, which iteratively, approximately call the original algorithm MB-SVRP to solve an augmented proximal point problem. The main iteration complexity is stated in the theorem below.

Theorem 22 *For ill-condition problems where $L/\lambda \ge n^{3/2}$, if we set the parameter $\gamma \asymp \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{n^{3/2}} - \lambda$, Algorithm 2 has iteration complexity of*

$$\widetilde{\mathcal{O}}\left(\left(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\right)^{1/2} \cdot n^{1/4} \left(\frac{L}{\lambda}\right)^{1/2}\right).$$

Remark 23 *From theorem 22 we see the iteration complexity of accelerated MB-SVRP grows at a square root rate with respect to the condition number, which is much better than that of the non-accelerated algorithms, and this is similar to the behavior of accelerated SVRG algorithms. Moreover, accelerated MB-SVRP improves the iteration complexity of accelerated SVRG by a factor of $n^{1/4}$ when $\sqrt{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}$ is small.*

4. Convergence Analysis of Inexact Accelerated Minibatch SVRG

Algorithm 3 IMBA-SVRG: Inexact Minibatch Accelerated SVRG Method.

Parameters $\alpha = \sqrt{\eta\lambda/2}$.
Initialize $\widetilde{w}_0 = 0$.
for $s = 1, 2, \ldots, S$ **do**
Calculate $\widetilde{v} = \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}_{s-1})$.
Initialize $y_0 = w_0 = \widetilde{w}_s$.
for $t = 1, 2, \ldots, T$ **do**
Sampling b items from $[n]$ to form a minibatch B_t.
Inexact update w_t such that

$$w_t = \bar{w}_t + \xi_t, \tag{24}$$

where:

$$\bar{w}_t = y_{t-1} - \eta\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(y_{t-1}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}_{s-1}) + \widetilde{v}\right).$$

Update

$$y_t = w_t + \left(\frac{1-\alpha}{1+\alpha}\right)(w_t - w_{t-1}).$$

end for
Update $\widetilde{w}_s = w_m$.
end for
Return $\widetilde{w}_s$

As discussed in Propositions 2 and 3, the proposed MB-SVRP method (Algorithm 1) is essentially perform the inexact minibatch accelerated SVRG updates in the preconditioned space using $\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)$ as the preconditioner. Thus, the main results established in Section 3 rely on the analysis for inexact, minibatch, accelerated SVRG update (IMBA-SVRG Algorithm 3), where in each stochastic step, we allow a small error ξ_t in the updating. In this section, we show that as long as the inexactness at each iteration is small enough, IMBA-SVRG can use a large minibatch size without slowing down the convergence.

Theorem 24 *Consider the IMBA-SVRG algorithm. If we choose the stepsize as*

$$\eta = \min\left\{\frac{b^2\lambda}{6400L^2}, \frac{1}{8L}\right\},$$

and when the deviation ξ_t satisfies $\forall 1 \le t \le T$

$$\|\xi_t\|^2 \le \frac{2\lambda^2\eta^3\sqrt{\lambda\eta}}{15}(f(\widetilde{w}_{s-1}) - f(w^*)), \tag{25}$$

and the number of iterations T satisfies

$$T \ge \frac{10}{9\sqrt{\lambda\eta}}\log(36),$$

then

$$\mathbb{E}\left[f(\widetilde{w}_s) - f(w^*)\right] \le \frac{1}{2}\left[f(\widetilde{w}_{s-1}) - f(w^*)\right].$$

Remark 25 *Depending on the relative magnitude of minibatch size b and condition number $\frac{L}{\lambda}$, the overall iteration complexity can be divided into the following two situations.*

- $b \le 20\sqrt{\frac{2L}{\lambda}}$. *If we choose the stepsize as $\eta = \frac{b^2\lambda}{6400L^2}$, and the deviation ξ_t satisfies $\forall 1 \le t \le T$: $\|\xi_t\|^2 \le \frac{2\lambda^2\eta^3\sqrt{\lambda\eta}}{15}(f(\widetilde{w}_{s-1}) - f(w^*))$, then $\mathbb{E}\left[f(\widetilde{w}_s) - f(w^*)\right] \le \frac{1}{2}\left[f(\widetilde{w}_{s-1}) - f(w^*)\right]$ when $T \ge \frac{90L}{\lambda b}$.*
- $20\sqrt{\frac{2L}{\lambda}} \le b \le n$. *If we choose stepsize as $\eta = \frac{1}{8L}$, and when the deviation ξ_t satisfies $\forall 1 \le t \le T$: $\|\xi_t\|^2 \le \frac{2\lambda^2\eta^3\sqrt{\lambda\eta}}{15}(f(\widetilde{w}_{s-1}) - f(w^*))$, then $\mathbb{E}\left[f(\widetilde{w}_s) - f(w^*)\right] \le \frac{1}{2}\left[f(\widetilde{w}_{s-1}) - f(w^*)\right]$ when $T \ge \sqrt{\frac{8L}{\lambda}}$.*

A direct consequence of Theorem 24 is the following iteration complexity of IMBA-SVRG.

Corollary 26 *For IMBA-SVRG algorithm, If we choose stepsize as $\eta = \min\left\{\frac{b^2\lambda}{6400L^2}, \frac{1}{8L}\right\}$, and when at every state s, the deviation ξ_t at every iteration satisfies $\forall 1 \le t \le T$: $\|\xi_t\|^2 \le \frac{2\lambda^2\eta^3\sqrt{\lambda\eta}}{15}(f(\widetilde{w}_{s-1}) - f(w^*))$, then $\mathcal{O}\left(\log\left(\frac{1}{\epsilon}\right)\right)$ full gradient evaluations and*

$$\mathcal{O}\left(\max\left\{\frac{L}{\lambda b}, \sqrt{\frac{L}{\lambda}}\right\} \cdot \log\left(\frac{1}{\epsilon}\right)\right)$$

inexact update steps of form (24) are sufficient to ensure $\mathbb{E}f(\widetilde{w}_s) - f(w^*) \le \epsilon$.

Our convergence proof of IMBA-SVRG relies on the machinery of stochastic estimation sequence (Lin et al., 2014), which originated from the framework of estimation sequence developed in (Nesterov, 2004). The details are given in Appendix B.

The main difference between our analysis and that of (Lin et al., 2014) is that we no longer require the inequalities in estimation sequences hold almost surely. Instead we only make sure they hold in expectation, and thus the quadratic lower bound used to construct the stochastic estimation sequence is also different. IMBA-SVRG can be viewed as an inexact extension of accelerated minibatch SVRG (Nitanda, 2014). Although (Nitanda, 2014) also considered stochastic estimation sequences, here we allow error in the stochastic gradient update, and thus need to construct a different estimation sequence which takes the inexactness into consideration. On the other hand, batch (accelerated) gradient methods with inexact first order oracle have been studied in (Schmidt et al., 2011; Villa et al., 2013; Devolder et al., 2014), and the analysis of IMBA-SVRG extends these results in the context of stochastic gradient methods with variance reduction.

Algorithm 4 Practical implementation of MB-SVRP Algorithm used in Experiments.

Parameters: b.
Initialize $\eta = \frac{1}{L}$, $\nu = \frac{1-\sqrt{\lambda\eta}}{1+\sqrt{\lambda\eta}}$, $m = \lceil\frac{n}{b}\rceil$, $\bar{\lambda} = \frac{1}{\sqrt{b}}$, $\widetilde{w}_0 = 0$.
Sampling Sampling b items from $[n]$ to form a minibatch $\bar{B}$.
for $s = 1, 2, \ldots$ **do**
  Calculate $\widetilde{v} = \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}_{s-1})$.
  Initialize $y_0 = w_0 = \widetilde{w}_s$.
  for $t = 1, 2, \ldots, \lceil 2n/b \rceil$ **do**
    Sampling b items from $[n]$ to form a minibatch B_t.
    Initialize $w_t = y_{t-1}$.
    Calculate $\widetilde{u} = \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(y_{t-1}) + \eta\widetilde{v} - \frac{\eta}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}_{s-1})$.
    for $k = 1, 2, \ldots, b$ **do**
      Sampling Sampling an index i_k from $\bar{B}$.
      Update (**MB-SVRP-I**): $w_t \leftarrow w_t - \eta\left(\nabla f_{i_k}(w_t) - \nabla f_{i_k}(y_{t-1}) + \bar{\lambda}(w_t - y_{t-1}) + \widetilde{u}\right)$.
      Update (**MB-SVRP-II**): $w_t \leftarrow w_t - \eta\left(\nabla^2 f_{i_k}(y_{t-1})(w_t - y_{t-1}) + \bar{\lambda}(w_t - y_{t-1}) + \widetilde{u}\right)$.
    end for
    Update: $y_t = w_t + \nu(w_t - w_{t-1})$.
  end for
  Update $\widetilde{w}_s = w_m$.
end for
Return $\widetilde{w}_s$

5. Experiments

In this section we compare the proposed MB-SVRP algorithm to several state-of-the-art methods for minimizing (1). The datasets are summarized in Table 2, most of which can be download from the LibSVM website[2]. We also considered a synthetic dataset for each task, where the data $\{x_i, b_i\}_{i=1}^n$ are i.i.d. drawn from the following model:

$$\text{Regression}: \quad b_i = \langle x_i, \bar{w}\rangle + a_i, \quad x_i \sim \mathcal{N}(0,\Sigma), \quad a_i \sim \mathcal{N}(0,1), \quad \forall i \in [n],$$

$$\text{Classification}: \quad P(b_i = \pm 1) = \frac{\exp(b_i\langle x_i, \bar{w}\rangle)}{1+\exp(b_i\langle x_i, \bar{w}\rangle)}, \quad x_i \sim \mathcal{N}(0,\Sigma), \quad \forall i \in [n],$$

where entries of $\bar{w}$ are drawn i.i.d. from $\mathcal{N}(0,1)$. To make the problem ill-conditioned with fast decaying spectrum, we set $\Sigma_{ij} = 2^{-|i-j|/500}, \forall i,j \in [n]$.

5.1 Empirical Results for Smooth Optimization

We consider ridge regression and logistic regression models for regression and classification problems, respectively. We normalize the dataset by $x_i \leftarrow x_i / \left(\max_i \|x_i\|^2\right)$ to ensure that the maximum norm of data points is 1. Note that the normalization will not change statistical property of the problem, the purpose here is to make the smoothness parameter fixed and invariant across different datasets, thus easier for us to set a suitable regularization parameter λ for the target condition number. We tried three settings of λ, as $1/n, 10^{-1}/n$ and $10^{-2}/n$ to represent different levels of regularization. It is expected that when $\lambda = 1/n$, the SVRG/SAGA/SDCA algorithms should converge very fast since the condition number is of the same order as sample size n, while for weak regularization case $\lambda = 10^{-2}/n$ these algorithms are expected to converge slowly.

We compare with SVRG (Johnson and Zhang, 2013), SDCA (Shalev-Shwartz and Zhang, 2013), and SAGA (Defazio et al., 2014), as they represent popular variance reduced optimization algorithms. We also compare with the minibatch version of SVRG and SAGA, in particular, we compare with a related minibatch accelerated SVRG (MB-SVRG) (Nitanda, 2014), which allows large minibatch size without slowing down convergence; while for SAGA, we apply the standard minibatch technique for SAGA and get the MB-SAGA algorithm. For quasi-Newton methods, we compare with L-BFGS with 10 as the limited memory size, and with line search of stepsize to satisfy the Wolfe condition (Wright and Nocedal, 1999). For the proposed MB-SVRP method, we implemented both Option I (MB-SVRP-I) and Option II (MB-SVRP-II), for ridge regression problem, these the two options are equivalent. At every iteration we simply run one pass of SVRG method initialized with y_{t-1}, to approximately solve (4). The implementation is summarized in Algorithm 4, where we fixed many parameters except the minibatch size b as the main tuning parameter. For SVRG and MB-SVRP method, we set $T = \lceil 2n/b \rceil$ as suggested in (Johnson and Zhang, 2013). The minibatch size of MB-SVRP are set to be $\max(\min((L/\lambda)^{1/3}, d), 40)$ inspired by theoretical analysis in Section 3, the minibatch size of MB-SVRG and MB-SAGA is set to be the same as MB-SVRP to demonstrate the direct comparison. In Section 5.3 we also performed a sensitivity study on the minibatch size b in MB-SVRP algorithm. Other parameters, such as stepsize in SVRG and SAGA, are tuned to give the fastest convergence.

We use primal objective suboptimality and the number of gradient evaluations as the evaluation metrics. Since gradient calculations account for the major computing part of

2. https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/

first-order optimization methods, it is used as a good estimate (Johnson and Zhang, 2013; Shalev-Shwartz and Zhang, 2013; Defazio et al., 2014) of the computation cost, and it can be evaluated independent of specific implementation and computing hardware. Figure 2 and 3 showed the results for ℓ_2 regularized logistic regression and ridge regression, respectively, where we plot how the objective suboptimality $f(w_t) - f(w^*)$ decreases as the number of gradient evaluations divided by sample size (a.k.a. number of effective passes) increases. We have the following observations:

- When the regularization parameter λ (thus strong convexity) is large enough, all methods (except L-BFGS and MB-SAGA) converges very fast, typically using less than 50 passes over data to converges to numerical precision. The slow convergence of MB-SAGA is due to the usage of minibatch which slow down its computation efficiency.
- The convergence of L-BFGS is typically the slowest. When λ is large, the advantages of variance-reduced stochastic methods over L-BFGS are significant.
- When the regularization parameter is small, the proposed MB-SVRP method starts to show advantages. In particular, when $\lambda = 10^{-2}/n$, MB-SVRP is substantially faster than all other methods compared in our study. We also observed there is only negligible performance difference between MB-SVRP-I and MB-SVRP-II.

5.2 Empirical Results for Composite Optimization

We also consider empirical comparisons in the setting of non-smooth composition optimization problems. We adopted the same datasets used for the smooth optimization problems, but considered the elastic-net regularized logistic regression and linear regression models (Zou and Hastie, 2005). Where the objective is in the form of (12) but with a elastic-net regularization:

$$g(w) = \frac{\lambda}{2}\|w\|^2 + \mu\|w\|_1,$$

where μ is set to be $10^{-1}/n$. We follow the same settings as in the previous section, and compare with prox-SVRG (Xiao and Zhang, 2014), prox-SAGA (Defazio et al., 2014), prox MB-SVRG (Nitanda, 2014), and prox MB-SAGA, but didn't compare with L-BFGS because the method is generally only applicable for smooth problems. The results are shown in Figure 4 and 5, and we have similar observations as those of the smooth optimization case: all variance-reduced methods converges reasonably fast when λ is large, but when λ becomes small, the proposed prox MB-SVRP method converges significantly faster because it effectively leveraged the higher-order information from minibatches.

5.3 Sensitivity Study on the Minibatch Size in MB-SVRP

We also performed a sensitivity study on the minibatch size b, to see how b will affect the convergence behavior of MB-SVRP method. The experimental setting follows Section 5.1 and 5.2, except that we varying b to be $16, 32, 64, 128$ for MB-SVRP, and the regularization parameter λ is fixed to be $10^{-2}/n$. The results were shown in Figure 6, we observed that MB-SVRP method performed well on a wide range settings of minibatch sizes, and converges fast than SVRG in most cases.

6. Conclusion

In this paper, we proposed a novel minibatch stochastic optimization approach for regularized loss minimization in machine learning. This approach efficiently utilizes both variance-reduced first-order gradients and sub-sampled higher order information, and under suitable conditions, it can provably improve the iteration complexity over that of the previous state-of-the-art. Empirical experiments demonstrated that this approach performs well on a variety of smooth and composite optimization tasks in practice. The minibatch nature of the algorithm makes it useful for parallel and distributed computing environment, where additional speed up can be obtained by using many CPU cores for computation.

Appendix

The appendix contains proofs of some theorems and lemmas stated in the main paper.

Appendix A. Proofs for Section 3

A.1 Proof of Proposition 3

Proof Let $w^* = \arg\min_w f(w)$, and $z^* = \arg\min_z f(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z)$, it is clear that $w^* = \bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z^*$, which is coincident with the exchange of variable rule $z = \bar{H}_{\widetilde{\lambda}}^{1/2}(w^*)w$. Moreover, since

$$\eta\left(\frac{1}{b}\sum_{i\in B_t}\nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z}) - \frac{1}{b}\sum_{i\in B_t}\nabla_z f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z})\right)$$
$$\overset{①}{=} \eta H_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)z_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\widetilde{z})\right)$$
$$\overset{②}{=} \eta H_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})\right),$$

where at step ① we have used the gradient chain rule, at step ② we used the exchange of variables $z = \bar{H}_{\widetilde{\lambda}}^{1/2}(w^*)w$. Substitute to (15), and multiplying both sides of above equation with $\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)$, we get

$$w_t \leftarrow w_{t-1} - \eta\bar{H}_{\widetilde{\lambda}}(w_{t-1})^{-1}\left(\frac{1}{b}\sum_{i\in B_t}\nabla f_i(w_{t-1}) + \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w})\right),$$

which recovers the exact formulation of (14). ■

A.2 Proof of Lemma 4

Proof We first perform the following decomposition:

$$\|z_t - \bar{z}_t\| \le \|z_t - z_t^*\| + \|z_t^* - \bar{z}_t\|, \tag{26}$$

then we can bound $\|z_t - z_t^*\|$ by

$$\begin{aligned}\|z_t - z_t^*\| =& \left\|\bar{H}_{\widetilde{\lambda}}^{1/2}(w^*)(w_t - w_t^*)\right\| \le \left\|\bar{H}_{\widetilde{\lambda}}(w^*)\right\|^{1/2}\|w_t - w_t^*\| \le \sqrt{L+\widetilde{\lambda}}\,\|w_t - w_t^*\| \\ \le& \sqrt{\frac{2(\widetilde{f}_t(w_t) - \widetilde{f}_t(w_t^*))(L+\widetilde{\lambda})}{\lambda+\widetilde{\lambda}}},\end{aligned} \tag{27}$$

where in the last inequality we use the $\lambda+\widetilde{\lambda}$-strong convexity of $\widetilde{f}_t(w)$. For the term $\|z_t^* - \bar{z}_t\|$, we can bounded it using Hessian Lipschitz property,

$$\begin{aligned}\|z_t^* - \bar{z}_t\| =& \left\|\eta\bar{H}_{\widetilde{\lambda}}^{1/2}(w^*)\left(\bar{H}_{\widetilde{\lambda}}(w^*)^{-1} - \bar{H}_{\widetilde{\lambda}}(w_{t-1})^{-1}\right)\vartheta_t\right\| \\ \le& \eta\left\|\left(\bar{H}_{\widetilde{\lambda}}(w^*)^{-1/2}\bar{H}_{\widetilde{\lambda}}(w_{t-1})^{-1}\right)\left(\bar{H}_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w_{t-1})\right)\right\|\|\vartheta_t\| \\ \le& \frac{\eta}{\widetilde{\lambda}^{3/2}}M\|w_{t-1} - w^*\|\|\vartheta_t\|.\end{aligned} \tag{28}$$

Combining (26), (27) and (28) finishes the proof. ■

A.3 Proof of Lemma 7

Proof We first decompose the terms $\frac{\lambda_j}{\lambda_j+\widetilde{\lambda}}$ into two parts, the first one contains indexes smaller or equal than k and the second part contains indexes larger than k, then we upper bound these two parts get obtain the stated results.

$$\begin{aligned}d_{\widetilde{\lambda}} =& \sum_j \frac{\lambda_j}{\lambda_j+\widetilde{\lambda}} = \min_k\left\{\sum_{j\le k}\frac{\lambda_j}{\lambda_j+\widetilde{\lambda}} + \sum_{j>k}\frac{\lambda_j}{\lambda_j+\widetilde{\lambda}}\right\} \\ \le& \min_k\left\{\sum_{j\le k}\frac{\lambda_j+\widetilde{\lambda}}{\lambda_j+\widetilde{\lambda}} + \sum_{j>k}\frac{\lambda_j}{\widetilde{\lambda}}\right\} = \min_k\left\{k + \frac{\sum_{j>k}\lambda_j}{\widetilde{\lambda}}\right\}\end{aligned}$$

■

A.4 Proof of Lemma 9

Proof For $j = 1, ..., b$, define random matrix

$$v_j = \frac{1}{b}\left(H_{\widetilde{\lambda}}^{-1/2}(w^*)\ell''(w^{*\top}x_k; b_k)x_k x_k^\top H_{\widetilde{\lambda}}^{-1/2}(w^*) - \frac{1}{n}\sum_{i=1}^n H_{\widetilde{\lambda}}^{-1/2}(w^*)\ell''(w^{*\top}x_i; b_i)x_i x_i^\top H_{\widetilde{\lambda}}^{-1/2}(w^*)\right),$$

with probability $1/n, \forall k \in [n]$. It is easy to check that $\mathbb{E}[v_j] = 0$, and

$$\begin{aligned}\|v_j\| \le& \frac{1}{b}\left(\left\|H_{\widetilde{\lambda}}^{-1/2}(w^*)\ell''(w^{*\top}x_k; b_k)x_k x_k^\top H_{\widetilde{\lambda}}^{-1/2}(w^*)\right\|\right) \\ &+ \frac{1}{b}\left(\left\|\frac{1}{n}\sum_{i=1}^n H_{\widetilde{\lambda}}^{-1/2}(w^*)\ell''(w^{*\top}x_i; b_i)x_i x_i^\top H_{\widetilde{\lambda}}^{-1/2}(w^*)\right\|\right) \\ \le& \frac{1}{b}\left(2\max_{i\in[n]}\ell''(w^{*\top}x_i; b_i)x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i\right) \le \frac{2\rho_{\widetilde{\lambda}}^2}{b}\left(\frac{1}{n}\sum_{i=1}^n \ell''(w^{*\top}x_i; b_i)x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i\right) \\ =& \frac{2\rho_{\widetilde{\lambda}}^2}{b}\operatorname{tr}\left(H_{\widetilde{\lambda}}^{-1}(w^*)\left(\frac{1}{n}\sum_{i=1}^n \ell''(w^{*\top}x_i; b_i)x_i x_i^\top\right)\right) = \frac{2\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}.\end{aligned}$$

for the expected second order moment, denote $\widetilde{x}_k = (\ell''(w^{*\top}x_k;b_k))^{1/2}H_{\widetilde{\lambda}}^{-1/2}(w^*)x_k$ we have

$$\begin{aligned}
\left\|\mathbb{E}\left[v_j^2\right]\right\| &= \left\|\frac{1}{nb^2}\sum_{k=1}^n\left(\widetilde{x}_k\widetilde{x}_k^\top - \frac{1}{n}\sum_{i=1}^n\widetilde{x}_i\widetilde{x}_i^\top\right)^2\right\| \\
&= \left\|\frac{1}{nb^2}\sum_{k=1}^n\left(\left(\widetilde{x}_k\widetilde{x}_k^\top\right)^2 - 2\left(\widetilde{x}_k\widetilde{x}_k^\top\right)\left(\frac{1}{n}\sum_{i=1}^n\widetilde{x}_i\widetilde{x}_i^\top\right) + \left(\frac{1}{n}\sum_{i=1}^n\widetilde{x}_i\widetilde{x}_i^\top\right)^2\right)\right\| \\
&= \left\|\frac{1}{nb^2}\sum_{k=1}^n\left(\widetilde{x}_k\widetilde{x}_k^\top\right)^2 - \frac{2}{b^2}\left(\frac{1}{n}\sum_{i=1}^n\widetilde{x}_i\widetilde{x}_i^\top\right)^2 + \frac{1}{b^2}\left(\frac{1}{n}\sum_{i=1}^n\widetilde{x}_i\widetilde{x}_i^\top\right)^2\right\| \\
&= \left\|\frac{1}{nb^2}\sum_{k=1}^n\left(\widetilde{x}_k\widetilde{x}_k^\top\right)^2 - \frac{1}{b^2}\left(\frac{1}{n}\sum_{i=1}^n\widetilde{x}_i\widetilde{x}_i^\top\right)^2\right\| \\
&\le \left\|\frac{1}{nb^2}\sum_{k=1}^n\left(\widetilde{x}_k\widetilde{x}_k^\top\right)^2\right\| \le \left\|\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b^2}\left(\frac{1}{n}\sum_{k=1}^n\widetilde{x}_k\widetilde{x}_k^\top\right)\right\| \\
&= \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b^2}\left\|H_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\frac{1}{n}\sum_{i=1}^n\ell''(w^{*\top}x_i;b_i)x_ix_i^\top\right)H_{\widetilde{\lambda}}^{-1/2}(w^*)\right\| \\
&\le \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b^2}.
\end{aligned}$$

Thus

$$\left\|\sum_{j=1}^b\mathbb{E}\left[v_j^2\right]\right\| \le \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b},$$

using Lemma 35, we know

$$\begin{aligned}
&P\left(\left\|H_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\frac{1}{b}\sum_{i\in\bar{B}}\ell''(w^{*\top}x_i;b_i)x_ix_i^\top - \frac{1}{n}\sum_{i=1}^n\ell''(w^{*\top}x_i;b_i)x_ix_i^\top\right)H_{\widetilde{\lambda}}^{-1/2}(w^*)\right\|_2 \ge t\right) \\
&= P\left(\left\|\sum_{j=1}^b v_j\right\| \ge t\right) \le d\exp\left(\frac{-t^2/2}{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}/b + 2\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} t/(3b)}\right),
\end{aligned}$$

setting $t = 2\log\left(\frac{d}{\delta}\right)\cdot\sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}}$ we conclude the proof. ■

A.5 Proof of Lemma 10

Proof When $\widetilde{\lambda} \ge \lambda$, we know

$$\begin{aligned}
&\lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_\lambda(w)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)) \\
&\ge \lambda_{\min}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\left(\frac{\lambda}{\widetilde{\lambda}}\left(\frac{1}{n}\sum_{i=1}^n\ell''(w^\top x_i;b_i)x_ix_i^\top\right) + \lambda I\right)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right) \\
&= \frac{\lambda}{\widetilde{\lambda}}\lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_{\widetilde{\lambda}}(w)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)).
\end{aligned}$$

Further more we can lower bound $\lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_{\widetilde{\lambda}}(w)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*))$ by

$$\begin{aligned}
&\lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_{\widetilde{\lambda}}(w)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)) \\
&= \lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}(w)) \\
&= \frac{1}{\lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)\bar{H}_{\widetilde{\lambda}}(w^*))} \\
&\ge \frac{1}{\lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)H_{\widetilde{\lambda}}(w)) + \lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)(H_{\widetilde{\lambda}}(w) - \bar{H}_{\widetilde{\lambda}}(w^*)))} \\
&\ge \frac{1}{1 + \lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*))) + \lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)(H_{\widetilde{\lambda}}(w) - H_{\widetilde{\lambda}}(w^*)))},
\end{aligned} \tag{29}$$

For the term $\lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*)))$, we have the following decomposition:

$$\begin{aligned}
\lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*))) \le &\lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w^*)(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*))) \\
&+ \lambda_{\max}((H_{\widetilde{\lambda}}^{-1}(w^*) - H_{\widetilde{\lambda}}^{-1}(w))(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*)))
\end{aligned} \tag{30}$$

since with probability at least $1-\delta$, we have

$$\lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w^*)(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*))) \le 2\log\left(\frac{d}{\delta}\right)\sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}}, \tag{31}$$

and

$$\begin{aligned}
&\lambda_{\max}((H_{\widetilde{\lambda}}^{-1}(w^*) - H_{\widetilde{\lambda}}^{-1}(w))(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*))) \\
&= \lambda_{\max}((H_{\widetilde{\lambda}}(w^*) - H_{\widetilde{\lambda}}(w))H_{\widetilde{\lambda}}^{-1}(w)H_{\widetilde{\lambda}}^{-1}(w^*)(H_{\widetilde{\lambda}}(w^*) - \bar{H}_{\widetilde{\lambda}}(w^*))) \\
&\le \lambda_{\max}(H_{\widetilde{\lambda}}(w^*) - H_{\widetilde{\lambda}}(w))2\log\left(\frac{d}{\delta}\right)\sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}}\cdot\frac{1}{\widetilde{\lambda}} \\
&\le \frac{M\left\|w-w^*\right\|}{\widetilde{\lambda}}\cdot 2\log\left(\frac{d}{\delta}\right)\sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}},
\end{aligned} \tag{32}$$

using the results of Lemma (9), and also Lipschitz Hessian property (Condition 1). Moreover,

$$\lambda_{\max}(H_{\widetilde{\lambda}}^{-1}(w)(H_{\widetilde{\lambda}}(w)-H_{\widetilde{\lambda}}(w^*))) \leq \frac{\lambda_{\max}(H_{\widetilde{\lambda}}(w)-H_{\widetilde{\lambda}}(w^*))}{\widetilde{\lambda}} \leq \frac{M\|w-w^*\|}{\widetilde{\lambda}}. \tag{33}$$

Combining (29), (31), (32), (33) we have with probability at least $1-\delta$

$$\min_{\|w-w^*\|\leq R}\lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_\lambda(w)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)) \geq \frac{\lambda}{\widetilde{\lambda}}\cdot\frac{1}{1+2\log\left(\frac{d}{\delta}\right)\sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}}+2\log\left(\frac{d}{\delta}\right)\sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}}\cdot\frac{MR}{\widetilde{\lambda}}+\frac{MR}{\widetilde{\lambda}}},$$

which finishes the proof. ■

A.6 Proof of Lemma 11

Proof First we perform the following decomposition:

$$\begin{aligned}\max_{i\in[n]}\max_{\|w-w^*\|\leq R}\ell''(w^\top x_i;b_i)x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i \leq& \max_{i\in[n]}\max_{\|w-w^*\|\leq R}|\ell''(w^\top x_i;b_i)-\ell''(w^{*\top}x_i;b_i)|x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i\\ &+\max_{i\in[n]}\ell''(w^{*\top}x_i;b_i)x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i,\end{aligned}$$

where

$$\begin{aligned}\max_{i\in[n]}\max_{\|w-w^*\|\leq R}|\ell''(w^\top x_i;b_i)-\ell''(w^{*\top}x_i;b_i)|x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i \leq& \max_{i\in[n]}\bar{M}Rx_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i\\ \leq& \frac{\bar{M}RD}{\widetilde{\lambda}}=\frac{MR}{\widetilde{\lambda}}.\end{aligned}$$

Thus we have

$$\max_{i\in[n]}\max_{\|w-w^*\|\leq R}\ell''(w^\top x_i;b_i)x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i \leq \max_{i\in[n]}\ell''(w^{*\top}x_i;b_i)x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i+\frac{MR}{\widetilde{\lambda}}.$$

Then we relate $x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i$ to $x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i$, for this purpose, we first upper bound $\lambda_{\max}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_{\widetilde{\lambda}}(w^*)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right)$. By Lemma 9, when $b\geq 16\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\log^2(d/\delta)$ we have

$$\left\|H_{\widetilde{\lambda}}^{-1}(w^*)(H_{\widetilde{\lambda}}(w^*)-\bar{H}_{\widetilde{\lambda}}(w^*))\right\|_2 \leq 2\log\left(\frac{d}{\delta}\right)\sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{b}} \leq \frac{1}{2},$$

thus

$$\begin{aligned}\lambda_{\max}\left(\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)H_{\widetilde{\lambda}}(w^*)\bar{H}_{\widetilde{\lambda}}^{-1/2}(w^*)\right)=&\frac{1}{\lambda_{\min}\left(H_{\widetilde{\lambda}}^{-1}(w^*)\bar{H}_{\widetilde{\lambda}}(w^*)\right)}\\ \leq&\frac{1}{1-\left\|H_{\widetilde{\lambda}}^{-1}(w^*)(H_{\widetilde{\lambda}}(w^*)-\bar{H}_{\widetilde{\lambda}}(w^*))\right\|_2}\\ \leq&\frac{1}{1-1/2}\leq 2.\end{aligned}$$

Then we bound $\max_{i\in[n]}\ell''(w^{*\top}x_i;b_i)x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i$ through $\max_{i\in[n]}\ell''(w^{*\top}x_i;b_i)x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i$, because

$$\begin{aligned}x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i=&x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i+x_i^\top\left(\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)-H_{\widetilde{\lambda}}^{-1}(w^*)\right)x_i\\ =&x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i+x_i^\top H_{\widetilde{\lambda}}^{-1/2}(w^*)\left(H_{\widetilde{\lambda}}^{1/2}(w^*)\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}^{1/2}(w^*)-I\right)H_{\widetilde{\lambda}}^{-1/2}(w^*)x_i\\ \leq&x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i+\lambda_{\max}\left(H_{\widetilde{\lambda}}^{1/2}(w^*)\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}^{1/2}(w^*)-I\right)x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i\\ \overset{①}{\leq}&2x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i,\end{aligned}$$

where in step ① we used the fact that

$$\begin{aligned}&\lambda_{\max}\left(H_{\widetilde{\lambda}}^{1/2}(w^*)\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}^{1/2}(w^*)-I\right)\\ &\leq\max\left\{|\lambda_{\max}(H_{\widetilde{\lambda}}^{1/2}(w^*)\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}^{1/2}(w^*))-1|,|\lambda_{\min}(H_{\widetilde{\lambda}}^{1/2}(w^*)\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}^{1/2}(w^*))-1|\right\}\\ &=\max\left\{|\lambda_{\max}(\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}(w^*))-1|,|\lambda_{\min}(\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)H_{\widetilde{\lambda}}(w^*))-1|\right\}\leq 1.\end{aligned}$$

Based on the definition of effective dimension (Definition 6) and condition of bounded statistical leverage (Assumption 8), we can bound the smoothness as

$$\begin{aligned}\max_{i\in[n]}\max_{\|w-w^*\|\leq R}\ell''(w^\top x_i;b_i)x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i \leq&2\max_{i\in[n]}\ell''(w^{*\top}x_i;b_i)x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i+\frac{MR}{\widetilde{\lambda}}\\ \leq&2\rho_{\widetilde{\lambda}}^2\left(\frac{1}{n}\sum_{i=1}^n\ell''(w^{*\top}x_i;b_i)x_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)x_i\right)+\frac{MR}{\widetilde{\lambda}}\\ \overset{①}{=}&2\rho_{\widetilde{\lambda}}^2\left(\frac{1}{n}\sum_{i=1}^n\mathrm{tr}(\ell''(w^{*\top}x_i;b_i)x_ix_i^\top H_{\widetilde{\lambda}}^{-1}(w^*))\right)+\frac{MR}{\widetilde{\lambda}},\end{aligned}$$

where in step ① we have used the fact that $\mathrm{tr}(ABC)=\mathrm{tr}(CAB)$ for any A,B,C. Furthermore we have

$$\begin{aligned}2\rho_{\widetilde{\lambda}}^2\left(\frac{1}{n}\sum_{i=1}^n\mathrm{tr}(\ell''(w^{*\top}x_i;b_i)x_ix_i^\top H_{\widetilde{\lambda}}^{-1}(w^*))\right)=&2\rho_{\widetilde{\lambda}}^2\left(\mathrm{tr}\left(\frac{1}{n}\sum_i\ell''(w^{*\top}x_i;b_i)x_ix_i^\top H_{\widetilde{\lambda}}^{-1}(w^*)\right)\right)\\ =&2\rho_{\widetilde{\lambda}}^2\left(\mathrm{tr}\left(\left(\frac{1}{n}\sum_i\ell''(w^{*\top}x_i;b_i)x_ix_i^\top\right)H_{\widetilde{\lambda}}^{-1}(w^*)\right)\right)\\ =&2\rho_{\widetilde{\lambda}}^2\sum_{j=1}^d\frac{\lambda_j}{\lambda_j+\widetilde{\lambda}}=2\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}.\end{aligned}$$

Combining above analysis, we get

$$\max_{i\in[n]}\max_{\|w-w^*\|\leq R}\ell''(w^\top x_i;b_i)x_i^\top\bar{H}_{\widetilde{\lambda}}^{-1}(w^*)x_i \leq 2\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}+\frac{MR}{\widetilde{\lambda}},$$

which concludes the proof. ■

A.7 Proof of Theorem 13

Proof Since we choose $\widetilde{\lambda}$ at the scale of $\widetilde{\lambda} = \max\left\{\lambda, \frac{L}{b}\right\}$, then we can apply Lemma 10 and Lemma 11 to verify that the new condition number after "preconditioning" will be

$$\max\left\{4\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}, \frac{4L\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}{\lambda b}\right\},$$

applying Corollary 26 we know as long as the inexactness condition (25) is satisfied, we requires $\mathcal{O}\left(\log\left(\frac{1}{\epsilon}\right)\right)$ full gradient evaluations and

$$\max\left\{C_{\rm sb}, C_{\rm lb}\right\} \cdot \frac{10}{9}\log(36)\log\left(\frac{1}{\epsilon}\right) \tag{34}$$

total calls of approximate minimization of (8) to ensure $\mathbb{E}f(\widetilde{w}_s) - f(w^*) \leq \epsilon$, where the factors $C_{\rm sb}, C_{\rm lb}$ are

$$\begin{aligned} C_{\rm sb} =& \mathcal{O}\left(\max\left\{\frac{240}{b}, \frac{240L}{\lambda b^2}\right\} \cdot \rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}\right), \\ C_{\rm lb} =& \mathcal{O}\left(\max\left\{2\sqrt{6}, 2\sqrt{6}\sqrt{\frac{L}{\lambda b}}\right\} \cdot \sqrt{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}}\right), \end{aligned}$$

which represent the cases of small and large minibatch sizes, respectively. Since $\widetilde{\lambda} \geq \frac{L}{b}$, then the condition number of (8) is never larger than $\frac{L}{\widetilde{\lambda}} \leq L \cdot \frac{b}{L} = b$, we know from Lemma 36, when applying SVRG to solve (8), to reach some point of which objective the suboptimality of (8) satisfies

$$\widetilde{f}_t(w_t) - \min_w \widetilde{f}_t(w) \leq \frac{1}{10^5} \cdot \left(\frac{\lambda}{L}\right)^7 \epsilon, \tag{35}$$

the following number of gradient calls sufficient:

$$C \cdot b \cdot \log\left(\frac{L}{\lambda}\right) \cdot \log\left(\frac{1}{\epsilon}\right), \tag{36}$$

for some universal constant C. On the other hand, for every subproblem (8), if (35) is satisfied, applying Lemma 4 and Lemma 33 we know the gradient error in IMBA-SVRG (Algorithm 3)in the preconditioned space can be upper bounded by

$$\|\xi_t\|^2 \leq \left(\frac{\lambda}{L}\right)^6 \cdot \frac{2\epsilon}{10^5} + \frac{\eta^2 M^2 R^2 L}{\widetilde{\lambda}^4}(f(\widetilde{w}_{s-1}) - f(w^*)),$$

thus condition (25) in Theorem 24 is satisfied. Combining (34) and (36) we know the total number of gradient calls:

$$n \cdot \log\left(\frac{1}{\epsilon}\right) + \frac{10C}{9}\log(36) \cdot \max\left\{C_{\rm sb}, C_{\rm lb}\right\} \cdot b \cdot \log\left(\frac{L}{\lambda}\right) \cdot \log^2\left(\frac{1}{\epsilon}\right) \tag{37}$$

is sufficient to obtain a solution such that $\mathbb{E}f(\widetilde{w}_s) - f(w^*) \leq \epsilon$ is satisfied. Next we choose b such that the total iteration complexity of above expression is minimized. Start from here we will ignore the constants before these factors for simplicity, we know the term $\max\left\{C_{\rm sb}, C_{\rm lb}\right\} \cdot b$ is of order

$$\mathcal{O}\left(\max\left\{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}, \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{\lambda b}, \sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L b}{\lambda}}\right\}\right),$$

when $n \gtrsim \rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \left(\frac{L}{\lambda}\right)^{1/3}$, we can choose $b \asymp \rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \left(\frac{L}{\lambda}\right)^{1/3}$, then $\max\left\{C_{\rm sb}, C_{\rm lb}\right\} \cdot b$ is of order

$$\mathcal{O}\left(\max\left\{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}}, \left(\frac{L}{\lambda}\right)^{2/3}, \rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \left(\frac{L}{\lambda}\right)^{2/3}\right\}\right) = \mathcal{O}\left(\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \left(\frac{L}{\lambda}\right)^{2/3}\right), \tag{38}$$

when $n \lesssim \rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \left(\frac{L}{\lambda}\right)^{1/3}$, we can choose $b \asymp n$, in which case $\max\left\{C_{\rm sb}, C_{\rm lb}\right\} \cdot b$ can be upper bounded by

$$\mathcal{O}\left(\max\left\{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{\lambda n}, \sqrt{\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L n}{\lambda}}\right\}\right) = \mathcal{O}\left(\frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{\lambda n}\right), \tag{39}$$

Combining (37), (38) and (39), we know the total number of individual function gradient calls to reach ϵ-suboptimality is

$$\mathcal{O}\left(\widetilde{\kappa} \cdot \log\left(\frac{L}{\lambda}\right) \cdot \log^2\left(\frac{1}{\epsilon}\right) + n \cdot \log\left(\frac{1}{\epsilon}\right)\right),$$

where

$$\widetilde{\kappa} = \max\left\{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \left(\frac{L}{\lambda}\right)^{2/3}, \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{\lambda n}\right\},$$

which finishes the proof. ■

A.8 Proof of Theorem 22

Proof Applying the theory of catalyst acceleration (Lemma 37) we know only $\mathcal{O}\left(\left(\sqrt{\frac{\lambda+\gamma}{\lambda}}\right)\log\left(\frac{1}{\epsilon}\right)\right)$ calls of MB-SVRP is sufficient to reach ϵ-objective suboptimality, as long as each iterate w_r satisfies

$$f(w_r) + \frac{\gamma}{2}\|w_r - z_{r-1}\|^2 \leq \min_w f(w) + \frac{\gamma}{2}\|w - z_{r-1}\|^2 + \frac{\lambda\epsilon}{3600(\lambda+\gamma)}\left(1 - \frac{9}{10}\sqrt{\frac{\lambda}{\lambda+\gamma}}\right).$$

Moreover, according to Theorem 13, the iteration complexity of solving a $\lambda+\gamma$ strongly convex problem (23) is

$$\widetilde{\mathcal{O}}\left(n + \max\left\{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} \left(\frac{L}{(\lambda+\gamma)}\right)^{2/3}, \frac{\rho_{\widetilde{\lambda}}^2 d_{\widetilde{\lambda}} L}{(\lambda+\gamma)n}\right\}\right),$$

combining these two results we know the total iteration complexity of Algorithm 2 can be upper bounded by

$$\widetilde{\mathcal{O}}\left(\left(\sqrt{\frac{\lambda+\gamma}{\lambda}}\right)\left(n+\max\left\{\left(\frac{\rho_\lambda^2 d_{\widetilde{\lambda}} L}{(\lambda+\gamma)}\right)^{2/3}, \frac{\rho_\lambda^2 d_{\widetilde{\lambda}} L}{(\lambda+\gamma)n}\right\}\right)\right),$$

When $\frac{\rho_\lambda^2 d_{\widetilde{\lambda}} L}{\lambda} \geq n^{3/2}$, if we choose

$$\gamma = \frac{\rho_\lambda^2 d_{\widetilde{\lambda}} L}{n^{3/2}} - \lambda,$$

we obtain the iteration complexity can be upper bounded by

$$\widetilde{\mathcal{O}}\left(\left(\sqrt{\frac{\rho_\lambda^2 d_{\widetilde{\lambda}} L}{n^{3/2}\lambda}}\right)\cdot n\right) = \widetilde{\mathcal{O}}\left(\sqrt{\rho_\lambda^2 d_{\widetilde{\lambda}}}\cdot n^{1/4}\left(\frac{L}{\lambda}\right)^{1/2}\right),$$

which concludes the proof. ■

Appendix B. Proofs for Section 4

In this appendix, we describe the stochastic estimation sequence approach for inexact accelerated minibatch SVRG in Section 4, and provide the detailed analysis.

B.1 Stochastic Estimation Sequences

We introduce the following definition.

Definition 27 *(**Stochastic estimation sequence**) A sequence of pairs $\{V_t(w), \theta_t\}_{t\geq 0}$ is called an estimation sequence of the function $f(w)$ if $\theta_t > 0$ and for any $w \in \mathbb{R}^d, t \geq 0$ we have*

$$V_t(w) \leq (1-\theta_t)f(w) + \theta_t V_0(w), \tag{40}$$

if $\{V_t(w)\}_{t\geq 0}$ is a sequence of random functions, we call the sequence of pairs $\{V_t(w), \theta_t\}_{t\geq 0}$ a stochastic estimation sequence if (40) holds in expectation, i.e.

$$\mathbb{E}\left[V_t(w)\right] \leq (1-\theta_t)f(w) + \theta_t V_0(w).$$

The following lemma is a generalized version of Lemma 1 in (Lin et al., 2014), which shows if we can construct upper bound of $\mathbb{E}\left[f(w_t)\right]$ using $\mathbb{E}\left[V_t(w)\right]$, then we get convergence of $\mathbb{E}\left[f(w_t)\right]$.

Lemma 28 *Suppose $\{V_t(w), \theta_t\}_{t\geq 0}$ is a stochastic estimation sequence of the function $f(w)$. Let w^* be the minimizer of $f(w)$. If there are sequences of random variables $\{w_t\}_{t\geq 0}$ and $\{\epsilon_t\}_{t\geq 0}$ in $\mathbb{R}^d$, $\{\delta_t\}_{t\geq 0}$ in $\mathbb{R}$ such that*

$$\mathbb{E}\left[f(w_t)\right] \leq \min_w \left\{\mathbb{E}\left[V_t(w)\right]\right\} + \mathbb{E}\left[\delta_t\right] \tag{41}$$

holds for all $t \geq 0$, then

$$\mathbb{E}\left[f(w_t)\right] - f(w^*) \leq \theta_t(V_0(w^*) - f(w^*)) + \mathbb{E}\left[\delta_t\right].$$

The following lemma constructs a concrete stochastic estimation sequence.

Lemma 29 *Assume $f(w) = \frac{1}{n}\sum_{i=1}^n f_i(w)$, where each $f_i(w)$ is λ-strongly convex and L-smooth. Suppose that*

- *$V_0(w)$ is an arbitrary deterministic function on $\mathbb{R}^d$;*
- *$\{\alpha_t\}_{t\geq 0}$ is a sequence that satisfies $\alpha_t \in (0,1), \forall t \geq 0$, and $\sum_{t=0}^\infty \alpha_t = \infty$.*
- *$\{y_t\}_{t=0}^\infty$ is an arbitrary sequence in $\mathbb{R}^d$;*
- *Define $\{v_t\}_{t\geq 1}$ as:*

$$v_t = \frac{1}{b}\sum_{i\in B_t}\nabla f_i(y_{t-1}) - \frac{1}{b}\sum_{i\in B_t}\nabla f_i(\widetilde{w}_{s-1}) + \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{w}_{s-1}).$$

Define the sequence $\{w_t\}_{t\geq 0}$ and $\{V_t(w)\}_{t\geq 0}$ as follows. Let $y_0 = w_0$ and w_t be arbitrary vector in $\mathbb{R}^d$ such that

$$w_t = y_{t-1} - \eta v_t + \xi_t,$$

where the stepsize η satisfies $0 < \eta \leq \frac{1}{L}$. Let

$$\begin{aligned} V_t(w) =& (1-\alpha_{t-1})V_{t-1}(w) \\ &+ \alpha_{t-1}\left(\frac{1}{b}\sum_{i\in B_t} f_i(y_{t-1}) + \left\langle v_t - \frac{\xi_t}{\eta}, w - y_{t-1}\right\rangle + \frac{\lambda}{4}\left\|w - y_{t-1}\right\|^2 - \frac{\left\|\xi_t\right\|^2}{\lambda\eta^2}\right), \end{aligned} \tag{42}$$

let $\theta_0 = 1$, and $\theta_t = (1-\alpha_{t-1})\theta_{t-1}, \forall t \geq 1$. Then the sequence $\{V_t(w), \theta_t\}_{t\geq 0}$ is a stochastic estimation sequence of $f(w)$.

By above construction, we know $V_t(w)$ is a quadratic function, its minimizer and minimum value has the following iterative form:

Lemma 30 *Define $\forall t \geq 0$:*

$$V_t^* = \min_w V_t(w),$$

suppose we choose the function $V_0(w)$ in Lemma 29 as

$$V_0(w) = V_0^* + \frac{\lambda}{4}\left\|w - z_0\right\|^2,$$

with $V_0^* = f(z_0), \epsilon_0 = 0$ and $\delta_0 = 0$ for $z_0 = w_0$. Then the sequence $\{V_t(w)\}_{t\geq 0}$ defined in 42 can be written as

$$V_t(w) = V_t^* + \frac{\lambda}{4}\left\|w - z_t\right\|^2, \tag{43}$$

where the sequences $\{V_t^*\}, \{z_t\}$ *are defined recursively as:*

$$z_t = (1-\alpha_{t-1})z_{t-1} + \alpha_{t-1}y_{t-1} - \frac{2\alpha_{t-1}}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right), \tag{44}$$

$$V_t^* = (1-\alpha_{t-1})V_{t-1}^* + \frac{\alpha_{t-1}(1-\alpha_{t-1})\lambda}{4}\|z_{t-1}-y_{t-1}\|^2 + \alpha_{t-1}(1-\alpha_{t-1})\left\langle v_t - \frac{\xi_t}{\eta}, z_{t-1}-y_{t-1}\right\rangle - \frac{\alpha_{t-1}^2}{\lambda}\|v_t\|^2 + \frac{\alpha_{t-1}}{b}\sum_{i\in B_t} f_i(y_{t-1}) - \frac{(\alpha_{t-1}+\alpha_{t-1}^2)\|\xi_t\|^2}{\lambda\eta^2} + \frac{2\alpha_{t-1}^2}{\lambda\eta}\langle \xi_t, v_t\rangle. \tag{45}$$

The following lemma establishes a connection between z_t, y_t, w_t when z_t is updated as (44), and y_t, w_t is updated as Algorithm 3.

Lemma 31 *Based on the updating rule of* z_t *in* (44)*, if we choose* $\alpha_t = \alpha = \sqrt{\frac{\lambda\eta}{2}}, \forall t \geq 0$*, we have the following inequalities hold for all* $t \geq 0$*:*

$$z_t - y_t = \frac{1}{\alpha}(y_t - w_t).$$

The following lemma gives concrete expression of δ_t such that for the IMBA-SVRG algorithm, the condition (41) in Lemma 28 is satisfied.

Lemma 32 *Suppose we choose* $\forall t \geq 0$

$$\alpha_t = \alpha = \sqrt{\frac{\lambda\eta}{2}},$$

and the stepsize η *satisfying* $\eta \leq \frac{1}{8L}$*, we have* $\forall t \geq 0$

$$\mathbb{E}\left[f(w_t)\right] \leq \mathbb{E}\left[V_t^*\right] + \mathbb{E}\left[\delta_t\right],$$

where $\delta_0 = 0$ *and* $\forall t \geq 1$*:*

$$\delta_t = \left(1 - \sqrt{\frac{\lambda\eta}{2}}\right)\delta_{t-1} + \left(\eta\|v_t - \nabla f(y_{t-1})\|^2 - \frac{(1-\sqrt{\lambda\eta/2})\lambda}{\sqrt{2\lambda\eta}}\|y_{t-1}-w_{t-1}\|^2 + \frac{1}{4\lambda^2\eta^3}\|\xi_t\|^2\right).$$

The lemma below bounds the term $\mathbb{E}\left[\eta\|v_t - \nabla f(y_{t-1})\|^2 - \frac{(1-\sqrt{\lambda\eta/2})\lambda}{\sqrt{2\lambda\eta}}\|y_{t-1}-w_{t-1}\|^2\right]$.

Lemma 33 *Suppose* B_t *is constructed by uniform sampling with or without replacement, we have the following inequality holds:*

$$\mathbb{E}\left[\eta\|v_t - \nabla f(y_{t-1})\|^2 - \frac{(1-\sqrt{\lambda\eta/2})\lambda}{\sqrt{2\lambda\eta}}\|y_{t-1}-w_{t-1}\|^2\right] \leq \frac{8\eta L}{b}\left(f(w_{t-1}) - f(w^*) + f(\widetilde{w}_{s-1}) - f(w^*)\right) + \left(\frac{2\eta L^2}{b} - \frac{(1-\sqrt{\lambda\eta/2})\lambda}{\sqrt{2\lambda\eta}}\right)\|y_{t-1}-w_{t-1}\|^2.$$

Based on above lemma, by carefully choosing the stepsize η, we get the following lemma which is important to obtain iteration complexity for IMBA-SVRG.

Lemma 34 *If we choose the stepsize satisfying*

$$\eta \leq \min\left\{\frac{b^2\lambda}{6400L^2}, \frac{1}{8L}\right\}$$

then the following inequality holds $\forall t \geq 0$*:*

$$\mathbb{E}f(w_t) - f(w^*) \leq \left(1 - \sqrt{\frac{\lambda\eta}{2}}\right)^t (V_0(w^*) - f(w^*)) + \mathbb{E}\left[\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\left(\frac{1}{4\lambda^2\eta^3}\|\xi_k\|^2 + \frac{8\eta L}{b}(f(w_{k-1}) + f(\widetilde{w}_{s-1}) - 2f(w^*))\right)\right],$$

B.2 Proof of Lemma 28

Proof Since

$$\begin{aligned}\mathbb{E}\left[f(w_t)\right] \leq& \min_w\left\{\mathbb{E}\left[V_t(w)\right]\right\} + \mathbb{E}\left[\delta_t\right]\\ \leq& \mathbb{E}\left[V_t(w^*)\right] + \mathbb{E}\left[\delta_t\right]\\ \leq& (1-\theta_t)f(w^*) + \theta_t V_0(w^*) + \mathbb{E}\left[\delta_t\right],\end{aligned}$$

subtracting both sides by $f(w^*)$ finishes the proof. ■

B.3 Proof of Lemma 29

Proof We proceed the proof by induction. When $t = 0$, we have

$$V_0(w) = (1-\theta_0)f(w) + \theta_0 V_0(w) = V_0(w),$$

suppose

$$\mathbb{E}\left[V_{t-1}(w)\right] \leq (1-\theta_{t-1})f(w) + \theta_{t-1}V_0(w)$$

is true for some $t \geq 1$, then for $\mathbb{E}[V_t(w)]$, since $\mathbb{E}[v_t] = \nabla f(y_{t-1})$,we have

$$\begin{aligned}
\mathbb{E}[V_t(w)] =&(1-\alpha_{t-1})\mathbb{E}[V_{t-1}(w)] \\
&+\alpha_{t-1}\mathbb{E}\left[\left(\frac{1}{b}\sum_{i\in B_t} f_i(y_{t-1}) + \left\langle v_t - \frac{\xi_t}{\eta}, w - y_{t-1}\right\rangle + \frac{\lambda}{4}\|w-y_{t-1}\|^2 - \frac{\|\xi_t\|^2}{\lambda\eta^2}\right)\right] \\
=&(1-\alpha_{t-1})\mathbb{E}[V_{t-1}(w)] \\
&+\alpha_{t-1}\left(f(y_{t-1}) + \langle \nabla f(y_{t-1}), w - y_{t-1}\rangle + \frac{\lambda}{4}\|w-y_{t-1}\|^2 - \left\langle \frac{\xi_t}{\eta}, w - y_{t-1}\right\rangle - \frac{\|\xi_t\|^2}{\lambda\eta^2}\right) \\
\overset{①}{\leq}&(1-\alpha_{t-1})\mathbb{E}[V_{t-1}(w)] + \alpha_{t-1}\left(f(y_{t-1}) + \langle \nabla f(y_{t-1}), w - y_{t-1}\rangle + \frac{\lambda}{2}\|w-y_{t-1}\|^2\right) \\
\overset{②}{\leq}&(1-\alpha_{t-1})(1-\theta_{t-1})f(w) + (1-\alpha_{t-1})\theta_{t-1}V_0(w) + \alpha_{t-1}f(w) \\
=&(1-(1-\alpha_{t-1})\theta_{t-1})f(w) + (1-\alpha_{t-1})\theta_{t-1}V_0(w) \\
=&(1-\theta_t)f(w) + \theta_t V_0(w),
\end{aligned}$$

which concludes the proof, where at step ① we used the inequality $-\langle v_1, v_2\rangle - \|v_2\|^2 \leq \frac{\|v_1\|^2}{4}$,at step ② we used the inductive hypothesis and the fact that $f(w)$ is λ-strongly convex. ■

B.4 Proof of Lemma 30

Proof We proceed the proof by induction, when $t = 0$ this is true by construction. Suppose for some $t \geq 1$ the following holds:

$$V_{t-1}(w) = V_{t-1}^* + \frac{\lambda}{4}\|w - z_{t-1}\|^2,$$

then at time t, we have

$$\begin{aligned}
V_t(w) =&(1-\alpha_{t-1})V_{t-1}(w) \\
&+\alpha_{t-1}\left(\frac{1}{b}\sum_{i\in B_t} f_i(y_{t-1}) + \left\langle v_t - \frac{\xi_t}{\eta}, w - y_{t-1}\right\rangle + \frac{\lambda}{4}\|w-y_{t-1}\|^2 - \frac{\|\xi_t\|^2}{\lambda\eta^2}\right) \\
=&(1-\alpha_{t-1})V_{t-1}^* + \frac{(1-\alpha_{t-1})\lambda}{4}\|w - z_{t-1}\|^2 + \frac{\alpha_{t-1}\lambda}{4}\|w-y_{t-1}\|^2 + \alpha_{t-1}\left\langle v_t - \frac{\xi_t}{\eta}, w\right\rangle \\
&+\frac{\alpha_{t-1}}{b}\sum_{i\in B_t} f_i(y_{t-1}) - \alpha_{t-1}\left\langle v_t - \frac{\xi_t}{\eta}, y_{t-1}\right\rangle - \frac{\alpha_{t-1}\|\xi_t\|^2}{\lambda\eta^2},
\end{aligned}$$

by first order optimality condition, it is clear that the minimizer of $V_t(w)$: z_t satisfies the following:

$$(1-\alpha_{t-1})\lambda(z_t - z_{t-1}) + \alpha_{t-1}\lambda(z_t - y_{t-1}) + 2\alpha_{t-1}\left(v_t - \frac{\xi_t}{\eta}\right) = 0,$$

from above we obtain the recursive form of z_t as (44) defines. Plug in (44) to (42) we get

$$\begin{aligned}
V_t^* =&V_t(z_t) = (1-\alpha_{t-1})V_{t-1}^* + \frac{(1-\alpha_{t-1})\lambda}{4}\|z_t - z_{t-1}\|^2 + \frac{\alpha_{t-1}\lambda}{4}\|z_t - y_{t-1}\|^2 + \alpha_{t-1}\left\langle v_t - \frac{\xi_t}{\eta}, z_t\right\rangle \\
&+\frac{\alpha_{t-1}}{b}\sum_{i\in B_t} f_i(y_{t-1}) - \alpha_{t-1}\left\langle v_t - \frac{\xi_t}{\eta}, y_{t-1}\right\rangle - \frac{\alpha_{t-1}\|\xi_t\|^2}{\lambda\eta^2} \\
=&(1-\alpha_{t-1})V_{t-1}^* + \frac{(1-\alpha_{t-1})\lambda}{4}\left\|\alpha_{t-1}(y_{t-1} - z_{t-1}) - \frac{2\alpha_{t-1}}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right)\right\|^2 + \frac{\alpha_{t-1}}{b}\sum_{i\in B_t} f_i(y_{t-1}) \\
&+\frac{\alpha_{t-1}\lambda}{4}\left\|(1-\alpha_{t-1})(z_{t-1} - y_{t-1}) - \frac{2\alpha_{t-1}}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right)\right\|^2 - \frac{\alpha_{t-1}\|\xi_t\|^2}{\lambda\eta^2} \\
&+\alpha_{t-1}\left\langle v_t - \frac{\xi_t}{\eta}, (1-\alpha_{t-1})(z_{t-1} - y_{t-1}) - \frac{2\alpha_{t-1}}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right)\right\rangle \\
=&(1-\alpha_{t-1})V_{t-1}^* + \frac{\alpha_{t-1}(1-\alpha_{t-1})\lambda}{4}\|z_{t-1} - y_{t-1}\|^2 + \alpha_{t-1}(1-\alpha_{t-1})\left\langle v_t - \frac{\xi_t}{\eta}, z_{t-1} - y_{t-1}\right\rangle \\
&-\frac{\alpha_{t-1}^2}{\lambda}\|v_t\|^2 + \frac{\alpha_{t-1}}{b}\sum_{i\in B_t} f_i(y_{t-1}) - \frac{(\alpha_{t-1} + \alpha_{t-1}^2)\|\xi_t\|^2}{\lambda\eta^2} + \frac{2\alpha_{t-1}^2}{\lambda\eta}\langle \xi_t, v_t\rangle,
\end{aligned}$$

which verified (45). ■

B.5 Proof of Lemma 31

Proof We prove by induction, when $t = 0$ it is obviously true, suppose it is true for $t-1, \forall t \geq 1$, i.e.

$$z_{t-1} - y_{t-1} = \frac{1}{\alpha}(y_{t-1} - w_{t-1}),$$

for iteration t, based on (44) we have

$$\begin{aligned}
z_t - y_t =&(1-\alpha)z_{t-1} + \alpha y_{t-1} - \frac{2\alpha}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right) - y_t \\
=&(1-\alpha)(z_{t-1} - y_{t-1}) + y_{t-1} - \frac{2\alpha}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right) - y_t \\
\overset{①}{=}&\frac{1-\alpha}{\alpha}(y_{t-1} - w_{t-1}) + y_{t-1} - \frac{2\alpha}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right) - y_t \\
=&\frac{1}{\alpha}\left(y_{t-1} - \frac{2\alpha^2}{\lambda}\left(v_t - \frac{\xi_t}{\eta}\right)\right) - \frac{1-\alpha}{\alpha}w_{t-1} - y_t \\
\overset{②}{=}&\frac{1}{\alpha}w_t - \frac{1-\alpha}{\alpha}w_{t-1} - y_t \\
\overset{③}{=}&\frac{1}{\alpha}\left(w_t + \frac{1-\alpha}{1+\alpha}(w_t - w_{t-1}) - w_t\right) \\
\overset{④}{=}&\frac{1}{\alpha}(y_t - w_t),
\end{aligned}$$

which concludes the proof, where step ① used the inductive hypothesis, step ② used the update rule of w_t in Algorithm 3, step ③ and ④ used the update rule of y_t in Algorithm 3. ■

B.6 Proof of Lemma 32

Proof We prove by induction, when $t = 0$, it is true that

$$f(w_0) \leq V_0^* = f(z_0) = f(w_0),$$

suppose

$$\mathbb{E}\left[f(w_{t-1})\right] \leq \mathbb{E}\left[V_{t-1}^*\right] + \mathbb{E}\left[\delta_{t-1}\right], \tag{46}$$

for some $t \geq 1$, then based on smoothness, we know

$$f(w_t) \leq f(y_{t-1}) + \langle \nabla f(y_{t-1}), w_t - y_{t-1}\rangle + \frac{L}{2}\left\|w_t - y_{t-1}\right\|^2,$$

thus

$$\begin{aligned}
V_t^* =& (1-\alpha_{t-1})V_{t-1}^* + \frac{\alpha_{t-1}(1-\alpha_{t-1})\lambda}{4}\left\|z_{t-1} - y_{t-1}\right\|^2 \\
&+ \alpha_{t-1}(1-\alpha_{t-1})\left\langle v_t - \frac{\xi_t}{\eta}, z_{t-1} - y_{t-1}\right\rangle \\
&- \frac{\alpha_{t-1}^2}{\lambda}\left\|v_t\right\|^2 + \frac{\alpha_{t-1}}{b}\sum_{i\in B_t} f_i(y_{t-1}) - \frac{(\alpha_{t-1} + \alpha_{t-1}^2)\left\|\xi_t\right\|^2}{\lambda\eta^2} + \frac{2\alpha_{t-1}^2}{\lambda\eta}\langle \xi_t, v_t\rangle.
\end{aligned}$$

Hence we have

$$\begin{aligned}
&\mathbb{E}\left[f(w_t) - V_t^*\right] \leq \mathbb{E}\left[f(y_{t-1}) + \langle \nabla f(y_{t-1}), w_t - y_{t-1}\rangle + \frac{L}{2}\left\|w_t - y_{t-1}\right\|^2\right] \\
&- \mathbb{E}\left[(1-\alpha)V_{t-1}^* - \frac{\alpha(1-\alpha)\lambda}{4}\left\|z_{t-1} - y_{t-1}\right\|^2 - \alpha(1-\alpha)\left\langle v_t - \frac{\xi_t}{\eta}, z_{t-1} - y_{t-1}\right\rangle\right] \\
&+ \mathbb{E}\left[\frac{\alpha^2}{\lambda}\left\|v_t\right\|^2 - \frac{\alpha}{b}\sum_{i\in B_t} f_i(y_{t-1}) + \frac{(\alpha+\alpha^2)\left\|\xi_t\right\|^2}{\lambda\eta^2} - \frac{2\alpha^2}{\lambda\eta}\langle \xi_t, v_t\rangle\right] \\
&\overset{①}{=} \mathbb{E}\left[(1-\alpha)(f(y_{t-1}) - V_{t-1}^* + \langle v_t, w_{t-1} - y_{t-1}\rangle) - \langle \nabla f(y_{t-1}), \eta v_t - \xi_t\rangle + \frac{\eta}{2}\left\|v_t\right\|^2\right] \\
&+ \mathbb{E}\left[\frac{L}{2}\left\|\eta v_t - \xi_t\right\|^2 - \frac{(1-\alpha)\lambda}{4\alpha}\left\|y_{t-1} - w_{t-1}\right\|^2 + \frac{(\alpha+\alpha^2)\left\|\xi_t\right\|^2}{\lambda\eta^2}\right] \\
&+ \mathbb{E}\left[-\frac{2\alpha^2}{\lambda\eta}\langle \xi_t, v_t\rangle - (1-\alpha)\left\langle \frac{\xi_t}{\eta}, w_{t-1} - y_{t-1}\right\rangle\right] \\
&\overset{②}{\leq} \mathbb{E}\left[(1-\alpha)(f(y_{t-1}) - V_{t-1}^* + \langle v_t, w_{t-1} - y_{t-1}\rangle) - \langle \nabla f(y_{t-1}), \eta v_t - \xi_t\rangle + \frac{9\eta}{16}\left\|v_t\right\|^2\right] \\
&+ \mathbb{E}\left[\frac{L}{2}\left\|\eta v_t - \xi_t\right\|^2 + \left(\frac{2\alpha}{\lambda\eta^2} + \frac{16\alpha^4}{\lambda^2\eta^3} + \frac{(1-\alpha)}{2\lambda\eta^2}\right)\left\|\xi_t\right\|^2\right] \\
&+ \mathbb{E}\left[\left(\frac{(1-\alpha)\lambda}{2} - \frac{(1-\alpha)\lambda}{4\alpha}\right)\left\|w_{t-1} - y_{t-1}\right\|^2\right]
\end{aligned} \tag{47}$$

where at step ① we used the fact of updating rule

$$w_t = y_{t-1} - \eta v_t + \xi_t,$$

as well as Lemma 31, and $\mathbb{E}\left[\frac{1}{b}\sum_{i\in B_t} f_i(y_{t-1})\right] = f(y_{t-1})$; and at step ② we used the following two inequalities:

$$\begin{aligned}
\left|(1-\alpha)\left\langle \frac{\xi_t}{\eta}, w_{t-1} - y_{t-1}\right\rangle\right| \leq& \frac{(1-\alpha)\lambda}{2}\left\|y_{t-1} - w_{t-1}\right\|^2 + \frac{(1-\alpha)}{2\lambda\eta^2}\left\|\xi_t\right\|^2, \\
\left|\frac{2\alpha^2}{\lambda\eta}\langle \xi_t, v_t\rangle\right| \leq& \frac{\eta}{16}\left\|v_t\right\|^2 + \frac{16\alpha^4}{\lambda^2\eta^3}\left\|\xi_t\right\|^2
\end{aligned}$$

Since

$$\begin{aligned}
\mathbb{E}\left[f(y_{t-1}) - V_{t-1}^* + \langle v_t, w_{t-1} - y_{t-1}\rangle\right] =& \mathbb{E}\left[f(y_{t-1}) - V_{t-1}^* + \langle \nabla f(y_{t-1}), w_{t-1} - y_{t-1}\rangle\right] \\
\overset{①}{\leq}& \mathbb{E}\left[f(w_{t-1}) - \frac{\lambda}{2}\left\|w_{t-1} - y_{t-1}\right\|^2 - V_{t-1}^*\right] \\
\overset{②}{\leq}& \mathbb{E}\left[\delta_{t-1} - \frac{\lambda}{2}\left\|w_{t-1} - y_{t-1}\right\|^2\right],
\end{aligned} \tag{48}$$

where at step ① we used the λ-strong convexity of $f(w)$, at step ② we used the inductive hypothesis (46). Combining (47) and (48) we obtain

$$\begin{aligned}
&\mathbb{E}\left[f(w_t) - V_t^*\right] \leq (1-\alpha)\delta_{t-1} - \mathbb{E}\left[\frac{(1-\alpha)\lambda}{4\alpha}\left\|y_{t-1} - w_{t-1}\right\|^2\right] \\
&+ \mathbb{E}\left[\frac{L}{2}\left\|\eta v_t - \xi_t\right\|^2 + \frac{9\eta}{16}\left\|v_t\right\|^2 - \langle \nabla f(y_{t-1}), \eta v_t - \xi_t\rangle + \left(\frac{2\alpha}{\lambda\eta^2} + \frac{16\alpha^4}{\lambda^2\eta^3} + \frac{(1-\alpha)}{2\lambda\eta^2}\right)\left\|\xi_t\right\|^2\right].
\end{aligned} \tag{49}$$

Next we bound the third term on the right hand side, since

$$\begin{aligned}
&\frac{L}{2}\left\|\eta v_t - \xi_t\right\|^2 + \frac{9\eta}{16}\left\|v_t\right\|^2 - \langle \nabla f(y_{t-1}), \eta v_t + \xi_t\rangle \\
&\overset{①}{\leq} L\eta^2\left\|v_t\right\|^2 + L\left\|\xi_t\right\|^2 + \frac{9\eta}{16}\left\|v_t\right\|^2 - \langle \nabla f(y_{t-1}), \eta v_t - \xi_t\rangle \\
&= \frac{\eta}{2}\left\|v_t - \nabla f(y_{t-1})\right\|^2 - \frac{\eta}{2}\left\|\nabla f(y_{t-1})\right\|^2 \\
&+ \left(L\eta^2 + \frac{\eta}{16}\right)\left\|v_t\right\|^2 + \langle \nabla f(y_{t-1}), \xi_t\rangle + L\left\|\xi_t\right\|^2 \\
&\overset{②}{\leq} \frac{\eta}{2}\left\|v_t - \nabla f(y_{t-1})\right\|^2 - \frac{\eta}{2}\left\|\nabla f(y_{t-1})\right\|^2 \\
&+ \left(2L\eta^2 + \frac{\eta}{8}\right)\left(\left\|v_t - \nabla f(y_{t-1})\right\|^2 + \left\|\nabla f(y_{t-1})\right\|^2\right) \\
&+ \frac{\eta}{8}\left\|\nabla f(y_{t-1})\right\|^2 + \frac{2}{\eta}\left\|\xi_t\right\|^2 + L\left\|\xi_t\right\|^2,
\end{aligned}$$

where at step ① we used $\|v_1+v_2\|^2 \le 2(\|v_1\|^2+\|v_2\|^2)$, and at step ② we used it again and also the inequality $2|\langle v_1, v_2\rangle| \le \|v_1\|^2 + \|v_2\|^2$. Thus we know when $\eta \le \frac{1}{8L}$, we have

$$\begin{aligned}
&\frac{L}{2}\|\eta v_t - \xi_t\|^2 + \frac{9\eta}{16}\|v_t\|^2 - \langle \nabla f(y_{t-1}), \eta v_t + \xi_t\rangle \qquad (50)\\
&\le \left(\frac{\eta}{2} + 2L\eta^2 + \frac{\eta}{8}\right)\|v_t - \nabla f(y_{t-1})\|^2 + \left(L + \frac{2}{\eta}\right)\|\xi_t\|^2\\
&- \left(\frac{\eta}{2} - \frac{\eta}{8} - \frac{\eta}{8} - 2L\eta^2\right)\|\nabla f(y_{t-1})\|^2\\
&\le \eta\|v_t - \nabla f(y_{t-1})\|^2 + \frac{3}{\eta}\|\xi_t\|^2. \qquad (51)
\end{aligned}$$

Combining (49) and (51) we obtain

$$\begin{aligned}
\mathbb{E}\left[f(w_t) - V_t^*\right] \le& (1-\alpha)\delta_{t-1} + \mathbb{E}\left[\eta\|v_t - \nabla f(y_{t-1})\|^2 - \frac{(1-\alpha)\lambda}{4\alpha}\|y_{t-1} - w_{t-1}\|^2\right]\\
&+ \mathbb{E}\left[\left(\frac{2\alpha}{\lambda\eta^2} + \frac{16\alpha^4}{\lambda^2\eta^3} + \frac{(1-\alpha)}{2\lambda\eta^2} + \frac{3}{\eta}\right)\|\xi_t\|^2\right], \qquad (52)
\end{aligned}$$

also since

$$\alpha = \sqrt{\frac{\lambda\eta}{2}} \le \frac{1}{4}\sqrt{\frac{\lambda}{L}} \le \frac{1}{4},$$

we know

$$\frac{2\alpha}{\lambda\eta^2} + \frac{16\alpha^4}{\lambda^2\eta^3} + \frac{(1-\alpha)}{2\lambda\eta^2} + \frac{3}{\eta} \le \frac{1}{16\lambda^2\eta^3} + \frac{1}{16\lambda^2\eta^3} + \frac{1}{16\lambda^2\eta^3} + \frac{3}{64\lambda^2\eta^3} \le \frac{1}{4\lambda^2\eta^3},$$

combining the inequality above and (52), then substituting $\alpha = \sqrt{\frac{\lambda\eta}{2}}$ finishes the proof. ■

B.7 Proof of Lemma 33

Proof The proof follows the strategy in (Johnson and Zhang, 2013; Nitanda, 2014). First, based on the minibatch sampling (here for simplicity we only consider sampling with replacement, for sampling without replacement, the bound below can be tightened by a factor

of $\frac{n-b}{n-1}$, see, e.g. Section 2.8 of (Lohr, 2009)) we know

$$\begin{aligned}
\mathbb{E}\left[\|v_t - \nabla f(y_{t-1})\|^2\right] =& \frac{1}{b^2}\mathbb{E}\left[\sum_{j\in B_t}\|\nabla f_j(y_{t-1}) - \nabla f(y_{t-1}) - (\nabla f_j(\widetilde{w}_{s-1}) - \nabla f(\widetilde{w}_{s-1}))\|^2\right]\\
\overset{①}{\le}& \frac{1}{b^2}\mathbb{E}\left[\sum_{j\in B_t}\|\nabla f_j(y_{t-1}) - \nabla f_j(\widetilde{w}_{s-1})\|^2\right]\\
\overset{②}{\le}& \frac{2}{b^2}\mathbb{E}\left[\sum_{j\in B_t}(\|\nabla f_j(y_{t-1}) - \nabla f_j(w_{t-1})\|^2 + \|\nabla f_j(\widetilde{w}_{s-1}) - \nabla f_j(w_{t-1})\|^2)\right]\\
\overset{③}{\le}& \frac{4}{b^2}\mathbb{E}\left[\sum_{j\in B_t}(\|\nabla f_j(\widetilde{w}_{s-1}) - \nabla f_j(w^*)\|^2) + \|\nabla f_j(w^*) - \nabla f_j(w_{t-1})\|^2)\right]\\
&+ \frac{2L^2}{b}\|y_{t-1} - w_{t-1}\|^2\\
\overset{④}{\le}& \frac{8L}{b}\left(f(w_{t-1}) - f(w^*) + f(\widetilde{w}_{s-1}) - f(w^*)\right) + \frac{2L^2}{b}\|y_{t-1} - w_{t-1}\|^2,
\end{aligned}$$

where at step ① we used $\mathbb{E}\|v - \mathbb{E}v\|^2 \le \mathbb{E}\|v\|^2$, at step ② we used $\|v_1+v_2\|^2 \le 2(\|v_1\|^2 + \|v_2\|^2)$, at step ③ we used it again along with the L-smoothness of $f_j(w)$, at step ④ we used standard results in SVRG analysis, e.g. Lemma 1 of (Xiao and Zhang, 2014). Substituting above into the term $\mathbb{E}\left[\eta\|v_t - \nabla f(y_{t-1})\|^2 - \frac{(1-\sqrt{\lambda\eta/2})\lambda}{\sqrt{2\lambda\eta}}\|y_{t-1} - w_{t-1}\|^2\right]$ concludes the proof. ■

B.8 Proof of Lemma 34

Proof Combining Lemma 32 and 33, we have

$$\begin{aligned}
\delta_t =& \left(1 - \sqrt{\frac{\lambda\eta}{2}}\right)\delta_{t-1} \qquad (53)\\
&+ \left(\eta\|v_t - \nabla f(y_{t-1})\|^2 - \frac{(1-\sqrt{\lambda\eta/2})\lambda}{\sqrt{2\lambda\eta}}\|y_{t-1} - w_{t-1}\|^2 + \frac{1}{4\lambda^2\eta^3}\|\xi_t\|^2\right)\\
\le& \left(1 - \sqrt{\frac{\lambda\eta}{2}}\right)\delta_{t-1} + \left(\frac{1}{4\lambda^2\eta^3}\|\xi_t\|^2 + \frac{8\eta L}{b}(f(w_{t-1}) + f(\widetilde{w}_{s-1}) - 2f(w^*))\right)\\
&+ \left(\frac{2\eta L^2}{b} - \frac{(1-\sqrt{\lambda\eta/2})\lambda}{\sqrt{2\lambda\eta}}\right)\|y_{t-1} - w_{t-1}\|^2. \qquad (54)
\end{aligned}$$

First we verify the factor before $\|y_{t-1} - w_{t-1}\|^2$ is non positive, since $1 - \eta\lambda \ge 1 - \frac{\lambda}{8L} \ge \frac{1}{2}$, then

$$\frac{2\eta L^2}{b}\cdot\frac{\sqrt{2\lambda\eta}}{(1-\sqrt{\eta\lambda/2})\lambda} \le \frac{4\eta^{3/2}L^2}{b\sqrt{\lambda}} \le \min\left\{\frac{b^2\lambda}{128000L}, \frac{L^{1/2}}{4b\sqrt{\lambda}}\right\} \le 1,$$

where the last inequality is true because

$$\frac{b^2\lambda}{128000L}\left(\frac{L^{1/2}}{4b\sqrt{\lambda}}\right)^2 \leq 1,$$

thus we must have $\min\left\{\frac{b^2\lambda}{128000L}, \frac{L^{1/2}}{4b\sqrt{\lambda}}\right\} \leq 1$ otherwise it leads to a contradiction. Thus $\frac{2\eta L^2}{b} - \frac{(1-\sqrt{\eta\lambda/2})\lambda}{\sqrt{2\eta\lambda}} \leq 0$, combining with (54), we have

$$\delta_t \leq \left(1-\sqrt{\frac{\lambda\eta}{2}}\right)\delta_{t-1} + \left(\frac{1}{4\lambda^2\eta^3}\left\|\xi_t\right\|^2 + \frac{8\eta L}{b}(f(w_{t-1}) + f(\widetilde{w}_{s-1}) - 2f(w^*))\right),$$

applying above inequality recursively, we get

$$\delta_t \leq \sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\left(\frac{1}{4\lambda^2\eta^3}\left\|\xi_k\right\|^2 + \frac{8\eta L}{b}(f(w_{k-1}) + f(\widetilde{w}_{s-1}) - 2f(w^*))\right),$$

then applying Lemma 28 and Lemma 32 concludes the proof. ■

B.9 Proof of Theorem 24

Proof We prove this theorem by induction, note that when $b \leq 20\sqrt{\frac{2L}{\lambda}}$, it is clear that

$$\frac{8\eta L}{b} \leq \frac{b^2\lambda}{6400L^2}\cdot\frac{8L}{b} = \frac{\lambda b}{800L} = \frac{\sqrt{\eta\lambda}}{10},$$

and when $b \geq 20\sqrt{\frac{2L}{\lambda}}$,

$$\frac{8\eta L}{b} = \frac{1}{b} \leq \frac{\sqrt{\lambda}}{20\sqrt{2L}} = \frac{\sqrt{\eta\lambda}}{10},$$

thus in both cases we have $\frac{8\eta L}{b} \leq \frac{\sqrt{\eta\lambda}}{10}$, thus

$$\begin{aligned}\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\left(\frac{8\eta L}{b}\right) \leq& \frac{1}{10}\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\sqrt{\lambda\eta}\\ \leq& \frac{1}{10}\sum_{k=1}^{\infty}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{k}\sqrt{\lambda\eta} \leq \frac{\sqrt{2}}{10}.\end{aligned}$$

By Lemma 34 we know

$$\begin{aligned}\mathbb{E}f(w_t) - f(w^*) \leq& \left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t}(V_0(w^*) - f(w^*)) + \frac{\sqrt{2}(f(\widetilde{w}_{s-1}) - f(w^*))}{10} \qquad (55)\\ &+ \mathbb{E}\left[\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\left(\frac{1}{4\lambda^2\eta^3}\left\|\xi_k\right\|^2 + \frac{\sqrt{\lambda\eta}}{10}(f(w_{k-1}) - f(w^*))\right)\right], \qquad (56)\end{aligned}$$

also when $\forall k \in [t]$,

$$\left\|\xi_k\right\|^2 \leq \frac{2\lambda^2\eta^3\sqrt{\lambda\eta}}{15}(f(\widetilde{w}_{s-1}) - f(w^*)),$$

we know

$$\begin{aligned}\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\left(\frac{1}{4\lambda^2\eta^3}\left\|\xi_k\right\|^2\right) \leq& \frac{1}{30}\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\sqrt{\lambda\eta}(f(\widetilde{w}_{s-1}) - f(w^*))\\ \leq& \frac{1}{30}\sum_{k=1}^{\infty}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{k}\sqrt{\lambda\eta}(f(\widetilde{w}_{s-1}) - f(w^*))\\ \leq& \frac{(f(\widetilde{w}_{s-1}) - f(w^*))}{20}. \qquad (57)\end{aligned}$$

Combining (56) and (57), we have

$$\begin{aligned}\mathbb{E}f(w_t) - f(w^*) \leq& \left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t}(V_0(w^*) - f(w^*)) + \frac{(f(\widetilde{w}_{s-1}) - f(w^*))}{5}\\ &+ \mathbb{E}\left[\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\left(\frac{\sqrt{\lambda\eta}}{10}(f(w_{k-1}) - f(w^*))\right)\right],\end{aligned}$$

denote A_t be the right hand side on above inequality, i.e.

$$\begin{aligned}A_t =& \left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t}(V_0(w^*) - f(w^*)) + \frac{(f(\widetilde{w}_{s-1}) - f(w^*))}{5}\\ &+ \mathbb{E}\left[\sum_{k=1}^{t}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-k}\left(\frac{\sqrt{\lambda\eta}}{10}(f(w_{k-1}) - f(w^*))\right)\right]\\ =& \left(1-\sqrt{\frac{\lambda\eta}{2}}\right)\left(\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-1}(V_0(w^*) - f(w^*)) + \frac{(f(\widetilde{w}_{s-1}) - f(w^*))}{5}\right)\\ &+ \left(1-\sqrt{\frac{\lambda\eta}{2}}\right)\mathbb{E}\left[\sum_{k=1}^{t-1}\left(1-\sqrt{\frac{\lambda\eta}{2}}\right)^{t-1-k}\left(\frac{\sqrt{\lambda\eta}}{10}(f(w_{k-1}) - f(w^*))\right)\right]\\ &+ \frac{\sqrt{\lambda\eta}}{5\sqrt{2}}(f(\widetilde{w}_{s-1}) - f(w^*)) + \frac{\sqrt{\lambda\eta}}{10}(f(w_{t-1}) - f(w^*))\\ \overset{①}{\leq}& \left(1-\sqrt{\frac{\lambda\eta}{2}}\right)A_{t-1} + \frac{\sqrt{\lambda\eta}}{5\sqrt{2}}A_0 + \frac{\sqrt{\lambda\eta}}{10}A_{t-1}\\ =& \left(1-\frac{9\sqrt{\lambda\eta}}{10}\right)A_{t-1} + \frac{\sqrt{\lambda\eta}}{5\sqrt{2}}A_0,\end{aligned}$$

where at step ① we used the fact that $f(\widetilde{w}_{s-1}) - f(w^*) \leq A_0$, and $f(w_{t-1}) - f(w^*) \leq A_{t-1}$, applying above inequality recursively we get

$$\begin{aligned} A_t &\leq \left(1 - \frac{9\sqrt{\lambda\eta}}{10}\right)^t A_0 + \frac{\sqrt{\lambda\eta}}{5\sqrt{2}} \sum_{k=0}^{t-1} \left(1 - \frac{9\sqrt{\lambda\eta}}{10}\right)^k A_0 \\ &\leq \left(1 - \frac{9\sqrt{\lambda\eta}}{10}\right)^t A_0 + \frac{\sqrt{\lambda\eta}}{5\sqrt{2}} \sum_{k=0}^{\infty} \left(1 - \frac{9\sqrt{\lambda\eta}}{10}\right)^k A_0 \leq \left(\left(1 - \frac{9\sqrt{\lambda\eta}}{10}\right)^t + \frac{2}{9}\right) A_0, \end{aligned}$$

thus we know when $t \geq \frac{10}{9\sqrt{\lambda\eta}} \log(36)$, we have

$$A_t \leq \left(\frac{1}{36} + \frac{2}{9}\right) A_0 = \frac{1}{4} A_0,$$

also since

$$A_0 = V_0(w^*) - f(w^*) = f(\widetilde{w}_{s-1}) - f(w^*) + \frac{\lambda}{2} \|\widetilde{w}_{s-1} - w^*\| \overset{①}{\leq} 2(f(\widetilde{w}_{s-1}) - f(w^*)),$$

where at step ① we used the λ-strong convexity of $f(w)$. Combine above two inequality we get when $t \geq \frac{10}{9\sqrt{\lambda\eta}} \log(36)$, the expected objective suboptimality is halved:

$$\mathbb{E} f(w_t) - f(w^*) \leq A_t \leq \frac{1}{4} A_0 \leq \frac{1}{2}(f(\widetilde{w}_{s-1}) - f(w^*)),$$

which concludes the proof. ■

Appendix C. Collections of Tools in the Analysis

Lemma 35 ***(Matrix Bernstein**, Theorem 1.4 of (Tropp, 2012) rephrased) Let $X_1, ..., X_k$ be some independent, self-adjoint random matrices with dimension d, and assume each random matrix satisfies:*

$$\mathbb{E} X_k = 0 \quad \text{and} \quad \|X_k\| \leq R \quad \textit{almost surely.}$$

Then, for all $t \geq 0$,

$$P\left(\left\|\sum_k X_k\right\| \geq t\right) \leq d \exp\left(\frac{-t^2/2}{\sigma^2 + Rt/3}\right)$$

where

$$\sigma^2 := \left\|\sum_k \mathbb{E}(X_k^2)\right\|.$$

Lemma 36 ***(Iteration complexity of SVRG**, Corollary 1 of (Xiao and Zhang, 2014) rephrased) If we apply SVRG to any finite-sum optimization objective $f(w)$ where each individual function is λ-strongly convex and L-smooth, then there are universal constant C such that for any target accuracy ε, and success probability $1 - \delta$, SVRG is able to find a solution that satisfies ε objective suboptimality using*

$$C \cdot \left(n + \frac{L}{\lambda}\right) \log\left(\frac{\varepsilon_0}{\delta\varepsilon}\right)$$

first order oracle calls of individual functions, where n is the total number of individual functions in $f(w)$, ε_0 is the initial objective suboptimality.

Lemma 37 ***(Iteration complexity of catalyst acceleration**, Theorem 3.1 of (Lin et al., 2015a) rephrased) For any λ-strongly convex and L-smooth function $f(w)$, If the minimization step of (23) satisfies*

$$f(w_r) - \frac{\gamma}{2}\|w_r - z_{r-1}\| - \min_w \left(f(w) + \frac{\gamma}{2}\|w - z_{r-1}\|\right) \leq \frac{2}{9}(f(w_0) - f(w^*)) \left(1 - \frac{9}{10}\sqrt{\frac{\lambda}{\lambda+\gamma}}\right)^r,$$

then if we initialize $\nu_0 = \sqrt{\frac{\lambda}{\lambda+\gamma}}$ and set ν_r such that $\nu_r^2 = (1-\nu_r)\nu_{r-1}^2 + (\lambda\nu_r)/(\lambda+\gamma)$, then the sequences $\{w_r\}$ in Algorithm 2 satisfies

$$f(w_r) - f(w^*) \leq \frac{800(\lambda+\gamma)}{\lambda} \left(1 - \frac{9}{10}\sqrt{\frac{\lambda}{\lambda+\gamma}}\right)^{r+1} (f(w_0) - f(w^*)).$$

Abstract

Machine learning with big data often involves large optimization models. For distributed optimization over a cluster of machines, frequent communication and synchronization of all model parameters (optimization variables) can be very costly. A promising solution is to use parameter servers to store different subsets of the model parameters, and update them asynchronously at different machines using local datasets. In this paper, we focus on distributed optimization of large linear models with convex loss functions, and propose a family of randomized primal-dual block coordinate algorithms that are especially suitable for asynchronous distributed implementation with parameter servers. In particular, we work with the saddle-point formulation of such problems which allows simultaneous data and model partitioning, and exploit its structure by doubly stochastic coordinate optimization with variance reduction (DSCOVR). Compared with other first-order distributed algorithms, we show that DSCOVR may require less amount of overall computation and communication, and less or no synchronization. We discuss the implementation details of the DSCOVR algorithms, and present numerical experiments on an industrial distributed computing system.

1. Introduction

Algorithms and systems for distributed optimization are critical for solving large-scale machine learning problems, especially when the dataset cannot fit into the memory or storage of a single machine. In this paper, we consider distributed optimization problems of the form

$$\underset{w\in\mathbf{R}^d}{\text{minimize}} \quad \frac{1}{m}\sum_{i=1}^{m} f_i(X_i w) + g(w), \tag{1}$$

where $X_i \in \mathbf{R}^{N_i\times d}$ is the local data stored at the ith machine, $f_i : \mathbf{R}^{N_i} \to \mathbf{R}$ is a convex cost function associated with the linear mapping $X_i w$, and $g(w)$ is a convex regularization function. In addition, we assume that g is separable, i.e., for some integer $n > 0$, we can write

$$g(w) = \sum_{k=1}^{n} g_k(w_k), \tag{2}$$

where $g_k : \mathbf{R}^{d_k} \to \mathbf{R}$, and $w_k \in \mathbf{R}^{d_k}$ for $k = 1, \ldots, n$ are non-overlapping subvectors of $w \in \mathbf{R}^d$ with $\sum_{k=1}^n d_k = d$ (they form a partition of w). Many popular regularization functions in machine learning are separable, for example, $g(w) = (\lambda/2)\|w\|_2^2$ or $g(w) = \lambda\|w\|_1$ for some $\lambda > 0$.

An important special case of (1) is distributed empirical risk minimization (ERM) of linear predictors. Let $(x_1, y_1), \ldots, (x_N, y_N)$ be N training examples, where each $x_j \in \mathbf{R}^d$ is a feature vector and $y_j \in \mathbf{R}$ is its label. The ERM problem is formulated as

$$\underset{w\in\mathbf{R}^d}{\text{minimize}} \quad \frac{1}{N}\sum_{j=1}^{N} \phi_j(x_j^T w) + g(w), \tag{3}$$

where each $\phi_j : \mathbf{R} \to \mathbf{R}$ is a loss function measuring the mismatch between the linear prediction $x_j^T w$ and the label y_j. Popular loss functions in machine learning include, e.g., for regression, the squared loss $\phi_j(t) = (1/2)(t - y_j)^2$, and for classification, the logistic loss $\phi_j(t) = \log(1 + \exp(-y_j t))$ where $y_j \in \{\pm 1\}$. In the distributed optimization setting, the N examples are divided into m subsets, each stored on a different machine. For $i = 1, \ldots, m$, let $\mathcal{I}_i$ denote the subset of $\{1, \ldots, N\}$ stored at machine i and let $N_i = |\mathcal{I}_i|$ (they satisfy $\sum_{i=1}^m N_i = N$). Then the ERM problem (3) can be written in the form of (1) by letting X_i consist of x_j^T with $j \in \mathcal{I}_i$ as its rows and defining $f_i : \mathbf{R}^{N_i} \to \mathbf{R}$ as

$$f_i(u_{\mathcal{I}_i}) = \frac{m}{N}\sum_{j\in\mathcal{I}_i} \phi_j(u_j), \tag{4}$$

where $u_{\mathcal{I}_i} \in \mathbf{R}^{N_i}$ is a subvector of $u \in \mathbf{R}^N$, consisting of u_j with $j \in \mathcal{I}_i$.

The nature of distributed algorithms and their convergence properties largely depend on the model of the communication network that connects the m computing machines. A popular setting in the literature is to model the communication network as a graph, and each node can only communicate (in one step) with their neighbors connected by an edge, either synchronously or asynchronously (e.g., Bertsekas and Tsitsiklis, 1989; Nedić and Ozdaglar, 2009). The convergence rates of distributed algorithms in this setting often depend on characteristics of the graph, such as its diameter and the eigenvalues of the graph Laplacian (e.g. Xiao and Boyd, 2006; Duchi et al., 2012; Nedić et al., 2017; Scaman et al., 2017). This is often called the *decentralized* setting.

Another model for the communication network is *centralized*, where all the machines participate synchronous, collective communication, e.g., broadcasting a vector to all m machines, or computing the sum of m vectors, each from a different machine (AllReduce). These collective communication protocols hide the underlying implementation details, which often involve operations on graphs. They are adopted by many popular distributed computing standards and packages, such as MPI (MPI Forum, 2012), MapReduce (Dean and Ghemawat, 2008) and Aparche Spark (Zaharia et al., 2016), and are widely used in machine learning practice (e.g., Lin et al., 2014; Meng et al., 2016). In particular, collective communications are very useful for addressing *data parallelism*, i.e., by allowing different machines to work in parallel to improve the same model $w \in \mathbf{R}^d$ using their local dataset. A disadvantage of collective communications is their synchronization cost: faster machines or machines with less computing tasks have to become idle while waiting for other machines to finish their tasks in order to participate a collective communication.

One effective approach for reducing synchronization cost is to exploit *model parallelism* (here "model" refers to $w \in \mathbf{R}^d$, including all optimization variables). The idea is to allow different machines work in parallel with different versions of the full model or different parts of a common model, with little or no synchronization. The model partitioning approach can be very effective for solving problems with large models (large dimension d). Dedicated *parameter servers* can be set up to store and maintain different subsets of the model parameters, such as the w_k's in (2), and be responsible for coordinating their updates at different workers (Li et al., 2014; Xing et al., 2015). This requires flexible point-to-point communication.

In this paper, we develop a family of randomized algorithms that exploit *simultaneous* data and model parallelism. Correspondingly, we adopt a centralized communication model that support both synchronous collective communication and asynchronous point-to-point communication. In particular, it allows any pair of machines to send/receive a message in a single step, and multiple point-to-point communications may happen in parallel in an event-driven, asynchronous manner. Such a communication model is well supported by the MPI standard. To evaluate the performance of distributed algorithms in this setting, we consider the following three measures.

- *Computation complexity:* total amount of computation, measured by the number of passes over all datasets X_i for $i = 1, \ldots, m$, which can happen in parallel on different machines.
- *Communication complexity:* the total amount of communication required, measured by the equivalent number of vectors in $\mathbf{R}^d$ sent or received across all machines.
- *Synchronous communication:* measured by the total number of vectors in $\mathbf{R}^d$ that requires synchronous collective communication involving all m machines. We single it out from the overall communication complexity as a (partial) measure of the synchronization cost.

In Section 2, we introduce the framework of our randomized algorithms, **D**oubly **S**tochastic **C**oordinate **O**ptimization with **V**ariance **R**eduction (DSCOVR), and summarize our theoretical results on the three measures achieved by DSCOVR. Compared with other first-order methods for distributed optimization, we show that DSCOVR may require less amount of overall computation and communication, and less or no synchronization. Then we present the details of several DSCOVR variants and their convergence analysis in Sections 3-6. We discuss the implementation of different DSCOVR algorithms in Section 7, and present results of our numerical experiments in Section 8.

2. The DSCOVR Framework and Main Results

First, we derive a saddle-point formulation of the convex optimization problem (1). Let f_i^* be the convex conjugate of f_i, i.e., $f_i^*(\alpha_i) = \sup_{u_i \in \mathbf{R}^{N_i}} \left\{\alpha_i^T u_i - f_i(u_i)\right\}$, and define

$$L(w, \alpha) \equiv \frac{1}{m}\sum_{i=1}^m \alpha_i^T X_i w - \frac{1}{m}\sum_{i=1}^m f_i^*(\alpha_i) + g(w), \tag{5}$$

where $\alpha = [\alpha_1; \ldots; \alpha_m] \in \mathbf{R}^N$. Since both the f_i's and g are convex, $L(w, \alpha)$ is convex in w and concave in α. We also define a pair of *primal* and *dual* functions:

$$P(w) = \max_{\alpha \in \mathbf{R}^N} L(w, \alpha) = \frac{1}{m}\sum_{i=1}^m f_i(X_i w) + g(w), \tag{6}$$

$$D(\alpha) = \min_{w \in \mathbf{R}^d} L(w, \alpha) = -\frac{1}{m}\sum_{i=1}^m f_i^*(\alpha_i) - g^*\Big(-\frac{1}{m}\sum_{i=1}^m (X_i)^T \alpha_i\Big), \tag{7}$$

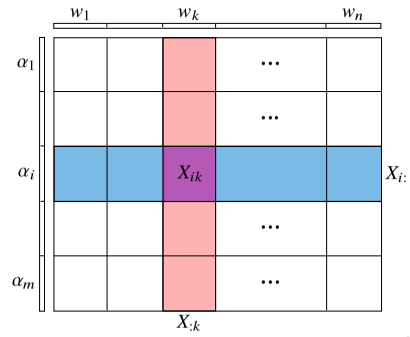

Figure 1: Partition of primal variable w, dual variable α, and the data matrix X.

where $P(w)$ is exactly the objective function in (1)[1] and g^* is the convex conjugate of g. We assume that L has a saddle point $(w^\star, \alpha^\star)$, that is,

$$L(w^\star, \alpha) \le L(w^\star, \alpha^\star) \le L(w, \alpha^\star), \qquad \forall (w, \alpha) \in \mathbf{R}^d \times \mathbf{R}^N.$$

In this case, we have $w^\star = \arg\min\ P(w)$ and $\alpha^\star = \arg\min\ D(\alpha)$, and $P(w^\star) = D(\alpha^\star)$.

The DSCOVR framework is based on solving the convex-concave saddle-point problem

$$\min_{w \in \mathbf{R}^d}\ \max_{\alpha \in \mathbf{R}^N}\ L(w, \alpha). \tag{8}$$

Since we assume that g has a separable structure as in (2), we rewrite the saddle-point problem as

$$\min_{w \in \mathbf{R}^d}\ \max_{\alpha \in \mathbf{R}^N}\ \left\{\frac{1}{m}\sum_{i=1}^m\sum_{k=1}^n \alpha_i^T X_{ik} w_k - \frac{1}{m}\sum_{i=1}^m f_i^*(\alpha_i) + \sum_{k=1}^n g_k(w_k)\right\}, \tag{9}$$

where $X_{ik} \in \mathbf{R}^{N_i \times d_k}$ for $k = 1, \ldots, n$ are column partitions of X_i. For convenience, we define the following notations. First, let $X = [X_1; \ldots; X_m] \in \mathbf{R}^{N \times d}$ be the overall data matrix, by stacking the X_i's vertically. Conforming to the separation of g, we also partition X into block columns $X_{:k} \in \mathbf{R}^{N \times d_k}$ for $k = 1, \ldots, n$, where each $X_{:k} = [X_{1k}; \ldots; X_{mk}]$ (stacked vertically). For consistency, we also use $X_{i:}$ to denote X_i from now on. See Figure 1 for an illustration.

We exploit the doubly separable structure in (9) by a doubly stochastic coordinate update algorithm outlined in Algorithm 1. Let $p = \{p_1, \ldots, p_m\}$ and $q = \{q_1, \ldots, q_n\}$ be two probability distributions. During each iteration t, we randomly pick an index $j \in \{1, \ldots, m\}$ with probability p_j, and independently pick an index $l \in \{1, \ldots, n\}$ with probability q_l. Then we compute two vectors $u_j^{(t+1)} \in \mathbf{R}^{N_j}$ and $v_l^{(t+1)} \in \mathbf{R}^{d_l}$ (details to be discussed later), and use them to update the block coordinates α_j and w_l while leaving other block coordinates unchanged. The update formulas in (10) and (11) use the proximal mappings of the (scaled) functions f_j^* and g_l respectively. We

1. More technically, we need to assume that each f_i is convex and lower semi-continuous so that $f_i^{**} = f_i$ (see, e.g., Rockafellar, 1970, Section 12). It automatically holds if f_i is convex and differentiable, which we will assume later.

Algorithm 1 DSCOVR framework

input: initial points $w^{(0)}, \alpha^{(0)}$, and step sizes σ_i for $i = 1, \ldots, m$ and τ_k for $k = 1, \ldots, n$.

1: **for** $t = 0, 1, 2, \ldots,$ **do**

2: pick $j \in \{1, \ldots, m\}$ and $l \in \{1, \ldots, n\}$ randomly with distributions p and q respectively.

3: compute *variance-reduced* stochastic gradients $u_j^{(t+1)}$ and $v_l^{(t+1)}$.

4: update primal and dual block coordinates:

$$\alpha_i^{(t+1)} = \begin{cases} \mathbf{prox}_{\sigma_j f_j^*}(\alpha_j^{(t)} + \sigma_j u_j^{(t+1)}) & \text{if } i = j, \\ \alpha_i^{(t)}, & \text{if } i \neq j, \end{cases} \tag{10}$$

$$w_k^{(t+1)} = \begin{cases} \mathbf{prox}_{\tau_l g_l}(w_l^{(t)} - \tau_l v_l^{(t+1)}) & \text{if } k = l, \\ w_k^{(t)}, & \text{if } k \neq l. \end{cases} \tag{11}$$

5: **end for**

recall that the proximal mapping for any convex function $\phi : \mathbf{R}^d \to \mathbf{R} \cup \{\infty\}$ is defined as

$$\mathbf{prox}_\phi(v) \triangleq \arg\min_{u \in \mathbf{R}^d} \left\{ \phi(u) + \frac{1}{2}\|u - v\|^2 \right\}.$$

There are several different ways to compute the vectors $u_j^{(t+1)}$ and $v_l^{(t+1)}$ in Step 3 of Algorithm 1. They should be the partial gradients or stochastic gradients of the bilinear coupling term in $L(w, \alpha)$ with respect to α_j and w_l respectively. Let

$$K(w, \alpha) = \alpha^T X w = \sum_{i=1}^m \sum_{k=1}^n \alpha_i^T X_{ik} w_k,$$

which is the bilinear term in $L(w, \alpha)$ without the factor $1/m$. We can use the following partial gradients in Step 3:

$$\begin{aligned} \tilde{u}_j^{(t+1)} &= \frac{\partial K(w^{(t)}, \alpha^{(t)})}{\partial \alpha_j} = \sum_{k=1}^n X_{jk} w_k^{(t)}, \\ \tilde{v}_l^{(t+1)} &= \frac{1}{m} \frac{\partial K(w^{(t)}, \alpha^{(t)})}{\partial w_l} = \frac{1}{m} \sum_{i=1}^m (X_{il})^T \alpha_i^{(t)}. \end{aligned} \tag{12}$$

We note that the factor $1/m$ does not appear in the first equation because it multiplies both $K(w, \alpha)$ and $f_j^*(\alpha_j)$ in (9) and hence does not appear in updating α_j. Another choice is to use

$$\begin{aligned} u_j^{(t+1)} &= \frac{1}{q_l} X_{jl} w_l^{(t)}, \\ v_l^{(t+1)} &= \frac{1}{p_j} \frac{1}{m} (X_{jl})^T \alpha_j^{(t)}, \end{aligned} \tag{13}$$

which are unbiased stochastic partial gradients, because

$$\begin{aligned} \mathbf{E}_l[u_j^{(t+1)}] &= \sum_{k=1}^n q_k \frac{1}{q_k} X_{jk} w_k^{(t)} = \sum_{k=1}^n X_{jk} w_k^{(t)} = \tilde{u}_j^{(t+1)}, \\ \mathbf{E}_j[v_l^{(t+1)}] &= \sum_{i=1}^m p_i \frac{1}{p_i} \frac{1}{m} (X_{il})^T \alpha_i^{(t)} = \frac{1}{m} \sum_{i=1}^m (X_{il})^T \alpha_i^{(t)} = \tilde{v}_l^{(t+1)}, \end{aligned}$$

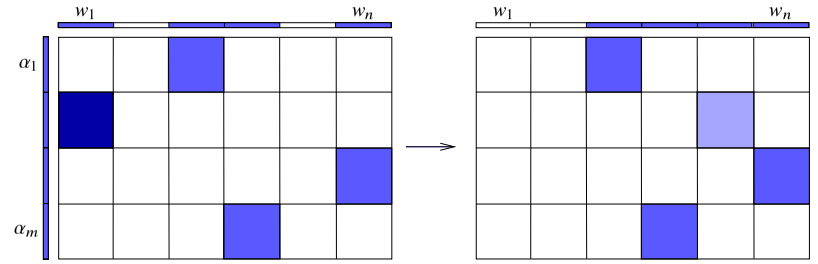

Figure 2: Simultaneous data and model parallelism. At any given time, each machine is busy updating one parameter block and its own dual variable. Whenever some machine is done, it is assigned to work on a random block that is not being updated.

where $\mathbf{E}_j$ and $\mathbf{E}_l$ are expectations with respect to the random indices j and l respectively.

It can be shown that, Algorithm 1 converges to a saddle point of $L(w, \alpha)$ with either choice (12) or (13) in Step 3, and with suitable *step sizes* σ_i and τ_k. It is expected that using the stochastic gradients in (13) leads to a slower convergence rate than applying (12). However, using (13) has the advantage of much less computation during each iteration. Specifically, it employs only one block matrix-vector multiplication for both updates, instead of n and m block multiplications done in (12).

More importantly, the choice in (13) is suitable for parallel and distributed computing. To see this, let $(j^{(t)}, l^{(t)})$ denote the pair of random indices drawn at iteration t (we omit the superscript (t) to simplify notation whenever there is no confusion from the context). Suppose for a sequence of consecutive iterations $t, \ldots, t+s$, there is no common index among $j^{(t)}, \ldots, j^{(t+s)}$, nor among $l^{(t)}, \ldots, l^{(t+s)}$, then these $s+1$ iterations can be done in parallel and they produce the same updates as being done sequentially. Suppose there are $s+1$ processors or machines, then each can carry out one iteration, which includes the updates in (13) as well as (10) and (11). These $s+1$ iterations are independent of each other, and in fact can be done in any order, because each only involve one primal block $w_{l^{(t)}}$ and one dual block $\alpha_{j^{(t)}}$, for both input and output (variables on the right and left sides of the assignments respectively). In contrast, the input for the updates in (12) depend on all primal and dual blocks at the previous iteration, thus cannot be done in parallel.

In practice, suppose we have m machines for solving problem (9), and each holds the data matrix $X_{i:}$ in memory and maintains the dual block α_i, for $i = 1, \ldots, m$. We assume that the number of model partitions n is larger than m, and the n model blocks $\{w_1, \ldots, w_n\}$ are stored at one or more parameter servers. In the beginning, we can randomly pick m model blocks (sampling without replacement) from $\{w_1, \ldots, w_n\}$, and assign each machine to update one of them. If machine i is assigned to update block k, then both α_i and w_k are updated, using only the matrix X_{ik}; moreover, it needs to communicate only the block w_k with the parameter server that are responsible to maintain it. Whenever one machine finishes its update, a scheduler can randomly pick another parameter block that is not currently updated by other machines, and assign it to the free machine. Therefore all machines can work in parallel, in an asynchronous, event-driven manner. Here an event is the completion of a block update at any machine, as illustrated in Figure 2. We will discuss the implementation details in Section 7.

The idea of using doubly stochastic updates for distributed optimization in not new. It has been studied by Yun et al. (2014) for solving the matrix completion problem, and by Matsushima et al. (2014) for solving the saddle-point formulation of the ERM problem. Despite their nice features for parallelization, these algorithms inherit the $O(1/\sqrt{t})$ (or $O(1/t)$ with strong convexity) sublinear convergence rate of the classical stochastic gradient method. They translate into high communication and computation cost for distributed optimization. In this paper, we propose new variants of doubly stochastic update algorithms by using *variance-reduced* stochastic gradients (Step 3 of Algorithm 1). More specifically, we borrow the variance-reduction techniques from SVRG (Johnson and Zhang, 2013) and SAGA (Defazio et al., 2014) to develop the DSCOVR algorithms, which enjoy fast linear rates of convergence. In the rest of this section, we summarize our theoretical results characterizing the three measures for DSCOVR: computation complexity, communication complexity, and synchronization cost. We compare them with distributed implementation of batch first-order algorithms.

2.1. Summary of Main Results

Throughout this paper, we use $\|\cdot\|$ to denote the standard Euclidean norm for vectors. For matrices, $\|\cdot\|$ denotes the operator (spectral) norm and $\|\cdot\|_F$ denotes the Frobenius norm. We make the following assumption regarding the optimization problem (1).

Assumption 1 *Each f_i is convex and differentiable, and its gradient is $(1/\gamma_i)$-Lipschitz continuous, i.e.,*

$$\|\nabla f_i(u) - \nabla f_i(v)\| \le \frac{1}{\gamma_i}\|u - v\|, \quad \forall\, u, v \in \mathbf{R}^{N_i}, \quad i = 1, \ldots, m. \tag{14}$$

In addition, the regularization function g is λ-strongly convex, i.e.,

$$g(w') \ge g(w) + \xi^T(w' - w) + \frac{\lambda}{2}\|w' - w\|^2, \quad \forall\, \xi \in \partial g(w), \quad w', w \in \mathbf{R}^d.$$

Under Assumption 1, each f_i^* is γ_i-strongly convex (see, e.g., Hiriart-Urruty and Lemaréchal, 2001, Theorem 4.2.2), and $L(w, \alpha)$ defined in (5) has a unique saddle point $(w^\star, \alpha^\star)$.

The condition (14) is often referred to as f_i being $1/\gamma_i$-smooth. To simplify discussion, here we assume $\gamma_i = \gamma$ for $i = 1, \ldots, m$. Under these assumptions, each composite function $f_i(X_i w)$ has a smoothness parameter $\|X_i\|^2/\gamma$ (upper bound on the largest eigenvalue of its Hessian). Their average $(1/m)\sum_{i=1}^m f_i(X_i w)$ has a smooth parameter $\|X\|^2/(m\gamma)$, which no larger than the average of the individual smooth parameters $(1/m)\sum_{i=1}^m \|X_i\|^2/\gamma$. We define a condition number for problem (1) as the ratio between this smooth parameter and the convexity parameter λ of g:

$$\kappa_{\rm bat} = \frac{\|X\|^2}{m\lambda\gamma} \le \frac{1}{m}\sum_{i=1}^m \frac{\|X_{i:}\|^2}{\lambda\gamma} \le \frac{\|X\|_{\max}^2}{\lambda\gamma}, \tag{15}$$

where $\|X\|_{\max} = \max_i\{\|X_{i:}\|\}$. This condition number is a key factor to characterize the iteration complexity of *batch* first-order methods for solving problem (1), i.e., minimizing $P(w)$. Specifically, to find a w such that $P(w) - P(w^\star) \le \epsilon$, the proximal gradient method requires $O\left((1 + \kappa_{\rm bat})\log(1/\epsilon)\right)$ iterations, and their accelerated variants require $O\left((1 + \sqrt{\kappa_{\rm bat}})\log(1/\epsilon)\right)$ iterations (e.g., Nesterov, 2004; Beck and Teboulle, 2009; Nesterov, 2013). Primal-dual first order methods for solving the saddle-point problem (8) share the same complexity (Chambolle and Pock, 2011, 2015).

Algorithms	Computation complexity (number of passes over data)	Communication complexity (number of vectors in $\mathbf{R}^d$)
batch first-order methods	$(1 + \kappa_{\rm bat})\log(1/\epsilon)$	$m(1 + \kappa_{\rm bat})\log(1/\epsilon)$
DSCOVR	$(1 + \kappa_{\rm rand}/m)\log(1/\epsilon)$	$(m + \kappa_{\rm rand})\log(1/\epsilon)$
accelerated batch first-order methods	$\left(1 + \sqrt{\kappa_{\rm bat}}\right)\log(1/\epsilon)$	$m\left(1 + \sqrt{\kappa_{\rm bat}}\right)\log(1/\epsilon)$
accelerated DSCOVR	$(1 + \sqrt{\kappa_{\rm rand}/m})\log(1/\epsilon)$	$\left(m + \sqrt{m\cdot\kappa_{\rm rand}}\right)\log(1/\epsilon)$

Table 1: Computation and communication complexities of batch first-order methods and DSCOVR (for both SVRG and SAGA variants). We omit the $O(\cdot)$ notation in all entries and an extra $\log(1 + \kappa_{\rm rand}/m)$ factor for accelerated DSCOVR algorithms.

A fundamental baseline for evaluating any distributed optimization algorithms is the distributed implementation of batch first-order methods. Let's consider solving problem (1) using the proximal gradient method. During every iteration t, each machine receives a copy of $w^{(t)} \in \mathbf{R}^d$ from a master machine (through Broadcast), and computes the local gradient $z_i^{(t)} = X_i^T \nabla f_i(X_i w^{(t)}) \in \mathbf{R}^d$. Then a collective communication is invoked to compute the batch gradient $z^{(t)} = (1/m)\sum_{i=1}^m z_i^{(t)}$ at the master (Reduce). The master then takes a proximal gradient step, using $z^{(t)}$ and the proximal mapping of g, to compute the next iterate $w^{(t+1)}$ and broadcast it to every machine for the next iteration. We can also use the AllReduce operation in MPI to obtain $z^{(t)}$ at each machine without a master. In either case, the total number of passes over the data is twice the number of iterations (due to matrix-vector multiplications using both X_i and X_i^T), and the number of vectors in $\mathbf{R}^d$ sent/received across all machines is $2m$ times the number of iterations (see Table 1). Moreover, all communications are collective and synchronous.

Since DSCOVR is a family of randomized algorithms for solving the saddle-point problem (8), we would like to find (w, α) such that $\|w^{(t)} - w^\star\|^2 + (1/m)\|\alpha^{(t)} - \alpha^\star\|^2 \le \epsilon$ holds in expectation and with high probability. We list the communication and computation complexities of DSCOVR in Table 1, comparing them with batch first-order methods. Similar guarantees also hold for reducing the duality gap $P(w^{(t)}) - D(\alpha^{(t)})$, where P and D are defined in (6) and (7) respectively.

The key quantity characterizing the complexities of DSCOVR is the condition number $\kappa_{\rm rand}$, which can be defined in several different ways. If we pick the data block i and model block k with uniform distribution, i.e., $p_i = 1/m$ for $i = 1, \ldots, m$ and $q_k = 1/n$ for $k = 1, \ldots, n$, then

$$\kappa_{\rm rand} = \frac{n\|X\|_{m\times n}^2}{\lambda\gamma}, \qquad \text{where} \qquad \|X\|_{m\times n} = \max_{i,k}\|X_{ik}\|. \tag{16}$$

Comparing the definition of $\kappa_{\rm bat}$ in (15), we have $\kappa_{\rm bat} \le \kappa_{\rm rand}$ because

$$\frac{1}{m}\|X\|^2 \le \frac{1}{m}\sum_{i=1}^m \|X_i\|^2 \le \frac{1}{m}\sum_{i=1}^m\sum_{k=1}^n \|X_{ik}\|^2 \le n\|X\|_{m\times n}^2.$$

With $X_{i:} = [X_{i1}\cdots X_{im}] \in \mathbf{R}^{N_i\times d}$ and $X_{:k} = [X_{1k}; \ldots; X_{mk}] \in \mathbf{R}^{N\times d_k}$, we can also define

$$\kappa'_{\rm rand} = \frac{\|X\|_{\max,F}^2}{\lambda\gamma}, \qquad \text{where} \qquad \|X\|_{\max,F} = \max_{i,k}\{\|X_{i:}\|_F,\ \|X_{:k}\|_F\}. \tag{17}$$

Algorithms	Synchronous Communication (number of vectors in $\mathbf{R}^d$)	Asynchronous Communication (equiv. number of vectors in $\mathbf{R}^d$)
DSCOVR-SVRG	$m \log(1/\epsilon)$	$\kappa_{\text{rand}} \log(1/\epsilon)$
DSCOVR-SAGA	m	$(m + \kappa_{\text{rand}}) \log(1/\epsilon)$
accelerated DSCOVR-SVRG	$m \log(1/\epsilon)$	$\left(1 + \sqrt{m \cdot \kappa_{\text{rand}}}\right) \log(1/\epsilon)$
accelerated DSCOVR-SAGA	m	$\left(1 + \sqrt{m \cdot \kappa_{\text{rand}}}\right) \log(1/\epsilon)$

Table 2: Breakdown of communication complexities into synchronous and asynchronous communications for two different types of DSCOVR algorithms. We omit the $O(\cdot)$ notation and an extra $\log(1 + \kappa_{\text{rand}}/m)$ factor for accelerated DSCOVR algorithms.

In this case, we also have $\kappa_{\text{bat}} \leq \kappa'_{\text{rand}}$ because $\|X\|_{\max} \leq \|X\|_{\max,F}$. Finally, if we pick the pair (i, k) with non-uniform distribution $p_i = \|X_{i:}\|_F^2 / \|X\|_F^2$ and $q_k = \|X_{:k}\|_F^2 / \|X\|_F^2$, then we can define

$$\kappa''_{\text{rand}} = \frac{\|X\|_F^2}{m\lambda\gamma}. \tag{18}$$

Again we have $\kappa_{\text{bat}} \leq \kappa''_{\text{rand}}$ because $\|X\| \leq \|X\|_F$. We may replace κ_{rand} in Tables 1 and 2 by either κ'_{rand} or κ''_{rand}, depending on the probability distributions p and q and different proof techniques.

From Table 1, we observe similar type of speed-ups in computation complexity, as obtained by variance reduction techniques over the batch first-order algorithms for convex optimization (e.g., Le Roux et al., 2012; Johnson and Zhang, 2013; Defazio et al., 2014; Xiao and Zhang, 2014; Lan and Zhou, 2018; Allen-Zhu, 2017), as well as for convex-concave saddle-point problems (Zhang and Xiao, 2017; Balamurugan and Bach, 2016). Basically, DSCOVR algorithms have potential improvement over batch first-order methods by a factor of m (for non-accelerated algorithms) or $\sqrt{m}$ (for accelerated algorithms), but with a worse condition number. In the worst case, the ratio between κ_{rand} and κ_{bat} may be of order m or larger, thus canceling the potential improvements.

More interestingly, DSCOVR also has similar improvements in terms of communication complexity over batch first-order methods. In Table 2, we decompose the communication complexity of DSCOVR into synchronous and asynchronous communication. The decomposition turns out to be different depending on the variance reduction techniques employed: SVRG (Johnson and Zhang, 2013) versus SAGA (Defazio et al., 2014). We note that DSCOVR-SAGA essentially requires only asynchronous communication, because the synchronous communication of m vectors are only necessary for initialization with non-zero starting point.

The comparisons in Table 1 and 2 give us good understanding of the complexities of different algorithms. However, these complexities are not accurate measures of their performance in practice. For example, collective communication of m vectors in $\mathbf{R}^d$ can often be done in parallel over a spanning tree of the underlying communication network, thus only cost $\log(m)$ times (instead of m times) compared with sending only one vector. Also, for point-to-point communication, sending one vector in $\mathbf{R}^d$ altogether can be much faster than sending n smaller vectors of total length d separately. A fair comparison in term of wall-clock time on a real-world distributed computing system requires customized, efficient implementation of different algorithms. We will shed some light on timing comparisons with numerical experiments in Section 8.

2.2. Related Work

There is an extensive literature on distributed optimization. Many algorithms developed for machine learning adopt the centralized communication setting, due to the wide availability of supporting standards and platforms such as MPI, MapReduce and Spark (as discussed in the introduction). They include parallel implementations of the batch first-order and second-order methods (e.g., Lin et al., 2014; Chen et al., 2014; Lee et al., 2017a), ADMM (Boyd et al., 2011), and distributed dual coordinate ascent (Yang, 2013; Jaggi et al., 2014; Ma et al., 2015).

For minimizing the average function $(1/m) \sum_{i=1}^m f_i(w)$, in the centralized setting and with only first-order oracles (i.e., gradients of f_i's or their conjugates), it has been shown that distributed implementation of accelerated gradient methods achieves the optimal convergence rate and communication complexity (Arjevani and Shamir, 2015; Scaman et al., 2017). The problem (1) we consider has the extra structure of composition with a linear transformation by the local data, which allows us to exploit simultaneous data and model parallelism using randomized algorithms and obtain improved communication and computation complexity.

Most work on asynchronous distributed algorithms exploit model parallelism in order to reduce the synchronization cost, especially in the setting with parameter servers (e.g., Li et al., 2014; Xing et al., 2015; Aytekin et al., 2016). Besides, delay caused by the asynchrony can be incorporated to the step size to gain practical improvement on convergence (e.g., Agarwal and Duchi, 2011; McMahan and Streeter, 2014; Sra et al., 2016), though the theoretical sublinear rates remain. There are also many recent work on asynchronous parallel stochastic gradient and coordinate-descent algorithms for convex optimization (e.g., Recht et al., 2011; Liu et al., 2014; Shi et al., 2015; Reddi et al., 2015; Richtárik and Takáč, 2016; Peng et al., 2016). When the workloads or computing power of different machines or processors are nonuniform, they may significantly increase *iteration efficiency* (number of iterations done in unit time), but often at the cost of requiring more iterations than their synchronous counterparts (due to delays and stale updates). So there is a subtle balance between iteration efficiency and iteration complexity (e.g., Hannah and Yin, 2017). Our discussions in Section 2.1 show that DSCOVR is capable of improving both aspects.

For solving bilinear saddle-point problems with a finite-sum structure, Zhang and Xiao (2017) proposed a randomized algorithm that works with dual coordinate update but full primal update. Yu et al. (2015) proposed a doubly stochastic algorithm that works with both primal and dual coordinate updates based on equation (12). Both of them achieved accelerated linear convergence rates, but neither can be readily applied to distributed computing. In addition, Balamurugan and Bach (2016) proposed stochastic variance-reduction methods (also based on SVRG and SAGA) for solving more general convex-concave saddle point problems. For the special case with bilinear coupling, they obtained similar computation complexity as DSCOVR. However, their methods require full model updates at each iteration (even though working with only one sub-block of data), thus are not suitable for distributed computing.

With additional assumptions and structure, such as similarity between the local cost functions at different machines or using second-order information, it is possible to obtain better communication complexity for distributed optimization; see, e.g., Shamir et al. (2014); Zhang and Xiao (2015); Reddi et al. (2016). However, these algorithms rely on much more computation at each machine for solving a local sub-problem at each iteration. With additional memory and preprocessing at each machine, Lee et al. (2017b) showed that SVRG can be adapted for distributed optimization to obtain low communication complexity.

Algorithm 2 DSCOVR-SVRG

input: initial points $\bar{w}^{(0)}$, $\bar{\alpha}^{(0)}$, number of stages S and number of iterations per stage M.

for $s = 0, 1, 2, \ldots, S-1$ **do**

  $\bar{u}^{(s)} = X\bar{w}^{(s)}$ and $\bar{v}^{(s)} = \frac{1}{m}X^T\bar{\alpha}^{(s)}$

  $w^{(0)} = \bar{w}^{(s)}$ and $\alpha^{(0)} = \bar{\alpha}^{(s)}$

  for $t = 0, 1, 2, \ldots, M-1$ **do**

    pick $j \in \{1, \ldots, m\}$ and $l \in \{1, \ldots, n\}$ randomly with distributions p and q respectively.

    compute variance-reduced stochastic gradients:

$$u_j^{(t+1)} = \bar{u}_j^{(s)} + \frac{1}{q_l}X_{jl}(w_l^{(t)} - \bar{w}_l^{(s)}), \tag{19}$$

$$v_l^{(t+1)} = \bar{v}_l^{(s)} + \frac{1}{p_j}\frac{1}{m}(X_{jl})^T(\alpha_j^{(t)} - \bar{\alpha}_j^{(s)}). \tag{20}$$

    update primal and dual block coordinates:

$$\alpha_i^{(t+1)} = \begin{cases} \mathbf{prox}_{\sigma_j f_j^*}(\alpha_j^{(t)} + \sigma_j u_j^{(t+1)}) & \text{if } i = j, \\ \alpha_i^{(t)}, & \text{if } i \neq j, \end{cases}$$

$$w_k^{(t+1)} = \begin{cases} \mathbf{prox}_{\tau_l g_l}(w_l^{(t)} - \tau_l v_l^{(t+1)}) & \text{if } k = l, \\ w_k^{(t)}, & \text{if } k \neq l. \end{cases}$$

  end for

  $\bar{w}^{(s+1)} = w^{(M)}$ and $\bar{\alpha}^{(s+1)} = \alpha^{(M)}$.

end for

output: $\bar{w}^{(S)}$ and $\bar{\alpha}^{(S)}$.

3. The DSCOVR-SVRG Algorithm

From this section to Section 6, we present several realizations of DSCOVR using different variance reduction techniques and acceleration schemes, and analyze their convergence properties. These algorithms are presented and analyzed as sequential randomized algorithms. We will discuss how to implement them for asynchronous distributed computing in Section 7.

Algorithm 2 is a DSCOVR algorithm that uses the technique of SVRG (Johnson and Zhang, 2013) for variance reduction. The iterations are divided into stages and each stage has a inner loop. Each stage is initialized by a pair of vectors $\bar{w}^{(s)} \in \mathbf{R}^d$ and $\bar{\alpha}^{(s)} \in \mathbf{R}^N$, which come from either initialization (if $s = 0$) or the last iterate of the previous stage (if $s > 0$). At the beginning of each stage, we compute the batch gradients

$$\bar{u}^{(s)} = \frac{\partial}{\partial\bar{\alpha}^{(s)}}\left((\bar{\alpha}^{(s)})^T X\bar{w}^{(s)}\right) = X\bar{w}^{(s)}, \qquad \bar{v}^{(s)} = \frac{\partial}{\partial\bar{w}^{(s)}}\left(\frac{1}{m}(\bar{\alpha}^{(s)})^T X\bar{w}^{(s)}\right) = \frac{1}{m}X^T\bar{\alpha}^{(s)}.$$

The vectors $\bar{u}^{(s)}$ and $\bar{v}^{(s)}$ share the same partitions as $\alpha^{(t)}$ and $w^{(t)}$, respectively. Inside each stage s, the variance-reduced stochastic gradients are computed in (19) and (20). It is easy to check that they

are unbiased. More specifically, taking expectation of $u_j^{(t+1)}$ with respect to the random index l gives

$$\mathbf{E}_l[u_j^{(t+1)}] = \bar{u}_j^{(s)} + \sum_{k=1}^n q_k\frac{1}{q_k}X_{jk}(w_k^{(t)} - \bar{w}_k^{(s)}) = \bar{u}_j^{(s)} + X_{j:}w^{(t)} - X_{j:}\bar{w}^{(s)} = X_{j:}w^{(t)},$$

and taking expectation of $v_l^{(t+1)}$ with respect to the random index j gives

$$\mathbf{E}_j[v_l^{(t+1)}] = \bar{v}_l^{(s)} + \sum_{i=1}^m p_i\frac{1}{p_i}\frac{1}{m}(X_{il})^T(\alpha_i^{(t)} - \bar{\alpha}_i^{(s)}) = \bar{v}_l^{(s)} + \frac{1}{m}(X_{:l})^T\left(\alpha^{(t)} - \bar{\alpha}^{(s)}\right) = \frac{1}{m}(X_{:l})^T\alpha^{(t)}.$$

In order to measure the distance of any pair of primal and dual variables to the saddle point, we define a weighted squared Euclidean norm on $\mathbf{R}^{d+N}$. Specifically, for any pair (w, α) where $w \in \mathbf{R}^d$ and $\alpha = [\alpha_1, \ldots, \alpha_m] \in \mathbf{R}^N$ with $\alpha_i \in \mathbf{R}^{N_i}$, we define

$$\Omega(w, \alpha) = \lambda\|w\|^2 + \frac{1}{m}\sum_{i=1}^m \gamma_i\|\alpha_i\|^2. \tag{21}$$

If $\gamma_i = \gamma$ for all $i = 1, \ldots, m$, then $\Omega(w, \alpha) = \lambda\|w\|^2 + \frac{\gamma}{m}\|\alpha\|^2$. We have the following theorem concerning the convergence rate of Algorithm 2.

Theorem 1 *Suppose Assumption 1 holds, and let $(w^\star, \alpha^\star)$ be the unique saddle point of $L(w, \alpha)$. Let Γ be a constant that satisfies*

$$\Gamma \geq \max_{i,k}\left\{\frac{1}{p_i}\left(1 + \frac{9\|X_{ik}\|^2}{2q_k\lambda\gamma_i}\right), \frac{1}{q_k}\left(1 + \frac{9n\|X_{ik}\|^2}{2mp_i\lambda\gamma_i}\right)\right\}. \tag{22}$$

In Algorithm 2, if we choose the step sizes as

$$\sigma_i = \frac{1}{2\gamma_i(p_i\Gamma - 1)}, \qquad i = 1, \ldots, m, \tag{23}$$

$$\tau_k = \frac{1}{2\lambda(q_k\Gamma - 1)}, \qquad k = 1, \ldots, n, \tag{24}$$

and the number of iterations during each stage satisfies $M \geq \log(3)\Gamma$, then for any $s > 0$,

$$\mathbf{E}\left[\Omega(\bar{w}^{(s)} - w^\star, \bar{\alpha}^{(s)} - \alpha^\star)\right] \leq \left(\frac{2}{3}\right)^s \Omega(\bar{w}^{(0)} - w^\star, \bar{\alpha}^{(0)} - \alpha^\star). \tag{25}$$

The proof of Theorem 1 is given in Appendix A. Here we discuss how to choose the parameter Γ to satisfy (22). For simplicity, we assume $\gamma_i = \gamma$ for all $i = 1, \ldots, m$.

- If we let $\|X\|_{m\times n} = \max_{i,k}\{\|X_{ik}\|\}$ and sample with the uniform distribution across both rows and columns, i.e., $p_i = 1/m$ for $i = 1, \ldots, m$ and $q_k = 1/n$ for $k = 1, \ldots, n$, then we can set

$$\Gamma = \max\{m, n\}\left(1 + \frac{9n\|X\|_{m\times n}^2}{2\lambda\gamma}\right) = \max\{m, n\}\left(1 + \frac{9}{2}\kappa_{\text{rand}}\right),$$

  where $\kappa_{\text{rand}} = n\|X\|_{m\times n}^2/(\lambda\gamma)$ as defined in (16).

- An alternative condition for Γ to satisfy is (shown in Section A.1 in the Appendix)

$$\Gamma \geq \max_{i,k} \left\{ \frac{1}{p_i} \left(1 + \frac{9\|X_{:k}\|_F^2}{2q_k m\lambda\gamma_i} \right), \ \frac{1}{q_k} \left(1 + \frac{9\|X_{i:}\|_F^2}{2p_i m\lambda\gamma_i} \right) \right\}. \tag{26}$$

  Again using uniform sampling, we can set

$$\Gamma = \max\{m,n\} \left(1 + \frac{9\|X\|_{\max,F}^2}{2\lambda\gamma} \right) = \max\{m,n\} \left(1 + \frac{9}{2}\kappa'_{\text{rand}} \right),$$

  where $\|X\|_{\max,F} = \max_{i,k}\{\|X_{i:}\|_F, \|X_{:k}\|_F\}$ and $\kappa'_{\text{rand}} = \|X\|_{\max,F}^2/(\lambda\gamma)$ as defined in (17).

- Using the condition (26), if we choose the probabilities to be proportional to the squared Frobenius norms of the data partitions, i.e.,

$$p_i = \frac{\|X_{i:}\|_F^2}{\|X\|_F^2}, \qquad q_k = \frac{\|X_{:k}\|_F^2}{\|X\|_F^2}, \tag{27}$$

  then we can choose

$$\Gamma = \frac{1}{\min_{i,k}\{p_i, q_k\}} \left(1 + \frac{9\|X\|_F^2}{2m\lambda\gamma} \right) = \frac{1}{\min_{i,k}\{p_i, q_k\}} \left(1 + \frac{9}{2}\kappa''_{\text{rand}} \right),$$

  where $\kappa''_{\text{rand}} = \|X\|_F^2/(m\lambda\gamma)$. Moreover, we can set the step sizes as (see Appendix A.1)

$$\sigma_i = \frac{m\lambda}{9\|X\|_F^2}, \qquad \tau_k = \frac{m\gamma_i}{9\|X\|_F^2}.$$

- For the ERM problem (3), we assume that each loss function ϕ_j, for $j = 1, \ldots, N$, is $1/\nu$-smooth. According to (4), the smooth parameter for each f_i is $\gamma_i = \gamma = (N/m)\nu$. Let R be the largest Euclidean norm among all rows of X (or we can normalize each row to have the same norm R), then we have $\|X\|_F^2 \leq NR^2$ and

$$\kappa''_{\text{rand}} = \frac{\|X\|_F^2}{m\lambda\gamma} \leq \frac{NR^2}{m\lambda\gamma} = \frac{R^2}{\lambda\nu}. \tag{28}$$

  The upper bound $R^2/(\lambda\nu)$ is a condition number used for characterizing the iteration complexity of many randomized algorithms for ERM (e.g., Shalev-Shwartz and Zhang, 2013; Le Roux et al., 2012; Johnson and Zhang, 2013; Defazio et al., 2014; Zhang and Xiao, 2017). In this case, using the non-uniform sampling in (27), we can set the step sizes to be

$$\sigma_i = \frac{\lambda}{9R^2}\frac{m}{N}, \qquad \tau_k = \frac{\gamma}{9R^2}\frac{m}{N} = \frac{\nu}{9R^2}. \tag{29}$$

Next we estimate the overall computation complexity of DSCOVR-SVRG in order to achieve $\mathbf{E}[\Omega(\bar{w}^{(s)} - w^\star, \bar{\alpha}^{(s)} - \alpha^\star)] \leq \epsilon$. From (25), the number of stages required is $\log(\Omega^{(0)}/\epsilon)/\log(3/2)$, where $\Omega^{(0)} = \Omega(\bar{w}^{(0)} - w^\star, \bar{\alpha}^{(0)} - \alpha^\star)$. The number of inner iterations within each stage is $M = \log(3)\Gamma$. At the beginning of of each stage, computing the batch gradients $\bar{u}^{(s)}$ and $\bar{v}^{(s)}$

requires going through the whole data set X, whose computational cost is equivalent to $m \times n$ inner iterations. Therefore, the overall complexity of Algorithm 2, measured by total number of inner iterations, is

$$O\left((mn + \Gamma) \log\left(\frac{\Omega^{(0)}}{\epsilon} \right) \right).$$

To simplify discussion, we further assume $m \leq n$, which is always the case for distributed implementation (see Figure 2 and Section 7). In this case, we can let $\Gamma = n(1 + (9/2)\kappa_{\text{rand}})$. Thus the above iteration complexity becomes

$$O\big(n(1 + m + \kappa_{\text{rand}}) \log(1/\epsilon)\big). \tag{30}$$

Since the iteration complexity in (30) counts the number of blocks X_{ik} being processed, the number of passes over the whole dataset X can be obtained by dividing it by mn, i.e.,

$$O\left(\left(1 + \frac{\kappa_{\text{rand}}}{m} \right) \log(1/\epsilon) \right). \tag{31}$$

This is the computation complexity of DSCOVR listed in Table 1. We can replace κ_{rand} by κ'_{rand} or κ''_{rand} depending on different proof techniques and sampling probabilities as discussed above. We will address the communication complexity for DSCOVR-SVRG, including its decomposition into synchronous and asynchronous ones, after describing its implementation details in Section 7.

In addition to convergence to the saddle point, our next result shows that the primal-dual optimality gap also enjoys the same convergence rate, under slightly different conditions.

Theorem 2 *Suppose Assumption 1 holds, and let $P(w)$ and $D(\alpha)$ be the primal and dual functions defined in* (6) *and* (7)*, respectively. Let Λ and Γ be two constants that satisfy*

$$\Lambda \ \geq \ \|X_{ik}\|_F^2, \qquad i = 1, \ldots, m, \quad k = 1, \ldots, n,$$

and

$$\Gamma \ \geq \ \max_{i,k} \left\{ \frac{1}{p_i} \left(1 + \frac{18\Lambda}{q_k\lambda\gamma_i} \right), \ \frac{1}{q_k} \left(1 + \frac{18n\Lambda}{p_i m\lambda\gamma_i} \right) \right\}.$$

In Algorithm 2, if we choose the step sizes as

$$\sigma_i \ = \ \frac{1}{\gamma_i(p_i\Gamma - 1)}, \qquad i = 1, \ldots, m, \tag{32}$$

$$\tau_k \ = \ \frac{1}{\lambda(q_k\Gamma - 1)}, \qquad k = 1, \ldots, n, \tag{33}$$

and the number of iterations during each stage satisfies $M \geq \log(3)\Gamma$, then

$$\mathbf{E}\left[P(\bar{w}^{(s)}) - D(\bar{\alpha}^{(s)}) \right] \ \leq \ \left(\frac{2}{3} \right)^s 2\Gamma \left(P(\bar{w}^{(0)}) - D(\bar{\alpha}^{(0)}) \right). \tag{34}$$

The proof of Theorem 2 is given in Appendix B. In terms of iteration complexity or total number of passes to reach $\mathbf{E}[P(\bar{w}^{(s)}) - D(\bar{\alpha}^{(s)})] \leq \epsilon$, we need to add an extra factor of $\log(1 + \kappa_{\text{rand}})$ to (30) or (31), due to the factor Γ on the right-hand side of (34).

Algorithm 3 DSCOVR-SAGA

input: initial points $w^{(0)}, \alpha^{(0)}$, and number of iterations M.

1: $\bar{u}^{(0)} = Xw^{(0)}$ and $\bar{v}^{(0)} = \frac{1}{m}X^T\alpha^{(0)}$

2: $U_{ik}^{(0)} = X_{ik}w_k^{(0)}$, $V_{ik}^{(0)} = \frac{1}{m}(\alpha_i^{(0)})^T X_{ik}$, for all $i = 1, \ldots, m$ and $k = 1, \ldots, K$.

3: **for** $t = 0, 1, 2, \ldots, M-1$ **do**

4: pick $j \in \{1, \ldots, m\}$ and $l \in \{1, \ldots, n\}$ randomly with distributions p and q respectively.

5: compute variance-reduced stochastic gradients:

$$u_j^{(t+1)} = \bar{u}_j^{(t)} - \frac{1}{q_l}U_{jl}^{(t)} + \frac{1}{q_l}X_{jl}w_l^{(t)}, \tag{35}$$

$$v_l^{(t+1)} = \bar{v}_l^{(t)} - \frac{1}{p_j}(V_{jl}^{(t)})^T + \frac{1}{p_j}\frac{1}{m}(X_{jl})^T\alpha_j^{(t)}. \tag{36}$$

6: update primal and dual block coordinates:

$$\alpha_i^{(t+1)} = \begin{cases} \mathbf{prox}_{\sigma_j\Phi_j^*}(\alpha_j^{(t)} + \sigma_j u_j^{(t+1)}) & \text{if } i = j. \\ \alpha_i^{(t)}, & \text{if } i \neq j, \end{cases}$$

$$w_k^{(t+1)} = \begin{cases} \mathbf{prox}_{\tau_l g_l}(w_l^{(t)} - \tau_l v_l^{(t+1)}) & \text{if } k = l, \\ w_k^{(t)}, & \text{if } i \neq j. \end{cases}$$

7: update averaged stochastic gradients:

$$\bar{u}_i^{(t+1)} = \begin{cases} \bar{u}_j^{(t)} - U_{jl}^{(t)} + X_{jl}w_l^{(t)} & \text{if } i = j, \\ \bar{u}_i^{(t)} & \text{if } i \neq j, \end{cases}$$

$$\bar{v}_k^{(t+1)} = \begin{cases} \bar{v}_l^{(t)} - (V_{jl}^{(t)})^T + \frac{1}{m}(X_{jl})^T\alpha_j^{(t)} & \text{if } k = l, \\ \bar{v}_k^{(t)} & \text{if } k \neq l, \end{cases}$$

8: update the table of historical stochastic gradients:

$$U_{ik}^{(t+1)} = \begin{cases} X_{jl}w_l^{(t)} & \text{if } i = j \text{ and } k = l, \\ U_{ik}^{(t)} & \text{otherwise.} \end{cases}$$

$$V_{ik}^{(t+1)} = \begin{cases} \frac{1}{m}((X_{jl})^T\alpha_j^{(t)})^T & \text{if } i = j \text{ and } k = l, \\ V_{ik}^{(t)} & \text{otherwise.} \end{cases}$$

9: **end for**

output: $w^{(M)}$ and $\alpha^{(M)}$.

4. The DSCOVR-SAGA Algorithm

Algorithm 3 is a DSCOVR algorithm that uses the techniques of SAGA (Defazio et al., 2014) for variance reduction. This is a single stage algorithm with iterations indexed by t. In order to compute the variance-reduced stochastic gradients $u_j^{(t+1)}$ and $v_l^{(t+1)}$ at each iteration, we also need to maintain and update two vectors $\bar{u}^{(t)} \in \mathbf{R}^N$ and $\bar{v}^{(t)} \in \mathbf{R}^d$, and two matrices $U^{(t)} \in \mathbf{R}^{N\times n}$ and $V^{(t)} \in \mathbf{R}^{m\times d}$.

The vector $\bar{u}^{(t)}$ shares the same partition as $\alpha^{(t)}$ into m blocks, and $\bar{v}^{(t)}$ share the same partitions as $w^{(t)}$ into n blocks. The matrix $U^{(t)}$ is partitioned into $m \times n$ blocks, with each block $U_{ik}^{(t)} \in \mathbf{R}^{N_i\times 1}$. The matrix $V^{(t)}$ is also partitioned into $m \times n$ blocks, with each block $V_{ik}^{(t)} \in \mathbf{R}^{1\times d_k}$. According to the updates in Steps 7 and 8 of Algorithm 3, we have

$$\bar{u}_i^{(t)} = \sum_{k=1}^n U_{ik}^{(t)}, \qquad i = 1, \ldots, m, \tag{37}$$

$$\bar{v}_k^{(t)} = \sum_{i=1}^m (V_{ik}^{(t)})^T, \qquad k = 1, \ldots, n. \tag{38}$$

Based on the above constructions, we can show that $u_j^{(t+1)}$ is an unbiased stochastic gradient of $(\alpha^{(t)})^T Xw^{(t)}$ with respect to α_j, and $v_l^{(t+1)}$ is an unbiased stochastic gradient of $(1/m)((\alpha^{(t)})^T Xw^{(t)})$ with respect to w_l. More specifically, according to (35), we have

$$\begin{aligned} \mathbf{E}_l[u_j^{(t+1)}] &= \bar{u}_j^{(t)} - \sum_{k=1}^n q_k\left(\frac{1}{q_k}U_{jk}^{(t)}\right) + \sum_{k=1}^n q_k\left(\frac{1}{q_k}X_{jk}w_k^{(t)}\right) \\ &= \bar{u}_j^{(t)} - \sum_{k=1}^n U_{jk}^{(t)} + \sum_{k=1}^n X_{jk}w_k^{(t)} \\ &= \bar{u}_j^{(t)} - \bar{u}_j^{(t)} + X_{j:}w^{(t)} \\ &= X_{j:}w^{(t)} = \frac{\partial}{\partial\alpha_j}\left((\alpha^{(t)})^T Xw^{(t)}\right), \end{aligned} \tag{39}$$

where the third equality is due to (37). Similarly, according to (36), we have

$$\begin{aligned} \mathbf{E}_j[v_l^{(t+1)}] &= \bar{v}_l^{(t)} - \sum_{i=1}^m p_i\left(\frac{1}{p_i}(V_{il}^{(t)})^T\right) + \sum_{i=1}^m p_i\left(\frac{1}{p_i m}(X_{il})^T\alpha_i^{(t)}\right) \\ &= \bar{v}_l^{(t)} - \sum_{i=1}^m V_{il}^{(t)} + \frac{1}{m}\sum_{i=1}^m (X_{il})^T\alpha_i^{(t)} \\ &= \bar{v}_l^{(t)} - \bar{v}_l^{(t)} + \frac{1}{m}(X_{:l})^T\alpha^{(t)} \\ &= \frac{1}{m}(X_{:l})^T\alpha^{(t)} = \frac{\partial}{\partial w_l}\left(\frac{1}{m}(\alpha^{(t)})^T Xw^{(t)}\right), \end{aligned} \tag{40}$$

where the third equality is due to (38). The following theorem is proved in Appendix C.

Theorem 3 *Suppose Assumption 1 holds, and let $(w^\star, \alpha^\star)$ be the unique saddle point of $L(w, \alpha)$. Let Γ be a constant that satisfies*

$$\Gamma \geq \max_{i,k}\left\{\frac{1}{p_i}\left(1 + \frac{9\|X_{ik}\|^2}{2q_k\lambda\gamma_i}\right), \frac{1}{q_k}\left(1 + \frac{9n\|X_{ik}\|^2}{2p_i m\lambda\gamma_i}\right), \frac{1}{p_i q_k}\right\}. \tag{41}$$

If we choose the step sizes as

$$\sigma_i = \frac{1}{2\gamma_i(p_i\Gamma - 1)}, \qquad i = 1, \ldots, m, \tag{42}$$

$$\tau_k = \frac{1}{2\lambda(q_k\Gamma - 1)}, \qquad k = 1, \ldots, n, \tag{43}$$

Algorithm 4 Accelerated DSCOVR

input: initial points $\tilde{w}^{(0)}$, $\tilde{\alpha}^{(0)}$, and parameter $\delta > 0$.

1: **for** $r = 0, 1, 2, \ldots,$ **do**

2: find an approximate saddle point of (46) using one of the following two options:

- *option 1:* run Algorithm 2 with $S = \frac{2\log(2(1+\delta))}{\log(3/2)}$ and $M = \log(3)\Gamma_\delta$ to obtain

$$(\tilde{w}^{(r+1)}, \tilde{\alpha}^{(r+1)}) = \text{DSCOVR-SVRG}(\tilde{w}^{(r)}, \tilde{\alpha}^{(r)}, S, M).$$

- *option 2:* run Algorithm 3 with $M = 6\log\left(\frac{8(1+\delta)}{3}\right)\Gamma_\delta$ to obtain

$$(\tilde{w}^{(r+1)}, \tilde{\alpha}^{(r+1)}) = \text{DSCOVR-SAGA}(\tilde{w}^{(r)}, \tilde{\alpha}^{(r)}, M).$$

3: **end for**

Then the iterations of Algorithm 3 satisfy, for $t = 1, 2, \ldots$,

$$\mathbf{E}\left[\Omega(w^{(t)} - w^\star, \alpha^{(t)} - \alpha^\star)\right] \;\le\; \left(1 - \frac{1}{3\Gamma}\right)^t \frac{4}{3}\Omega(w^{(0)} - w^\star, \alpha^{(0)} - \alpha^\star). \tag{44}$$

The condition on Γ in (41) is very similar to the one in (22), except that here we have an additional term $1/(p_i q_k)$ when taking the maximum over i and k. This results in an extra mn term in estimating Γ under uniform sampling. Assuming $m \le n$ (true for distributed implementation), we can let

$$\Gamma = n\left(1 + \frac{9}{2}\kappa_{\text{rand}}\right) + mn.$$

According to (44), in order to achieve $\mathbf{E}[\Omega(w^{(t)} - w^\star, \alpha^{(t)} - \alpha^\star)] \le \epsilon$, DSCOVR-SAGA needs $O\left(\Gamma\log(1/\epsilon)\right)$ iterations. Using the above expression for Γ, the iteration complexity is

$$O\big(n(1 + m + \kappa_{\text{rand}})\log(1/\epsilon)\big), \tag{45}$$

which is the same as (30) for DSCOVR-SVRG. This also leads to the same computational complexity measured by the number of passes over the whole dataset, which is given in (31). Again we can replace κ_{rand} by κ'_{rand} or κ''_{rand} as discussed in Section 3. We will discuss the communication complexity of DSCOVR-SAGA in Section 7, after describing its implementation details.

5. Accelerated DSCOVR Algorithms

In this section, we develop an accelerated DSCOVR algorithm by following the "catalyst" framework (Lin et al., 2015; Frostig et al., 2015). More specifically, we adopt the same procedure by Balamurugan and Bach (2016) for solving convex-concave saddle-point problems.

Algorithm 4 proceeds in rounds indexed by $r = 0, 1, 2, \ldots$. Given the initial points $\tilde{w}^{(0)} \in \mathbf{R}^d$ and $\tilde{\alpha}^{(0)} \in \mathbf{R}^N$, each round r computes two new vectors $\tilde{w}^{(r+1)}$ and $\tilde{\alpha}^{(r+1)}$ using either the DSCOVR-SVRG or DSCOVR-SAGA algorithm for solving a regulated saddle-point problem, similar to the classical proximal point algorithm (Rockafellar, 1976).

Let $\delta > 0$ be a parameter which we will determine later. Consider the following perturbed saddle-point function for round r:

$$L_\delta^{(r)}(w, a) = L(w, \alpha) + \frac{\delta\lambda}{2}\|w - \tilde{w}^{(r)}\|^2 - \frac{\delta}{2m}\sum_{i=1}^m \gamma_i\|\alpha_i - \tilde{\alpha}_i^{(r)}\|^2. \tag{46}$$

Under Assumption 1, the function $L_\delta^{(r)}(w, a)$ is $(1+\delta)\lambda$-strongly convex in w and $(1+\delta)\gamma_i/m$-strongly concave in α_i. Let Γ_δ be a constant that satisfies

$$\Gamma_\delta \;\ge\; \max_{i,k}\left\{\frac{1}{p_i}\left(1 + \frac{9\|X_{ik}\|^2}{2q_k\lambda\gamma_i(1+\delta)^2}\right),\; \frac{1}{q_k}\left(1 + \frac{9n\|X_{ik}\|^2}{2p_i m\lambda\gamma_i(1+\delta)^2}\right),\; \frac{1}{p_i q_k}\right\},$$

where the right-hand side is obtained from (41) by replacing λ and γ_i with $(1+\delta)\lambda$ and $(1+\delta)\gamma_i$ respectively. The constant Γ_δ is used in Algorithm 4 to determine the number of inner iterations to run with each round, as well as for setting the step sizes. The following theorem is proved in Appendix D.

Theorem 4 *Suppose Assumption 1 holds, and let $(w^\star, \alpha^\star)$ be the saddle-point of $L(w, \alpha)$. With either options in Algorithm 4, if we choose the step sizes (inside Algorithm 2 or Algorithm 3) as*

$$\sigma_i \;=\; \frac{1}{2(1+\delta)\gamma_i(p_i\Gamma_\delta - 1)}, \qquad i = 1, \ldots, m, \tag{47}$$

$$\tau_k \;=\; \frac{1}{2(1+\delta)\lambda(q_k\Gamma_\delta - 1)}, \qquad k = 1, \ldots, n. \tag{48}$$

Then for all $r \ge 1$,

$$\mathbf{E}\left[\Omega(\tilde{w}^{(r)} - w^\star, \tilde{\alpha}^{(r)} - \alpha^\star)\right] \;\le\; \left(1 - \frac{1}{2(1+\delta)}\right)^{2r}\Omega(\tilde{w}^{(0)} - w^\star, \tilde{\alpha}^{(0)} - \alpha^\star).$$

According to Theorem 4, in order to have $\mathbf{E}[\Omega(\tilde{w}^{(r)} - w^\star, \tilde{\alpha}^{(r)} - \alpha^\star)] \le \epsilon$, we need the number of rounds r to satisfy

$$r \ge (1+\delta)\log\Big(\frac{\Omega(\tilde{w}^{(0)} - w^\star, \tilde{\alpha}^{(0)} - \alpha^\star)}{\epsilon}\Big).$$

Following the discussions in Sections 3 and 4, when using uniform sampling and assuming $m \le n$, we can have

$$\Gamma_\delta = n\left(1 + \frac{9\kappa_{\text{rand}}}{2(1+\delta)^2}\right) + mn. \tag{49}$$

Then the total number of block coordinate updates in Algorithm 4 is

$$O((1+\delta)\Gamma_\delta\log(1+\delta)\log(1/\epsilon)),$$

where the $\log(1+\delta)$ factor comes from the number of stages S in option 1 and number of steps M in option 2. We hide the $\log(1+\delta)$ factor with the $\widetilde{O}$ notation and plug (49) into the expression above to obtain

$$\widetilde{O}\left(n\left((1+\delta)(1+m) + \frac{\kappa_{\text{rand}}}{(1+\delta)}\right)\log\left(\frac{1}{\epsilon}\right)\right).$$

Now we can choose δ depending on the relative size of κ_{rand} and m:

- If $\kappa_{\text{rand}} > 1 + m$, we can minimizing the above expression by choosing $\delta = \sqrt{\frac{\kappa_{\text{rand}}}{1+m}} - 1$, so that the overall iteration complexity becomes $\widetilde{O}\left(n\sqrt{m\kappa_{\text{rand}}}\log(1/\epsilon)\right)$.
- If $\kappa_{\text{rand}} \le m + 1$, then no acceleration is necessary and we can choose $\delta = 0$ to proceed with a single round. In this case, the iteration complexity is $O(mn)$ as seen from (49).

Therefore, in either case, the total number of block iterations by Algorithm 4 can be written as

$$\widetilde{O}\left(mn + n\sqrt{m\kappa_{\text{rand}}}\log(1/\epsilon)\right). \tag{50}$$

As discussed before, the total number of passes over the whole dataset is obtained by dividing by mn:

$$\widetilde{O}\left(1 + \sqrt{\kappa_{\text{rand}}/m}\log(1/\epsilon)\right).$$

This is the computational complexity of accelerated DSCOVR listed in Table 1.

5.1. Proximal Mapping for Accelerated DSCOVR

When applying Algorithm 2 or 3 to approximate the saddle-point of (46), we need to replace the proximal mappings of $g_k(\cdot)$ and $f_i^*(\cdot)$ by those of $g_k(\cdot) + (\delta\lambda/2)\|\cdot - \tilde{w}_k^{(r)}\|^2$ and $f_i^*(\cdot) + (\delta\gamma_i/2)\|\cdot - \tilde{\alpha}_i^{(r)}\|^2$, respectively. More precisely, we replace $w_k^{(t+1)} = \mathbf{prox}_{\tau_k g_k}\left(w_k^{(t)} - \tau_k v_k^{(t+1)}\right)$ by

$$\begin{aligned} w_k^{(t+1)} &= \operatorname*{arg\,min}_{w_k \in \mathbf{R}^{d_k}} \left\{ g_k(w_k) + \frac{\delta\lambda}{2}\|w_k - \tilde{w}_k^{(r)}\|^2 + \frac{1}{2\tau_k}\left\|w_k - \left(w_k^{(t)} - \tau_k v_k^{(t+1)}\right)\right\|^2 \right\} \\ &= \mathbf{prox}_{\frac{\tau_k}{1+\tau_k\delta\lambda} g_k}\left(\frac{1}{1+\tau_k\delta\lambda}\left(w_k^{(t)} - \tau_k v_k^{(t+1)}\right) + \frac{\tau_k\delta\lambda}{1+\tau_k\delta\lambda}\tilde{w}_k^{(r)}\right), \end{aligned} \tag{51}$$

and replace $\alpha_i^{(t+1)} = \mathbf{prox}_{\sigma_i f_i^*}\left(\alpha_i^{(t)} + \sigma_i u_i^{(t+1)}\right)$ by

$$\begin{aligned} \alpha_i^{(t+1)} &= \operatorname*{arg\,min}_{\alpha_i \in \mathbf{R}^{N_i}} \left\{ f_i^*(\alpha_i) + \frac{\delta\gamma_i}{2}\|\alpha_i - \tilde{\alpha}_i^{(r)}\|^2 + \frac{1}{2\sigma_i}\left\|\alpha_i - \left(\alpha_i^{(t)} + \sigma_i u_i^{(t+1)}\right)\right\|^2 \right\} \\ &= \mathbf{prox}_{\frac{\sigma_i}{1+\sigma_i\delta\gamma_i} f_i^*}\left(\frac{1}{1+\sigma_i\delta\gamma_i}\left(\alpha_i^{(t)} + \sigma_i u_i^{(t+1)}\right) + \frac{\sigma_i\delta\gamma_i}{1+\sigma_i\delta\gamma_i}\tilde{\alpha}_i^{(r)}\right). \end{aligned} \tag{52}$$

We also examine the number of inner iterations determined by Γ_δ and how to set the step sizes. If we choose $\delta = \sqrt{\frac{\kappa_{\text{rand}}}{1+m}} - 1$, then Γ_δ in (49) becomes

$$\Gamma_\delta = n\left(1 + \frac{9\kappa_{\text{rand}}}{2(1+\delta)^2}\right) + mn = n\left(1 + \frac{9\kappa_{\text{rand}}}{2\kappa_{\text{rand}}/(m+1)}\right) + mn = 5.5(m+1)n.$$

Therefore a small constant number of passes is sufficient within each round. Using the uniform sampling, the step sizes can be estimated as follows:

$$\sigma_i = \frac{1}{2(1+\delta)\gamma_i(p_i\Gamma_\delta - 1)} \approx \frac{1}{2\sqrt{\kappa_{\text{rand}}/m}\gamma_i(5.5n-1)} \approx \frac{1}{11\gamma_i n\sqrt{\kappa_{\text{rand}}/m}}, \tag{53}$$

$$\tau_k = \frac{1}{2(1+\delta)\lambda(q_k\Gamma_\delta - 1)} \approx \frac{1}{2\sqrt{\kappa_{\text{rand}}/m}\lambda(5.5m-1)} \approx \frac{1}{11\lambda\sqrt{m\cdot\kappa_{\text{rand}}}}. \tag{54}$$

As shown by our numerical experiments in Section 8, the step sizes can be set much larger in practice.

6. Conjugate-Free DSCOVR Algorithms

A major disadvantage of primal-dual algorithms for solving problem (1) is the requirement of computing the proximal mapping of the conjugate function f_i^*, which may not admit closed-formed solution or efficient computation. This is especially the case for logistic regression, one of the most popular loss functions used in classification.

Lan and Zhou (2018) developed "conjugate-free" variants of primal-dual algorithms that avoid computing the proximal mapping of the conjugate functions. The main idea is to replace the Euclidean distance in the dual proximal mapping with a Bregman divergence defined over the conjugate function itself. This technique has been used by Wang and Xiao (2017) to solve structured ERM problems with primal-dual first order methods. Here we use this approach to derive conjugate-free DSCOVR algorithms. In particular, we replace the proximal mapping for the dual update

$$\alpha_i^{(t+1)} = \mathbf{prox}_{\sigma_i f_i^*}\left(\alpha_i^{(t)} + \sigma_i u_i^{(t+1)}\right) = \operatorname*{arg\,min}_{\alpha_i \in \mathbf{R}^{n_i}}\left\{ f_i^*(\alpha_i) - \langle \alpha_i, u_i^{(t+1)}\rangle + \frac{1}{2\sigma_i}\|\alpha_i - \alpha_i^{(t)}\|^2 \right\},$$

by

$$\alpha_i^{(t+1)} = \operatorname*{arg\,min}_{\alpha_i \in \mathbf{R}^{n_i}}\left\{ f_i^*(\alpha_i) - \langle \alpha_i, u_i^{(t+1)}\rangle + \frac{1}{\sigma_i}\mathcal{B}_i(\alpha_i, \alpha_i^{(t)}) \right\}, \tag{55}$$

where $\mathcal{B}_i(\alpha_i, \alpha_i^{(t)}) = f_i^*(\alpha_i) - \langle \nabla f_i^*(\alpha_i^{(t)}),\, \alpha_i - \alpha_i^{(t)}\rangle$. The solution to (55) is given by

$$\alpha_i^{(t+1)} = \nabla f_i(\beta_i^{(t+1)}),$$

where $\beta_i^{(t+1)}$ can be computed recursively by

$$\beta_i^{(t+1)} = \frac{\beta_i^{(t)} + \sigma_i u_i^{(t+1)}}{1+\sigma_i}, \qquad t \ge 0,$$

with initial condition $\beta_i^{(0)} = \nabla f_i^*(\alpha_i^{(0)})$ (see Lan and Zhou, 2018, Lemma 1). Therefore, in order to update the dual variables α_i, we do not need to compute the proximal mapping for the conjugate function f_i^*; instead, taking the gradient of f_i at some easy-to-compute points is sufficient. This conjugate-free update can be applied in Algorithms 1, 2 and 3.

For the accelerated DSCOVR algorithms, we replace (52) by

$$\alpha_i^{(t+1)} = \operatorname*{arg\,min}_{\alpha_i \in \mathbf{R}^{n_i}}\left\{ f_i^*(\alpha_i) - \langle \alpha_i, u_i^{(t+1)}\rangle + \frac{1}{\sigma_i}\mathcal{B}_i(\alpha_i, \alpha_i^{(t)}) + \delta\gamma\mathcal{B}_i(\alpha_i, \tilde{\alpha}_i^{(t+1)}) \right\}.$$

The solution to the above minimization problem can also be written as

$$\alpha_i^{(t+1)} = \nabla f_i(\beta_i^{(t+1)}),$$

where $\beta_i^{(t+1)}$ can be computed recursively as

$$\beta_i^{(t+1)} = \frac{\beta_t^{(t)} + \sigma_i u_i^{(t+1)} + \sigma_i\delta\gamma\tilde{\beta}_i}{1+\sigma_i+\sigma_i\delta\gamma}, \qquad t \ge 0,$$

with the initialization $\beta_i^{(0)} = \nabla f_i^*(\alpha_i^{(0)})$ and $\tilde{\beta}_i = \nabla f_i^*(\tilde{\alpha}_i^{(r)})$.

The convergence rates and computational complexities of the conjugate-free DSCOVR algorithms are very similar to the ones given in Sections 3–5. We omit details here, but refer the readers to Lan and Zhou (2018) and Wang and Xiao (2017) for related results.

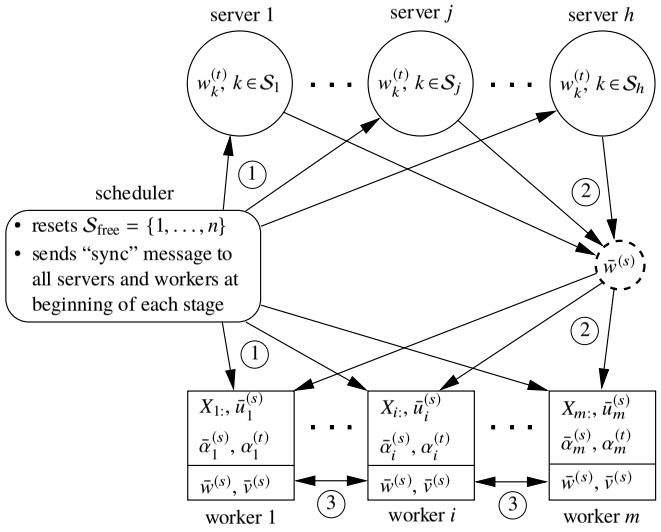

Figure 3: A distributed system for implementing DSCOVR consists of m workers, h parameter servers, and one scheduler. The arrows labeled with the numbers 1, 2 and 3 represent three collective communications at the beginning of each stage in DSCOVR-SVRG.

7. Asynchronous Distributed Implementation

In this section, we show how to implement the DSCOVR algorithms presented in Sections 3–6 in a distributed computing system. We assume that the system provide both synchronous collective communication and asynchronous point-to-point communication, which are all supported by the MPI standard (MPI Forum, 2012). Throughout this section, we assume $m < n$ (see Figure 2).

7.1. Implementation of DSCOVR-SVRG

In order to implement Algorithm 2, the distributed system need to have the following components (see Figure 3):

- *m workers*. Each worker i, for $i = 1, \ldots, m$, stores the following local data and variables :
  - data matrix $X_{i:} \in \mathbf{R}^{N_i \times d}$.
  - vectors in $\mathbf{R}^{N_i}$: $\bar{u}_i^{(s)}, \alpha_i^{(t)}, \bar{\alpha}_i^{(s)}$.
  - vectors in $\mathbf{R}^d$: $\bar{w}^{(s)}, \bar{v}^{(s)}$.
  - extra buffers for computation and communication: $u_j^{(t+1)}, v_l^{(t+1)}, w_l^{(t)}$ and $w_l^{(t+1)}$.

- *h parameter servers*. Each server j stores a subset of the blocks $\{w_k^{(t)} \in \mathbf{R}^{d_k} : k \in \mathcal{S}_j\}$, where $\mathcal{S}_1, \ldots, \mathcal{S}_h$ form a partition of the set $\{1, \ldots, n\}$.
- *one scheduler*. It maintains a set of block indices $\mathcal{S}_{\text{free}} \subseteq \{1, \ldots, n\}$. At any given time, $\mathcal{S}_{\text{free}}$ contains indices of parameter blocks that are not currently updated by any worker.

The reason for having $h > 1$ servers is not about insufficient storage for parameters, but rather to avoid the communication overload between only one server and all m workers (m can be in hundreds).

At the beginning of each stage s, the following three collective communications take place across the system (illustrated in Figure 3 by arrows with circled labels 1, 2 and 3):

(1) The scheduler sends a "sync" message to all servers and workers, and resets $\mathcal{S}_{\text{free}} = \{1, \ldots, n\}$.

(2) Upon receiving the "sync" message, the servers aggregate their blocks of parameters together to form $\bar{w}^{(s)}$ and send it to all workers (e.g., through the AllReduce operation in MPI).

(3) Upon receiving $\bar{w}^{(s)}$, each worker compute $\bar{u}_i^{(s)} = X_{i:}\bar{w}^{(s)}$ and $(X_{i:})^T\bar{\alpha}_i^{(s)}$, then invoke a collective communication (AllReduce) to compute $\bar{v}^{(s)} = (1/m)\sum_{i=1}^m (X_{i:})^T\bar{\alpha}_i^{(s)}$.

The number of vectors in $\mathbf{R}^d$ sent and received during the above process is $2m$, counting the communications to form $\bar{w}^{(s)}$ and $\bar{v}^{(s)}$ at m workers (ignoring the short "sync" messages).

After the collective communications at the beginning of each stage, all workers start working on the inner iterations of Algorithm 2 in parallel in an asynchronous, event-driven manner. Each worker interacts with the scheduler and the servers in a four-step loop shown in Figure 4. There are always m iterations taking place concurrently (see also Figure 2), each may at a different phase of the four-step loop:

(1) Whenever worker i finishes updating a block k', it sends the pair (i, k') to the scheduler to request for another block to update. At the beginning of each stage, k' is not needed.

(2) When the scheduler receives the pair (i, k'), it randomly choose a block k from the list of free blocks $\mathcal{S}_{\text{free}}$ (which are not currently updated by any worker), looks up for the server j which stores the parameter block $w_k^{(t)}$ (i.e., $\mathcal{S}_j \ni k$), and then send the pair (i, k) to server j. In addition, the scheduler updates the list $\mathcal{S}_{\text{free}}$ by adding k' and deleting k.

(3) When server j receives the pair (i, k), it sends the vector $w_k^{(t)}$ to worker i, and waits for receiving the updated version $w_k^{(t+1)}$ from worker i.

(4) After worker i receives $w_k^{(t)}$, it computes the updates $\alpha_i^{(t)}$ and $w_k^{(t)}$ following steps 6-7 in Algorithm 2, and then send $w_k^{(t+1)}$ back to server j. At last, it assigns the value of k to k' and send the pair (i, k') to the scheduler, requesting the next block to work on.

The amount of point-to-point communication required during the above process is $2d_k$ float numbers, for sending and receiving $w_k^{(t)}$ and $w_k^{(t+1)}$ (we ignore the small messages for sending and receiving (i, k') and (i, k)). Since the blocks are picked randomly, the average amount of communication per iteration is $2d/n$, or equivalent to $2/n$ vectors in $\mathbf{R}^d$. According to Theorem 1, each stage of Algorithm 2 requires $\log(3)\Gamma$ inner iterations; In addition, the discussions above (30) show that we can take $\Gamma = n(1 + (9/2)\kappa_{\text{rand}})$. Therefore, the average amount of point-to-point communication within each stage is $O(\kappa_{\text{rand}})$ vectors in $\mathbf{R}^d$.

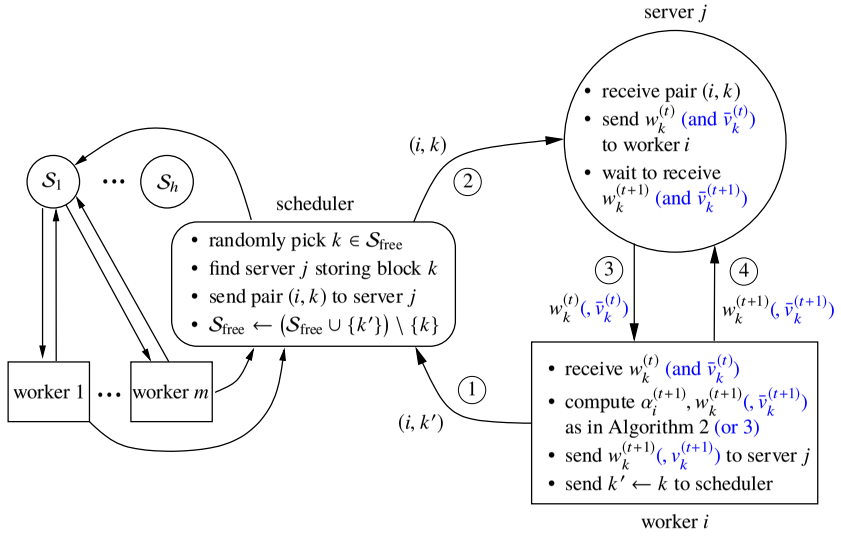

Figure 4: Communication and computation processes for one inner iteration of DSCOVR-SVRG (Algorithm 2). The blue texts in the parentheses are the additional vectors required by DSCOVR-SAGA (Algorithm 3). There are always m iterations taking place in parallel asynchronously, each evolving around one worker. A server may support multiple (or zero) iterations if more than one (or none) of its stored parameter blocks are being updated.

Now we are ready to quantify the communication complexity of DSCOVR-SVRG to find an ϵ-optimal solution. Our discussions above show that each stage requires collective communication of $2m$ vectors in $\mathbf{R}^d$ and asynchronous point-to-point communication of equivalently κ_{rand} such vectors. Since there are total $O(\log(1/\epsilon))$ stages, the total communication complexity is

$$O\left((m + \kappa_{\text{rand}}) \log(1/\epsilon)\right).$$

This gives the communication complexity shown in Table 1, as well as its decomposition in Table 2.

7.2. Implementation of DSCOVR-SAGA

We can implement Algorithm 3 using the same distributed system shown in Figure 3, but with some modifications described below. First, the storage at different components are different:

- *m workers.* Each worker i, for $i = 1, \ldots, m$, stores the following data and variables:
  - data matrix $X_{i:} \in \mathbf{R}^{N_i \times d}$
  - vectors in $\mathbf{R}^{N_i}$: $\alpha_i^{(t)}$, $u_i^{(t)}$, $\bar{u}_i^{(t)}$, and $U_{ik}^{(t)}$ for $k = 1, \ldots, n$.

  - vector in $\mathbf{R}^d$: $V_{i:}^{(t)} = [V_{i1}^{(t)} \cdots V_{in}^{(t)}]^T$ (which is the ith row of $V^{(t)}$, with $V_{ik}^{(t)} \in \mathbf{R}^{1 \times d_k}$).
  - buffers for communication and update of $w_k^{(t)}$ and $\bar{v}_k^{(t)}$ (both stored at some server).
- *h servers.* Each server j stores a subset of blocks $\{w_k^{(t)}, \bar{v}_k^{(t)} \in \mathbf{R}^{d_k} : k \in \mathcal{S}_j\}$, for $j = 1, \ldots, n$.
- *one scheduler.* It maintains the set of indices $\mathcal{S}_{\text{free}} \subseteq \{1, \ldots, n\}$, same as in DSCOVR-SVRG.

Unlike DSCOVR-SVRG, there is no stage-wise "sync" messages. All workers and servers work in parallel asynchronously all the time, following the four-step loops illustrated in Figure 4 (including blue colored texts in the parentheses). Within each iteration, the main difference from DSCOVR-SVRG is that, the server and worker need to exchange two vectors of length d_k: $w_k^{(t)}$ and $v_k^{(t)}$ and their updates. This doubles the amount of point-to-point communication, and the average amount of communication per iteration is $4/n$ vectors of length d. Using the iteration complexity in (45), the total amount of communication required (measured by number of vectors of length d) is

$$O\left((m + \kappa_{\text{rand}}) \log(1/\epsilon)\right),$$

which is the same as for DSCOVR-SVRG. However, its decomposition into synchronous and asynchronous communication is different, as shown in Table 2. If the initial vectors $w^{(0)} \neq 0$ or $\alpha^{(0)} \neq 0$, then one round of collective communication is required to propagate the initial conditions to all servers and workers, which reflect the $O(m)$ synchronous communication in Table 2.

7.3. Implementation of Accelerated DSCOVR

Implementation of the accelerated DSCOVR algorithm is very similar to the non-accelerated ones. The main differences lie in the two proximal mappings presented in Section 5.1. In particular, the primal update in (51) needs the extra variable $\tilde{w}_k^{(r)}$, which should be stored at a parameter server together with $w_k^{(t)}$. We modify the four-step loops shown in Figures 4 as follows:

- Each parameter server j stores the extra block parameters $\{\tilde{w}_k^{(r)}, k \in \mathcal{S}_j\}$. During step (3), $\tilde{w}_k^{(r)}$ is send together with $w_k^{(t)}$ (for SVRG) or $(w_k^{(t)}, v_k^{(t)})$ (for SAGA) to a worker.
- In step (4), no update of $\tilde{w}_k^{(r)}$ is sent back to the server. Instead, whenever switching rounds, the scheduler will inform each server to update their $\tilde{w}_k^{(r)}$ to the most recent $w_k^{(t)}$.

For the dual proximal mapping in (52), each worker i needs to store an extra vector $\tilde{\alpha}_i^{(r)}$, and reset it to the most recent $\alpha_i^{(t)}$ when moving to the next round. There is no need for additional synchronization or collective communication when switching rounds in Algorithm 4. The communication complexity (measured by the number of vectors of length d sent or received) can be obtained by dividing the iteration complexity in (50) by n, i.e., $O((m + \sqrt{m\kappa_{\text{rand}}}) \log(1/\epsilon))$, as shown in Table 1.

Finally, in order to implement the conjugate-free DSCOVR algorithms described in Section 6, each worker i simply need to maintain and update an extra vector $\beta_i^{(t)}$ locally.

8. Experiments

In this section, we present numerical experiments on an industrial distributed computing system. This system has hundreds of computers connected by high speed Ethernet in a data center. The hardware and software configurations for each machine are listed in Table 3. We implemented all DSCOVR

CPU	#cores	RAM	network	operating system
dual Intel® Xeon® processors E5-2650 (v2), 2.6 GHz	16	128 GB 1.8 GHz	10 Gbps Ethernet adapter	Windows® Server (version 2012)

Table 3: Configuration of each machine in the distributed computing system.

algorithms presented in this paper, including the SVRG and SAGA versions, their accelerated variants, as well as the conjugate-free algorithms. All implementations are written in C++, using MPI for both collective and point-to-point communications (see Figures 3 and 4 respectively). On each worker machine, we also use OpenMP (OpenMP Architecture Review Board, 2011) to exploit the multi-core architecture for parallel computing, including sparse matrix-vector multiplications and vectorized function evaluations.

Implementing the DSCOVR algorithms requires $m+h+1$ machines, among them m are workers with local datasets, h are parameter servers, and one is a scheduler (see Figure 3). We focus on solving the ERM problem (3), where the total of N training examples are evenly partitioned and stored at m workers. We partition the d-dimensional parameters into n subsets of roughly the same size (differ at most by one), where each subset consists of randomly chosen coordinates (without replacement). Then we store the n subsets of parameters on h servers, each getting either $\lfloor n/h \rfloor$ or $\lceil n/h \rceil$ subsets. As described in Section 7, we make the configurations to satisfy $n > m > h \geq 1$.

For DSCOVR-SVRG and DSCOVR-SAGA, the step sizes in (29) are very conservative. In the experiments, we replace the coefficient $1/9$ by two tuning parameter $\eta_{\rm d}$ and $\eta_{\rm p}$ for the dual and primal step sizes respectively, i.e.,

$$\sigma_i = \eta_{\rm d} \frac{\lambda}{R^2} \cdot \frac{m}{N}, \qquad \tau_k = \eta_{\rm p} \frac{\nu}{R^2}. \tag{56}$$

For the accelerated DSCOVR algorithms, we use $\kappa_{\rm rand} = R^2/(\lambda\nu)$ as shown in (28) for ERM. Then the step sizes in (53) and (54), with $\gamma_i = (m/N)\nu$ and a generic constant coefficient η, become

$$\sigma_i = \frac{\eta_{\rm d}}{nR} \sqrt{\frac{m\lambda}{\nu}} \cdot \frac{m}{N}, \qquad \tau_k = \frac{\eta_{\rm p}}{R} \sqrt{\frac{\nu}{m\lambda}}. \tag{57}$$

For comparison, we also implemented the following first-order methods for solving problem 1:

- PGD: parallel implementation of the Proximal Gradient Descent method (using synchronous collective communication over m machines). We use the adaptive line search procedure proposed in Nesterov (2013), and the exact form used is Algorithm 2 in Lin and Xiao (2015).
- APG: parallel implementation of the Accelerated Proximal Gradient method (Nesterov, 2004, 2013). We use a similar adaptive line search scheme to the one for PGD, and the exact form used (with strong convexity) is Algorithm 4 in Lin and Xiao (2015).
- ADMM: the Alternating Direction Method of Multipliers. We use the regularized consensus version in Boyd et al. (2011, Section 7.1.1). For solving the local optimization problems at each node, we use the SDCA method (Shalev-Shwartz and Zhang, 2013).
- CoCoA+: the adding version of CoCoA in Ma et al. (2015). Following the suggestion in Ma et al. (2017), we use a randomized coordinate descent algorithm (Nesterov, 2012; Richtárik and Takáč, 2014) for solving the local optimization problems.

Dataset	#instances (N)	#features (d)	#nonzeros
`rcv1-train`	677,399	47,236	49,556,258
`webspam`	350,000	16,609,143	1,304,697,446
`splice-site`	50,000,000	11,725,480	166,167,381,622

Table 4: Statistics of three datasets. Each feature vector is normalized to have unit norm.

These four algorithms all require m workers only. Specifically, we use the AllReduce call in MPI for the collective communications so that a separate master machine is not necessary.

We conducted experiments on three binary classification datasets obtained from the collection maintained by Fan and Lin (2011). Table 4 lists their sizes and dimensions. In our experiments, we used two configurations: one with $m = 20$ and $h = 10$ for two relatively small datasets, `rcv1-train` and `webspam`, and the other with $m = 100$ and $h = 20$ for the large dataset `splice-site`.

For `rcv1-train`, we solve the ERM problem (3) with a smoothed hinge loss defined as

$$\phi_j(t) = \begin{cases} 0 & \text{if } y_j t \geq 1, \\ \frac{1}{2} - y_j t & \text{if } y_j t \leq 0, \\ \frac{1}{2}(1 - y_j t)^2 & \text{otherwise,} \end{cases} \qquad \text{and} \qquad \phi_j^*(\beta) = \begin{cases} y_j\beta + \frac{1}{2}\beta^2 & \text{if } -1 \leq y_j\beta \leq 0, \\ +\infty & \text{otherwise.} \end{cases}$$

for $j = 1, \ldots, N$. This loss function is 1-smooth, therefore $\nu = 1$; see discussion above (28). We use the ℓ_2 regularization $g(w) = (\lambda/2)\|w\|^2$. Figures 5 and 6 show the reduction of the primal objective gap $P(w^{(t)}) - P(w^\star)$ by different algorithms, with regularization parameter $\lambda = 10^{-4}$ and $\lambda = 10^{-6}$ respectively. All started from the zero initial point. Here the N examples are randomly shuffled and then divided into m subsets. The labels SVRG and SAGA mean DSCOVR-SVRG and DSCOVR-SAGA, respectively, and A-SVRG and A-SAGA are their accelerated versions.

Since PGD and APG both use adaptive line search, there is no parameter to tune. For ADMM, we manually tuned the penalty parameter ρ (see Boyd et al., 2011, Section 7.1.1) to obtain good performance: $\rho = 10^{-5}$ in Figure 5 and $\rho = 10^{-6}$ in Figure 6. For CoCoA+, two passes over the local datasets using a randomized coordinate descent method are sufficient for solving the local optimization problem (more passes do not give meaningful improvement). For DSCOVR-SVRG and SAGA, we used $\eta_{\rm p} = \eta_{\rm d} = 20$ to set the step sizes in (56). For DSCOVR-SVRG, each stage goes through the whole dataset 10 times, i.e., the number of inner iterations in Algorithm 2 is $M = 10mn$. For the accelerated DSCOVR algorithms, better performance are obtained with small periods to update the proximal points and we set it to be every 0.2 passes over the dataset, i.e., $0.2mn$ inner iterations. For accelerated DSCOVR-SVRG, we set the stage period (for variance reduction) to be $M = mn$, which is actually longer than the period for updating the proximal points.

From Figures 5 and 6, we observe that the two distributed algorithms based on model averaging, ADMM and CoCoA+, converges relatively fast in the beginning but becomes very slow in the later stage. Other algorithms demonstrate more consistent linear convergence rates. For $\lambda = 10^{-4}$, the DSCOVR algorithms are very competitive compared with other algorithms. For $\lambda = 10^{-6}$, the non-accelerated DSCOVR algorithms become very slow, even after tuning the step sizes. But the accelerated DSCOVR algorithms are superior in terms of both number of passes over data and wall-clock time (with adjusted step size coefficient $\eta_{\rm p} = 10$ and $\eta_{\rm d} = 40$).

For ADMM and CoCoA+, each marker represents the finishing of one iteration. It can be seen that they are mostly evenly spaced in terms of number of passes over data, but have large variations in terms of wall-clock time. The variations in time per iteration are due to resource sharing with

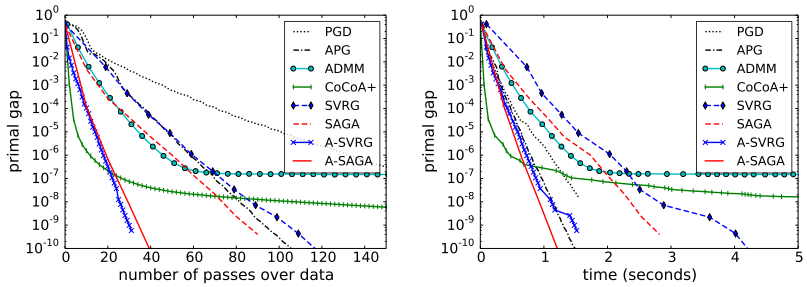

Figure 5: `rcv1-train`: smoothed-hinge loss, $\lambda = 10^{-4}$, randomly shuffled, $m = 20$, $n = 37$, $h = 10$.

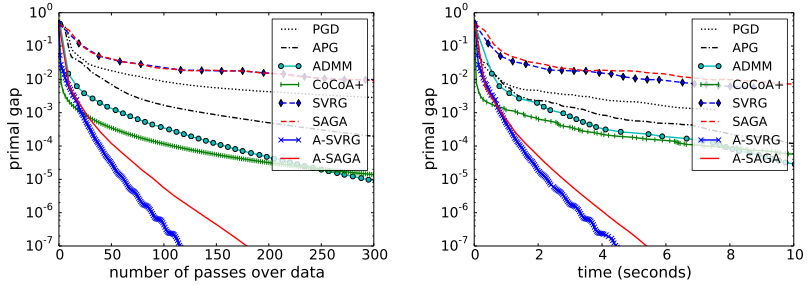

Figure 6: `rcv1-train`: smoothed-hinge loss, $\lambda = 10^{-6}$, randomly shuffled, $m = 20$, $n = 37$, $h = 10$.

other jobs running simultaneously on the distributed computing cluster. Even if we have exclusive use of each machine, sharing communications with other jobs over the Ethernet is unavoidable. This reflects the more realistic environment in cloud computing.

For the `webspam` dataset, we solve the ERM problem with logistic loss $\phi_j(t) = \log(1+\exp(-y_j t))$ where $y_j \in \{\pm 1\}$. The logistic loss is 1/4-smooth, so we have $\nu = 4$. Since the proximal mapping of its conjugate ϕ_j^* does not have a closed-form solution, we used the conjugate-free DSCOVR algorithms described in Section 6. Figures 7 and 8 shows the reduction of primal objective gap by different algorithms, for $\lambda = 10^{-4}$ and $\lambda = 10^{-6}$ respectively. Here the starting point is no longer the all-zero vectors. Instead, each machine i first computes a local solution by minimizing $f_i(X_i w) + g(w)$, and then compute their average using an AllReduce operation. Each algorithm starts from this average point. This averaging scheme has been proven to be very effective to warm start distributed algorithms for ERM (Zhang et al., 2013). In addition, it can be shown that when starting from the zero initial point, the first step of CoCoA+ computes exactly such an averaged point.

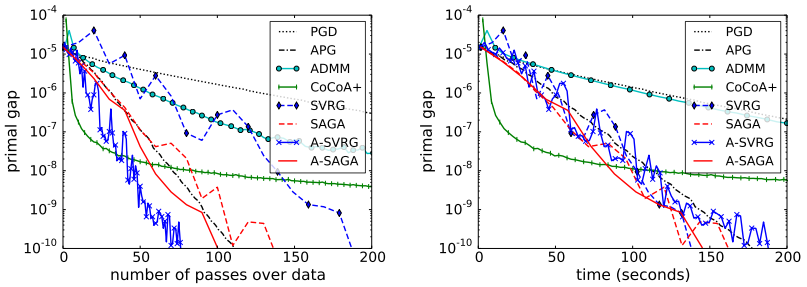

Figure 7: `webspam`: logistic regression, $\lambda = 10^{-4}$, randomly shuffled, $m = 20$, $n = 50$, $h = 10$.

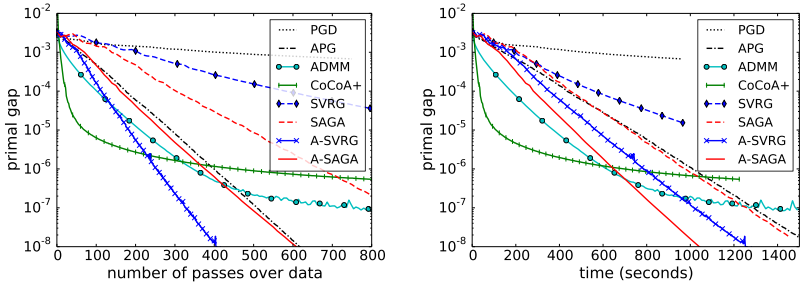

Figure 8: `webspam`: logistic regression, $\lambda = 10^{-6}$, randomly shuffled, $m = 20$, $n = 50$, $h = 10$.

From Figures 7 and 8, we again observe that CoCoA+ has very fast convergence in the beginning but converges very slowly towards higher precision. The DSCOVR algorithms, especially the accelerated variants, are very competitive in terms of both number of iterations and wall-clock time.

In order to investigate the fast initial convergence of CoCoA+ and ADMM, we repeated the experiments on `webspam` without random shuffling. More specifically, we sorted the N examples by their labels, and then partitioned them into m subsets sequentially. That is, most of the machines have data with only $+1$ or -1 labels, and only one machine has mixed ± 1 examples. The results are shown in Figures 9 and 10. Now the fast initial convergence of CoCoA+ and ADMM disappeared. In particular, CoCoA+ converges with very slow linear rate. This shows that statistical properties of random shuffling of the dataset is the main reason for the fast initial convergence of model-averaging based algorithms such as CoCoA+ and ADMM (see, e.g., Zhang et al., 2013).

On the other hand, this should not have any impact on PGD and APG, because their iterations are computed over the whole dataset, which is the same regardless of random shuffling or sorting. The differences between the plots for PGD and APG in Figures 7 and 9 (also for Figures 8 and 10) are due to different initial points computed through averaging local solutions, which does depends on the distribution of data at different machines.

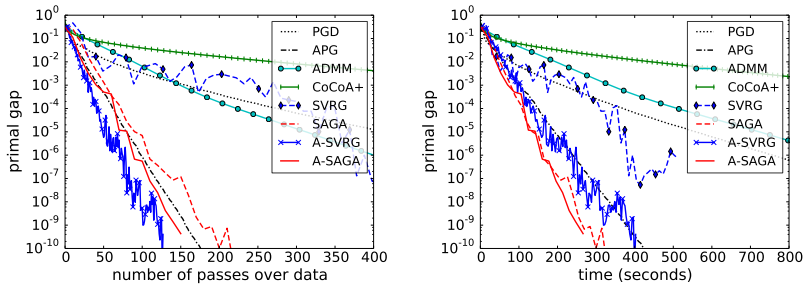

Figure 9: `webspam`: logistic regression, $\lambda = 10^{-4}$, sorted labels, $m = 20$, $n = 50$, $h = 10$.

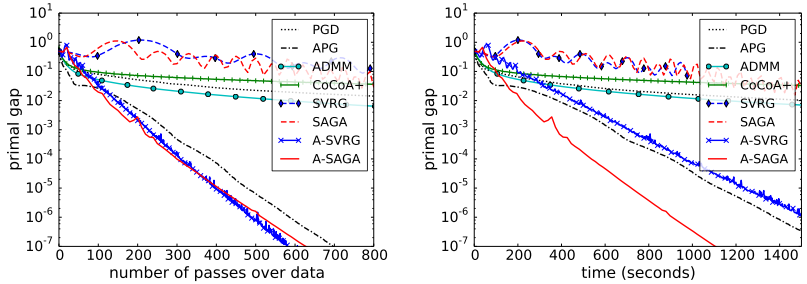

Figure 10: `webspam`: logistic regression, $\lambda = 10^{-6}$, sorted labels, $m = 20$, $n = 50$, $h = 10$.

Different ways for splitting the data over the m workers also affect the DSCOVR algorithms. In particular, the non-accelerated DSCOVR algorithms become very slow, as shown in Figures 9 and 10. However, the accelerated DSCOVR algorithms are still very competitive against the adaptive APG. The accelerated DSCOVR-SAGA algorithm performs best. In fact, the time spent by accelerated DSCOVR-SAGA should be even less than shown in Figures 9 and 10. Recall that other than the initialization with non-zero starting point, DSCOVR-SAGA is completely asynchronous and does not need any collective communication (see Section 7.2). However, in order to record the objective function for the purpose of plotting its progress, we added collective communication and computation to evaluate the objective value for every 10 passes over the data. For example, in Figure 10, such extra collective communications take about 160 seconds (about 15% of total time) for accelerated DSCOVR-SAGA, which can be further deducted from the horizontal time axis.

Finally, we conducted experiments on the `splice-site` dataset with 100 workers and 20 parameter servers. The results are shown in Figure 11. Here the dataset is again randomly shuffled and evenly distributed to the workers. The relative performance of different algorithms are similar to those for the other datasets.

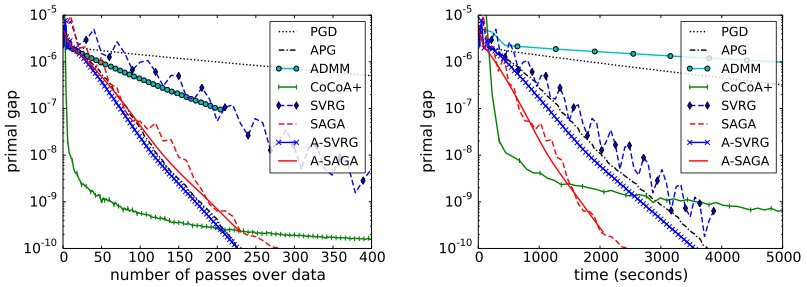

Figure 11: `splice-site`: logistic loss, $\lambda = 10^{-6}$, randomly shuffled, $m = 100$, $n = 150$, $h = 20$.

9. Conclusions and Discussions

We proposed a class of DSCOVR algorithms for asynchronous distributed optimization of large linear models with convex loss functions. They avoid dealing with delays and stale updates in an asynchronous, event-driven environment by exploiting simultaneous data and model parallelism. Compared with other first-order distributed algorithms, DSCOVR may require less amount of overall communication and computation, and especially much less or no synchronization. These conclusions are well supported by our computational experiments on a distributed computing cluster.

We note that there is still some gap between theory and practice. In our theoretical analysis, we assume that the primal and dual block indices in different iterations of DSCOVR are i.i.d. random variables, sampled sequentially with replacement. But the parallel implementations described in Section 7 impose some constraints on how they are generated. In particular, the parameter block to be updated next is randomly chosen from the set of blocks that are not being updated by any worker simultaneously, and the next worker available is event-driven, depending on the loads and processing power of different workers as well as random communication latency. These constraints violate the i.i.d. assumption, but our experiments show that they still lead to very competitive performance. Intuitively some of them can be potentially beneficial, reminiscent of the practical advantage of sampling without replacement over sampling with replacement in randomized coordinate descent methods (e.g., Shalev-Shwartz and Zhang, 2013). This is an interesting topic worth future study.

In our experiments, the parallel implementation of Nesterov's accelerated gradient method (APG) is very competitive on all the datasets we tried and for different regularization parameters used. In addition to the theoretical justifications in Arjevani and Shamir (2015) and Scaman et al. (2017), the adaptive line-search scheme turns out to be critical for its good performance in practice. The accelerated DSCOVR algorithms demonstrated comparable or better performance than APG in the experiments, but need careful tuning of the constants in their step size formula. On one hand, it supports our theoretical results that DSCOVR is capable of outperforming other first-order algorithms including APG, in terms of both communication and computation complexity (see Section 2.1). On the other hand, there are more to be done in order to realize the full potential of DSCOVR in practice. In particular, we plan to follow the ideas in Wang and Xiao (2017) to develop adaptive schemes that can automatically tune the step size parameters, as well as exploit strong convexity from data.

Appendix A. Proof of Theorem 1

We first prove two lemmas concerning the primal and dual proximal updates in Algorithm 2. Throughout this appendix, $\mathbf{E}_t[\cdot]$ denotes the conditional expectation taken with respect to the random indices j and l generated during the tth inner iteration in Algorithm 2, conditioned on all quantities available at the beginning of the tth iteration, including $w^{(t)}$ and $\alpha^{(t)}$. Whenever necessary, we also use the notation $j^{(t)}$ and $l^{(t)}$ to denote the random indices generated in the tth iteration.

Lemma 5 *For each $i = 1, \ldots, m$, let $u_i^{(t+1)} \in \mathbf{R}^{N_i}$ be a random variable and define*

$$\tilde{\alpha}_i^{(t+1)} = \mathbf{prox}_{\sigma_i f_i^*}(\alpha_i^{(t)} + \sigma_i u_i^{(t+1)}). \tag{58}$$

We choose an index j randomly from $\{1, \ldots, m\}$ with probability distribution $\{p_j\}_{j=1}^m$ and let

$$\alpha_i^{(t+1)} = \begin{cases} \tilde{\alpha}_i^{(t+1)} & \text{if } i = j, \\ \alpha_i^{(t)} & \text{otherwise.} \end{cases}$$

If each $u_i^{(t+1)}$ is independent of j and satisfies $\mathbf{E}_t[u_i^{(t+1)}] = X_{i:}w^{(t)}$ for $i = 1, \ldots, m$, then we have

$$\begin{aligned} & \sum_{i=1}^m \left(\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \gamma_i\right) - \gamma_i\right)\|\alpha_i^{(t)} - \alpha_i^\star\|^2 \\ \geq\ & \sum_{i=1}^m \frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \gamma_i\right)\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2] + \sum_{i=1}^m \frac{1}{p_i}\left(\frac{1}{2\sigma_i} - \frac{1}{a_i}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] \\ & - \sum_{i=1}^m \frac{a_i}{4}\mathbf{E}_t\left[\|u_i^{(t+1)} - X_{i:}w^{(t)}\|^2\right] + \left\langle w^{(t)} - w^\star,\, X^T(\alpha^\star - \alpha^{(t)})\right\rangle \\ & - \sum_{i=1}^m \frac{1}{p_i}\mathbf{E}_t\left[\left\langle \alpha_i^{(t+1)} - \alpha_i^{(t)},\, X_{i:}(w^{(t)} - w^\star)\right\rangle\right], \end{aligned} \tag{59}$$

where $(w^\star, \alpha^\star)$ is the saddle point of $L(w, \alpha)$ in (5), and the a_i's are arbitrary positive numbers.

Proof First, consider a fixed index $i \in \{1, \ldots, m\}$. The definition of $\tilde{\alpha}_i^{(t+1)}$ in (58) is equivalent to

$$\tilde{\alpha}_i^{(t+1)} = \operatorname*{arg\,min}_{\beta \in \mathbf{R}^{N_i}}\left\{ f_i^*(\beta) - \langle \beta, u_i^{(t+1)}\rangle + \frac{\|\beta - \alpha_i^{(t)}\|^2}{2\sigma_i}\right\}. \tag{60}$$

By assumption, $f_i^*(\beta)$ and $\frac{1}{2\sigma_i}\|\beta - \alpha_i^{(t)}\|^2$ are strongly convex with convexity parameters γ_i and $\frac{1}{\sigma_i}$ respectively. Therefore, the objective function in (60) is $(\frac{1}{\sigma_i} + \gamma_i)$-strongly convex, which implies

$$\begin{aligned} & \frac{\|\alpha_i^\star - \alpha_i^{(t)}\|^2}{2\sigma_i} - \langle \alpha_i^\star, u_i^{(t+1)}\rangle + f_i^*(\alpha_i^\star) \\ \geq\ & \frac{\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2}{2\sigma_i} - \langle \tilde{\alpha}_i^{(t+1)}, u_i^{(t+1)}\rangle + f_i^*(\tilde{\alpha}_i^{(t+1)}) + \left(\frac{1}{\sigma_i} + \gamma_i\right)\frac{\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^\star\|^2}{2}. \end{aligned} \tag{61}$$

In addition, since $(w^\star, \alpha^\star)$ is the saddle-point of $L(w, \alpha)$, the function $f_i^*(\alpha_i) - \langle \alpha_i, X_{i:}w^\star\rangle$ is γ_i-strongly convex in α_i and attains its minimum at $\alpha_i^\star$. Thus we have

$$f_i^*(\tilde{\alpha}_i^{(t+1)}) - \langle \tilde{\alpha}_i^{(t+1)},\, X_{i:}w^\star\rangle \geq f_i^*(\alpha_i^\star) - \langle \alpha_i^\star,\, X_{i:}w^\star\rangle + \frac{\gamma_i}{2}\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^\star\|^2.$$

Summing up the above two inequalities gives

$$\begin{aligned} \frac{\|\alpha_i^\star - \alpha_i^{(t)}\|^2}{2\sigma_i} &\geq \frac{\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2}{2\sigma_i} + \left(\frac{1}{2\sigma_i} + \gamma_i\right)\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^\star\|^2 + \left\langle \alpha_i^\star - \tilde{\alpha}_i^{(t+1)},\, u_i^{(t+1)} - X_{i:}w^\star\right\rangle \\ &= \frac{\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2}{2\sigma_i} + \left(\frac{1}{2\sigma_i} + \gamma_i\right)\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^\star\|^2 + \left\langle \alpha_i^\star - \tilde{\alpha}_i^{(t+1)},\, X_{i:}(w^{(t)} - w^\star)\right\rangle \\ &\quad + \left\langle \alpha_i^\star - \alpha_i^{(t)},\, u_i^{(t+1)} - X_{i:}w^{(t)}\right\rangle + \left\langle \alpha_i^{(t)} - \tilde{\alpha}_i^{(t+1)},\, u_i^{(t+1)} - X_{i:}w^{(t)}\right\rangle \\ &\geq \frac{\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2}{2\sigma_i} + \left(\frac{1}{2\sigma_i} + \gamma_i\right)\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^\star\|^2 + \left\langle \alpha_i^\star - \tilde{\alpha}_i^{(t+1)},\, X_{i:}(w^{(t)} - w^\star)\right\rangle \\ &\quad + \left\langle \alpha_i^\star - \alpha_i^{(t)},\, u_i^{(t+1)} - X_{i:}w^{(t)}\right\rangle - \frac{\|\alpha_i^{(t)} - \tilde{\alpha}_i^{(t+1)}\|^2}{a_i} - \frac{a_i\|u_i^{(t+1)} - X_{i:}w^{(t)}\|^2}{4}, \end{aligned}$$

where in the last step we used Young's inequality with a_i being an arbitrary positive number. Taking conditional expectation $\mathbf{E}_t$ on both sides of the above inequality, and using the assumption $\mathbf{E}_t[u_i^{(t+1)}] = X_{i:}w^{(t)}$, we have

$$\begin{aligned} \frac{\|\alpha_i^\star - \alpha_i^{(t)}\|^2}{2\sigma_i} \geq\ & \frac{\mathbf{E}_t[\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2]}{2\sigma_i} + \left(\frac{1}{2\sigma_i} + \gamma_i\right)\mathbf{E}_t[\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^\star\|^2] + \mathbf{E}_t\left[\left\langle \alpha_i^\star - \tilde{\alpha}_i^{(t+1)}, X_{i:}(w^{(t)} - w^\star)\right\rangle\right] \\ & - \frac{\mathbf{E}_t[\|\alpha_i^{(t)} - \tilde{\alpha}_i^{(t+1)}\|^2]}{a_i} - \frac{a_i\mathbf{E}_t[\|u_i^{(t+1)} - X_{i:}w^{(t)}\|^2]}{4}. \end{aligned} \tag{62}$$

Notice that each $\tilde{\alpha}_i^{(t+1)}$ depends on the random variable $u_i^{(t+1)}$ and is independent of the random index j. But $\alpha_i^{(t+1)}$ depends on both $u_i^{(t+1)}$ and j. Using the law of total expectation,

$$\mathbf{E}_t[\,\cdot\,] \;=\; \mathbf{P}(j = i)\mathbf{E}_t[\,\cdot\,|\,j = i] + \mathbf{P}(j \neq i)\mathbf{E}_t[\,\cdot\,|\,j \neq i],$$

we obtain

$$\mathbf{E}_t[\alpha_i^{(t+1)}] = p_i\mathbf{E}_t[\tilde{\alpha}_i^{(t+1)}] + (1 - p_i)\alpha_i^{(t)}, \tag{63}$$

$$\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] = p_i\mathbf{E}_t[\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2], \tag{64}$$

$$\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2] = p_i\mathbf{E}_t[\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^\star\|^2] + (1 - p_i)\mathbf{E}_t[\|\alpha_i^{(t)} - \alpha_i^\star\|^2]. \tag{65}$$

Next, using the equalities (63), (64) and (65), we can replace each term in (62) containing $\tilde{\alpha}_i^{(t+1)}$ with terms that contain only $\alpha_i^{(t)}$ and $\alpha_i^{(t+1)}$. By doing so and rearranging terms afterwards, we obtain

$$\begin{aligned}
&\left(\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)-\gamma_i\right)\|\alpha_i^{(t)}-\alpha_i^\star\|^2 \\
\geq\ & \frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2+\frac{1}{p_i}\left(\frac{1}{2\sigma_i}-\frac{1}{a_i}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^{(t)}\|^2 \\
& -\frac{a_i\mathbf{E}_t[\|u_i^{(t+1)}-X_{i:}w^{(t)}\|^2]}{4}+\left\langle\alpha_i^\star-\alpha_i^{(t)},\, X_{i:}(w^{(t)}-w^\star)\right\rangle \\
& -\mathbf{E}_t\left[\left\langle\frac{1}{p_i}(\alpha_i^{(t+1)}-\alpha_i^{(t)}),\, X_{i:}(w^{(t)}-w^\star)\right\rangle\right].
\end{aligned}$$

Summing up the above inequality for $i=1,\ldots,m$ gives the desired result in (59). ■

Lemma 6 *For each $k=1,\ldots,n$, let $v_k^{(t+1)}\in\mathbf{R}^{d_i}$ be a random variable and define*

$$\tilde{w}_k^{(t+1)}=\mathbf{prox}_{\tau_k g_k}(w_k^{(t)}-\tau_k v_k^{(t+1)}).$$

We choose an index l randomly from $\{1,\ldots,n\}$ with probability distribution $\{q_l\}_{l=1}^n$ and let

$$w_k^{(t+1)}=\begin{cases}\tilde{w}_k^{(t+1)} & \text{if } k=l,\\ w_k^{(t)} & \text{otherwise.}\end{cases}$$

If each $v_k^{(t+1)}$ is independent of l and satisfies $\mathbf{E}_t[v_k^{(t+1)}]=\frac{1}{m}(X_{:k})^T\alpha^{(t)}$, then we have

$$\begin{aligned}
&\sum_{k=1}^n\left(\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)-\lambda\right)\|w_k^{(t)}-w_k^\star\|^2 \\
\geq\ & \sum_{k=1}^n\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2]+\sum_{k=1}^n\frac{1}{q_k}\left(\frac{1}{2\tau_k}-\frac{1}{b_k}\right)\mathbf{E}_t[\|w_k^{(t+1)}-w_k^{(t)}\|^2] \\
& -\sum_{k=1}^n\frac{b_k}{4}\mathbf{E}_t\left[\left\|v_k^{(t+1)}-\frac{1}{m}(X_{:k})^T\alpha^{(t)}\right\|^2\right]+\frac{1}{m}\left\langle X(w^{(t)}-w^\star),\,\alpha^{(t)}-\alpha^\star\right\rangle \\
& +\sum_{k=1}^n\frac{1}{q_k}\mathbf{E}_t\left[\left\langle w_k^{(t+1)}-w_k^{(t)},\,\frac{1}{m}(X_{:k})^T(\alpha^{(t)}-\alpha^\star)\right\rangle\right],
\end{aligned}\tag{66}$$

where $(w^\star,\alpha^\star)$ is the saddle point of $L(w,\alpha)$ defined in (5)*, and the b_i's are arbitrary positive numbers.*

Lemma 6 is similar to Lemma 5 and can be proved using the same techniques. Based on these two lemmas, we can prove the following proposition.

Proposition 7 *The t-th iteration within the s-th stage of Algorithm 2 guarantees*

$$\begin{aligned}
&\sum_{i=1}^m\frac{1}{m}\left[\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)-\gamma_i+\sum_{k=1}^n\frac{3\tau_k\|X_{ik}\|^2}{mp_i}\right]\|\alpha_i^{(t)}-\alpha_i^\star\|^2+\sum_{i=1}^m\sum_{k=1}^n\frac{2\tau_k\|X_{ik}\|^2}{m^2p_i}\|\tilde{\alpha}_i^{(s)}-\alpha_i^\star\|^2 \\
&+\sum_{k=1}^n\left[\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)-\lambda+\sum_{i=1}^m\frac{3\sigma_i\|X_{ik}\|^2}{mq_k}\right]\|w_k^{(t)}-w_k^\star\|^2+\sum_{i=1}^m\sum_{k=1}^n\frac{2\sigma_i\|X_{ik}\|^2}{mq_k}\|\tilde{w}_k^{(s)}-w_k^\star\|^2 \\
\geq\ & \sum_{i=1}^m\frac{1}{mp_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2]+\sum_{k=1}^n\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2].
\end{aligned}\tag{67}$$

Proof Multiplying both sides of the inequality (59) by $\frac{1}{m}$ and adding to the inequality (66) gives

$$\begin{aligned}
&\sum_{i=1}^m\frac{1}{m}\left(\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)-\gamma_i\right)\|\alpha_i^{(t)}-\alpha_i^\star\|^2+\sum_{k=1}^n\left(\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)-\lambda\right)\|w_k^{(t)}-w_k^\star\|^2 \\
\geq\ & \sum_{i=1}^m\frac{1}{mp_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2]+\sum_{k=1}^n\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2] \\
& +\sum_{i=1}^m\frac{1}{mp_i}\left(\frac{1}{2\sigma_i}-\frac{1}{a_i}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^{(t)}\|^2]+\sum_{k=1}^n\frac{1}{q_k}\left(\frac{1}{2\tau_k}-\frac{1}{b_k}\right)\mathbf{E}_t[\|w_k^{(t+1)}-w_k^{(t)}\|^2] \\
& -\sum_{k=1}^n\frac{b_k}{4}\mathbf{E}_t\left[\left\|v_k^{(t+1)}-\frac{1}{m}(X_{:k})^T\alpha^{(t)}\right\|^2\right]+\sum_{k=1}^n\frac{1}{q_k}\mathbf{E}_t\left[\left\langle w_k^{(t+1)}-w_k^{(t)},\,\frac{1}{m}(X_{:k})^T(\alpha^{(t)}-\alpha^\star)\right\rangle\right] \\
& -\sum_{i=1}^m\frac{a_i}{4m}\mathbf{E}_t[\|u_i^{(t+1)}-X_{i:}w^{(t)}\|^2]-\sum_{i=1}^m\frac{1}{mp_i}\mathbf{E}_t\left[\left\langle\alpha_i^{(t+1)}-\alpha_i^{(t)},\,X_{i:}(w^{(t)}-w^\star)\right\rangle\right].
\end{aligned}\tag{68}$$

We notice that the terms containing $\frac{1}{m}\left\langle X(w^{(t)}-w^\star),\,\alpha^{(t)}-\alpha^\star\right\rangle$ from (59) and (66) canceled each other. Next we bound the last four terms on the right-hand side of (68).

As in Algorithm 2, for each $i=1,\ldots,m$, we define a random variable

$$u_i^{(t+1)}=\bar{u}_i^{(s)}-\frac{1}{q_l}X_{il}\bar{w}_l^{(s)}+\frac{1}{q_l}X_{il}w_l^{(t)},$$

which depends on the random index $l\in\{1,\ldots,n\}$. Taking expectation with respect to l yields

$$\mathbf{E}_t[u_i^{(t+1)}]=\sum_{k=1}^n q_k\left(\bar{u}_i^{(s)}-\frac{1}{q_k}X_{ik}\bar{w}_k^{(s)}+\frac{1}{q_k}X_{ik}w_k^{(t)}\right)=X_{i:}w^{(t)},\qquad i=1,2,\ldots,m.$$

Therefore $u_i^{(t+1)}$ satisfies the assumption in Lemma 5. In order to bound its variance, we notice that

$$\sum_{k=1}^n q_k\left(\frac{1}{q_k}X_{ik}\bar{w}_k^{(s)}-\frac{1}{q_k}X_{ik}w_k^{(t)}\right)=X_{i:}\bar{w}^{(s)}-X_{i:}w^{(t)}=\bar{u}_i^{(s)}-X_{i:}w^{(t)}.$$

Using the relation between variance and the second moment, we have

$$\begin{aligned}\mathbf{E}_t\left[\|u_i^{(t+1)} - X_{i:}w^{(t)}\|^2\right] &= \sum_{k=1}^n q_k\left\|\bar{u}_i^{(s)} - \frac{1}{q_k}X_{ik}\bar{w}_k^{(s)} + \frac{1}{q_k}X_{ik}w_k^{(t)} - X_{i:}w^{(t)}\right\|^2 \\ &= \sum_{k=1}^n \frac{1}{q_k}\left\|X_{ik}\bar{w}_k^{(s)} - X_{ik}w_k^{(t)}\right\|^2 - \|\bar{u}_i^{(s)} - X_{i:}w^{(t)}\|^2 \\ &\le \sum_{k=1}^n \frac{1}{q_k}\left\|X_{ik}(\bar{w}_k^{(s)} - w_k^{(t)})\right\|^2 \\ &\le \sum_{k=1}^n \frac{2\|X_{ik}\|^2}{q_k}\left(\|\bar{w}_k^{(s)} - w_k^\star\|^2 + \|w_k^{(t)} - w_k^\star\|^2\right). \end{aligned} \tag{69}$$

Similarly, for $k = 1, \ldots, n$, we have

$$\mathbf{E}_t[v_k^{(t+1)}] = \sum_{i=1}^m p_i\left(\bar{v}_k^{(s)} - \frac{1}{p_i}\frac{1}{m}(X_{ik})^T\bar{\alpha}_i^{(s)} + \frac{1}{p_i}\frac{1}{m}(X_{ik})^T\alpha_i^{(t)}\right) = \frac{1}{m}(X_{:k})^T\alpha^{(t)}.$$

Therefore $v_k^{(t+1)}$ satisfies the assumption in Lemma 6. Furthermore, we have

$$\begin{aligned}\mathbf{E}_t\left[\left\|v_k^{(t+1)} - \frac{1}{m}(X_{:k})^T\alpha^{(t)}\right\|^2\right] &= \sum_{i=1}^m p_i\left\|\bar{v}_k^{(s)} - \frac{1}{p_i}\frac{1}{m}(X_{ik})^T\bar{\alpha}_i^{(s)} + \frac{1}{p_i}\frac{1}{m}(X_{ik})^T\alpha_i^{(t)} - \frac{1}{m}(X_{:k})^T\alpha^{(t)}\right\|^2 \\ &= \sum_{i=1}^m \frac{1}{p_i}\left\|\frac{1}{m}(X_{ik})^T\bar{\alpha}_i^{(s)} - \frac{1}{m}(X_{ik})^T\alpha_i^{(t)}\right\|^2 - \left\|\bar{v}_k^{(s)} - \frac{1}{m}(X_{:k})^T\alpha^{(t)}\right\|^2 \\ &\le \sum_{i=1}^m \frac{1}{p_i}\left\|\frac{1}{m}(X_{ik})^T\left(\bar{\alpha}_i^{(s)} - \alpha_i^{(t)}\right)\right\|^2 \\ &\le \sum_{i=1}^m \frac{2\|X_{ik}\|^2}{p_i m^2}\left(\|\bar{\alpha}_i^{(s)} - \alpha_i^\star\|^2 + \|\alpha_i^{(t)} - \alpha_i^\star\|^2\right). \end{aligned} \tag{70}$$

Now we consider the two terms containing inner products in (68). Using the conditional expectation relation (63), we have

$$\begin{aligned}\mathbf{E}_t\left[-\left\langle\alpha_i^{(t+1)} - \alpha_i^{(t)},\, X_{i:}(w^{(t)} - w^\star)\right\rangle\right] &= p_i\mathbf{E}_t\left[-\left\langle\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)},\, X_{i:}(w^{(t)} - w^\star)\right\rangle\right] \\ &\ge p_i\mathbf{E}_t\left[-\frac{1}{c_i}\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2 - \frac{c_i}{4}\|X_{i:}(w^{(t)} - w^\star)\|^2\right] \\ &= -\frac{p_i}{c_i}\mathbf{E}_t[\|\tilde{\alpha}_i^{(t+1)} - \alpha_i^{(t)}\|^2] - \frac{c_i p_i}{4}\|X_{i:}(w^{(t)} - w^\star)\|^2 \\ &= -\frac{1}{c_i}\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] - \frac{c_i p_i}{4}\|X_{i:}(w^{(t)} - w^\star)\|^2, \end{aligned} \tag{71}$$

where we used Young's inequality with c_i being an arbitrary positive number, and the last equality used (64). We note that for any n vectors $z_1, \ldots, z_n \in \mathbf{R}^{N_i}$, it holds that

$$\left\|\sum_{k=1}^n z_k\right\|^2 \le \sum_{k=1}^n \frac{1}{q_k}\|z_k\|^2.$$

To see this, we let $z_{k,j}$ denote the jth component of z_k and use the Cauchy-Schwarz inequality:

$$\begin{aligned}\left\|\sum_{k=1}^n z_k\right\|^2 &= \sum_{j=1}^{N_i}\left(\sum_{k=1}^n z_{k,j}\right)^2 = \sum_{j=1}^{N_i}\left(\sum_{k=1}^n \frac{z_{k,j}}{\sqrt{q_k}}\sqrt{q_k}\right)^2 \\ &\le \sum_{j=1}^{N_i}\left(\sum_{k=1}^n\left(\frac{z_{k,j}}{\sqrt{q_k}}\right)^2\right)\left(\sum_{k=1}^n(\sqrt{q_k})^2\right) \\ &= \sum_{j=1}^{N_i}\left(\sum_{k=1}^n \frac{z_{k,j}^2}{q_k}\right) = \sum_{k=1}^n \frac{1}{q_k}\sum_{j=1}^{N_i} z_{k,j}^2 = \sum_{k=1}^n \frac{1}{q_k}\|z_k\|^2. \end{aligned}$$

Applying this inequality to the vector $X_{i:}(w^{(t)} - w^\star) = \sum_{k=1}^n X_{ik}(w_k^{(t)} - w_k^\star)$, we get

$$\|X_{i:}(w^{(t)} - w^\star)\|^2 \le \sum_{k=1}^n \frac{1}{q_k}\|X_{ik}(w_k^{(t)} - w_k^\star)\|^2.$$

Therefore we can continue the inequality (71), for each $i = 1, \ldots, m$, as

$$\begin{aligned}&\mathbf{E}_t\left[-\left\langle\alpha_i^{(t+1)} - \alpha_i^{(t)},\, X_{i:}(w^{(t)} - w^\star)\right\rangle\right] \\ \ge\ & -\frac{1}{c_i}\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] - \frac{c_i p_i}{4}\sum_{k=1}^n \frac{1}{q_k}\|X_{ik}(w_k^{(t)} - w_k^\star)\|^2 \\ \ge\ & -\frac{1}{c_i}\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] - \frac{c_i p_i}{4}\sum_{k=1}^n \frac{1}{q_k}\|X_{ik}\|^2\|w_k^{(t)} - w_k^\star\|^2. \end{aligned} \tag{72}$$

Using similarly arguments, we can obtain, for each $k = 1, \ldots, n$ and arbitrary $h_k > 0$,

$$\begin{aligned}&\mathbf{E}_t\left[\left\langle w_k^{(t+1)} - w_k^{(t)},\, \frac{1}{m}(X_{:k})^T(\alpha^{(t)} - \alpha^\star)\right\rangle\right] \\ \ge\ & -\frac{1}{h_k}\mathbf{E}_t[\|w_k^{(t+1)} - w_k^{(t)}\|^2] - \frac{h_k q_k}{4m^2}\sum_{i=1}^m \frac{1}{p_i}\|X_{ik}\|^2\|\alpha_i^{(t)} - \alpha_i^\star\|^2. \end{aligned} \tag{73}$$

Applying the bounds in (69), (70), (72) and (73) to (68) and rearranging terms, we have

$$\begin{aligned}&\sum_{i=1}^m \frac{1}{m}\left[\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \gamma_i\right) - \gamma_i + \sum_{k=1}^n \frac{b_k\|X_{ik}\|^2}{2mp_i} + \sum_{k=1}^n \frac{h_k\|X_{ik}\|^2}{4mp_i}\right]\|\alpha_i^{(t)} - \alpha_i^\star\|^2 \\ &+ \sum_{k=1}^n\left[\frac{1}{q_k}\left(\frac{1}{2\tau_k} + \lambda\right) - \lambda + \sum_{i=1}^m \frac{a_i\|X_{ik}\|^2}{2mq_k} + \sum_{i=1}^m \frac{c_i\|X_{ik}\|^2}{4mq_k}\right]\|w_k^{(t)} - w_k^\star\|^2 \\ &+ \sum_{i=1}^m\sum_{k=1}^n \frac{b_k\|X_{ik}\|^2}{2m^2p_i}\|\bar{\alpha}_i^{(s)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{a_i\|X_{ik}\|^2}{2mq_k}\|\bar{w}_k^{(s)} - w_k^\star\|^2 \\ \ge\ & \sum_{i=1}^m \frac{1}{mp_i}\left(\frac{1}{2\sigma_i} + \gamma_i\right)\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2] + \sum_{k=1}^n \frac{1}{q_k}\left(\frac{1}{2\tau_k} + \lambda\right)\mathbf{E}_t[\|w_k^{(t+1)} - w_k^\star\|^2] \\ &+ \sum_{i=1}^m \frac{1}{mp_i}\left(\frac{1}{2\sigma_i} - \frac{1}{a_i} - \frac{1}{c_i}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] \\ &+ \sum_{k=1}^n \frac{1}{q_k}\left(\frac{1}{2\tau_k} - \frac{1}{b_k} - \frac{1}{h_k}\right)\mathbf{E}_t[\|w_k^{(t+1)} - w_k^{(t)}\|^2]. \end{aligned}$$

The desired result (67) is obtained by choosing $a_i = c_i = 4\sigma_i$ and $b_k = h_k = 4\tau_k$. ■

Finally, we are ready to prove Theorem 1. Let $\theta \in (0,1)$ be a parameter to be determined later, and let Γ and η be two constants such that

$$\Gamma \geq \max_{i,k}\left\{\frac{1}{p_i}\left(1+\frac{3\|X_{ik}\|^2}{2\theta q_k\lambda\gamma_i}\right),\ \frac{1}{q_k}\left(1+\frac{3n\|X_{ik}\|^2}{2\theta m p_i\lambda\gamma_i}\right)\right\}, \tag{74}$$

$$\eta = 1-\frac{1-\theta}{\Gamma}. \tag{75}$$

It is easy to check that $\Gamma > 1$ and $\eta \in (0,1)$. By the choices of σ_i and τ_k in (23) and (24) respectively, we have

$$\frac{1}{p_i}\left(1+\frac{1}{2\sigma_i\gamma_i}\right) = \frac{1}{q_k}\left(1+\frac{1}{2\tau_k\lambda}\right) = \Gamma, \tag{76}$$

for all $i = 1,\ldots,m$ and $k = 1,\ldots,n$. Comparing the above equality with the definition of Γ in (74), we have

$$\frac{3\|X_{ik}\|^2}{2\theta q_k\lambda\gamma_i} \leq \frac{1}{2\sigma_i\gamma_i} \qquad \text{and} \qquad \frac{3n\|X_{ik}\|^2}{2\theta m p_i\lambda\gamma_i} \leq \frac{1}{2\tau_k\lambda},$$

which implies

$$\frac{3\sigma_i\|X_{ik}\|^2}{q_k} \leq \theta\lambda \qquad \text{and} \qquad \frac{3n\tau_k\|X_{ik}\|^2}{mp_i} \leq \theta\gamma_i,$$

for all $i = 1,\ldots,m$ and $k = 1,\ldots,n$. Therefore, we have

$$\sum_{k=1}^n \frac{3\tau_k\|X_{ik}\|^2}{mp_i} = \frac{1}{n}\sum_{k=1}^n \frac{3n\tau_k\|X_{ik}\|^2}{mp_i} \leq \frac{1}{n}\sum_{k=1}^n \theta\gamma_i = \theta\gamma_i, \qquad i = 1,\ldots,m, \tag{77}$$

$$\sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{mq_k} = \frac{1}{m}\sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{q_k} \leq \frac{1}{m}\sum_{i=1}^m \theta\lambda = \theta\lambda, \qquad k = 1,\ldots,n. \tag{78}$$

Now we consider the inequality (67), and examine the ratio between the coefficients of $\|\alpha_i^{(t)}-\alpha_i^\star\|^2$ and $\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2]$. Using (77) and (76), we have

$$\frac{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)-\gamma_i+\sum_{k=1}^n\frac{3\tau_k\|X_{ik}\|^2}{mp_i}}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)} \leq 1-\frac{(1-\theta)\gamma_i}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)} = 1-\frac{1-\theta}{\Gamma} = \eta. \tag{79}$$

Similarly, the ratio between the coefficients of $\|w_k^{(t)}-w_k^\star\|^2$ and $\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2]$ can be bounded using (78) and (76):

$$\frac{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)-\lambda+\sum_{i=1}^m\frac{3\sigma_i\|X_{ik}\|^2}{mq_k}}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)} \leq 1-\frac{(1-\theta)\lambda}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)} = 1-\frac{1-\theta}{\Gamma} = \eta. \tag{80}$$

In addition, the ratio between the coefficients of $\|\bar\alpha_i^{(s)}-\alpha_i^\star\|^2$ and $\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2]$ and that of $\|\bar w_k^{(s)}-w_k^\star\|^2$ and $\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2]$ can be bounded as

$$\frac{\sum_{k=1}^k\frac{2\tau_k\|X_{ik}\|^2}{mp_i}}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)} \leq \frac{(2/3)\theta\gamma_i}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)} = \frac{(2/3)\theta}{\Gamma} = \frac{2\theta(1-\eta)}{3(1-\theta)}, \tag{81}$$

$$\frac{\sum_{i=1}^m\frac{3\sigma_i\|X_{ik}\|^2}{mq_k}}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)} \leq \frac{(2/3)\theta\lambda}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)} = \frac{(2/3)\theta}{\Gamma} = \frac{2\theta(1-\eta)}{3(1-\theta)}. \tag{82}$$

Using (76) and the four inequalities (79), (80), (81) and (82), we conclude that the inequality (67) implies

$$\begin{aligned}
&\eta\sum_{i=1}^m\frac{\Gamma\gamma_i}{m}\|\alpha_i^{(t)}-\alpha_i^\star\|^2+\frac{2\theta(1-\eta)}{3(1-\theta)}\sum_{i=1}^m\frac{\Gamma\gamma_i}{m}\|\bar\alpha_i^{(s)}-\alpha_i^\star\|^2\\
&+\eta\sum_{k=1}^n\Gamma\lambda\|w_k^{(t)}-w_k^\star\|^2+\frac{2\theta(1-\eta)}{3(1-\theta)}\sum_{k=1}^n\Gamma\lambda\|\bar w_k^{(s)}-w_k^\star\|^2\\
\geq\ &\sum_{i=1}^m\frac{\Gamma\gamma_i}{m}\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2]+\sum_{k=1}^n\Gamma\lambda\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2].
\end{aligned}$$

Using the definite of $\Omega(\cdot)$ in (21), the inequality above is equivalent to

$$\begin{aligned}
&\eta\,\Omega(w^{(t)}-w^\star,\alpha^{(t)}-\alpha^\star)+\frac{2\theta(1-\eta)}{3(1-\theta)}\Omega(\bar w^{(s)}-w^\star,\bar\alpha^{(s)}-\alpha^\star)\\
\geq\ &\mathbf{E}_t\left[\Omega(w^{(t+1)}-w^\star,\alpha^{(t+1)}-\alpha^\star)\right].
\end{aligned} \tag{83}$$

To simplify further derivation, we define

$$\begin{aligned}
\Delta^{(t)} &= \mathbf{E}\left[\Omega(w^{(t)}-w^\star,\alpha^{(t)}-\alpha^\star)\right],\\
\bar\Delta^{(s)} &= \mathbf{E}\left[\Omega(\bar w^{(s)}-w^\star,\bar\alpha^{(s)}-\alpha^\star)\right],
\end{aligned}$$

where the expectation is taken with respect to all randomness in the sth stage, that is, the random variables $\{(j^{(0)},l^{(0)}),(j^{(1)},l^{(1)}),\ldots,(j^{(M-1)},l^{(M-1)})\}$. Then the inequality (83) implies

$$\frac{2\theta(1-\eta)}{3(1-\theta)}\bar\Delta^{(s)}+\eta\Delta^{(t)} \geq \Delta^{(t+1)}.$$

Dividing both sides of the above inequality by η^{t+1} gives

$$\frac{2\theta(1-\eta)}{3(1-\theta)}\frac{\bar\Delta^{(s)}}{\eta^{t+1}}+\frac{\Delta^{(t)}}{\eta^t} \geq \frac{\Delta^{(t+1)}}{\eta^{t+1}}.$$

Summing for $t = 0,1,,\ldots,M-1$ gives

$$\left(\frac{1}{\eta}+\frac{1}{\eta^2}+\cdots+\frac{1}{\eta^M}\right)\frac{2\theta(1-\eta)}{3(1-\theta)}\bar\Delta^{(s)}+\Delta^{(0)} \geq \frac{\Delta^{(T)}}{\eta^M},$$

which further leads to

$$(1-\eta^M)\frac{2\theta}{3(1-\theta)}\bar{\Delta}^{(s)} + \eta^M \Delta^{(0)} \geq \Delta^{(M)}.$$

Now choosing $\theta = 1/3$ and using the relation $\bar{\Delta}^{(s)} = \Delta^{(0)}$ for each stage, we obtain

$$\left(\frac{1}{3} + \frac{2}{3}\eta^M\right)\Delta^{(0)} \geq \Delta^{(M)}.$$

Therefore if we choose M large enough such that $\eta^M \leq \frac{1}{2}$, then

$$\Delta^{(M)} \leq \frac{2}{3}\Delta^{(0)}, \quad \text{or equivalently,} \quad \bar{\Delta}^{(s+1)} \leq \frac{2}{3}\bar{\Delta}^{(s)}.$$

The condition $\eta^M \leq \frac{1}{2}$ is equivalent to $M \geq \frac{\log(2)}{\log(1/\eta)}$, which can be guaranteed by

$$M \geq \frac{\log(2)}{1-\eta} = \frac{\log(2)}{1-\theta}\Gamma = \frac{3\log(2)}{2}\Gamma = \log(\sqrt{8})\Gamma.$$

To further simplify, it suffices to have $M \geq \log(3)\Gamma$. Finally, we notice that $\bar{\Delta}^{(s+1)} \leq (2/3)\bar{\Delta}^{(s)}$ implies $\bar{\Delta}^{(s)} \leq (2/3)^s\, \bar{\Delta}^{(0)}$, which is the desired result in Theorem 1.

A.1. Alternative bounds and step sizes

Alternatively, we can let Γ to satisfy

$$\Gamma \geq \max_{i,k}\left\{\frac{1}{p_i}\left(1 + \frac{3\|X_{:k}\|_F^2}{2\theta m q_k \lambda \gamma_i}\right),\ \frac{1}{q_k}\left(1 + \frac{3\|X_{i:}\|_F^2}{2\theta m p_i \lambda \gamma_i}\right)\right\}, \tag{84}$$

where $\|\cdot\|_F$ denotes the Frobenius norm of a matrix. Then by choosing σ_i and τ_k that satisfy (76), we have

$$\frac{3\sigma_i\|X_{:k}\|_F^2}{mq_k} \leq \theta\lambda \qquad \text{and} \qquad \frac{3\tau_k\|X_{i:}\|_F^2}{mp_i} \leq \theta\gamma_i,$$

We can bound the left-hand sides in (77) and (78) using Hölder's inequality, which results in

$$\sum_{k=1}^n \frac{3\tau_k\|X_{ik}\|^2}{mp_i} \leq \sum_{k=1}^n \frac{3\tau_k\|X_{ik}\|_F^2}{mp_i} \leq \frac{3\max_k\{\tau_k\}\|X_{i:}\|_F^2}{mp_i} \leq \theta\gamma_i, \qquad i = 1,\ldots,m, \tag{85}$$

$$\sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{mq_k} \leq \sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|_F^2}{mq_k} \leq \frac{3\max_i\{\sigma_i\}\|X_{:k}\|_F^2}{mq_k} \leq \theta\lambda, \qquad k = 1,\ldots,n. \tag{86}$$

The rest of the proof hold without any change. Setting $\theta = 1/3$ gives the condition on Γ in (26).

In Theorem 1 and the proof above, we choose Γ as a uniform bound over all combinations of (i,k) in order to obtain a uniform convergence rates on all blocks of the primal and dual variables $w_k^{(t)}$ and $\alpha_i^{(t)}$, so we have a simple conclusion as in (25). In practice, we can use different bounds on different blocks and choose step sizes to allow them to converge at different rates.

For example, we can choose the step sizes σ_i and τ_k such that

$$\begin{aligned}
\frac{1}{p_i}\left(1 + \frac{1}{2\sigma_i\gamma_i}\right) &= \max_k\left\{\frac{1}{p_i}\left(1 + \frac{3\|X_{:k}\|_F^2}{2\theta m q_k \lambda\gamma_i}\right)\right\}, \qquad i = 1,\ldots,m,\\
\frac{1}{q_k}\left(1 + \frac{1}{2\tau_k\lambda}\right) &= \max_i\left\{\frac{1}{q_k}\left(1 + \frac{3\|X_{i:}\|_F^2}{2\theta m p_i \lambda\gamma_i}\right)\right\}, \qquad k = 1,\ldots,n.
\end{aligned}$$

Then the inequalities (85) and (86) still hold, and we can still show linear convergence with a similar rate. In this case, the step sizes are chosen as

$$\begin{aligned}
\sigma_i &= \min_k\left\{\frac{\theta m q_k \lambda}{3\|X_{:k}\|_F^2}\right\}, \qquad i = 1,\ldots,m,\\
\tau_k &= \min_i\left\{\frac{\theta m p_i \gamma_i}{3\|X_{i:}\|_F^2}\right\}, \qquad k = 1,\ldots,n.
\end{aligned}$$

If we choose the probabilities to be proportional to the norms of the data blocks, i.e.,

$$p_i = \frac{\|X_{i:}\|_F^2}{\|X\|_F^2}, \qquad q_k = \frac{\|X_{:k}\|_F^2}{\|X\|_F^2},$$

then we have

$$\sigma_i = \frac{\theta m\lambda}{3\|X\|_F^2}, \qquad \tau_k = \frac{\theta m\gamma_i}{3\|X\|_F^2}.$$

If we further normalize the rows of X, and let R be the norm of each row, then (with $\theta = 1/3$)

$$\sigma_i = \frac{\theta\lambda}{3R^2}\frac{m}{N} = \frac{\lambda}{9R^2}\frac{m}{N}, \qquad \tau_k = \frac{\theta\gamma_i}{3R^2}\frac{m}{N} = \frac{\gamma_i}{9R^2}\frac{m}{N}.$$

For distributed ERM, we have $\gamma_i = \frac{N}{m}\gamma$, thus $\tau_k = \frac{\gamma}{9R^2}$ as in (29).

Appendix B. Proof of Theorem 2

Consider the following saddle-point problem with doubly separable structure:

$$\min_{w\in\mathbf{R}^D}\max_{\alpha\in\mathbf{R}^N}\left\{L(w,\alpha) \equiv \frac{1}{m}\sum_{i=1}^m\sum_{k=1}^n \alpha_i^T X_{ik} w_k - \frac{1}{m}\sum_{i=1}^m f_i^*(\alpha_i) + \sum_{k=1}^n g_k(w_k)\right\}. \tag{87}$$

Under Assumption 1, L has a unique saddle point $(w^\star, \alpha^\star)$. We define

$$\widetilde{P}_k(w_k) \equiv \frac{1}{m}(\alpha^\star)^T X_{:k} w_k + g_k(w_k) - \frac{1}{m}(\alpha^\star)^T X_{:k} w_k^\star - g_k(w_k^\star), \qquad k = 1,\ldots,n, \tag{88}$$

$$\widetilde{D}_i(\alpha_i) \equiv \frac{1}{m}\left(\alpha_i^T X_{i:} w^\star - f_i^*(\alpha_i) - (\alpha_i^\star)^T X_{i:} w^\star + f_i^*(\alpha_i^\star)\right), \qquad i = 1,\ldots,m. \tag{89}$$

We note that $w_k^\star$ is the minimizer of $\widetilde{P}_k$ with $\widetilde{P}_k(w_k^\star) = 0$ and $\alpha_i^\star$ is the maximizer of $\widetilde{D}_i$ with $\widetilde{D}_i(\alpha_i^\star) = 0$. Moreover, by the assumed strong convexity,

$$\widetilde{P}_k(w_k) \geq \frac{\lambda}{2}\|w_k - w_k^\star\|^2, \qquad \widetilde{D}_i(\alpha_i) \leq -\frac{\gamma_i}{2m}\|\alpha_i - \alpha_i^\star\|^2. \tag{90}$$

Moreover, we have the following lower bound for the duality gap $P(w) - D(\alpha)$:

$$\sum_{k=1}^{n} \widetilde{P}_k(w_k) - \sum_{i=1}^{m} \widetilde{D}_i(\alpha_i) \;=\; L(w, \alpha^\star) - L(w^\star, \alpha) \;\le\; P(w) - D(\alpha). \tag{91}$$

We can also use them to derive an upper bound for the duality gap, as in the following lemma.

Lemma 8 *Suppose Assumption 1 holds. Let $(w^\star, \alpha^\star)$ be the saddle-point of $L(w, \alpha)$ and define*

$$P(w) = \sup_{\alpha} L(w, \alpha), \qquad D(\alpha) = \inf_{w} L(w, \alpha).$$

Then we have

$$P(w) - D(\alpha) \;\le\; L(w, \alpha^\star) - L(w^\star, \alpha) + \Big(\frac{1}{m}\sum_{i=1}^{m} \frac{\|X_{i:}\|^2}{2\gamma_i}\Big)\|w - w^\star\|^2 + \frac{\|X\|^2}{2m^2\lambda}\|\alpha - \alpha^\star\|^2.$$

Proof By definition, the primal function can be written as $P(w) = F(w) + g(w)$, where

$$F(w) = \frac{1}{m}\sum_{i=1}^{m} f_i(X_{i:}w) = \frac{1}{m}\max_{\alpha}\Big\{\alpha^T X w - \sum_{i=1}^{m} f_i^*(\alpha_i)\Big\}.$$

From the optimality conditions satisfied by the saddle point $(w^\star, \alpha^\star)$, we have

$$\nabla F(w^\star) = \frac{1}{m} X^T \alpha^\star.$$

By assumption, $\nabla F(w)$ is Lipschitz continuous with smooth constant $\frac{1}{m}\sum_{i=1}^{m} \frac{\|X_{i:}\|^2}{\gamma_i}$, which implies

$$\begin{aligned}
F(w) \;&\le\; F(w^\star) + \langle \nabla F(w^\star), w - w^\star\rangle + \Big(\frac{1}{m}\sum_{i=1}^{m} \frac{\|X_{i:}\|^2}{2\gamma_i}\Big)\|w - w^\star\|^2 \\
&=\; \frac{1}{m}\Big((\alpha^\star)^T X w^\star - \sum_{i=1}^{m} f_i^*(\alpha_i^\star)\Big) + \frac{1}{m}(\alpha^\star)^T X (w - w^\star) + \Big(\frac{1}{m}\sum_{i=1}^{m} \frac{\|X_{i:}\|^2}{2\gamma_i}\Big)\|w - w^\star\|^2 \\
&=\; \frac{1}{m}\Big((\alpha^\star)^T X w - \sum_{i=1}^{m} f_i^*(\alpha_i^\star)\Big) + \Big(\frac{1}{m}\sum_{i=1}^{m} \frac{\|X_{i:}\|^2}{2\gamma_i}\Big)\|w - w^\star\|^2.
\end{aligned}$$

Therefore,

$$\begin{aligned}
P(w) \;&=\; F(w) + g(w) \\
&\le\; \frac{1}{m}(\alpha^\star)^T X w - \frac{1}{m}\sum_{i=1}^{m} f_i^*(\alpha_i^\star) + g(w) + \Big(\frac{1}{m}\sum_{i=1}^{m} \frac{\|X_{i:}\|^2}{2\gamma_i}\Big)\|w - w^\star\|^2 \\
&=\; L(w, \alpha^\star) + \Big(\frac{1}{m}\sum_{i=1}^{m} \frac{\|X_{i:}\|^2}{2\gamma_i}\Big)\|w - w^\star\|^2.
\end{aligned}$$

Using similar arguments, especially that $\nabla g^*(\alpha)$ has Lipschitz constant $\frac{\|X\|}{m^2\lambda}$, we can show that

$$D(\alpha) \;\ge\; L(w^\star, \alpha) - \frac{\|X\|^2}{2m^2\lambda}\|\alpha - \alpha^\star\|^2.$$

Combining the last two inequalities gives the desired result. ■

The rest of the proof follow similar steps as in the proof of Theorem 1. The next two lemmas are variants of Lemmas 5 and 6.

Lemma 9 *Under the same assumptions and setup in Lemma 5, we have*

$$\begin{aligned}
&\sum_{i=1}^{m}\left(\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \frac{\gamma_i}{2}\right) - \frac{\gamma_i}{2}\right)\|\alpha_i^{(t)} - \alpha_i^\star\|^2 - \sum_{i=1}^{m}\left(\frac{1}{p_i} - 1\right) m\widetilde{D}_i(\alpha_i^{(t)}) \\
\ge\;& \sum_{i=1}^{m}\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \frac{\gamma_i}{2}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2] + \sum_{i=1}^{m}\frac{1}{2p_i\sigma_i}\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] - \sum_{i=1}^{m}\frac{m}{p_i}\mathbf{E}_t\,[\widetilde{D}_i(\alpha_i^{(t+1)})] \\
&+ \left\langle w^{(t)} - w^\star,\, X^T(\alpha^\star - \alpha^{(t)})\right\rangle - \sum_{i=1}^{m}\frac{1}{p_i}\mathbf{E}_t\left[\left\langle \alpha_i^{(t+1)} - \alpha_i^{(t)},\, u_i^{(t+1)} - X_{i:}w^\star\right\rangle\right].
\end{aligned} \tag{92}$$

Proof We start by taking conditional expectation $\mathbf{E}_t$ on both sides of the inequality (61), and would like to replace every term containing $\tilde{\alpha}_i^{(t+1)}$ with terms that contain only $\alpha_i^{(t)}$ and $\alpha_i^{(t+1)}$. In addition to the relations in (63), (64) and (65), we also need

$$\mathbf{E}_t\,[f_i^*(\alpha_i^{(t+1)})] \;=\; p_i f_i^*(\tilde{\alpha}_i^{(t+1)}) + (1 - p_i) f_i^*(\alpha_i^{(t)}).$$

After the substitutions and rearranging terms, we have

$$\begin{aligned}
&\left(\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \frac{\gamma_i}{2}\right) - \frac{\gamma_i}{2}\right)\|\alpha_i^{(t)} - \alpha_i^\star\|^2 + \left(\frac{1}{p_i} - 1\right)(f_i^*(\alpha_i^{(t)}) - f_i^*(\alpha_i^\star)) \\
\ge\;& \frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \frac{\gamma_i}{2}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2] + \frac{1}{2p_i\sigma_i}\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] + \frac{1}{p_i}\mathbf{E}_t[(f_i^*(\alpha_i^{(t+1)}) - f_i^*(\alpha_i^\star))] \\
&\mathbf{E}_t\,[\langle \alpha_i^\star - \alpha_i^{(t)},\, u_i^{(t+1)}\rangle] - \frac{1}{p_i}\mathbf{E}_t\left[\left\langle \alpha_i^{(t+1)} - \alpha_i^{(t)},\, u_i^{(t+1)}\right\rangle\right].
\end{aligned}$$

Next, we use the assumption $\mathbf{E}_t\,[u_i^{(t+1)}] = X_{i:}w^{(t)}$ and the definition of $\widetilde{D}_i(\cdot)$ in (89) to obtain

$$\begin{aligned}
&\left(\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \frac{\gamma_i}{2}\right) - \frac{\gamma_i}{2}\right)\|\alpha_i^{(t)} - \alpha_i^\star\|^2 - \left(\frac{1}{p_i} - 1\right) m\widetilde{D}_i(\alpha_i^{(t)}) \\
\ge\;& \frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \frac{\gamma_i}{2}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2] + \frac{1}{2p_i\sigma_i}\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^{(t)}\|^2] - \frac{m}{p_i}\mathbf{E}_t\,[\widetilde{D}_i(\alpha_i^{(t+1)})] \\
&+ \left\langle \alpha_i^\star - \alpha_i^{(t)},\, X_{i:}(w^{(t)} - w^\star)\right\rangle - \frac{1}{p_i}\mathbf{E}_t\left[\left\langle \alpha_i^{(t+1)} - \alpha_i^{(t)},\, u_i^{(t+1)} - X_{i:}w^\star\right\rangle\right].
\end{aligned}$$

Summing up the above inequality for $i = 1, \ldots, m$ gives the desired result (92). ■

Lemma 10 *Under the same assumptions and setup in Lemma 6, we have*

$$\begin{aligned}
&\sum_{k=1}^{K}\left(\frac{1}{q_k}\left(\frac{1}{2\tau_k} + \frac{\lambda}{2}\right) - \frac{\lambda}{2}\right)\|w_k^{(t)} - w_k^\star\|^2 + \sum_{k=1}^{n}\left(\frac{1}{q_k} - 1\right)\widetilde{P}_k(w_k^{(t)}) \\
\ge\;& \sum_{k=1}^{n}\frac{1}{q_k}\left(\frac{1}{2\tau_k} + \frac{\lambda}{2}\right)\mathbf{E}_t[\|w_k^{(t+1)} - w_k^\star\|^2] + \sum_{k=1}^{n}\frac{1}{2q_k\tau_k}\mathbf{E}_t[\|w_k^{(t+1)} - w_k^{(t)}\|^2] + \sum_{k=1}^{n}\frac{1}{q_k}\mathbf{E}_t[\widetilde{P}_k(w_k^{(t+1)})] \\
&+ \frac{1}{m}\left\langle X(w^{(t)} - w^\star),\, \alpha^{(t)} - \alpha^\star\right\rangle + \sum_{k=1}^{n}\frac{1}{q_k}\mathbf{E}_t\left[\left\langle w_k^{(t+1)} - w_k^{(t)},\, v_k^{(t+1)} - \frac{1}{m}(X_{:k})^T\alpha^\star\right\rangle\right].
\end{aligned}$$

Based on Lemma 9 and Lemma 10, we can prove the following proposition. The proof is very similar to that of Proposition 7, thus we omit the details here.

Proposition 11 *The t-th iteration within the s-th stage of Algorithm 2 guarantees*

$$\begin{aligned}
&\sum_{k=1}^n \left(\frac{1}{q_k}-1\right)\widetilde{P}_k(w_k^{(t)}) - \sum_{i=1}^m \left(\frac{1}{p_i}-1\right)\widetilde{D}_i(\alpha_i^{(t)}) \\
&+\sum_{i=1}^m \frac{1}{m}\left[\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\frac{\gamma_i}{2}\right)-\frac{\gamma_i}{2}+\sum_{k=1}^n \frac{3\tau_k\|X_{ik}\|^2}{mp_i}\right]\|\alpha_i^{(t)}-\alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{2\tau_k\|X_{ik}\|^2}{m^2p_i}\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2 \\
&+\sum_{k=1}^n \left[\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\frac{\lambda}{2}\right)-\frac{\lambda}{2}+\sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{mq_k}\right]\|w_k^{(t)}-w_k^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{2\sigma_i\|X_{ik}\|^2}{mq_k}\|\bar{w}_k^{(s)}-w_k^\star\|^2 \\
\geq\ &\sum_{k=1}^n \frac{1}{q_k}\mathbf{E}_t[\widetilde{P}_k(w_k^{(t+1)})] - \sum_{i=1}^m \frac{1}{p_i}\mathbf{E}_t[\widetilde{D}_i(\alpha_i^{(t+1)})] \\
&+\sum_{i=1}^m \frac{1}{mp_i}\left(\frac{1}{2\sigma_i}+\frac{\gamma_i}{2}\right)\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2] + \sum_{k=1}^n \frac{1}{q_k}\left(\frac{1}{2\tau_k}+\frac{\lambda}{2}\right)\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2]. \qquad (93)
\end{aligned}$$

Now we proceed to prove Theorem 2. Let $\theta \in (0,1)$ be a parameter to be determined later, and let Γ and η be two constants such that

$$\Gamma \geq \max_{i,k}\left\{\frac{1}{p_i}\left(1+\frac{6\Lambda}{\theta q_k\lambda\gamma_i}\right),\ \frac{1}{q_k}\left(1+\frac{6n\Lambda}{\theta p_i m\lambda\gamma_i}\right)\right\}, \qquad (94)$$

$$\eta = 1-\frac{1-\theta}{\Gamma}. \qquad (95)$$

It is easy to check that $\Gamma > 1$ and $\eta \in (0,1)$. The choices of σ_i and τ_k in (32) and (33) satisfy

$$\frac{1}{p_i}\left(\frac{1}{2}+\frac{1}{2\sigma_i\gamma_i}\right) = \frac{\Gamma}{2}, \qquad i=1,\ldots,m, \qquad (96)$$

$$\frac{1}{q_k}\left(\frac{1}{2}+\frac{1}{2\tau_k\lambda}\right) = \frac{\Gamma}{2}, \qquad k=1,\ldots,n. \qquad (97)$$

Comparing them with the definition of Γ in (94), and using the assumption $\Lambda \geq \|X_{ik}\|_F^2 \geq \|X_{ik}\|^2$, we get

$$\frac{6\|X_{ik}\|^2}{\theta q_k\lambda\gamma_i} \leq \frac{6\Lambda}{\theta q_k\lambda\gamma_i} \leq \frac{1}{\sigma_i\gamma_i} \qquad \text{and} \qquad \frac{6n\|X_{ik}\|^2}{\theta p_i m\lambda\gamma_i} \leq \frac{6n\Lambda}{\theta p_i m\lambda\gamma_i} \leq \frac{1}{\tau_k\lambda},$$

which implies

$$\frac{3\sigma_i\|X_{ik}\|^2}{q_k} \leq \theta\frac{\lambda}{2} \qquad \text{and} \qquad \frac{3n\tau_k\|X_{ik}\|^2}{mp_i} \leq \theta\frac{\gamma_i}{2},$$

for all $i=1,\ldots,m$ and $k=1,\ldots,n$. Therefore, we have

$$\sum_{k=1}^n \frac{3\tau_k\|X_{ik}\|^2}{mp_i} = \frac{1}{n}\sum_{k=1}^n \frac{3n\tau_k\|X_{ik}\|^2}{mp_i} \leq \theta\frac{\gamma_i}{2}, \qquad i=1,\ldots,m, \qquad (98)$$

$$\sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{mq_k} = \frac{1}{m}\sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{q_k} \leq \theta\frac{\lambda}{2}, \qquad k=1,\ldots,n. \qquad (99)$$

Now we consider the inequality (93), and examine the ratio between the coefficients of $\|\alpha_i^{(t)}-\alpha_i^\star\|^2$ and $\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2]$. Using (98) and (96), we have

$$\frac{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\frac{\gamma_i}{2}\right)-\frac{\gamma_i}{2}+\sum_{k=1}^n \frac{3\tau_k\|X_{ik}\|^2}{mp_i}}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\frac{\gamma_i}{2}\right)} \leq 1-\frac{(1-\theta)\frac{\gamma_i}{2}}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\frac{\gamma_i}{2}\right)} = 1-\frac{1-\theta}{\Gamma} = \eta. \qquad (100)$$

Similarly, the ratio between the coefficients of $\|w_k^{(t)}-w_k^\star\|^2$ and $\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2]$ can be bounded using (99) and (97):

$$\frac{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\frac{\lambda}{2}\right)-\frac{\lambda}{2}+\sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{mq_k}}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\frac{\lambda}{2}\right)} \leq 1-\frac{(1-\theta)\frac{\lambda}{2}}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\frac{\lambda}{2}\right)} = 1-\frac{1-\theta}{\Gamma} = \eta. \qquad (101)$$

In addition, the ratio between the coefficients of $\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2$ and $\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2]$ and that of $\|\bar{w}_k^{(s)}-w_k^\star\|^2$ and $\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2]$ can be bounded as

$$\frac{\sum_{k=1}^n \frac{2\tau_k\|X_{ik}\|^2}{mp_i}}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\frac{\gamma_i}{2}\right)} \leq \frac{(2/3)\theta\frac{\gamma_i}{2}}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\frac{\gamma_i}{2}\right)} = \frac{(2/3)\theta}{\Gamma} = \frac{2\theta(1-\eta)}{3(1-\theta)}, \qquad (102)$$

$$\frac{\sum_{i=1}^m \frac{2\sigma_i\|X_{ik}\|^2}{mq_k}}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\frac{\lambda}{2}\right)} \leq \frac{(2/3)\theta\frac{\lambda}{2}}{\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\frac{\lambda}{2}\right)} = \frac{(2/3)\theta}{\Gamma} = \frac{2\theta(1-\eta)}{3(1-\theta)}. \qquad (103)$$

Also, the ratios between the coefficients of $\widetilde{P}_k(w_k^{(t)})$ and $\mathbf{E}_t[\widetilde{P}_k(w_k^{(t+1)})]$ is $1-q_k$, and that of $\widetilde{D}_k(\alpha_i^{(t)})$ and $\mathbf{E}_t[\widetilde{D}_i(\alpha_i^{(t+1)})]$ is $1-p_i$. From the definition of Γ and η in (94) and (95), we have

$$1-p_i \leq \eta \quad \text{for} \quad i=1,\ldots,m, \quad \text{and} \quad 1-q_k \leq \eta \quad \text{for} \quad k=1,\ldots,n. \qquad (104)$$

Using the relations in (96) and (97) and the inequalities (100), (101), (102), (103) and (104), we conclude that the inequality (93) implies

$$\begin{aligned}
&\eta\left(\sum_{k=1}^n \frac{1}{q_k}\widetilde{P}_k(w_k^{(t)}) - \sum_{i=1}^m \frac{1}{p_i}\widetilde{D}_i(\alpha_i^{(t)})\right) + \eta\left(\sum_{i=1}^m \frac{\Gamma\gamma_i}{2m}\|\alpha_i^{(t)}-\alpha_i^\star\|^2 + \sum_{k=1}^n \frac{\Gamma\lambda}{2}\|w_k^{(t)}-w_k^\star\|^2\right) \\
&+\frac{2\theta(1-\eta)}{3(1-\theta)}\left(\sum_{i=1}^m \frac{\Gamma\gamma_i}{2m}\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2 \sum_{k=1}^n \frac{\Gamma\lambda}{2}\|\bar{w}_k^{(s)}-w_k^\star\|^2\right) \\
\geq\ &\sum_{k=1}^n \frac{1}{q_k}\mathbf{E}_t[\widetilde{P}_k(w_k^{(t+1)})] - \sum_{i=1}^m \frac{1}{p_i}\mathbf{E}_t[\widetilde{D}_i(\alpha_i^{(t+1)})] \\
&+\sum_{i=1}^m \frac{\Gamma\gamma_i}{2m}\mathbf{E}_t[\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2] + \sum_{k=1}^n \frac{\Gamma\lambda}{2}\mathbf{E}_t[\|w_k^{(t+1)}-w_k^\star\|^2],
\end{aligned}$$

which is equivalent to

$$\eta\left(\sum_{k=1}^{n}\frac{1}{q_k}\widetilde{P}_k(w_k^{(t)})-\sum_{i=1}^{m}\frac{1}{p_i}\widetilde{D}_i(\alpha_i^{(t)})+\frac{\Gamma\lambda}{2}\|w^{(t)}-w^\star\|^2+\frac{1}{m}\sum_{i=1}^{m}\frac{\Gamma\gamma_i}{2}\|\alpha_i^{(t)}-\alpha_i^\star\|^2\right)$$
$$+\frac{2\theta(1-\eta)}{3(1-\theta)}\left(\frac{\Gamma\lambda}{2}\|\bar{w}^{(s)}-w^\star\|^2+\frac{1}{m}\sum_{i=1}^{m}\frac{\Gamma\gamma_i}{2}\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2\right) \tag{105}$$
$$\geq \mathbf{E}_t\left[\sum_{k=1}^{n}\frac{1}{q_k}\widetilde{P}_k(w_k^{(t+1)})-\sum_{i=1}^{m}\frac{1}{p_i}\widetilde{D}_i(\alpha_i^{(t+1)})+\frac{\Gamma\lambda}{2}\|w^{(t+1)}-w^\star\|^2+\frac{1}{m}\sum_{i=1}^{m}\frac{\Gamma\gamma_i}{2}\|\alpha_i^{(t+1)}-\alpha_i^\star\|^2\right].$$

To simplify further derivation, we define

$$\Delta^{(t)} = \sum_{k=1}^{n}\frac{1}{q_k}\widetilde{P}_k(w_k^{(t)})-\sum_{i=1}^{m}\frac{1}{p_i}\widetilde{D}_i(\alpha_i^{(t)})+\frac{\Gamma\lambda}{2}\|w^{(t)}-w^\star\|^2+\frac{1}{m}\sum_{i=1}^{m}\frac{\Gamma\gamma_i}{2}\|\alpha_i^{(t)}-\alpha_i^\star\|^2,$$
$$\bar{\Delta}^{(s)} = \sum_{k=1}^{n}\frac{1}{q_k}\widetilde{P}_k(\bar{w}_k^{(s)})-\sum_{i=1}^{m}\frac{1}{p_i}\widetilde{D}_i(\bar{\alpha}_i^{(s)})+\frac{\Gamma\lambda}{2}\|\bar{w}^{(s)}-w^\star\|^2+\frac{1}{m}\sum_{i=1}^{m}\frac{\Gamma\gamma_i}{2}\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2.$$

Using the facts that $\widetilde{P}_k(\bar{w}_k^{(s)})\geq 0$ and $-\widetilde{D}_i(\bar{\alpha}_i^{(s)})\geq 0$, the inequality (105) implies

$$\frac{2\theta(1-\eta)}{3(1-\theta)}\bar{\Delta}^{(s)}+\eta\mathbf{E}[\Delta^{(t)}] \;\geq\; \mathbf{E}[\Delta^{(t+1)}],$$

where the expectation is taken with respect to all randomness in the s-th stage, that is, the random variables $\{(j^{(0)},l^{(0)}),(j^{(1)},l^{(1)}),\ldots,(j^{(M-1)},l^{(M-1)})\}$. Next we choose $\theta=1/3$ and follow the same arguments as in the proof for Theorem 1 to obtain $\mathbf{E}[\Delta^{(M)}]\leq\frac{2}{3}\Delta^{(0)}$, provided $M\geq\log(3)\Gamma$. This further implies

$$\mathbf{E}[\bar{\Delta}^{(s)}] \;\leq\; \left(\frac{2}{3}\right)^s\bar{\Delta}^{(0)}. \tag{106}$$

By definition of Γ in (94), we have $\frac{1}{q_k}<\Gamma$ for $k=1,\ldots,n$ and $\frac{1}{p_i}<\Gamma$ for $i=1,\ldots,m$. Therefore,

$$\bar{\Delta}^{(0)} \leq \Gamma\left(\sum_{k=1}^{n}\widetilde{P}_k(\bar{w}_k^{(0)})-\sum_{i=1}^{m}\widetilde{D}_i(\bar{\alpha}_i^{(0)})+\frac{\lambda}{2}\|\bar{w}^{(0)}-w^\star\|^2+\frac{1}{m}\sum_{i=1}^{m}\frac{\gamma_i}{2}\|\bar{\alpha}_i^{(0)}-\alpha_i^\star\|^2\right)$$
$$\leq 2\Gamma\left(\sum_{k=1}^{n}\widetilde{P}_k(\bar{w}_k^{(0)})-\sum_{i=1}^{m}\widetilde{D}_i(\bar{\alpha}_i^{(0)})\right)$$
$$\leq 2\Gamma\left(P(\bar{w}^{(0)})-D(\bar{\alpha}^{(0)})\right), \tag{107}$$

where the second inequality used (90) and the last inequality used (91). On the other hand, we can also lower bound $\bar{\Delta}^{(s)}$ using $P(\bar{w}^{(s)})-D(\bar{\alpha}^{(s)})$. To this end, we notice that with $\theta=1/3$,

$$\Gamma \;\geq\; \max_{i,k}\left\{\frac{1}{p_i}\left(1+\frac{18\Lambda}{q_k\lambda\gamma_i}\right),\;\frac{1}{q_k}\left(1+\frac{18n\Lambda}{p_i m\lambda\gamma_i}\right)\right\} \;\geq\; \max_{i,k}\left\{\frac{18\Lambda}{p_iq_k\lambda\gamma_i},\;\frac{18n\Lambda}{p_iq_m\lambda\gamma_i}\right\}.$$

Noticing that $\max_k\{1/q_k\}\geq n$ and $n\Lambda\geq\|X_{i:}\|_F^2$ for all $i=1,\ldots,m$, we have

$$\Gamma\geq\max_{i,k}\left\{\frac{18\Lambda}{q_k\lambda\gamma_i}\right\}\geq\max_i\left\{\frac{18n\Lambda}{\lambda\gamma_i}\right\}\geq\frac{18}{m\lambda}\sum_{i=1}^{m}\frac{n\Lambda}{\gamma_i}\geq\frac{18}{m\lambda}\sum_{i=1}^{m}\frac{\|X_{i:}\|_F^2}{\gamma_i}\geq\frac{18}{m\lambda}\sum_{i=1}^{m}\frac{\|X_{i:}\|^2}{\gamma_i}.$$

Moreover, since $\Gamma\geq\max_k\left\{\frac{18\Lambda}{p_iq_k\lambda\gamma_i}\right\}\geq\frac{18n\Lambda}{p_i\lambda\gamma_i}$ for all i and $mn\Lambda\geq\|X\|_F^2$, we have

$$\frac{1}{m}\sum_{i=1}^{m}\Gamma\gamma_i\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2 \geq \frac{1}{m}\sum_{i=1}^{m}\frac{18n\Lambda}{p_i\lambda\gamma_i}\gamma_i\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2=\frac{18mn\Lambda}{m^2\lambda}\sum_{i=1}^{m}\frac{\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2}{p_i}$$
$$\geq \frac{18\|X\|_F^2}{m^2\lambda}\Big(\sum_{i=1}^{m}\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|\Big)^2$$
$$\geq \frac{18\|X\|^2}{m^2\lambda}\sum_{i=1}^{m}\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2=\frac{18\|X\|^2}{m^2\lambda}\|\bar{\alpha}^{(s)}-\alpha^\star\|^2.$$

Therefore, from the definition of $\bar{\Delta}^{(s)}$,

$$\bar{\Delta}^{(s)} = \sum_{k=1}^{n}\frac{1}{q_k}\widetilde{P}_k(\bar{w}_k^{(s)})-\sum_{i=1}^{m}\frac{1}{p_i}\widetilde{D}_i(\bar{\alpha}_i^{(s)})+\frac{\Gamma\lambda}{2}\|\bar{w}^{(s)}-w^\star\|^2+\frac{1}{m}\sum_{i=1}^{m}\frac{\Gamma\gamma_i}{2}\|\bar{\alpha}_i^{(s)}-\alpha_i^\star\|^2$$
$$\geq \sum_{k=1}^{n}\widetilde{P}_k(\bar{w}_k^{(s)})-\sum_{i=1}^{m}\widetilde{D}_i(\bar{\alpha}_i^{(s)})+\Big(\frac{18}{m}\sum_{i=1}^{m}\frac{\|X_{i:}\|^2}{\gamma_i}\Big)\|\bar{w}^{(s)}-w^\star\|^2+\frac{18\|X\|^2}{m^2\lambda}\|\bar{\alpha}^{(s)}-\alpha^\star\|^2$$
$$= L(\bar{w}^{(s)},\alpha^\star)-L(w^\star,\bar{\alpha}^{(s)})+\Big(\frac{18}{m}\sum_{i=1}^{m}\frac{\|X_{i:}\|^2}{\gamma_i}\Big)\|\bar{w}^{(s)}-w^\star\|^2+\frac{18\|X\|^2}{m^2\lambda}\|\bar{\alpha}^{(s)}-\alpha^\star\|^2$$
$$\geq P(\bar{w}^{(s)})-D(\bar{\alpha}^{(s)}), \tag{108}$$

where the last inequality is due to Lemma 8. Combining (106), (107) and (108) gives the result:

$$\mathbf{E}\left[P(\bar{w}^{(s)})-D(\bar{\alpha}^{(s)})\right] \;\leq\; \left(\frac{2}{3}\right)^s 2\Gamma\left(P(\bar{w}^{(0)})-D(\bar{\alpha}^{(0)})\right).$$

Appendix C. Proof of Theorem 3

To facilitate the analysis of DSCOVR-SAGA in Algorithm 3, we define two sequences of matrices recursively. The first is $\{W^{(t)}\}_{t\geq 0}$, where each $W^{(t)}\in\mathbf{R}^{m\times d}$. They are partitioned into $m\times n$ blocks, and we denote each block as $W_{ik}^{(t)}\in\mathbf{R}^{1\times d_k}$. The recursive updates for $W^{(t)}$ are as follows:

$$W^{(0)} = \mathbf{1}_m\otimes(w^{(0)})^T,$$
$$W_{ik}^{(t+1)} = \begin{cases}(w_l^{(t)})^T & \text{if } i=j \text{ and } k=l,\\ W_{ik}^{(t)} & \text{otherwise,}\end{cases} \qquad t=0,1,2,\ldots, \tag{109}$$

where $\mathbf{1}_m$ denotes the vector of all ones in $\mathbf{R}^m$, and $\otimes$ denotes the Kronecker product of two matrices. The second sequence is $\{A^{(t)}\}_{t\geq 0}$, where each $A^{(t)}\in\mathbf{R}^{N\times n}$. They are partitioned into $m\times n$ blocks, and we denote each block as $A_{ik}^{(t)}\in\mathbf{R}^{N_i\times 1}$. The recursive updates for $A^{(t)}$ are as follows:

$$A^{(0)} = \alpha^{(0)}\otimes\mathbf{1}_n^T,$$
$$A_{ik}^{(t+1)} = \begin{cases}\alpha_j^{(t)} & \text{if } i=j \text{ and } k=l,\\ A_{ik}^{(t)} & \text{otherwise,}\end{cases} \qquad t=0,1,2,\ldots. \tag{110}$$

The matrices $W^{(t)}$ and $A^{(t)}$ consist of most recent values of the primal and dual block coordinates, updated at different times, up to time t.

Notice that in Algorithm 3, the matrices $U^{(t)} \in \mathbf{R}^{N\times n}$ follow the same partitioning as the matrices $A^{(t)}$, and the matrices $V^{(t)} \in \mathbf{R}^{m\times d}$ follow the same partitioning as the matrices $W^{(t)}$. According to the updates of $U^{(t)}$, $V^{(t)}$, $\bar{u}^{(t)}$ and $\bar{v}^{(t)}$ in Algorithm 3, we have for each $t \geq 0$,

$$\begin{aligned} U_{ik}^{(t)} &= X_{ik}(W_{ik}^{(t)})^T, \quad i = 1,\ldots,m, \quad k = 1,\ldots,n, \\ V_{ik}^{(t)} &= \frac{1}{m}(A_{ik}^{(t)})^T X_{ik}, \quad i = 1,\ldots,m, \quad k = 1,\ldots,n. \end{aligned}$$

Proposition 12 *Suppose Assumption 1 holds. The t-th iteration of Algorithm 3 guarantees*

$$\begin{aligned} &\sum_{i=1}^m \frac{1}{m}\left[\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right) - \gamma_i + \sum_{k=1}^n \frac{3\tau_k\|X_{ik}\|^2}{mp_i}\right]\|\alpha_i^{(t)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{2\tau_k\|X_{ik}\|^2}{m^2p_i}\|A_{ik}^{(t)} - \alpha_i^\star\|^2 \\ &+ \sum_{k=1}^n\left[\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right) - \lambda + \sum_{i=1}^m \frac{3\sigma_i\|X_{ik}\|^2}{mq_k}\right]\|w_k^{(t)} - w_k^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{2\sigma_i\|X_{ik}\|^2}{mq_k}\|(W_{ik}^{(t)})^T - w_k^\star\|^2 \\ \geq\ & \sum_{i=1}^m \frac{1}{mp_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)\mathbf{E}_t\left[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2\right] + \sum_{k=1}^n \frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)\mathbf{E}_t\left[\|w_k^{(t+1)} - w_k^\star\|^2\right] \end{aligned} \tag{111}$$

Proof The main differences between Algorithm 2 and Algorithm 3 are the definitions of $u_j^{(t+1)}$ and $v_l^{(t+1)}$. We start with the inequality (68) and revisit the bounds for the following two quantities:

$$\mathbf{E}_t\left[\|u_i^{(t+1)} - X_{i:}w^{(t)}\|^2\right] \qquad \text{and} \qquad \mathbf{E}_t\left[\left\|v_k^{(t+1)} - \frac{1}{m}(X_{:k})^T\alpha^{(t)}\right\|^2\right].$$

For Algorithm 3, we have

$$\begin{aligned} u_i^{(t+1)} &= \bar{u}_i^{(t)} - \frac{1}{q_l}U_{il}^{(t)} + \frac{1}{q_l}X_{il}w_l^{(t)}, \qquad i = 1,\ldots,m, \\ v_k^{(t+1)} &= \bar{v}_k^{(t)} - \frac{1}{p_j}(V_{jk}^{(t)})^T + \frac{1}{p_j}\frac{1}{m}(X_{jk})^T\alpha_j^{(t)}, \qquad k = 1,\ldots,n. \end{aligned}$$

We can apply the reasoning in (39) and (40) to every block coordinate and obtain

$$\begin{aligned} \mathbf{E}_t\left[u_i^{(t+1)}\right] &= X_{i:}w^{(t)}, \qquad i = 1,\ldots,m, \\ \mathbf{E}_t\left[v_k^{(t+1)}\right] &= \frac{1}{m}(X_{:k})^T\alpha^{(t)}, \qquad k = 1,\ldots,n. \end{aligned}$$

Therefore they satisfy the assumptions in Lemma 5 and Lemma 6, respectively. Moreover, following similar arguments as in (69) and (70), we have

$$\begin{aligned} \mathbf{E}_t\left[\|u_i^{(t+1)} - X_{i:}w^{(t)}\|^2\right] &\leq \sum_{k=1}^n \frac{2\|X_{ik}\|^2}{q_k}\left(\left\|(W_{ik}^{(t)})^T - w_k^\star\right\|^2 + \|w_k^{(t)} - w_k^\star\|^2\right), \\ \mathbf{E}_t\left[\left\|v_k^{(t+1)} - \frac{1}{m}(X_{:k})^T\alpha^{(t)}\right\|^2\right] &\leq \sum_{i=1}^m \frac{2\|X_{ik}\|^2}{m^2p_i}\left(\left\|(A_{ik}^{(t)})^T - \alpha_i^\star\right\|^2 + \|\alpha_i^{(t)} - \alpha_i^\star\|^2\right). \end{aligned}$$

The rest of the proof are the same as in the proof of Proposition 7. ■

Now we are ready to prove Theorem 3. By definition of $W^{(t)}$ in (109) and $A^{(t)}$ in (110), we have

$$\begin{aligned} \mathbf{E}_t\left[\|(W_{ik}^{(t+1)})^T - w_k^\star\|^2\right] &= p_iq_k\|w_k^{(t)} - w_k^\star\|^2 + (1-p_iq_k)\|(W_{ik}^{(t)})^T - w_k^\star\|^2, \qquad (112) \\ \mathbf{E}_t\left[\|A_{ik}^{(t+1)} - \alpha_i^\star\|^2\right] &= p_iq_k\|\alpha_i^{(t)} - \alpha_i^\star\|^2 + (1-p_iq_k)\|A_{ik}^{(t)} - \alpha_i^\star\|^2. \qquad (113) \end{aligned}$$

For all $i = 1,\ldots,m$ and $k = 1,\ldots,n$, let

$$\xi_{ik} = \frac{3\sigma_i\|X_{ik}\|^2}{mp_iq_k^2} \qquad \text{and} \qquad \zeta_{ik} = \frac{3\tau_k\|X_{ik}\|^2}{m^2p_i^2q_k}. \tag{114}$$

We multiply (112) by ξ_{ik} and (113) by ζ_{ik} and add them to (111) to obtain

$$\begin{aligned} &\sum_{i=1}^m \frac{1}{m}\left[\frac{1}{p_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right) - \gamma_i + \sum_{k=1}^n \frac{6\tau_k\|X_{ik}\|^2}{mp_i}\right]\|\alpha_i^{(t)} - \alpha_i^\star\|^2 \\ &+ \sum_{k=1}^n\left[\frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right) - \lambda + \sum_{i=1}^m \frac{6\sigma_i\|X_{ik}\|^2}{mq_k}\right]\|w_k^{(t)} - w_k^\star\|^2 \\ &+ \sum_{i=1}^m\sum_{k=1}^n\left(1-\frac{1}{3}p_iq_k\right)\zeta_{ik}\|A_{ik}^{(t)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n\left(1-\frac{1}{3}p_iq_k\right)\xi_{ik}\|(W_{ik}^{(t)})^T - w_k^\star\|^2 \\ \geq\ & \sum_{i=1}^m \frac{1}{mp_i}\left(\frac{1}{2\sigma_i}+\gamma_i\right)\mathbf{E}_t\left[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2\right] + \sum_{k=1}^n \frac{1}{q_k}\left(\frac{1}{2\tau_k}+\lambda\right)\mathbf{E}_t\left[\|w_k^{(t+1)} - w_k^\star\|^2\right] \\ &+ \sum_{i=1}^m\sum_{k=1}^n \zeta_{ik}\mathbf{E}_t\left[\|A_{ik}^{(t+1)} - \alpha_i^\star\|^2\right] + \sum_{i=1}^m\sum_{k=1}^n \xi_{ik}\mathbf{E}_t\left[\|(W_{ik}^{(t+1)})^T - w_k^\star\|^2\right]. \end{aligned} \tag{115}$$

Let $\theta \in (0,1)$ be a parameter to be determined later, and Γ be a constant such that

$$\Gamma \geq \max_{i,k}\left\{\frac{1}{p_i}\left(1+\frac{3\|X_{ik}\|^2}{2\theta q_k\lambda\gamma_i}\right), \frac{1}{q_k}\left(1+\frac{3n\|X_{ik}\|^2}{2\theta p_im\lambda\gamma_i}\right), \frac{1}{p_iq_k}\right\}. \tag{116}$$

The choices of σ_i in (42) and τ_k in (43) satisfy

$$\frac{1}{p_i}\left(1+\frac{1}{2\sigma_i\gamma_i}\right) = \frac{1}{q_k}\left(1+\frac{1}{2\tau_k\lambda}\right) = \Gamma. \tag{117}$$

Comparing the above equality with the definition of Γ in (116), we have

$$\frac{3\|X_{ik}\|^2}{2\theta q_k\lambda\gamma_i} \leq \frac{1}{2\sigma_i\gamma_i} \qquad \text{and} \qquad \frac{3n\|X_{ik}\|^2}{2\theta p_im\lambda\gamma_i} \leq \frac{1}{2\tau_k\lambda},$$

which implies that

$$\frac{6\sigma_i\|X_{ik}\|^2}{q_k} \leq 2\theta\lambda \qquad \text{and} \qquad \frac{6n\tau_k\|X_{ik}\|^2}{mp_i} \leq 2\theta\gamma_i \tag{118}$$

hold for all $i = 1,\ldots,m$ and $k = 1,\ldots,n$. Therefore, we have

$$\sum_{k=1}^n \frac{6\tau_k\|X_{ik}\|^2}{mp_i} = \frac{1}{n}\sum_{k=1}^n \frac{6n\tau_k\|X_{ik}\|^2}{mp_i} \leq 2\theta\gamma_i, \qquad i = 1,\ldots,m, \tag{119}$$

$$\sum_{i=1}^m \frac{6\sigma_i\|X_{ik}\|^2}{mq_k} = \frac{1}{m}\sum_{i=1}^m \frac{6\sigma_i\|X_{ik}\|^2}{q_k} \leq 2\theta\lambda, \qquad k = 1,\ldots,n. \tag{120}$$

Now we consider the inequality (115), and examine the ratio between the coefficients of $\|\alpha_i^{(t)} - \alpha_i^\star\|^2$ and $\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2]$. Using (119) and (117), we have

$$\frac{\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \gamma_i\right) - \gamma_i + \sum_{k=1}^n \frac{6\tau_k \|X_{ik}\|^2}{mp_i}}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \gamma_i\right)} \le 1 - \frac{(1-2\theta)\gamma_i}{\frac{1}{p_i}\left(\frac{1}{2\sigma_i} + \gamma_i\right)} = 1 - \frac{1-2\theta}{\Gamma}. \tag{121}$$

Similarly, the ratio between the coefficients of $\|w_k^{(t)} - w_k^\star\|^2$ and $\mathbf{E}_t[\|w_k^{(t+1)} - w_k^\star\|^2]$ can be bounded using (120) and (117):

$$\frac{\frac{1}{q_k}\left(\frac{1}{2\tau_k} + \lambda\right) - \lambda + \sum_{i=1}^m \frac{6\sigma_i \|X_{ik}\|^2}{mq_k}}{\frac{1}{q_k}\left(\frac{1}{2\tau_k} + \lambda\right)} \le 1 - \frac{(1-2\theta)\lambda}{\frac{1}{q_k}\left(\frac{1}{2\tau_k} + \lambda\right)} = 1 - \frac{1-2\theta}{\Gamma}. \tag{122}$$

We notice that in (115), the ratios between the coefficients of $\zeta_{ik}\|A_{ik}^{(t)} - \alpha_i^\star\|^2$ and $\zeta_{ik}\mathbf{E}_t\left[\|A_{ik}^{(t+1)} - \alpha_i^\star\|^2\right]$, as well as and that of $\xi_{ik}\|(W_{ik}^{(t)})^T - w_k^\star\|^2$ and $\xi_{ik}\mathbf{E}_t[\|(W_{ik}^{(t+1)})^T - w_k^\star\|^2]$, are all $1 - \frac{1}{3}p_i q_k$. By definition of Γ in (116), we have

$$1 - \frac{1}{3}p_i q_k \;\le\; 1 - \frac{1}{3\Gamma}, \qquad i = 1, \ldots, m, \quad k = 1, \ldots, n. \tag{123}$$

We choose $\theta = 1/3$ so that the ratios in (121) and (122) have the same bound $1 - \frac{1}{3\Gamma}$. Therefore, it follows from inequality (115) that

$$\begin{aligned}
&\sum_{i=1}^m \frac{\Gamma\gamma_i}{m}\mathbf{E}_t[\|\alpha_i^{(t+1)} - \alpha_i^\star\|^2] + \sum_{k=1}^n \Gamma\lambda\mathbf{E}_t[\|w_k^{(t+1)} - w_k^\star\|^2] \\
&+ \sum_{i=1}^m\sum_{k=1}^n \zeta_{ik}\mathbf{E}_t[\|A_{ik}^{(t+1)} - \alpha_i^\star\|^2] + \sum_{i=1}^m\sum_{k=1}^n \xi_{ik}\mathbf{E}_t[\|(W_{ik}^{(t+1)})^T - w_k^\star\|^2]. \\
\le\;& \left(1 - \frac{1}{3\Gamma}\right)\left(\sum_{i=1}^m \frac{\Gamma\gamma_i}{m}\|\alpha_i^{(t)} - \alpha_i^\star\|^2 + \sum_{k=1}^n \Gamma\lambda\|w_k^{(t)} - w_k^\star\|^2\right. \\
&\left. + \sum_{i=1}^m\sum_{k=1}^n \zeta_{ik}\|A_{ik}^{(t)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \xi_{ik}\|(W_{ik}^{(t)})^T - w_k^\star\|^2\right).
\end{aligned} \tag{124}$$

Let's define

$$\Delta^{(t)} = \lambda\|w^{(t)} - w^\star\|^2 + \frac{1}{m}\sum_{i=1}^m \gamma_i\|\alpha_i^{(t)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{\zeta_{ik}}{\Gamma}\|A_{ik}^{(t)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{\xi_{ik}}{\Gamma}\|(W_{ik}^{(t)})^T - w_k^\star\|^2.$$

Then (124) implies

$$\mathbf{E}\left[\Delta^{(t)}\right] \le \left(1 - \frac{1}{3\Gamma}\right)^t \Delta^{(0)}, \tag{125}$$

where the expectation is taken with respect to all random variables generated by Algorithm 3 up to iteration t.

By the definition of ξ_{ik} in (114), we have

$$\frac{\xi_{ik}}{\Gamma} = \frac{3\sigma_i\|X_{ik}\|^2}{mp_i q_k^2}\frac{1}{\Gamma} \le \frac{\theta\lambda}{mp_i q_k}\frac{1}{\Gamma} \le \frac{\theta\lambda}{m} = \frac{\lambda}{3m},$$

where the first inequality is due to (118) and the second inequality is due to the relation $\Gamma \ge \frac{1}{p_i q_k}$ from the definition of Γ in (116). Similarly, we have

$$\frac{\zeta_{ik}}{\Gamma} = \frac{3\tau_k\|X_{ik}\|^2}{m^2 p_i^2 q_k}\frac{1}{\Gamma} \le \frac{\theta\gamma_i}{mnp_i q_k}\frac{1}{\Gamma} \le \frac{\theta\gamma_i}{3mn} = \frac{\gamma_i}{3mn}.$$

Moreover, by the construction in (109) and (110), we have for $t = 0$,

$$\begin{aligned}
A_{ik}^{(0)} &= \alpha_i^{(0)}, \quad \text{for} \quad k = 1, \ldots, n \quad \text{and} \quad i = 1, \ldots, m, \\
(W_{ik}^{(0)})^T &= w_k^{(0)}, \quad \text{for} \quad i = 1, \ldots, m \quad \text{and} \quad k = 1, \ldots, n.
\end{aligned}$$

Therefore, the last two terms in the definition of $\Delta^{(0)}$ can be bounded as

$$\begin{aligned}
&\sum_{i=1}^m\sum_{k=1}^n \frac{\zeta_{ik}}{\Gamma}\|A_{ik}^{(0)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{\xi_{ik}}{\Gamma}\|(W_{ik}^{(0)})^T - w_k^\star\|^2 \\
\le\;& \sum_{i=1}^m\sum_{k=1}^n \frac{\gamma_i}{3mn}\|\alpha_i^{(0)} - \alpha_i^\star\|^2 + \sum_{i=1}^m\sum_{k=1}^n \frac{\lambda}{3m}\|w_k^{(0)} - w_k^\star\|^2 \\
=\;& \frac{1}{3m}\sum_{i=1}^m \gamma_i\|\alpha_i^{(0)} - \alpha_i^\star\|^2 + \frac{\lambda}{3}\|w^{(0)} - w^\star\|^2,
\end{aligned}$$

which implies

$$\Delta^{(0)} \le \frac{4}{3}\left(\lambda\|w^{(0)} - w^\star\|^2 + \frac{1}{m}\sum_{i=1}^m \gamma_i\|\alpha_i^{(0)} - \alpha_i^\star\|^2\right).$$

Finally, combining with (125), we have

$$\mathbf{E}\left[\Delta^{(t)}\right] \le \left(1 - \frac{1}{3\Gamma}\right)^t \frac{4}{3}\left(\lambda\|w^{(0)} - w^\star\|^2 + \frac{1}{m}\sum_{i=1}^m \gamma_i\|\alpha_i^{(0)} - \alpha_i^\star\|^2\right),$$

which further implies the desired result.

Appendix D. Proof of Theorem 4

To simplify the presentation, we present the proof for the case $\gamma_i = \gamma$ for all $i = 1, \ldots, m$. It is straightforward to generalize to the case where the γ_i's are different.

Lemma 13 *Let $g : \mathbf{R}^D \to \mathbf{R}$ be λ-strongly convex, and $f_i^* : \mathbf{R}^{N_i} \to \mathbf{R} \cup \{\infty\}$ be γ-strongly convex over its domain. Given any $\tilde{w} \in \mathbf{R}^d$ and $\tilde{\alpha} \in \mathbf{R}^N$, we define the following two functions:*

$$L(w, \alpha) = g(w) + \frac{1}{m}\alpha^T X w - \frac{1}{m}\sum_{i=1}^m f_i*(\alpha_i), \tag{126}$$

$$L_\delta(w, \alpha) = L(w, \alpha) + \frac{\delta\lambda}{2}\|w - \tilde{w}\|^2 - \frac{\delta\gamma}{2m}\|\alpha - \tilde{\alpha}\|^2. \tag{127}$$

Let $(w^\star, \alpha^\star)$ and $(\tilde{w}^\star, \tilde{\alpha}^\star)$ be the (unique) saddle points of $L(w, \alpha)$ and $L_\delta(w, \alpha)$, respectively. Then we have

$$\lambda\|\tilde{w} - \tilde{w}^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha} - \tilde{\alpha}^\star\|^2 \le \lambda\|\tilde{w} - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha} - \alpha^\star\|^2, \tag{128}$$

$$\left(\lambda\|\tilde{w}^\star - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha}^\star - \alpha^\star\|^2\right)^{1/2} \le \frac{\delta}{1+\delta}\left(\lambda\|\tilde{w} - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha} - \alpha^\star\|^2\right)^{1/2}. \tag{129}$$

Proof This lemma can be proved using the theory of monotone operators (e.g., Rockafellar, 1976; Ryu and Boyd, 2016), as done by Balamurugan and Bach (2016). Here we give an elementary proof based on first-order optimality conditions.

By assumption, we have

$$\begin{aligned}(w^\star, \alpha^\star) &= \arg\min_w \max_\alpha L(w, \alpha),\\ (\tilde{w}^\star, \tilde{\alpha}^\star) &= \arg\min_w \max_\alpha L_\delta(w, \alpha).\end{aligned}$$

Optimality conditions for $(\tilde{w}^\star, \tilde{\alpha}^\star)$ as a saddle point of L_δ:

$$-\frac{1}{m}X^T\tilde{\alpha}^\star - \delta\lambda\left(\tilde{w}^\star - \tilde{w}\right) \in \partial g(\tilde{w}^\star), \tag{130}$$

$$X\tilde{w}^\star - \delta\gamma\left(\tilde{\alpha}^\star - \tilde{\alpha}\right) \in \partial\sum_{i=1}^m f_i^*(\tilde{\alpha}^\star). \tag{131}$$

For any $\xi \in \partial g(\tilde{w}^\star)$, it holds that $\xi + \frac{1}{m}X^T\alpha^\star \in \partial_w L(\tilde{w}^\star, \alpha^\star)$. Therefore using (130) we have

$$\frac{1}{m}X^T(\alpha^\star - \tilde{\alpha}^\star) - \delta\lambda\left(\tilde{w}^\star - \tilde{w}\right) \in \partial_w L(\tilde{w}^\star, \alpha^\star).$$

Since $L(w, \alpha^\star)$ is strongly convex in w with convexity parameter λ, we have

$$L(\tilde{w}^\star, \alpha^\star) + \left(\frac{1}{m}X^T(\alpha^\star - \tilde{\alpha}^\star) - \delta\lambda\left(\tilde{w}^\star - \tilde{w}\right)\right)^T(w^\star - \tilde{w}^\star) + \frac{\lambda}{2}\|\tilde{w}^\star - w^\star\|^2 \le L(w^\star, \alpha^\star). \tag{132}$$

Similarly, we have

$$\frac{1}{m}X^T(\tilde{w}^\star - w^\star) - \frac{\delta\gamma}{m}\left(\tilde{\alpha}^\star - \tilde{\alpha}\right) \in \partial_\alpha\left(-L(w^\star, \tilde{\alpha}^\star)\right),$$

and since $-L(w^\star, \alpha)$ is strongly convex in α with convexity parameter $\frac{\gamma}{m}$, we have

$$-L(w^\star, \tilde{\alpha}^\star) + \left(\frac{1}{m}X^T(\tilde{w}^\star - w^\star) - \frac{\delta\gamma}{m}\left(\tilde{\alpha}^\star - \tilde{\alpha}\right)\right)^T(\alpha^\star - \tilde{\alpha}^\star) + \frac{\gamma}{2m}\|\tilde{\alpha}^\star - \alpha^\star\|^2 \le -L(w^\star, \alpha^\star). \tag{133}$$

Adding inequalities (132) and (133) together gives

$$\begin{aligned}&L(\tilde{w}^\star, \alpha^\star) - L(w^\star, \tilde{\alpha}^\star)\\ &+ \delta\lambda(\tilde{w}^\star - \tilde{w})^T(\tilde{w}^\star - w^\star) + \frac{\delta\gamma}{m}(\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \alpha^\star) + \frac{\lambda}{2}\|\tilde{w}^\star - w^\star\|^2 + \frac{\gamma}{2m}\|\tilde{\alpha}^\star - \alpha^\star\|^2 \le 0.\end{aligned}$$

Combining with the inequality

$$L(\tilde{w}^\star, \alpha^\star) - L(w^\star, \tilde{\alpha}^\star) \ge \frac{\lambda}{2}\|\tilde{w}^\star - w^\star\|^2 + \frac{\gamma}{2m}\|\tilde{\alpha}^\star - \alpha^\star\|^2,$$

we obtain

$$\lambda\|\tilde{w}^\star - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha}^\star - \alpha^\star\|^2 + \delta\lambda(\tilde{w}^\star - \tilde{w})^T(\tilde{w}^\star - w^\star) + \frac{\delta\gamma}{m}(\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \alpha^\star) \le 0. \tag{134}$$

Proof of the first claim. We can drop the nonnegative terms on the left-hand side of (134) to obtain

$$\lambda(\tilde{w}^\star - \tilde{w})^T(\tilde{w}^\star - w^\star) + \frac{\gamma}{m}(\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \alpha^\star) \le 0.$$

The two inner product terms on the left-hand side of the inequality above can be expanded as follows:

$$\begin{aligned}(\tilde{w}^\star - \tilde{w})^T(\tilde{w}^\star - w^\star) &= (\tilde{w}^\star - \tilde{w})^T(\tilde{w}^\star - \tilde{w} + \tilde{w} - w^\star) = \|\tilde{w}^\star - \tilde{w}\|^2 + (\tilde{w}^\star - \tilde{w})^T(\tilde{w} - w^\star),\\ (\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \alpha^\star) &= (\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \tilde{\alpha} + \tilde{\alpha} - \alpha^\star) = \|\tilde{\alpha}^\star - \tilde{\alpha}\|^2 + (\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha} - \alpha^\star).\end{aligned}$$

Combining them with the last inequality, we have

$$\begin{aligned}\lambda\|\tilde{w}^\star - \tilde{w}\|^2 + \frac{\gamma}{m}\|\tilde{\alpha}^\star - \tilde{\alpha}\|^2 &\le -\lambda(\tilde{w}^\star - \tilde{w})^T(\tilde{w} - w^\star) - \frac{\gamma}{m}(\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha} - \alpha^\star)\\ &\le \frac{\lambda}{2}\left(\|\tilde{w}^\star - \tilde{w}\|^2 + \|\tilde{w} - w^\star\|^2\right) + \frac{\gamma}{2m}\left(\|\tilde{\alpha}^\star - \tilde{\alpha}\|^2 + \|\tilde{\alpha} - \alpha^\star\|^2\right),\end{aligned}$$

which implies

$$\frac{\lambda}{2}\|\tilde{w}^\star - \tilde{w}\|^2 + \frac{\gamma}{2m}\|\tilde{\alpha}^\star - \tilde{\alpha}\|^2 \le \frac{\lambda}{2}\|\tilde{w} - w^\star\|^2 + \frac{\gamma}{2m}\|\tilde{\alpha} - \alpha^\star\|^2.$$

Proof of the second claim. We expand the two inner product terms in (134) as follows:

$$\begin{aligned}(\tilde{w}^\star - \tilde{w})^T(\tilde{w}^\star - w^\star) &= (\tilde{w}^\star - w^\star + w^\star - \tilde{w})^T(\tilde{w}^\star - w^\star) = \|\tilde{w}^\star - w^\star\|^2 + (w^\star - \tilde{w})^T(\tilde{w}^\star - w^\star),\\ (\tilde{\alpha}^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \alpha^\star) &= (\tilde{\alpha}^\star - \alpha^\star + \alpha^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \alpha^\star) = \|\tilde{\alpha}^\star - \alpha^\star\|^2 + (\alpha^\star - \tilde{\alpha})^T(\tilde{\alpha}^\star - \alpha^\star).\end{aligned}$$

Then (134) becomes

$$\begin{aligned}&(1+\delta)\lambda\|\tilde{w}^\star - w^\star\|^2 + (1+\delta)\frac{\Gamma}{m}\|\tilde{w}^\star - w^\star\|^2\\ \le\ &\delta\lambda(\tilde{w} - w^\star)^T(\tilde{w}^\star - w^\star) + \frac{\delta\gamma}{m}(\tilde{\alpha} - \alpha^\star)^T(\tilde{\alpha}^\star - \alpha^\star)\\ \le\ &\delta\left(\lambda\|\tilde{w} - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha} - \alpha^\star\|^2\right)^{1/2}\left(\lambda\|\tilde{w}^\star - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha}^\star - \alpha^\star\|^2\right)^{1/2},\end{aligned}$$

where in the second inequality we used the Cauchy-Schwarz inequality. Therefore we have

$$\left(\lambda\|\tilde{w}^\star - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha}^\star - \alpha^\star\|^2\right)^{1/2} \le \frac{\delta}{1+\delta}\left(\lambda\|\tilde{w} - w^\star\|^2 + \frac{\gamma}{m}\|\tilde{\alpha} - \alpha^\star\|^2\right)^{1/2},$$

which is the desired result. ■

To simplify notations in the rest of the proof, we let $z = (w, \alpha)$ and define

$$\|z\| = \left(\lambda\|w\|^2 + \frac{\gamma}{m}\|\alpha\|^2\right)^{1/2}.$$

The results of Lemma 13 can be written as

$$\|\tilde{z} - \tilde{z}^\star\| \le \|\tilde{z} - z^\star\|, \tag{135}$$

$$\|\tilde{z}^\star - z^\star\| \le \frac{\delta}{1+\delta}\|\tilde{z} - z^\star\|. \tag{136}$$

Next consider the convergence of Algorithm 4, and follow the proof ideas in Balamurugan and Bach (2016, Section D.3).

If we use DSCOVR-SVRG (option 1) in each round of Algorithm 4, then Algorithm 2 is called with initial point $\tilde{z}^{(r)} = (\tilde{w}^{(r)}, \tilde{\alpha}^{(r)})$ and after S stages, it outputs $\tilde{z}^{(r+1)}$ as an approximate saddle point of $L_\delta^{(r)}(w, \alpha)$, which is defined in (46). Then Theorem 1 implies

$$\mathbf{E}[\|\tilde{z}^{(r+1)} - \tilde{z}^{\star(r)}\|^2] \le \left(\frac{2}{3}\right)^S \mathbf{E}[\|\tilde{z}^{(r)} - \tilde{z}^{\star(r)}\|^2], \tag{137}$$

where $\tilde{z}^{\star(r)}$ denotes the unique saddle point of $L_\delta^{(r)}(w, \alpha)$. By Minkowski's inequality, we have

$$\left(\mathbf{E}[\|\tilde{z}^{(r+1)} - z^\star\|^2]\right)^{1/2} \le \left(\mathbf{E}[\|\tilde{z}^{(r+1)} - \tilde{z}^{\star(r)}\|^2]\right)^{1/2} + \left(\mathbf{E}[\|\tilde{z}^{\star(r)} - z^\star\|^2]\right)^{1/2},$$

where $z^\star$ is the unique saddle point of $L(w, \alpha)$. Using (137), (135) and (136), we obtain

$$\begin{aligned}
\left(\mathbf{E}[\|\tilde{z}^{(r+1)} - z^\star\|^2]\right)^{1/2} &\le \left(\frac{2}{3}\right)^{S/2} \left(\mathbf{E}[\|\tilde{z}^{(r)} - \tilde{z}^{\star(r)}\|^2]\right)^{1/2} + \left(\mathbf{E}[\|\tilde{z}^{\star(r)} - z^\star\|^2]\right)^{1/2} \\
&\le \left(\frac{2}{3}\right)^{S/2} \left(\mathbf{E}[\|\tilde{z}^{(r)} - z^\star\|^2]\right)^{1/2} + \frac{\delta}{1+\delta} \left(\mathbf{E}[\|\tilde{z}^{(r)} - z^\star\|^2]\right)^{1/2} \\
&= \left[\left(\frac{2}{3}\right)^{S/2} + \frac{\delta}{1+\delta}\right] \left(\mathbf{E}[\|\tilde{z}^{(r)} - z^\star\|^2]\right)^{1/2},
\end{aligned} \tag{138}$$

Therefore, if $S \ge \frac{2\log(2(1+\delta))}{\log(3/2)}$, we have

$$\left(\frac{2}{3}\right)^{S/2} + \frac{\delta}{1+\delta} \le \frac{1}{2(1+\delta)} + \frac{\delta}{1+\delta} = \frac{1+2\delta}{2(1+\delta)} = 1 - \frac{1}{2(1+\delta)},$$

which implies

$$\mathbf{E}[\|\tilde{z}^{(r+1)} - z^\star\|^2] \le \left(1 - \frac{1}{2(1+\delta)}\right)^2 \mathbf{E}[\|\tilde{z}^{(r)} - z^\star\|^2]. \tag{139}$$

If we use DISCOVR-SAGA (option 2) in Algorithm 4, then Algorithm 3 is called with initial point $\tilde{z}^{(r)} = (\tilde{w}^{(r)}, \tilde{\alpha}^{(r)})$ and after M steps, it outputs $\tilde{z}^{(r+1)}$ as an approximate saddle point of $L_\delta^{(r)}(w, \alpha)$. Then Theorem 3 implies

$$\mathbf{E}[\|\tilde{z}^{(r+1)} - \tilde{z}^{\star(r)}\|^2] \le \frac{4}{3}\left(1 - \frac{1}{3\Gamma_\delta}\right)^M \mathbf{E}[\|\tilde{z}^{(r)} - \tilde{z}^{\star(r)}\|^2].$$

Using similar arguments as in (138), we have

$$\left(\mathbf{E}[\|\tilde{z}^{(r+1)} - z^\star\|]^2\right)^{1/2} \le \left[\frac{4}{3}\left(1 - \frac{1}{3\Gamma_\delta}\right)^{M/2} + \frac{\delta}{1+\delta}\right] \left(\mathbf{E}[\|\tilde{z}^{(r)} - z^\star\|^2]\right)^{1/2}.$$

Therefore, if $M \ge 6\log\left(\frac{8(1+\delta)}{3}\right)\Gamma_\delta$, we have

$$\frac{4}{3}\left(1 - \frac{1}{3\Gamma_\delta}\right)^{M/2} + \frac{\delta}{1+\delta} \le \frac{1}{2(1+\delta)} + \frac{\delta}{1+\delta} = \frac{1+2\delta}{2(1+\delta)} = 1 - \frac{1}{2(1+\delta)},$$

which implies the same inequality in (139).

In summary, using either option 1 or option 2 in Algorithm 4, we have

$$\mathbf{E}[\|\tilde{z}^{(r)} - z^\star\|^2] \le \left(1 - \frac{1}{2(1+\delta)}\right)^{2r} \|\tilde{z}^{(0)} - z^\star\|^2.$$

In order to have $\mathbf{E}[\|\tilde{z}^{(r)} - z^\star\|^2] \le \epsilon$, it suffices to have $r \ge (1+\delta)\log\left(\|\tilde{z}^{(0)} - z^\star\|^2/\epsilon\right)$.

Abstract

We describe a new library named `picasso` [1], which implements a unified framework of pathwise coordinate optimization for a variety of sparse learning problems (e.g., sparse linear regression, sparse logistic regression, sparse Poisson regression and scaled sparse linear regression) combined with efficient active set selection strategies. Besides, the library allows users to choose different sparsity-inducing regularizers, including the convex ℓ_1, nonvoncex MCP and SCAD regularizers. The library is coded in `C++` and has user-friendly `R` and `Python` wrappers. Numerical experiments demonstrate that `picasso` can scale up to large problems efficiently.

1. Overview

Sparse Learning arises due to the demand of analyzing high-dimensional data such as high-throughput genomic data (Neale et al., 2012) and functional Magnetic Resonance Imaging (Liu et al., 2015). The pathwise coordinate optimization is undoubtedly one the of the most popular solvers for a large variety of sparse learning problems. By leveraging the solution sparsity through a simple but elegant algorithmic structure, it significantly boosts the computational performance in practice (Friedman et al., 2007). Some recent progresses in (Zhao et al., 2017; Li et al., 2017) establish theoretical guarantees to further justify its computational and statistical superiority for both convex and nonvoncex sparse learning, which makes it even more attractive to practitioners.

We recently developed a new library named `picasso`, which implements a unified toolkit of pathwise coordinate optimization for solving a large class of convex and nonconvex regularized sparse learning problems. Efficient active set selection strategies are provided to guarantee superior statistical and computational preference. Specifically, we implement sparse linear regression, sparse logistic regression, sparse Poisson regression and scaled sparse linear regression (Tibshirani, 1996; Belloni et al., 2011; Sun and Zhang, 2012). The options of regularizers include the ℓ_1, MCP, and SCAD regularizers (Fan and Li, 2001; Zhang, 2010). Unlike existing libraries implementing heuristic optimization algorithms such as `ncvreg` or `glmnet` (Breheny, 2013; Friedman et al., 2010), our implemented algorithm `picasso` have strong theoretical guarantees that it attains a global linear convergence to a unique sparse local optimum with optimal statistical properties (e.g. minimax optimality and oracle properties). See more details in Zhao et al. (2017); Li et al. (2017).

2. Algorithm Design and Implementation

The algorithm implemented in `picasso` is mostly based on the generic pathwise coordinate optimization framework proposed by Zhao et al. (2017); Li et al. (2017), which integrates the warm start initialization, active set selection strategy, and strong rule for coordinate preselection into the classical coordinate optimization. The algorithm contains three structurally nested loops as shown in Figure 1:

(1) Outer loop: The warm start initialization, also referred to as the pathwise optimization scheme, is applied to minimize the objective function in a multistage manner using a sequence of decreasing regularization parameters, which yields a sequence of solutions from sparse to dense. At each stage, the algorithm uses the solution from the previous stage as initialization.

(2) Middle loop: The algorithm first divides all coordinates into active ones (active set) and inactive ones (inactive set) by a so-called strong rule based on coordinate gradient thresholding (Tibshirani et al., 2012). Then the algorithm calls an inner loop to optimize the objective, and update the active set based on efficient active set selection strategies. Such a routine is repeated until the active set no longer changes

(3) Inner loop: The algorithm conducts coordinate optimization (for sparse linear regression) or proximal Newton optimization combined with coordinate optimization (for sparse logistic regression, Possion regression, scaled sparse linear regression, sparse undirected graph estimation) only over active coordinates until convergence, with all inactive coordinates staying zero values. The active coordinates are updated efficiently using an efficient "naive update" rule that only operates on the non-zero coefficients. Better efficiency is achieved by the "covariance update" rule. See more details in (Friedman et al., 2010). The inner loop terminates when the successive descent is within a predefined numerical precision.

The warm start initialization, active set selection strategies, and strong rule for coordinate preselection significantly boost the computational performance, making pathwise coordinate optimization one of the most important computational frameworks for sparse learning. The numerical evaluations show that `picasso` is highly scalable and efficient.

The library is implemented in `C++` with the memory optimized using sparse matrix output, and called from `R` and `Python` by user-friendly interfaces. Linear algebra is supported by the Eigen3 library (Guennebaud et al., 2010) for portable high performance computation.

*. Jason Ge and Xingguo Li contributed equally. Tuo Zhao is the corresponding author.
1. More details can be found in our Github page: `https://github.com/jasonge27/picasso`

The implementation is modularized so that the algorithm in `src/solver/actnewton.cpp` works with popular sparsity-inducing regularizer functions and any convex objective function that exhibits restricted strong convexity property (Zhao et al., 2017). Users can easily extend the package by writing customized objective function subclass and regularizer function subclass following the virtual function interfaces of `class ObjFunction` and `class RegFunction` in `include/picasso/objective.hpp`.

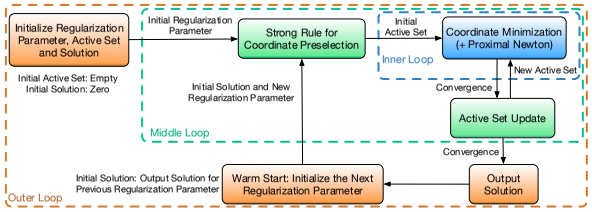

Figure 1: The pathwise coordinate optimization framework with 3 nested loops: (1) Warm start initialization; (2) Active set selection, and strong rule for coordinate preselection; (3) Active coordinate minimization.

3. Example of R User Interface

We illustrate the user interface by analyzing the eye disease data set in `picasso`.

```
> library(picasso); data(eyedata) # Load the data set
> out1 = picasso(x,y,method="l1",type.gaussian="naive",nlambda=20,
+                lambda.min.ratio=0.2) # Lasso
> out2 = picasso(x,y,method="mcp", gamma = 1.25, prec=1e-4)  # MCP regularizer
> plot(out1); plot(out2) # Plot solution paths
```

The program automatically generates a sequence of regularization parameters and estimate the corresponding solution paths based on the ℓ_1 and MCP regularizers respectively. For the ℓ_1 regularizer, we set the number of regularization parameters as 20, and the minimum regularization parameter as `0.2*lambda.max`. For the MCP regularizer, we set the concavity parameter as $\gamma = 1.25$, and the pre-defined accuracy as 10^{-4}. Here `nlambda` and `lambda.min.ratio` are omitted, and therefore set by the default values (`nlambda=100` and `lambda.min.ratio=0.05`). We further plot two solution paths in Figure 2.

4. Numerical Simulation

To demonstrate the superior efficiency of our library, we compare `picasso` with a popular `R` library `ncvreg` (version 3.9.1) for nonconvex regularized sparse regression, the most popular `R` library `glmnet` (version 2.0-13) for convex regularized sparse regression, and two `R` libraries `scalreg-v1.0` and `flare-v1.5.0` for scaled sparse linear regression. All experiments are evaluated on an Intel Core CPU i7-7700k 4.20GHz and under R version 3.4.3. Timings of the CPU execution are recored in seconds and averaged over 10 replications on a sequence of 100 regularization parameters. All algorithms are compared on the same regularization path and the convergence threshold are adjusted so that similar objective gaps are achieved.

We compare the timing performance and the optimization performance in Table 1. We choose the problem size to be $(n = 3000, d = 30000)$, where n is the number of observation and d is the dimension of the parameter vector. We tests the algorithms for both well-conditioned cases and ill-conditioned cases. The details of data generation can be found in the `R` library vignette. Here is our summary:

(1) For sparse linear regression using any regularizer and sparse logistic regression using the ℓ_1 regularizer, all libraries achieve almost identical optimization objective values, and `picasso` slightly outperforms `glmnet` and `ncvreg` in the timing performance.

(2) For sparse logistic regression using nonconvex regularizers, `picasso` achieves comparable objective value with `ncvreg`, and significantly outperforms `ncvreg` in timing performance. We also remark that `picasso` performs stably for various settings and tuning parameters. However, `ncvreg` may converge very slow or fail to converge for sparse logistic regression using nonconvex regularizers, especially when the tuning parameters are relatively small (corresponding to denser estimators), as the ill-conditioned SCAD case shows.

(3) For scaled Lasso, in order to make other competitors (`flare` and `scalreg`) converges in resonable time, we swtich to a smaller problem size $(n = 1000, d = 10000)$. We see that `picasso` much more time saving than `flare` and `scalreg`.

Table 1: Average timing performance (in seconds) with standard errors in the parentheses and achieved objective values.

		well-conditioned		ill-conditioned	
Sparse Linear Regression					
ℓ_1	picasso	1.61(0.03)s	27.691	3.62(0.02)s	32.543
	glmnet	4.15(0.03)s	27.692	9.43(0.01)s	32.537
	ncvreg	5.92(0.01)s	27.690	6.66(0.01)s	32.536
SCAD	picasso	1.56(0.01)s	27.668	3.74(0.01)s	33.133
	ncvreg	5.61(0.01)s	27.673	7.05(0.01)s	33.156
MCP	picasso	1.47(0.02)s	27.161	1.89(0.02)s	32.468
	ncvreg	4.07(0.03)s	27.161	2.56(0.01)s	32.468
Sparse Logistic Regression					
ℓ_1	picasso	2.03(0.01)s	0.363	2.10(0.03)s	0.327
	glmnet	16.32(0.12)s	0.363	20.31(0.02)s	0.327
	ncvreg	4.04(0.01)s	0.363	62.89(0.04)s	0.327
SCAD	picasso	4.25(0.01)s	0.227	4.35(0.02)s	0.172
	ncvreg	11.47(0.04)s	0.278	error (>300s)	
MCP	picasso	4.32(0.01)s	0.221	4.38(0.02)s	0.165
	ncvreg	9.37(0.08)s	0.248	6.99(0.01)s	0.242
Scaled Lasso					
ℓ_1	picasso	0.36(0.01)s	4.454	0.15(0.01)s	5.495
	flare	5.23(0.06)s	5.188	297.36(2.77)s	5.959
	scalreg	40.20(0.63)s	4.492	49.12(10.98)s	5.507

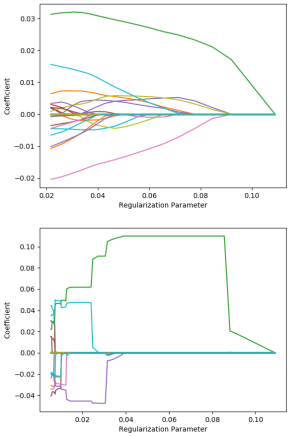

Figure 2: The solution paths of ℓ_1 (up) and MCP (down) regularizers.

5. Conclusion

The `picasso` library demonstrates significantly improved computational and statistical performance over existing libraries for nonconvex regularized sparse learning such as `ncvreg`. Besides, `picasso` also shows improvement over the popular libraries for convex regularized sparse learning such as `glmnet`. Overall, the `picasso` library has the potential to serve as a powerful toolbox for high dimensional sparse learning. We will continue to maintain and support this library.

Abstract

The frequent directions (FD) technique is a deterministic approach for online sketching that has many applications in machine learning. The conventional FD is a heuristic procedure that often outputs rank deficient matrices. To overcome the rank deficiency problem, we propose a new sketching strategy called robust frequent directions (RFD) by introducing a regularization term. RFD can be derived from an optimization problem. It updates the sketch matrix and the regularization term adaptively and jointly. RFD reduces the approximation error of FD without increasing the computational cost. We also apply RFD to online learning and propose an effective hyperparameter-free online Newton algorithm. We derive a regret bound for our online Newton algorithm based on RFD, which guarantees the robustness of the algorithm. The experimental studies demonstrate that the proposed method outperforms state-of-the-art second order online learning algorithms.

Keywords: Matrix approximation, sketching, frequent directions, online convex optimization, online Newton algorithm

1. Introduction

The sketching technique is a powerful tool to deal with large scale matrices (Ghashami et al., 2016; Halko et al., 2011; Woodruff, 2014), and it has been widely used to speed up machine learning algorithms such as second order optimization algorithms (Erdogdu and Montanari, 2015; Luo et al., 2016; Pilanci and Wainwright, 2017; Roosta-Khorasani and Mahoney, 2016a,b; Xu et al., 2016; Ye et al., 2017). There exist several families of matrix sketching strategies, including sparsification, column sampling, random projection (Achlioptas, 2003; Indyk and Motwani, 1998; Kane and Nelson, 2014; Wang et al., 2016), and frequent directions (FD) (Desai et al., 2016; Ghashami et al., 2016; Huang, 2018; Liberty, 2013; Mroueh et al., 2017; Ye et al., 2016).

Sparsification techniques (Achlioptas and McSherry, 2007; Achlioptas et al., 2013; Arora et al., 2006; Drineas and Zouzias, 2011) generate a sparse version of the matrix by element-wise sampling, which allows the matrix multiplication to be more efficient with lower space. Column (row) sampling algorithms (Mahoney, 2011) include the importance sampling (Drineas et al., 2006a,b; Frieze et al., 2004) and leverage score sampling (Drineas et al., 2012, 2008; Papailiopoulos et al., 2014). They define a probability for each row (column) and select a subset by the probability to construct the estimation. Random projection maps the rows (columns) of the matrix into lower dimensional space by a projection matrix. The projection matrix can be constructed in various ways (Woodruff, 2014) such as Gaussian random projections (Johnson and Lindenstrauss, 1984; Sarlos, 2006), fast Johnson-Lindenstrauss transforms (Ailon and Chazelle, 2006; Ailon and Liberty, 2009, 2013; Kane and Nelson, 2014) and sparse random projections (Clarkson and Woodruff, 2013; Nelson and Nguyên, 2013). The frequent directions (Ghashami et al., 2016; Liberty, 2013) is a deterministic sketching algorithm and achieves optimal tradeoff between approximation error and space.

In this paper we are especially concerned with the FD sketching (Desai et al., 2016; Ghashami et al., 2016; Liberty, 2013), because it is a stable online sketching approach. FD considers the matrix approximation in the streaming setting. In this case, the data is available in a sequential order and should be processed immediately. Typically, streaming algorithms can only use limited memory at any time. The FD algorithm extends the method of frequent items (Misra and Gries, 1982) to matrix approximation and has tight approximation error bound. However, FD usually leads to a rank deficient approximation, which in turn makes its applications less robust. For example, Newton-type algorithms require a non-singular and well-conditioned approximated Hessian matrix but FD sketching usually generates low-rank matrices. An intuitive and simple way to conquer this gap is to introduce a regularization term to enforce the matrix to be invertible (Luo et al., 2016; Roosta-Khorasani and Mahoney, 2016a,b). Typically, the regularization parameter is regarded as a hyperparameter and its choice is separable from the sketching procedure. Since the regularization parameter affects the the performance heavily in practice, it should be chosen carefully.

To overcome the weakness of the FD algorithm, we propose a new sketching approach that we call *robust frequent directions* (RFD). Unlike conventional sketching methods which only approximate the matrix with a low-rank structure, RFD constructs the low-rank part and updates the regularization term simultaneously. In particular, the update procedure of RFD can be regarded as solving an optimization problem (see Theorem 2). This method is different from the standard FD, giving rise to a tighter error bound.

Note that Zhang (2014) proposed matrix ridge approximation (MRA) to approximate a positive semi-definite matrix using an idea similar to RFD. There are two main differences between RFD and MRA. First, RFD is designed for the case that data samples come sequentially and memory is limited, while MRA has to access the whole data set. Second, MRA aims to minimize the approximation error with respect to the Frobenius norm while RFD tries to minimize the spectral-norm approximation error. In general, the spectral norm error bound is more meaningful than the Frobenius norm error bound (Tropp, 2015).

In a recent study, Luo et al. (2016) proposed a FD-based sketched online Newton (SON) algorithm (FD-SON) to accelerate the standard online Newton algorithms. Owing to the shortcoming of FD, the performance of FD-SON is significantly affected by the choice of the hyperparameter. Naturally, we can leverage RFD to improve online Newton algorithms. Accordingly, we propose a sketched online Newton step based on RFD (RFD-SON). Different from conventional sketched Newton algorithms, RFD-SON is hyperparameter-free. Setting the regularization parameter to be zero initially, RFD-SON will adaptively increase the regularization term. The approximation Hessian will be well-conditioned after a few iterations. Moreover, we prove that RFD-SON has a more robust regret bound than FD-SON, and the experimental results also validate better performance of RFD-SON.

The remainder of the paper is organized as follows. In Section 2 we present notation and preliminaries. In Section 3 we review the background of second order online learning and its sketched variants. In Sections 4 and 5 we propose our robust frequent directions (RFD) method and the applications in online learning, with some related theoretical analysis. In Section 6 we demonstrate empirical comparisons with baselines on serval real-world data sets to show the superiority of our algorithms. Finally, we conclude our work in Section 7.

2. Notation and Preliminaries

We let $\mathbf{I}_d$ denote the $d\times d$ identity matrix. For a matrix $\mathbf{A} = [A_{ij}] \in \mathbb{R}^{n\times d}$ of rank r where $r \leq \min(n,d)$, we let the condensed singular value decomposition (SVD) of $\mathbf{A}$ be $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$ where $\mathbf{U} \in \mathbb{R}^{n\times r}$ and $\mathbf{V} \in \mathbb{R}^{d\times r}$ are column orthogonal and $\mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_r)$ with $\sigma_1 \geq \sigma_2 \geq \ldots, \geq \sigma_r > 0$ places the nonzero singular values on its diagonal entries.

We use $\sigma_{\max}(\mathbf{A})$ to denote the largest singular value and $\sigma_{\min}(\mathbf{A})$ to denote the smallest non-zero singular value. Thus, the condition number of $\mathbf{A}$ is $\kappa(\mathbf{A}) = \frac{\sigma_{\max}(\mathbf{A})}{\sigma_{\min}(\mathbf{A})}$. The matrix pseudoinverse of $\mathbf{A}$ is defined by $\mathbf{A}^\dagger = \mathbf{V}\mathbf{\Sigma}^{-1}\mathbf{U}^\top \in \mathbb{R}^{d\times n}$.

Additionally, we let $\|\mathbf{A}\|_F = \sqrt{\sum_{i,j} A_{ij}^2} = \sqrt{\sum_{i=1}^r \sigma_i^2}$ be the Frobenius norm and $\|\mathbf{A}\|_2 = \sigma_{\max}(\mathbf{A})$ be the spectral norm. A matrix norm $\|\cdot\|$ is said to be unitarily invariant if $\|\mathbf{PAQ}\| = \|\mathbf{A}\|$ for any unitary matrices $\mathbf{P} \in \mathbb{R}^{n\times n}$ and $\mathbf{Q} \in \mathbb{R}^{d\times d}$. It is easy to verify that both the Frobenius norm and spectral norm are unitarily invariant. We define $[\mathbf{A}]_k = \mathbf{U}_k\mathbf{\Sigma}_k\mathbf{V}_k^\top$ for $k \leq r$, where $\mathbf{U}_k \in \mathbb{R}^{n\times k}$ and $\mathbf{V}_k \in \mathbb{R}^{d\times k}$ are the first k columns of $\mathbf{U}$ and $\mathbf{V}$, and $\mathbf{\Sigma}_k = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_k) \in \mathbb{R}^{k\times k}$. Then $[\mathbf{A}]_k$ is the best rank-k approximation to $\mathbf{A}$ in both the Frobenius and spectral norms, that is,

$$[\mathbf{A}]_k = \operatorname*{argmin}_{\operatorname{rank}(\widehat{\mathbf{A}})\leq k} \|\mathbf{A} - \widehat{\mathbf{A}}\|_F = \operatorname*{argmin}_{\operatorname{rank}(\widehat{\mathbf{A}})\leq k} \|\mathbf{A} - \widehat{\mathbf{A}}\|_2.$$

Given a positive semidefinite matrix $\mathbf{H} \in \mathbb{R}^{d\times d}$, the notation $\|\mathbf{x}\|_\mathbf{H}$ is called $\mathbf{H}$-norm of vector $\mathbf{x} \in \mathbb{R}^d$, that is, $\|\mathbf{x}\|_\mathbf{H} = \sqrt{\mathbf{x}^\top\mathbf{H}\mathbf{x}}$. If matrices $\mathbf{A}$ and $\mathbf{B}$ have the same size, we let $\langle \mathbf{A}, \mathbf{B}\rangle$ denote $\sum_{i,j} A_{ij}B_{ij}$.

2.1. Frequent Directions

We give a brief review of frequent directions (FD) (Ghashami et al., 2016; Liberty, 2013), because it is closely related to our proposed method. FD is a deterministic matrix sketching in the row-updates model. For any input matrix $\mathbf{A} \in \mathbb{R}^{T\times d}$ whose rows come sequentially, it maintains a sketch matrix $\mathbf{B} \in \mathbb{R}^{(m-1)\times d}$ with $m \ll T$ to approximate $\mathbf{A}^\top\mathbf{A}$ by $\mathbf{B}^\top\mathbf{B}$.

We present the detailed implementation of FD in Algorithm 1. The intuition behind FD is similar to that of frequent items. FD periodically shrinks orthogonal vectors by roughly the same amount (Line 5 of Algorithm 1). The shrinking step reduces the square Frobenius norm of the sketch reasonable and guarantees that no direction is reduced too much.

Algorithm 1 Frequent Directions

1: **Input:** $\mathbf{A} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(T)}]^\top \in \mathbb{R}^{T\times d}$, $\mathbf{B}^{(m-1)} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(m-1)}]^\top$
2: **for** $t = m, \ldots, T$ **do**
3: $\quad\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix}\mathbf{B}^{(t-1)} \\ (\mathbf{a}^{(t)})^\top\end{bmatrix}$
4: $\quad$Compute SVD: $\widehat{\mathbf{B}}^{(t-1)} = \mathbf{U}^{(t-1)}\mathbf{\Sigma}^{(t-1)}(\mathbf{V}^{(t-1)})^\top$
5: $\quad\mathbf{B}^{(t)} = \sqrt{\left(\mathbf{\Sigma}_{m-1}^{(t-1)}\right)^2 - \left(\sigma_m^{(t-1)}\right)^2\mathbf{I}_{m-1}} \cdot \left(\mathbf{V}_{m-1}^{(t-1)}\right)^\top$
6: **end for**
7: **Output:** $\mathbf{B} = \mathbf{B}^{(T)}$

FD has the following error bound for any $k < m$,

$$\|\mathbf{A}^\top\mathbf{A} - \mathbf{B}^\top\mathbf{B}\|_2 \leq \frac{1}{m-k}\|\mathbf{A} - [\mathbf{A}]_k\|_F^2. \tag{1}$$

The above result means that the space complexity of FD is optimal regardless of streaming issues because any algorithm satisfying $\|\mathbf{A}^\top\mathbf{A} - \mathbf{B}^\top\mathbf{B}\|_2 \leq \|\mathbf{A} - [\mathbf{A}]_k\|_F^2/(m-k)$ requires $\mathcal{O}(md)$ space to represent matrix $\mathbf{B}$ (Ghashami et al., 2016). The dominated computation of the algorithm is computating the SVD of $\widehat{\mathbf{B}}^{(t-1)}$, which costs $\mathcal{O}(m^2d)$ by the standard SVD implementation. However, the total cost can be reduced from $\mathcal{O}(Tm^2d)$ to $\mathcal{O}(Tmd)$ by doubling the space (Algorithm 4 in Appendix A) or using the Gu-Eisenstat procedure (Gu and Eisenstat, 1993).

Desai et al. (2016) proposed some extensions of FD. More specifically, Parameterized FD (PFD) uses an extra hyperparameter to describe the proportion of singular values shrunk in each iteration. PFD improves the performance empirically, but has worse error bound than FD by a constant. Compensative FD (CFD) modifies the output of FD by increasing the singular values and keeps the same error guarantees as FD.

3. Online Newton Methods

For ease of demonstrating our work, we would like to introduce sketching techniques in online learning scenarios. First of all, we introduce the background of convex online learning including online Newton step algorithms. Then we discuss the connection between online learning and sketched second order methods, which motivates us to propose a more robust sketching algorithm.

3.1. Convex Online Learning

Online learning is performed in a sequence of consecutive rounds (Shalev-Shwartz, 2011). We consider the problem of convex online optimization as follows. For a sequence of examples $\{\mathbf{x}^{(t)} \in \mathbb{R}^d\}$, and convex smooth loss functions $\{f_t : \mathcal{K}_t \to \mathbb{R}\}$ where $f_t(\mathbf{w}) \triangleq \ell_t(\mathbf{w}^\top\mathbf{x}^{(t)})$ and $\mathcal{K}_t \subset \mathbb{R}^d$

are convex compact sets, the learner outputs a predictor $\mathbf{w}^{(t)}$ and suffers the loss $f_t(\mathbf{w}^{(t)})$ at the t-th round. The cumulative regret at round T is defined as:

$$R_T(\mathbf{w}^*) = \sum_{t=1}^{T} f_t(\mathbf{w}^{(t)}) - \sum_{t=1}^{T} f_t(\mathbf{w}^*),$$

where $\mathbf{w}^* = \operatorname{argmin}_{\mathbf{w}\in\mathcal{K}} \sum_{t=1}^{T} f_t(\mathbf{w})$ and $\mathcal{K} = \bigcap_{t=1}^{T} \mathcal{K}_t$.

We make the following assumptions on the loss functions.

Assumption 1 *The loss functions ℓ_t satisfy $|\ell_t'(z)| \leq L$ whenever $|z| \leq C$, where L and C are positive constants.*

Assumption 2 *There exists a $\mu_t \leq 0$ such that for all $\mathbf{u}, \mathbf{w} \in \mathcal{K}$, we have*

$$f_t(\mathbf{w}) \geq f_t(\mathbf{u}) + \nabla f_t(\mathbf{u})^\top(\mathbf{w}-\mathbf{u}) + \frac{\mu_t}{2}\big(\nabla f_t(\mathbf{u})^\top(\mathbf{w}-\mathbf{u})\big)^2.$$

Note that for a loss function f_t whose domain and gradient have bounded diameter, holding Assumption 2 only requires the exp-concave property, which is more general than strong convexity (Hazan, 2016). For example, the square loss function $f_t(\mathbf{w}) = (\mathbf{w}^\top\mathbf{x}_t - y_t)^2$ satisfies Assumption 2 with $\mu_t = \frac{1}{8C^2}$ if the function is subject to constraints $|\mathbf{w}^\top\mathbf{x}_t| \leq C$ and $y_t \leq C$ (Luo et al., 2016), but it is not strongly convex.

One typical online learning algorithm is online gradient descent (OGD) (Hazan et al., 2007; Zinkevich, 2003). At the $(t+1)$-th round, OGD exploits the following update rules:

$$\begin{aligned}\mathbf{u}^{(t+1)} &= \mathbf{w}^{(t)} - \beta_t \mathbf{g}^{(t)},\\ \mathbf{w}^{(t+1)} &= \operatorname*{argmin}_{\mathbf{w}\in\mathcal{K}_{t+1}} \|\mathbf{w} - \mathbf{u}^{(t+1)}\|,\end{aligned}$$

where $\mathbf{g}^{(t)} = \nabla f_t(\mathbf{w}^{(t)})$ and β_t is the learning rate. The algorithm has linear computation cost and achieves $\mathcal{O}(\frac{L^2}{H}\log T)$ regret bound for the H-strongly convex loss.

In this paper, we are more interested in online Newton step algorithms (Hazan et al., 2007; Luo et al., 2016). The standard online Newton step keeps the curvature information in the matrix $\mathbf{H}^{(t)} \in \mathbb{R}^{d\times d}$ sequentially and iterates as follows:

$$\begin{aligned}\mathbf{u}^{(t+1)} &= \mathbf{w}^{(t)} - \beta_t (\mathbf{H}^{(t)})^{-1}\mathbf{g}^{(t)},\\ \mathbf{w}^{(t+1)} &= \operatorname*{argmin}_{\mathbf{w}\in\mathcal{K}_{t+1}} \|\mathbf{w} - \mathbf{u}^{(t+1)}\|_{\mathbf{H}^{(t)}}.\end{aligned} \tag{2}$$

The matrix $\mathbf{H}^{(t)}$ is constructed by the outer product of historical gradients (Duchi et al., 2011; Luo et al., 2016), such as

$$\mathbf{H}^{(t)} = \sum_{i=1}^{t} \mathbf{g}^{(i)}(\mathbf{g}^{(i)})^\top + \alpha_0\mathbf{I}_d, \tag{3}$$

$$\text{or}\quad \mathbf{H}^{(t)} = \sum_{i=1}^{t} (\mu_t + \eta_t)\mathbf{g}^{(i)}(\mathbf{g}^{(i)})^\top + \alpha_0\mathbf{I}_d, \tag{4}$$

where $\alpha_0 \geq 0$ is a fixed regularization parameter, μ_t is the constant in Assumption 2, and η_t is typically chosen as $\mathcal{O}(1/t)$. The second order algorithms enjoy logarithmical regret bound without the strongly convex assumption but require quadratical space and computation cost. Some variants of online Newton algorithms have been applied to optimize neural networks (Martens and Grosse, 2015; Grosse and Martens, 2016; Ba et al., 2017), but they do not provide theoretical guarantee on nonconvex cases.

3.2. Efficient Algorithms by Sketching

To make the online Newton step scalable, it is natural to use sketching techniques (Woodruff, 2014). The matrix $\mathbf{H}^{(t)}$ in online learning has the form $\mathbf{H}^{(t)} = (\mathbf{A}^{(t)})^\top\mathbf{A}^{(t)} + \alpha_0\mathbf{I}_d$, where $\mathbf{A}^{(t)} \in \mathbb{R}^{t\times d}$ is the corresponding term of (3) or (4) such as

$$\mathbf{A}^{(t)} = [\mathbf{g}^{(1)}, \ldots, \mathbf{g}^{(t)}]^\top, \quad \text{or} \quad \mathbf{A}^{(t)} = [\sqrt{\mu_1+\eta_1}\mathbf{g}^{(1)}, \ldots, \sqrt{\mu_t+\eta_t}\mathbf{g}^{(t)}]^\top.$$

The sketching algorithm employs an approximation of $(\mathbf{A}^{(t)})^\top\mathbf{A}^{(t)}$ by $(\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)}$, where the sketch matrix $\mathbf{B}^{(t)} \in \mathbb{R}^{m\times d}$ is much smaller than $\mathbf{A}^{(t)}$ and $m \ll d$. Then we can use $(\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} + \alpha_0\mathbf{I}_d$ to replace $\mathbf{H}^{(t)}$ in update (2) (Luo et al., 2016). By the Woodbury identity formula, we can reduce the computation of the update from $\mathcal{O}(d^2)$ to $\mathcal{O}(m^2d)$ or $\mathcal{O}(md)$. There are several choices of sketching techniques, such as random projection (Achlioptas, 2003; Indyk and Motwani, 1998; Kane and Nelson, 2014), frequent directions (Ghashami et al., 2016; Liberty, 2013) and Oja's algorithm (Oja, 1982; Oja and Karhunen, 1985). However, all above methods treat α_0 as a given hyperparameter which is independent of the sketch matrix $\mathbf{B}^{(t)}$. In practice, the performance of sketched online Newton methods is sensitive to the choice of the hyperparamter α_0.

4. Robust Frequent Directions

In many machine learning applications such as online learning (Hazan and Arora, 2006; Hazan et al., 2007; Hazan, 2016; Luo et al., 2016), Gaussian process regression (Rasmussen and Williams, 2006) and kernel ridge regression (Drineas and Mahoney, 2005), we usually require an additional regularization term to make the matrix invertible and well-conditioned, while conventional sketching methods only focus on the low-rank approximation. On the other hand, the update of frequent directions is not optimal in the view of minimizing the approximation error in each iteration. Both of them motivate us to propose robust frequent directions (RFD) that incorporates the update of sketch matrix and the regularization term into one framework.

4.1. The Algorithm

The RFD approximates $\mathbf{A}^\top\mathbf{A}$ by $\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d$ with $\alpha > 0$. We demonstrate the detailed implementation of RFD in Algorithm 2.

The main difference between RFD and conventional sketching algorithms is the additional term $\alpha\mathbf{I}_d$. We can directly use Algorithm 2 to approximate $\mathbf{A}^\top\mathbf{A}$ with $\alpha^{(m-1)} = \alpha_0 > 0$ if the target matrix is $\mathbf{A}^\top\mathbf{A} + \alpha_0\mathbf{I}_d$. Compared with the standard FD, RFD only needs to maintain one extra variable $\alpha^{(t)}$ by scalar operations in each iteration, hence the cost of RFD is almost the same as FD. Because the value of $\alpha^{(t)}$ is typically increasing from the $(m+1)$-th round in practice, the resulting $\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d$ is positive definite even the initial $\alpha^{(0)}$ is zero. Also, we can further accelerate the algorithm by doubling the space.

Algorithm 2 Robust Frequent Directions

Input: $\mathbf{A} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(T)}]^\top \in \mathbb{R}^{T\times d}$, $\mathbf{B}^{(m-1)} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(m-1)}]^\top$, $\alpha^{(m-1)} = 0$
for $t = m, \ldots, T$ **do**
  $\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix} \mathbf{B}^{(t-1)} \\ (\mathbf{a}^{(t)})^\top \end{bmatrix}$
  Compute SVD: $\widehat{\mathbf{B}}^{(t-1)} = \mathbf{U}^{(t-1)}\mathbf{\Sigma}^{(t-1)}(\mathbf{V}^{(t-1)})^\top$
  $\mathbf{B}^{(t)} = \sqrt{(\mathbf{\Sigma}_{m-1}^{(t-1)})^2 - (\sigma_m^{(t-1)})^2\mathbf{I}_{m-1}} \cdot (\mathbf{V}_{m-1}^{(t-1)})^\top$
  $\alpha^{(t)} = \alpha^{(t-1)} + (\sigma_m^{(t-1)})^2/2$
end for
Output: $\mathbf{B} = \mathbf{B}^{(T)}$ and $\alpha = \alpha^{(T)}$.

4.2. Theoretical Analysis

Before demonstrating the theoretical results of RFD, we review FD from the aspect of low-rank approximation which provides a motivation to the design of our algorithm. At the t-th round iteration of FD (Algorithm 1), we have the matrix $\mathbf{B}^{(t-1)}$ which is used to approximate $(\mathbf{A}^{(t-1)})^\top\mathbf{A}^{(t-1)}$ by $(\mathbf{B}^{(t-1)})^\top\mathbf{B}^{(t-1)}$ and we aim to construct a new approximation which includes the new data $\mathbf{a}^{(t)}$, that is,

$$(\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} \approx (\mathbf{B}^{(t-1)})^\top\mathbf{B}^{(t-1)} + \mathbf{a}^{(t)}(\mathbf{a}^{(t)})^\top = (\widehat{\mathbf{B}}^{(t-1)})^\top\widehat{\mathbf{B}}^{(t-1)}. \tag{5}$$

The straightforward way to find $\mathbf{B}^{(t)}$ is to minimize the approximation error of (5) based on the spectral norm with low-rank constraint:

$$\mathbf{B}'^{(t)} = \operatorname*{argmin}_{\mathrm{rank}(\mathbf{C})=m-1} \left\|(\widehat{\mathbf{B}}^{(t-1)})^\top\widehat{\mathbf{B}}^{(t-1)} - \mathbf{C}^\top\mathbf{C}\right\|_2. \tag{6}$$

By the SVD of $\widehat{\mathbf{B}}^{(t-1)}$, we have the solution $\mathbf{B}'^{(t)} = \mathbf{\Sigma}_{m-1}^{(t-1)}(\mathbf{V}_{m-1}^{(t-1)})^\top$. In this view, the update of FD

$$\mathbf{B}^{(t)} = \sqrt{(\mathbf{\Sigma}_{m-1}^{(t-1)})^2 - (\sigma_m^{(t-1)})^2\mathbf{I}_{m-1}} \cdot (\mathbf{V}_{m-1}^{(t-1)})^\top \tag{7}$$

looks imperfect, because it is not an optimal low-rank approximation. However, the shrinkage operation in (7) is necessary. If we take a greedy strategy (Brand, 2002; Hall et al., 1998; Levey and Lindenbaum, 2000; Ross et al., 2008) which directly replaces $\mathbf{B}^{(t)}$ with $\mathbf{B}'^{(t)}$ in FD, it will perform worse in some specific cases[1] and also has no valid global error bound like (1).

Hence, the question is: can we devise a method which enjoys the optimality in each step and maintains global tighter error bound in the same time? Fortunately, RFD is just such an algorithm holding both the properties. We now explain the update rule of RFD formally, and provide the approximation error bound. We first give the following theorem which plays an important role in our analysis.

1. We provide an example in Appendix F.

Theorem 1 *Given a positive semi-definite matrix $\mathbf{M} \in \mathbb{R}^{d\times d}$ and a positive integer $k < d$, let $\mathbf{M} = \mathbf{U}\mathbf{\Sigma}\mathbf{U}^\top$ be the SVD of $\mathbf{M}$. Let $\mathbf{U}_k$ denote the matrix of the first k columns of $\mathbf{U}$ and σ_k be the k-th singular value of $\mathbf{M}$. Then the pair $(\widehat{\mathbf{C}}, \widehat{\delta})$, defined as*

$$\widehat{\mathbf{C}} = \mathbf{U}_k(\mathbf{\Sigma}_k - \xi\mathbf{I}_k)^{1/2}\mathbf{Q} \quad \textit{and} \quad \widehat{\delta} = (\sigma_{k+1} + \sigma_d)/2$$

where $\xi \in [\sigma_d, \sigma_{k+1}]$ and $\mathbf{Q}$ is an arbitrary $k \times k$ orthonormal matrix, is the global minimizer of

$$\min_{\mathbf{C}\in\mathbb{R}^{d\times k}, \delta\in\mathbb{R}} \|\mathbf{M} - (\mathbf{C}\mathbf{C}^\top + \delta\mathbf{I}_d)\|_2. \tag{8}$$

Additionally, we have

$$\|\mathbf{M} - (\widehat{\mathbf{C}}\widehat{\mathbf{C}}^\top + \widehat{\delta}\mathbf{I}_d)\|_2 \le \|\mathbf{M} - \mathbf{U}_k\mathbf{\Sigma}_k\mathbf{U}_k^\top\|_2,$$

and the equality holds if and only if $\mathrm{rank}(\mathbf{M}) \le k$.

Theorem 1 provides the optimal solution with the closed form for matrix approximation with a regularization term. In the case of $\mathrm{rank}(\mathbf{M}) > k$, the approximation $\widehat{\mathbf{C}}\widehat{\mathbf{C}}^\top + \widehat{\delta}\mathbf{I}_d$ is full rank and has strictly lower spectral norm error than the rank-k truncated SVD. Note that Zhang (2014) has established the Frobenius norm based result about the optimal analysis[2].

Recall that in the streaming case, our goal is to approximate the concentration of historical approximation and current data at the t-th round. The following theorem shows that the update of RFD is optimal with respect to the spectral norm for each step.

Theorem 2 *Based on the updates in Algorithm 2, we have*

$$(\mathbf{B}^{(t)}, \alpha^{(t)}) = \operatorname*{argmin}_{\mathbf{B}\in\mathbb{R}^{d\times(m-1)}, \alpha\in\mathbb{R}} \left\|(\widehat{\mathbf{B}}^{(t-1)})^\top\widehat{\mathbf{B}}^{(t-1)} + \alpha^{(t-1)}\mathbf{I}_d - (\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d)\right\|_2. \tag{9}$$

Theorem 2 explains RFD from an optimization viewpoint. It shows that each step of RFD is optimal for current information. Based on this theorem, the update of the standard FD corresponds $(\mathbf{B}, \alpha) = (\mathbf{B}^{(t)}, 0)$, which is not the optimal solution of (9). Intuitively, the regularization term of RFD compensates each direction for the over reduction from the shrinkage operation of FD. Theorem 2 also implies RFD is an online extension to the approximation of Theorem 1. We can prove Theorem 2 by using Theorem 1 with $\mathbf{M} = (\widehat{\mathbf{B}}^{(t-1)})^\top\widehat{\mathbf{B}}^{(t-1)} + \alpha^{(t-1)}\mathbf{I}_d$. We defer the details to Appendix C.

RFD also enjoys a tighter approximation error than FD as the following theorem shows.

Theorem 3 *For any $k < m$ and using the notation of Algorithm 2, we have*

$$\left\|\mathbf{A}^\top\mathbf{A} - (\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d)\right\|_2 \le \frac{1}{2(m-k)}\|\mathbf{A} - [\mathbf{A}]_k\|_F^2, \tag{10}$$

where $[\mathbf{A}]_k$ is the best rank-k approximation to $\mathbf{A}$ in both the Frobenius and spectral norms.

The right-hand side of inequality (10) is the half of the one in (1), which means RFD reduces the approximation error significantly with only one extra scalar.

The real applications usually consider the matrix with a regularization term. Hence we also consider approximating the matrix $\mathbf{M} = \mathbf{A}^\top\mathbf{A} + \alpha_0\mathbf{I}_d$ where $\alpha_0 > 0$ and the rows of $\mathbf{A}$ are available

2. We also give a concise proof for the result of Zhang (2014) in Appendix B.

in sequentially order. Suppose that the standard FD approximates $\mathbf{A}^\top\mathbf{A}$ by $\mathbf{B}^\top\mathbf{B}$. Then it estimates $\mathbf{M}$ as $\mathbf{M}_{\text{FD}} = \mathbf{B}^\top\mathbf{B} + \alpha_0\mathbf{I}_d$. Meanwhile, RFD generates the approximation $\mathbf{M}_{\text{RFD}} = \mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d$ by setting $\alpha^{(m-1)} = \alpha_0$. Theorem 4 shows that the condition number of $\mathbf{M}_{\text{RFD}}$ is better than $\mathbf{M}_{\text{FD}}$ and $\mathbf{M}$. In general, the equality in Theorem 4 usually can not be achieved for $t > m$ unless $(\mathbf{a}^{(t)})^\top$ lies in the row space of $\mathbf{B}^{(t-1)}$ exactly or the first t rows of $\mathbf{A}$ have perfect low rank structure. Hence RFD is more likely to generate a well-conditioned approximation than others.

Theorem 4 *With the notation of Algorithms 1 and 2, let* $\mathbf{M} = \mathbf{A}^\top\mathbf{A} + \alpha_0\mathbf{I}_d$, $\mathbf{M}_{\text{FD}} = \mathbf{B}^\top\mathbf{B} + \alpha_0\mathbf{I}_d$, $\mathbf{M}_{\text{RFD}} = \mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d$ *and* $\alpha^{(m-1)} = \alpha_0$, *where* $\alpha_0 > 0$ *is a fixed scalar. Then we have* $\kappa(\mathbf{M}_{\text{RFD}}) \leq \kappa(\mathbf{M}_{\text{FD}})$ *and* $\kappa(\mathbf{M}_{\text{RFD}}) \leq \kappa(\mathbf{M})$.

5. The Online Newton Step by RFD

We now present the sketched online Newton step by robust frequent directions (RFD-SON). The procedure is shown in Algorithm 3, which is similar to sketched online Newton step (SON) algorithms (Luo et al., 2016) but uses the new sketching method RFD. The matrix $\mathbf{H}^{(t)}$ in Line 10 will not be constructed explicitly in practice, which is only used to the ease of analysis. The updates of $\mathbf{u}^{(t)}$ and $\mathbf{w}^{(t)}$ can be finished in $\mathcal{O}(md)$ time and space complexity by the Woodbury identity. We demonstrate the details in Appendix . When d is large, RFD-SON is much efficient than the standard online Newton step with the full Hessian that requires $\mathcal{O}(d^2)$ both in time and space.

Note that we do not require the hyperparameter α_0 to be strictly positive in RFD-SON. In practice, RFD-SON always archives good performance by setting $\alpha_0 = 0$, which leads to a hyperparameter-free algorithm, while the existing SON algorithm needs to select α_0 carefully. We consider the general case that $\alpha_0 \geq 0$ in this section for the ease of analysis.

Theorem 5 *Let* $\mu = \min_{t=1}^T\{\mu_t\}$ *and* $\mathcal{K} = \bigcap_{t=1}^T\mathcal{K}_t$. *Then under Assumptions 1 and 2 for any* $\mathbf{w} \in \mathcal{K}$, *Algorithm 3 has the following regret for* $\alpha_0 > 0$

$$R_T(\mathbf{w}) \leq \frac{\alpha_0}{2}\|\mathbf{w}\|^2 + 2(CL)^2\sum_{t=1}^T\eta_t + \frac{m}{2(\mu+\eta_T)}\ln\Big(\frac{\text{tr}\big((\mathbf{B}^{(T)})^\top\mathbf{B}^{(T)}\big)}{m\alpha_0} + \frac{\alpha^{(T)}}{\alpha_0}\Big) + \Omega_{\text{RFD}} \tag{11}$$

where

$$\Omega_{\text{RFD}} = \frac{d-m}{2(\mu+\eta_T)}\ln\frac{\alpha^{(T)}}{\alpha_0} + \frac{m}{4(\mu+\eta_T)}\sum_{t=1}^T\frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}} + C^2\sum_{t=1}^T(\sigma_m^{(t-1)})^2.$$

We present the regret bound of RFD-SON for positive α_0 in Theorem 5. The term Ω_{RFD} in (11) is the main gap between RFD-SON and the standard online Newton step without sketching. Ω_{RFD} is dominated by the last term which can be bounded as (1). If we exploit the standard FD to sketched online Newton step (Luo et al., 2016) (FD-SON), the regret bound is similar to (11) but the gap will be

$$\Omega_{\text{FD}} = \frac{m\Omega_k}{2(m-k)(\mu+\eta_T)\alpha_0},$$

Algorithm 3 RFD for Online Newton Step

1: **Input:** $\alpha^{(0)} = \alpha_0 \geq 0$, $m < d$, $\eta_t = \mathcal{O}(1/t)$, $\mathbf{w}^{(0)} = \mathbf{0}^d$ and $\mathbf{B}^{(0)}$ be empty.
2: **for** $t = 0, \ldots, T-1$ **do**
3: Receive example $\mathbf{x}^{(t)}$, and loss function $f_t(\mathbf{w})$
4: Predict the output of $\mathbf{x}^{(t)}$ by $\mathbf{w}^{(t)}$ and suffer loss $f_t(\mathbf{w}^{(t)})$
5: $\mathbf{g}^{(t)} = \nabla f_t(\mathbf{w}^{(t)})$
6: $\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix}\mathbf{B}^{(t-1)} \\ (\sqrt{\mu_t+\eta_t}\mathbf{g}^{(t)})^\top\end{bmatrix}$
7: Compute SVD: $\widehat{\mathbf{B}}^{(t-1)} = \mathbf{U}^{(t-1)}\mathbf{\Sigma}^{(t-1)}(\mathbf{V}^{(t-1)})^\top$
8: $\mathbf{B}^{(t)} = \sqrt{\big(\mathbf{\Sigma}_{m-1}^{(t-1)}\big)^2 - \big(\sigma_m^{(t-1)}\big)^2\mathbf{I}_{m-1}}\cdot(\mathbf{V}_{m-1}^{(t-1)})^\top$
9: $\alpha^{(t)} = \alpha^{(t-1)} + \big(\sigma_m^{(t-1)}\big)^2/2$
10: $\mathbf{H}^{(t)} = (\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} + \alpha^{(t)}\mathbf{I}_d$
11: $\mathbf{u}^{(t+1)} = \mathbf{w}^{(t)} - (\mathbf{H}^{(t)})^\dagger\mathbf{g}^{(t)}$
12: $\mathbf{w}^{(t+1)} = \text{argmin}_{\mathbf{w}\in\mathcal{K}_{t+1}}\|\mathbf{w} - \mathbf{u}^{(t+1)}\|_{\mathbf{H}^{(t)}}$
13: **end for**

where Ω_k plays the similar role to term $\sum_{t=1}^T(\sigma_m^{(t-1)})^2$ in RFD-SON and the detailed definition can be found in Luo et al. (2016). This result is heavily dependent on the hyperparameter α_0. If we increase the value of α_0, the gap Ω_{FD} can be reduced but the term $\frac{\alpha_0}{2}\|\mathbf{w}\|^2$ in the bound will increase, and vice versa. In other words, we need to trade off $\frac{\alpha_0}{2}\|\mathbf{w}\|^2$ and Ω_{FD} by tuning α_0 carefully. For RFD-SON, Theorem 5 implies that we can set α_0 be sufficiently small to reduce $\frac{\alpha_0}{2}\|\mathbf{w}\|^2$ and it has limited effect on the term Ω_{RFD}. The reason is that the first term of Ω_{RFD} contains $\frac{1}{\alpha_0}$ in the logarithmic function and the second term contains $\alpha^{(t)} = \alpha_0 + \frac{1}{2}\sum_{i=1}^{t-1}(\sigma_m^{(i)})^2$ in the denominator. For large t, $\alpha^{(t)}$ is mainly dependent on $\sum_{i=1}^{t-1}(\sigma_m^{(i)})^2$, rather than α_0. Hence the regret bound of RFD-SON is much less sensitive to the hyperparameter α_0 than FD-SON. We have $\sum_{t=1}^T(\sigma_m^{(t-1)})^2 \leq \|\mathbf{A} - [\mathbf{A}]_k\|_F^2/(m-k)$ for $k < m$ by using (17) with $\mathbf{A} = \sum_{t=1}^T(\mu_t+\eta_t)\mathbf{g}^{(t)}(\mathbf{g}^{(t)})^\top$.

Consider RFD-SON with $\alpha_0 = 0$. Typically, the parameter $\alpha^{(t)}$ is zero at very few first iterations and increase to be strictly positive later. Hence the learning algorithm can be divided into two phases based on whether $\alpha^{(t)}$ is zero. Suppose that T' satisfies

$$\alpha^{(t)}\begin{cases}= 0, & t < T' \\ > 0, & t \geq T'.\end{cases} \tag{12}$$

Then the regret can be written as

$$R_T(\mathbf{w}) = R_{1:T'}(\mathbf{w}) + R_{(T'+1):T}(\mathbf{w}),$$

where

$$R_{1:T'}(\mathbf{w}) = \sum_{t=1}^{T'} f_t(\mathbf{w}^{(t)}) - \sum_{t=1}^{T'} f_t(\mathbf{w})$$

and

$$R_{(T'+1):T}(\mathbf{w}) = \sum_{t=T'+1}^{T} f_t(\mathbf{w}^{(t)}) - \sum_{t=T'+1}^{T'} f_t(\mathbf{w}).$$

The regret from the first T' iterations can be bounded by Theorem 6 and the bound of $R_{(T'+1):T}(\mathbf{w})$ can be derived by the similar proof of Theorem 5.

Theorem 6 *By the condition of Theorem 5, $\mu' = \max_{t=1}^{T'}\{\mu_t\}$ and letting $\alpha_0 = 0$, σ^* be the smallest nonzero singular values of $\sum_{t=1}^{T'} \mathbf{g}^{(t)}(\mathbf{g}^{(t)})^\top$ and T' satisfy (12), we have that the first T' iterations of Algorithm 3 has the following regret*

$$R_{1:T'}(\mathbf{w}) \leq 2(CL)^2 \sum_{t=1}^{T'} \eta_t + \frac{m-1}{2(\eta_1+\mu')} + \frac{m(m-1)}{2(\eta_1+\mu')} \ln\Big(1 + \frac{2\sum_{t=1}^{T'} \|\mathbf{g}^{(t)}\|_2^2}{(1+r)r\sigma^*}\Big). \tag{13}$$

Combining above results, we can conclude the regret bound for the hyperparameter-free algorithm in Theorem 7. In practice, we often set m to be much smaller than d and T, which implies T' is much smaller than T. Hence, the regret bound of Theorem 7 is similar to the one of Theorem 5 when α_0 is close to 0. We can use RFD-SON with $\alpha_0 = 0$ and $\eta_t = 1/t$ to obtain a hyperparameter-free sketched online Newton algorithm. Luo et al. (2016) have proposed a hyperparameter-free online Newton algorithm without sketching and their regret contains a term with coefficient d.

Theorem 7 *Consider Algorithm 3 with $\alpha_0 = 0$, let T' satisfy (12), $\mu = \min_{t=1}^{T}\{\mu_t\}$, $\mu' = \max_{t=1}^{T'}\{\mu_t\}$, $\mathcal{K} = \bigcap_{t=1}^{T}\mathcal{K}_t$, σ^* has the same definition of Theorem 6 and $\alpha_0' = \det(\mathbf{H}^{(T')})$. Then under Assumptions 1 and 2 for any $\mathbf{w} \in \mathcal{K}$, we have that*

$$\begin{aligned} R_T(\mathbf{w}) \leq\ & 2(CL)^2 \sum_{t=1}^{T} \eta_t + \frac{m-1}{2(\eta_1+\mu')} + \frac{m(m-1)}{2(\eta_1+\mu')} \ln\Big(1 + \frac{2\sum_{t=1}^{T'} \|\mathbf{g}^{(t)}\|_2^2}{(1+r)r\sigma^*}\Big) \\ & + \frac{1}{2}\|\mathbf{w}^{(T')}\|^2_{\mathbf{H}^{(T')}} + \frac{m}{2(\mu+\eta_T)} \ln\Big(\mathrm{tr}\frac{\big((\mathbf{B}^{(T)})^\top \mathbf{B}^{(T)}\big)}{m\alpha^{(T')}} + \frac{\alpha^{(T)}}{\alpha_0'}\Big) + \Omega'_{\mathrm{RFD}} \end{aligned} \tag{14}$$

where

$$\Omega'_{\mathrm{RFD}} = \frac{d-m}{2(\mu+\eta_T)} \ln\frac{\alpha^{(T)}}{\alpha_0'} + \frac{m}{4(\mu+\eta_T)} \sum_{t=T'+1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}} + C^2 \sum_{t=T'+1}^{T} (\sigma_m^{(t-1)})^2.$$

6. Experiments

In this section, we evaluate the performance of robust frequent directions (RFD) and online Newton step by RFD (RFD-SON) on six real-world data sets "a9a," "gisette," "sido0," "farm-ads," "rcv1" and "real-sim," whose details are listed in Table 1. The data sets "sido0" and "farm-ads"can be found

on Causality Workbench[3], and UCI Machine Learning Repository[4]. The others can be downloaded from LIBSVM repository[5]. The experiments are conducted in Matlab and run on a server with Intel (R) Core (TM) i7-3770 CPU 3.40GHz×2, 8GB RAM and 64-bit Windows Server 2012 system.

data sets	n	d	source
a9a	32,561	123	(Platt, 1999)
gisette	6,000	5,000	(Guyon et al., 2004)
sido0	12,678	4,932	(Guyon et al., 2008)
farm-ads	4,143	54,877	(Mesterharm and Pazzani, 2011)
rcv1	20,242	47,236	(Lewis et al., 2004)
real-sim	72,309	20,958	(McCallum)

Table 1: Summary of data sets used in our experiments

6.1. Matrix Approximation

We evaluate the approximation errors of the deterministic sketching algorithms including frequent directions (FD) (Liberty, 2013; Ghashami et al., 2016), parameterized frequent directions (PFD), compensative frequent directions (CFD) (Desai et al., 2016) and robust frequent directions (RFD). For a given data set $\mathbf{A} \in \mathbb{R}^{n\times d}$ of n samples with d features, we use the accelerated algorithms (see details in Appendix A) to approximate the covariance matrix $\mathbf{A}^\top\mathbf{A}$ by $\mathbf{B}^\top\mathbf{B}$ for FD, PFD, CFD and by $\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d$ for RFD, respectively. We measure the performance according to the relative spectral norm error. We report the relative spectral norm error by varying the sketch size m.

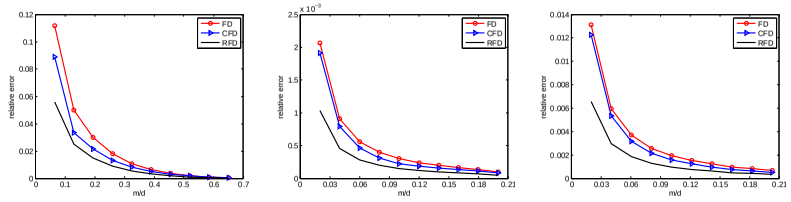

Figure 1 shows the performance of FD, CFD and RFD. These three methods have no extra hyperparameter and their outputs only rely on the sketch size. The relative error of RFD is always smaller than that of FD and CFD. The error of RFD is nearly half of the error of FD in most cases, which matches our theoretical analysis in Theorem 3 very well.

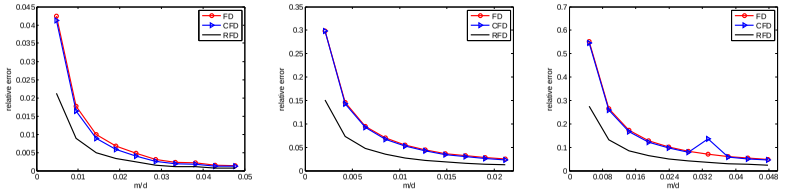
Figure 2 compares the performance of RFD and PFD with different choices of the hyperparameter. We use PFD-β to refer the PFD algorithm where $\lfloor \beta m \rfloor$ singular values will get affected by the shrinkage steps. The extra hyperparameter β is tuned from $\{0.2, 0.4, 0.6, 0.8\}$. The result shows that RFD is better than PFD in most cases. PFD sometimes can achieve lower approximation error with a good choice of β. However, selecting the hyperparameter requires additional computation.



6.2. Online Learning

We now evaluate the performance of RFD-SON. We use the least squares loss $f_t(\mathbf{w}) = (\mathbf{w}^\top\mathbf{x}^{(t)} - y^{(t)})^2$, and set $\mathcal{K}_t = \{\mathbf{w} : |\mathbf{w}^\top\mathbf{x}^{(t)}| \leq 1\}$. In the experiments, we use the doubling space strategy (Algorithm 5 in Appendix A). We use 70% of the data set for training and the rest for test. The algorithms in the experiments include ADAGRAD, the standard online Newton step with the full Hessian (Duchi et al., 2011) (FULL-ON), the sketched online Newton step with frequent directions (FD-SON), the parameterized frequent directions (PFD-SON), the random projections (RP-SON), Oja's algorithms (Oja-SON) (Luo et al., 2016; Desai et al., 2016), and our proposed sketched online Newton step with RFD (RFD-SON).

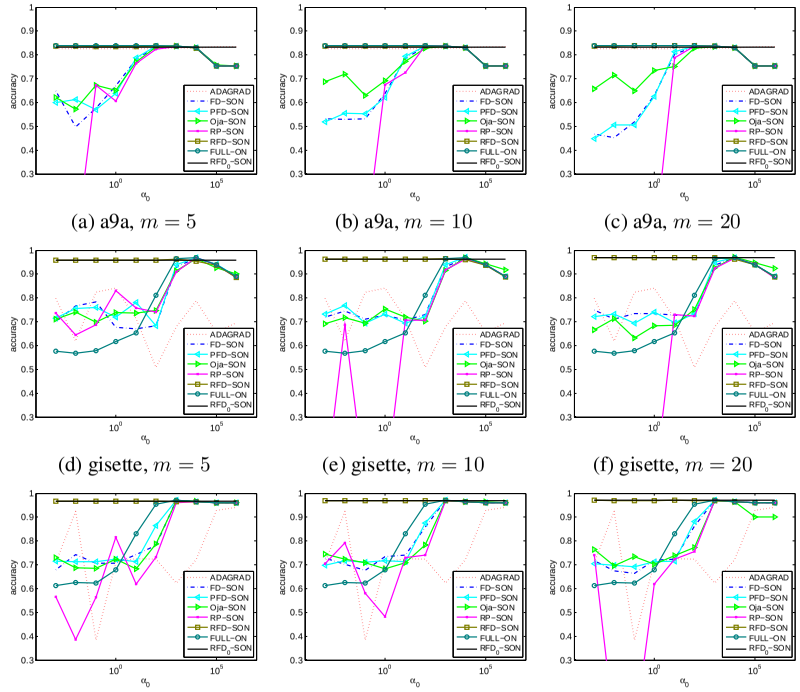

Figure 2: Comparison of relative spectral error of PFD and RFD with proportion of sketching

The hyperparameter α_0 is tuned from $\{10^{-3}, 10^{-2} \dots 10^5, 10^6\}$ for all methods and let $\eta = 1/t$ for SON algorithms. FULL-ON is too expensive and impractical for large d, so we exclude it from experiments on "farm-ads," "rcv1" and "real-sim." For PFD-SON, we let $\beta = 0.2$ heuristically because it usually achieves good performance on approximating the covariance matrix. Additionally, RFD-SON includes the result with $\alpha_0 = 0$ (RFD$_0$-SON). The sketch size of sketched online Newton methods is chosen from $\{5, 10, 20\}$ for "a9a," "gisette," "sido0," and $\{20, 30, 50\}$ for "farm-ads," "rcv1" and "real-sim." We measure performance according to two metrics (Duchi et al., 2011): the

online error rate and the test set performance of the predictor at the end of one pass through the training data.

We are interested in how the hyperparameter α_0 affects the performance of the algorithms. We display the test set performance in Figures 3 and 4. We compare the online error rate of RFD$_0$-SON with the one of FULL-ON in Figure 5 and show the comparison between RFD$_0$-SON and other SON methods with different choices of α_0 in Figures 6 - 11.

We also report the accuracy on the test sets for all algorithms at one pass with the best α_0 in Table 2 and the corresponding running times in Table 3. All SON algorithms can perform well with the best choice of α_0. However, only RFD$_0$-SON can perform well without tuning the hyperparameter while all baseline methods ADAGRAD, FD-SON, PFD-SON, RP-SON and Oja-SON are very sensitive to the value of α_0. The sub-figure (j)-(l) in Figures 5-11 shows RFD-SON usually has good performance with small α_0, which validates our theoretical analysis in Theorem 5. The choice of the hyperparameter almost has no effect of RFD-SON on data set "a9a'," "gisette," "sido0" and "farm-ads." These results verify that RFD-SON is a very stable algorithm in practice.

Table 2: We list the accuracy (%) on test set at the end of one pass with best choice of α_0. The sketch size is set $(m_1, m_2, m_3) = (5, 10, 20)$ for "a9a", "gisette", "sido0" and $(m_1, m_2, m_3) = (20, 30, 50)$ for "farm-ads", "rcv1" and "real-sim".

7. Conclusions

In this paper we have proposed a novel sketching method robust frequent directions (RFD), and our theoretical analysis shows that RFD is superior to FD. We have also studied the use of RFD in the second order online learning algorithms. The online learning algorithm with RFD achieves better performance than baselines. It is worth pointing out that the application of RFD is not limited to convex online optimization. In future work, we would like to explore the use of RFD in stochastic optimization and non-convex problems.

Table 3: We list the average iteration cost corresponding to Table 2.

Appendix A. Accelerating by Doubling Space

The cost of FD (Algorithm 1) is dominated by the steps of SVD. It takes $\mathcal{O}(Tm^2d)$ time by standard SVD in total. We can accelerate FD by doubling the sketch size (Liberty, 2013). The details are shown in Algorithm 4. Then the SVD is called only every m rows of $\mathbf{A}$ come and the time complexity is reduced to $\mathcal{O}(Tmd)$. Similarly, RFD can also be speeded up in this way. We demonstrate it in Algorithm 5.

We can apply similar strategy on RFD-SON, just as Algorithm 6 shows. For $\alpha^{(t)} > 0$, the parameter $\mathbf{w}^{(t)}$ can be updated in $\mathcal{O}(md)$ cost by Woodbury identity (Luo et al., 2016). Suppose $\mathbf{B}^{(t)} \in \mathbb{R}^{m' \times d}$, where $m' \leq 2m$. We have

$$\mathbf{u}^{(t+1)} = \mathbf{w}^{(t)} - \frac{1}{\alpha^{(t)}}\big(\mathbf{g}^{(t)} - (\mathbf{B}^{(t)})^\top \mathbf{M}^{(t)} \mathbf{B}^{(t)} \mathbf{g}^{(t)}\big),$$
$$\mathbf{w}^{(t+1)} = \mathbf{u}^{(t+1)} - \gamma^{(t)}\big(\mathbf{x}^{(t)} - (\mathbf{B}^{(t)})^\top \mathbf{M}^{(t)} \mathbf{B}^{(t)} \mathbf{x}^{(t)}\big),$$

where

$$\gamma^{(t)} = \frac{\tau\big((\mathbf{u}^{(t)})^\top \mathbf{x}^{(t)}\big)}{(\mathbf{x}^{(t)})^\top \mathbf{x}^{(t)} - (\mathbf{x}^{(t)})^\top (\mathbf{B}^{(t)})^\top \mathbf{M}^{(t)} \mathbf{B}^{(t)} \mathbf{x}^{(t)}},$$
$$\mathbf{M}^{(t)} = \big(\mathbf{B}^{(t)}(\mathbf{B}^{(t)})^\top + \alpha^{(t)} \mathbf{I}_m\big)^{-1},$$
$$\tau(z) = \operatorname{sgn}(z) \max\{|z| - 1, 0\}.$$

Let's check the cost of the above steps in detail. The matrix $\mathbf{M}^{(t)}$ costs $\mathcal{O}(m^2)$ space and the computation of $\mathbf{M}^{(t)}(\mathbf{B}^{(t)}\mathbf{g}^{(t)})$ or $\mathbf{M}^{(t)}(\mathbf{B}^{(t)}\mathbf{x}^{(t)})$ takes $\mathcal{O}(md + m^3)$ time given $\mathbf{B}^{(t)}(\mathbf{B}^{(t)})^\top + \alpha^{(t)}\mathbf{I}_{m'}$. The result of $\mathbf{B}^{(t)}(\mathbf{B}^{(t)})^\top$ also can be obtained in $\mathcal{O}(md)$ time. If we have executed SVD at current iteration (when $\widehat{\mathbf{B}}^{(t-1)}$ has $2m$ rows), $\mathbf{B}^{(t)}(\mathbf{B}^{(t)})$ is diagonal and we can directly obtain

Algorithm 4 Fast Frequent Directions

Input: $\mathbf{A} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(T)}]^\top \in \mathbb{R}^{T \times d}$, $\mathbf{B}^{(0)} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(m-1)}]^\top$
for $t = m, \ldots, T$ **do**
  $\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix} \mathbf{B}^{(t-1)} \\ (\mathbf{a}^{(t)})^\top \end{bmatrix}$
  if $\widehat{\mathbf{B}}^{(t-1)}$ has $2m$ rows
    Compute SVD: $\widehat{\mathbf{B}}^{(t-1)} = \mathbf{U}^{(t-1)}\mathbf{\Sigma}^{(t-1)}(\mathbf{V}^{(t-1)})^\top$
    $\mathbf{B}^{(t)} = \sqrt{\big(\mathbf{\Sigma}_{m-1}^{(t-1)}\big)^2 - \big(\sigma_m^{(t-1)}\big)^2 \mathbf{I}_{m-1}} \cdot \big(\mathbf{V}_{m-1}^{(t-1)}\big)^\top$
  else
    $\mathbf{B}^{(t)} = \widehat{\mathbf{B}}^{(t-1)}$
  end if
end for
Output: $\mathbf{B} = \mathbf{B}^{(T)}$

Algorithm 5 Fast Robust Frequent Directions

Input: $\mathbf{A} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(T)}]^\top \in \mathbb{R}^{T \times d}$, $\mathbf{B}^{(m-1)} = [\mathbf{a}^{(1)}, \ldots, \mathbf{a}^{(m-1)}]^\top$, $\alpha^{(m-1)} = 0$
for $t = m, \ldots, T$ **do**
  $\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix} \mathbf{B}^{(t-1)} \\ (\mathbf{a}^{(t)})^\top \end{bmatrix}$
  if $\widehat{\mathbf{B}}^{(t-1)}$ has $2m$ rows
    Compute SVD: $\widehat{\mathbf{B}}^{(t-1)} = \mathbf{U}^{(t-1)}\mathbf{\Sigma}^{(t-1)}(\mathbf{V}^{(t-1)})^\top$
    $\mathbf{B}^{(t)} = \sqrt{\big(\mathbf{\Sigma}_{m-1}^{(t-1)}\big)^2 - \big(\sigma_m^{(t-1)}\big)^2 \mathbf{I}_{m-1}} \cdot \big(\mathbf{V}_{m-1}^{(t-1)}\big)^\top$
    $\alpha^{(t)} = \alpha^{(t-1)} + \big(\sigma_m^{(t-1)}\big)^2/2$
  else
    $\mathbf{B}^{(t)} = \widehat{\mathbf{B}}^{(t-1)}$
    $\alpha^{(t)} = \alpha^{(t-1)}$
  end if
end for
Output: $\mathbf{B} = \mathbf{B}^{(T)}$ and $\alpha = \alpha^{(T)}$

the SVD of

$$\mathbf{B}^{(t)}(\mathbf{B}^{(t)})^\top = \left(\mathbf{\Sigma}_{m-1}^{(t-1)}\right)^2 - \left(\sigma_m^{(t-1)}\right)^2\mathbf{I}_{m-1},$$

otherwise it can be updated incrementally in $\mathcal{O}(md)$ as follows

$$\mathbf{B}^{(t)}(\mathbf{B}^{(t)})^\top = \begin{bmatrix} \mathbf{B}^{(t-1)}(\mathbf{B}^{(t-1)})^\top & \sqrt{\mu_t+\eta_t}\mathbf{B}^{(t-1)}\mathbf{g}^{(t)} \\ \sqrt{\mu_t+\eta_t}(\mathbf{B}^{(t-1)}\mathbf{g}^{(t)})^\top & (\mu_t+\eta_t)(\mathbf{g}^{(t)})^\top\mathbf{g}^{(t)} \end{bmatrix}.$$

Since we have $m \ll d$, all above operations only require $\mathcal{O}(md)$ time and space complexity in total for each iteration.

In the case of $\alpha^{(t)} = 0$, we can iterate $\mathbf{u}^{(t)}$ and $\mathbf{w}^{(t)}$ by using SVD on $\mathbf{B}^{(t)}$. Let the condensed SVD of $\mathbf{B}^{(t)}$ be $\mathbf{B}^{(t)} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$, where $\mathbf{U} \in \mathbb{R}^{m'\times r}$, $\mathbf{\Sigma} \in \mathbb{R}^{r\times r}$, $\mathbf{V} \in \mathbb{R}^{r\times d}$ and $r = \operatorname{rank}(\mathbf{B}^{(t)}) < m'$. Then we have

$$\mathbf{H}^{(t)} = (\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} = \mathbf{V}\mathbf{\Sigma}^2\mathbf{V}^\top,$$
$$(\mathbf{H}^{(t)})^\dagger = \mathbf{V}\mathbf{\Sigma}^{-2}\mathbf{V}^\top.$$

We can update $\mathbf{u}^{(t+1)}$ and $\mathbf{w}^{(t+1)}$ as follows

$$\mathbf{u}^{(t+1)} = \mathbf{w}^{(t)} - \mathbf{V}^\top(\mathbf{\Sigma}^{-2}(\mathbf{V}^\top\mathbf{g}^{(t)})),$$
$$\mathbf{w}^{(t+1)} = \operatorname*{argmin}_{\mathbf{w}\in\{\mathbf{w}_1^{(t)},\mathbf{w}_2^{(t)}\}} \|\mathbf{w} - \mathbf{u}^{(t+1)}\|_{\mathbf{H}^{(t)}},$$

where

$$\mathbf{w}_1^{(t)} = \mathbf{u}^{(t+1)} - \frac{\tau\left((\mathbf{u}^{(t+1)})^\top\mathbf{x}^{(t)}\right)}{(\mathbf{x}^{(t)})^\top\mathbf{V}\mathbf{\Sigma}^{-2}\mathbf{V}^\top\mathbf{x}^{(t)}}\mathbf{V}\mathbf{\Sigma}^{-2}\mathbf{V}^\top\mathbf{x}^{(t)},$$
$$\mathbf{w}_2^{(t)} = \mathbf{u}^{(t+1)} - \frac{\tau\left((\mathbf{u}^{(t+1)})^\top\mathbf{x}^{(t)}\right)}{(\mathbf{x}^{(t)})^\top\mathbf{x}^{(t)} - (\mathbf{x}^{(t)})^\top\mathbf{V}\mathbf{\Sigma}^{-2}\mathbf{V}^\top\mathbf{x}^{(t)}}(\mathbf{x}^{(t)} - \mathbf{V}\mathbf{\Sigma}^{-2}\mathbf{V}^\top\mathbf{x}^{(t)}).$$

The iteration costs $\mathcal{O}(m^2d)$ in total (dominated by the SVD of $\mathbf{B}^\top$), but $\alpha^{(t)} = 0$ only appears at a few early iterations. Hence the average iteration complexity of RFD-SON is dominated by the case $\alpha^{(t)} > 0$ which takes $\mathcal{O}(md)$. Note that the algorithm is also valid without the smoothness of f_t. We can replace the gradient ∇f_t with the corresponding subgradient.

Appendix B. The Proof of Theorem 1

In this section, we firstly provide several lemmas from the book "Topics in matrix analysis" (Horn and Johnson, 1991), then we prove Theorem 1. The proof of Lemma 1 and 2 can be found in the book and we give the proof of Lemma 3 here.

Lemma 1 (Theorem 3.4.5 of (Horn and Johnson, 1991)) *Let $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{m\times n}$ be given, and suppose $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{A}-\mathbf{B}$ have decreasingly ordered singular values, $\sigma_1(\mathbf{A}) \geq \cdots \geq \sigma_q(\mathbf{A})$, $\sigma_1(\mathbf{B}) \geq \cdots \geq \sigma_q(\mathbf{B})$, and $\sigma_1(\mathbf{A}-\mathbf{B}) \geq \cdots \geq \sigma_q(\mathbf{A}-\mathbf{B})$, where $q = \min\{m,n\}$. Define $s_i(\mathbf{A},\mathbf{B}) \equiv |\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})|$, $i = 1,\ldots,q$ and let $s_{[1]}(\mathbf{A},\mathbf{B}) \geq \cdots \geq s_{[i]}(\mathbf{A},\mathbf{B})$ denote a decreasingly ordered rearrangement of the values $s_i(\mathbf{A},\mathbf{B})$. Then*

$$\sum_{i=1}^k s_{[i]}(\mathbf{A},\mathbf{B}) \leq \sum_{i=1}^k \sigma_i(\mathbf{A}-\mathbf{B}) \text{ for } k = 1,\ldots,q.$$

Algorithm 6 Fast RFD for Online Newton Step

for $t = 1,\ldots,T$ **do**
  Receive example $\mathbf{x}^{(t)}$, and loss function $f_t(\mathbf{w})$
  Predict the output of $\mathbf{x}^{(t)}$ by $\mathbf{w}^{(t)}$ and suffer loss $f_t(\mathbf{w}^{(t)})$
  $\mathbf{g}^{(t)} = \nabla f_t(\mathbf{w}^{(t)})$
  $\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix} \mathbf{B}^{(t-1)} \\ (\sqrt{\mu_t+\eta_t}\mathbf{g}^{(t)})^\top \end{bmatrix}$
  if $\widehat{\mathbf{B}}^{(t-1)}$ has $2m$ rows
    Compute SVD: $\widehat{\mathbf{B}}^{(t-1)} = \mathbf{U}^{(t-1)}\mathbf{\Sigma}^{(t-1)}(\mathbf{V}^{(t-1)})^\top$
    $\mathbf{B}^{(t)} = \sqrt{\left(\mathbf{\Sigma}_{m-1}^{(t-1)}\right)^2 - \left(\sigma_m^{(t-1)}\right)^2\mathbf{I}_{m-1}}\cdot(\mathbf{V}_{m-1}^{(t-1)})^\top$
    $\alpha^{(t)} = \alpha^{(t-1)} + \left(\sigma_m^{(t-1)}\right)^2/2$
  else
    $\mathbf{B}^{(t)} = \widehat{\mathbf{B}}^{(t-1)}$
    $\alpha^{(t)} = \alpha^{(t-1)}$
  end if
  $\mathbf{H}^{(t)} = (\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} + \alpha^{(t)}\mathbf{I}_d$
  $\mathbf{u}^{(t+1)} = \mathbf{w}^{(t)} - (\mathbf{H}^{(t)})^\dagger\mathbf{g}^{(t)}$
  $\mathbf{w}^{(t+1)} = \operatorname{argmin}_{\mathbf{w}\in\mathcal{K}_t}\|\mathbf{w} - \mathbf{u}^{(t+1)}\|_{\mathbf{H}^{(t)}}$
end for

Lemma 2 (Corollary 3.5.9 of (Horn and Johnson, 1991)) *Let $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{m\times n}$ be given, and let $q = \min\{m,n\}$. The following are equivalent*

1. *$\|\mathbf{A}\| \leq \|\mathbf{B}\|$ for every unitarily invariant norm $\|\cdot\|$ on $\mathbb{R}^{m\times n}$.*
2. *$N_k(\mathbf{A}) \leq N_k(\mathbf{B})$ for $k = 1,\ldots,q$ where $N_k(\mathbf{X}) \equiv \sum_{i=1}^k \sigma_k(\mathbf{X})$ denotes Ky Fan k-norm.*

Lemma 3 (Page 215 of (Horn and Johnson, 1991)) *Let $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{m\times n}$ be given, and let $q = \min\{m,n\}$. Define the diagonal matrix $\mathbf{\Sigma}(\mathbf{A}) = [\sigma_{ij}] \in \mathbb{R}^{m\times n}$ by $\sigma_{ii} = \sigma_i(\mathbf{A})$, all other $\sigma_{ij} = 0$, where $\sigma_1(\mathbf{A}) \geq, \ldots, \geq \sigma_q(\mathbf{A})$ are the decreasingly ordered singular values of $\mathbf{A}$. We define $\mathbf{\Sigma}(\mathbf{B})$ similarly. Then we have $\|\mathbf{A}-\mathbf{B}\| \geq \|\mathbf{\Sigma}(\mathbf{A}) - \mathbf{\Sigma}(\mathbf{B})\|$ for every unitarily invariant norm $\|\cdot\|$.*

Proof Using the notation of Lemma 1 and 2, matrices $\mathbf{A}-\mathbf{B}$ and $\mathbf{\Sigma}(\mathbf{A})-\mathbf{\Sigma}(\mathbf{B})$ have the decreasingly ordered singular values $\sigma_1(\mathbf{A}-\mathbf{B}) \geq \cdots \geq \sigma_q(\mathbf{A}-\mathbf{B})$ and $s_{[1]}(\mathbf{A},\mathbf{B}) \geq \cdots \geq s_{[q]}(\mathbf{A},\mathbf{B})$. Then we have

$$N_k(\mathbf{A}-\mathbf{B}) = \sum_{i=1}^k \sigma_i(\mathbf{A}-\mathbf{B}) \geq \sum_{i=1}^k s_{[i]}(\mathbf{A},\mathbf{B}) = N_k(\mathbf{\Sigma}(\mathbf{A}) - \mathbf{\Sigma}(\mathbf{B})), \tag{15}$$

where the inequality is obtained by Lemma 1. The Lemma 2 implies (15) is equivalent to $\|\mathbf{A}-\mathbf{B}\| \geq \|\mathbf{\Sigma}(\mathbf{A}) - \mathbf{\Sigma}(\mathbf{B})\|$ for every unitarily invariant norm $\|\cdot\|$. ■

Then we give the proof of Theorem 1 as follows:

Proof Using the notation in above lemmas, we can bound the objective function as follows

$$\begin{aligned}
\left\|\mathbf{M}-\mathbf{C}\mathbf{C}^\top-\delta\mathbf{I}_d\right\|_2 &\geq \left\|\mathbf{\Sigma}(\mathbf{M})-\mathbf{\Sigma}(\mathbf{C}\mathbf{C}^\top+\delta\mathbf{I}_d)\right\|_2 \\
&= \max_{i\in\{1,\ldots,d\}} \left|\sigma_i(\mathbf{M})-\sigma_i(\mathbf{C}\mathbf{C}^\top)-\delta\right| \\
&\geq \max_{i\in\{k+1,\ldots,d\}} \left|\sigma_i(\mathbf{M})-\sigma_i(\mathbf{C}\mathbf{C}^\top)-\delta\right| \\
&= \max_{i\in\{k+1,\ldots,d\}} \left|\sigma_i(\mathbf{M})-\delta\right| \\
&\geq \max_{i\in\{k+1,\ldots,d\}} \left|\sigma_i(\mathbf{M})-\widehat{\delta}\right|.
\end{aligned}$$

The first inequality is obtained by Lemma 3 since the spectral norm is unitarily invariant, and the second inequality is the property of maximization operator. The last inequality can be checked easily by the property of max operation and the equivalence of SVD and eigenvector decomposition for positive semi-definite matrix. The first equality is based on the definition of spectral norm. The second equality holds due to the fact $\mathrm{rank}(\mathbf{C}\mathbf{C}^\top) \leq k$ which leads $\sigma_i(\mathbf{C}\mathbf{C}^\top) = 0$ for any $i > k$. Note that all above equalities occur for $\mathbf{C} = \widehat{\mathbf{C}} = \mathbf{U}_k(\mathbf{\Sigma}_k - \xi\mathbf{I}_k)^{1/2}\mathbf{Q}$, $\delta = \widehat{\delta}$ and $\xi \in [\sigma_d, \sigma_{k+1}]$. Hence we prove the optimality of $(\widehat{\mathbf{C}}, \widehat{\delta})$.

The approximation error of rank-k SVD corresponds to the objective of (8) by taking $\mathbf{C} = \mathbf{U}_k(\mathbf{\Sigma}_k)^{1/2}$ and $\delta = 0$, which is impossible to be smaller than the minimum. It is easy to verify we have $\widehat{\mathbf{C}} = \mathbf{U}_k(\mathbf{\Sigma}_k)^{1/2}$ and $\widehat{\delta} = 0$ if and only of $\mathrm{rank}(\mathbf{M}) \leq k$. ■

Theorem 1 means the choice of ξ in the solution of problem (9) is not unique, but taking $\xi = \sigma_{k+1}$ minimizes the condition number of $\widehat{\mathbf{C}}\widehat{\mathbf{C}}^\top + \widehat{\delta}\mathbf{I}_d$. Hence, we use $\xi = \sigma_{k+1}$ in the derivation of RFD. We also demonstrate similar result with respect to Frobenius norm in Corollary 1. This analysis includes the global optimality of the problem, while Zhang (2014)'s analysis only prove the solution is locally optimal.

Corollary 1 *Using the same notation in Theorem 1, the pair* $(\tilde{\mathbf{C}}, \tilde{\delta})$ *defined as*

$$\tilde{\mathbf{C}} = \mathbf{U}_k(\mathbf{\Sigma}_k - \tilde{\delta}\mathbf{I}_k)^{1/2}\mathbf{V} \quad \textit{and} \quad \tilde{\delta} = \frac{1}{d-k}\sum_{i=j+1}^{d}\sigma_i$$

is the global minimizer of

$$\min_{\mathbf{C}\in\mathbb{R}^{d\times k},\delta\in\mathbb{R}} \|\mathbf{M}-\mathbf{C}\mathbf{C}^\top-\delta\mathbf{I}_d\|_F^2,$$

where $\mathbf{V}$ *is an arbitrary* $k \times k$ *orthogonal matrix.*

Proof We have the result similar to Theorem 1.

$$\begin{aligned}
\|\mathbf{M}-\mathbf{C}\mathbf{C}^\top-\delta\mathbf{I}_d\|_F^2 &\geq \|\mathbf{\Sigma}(\mathbf{M})-\mathbf{\Sigma}(\mathbf{C}\mathbf{C}^\top+\delta\mathbf{I}_d)\|_F^2 \\
&= \sum_{i=1}^{d}(\sigma_i(\mathbf{M})-\sigma_i(\mathbf{C}\mathbf{C}^\top)-\delta)^2 \\
&\geq \sum_{i=k+1}^{d}(\sigma_i(\mathbf{M})-\sigma_i(\mathbf{C}\mathbf{C}^\top)-\delta)^2 \\
&= \sum_{i=k+1}^{d}(\sigma_i(\mathbf{M})-\delta)^2 \\
&\geq \sum_{i=k+1}^{d}(\sigma_i(\mathbf{M})-\tilde{\delta})^2
\end{aligned}$$

The first four steps are similar to the ones of Theorem 1, but replace the spectral norm and absolute operator with Frobenius norm and square function. The last step comes from the property of the mean value.

We can check that all above equalities occur for $\mathbf{C} = \tilde{\mathbf{C}}$ and $\delta = \tilde{\delta}$, which completes the proof. ■

Appendix C. The Proof of Theorem 2

Proof The Algorithm 2 implies the singular values of $(\widehat{\mathbf{B}}^{(t-1)})^\top\widehat{\mathbf{B}}^{(t-1)} + \alpha^{(t-1)}\mathbf{I}$ are

$$(\sigma_1^{(t-1)})^2 + \alpha^{(t-1)} \geq \cdots \geq (\sigma_m^{(t-1)})^2 + \alpha^{(t-1)} \geq \alpha^{(t-1)} = \cdots = \alpha^{(t-1)}.$$

Then we can use Theorem 1 by taking

$$\begin{aligned}
\mathbf{M} &= (\widehat{\mathbf{B}}^{(t-1)})^\top\widehat{\mathbf{B}}^{(t-1)} + \alpha^{(t-1)}\mathbf{I}, \\
k &= m-1, \\
\xi &= \sigma_{k+1} = (\sigma_m^{(t-1)})^2 + \alpha^{(t-1)} \\
\widehat{\mathbf{C}} &= \mathbf{V}_{m-1}^{(t-1)}\sqrt{\left(\mathbf{\Sigma}_{m-1}^{(t-1)}\right)^2 - \left(\sigma_m^{(t-1)}\right)^2\mathbf{I}_{m-1}} = (\mathbf{B}^{(t)})^\top, \\
\widehat{\delta} &= [(\sigma_m^{(t-1)})^2 + \alpha^{(t-1)} + \alpha^{(t-1)}]/2 = \alpha^{(t)},
\end{aligned}$$

which just means that $(\mathbf{B}^{(t)}, \alpha^{(t)})$ is the minimizer of the problem in this theorem. ■

Appendix D. The Proof of Theorem 3

The algorithms of FD and RFD share the same $\mathbf{B}^{(t)}$ and we have Lemma 4 (Ghashami et al., 2016) as follows.

Lemma 4 *For any $k < m$ and using the notation of Algorithm 1 or Algorithm 2, we have*

$$\mathbf{A}^\top\mathbf{A} - \mathbf{B}^\top\mathbf{B} \succeq \mathbf{0}, \tag{16}$$

$$\sum_{t=1}^{T-1}(\sigma_m^{(t)})^2 \leq \frac{1}{m-k}\|\mathbf{A} - [\mathbf{A}]_k\|_F^2. \tag{17}$$

Then we prove the Theorem 3 based on Lemma 4.

Proof Define $(\mathbf{B}^{(0)})^\top\mathbf{B}^{(0)} = \mathbf{0}^{d\times d}$, then we can derive the error bound as follows

$$\begin{aligned}
&\left\|\mathbf{A}^\top\mathbf{A} - (\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d)\right\|_2\\
=&\left\|\sum_{t=1}^{T}\left[(\mathbf{a}^{(t)})^\top\mathbf{a}^{(t)} - (\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} + (\mathbf{B}^{(t-1)})^\top\mathbf{B}^{(t-1)} - \frac{1}{2}(\sigma_m^{(t-1)})^2\mathbf{I}_d\right]\right\|_2\\
\leq&\sum_{t=1}^{T}\left\|(\mathbf{a}^{(t)})^\top\mathbf{a}^{(t)} - (\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} + (\mathbf{B}^{(t-1)})^\top\mathbf{B}^{(t-1)} - \frac{1}{2}(\sigma_m^{(t-1)})^2\mathbf{I}_d\right\|_2\\
=&\sum_{t=1}^{T}\left\|\mathbf{V}_{m-1}^{(t-1)}(\mathbf{\Sigma}_{m-1}^{(t-1)})^2(\mathbf{V}_{m-1}^{(t-1)})^\top - \mathbf{V}_{m-1}^{(t-1)}[(\mathbf{\Sigma}_{m-1}^{(t-1)})^2 - (\sigma_m^{(t-1)})^2\mathbf{I}_d](\mathbf{V}_{m-1}^{(t-1)})^\top - \frac{1}{2}(\sigma_m^{(t-1)})^2\mathbf{I}_d\right\|_2\\
=&\sum_{t=1}^{T}\left\|(\sigma_m^{(t-1)})^2\mathbf{V}_m^{(t-1)}(\mathbf{V}_m^{(t-1)})^\top - \frac{1}{2}(\sigma_m^{(t-1)})^2\mathbf{I}_d\right\|_2\\
=&\frac{1}{2}\sum_{t=1}^{T-1}(\sigma_m^{(t)})^2\\
\leq&\frac{1}{2(m-k)}\|\mathbf{A} - [\mathbf{A}]_k\|_F^2.
\end{aligned}$$

The first three equalities are direct from the procedure of the algorithm, and the last one is based on the fact that $\mathbf{V}^{(t-1)}$ is column orthonormal. The first inequality comes from the triangle inequality of spectral norm. The last one can be obtained by the result (17) of Lemma 4. ■

We also have similar error bound for fast RFD with doubling space. We first rewrite Algorithm 5 as the block formulation. Consider the procedure of Algorithm 5, we suppose that matrix $\widehat{\mathbf{B}}^{(t-1)}$ has $2m$ rows at round $t = p_1, p_2, \ldots, p_{T'-1}$, where $1 < p_1 < p_2 < \cdots < p_{T'-1} \leq T$. Letting $p_0 = 0$ and $p_{T'} = T$, we can partition matrix $\mathbf{A}$ into T' blocks

$$\mathbf{A} = \left[\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \cdots, \mathbf{A}^{(T')}\right]^\top, \tag{18}$$

where

$$\mathbf{A}^{(t')} = \left[\mathbf{a}^{(p_{t'-1}+1)}, \mathbf{a}^{(p_{t'-1}+2)}, \cdots, \mathbf{a}^{(p_{t'})}\right]^\top \text{ for } t' = 1, 2, \ldots, T'. \tag{19}$$

Based on the notation of (18) and (19), we can rewrite Algorithm 5 as Algorithm 7. It is obvious that two algorithms have the same output results. We present Lemma 5 which extends Lemma 4 to block version and establishes the error bound for Algorithm 7 in Corollary 2.

Algorithm 7 Fast Robust Frequent Directions (Block Formulation)

Input: $\mathbf{A} = [\mathbf{A}^{(1)}, \ldots, \mathbf{A}^{(T')}]^\top \in \mathbb{R}^{T\times d}$, $\mathbf{B}^{(1)} = (\mathbf{A}^{(1)})^\top$, $\alpha^{(1)} = 0$

for $t' = 2, \ldots, T'$ **do**

$\quad\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix}\mathbf{B}^{(t'-1)}\\ (\mathbf{A}^{(t')})^\top\end{bmatrix}$

$\quad$Compute SVD: $\widehat{\mathbf{B}}^{(t'-1)} = \mathbf{U}^{(t'-1)}\mathbf{\Sigma}^{(t'-1)}(\mathbf{V}^{(t'-1)})^\top$

$\quad\mathbf{B}^{(t')} = \sqrt{\left(\mathbf{\Sigma}_{m-1}^{(t'-1)}\right)^2 - \left(\sigma_m^{(t'-1)}\right)^2\mathbf{I}_{m-1}}\cdot\left(\mathbf{V}_{m-1}^{(t'-1)}\right)^\top$

$\quad\alpha^{(t')} = \alpha^{(t'-1)} + \left(\sigma_m^{(t'-1)}\right)^2/2$

end for

Output: $\mathbf{B} = \mathbf{B}^{(T')}$ and $\alpha = \alpha^{(T')}$

Lemma 5 *For any $k < m$ and using the notation of Algorithm 7, we have*

$$\sum_{t'=1}^{T'-1}(\sigma_m^{(t')})^2 \leq \frac{1}{m-k}\|\mathbf{A} - [\mathbf{A}]_k\|_F^2.$$

Proof We let $\sigma_m^{(T')} = 0$. For any unit vector $\mathbf{x} \in \mathbb{R}^d$, the procedure of Algorithm 7 implies

$$\begin{aligned}
&\|\mathbf{A}\mathbf{x}\|^2 - \|\mathbf{B}\mathbf{x}\|^2\\
=&\sum_{t'=1}^{T'}\left(\|\mathbf{A}^{(t')}\mathbf{x}\|^2 + \|\mathbf{B}^{(t'-1)}\mathbf{x}\|^2 - \|\mathbf{B}^{(t')}\mathbf{x}\|^2\right)\\
=&\sum_{t'=1}^{T'}\mathbf{x}^\top\left((\mathbf{A}^{(t')})^\top\mathbf{A}^{(t')} + (\mathbf{B}^{(t'-1)})^\top(\mathbf{B}^{(t'-1)}) - (\mathbf{B}^{(t')})^\top\mathbf{B}^{(t')}\right)\mathbf{x}\\
=&\sum_{t'=1}^{T'}\mathbf{x}^\top\left((\widehat{\mathbf{B}}^{(t')})^\top\widehat{\mathbf{B}}^{(t')} - (\mathbf{B}^{(t')})^\top\mathbf{B}^{(t')}\right)\mathbf{x}\\
\leq&\sum_{t'=1}^{T'}\left(\sigma_m^{(t')}\right)^2.
\end{aligned} \tag{20}$$

Using the property of Frobenius norm, we have

$$\begin{aligned}
\|\widehat{\mathbf{B}}^{(t'-1)}\|_F^2 =&\|\mathbf{\Sigma}^{(t'-1)}\|_F^2\\
\geq&\left\|\sqrt{\left(\mathbf{\Sigma}_m^{(t'-1)}\right)^2 - \left(\sigma_m^{(t'-1)}\right)^2\mathbf{I}_m}\right\|_F^2 + m(\sigma_m^{(t'-1)})^2\\
=&\|\mathbf{B}^{(t')}\|_F^2 + m(\sigma_m^{(t'-1)})^2.
\end{aligned} \tag{21}$$

The term $\|\mathbf{A}\|_F^2$ satisfies

$$\|\mathbf{A}\|_F^2 = \sum_{t'=1}^{T'}\|\mathbf{A}^{(t')}\|_F^2$$

$$
\begin{aligned}
&= \sum_{t'=1}^{T'} \left(\|\widehat{\mathbf{B}}^{(t'-1)}\|_F^2 - \|\mathbf{B}^{(t'-1)}\|_F^2 \right) \\
&\geq \sum_{t'=1}^{T'} \left(\|\mathbf{B}^{(t')}\|_F^2 + m(\sigma_m^{(t'-1)})^2 - \|\mathbf{B}^{(t'-1)}\|_F^2 \right) \\
&= \|\mathbf{B}\|_F^2 + m \sum_{t'=1}^{T'} \left(\sigma_m^{(t')}\right)^2, \qquad (22)
\end{aligned}
$$

where the inequality is due to (21).

Let $\mathbf{y}_i$ be the singular vectors of $\mathbf{A}$ with respect to $\sigma_i(\mathbf{A})$. Then we have

$$
\begin{aligned}
m \sum_{t'=1}^{T'} (\sigma_m^{(t'-1)})^2 \leq & \|\mathbf{A}\|_F^2 - \|\mathbf{B}\|_F^2 \\
= & \sum_{i=1}^{k} \|\mathbf{A}\mathbf{y}_i\|_F^2 + \sum_{i=k+1}^{d} \|\mathbf{A}\mathbf{y}_i\|_F^2 - \|\mathbf{B}\|_F^2 \\
= & \sum_{i=1}^{k} \|\mathbf{A}\mathbf{y}_i\|_F^2 + \|\mathbf{A} - [\mathbf{A}]_k\|_F^2 - \|\mathbf{B}\|_F^2 \\
\leq & \|\mathbf{A} - [\mathbf{A}]_k\|_F^2 + \sum_{i=1}^{k} \left(\|\mathbf{A}\mathbf{y}_i\|_F^2 - \|\mathbf{B}\mathbf{y}_i\|_F^2 \right) \\
\leq & \|\mathbf{A} - [\mathbf{A}]_k\|_F^2 + k \sum_{t'=1}^{T'} \left(\sigma_m^{(t')}\right)^2, \qquad (23)
\end{aligned}
$$

where the first inequality comes from (22), the second inequality is based on the fact $\sum_{i=1}^{k} \|\mathbf{B}\mathbf{y}_i\|^2 \leq \|\mathbf{B}\|_F^2$, and the last one comes from (20). We can obtain the result of this lemma by (23) directly. ■

Corollary 2 *For any $k < m$ and using the notation of Algorithm 7, we have*

$$
\left\|\mathbf{A}^\top\mathbf{A} - (\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d)\right\|_2 \leq \frac{1}{2(m-k)} \|\mathbf{A} - [\mathbf{A}]_k\|_F^2,
$$

where $[\mathbf{A}]_k$ is the best rank-k approximation to $\mathbf{A}$ in both the Frobenius and spectral norms.

Proof Define $(\mathbf{B}^{(0)})^\top \mathbf{B}^{(0)} = \mathbf{0}^{d\times d}$, then we can derive the error bound as follows

$$
\begin{aligned}
&\left\|\mathbf{A}^\top\mathbf{A} - (\mathbf{B}^\top\mathbf{B} + \alpha\mathbf{I}_d)\right\|_2 \\
=& \left\| \sum_{t'=1}^{T'} \left[(\mathbf{A}^{(t')})^\top \mathbf{A}^{(t')} - (\mathbf{B}^{(t')})^\top \mathbf{B}^{(t')} + (\mathbf{B}^{(t'-1)})^\top \mathbf{B}^{(t'-1)} - \frac{1}{2}(\sigma_m^{(t'-1)})^2 \mathbf{I}_d \right] \right\|_2 \\
\leq & \sum_{t'=1}^{T'} \left\| (\mathbf{A}^{(t')})^\top \mathbf{A}^{(t')} - (\mathbf{B}^{(t')})^\top \mathbf{B}^{(t')} + (\mathbf{B}^{(t'-1)})^\top \mathbf{B}^{(t'-1)} - \frac{1}{2}(\sigma_m^{(t'-1)})^2 \mathbf{I}_d \right\|_2
\end{aligned}
$$

$$
\begin{aligned}
&= \sum_{t'=1}^{T'} \left\| \mathbf{V}_{m-1}^{(t'-1)} (\mathbf{\Sigma}_{m-1}^{(t'-1)})^2 (\mathbf{V}_{m-1}^{(t'-1)})^\top - \mathbf{V}_{m-1}^{(t'-1)} [(\mathbf{\Sigma}_{m-1}^{(t'-1)})^2 - (\sigma_m^{(t'-1)})^2 \mathbf{I}_d] (\mathbf{V}_{m-1}^{(t'-1)})^\top - \frac{1}{2}(\sigma_m^{(t'-1)})^2 \mathbf{I}_d \right\|_2 \\
&= \sum_{t'=1}^{T'} \left\| (\sigma_m^{(t'-1)})^2 \mathbf{V}_m^{(t'-1)} (\mathbf{V}_m^{(t'-1)})^\top - \frac{1}{2}(\sigma_m^{(t'-1)})^2 \mathbf{I}_d \right\|_2 \\
&= \frac{1}{2} \sum_{t'=1}^{T'-1} (\sigma_m^{(t')})^2 \\
&\leq \frac{1}{2(m-k)} \|\mathbf{A} - [\mathbf{A}]_k\|_F^2.
\end{aligned}
$$

The last inequality is based on Lemma 5 and other steps are similar to the proof of Theorem 3. ■

Appendix E. The Proof of Theorem 4

Proof We can compare $\kappa(\mathbf{M}_{\text{RFD}})$ and $\kappa(\mathbf{M}_{\text{FD}})$ by the fact $\alpha \geq \alpha^{(0)}$ as follows

$$
\begin{aligned}
\kappa(\mathbf{M}_{\text{RFD}}) &= \frac{\sigma_{\max}(\mathbf{B}^\top\mathbf{B}) + \alpha}{\alpha} \\
&\leq \frac{\sigma_{\max}(\mathbf{B}^\top\mathbf{B}) + \alpha_0}{\alpha_0} \\
&= \kappa(\mathbf{M}_{\text{FD}}).
\end{aligned}
$$

The other inequality can be derived as

$$
\begin{aligned}
\kappa(\mathbf{M}_{\text{RFD}}) &= \frac{\sigma_{\max}(\mathbf{B}^\top\mathbf{B}) + \alpha}{\alpha} \\
&\leq \frac{\sigma_{\max}(\mathbf{A}^\top\mathbf{A}) + \alpha}{\alpha} \\
&\leq \frac{\sigma_{\max}(\mathbf{A}^\top\mathbf{A}) + \alpha_0}{\alpha_0} \\
&= \kappa(\mathbf{M}),
\end{aligned}
$$

where the first inequality comes from (16) of Lemma 4 and the others are easy to obtain. ■

Appendix F. The Greedy Low-rank Approximation

We present the greedy low-rank approximation (Brand, 2002; Hall et al., 1998; Levey and Lindenbaum, 2000; Ross et al., 2008) as Algorithm 8. The algorithm does not work in general although $(\mathbf{B}'^{(t)})^\top \mathbf{B}'^{(t)}$ is the best low-rank approximation to $(\widehat{\mathbf{B}}^{(t)})^\top \widehat{\mathbf{B}}^{(t)}$.

We provide an example to show the failure of this method. We define $\tilde{\mathbf{A}} = [\tilde{\mathbf{A}}_1^\top, \tilde{\mathbf{A}}_2^\top]^\top \in \mathbb{R}^{(m-s+1)\times d}$, where $\tilde{\mathbf{A}}_1 \in \mathbb{R}^{(m-1)\times d}$, $\tilde{\mathbf{A}}_2 \in \mathbb{R}^{s\times d}$ and $m \ll s$. Suppose that the smallest singular value of $\tilde{\mathbf{A}}_1$ is λ, and each row of $\tilde{\mathbf{A}}_2$ is $\mathbf{a} \in \mathbb{R}^d$ that satisfies $\|\mathbf{a}\| = \lambda - \epsilon$ and $\tilde{\mathbf{A}}_1^\top \mathbf{a} = \mathbf{0}$, where ϵ is a very small positive number. Since s is much larger than m, a good approximation to $\tilde{\mathbf{A}}^\top\tilde{\mathbf{A}}$ is

Algorithm 8 Greedy Low-rank Approximation

Input: $\mathbf{A} = [\mathbf{a}^{(1)}, \dots, \mathbf{a}^{(T)}]^\top \in \mathbb{R}^{T\times d}$, $\mathbf{B}'^{(m-1)} = [\mathbf{a}^{(1)}, \dots, \mathbf{a}^{(m-1)}]^\top$
for $t = m, \dots, T$ **do**
  $\widehat{\mathbf{B}}^{(t-1)} = \begin{bmatrix} \mathbf{B}'^{(t-1)} \\ (\mathbf{a}^{(t)})^\top \end{bmatrix}$
  Compute SVD: $\widehat{\mathbf{B}}^{(t-1)} = \mathbf{U}^{(t-1)}\mathbf{\Sigma}^{(t-1)}(\mathbf{V}^{(t-1)})^\top$
  $\mathbf{B}'^{(t)} = \mathbf{\Sigma}_{m-1}^{(t-1)}(\mathbf{V}_{m-1}^{(t-1)})^\top$
end for
Output: $\mathbf{B}' = \mathbf{B}'^{(T)}$

dominated by $\tilde{\mathbf{A}}_2^\top\tilde{\mathbf{A}}_2$. If we use Algorithm 8 with $\mathbf{A} = \tilde{\mathbf{A}}$, any row of $\tilde{\mathbf{A}}_2$ will be neglected because the m-th singular value of $\widehat{\mathbf{B}}^{(t-1)}$ is $\|\mathbf{a}\| = \lambda - \epsilon < \lambda$, which leads to the fact that output is $\mathbf{B}' = \tilde{\mathbf{A}}_1$. Apparently, $\tilde{\mathbf{A}}_1^\top\tilde{\mathbf{A}}_1$ is not a good approximation to $\mathbf{A}^\top\mathbf{A}$. Hence the shrinking of FD or RFD is necessary. In this example, it reduces the impact of $\tilde{\mathbf{A}}_1$ and let $\tilde{\mathbf{A}}_2$ be involved in final result.

Besides above discussion, Desai et al. (2016) has shown that the greedy algorithm is much worse than FD based methods on data sets "Adversarial" and "ConnectUS".

Appendix G. The Proof of Theorem 5

Lemma 6 shows the general regret bound for any choice of $\mathbf{H}^{(t)} \succ \mathbf{0}$ in update (2)

$$\mathbf{u}^{(t+1)} = \mathbf{w}^{(t)} - \beta_t(\mathbf{H}^{(t)})^{-1}\mathbf{g}^{(t)},$$
$$\mathbf{w}^{(t+1)} = \operatorname*{argmin}_{\mathbf{w}\in\mathcal{K}_{t+1}} \|\mathbf{w} - \mathbf{u}^{(t+1)}\|_{\mathbf{H}^{(t)}}.$$

Lemma 6 (Proposition 1 of Luo et al. (2016)) *For any sequence of positive definite matrices $\mathbf{H}^{(t)}$ and sequences of losses satisfying Assumption 1 and 2, regret of updates (2) satisfies*

$$2R_T(\mathbf{w}) \le \|\mathbf{w}\|^2_{\mathbf{H}^{(0)}} + R_G + R_D,$$

where

$$R_G = \sum_{t=1}^T (\mathbf{g}^{(t)})^\top(\mathbf{H}^{(t)})^{-1}\mathbf{g}^{(t)},$$
$$R_D = \sum_{t=1}^T (\mathbf{w}^{(t)} - \mathbf{w})^\top(\mathbf{H}^{(t)} - \mathbf{H}^{(t-1)} - \mu^{(t)}\mathbf{g}^{(t)}(\mathbf{g}^{(t)})^\top)(\mathbf{w}^{(t)} - \mathbf{w}).$$

Then we prove the regret bound for RFD-SON based on Lemma 6 and property of RFD.

Proof Let $\mathbf{V}_\perp^{(t)}$ be the orthogonal complement of $\mathbf{V}_{m-1}^{(t)}$'s column space, that is $\mathbf{V}_{m-1}^{(t)}(\mathbf{V}_{m-1}^{(t)})^\top + \mathbf{V}_\perp^{(t)}(\mathbf{V}_\perp^{(t)})^\top = \mathbf{I}_d$, then we have

$$\begin{aligned}
&\mathbf{H}^{(t)} - \mathbf{H}^{(t-1)} \\
=&\alpha^{(t)}\mathbf{I} + (\mathbf{B}^{(t)})^\top\mathbf{B}^{(t)} - \alpha^{(t-1)}\mathbf{I} - (\mathbf{B}^{(t-1)})^\top\mathbf{B}^{(t-1)} \\
=&\frac{1}{2}(\sigma_m^{(t-1)})^2\mathbf{I} - (\sigma_m^{(t-1)})^2\mathbf{V}_{m-1}^{(t-1)}(\mathbf{V}_{m-1}^{(t-1)})^\top + (\mu_t + \eta_t)\mathbf{g}^{(t)}(\mathbf{g}^{(t)})^\top \\
=&\frac{1}{2}(\sigma_m^{(t-1)})^2\big[\mathbf{V}_\perp^{(t-1)}(\mathbf{V}_\perp^{(t-1)})^\top - \mathbf{V}_{m-1}^{(t-1)}(\mathbf{V}_{m-1}^{(t-1)})^\top\big] + (\mu_t + \eta_t)\mathbf{g}^{(t)}(\mathbf{g}^{(t)})^\top. \qquad (24)
\end{aligned}$$

Since $\mathbf{H}^{(t)}$ is positive semidefinite for any t, we have $(\mathbf{H}^{(t)})^\dagger = (\mathbf{H}^{(t)})^{-1}$. Combining with Lemma 6, we have

$$2R_T(\mathbf{w}) \le \alpha_0\|\mathbf{w}\|^2 + R_G + R_D,$$

where

$$R_G = \sum_{t=1}^T (\mathbf{g}^{(t)})^\top(\mathbf{H}^{(t)})^{-1}\mathbf{g}^{(t)},$$

and

$$R_D = \sum_{t=1}^T (\mathbf{w}^{(t)} - \mathbf{w})^\top[\mathbf{H}^{(t)} - \mathbf{H}^{(t-1)} - \mu_t\mathbf{g}^{(t)}(\mathbf{g}^{(t)})^\top](\mathbf{w}^{(t)} - \mathbf{w}).$$

We can bound R_G as follows

$$\begin{aligned}
&\sum_{t=1}^T (\mathbf{g}^{(t)})^\top(\mathbf{H}^{(t)})^{-1}\mathbf{g}^{(t)} \\
=&\sum_{t=1}^T \big\langle(\mathbf{H}^{(t)})^{-1}, \mathbf{g}^{(t)}(\mathbf{g}^{(t)})^\top\big\rangle \\
=&\sum_{t=1}^T \frac{1}{\mu_t + \eta_t}\big\langle(\mathbf{H}^{(t)})^{-1}, \mathbf{H}^{(t)} - \mathbf{H}^{(t-1)} + \frac{1}{2}(\sigma_m^{(t-1)})^2[\mathbf{V}_\perp^{(t-1)}(\mathbf{V}_\perp^{(t-1)})^\top - \mathbf{V}^{(t-1)}(\mathbf{V}^{(t-1)})^\top]\big\rangle \\
\le&\frac{1}{\mu + \eta_T}\sum_{t=1}^T \big\langle(\mathbf{H}^{(t)})^{-1}, \mathbf{H}^{(t)} - \mathbf{H}^{(t-1)} + \frac{1}{2}(\sigma_m^{(t-1)})^2\mathbf{V}^{(t-1)}(\mathbf{V}^{(t-1)})^\top\big\rangle \\
=&\frac{1}{\mu + \eta_T}\sum_{t=1}^T \Big[\big\langle(\mathbf{H}^{(t)})^{-1}, \mathbf{H}^{(t)} - \mathbf{H}^{(t-1)}\big\rangle + \frac{1}{2}(\sigma_m^{(t-1)})^2\mathrm{tr}\big(\mathbf{V}^{(t-1)}(\mathbf{H}^{(t)})^{-1}(\mathbf{V}^{(t-1)})^\top\big)\Big].
\end{aligned}$$

The above equalities come from the properties of trace operator and (24) and the inequality is due to the fact that η_t is non-increasing.

The term $\sum_{t=1}^T\langle(\mathbf{H}^{(t)})^{-1}, \mathbf{H}^{(t)} - \mathbf{H}^{(t-1)}\rangle$ can be bounded as

$$\begin{aligned}
\sum_{t=1}^T\big\langle(\mathbf{H}^{(t)})^{-1}, \mathbf{H}^{(t)} - \mathbf{H}^{(t-1)}\big\rangle &\le \sum_{t=1}^T \ln\frac{\det(\mathbf{H}^{(t)})}{\det(\mathbf{H}^{(t-1)})} \\
&= \ln\frac{\det(\mathbf{H}^{(T)})}{\det(\mathbf{H}^{(0)})}
\end{aligned}$$

$$
\begin{aligned}
&= \ln \frac{\prod_{i=1}^{d} \sigma_i(\mathbf{H}^{(T)})}{\alpha_0} \\
&= \sum_{i=1}^{d} \ln \frac{\sigma_i\big((\mathbf{B}^{(T)})^\top \mathbf{B}^{(T)} + \alpha^{(T)} \mathbf{I}_d\big)}{\alpha_0} \\
&= \sum_{i=1}^{m} \ln \frac{\sigma_i\big((\mathbf{B}^{(T)})^\top \mathbf{B}^{(T)}\big) + \alpha^{(T)}}{\alpha_0} + (d-m) \ln \frac{\alpha^{(T)}}{\alpha_0} \\
&\leq m \ln \frac{\sum_{i=1}^{m} [\sigma_i\big((\mathbf{B}^{(T)})^\top \mathbf{B}^{(T)}\big) + \alpha^{(T)}]}{m\alpha_0} + (d-m) \ln \frac{\alpha^{(T)}}{\alpha_0} \\
&= m \ln \Big(\frac{\mathrm{tr}\big((\mathbf{B}^{(T)})^\top \mathbf{B}^{(T)}\big)}{m\alpha_0} + \frac{\alpha^{(T)}}{\alpha_0} \Big) + (d-m) \ln \frac{\alpha^{(T)}}{\alpha_0}.
\end{aligned}
$$

The first inequality is obtained by the concavity of the log determinant function (Boyd and Vandenberghe, 2004), the second inequality comes from the Jensen's inequality and the other steps are based on the procedure of the algorithm.

The other one $\frac{1}{2}\sum_{t=1}^{T} (\sigma_m^{(t)})^2 \mathrm{tr}\big(\mathbf{V}^{(t)} (\mathbf{H}^{(t)})^{-1} (\mathbf{V}^{(t)})^\top\big)$ can be bounded as

$$
\begin{aligned}
\frac{1}{2}\sum_{t=1}^{T} (\sigma_m^{(t)})^2 \mathrm{tr}\big(\mathbf{V}^{(t)} (\mathbf{H}^{(t)})^{-1} (\mathbf{V}^{(t)})^\top\big) &\leq \frac{1}{2}\sum_{t=1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}} \mathrm{tr}\big(\mathbf{V}^{(t)} (\mathbf{V}^{(t)})^\top\big) \\
&= \frac{m}{2}\sum_{t=1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}}. \qquad (25)
\end{aligned}
$$

Hence, we have

$$
R_G \leq \frac{1}{\mu + \eta_T} \left[m \ln \Big(\mathrm{tr}\big((\mathbf{B}^{(T)})^\top \mathbf{B}^{(T)}\big) + \frac{\alpha^{(T)}}{\alpha_0} \Big) + (d-m) \ln \frac{\alpha^{(T)}}{\alpha_0} + \frac{m}{2}\sum_{t=1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}} \right]. \qquad (26)
$$

Then we bound the term R_D by using equation (24), Assumption 1 and Assumption 2.

$$
\begin{aligned}
R_D =& \sum_{t=1}^{T} (\mathbf{w}^{(t)} - \mathbf{w})^\top \big[\eta_t \mathbf{g}^{(t)} (\mathbf{g}^{(t)})^\top + \frac{1}{2}(\sigma_m^{(t-1)})^2 \mathbf{I} - \mathbf{V}^{(t-1)} (\mathbf{V}^{(t-1)})^\top\big] (\mathbf{w}^{(t)} - \mathbf{w}) \\
\leq& \sum_{t=1}^{T} \eta_t (\mathbf{w}^{(t)} - \mathbf{w})^\top \mathbf{g}^{(t)} (\mathbf{g}^{(t)})^\top (\mathbf{w}^{(t)} - \mathbf{w}) + \frac{1}{2}\sum_{t=1}^{T} (\sigma_m^{(t-1)})^2 (\mathbf{w}^{(t)} - \mathbf{w})^\top (\mathbf{w}^{(t)} - \mathbf{w}) \\
\leq& 4(CL)^2 \sum_{t=1}^{T} \eta_t + 2C^2 \sum_{t=1}^{T} (\sigma_m^{(t-1)})^2. \qquad (27)
\end{aligned}
$$

Finally, we obtain the result by combining (26) and (27). ■

Additionally, the term $\sum_{t=1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}}$ in Ω_{RFD} can be bounded by $\mathcal{O}(\ln T)$ if we further assume all $\sigma_m^{(t)}$ are bounded by positive constants. Exactly, suppose that $0 < C_1 \leq \big(\sigma_m^{(t)}\big)^2 \leq C_2$ for any

$t = 0, \ldots, T-1$, then we have

$$
\begin{aligned}
\sum_{t=1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}} &= \sum_{t=1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha_0 + \frac{1}{2}\sum_{i=0}^{t-1} \big(\sigma_m^{(i)}\big)^2} \\
&\leq \sum_{t=1}^{T} \frac{C_2}{\alpha_0 + \frac{1}{2} C_1 t} \\
&\leq \frac{2C_2}{C_1} \sum_{t=1}^{T} \frac{1}{t} \\
&= \mathcal{O}(\ln T).
\end{aligned}
$$

The last inequality is due to the property of harmonic series.

Appendix H. The Proof of Theorem 6

Considering the update without positive semidefinite assumption on $\mathbf{H}^{(t)}$

$$
\begin{aligned}
\mathbf{u}^{(t+1)} &= \mathbf{w}^{(t)} - \beta_t (\mathbf{H}^{(t)})^\dagger \mathbf{g}^{(t)}, \\
\mathbf{w}^{(t+1)} &= \operatorname*{argmin}_{\mathbf{w} \in \mathcal{K}_{t+1}} \|\mathbf{w} - \mathbf{u}^{(t+1)}\|_{\mathbf{H}^{(t)}}, \qquad (28)
\end{aligned}
$$

we have the results as follows.

Lemma 7 (Appendix D of Luo et al. (2016)) *Let $\widehat{\mathbf{H}}^{(t)} = \sum_{s=1}^{t} \mathbf{g}^{(t)} (\mathbf{g}^{(t)})^\top$ with $\mathrm{rank}(\widehat{\mathbf{H}}^{(T)}) = r$ and σ^* be the minimum among the smallest non-zeros singular values of $\widehat{\mathbf{H}}^{(T)}$. Then the regret of update (28) satisfies*

$$
R_T(\mathbf{w}) \leq 2(CL)^2 \sum_{t=1}^{T} \eta^{(t)} + \frac{1}{2}\sum_{t=1}^{T} (\mathbf{g}^{(t)})^\top (\mathbf{H}^{(t)})^\dagger \mathbf{g}^{(t)}. \qquad (29)
$$

and

$$
\sum_{t=1}^{T} \mathbf{g}_t^\top (\widehat{\mathbf{H}}^{(t)})^\dagger \mathbf{g}_t \leq m - 1 + \frac{m(m-1)}{2} \ln \Big(1 + \frac{2\sum_{t=1}^{T} \|\mathbf{g}^{(t)}\|_2^2}{m(m-1)\sigma^*}\Big) \qquad (30)
$$

Then we can derive Theorem 6.

Proof For any $t \leq T'$, RFD-SON with $\alpha^{(0)} = 0$ satisfies $\mathrm{rank}(\widehat{\mathbf{B}}^{(t)}) \leq m - 1$. Hence we have

$$
\begin{aligned}
\mathbf{H}^{(t)} &= (\mathbf{B}^{(t)})^\top \mathbf{B}^{(t)} \\
&= \sum_{s=1}^{t} \frac{1}{\eta_t + \mu_t} (\mathbf{g}^{(t)})(\mathbf{g}^{(t)})^\top \\
&\succeq \frac{1}{\eta_1 + \mu'} \sum_{s=1}^{t} (\mathbf{g}^{(t)})(\mathbf{g}^{(t)})^\top \\
&= \frac{1}{\eta_1 + \mu'} \widehat{\mathbf{H}}^{(t)}. \qquad (31)
\end{aligned}
$$

Then we can bound the regret for the first T' iterations

$$\begin{aligned}
R_{1:T'}(\mathbf{w}) &\leq 2(CL)^2 \sum_{t=1}^{T'} \eta^{(t)} + \frac{1}{2} \sum_{t=1}^{T'} (\mathbf{g}^{(t)})^\top (\mathbf{H}^{(t)})^\dagger \mathbf{g}^{(t)} \\
&\leq 2(CL)^2 \sum_{t=1}^{T'} \eta^{(t)} + \frac{1}{2(\eta_1 + \mu')} \sum_{t=1}^{T'} (\mathbf{g}^{(t)})^\top (\widehat{\mathbf{H}}^{(t)})^\dagger \mathbf{g}^{(t)} \\
&\leq 2(CL)^2 \sum_{t=1}^{T'} \eta^{(t)} + \frac{m-1}{2(\eta_1 + \mu')} + \frac{m(m-1)}{2(\eta_1 + \mu')} \ln \Big(1 + \frac{2\sum_{t=1}^{T'} \|\mathbf{g}^{(t)}\|_2^2}{m(m-1)\sigma^*}\Big).
\end{aligned}$$

The first inequality is based on the inequality (29). The second inequality comes from (31) that is $\mathbf{H}^{(t)} \succeq \frac{1}{\eta_1 + \mu'} \widehat{\mathbf{H}}^{(t)}$. And the last one is due to the result (30). ■

Appendix I. The Proof of Theorem 7

Proof Since $\mathbf{H}^{(t)} \succ \mathbf{0}$ for $t \geq T'$, by similar proof of Theorem 5, we have

$$2R_{T'+1:T}(\mathbf{w}) \leq \alpha_0 \|\mathbf{w}^{(T')}\|^2_{\mathbf{H}^{(T')}} + R'_G + R'_D, \tag{32}$$

where

$$\begin{aligned}
R'_G &= \sum_{t=T'+1}^{T} (\mathbf{g}^{(t)})^\top (\mathbf{H}^{(t)})^{-1} \mathbf{g}^{(t)} \\
&\leq \frac{1}{\mu + \eta_T} \left[m \ln \Big(\frac{\mathrm{tr}\big((\mathbf{B}^{(T)})^\top \mathbf{B}^{(T)}\big)}{m\alpha^{(T')}} + \frac{\alpha^{(T)}}{\alpha'_0} \Big) + (d-m) \ln \frac{\alpha^{(T)}}{\alpha'_0} + \frac{m}{2} \sum_{t=T'+1}^{T} \frac{(\sigma_m^{(t)})^2}{\alpha^{(t)}} \right],
\end{aligned} \tag{33}$$

$$\begin{aligned}
R'_D &= \sum_{t=T'+1}^{T} (\mathbf{w}^{(t)} - \mathbf{w})^\top [\mathbf{H}^{(t)} - \mathbf{H}^{(t-1)} - \mu_t \mathbf{g}^{(t)} (\mathbf{g}^{(t)})^\top] (\mathbf{w}^{(t)} - \mathbf{w}) \\
&\leq 4(CL)^2 \sum_{t=T'+1}^{T} \eta_t + 2C^2 \sum_{t=T'+1}^{T} (\sigma_m^{(t-1)})^2.
\end{aligned} \tag{34}$$

Combining Theorem 6, (32), (33) and (34), we have the final result of (14). ■

Abstract

In this paper, we introduce a learning algorithm, boosted kernel ridge regression (BKRR), that combines L_2-Boosting with the kernel ridge regression (KRR). We analyze the learning performance of this algorithm in the framework of learning theory. We show that BKRR provides a new bias-variance trade-off via tuning the number of boosting iterations, which is different from KRR via adjusting the regularization parameter. A (semi-)exponential bias-variance trade-off is derived for BKRR, exhibiting a stable relationship between the generalization error and the number of iterations. Furthermore, an adaptive stopping rule is proposed, with which BKRR achieves the optimal learning rate without saturation.

Keywords: learning theory, kernel ridge regression, boosting, integral operator

1. Introduction

Supervised learning aims at learning function relationships between input and output variables, based on input-output pair samples. Kernel ridge regression (KRR) is a classical and standard approach for supervised learning due to its easy implementation and theoretical optimality (Evgeniou et al., 2000; Caponnetto and De Vito, 2007; Steinwart et al., 2009; Lin et al., 2017) and thus has triggered enormous research activities in the statistical and machine learning communities (Bauer et al., 2007; Caponnetto and De Vito, 2007; Cucker and Zhou, 2007; Smale and Zhou, 2007; Steinwart et al., 2009; Lin et al., 2017). However, KRR suffers from a so-called saturation phenomenon (Gerfo et al., 2008) meaning that its learning rate cannot be improved once the target (regression) function goes beyond a certain level of regularity. Furthermore, there lacks efficient parameter-selection strategies for KRR to realize its theoretically optimal learning performance. Many users' spirit is dampened by these drawbacks and then turns to other learning algorithms such as the kernel-based gradient descent (Yao et al., 2007), kernel-based conjugate gradient descent (Blanchard and Krämer, 2016) and kernel-based partial least squares (Lin and Zhou, 2018b).

Boosting, originally proposed by Schapire (1990); Freund (1995), is devoted to producing a strong composite learner from a given class of weak learners. Some boosting algorithms can be interpreted from a viewpoint of statistical gradient descent to solve optimization problems with different loss functions (Friedman et al., 2000; Friedman, 2001). In this way, a special boosting algorithm, L_2-Boosting, was interpreted as an iterative least squares fitting of residuals (Friedman, 2001; Bühlmann and Yu, 2003). L_2-Boosting was utilized by Park et al. (2009) to improve the learning performance of Nadaya-Watson kernel estimators by overcoming saturation and was also proved in Bühlmann and Yu (2003) to be almost over-fitting resistant by exhibiting its exponential bias-variance trade-off for linear regression, reducing the difficulty of model selection.

The aim of this paper is to combine L_2-Boosting with KRR to overcome the saturation and reduce the difficulty of model selection of KRR. Let $(\mathcal{H}_K, \|\cdot\|_K)$ be the reproducing kernel Hilbert space (RKHS) induced by a Mercer kernel K on a metric (input) space $\mathcal{X}$ and $D = \{(x_i, y_i)\}_{i=1}^N \subset \mathcal{X} \times \mathcal{Y}$ be a sample with $\mathcal{Y} \subseteq \mathbb{R}$ the output space. KRR is defined by

$$f_{D,\lambda}^{(1)} := \arg\min_{f\in\mathcal{H}_K} \left\{ \frac{1}{|D|} \sum_{(x,y)\in D} (f(x)-y)^2 + \lambda \|f\|_K^2 \right\}, \tag{1}$$

where $\lambda > 0$ is a regularization parameter and $|D| = N$ is the cardinality of D. Implementing KRR needs the inverse of the matrix $\mathbb{K}+\lambda|D|\mathbb{I}$ and thus requires $\mathcal{O}(|D|^3)$ computational complexity in time for a fixed λ, where $\mathbb{K}$ is the kernel matrix $(K(x_i,x_j))_{i,j=1}^{|D|}$ and $\mathbb{I}$ is the $|D| \times |D|$ identity matrix. The performance of KRR is sensitive to regularization parameters, which need be carefully tuned to achieve satisfactory learning rates close to the optimal one.

Boosted KRR (BKRR) studied in this paper iteratively defines an estimator $f_{D,\lambda}^{(k)}$ by running KRR on the data set $\{(x_i, y_i - f_{D,\lambda}^{(k-1)}(x_i))\}_{(x_i,y_i)\in D}$, whose outputs are residuals of the previous iteration $f_{D,\lambda}^{(k-1)}$. To be detailed, the estimator at the k-th boosting iteration is given by

$$f_{D,\lambda}^{(k)} := f_{D,\lambda}^{(k-1)} + f_{D,\lambda}^{(k)\diamond}, \qquad k > 1, \tag{2}$$

where

$$f_{D,\lambda}^{(k)\diamond} := \arg\min_{f\in\mathcal{H}_K} \left\{ \frac{1}{|D|} \sum_{(x,y)\in D} \left\{ f(x) - [y - f_{D,\lambda}^{(k-1)}(x)] \right\}^2 + \lambda \|f\|_K^2 \right\}, \qquad k > 1. \tag{3}$$

An advantage of BKRR over KRR is the flexibility of choosing some relatively large regularization parameter λ. Satisfactory learning rates are achieved by the boosting iterations. As the inputs $\{x_i\}_{i=1}^N$ of KRR and $f_{D,\lambda}^{(k)\diamond}$ are the same and the inverse of $\mathbb{K}+\lambda|D|\mathbb{I}$ has already been derived in the first step, it only requires $\mathcal{O}(|D|^2)$ computational complexity to solve (3). Then, BKRR with k iterations only needs $\mathcal{O}(|D|^3 + k|D|^2)$ computational complexity, which does not bring additional computational burden over KRR.

As pointed out by Friedman (2001), boosting leads to over-fitting if the weak learners are already over-fitting. So the regularization parameter of (1) must be relatively large,

implying under-fitting of the original KRR. BKRR then tunes k to reduce the bias, which enlarges the variance, reflecting the bias-variance trade-off. Our first main result is to deduce a (semi-)exponential bias-variance trade-off of BKRR: the bias of BKRR decreases exponentially with respect to k, while the variance increases by an exponentially diminishing amount as k gets large for the in-sample estimate and by an algebraic diminishing amount with respect to k for the out-sample estimate. The (semi-)exponential bias-variance trade-off shows that BKRR can reach its optimal learning performance with a relatively small number of iterations. It also exhibits that moderately large k does not degrade the learning performance of BKRR very much, making the model selection much easier than that of other iteration-based learning algorithms such as kernel-based gradient descent, kernel-based conjugate gradient descent and kernel-based partial least squares for which only polynomial bias-variance trade-off is obtained (Yao et al., 2007; Blanchard and Krämer, 2016; Lin and Zhou, 2018b).

The exponential bias-variance trade-off does not mean that over-fitting never happens for BKRR, and it requires a stopping rule of high quality. Our second main result is to propose an adaptive stopping rule based on an empirical effective dimension (Lu et al., 2018; Mücke, 2018), with which we prove that BKRR achieves the optimal learning rate without saturation. In a nutshell, our analysis shows that BKRR reduces the difficulty of model selection of KRR in terms of providing a stable relationship between the learning performance and model selection. Furthermore, BKRR with an adaptive stopping rule can improve the learning performance of KRR via overcoming the saturation. The main tools of our analysis are detailed spectral analysis of BKRR, the recently developed integral operator approach (Lin et al., 2017; Guo et al., 2017) and a tight bound for the number of iterations of the stopping rule.

2. Main Results

Our analysis is conducted in a standard learning theory framework for regression (Cucker and Zhou, 2007), in which the samples in D are independently drawn according to ρ, a Borel probability measure on $\mathcal{Z} := \mathcal{X} \times \mathcal{Y}$. The purpose of regression is to derive an estimator based on D to approximate the regression function $f_\rho(x) := \int_{\mathcal{Y}} y d\rho(y|x)$ with $\rho(\cdot|x)$ being the conditional distribution of ρ induced at $x \in \mathcal{X}$. Let ρ_X be the marginal distribution of ρ on $\mathcal{X}$ and $L^2_{\rho_X}$ be the space of ρ_X square integrable functions endowed with norm $\|\cdot\|_\rho$. Throughout this paper, we assume $\mathcal{X}$ is compact, which implies $\kappa := \sqrt{\sup_{x\in\mathcal{X}} K(x,x)} < \infty$.

2.1. Optimal Learning Rates

Before presenting the exponential bias-variance trade-off and stopping rule, we derive optimal learning rates for BKRR with a priori knowledge involving λ and k to show the necessity of our studies. For this purpose, some assumptions on the decay of the outputs, regularity of the regression function and capacity of $\mathcal{H}_K$ are needed. To be detailed, we assume $\int_{\mathcal{Y}} y^2 d\rho < \infty$ and the following output decay condition

$$\int_{\mathcal{Y}} \left(e^{\frac{|y-f_\rho(x)|}{M}} - \frac{|y-f_\rho(x)|}{M} - 1 \right) d\rho(y|x) \le \frac{\gamma^2}{2M^2}, \qquad \forall x \in \mathcal{X}, \tag{4}$$

where M and γ are positive constants. Condition (4) is satisfied if the noise is uniformly bounded, Gaussian or sub-Gaussian (Caponnetto and De Vito, 2007). In particular, if $|y| \le \mathcal{B}$ almost surely for some $\mathcal{B} > 0$, then (4) holds with $\gamma/2 = M = \mathcal{B}$.

Let $L_K : \mathcal{H}_K \to \mathcal{H}_K$ (or $L^2_{\rho_X} \to L^2_{\rho_X}$) be the integral operator defined by

$$L_K f = \int_{\mathcal{X}} K_x f(x) d\rho_X(x)$$

with $K_x := K(\cdot, x)$. We assume that f_ρ satisfies the standard regularity condition

$$f_\rho = L_K^r h_\rho, \quad \text{for some } r > 0 \text{ and } h_\rho \in L^2_{\rho_X}, \tag{5}$$

where L_K^r is the r-th power of $L_K : L^2_{\rho_X} \to L^2_{\rho_X}$. The regularity condition (5) describes the regularity of f_ρ and has been adopted in a large literature to quantify learning rates for some algorithms (Smale and Zhou, 2007; Bauer et al., 2007; Caponnetto and De Vito, 2007; Caponnetto and Yao, 2010; Shi et al., 2011; Blanchard and Krämer, 2016; Guo et al., 2017; Lin et al., 2017; Lin and Zhou, 2018b; Ying and Zhou, 2017) .

We also introduce the effective dimension $\mathcal{N}(\lambda) := \mathrm{Tr}[(L_K + \lambda I)^{-1} L_K]$ to measure the capacity of $\mathcal{H}_K$. Here $\mathrm{Tr}(A)$ denotes the trace of an operator A with a detailed definition to be given in Appendix B. In particular, we assume with a parameter $0 < s \le 1$ and a constant $C_0 > 0$ that

$$\mathcal{N}(\lambda) \le C_0 \lambda^{-s}, \qquad \forall \lambda > 0. \tag{6}$$

Condition (6) with $s = 1$ is always satisfied by taking $C_0 = \mathrm{Tr}(L_K) \le \kappa^2$. For $0 < s < 1$, it was shown in Guo et al. (2017, Page 7) that (6) is slightly more general than the eigenvalue decaying assumption in the literature (Caponnetto and De Vito, 2007) and has been extensively employed to derive fast learning rates for some algorithms (Caponnetto and De Vito, 2007; Blanchard and Krämer, 2016; Guo et al., 2017; Lin et al., 2017; Lin and Zhou, 2018a,b). With these assumptions, we present in the following theorem the optimal learning rates for BKRR.

Theorem 1 *Let $0 < \delta < 1$, $k \le \sqrt{|D|}$ and $\lambda = \left(k^2/|D|\right)^{1/(2\min\{k,r\}+s)}$ with $r > 3/2$ and $0 < s \le 1$. Under assumptions (4), (5) and (6), with confidence $1-\delta$ there holds*

$$\left\| f_{D,\lambda}^{(k)} - f_\rho \right\|_\rho \le \tilde{C} (k^2/|D|)^{\frac{\min\{k,r\}}{2\min\{k,r\}+s}} \log^3 \frac{8}{\delta}, \tag{7}$$

where $\tilde{C}$ is a constant independent of $|D|$, k or δ.

For an iteration number $k \ge r$ independent of $|D|$, Theorem 1 presents an optimal learning rate for BKRR since (7) achieves the minimax lower bound established by Caponnetto and De Vito (2007). However, as shown in (7), too large k may worsen the learning rate. An extreme case is $k = \sqrt{|D|}$ which leads to a constant upper bound. In a nutshell, small k (smaller than r) suffers from the saturation but too large k leads to slow learning rates. Thus, it is important to derive an adaptive stopping rule on selecting k. Furthermore, Theorem 1 implies that as long as $k \ge r$, the boosting iteration with large k does not have any benefits in the learning process, which contradicts the boosting theory developed in Friedman (2001); Bühlmann and Yu (2003) at first glance. Thus, it requires a more

delicate analysis to explore the power of iterations, especially when $k \geq r$. Based on this observation, we conduct a detailed bias-variance analysis in the following subsection and find a so-called exponential bias-variance trade-off of BKRR.

Remark 2 *In Theorem 1 as well as Theorem 4 below, we require $r > \frac{3}{2}$. We believe that similar optimal learning rates can be derived for $r \geq 1/2$ by using the technique in Caponnetto and Yao (2010); Guo et al. (2017). Since one of the main advantages of BKRR is to conquer the saturation, we focus on relatively large r in this paper. Throughout this paper, we assume $r \geq 1/2$, implying $f_\rho \in \mathcal{H}_K$. For $0 < r < \frac{1}{2}$, i.e. $f_\rho \notin \mathcal{H}_K$, like KRR (Caponnetto and Yao, 2010; Chang et al., 2017), BKRR usually requires additional unlabeled data to achieve the optimal learning rates.*

2.2. Exponential Bias-variance Trade-off

One of the most important advantages of L_2 boosting in linear regression is its almost over-fitting resistance (Bühlmann and Yu, 2003) meaning that for the in-sample error estimate, the bias decreases exponentially fast and the variance increases with exponentially diminishing terms as k increases. In this subsection, we will show that BKRR also possesses this property and show the power of boosting iteration for $k \geq r$.

Let $S_D : \mathcal{H}_K \to \mathbb{R}^{|D|}$ be the sampling operator (Smale and Zhou, 2004) defined by

$$S_D f := (f(x))_{(x,y)\in D}.$$

Its scaled adjoint $S_D^T : \mathbb{R}^{|D|} \to \mathcal{H}_K$ (or $\mathbb{R}^{|D|} \to L^2_{\rho_X}$) is given by

$$S_D^T \mathbf{c} := \frac{1}{|D|}\sum_{i=1}^{|D|} c_i K_{x_i}, \qquad \mathbf{c} := (c_1, c_2, \ldots, c_{|D|})^T \in \mathbb{R}^{|D|}.$$

Define a discretization of the integral operator L_K by

$$L_{K,D} f := S_D^T S_D f = \frac{1}{|D|}\sum_{(x,y)\in D} f(x) K_x.$$

Our bias-variance trade-off will be stated in terms of some quantities involving the difference between the compact and positive operators L_K and $L_{K,D}$ given by

$$\mathcal{Q}_{D,\lambda} := \|(L_{K,D} + \lambda I)^{-1/2}(L_K + \lambda I)^{1/2}\|, \qquad \mathcal{R}_D := \|L_{K,D} - L_K\|_{HS} \tag{8}$$

and the difference between $S_D^T y_D$ and $L_{K,D} f_\rho$ given by

$$\mathcal{P}_{D,\lambda} := \left\|(L_K + \lambda I)^{-1/2}(L_{K,D} f_\rho - S_D^T y_D)\right\|_K, \tag{9}$$

where $\|A\|_{HS}$ denotes the Hilbert-Schmidt norm of a Hilbert-Schmidt operator A, $\|\cdot\|$ denotes the operator norm, $y_D := (y_1, \ldots, y_{|D|})^T$ and I is the identity operator. We refer the readers to Appendix B for some basic definitions of linear operators. Let $\{(\sigma_i^{\mathbf{x}}, \phi_i^{\mathbf{x}})\}$ be a set of normalized eigenpairs of $L_{K,D}$ with the eigenfunctions $\{\phi_i^{\mathbf{x}}\}_i$ forming an orthonormal basis of $\mathcal{H}_K$ and the eigenvalue sequence $\{\sigma_i^{\mathbf{x}}\}$ non-increasing. Since $L_{K,D}$ is a positive

operator of rank at most $|D|$, we have $\sigma_k^{\mathbf{x}} = 0$ for $k \geq |D|+1$. Denote by $\sigma_{min}^{\mathbf{x}}$ the minimum positive eigenvalue of $L_{K,D}$. Denote by $\|f\|_D^2 := \frac{1}{|D|}\sum_{i=1}^{|D|} f^2(x_i)$. The following theorem shows a trade-off between the bias and variance of BKRR under the $\|\cdot\|_D$ semi-norm.

Theorem 3 *Let $k \geq 1$. Then, under condition (5) with $r \geq 1/2$, there holds*

$$\begin{aligned}\left\|f_{D,\lambda}^{(k)} - f_\rho\right\|_D &\leq \frac{(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho}{\sqrt{k}}\lambda^{1/2}\mathcal{R}_D + \mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda} \\ + \quad \mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}&\sum_{j=1}^{k-1}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-1/2} + 4(\mathcal{Q}_{D,\lambda}^2+1)\lambda^k\|h_\rho\|_\rho \begin{cases} (\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k > r, \\ \kappa^{2r-2k}+\lambda^{r-k}, & \text{if } k \leq r. \end{cases}\end{aligned} \tag{10}$$

The dominant terms on the right-hand side of (10) are the third and fourth terms and we call them the variance and bias for BKRR, respectively. For $0 < \lambda \leq 1$, it follows from Theorem 3 that the bias of BKRR decreases exponentially fast while the variance increases with exponentially diminishing terms as k increases, showing the exponential bias-variance trade-off. Bound (10) also exhibits a sudden change of the rate of bias decay when k is around the regularity level r of f_ρ. Its rate drops from λ^k to $\lambda^k(\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k} = \lambda^r\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r}$. Since Proposition 17 below shows that the variance of KRR can be bounded by $\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}$, the additional term in the variance of BKRR, $\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}\sum_{j=1}^{k-1}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-1/2}$, implies that BKRR degrades the learning performance of KRR if their regularization parameters are identical. This coincides with the consensus that boosting is not worthwhile if the learner is already complex. Hence, in BKRR, a large λ should be chosen to guarantee under-fitting of the original KRR, i.e., large bias and small variance. The trade-off can be achieved via an appropriately tuned k such that the bias and variance are close.

Theorem 3 presents an error estimate for BKRR in terms of the empirical semi-norm $\|\cdot\|_D$. In the following theorem, we present error analysis for BKRR in terms of the $\|\cdot\|_\rho$ norm.

Theorem 4 *Let $k \geq 1$. Assume condition (5) with $r > 3/2$. Then there holds*

$$\begin{aligned}\|f_{D,\lambda}^{(k)} - f_\rho\|_\rho &\leq 2\mathcal{Q}_{D,\lambda}(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\lambda^{1/2}\mathcal{R}_D + 2k\mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda} \\ + \quad \mathcal{Q}_{D,\lambda}\lambda^k\|h_\rho\|_\rho &\begin{cases} \lambda^{r-k} + \kappa^{2r-2k-1}(\kappa+\lambda^{\frac{1}{2}}), & \text{if } k \leq r, \\ 2(\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k > r. \end{cases}\end{aligned} \tag{11}$$

Different from the exponential bias-variance trade-off of the error estimate in terms of the $\|\cdot\|_D$ semi-norm shown in Theorem 3, there exhibits a semi-exponential bias-variance trade-off for the error estimate in terms of the $\|\cdot\|_\rho$ norm. To be detailed, the bias decreases exponentially, while the variance increases polynomially as k increases. Based on Theorem 3 and Theorem 4, we can derive the following corollary.

Corollary 5 *Under condition (5) with $r \geq 1/2$, $\|L_{K,D} f_{D,\lambda}^{(k)} - S_D^T y_D\|_K$ decreases with respect to k. Moreover,*

$$\lim_{k\to\infty}\|L_{K,D} f_{D,\lambda}^{(k)} - S_D^T y_D\|_K \leq \lambda^{\frac{1}{2}}\mathcal{P}_{D,\lambda}\mathcal{Q}_{D,\lambda} \tag{12}$$

and

$$\lim_{k\to\infty}\left\|f_{D,\lambda}^{(k)}-f_\rho\right\|_D\le\left(1+\frac{(\sigma_{min}^{\mathbf{x}}+\lambda)^{1/2}\lambda^{1/2}}{\sigma_{min}^{\mathbf{x}}}\right)\mathcal{P}_{D,\lambda}\mathcal{Q}_{D,\lambda}. \tag{13}$$

Corollary 5 exhibits an almost over-fitting resistance phenomenon of BKRR (neglecting the constant) for some kernels, since the sample error of KRR is bounded by $\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}$ (see Proposition 17 below). The behavior of the boosting iteration in (13) is different from that of the kernel-based (conjugate) gradient descent (Blanchard and Krämer, 2016; Lin and Zhou, 2018a), where the generalization error becomes ∞ for an arbitrary kernel, as the iteration number tends to infinity.

2.3. Adaptive Stopping Rule

We present in this subsection an adaptive stopping rule for BKRR to guarantee its optimal learning rates. To introduce the stopping rule, a user-friendly measurement of the capacity, empirical effective dimension (Lu et al., 2018; Mücke, 2018), defined by

$$\mathcal{N}_D(\lambda)=\mathrm{Tr}[(L_{K,D}+\lambda I)^{-1}L_{K,D}]=\mathrm{Tr}[(\lambda|D|I+\mathbb{K})^{-1}\mathbb{K}] \tag{14}$$

is needed. Denote

$$\mathcal{W}_{D,\lambda}=\frac{16\sqrt{2}(\kappa^2+\kappa+1)(\kappa M+\gamma)}{\sqrt{|D|}}\left(\frac{(\sqrt{|D|\lambda}+9)\sqrt{\max\{\mathcal{N}_D(\lambda),1\}}}{|D|\lambda}+1\right)\frac{(\sqrt{|D|\lambda}+9)\sqrt{\max\{\mathcal{N}_D(\lambda),1\}}}{\sqrt{|D|\lambda}}. \tag{15}$$

If $\delta\in(0,1)$ is the parameter corresponding to the confidence level, the boosting iteration will stop at the first positive integer $\hat{k}:=\hat{k}_{D,\lambda,\delta,K}$ satisfying

$$\|L_{K,D}f_{D,\lambda}^{(\hat{k})}-S_D^Ty_D\|_K\le\lambda^{\frac{1}{2}}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}. \tag{16}$$

Since

$$L_{K,D}f_{D,\lambda}^{(\hat{k})}-S_D^Ty_D=\frac{1}{|D|}\sum_{i=1}^{|D|}(f_{D,\lambda}^{(\hat{k})}(x_i)-y_i)K_{x_i},$$

we have

$$\|L_{K,D}f_{D,\lambda}^{(\hat{k})}-S_D^Ty_D\|_K^2=\frac{1}{|D|^2}(f_{D,\lambda}^{(\hat{k})}(\mathbf{x})-\mathbf{y})^T\mathbb{K}(f_{D,\lambda}^{(\hat{k})}(\mathbf{x})-\mathbf{y}),$$

where $f_{D,\lambda}^{(\hat{k})}(\mathbf{x})-\mathbf{y}$ is the vector $\left(f_{D,\lambda}^{(\hat{k})}(x_i)-y_i\right)_{i=1}^{|D|}$. This together with (14) shows that the stopping rule in (16) is implementable. Moreover, Lemma 23 in Appendix A shows that

$$\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}\le\frac{1}{2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \tag{17}$$

holds with confidence $1-\delta$. Then Corollary 5 verifies the existence of $\hat{k}$ with high probability since (16) is satisfied for sufficiently large $\hat{k}$ with high probability.

We are now in a position to present our second main result in the following theorem.

Theorem 6 *Let $\delta\in(0,1)$. Under conditions (4), (6) with $0<s\le1$ and condition (5) with $r\ge1/2$, if $\lambda=(c/|D|)^{1/(2r+s)}$ for some $c\ge1$, and $\hat{k}$ is the smallest positive integer satisfying (16), then with confidence at least $1-\delta$, there holds*

$$\|f_{D,\lambda}^{(\hat{k})}-f_\rho\|_\rho\le C|D|^{-\frac{r}{2r+s}}\log^{10}\frac{16}{\delta}, \tag{18}$$

where C is a constant independent of δ or $|D|$.

Theorem 6 shows that BKRR equipped with the stopping rule (16) achieves the same optimal learning rate without saturation, that is, the optimal learning rate holds for an arbitrary $r\ge1/2$ rather than $\frac{1}{2}\le r\le1$ shown by Caponnetto and De Vito (2007) and Lin et al. (2017) for KRR. Theorem 4 and Theorem 6 state that BKRR provides a novel semi-exponential bias-variance trade-off achieved by the boosting iteration, and the stopping rule (16) can realize its good performance. It follows from Corollary 5 and Theorem 6 that combining L_2 boosting with KRR reduces the difficulty of model selection (almost over-fitting resistance) and overcomes the saturation of KRR.

Remark 7 *Theoretically, a more delicate stopping rule for BKRR should be the first positive integer satisfying*

$$\|L_{K,D}f_{D,\lambda}^{(\hat{k})}-S_D^Ty_D\|_K\le2\lambda^{\frac{1}{2}}\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}.$$

Since the quantities $\mathcal{Q}_{D,\lambda}$ and $\mathcal{P}_{D,\lambda}$ cannot be implemented, we have to present a bound for them and thus get a confidence-dependent stopping rule (16). It should be noted that the constant in the definition of $\mathcal{W}_{D,\lambda}$ is not tight, which makes the algorithm stop much earlier than the optimal one. Due to the (semi-)exponential bias-variance trade-off presented in the previous subsection, a relatively large number of iterations does not degrade the generalization ability of BKRR very much. We thus multiply by a small factor to make the algorithm stop later. In a word, we implement the stopping rule (16) as

$$\begin{aligned}&\|L_{K,D}f_{D,\lambda}^{(\hat{k})}-S_D^Ty_D\|_K\\ \le\ &\frac{\theta\sqrt{\lambda}}{\sqrt{|D|}}\left(\frac{(\sqrt{|D|\lambda}+1)\sqrt{\max\{\mathcal{N}_D(\lambda),1\}}}{|D|\lambda}+1\right)\frac{(\sqrt{|D|\lambda}+1)\sqrt{\max\{\mathcal{N}_D(\lambda),1\}}}{\sqrt{|D|\lambda}}\end{aligned} \tag{19}$$

for some small θ such as $\theta=0.05$ (or other values).

Remark 8 *In Theorem 6, although k can be adaptively determined by (16), λ depends on r and s. It should be noted in Theorem 1 that $\lambda\sim|D|^{-1/(2r+s)}$ is the optimal regularization parameter for BKRR to achieve the optimal learning rate. The reason for this phenomenon is that we do not impose additional restrictions to the kernel K and the marginal distribution ρ_X other than (6). In particular, we use $\frac{\lambda}{\lambda+\sigma_{min}^{\mathbf{x}}}\le1$ directly in the proof. For some particular kernel and ρ_X, the minimum positive eigenvalue $\sigma_{min}^{\mathbf{x}}$ for the matrix $\mathbb{K}/|D|$ can be computed. Then, we can derive similar error estimates by Theorem 4. In this way, optimal learning rates of BKRR hold for large values of λ. It would be interesting to determine the kernel and marginal distribution ρ_X, with which BKRR achieves the similar optimal*

learning rates as Theorem 6 for large λ. The other reason that we do not focus on the selection of λ is that boosting theory usually requires large λ to keep the algorithm underfitting and using iteration to reduce the bias. Thus, we can select a relatively large λ in advance numerically. Our experimental results in Section 6 show that the generalization ability of BKRR is not very sensitive to λ provided it is larger than some value.

Remark 9 *The constant exhibited in (18) is a bit pessimistic, compared with the classical results in the literature (Caponnetto and De Vito, 2007; Caponnetto and Yao, 2010; Blanchard and Krämer, 2016; Lin et al., 2017; Guo et al., 2017). One of the reasons for this pessimistic estimate is that we do not impose any restriction on the relation between $|D|$ and δ. In particular, as shown in our proof, if we assume $2\log(16/\delta) \le \sqrt{|D|\lambda}$, i.e. $\delta \ge 16\exp\left\{-\frac{1}{2}c^{-1/(4r+2s)}|D|^{\frac{2r+s-1}{4r+2s}}\right\}$, then the exponent should be reduced from 10 to 6. Since the optimal constant is difficult to obtain, we only pursue the optimal learning rate in Theorem 6.*

3. Related Work

In this section, we discuss some related work in the literature and show the novelty of our results.

3.1. Boosting

A functional gradient descent viewpoint in statistics (Friedman et al., 2000; Friedman, 2001) reformulates boosting as a family of stage-wise optimization problems with different loss functions. Gradient boosting requires computing the negative gradient vector and line search in each boosting iteration. For L_2-Boosting, the gradient computation and line search can be unified in solving least squares fitting of residuals (Bühlmann and Yu, 2003). Thus, L_2-Boosting is essentially iterative least squares of residuals. An important advantage of boosting is its almost resistance to over-fitting (e.g. Friedman (2001) and its discussion papers), showing an easy way for model selection.

In Bühlmann and Yu (2003), an exponential bias-variance trade-off for linear regression was derived to illustrate the almost resistance to over-fitting for L_2-Boosting in a fixed design setting. In particular, Theorem 1 in Bühlmann and Yu (2003) shows that as the boosting iteration goes on, the bias decreases exponentially with a quantity depending on the minimum eigenvalue of the data matrix, while the variance increases with exponentially diminishing terms. Our Theorem 3 presents a similar result as Theorem 1 of Bühlmann and Yu (2003) for taking KRR as weak learners in L_2-Boosting, but highlights the importance of the regularity of the regression function by showing a sudden change of bias decaying. In Theorem 4, we also analyze the changes of bias and variance in a random design setting and show a semi-exponential bias-variance trade-off.

In Park et al. (2009), the learning performance of L_2-Boosting whose weak learners are Nadaraya-Watson kernel estimates was analyzed in the same framework as ours. It was shown in Theorem 2 and Theorem 3 of Park et al. (2009) that L_2-Boosting overcomes the saturation of Nadaraya-Watson kernel estimates (Györfi et al., 2002, Chapter 5). Differently, we utilize KRR as the weak learners instead of the kernel estimates, requiring totally different analysis. Furthermore, we present an adaptive stopping rule to select the number of boosting iterations, while Park et al. (2009) requires an a priori knowledge-dependent number of boosting iterations. In this paper, we are concerned with combining L_2-Boosting with KRR. It would be interesting to consider boosted versions of other algorithms such as the kernel-based gradient descent (Yao et al., 2007) and more generally the kernel-based spectral algorithms (Gerfo et al., 2008).

3.2. Iterated Tikhonov Regularization

From Lemma 12 below, we find that for a fixed k, BKRR can be regarded as a special spectral algorithm, the iterated Tikhonov regularization (Gerfo et al., 2008). In this framework, the learning rate of BKRR with a fixed k may be derived directly from general results for spectral algorithms (Bauer et al., 2007; Caponnetto and Yao, 2010; Guo et al., 2017,b).

Different from the iterated Tikhonov regularization, BKRR focuses on fixed but relatively large λ and parameterizes the number of iterations, though they possess the same spectral representation (see (27) below). It follows from Theorem 3 that BKRR has an eventually stable relationship between the generalization error and boosting iteration in the sense that the generalization error does not increase much with the boosting iteration after some k. Theorem 6 shows that BKRR with adaptive stopping rule (16) can overcome the saturation of KRR, just as iterated Tikhonov regularization does but with an a priori knowledge-dependent selected and fixed k.

In a recent paper (Wu, 2017), a bias correction algorithm was proposed for ridge regression and detailed analysis was provided for the changes of bias and variance. It was found that one-step iteration can reduce the bias without increasing the variance much. The analysis in Wu (2017) is carried out in a more general framework than that in this paper. It should be pointed out that with the same setting in this paper, the algorithm in (Wu, 2017) possesses the spectral representation (27) below with $k = 1$.

Iterated Tikhonov regularization is closely related to BKRR and widely used in the community of inverse problems. Analysis of iterated Tikhonov regularization in solving ill-posed inverse problems can be dated back to the 1970's (e.g. King and Chillingworth (1979)). The optimal convergence rates and parameter selection of iterated Tikhonov regularization are important topics in inverse problems (Engl, 1987; Jin and Hou, 1997; Hanke and Groetsch, 1998; Jin and Stals, 2012). In particular, our stopping rule (16) is motivated by the discrepancy principle provided in Hanke and Groetsch (1998).

3.3. Iteration-based Learning Schemes and Stopping Rules

Saturation is a well known design-flaw of KRR (Gerfo et al., 2008) and limits its usage. Due to this phenomenon, researchers turn to other iteration-based learning schemes such as the kernel-based gradient descent (Yao et al., 2007), kernel-based conjugate gradient descent (Blanchard and Krämer, 2016) and kernel-based partial least squares (Lin and Zhou, 2018b). The theoretical results in Blanchard and Krämer (2016); Lin and Zhou (2018a,b) showed that these strategies can reach the optimal learning rates without saturation.

As an iteration-based algorithm, the bias and variance of the kernel-based gradient descent algorithm were analyzed in Lin and Zhou (2018a) and a polynomial bias-variance trade-off was exhibited. In particular, as the iteration goes on, its bias decreases as $\mathcal{O}(k^{-r})$ and its variance increases as a polynomial of k. Similar results on polynomial

bias-variance trade-off of the kernel-based conjugate gradient descent and kernel-based partial least squares were derived in Blanchard and Krämer (2016) and Lin and Zhou (2018b), respectively. Different from these iteration-based algorithms, BKRR shows an exponential bias-variance trade-off, reducing the difficulty of model selection.

Stopping rules play an important role in iteration-based learning schemes. Learning rates of iteration-based algorithms were built in Bauer et al. (2007); Yao et al. (2007); Guo et al. (2017); Blanchard and Krämer (2016) upon prior knowledge-based stopping rules. In Caponnetto and Yao (2010); Lin and Zhou (2018b), cross-validation based stopping rules were presented for general spectral algorithms and kernel-based partial least squares. In Raskutti et al. (2014), an adaptive stopping rule was deduced for the kernel-based gradient descent algorithm under the regularity condition (5) with $r = 1/2$. More recently, another adaptive stopping rule based on a balancing principle for general spectral algorithms was presented in Lu et al. (2018). Different from these results, our stopping rule presented in (16) requires neither dividing the sample set (compared with the cross-validation), nor computing estimators with various λ (compared with the balancing principle). Compared with Raskutti et al. (2014), our results hold under condition (5) with all $r \geq 1/2$, i.e., we adaptively select r rather than fixing it to be $1/2$. At first glance, the dependence of the confidence level in (16) may make the stopping rule not so stable. However, the (semi-) exponential bias-variance trade-off of BKRR compensates this instability by showing that the learning performance remains stable for a large range of k. It would be interesting to derive a confidence-independent stopping rule for BKRR.

4. Operator Representations and Error Estimates

We analyze the learning performance of BKRR by using the integral operator approach (Smale and Zhou, 2007; Lin et al., 2017; Guo et al., 2017). The novelties of our proof are special operator representations of BKRR, special spectral properties of BKRR and a tight bound for $\hat{k}$ defined by (16). In Subsections 4.1 and 4.2, we provide detailed spectral analysis for BKRR, which is crucial for deriving the bias and variance estimates in Subsections 4.3 and 4.4. In Subsection 4.5, we provide a tight bound on the number of boosting iteration defined by (16) by utilizing the special spectral properties of BKRR.

4.1. Special Operator Representations of BKRR

Define the noise-free version of $f_{D,\lambda}^{(k)}$ by

$$f_{D,\lambda}^{(1,*)} := \arg\min_{f\in\mathcal{H}_K} \left\{ \frac{1}{|D|} \sum_{(x,y)\in D} (f(x) - f_\rho(x))^2 + \lambda \|f\|_K^2 \right\} \tag{20}$$

and

$$f_{D,\lambda}^{(k,*)} := f_{D,\lambda}^{(k-1,*)} + f_{D,\lambda}^{(k,*)\diamond}, \qquad k > 1, \tag{21}$$

where

$$f_{D,\lambda}^{(k,*)\diamond} := \arg\min_{f\in\mathcal{H}_K} \left\{ \frac{1}{|D|} \sum_{(x,y)\in D} [f(x) - (f_\rho(x) - f_{D,\lambda}^{(k-1,*)}(x))]^2 + \lambda \|f\|_K^2 \right\}, \qquad k > 1. \tag{22}$$

For KRR, the classical result in Smale and Zhou (2007) shows

$$f_{D,\lambda}^{(1)} = (L_{K,D} + \lambda I)^{-1} S_D^T y_D, \quad \text{and} \quad f_{D,\lambda}^{(1,*)} = (L_{K,D} + \lambda I)^{-1} L_{K,D} f_\rho. \tag{23}$$

Similar to (23), the following Lemma 10 presents operator representations for $f_{D,\lambda}^{(k)}$ and $f_{D,\lambda}^{(k,*)}$.

Lemma 10 *Let $k \geq 2$. We have*

$$f_{D,\lambda}^{(k)} = [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}] f_{D,\lambda}^{(k-1)} + f_{D,\lambda}^{(1)}, \tag{24}$$

$$L_{K,D} f_{D,\lambda}^{(k)} = S_D^T y_D - [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}]^k S_D^T y_D \tag{25}$$

and

$$f_{D,\lambda}^{(k,*)} = [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}] f_{D,\lambda}^{(k-1,*)} + f_{D,\lambda}^{(1,*)} = f_\rho - [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}]^k f_\rho. \tag{26}$$

Proof. Since $f_{D,\lambda}^{(k)\diamond}$ is the solution to KRR (1) with data $\{x_i, y_i - f_{D,\lambda}^{(k-1)}(x_i)\}_{(x_i,y_i)\in D}$, it follows from (2), (23) and the definition $L_{K,D} = S_D^T S_D$ that

$$\begin{aligned} f_{D,\lambda}^{(k)} &= f_{D,\lambda}^{(k-1)} + (L_{K,D} + \lambda I)^{-1} S_D^T (y_D - S_D f_{D,\lambda}^{(k-1)}) \\ &= [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}] f_{D,\lambda}^{(k-1)} + f_{D,\lambda}^{(1)}. \end{aligned}$$

This verifies (24). Combining this with (23) yields

$$\begin{aligned} & L_{K,D} f_{D,\lambda}^{(k)} - S_D^T y_D = L_{K,D}[I - (L_{K,D} + \lambda I)^{-1} L_{K,D}] f_{D,\lambda}^{(k-1)} + L_{K,D} f_{D,\lambda}^{(1)} - S_D^T y_D \\ = \; & [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}] L_{K,D} f_{D,\lambda}^{(k-1)} + [(L_{K,D} + \lambda I)^{-1} L_{K,D} - I] S_D^T y_D \\ = \; & [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}][L_{K,D} f_{D,\lambda}^{(k-1)} - S_D^T y_D]. \end{aligned}$$

Applying this relation iteratively and using (23) give

$$\begin{aligned} L_{K,D} f_{D,\lambda}^{(k)} - S_D^T y_D &= [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}]^{k-1} [L_{K,D} f_{D,\lambda}^{(1)} - S_D^T y_D] \\ &= -[I - (L_{K,D} + \lambda I)^{-1} L_{K,D}]^k S_D^T y_D. \end{aligned}$$

This proves (25). As for deriving (26), we have

$$f_{D,\lambda}^{(k,*)} = [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}] f_{D,\lambda}^{(k-1,*)} + (L_{K,D} + \lambda I)^{-1} L_{K,D} f_\rho.$$

It follows that

$$f_{D,\lambda}^{(k,*)} - f_\rho = [I - (L_{K,D} + \lambda I)^{-1} L_{K,D}][f_{D,\lambda}^{(k-1,*)} - f_\rho]$$

and by iterations,

$$\begin{aligned} f_{D,\lambda}^{(k,*)} - f_\rho &= [I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^{k-1}[f_{D,\lambda}^{(1,*)} - f_\rho] \\ &= -[I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^k f_\rho. \end{aligned}$$

This completes the proof of Lemma 10. ∎

From Lemma 10, we have

$$f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)} = [I - (L_{K,D}+\lambda I)^{-1}L_{K,D}](f_{D,\lambda}^{(k-1)} - f_{D,\lambda}^{(k-1,*)}) + f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)},$$

from which the following expression is obtained by iterations.

Lemma 11 *For $k \in \mathbb{N}$, we have*

$$f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)} = \sum_{j=0}^{k-1}[I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^j[f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)}].$$

4.2. Special Spectral Properties of BKRR

Our analysis depends on some spectral analysis of BKRR, viewed as a special class of spectral algorithms. It follows iteratively from the identity

$$f_{D,\lambda}^{(k)} = \lambda(L_{K,D}+\lambda I)^{-1}f_{D,\lambda}^{(k-1)} + (L_{K,D}+\lambda I)^{-1}S_D^T y_D$$

obtained from (24) by writing $L_{K,D} = L_{K,D} + \lambda I - \lambda I$.

Lemma 12 *For $k \in \mathbb{N}$, we have*

$$f_{D,\lambda}^{(k)} = g_\lambda^{(k)}(L_{K,D})S_D^T y_D, \tag{27}$$

where $g_\lambda^{(k)}(L_{K,D})$ is an operator on $\mathcal{H}_K$ defined by spectral calculus and

$$g_\lambda^{(k)}(\sigma) = \sum_{j=0}^{k-1}(\lambda(\sigma+\lambda)^{-1})^{k-j-1}(\sigma+\lambda)^{-1} = \sum_{j=0}^{k-1}\frac{\lambda^{k-1-j}}{(\sigma+\lambda)^{k-j}}. \tag{28}$$

Based on Lemma 12, we derive the following two lemmas, showing some special spectral properties of BKRR.

Lemma 13 *Let $g_\lambda^{(k)}$ be defined by (28), then we have*

$$I - L_{K,D}g_\lambda^{(k)}(L_{K,D}) = \lambda^k(L_{K,D}+\lambda I)^{-k}, \tag{29}$$

$$\|L_{K,D}g_\lambda^{(k)}(L_{K,D})]\| \le 1, \qquad \lambda\|g_\lambda^{(k)}(L_{K,D})\| \le k, \tag{30}$$

and for all $u > v > 0$, there holds

$$\|L_{K,D}^v\lambda^u(L_{K,D}+\lambda I)^{-u}\| \le v^v\left(\frac{\lambda}{u}\right)^v. \tag{31}$$

Proof. Observe from (28) that

$$\begin{aligned} \sigma g_\lambda^{(k)}(\sigma) &= (\sigma+\lambda-\lambda)\sum_{j=0}^{k-1}((\sigma+\lambda)^{-1})^{-j}\lambda^{k-j-1}(\sigma+\lambda)^{-k} \\ &= \left\{\sum_{j=0}^{k-1}(\sigma+\lambda)^{j+1}\lambda^{k-j-1} - \sum_{j=0}^{k-1}(\sigma+\lambda)^j\lambda^{k-j}\right\}(\sigma+\lambda)^{-k} \\ &= \{(\sigma+\lambda)^k - \lambda^k\}(\sigma+\lambda)^{-k}. \end{aligned}$$

Hence

$$L_{K,D}g_\lambda^{(k)}(L_{K,D}) = \left[(L_{K,D}+\lambda I)^k - \lambda^k I\right](L_{K,D}+\lambda I)^{-k} \tag{32}$$

and (29) follows. Then spectral analysis with the eigenpairs $\{(\sigma_i^{\mathbf{x}}, \phi_i^{\mathbf{x}})\}$ of $L_{K,D}$ verifies the first inequality of (30). The second inequality of (30) follows directly from (28). Set a function $h_{v,u}$ on $[0,\infty)$ by

$$h_{v,u}(\sigma) = \frac{\sigma^v\lambda^u}{(\sigma+\lambda)^u}.$$

Since $u > v$, we have $h_{v,u}(0) = h_{v,u}(\infty) = 0$. It is easy to check that $\sigma = \frac{v\lambda}{u-v}$ is the unique maximum point of $h_{v,u}$ on $(0,\infty)$. Thus, $\|L_{K,D}\| \le \kappa^2$ yields

$$\begin{aligned} \|L_{K,D}^v\lambda^u(L_{K,D}+\lambda I)^{-u}\| &\le \max_{0\le\sigma\le\kappa^2} h_{v,u}(\sigma) \le \max_{0\le\sigma<\infty} h_{v,u}(\sigma) \le h_{v,u}\left(\frac{v\lambda}{u-v}\right) \\ = \lambda^v v^v\frac{(u-v)^u}{(u-v)^v u^u} &= v^v\left(\frac{\lambda}{u}\right)^v\left(\frac{u-v}{u}\right)^{u-v} \le v^v\left(\frac{\lambda}{u}\right)^v. \end{aligned}$$

This completes the proof of Lemma 13. ∎

Lemma 14 *Let $u > 0$ and $\ell \in \mathbb{N}_0 := \{0\} \cup \mathbb{N}$. Then for $f \in \mathcal{H}_K$, we have*

$$\|L_{K,D}^u[I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^\ell f\|_K \le \begin{cases} \kappa^{2(u-\ell)}\lambda^\ell\|f\|_K, & \text{if } \ell \le u, \\ \lambda^u\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{\ell-u}\|f\|_K, & \text{if } \ell > u. \end{cases} \tag{33}$$

Proof. Due to spectral calculus with $f = \sum_i\langle f, \phi_i^{\mathbf{x}}\rangle_K\phi_i^{\mathbf{x}}$, we have

$$\begin{aligned} \|L_{K,D}^u[I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^\ell f\|_K^2 &= \sum_i\frac{(\sigma_i^{\mathbf{x}})^{2u}\lambda^{2\ell}}{(\sigma_i^{\mathbf{x}}+\lambda)^{2\ell}}|\langle f, \phi_i^{\mathbf{x}}\rangle_K|^2 \\ = \sum_{\sigma_i^{\mathbf{x}}>0}\frac{(\sigma_i^{\mathbf{x}})^{2u}\lambda^{2\ell}}{(\sigma_i^{\mathbf{x}}+\lambda)^{2\ell}}|\langle f, \phi_i^{\mathbf{x}}\rangle_K|^2. \end{aligned} \tag{34}$$

If $\ell \le u$, we have from $\max_i\sigma_i^{\mathbf{x}} \le \kappa^2$ and (34) that

$$\|L_{K,D}^u[I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^\ell f\|_K^2 \le \lambda^{2\ell}\kappa^{4(u-\ell)}\sum_{\sigma_i^{\mathbf{x}}>0}|\langle f, \phi_i^{\mathbf{x}}\rangle_K|^2.$$

Then

$$\|L_{K,D}^u[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^\ell f\|_K \le \kappa^{2(u-\ell)}\lambda^\ell \|f\|_K.$$

If $\ell > u$, we get from (34) that

$$\begin{aligned}\|L_{K,D}^u[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^\ell f\|_K^2 &\le \lambda^{2u}\sum_{\sigma_i^{\mathbf{x}}>0}\frac{\lambda^{2\ell-2u}}{(\sigma_i^{\mathbf{x}}+\lambda)^{2\ell-2u}}|\langle f,\phi_i^{\mathbf{x}}\rangle_K|^2\\ \le\ \lambda^{2u}\frac{\lambda^{2\ell-2u}}{(\sigma_{min}^{\mathbf{x}}+\lambda)^{2\ell-2u}}\sum_{\sigma_i^{\mathbf{x}}>0}|\langle f,\phi_i^{\mathbf{x}}\rangle_K|^2 &\le \lambda^{2u}\frac{\lambda^{2\ell-2u}}{(\sigma_{min}^{\mathbf{x}}+\lambda)^{2\ell-2u}}\sum_i|\langle f,\phi_i^{\mathbf{x}}\rangle_K|^2.\end{aligned}$$

Hence,

$$\|L_{K,D}^u[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^\ell f\|_K \le \lambda^u\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{\ell-u}\|f\|_K.$$

This completes the proof of Lemma 14. ■

4.3. Bounding the Bias

Our error decomposition will be carried out by bounding the two terms, bias and variance, as follows

$$\|f_{D,\lambda}^{(k)}-f_\rho\| \le \|f_{D,\lambda}^{(k,*)}-f_\rho\| + \|f_{D,\lambda}^{(k)}-f_{D,\lambda}^{(k,*)}\|,$$

where $\|\cdot\|$ denotes either the $\|\cdot\|_D$ semi-norm or $\|\cdot\|_\rho$ norm. For $f\in\mathcal{H}_K$, it is easy to check that

$$\|f-f_\rho\|_D = \|L_{K,D}^{1/2}(f-f_\rho)\|_K. \tag{35}$$

In this subsection, we present two bounds for the bias term $f_{D,\lambda}^{(k,*)}-f_\rho$ in terms of the $\|\cdot\|_D$ semi-norm and $\|\cdot\|_\rho$ norm.

Proposition 15 *Let $0\le\nu\le 1/2$. Under condition (5) with $r>3/2$, we have*

$$\begin{aligned}\|L_{K,D}^\nu(f_{D,\lambda}^{(k,*)}-f_\rho)\|_K &\le \frac{(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho}{k^\nu}\lambda^\nu\mathcal{R}_D\\ +\ &\begin{cases}\kappa^{2(r+\nu-1/2-k)}\lambda^k\|h_\rho\|_\rho, & \text{if } k\le r+\nu-1/2,\\ \lambda^{r+\nu-1/2}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r-\nu+1/2}\|h_\rho\|_\rho, & \text{if } k>r+\nu-1/2.\end{cases}\end{aligned} \tag{36}$$

Proof. Since $r>3/2$, from (5) and (26) we find

$$\begin{aligned}&\|L_{K,D}^\nu(f_{D,\lambda}^{(k,*)}-f_\rho)\|_K = \|L_{K,D}^\nu[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k L_K^{r-1/2}L_K^{1/2}h_\rho\|_K\\ =\ &\left\|L_{K,D}^\nu[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k\left(L_K^{r-1/2}-L_{K,D}^{r-1/2}+L_{K,D}^{r-1/2}\right)L_K^{1/2}h_\rho\right\|_K\\ \le\ &\left\|L_{K,D}^{r+\nu-1/2}[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k L_K^{1/2}h_\rho\right\|_K\\ +\ &\left\|L_{K,D}^\nu[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k\left(L_K^{r-1/2}-L_{K,D}^{r-1/2}\right)L_K^{1/2}h_\rho\right\|_K\\ =:\ &A_1+A_2.\end{aligned} \tag{37}$$

We first estimate A_2. Since $r>3/2$, the bounds $\|L_{K,D}\|\le\kappa^2$, $\|L_K\|\le\kappa^2$, we get from (68) in Appendix A that

$$\|L_{K,D}^{r-1/2}-L_K^{r-1/2}\|_{HS} \le (r-1/2)\kappa^{2r-3}\|L_{K,D}-L_K\|_{HS}. \tag{38}$$

When $\nu>0$, we apply (31) with $v=\nu$ to obtain

$$\begin{aligned}A_2 &\le \|L_{K,D}^\nu[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k\|\left\|L_K^{r-1/2}-L_{K,D}^{r-1/2}\right\|\|L_K^{1/2}h_\rho\|_K\\ &\le \frac{(r-1/2)\nu^\nu\kappa^{2r-3}\|h_\rho\|_\rho}{k^\nu}\lambda^\nu\mathcal{R}_D.\end{aligned}$$

If $\nu=0$, we can also obtain from $\|[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k\|\le 1$ that

$$A_2 \le (r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\mathcal{R}_D.$$

Then we estimate A_1 by applying (33) with $u=r+\nu-1/2$ and $f=L_K^{1/2}h_\rho$ to get

$$A_1 \le \begin{cases}\kappa^{2(r+\nu-1/2-k)}\lambda^k\|h_\rho\|_\rho, & \text{if } k\le r+\nu-1/2,\\ \lambda^{r+\nu-1/2}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r-\nu+1/2}\|h_\rho\|_\rho, & \text{if } k>r+\nu-1/2.\end{cases}$$

Plugging the estimates of A_1 and A_2 into (37), we obtain (36), which completes the proof of Proposition 15. ■

Proposition 16 *Under condition (5) with $r>3/2$, we have*

$$\begin{aligned}\|f_{D,\lambda}^{(k,*)}-f_\rho\|_\rho &\le 2\mathcal{Q}_{D,\lambda}(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\lambda^{\frac12}\mathcal{R}_D\\ +\ \mathcal{Q}_{D,\lambda}\|h_\rho\|_\rho&\begin{cases}\kappa^{2r-2k-1}(\lambda^{\frac12}+\kappa)\lambda^k, & \text{if } k\le r-1/2,\\ \lambda^r\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r+1/2}+\kappa^{2r-2k}\lambda^k, & \text{if } r-1/2<k\le r,\\ 2\lambda^r\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r}, & \text{if } k>r.\end{cases}\end{aligned}$$

Proof. Since $f_{D,\lambda}^{(k,*)}-f_\rho\in\mathcal{H}_K$, we have from Lemma 24 in Appendix A that

$$\|f_{D,\lambda}^{(k,*)}-f_\rho\|_\rho \le \mathcal{Q}_{D,\lambda}\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k,*)}-f_\rho)\|_K + \mathcal{Q}_{D,\lambda}\lambda^{1/2}\|f_{D,\lambda}^{(k,*)}-f_\rho\|_K.$$

For $k\le r-1/2$, it follows from (36) with $\nu=1/2$ and $\nu=0$ that

$$\begin{aligned}\|f_{D,\lambda}^{(k,*)}-f_\rho\|_\rho &\le \mathcal{Q}_{D,\lambda}\left(\frac{(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho}{\sqrt{k}}\lambda^{1/2}\mathcal{R}_D+\kappa^{2(r-k)}\lambda^k\|h_\rho\|_\rho\right)\\ +\ \lambda^{1/2}\mathcal{Q}_{D,\lambda}&\left((r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\mathcal{R}_D+\kappa^{2(r-1/2-k)}\lambda^k\|h_\rho\|_\rho\right).\end{aligned}$$

For $r-1/2<k\le r$,

$$\begin{aligned}\|f_{D,\lambda}^{(k,*)}-f_\rho\|_\rho &\le \mathcal{Q}_{D,\lambda}\left(\frac{(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho}{\sqrt{k}}\lambda^{1/2}\mathcal{R}_D+\kappa^{2(r-k)}\lambda^k\|h_\rho\|_\rho\right)\\ +\ \lambda^{1/2}\mathcal{Q}_{D,\lambda}&\left((r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\mathcal{R}_D+\lambda^{r-1/2}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r+1/2}\|h_\rho\|_\rho\right).\end{aligned}$$

For $k > r$,

$$\|f_{D,\lambda}^{(k,*)} - f_\rho\|_\rho \le \mathcal{Q}_{D,\lambda}\left(\frac{(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\lambda^{1/2}}{\sqrt{k}}\mathcal{R}_D + \lambda^r\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r}\|h_\rho\|_\rho\right)$$
$$+ \quad \lambda^{1/2}\mathcal{Q}_{D,\lambda}\left((r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\mathcal{R}_D + \lambda^{r-1/2}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r+1/2}\|h_\rho\|_\rho\right).$$

This completes the proof of Proposition 16. ∎

4.4. Bounding the Variance

In this subsection, we present the bounds for the variance term $f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}$.

Proposition 17 *Let $0 < \nu \le 1/2$. We have*

$$\left\|L_{K,D}^\nu(f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)})\right\|_K \le \lambda^{\nu-1/2}\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}\left(1 + \sum_{j=1}^{k-1}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-\nu}\right). \tag{39}$$

Proof. Due to Lemma 11, we get

$$L_{K,D}^\nu(f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}) = \sum_{j=0}^{k-1} L_{K,D}^\nu[I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^j[f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)}].$$

It then follows from (33) with $u = \nu$, $\ell = 1, 2, \ldots, k-1$ and $f = f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)}$ that

$$\left\|L_{K,D}^\nu(f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)})\right\|_K \le \sum_{j=0}^{k-1}\left\|L_{K,D}^\nu[I - (L_{K,D}+\lambda I)^{-1}L_{K,D}]^j[f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)}]\right\|_K$$
$$\le \quad \|L_{K,D}^\nu(f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)})\|_K + \sum_{j=1}^{k-1}\lambda^\nu\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-\nu}\|f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)}\|_K.$$

But (23) implies that for $0 \le u \le 1/2$, there holds

$$\|L_{K,D}^u(f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)})\|_K = \|L_{K,D}^u(L_{K,D}+\lambda I)^{-1}(S_D^T y_D - L_{K,D}f_\rho)\|_K$$
$$\le \quad \lambda^{-1/2+u}\|(L_{K,D}+\lambda I)^{-1/2}(S_D^T y_D - L_{K,D}f_\rho)\|_K \le \lambda^{-1/2+u}\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}. \tag{40}$$

Applying this inequality with $u = \nu$ and $u = 0$ yields

$$\left\|L_{K,D}^\nu(f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)})\right\|_K \quad \le \quad \lambda^{\nu-1/2}\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda} + \sum_{j=1}^{k-1}\lambda^{\nu-1/2}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-\nu}\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}.$$

This completes the proof of Proposition 17. ∎

Different from Proposition 15, Proposition 17 does not hold for $\nu = 0$, which makes the bound of variance in the out-sample case totally different from that in the in-sample case.

Proposition 18 *For $k \in \mathbb{N}$, we have*

$$\|f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}\|_\rho \le 2k\mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda}.$$

Proof. We obtain from Lemma 11 and (40) with $u = 0$ that

$$\|f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}\|_K \le \sum_{j=0}^{k-1}\|f_{D,\lambda}^{(1)} - f_{D,\lambda}^{(1,*)}\|_K \le k\lambda^{-\frac{1}{2}}\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}.$$

Then it follows from Lemma 24 in Appendix A and (39) with $\nu = 1/2$ that

$$\|f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}\|_\rho \le \mathcal{Q}_{D,\lambda}\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)})\|_K + \mathcal{Q}_{D,\lambda}\lambda^{1/2}\|f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}\|_K$$
$$\le \quad \mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda}\left(1 + \sum_{j=1}^{k-1}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-1/2}\right) + k\mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda} \le 2k\mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda}.$$

This completes the proof of Proposition 18. ∎

4.5. Bounding the Number of Boosting Iterations

We first show the important role of the stopping rule (16) in controlling the bias.

Lemma 19 *Let $\delta \in (0,1)$ and $\lambda > 0$. If $\hat{k}$ is the smallest positive integer satisfying (16), then with confidence $1-\delta$, there holds*

$$\|L_{K,D}f_\rho - L_{K,D}f_{D,\lambda}^{(\hat{k},*)}\|_K \le \frac{3}{2}\lambda^{\frac{1}{2}}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}, \tag{41}$$

and

$$\|L_{K,D}f_\rho - L_{K,D}f_{D,\lambda}^{(\hat{k}-1,*)}\|_K \ge \frac{1}{2}\lambda^{\frac{1}{2}}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}, \qquad \text{if } \hat{k} \ge 2. \tag{42}$$

Proof. For $k \in \mathbb{N}$, we have

$$L_{K,D}f_\rho - L_{K,D}f_{D,\lambda}^{(k,*)} = S_D^T y_D - L_{K,D}f_{D,\lambda}^{(k)} + L_{K,D}f_{D,\lambda}^{(k)} - L_{K,D}f_{D,\lambda}^{(k,*)} + L_{K,D}f_\rho - S_D^T y_D.$$

But (27) and

$$f_{D,\lambda}^{(k,*)} = g_\lambda^{(k)}(L_{K,D})L_{K,D}f_\rho \tag{43}$$

yield

$$f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)} = g_\lambda^{(k)}(L_{K,D})(S_D^T y_D - L_{K,D}f_\rho). \tag{44}$$

It then follows from (32) that

$$L_{K,D}f_\rho - L_{K,D}f_{D,\lambda}^{(k,*)} \quad = \quad S_D^T y_D - L_{K,D}f_{D,\lambda}^{(k)} + [L_{K,D}g_\lambda^{(k)}(L_{K,D}) - I](S_D^T y_D - L_{K,D}f_\rho)$$
$$= \quad S_D^T y_D - L_{K,D}f_{D,\lambda}^{(k)} - \lambda^k(L_{K,D}+\lambda I)^{-k}(S_D^T y_D - L_{K,D}f_\rho). \tag{45}$$

Moreover, (17) implies

$$\begin{aligned}
&\|\lambda^k(L_{K,D}+\lambda I)^{-k}(S_D^T y_D - L_{K,D}f_\rho)\|_K \le \|\lambda^k(L_{K,D}+\lambda I)^{-k}(L_{K,D}+\lambda I)^{1/2}\| \\
\times\ &\|(L_{K,D}+\lambda I)^{-1/2}(L_K+\lambda I)^{1/2}\|\|(L_K+\lambda I)^{-1/2}(S_D^T y_D - L_{K,D}f_\rho)\|_K \\
\le\ &\lambda^{1/2}\mathcal{P}_{D,\lambda}\mathcal{Q}_{D,\lambda} \le \frac{1}{2}\lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \qquad (46)
\end{aligned}$$

with confidence $1-\delta$. Combining this with (16) and (45), we have that with confidence $1-\delta$, there holds

$$\|L_{K,D}f_\rho - L_{K,D}f_{D,\lambda}^{(\hat{k},*)}\|_K \le \frac{3}{2}\lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta},$$

which proves (41). To prove (42), the definition of $\hat{k}$ implies

$$\|S_D^T y_D - L_{K,D}f_{D,\lambda}^{(\hat{k}-1)}\|_K > \lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}, \qquad \text{if } \hat{k}\ge 2.$$

It follows from (45) with $k=\hat{k}-1$ when $\hat{k}\ge 2$ that

$$\|L_{K,D}f_\rho - L_{K,D}f_{D,\lambda}^{(\hat{k}-1,*)}\|_K \ge \lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} - \frac{1}{2}\lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} = \frac{1}{2}\lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}$$

holds with confidence at least $1-\delta$. This completes the proof of Lemma 19. ■

Based on the above important lemma, we derive the following bound for $\hat{k}$.

Proposition 20 *Let $\delta\in(0,1)$ and $\hat{k}$ be the smallest positive integer satisfying (16). We have with confidence $1-\delta$ that*

$$\begin{aligned}
\hat{k} \ &\le\ (4r+2) + 4\mathcal{W}_{D,\lambda}^{-1}\left(\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}\right)^2+1\right)\lambda^r\|h_\rho\|_\rho\log^{-2}\frac{16}{\delta} \\
&+\ (4r-2)\mathcal{W}_{D,\lambda}^{-1}\frac{4\kappa^{2r-1}}{\sqrt{|D|}}\lambda^{1/2}\|h_\rho\|_\rho\log^{-3}\frac{16}{\delta}, \qquad (47)
\end{aligned}$$

where

$$\mathcal{A}_{D,\lambda} := \frac{1}{\sqrt{|D|}}\left(\frac{1}{\sqrt{|D|\lambda}}+\sqrt{\mathcal{N}(\lambda)}\right). \qquad (48)$$

Proof. If $\hat{k}\le r+3/2$, (47) obviously holds. Now we prove (47) for $\hat{k}>r+3/2$. Due to Lemma 12, Lemma 19 and (43), we have with confidence at least $1-\delta$ that

$$\begin{aligned}
&\lambda^{\frac{1}{2}}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le 2\|L_{K,D}(f_\rho - f_{D,\lambda}^{(\hat{k}-1,*)})\|_K \\
=\ &2\left\|L_{K,D}\left(g_\lambda^{(\hat{k}-1)}(L_{K,D})L_{K,D}-I\right)f_\rho\right\|_K \le 2\|L_{K,D}\lambda^{\hat{k}-1}(L_{K,D}+\lambda I)^{-\hat{k}+1}L_K^{r-1/2}\|\|h_\rho\|_\rho,
\end{aligned}$$

where the last inequality is due to (32).

If $\frac{1}{2}\le r\le\frac{3}{2}$, we have from Lemma 13 and $\hat{k}-r-\frac{1}{2}>1$ that

$$\begin{aligned}
&\lambda^{\frac{1}{2}}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le 2\|L_{K,D}\lambda^{\hat{k}-1}(L_{K,D}+\lambda I)^{-\hat{k}+1}(L_{K,D}+\lambda I)^{r-1/2}\|\mathcal{Q}_{D,\lambda}^{2r-1}\|h_\rho\|_\rho \\
=\ &2\mathcal{Q}_{D,\lambda}^{2r-1}\|h_\rho\|_\rho\lambda^{r-1/2}\|L_{K,D}\lambda^{\hat{k}-1-r+1/2}(L_{K,D}+\lambda I)^{-\hat{k}+1+r-1/2}\| \\
\le\ &2\max(\mathcal{Q}_{D,\lambda}^2,1)\|h_\rho\|_\rho\lambda^{r+1/2}(\hat{k}-r-1/2)^{-1}.
\end{aligned}$$

Thus, it follows from Lemma 22 in Appendix A that with confidence at least $1-\delta$

$$\hat{k}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le (r+1/2)\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} + 4\log^2\frac{16}{\delta}\left(\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}\right)^2+1\right)\lambda^r\|h_\rho\|_\rho,$$

which implies (47).

If $r>3/2$, it follows from (38), Lemma 13 and $\hat{k}>r+3/2$ that

$$\begin{aligned}
&\lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le 2\|L_{K,D}\lambda^{\hat{k}-1}(L_{K,D}+\lambda I)^{-\hat{k}+1}L_{K,D}^{r-1/2}\|\|h_\rho\|_\rho \\
+\ &2\|L_{K,D}\lambda^{\hat{k}-1}(L_{K,D}+\lambda I)^{-\hat{k}+1}(L_K^{r-1/2}-L_{K,D}^{r-1/2})\|\|h_\rho\|_\rho \\
\le\ &2\|h_\rho\|_\rho\lambda^{r-1/2}\|L_{K,D}\lambda^{\hat{k}-1-r+1/2}(L_{K,D}+\lambda I)^{-\hat{k}+1+r-1/2}\| \\
+\ &(2r-1)\kappa^{2r-3}\|h_\rho\|_\rho\|L_{K,D}\lambda^{\hat{k}-1}(L_{K,D}+\lambda I)^{-\hat{k}+1}\|\|L_K-L_{K,D}\| \\
\le\ &2\|h_\rho\|_\rho\lambda^{r+1/2}(\hat{k}-r-1/2)^{-1} + (2r-1)\kappa^{2r-3}\|h_\rho\|_\rho\frac{\lambda}{\hat{k}-1}\mathcal{R}_D.
\end{aligned}$$

If

$$\lambda^{r+1/2}(\hat{k}-r-1/2)^{-1} \le (r-1/2)\kappa^{2r-3}\frac{\lambda}{\hat{k}-1}\mathcal{R}_D,$$

we have

$$\lambda^{\frac{1}{2}}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le (4r-2)\kappa^{2r-3}\frac{\lambda}{\hat{k}-1}\mathcal{R}_D\|h_\rho\|_\rho,$$

which together with Lemma 22 in Appendix A yields with confidence $1-\delta$

$$\hat{k}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le \mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} + (4r-2)\frac{4\kappa^{2r-1}}{\sqrt{|D|}}\lambda^{1/2}\|h_\rho\|_\rho\log\frac{16}{\delta}.$$

Thus, (47) holds. If

$$\lambda^{r+1/2}(\hat{k}-r-1/2)^{-1} > (r-1/2)\kappa^{2r-3}\frac{\lambda}{\hat{k}-1}\mathcal{R}_D,$$

we get

$$\lambda^{\frac{1}{2}}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le 4\lambda^{r+1/2}(\hat{k}-r-1/2)^{-1}\|h_\rho\|_\rho.$$

Hence,

$$\hat{k}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} \le (r+\frac{1}{2})\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta} + 4\lambda^r\|h_\rho\|_\rho,$$

which together with $\log\frac{16}{\delta}>1$ yields (47). The proof of Proposition 20 is completed. ■

5. Proofs of Main Results

Based on the previous bounds we can now prove our main results.

Proof of Theorem 3. If $1/2 \le r \le 3/2$, we get from (5) and (26) that

$$\begin{aligned}
&\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k,*)} - f_\rho)\|_K = \|L_{K,D}^{1/2}[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k L_K^r h_\rho\|_K \\
= \;& \|L_{K,D}^{1/2}[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k (L_{K,D}+\lambda I)^{r-1/2}(L_{K,D}+\lambda I)^{1/2-r}L_K^r h_\rho\|_K \\
\le \;& 2^{r-1/2}\|L_{K,D}^{r}[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k (L_{K,D}+\lambda I)^{1/2-r}L_K^r h_\rho\|_K \\
+ \;& 2^{r-1/2}\lambda^{r-1/2}\|L_{K,D}^{1/2}[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k (L_{K,D}+\lambda I)^{1/2-r}L_K^r h_\rho\|_K.
\end{aligned}$$

Here we have used the inequality

$$\|(L_{K,D}+\lambda I)^r f\|_K \le 2^{r-1/2}\big[\|L_{K,D}^r f\|_K + \lambda^r \|f\|_K\big], \quad \forall f \in \mathcal{H}_K$$

which follows by means of the normalized eigenpairs $\{(\sigma_i^{\mathbf{x}}, \phi_i^{\mathbf{x}})\}_i$ of $L_{K,D}: \mathcal{H}_K \to \mathcal{H}_K$ as

$$\begin{aligned}
\|(L_{K,D}+\lambda I)^r f\|_K^2 &= \sum_i \big(\sigma_i^{\mathbf{x}}+\lambda\big)^{2r} |\langle \phi_i^{\mathbf{x}}, f\rangle_K|^2 \\
&\le 2^{2r-1}\sum_i \big[(\sigma_i^{\mathbf{x}})^{2r}|\langle \phi_i^{\mathbf{x}}, f\rangle_K|^2 + \lambda^{2r}|\langle \phi_i^{\mathbf{x}}, f\rangle_K|^2\big].
\end{aligned}$$

Since $0 \le r - \frac{1}{2} \le 1$, (67) in Appendix B shows

$$\|(L_{K,D}+\lambda I)^{1/2-r}L_K^r h_\rho\|_K \le \mathcal{Q}_{D,\lambda}^{2r-1}\|h_\rho\|_\rho.$$

It then follows from (33) with $u = r$, $f = (L_{K,D}+\lambda I)^{1/2-r}L_K^r h_\rho$ and $u = 1/2$, $f = (L_{K,D}+\lambda I)^{1/2-r}L_K^r h_\rho$ that

$$\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k,*)} - f_\rho)\|_K \le 2\sqrt{2}\mathcal{Q}_{D,\lambda}^{2r-1}\|h_\rho\|_\rho \lambda^r \left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r}, \qquad \text{if } 1/2 \le r < 1,$$

$$\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k,*)} - f_\rho)\|_K \le 2\mathcal{Q}_{D,\lambda}^{2r-1}\lambda\|h_\rho\|_\rho(\kappa^{2r-2}+\lambda^{r-1}), \qquad \text{if } 1 \le r \le 3/2, k = 1,$$

and

$$\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k,*)} - f_\rho)\|_K \le 4\mathcal{Q}_{D,\lambda}^{2r-1}\lambda^r\|h_\rho\|_\rho \left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-r}, \qquad \text{if } 1 \le r \le 3/2, k \ge 2.$$

The above estimates together with (36) with $\nu = 1/2$ yield for $r \ge 1/2$,

$$\begin{aligned}
\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k,*)} - f_\rho)\|_K &\le \frac{(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho}{\sqrt{k}}\lambda^{1/2}\mathcal{R}_D \\
&+ 4(\mathcal{Q}_{D,\lambda}^2+1)\lambda^k\|h\|_\rho \begin{cases} (\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k > r, \\ \kappa^{2r-2k}+\lambda^{r-k}, & \text{if } k \le r. \end{cases}
\end{aligned}$$

Furthermore, (39) with $\nu = 1/2$ implies

$$\Big\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)})\Big\|_K \le \mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}\left(1 + \sum_{j=1}^{k-1}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-1/2}\right).$$

Hence

$$\begin{aligned}
&\Big\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k)} - f_\rho)\Big\|_K \le \|L_{K,D}^{1/2}(f_{D,\lambda}^{(k,*)} - f_\rho)\|_K + \Big\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)})\Big\|_K \\
\le \;& \mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}\sum_{j=1}^{k-1}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-1/2} + \frac{(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho}{\sqrt{k}}\lambda^{1/2}\mathcal{R}_D + \mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda} \\
+ \;& 4(\mathcal{Q}_{D,\lambda}^2+1)\lambda^k\|h\|_\rho \begin{cases} (\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k > r, \\ \kappa^{2r-2k}+\lambda^{r-k}, & \text{if } k \le r. \end{cases}
\end{aligned}$$

This completes the proof of Theorem 3. ∎

Proof of Theorem 4. Since $r > 3/2$, we get from Proposition 16 that

$$\begin{aligned}
\|f_{D,\lambda}^{(k,*)} - f_\rho\|_\rho &\le 2\mathcal{Q}_{D,\lambda}(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\lambda^{1/2}\mathcal{R}_D \\
+ \;& \mathcal{Q}_{D,\lambda}\lambda^k\|h_\rho\|_\rho \begin{cases} \lambda^{r-k}+\kappa^{2r-2k-1}(\kappa+\lambda^{\frac{1}{2}}), & \text{if } k \le r, \\ 2(\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k > r. \end{cases}
\end{aligned}$$

Furthermore, it follows from Proposition 18 that

$$\|f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}\|_\rho \le 2k\mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda}.$$

Then

$$\begin{aligned}
&\|f_{D,\lambda}^{(k)} - f_\rho\|_\rho \le \|f_{D,\lambda}^{(k,*)} - f_\rho\|_\rho + \|f_{D,\lambda}^{(k)} - f_{D,\lambda}^{(k,*)}\|_\rho \\
\le \;& 2\mathcal{Q}_{D,\lambda}(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\lambda^{1/2}\mathcal{R}_D \\
+ \;& 2k\mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda} + \mathcal{Q}_{D,\lambda}\lambda^k\|h_\rho\|_\rho \begin{cases} \lambda^{r-k}+\kappa^{2r-2k-1}(\kappa+\lambda^{\frac{1}{2}}), & \text{if } k \le r, \\ 2(\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k > r. \end{cases}
\end{aligned}$$

This completes the proof of Theorem 4. ∎

Proof of Theorem 1. We get from Lemma 22 in Appendix A, (48), $r > 3/2$, (6) and $\lambda = \left(\frac{k^2}{|D|}\right)^{\frac{1}{2\min\{k,r\}+s}}$ with $k \le \sqrt{|D|}$ that with confidence $1-\delta$,

$$\mathcal{R}_D \le \frac{4\kappa^2}{\sqrt{|D|}}\log\frac{8}{\delta} \le \frac{4\kappa^2}{\sqrt{|D|\lambda^s}}\log\frac{8}{\delta},$$

$$\mathcal{Q}_{D,\lambda}^2 \le 2\left(2(\kappa^2+\kappa)\left(\frac{1}{|D|\lambda}+\sqrt{\frac{\mathcal{N}(\lambda)}{|D|\lambda}}\right)\log\frac{8}{\delta}\right)^2 + 2 \le 8(\kappa^2+\kappa+1)^2(1+\sqrt{C_0})^2\log^2\frac{8}{\delta},$$

and

$$\begin{aligned}
&\mathcal{P}_{D,\lambda}\mathcal{Q}_{D\lambda} \le \frac{4\sqrt{2}(\kappa^2+\kappa+1)(\kappa M+\gamma)}{\sqrt{|D|}}\left(\frac{1}{\lambda|D|}+\frac{\sqrt{\mathcal{N}(\lambda)}}{\sqrt{|D|\lambda}}+1\right)\left(\frac{1}{\sqrt{\lambda|D|}}+\sqrt{\mathcal{N}(\lambda)}\right)\log^2\frac{8}{\delta} \\
\le \;& \frac{4\sqrt{2}(\kappa^2+\kappa+1)(\kappa M+\gamma)(2+\sqrt{C_0})(1+\sqrt{C_0})}{\sqrt{|D|\lambda^s}}\log^2\frac{8}{\delta}.
\end{aligned}$$

Here we have used $\frac{1}{\sqrt{\lambda|D|}} + \sqrt{\mathcal{N}(\lambda)} \le \frac{\sqrt{C_0}+1}{\sqrt{\lambda^s}}$. Applying these three estimates to Theorem 4, we get

$$\begin{aligned}
&\|f_{D,\lambda}^{(k)} - f_\rho\|_\rho \le 4\sqrt{2}(\kappa^2+\kappa+1)(1+\sqrt{C_0})(r-1/2)\kappa^{2r-3}\|h_\rho\|_\rho\lambda^{1/2}\frac{4\kappa^2}{\sqrt{|D|\lambda^s}}\log^2\frac{8}{\delta}\\
+\;& 32(2+\sqrt{C_0})^3(\kappa^2+\kappa+1)^2(\kappa M+\gamma)\frac{k}{\sqrt{|D|\lambda^s}}\log^3\frac{8}{\delta}\\
+\;& 2\sqrt{2}(1+\sqrt{C_0})(\kappa^2+\kappa+1)\log\frac{8}{\delta}\lambda^k\|h_\rho\|_\rho\begin{cases}\lambda^{r-k}+\kappa^{2r-2k-1}(\kappa+\lambda^{\frac{1}{2}}), & \text{if } k\le r,\\ 2(\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k>r.\end{cases}\\
\le\;& \frac{\tilde{C}k}{2\sqrt{|D|\lambda^s}}\log^3\frac{8}{\delta}+\frac{\tilde{C}\log\frac{8}{\delta}}{2}\lambda^k\begin{cases}1, & \text{if } k\le r,\\ (\sigma_{min}^{\mathbf{x}}+\lambda)^{r-k}, & \text{if } k>r,\end{cases}
\end{aligned}$$

where $\tilde{C}$ is a constant independent of $|D|, k$ or δ given by

$$\begin{aligned}\tilde{C} = 2(\kappa^2+\kappa+1)\max\{&16\sqrt{2}(1+\sqrt{C_0})(r-1/2)\kappa^{2r-1}\|h_\rho\|_\rho+32(2+\sqrt{C_0})^3(\kappa^2+\kappa+1)(\kappa M+\gamma),\\ &2\sqrt{2}(1+\sqrt{C_0})\|h_\rho\|_\rho(2+\kappa^{2r-2k}+\kappa^{2r-2k-1})\}.\end{aligned}$$

Plugging $\lambda = (k^2/|D|)^{\frac{1}{2\min\{k,r\}+s}}$ into the above estimate and noting $\sigma_{min}^{\mathbf{x}} > 0$, we get that

$$\left\|f_{D,\lambda}^{(k)} - f_\rho\right\|_\rho \le \tilde{C}(k^2/|D|)^{\frac{\min\{k,r\}}{2\min\{k,r\}+s}}\log^3\frac{8}{\delta},$$

holds with confidence $1-\delta$. This completes the proof of Theorem 1. ∎

Proof of Corollary 5. It follows from (25) that

$$\begin{aligned}
&\|L_{K,D}f_{D,\lambda}^{(k+1)} - S_D^T y_D\|_K = \left\|[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^{k+1}S_D^T y_D\right\|_K\\
\le\;& \|I-(L_{K,D}+\lambda I)^{-1}L_{K,D}\|\|[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k S_D^T y_D\|_K\\
\le\;& \|L_{K,D}f_{D,\lambda}^{(k)} - S_D^T y_D\|_K.
\end{aligned}$$

Thus $\|L_{K,D}f_{D,\lambda}^{(k)} - S_D^T y_D\|_K$ decreases with respect to k. Furthermore, we have from (25) again and Lemma 14 that for $k>1$

$$\begin{aligned}
&\|L_{K,D}f_{D,\lambda}^{(k)} - S_D^T y_D\|_K \le \|[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k(S_D^T y_D - L_{K,D}f_\rho)\|_K\\
+\;& \|[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k L_{K,D}f_\rho\|_K\\
\le\;& \|[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k(L_{K,D}+\lambda I)^{1/2}\|\|(L_{K,D}+\lambda I)^{-1/2}(S_D^T y_D - L_{K,D}f_\rho)\|_K\\
+\;& \|[I-(L_{K,D}+\lambda I)^{-1}L_{K,D}]^k L_{K,D}f_\rho\|_K\\
\le\;& \lambda^{1/2}\|(L_{K,D}+\lambda I)^{-1/2}(L_{K,D}f_\rho - S_D^T y_D)\|_K + \lambda\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{k-1}\|f_\rho\|_K.
\end{aligned}$$

Thus,

$$\begin{aligned}
\lim_{k\to\infty}\|L_{K,D}f_{D,\lambda}^{(k)} - S_D^T y_D\|_K &\le \lambda^{1/2}\|(L_{K,D}+\lambda I)^{-1/2}(L_{K,D}f_\rho - S_D^T y_D)\|_K\\
&\le \lambda^{1/2}\mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}.
\end{aligned}$$

This verifies (12). To prove (13), it follows from Theorem 3 that

$$\begin{aligned}
&\lim_{k\to\infty}\left\|L_{K,D}^{1/2}(f_{D,\lambda}^{(k)} - f_\rho)\right\|_K \le \mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda} + \mathcal{Q}_{D,\lambda}\mathcal{P}_{D,\lambda}\lim_{k\to\infty}\sum_{j=1}^{k-1}\left(\frac{\lambda}{\sigma_{min}^{\mathbf{x}}+\lambda}\right)^{j-1/2}\\
=\;& \left(1+\frac{(\sigma_{min}^{\mathbf{x}}+\lambda)^{1/2}\lambda^{1/2}}{\sigma_{min}^{\mathbf{x}}}\right)\mathcal{P}_{D,\lambda}\mathcal{Q}_{D,\lambda}.
\end{aligned}$$

This completes the proof of Corollary 5. ∎

Proof of Theorem 6. Since

$$\|f_{D,\lambda}^{(\hat{k})} - f_\rho\|_\rho \le \|f_{D,\lambda}^{(\hat{k},*)} - f_\rho\|_\rho + \|f_{D,\lambda}^{(\hat{k})} - f_{D,\lambda}^{(\hat{k},*)}\|_\rho =: A(D,\lambda,\hat{k}) + S(D,\lambda,\hat{k}). \tag{49}$$

We divide the proof into four steps.

Step 1: Bounding $A(D,\lambda,\hat{k})$. Define

$$\widetilde{\mathcal{Q}}_{D,\lambda} = \|(L_{K,D}+\lambda I)^{-1}(L_K+\lambda I)\|. \tag{50}$$

We obtain from $\|L_K^{1/2}(L_K+\lambda I)^{-1/2}\| \le 1$ and $\|(L_K+\lambda I)^{-\frac{1}{2}}\| \le \lambda^{-\frac{1}{2}}$ that

$$\begin{aligned}
A(D,\lambda,\hat{k}) &= \|L_K^{1/2}(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)\|_K \le \lambda^{-1/2}\|(L_K+\lambda I)(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)\|_K\\
&\le \lambda^{-1/2}\widetilde{\mathcal{Q}}_{D,\lambda}\|(L_{K,D}+\lambda I)(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)\|_K\\
&\le \lambda^{-1/2}\widetilde{\mathcal{Q}}_{D,\lambda}\|L_{K,D}(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)\|_K + \lambda^{1/2}\widetilde{\mathcal{Q}}_{D,\lambda}\|f_{D,\lambda}^{(\hat{k},*)} - f_\rho\|_K.
\end{aligned} \tag{51}$$

By Lemma 19, with confidence at least $1-\delta$, there holds

$$\|L_{K,D}(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)\|_K \le \frac{3}{2}\lambda^{1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}. \tag{52}$$

Let F_λ be the orthogonal projection onto the subspace of $\mathcal{H}_K$ spanned by the eigenvectors of $L_{K,D}$ associated with eigenvalues less than λ and $F_\lambda^\perp = I - F_\lambda$. We have

$$\|f_{D,\lambda}^{(\hat{k},*)} - f_\rho\|_K \le \lambda^{-1}\|F_\lambda[\lambda(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)]\|_K + \lambda^{-1}\|F_\lambda^\perp[\lambda(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)]\|_K =: A_1 + A_2. \tag{53}$$

By the definition of $F_\lambda^\perp$ and Lemma 19, it follows with confidence $1-\delta$,

$$A_2 \le \lambda^{-1}\|F_\lambda^\perp[L_{K,D}(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)]\|_K \le \lambda^{-1}\|L_{K,D}(f_{D,\lambda}^{(\hat{k},*)} - f_\rho)\|_K \le \frac{3}{2}\lambda^{-1/2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}. \tag{54}$$

Due to (43) and (5), we have

$$A_1 \le \|F_\lambda[g_\lambda^{(\hat{k})}(L_{K,D})L_{K,D}f_\rho - f_\rho)]\|_K \le \|F_\lambda[\lambda^{\hat{k}}(L_{K,D}+\lambda I)^{-\hat{k}}L_K^{r-1/2}]\|\|h_\rho\|_\rho.$$

If $\frac{1}{2} \le r \le \frac{3}{2}$, we have

$$A_1 \le \|F_\lambda[\lambda^{\hat{k}}(L_{K,D}+\lambda I)^{-\hat{k}}(L_{K,D}+\lambda I)^{r-1/2}]\|(\widetilde{\mathcal{Q}}_{D,\lambda})^{r-1/2}\|h_\rho\|_\rho \le (\widetilde{\mathcal{Q}}_{D,\lambda})^{r-1/2}\|h_\rho\|_\rho\lambda^{r-1/2}. \tag{55}$$

If $r > 3/2$, (38) implies

$$\begin{aligned} A_1 &\leq \|F_\lambda[\lambda^{\hat{k}}(L_{K,D}+\lambda I)^{-\hat{k}}(L_K^{r-1/2}-L_{K,D}^{r-1/2})]\|\|h_\rho\|_\rho + \|F_\lambda[\lambda^{\hat{k}}(L_{K,D}+\lambda I)^{-\hat{k}}L_{K,D}^{r-1/2}]\|\|h_\rho\|_\rho \\ &\leq \|h_\rho\|_\rho\left((r-1/2)\kappa^{2r-3}\mathcal{R}_D+\lambda^{r-1/2}\right). \end{aligned} \tag{56}$$

Inserting (56), (55) and (54) into (53) and then plugging (53) and (52) into (51), we have from Lemma 22 in Appendix A that with confidence $1-\delta$,

$$\begin{aligned} A(D,\lambda,\hat{k}) &\leq 3\log^6\frac{16}{\delta}\left[\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]\mathcal{W}_{D,\lambda} \\ &+ 4\lambda^{\frac{1}{2}}\|h_\rho\|_\rho\log^4\frac{16}{\delta}\left[\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2\left(\lambda^{r-\frac{1}{2}}+\frac{(4r-2)\kappa^{2r-1}}{\sqrt{|D|}}\right). \end{aligned} \tag{57}$$

Step 2: Bounding $S(D,\lambda,\hat{k})$. It follows from (30), (44) and the definitions of $\mathcal{Q}_{D,\lambda}$ and $\mathcal{P}_{D,\lambda}$ that

$$\begin{aligned} S(D,\lambda,\hat{k}) &= \|L_K^{1/2}[f_{D,\lambda}^{(\hat{k})}-f_{D,\lambda}^{(\hat{k},*)}]\|_K \\ &\leq \|(L_K+\lambda I)^{1/2}g_\lambda^{(\hat{k})}(L_{K,D})(L_{K,D}+\lambda I)^{1/2}(L_{K,D}+\lambda I)^{-1/2}(L_{K,D}f_\rho-S_D^Ty_D)\|_K \\ &\leq \mathcal{Q}_{D,\lambda}^2\|g_\lambda^{(\hat{k})}(L_{K,D})(L_{K,D}+\lambda I)\|\mathcal{P}_{D,\lambda} \\ &\leq \mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda}\left[\|g_\lambda^{(\hat{k})}(L_{K,D})L_{K,D}\|+\lambda\|g_\lambda^{(\hat{k})}(L_{K,D})\|\right] \\ &\leq (\hat{k}+1)\mathcal{Q}_{D,\lambda}^2\mathcal{P}_{D,\lambda}. \end{aligned}$$

This together with (17) and Lemma 22 in Appendix A implies with confidence $1-\delta$

$$S(D,\lambda,\hat{k}) \leq \frac{\hat{k}+1}{2}\mathcal{W}_{D,\lambda}\log^5\frac{16}{\delta}\left[\sqrt{2}\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}\right)+\sqrt{2}\right].$$

Combining the above inequality with (47) yields

$$\begin{aligned} S(D,\lambda,\hat{k}) &\leq \left[\sqrt{2}\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}\right)+\sqrt{2}\right]\log\frac{16}{\delta}\left\{(2r+1)\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}\right. \\ &+ 2\left[\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]\lambda^r\|h_\rho\|_\rho\log^2\frac{16}{\delta} \\ &+ \left.(2r-1)\frac{4\kappa^{2r-1}}{\sqrt{|D|}}\lambda^{1/2}\|h_\rho\|_\rho\log\frac{16}{\delta}\right\}. \end{aligned} \tag{58}$$

Step 3: Bounding $\mathcal{A}_{D,\lambda}$ and $\mathcal{W}_{D,\lambda}$. Since $r \geq 1/2$, and $\lambda = (c/|D|)^{1/(2r+s)}$ with $c \geq 1$, it follows from (6), (48) and $r \geq \frac{1}{2}$ that

$$\mathcal{A}_{D,\lambda} = \frac{1}{\sqrt{|D|}}\left\{\frac{1}{\sqrt{|D|\lambda}}+\sqrt{\mathcal{N}(\lambda)}\right\} \leq (1+\sqrt{C_0})c^{-s/(4r+2s)}|D|^{-r/(2r+s)}. \tag{59}$$

This implies

$$\mathcal{A}_{D,\lambda}^2/\lambda \leq (1+\sqrt{C_0})^2c^{(-s-1)/(2r+s)}|D|^{\frac{1-2r}{2r+s}}$$

and

$$\frac{\mathcal{A}_{D,\lambda}}{\sqrt{\lambda}}+1 \leq \tilde{C}_1 \tag{60}$$

with $\tilde{C}_1 := (1+\sqrt{C_0})c^{\frac{-s-1}{4r+2s}}+1$. Now we turn to bound $\mathcal{W}_{D,\lambda}$. If $\eta_{\delta/4} := 2\log(16/\delta)/\sqrt{|D|\lambda} \leq 1$, we have from Lemma 22 in Appendix A that

$$\sqrt{\max\{\mathcal{N}_D(\lambda),1\}} \leq 5\sqrt{\max\{\mathcal{N}(\lambda),1\}}.$$

Then, it follows from (6) and $\lambda = (c/|D|)^{1/(2r+s)}$ that

$$(\sqrt{|D|\lambda}+9)\sqrt{\max\{\mathcal{N}_D(\lambda),1\}} \leq 5\max\{c^{1/(4r+2s)},9\}\max\{C_0^{1/2}c^{-s/(4r+2s)},1\}|D|^{\frac{2r+2s-1}{4r+2s}}.$$

Thus, it follows from (15) that

$$\mathcal{W}_{D,\lambda} \leq \tilde{C}_2'|D|^{-\frac{r}{2r+s}}, \tag{61}$$

where

$$\tilde{C}_2' := 16\sqrt{2}(\kappa^2+\kappa+1)(\kappa M+\gamma)\left(5(c^{-1/(2r+s)}+1)(c^{1/(4r+2s)}+9)(C_0^{1/2}c^{-s/(4r+2s)}+1)+1\right)^2.$$

If $\eta_{\delta/4} > 1$, we get from Lemma 22 in Appendix A again and $\lambda = (c/|D|)^{1/(2r+s)}$ that with confidence $1-\delta$

$$\sqrt{\max\{\mathcal{N}_D(\lambda),1\}} \leq (1+16c^{-1/(2r+s)})\sqrt{\max\{\mathcal{N}(\lambda),1\}}\log^2\frac{16}{\delta}.$$

The same argument as above shows that with confidence $1-\delta$,

$$\mathcal{W}_{D,\lambda} \leq \tilde{C}_2''|D|^{-\frac{r}{2r+s}}\log^4\frac{16}{\delta}, \tag{62}$$

where

$$\begin{aligned} \tilde{C}_2'' &:= 16\sqrt{2}(\kappa^2+\kappa+1)(\kappa M+\gamma) \\ &\times \left((1+16c^{-1/(2r+s)})(c^{-1/(2r+s)}+1)(c^{1/(4r+2s)}+9)(C_0^{1/2}c^{-s/(4r+2s)}+1)+1\right)^2. \end{aligned}$$

Combining (61) with (62), we obtain with confidence $1-\delta$

$$\mathcal{W}_{D,\lambda} \leq \tilde{C}_2|D|^{-\frac{r}{2r+s}}\log^4\frac{16}{\delta} \tag{63}$$

with $\tilde{C}_2 := \max\{\tilde{C}_2', \tilde{C}_2''\}$.

Step 4: Deriving the learning rate. Plugging (63) and (60) into (57) and (58), we have with confidence $1-\delta$ that

$$A(D,\lambda,\hat{k}) \leq \tilde{C}_3|D|^{-\frac{r}{2r+s}}\log^{10}\frac{16}{\delta} \tag{64}$$

with $\tilde{C}_3 = 3(4(\kappa^2+\kappa)^2\tilde{C}_1^2+1)\tilde{C}_2 + 4(4(\kappa^2+\kappa)^2\tilde{C}_1^2+1)^2\|h_\rho\|\big(c^{\frac{r}{2r+s}} + (4r-2)\kappa^{2r-1}c^{\frac{1}{4r+2s}}\big)$ and

$$S(D,\lambda,\hat{k}) \le \tilde{C}_4|D|^{-\frac{r}{2r+s}}\log^9\frac{16}{\delta} \tag{65}$$

with $\tilde{C}_4 = \sqrt{2}(2(\kappa^2+\kappa)\tilde{C}_1+1)\big[(2r+1)\tilde{C}_2 + 2(2(\kappa^2+\kappa)^2\tilde{C}_1^2+1)c^{\frac{r}{2r+s}}\|h_\rho\|_\rho + (8r-4)\kappa^{2r-1}\|h_\rho\|_\rho c^{\frac{1}{4r+2s}}\big]$. Putting (64) and (65) into (49), we have

$$\|f_{D,\lambda}^{(\hat{k})} - f_\rho\|_\rho \le (\tilde{C}_3+\tilde{C}_4)|D|^{-\frac{r}{2r+s}}\log^{10}\frac{16}{\delta}.$$

This completes the proof of Theorem 6 with the constant $C := \tilde{C}_3 + \tilde{C}_4$. ■

6. Empirical Studies

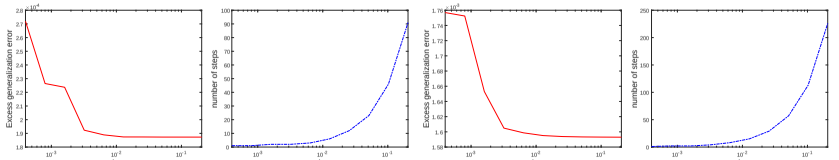
In this section, we report experimental results to study the behavior of BKRR and the adaptive stopping rule (16) in practice. We consider two regression problems. For the j-th regression problem ($j = 1, 2$), we assume that training examples are independently drawn from the regression model $y_i = g_j(x_i) + \xi_i, i = 1, \ldots, |D|$, where $\{x_i\}_{i=1}^{|D|}$ are drawn from the uniform distribution on the (hyper)-cube $[0,1]^{d_j}$ (d_j is the input dimension) and $\{\xi_i\}_{i=1}^{|D|}$ are noise components independently drawn from the Gaussian distribution $\mathcal{N}(0, 1/5)$. For the j-th problem, we build the estimator by applying BKRR in the RKHS induced by a Mercer kernel K_j. We consider the following two regression functions

$$g_1(x) = \min(x, 1-x), \quad x \in [0,1],$$

$$g_2(x) = (1-\|x\|_2)_+^6(35\|x\|_2^2 + 18\|x\|_2 + 3), \quad x \in [0,1]^3.$$

The two Mercer kernels are $K_1 : \mathbb{R}\times\mathbb{R} \mapsto \mathbb{R}, K_2 : \mathbb{R}^3\times\mathbb{R}^3 \mapsto \mathbb{R}$ defined by

$$K_1(x,\tilde{x}) = 1 + \min(x,\tilde{x}) \quad \text{and} \quad K_2(x,\tilde{x}) = g_3(x-\tilde{x}),$$



where $g_3(x) = (1-\|x\|_2)_+^4(4\|x\|_2+1), x \in [0,1]^3$. It can be found in Chang et al. (2017) that $g_1 \in \mathcal{H}_{K_1}$ with exponent $r = 1/2$ in (5) and $g_2 \in \mathcal{H}_{K_2}$ with exponent $r > 1/2$. We repeat each experiment 40 times and report the average of these experimental results.

Our numerical results are divided into three parts. In the first part, we study the relation between the generalization ability of BKRR and the regularization parameter to verify our motivation to combine KRR with boosting. In the second part, we validate the empirical behavior of BKRR and its comparison with iterated Tikhonov regularization (ITR). In the last part we show the effectiveness of adaptive stopping rule (16) in practical regression problems.

6.1. Regularization Parameters in BKRR

A common consensus in boosting theory (Friedman, 2001) is that the weak learners should be under-fitting and the boosting iteration will reduce the bias and increase the variance accordingly. For estimators with high-level under-fitting, more boosting iterations are imposed and lead to a similar learning performance as other efficient algorithms. If KRR is used to build up a weak learner, this argument then shows that we should select a relatively large λ, larger than some value, so that BKRR with a suitable number of iterations can reach a similar learning performance as KRR. Our first simulation is to verify this argument and show a relation between the generalization ability and regularization parameters in BKRR.

In this simulation, We traverse the regularization parameter λ over the set $0.0002 \times \{1, 2, 2^2, \ldots, 2^{10}\}$. For each regularization parameter, we run BKRR until k reaches 150 for $f_\rho = g_1$ and 300 for $f_\rho = g_2$, respectively. For each considered k and λ, we estimate the excess generalization error (EGE) $\mathcal{E}(f_{D,\lambda}^{(k)}) - \mathcal{E}(f_\rho)$ by $\frac{1}{2000}\sum_{i=1}^{2000}[f_{D,\lambda}^{(k)}(x_i') - f_\rho(x_i')]^2$, where $\{x_i'\}_{i=1}^{2000}$ are independently drawn from the uniform distribution on the corresponding input space. For each λ, we record the optimal k (selected to be optimal to the test data directly) and the corresponding EGE. Figure 1 reports EGEs and iteration numbers versus regularization parameters. It is shown in Figure 1 that if λ is larger than some value (near 10^{-2} in this simulation), then BKRR with different λ possesses similar learning performances provided the number of iterations is appropriately selected. Figure 1 also shows that the more high-level of under-fitting, the more boosting iterations required, which verifies the previous common consensus. All these results show that using KRR to build up a weak learner for boosting is reasonable and the selection of λ does not affect the generalization ability very much.

(a) $f_\rho = g_1$. (b) $f_\rho = g_2$.

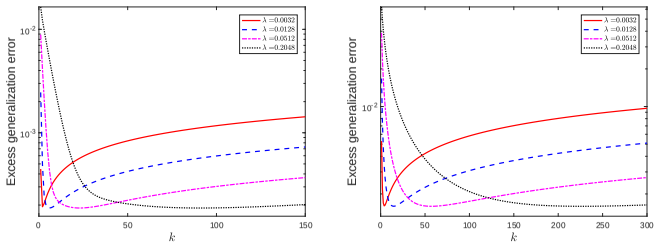


Figure 1: Excess generalization errors of BKRR versus regularization parameters. We also plot the iteration number at which the optimal EGEs are achieved.

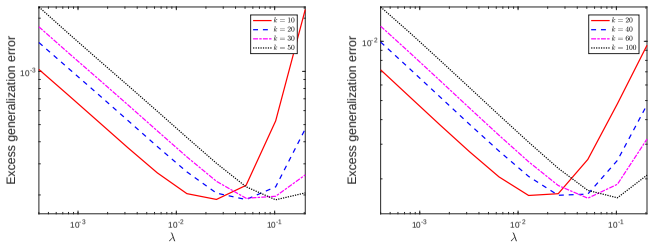
6.2. Behavior of BKRR

In this subsection, we want to validate the empirical behavior of BKRR and its comparison with ITR. It should be mentioned that BKRR focuses on fixed regularization parameters and varying iteration numbers, while ITR focuses on fixed iteration numbers and varying regularization parameters. The aim of this simulation is to verify an advantage of BKRR over ITR in the parameter selection, showing that selecting an appropriate number of iterations in BKRR is easier than selecting an appropriate regularization parameter in ITR.



We first study how BKRR would behave along the iterations. In the first experiment, we aim to study how EGEs would change as a function of iteration numbers. We fix regularization parameters $\lambda \in \{0.0032, 0.0128, 0.0512, 0.2048\}$, and show in Figure 2 EGEs versus the iteration number for two regression problems. From Figure 2 we see that EGEs

would typically decrease first as k increases from 1 to some number, after which it increases slowly as a function of k. To be detailed, the increasing curve behaves as a concave function with respect to k, which validates our arguments in Theorem 3 and Theorem 4 that the variance increases with exponentially diminishing terms as k increases. Furthermore, for some large λ ($\lambda = 0.2048$ for example), BKRR shows a rather stable relationship between the generalization performance and iteration numbers. This is consistent with our theoretical findings in Theorem 3 and Theorem 4. We can also see clearly that the iteration number k at which EGEs achieve the minimal value would increase as λ increases.

(a) $f_\rho = g_1$. (b) $f_\rho = g_2$.

Figure 2: Excess generalization errors versus the number of iterations for different regularization parameters. We consider four λ and two regression problems with the regression function being g_1 and g_2 in panel (a) and panel (b), respectively.

(a) $f_\rho = g_1$. (b) $f_\rho = g_2$.

Figure 3: Excess generalization errors versus regularization parameters for different number of iterations. We consider four k and two regression problems with the regression function being g_1 and g_2 in panel (a) and panel (b), respectively.

We then illustrate the behavior of ITR with fixed k versus regularization parameters. We fix the iteration numbers to some predefined values, and report EGEs of $f_{D,\lambda}^{(k)}$ as a function of regularization parameters in Figure 3. According to Figure 3, we see that EGEs first decrease and then increase as a function of λ. As compared to the stable relationship between EGEs and the number of iterations for BKRR, EGEs change more rapidly with the regularization parameters for ITR. This gives empirical evidence that the selection of iteration number in BKRR is more tractable than the selection of regularization parameters in ITR. It is also clear that the optimal regularization parameter becomes larger as k increases, which is consistent with Theorem 1.

In Table 1, we record the optimal EGEs achieved by BKRR over all iterates for different regularization parameters. We list in the first row the considered regularization parameters. In the second and third rows, we report the optimal EGEs achieved by BKRR with the fixed regularization parameters on two regression problems. In Table 2, we record the optimal EGEs achieved by ITR over all regularization parameters for different iteration numbers. We list in the first and third rows the considered number of iterations. In the second and fourth rows, we report the optimal EGEs achieved by ITR with fixed iteration number on two regression problems. It can be found that BKRR can achieve similar accuracies to ITR with a much easier parameter-selection strategy.

λ	0.0004	0.0008	0.0016	0.0032	0.0064	0.0128	0.0256	0.0512	0.1024	0.2048
g_1	2.72e–4	2.26e–4	2.24e–4	1.92e–4	1.89e–4	1.87e–4	1.87e–4	1.87e–4	1.87e–4	1.87e–4
g_2	1.76e–3	1.75e–3	1.65e–3	1.60e–3	1.60e–3	1.60e–3	1.59e–3	1.59e–3	1.59e–3	1.59e–3

Table 2: Excess generalization errors of ITR with different iteration numbers.

6.3. BKRR with Early Stopping

In this subsection, we aim to validate the effectiveness of adaptive stopping rule (19) in practical regression problems for some $\theta \in \mathbb{R}_+$. It should be noted that (19) is independent of the confidence level and also different from (16) in the constant term. As discussed in Remark 7, such a modification is reasonable due to the (semi) exponential bias-variance trade-off of BKRR. We apply BKRR to regression problems with different sample sizes ($|D| \in \{800, 1200, 1600, 2000, 2400, 2800, 3200, 3600, 4000\}$) and different regularization parameters ($\lambda \in \{0.016, 0.032, 0.064, 0.128\}$). For each sample size and regularization parameter, we run BKRR with several iterations to get a sequence of candidate models. We record the iteration number $\hat{k}_{\text{ASR}}$ selected by the adaptive stopping rule (ASR) (19) with $\theta = 0.05$, the iteration number $\hat{k}_{\text{CV}}$ selected by the five-fold cross validation (CV) and the iteration number $\hat{k}_{\text{Oracle}}$ with the minimal generalization error over all candidate models.

(a) $\lambda = 0.016$ (b) $\lambda = 0.032$ (c) $\lambda = 0.064$ (d) $\lambda = 0.128$

Figure 4: Excess generalization errors of the model selected by ASR (red color), the model selected by CV (black color) and the best candidate model (blue color) versus the number of training examples. We consider the regression problem $y = g_1(x) + \epsilon$ and four regularization parameters: $\lambda = 0.016$, $\lambda = 0.032$, $\lambda = 0.064$ and $\lambda = 0.128$.

In Figure 4, we fix different regularization parameters and plot the EGEs of $f_{D,\lambda}^{\hat{k}_{\rm ASR}}$, $f_{D,\lambda}^{\hat{k}_{\rm CV}}$ and $f_{D,\lambda}^{\hat{k}_{\rm Oracle}}$ versus the number of training examples for the regression problem with the regression function g_1. According to Figure 4, it is clear that ASR (19) works well in selecting a good model with EGEs comparable to the best candidate model. Furthermore, ASR also behaves slightly better than the CV widely used in practical learning problems. It should be mentioned that the five-fold CV requires the training of an additional five models based on different assignments of validation sets, which can be time-consuming. This repeated training is not required in ASR and therefore ASR requires significantly less computational costs than CV.

Appendix A. Auxiliary Lemmas

In this appendix, we present some useful lemmas. The first one (Mücke, 2018, Corollary 2.2) (see also Lu et al. (2018)) describes the difference between the effective dimension and its empirical counterpart.

Lemma 21 *For any $0 < \delta < 1$, with confidence $1 - \delta$, there holds*

$$(1 + 4\eta_\delta)^{-1}\sqrt{\max\{\mathcal{N}(\lambda), 1\}} \le \sqrt{\max\{\mathcal{N}_D(\lambda), 1\}} \le (1 + 4\max\{\sqrt{\eta_\delta}, \eta_\delta^2\})\sqrt{\max\{\mathcal{N}(\lambda), 1\}},$$

where $\eta_\delta := 2\log(4/\delta)/\sqrt{|D|\lambda}$.

Based on Lemma 21, we can get the following lemma.

Lemma 22 *Let D be a sample drawn independently according to ρ and $0 < \delta < 1$. With confidence at least $1 - \delta$,*

$$\begin{aligned}
\mathcal{Q}_{D,\lambda}^2 &\le \widetilde{\mathcal{Q}}_{D,\lambda} \le 2\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}\log\frac{8}{\delta}}{\sqrt{\lambda}}\right)^2 + 2,\\
\mathcal{R}_D &\le \frac{4\kappa^2}{\sqrt{|D|}}\log\frac{8}{\delta},\\
\mathcal{P}_{D,\lambda} &\le 2(\kappa M + \gamma)\mathcal{A}_{D,\lambda}\log\big(8/\delta\big),\\
(1 + 4\eta_{\delta/4})^{-1}\sqrt{\max\{\mathcal{N}(\lambda), 1\}} &\le \sqrt{\max\{\mathcal{N}_D(\lambda), 1\}} \le (1 + 4\sqrt{\eta_{\delta/4}} \vee \eta_{\delta/4}^2)\sqrt{\max\{\mathcal{N}(\lambda), 1\}}
\end{aligned}$$

hold simultaneously.

Proof. From Guo et al. (2017, Proposition 1) and (67) in Appendix B below, there exists a subset $\mathcal{Z}_{\delta,1}^{|D|}$ of $\mathcal{Z}^{|D|}$ with measure at least $1 - \delta$ such that for all $D \in \mathcal{Z}_{\delta,1}^{|D|}$

$$\mathcal{Q}_{D,\lambda}^2 \le \widetilde{\mathcal{Q}}_{D,\lambda} \le 2\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}\log\frac{2}{\delta}}{\sqrt{\lambda}}\right)^2 + 2.$$

From Yao et al. (2007, Proposition 5.3), there exists a subset $\mathcal{Z}_{\delta,2}^{|D|}$ of $\mathcal{Z}^{|D|}$ with measure at least $1 - \delta$ such that for all $D \in \mathcal{Z}_{\delta,2}^{|D|}$

$$\mathcal{R}_D \le \frac{4\kappa^2}{\sqrt{|D|}}\log\frac{2}{\delta}.$$

It also follows from Blanchard and Krämer (2016, Lemma 5.1) that there exists a subset $\mathcal{Z}_{\delta,3}^{|D|}$ of $\mathcal{Z}^{|D|}$ with measure at least $1 - \delta$ such that for all $D \in \mathcal{Z}_{\delta,3}^{|D|}$

$$\mathcal{P}_{D,\lambda} \le 2(\kappa M + \gamma)\mathcal{A}_{D,\lambda}\log\big(2/\delta\big).$$

According to Lemma 21, there exists a subset $\mathcal{Z}_{\delta,4}^{|D|}$ of $\mathcal{Z}^{|D|}$ with measure at least $1 - \delta$ such that for all $D \in \mathcal{Z}_{\delta,4}^{|D|}$

$$(1 + 4\eta_\delta)^{-1}\sqrt{\max\{\mathcal{N}(\lambda), 1\}} \le \sqrt{\max\{\mathcal{N}_D(\lambda), 1\}} \le (1 + 4\sqrt{\eta_\delta} \vee \eta_\delta^2)\sqrt{\max\{\mathcal{N}(\lambda), 1\}}.$$

Thus, for $D \in \mathcal{Z}_{\delta,1}^{|D|} \cap \mathcal{Z}_{\delta,2}^{|D|} \cap \mathcal{Z}_{\delta,3}^{|D|} \cap \mathcal{Z}_{\delta,4}^{|D|}$, the above four inequalities hold simultaneously. Then Lemma 22 follows by scaling δ to $\delta/4$. ∎

From Lemma 22, we derive the following estimate.

Lemma 23 *For any $0 < \delta < 1$, with confidence $1-\delta$, there holds*

$$\mathcal{P}_{D,\lambda}\mathcal{Q}_{D\lambda} \le \frac{1}{2}\mathcal{W}_{D,\lambda}\log^4\frac{16}{\delta}.$$

Proof. It follows from Lemma 22 and (48) that with confidence $1-\delta$, there holds

$$\begin{aligned}\mathcal{P}_{D,\lambda}\mathcal{Q}_{D\lambda} &\le \frac{4\sqrt{2}(\kappa^2+\kappa+1)(\kappa M+\gamma)}{\sqrt{|D|}}\left(\frac{1}{\lambda|D|}+\frac{\sqrt{\mathcal{N}(\lambda)}}{\sqrt{|D|\lambda}}+1\right)\left(\frac{1}{\sqrt{\lambda|D|}}+\sqrt{\mathcal{N}(\lambda)}\right)\log^2\frac{16}{\delta}\\ &\le \frac{4\sqrt{2}(\kappa^2+\kappa+1)(\kappa M+\gamma)}{\sqrt{|D|}}\left(\frac{(\sqrt{|D|\lambda}+9)\sqrt{\max\{\mathcal{N}_D(\lambda),1\}}}{|D|\lambda}+1\right)\\ &\times\frac{(\sqrt{|D|\lambda}+9)\sqrt{\max\{\mathcal{N}_D(\lambda),1\}}}{\sqrt{|D|\lambda}}\log^4\frac{16}{\delta}.\end{aligned}$$

This together with (15) completes the proof of Lemma 23. ∎

Our final lemma establishes a relation between the in-sample norm and out-sample norm of functions in $\mathcal{H}_K$.

Lemma 24 *Let $f \in \mathcal{H}_K$. Then*

$$\|f\|_\rho \le \mathcal{Q}_{D,\lambda}\|L_{K,D}^{1/2}f\|_K + \mathcal{Q}_{D,\lambda}\lambda^{1/2}\|f\|_K. \tag{66}$$

Proof. Since $f \in \mathcal{H}_K$, it follows from the definition of $\mathcal{Q}_{D,\lambda}$ that

$$\begin{aligned}\|f\|_\rho &= \|L_K^{1/2}f\|_K \le \|(L_K+\lambda I)^{1/2}f\|_K \le \mathcal{Q}_{D,\lambda}\|(L_{K,D}+\lambda I)^{1/2}f\|_K\\ &\le \mathcal{Q}_{D,\lambda}\|L_{K,D}^{1/2}f\|_K + \mathcal{Q}_{D,\lambda}\lambda^{1/2}\|f\|_K.\end{aligned}$$

This finishes the proof of Lemma 24. ∎

Appendix B. Some Inequalities for Positive Linear Operators

In this part, we recall some basic definitions and properties for linear operators which can be found in Bhatia (2013). Let $\mathcal{H}_1$ and $\mathcal{H}_2$ be two Hilbert spaces. Let $\mathcal{L}(\mathcal{H}_1,\mathcal{H}_2)$ be the space of all bounded linear operators from $\mathcal{H}_1$ to $\mathcal{H}_2$. The adjoint of an operator A is the unique operator A^* in $\mathcal{L}(\mathcal{H}_2,\mathcal{H}_1)$ that satisfies the relation

$$\langle g, Af\rangle_{\mathcal{H}_2} = \langle A^*g, f\rangle_{\mathcal{H}_1}$$

for all $f \in \mathcal{H}_1$ and $g \in \mathcal{H}_2$. For the space $\mathcal{L}(\mathcal{H},\mathcal{H})$, we use the more compact notation $\mathcal{L}(\mathcal{H})$. For $A \in \mathcal{L}(\mathcal{H})$, if $A = A^*$, we then call A a self-adjoint operator. A self-adjoint operator is said to be positive, if $\langle f, Af\rangle_{\mathcal{H}} \ge 0$ for all $f \in \mathcal{H}$. If $\langle f, Af\rangle_{\mathcal{H}} > 0$ for all nonzero f, we say A is strictly positive.

For $A \in \mathcal{L}(\mathcal{H})$, the operator norm is defined by

$$\|A\| = \sup_{\|f\|_{\mathcal{H}}=1}\|Af\|_{\mathcal{H}}.$$

If A is compact and positive, there exists a normalized eigenpairs of A, denoted by $\{(\lambda_i,\varphi_i)\}_{i=1}^\infty$, with eigenvectors $\{\varphi_i\}$ forming an orthonormal basis for $\mathcal{H}$ and eigenvalues satisfying $\lambda_1 \ge \lambda_2 \ge \cdots \ge 0$. There also holds $\|A\| = \lambda_1$. Write the trace of the positive operator A by

$$\mathrm{Tr}(A) = \sum_{i=1}^\infty \lambda_i.$$

The Hilbert-Schmidt norm of A is then defined by

$$\|A\|_{HS} = (\mathrm{Tr}(A^2))^{1/2} = \left(\sum_{j=1}^\infty \lambda_j^2\right)^{1/2}.$$

If $\|A\|_{HS} < \infty$, we then call A a Hilbert-Schmidt operator. If A is Hilbert-Schmidt, it follows from the definition that $\|A\| \le \|A\|_{HS}$. For $F : \mathbf{R}_+ \cap \{0\} \to \mathbf{R}$, we define the operator

$$F(A) = \sum_{i=1}^\infty F(\lambda_i)\varphi_i\otimes\varphi_i = \sum_{i=1}^\infty F(\lambda_i)\langle\cdot,\varphi_i\rangle_{\mathcal{H}}\varphi_i$$

by spectral calculus. For positive operators A and B, there holds $\|AB\| = \|BA\|$. We also need the following two important inequalities, which can be found in Lemma 1 and Lemma 4 in Guo et al. (2017) (see also Bhatia (2013, Lemma VII.5.5) for the second one).

Lemma 25 *Let A and B be positive operators. Then for any $0 \le \tau \le 1$, there holds*

$$\|A^\tau B^\tau\| \le \|AB\|^\tau. \tag{67}$$

If in addition A and B are Hilbert-Schmidt and $\max\{\|A\|,\|B\|\} \le \kappa$, then for arbitrary $\mu \ge 1$, there holds

$$\|A^\mu - B^\mu\|_{HS} \le \mu\kappa^{\mu-1}\|A-B\|_{HS}. \tag{68}$$

Editor: Ulrike von Luxburg

Abstract

We consider spectral clustering algorithms for community detection under a general bipartite stochastic block model (SBM). A modern spectral clustering algorithm consists of three steps: (1) regularization of an appropriate adjacency or Laplacian matrix (2) a form of spectral truncation and (3) a k-means type algorithm in the reduced spectral domain. We focus on the adjacency-based spectral clustering and for the first step, propose a new data-driven regularization that can restore the concentration of the adjacency matrix even for the sparse networks. This result is based on recent work on regularization of random binary matrices, but avoids using unknown population level parameters, and instead estimates the necessary quantities from the data. We also propose and study a novel variation of the spectral truncation step and show how this variation changes the nature of the misclassification rate in a general SBM. We then show how the consistency results can be extended to models beyond SBMs, such as inhomogeneous random graph models with approximate clusters, including a graphon clustering problem, as well as general sub-Gaussian biclustering. A theme of the paper is providing a better understanding of the analysis of spectral methods for community detection and establishing consistency results, under fairly general clustering models and for a wide regime of degree growths, including sparse cases where the average expected degree grows arbitrarily slowly.

Keywords: Spectral clustering; bipartite networks; stochastic block model; regularization of random graphs; community detection; sub-Gaussian biclustering; graphon clustering.

1. Introduction

Spectral clustering is one of the most popular and successful approaches to clustering and has appeared in various contexts in statistics and computer science among other disciplines. The idea generally applies when one can define a similarity matrix between pairs of objects to be clustered (Ng et al., 2002; Von Luxburg, 2007; Von Luxburg et al., 2008). Recently, there has been a resurgence of interest in the spectral approaches and their analysis in the context of network clustering (Boppana, 1987; McSherry, 2001; Dasgupta et al., 2006; Coja-Oghlan, 2010; Tomozei and Massoulié, 2010; Rohe et al., 2011; Balakrishnan et al., 2011; Chaudhuri et al., 2012; Fishkind et al., 2013; Qin and Rohe, 2013; Joseph and Yu, 2013; Krzakala et al., 2013; Lei et al., 2015; Yun and Proutiere, 2014a,b; Binkiewicz et al., 2014; Lyzinski et al., 2014; Chin et al., 2015; Gao et al., 2017). The interest has been partly fueled by the recent activity in understanding statistical network models for clustering and community detection, and in particular by the flurry of theoretical work on the stochastic block model (SBM)—also called the planted partition model—and its variants (Abbe, 2017).

There has been significant recent advances in analyzing spectral clustering approaches in SBMs. We start by identifying the main components of the analysis in Section 3, and then show how variations can be introduced at each step to obtain improved consistency results and novel algorithms. We will work in the general bipartite setting which has received comparatively less attention, but most results in the paper can be easily extended to the (symmetric) unipartite models (cf. Remark 7). It is worth noting that clustering bipartite SBMs is closely related to the biclustering (Hartigan, 1972) and co-clustering (Dhillon, 2001; Rohe and Yu, 2012) problems.

A modern spectral clustering algorithm often consists of three steps: (a) the regularization and concentration of the adjacency matrix (or the Laplacian) (b) the spectral truncation step, and (c) the k-means step. By using variations in each step one obtains different spectral algorithms, which is then reflected in the variations in the consistency results.

The regularization step is fairly recent and is motivated by the observation that proper regularization significantly improves the performance of spectral methods in sparse networks (Chaudhuri et al., 2012; Amini et al., 2013; Joseph and Yu, 2013; Le et al., 2015; Chin et al., 2015). In particular, regularization restores the concentration of the adjacency matrix (or the Laplacian) around its expectation in the *sparse regime*, where the average degree of the network is constant or grows very slowly with the number of nodes. In this paper, building on these recent advances, we introduce a novel regularization scheme for the adjacency matrix that is fully data-driven and avoids relying on unknown quantities such as maximum expected degrees (for rows and columns) of the network. This regularization scheme is introduced as Algorithm 1 in Section 4 and we show that under a general SBM it achieves the same concentration bound (Theorem 3) as its oracle counterpart.

For the spectral truncation step, we will consider three variations, one of which (Algorithm 2) is the common approach of keeping the top k leading eigenvectors as columns of the matrix passed to the k-means step. In this traditional approach, the spectral truncation can be viewed as obtaining a low-dimensional representation of the data, suitable for an application of simple k-means type algorithms. We also consider a recent variant (Algorithm 3) proposed in Yun and Proutiere (2014b) and Gao et al. (2017), in which the spectral truncation step acts more as a denoising step. We then propose a third alternative (Algorithm 4 in Section 5) which combines the benefits of both approaches while improving the computational complexity. One of our novel contributions is to derive consistency results for Algorithms 3 and 4, under a general SBM, showing that the behavior of the two algorithms is the same (but different than Algorithm 2) assuming that the k-means step satisfies a property we refer to as *isometry invariance* (Theorems 5 and 6).

In the final step of spectral clustering, one runs a k-means type algorithm on the output of the truncation step. We discuss this step in some detail since it is often mentioned

briefly in the analyses of spectral clustering, with the exception of a few recent works (Lei et al., 2015; Gao et al., 2017, 2018). By the k-means step, we do not necessarily mean the solution of the well-known k-means problem, although, this step is usually implemented by an algorithm that approximately minimizes the k-means objective. We will consider the k-means step in some generality, by introducing the notation of a *k-means matrix* (cf. Section 3.3). The goal of the final step of spectral clustering is to obtain a k-means matrix which is close to the output of the truncation step. We characterize sufficient conditions on this approximation so that the overall algorithm produces consistent clustering. Any approach that satisfies these conditions can be used in the k-means step, even if it is not an approximate k-means solver.

Most of the above ideas extend beyond SBMs and, in Section 6, we consider various extensions. We first consider some unique aspects of the bipartite setting, for example, the possibility of having clusters only on one side of the network, or having more clusters on one side than the rank of the expected adjacency matrix. We then show how the results extend to general sub-Gaussian biclustering (Section 6.3) and general inhomogeneous random graphs with approximate clusters (Section 6.4).

The organization of the rest of the paper is as follows: After introducing some notation in Section 1.1, we discuss the general (bipartite) SBM in Section 2. An outline of the analysis is given in Section 3, which also provides the high-level intuition of why the spectral clustering works in SBMs and what each step will achieve in terms of guarantees on its output. This section provides a typical blueprint theorem on consistency (Theorem 1 in Section 3.1) which serves as a prelude to later consistency results. The rest of Section 3 provides the details of the last two steps of the analysis sketched in Section 3.1. The regularization and concentration (the first step) is detailed in Section 4 where we also introduce our data-driven regularization. We then give explicit algorithms and their corresponding consistency results in Section 5. Extensions of the results are discussed in Section 6. Some simulations showing the effectiveness of the regularization are provided in Section 7.

Related work. There are numerous papers discussing aspect of spectral clustering and its analysis. Our paper is mostly inspired by recent developments in the field, especially by the consistency results of Lei et al. (2015), Yun and Proutiere (2014a), Chin et al. (2015), Gao et al. (2017) and concentration results for the regularized adjacency (and Laplacian) matrices such as Le et al. (2015) and Bandeira et al. (2016). Theorem 4 on the consistency of the typical adjacency-based spectral clustering algorithm—which we will call SC-1—is generally known (Lei et al., 2015; Gao et al., 2017), though our version is slightly more general; see Remark 5. The spectral algorithm SC-RR is proposed and analyzed in Yun and Proutiere (2014b), Gao et al. (2017) and Gao et al. (2018) for special cases of the SBM (and its degree-corrected version); the new consistency result we give for SC-RR is for the general SBM and reveals the contrast with SC-1. Previous analyses did not reveal this difference due to focusing on the special case; see Examples 1 and 2 in Section 5 for details. We also propose the new SC-RRE which has the same performance as SC-RR (assuming a proper k-means step) but is much more computationally efficient. The results that we prove for SC-RR and SC-RRE can be recast in terms of the *mean parameters* of the SBM (in contrast to SC-1), as demonstrated in Corollary 4 of Section 5.3. For an application of

this result, we refer to our work on optimal bipartite network clustering (Zhou and Amini, 2018).

1.1. Notation

Orthogonal matrices. We write $\mathbb{O}^{n\times k}$ for the set of $n\times k$ matrices with orthonormal columns. The condition $k\le n$ is implicit in defining $\mathbb{O}^{n\times k}$. The case $\mathbb{O}^{n\times n}$ is the set of orthogonal matrices, though with some abuse of terminology we also refer to matrices in $\mathbb{O}^{n\times k}$ as orthogonal even if $k<n$. Thus, $Z\in\mathbb{O}^{n\times k}$ iff $Z^TZ=I_k$. We also note that $Z\in\mathbb{O}^{n\times k_1}$ and $U\in\mathbb{O}^{k_1\times k}$ implies $ZU\in\mathbb{O}^{n\times k}$. The following holds:

$$\|Ux\|_2=\|x\|_2,\quad \forall x\in\mathbb{R}^k,\ U\in\mathbb{O}^{k_1\times k}, \tag{1}$$

for any $k_1\ge k$. On the other hand,

$$\|U^Tx\|_2\le\|x\|_2,\quad \forall x\in\mathbb{R}^{k_1},\ U\in\mathbb{O}^{k_1\times k}, \tag{2}$$

where equality holds for all $x\in\mathbb{R}^{k_1}$, iff $k_1=k$. To see (2), let $u_1,\dots,u_k\in\mathbb{R}^{k_1}$ be the columns of U, constituting an orthonormal sequence which can be completed to an orthonormal basis by adding say $u_{k+1},\dots,u_{k_1}$. Then, $\|U^Tx\|_2^2=\sum_{j=1}^k\langle u_j,x\rangle^2\le\sum_{j=1}^{k_1}\langle u_j,x\rangle^2=\|x\|_2^2$.

Membership matrices and misclassification. We let $\mathbb{H}^{n\times k}$ denote the set of *hard* cluster labels: $\{0,1\}$-valued $n\times k$ matrices where each row has exactly a single 1. A matrix $Z\in\mathbb{H}^{n\times k}$ is also called a membership matrix, where row i is interpreted as the membership of node i to one of k clusters (or communities). Here we implicitly assume that we have a network on nodes in $[n]=\{1,\dots,n\}$, and there is a latent partition of $[n]$ into k clusters. In this sense, $Z_{ik}=1$ iff node i belongs to cluster k. Given, two membership matrices $Z,Z'\in\mathbb{H}^{n\times k}$, we can consider the average misclassification rate between them, which we denote as $\overline{\mathrm{Mis}}(Z,Z')$: Letting z_i^T and $(z_i')^T$ denote the ith row of Z and Z' respectively, we have

$$\overline{\mathrm{Mis}}(Z,Z'):=\min_Q\frac{1}{n}\sum_{i=1}^n 1\{z_i\ne Qz_i'\} \tag{3}$$

where the minimum is taken over $k\times k$ permutations matrices Q. We also let $\mathrm{Mis}_r(Z,Z')$ be the misclassification rate between the two, over the rth cluster of Z, that is, $\mathrm{Mis}_r(Z,Z')=\frac{1}{n_r}\sum_{i:\ z_i=r}1\{z_i\ne Q^*z_i'\}$ where $n_r=\sum_{i=1}^n1\{z_i=r\}$ is the size of the rth cluster of Z, and Q^* is the optimal permutation in (3). Note that in contrast to $\overline{\mathrm{Mis}}$, Mis_r is not symmetric in its two arguments. We also write $\mathrm{Mis}_\infty:=\max_r\mathrm{Mis}_r$. These definitions can be extended to misclassification rates between k-means matrices introduced in Section 3.3.

2. Stochastic Block Model

We consider the general, not necessarily symmetric, Stochastic Block Model (SBM) with bi-adjacency matrix $A\in\{0,1\}^{n_1\times n_2}$. We assume throughout that $n_2\ge n_1$, without loss of generality. We have membership matrices $Z_r\in\mathbb{H}^{n_r\times k_r}$ for each of the two sides $r=1,2$,

where $k_r \le n_r$ denotes the number of communities on side r. Each element of A is an independent draw from a Bernoulli variable, and

$$P := \mathbb{E}[A] = Z_1 B Z_2^T, \quad B = \frac{\Psi}{\sqrt{n_1 n_2}} \tag{4}$$

where $B \in [0,1]^{k_1 \times k_2}$ is the connectivity— or the edge probability—matrix, and Ψ is a rescaled version. We also use the notation

$$A \sim \mathrm{Ber}(P) \iff A_{ij} \sim \mathrm{Ber}(P_{ij}), \text{ independent across } (i,j) \in [n_1] \times [n_2]. \tag{5}$$

Classical SBM which we refer to as *symmetric SBM* corresponds to the following modifications:

(a) A is assumed to be symmetric: Only the upper diagonal elements are drawn independently and the bottom half is filled symmetrically. For simplicity, we allow for self-loops, i.e., draw the diagonal elements from the same model. This will have a negligible effect in the arguments.

(b) $n_1 = n_2 = n,\ k_1 = k_2 = k,\ Z_1 = Z_2 = Z$.

(c) B is assumed symmetric.

We note that (4) still holds over all the elements. Directed SBM is also a special case, where (b) is assumed but not (a) or (c). That is, A is not assumed to be symmetric and all the entries are independently drawn, while B may or may not be symmetric.

We refer to P as the *mean matrix* and note that it is of rank at most $k := \min\{k_1, k_2\}$. Often $k \ll n_1, n_2$, that is P is a low-rank matrix which is the key in why spectral clustering works well for SBMs. However, the case where either $k_1 \gtrsim n_1$ or $k_2 \gtrsim n_2$ is allowed. (Here, $k_1 \gtrsim n_1$ means $k_1 \ge c n_1$ for some universal constant $c > 0$.) An extreme example of such setup can be found in Section 6.1.

We let $N_r = \mathrm{diag}(n_{r1}, \dots, n_{rk_r})$ for $r = 1, 2$ where n_{rj} is the size of the jth cluster of Z_r; that is, N_r is a diagonal matrix whose diagonal elements are the sizes of the clusters on side r. We also consider the normalized version of N_r,

$$\bar{N}_r := N_r / n_r = \mathrm{diag}(\pi_{r1}, \dots, \pi_{rk_r}), \tag{6}$$

collecting the cluster proportions $\pi_{rj} := n_{rj}/n_r$. Let us define

$$\bar{B} := N_1^{1/2} B N_2^{1/2} = \bar{N}_1^{1/2} \Psi \bar{N}_2^{1/2}.$$

For sparse graphs, we expect $\bar{N}_r$ and Ψ to remain stable as $n_r \to \infty$, hence $\bar{B}$ remains stable; in contrast, the entries of B itself vanish under scaling (4). See Remark 2 below for details. Throughout the paper, barred parameters refer to quantities that remain stable or slowly vary with $n_r \to \infty$. The following lemma is key in understanding spectral clustering for SBMs:

Lemma 1 *Assume that $\bar{B} = U_\psi \Sigma V_\psi^T$ is the reduced SVD of $\bar{B}$, where $U_\psi \in \mathbb{O}^{k_1 \times k}, V_\psi \in \mathbb{O}^{k_2 \times k}$, $\Sigma = \mathrm{diag}(\sigma_1, \dots, \sigma_k)$, and $k = \min\{k_1, k_2\}$. Then,*

$$P = (\bar{Z}_1 U_\psi)\, \Sigma\, (\bar{Z}_2 V_\psi)^T \tag{7}$$

is the reduced SVD of P where $\bar{Z}_r := Z_r N_r^{-1/2}$ is itself an orthogonal matrix, $\bar{Z}_r^T \bar{Z}_r = I_{k_r}$.

Proof We first show that $Z_r^T Z_r = N_r$ which then implies that $\bar{Z}_r$ is orthogonal. Let z_{ri}^T be the ith row of Z_r and note that $Z_r^T Z_r = \sum_{i=1}^n z_{ri} z_{ri}^T$. Since $z_{ri} \in \mathbb{H}^{1 \times k_r}$, each $z_{ri} z_{ri}^T$ is a diagonal matrix with a single 1 on the diagonal at the position determined by the cluster assignment of node i on side r. Now, a little algebra on (4) shows that $P = \bar{Z}_1 \bar{B} \bar{Z}_2^T$, hence (7) holds. Since $\bar{Z}_r \in \mathbb{O}^{n_r \times k_r}$, we have $\bar{Z}_1 U_\psi \in \mathbb{O}^{n_1 \times k}$ and $\bar{Z}_2 V_\psi \in \mathbb{O}^{n_2 \times k}$ showing that (7) is in fact a (reduced) SVD of P. ■

When dealing with the symmetric SBM, we will drop the subscript r from all the relevant quantities; for example, we write $N = N_1 = N_2$, $\bar{Z} = \bar{Z}_1 = \bar{Z}_2$, $\pi_j = \pi_{1j} = \pi_{2j}$, and so on.

Remark 1 (Reduced versus truncated) *The term* reduced SVD *in Lemma 1 (also known as compact SVD) means that we reduce the orthogonal matrices in a full SVD by removing the columns corresponding to zero singular values. The number of columns of the resulting matrices will be equal to the rank of the underlying matrix (i.e., both $\bar{Z}_1 U_\psi$ and $\bar{Z}_2 V_\psi$ will have $k = \min\{k_1, k_2\}$ columns in the case of P). Hence, a reduced SVD is still an exact SVD. Later, we will use the term* truncated SVD *to refer to an "approximation" of the original matrix by a lower rank matrix obtained by further removing columns corresponding to small nonzero singular values (starting from a reduced SVD). Hence, a truncated SVD is only an approximation of the original matrix.*

Remark 2 (Scaling and sparsity) *As can be seen from the above discussion, the normalization in (4) is natural for studying spectral clustering. In the symmetric case, where $n_1 = n_2 = n$, the normalization reduces to $B = \Psi/n$, which is often assumed when studying sparse SBMs by requiring that either $\|\Psi\|_\infty$ is $O(1)$ or grows slowly with n. To see why this implies a sparse network, note that the expected average degree of the symmetric SBM (under this scaling) is*

$$\frac{1}{n} 1^T P 1 = \frac{1}{n} 1^T N B N 1 = 1^T \bar{N} \Psi \bar{N} 1 = \sum_{i,j=1}^k \pi_i \pi_j \Psi_{ij} =: d_{av}$$

using $1_n^T Z = 1_k^T N$. (Here and elsewhere, 1 is the vector of all ones of an appropriate dimension; we write 1_n if we want to emphasize the dimension n.) Thus, the growth of the average expected degree, d_{av}, is the same as Ψ, and as long as Ψ is $O(1)$ or grows very slowly with n, the network is sparse. Alternatively, we can view the expected density of the network (the expected number of edges divided by the total number of possible edges) as a measure of sparsity. For the symmetric case, the expected density is $(\frac{1}{2} 1^T P 1)/\binom{n}{2} \sim d_{av}/n$ and is $O(n^{-1})$ if $d_{av} = O(1)$. Similar observations hold in the general bipartite case if we

let $n = \sqrt{n_1 n_2}$, the geometric mean of the dimensions. The expected density of the bipartite network under the scaling of (4) *is*

$$\frac{1^T P 1}{n^2} = \frac{1}{n^2} 1^T N_1 B N_2 1 = \frac{1}{n} 1^T \bar{N}_1 \Psi \bar{N}_2 1 = \frac{d_{av}}{n}, \quad (n = \sqrt{n_1 n_2})$$

where $d_{av} := 1^T \bar{N}_1 \Psi \bar{N}_2 1 = \sum_{i,j} \pi_{1i} \pi_{2j} \Psi_{ij}$ can be thought of as the analog of the expected average degree in the bipartite case. As long as $\|\Psi\|_\infty$ grows slowly relative to $n = \sqrt{n_1 n_2}$, the bipartite network is sparse.

3. Analysis steps

Throughout, we focus on recovering the row clusters. Everything that we discuss goes through, with obvious modifications, for recovering the column clusters. Recalling the decomposition (7), the idea of spectral clustering in the context of SBMs is that $\bar{Z}_1 U_\psi$ has enough information for recovering the clusters and can be obtained by computing a reduced SVD of P. In particular, applying a k-means type clustering on the rows of $\bar{Z}_1 U_\psi$ should recover the cluster labels. On the other hand, the actual random adjacency matrix, A, is concentrated around the mean matrix P, after proper regularization if need be. We denote this potentially *regularized version as* A_{re}. Then, by the spectral perturbation theory, if we compute a reduced SVD of $A_{\rm re} = \hat{Z}_1 \hat{\Sigma} \hat{Z}_2^T$ where $\hat{Z}_r \in \mathbb{O}^{n_r \times k}$, $r = 1, 2$ and $\hat{\Sigma}$ is diagonal, we can conclude that $\hat{Z}_1$ concentrates around $\bar{Z}_1 U_\psi$. Hence, applying a continuous k-means algorithm on $\hat{Z}_1$ should be able to recover the labels with a small error.

3.1. Analysis sketch

Let us sketch the argument above in more details. A typical approach in proving consistency of spectral clustering consists of the following steps:

1. We replace A with a properly regularized version $A_{\rm re}$. We provide the details for one such regularization in Theorem 2 (Section 4). However, the only property we require of the regularized version is that it concentrates, with high probability, around the mean of A, at the following rate (assuming $n_2 \geq n_1$):

$$\|A_{\rm re} - \mathbb{E}[A]\|_{\rm op} \leq C\sqrt{d}, \quad \text{where} \quad d = \sqrt{\frac{n_2}{n_1}} \|\Psi\|_\infty. \tag{8}$$

Here and throughout $\|\cdot\|_{\rm op}$ is the $\ell_2 \to \ell_2$ operator norm and $\|\Psi\|_\infty = \max_{ij} \Psi_{ij}$.

2. We pass from $A_{\rm re}$ and $P = \mathbb{E}[A]$ to their (symmetrically) dilated versions $A_{\rm re}^\dagger$ and $P^\dagger$. The symmetric dilation operator will be given in (13) (Section 3.2) and allows us to use spectral perturbation bounds for symmetric matrices. A typical final result of this step is

$$\|\hat{Z}_1 - \bar{Z}_1 U_\psi Q\|_F \leq \frac{C_2}{\sigma_k} \sqrt{kd}, \quad \text{w.h.p.} \tag{9}$$

for some $Q \in \mathbb{O}^{k \times k}$. We recall that $\|\cdot\|_F$ is the Frobenius norm. Here, σ_k is the smallest nonzero singular value of $\bar{B}$ as defined in Lemma 1. The form of (9) will be different

if instead of $\hat{Z}_1$ one considers other objects as the end result of this step; see Section 5 (e.g., (34)) for instances of such variations. The appearance of Q is inevitable and is a consequence of the necessity of *properly aligning* the bases of spectral subspaces, before they can be compared in Frobenius norm (cf. Lemma 3). Nevertheless, the growing stack of orthogonal matrices on the RHS of $\bar{Z}_1$ has little effect on the performance of row-wise k-means, as we discuss shortly.

3. The final step is to analyze the effect of applying a k-means algorithm to $\hat{Z}_1$. Here, we introduce the concept of a *k-means matrix*, one whose rows take at most k distinct values. (See Section 3.3 for details). A k-means algorithm $\mathscr{K}$ takes a matrix $\hat{X} \in \mathbb{R}^{n \times m}$ and outputs a k-means matrix $\mathscr{K}(\hat{X}) \in \mathbb{R}^{n \times m}$. Our focus will be on k-means algorithms with the following property: If $X^* \in \mathbb{R}^{n \times m}$ is a k-means matrix, then for some constant $c > 0$,

$$\|\hat{X} - X^*\|_F^2 \leq \varepsilon^2 \implies \overline{\rm Mis}(\mathscr{K}(\hat{X}), X^*) \leq c\varepsilon^2/(n\delta^2). \tag{10}$$

where $\delta^2 = \delta^2(X^*)$ is the minimum center separation of X^* (cf. Definition 2), and $\overline{\rm Mis}$ is the average misclassification rate between two k-means matrices. For future reference, we refer to property (10) as the *local quadratic continuity (LQC)* of algorithm $\mathscr{K}$; see Remark 6 for the rationale behind the naming. As will become clear in Section 3.3, k-means matrices encode both the cluster label information and cluster center information, and these two pieces can be recovered from them in a lossless fashion. Thus, it makes sense to talk about misclassification rate between k-means matrices, by interpreting it as a statement about their underlying label information. In Section 3.3, we will discuss k-means algorithms that satisfy (10).

The preceding three steps of the analysis follow the three steps of a general spectral clustering algorithm, which we refer to as *regularization*, *spectral truncation* and *k-means* steps, respectively. Recalling the definition of cluster proportions, let us assume for some $\beta_r \geq 1$,

$$\max_{(t,s):\, t \neq s} \frac{2}{\pi_{rt}^{-1} + \pi_{rs}^{-1}} \leq \frac{\beta_r}{k_r}, \quad r = 1, 2. \tag{A1}$$

The LHS is the maximum *harmonic mean* of pairs of distinct cluster proportions. For balanced clusters, we have $\pi_{rt} = 1/k_r$ for all $t \in [k_r]$ and we can take $\beta_r = 1$. In general, β_r measures the deviation of the clusters (on side r) from balancedness. The following is a prototypical consistency theorem for a spectral clustering algorithm:

Theorem 1 (Prototype SC consistency) *Consider a spectral algorithm with a k-means step satisfying* (10)*, and the "usual" spectral truncation step, applied to a regularized bi-adjacency matrix A_{re} satisfying concentration bound* (8)*. Let $\mathscr{K}(\hat{Z}_1)$ be the resulting estimate for membership matrix Z_1, and assume $k_1 = k =: \min\{k_1, k_2\}$. Then, under the SBM model of Section 2 and assuming* (A1)*, w.h.p.,*

$$\overline{\rm Mis}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1) \lesssim \beta_1 \Big(\frac{d}{\sigma_k^2} \Big).$$

Here, and in the sequel, "with high probability", abbreviated w.h.p., means with probability at least $1 - n^{-c_1}$ for some universal constant $c_1 > 0$. The notation $f \lesssim g$ means $f \leq c_2\, g$ where $c_2 > 0$ is a universal constant. In addition, $f \asymp g$ means $f \lesssim g$ and $g \lesssim f$.

Proof By assumption, concentration bound (8) holds. By Lemma 3 in Section 3.2, (8) implies (9) for the usual truncation step. Let $O := U_\psi Q$ and $\varepsilon^2 = C_2^2\, kd/\sigma_k^2$ so that (9) reads $\|\hat{Z}_1 - \bar{Z}_1 O\|_F \leq \varepsilon^2$. The k-means step satisfies (10) by assumption. Applying (10) with $\hat{X} = \hat{Z}_1$, $X^* = \bar{Z}_1 O$ and ε^2 defined earlier leads to

$$\overline{\text{Mis}}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1) = \overline{\text{Mis}}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1 O) \;\lesssim\; \frac{\varepsilon^2}{n_1 \delta^2}. \tag{11}$$

It remains to calculate the minimum center separation of $X^* = \bar{Z}_1 O \in \mathbb{R}^{n_1 \times k}$, where $\bar{Z}_1 \in \mathbb{O}^{n_1 \times k_1}$ and $O := U_\psi Q \in \mathbb{O}^{k_1 \times k}$. We have

$$\delta^2 = \delta^2(\bar{Z}_1 O) = \delta^2(\bar{Z}_1) = \min_{t \neq s} \|n_{1t}^{-1/2} e_t - n_{1s}^{-1/2} e_s\|_2^2 = \min_{t \neq s} (n_{1t}^{-1} + n_{1s}^{-1})$$

where $e_s \in \mathbb{R}^{k_1}$ is the sth standard basis vector. The second equality uses invariance of δ^2 to right-multiplication by a square orthogonal matrix. This is a consequence of $\|u^T O - v^T O\|_2 = \|u - v\|_2$ for $u, v \in \mathbb{R}^{k_1}$ and $O \in \mathbb{O}^{k_1 \times k}$ when $k_1 = k$; see (1). The third equality is from the definition $\bar{Z}_1 = Z_1 N_1^{-1/2}$. Using (A1),

$$(n_1 \delta^2)^{-1} \leq \max_{t \neq s} (\pi_{1t}^{-1} + \pi_{1s}^{-1})^{-1} \leq \frac{\beta_1}{2k_1}.$$

Thus, $\frac{\varepsilon^2}{n_1 \delta^2} \lesssim \beta_1 \frac{k}{k_1} \frac{d}{\sigma_k^2}$ which gives the result in light of (11) and assumption $k_1 = k$. ■

The case $k_1 > k$ will be discussed in Section 6.2. For (10) to hold for a k-means algorithm, one usually requires some additional constraints on $\varepsilon^2/(n\delta^2)$, ensuring that this quantity is small. We will restate Theorem 1 with such conditions explicitly once we consider the details of some k-means algorithms. For now, Theorem 1 should be thought of as a general blueprint, with specific variations obtained in Section 5 for various spectral clustering algorithms.

Remark 3 *To see that Theorem 1 is a consistency result, consider the typical case where $\beta_1 \asymp 1$, and $\sigma_k \asymp d$, so that $\overline{\text{Mis}}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1) = O(d^{-1})$. Then, as long as $d \to \infty$, i.e., the average degree of the network grows with n, assuming $n_1 \asymp n_2 \asymp n$ (for some n), we have $\overline{\text{Mis}}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1) = o(1)$, i.e., the average misclassification rate vanishes with high probability. One might ask why $\sigma_k \asymp d$ is reasonable. Consider the typical case where $\Psi = \rho_n \Psi'$ for some constant matrix Ψ' and a scalar parameter ρ_n that captures the dependence on n. This setup is common in network modeling (Bickel and Chen, 2009). Then, $d \asymp \|\Psi\|_\infty = \rho_n \|\Psi'\|_\infty$ and $\sigma_k = \rho_n \sigma_k'$ where σ_k' is defined based on Ψ' and hence constant. It follows that $d \asymp \rho_n \asymp \sigma_k$ and $\overline{\text{Mis}}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1) = o(\rho_n^{-1})$. Note that, in general, ρ_n can grow as fast as n (cf. (4)). More specific examples are given in Section 5.*

Remark 4 *We note that bounds similar to (9) appear in the recent literature (Abbe et al., 2017; Cape et al., 2018) but for the $2 \to \infty$ operator norm, as opposed to the Frobenius norm, assuming that the network is dense enough. These bounds can be used to show that spectral clustering achieves exact recovery when the degree grows as $\log n$ for the two-community case (Abbe et al., 2017). A similar exact recovery result for general K is obtained in (Su et al., 2017) assuming a degree growth of $(\log n)^a$ for sufficiently large a. Whether the $2 \to \infty$ bounds can be used to sharpen the misclassification rate of spectral clustering below the $\log n$ regime is open.*

Remark 5 *Condition (A1) is more relaxed that what is commonly assumed in the literature (though the proof is the same). Stating the condition as a harmonic mean allows one to have similar results as the balanced case when one cluster is large, while others remain more or less balanced. For example, let $\pi_{r1} = 1 - c$ for some constant $c \in (0, 1)$, say $c = 0.4$, and let $\pi_{rt} = c/(k_r - 1)$ for $t \neq 1$. Then, we have for $s \neq t$*

$$\frac{2}{\pi_{rt}^{-1} + \pi_{rs}^{-1}} \leq 2 \min\{\pi_{rt}, \pi_{rs}\} = \frac{2c}{k_r - 1} \leq \frac{4}{k_r}$$

assuming $k_r \geq 2$. Hence (A1) holds with $\beta_r = 4$. Note that as k_r is increased, all but one cluster get smaller.

Remark 6 (LQC naming) *The rationale behind the naming of (10) is as follows: Let $\Delta(X, Y) := \frac{1}{\sqrt{n}} \|X - Y\|_F$ be the metric induced by the normalized Frobenius norm on the space of $n \times m$ matrices. Assume that X^* is a k-means matrix and that k-means matrices are fixed points of algorithm $\mathscr{K}$, hence $X^* = \mathscr{K}(X^*)$. Then, by taking the infimum over ε^2, (10) can be written as*

$$\overline{\text{Mis}}\left(\mathscr{K}(\hat{X}), \mathscr{K}(X^*)\right) \leq \omega\big(\Delta(\hat{X}, X^*)\big) \tag{12}$$

where $\omega(t) = ct^2/\delta^2(X^*)$, showing that $\mathscr{K}$ is continuous w.r.t. the two (pseudo)-metrics, locally at X^*, with a quadratic modulus of continuity. Note that this continuity is only required to hold around a k-means matrix X^* (and not in general). Another reason for the "locality" is that such statements often only hold for sufficiently small $\Delta(\hat{X}, X^*)$.

In this rest of this section, we fill in some details of the last two steps of the plan sketched above, deferring Step 1 to Section 4.

3.2. SV truncation (Step 2)

We now show how the concentration bound (8) implies the deviation bound (9) for the usual spectral truncation step. Consider the *symmetric dilation* operator : $\mathbb{R}^{n_1 \times n_2} \to \mathbb{S}^{n_1 + n_2}$, given by

$$P^\dagger := \begin{pmatrix} 0 & P \\ P^T & 0 \end{pmatrix}, \tag{13}$$

where $\mathbb{S}^n$ is the set of symmetric $n \times n$ matrices. This operator will be very useful in translating the results between the symmetric and non-symmetric cases. Let us collect some of its properties:

Lemma 2 (Symmetric Dilation) *Let $P \in \mathbb{R}^{n_1 \times n_2}$ have a reduced SVD given by $P = U\Sigma V^T$ where $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_k)$ is a $k \times k$ nonnegative diagonal matrix . Then,*

(a) $P^\dagger$ has a reduced EVD given by

$$P^\dagger = W \begin{pmatrix} \Sigma & 0 \\ 0 & -\Sigma \end{pmatrix} W^T, \quad W = \frac{1}{\sqrt{2}} \begin{pmatrix} U & U \\ V & -V \end{pmatrix} \in \mathbb{O}^{(n_1+n_2)\times 2k}.$$

(b) $P \mapsto P^\dagger$ is a linear operator with $\|P^\dagger\| = \|P\|$ and $\|P^\dagger\|_F = \sqrt{2}\|P\|_F$.

(c) The gap between k top (signed) eigenvalues of $P^\dagger$ and the rest of its spectrum is $2\sigma_k$.

Proof Part (a) can be verified directly (e.g. $W^TW = I_{2k}$ follows from $U^TU = V^TV = I_k$) and part (c) follows by noting that $\sigma_j \geq 0$ for all j. Part (b) also follows directly from part (a), using unitary-invariance of the two norms. ■

In addition, let us define a singular value (SV) truncation operator $\mathscr{T}_k : \mathbb{R}^{n_1 \times n_2} \to \mathbb{R}^{n_1 \times n_2}$ that takes a matrix A with SVD $A = \sum_i \sigma_i u_i v_i^T$ to the matrix

$$A^{(k)} := \mathscr{T}_k(A) := \sum_{i=1}^{k} \sigma_i u_i v_i^T. \tag{14}$$

In other words, $\mathscr{T}_k$ keeps the largest k singular values (and the corresponding singular vectors) and zeros out the rest. Recall that we order singular values in nonincreasing fashion $\sigma_1 \geq \sigma_2 \geq \cdots$. We also refer to (14) as the *k-truncated SVD* of A. Using the dilation and the Davis–Kahan (DK) theorem for symmetric matrices (Bhatia, 2013, Theorem VII.3.1), we have:

Lemma 3 *Let $A_{re}^{(k)} = \hat{Z}_1 \hat{\Sigma} \hat{Z}_2^T$ be the k-truncated SVD of A_{re} and assume that the concentration bound* (8) *holds. Let $\bar{Z}_1 U_\psi$ be given by the reduced SVD of P in* (7)*. Then, the deviation bound* (9) *holds for some $k \times k$ orthogonal matrix Q, and $C_2 = 2C$.*

Later, in Section 5, we introduce an alternative spectral truncation scheme. It is worth comparing the above lemma to Lemma 6 which establishes a similar result for the alternative truncation.

Remark 7 (Symmetric case) *When P is symmetric one can still use the dilation operator. In this case, since P itself is symmetric, it has an eigenvalue decomposition (EVD), say $P = U\Lambda U^T$, where $\Lambda = \mathrm{diag}(\lambda_1, \ldots, \lambda_k)$ is the diagonal matrix of the eigenvalues of P. Since these eigenvalues could be negative, there is a slight modification needed to go from the EVD to the SVD of P. Let s_i be the sign of λ_i and set $S = \mathrm{diag}(s_i, i = 1, \ldots, k)$. Then, it is not hard to see that with $V = US$ and $\Sigma = \Lambda S = \mathrm{diag}(|\lambda_i|, i = 1, \ldots, k)$, we obtain the SVD $P = U\Sigma V^T$. In other words, all the discussion in this section, and in particular Lemma 3 hold with $V = US$ and $\sigma_i = |\lambda_i|$. The special case of Lemmas 2 and 3 for the symmetric case appears in Lei et al. (2015). These observations combined with the fact that the concentration inequality discussed in Section 4 holds in the symmetric case leads to the following conclusion: All the results discussed in this paper apply to the symmetric SBM, for the version of the adjacency-based spectral clustering that* sorts the eigenvalues based on their absolute values. *This is the most common version of spectral algorithms in use. On the other hand, one gets a different behavior for the algorithm that considers the top k (signed) eigenvalues. We have borrowed the term "symmetric dilation" from Tropp (2015) where these ideas have been successfully used in translating matrix concentration inequalities to the symmetric case.*

3.3. k-means algorithms (Step 3)

Let us now give the details of the third and final step of the analysis. We introduce some notations and concepts that help in the discussion of k-means (type) algorithms.

k-means matrices. Recall that $\mathbb{H}^{n\times k}$ denotes the set of *hard* (cluster) labels: $\{0,1\}$-valued $n \times k$ matrices where each row has exactly a single 1. Take $Z \in \mathbb{H}^{n\times k}$. A related notion is that of a *cluster* matrix $Y = ZZ^T \in \{0,1\}^n$ where each entry denotes whether the corresponding pair are in the same cluster. Relative to Z, Y loses the information about the ordering of the cluster labels. We define the class of *k-means matrices* as follows:

$$\begin{aligned} \mathbb{M}_{n,m}^k &:= \{X \in \mathbb{R}^{n\times m} : \ X \text{ has at most } k \text{ distinct rows}\} \\ &= \{ZR : \ Z \in \mathbb{H}^{n\times k}, R \in \mathbb{R}^{k\times m}\}. \end{aligned} \tag{15}$$

The rows of R, which we denote as r_i^T, play the role of cluster centers. Let us also denote the rows of X as x_i^T. The second equality in (15) is due to the following correspondence: Any matrix $X \in \mathbb{M}_{n,m}^k$ uniquely identifies a *cluster* matrix $Y \in \{0,1\}^{n\times n}$ via, $Y_{ij} = 1$ iff $x_i = x_j$. This in turn "uniquely" identifies a label matrix Z up to $k!$ permutation of the labels. From Z, we "uniquely" recover R, with the convention of setting rows of R for which there is no label equal to zero. (This could happen if X has fewer than k distinct rows.)

With these conventions, there is a one-to-one correspondence between $X \in \mathbb{M}_{n,m}^k$ and $(Z, R) \in \mathbb{H}^{n\times k} \times \mathbb{R}^{k\times m}$, up to label permutations. That is, (Z, R) and (ZQ, QR) are considered equivalent for any permutation matrix Q. The correspondence allows us to talk about a (relative) misclassification rate between two k-means matrices: If $X_1, X_2 \in \mathbb{M}_{n,m}^k$ with membership matrices $Z_1, Z_2 \in \mathbb{H}^{n\times k}$, respectively, we set

$$\overline{\mathrm{Mis}}(X_1, X_2) := \overline{\mathrm{Mis}}(Z_1, Z_2). \tag{16}$$

k-means as projection. Now consider a general $\hat{X} \in \mathbb{R}^{n\times m}$. The classical k-means problem can be thought of as projecting $\hat{X}$ onto $\mathbb{M}_{n,m}^k$, in the sense of finding a nearest member of $\mathbb{M}_{n,m}^k$ to $\hat{X}$ in Frobenius norm. Let us write $d_F(\cdot,\cdot)$ for the distance induced by the Frobenius norm, i.e., $d_F(\hat{X}, X) = \|\hat{X} - X\|_F$. The k-means problem is that of solving the following optimization:

$$d_F(\hat{X}, \mathbb{M}_{n,m}^k) := \min_{X \in \mathbb{M}_{n,m}^k} d_F(\hat{X}, X). \tag{17}$$

The arguments to follow go through for any distance on matrices that has a ℓ_2 decomposition over the rows:

$$d_F(\hat{X}, X)^2 = \sum_{i=1}^{n} d(\hat{x}_i, x_i)^2, \tag{18}$$

where x_i^T and $\hat{x}_i^T$ are the rows of X and $\hat{X}$ respectively, and $d(\hat{x}_i, x_i)$ is some distance over vectors in $\mathbb{R}^d$. For the case of the Frobenius norm: $d(\hat{x}_i, x_i) = \|\hat{x} - x_i\|_2$, the usual ℓ_2 distance. This is the primary case we are interested in, though the result should be understood for the general case of (18). Since solving the k-means problem (17) is NP-hard, one can look for approximate solutions:

Definition 1 *A κ-approximate k-means solution for $\hat{X}$ is a matrix $\widetilde{X} \in \mathbb{M}_{n,m}^k$ that achieves κ times the optimal distance:*

$$d_F(\hat{X}, \widetilde{X}) \leq \kappa\, d_F(\hat{X}, \mathbb{M}_{n,m}^k). \tag{19}$$

We write $\mathcal{P}_\kappa : \mathbb{R}^{n\times m} \mapsto \mathbb{M}_{n,m}^k$ for the (set-valued) function that maps matrices $\hat{X}$ to κ-approximate solutions $\widetilde{X}$.

An equivalent restatement of (19) is

$$d_F(\hat{X}, \widetilde{X}) \leq \kappa\, d_F(\hat{X}, X), \quad \forall X \in \mathbb{M}_{n,m}^k. \tag{20}$$

Note that $\mathcal{P}_\kappa(\hat{X}) = \{\widetilde{X} \in \mathbb{M}_{n,m}^k : \ \widetilde{X} \text{ satisfies (20)}\}$. Our goal is to show that whenever $\hat{X}$ is close to some $X^* \in \mathbb{M}_{n,m}^k$, then any κ-approximate k-means solution based on it, namely $\widetilde{X} \in \mathcal{P}_\kappa(\hat{X})$ will be close to X^* as well. This is done in two steps:

1. If the distance $d_F(X, \widetilde{X})$ between two k-means matrices $X, \widetilde{X} \in \mathbb{M}_{n,m}^k$ is small, then their relative misclassification rate $\overline{\text{Mis}}(X, \widetilde{X})$ is so.

2. If a general matrix $\hat{X} \in \mathbb{R}^{n\times d}$ is close to a k-means matrix $X \in \mathbb{M}_{n,m}^k$, then so is its κ-approximate k-means projection. More specifically,

$$d_F(\widetilde{X}, X) \leq (1+\kappa)\, d_F(\hat{X}, X), \quad \forall \widetilde{X} \in \mathcal{P}_\kappa(\hat{X}), \tag{21}$$

   which follows from the triangle inequality $d_F(\widetilde{X}, X) \leq d_F(\widetilde{X}, \hat{X}) + d_F(\hat{X}, X)$ and (20).

Combining the two steps (taking $X = X^*$), we will have the result.

Let us now give the details of the first step above. For this result, we need the key notion of center separation. k-means matrices have more information that just a membership assignment. They also contain an encoding of the relative positions of the clusters, and hence the minimal pairwise distance between them, which is key in establishing a misclassification rate.

Definition 2 (Center separation) *For any $X \in \mathbb{M}_{n,m}^k$, let us denote its centers, i.e. distinct rows, as $\{q_r(X), r \in [k]\}$, and let*

$$\delta_r(X) = \min_{\ell:\, \ell \neq r} d(q_\ell(X), q_r(X)), \quad \delta_\wedge(X) = \min_r \delta_r(X). \tag{22}$$

In addition, let $n_r(X)$ be the number of nodes in cluster r according to X, and $n_\wedge(X) = \min_r n_r(X)$, the minimum cluster size.

If X has $m < k$, the convention would be to let $q_k(X) = 0$ for $k = m+1, \ldots, k$. We usually do not work with these degenerate cases. Implicit in the above definition is an enumeration of the clusters of X. We note that definition of $\delta_r = \delta_r(X)$ in (22) implies

$$d(q_\ell(X), q_r(X)) \geq \max\{\delta_\ell, \delta_r\}, \quad \forall (r, \ell) : r \neq \ell. \tag{23}$$

We are now ready to show that that any algorithm that computes a κ-approximate solution to the k-means problem (17) (where κ is some constant) satisfies the LQC property (10) needed in the last step of the analysis sketched in Section 3.1. Recall that $\text{Mis}_r(X; \widetilde{X})$ is the misclassification rate over the rth cluster of X (Section 1.1).

Proposition 1 *Let $X, \widetilde{X} \in \mathbb{M}_{n,m}^k$ be two k-means matrices, and write $n_r = n_r(X)$, $n_\wedge = n_\wedge(X)$ and $\delta_r = \delta_r(X)$. Assume that $d_F(X, \widetilde{X}) \leq \varepsilon$ and*

(a) X has exactly k nonempty clusters, and

(b) $c_r^{-2}\, \varepsilon^2/(\delta_r^2 n_r) < 1$ for $r \in [k]$, and constants $c_r > 0$ such that $c_r + c_\ell \leq 1$, $r \neq \ell$.

Then, $\widetilde{X}$ has exactly k clusters and

$$\text{Mis}_r(X; \widetilde{X}) \leq \frac{c_r^{-2}\, \varepsilon^2}{n_r\, \delta_r^2}, \quad \forall r \in [k]. \tag{24}$$

In particular, under the conditions of Proposition 1 with $c_r = 1/2$, we have

$$\text{Mis}_\infty(X, \widetilde{X}) \leq \frac{4\,\varepsilon^2}{\min_r n_r \delta_r^2} \leq \frac{4\,\varepsilon^2}{n_\wedge \delta_\wedge^2}, \qquad \overline{\text{Mis}}(X, \widetilde{X}) \leq \frac{4\,\varepsilon^2}{n\, \delta_\wedge^2}.$$

where the second one follows from the identity $\overline{\text{Mis}}(X, \widetilde{X}) = \sum_{r=1}^k (n_r/n)\, \text{Mis}_r(X, \widetilde{X})$. Combining Proposition 1 with (21), we obtain the following corollary:

Corollary 1 *Let $X^* \in \mathbb{M}_{n,m}^k$ be a k-means matrix, and write $n_r = n_r(X^*)$, $n_\wedge = n_\wedge(X^*)$ and $\delta_r = \delta_r(X^*)$. Assume that $\hat{X} \in \mathbb{R}^{n\times m}$ is such that $d_F(X^*, \hat{X}) \leq \varepsilon$ and*

(a) X^* has exactly k nonempty clusters, and

(b) $c_r^{-2}\, (1+\kappa)^2 \varepsilon^2/(\delta_r^2 n_r) < 1$ for $r \in [k]$, and constants $c_r > 0$ such that $c_r + c_\ell \leq 1$, $r \neq \ell$.

Then, any $\widetilde{X} \in \mathcal{P}_\kappa(\hat{X})$ has exactly k clusters and

$$\text{Mis}_r(X^*; \mathcal{P}_\kappa(\hat{X})) \leq \frac{c_r^{-2}\, (1+\kappa)^2 \varepsilon^2}{n_r\, \delta_r^2}, \quad \forall r \in [k]. \tag{25}$$

As before, $\text{Mis}_r(X^*, \mathcal{P}_\kappa(\hat{X}))$ should be interpreted as $\max_{\widetilde{X} \in \mathcal{P}_\kappa(\hat{X})} \text{Mis}_r(X^*, \widetilde{X})$, that is, the result hold for any κ-approximate k-means solution for $\hat{X}$. In particular, under the conditions of Corollary 1 with $c_r = 1/2$, we have

$$\overline{\text{Mis}}(X^*, \mathcal{P}_\kappa(\hat{X})) \ \leq \ 4(1+\kappa)^2 \frac{\varepsilon^2}{n\, \delta_\wedge^2}. \tag{26}$$

A similar bound holds for Mis_∞. Note that (26) is of the desired form needed in (10).

Remark 8 *Corollary 1 shows that any constant-factor approximation to the k-means problem* (17) *satisfies the LCQ property* (10)*. Such approximations can be computed in polynomial time; see for example Kumar et al. (2004). One can also use Lloyd's algorithm with* `kmeans++` *initialization to get a* $\kappa \lesssim \log k$ *approximation (Arthur and Vassilvitskii, 2007). Both Kumar et al. (2004) and Arthur and Vassilvitskii (2007) give constant probability approximations, hence if such algorithms are used in our subsequent results, "w.h.p." should be interpreted as with high constant probability (rather than* $1 - o(1)$*). Recently Lu and Zhou (2016) has shown that Lloyd's algorithm with random initialization can achieve near optimal misclassification rate in certain random models. Their analysis is complementary to ours in that we establish and use the LQC property* (10) *which uniformly holds for any input matrix* $\hat{X}$ *and we do not consider specific algorithms. The core ideas of our analysis in this section are borrowed from Lei et al. (2015) and Jin (2015). It is worth noting that there are other algorithms that turn a general matrix into a k-means matrix, without trying to approximate the k-means problem* (17)*, and still satisfy the LQC. We will give one such example, Algorithm 6, in Appendix B. Interestingly, in contrast to the k-means approximation algorithms, the LQC guarantee for Algorithm 6 is not probabilistic.*

4. Regularization and concentration

Here, we provide the details of Step 1, namely, the concentration of the regularized adjacency matrix. We start by a slight generalization of the results of Le et al. (2017) to the rectangular case:

Theorem 2 *Assume* $n_1 \le n_2$ *and let* $A \in \{0,1\}^{n_1 \times n_2}$ *have independent Bernoulli entries with mean* $\mathbb{E}[A_{ij}] = p_{ij}$*. Take* $d \ge \max_{ij} n_2 p_{ij}$*. Pick any subsets* $\mathcal{I}_1 \subset [n_1]$ *and* $\mathcal{I}_2 \subset [n_2]$ *such that*

$$|\mathcal{I}_1| \le 10 n_2/d, \quad \text{and} \quad |\mathcal{I}_2| \le 10 n_2/d \tag{27}$$

and fix some $d' > 0$*. Define a regularized adjacency matrix* A_{re} *as follows:*

(a) Set $[A_{re}]_{ij} = A_{ij}$ *for all* $(i,j) \in \mathcal{I}_1^c \times \mathcal{I}_2^c$*.*

(b) Set $[A_{re}]_{ij}$ *arbitrarily when* $i \in \mathcal{I}_1$ *or* $j \in \mathcal{I}_2$*, but subject to the constraints* $\|[A_{re}]_{i*}\|_1 \le d'$ *and* $\|[A_{re}]_{*j}\|_1 \le d'$ *for all* $i \in \mathcal{I}_1$ *and* $j \in \mathcal{I}_2$*.*

Then, for any $r \ge 1$*, with probability at least* $1 - n_2^{-r}$*, the new adjacency matrix* A_{re} *satisfies*

$$\|A_{re} - \mathbb{E}[A]\|_{op} \le C_2 r^{3/2}(\sqrt{d} + \sqrt{d'}). \tag{28}$$

The same result holds if in step (b) one uses ℓ_2 *norm instead of* ℓ_1*.*

Theorem 2 follows directly from the non-symmetric (i.e., directed) version of (Le et al., 2017, Theorem 2.1), by padding A with rows of zeros to get a square $n_2 \times n_2$ matrix. The result then follows by the same argument as in (Le et al., 2017, Theorem 2.1). The term "arbitrary" in the statement of the theorem includes any reduction even if the scheme is stochastic and depends on A itself. This feature will be key in developing data-driven schemes.

To apply Theorem 2, take $\mathcal{I}_1 = \{i \in [n_1] : \sum_j A_{ij} > 2d\}$ and $\mathcal{I}_2 = \{j \in [n_2] : \sum_i A_{ij} > 2d\}$, i.e., the set of rows and columns with degrees larger than $2d$. It is not hard to see that if d is any upper bound on the expected row and column degrees, then the sizes of these sets satisfy (27) with high probability. This follows, for example, from the same argument as that leading to (64) in Appendix A.2. Recalling the scaling of the connectivity matrix in (4), taking $d = n_2\|P\|_\infty$ gives an upper bound on the expected row and column degrees, assuming $n_2 \ge n_1$. Thus, we can apply Theorem 2 with $d' = d = \sqrt{n_2/n_1}\|\Psi\|_\infty = n_2\|P\|_\infty$, to obtain the desired concentration bound (8). Note that this concentration result does not require $d = n_2\|P\|_\infty$ to satisfy any lower bound (such as $d = \Omega(\log n_2)$). See Remarks 9 and 10 for the significance of this fact.

A disadvantage of the regularization scheme described in Theorem 2 is the required knowledge of a good upper bound on $d = n_2\|P\|_\infty$. In the next section, under a SBM with some mild regularity assumptions, we develop a fully data-driven scheme with the same guarantees as those of Theorem 2.

4.1. Data-driven regularization

We now describe a regularization scheme that is data-driven and does not require the knowledge of d as in Theorem 2. Let us write $D_i = \sum_{j=1}^{n_2} A_{ij}$ for the degree of node i on side 1 and $\overline{D} = \frac{1}{n_1}\sum_{i=1}^{n_1} D_i$ for the average degree on side 1. Consider the following order statistics for the degree sequence:

$$D_{(1)} \ge D_{(2)} \ge \cdots \ge D_{(n_1)}. \tag{29}$$

The idea is that under a block model, we can achieve concentration (8) by reducing the row degrees that are roughly above $D_{(\alpha)}$ for $\alpha = \lfloor n_1/\overline{D} \rfloor$ (and similarly for the columns). The overall scheme is described in Algorithm 1. The algorithm has a tuning parameter τ; however, we will show that taking $\tau = 3$ is enough. This constant is for convenience and has no special meaning. Note that the regularization described in Step 6 is a special case of that in Step 5; it is equivalent to first reducing the row degrees by setting $[A_{\mathrm{re}}]_{i*} \leftarrow A_{i*}\widehat{d}_1/D_i$ for $i \in \widehat{\mathcal{I}}_1$ followed by reducing the column degrees $[A_{\mathrm{re}}]_{*j} \leftarrow [A_{\mathrm{re}}]_{*j}\widehat{d}_2/D_j$ for $j \in \widehat{\mathcal{I}}_2$, or vice versa. Alternatively, we can replace the ℓ_1 norm constraints in Step 5 with ℓ_2 norm version and replace Step 6 with $[A_{\mathrm{re}}]_{ij} = A_{ij}\sqrt{w_i w'_j}$ for all $i \in [n_1], j \in [n_2]$.

Let $p_{ij} = \mathbb{E}[A_{ij}]$ and define $d_i := \mathbb{E}[D_i] = \sum_j p_{ij}$ and

$$\bar{d} = \frac{1}{n_1}\sum_{i=1}^{n} d_i, \quad d_{\max} := \max_i d_i, \quad d := n_2 \cdot \max_{i,j} p_{ij}. \tag{30}$$

Note that $\bar{d} \le d_{\max} \le d$ and we have $\bar{d} = \mathbb{E}[\overline{D}]$, that is, the expected average degree of the network (on side 1). We need the following mild regularity assumption:

(A2) Consider the SBM model given by (4) and (5) with $n_1 \le n_2$. Assume further that for some $\beta \ge 1$, and for all $t \in [k_1]$ and $s \in [k_2]$,

$$n_{1t} \ge \frac{n_1}{\beta k_1}, \quad n_{2s} \ge \frac{n_2}{\beta k_2}, \quad \text{and} \quad \left(\frac{n_2}{n_1}\right)^2 \max\{8\beta k_1, 8\beta k_2, 90\} \le \bar{d} \le \frac{1}{2}n_1. \tag{31}$$

Algorithm 1 Data-driven adjacency regularization

Input: Adjacency matrix $A \in \mathbb{R}^{n_1 \times n_2}$ and regularization parameter τ. (Default: $\tau = 3$)

Output: Regularized adjacency matrix $A_{\rm re} \in \mathbb{R}^{n_1 \times n_2}$.

1: Form the degree sequence $D_i = \sum_{j=1}^{n_2} A_{ij}$ for $i = 1, \ldots, n$ and the corresponding order statistics: $D_{(1)} \geq D_{(2)} \geq \cdots \geq D_{(n_1)}$.

2: Let $\overline{D} = \frac{1}{n_1} \sum_{i=1}^{n_1} D_i$ and $\alpha = \lfloor n_1 / \overline{D} \rfloor$.

3: Set $\widehat{d}_1 = \tau D_{(\alpha)}$ and $\widehat{\mathcal{I}}_1 = \{i : D_i \geq \widehat{d}_1\}$.

4: Repeat Steps 1–3 on A^T to get $\widehat{\mathcal{I}}_2$ and $\widehat{d}_2$, and let D'_j be the corresponding degrees (i.e., column degrees in the original matrix A).

5: Set $[A_{\rm re}]_{ij} = A_{ij}$ for all $(i,j) \in \widehat{\mathcal{I}}_1^c \times \widehat{\mathcal{I}}_2^c$, and set $[A_{\rm re}]_{ij}$ arbitrarily when $i \in \widehat{\mathcal{I}}_1$ or $j \in \widehat{\mathcal{I}}_2$, but subject to: $\|[A_{\rm re}]_{i*}\|_1 \leq \widehat{d}_1$ for all $i \in \widehat{\mathcal{I}}_1$ and $\|[A_{\rm re}]_{*j}\|_1 \leq \widehat{d}_2$ for all $j \in \widehat{\mathcal{I}}_2$.

6: For example, $[A_{\rm re}]_{ij} = A_{ij} w_i w'_j$ for all $(i,j) \in [n_1] \times [n_2]$, where $w_i = \frac{\widehat{d}_1}{D_i} \wedge 1$ and $w'_j = \frac{\widehat{d}_2}{D'_j} \wedge 1$ satisfies the conditions in Step 5.

The next key lemma shows that $D_{(\alpha)}$ is a good proxy for $d_{\max}$ and d under a SBM:

Lemma 4 *Let $\alpha = \lfloor n_1 / \overline{D} \rfloor$ where $\overline{D}$ is the average degree on side 1 as defined earlier. Under assumption (A2), the following hold, with probability at least $1 - 3e^{-n_1/80} - e^{-n_1/(\beta k_2)}$,*

(a) $d_{\max}/2 \leq D_{(\alpha)} \leq 3 d_{\max}/2$.

(b) $\big|i : D_i > 3 D_{(\alpha)}\big| \leq 10 n_1 / d$.

Conditions in (31) are quite mild: The first and second require that the clusters associated with the maximum degree are not too small. In the balanced case, where all clusters are of equal size, we have $n_{rt} = n_r / k_r$ (for all $t \in [k_r]$ and $r = 1, 2$) hence the condition is satisfied with $\beta = 1$. In general, β measures deviations from balancedness. Note that (A1) and the first two conditions in (31) do not imply each other. The last condition in (31) is satisfied if $\bar{d} \to \infty$ slower than n_1 and faster than $\max\{k_1, k_2\}$ (assuming $\beta = O(1)$ and $n_1 \asymp n_2$).

A result similar to Lemma 4 holds for the column degrees with appropriate modifications: Let $D'_j = \sum_i A_{ij}$ be the column degrees with expectation $d'_j = \sum_i p_{ij}$, and define the corresponding average $\bar{d}' = \frac{1}{n_2} \sum_j d'_j$ and $d'_{\max} = \max_j d'_j$. We, however, keep d as defined in (30).

Lemma 5 *Let $\alpha' = \lfloor n_2 / \overline{D}' \rfloor$ where $\overline{D}'$ is the average degree on side 2 as defined earlier. Under assumption (A2), the following hold, with probability at least $1 - 3e^{-n_2/80} - e^{-n_1/(\beta k_1)}$,*

(a) $d'_{\max}/2 \leq D'_{(\alpha')} \leq 3 d'_{\max}/2$.

(b) $\big|j : D'_j > 3 D'_{(\alpha')}\big| \leq 10 n_2 / d$.

Equipped with Lemmas 4 and 5, we have the following for Algorithm 1:

Theorem 3 *Assume that $A \in \mathbb{R}^{n_1 \times n_2}$ is generated from the SBM model satisfying (A2). Then, for any $r \geq 1$, with probability at least $1 - n_2^{-r} - 6e^{-n_1/80} - 2e^{-n_1/\beta \max\{k_1,k_2\}}$, the regularized output A_{re} of Algorithm 1 (with $\tau = 3$) satisfies*

$$\|A_{re} - \mathbb{E}[A]\|_{op} \leq C_3 r^{3/2} \sqrt{d}, \tag{32}$$

where d is as in (30) and $C_3 > 0$ is a universal constant.

Proof [Proof of Theorem 3] Recall the definitions of $\widehat{\mathcal{I}}_r$ and $\widehat{d}_r$ ($r = 1, 2$) in Algorithm 1. On the union of the events described in Lemmas 4 and 5, both $|\widehat{\mathcal{I}}_1|$ and $|\widehat{\mathcal{I}}_2|$ are bounded by $10 n_2/d$ (since $n_1 \leq n_2$), $\widehat{d}_1 = 3 D_{(\alpha)} \leq 9 d_{\max}/2$ and $\widehat{d}_2 = 3 D'_{(\alpha')} \leq 9 d'_{\max}/2$. Since $d_{\max} \leq n_2 \|P\|_\infty = d$ and $d'_{\max} \leq n_1 \|P\|_\infty \leq d$, we can apply Theorem 2 with $d' = 9d/2$ completing the proof. ■

Theorem 3 thus provides the same concentration guarantee as in Theorem 2 without the knowledge of d. See Appendix A.2 for the proof of the two lemmas of this section.

Remark 9 (Comparison with existing work) *Results of the form (8) hold for A itself without any regularization if one further assumes that $d \gtrsim \log n_2$. These result are often derived for the symmetric case; see for example Tomozei and Massoulié (2010), Lei et al. (2015) and Chen and Xu (2016); or Bandeira et al. (2016) for the more general result with $d = \max_i \sum_j p_{ij}$. In order to break the $\log n_2$ barrier on the degrees, one has to resort to some form of regularization. When d is given, the general regularization for the adjacency matrix is to either to remove the high degree nodes as in Chin et al. (2015) or reduce their effect as in Le et al. (2017) and Theorem 2 above. In contrast, there is little work on data-driven regularization for the adjacency matrix. One such algorithm was investigated in Gao et al. (2017) for the special case of the SPBB model—discussed in Example 1 (Section 5)—under the assumption $a = O(b)$. The algorithm truncates the degrees to a multiple of the average degree, i.e., $\widehat{d}_1 = C\overline{D}$ for some large $C > 0$. A possible choice of $C = 5$ is given in Yun and Proutiere (2014a) assuming that the expected degrees of the nodes are similar.*

In contrast to existing results, our data-driven regularization holds for a general SBM and only requires the mild assumptions in (A2) while preserving the same upper bound (32) that holds with the knowledge of d. In particular, we do not require $\min_{k\ell} \Psi_{k\ell} \asymp \max_{k\ell} \Psi_{k\ell}$ (which is what $a = O(b)$ means in the SPBB model). Algorithm 1 enables effective and provable regularization without knowing any parameters.

5. Consistency results

We now state our various consistency results. The proofs are deferred to Appendix A.4. We start with a refinement of Theorem 1 for the specific algorithm SC-1 given in Algorithm 2.

Theorem 4 *Consider the spectral algorithm* SC-1 *given in Algorithm 2. Assume $k_1 = k =: \min\{k_1, k_2\}$, and for a sufficiently small $C > 0$,*

$$k d\, \sigma_k^{-2} \leq C (1 + \kappa)^{-2}.$$

Then, under the SBM model satisfying (A2), w.h.p.,

$$\overline{\rm Mis}(\mathcal{P}_\kappa(\hat{Z}_1), \bar{Z}_1) \;\lesssim\; (1+\kappa)^2 \beta_1\Big(\frac{d}{\sigma_k^2}\Big).$$

Algorithm 2 SC-1

1: Apply regularization Algorithm 1 to A to obtain $A_{\rm re}$.
2: Obtain the k-truncated SVD of $A_{\rm re}$ as $A_{\rm re}^{(k)} = \hat{Z}_1\hat{\Sigma}\hat{Z}_2^T$. See (14).
3: Output an element of $\mathcal{P}_\kappa(\hat{Z}_1)$, i.e., a κ-approximate k-means solution for input $\hat{Z}_1$.

Algorithm 3 SC-RR

1: Apply regularization Algorithm 1 to A to obtain $A_{\rm re}$.
2: Obtain the best rank k approximation of $A_{\rm re}$, that is, $A_{\rm re}^{(k)} = \mathscr{T}_k(A_{\rm re})$. See (14).
3: Output an element of $\mathcal{P}_\kappa(A_{\rm re}^{(k)})$, i.e., a κ-approximate k-means solution for input $A_{\rm re}^{(k)}$.

where β_1 is given in (A1) *and d is defined in* (8).

One can take κ to be a fixed small constant say 1.5, since there are κ-approximate k-means algorithms for any $\kappa > 1$. In that case, $(1+\kappa)^2$ can be absorbed into other constants, and the bound in Theorem 4 is qualitatively similar to Theorem 1.

5.1. Reduced-rank SC

Theorem 4 implicitly assumes $\sigma_k > 0$, otherwise the bound is vacuous. This assumption is clearly violated if B is rank deficient (or equivalently, P has rank less than k). A variant of SC suggested in Yun and Proutiere (2014a) and Gao et al. (2018) can resolve this issue. The idea is to use the entire rank k approximation of $A_{\rm re}$, and not just the singular vector matrix $\hat{Z}_1$, as the input to the k-means step. This approach, which we call reduced-rank SC, or SC-RR, is detailed in Algorithm 3. Recall the SV truncation operator $\mathscr{T}_k$ given in (14). It is well-known that $\mathscr{T}_k$ maps every matrix to its best rank-k approximation in Frobenius norm, i.e.,

$$\mathscr{T}_k(A_{\rm re}) = \min\big\{\|R - A_{\rm re}\|_F : \ {\rm rank}(R) \le k\big\}$$

with the approximation error satisfying

$$\|\mathscr{T}_k(A_{\rm re}) - A_{\rm re}\|_{\rm op} = \sigma_{k+1}(A_{\rm re}). \tag{33}$$

SC-RR uses this best rank-k approximation as a denoised version of $A_{\rm re}$ and runs a k-means algorithm on its rows. To analyze SC-RR, we need to replace bound (9) in Step 2 with an appropriate modification. The following lemma replaces Lemma 3 and provides the necessary bound in this case.

Lemma 6 *Let $A_{re}^{(k)} = \mathscr{T}_k(A_{re})$ be the k-truncated SVD of A_{re} and assume that the concentration bound* (8) *holds. Then,*

$$\|A_{re}^{(k)} - P\|_F \le C\sqrt{8\,kd}. \tag{34}$$

Comparing with (9), we observe that (34) provides an improvement by removing the dependence on the singular value gap σ_k. However, we note that in terms of the relative

error, i.e., $\|A_{\rm re}^{(k)} - P\|_F/\|P\|_F$ this may or may not be an improvement. There are cases where $\|P\|_F \approx \sqrt{k}\sigma_k$, in which case the relative error predicted by (34) is $O(\sqrt{d}/\sigma_k)$, similar to the relative error bound based on (9) (since $\|\bar{Z}_1 U_\psi Q\|_F = \sqrt{k}$); see Example 1 below.

Following through the three-step analysis of Section 3.1, with (9) replaced with (34), we obtain a qualitatively different bound on the misclassification error of Algorithm 3. The key is that center separation of P treated as a k-means matrix is different from that of $\bar{Z}_1 U_\psi Q$. Note that P is indeed a valid k-means matrix according to Definition (15); in fact, $P \in \mathbb{M}_{n_1,n_2}^{k_1}$. Similarly, $P^T \in \mathbb{M}_{n_2,n_1}^{k_2}$. Let us define

$$\Psi_{1,\wedge}^2 := \min_{(s,t):\, s\neq t} \sum_{\ell=1}^{k_2} \pi_{2\ell}(\Psi_{s\ell} - \Psi_{t\ell})^2, \tag{35}$$

$$\widetilde{\Psi}_{1,\wedge}^2 := \min_{(s,t):\, s\neq t} \Big[\pi_{1t} \sum_{\ell=1}^{k_2} \pi_{2\ell}(\Psi_{s\ell} - \Psi_{t\ell})^2\Big]. \tag{36}$$

Theorem 5 *Consider the spectral algorithm* SC-RR *given in Algorithm 3. Assume that for a sufficiently small $C_1 > 0$,*

$$kd\,\widetilde{\Psi}_{1,\wedge}^{-2} \le C_1(1+\kappa)^{-2}. \tag{37}$$

Then, under the SBM model satisfying (A2), with d as defined in (8)*, w.h.p.,*

$$\overline{\rm Mis}(\mathcal{P}_\kappa(A_{re}^{(k)}), P) \ \le \ C_1^{-1}(1+\kappa)^2\Big(\frac{kd}{\Psi_{1,\wedge}^2}\Big).$$

As is clear from the proof, one can take $C_1 = 1/(32C^2)$ where C is the constant in concentration bound (8). Condition (37) can be replaced with the stronger assumption

$$kd\,(\pi_{1,\wedge}\Psi_{1,\wedge}^2)^{-1} \le C_1(1+\kappa)^{-2} \tag{38}$$

a where $\pi_{1,\wedge} := \min_{t\in[k_1]}\pi_{1t}$, since $\widetilde{\Psi}_{1,\wedge}^2 \ge \pi_{1,\wedge}\Psi_{1,\wedge}^2$.

Although the bounds of Theorems 4 and 5 are different, surprisingly, in the case of the planted partition model, they give the same result as the next example shows.

Example 1 (Planted partition model, symmetric case) *Let us consider the simplest symmetric SBM, the symmetric balanced planted partition (SBPP) model, and consider the consequences of Theorems 4 and 5 in this case. Recall that in the symmetric case we drop index r from k_r, n_r, n_{rj}, $\bar{N}_r$, β_r, $\Psi_{r,\wedge}$ and so on. SBPP is characterized by the following assumptions:*

$$\Psi = bE_k + (a-b)I_k, \ \ a \ge b, \quad \pi_j = n_j/n = \frac{1}{k}, \ \forall j \in [k].$$

Here, $E_k \in \mathbb{R}^{k\times k}$ is the all ones matrix and balanced *refers to all the communities being of equal size, leading to cluster proportions $\pi_j = 1/k$. In particular, $\beta = 1$, as defined in* (A1)*. We have $\bar{B} = \bar{N}^{1/2}\Psi\bar{N}^{1/2} = \Psi/k$, recalling $\bar{N} = {\rm diag}(\pi_j)$. Hence, the smallest singular value of $\bar{B}$ is $\sigma_k = (a-b)/k$. Theorem 4 gives the following result:*

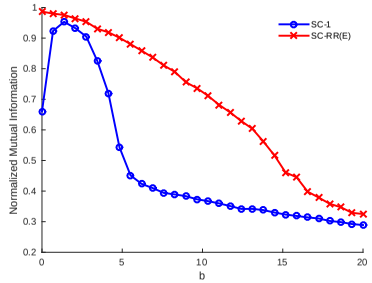

Figure 1: An example of the performance boost of SC-RR (or SC-RRE) relative to SC-1. The data is generated from the bipartite version of Example 2 with $n_2 = 2n_1 = 1000$, $k_1 = k_2 = 4$, $\pi_{r\ell} = n_r/k_r$ for all $\ell \in [k_r]$, $r = 1, 2$, and $\Psi = 2bE_4 + \mathrm{diag}(16, 16, 16, 2)$ similar to (39). The key is the significant difference in the two smallest diagonal elements of Ψ. The plot shows the normalized mutual information (a measure of cluster quality) between the output of the two spectral clustering algorithms and the true clusters, as b varies. Only row clusters are considered. The plot shows a significant improvement for SC-RR(E) relative to SC-1 over a range of b. As b increases, the relative difference between Ψ_{33} and Ψ_{44} reduces and the model approaches that of Example 1, leading to similar performances for both algorithms as expected. It is interesting to note that the monotone nature of the performance of SC-RR(E) as a function of b and the non-monotone nature of that of SC-1 is reflected in the upper bounds (40) and (41).

Corollary 2 *Under the SBPP model, as long as $k^3a/(a-b)^2$ is sufficiently small,* SC-1 *has average misclassification error of $O(k^2a/(a-b)^2)$ with high probability.*

Now consider SC-RR. *Using definitions* (35), *we have $k\widetilde{\Psi}_\wedge^2 = \Psi_\wedge^2 = 2(a-b)^2/k$. Then, Theorem 5 gives the exact same result for* SC-RR*:*

Corollary 3 *Corollary 2 holds with* SC-1 *replaced with* SC-RR.

Results of Corollary 2 and 3 are consistency results as long as $k^2a/(a-b)^2 = o(1)$. A typical example is when $k = O(1)$, $a = a_0 f_n$, $b = b_0 f_n$, $a_0 \asymp 1$ and $b_0 \asymp 1$ for some $f_n \to \infty$ as $n \to \infty$. Then, SC-1 *and* SC-RR *are both consistent at a rate $O(f_n^{-1})$.*

Let us now give an example where SC-1 and SC-RR behave differently.

Example 2 *Consider the symmetric balanced SBM, with*

$$\Psi = bE_k + \mathrm{diag}(\alpha_1, \ldots, \alpha_k), \quad \pi_j = n_j/n = \frac{1}{k}, \ \forall j \in [k]. \tag{39}$$

As in Example 1, we have dropped the index r determining the side of network in the bipartite case. Let us assume that $\alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_k \geq 0$. We have

$$k\widetilde{\Psi}_\wedge^2 = \Psi_\wedge^2 = k^{-1} \min_{s \neq t} \sum_\ell (\Psi_{s\ell} - \Psi_{t\ell})^2 = k^{-1}(\alpha_{k-1}^2 + \alpha_k^2).$$

Thus, Theorem 5 gives the following: With ρ defined as follows:

$$\rho := k^2 \frac{\alpha_1 + b}{\alpha_{k-1}^2 + \alpha_k^2}, \tag{40}$$

as long as $k\rho$ is sufficiently small, SC-RR *has average misclassification error $O(\rho)$ with high probability.*

To determine the performance of SC-1*, we need to estimate σ_k, the smallest singular value of $\bar{B} = \bar{N}^{1/2}\Psi\bar{N}^{1/2} = \Psi/k$. Since Ψ is obtained by a rank-one perturbation of a diagonal matrix, it is well-known that when $\{\alpha_t\}$ are distinct, the eigenvalues of Ψ are obtained by solving $\sum_{t=1}^k 1/(\alpha_t - \lambda) = -1/b$; the case where some of the $\{\alpha_t\}$ are repeated can be reasoned by the taking the limit of the general case. By plotting $\lambda \mapsto \sum_{t=1}^k 1/(\alpha_t - \lambda)$ and looking at the intersection with $\lambda \mapsto -1/b$, one can see that the smallest eigenvalue of Ψ, equivalently its smallest singular value, is in $[\alpha_k, \alpha_{k-1}]$, and can be made arbitrarily close to α_k by letting $b \to 0$. Letting $\alpha_k + \varepsilon_k(\alpha; b)$ denote this smallest singular value, we have $0 \leq \varepsilon_k(\alpha; b) \to 0$ as $b \to 0$.*

It follows that $\sigma_k = \sigma_k(\bar{B}) = k^{-1}(\alpha_k + \varepsilon_k(\alpha; b))$. Theorem 4 gives the following: With ρ defined as

$$\rho := k^2 \frac{\alpha_1 + b}{(\alpha_k + \varepsilon_k(\alpha; b))^2}, \tag{41}$$

as long as $k\rho$ is sufficiently small, SC-1 *has average misclassification error $O(\rho)$ with high probability.*

Comparing (41) *with* (40)*, the ratio of the two bounds is $(\alpha_{k-1}^2 + \alpha_k^2)/(\alpha_k + \varepsilon_k(\alpha; b))^2 \to 1 + (\alpha_{k-1}/\alpha_k)^2$ as $b \to 0$. This ratio could be arbitrarily large depending on the relative sizes of α_k and α_{k-1}. Thus, when the bounds give an accurate estimate of the misclassification rates of* SC-1 *and* SC-RR*, we observe that* SC-RR *has a clear advantage. This is empirically verified in Figure 1, for moderately dense cases. (In the very sparse case, the difference is not very much empirically.) In general, we expect* SC-RR *to perform better when there is a large gap between σ_k and σ_{k-1}, the two smallest nonzero singular values of $\bar{B}$.*

Example 3 (Rank-deficient connectivity) *Consider an extreme case where Ψ is rank one: $\Psi = uv^T$ for some $u, v \in \mathbb{R}_+^k$, where again for simplicity we have assumed $k_1 = k_2 = k > 1$. Also assume $n_1 \asymp n_2 = n$ and $\pi_{rj} = 1/k$ for $j \in [k]$ and $r = 1, 2$, i.e., the clusters are balanced. In this case, $\bar{B} = \Psi/k$ and $\sigma_k = 0$, hence Theorem 4 does not provide any guarantees for* SC-1*. However, Theorem 3 is still valid. We have $k\widetilde{\Psi}_{1,\wedge}^2 = \Psi_{1,\wedge}^2 = k^{-1}\|v\|_2^2 \min_{s \neq t}(u_s - u_t)^2$ and $d \lesssim \|\Psi\|_\infty \leq \|u\|_\infty \|v\|_\infty$. It follows from Theorem 3 that* SC-RR *has average misclassification rate bounded as*

$$O\Big(\frac{k^2\|u\|_\infty\|v\|_\infty}{\|v\|_2^2 \min_{s \neq t}(u_s - u_t)^2}\Big)$$

whenever k times the above is sufficiently small. This is a consistency result assuming that the coordinates of u are different, all the elements of u and v are growing at the same rate and $k = O(1)$.

Algorithm 4 SC-RRE

1: Apply degree regularization Algorithm 1 to A to obtain $A_{\rm re}$.
2: Obtain $A_{\rm re}^{(k)} = \hat{Z}_1\hat{\Sigma}\hat{Z}_2^T$, the k-truncated SVD of $A_{\rm re}$.
3: Output $\mathscr{K}(\hat{Z}_1\hat{\Sigma})$ where $\mathscr{K}$ is an isometry-invariant κ-approximate k-means algorithm.

5.2. Efficient reduced-rank SC

The SC-RR algorithm discussed above has the disadvantage of running a k-means algorithm on vectors in $\mathbb{R}^n$ (the rows of $A_{\rm re}^{(k)}$, or in the ideal case the rows of P). We now introduce a variant of this algorithm that has the same performance as SC-RR in terms of misclassification rate, while computationally is as efficient as SC-1. This approach which we call efficient reduced-rank spectral clustering, SC-RRE, is detailed in Algorithm 4. The efficiency comes from running the k-means step on vectors in $\mathbb{R}^k$ which is usually a much smaller space than $\mathbb{R}^n$ ($k \ll n$ in applications).

For the k-means step in SC-RRE, we need a k-means (type) algorithm $\mathscr{K}$ that only uses the pairwise distances between the data points. We call such k-means algorithms *isometry-invariant*:

Definition 3 *A k-means (type) algorithm $\mathscr{K}$ is isometry-invariant if for any two matrices $X^{(r)} \in \mathbb{R}^{n\times d_r}, r = 1, 2$, with the same pairwise distances among points—i.e., $d(x_i^{(1)}, x_j^{(1)}) = d(x_i^{(2)}, x_j^{(2)})$ for all distinct $i, j \in [n]$, where $(x_i^{(r)})^T$ is the ith row of $X^{(r)}$—one has*

$$\overline{\rm Mis}(\mathscr{K}(X^{(1)}), \mathscr{K}(X^{(2)})) = 0.$$

Although the rows of $\mathscr{K}(X^{(1)})$ and $\mathscr{K}(X^{(2)})$ lie in spaces of possibly different dimensions, it still makes sense to talk about their relative misclassification rate, since this quantity only depends on the membership information of the k-means matrices and not their center information. We have implicitly assumed that $d(\cdot,\cdot)$ defines a family of distances over all Euclidean spaces $\mathbb{R}^d, d = 1, 2, \ldots$. This is obviously true for the common choice $d(x, y) = \|x - y\|_2$. If algorithm $\mathscr{K}$ is randomized, we assume that the same source of randomness is used (e.g., the same random initialization) when applying to either of the two cases $X^{(1)}$ and $X^{(2)}$.

The following result guarantees that SC-RRE behaves the same as SC-RR when one uses an isometry-invariant approximate k-means algorithm in the final step.

Theorem 6 *Consider the spectral algorithm* SC-RRE *given in Algorithm 4. Assume that for a sufficiently small $C_1 > 0$, (37) holds. Then, under the SBM model of Section 2, w.h.p.,*

$$\overline{\rm Mis}(\mathscr{K}(\hat{Z}_1\hat{\Sigma}), P) \;\le\; C_1^{-1}\,(1+\kappa)^2\Big(\frac{kd}{\Psi_{1,\wedge}^2}\Big).$$

Remark 10 (Comparison with existing results) *The existing results hold under different assumptions. Table 1 provides a summary of some the recent results. The "p vs. q" denotes the assortative case where the diagonal entries of B are above p and off-diagonal entries are below q. The "e.v. dep" denotes whether the consistency result depends on the*

kth eigenvalue or singular value of B (or Ψ). The "k-means" column records the dimension of the matrix on which a k-means algorithm is applied. To allow for better comparison, let us consider a typical (special) case of the setting in this paper, where $n_1 = n_2$, $k_1 = k_2$, Ψ is symmetric and $d \asymp \Psi_{1,\wedge}$. Then all the spectral methods in Table 1 have misclassification rate guarantees that are polynomial in d^{-1}. General SBMs without assortative assumption (e.g., "p vs. q") were considered in earlier literature (Rohe et al., 2011; Lei et al., 2015). However, the theoretical guarantees were provided for sufficiently dense networks. The generalization to sparse networks is considered in Yun and Proutiere (2014a), Chin et al. (2015), Gao et al. (2017) and Gao et al. (2018) using some regularization on the adjacency matrix. However, these results only apply to assortative networks and with extra assumptions. Overall, the algorithms SC-1 *and* SC-RRE *require less assumptions than any existing works. We also note that the guarantees of Theorems 5 and 6 in the context of a general SBM are new and have not appeared before (not even in the dense case).*

5.3. Results in terms of mean parameters

One useful aspect of SC-RR(E) is that one can state its corresponding consistency result in terms of the *mean parameters* of the block model. Such results are useful when comparing to the optimal rates achievable in recovering the clusters. The row mean parameters of the SBM in Section 2 are defined as $\Lambda_{s\ell} := B_{s\ell}\, n_{2\ell}$ for $(s, \ell) \in [k_1] \times [k_2]$ which we collect in a matrix $\Lambda = (\Lambda_{s\ell}) \in \mathbb{R}^{k_1\times k_2}$. To get an intuition for Λ note that

$$\mathbb{E}[AZ_2] = PZ_2 = Z_1BN_2 = Z_1\Lambda.$$

Each row of AZ_2 is obtained by summing the corresponding row of A over each of the column clusters to get a k_2 vector. In other words, the rows of AZ_2 are the sufficient statistics for estimating the row clusters, had we known the true column clusters. Note that $\mathbb{E}[(AZ_2)_{i*}] = z_{1i}^T\Lambda$, where the notation $(\cdot)_{i*}$ denotes the ith row of a matrix. In other words, we have $\mathbb{E}[(AZ_2)_{i*}] = \Lambda_{s*}$ if node i belongs to row cluster s. Let us define the minimum separation among these row mean parameters:

$$\Lambda_\wedge^2 := \min_{t\neq s} \|\Lambda_{s*} - \Lambda_{t*}\|^2. \tag{42}$$

We have the following corollary of Theorem 5 which is proved in Appendix A.4.

Corollary 4 *Assume that* $\pi_{r,\wedge} := \min_t \pi_{rt} \geq (\beta_r k_r)^{-1}$ *for* $r = 1, 2$, *and let* $k = \min\{k_1, k_2\}$ *and* $\alpha = n_2/n_1$. *Consider the spectral algorithm* SC-RR *given in Algorithm 3. Assume that for a sufficiently small* $C_1 > 0$,

$$\beta_1\beta_2\, k\, k_1 k_2\, \alpha \frac{\|\Lambda\|_\infty}{\Lambda_\wedge^2} \leq C_1(1+\kappa)^{-2}. \tag{43}$$

Then, under the SBM model of Section 2, w.h.p.,

$$\overline{\mathrm{Mis}}(\mathcal{P}_\kappa(A_{re}^{(k)}), P) \;\leq\; C_1^{-1}\,(1+\kappa)^2\beta_2\, k\, k_2\, \alpha \frac{\|\Lambda\|_\infty}{\Lambda_\wedge^2}.$$

We note that the exact same result as Corollary 4 holds for SC-RRE assuming the k-means step uses an isometry invariant algorithm as discussed in Section 5. We refer to Zhou and Amini (2018) for an application of this result in constructing optimal clusterings in the bipartite setting.

6. Extensions

6.1. Clusters on one side only

The bipartite setting allows for the case where only one side has clusters. Assume that $A \sim \mathrm{Ber}(P)$ in the sense of (5) and, for example, only side 2 has k_2 clusters. Then we can model the problem as P having k_2 distinct columns. However, within columns we do not require any block constant structure, i.e., the k_2 distinct columns of P are general vectors in $[0,1]^{n_1}$. This problem can be considered a special case of the SBM model discussed in Section 2 where $k_1 = n_1$: We recall that $P = \bar{Z}_1 \bar{B} \bar{Z}_2^T$ where $\bar{Z}_1$ is an orthogonal matrix of dimension $n_1 \times k_1$, hence $\bar{Z}_1 = I_{n_1}$. All the consistency results of the paper thus hold, where we set $k_1 = n_1$.

6.2. More clusters than rank

One of the unique features of the bipartite setting relative to the symmetric one is the possibility of having more clusters on one side of the network than the rank of the connectivity matrix. In the notation established so far, this is equivalent to $k_1 > k = \min\{k_1, k_2\}$. Let us first examine the performance of SC-1. Recall the SVD of $\bar{B} = U_\psi \Sigma V_\psi^T$, as given in Lemma 1. In contrast to the case $k_1 = k$, where the singular vector matrix U_ψ has no effect on the results (cf. Theorem 4), in the case $k_1 > k$, these singular vectors play a role. Recall that U_ψ is a $k_1 \times k$ orthogonal matrix, i.e., $U_\psi \in \mathbb{O}^{k_1 \times k}$. For a matrix $k_1 \times k_1$ matrix M, and index set $\mathcal{I} \subset [k_1]$, let $M_\mathcal{I}$ be the principal sub-matrix of M on indices $\mathcal{I} \times \mathcal{I}$. We assume the following *incoherence* condition:

$$\max_{\mathcal{I} \subset [k_1]:\, |\mathcal{I}|=2} \|(U_\psi U_\psi^T - I_{k_1})_\mathcal{I}\|_{\mathrm{op}} \;\leq\; 1 - \rho_1, \tag{44}$$

for some $\rho_1 \in (0, 1]$. Letting u_s^T be the sth row of U_ψ, for $s \in [k_1]$, we note that $(U_\psi U_\psi^T)_{st} = \langle u_s, u_t \rangle$, that is, $U_\psi U_\psi^T$ is the Gram matrix of the vectors u_s, $s \in [k_1]$. We have the following extension of Theorem 4:

Algorithm 5 SC-RRE for sub-Gaussian noise

1: Obtain $A^{(k)} = \hat{Z}_1 \hat{\Sigma} \hat{Z}_2^T$, the k-truncated SVD of A.
2: Output $\mathscr{K}(\hat{Z}_1 \hat{\Sigma})$ where $\mathscr{K}$ is an isometry-invariant κ-approximate k-means algorithm.

Theorem 7 *Consider the spectral algorithm* SC-1 *given in Algorithm 2. Assume that for a sufficiently small* $C > 0$,

$$kd\, \sigma_k^{-2} \leq C(1+\kappa)^{-2}\rho_1.$$

Then, under the SBM model of Section 2, w.h.p.,

$$\overline{\mathrm{Mis}}(\mathcal{P}_\kappa(\hat{Z}_1), \bar{Z}_1) \;\lesssim\; (1+\kappa)^2\beta_1 \Big(\frac{k}{\rho_1 k_1}\Big)\Big(\frac{d}{\sigma_k^2}\Big). \tag{45}$$

The theorem is proven in Appendix A.5. The factor $k/(k_1\rho_1) = k_2/(k_1\rho_1)$ in (45) is the price one pays for the asymmetry of the number of communities, when applying SC-1. (Recall that $k := \min\{k_1, k_2\} = k_2$ by assumption.) Note that increasing k_1 decreases k/k_1, and at the same time, often increases ρ_1 since it is harder to have many nearly orthogonal unit vectors in low dimensions.

Remark 11 *It is interesting to note that in contrast to* SC-1, *the consistency results for* SC-RR(E) *do not need any modification for the case where the number of clusters is larger than the rank. In other words, the same Theorems 5 and 6 hold regardless of whether* $k_1 = k$ *or* $k_1 > k$, *though the difficulty of the latter case will be reflected implicitly via a reduction in* $\Psi_{1,\wedge}^2$ *and* $\tilde{\Psi}_{1,\wedge}^2$.

6.3. General sub-Gaussian case

The analysis presented so far for network clustering problems can be extended to general sub-Gaussian similarity matrices. Consider a random matrix A with block constant mean

$$P := \mathbb{E}[A] = Z_1 B Z_2^T, \tag{46}$$

as defined in (4), and where $Z_r, r = 1, 2$ are again membership matrices. However, here A is not necessarily an adjacency matrix. We assume that A_{ij} are sub-Gaussian random variables independent across $(i, j) \in [n_1] \times [n_2]$ and let $\sigma := \max_{i,j} \|A_{ij} - \mathbb{E}A_{ij}\|_{\psi_2}$. We recall that a univariate random variable X is called sub-Gaussian if its sub-Gaussian norm is finite (Vershynin, 2018):

$$\|X\|_{\psi_2} := \inf\{t > 0 : \mathbb{E}\exp(X^2/t^2) \leq 2\} < \infty \tag{47}$$

Note that we do not assume A_{ij} and $A_{i'j'}$ to have the same distribution or the same sub-Gaussian norm even if $Z_{1i} = Z_{1i'}$ and $Z_{2j} = Z_{2j'}$.

Adapting Algorithm 4 to the general sub-Gaussian case, we have Algorithm 5 with the following performance guarantee:

Theorem 8 *Let $B_{1,\wedge}$ and $\widetilde{B}_{1,\wedge}$ be defined as in (35) with Ψ replaced with B and let*

$$\bar{n} := (n_1^{-1} + n_2^{-1})^{-1}.$$

Consider the spectral algorithm for sub-Gaussian noise given in Algorithm 5. Assume that for a sufficiently small $C_1 > 0$,

$$\frac{\sigma^2}{\bar{n}} k \, \widetilde{B}_{1,\wedge}^{-2} \le C_1 (1+\kappa)^{-2}. \tag{48}$$

Then, under the model defined in this section,

$$\overline{\mathrm{Mis}}(\mathscr{K}(\hat{Z}_1 \hat{\Sigma}), P) \;\le\; C_1^{-1} \, (1+\kappa)^2 \Big(\frac{\sigma^2}{\bar{n}} \frac{k}{B_{1,\wedge}^2} \Big).$$

with probability at least $1 - 2e^{-(n_1+n_2)}$.

See Appendix A.6 for the proof. Consider the typical case where the number of clusters k and the separation between them, $B_{1,\wedge}^2$, remains fixed as $\bar{n} \to \infty$. Then, $\sigma^2/\bar{n}$ plays the role of the signal-to-noise ratio (SNR) for the clustering problem and as long as $\sigma^2/\bar{n} = o(1)$, Algorithm 5 is consistent in recovering the clusters. Of course, there are other conditions under which we have consistency, e.g., cluster separation quantity $B_{1,\wedge}^2$ could go to zero, and k could grow as well (as $\bar{n} \to \infty$) and as long as $\sigma^2/\bar{n} = o(B_{1,\wedge}^2/k)$ the algorithm remains consistent.

6.4. Inhomogeneous random graphs

Up to now, we have stated consistency results for the SBM of Section 2. SBM is often criticized for having constant expected degree for nodes in the same community, in contrast to degree variation observed in real networks. (Although, SBM in the sparse regime $d = O(1)$ can still exhibit degree variation within a community, since the node degrees will be roughly $\mathrm{Poi}(d)$ distributed, showing little concentration around their expectations unless $d \to \infty$.) The popular remedy is to look at the degree-corrected block model (DC-SBM) (Karrer and Newman, 2011; Zhao et al., 2012; Gao et al., 2018). Instead, we consider the more general inhomogeneous random graph model (IRGM) (Söderberg, 2002; Bollobás et al., 2007) which might be more natural in practice, since it does not impose the somewhat parametric restrictions of DC-SBM on the mean matrix.

We argue that consistency results for the spectral clustering can be extended to a general inhomogeneous random graph (IRGM) model $A \sim \mathrm{Ber}(P)$, assuming that the mean matrix can be well-approximated by a block structure. Let us consider a scaling as before:

$$P := \frac{P^0}{\sqrt{n_1 n_2}}, \quad \text{and take} \quad d = \sqrt{\frac{n_2}{n_1}} \|P^0\|_\infty. \tag{49}$$

Note that $P \in [0,1]^{n_1 \times n_2}$ is a not assumed to have any block structure. However, we assume that there are membership matrices $Z_r \in \mathbb{H}_{n_r,k_r}$, $r = 1,2$ such that P over the blocks defined by Z_1 and Z_2 is approximately constant. Let

$$\widetilde{B}_{st} := \frac{1}{n_{1s} n_{2t}} \sum_{ij} P_{ij} (Z_1)_{is} (Z_2)_{jt}, \quad s \in [k_1], \; t \in [k_2] \tag{50}$$

be the mean (or average) of P over these blocks, and let $\widetilde{B} = (\widetilde{B}_{st}) \in [0,1]^{k_1 \times k_2}$. Compactly, $\widetilde{B} = N_1^{-1} Z_1^T P Z_2 N_2^{-1}$, in the notation established in Section 2. We can define the SBM approximation of P as

$$\widetilde{P} := Z_1 \widetilde{B} Z_2^T = \bar{Z}_1 \bar{Z}_1^T P \bar{Z}_2 \bar{Z}_2^T = \Pi_1 P \Pi_2, \tag{51}$$

recalling $\bar{Z}_r = Z_r N_r^{-1/2}$ and introducing the notation $\Pi_r = \bar{Z}_r \bar{Z}_r^T$. Note that Π_r is a rank k_r projection matrix. According to (51), the map $P \mapsto \Pi_1 P \Pi_2$ takes a (mean) matrix to its SBM approximation relative to Z_1 and Z_2. We can thus define a similar approximation to P^0,

$$\widetilde{P}^0 := \Pi_1 P^0 \Pi_2, \quad \text{noting that} \quad \widetilde{P} = \frac{\widetilde{P}^0}{\sqrt{n_1 n_2}}.$$

In order to retain the qualitative nature of the consistency results, the deviation of each entry P_{ij}^0 from its block mean $(\widetilde{P}^0)_{ij}$ should not be much larger than $(\widetilde{P}^0)_{ij}^{1/2}$. In fact, we allow for a potentially larger deviation, assuming that:

$$\frac{1}{\sqrt{n_1 n_2}} \|P^0 - \widetilde{P}^0\|_F \le C_0 \sqrt{d}, \tag{52}$$

for some constant $C_0 > 0$ and a satisfying (49). The key is the following concentration result:

Proposition 2 *Assume that $A \sim \mathrm{Ber}(P)$ as in (5), with $n_1 \le n_2$, and let A_{re} be obtained from A by the regularization procedure in Theorem 2, with $d' = d$ as given in (49). Let $\widetilde{P}$ be as defined in (51), and assume that it satisfies (52). Then, with probability at least $1 - n_2^{-c}$,*

$$\|A_{re} - \widetilde{P}\|_{op} \le c_2 \sqrt{d}. \tag{53}$$

Proposition 2 provides the necessary concentration bound required in Step 1 of the analysis outlined in Section 3.1. In other words, bound (53) replaces (8) by guaranteeing a similar order of deviation for A_{re} around $\widetilde{P}$ instead of P. Thus, all the results of the paper follow under an IRGM with a mean matrix satisfying (52), with the modification that the connectivity matrix and all the related quantities (such as σ_k, $\Psi_{1,\wedge}^2$ and so on) are now based on $\widetilde{B}$, the connectivity matrix of the corresponding approximate SBM, as given in (50).

6.4.1. Graphon clustering

As a concrete example of the application of Proposition 2, let us consider a problem which we refer to as *graphon clustering*. For simplicity, consider the case $n_1 = n_2 = n$. Let $\rho_0 : [0,1]^2 \to \mathbb{R}_+$ be a bounded measurable function, and let $X_1, \dots, X_n, Y_1, \dots, Y_n \sim \mathrm{Unif}([0,1])$ be an i.i.d. sample. Assume that

$$A_{ij} \mid \{X_{i'}\}, \{Y_{j'}\} \;\sim\; \mathrm{Bern}\big(\rho_0(X_i, Y_j)/n \big), \tag{54}$$

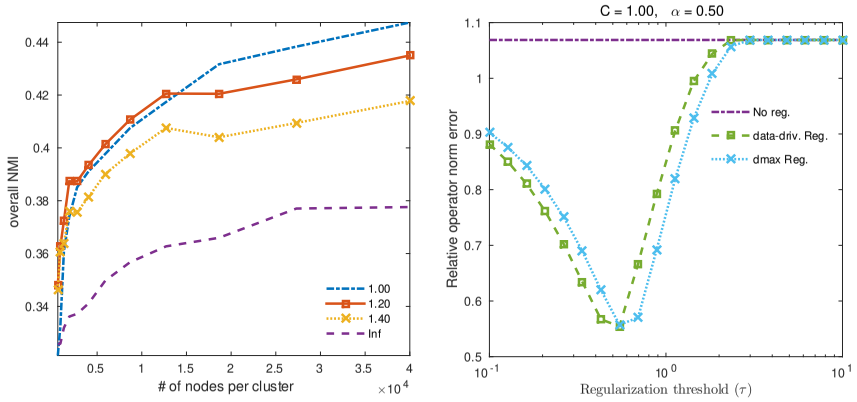
independently over $i, j = 1, \dots, n$. Consider two partitions of the unit interval: $\biguplus_{s=1}^{k_1} I_s = \biguplus_{t=1}^{k_2} J_t = [0,1]$ where I_s and J_t are (unknown) measurable sets. Let $\Psi \in [0,1]^{k_1 \times k_2}$ and

consider the block-constant function $\widetilde{\rho}_0$ on $[0,1]^2$ defined by

$$\widetilde{\rho}_0 := \sum_{s=1}^{k_1}\sum_{t=1}^{k_2} \Psi_{st} 1_{I_s \times J_t}, \tag{55}$$

where $1_{I_s \times J_t}(x,y) = 1_{I_s}(x)1_{J_t}(y)$ is the indicator of the set $I_s \times J_t$. Whenever ρ_0 has a block constant approximation such as $\widetilde{\rho}_0$, we can consider I_s and J_t as defining implicit (true) clusters over nodes. More precisely, row node i belongs to community s if $1\{X_i \in I_s\}$ and similarly for the column labels. Note that none of $\{X_i\}$, $\{Y_j\}$, $\{I_s\}$ and $\{J_t\}$ are observed. One can ask whether we can still recover these implicit clusters given an instance of A.

Proposition 3 *Assume that there exists a function $\widetilde{\rho}_0$ of the form (55), such that*



$$\|\widetilde{\rho}_0 - \rho_0\|_{L^4} = o(\sqrt{d}) \tag{56}$$

Consider normalized mean matrices P^0 and $\widetilde{P}^0$ with entries, $P^0_{ij} = \rho_0(X_i, Y_j)$ and $\widetilde{P}^0_{ij} = \widetilde{\rho}_0(X_i, Y_j)$. Then, with high probability $\|P^0 - \widetilde{P}^0\|_F \le n\sqrt{d}$.

Proposition 3 shows that a fourth moment bound of the form (56) is enough to guarantee (52) and as a consequence the result of Proposition 2. In order to apply the results of the paper, we require that (56) holds with $d = \|\rho_0\|_\infty$. Then, all the consistency results of the paper follow with Ψ replaced by that from (55), and regularization Algorithm 1 replaced with that of Theorem 2.

For example, with σ_k as defined in Section 2 (using Ψ from (55) in forming $\bar{B}$), Theorem 4 gives a misclassification rate at most $O(d/\sigma_k^2)$ for recovering the labels $1\{X_i \in I_s\}$ by the SC-1 algorithm. In typical cases, it is plausible to have $\sigma_k^2 \asymp d^2$ (cf. Remark 3), hence a misclassification rate of $O(1/d) = o(1)$ as $d \to \infty$. Proposition 3 is an illustrative example, and one can obtain other conditions by assuming more about the deviation $\widetilde{\rho}_0 - \rho_0$, such as boundedness.

Remark 12 *We note that graphon clustering problem considered above is different from what is typically called graphon estimation. In the latter problem, under a model of the form (54), one is interested in recovering the mean matrix $\mathbb{E}[A]$ or ρ_0 in the MSE sense. This problem has been studied extensively in recent years, often under the assumption of smoothness of ρ_0, for maximum likelihood SBM approximation (Airoldi et al., 2013; Olhede and Wolfe, 2014; Gao et al., 2015; Klopp et al., 2017) and spectral truncation (Xu, 2017). The graphon clustering problem, as far as we know, has not been considered before and is concerned with recovering the underlying clusters, assuming that such* true clusters exist. *We only need the existence of a block constant approximation $\widetilde{\rho}_0$, over the true clusters (of the form (55)) that satisfies $\|\widetilde{\rho}_0 - \rho_0\|_{L^4} = o(\sqrt{d})$ for $d = \|\widetilde{\rho}_0\|_\infty$. Then our results implicitly imply that the underlying clusters are identifiable and consistently recovered by spectral approaches. Note that we do not impose any explicit smoothness assumption on ρ and there is no lower bound requirement on d (such as $d = \Omega(\log n)$ in Xu (2017)).*

(a) (b)

Figure 2: (a) NMI plots for SC-RRE algorithm with degree regularization Algorithm 1 for various values of $\tau = 1, 1.2, 1.4$ and ∞. (b) Relative operator norm error between the adjacency matrix and its expectation, with data-driven and oracle ($d_{\max}$) regularization as well as no regularization.

7. Simulations

We now present some simulation results showing the performance of the data-driven regularization of Section 4.1. We sample from the bipartite SBM model with connectivity matrix

$$B = \sqrt{\frac{\log(n_1 n_2)}{n_1 n_2}} B_0, \quad \text{where} \quad B_0 = \frac{1}{2}\begin{bmatrix} 6 & 1 & 1 & 1 \\ 1 & 6 & 1 & 1 \\ 1 & 1 & 6 & 1 \end{bmatrix}, \tag{57}$$

for which $\Psi = \sqrt{\log(n_1 n_2)} B_0$ as in (4). We let $n_1 = n_0 k_1$ and $n_2 = n_0 k_2$, and we vary n_0. Note that $k_1 = 3$ and $k_2 = 4$. We measure the performance using the normalized mutual information (NMI) between the true and estimated clusters. The NMI belongs to the interval $[0,1]$ and is monotonically increasing with clustering accuracy. We consider Algorithm 1 with regularization parameter $\tau = 1, 1.2, 1.4$ and ∞, where $\tau = \infty$ corresponds to no regularization. Although we have established theoretical guarantees for $\tau = 3$, this constant is not optimal and any scalar $\asymp 1$ might perform well.

In this model, the key parameter $d = \sqrt{n_2/n_1}\|\Psi\|_\infty \sim \sqrt{\log n_0}$ as $n_0 \to \infty$. In other words, the maximum expected degree of the network scales as $\sqrt{\log n_0}$ which is enough for the consistency of spectral clustering; in fact, results in Section 5 predict a misclassification rate of $O(d^{-1}) = O\big((\log n_0)^{-1/2}\big)$ for various spectral algorithms discussed in this paper.

Figure 2(a) shows the NMI plots as a function of n_0 for the SC-RRE algorithm with the regularization scheme of Algorithm 1. In the k-means step, we have used `kmeans++` which as described in Remark 8 satisfies the approximation property of Section 3.3 with $\kappa = O(\log(k_1 \wedge k_2)) = O(1)$ in this case. The results are averaged over 15 replicates. The

plots clearly show that the regularization considerably boosts the performance of spectral clustering for model (57).

Figure 2(b) shows the relative operator norm error between the (regularized) adjacency matrix and its expectation, i.e., $\|A_{\rm re} - \mathbb{E}A\|_{\rm op}/\|\mathbb{E}A\|_{\rm op}$ with and without regularization ($A_{\rm re} = A$). The plots correspond to the same SBM model with $n_0 = 500$ (and the results are averaged over 3 replicates). For the regularization, we consider both the oracle where the degrees are truncated to $\tau d_{\max}$ and $\tau d'_{\max}$ for the rows and columns (see Section 4.1 for the definitions of these quantities) as well as the data-driven one that truncates as in Algorithm 1. The plots show the relative error as a function of τ and we see that the regularization clearly improves the concentration. We also note that the behavior of the data-driven truncation closely follows that of the oracle as predicted by Theorem 3.

The code is available at (Zhou and Amini, 2018).

Acknowledgement

We thank Zahra S. Razaee, Jiayin Guo and Yunfeng Zhang for helpful discussions. We are also grateful to the referees for their constructive suggestions.

Appendix A. Proofs

A.1. Proofs of Section 3.2

Proof [Proof of Lemma 3] Let $\bar{W}$ and $\widehat{W}$ be the W of Lemma 2(a) for $P^\dagger$ and $A^\dagger_{\rm re}$, respectively. Let us also write $\bar{W}_1$ and $\widehat{W}_1$ for the $(n_1+n_2)\times k$ matrices obtained by taking the submatrices of $\bar{W}$ and $\widehat{W}$ on columns $1,\dots,k$. We have

$$\bar{W}_1 = \frac{1}{\sqrt{2}}\begin{pmatrix}\bar{Z}_1 U_\psi \\ \bar{Z}_2 V_\psi\end{pmatrix}, \quad \widehat{W}_1 = \frac{1}{\sqrt{2}}\begin{pmatrix}\hat{Z}_1 \\ \hat{Z}_2\end{pmatrix}.$$

Note that $\bar{W}_1, \widehat{W}_1 \in \mathbb{O}^{(n_1+n_2)\times k}$. Let $\Pi_{\bar{W}_1}$ be the (orthogonal) projection operator, projecting onto $\mathrm{Im}(\bar{W}_1)$, i.e., the column span of $\bar{W}_1$, and similarly for $\Pi_{\widehat{W}_1}$. We have

$$\begin{aligned}
\|\Pi_{\widehat{W}_1} - \Pi_{\bar{W}_1}\|_{\rm op} &\le \frac{2}{2\sigma_k}\|A^\dagger_{\rm re} - P^\dagger\|_{\rm op} && \text{(Symmetric DK and Lemma 2(d))}\\
&= \frac{1}{\sigma_K}\|(A_{\rm re} - P)^\dagger\|_{\rm op} && \text{(Linearity of dilation)}\\
&= \frac{1}{\sigma_K}\|A_{\rm re} - P\|_{\rm op} && \text{(Lemma 2(b)).}
\end{aligned}$$

The next step is to translate the operator norm bound on spectral projections into a Frobenius bound. The key here is the bound on the rank of spectral deviations which leads to a $\sqrt{k}$ scaling as opposed to $\sqrt{n_1+n_2}$, when translating from operator norm to Frobenius:

$$\begin{aligned}
\min_{Q\in\mathbb{O}^{k\times k}} \|\widehat{W}_1 - \bar{W}_1 Q\|_F &\le \|\Pi_{\widehat{W}_1} - \Pi_{\bar{W}_1}\|_F && \text{(By Lemma 8 in Appendix C)}\\
&\le \sqrt{2k}\,\|\Pi_{\widehat{W}_1} - \Pi_{\bar{W}_1}\|_{\rm op} && (\,\mathrm{rank}(\Pi_{\widehat{W}_1} - \Pi_{\bar{W}_1}) \le 2k\,)\\
&\le \frac{\sqrt{2k}}{\sigma_k}\|A_{\rm re} - P\|_{\rm op}.
\end{aligned}$$

Since $2\|\widehat{W}_1 - \bar{W}_1 Q\|_F^2 = \|\hat{Z}_1 - \bar{Z}_1 U_\psi Q\|_F^2 + \|\hat{Z}_2 - \bar{Z}_2 V_\psi Q\|_F^2$, we obtain the desired result after combining with (8). ■

A.2. Proofs of Section 4

Let us start with a relatively well-known concentration inequality:

Proposition 4 (Prokhorov) *Let $S = \sum_i X_i$ for independent centered variables $\{X_i\}$, each bounded by $c < \infty$ in absolute value a.s. and suppose $v \ge \sum_i \mathbb{E}X_i^2$, then*

$$\mathbb{P}\big(S > vt\big) \le \exp[-vh_c(t)], \quad t \ge 0, \quad \textit{where } h_c(t) := \frac{3}{4c}t\log\big(1 + \frac{2c}{3}t\big). \tag{58}$$

Same bound holds for $\mathbb{P}(S < -vt)$.

We often apply this result with $c = 1$. We note that for any $u \ge \frac{2}{3}\alpha$ any $\alpha > 0$,

$$h_1(\alpha u) \ge \frac{3}{4}\alpha u \log\Big(\frac{2}{3}\alpha u\Big) \ge \frac{3}{4}\alpha u \log u^2 \ge \frac{3}{2}\alpha u \log u. \tag{59}$$

Proof [Proof of Lemma 4] We first note that

$$\mathbb{P}(D_i - d_i > vt) \le \exp(-vh_1(t)), \quad \forall v \ge d_i,\ t \ge 0, \tag{60}$$
$$\mathbb{P}(D_i - d_i < -vt) \le \exp(-vh_1(t)), \quad \forall v \ge d_i,\ t \ge 0. \tag{61}$$

Lower bound. Let $Y_i = 1\{D_i < d_{\max}/2\}$. Without loss of generality, assume that cluster 1 achieves the maximum in the definition of $d_{\max}$ (i.e., $t^* = 1$), and fix i such that $z_{1i} = 1$. We have $d_i = d_{\max}$, hence applying (61) with $v = d_i = d_{\max}$ and $t = 1/2$,

$$\mathbb{P}(D_i < d_{\max}/2) \ \le\ \exp(-d_{\max}/10),$$

using $h_1(1/2) = 0.2157 > 1/10$. Let $q := \exp(-d_{\max}/10)$ so that $\mathbb{E}Y_i \le q$. By assumption $d_{\max} \ge \bar{d}$ is sufficiently large that $q \le 1/4$. We then have

$$\begin{aligned}
\mathbb{P}(D_{(\lfloor n_1/\overline{D}\rfloor)} < d_{\max}/2) &\le \mathbb{P}\Big(\sum_{i=1}^{n_1} 1\{D_i \ge d_{\max}/2\} \le n_1/\overline{D}\Big) \le \mathbb{P}\Big(\sum_{i:z_{1i}=1} 1\{D_i \ge d_{\max}/2\} \le n_1/\overline{D}\Big)\\
&= \mathbb{P}\Big(\sum_{i:z_{1i}=1} Y_i > n_{11} - n_1/\overline{D}\Big)\\
&\le \mathbb{P}\Big(\sum_{i:z_{1i}=1} Y_i > n_{11} - 2n_1/\bar{d}\Big) + \mathbb{P}\Big(\overline{D} < \frac{\bar{d}}{2}\Big) \ =: T_1 + T_2
\end{aligned}$$

For the first term we have

$$T_1 \le \mathbb{P}\Big(\sum_{i:z_{1i}=1}(Y_i - \mathbb{E}Y_i) > n_{11}(1-q) - 2n_1/\bar{d}\Big).$$

By assumptions $n_{11} \geq n_1/(\beta k_1)$ and $\beta k_1/\bar{d} \leq 1/8$, we have $n_{11}(1-q) - 2n_1/\bar{d} \geq n_{11}/2$. Taking $c = 1$, $v = n_{11}q$, $t = 1/(2q)$ in Proposition 4, we have $vt = n_{11}/2$ and $t \geq 2$

$$T_1 \leq \mathbb{P}\Big(\sum_{i:\, z_{1i}=1} (Y_i - \mathbb{E}Y_i) > n_{11}/2 \Big) \leq \exp\Big(-n_{11}\, q\, h_1\big(\frac{1}{2q}\big) \Big) \\ \leq \exp\big(-c_1\, n_{11} d_{\max} \big) \leq e^{-3n_1/5}$$

where we have applied (59) with $\alpha = 1/2$ and $u = 1/q = e^{d_{\max}/10}$ to get

$$q\, h_1\big(\frac{1}{2q}\big) \geq q \frac{3}{2} \frac{1}{2q} \log(1/q) = \frac{3}{40} d_{\max}$$

and $n_{11} d_{\max} \geq n_1 d_{\max}/(\beta k_1) \geq 8 n_1$ since $\beta k_1/d_{\max} \leq \beta k_1/\bar{d} \leq 1/8$ by assumption.

For the second term T_2, we note that $n_1(\overline{D} - \bar{d}) = \sum_{i,j}(A_{ij} - \mathbb{E}A_{ij})$. Applying Proposition 4 with $v = n_1\bar{d}$ and $t = 1/2$, we have

$$T_2 = \mathbb{P}\Big(n_1(\overline{D} - \bar{d}) < -n_1\bar{d}/2 \Big) \leq \exp(-n_1\bar{d}/10) \leq e^{-n_1/5}. \tag{62}$$

using $h_1(1/2) \geq 1/10$ and $\bar{d} \geq 2$.

Upper bound. For any $\in [n_1]$, applying (60) with $v = d_{\max} \geq d_i$, and $t = 1/2$, we have

$$\mathbb{P}(D_i > 3d_{\max}/2) \;\leq\; \exp(-d_{\max}/10).$$

Let $Z_i = 1\{D_i > 3d_{\max}/2\}$ and note that $\mathbb{E}Z_i \leq q = \exp(-d_{\max}/10)$, as in the case of the lower bound. Then,

$$\mathbb{P}\Big(D_{(\lfloor n_1/\overline{D} \rfloor)} > \frac{3}{2} d_{\max} \Big) \leq \mathbb{P}\Big(\sum_{i=1}^{n_1} Z_i \geq \frac{n_1}{\overline{D}} - 1 \Big) \\ \leq \mathbb{P}\Big(\sum_{i=1}^{n_1} Z_i \geq \frac{2n_1}{3\bar{d}} - 1 \Big) + \mathbb{P}\Big(\overline{D} > \frac{3\bar{d}}{2} \Big) =: T_1' + T_2'.$$

Using assumption $n_1/\bar{d} \geq 2$, we have $2n_1/(3\bar{d}) - 1 \geq n_1/(6\bar{d}) \geq n_1/(6d_{\max})$, hence

$$T_1' \;\leq\; \mathbb{P}\Big(\sum_{i=1}^{n_1} (Z_i - \mathbb{E}Z_i) \geq \frac{n_1}{6d_{\max}} - n_1 q \Big) =: T_1'' \tag{63}$$

We claim that if $d_{\max} \geq 1$, then for any $\gamma \geq 1$,

$$f(\gamma) := \mathbb{P}\Big(\sum_{i=1}^{n_1} (Z_i - \mathbb{E}Z_i) \geq \frac{n_1}{\gamma d_{\max}} \Big) \leq e^{-3n_1/(20\gamma)}. \tag{64}$$

To see this, taking $c = 1$, $v = n_1 q$, $t = 1/(\gamma q d_{\max})$ in Proposition 4, we have

$$f(\gamma) \leq \exp\Big(-n_1 q\, h_1\Big(\frac{1}{\gamma q d_{\max}} \Big) \Big).$$

Applying (59) with $\alpha = 1/(\gamma d_{\max})$ and $u = 1/q = e^{d_{\max}/10}$, noting that $u \geq (2/3)\alpha$,

$$q\, h_1\big(\frac{1}{\gamma q d_{\max}}\big) \geq q \frac{3}{2} \frac{1}{\gamma q d_{\max}} \log(1/q) = \frac{3}{20\gamma}$$

showing (64).

Going back to bounding T_1'', for sufficiently large $d_{\max}$, we have $1/(6d_{\max}) - q \geq 1/(12 d_{\max})$. Hence, we can apply (64) with $\gamma = 12$ to conclude, $T_1'' \leq e^{-n_1/80}$. For T_2', by the same argument as in (62), we have $T_2 \leq e^{-n_1/5}$.

Proof of part (b). From the lower bound, we have that $3D_{(\lfloor n_1/\overline{D} \rfloor)} > \frac{3}{2} d_{\max}$ on an event $\mathcal{A}$ with probability $\mathbb{P}(\mathcal{A}) \geq 1 - 2e^{-n_1/80}$. Then,

$$W_i := 1\big\{ D_i > 3D_{(\lfloor n_1/\overline{D} \rfloor)} \big\} \;\leq\; 1\{D_i > 3d_{\max}/2\} = Z_i, \quad \text{on } \mathcal{A}.$$

Hence, $\big| i : D_i > 3D_{(\lfloor n_1/\overline{D} \rfloor)} \big| = \sum_i W_i$ and

$$\mathbb{P}\Big(\Big\{ \sum_{i=1}^{n_1} W_i > \frac{10 n_1}{d} \Big\} \cap \mathcal{A} \Big) \leq \mathbb{P}\Big(\sum_{i=1}^{n_1} Z_i > \frac{10n_1}{d} \Big) = \mathbb{P}\Big(\sum_{i=1}^{n_1} (Z_i - \mathbb{E}Z_i) > \frac{10n_1}{d} - n_1 q \Big).$$

Since $d_{\max} \geq n_2 \|P\|_\infty/(\beta k_2) = d/(\beta k_2)$, and $\beta k_2 \leq \bar{d}/8 \leq d_{\max}/8$ we have $d_{\max}^2 \geq 8d$. Recalling that $q = e^{-d_{\max}/10}$

$$qd = (qd_{\max}^2)(d/d_{\max}^2) \leq 1/8. \tag{65}$$

for $d_{\max} \geq 90$. We have

$$\frac{10n_1}{d} - n_1 q \geq \frac{9n_1}{d} \geq \frac{9n_1}{d_{\max}} \frac{1}{\beta k_2}$$

hence we can apply (64) with $\gamma = \beta k_2/9$ to obtain

$$\mathbb{P}\Big(\sum_{i=1}^{n_1} W_i > \frac{10n_1}{d} \Big) \leq \exp\Big(-\frac{27 n_1}{20 \beta k_2} \Big).$$

The proof is complete. ■

Proof [Proof of Lemma 5] The proof of part (a) follows exactly as in the case of row degrees establishing the result with probability at least $1 - 3e^{-n_2/80}$. For part (b), we have by the same argument as in the case of row degrees

$$\mathbb{P}\Big(\big| j : D_j' > 3D'_{(\lfloor n_2/\overline{D}' \rfloor)} \big| > \frac{10n_2}{d} \Big) \leq \mathbb{P}\Big(\sum_{j=1}^{n_2} (Z_j' - \mathbb{E}Z_j') > \frac{10n_2}{d} - n_2 q' \Big) + \mathbb{P}(\mathcal{A}'^c) \\ := T_3 + \mathbb{P}(\mathcal{A}'^c)$$

where $\mathcal{A}'$ is defined similar to $\mathcal{A}$ for column variables and is controlled similarly. We also have $q' := \exp(-d'_{\max}/10)$.

To simplify notation, let $\alpha := n_2/n_1 \geq 1$. We have $d'_{\max} \geq n_1\|P\|_\infty/(\beta k_1) = d/(\alpha\beta k_1)$, recalling $d = n_2\|P\|_\infty$. By assumption, $\bar{d} \geq 8\beta k_1\alpha^2$. Since $n_1\bar{d} = \sum_{ij} p_{ij} = n_2\bar{d}'$, that is, $\bar{d} = \alpha\bar{d}'$, we obtain $\beta k_1 \leq \bar{d}/(8\alpha^2) = \bar{d}'/(8\alpha) \leq d'_{\max}/(8\alpha)$. It follows that $(d'_{\max})^2 \geq 8d$ which is similar to what we had for the rows; hence, $q'd \leq 1/8$ as long as $d'_{\max} \geq 90$ (see (65)), which is true since $d'_{\max} \geq \bar{d}' = \bar{d}/\alpha \geq \bar{d}/\alpha^2 \geq 90$ by assumption. Then,

$$\frac{10n_2}{d} - n_2 q' \geq \frac{9n_2}{d} \geq \frac{9n_2}{d'_{\max}}\frac{1}{\alpha\beta k_1}.$$

Therefore, applying the column counterpart of (64) with $\gamma = \alpha\beta k_1/9$,

$$T_3 \leq \exp\Big(-\frac{27n_2}{20\alpha\beta k_1}\Big) = \exp\Big(-\frac{27n_1}{20\beta k_1}\Big).$$

The proof is complete. ■

A.3. Proofs of Section 3.3

Proof [Proof of Corollary 1] Using (21), we have $d_F(X^*, \widetilde{X}) \leq (1+\kappa)\varepsilon$ for any $\widetilde{X} \in \mathcal{P}_\kappa(\hat{X})$. We now apply Proposition 1 to X^* and $\widetilde{X}$, both k-means matrices, with $(1+\kappa)\varepsilon$ in place of ε. ■

Proof [Proof of Proposition 1] The proof follows the argument in (Lei et al., 2015, Lemma 5.3) which is further attributed to Jin (2015). Let $\mathcal{C}_r$ denote the rth cluster of X, having center $q_r = q_r(X)$. We have $|\mathcal{C}_r| = n_r$. Let x_i^T and $\widetilde{x}_i^T$ be the ith row of X and $\widetilde{X}$, respectively, and let

$$T_r := \{i \in \mathcal{C}_r :\ d(\widetilde{x}_i, q_r) < c_r\delta_r\} = \{i \in \mathcal{C}_r :\ d(\widetilde{x}_i, x_i) < c_r\delta_r\}$$

using $x_i = q_r$ for all $i \in \mathcal{C}_r$ which holds by definition. Let $S_r = \mathcal{C}_r \setminus T_r$. Then,

$$|S_r|c_r^2\delta_r^2 \ \leq \sum_{i\in S_r} d(\widetilde{x}_i, x_i)^2 \leq \varepsilon^2 \implies \frac{|S_r|}{|\mathcal{C}_r|} \leq \frac{c_r^{-2}\varepsilon^2}{n_r\delta_r^2} < 1. \tag{66}$$

where we have used assumption (b). It follows that S_r is a proper subset of $\mathcal{C}_r$, that is, T_r is nonempty for all $r \in [k]$.

Next, we argue that if two elements belong to different $T_r, r \in [k]$, they have different labels according to $\widetilde{X}$. That is, $i \in T_r$, $j \in T_\ell$ for $r \neq \ell$ implies $\widetilde{x}_i \neq \widetilde{x}_j$. Assume otherwise, that is, $\widetilde{x}_i = \widetilde{x}_j$. Then, by triangle inequality and $c_r + c_\ell \leq 1$,

$$d(q_k, q_\ell) \leq d(q_k, \widetilde{x}_i) + d(q_\ell, \widetilde{x}_j) < c_r\delta_r + c_\ell\delta_\ell \leq \max\{\delta_r, \delta_\ell\}$$

contradicting (23). This shows that $\widetilde{X}$ has at least k labels, since all T_r are nonempty, hence exactly k labels, since $\widetilde{X} \in \mathbb{M}^k_{n,m}$ by assumption.

Finally, we argue that if two elements belong to the same T_r, they have the same label according to $\widetilde{X}$. This immediately follows from the previous step since otherwise there will

be at least $k+1$ labels. Thus, we have shown that, for all $r \in [k]$, the labels in each T_r are in the same cluster according to both X and $\widetilde{X}$, that is, they are correctly classified. The misclassification rate over cluster $\mathcal{C}_r$ is then $\leq |S_r|/|\mathcal{C}_r|$ which establishes the result in view of (66). ■

A.4. Proofs of Section 5

Proof [Proof of Theorem 4] Going through the three-step plan of analysis in Section 3, we observe that (8) holds for $A_{\rm re}$ by Theorem 2, and (9) holds by Lemma 3. We only need to verify conditions of Corollary 1, so that κ-approximate k-means operator $\mathcal{P}_\kappa$ satisfies bound (10) of the k-means step. As in the proof of Theorem 1, $X^* = \bar{Z}_1 O \in \mathbb{R}^{n_1\times k}$, where $\bar{Z}_1 \in \mathbb{O}^{n_1\times k_1}$ and $O := U_\psi Q \in \mathbb{O}^{k_1\times k}$. Clearly, X^* has exactly k distinct rows (recalling $k = k_1$). Furthermore, using the calculation in the proof of Theorem 1,

$$n_{1t}\,\delta_t^2 = n_{1t}\min_{s:\ s\neq t}(n_{1t}^{-1} + n_{1s}^{-1}) = \min_{s:\ s\neq t}(1 + \frac{n_{1t}}{n_{1s}}) \geq 1.$$

Recalling that $\varepsilon^2 = C_2^2 kd/\sigma_k^2$, as long as

$$4(1+\kappa)^2\varepsilon^2 = 4C_2^2(1+\kappa)^2\, kd/\sigma_k^2 < 1 \leq n_{1t}\,\delta_t^2$$

condition (b) of Corollary 1 holds and $\mathcal{P}_\kappa$ satisfies (10) with $c = 4(1+\kappa)^2$ as in (26). The rest of the proof follows as in Theorem 1. ■

Proof [Proof of Lemma 6] Throughout the proof, let $\|\cdot\| = \|\cdot\|_{\rm op}$ be the operator norm. Recall that $P = \mathbb{E}A$ is the mean matrix itself, and let $\Delta_{\rm re} := A_{\rm re} - P$. By Weyl's theorem on the perturbation of singular values, $|\sigma_i(A_{\rm re}) - \sigma_i(P)| \leq \|\Delta_{\rm re}\|$ for all i. Since $\sigma_{k+1}(P) = 0$ (see (7)), we have $\sigma_{k+1}(A_{\rm re}) \leq \|\Delta_{\rm re}\|$, hence

$$\begin{aligned}
\|A_{\rm re}^{(k)} - P\| &\leq \|A_{\rm re}^{(k)} - A_{\rm re}\| + \|\Delta_{\rm re}\| && \text{(triangle inequality)}\\
&= \sigma_{k+1}(A_{\rm re}) + \|\Delta_{\rm re}\| && \text{(by (33))}\\
&\leq 2\|\Delta_{\rm re}\| && \text{(Weyl's theorem).}
\end{aligned}$$

Thus, in terms of the operator norm, we lose at most a constant in going from $A_{\rm re}$ to $A_{\rm re}^{(k)}$. However, we gain a lot in Frobenious norm deviation. Since $A_{\rm re}$ is full-rank in general, the best bound on $\Delta_{\rm re}$ based on its operator norm is $\|\Delta_{\rm re}\|_F \leq \sqrt{n_\wedge}\,\|\Delta_{\rm re}\|$ where $n_\wedge = \min\{n_1, n_2\}$. On the other hand, since $A_{\rm re}^{(k)} - P$ is of rank $\leq 2k$, we get

$$\|A_{\rm re}^{(k)} - P\|_F \leq \sqrt{2k}\|A_{\rm re}^{(k)} - P\| \leq 2\sqrt{2k}\|\Delta_{\rm re}\|.$$

Combining with (8), that is, $\|\Delta_{\rm re}\| \leq C\sqrt{d}$, we have the result. ■

Proof [Proof of Theorem 5] We only need to calculate $\delta(P) = \delta_\wedge(P)$ the minimum center separation of P viewed as an element of $\mathbb{M}^{k_1}_{n_1,n_2}$. Recall that

$$P = \bar{Z}_1\bar{B}\bar{Z}_2^T = Z_1 N_1^{-1/2}(\bar{N}_1^{1/2}\Psi\bar{N}_1^{1/2})\bar{Z}_2^T = n_1^{-1/2}Z_1\Psi\bar{N}_1^{1/2}\bar{Z}_2^T.$$

Let e_s be the sth standard basis vector of $\mathbb{R}^{k_1}$. Unique rows of P are $q_s^T := n_1^{-1/2} e_s^T (\Psi \bar{N}_2^{1/2}) \bar{Z}_2^T$ for $s \in [k_1]$. We have

$$\begin{aligned}\|q_s - q_t\|_2^2 &= n_1^{-1} \|\bar{Z}_2 \bar{N}_2^{1/2} \Psi^T (e_s - e_t)\|_2^2 \\ &= n_1^{-1} \|\bar{N}_2^{1/2} \Psi^T (e_s - e_t)\|_2^2 = n_1^{-1} \sum_{\ell=1}^{k_2} \pi_{2\ell} (\Psi_{s\ell} - \Psi_{t\ell})^2.\end{aligned}$$

It follows that $\delta^2(P) = \min_{t \neq s} \|q_s - q_t\|_2^2 = n_1^{-1} \Psi_{1,\wedge}^2$. We apply Corollary 1, with $X^* = P$ and $\hat{X} = A_{\mathrm{re}}^{(k)}$, taking $\varepsilon^2 = 8C^2 kd$ according to Lemma 6. Condition (b) of the corollary holds if

$$32C^2(1+\kappa)^2 kd = 4(1+\kappa)^2 \varepsilon^2 < n_{1t}\, \delta_t^2(P) = \pi_{1t} \min_{s:\, s \neq t} \sum_{\ell=1}^{k_2} \pi_{2\ell} (\Psi_{s\ell} - \Psi_{t\ell})^2$$

for all $t \in [k_1]$, which is satisfied under assumption (37). Corollary 1, and specifically (26) gives the desired bound on misclassification rate $\leq 4(1+\kappa)^2 \varepsilon^2 / (n_1 \delta^2(P))$. ■

Proof [Proof of Theorem 6] Recall that $A_{\mathrm{re}}^{(k)} = \hat{Z}_1 \hat{\Sigma} \hat{Z}_2^T$ is the k-truncated SVD of A_{re}. Let $X^{(1)} = \hat{Z}_1 \hat{\Sigma}$ and $X^{(2)} = A_{\mathrm{re}}^{(k)}$, and let $(x_i^{(1)})^T$ and $(x_i^{(2)})^T$ be their ith rows, respectively. Then,

$$\|x_2^{(i)} - x_2^{(j)}\| = \|\hat{Z}_2 (x_1^{(i)} - x_1^{(j)})\|_2 = \|x_1^{(i)} - x_1^{(j)}\|_2, \quad \forall i \neq j,$$

using $\hat{Z}_2 \in \mathbb{O}^{n_2 \times k}$ and (1). Isometry-invariance of $\mathscr{K}$ implies $\overline{\mathrm{Mis}}(\mathscr{K}(\hat{Z}_1 \hat{\Sigma}), \mathscr{K}(A_{\mathrm{re}}^{(k)})) = 0$. Since $\overline{\mathrm{Mis}}$ is a pseudo-metric on k-means matrices, using the triangle inequality, we get

$$\begin{aligned}\overline{\mathrm{Mis}}\left(\mathscr{K}(\hat{Z}_1 \hat{\Sigma}), P\right) &\leq \overline{\mathrm{Mis}}\left(\mathscr{K}(\hat{Z}_1 \hat{\Sigma}), \mathscr{K}(A_{\mathrm{re}}^{(k)})\right) + \overline{\mathrm{Mis}}\left(\mathscr{K}(A_{\mathrm{re}}^{(k)}), P\right) \\ &= \overline{\mathrm{Mis}}\left(\mathscr{K}(A_{\mathrm{re}}^{(k)}), P\right).\end{aligned}$$

(In fact, using the triangle inequality in the other direction, we conclude that the two sides are equal.) The result now follows from Theorem 5. ■

Proof [Proof of Corollary 4] We have

$$\|\Lambda_{s*} - \Lambda_{t*}\|^2 = \sum_{\ell=1}^{k_2} n_{2\ell}^2 (B_{s\ell} - B_{t\ell})^2 = \sum_{\ell=1}^{k_2} \frac{n_{2\ell}^2}{n_1 n_2} (\Psi_{s\ell} - \Psi_{t\ell})^2 = \alpha \sum_{\ell=1}^{k_2} \pi_{2\ell}^2 (\Psi_{s\ell} - \Psi_{t\ell})^2$$

where we have used $\alpha := n_2/n_1$. Recall from (42) that $\Lambda_\wedge^2 := \min_{t \neq s} \|\Lambda_{s*} - \Lambda_{t*}\|^2$. It follows that $\alpha^{-1} \Lambda_\wedge^2 \leq \Psi_{1,\wedge}^2$, using $\pi_{2,\ell} \leq 1$. We also have $\widetilde{\Psi}_{1,\wedge}^2 \geq \pi_{1,\wedge} \Psi_{1,\wedge}^2 \geq \pi_{1,\wedge} \alpha^{-1} \Lambda_\wedge^2$. Recalling the definition of a from (8), and using $\Psi_{s\ell} = (\sqrt{n_1 n_2}/n_{2\ell}) \Lambda_{s\ell}$, we have

$$d = \sqrt{\frac{n_2}{n_1}} \|\Psi\|_\infty \leq \sqrt{\frac{n_2}{n_1}} \frac{\sqrt{n_1 n_2}}{n_{2,\wedge}} \|\Lambda\|_\infty = \frac{1}{\pi_{2,\wedge}} \|\Lambda\|_\infty \leq \beta_2 k_2 \|\Lambda\|_\infty.$$

Hence, $kd\Psi_{1,\wedge}^{-2} \leq k\, \beta_2 k_2 \|\Lambda\|_\infty (\alpha^{-1} \Lambda_\wedge^2)^{-1} = \beta_2 k k_2 \alpha \|\Lambda\|_\infty \Lambda_\wedge^{-2}$ which is the desired bound. We also note that

$$kd\widetilde{\Psi}_{1,\wedge}^{-2} \leq kd\pi_{1,\wedge}^{-1} \Psi_{1,\wedge}^{-2} \leq (\beta_1 k_1)\, kd\Psi_{1,\wedge}^{-2}$$

which combined with the previous bound shows that the required condition (43) in the statement is enough to satisfy (37). ■

A.5. Proof of Theorem 7

As in the proof of Theorem 4, we only need to verify conditions of Corollary 1, with $X^* = \bar{Z}_1 U_\psi Q \in \mathbb{R}^{n_1 \times k}$, so that κ-approximate k-means operator $\mathcal{P}_\kappa$ satisfies bound (10) of the k-means step. Recall that $\bar{Z}_1 \in \mathbb{O}^{n_1 \times k_1}$, $U_\psi \in \mathbb{O}^{k_1 \times k}$ and $Q \in \mathbb{O}^{k \times k}$. Clearly, X^* has exactly k_1 distinct rows, $u_s^T Q$, $s \in [k_1]$. Furthermore,

$$\delta^2 := \delta_\wedge^2(\bar{Z}_1 U_\psi Q) = \delta_\wedge^2(\bar{Z}_1 U_\psi) = \min_{(t,s):\, t \neq s} \|n_{1t}^{-1/2} u_t - n_{1s}^{-1/2} u_s\|_2^2$$

where the second equality is by (1). Letting $\|\cdot\| = \|\cdot\|_2$, and $x = \pi_{1t}^{-1/2}$ and $y = \pi_{1s}^{-1/2}$ for simplicity, and $z = (x, -y) \in \mathbb{R}^2$, we have

$$\begin{aligned}n_1 \|n_{1t}^{-1/2} u_t - n_{1s}^{-1/2} u_s\|^2 &= \|\pi_{1t}^{-1/2} u_t - \pi_{1s}^{-1/2} u_s\|^2 \\ &= \| \begin{pmatrix} u_t & u_s \end{pmatrix} \begin{pmatrix} x \\ -y \end{pmatrix} \|^2 \\ &= z^T (U_\psi U_\psi^T)_{\mathcal{I}}\, z, \qquad \text{(where } \mathcal{I} = \{t, s\}\text{)}, \\ &= \|z\|^2 - z^T (I_{k_1} - U_\psi U_\psi^T)_{\mathcal{I}}\, z^T.\end{aligned}$$

Since $I_{k_1} - U_\psi U_\psi^T$ is positive semidefinite, using (44), we have

$$0 \leq z^T (I_{k_1} - U_\psi U_\psi^T)_{\mathcal{I}}\, z^T \leq (1 - \rho_1) \|z\|^2,$$

hence, $n_1 \|n_{1t}^{-1/2} u_t - n_{1s}^{-1/2} u_s\|^2 \geq \rho_1 \|z\|^2 = \rho_1 (\pi_{1t}^{-1} + \pi_{1s}^{-1})$. It follows by (A1),

$$(n_1 \delta^2)^{-1} \leq \frac{1}{\rho_1} \max_{t \neq s} (\pi_{1t}^{-1} + \pi_{1s}^{-1})^{-1} \leq \frac{1}{\rho_1} \Big(\frac{\beta_1}{2k_1} \Big).$$

We also have

$$n_{1t}\, \delta_t^2 = n_{1t} \min_{s:\, s \neq t} \|n_{1t}^{-1/2} u_t - n_{1s}^{-1/2} u_s\|_2^2 \;\geq\; \rho_1 \big(1 + \frac{\pi_{1t}}{\pi_{1s}}\big) \;\geq\; \rho_1.$$

We obtain, with $\varepsilon^2 = C_2^2 kd/\sigma_k^2$ and $O = U_\psi Q$,

$$\overline{\mathrm{Mis}}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1) = \overline{\mathrm{Mis}}(\mathscr{K}(\hat{Z}_1), \bar{Z}_1 O) \;\lesssim\; \frac{\varepsilon^2}{n_1 \delta^2} \;\lesssim\; \frac{\beta_1}{\rho_1} \frac{k}{k_1} \frac{d}{\sigma_k^2}$$

as long as $4(1+\kappa)^2 (n_{1t}\, \delta_t^2)^{-1} \varepsilon^2 = 4C_2^2 (1+\kappa)^2 \rho_1^{-1}\, kd/\sigma_k^2 < 1$, to guarantee that condition (b) of Corollary 1 holds, so that $\mathcal{P}_\kappa$ satisfies (10) with $c = 4(1+\kappa)^2$ as in (26). The proof is complete.

A.6. Proof of Theorem 8

The following concentration result for sub-Gaussian random matrices is well-known (Vershynin, 2018):

Lemma 7 *Let $A \in \mathbb{R}^{n_1 \times n_2}$ have independent sub-Gaussian entries, and $\sigma = \max_{i,j} \|A_{ij} - \mathbb{E}A_{ij}\|_{\psi_2}$. Then for any $t > 0$, we have*

$$\|A - \mathbb{E}A\|_{op} \le C\,\sigma(\sqrt{n_1} + \sqrt{n_2} + t), \tag{67}$$

with probability at least $1 - 2\exp(-t^2)$.

Let $t = \sqrt{n_1} + \sqrt{n_2}$ in Lemma 7, then $\|A - \mathbb{E}A\|_{\rm op} \le 2C\sigma(\sqrt{n_1} + \sqrt{n_2})$ with probability at least $1 - 2e^{-(n_1+n_2)}$. We thus have the concentration bound (8) with $\sqrt{d} = 2\sigma(\sqrt{n_1} + \sqrt{n_2})$. The proof of Theorem 5 goes through and the result follows by replacing d with the upper bound $d \le 4\sigma^2(n_1 + n_2)$, and replacing $\Psi^2_{1,\wedge}$ and $\widetilde{\Psi}^2_{1,\wedge}$ with $n_1 n_2 B^2_{1,\wedge}$ and $n_1 n_2 \widetilde{B}^2_{1,\wedge}$, respectively.

A.7. Proofs of Section 6.4

Proof [Proof of Proposition 2] We have with the given probability,

$$\begin{aligned}\|A_{\rm re} - \widetilde{P}\|_{\rm op} &\le \|A_{\rm re} - P\|_{\rm op} + \|P - \widetilde{P}\|_{\rm op} \\ &\le C\sqrt{d} + \frac{1}{\sqrt{n_1 n_2}}\|P^0 - \widetilde{P}^0\|_{\rm op} \\ &\le C\sqrt{d} + \frac{1}{\sqrt{n_1 n_2}}\|P^0 - \widetilde{P}^0\|_F \le (C_0 + C)\sqrt{d}\end{aligned}$$

where we have used Theorem 2 to bound the first term using $d' = d = \sqrt{n_2/n_1}\|P^0\|_\infty = n_2\|P\|_\infty$. The last inequality uses assumption (52). The proof is complete. ■

Proof [Proof of Proposition 3]
Letting $f(x,y) := [\rho_0(x,y) - \widetilde{\rho}_0(x,y)]^2$,

$$\|P^0 - \widetilde{P}^0\|_F^2 = \sum_{i=1}^n \sum_{j=1}^n f(X_i, Y_j) = \sum_{j \in \mathbb{Z}_n} \sum_{i \in \mathbb{Z}_n} f(X_i, Y_{i+j}),$$

where $\mathbb{Z}_n = \mathbb{Z}/n\mathbb{Z}$ is $\{1, \dots, n\}$ viewed as a cyclic group of order n. We have

$$\mathbb{E}[f(X_1, Y_1)^2] = \|f\|_{L^2}^2 = \|\rho_0 - \widetilde{\rho}_0\|_{L^4}^4 = o(d^2)$$

and $\mathbb{E}[f(X_1, Y_1)] = \|f\|_{L^1} \le \|f\|_{L^2} = o(d)$. Note that $\{f(X_i, Y_j) : i, j \in \mathbb{Z}_n\}$ are not independent, however, for each $j \in \mathbb{Z}_n$, $\{f(X_i, Y_{i+j}) : i \in \mathbb{Z}_n\}$ are i.i.d.. Let $Z_j := \sum_{i \in \mathbb{Z}_n} f(X_i, Y_{i+j})$. By independence,

$$\operatorname{var}(Z_j) = n \operatorname{var}(f(X_1, Y_1)) \le n\|f\|_{L^2}^2.$$

Since $\mathbb{E}Z_j = n\|f\|_{L^1}$, by the Chebyshev inequality, for any $j \in \mathbb{Z}_n$,

$$\begin{aligned}\mathbb{P}(Z_j \ge nd) &= \mathbb{P}\big(Z_j - \mathbb{E}Z_j \ge nd - n\|f\|_{L^1}\big) \\ &\le \frac{n\|f\|_{L^2}^2}{(na - n\|f\|_{L^1})^2} = \frac{1}{n}\frac{o(d^2)}{(d - o(d))^2} = o\Big(\frac{1}{n}\Big).\end{aligned}$$

It follows that $\mathbb{P}\big(\|P^0 - \widetilde{P}^0\|_F^2 \ge n^2 d\big) \le \sum_{j \in \mathbb{Z}_n} \mathbb{P}\big(Z_j \ge nd\big) \le n\, o\big(n^{-1}\big) = o(1)$. ■

Appendix B. Alternative algorithm for the k-means step

In this appendix, we present a simple general algorithm that can be used in the k-means step, replacing the κ-approximate k-means solver used throughout the text. The algorithm is based on the ideas in Gao et al. (2017) and Yun and Proutiere (2014b), and the version that we present here acheives the misclassification bound $\varepsilon^2/(n\delta^2)$ needed in Step 3 of the analysis (Section 3.1) without necessarily optimizing the k-means objective function. We present the results using the terminology of the k-means matrices (with rows in $\mathbb{R}^d$) introduced in Section 3.3, although the algorithm and the resulting bound work for data points in any metric space.

Let $X \in \mathbb{M}^k_{n,m}$ be a k-means matrix and let us denote its centers, i.e. distinct rows, as $\{q_r(X), r \in [k]\}$. As in Definition 2, we write $\delta_r(X)$ and $n_r(X)$ for the rth cluster center separation and size, respectively, and $\delta_\wedge(X) = \min_r \delta_r(X)$ and $n_\wedge = \min_r n_r(X)$. Assume that we have an estimate $\hat{X} \in \mathbb{R}^{n \times d}$ of X, and let us write $d(i,j) := d(\hat{x}_i, \hat{x}_j)$, $i, j \in [n]$ for the pairwise distances between the rows of $\hat{X}$.

Algorithm 6 which is a variant of the one presented in Gao et al. (2017), takes these pairwise distances and outputs cluster estimates $\widehat{\mathcal{C}}_1, \dots, \widehat{\mathcal{C}}_k \subset [n]$, after k recursive passes through the data. A somewhat more sophisticated version of this algorithm appears in Yun and Proutiere (2014b), where one also repeats the process for $i = 1, \dots, \log n$ and radii $R_i = iR_1$ in an outer loop, producing clusters $\widehat{\mathcal{C}}_r^{(i)}$, $r \in [k]$; one then picks, among these $\log n$ possible clusterings, the one that minimizes the k-means objective. The variant in Yun and Proutiere (2014b) also leaves no unlabeled nodes by assigning the unlabeled to the cluster whose estimated center is closest. In the rest of this section, we will focus on the simple version presented in Algorithm 6 as this is enough to establish our desired bound. The following theorem provides the necessary guarantee:

Theorem 9 *Consider the cluster model above and let $n_r = n_r(X)$, $n_\wedge = n_\wedge(X)$ and $\delta_\wedge = \delta_\wedge(X)$. Assume that we have approximate data $\hat{x}_1, \dots, \hat{x}_n$ such that $\sum_{i=1}^n d(x_i, \hat{x}_i)^2 \le \varepsilon^2$. In addition, assume that for some $\gamma \in (0,1)$ and $\beta \ge 1$:*

(i) $n_r \le \beta n_\wedge$ *for all* $r \in [k]$ *(Clusters are β-balanced.),*

(ii) $\dfrac{2\varepsilon}{\sqrt{\gamma n_\wedge}} < \dfrac{\delta_\wedge}{3}$ *(ε^2 small enough compared to $n_\wedge \delta_\wedge^2$.),*

(iii) $\xi\beta + \gamma < 1 - \gamma$ *where $\xi := \gamma/(1-\gamma)$. (Gamma small enough relative to β.)*

Algorithm 6 k-means replacement

Input: Pairwise distance $d(i,j)$, $i,j \in [n]$ and radius ρ.

$S \leftarrow [n]$
for $r = 1, \dots, k$ **do**
  For every $i \in S$, let $B_d(i;\rho) := \{j \in S : \ d(i,j) \le \rho\}$.
  Pick $i_0 \in S$ that maximizes $i \mapsto |B_d(i;\rho)|$.
  Let $\widehat{\mathcal{C}}_r = B_d(i_0;\rho)$.
  $S \leftarrow S \setminus \widehat{\mathcal{C}}_r$.
end for

Output: Return clusters $\widehat{\mathcal{C}}_r : 1, \dots, k$ and output remaining S as unlabeled.

Let $M_n(\rho)$ be the (average) misclassification rate of Algorithm 6 with input radius ρ. Then,

$$M_n(\rho) \le \frac{8\varepsilon^2}{n\rho^2}, \quad \forall \rho \in \Big[\frac{2\varepsilon}{\sqrt{\gamma n_\wedge}}, \frac{\delta_\wedge}{3}\Big).$$

Applying the algorithm with $\rho \ge \alpha\delta_\wedge$ for $\alpha < 1/3$ we obtain the misclassication bound $c_\alpha\, \varepsilon^2/(n\delta_\wedge^2)$ where $c_\alpha = 8/\alpha^2$. Thus, Algorithm 6 with a proper choice of the radius ρ satisfies the desired bound (10) of the k-means step.

Proof [Proof of Theorem 9] The proof follows the argument in Gao et al. (2017). As in the proof of Proposition 1, let $\mathcal{C}_r$ denote the rth cluster of X, having center $q_r = q_r(X)$. We have $|\mathcal{C}_r| = n_r$. Let x_i and $\hat{x}_i$ be the ith row of X and $\hat{X}$, respectively, and let

$$T_r \coloneqq \{i \in \mathcal{C}_r : \ d(\hat{x}_i, q_r) < \rho/2\} = \{i \in \mathcal{C}_r : \ d(\hat{x}_i, x_i) < \rho/2\}$$

using $x_i = q_r$ for all $i \in \mathcal{C}_r$ which holds by definition. $\{T_r\}$ are disjoint and clearly $T_r \subset \mathcal{C}_r$. Let $T := \biguplus_r T_r$, a disjoint union, and $T^c = [n] \setminus T$. We have

$$|T^c|\rho^2/4 \ \le \ \sum_{i \in T^c} d(\hat{x}_i, x_i)^2 \le \varepsilon^2 \implies |T^c| \le 4\varepsilon^2/\rho^2. \tag{68}$$

As a consequence of assumption (ii) and our choice of ρ, we have $4\varepsilon^2/(n_\wedge\rho^2) \le \gamma$, hence

$$|T_r| = |\mathcal{C}_r| - |\mathcal{C}_r \setminus T_r| \ \ge \ |\mathcal{C}_r| - |T^c| \ \ge \ n_\wedge\Big(1 - \frac{4\varepsilon^2}{n_\wedge\rho^2}\Big) \ge n_\wedge(1-\gamma) \tag{69}$$

for all $r \in [k]$. On the other hand, $|T^c| \le \gamma n_\wedge$. In particular, combining the two estimates

$$|T^c| \le \xi\, |T_r|, \quad \forall r \in [k] \tag{70}$$

where $\xi = \gamma/(1-\gamma)$. These size estimates will be used frequently in the course of the proof.

Recall that $d(i,j) := d(\hat{x}_i, \hat{x}_j)$, $i,j \in [n]$, the collection of pairwise distances between the data points $\hat{x}_1, \dots, \hat{x}_n$. Thus, with some abuse of notation, $(i,j) \mapsto d(i,j)$ defines a pseudo-metric on $[n]$ (and a proper metric if $\{\hat{x}_i\}$ are distinct). For any two subsets $A, B \subset [n]$ we write $d(A,B) = \inf\{d(i,j) : i \in A,\ j \in B\}$. For any $i \in [n]$, let $d(i,A) = d(\{i\}, A)$.

We say that node i_0 is near T if $d(i_0, T) \le \rho$, i.e., i_0 belongs to the ρ-enlargement of T. Similarly, we say that i_0 is near T_r if $d(i_0, T_r) \le \rho$ and far from T_r otherwise. Note that i_0 can be near at most one of $T_r, r \in [k]$. This is since $d(T_r, T_\ell) \ge \delta_\wedge - \rho$ for $r \ne \ell$, and we are assuming $\delta_\wedge > 3\rho$. In fact, *i_0 is near T iff i_0 is near exactly one of $T_r, r \in [k]$.*

To understand Algorithm 6, let us assume that we are at some iteration of the algorithm and we are picking the center i_0 and the corresponding cluster $\widehat{\mathcal{C}} := \{j : \ d(j, i_0) \le \rho\}$. One of the following happens:

(a) We pick the new center $i_0 \in T_r$ for some r, in which case $\widehat{\mathcal{C}}$ will include the entire T_r, none of $T_\ell, \ell \ne r$, and perhaps some of T^c. That is, $\widehat{\mathcal{C}} \supset T_r$ and $\widehat{\mathcal{C}} \cap T_\ell = \emptyset$ for $\ell \ne r$.

(b) We pick i_0 *near* T_r for some r. In this case, $|\widehat{\mathcal{C}}| \ge |T_r|$, otherwise any member of T_r would have created a bigger cluster by part (a) above. Now, $\widehat{\mathcal{C}}$ cannot contain any of $T_\ell, \ell \ne r$, because i_0 is far from those if it is near T_r. Hence, $\widehat{\mathcal{C}} \subset T_r \cup T^c$. Since $|T^c| \le \xi|T_r|$ by (70), and $|\widehat{\mathcal{C}}| \ge |T_r|$, we have $|\widehat{\mathcal{C}} \cap T_r| \ge (1-\xi)|T_r|$. That is, $\widehat{\mathcal{C}}$ contains a large fraction of T_r.

If either of the two cases above happen, we say that T_r is depleted, otherwise it is intact. If T_r is depleted, it will not be revisited in future iterations, as long as other intact $T_\ell, \ell \ne r$ exist. To see this, first note that $|T_r \cap \widehat{\mathcal{C}}^c| \le \xi|T_r| \le \xi\beta n_\wedge$, using assumption (i). Taking i_0 on or near T_r in a future iteration will give us a cluster of size at most $(\xi\beta+\gamma)n_\wedge < (1-\gamma)n_\wedge$ (by assumption (iii)) which is less that $|T_\ell|$ for an intact cluster.

To simplify notation, if either of (a) and (b) happen, i.e., we pick cluster center i_0 near T_r for some r, we name the corresponding cluster $\widehat{\mathcal{C}}_r$. This is to avoid carrying around a permutation of cluster labels different than the original one, and is valid since each T_r is visited at most once by the above argument. (In fact, each is visited exactly once, as we argue below.) That last possibility is

(c) We pick i_0 *far* from any T_r, that is $d(i_0, T) > \rho$. This gives $\widehat{\mathcal{C}} \subset T^c$, hence $|\widehat{\mathcal{C}}| \le |T^c| \le \gamma n_\wedge < (1-\gamma)n_\wedge \le |T_\ell|$ for any intact T_ℓ. Thus as along as there are intact T_ℓ, this case does not happen.

The above argument gives the following picture of the evolution of the algorithm: At each step $t = 1, \dots, k$, we pick i_0 near T_r for some previously unvisited r, making it depleted, creating estimated cluster $\widehat{\mathcal{C}}_r$ and proceeding to the next iteration. After the k-th iteration all $T_\ell, \ell \in [k]$ will be depleted. We have $|\widehat{\mathcal{C}}_r| \ge |T_r|$, and $\widehat{\mathcal{C}}_r \subset T_r \cap T^c$ for all $r \in [k]$.

By construction $\{\widehat{\mathcal{C}}_\ell\}$ are disjoint. Let $\widehat{\mathcal{C}} := \biguplus_{\ell \in [k]} \widehat{\mathcal{C}}_\ell$, and note that $|\widehat{\mathcal{C}}| \ge |T|$ hence $|\widehat{\mathcal{C}}^c| \le |T^c|$. Since $\widehat{\mathcal{C}}_\ell \cap T_r = \emptyset$ for $\ell \ne r$, we have $T_r \subset \bigcap_{\ell \ne r} \widehat{\mathcal{C}}_\ell^c$, hence $T_r \cap \widehat{\mathcal{C}}_r^c \subset \widehat{\mathcal{C}}^c$. All the misclassified or unclassified nodes produced by the algorithm are contained in $[\bigcup_r (T_r \cap \widehat{\mathcal{C}}_r^c)] \cup T^c$ which itself is contained in $\widehat{\mathcal{C}}^c \cup T^c$. Hence, the misclassification rate is bounded above by

$$\frac{1}{n}|\widehat{\mathcal{C}}^c \cup T^c| \le \frac{1}{n}(|\widehat{\mathcal{C}}^c| + |T^c|) \le \frac{2}{n}|T^c| \le \frac{8\varepsilon^2}{n\rho^2}.$$

where we have used (68). The proof is complete. ∎

Remark 13 *The last part of the argument can be made more transparent as follows: Each $\widehat{\mathcal{C}}_r$ consists of two disjoint part, $\widehat{\mathcal{C}}_r \cap T_r$ and $\widehat{\mathcal{C}}_r \cap T^c$. We have $|\widehat{\mathcal{C}}_r \cap T^c| \geq |T_r \setminus \widehat{\mathcal{C}}_r|$ (equivalent to $|\widehat{\mathcal{C}}_r| \geq |T_r|$). Then,*

$$\sum_k |T_r \setminus \widehat{\mathcal{C}}_r| \leq \sum_r |\widehat{\mathcal{C}}_r \cap T^c| = |\widehat{\mathcal{C}} \cap T^c| \leq |T^c|$$

and total misclassifications are bounded by $\sum_k |T_r \setminus \widehat{\mathcal{C}}_r| + |T^c|$.

Appendix C. Auxiliary lemmas

Lemma 8 *Let $Z, Y \in \mathbb{O}^{n\times k}$ and let $\Pi_Z = ZZ^T$ and $\Pi_Y = YY^T$ be the corresponding projection operators. We have*

$$\min_{Q\in\mathbb{O}^{k\times k}} \|Z - YQ\|_F \;\leq\; \|\Pi_Z - \Pi_Y\|_F.$$

Proof We first note that $\|\Pi_Z\|_F^2 = \mathrm{tr}(\Pi_Z^2) = \mathrm{tr}(\Pi_Z) = k$ (since projections are idempotent), and $\|Z\|_F^2 = \mathrm{tr}(Z^TZ) = \mathrm{tr}(\Pi_Z) = k$. Let $Z^TY = U\Sigma V^T$ be the SVD of Z^TY where $U, V \in \mathbb{O}^{k\times k}$ and $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_k) \succeq 0$. Then, using the change of variable $O = V^TQU$,

$$\begin{aligned}\frac{1}{2}\min_Q \|Z - YQ\|_F^2 &= k - \max_Q \mathrm{tr}(Z^TYQ)\\ &= k - \max_{O\,\in\,\mathbb{O}^{k\times k}} \mathrm{tr}(\Sigma O) = k - \|\Sigma\|_*,\end{aligned}$$

where $\|\Sigma\|_* = \sum_i \sigma_i$ is the nuclear norm of Σ. To see the last equality, we note that since O is orthogonal, we have $|O_{ii}| \leq 1$ for all i, hence $\max_O \mathrm{tr}(\Sigma O) \leq \max_{\forall i,\,|O_{ii}|\leq 1} \sum_i \sigma_i O_{ii} = \sum_i \sigma_i$ by the duality of ℓ_1 and ℓ_∞ norms and $\sigma_i \geq 0$. The equality is achieved by $O = I_k$. On the other hand

$$\frac{1}{2}\|\Pi_Z - \Pi_Y\|_F^2 = k - \mathrm{tr}(\Pi_Z\Pi_Y) = k - \|Z^TY\|_F^2 = k - \|\Sigma\|_F^2.$$

Since $\|\Sigma\|_{\mathrm{op}} = \|Z^TY\|_{\mathrm{op}} = \|Z\|_{\mathrm{op}}\|Y\|_{\mathrm{op}} \leq 1$, we have $\sigma_i \leq 1$ for all i. It follows that $\|\Sigma\|_F^2 \leq \|\Sigma\|_*$ completing the proof. ■

Abstract

Individualized treatment rules aim to identify if, when, which, and to whom treatment should be applied. A globally aging population, rising healthcare costs, and increased access to patient-level data have created an urgent need for high-quality estimators of individualized treatment rules that can be applied to observational data. A recent and promising line of research for estimating individualized treatment rules recasts the problem of estimating an optimal treatment rule as a weighted classification problem. We consider a class of estimators for optimal treatment rules that are analogous to convex large-margin classifiers. The proposed class applies to observational data and is doubly-robust in the sense that correct specification of either a propensity or outcome model leads to consistent estimation of the optimal individualized treatment rule. Using techniques from semiparametric efficiency theory, we derive rates of convergence for the proposed estimators and use these rates to characterize the bias-variance trade-off for estimating individualized treatment rules with classification-based methods. Simulation experiments informed by these results demonstrate that it is possible to construct new estimators within the proposed framework that significantly outperform existing ones. We illustrate the proposed methods using data from a labor training program and a study of inflammatory bowel syndrome.

1. Introduction

There is a growing consensus that the best possible care results from treatment decisions that are carefully tailored to individual patient characteristics (Sox and Greenfield, 2009). Individualized treatment rules (ITRs) formalize tailored treatment decisions as a function from patient information to a recommended treatment. We define an optimal ITR as maximizing the mean of a pre-specified clinical outcome if applied to recommend treatments in a population of interest (see Linn et al., 2016, for alternative definitions of optimality). With expanding access to patient-level data through electronic health records, adverse event reporting, insurance claims, and billing records, there is increasing interest in estimating optimal ITRs from observational data. An important use of an estimated optimal ITR is hypothesis-generation whereby the estimated optimal rule is used to discover covariate-treatment interactions or identify subgroups of patients with large treatment effects. In such applications, it is useful to directly control the class of ITRs within which the optimal ITR will be estimated. The form of this class can be chosen to ensure interpretability, enforce logistical or cost constraints, or make the tests of certain clinical hypotheses overt.

One approach to estimating an optimal ITR is to model some or all of the conditional distribution of the outcome given treatments and covariates and then to use this estimated distribution to infer the optimal ITR. These approaches are sometimes called indirect methods as they indirectly specify the form of the optimal ITR through postulated models for components of the conditional outcome distribution. Indirect methods have dominated the literature on estimating optimal ITRs; examples of indirect estimation methods include variations of g-estimation in structural nested models (Robins, 1989, 1997; Murphy, 2003; Robins, 2004); Q- and A-learning (Zhao et al., 2009; Qian and Murphy, 2011; Moodie et al., 2012; Chakraborty and Moodie, 2013; Schulte et al., 2014), and regret regression (Henderson et al., 2009). However, a major drawback with these approaches is that the postulated outcome models dictates the class of possible ITRs. A consequence is that to obtain a simple ITR requires specification of simple outcome models, which may not be correctly specified. Moreover, if these outcome models are misspecified, the foregoing methods may not be consistent for the optimal ITR within the class implied by the outcome models. For example, to ensure a linear ITR using Q-learning, it is common to use a linear conditional mean model. It can be shown that if the linear mean model is misspecified then the estimated optimal ITR using Q-learning need not converge to the optimal linear ITR (Qian and Murphy, 2011). Alternatively, flexible outcome models that mitigate the risk of misspecification (e.g., Zhao et al., 2009; Qian and Murphy, 2011; Moodie et al., 2013) can induce a class of ITRs that is difficult or impossible to interpret (see Section 2 for details).

An alternative to indirect estimation is to decouple models for the conditional outcome distribution from the class of ITRs. One way to do this is to form a flexible estimator of the mean outcome as a function of the ITR that is consistent under a large class of potential generative models and then to use the maximizer of this function over a pre-specified class of ITRs as the estimator of the optimal ITR. These approaches are called direct (Laber et al., 2014), policy-search (Sutton and Barto, 1998; Szepesvári, 2010), policy

learning (Athey and Wager, 2017) or value-search (Davidian et al., 2014) estimators. An advantage of direct estimators is that they permit flexible, e.g., semi- or non-parametric, models for modeled portions of the outcome distribution yet still control the form of the estimated optimal ITR. Direct estimators include outcome weighted learning (Zhao et al., 2012, 2015a, 2015b), robust value-search estimators (Zhang et al., 2012a, 2012b, 2013); marginal structural mean models (Robins et al., 2008; Orellana et al., 2010); and Q-learning with policy-search (Taylor et al., 2015; Zhang et al., 2015, 2017).

While the foregoing methods represent significant progress in direct estimation, computational and theoretical gaps remain. Outcome weighted learning uses a convex relaxation of an inverse-probability weighted estimator (IPWE) of the mean outcome. This convex relaxation makes their method computationally efficient and scalable to large problems; in addition, convexity simplifies derivations of convergence rates and generalization error bounds. However, the IPWE is known to be unstable under certain generative models (Zhang et al., 2012a, 2012b), and theoretical guarantees for outcome weighted learning were developed only for data from a randomized clinical trial. Robust value-search estimators directly maximize an augmented IPWE (AIPWE). The AIPWE is semi-parametric efficient and is significantly more stable than the IPWE. However, the AIPWE is a discontinuous function of the observed data, which makes direct maximization computationally burdensome even in moderate sized problems and complicates theoretical study of these estimators. We establish the theory for both AIPW and its convex relaxation, which fills the gap in the current literature on direct search methods. Marginal structural mean models are best suited for problems where the ITR depends only on a very small number of covariates. Liu et al. (2016) proposed a robust method for estimating optimal treatment rules in a multi-stage setup. At each stage in a multi-stage setup, they proposed a robust weight to replace the original weight in OWL based on the idea of augmentation. However, they still require consistent estimation of the propensity score at the present stage. In particular, their proposal for the single stage problem still relies on an IPWE, and does not possess the double robustness property.

We propose a class of estimators representable as the maximizer of a convex relaxation of the AIPWE; we term this class of estimators Efficient Augmentation and Relaxation Learning (EARL). EARL is computationally efficient, theoretically tractable, and applies to both observational and experimental data. Furthermore, EARL contains outcome weighted learning (OWL) (Zhao et al., 2012) as a special case. However, EARL is considerably more general than OWL, and this generality leads to new insights about classification-based estimation of ITRs, new algorithms, and new theoretical results. Unlike OWL, EARL makes use of both a propensity score and an outcome regression model. Estimators within the EARL framework are doubly-robust in the sense that they consistently estimate the optimal ITR if either the propensity score model or outcome regression model is correctly specified. Within the EARL framework, we are able to characterize convergence rates across a range of convex relaxations, propensity score models, and outcome regression models. In particular, making use of sample splitting, we are able to remove the dependence in estimating the nuisance functions and in constructing the estimated ITR. We show that under all convex relaxations considered, a fast convergence rate of the estimated optimal ITR can be achieved, and that the estimation of the propensity score and outcome regression models need not affect the upper bound of this rate. Our theoretical results complement existing work on

convergence rate for estimating optimal treatment decision rules, which primarily compared the estimated rules to the best-in-class rule (Kitagawa and Tetenov, 2017; Athey and Wager, 2017; **?**). The proposed method has been implemented in R and is freely available through the 'DynTxRegime' package hosted on the comprehensive R network (cran.org).

In Section 2, we introduce the EARL class of estimators. In Section 3, we investigate the theoretical properties of estimators within this class. In Section 4, we use simulation experiments to investigate the finite sample performance of EARL estimators. In Section 5, we present illustrative case studies using data from a labor training program and an inflammatory bowel disease study. In Section 6, we make concluding remarks and discuss potential extensions.

2. Methods

In this section, we first provide background of the proposed method. We then introduce Efficient Augmentation and Relaxation Learning (EARL) in details.

2.1. Background and preliminaries

The observed data, $\{(\boldsymbol{X}_i, A_i, Y_i)\}_{i=1}^n$, comprise n independent, identically distributed copies of $(\boldsymbol{X}, A, Y)$, where: $\boldsymbol{X} \in \mathbb{R}^p$ denotes baseline subject measurements; $A \in \{-1, 1\}$ denotes the assigned treatment; and $Y \in \mathbb{R}$ denotes the outcome, coded so that higher values are better. In this context, an ITR, d, is a map from $\mathbb{R}^p$ into $\{-1, 1\}$ so that a patient presenting with $\boldsymbol{X} = \boldsymbol{x}$ is recommended treatment $d(\boldsymbol{x})$. Let $\mathcal{D}$ denote a class of ITRs of interest. To define the optimal ITR, denoted d^*, we use the framework of potential outcomes (Rubin, 1974; Splawa-Neyman et al., 1990). Let $Y(a)$ denote the potential outcome under treatment $a \in \{-1, 1\}$ and define $Y(d) = \sum_{a\in\{-1,1\}} Y(a) I\{a = d(\boldsymbol{X})\}$ to be the potential outcome under d. The marginal mean outcome $V(d) \triangleq E\{Y(d)\}$ is called the value of the ITR d. The optimal ITR satisfies $d^* \in \mathcal{D}$ and $V(d^*) \geq V(d)$ for all $d \in \mathcal{D}$. Note that this definition of optimality depends on the class $\mathcal{D}$. To express the value in terms of the data generating model, we assume: (i) strong ignorability, $\{Y(-1), Y(1)\} \amalg A \big| \boldsymbol{X}$ (Rubin, 1974; Robins, 1986; Splawa-Neyman et al., 1990); (ii) consistency, $Y = Y(A)$; and (iii) positivity, there exists $\tau > 0$ so that $\tau < P(A = a|\boldsymbol{X})$ for each $a \in \{-1, 1\}$ with probability one. These assumptions are common and well-studied (see Schulte et al., 2014, for a recent review of potential outcomes for treatment rules). Assumption (i) is true in a randomized study but unverifiable in an observational study (Bang and Robins, 2005).

Define $Q(\boldsymbol{x}, a) \triangleq E(Y|\boldsymbol{X} = \boldsymbol{x}, A = a)$, then under the foregoing assumptions, it can be shown that

$$V(d) = E\left[Q\left\{\boldsymbol{X}, d(\boldsymbol{X})\right\}\right], \tag{1}$$

from which it follows that $d^*(\boldsymbol{x}) = \arg\max_{a\in\{-1,1\}} Q(\boldsymbol{x}, a)$. Q-learning is a common regression-based indirect approach for estimating d^* wherein an estimator $\widehat{Q}(\boldsymbol{x}, a)$ of $Q(\boldsymbol{x}, a)$ is constructed and subsequently the estimated optimal rule is $\widehat{d}(\boldsymbol{x}) = \arg\max_a \widehat{Q}(\boldsymbol{x}, a)$. Let $\mathcal{Q}$ denote the postulated class of models for $Q(\boldsymbol{x}, a)$, then the set of possible decision rules obtained using Q-learning is $\mathcal{D} = \{d : d(\boldsymbol{x}) = \arg\max_a Q(\boldsymbol{x}, a),\ Q \in \mathcal{Q}\}$. Thus, there is an inherent trade-off between choosing $\mathcal{Q}$ to be sufficiently rich to reduce the risk of model misspecification and the resultant complexity of the resultant class of ITRs.

Direct estimators specify a class of candidate ITRs independently from postulated models for some or all of the generative model. Let $\mathcal{D}$ denote a class of ITRS; direct search estimators first construct an estimator of the value function, say $\widehat{V}(\cdot)$, and then choose $\widehat{d} = \arg\max_{d\in\mathcal{D}} \widehat{V}(d)$ as the estimator of d^*. Thus, a complex model space for $V(\cdot)$ need not imply a complex class of rules $\mathcal{D}$. However, the class of models for $V(\cdot)$ must be sufficiently rich to avoid implicit, unintended restrictions on $\widehat{d}$. To avoid such restrictions and to avoid model-misspecification, it is common to use a flexible class of semi- or non-parametric models for $V(\cdot)$.

2.2. Augmentation for the value function

Define the propensity score $\pi(a;\boldsymbol{x}) \triangleq P(A = a|\boldsymbol{X} = \boldsymbol{x})$, then

$$V(d) = E\left[\frac{Y}{\pi(A;\boldsymbol{X})} I\{A = d(\boldsymbol{X})\}\right], \tag{2}$$

where $I\{\cdot\}$ denotes the indicator function (e.g., Qian and Murphy, 2011). Unlike (1), the preceding expression does not require an estimator of the Q-function. Given an estimator of the propensity score, $\widehat{\pi}(a;\boldsymbol{x})$, a plug-in estimator for $V(d)$ based on (2) is the inverse probability weighted estimator (IPWE) $\widehat{V}^{\text{IPWE}}(d) \triangleq \mathbb{P}_n[YI\{A = d(\boldsymbol{X})\}/\widehat{\pi}(A;X)]$, where $\mathbb{P}_n$ is the empirical distribution. The IPWE has potentially high variance as it only uses outcomes from subjects whose treatment assignments coincide with those recommended by d.

One approach to reduce variability is to augment the IPWE with a term involving both the propensity score and the Q-function that is estimated using data from all of the observed subjects (Robins et al., 1994; Cao et al., 2009). Let $\widehat{Q}(\boldsymbol{x}, a)$ denote an estimator of $Q(\boldsymbol{x}, a)$. The augmented inverse probability weighted estimator is

$$\widehat{V}^{\text{AIPWE}}(d) \triangleq \mathbb{P}_n\left[\frac{YI\{A = d(\boldsymbol{X})\}}{\widehat{\pi}\{d(X);X\}} - \frac{I\{A = d(\boldsymbol{X})\} - \widehat{\pi}\{d(\boldsymbol{X});\boldsymbol{X}\}}{\widehat{\pi}\{d(\boldsymbol{X});\boldsymbol{X}\}}\widehat{Q}\{\boldsymbol{X}, d(\boldsymbol{X})\}\right]. \tag{3}$$

It can be seen that $\widehat{V}^{\text{AIPWE}}(d)$ is equal to $\widehat{V}^{\text{IPWE}}(d)$ plus an estimator of zero built using outcomes from all subjects regardless of whether or not their treatment assignment is consistent with d. If $\widehat{Q}(\boldsymbol{x}, a) \equiv 0$ then $\widehat{V}^{\text{AIPWE}}(d) = \widehat{V}^{\text{IPWE}}(d)$ for all d.

Hereafter, we use $\widehat{Q}(\boldsymbol{x}, a)$ and $\widehat{\pi}(a;\boldsymbol{x})$ to denote generic estimators of the Q-function and propensity score. The following assumption is used to establish double robustness of $\widehat{V}^{\text{AIPWE}}(d)$.

Assumption 1 *$\widehat{Q}(\boldsymbol{x}, a)$ and $\widehat{\pi}(a;\boldsymbol{x})$ converge in probability uniformly to deterministic limits $Q^m(\boldsymbol{x}, a)$ and $\pi^m(a;\boldsymbol{x})$.*

This assumption does not require that the estimators $\widehat{Q}(\boldsymbol{x}, a)$, $\widehat{\pi}(a;\boldsymbol{x})$ are consistent for the truth, only that they converge to fixed functions. The following result is proved in Web Appendix A.

Lemma 2.1 *Let $d \in \mathcal{D}$ be fixed. If* either $\pi^m(a;\boldsymbol{x}) = \pi(a;\boldsymbol{x})$ *or* $Q^m(\boldsymbol{x}, a) = Q(\boldsymbol{x}, a)$ *for all $(\boldsymbol{x}, a)$ outside of a set of measure zero, then $\widehat{V}^{AIPWE}(d) \to_p V^{AIPWE,m}(d) = V(d)$, where*

$$V^{AIPWE,m}(d) \triangleq E\left[\frac{YI\{A = d(\boldsymbol{X})\}}{\pi^m(A;\boldsymbol{X})} - \frac{I\{A = d(\boldsymbol{X})\} - \pi^m\{d(\boldsymbol{X});\boldsymbol{X}\}}{\pi^m\{d(\boldsymbol{X});\boldsymbol{X}\}}Q^m\{\boldsymbol{X}, d(\boldsymbol{X})\}\right].$$

The preceding result shows that $\widehat{V}^{AIPWE}(d)$ is doubly-robust in the sense that if either the propensity model or the modeled Q-function is consistent, but not necessarily both, then $\widehat{V}^{AIPWE}(d)$ is consistent for $V(d)$. Thus, the maximizer of $\widehat{V}^{AIPWE}(d)$ over $d \in \mathcal{D}$ is termed a doubly-robust estimator of the optimal treatment rule (Zhang et al., 2012a, 2012b, 2013). However, because $\widehat{V}^{AIPWE}(d)$ is not continuous, computing this doubly-robust estimator can be computationally infeasible even in moderate problems (Zhang et al., 2012a). Instead, we form an estimator by maximizing a concave relaxation of $\widehat{V}^{AIPWE}(d)$. Maximizing this concave relaxation is computationally efficient even in very high-dimensional problems. We show that the maximizer of this relaxed criteria remains doubly-robust. Furthermore, we show that the rates of convergence of the proposed estimators depend on the chosen concave relaxation, the chosen propensity model, and the chosen model for the Q-function. The relationships among these choices provides new knowledge about direct search estimators based on concave surrogates (Zhang et al., 2012; Zhao et al., 2012, 2015a, 2015b).

2.3. Efficient augmentation and relaxation learning (EARL)

Let $\mathcal{M}$ be the class of measurable functions from $\mathbb{R}^p$ into $\mathbb{R}$. Any decision rule $d(\boldsymbol{x})$ can be written as $d(\boldsymbol{x}) = \text{sgn}\{f(\boldsymbol{x})\}$ for some function $f \in \mathcal{M}$, where we define $\text{sgn}(0) = 1$. For $d(\boldsymbol{x}) = \text{sgn}\{f(\boldsymbol{x})\}$, $I\{a = d(\boldsymbol{x})\} = I\{af(\boldsymbol{x}) \geq 0\}$. Define $V(f)$, $V^{\text{IPWE},m}(f)$, and $V^{\text{AIPWE},m}(f)$ by substituting $I\{Af(\boldsymbol{X}) \geq 0\}$ for $I\{A = d(\boldsymbol{X})\}$ in their respective definitions. Define

$$W_a^m = W_a(Y, \boldsymbol{X}, A, \pi^m, Q^m) = \frac{YI(A = a)}{\pi^m(a;\boldsymbol{X})} - \frac{I(A = a) - \pi^m(a;\boldsymbol{X})}{\pi^m(a;\boldsymbol{X})}Q^m(\boldsymbol{X}, a), a \in \{-1, 1\}.$$

The following result shows that maximizing $\widehat{V}^{\text{AIPWE}}(f)$ is equivalent to minimizing a sum of weighted misclassification rates; a proof is given in Web Appendix B.

Lemma 2.2 *Assume that $P\{f(\boldsymbol{X}) = 0\} = 0$. Define $\widehat{f}_n = \arg\sup_{f\in\mathcal{M}} \widehat{V}^{\text{AIPWE}}(f)$, then*

$$\widehat{f}_n = \arg\inf_{f\in\mathcal{M}} \mathbb{P}_n\left[|\widehat{W}_1|I\left\{\text{sgn}(\widehat{W}_1)f(\boldsymbol{X}) < 0\right\} + |\widehat{W}_{-1}|I\left\{-\text{sgn}(\widehat{W}_{-1})f(\boldsymbol{X}) < 0\right\}\right],$$

where $\widehat{W}_a = W_a(Y, \boldsymbol{X}, A, \widehat{\pi}, \widehat{Q}), a =\in \{-1, 1\}$.

Lemma 2.2 shows that the estimator, $\widehat{f}_n$, which maximizes $\widehat{V}^{\text{AIPWE}}(f)$ over $f \in \mathcal{M}$, can be viewed as minimizing a sum of weighted 0-1 losses. In this view, the class labels are $\text{sgn}(\widehat{W}_a) \cdot a$ and the misclassification weights are $|\widehat{W}_a|$, $a =\in \{-1, 1\}$ (see Zhang et al., 2012b, 2013). Directly minimizing the combined weighted 0-1 loss is a difficult non-convex optimization problem (Laber and Murphy, 2011). One strategy to reduce computational complexity is to replace the indicator function with a convex surrogate and to minimize the resulting relaxed objective function (Freund and Schapire, 1999; Bartlett et al., 2006; Hastie et al., 2009). This strategy has proved successful empirically and theoretically in classification and estimation of optimal treatment rules (Zhao et al., 2012). However, unlike previous applications of convex relaxations to the estimation of optimal treatment rules, we establish rates of convergence as a function of the: (i) choice of convex surrogate; (ii) convergence rate of the postulated propensity score estimator; and (iii) convergence rate

the postulated Q-function estimator. We characterize the relationship among these three components in Section 3.

The function f is conceptualized as being a smooth function of $\boldsymbol{x}$ that is more easily constrained to possess certain desired structure, e.g., sparsity, linearity, etc. Thus, we will focus on estimation of f within a class of functions $\mathcal{F}$ called the approximation space; we assume that $\mathcal{F}$ is a Hilbert space with norm $\|\cdot\|$. Let $\phi : \mathbb{R} \to \mathbb{R}$ denote a convex function and define EARL estimators as those taking the form

$$\tilde{f}_n^{\lambda_n} = \arg\inf_{f\in\mathcal{F}} \mathbb{P}_n\left[|\widehat{W}_1|\phi\left\{\mathrm{sgn}(\widehat{W}_1)f(\boldsymbol{X})\right\} + |\widehat{W}_{-1}|\phi\left\{-\mathrm{sgn}(\widehat{W}_{-1})f(\boldsymbol{X})\right\}\right] + \lambda_n\|f\|^2, \quad (4)$$

where $\lambda_n\|f\|^2$ is included to reduce overfitting and $\lambda_n \geq 0$ is a (possibly data-dependent) tuning parameter. Throughout, we assume that $\phi(t)$ is one of the following: hinge loss, $\phi(t) = \max(1-t, 0)$; exponential loss, $\phi(t) = e^{-t}$; logistic loss, $\phi(t) = \log(1+e^{-t})$; or squared hinge loss, $\phi(t) = \{\max(1-t,0)\}^2$. However, other convex loss functions are possible provided that they are differentiable, monotone, strictly convex, and satisfy $\phi(0) = 1$ (Bartlett et al., 2006). As noted previously, Zhao et al. (2012) proposed a special case of EARL called outcome weighted learning, which set $\phi(t) = \max(0, 1-t)$, $\widehat{Q}(\boldsymbol{x}, a) \equiv 0$, and assumed that the propensity score was known. Thus, as noted previously, EARL is considerably more general than OWL and, as shown in Section 4, the choice of a non-null model for the Q-function and alternative surrogate loss functions can lead to dramatically improved finite sample performance.

2.4. EARL via sample splitting

To facilitate the analysis of the statistical properties of EARL, we consider the following alternative estimator based on the sample splitting. Let $I_1, I_2, ..., I_K$ denote a random partition of the indices $\{1, 2, ..., n\}$ with $I_j \cap I_k = \emptyset$ for any $j \neq k$ and $\cup_{k=1}^K I_k = \{1, 2, ..., n\}$. We assume the size of the partitions is comparable, that is, $n_k = |I_k|$ with $n_1 \asymp n_2 \asymp ... \asymp n_K$. In practice, K is taken as a small integer (e.g., 2, or 5) and is assumed fixed. Recall that the EARL estimator based on the full sample is defined in (4). In particular, the same samples are used to estimate the nuisance functions $\hat{\pi}, \hat{Q}$ and construct the estimator $\tilde{f}_n^{\lambda_n}$ in (4). This creates the delicate dependence between the estimators $\hat{\pi}, \hat{Q}$ and the samples used in the empirical risk minimization in (4). To remove this dependence, we now modify the procedure via sample splitting. First, for $1 \leq k \leq K$, we construct estimators $\hat{\pi}_k, \hat{Q}_k$ based on the samples in I_k, i.e., $\{(\boldsymbol{X}_i, A_i, Y_i); i \in I_k\}$. Denote $I_{(-k)} = \{1, ..., n\} \backslash I_k$. Then, we use the remaining samples $I_{(-k)}$ for the EARL estimator

$$\widehat{f}_{n,k}^{\lambda_{nk}} = \arg\inf_{f\in\mathcal{F}} \mathbb{P}_n{}^{(-k)}\left[|\widehat{W}_{1k}|\phi\left\{\mathrm{sgn}(\widehat{W}_{1k})f(\boldsymbol{X})\right\} + |\widehat{W}_{-1k}|\phi\left\{-\mathrm{sgn}(\widehat{W}_{-1k})f(\boldsymbol{X})\right\}\right] + \lambda_{nk}\|f\|^2, \quad (5)$$

where $\widehat{W}_{ak} = W_a(Y, \boldsymbol{X}, A, \hat{\pi}_k, \widehat{Q}_k), a = \in \{-1, 1\}$ and $\mathbb{P}_n{}^{(-k)} f = \frac{1}{|I_{(-k)}|}\sum_{i\in I_{(-k)}} f(X_i)$. We note that independent samples are used for estimating the nuisance functions π, Q and the decision rule f. Thus, the dependence between the estimators $\hat{\pi}, \hat{Q}$ and the samples use in (4) is removed. Finally, to obtain a more stable estimator, we can aggregate the estimators

$$\widehat{f}_n^{\lambda_n} = \frac{1}{K}\sum_{k=1}^K \widehat{f}_{n,k}^{\lambda_{nk}}, \quad (6)$$

which is the final estimator based on sample splitting. While the estimator $\widehat{f}_n^{\lambda_n}$ requires more computational cost, it has important advantages over the original EARL estimator $\tilde{f}_n^{\lambda_n}$ in (4). From a theoretical perspective, one can still analyze the EARL estimator $\tilde{f}_n^{\lambda_n}$ based on the empirical process theory. This typically requires the entropy conditions on the function classes of π and Q. In comparison, we show in the following section that the sample splitting estimator $\widehat{f}_n^{\lambda_n}$ does not require this condition. To the best of our knowledge, similar sample splitting technique was first applied by Bickel (1982) in general semiparametric estimation problems; see also Schick (1986). Recently, this approach has received attention in causal inference problems as a means of relaxing technical conditions. We refer to Zheng and van der Laan (2011); Chernozhukov et al. (2016); Robins et al. (2017) for further discussion.

3. Theoretical properties

Let $f^* \in \mathcal{M}$ be such that $d^*(\boldsymbol{x}) = \mathrm{sgn}\{f^*(\boldsymbol{x})\}$, and $V^* \triangleq \sup_{f\in\mathcal{M}} V(f) = V(f^*)$. Define the population risk of function f as

$$\mathcal{R}(f) = E(YI[A \neq \mathrm{sgn}\{f(\boldsymbol{X})\}]/\pi(A; \boldsymbol{X})),$$

and $\mathcal{R}^* \triangleq \inf_{f\in\mathcal{M}} \mathcal{R}(f)$. We define the risk in this way to be consistent with the convention that higher risk is less desirable; however, inspection shows that the risk equals $K - V(f)$ where K is a constant that does not depend on f. Thus, minimizing risk is equivalent to maximizing value, and $V^* - V(f) = \mathcal{R}(f) - \mathcal{R}^*$. Accordingly, for a convex function ϕ, we define the ϕ-risk

$$\mathcal{R}_\phi^m(f) = E[|W_1^m|\phi\left\{\mathrm{sgn}(W_1^m)f(\boldsymbol{X})\right\} + |W_{-1}^m|\phi\left\{-\mathrm{sgn}(W_{-1}^m)f(\boldsymbol{X})\right\}].$$

By construction, $\mathcal{R}_\phi^m(f)$ is convex; we assume that it has a unique minimizer and that $\mathcal{R}_\phi^{m*} \triangleq \inf_{f\in\mathcal{M}} \mathcal{R}_\phi^m(f)$. The following result is proved in Web Appendix C.

Proposition 3.1 *Assume that either $\pi^m(a; \boldsymbol{x}) = \pi(a; \boldsymbol{x})$ or $Q^m(\boldsymbol{x}, a) = Q(\boldsymbol{x}, a)$. Define $\tilde{f} = argmin_{f\in\mathcal{M}} R_\phi^m(f)$ and $c_m(\boldsymbol{x}) = E\{|W_1(Y, \boldsymbol{x}, A, \pi^m, Q^m)| + |W_{-1}(Y, \boldsymbol{x}, A, \pi^m, Q^m)|\}$. Then:*

(a) $d^*(\boldsymbol{x}) = \mathrm{sgn}\{\tilde{f}(\boldsymbol{x})\}$;

(b) and

$$\psi\left\{\frac{V^* - V(f)}{\sup_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})}\right\} \leq \frac{\mathcal{R}_\phi^m(f) - \mathcal{R}_\phi^{m*}}{\inf_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})},$$

where $\psi(\theta) = |\theta|$ for hinge loss, $\psi(\theta) = 1 - \sqrt{1-\theta^2}$ for exponential loss, $\psi(\theta) = (1+\theta)\log(1+\theta)/2 + (1-\theta)\log(1-\theta)/2$ for logistic loss, and $\psi(\theta) = \theta^2$ for squared hinge loss.

Part (a) of the preceding proposition states that if either the model for the propensity score or for the Q-function is correctly specified, then the EARL procedure, optimized over the space of measurable functions, is Fisher consistent for the optimal rule. Part (b) bounds the difference between $V(f)$ and V^* through the surrogate risk difference $\mathcal{R}^m_\phi(f) - \mathcal{R}^{m*}_\phi$. The different forms of $\psi(\cdot)$ are due to the fact that different loss functions induce different distance measures of closeness of $f(x)$ to the true $f^*(x)$. We use these risk bounds to derive bounds on the convergence rates of the value of EARL estimators constructd using sample splitting.

Let Π denote the function spaces to which the postulated models for $\pi(a;\boldsymbol{x})$ belong; that is, the estimator $\widehat{\pi}(a;\boldsymbol{x})$ belongs to Π. Similarly, let $\mathcal{Q}$ denote a postulated class of models for $Q(\boldsymbol{x},a)$. In this section, we allow the approximation space, $\mathcal{F}$, to be arbitrary subject to complexity constraints; our results allow both parametric or non-parametric classes of models. Our primary result is a bound on the rate of convergence of $V^* - V(\widehat{f}^{\lambda_n}_n)$ in terms of the ϕ-risk difference $\mathcal{R}^m_\phi(\widehat{f}^{\lambda_n}_n) - \mathcal{R}^{m*}_\phi$.

For any $\epsilon > 0$ and measure P, let $N\{\epsilon, \mathcal{F}, L_2(P)\}$ denote the covering number of the space $\mathcal{F}$, that is, $N\{\epsilon, \mathcal{F}, L_2(P)\}$ is the minimal number of closed $L_2(P)$-balls of radius ϵ required to cover $\mathcal{F}$ (Kosorok, 2008). Denote $\|f\|^2_{P,2} = Ef^2(\boldsymbol{X})$. We make the following assumptions.

Assumption 2 *There exists $M_Q > 0$ such that $|Y| \le M_Q$ and $|Q(\boldsymbol{x},a)| \le M_Q$ for all $(\boldsymbol{x},a) \in \mathbb{R}^p \times \{-1,1\}$ and $Q \in \mathcal{Q}$; there exists $0 < L_\Pi < M_\Pi < 1$ such that $L_\Pi \le \pi(a;\boldsymbol{x}) \le M_\Pi$ for all $(\boldsymbol{x},a) \in \mathbb{R}^p \times \{-1,1\}$ and $\pi \in \Pi$.*

Assumption 3 *There exist constants $0 < v < 2$ and $c < \infty$ such that for all $0 < \epsilon \le 1$: $\sup_P \log N\{\epsilon, \mathcal{F}, L_2(P)\} \le c\epsilon^{-v}$, where the supremum is taken over all finitely discrete probability measures P.*

Assumption 4 *For some $\alpha, \beta > 0$, $E\|\widehat{\pi}_k(a;\boldsymbol{x}) - \pi(a;\boldsymbol{x})\|^2_{P,2} = O(n^{-2\alpha})$ and $E\|\widehat{Q}_k(\boldsymbol{x},a) - Q(\boldsymbol{x},a)\|^2_{P,2} = O(n^{-2\beta})$ for $a = \pm 1$ and $1 \le k \le K$.*

Assumption 2 assumes outcomes are bounded, which often holds in practice. Otherwise, we can always use a large constant to bound the outcome. We also assume propensity scores are bounded away from 0 and 1, which is a standard condition for the identification of the treatment effect in causal inference. Assumption 3 controls the complexity of the function spaces for estimating an optimal ITR. For example, if $\mathcal{F}$ is composed of linear combinations of elements in a fixed base class, $\mathcal{H}$, where $\mathcal{H}$ has finite Vapnik-Chervonenkis (VC) dimension vc, then there exists a constant c_{vc}, depending on vc, so that $\sup_P \log N\{\epsilon, \mathcal{F}, L_2(P)\} \le c_{vc}\epsilon^{-2vc/(vc+2)}$ (Theorem 9.4, Kosorok (2008)). We note that the entropy conditions on $\mathcal{Q}$ and Π are not needed by using the sample splitting technique, due to the independence between estimating π, Q and estimating f.

Assumption 4 specifies the rate of convergence of the estimators $\widehat{\pi}$ and $\widehat{Q}$ in terms of the $\|\cdot\|_{P,2}$ norm. It is well known that the L_2 rate of convergence is related to the smoothness of the function classes $\mathcal{Q}$ and Π and the dimension of $\boldsymbol{X}$. For instance, if $\mathcal{Q}$ corresponds to the Holder class with smoothness parameter s on the domain $[0,1]^p$, then Theorem 7 of Newey (1997) implies $E\|\widehat{Q}(\boldsymbol{x},a) - Q(\boldsymbol{x},a)\|^2_{P,2} = O_p(K/n + K^{-2s/p})$, where $\widehat{Q}(\boldsymbol{x},a)$ is the regression spline estimator and K is the number of basis functions.

Define the approximation error incurred by optimizing over $\mathcal{F}$ as

$$\mathcal{A}(\lambda_n) = \inf_{f\in\mathcal{F}} \left(\lambda_n\|f\|^2 + \sum_{a=\pm1} E\left[W^m_a \phi\{a\cdot f(\boldsymbol{X})\}\right]\right) - \inf_{f\in\mathcal{M}} \sum_{a=\pm1} E\left[W^m_a \phi\{a\cdot f(\boldsymbol{X})\}\right]. \quad (7)$$

The following result on the risk bound is the main result in this section and is proved in the Web Appendix D.

Theorem 3.1 *Suppose that assumptions 1-4 hold, $\lambda_n \to 0$. Define $c_m(\boldsymbol{x}) = E\{|W^m_1||\boldsymbol{X} = \boldsymbol{x}, A = 1\} + E\{|W^m_{-1}||\boldsymbol{X} = \boldsymbol{x}, A = -1\}$. If $Q^m(\boldsymbol{x},a) = Q(\boldsymbol{x},a)$ and $\pi^m(a;\boldsymbol{x}) = \pi(a;\boldsymbol{x})$, then*

$$\psi\left\{\frac{V^* - V(\widehat{f}^{\lambda_n}_n)}{\sup_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})}\right\} \lesssim \frac{1}{\inf_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})} \cdot \Big[\mathcal{A}(\lambda_n) + n^{-\frac{2}{v+2}}\lambda_n^{-\frac{v}{v+2}} + n^{-1}\lambda_n^{-1} + \lambda_n^{-1/2}n^{-(\alpha+\beta)} + \lambda_n^{-1/2}(n^{-(1/2+\alpha)} + n^{-(1/2+\beta)})\Big].$$

In all cases considered, the function ψ is invertible on $[0,1]$, and its inverse is monotone non-decreasing. Thus, for sufficiently large n (making the right-hand-side of the equation sufficiently small) the inequality can be re-arranged to yield a bound on $V^* - V(\widehat{f}^{\lambda_n}_n)$. The form of ψ^{-1} dictates the tightness of the bound as a function of the ϕ-risk. According to Lemma 3 in Bartlett et al (2006), a flatter loss function leads to better bound on ψ function. In other words, a flatter loss function gives better bounds on $V^* - V(f)$ in terms of $\mathcal{R}^m_\phi(f) - \mathcal{R}^{m*}_\phi$. In this respect, hinge-loss can be seen to provide the tightest bound; however, the ϕ-risk is not directly comparable across different loss functions as they are not on the same scale.

The right hand side of the bound in Theorem 3.1 consists of three parts: the approximation error $\mathcal{A}(\lambda_n)$ due to the size of the approximation space $\mathcal{F}$, the error $n^{-\frac{2}{v+2}}\lambda_n^{-\frac{v}{v+2}} + n^{-1}\lambda_n^{-1}$ due to the estimation in the function space $\mathcal{F}$, and the error $\lambda_n^{-1/2}n^{-(\alpha+\beta)} + \lambda_n^{-1/2}(n^{-(1/2+\alpha)} + n^{-(1/2+\beta)})$ incurred from plugging the estimators $\widehat{\pi}_k$ and $\widehat{Q}_k$. As expected, the approximation error decreases as the complexity of the class $\mathcal{F}$ increases, whereas the estimation error increases with the complexity of the class $\mathcal{F}$ and decreases as the sample size increases.

For the error incurred from plugging the estimators $\widehat{\pi}_k$ and $\widehat{Q}_k$, the component $\lambda_n^{-1/2}(n^{-(1/2+\alpha)} + n^{-(1/2+\beta)})$ converges to 0 faster than $\lambda_n^{-1/2}n^{-(\alpha+\beta)}$ in regular statistical models (i.e., $\alpha, \beta \le 1/2$). Thus, it suffices to only look at the term $\lambda_n^{-1/2}n^{-(\alpha+\beta)}$. This term can shrink to 0 sufficiently fast as long as one of the estimators $\widehat{\pi}_k$ and $\widehat{Q}_k$ has a fast rate, due to the multiplicative form of the estimation error. For example, if $\alpha = \beta = 1/4$, the error from plugging the estimators $\widehat{\pi}$ and $\widehat{Q}$ is $n^{-1/2}\lambda_n^{-1/2}$. Hence, the rate of the proposed method is faster compared with the outcome weighted learning method, which is developed based on an IPWE and does not enjoy this multiplicative form of the errors. This phenomenon can be viewed as a nonparametric version of the double robustness property (see Fan et al., 2016; Benkeser et al., 2017, for additional discussion). Compared with the results in Athey and Wager (2017), we allow for the surrogate loss to replace the 0-1 loss in solving for the optimizer. While the orders in the bound of convergence rates are comparable, the differences in the constants in the bounds might be due to the application of the surrogate function.

Remark 1 *If $\alpha = \beta$ and*

$$n^{2\alpha-1}\lambda_n^{-1/2} \to \infty, \text{ or } n^{2\alpha(v+2)-2}\lambda_n^{1-v/2} \to \infty, \tag{8}$$

then

$$\psi\left\{\frac{V^* - V(\widehat{f}_n^{\lambda_n})}{\sup_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})}\right\} \lesssim \frac{1}{\inf_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})} \cdot \left[\mathcal{A}(\lambda_n) + n^{-\frac{2}{v+2}}\lambda_n^{-\frac{v}{v+2}} + n^{-1}\lambda_n^{-1}\right], \tag{9}$$

where the upper bound is of the same order as that obtained if the conditional mean $Q(\boldsymbol{x}, a)$ and propensity score $\pi(a; \boldsymbol{x})$ are known. We note that the additional constraints on α and v in (8) are necessary to obtain the fast rate of convergence (9). For instance, if the function classes $\mathcal{Q}$ and Π are indexed by finite dimensional parameters, we can obtain $\alpha = \beta = 1/2$ under mild conditions. As a result, the first condition in (8) holds and the fast rate of convergence (9) is applied. On the other hand, if $\mathcal{F}$ is a simple class but $\|\widehat{\pi} - \pi\|_{P,2}$ and $\|\widehat{Q} - Q\|_{P,2}$ converge at slower rates, the rate for $V^* - V(\widehat{f}_n^{\lambda_n})$ will be driven by $\lambda_n^{-1/2} n^{-(\alpha+\beta)}$.

To estimate the value of the optimal treatment rule V^*, one can aggregate the empirical value of the sample splitting estimator $\hat{f}_{n,k}^{\lambda_{n,k}}$ in each subsamples $I_{(-k)}$, that is, $\bar{V} = \frac{1}{K}\sum_{k=1}^K \hat{V}_{(-k)}(\hat{f}_{n,k}^{\lambda_{n,k}})$, where

$$\hat{V}_{(-k)}(f) = \mathbb{P}_n{}^{(-k)}\left[|\widehat{W}_{1k}|\phi\left\{\text{sgn}(\widehat{W}_{1k})f(\boldsymbol{X})\right\} + |\widehat{W}_{-1k}|\phi\left\{-\text{sgn}(\widehat{W}_{-1k})f(\boldsymbol{X})\right\}\right],$$

The following corollary, provides a corresponding bound on the rate for $V^* - \bar{V}$. The proof is given in Web Appendix D.

Corollary 3.1 *Suppose that assumptions 1-4 hold, and $\lambda_n \to 0$. If $Q^m(\boldsymbol{x}, a) = Q(\boldsymbol{x}, a)$ and $\pi^m(a; \boldsymbol{x}) = \pi(a; \boldsymbol{x})$, then*

$$V^* - \bar{V} \lesssim \frac{1}{K}\sum_{k=1}^K [V^* - V(\hat{f}_{n,k}^{\lambda_{n,k}})] + n^{-1/2} + \lambda_n^{-1/2} n^{-(\alpha+\beta)} + \lambda_n^{-1/2}(n^{-(1/2+\alpha)} + n^{-(1/2+\beta)}),$$

where

$$\frac{1}{K}\sum_{k=1}^K [V^* - V(\hat{f}_{n,k}^{\lambda_{n,k}})] \lesssim \sup_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})\psi^{-1}\Big[\frac{1}{\inf_{\boldsymbol{x}\in\mathbb{R}^p} c_m(\boldsymbol{x})} \cdot \Big\{\mathcal{A}(\lambda_n) + n^{-\frac{2}{v+2}}\lambda_n^{-\frac{v}{v+2}} + n^{-1}\lambda_n^{-1} + \lambda_n^{-1/2} n^{-(\alpha+\beta)} + \lambda_n^{-1/2}(n^{-(1/2+\alpha)} + n^{-(1/2+\beta)})\Big\}\Big].$$

Remark 2 *Athey and Wager (2017) and Kitagawa and Tetenov (2017) investigated the binary-action policy learning problem, and established a risk bound of $n^{-1/2}$ for both known propensities (Kitagawa and Tetenov, 2017) and unknown propensities (Athey and Wager, 2017). However, they considered a restricted class of decision rules and subsequent risk bound were established with respect to the optimal rule within this restricted class. Hence, there was not consideration of the approximation error. In contrast, we considered the optimal rule within the space consisting of all measurable functions from $\mathbb{R}^p$ (the covariate space) to $\{-1, 1\}$ (the treatment space). We used a smaller space, for example, a reproducing kernel Hilbert space, to approximate the policy space and to avoid overfitting. This led to a tradeoff between approximation and estimation error, and λ_n was a tuning parameter to control this bias-variance tradeoff. Consequently, the achieved convergence rates are different.*

4. Simulation experiments

We compare EARL estimators with: Q-learning fit using ordinary least squares (QL, Qian and Murphy, 2011); estimating the optimal rule within a restricted class based on an AIPW estimator (AIPWE, Zhang et al., 2012b); and outcome weighted learning (OWL, Zhao et al., 2012). Comparisons are made in terms of the average value of the rule estimated by each method. For Q-learning, we fit a linear model for the Q-function that includes all two-way interactions between predictors and pairwise interactions between these terms and treatment. In the AIPWE method, an AIPW estimator for the value function is constructed and then the optimal linear rule that maximizes the AIPW estimator is identified via a genetic algorithm. Similar to EARL, both a propensity score model and a regression model need to be fitted in AIPWE. We will use the same set of models in EARL and the AIPWE, which are detailed in below. For OWL, we use a linear decision rule; recall that OWL is a special case of EARL with $\widehat{Q}(\boldsymbol{x}, a) \equiv 0$, $\phi(t) = \max(0, t)$, and a known propensity score. All estimation methods under consideration require penalization; we choose the amount of penalization using 10-fold cross-validation of the value. Within the class of EARL estimators, we considered hinge, squared-hinge, logistic, and exponential convex surrogates. An implementation of EARL is available in the R package 'DynTxRegime;' this package also includes implementations of AIPWE and OWL and therefore can be used to replicate the simulation studies presented here. We included an example for implementing EARL method using 'DynTxRegime' package in Web Appendix H.

We consider generative models of the form: $\boldsymbol{X} = (X_1, \ldots, X_p) \sim_{i.i.d.} N(0, 1)$ with $p = 10$; treatments are binary, taking the values in $\{-1, 1\}$ according to the model $p(A = 1|\boldsymbol{X}) = \exp\{\ell(\boldsymbol{X})\}/[1 + \exp\{\ell(\boldsymbol{X})\}]$, where $\ell(\boldsymbol{x}) = x_1 + x_2 + x_1x_2$ in Scenario 1, and $\ell(\boldsymbol{x}) = 0.5x_1 - 0.5$ in Scenario 2; $Y = \sum_{j=1}^p X_j^2 + \sum_{j=1}^p X_j + Ac(\boldsymbol{X}) + \epsilon$, where $\epsilon \sim N(0, 1)$, and $c(\boldsymbol{x}) = x_1 + x_2 - 0.1$. Write $\boldsymbol{X}^2$ to denote $(X_1^2, \ldots, X_p^2)$. The following modeling choices are considered for the propensity and outcome regression models.

CC. A correctly specified logistic regression model for $\pi(A; \boldsymbol{X})$ with predictors X_1, X_2 and X_1X_2 in Scenario 1, and with predictor X_1 in Scenario 2; and a correctly specified linear regression model for $Q(\boldsymbol{X}, A)$ with predictors $\boldsymbol{X}, \boldsymbol{X}^2, A, X_1A$ and X_2A in both scenarios.

CI. A correctly specified logistic regression model for $\pi(A; \boldsymbol{X})$ with predictors X_1, X_2 and X_1X_2 in Scenario 1, and with predictor X_1 in Scenario 2; and an incorrectly specified linear model for $Q(\boldsymbol{X}, A)$ with predictors $\boldsymbol{X}, A, \boldsymbol{X}A$ in both scenarios.

IC. An incorrectly specified logistic regression model for $\pi(A; \boldsymbol{X})$ with predictors $\boldsymbol{X}$ in Scenario 1, and without any predictors in Scenario 2; and a correctly specified linear model for $Q(\boldsymbol{X}, A)$ with predictors $\boldsymbol{X}, \boldsymbol{X}^2, A, X_1A$ and X_2A in both scenarios.

II. An incorrectly specified logistic regression model for $\pi(A; \boldsymbol{X})$ with predictors $\boldsymbol{X}$ in Scenario 1, and without any predictors in Scenario 2; and an incorrectly specified linear model for $Q(\boldsymbol{X}, A)$ with predictors $\boldsymbol{X}, A, \boldsymbol{X}A$ in both scenarios.

We use the same model specifications to carry out AIPWE, and denote them as CC-A, CI-A, IC-A, and II-A correspondingly. For the OWL method, we use correct and incorrect propensity models to construct the ITRs, and denote them as C. and I. respectively. Similarly, we use Q-learning to construct the ITRs based on correct and incorrect regression models, and term them as .C and .I respectively.

We consider sample sizes 200, 500, 1000, 2500, 5000 and 10000. We generate a large validation data set (size 10000) and 500 training sets under each sample size. The ITRs are constructed based on one training set out of 500 replicates using competing methods. For implementing EARL, we use logistic loss. We observe similar patterns for other surrogate loss functions (see the Web Appendix). We carry out cross-validation to select λ_n among a pre-specified set of values $(2^{-5}, 2^{-4}, \ldots, 2^5)$. Then we calculate the mean response had the whole population followed the rule (the value function) by averaging the outcomes over 10000 subjects under the estimated ITRs in the validation data set. Thus, there are 500 values of the estimated rules on the validation set for each sample size. Boxplots of these values are shown in Figures 1 and 3. The performance of OWL was generally worse than that of the EARL estimator or QL. The AIPWE method exhibits a larger bias and a higher variance compared to the proposed method, while running approximately 200 times slower. As expected, the QL method works best when the model is correctly specified but can perform poorly when this model is misspecified.

It appears that misspecification of the model for the Q-function has a bigger impact than misspecification of the propensity score model on the AIPWE and EARL methods. The relatively poor performance when the propensity is correctly specified but the regression model is not might be attributed in part to inverse weighting by the propensity score, which is problematic when some estimated propensity scores are close to zero, yielding large weights and subsequently induces bias (Kang and Schafer, 2007). This is illustrated by contrasting scenarios 1 and 2. Propensity scores in Scenario 2 are bounded away from zero, which yield a better result compared to Scenario 1. Furthermore, the large variability when the regression model is misspecified may be partly a consequence of the method used to estimate the coefficients in the regression model (see Cao et al., 2009).

Finally, we consider an example to illustrate the impact of a severely misspecified propensity score model. In Scenario 3, the data was generated as in Scenario 2 except that the propensity score was set to 0.025 for all subjects. The 'CI' setup outperformed the 'IC' setup, especially when the sample size was small. Furthermore, the performance of the AIPWE method was largely affected by this poorly imposed propensity model. The results of 'CI' and 'II' setups were unsatisfactory even when the sample size was increased to 10000. This example indicates that the performances in the 'CI' and 'IC' setups depend on the degree of misspecification in the outcome regression model and propensity score model.

We also conducted a set of simulation experiments to investigate the role of parametric and nonparametric models for the propensity score and outcome regression. In addition, we compared the performance across different surrogate loss functions, including logistic loss, exponential loss, squared hinge loss, and hinge loss. These additional simulation results can be found in Web Appendix F. In summary, we found that in the examples considered, using

nonparametric working models for propensity scores could improve results over parametric models. Hinge loss has a more robust performance when the regression model is incorrect compared to other smooth losses.

5. Application: Ocean State Crohn's and Colitis Area Registry (OSCCAR)

OSCCAR is a community—based incident cohort of subjects with inflammatory bowel disease (IBD) residing in the state of Rhode Island that was established in 2008 (Sands et al., 2009). Subjects enrolled in OSCCAR have ulcerative colitis (UC), Crohn's disease (CD), or indeterminate colitis (IC). Corticosteroids are commonly used to treat active symptoms. Although, corticosteroids often promptly achieve remission, long-term use is complicated by many potential side effects. One treatment strategy for IBD patients is a "step-up" approach in which patients are prescribed medications with increasing potential toxicity based on the severity of their disease. Alternatively, a "top-down" approach uses aggressive therapy early in the disease course to prevent long-term complications. Both approaches have been shown to be clinically effective, however, there is treatment response heterogeneity and it is not clear which treatment is right for each individual patient. Clinical theory dictates that those likely to experience a more aggressive disease progression would benefit more from "top-down" than "step-up"; whereas those likely to experience a less aggressive progression might benefit more from "step-up."

The primary outcome is the disease activity score measured at the end of the second year, as measured by the Harvey—Bradshaw Index for subjects with CD and the Simple Clinical Colitis Index for subjects with UC. In both measures, higher scores reflect more disease activity. A high-quality treatment rule would reduce disease activity by assigning patients to top-down if it is necessary and step-up otherwise. Among the 274 patients included in the observed data, 32 patients were assigned to the top-down strategy ($A = 1$) and 242 were assigned to step-up ($A = -1$). To remain consistent with our paradigm of maximizing mean response we used the negative disease activity score as the response, Y. 11 patient covariates were used, which included age, gender, ethnicity, marital status, race, body mass index, disease type, antibiotics drug usage, antidiarrheal drug usage, indicator for extra-intestinal manifestation and baseline disease activity scores. We used a linear regression model to estimate the Q-function, and a regularized logistic regression model to estimate the propensity score to avoid overfitting. In addition to the EARL estimators we applied QL and OWL to estimate an optimal treatment rule. Because this is an observational study with unknown propensity scores, we evaluated the estimated treatment rules $\widehat{d}$ using inverse probability weighting $\widehat{V}^{\text{IPWE}}(\widehat{d}) = \mathbb{P}_n \left[Y I\left\{A = \widehat{d}(\boldsymbol{X})\right\} / \widehat{\pi}(A; \boldsymbol{X}) \right] / \mathbb{P}_n \left[I\left\{A = \widehat{d}(\boldsymbol{X})\right\} / \widehat{\pi}(A; \boldsymbol{X}) \right]$, where $\widehat{\pi}$ is the estimated propensity score. Higher values of $\widehat{V}^{\text{IPWE}}(\widehat{d})$, that is, lower disease activity scores, indicate a better overall benefit.

The coefficients of the estimated optimal treatment rules constructed from EARL with logistic loss are presented in Table 1. A permutation test based on 2000 permutation times was conducted to obtain the p-value for each covariate, which showed that body mass index was significant at 0.05 level and gender was significant at 0.1 level. In general, patients with a more severe disease status at baseline are likely to benefit from a top-down therapy.

This is consistent with clinical theory as these symptoms are associated with higher disease severity.

Table 2 describes the agreement between the estimated optimal decision rules constructed using different methods, which shows that the rules estimated using EARL with different loss functions give quite similar treatment recommendations. In this table, we also present the agreement between the estimated decision rules and the observed treatments. Compared to the observed treatment allocations, the estimated rules encourage more patients to receive top-down therapy, where 161 patients are recommended to top-down treatment by EARL methods with all loss functions, 225 patients are recommended by OWL method using logistic loss and 145 patients are recommended by QL method respectively. The estimated disease activity score is 1.75 using logistic loss, compared with 1.80 for the QL estimator, and 1.75 for OWL using logistic loss. Although the achieved benefit of the ITR yielded by OWL and EARL were similar, EARL recommended less patients to the more intensive top-down therapy, which could benefit patients by reducing the side effects. The achieved benefits of the derived ITRs were greater than the benefit that was achieved in the observed dataset, where the average disease activity score was 2.24. Since top-down therapy is relative new in the practice, to be conservative, physicians tend not to provide such therapy to patients. Our analysis encourages the usage of top-down therapy for a greater benefit, which can be tailored according to individual characteristics. By looking into the relationship between the observed treatment and covariates, we found that in current practice, physicians were more likely to follow top-down therapy while giving out antibiotics and antidiarrheals drugs in patients with Crohn's disease. The ITRs resulted from EARL, on the other hand, were more likely to recommend top-down therapy for ulcerative colitis/indeterminate colitis patients while they are not taking antibiotics and antidiarrheals drugs.

We also applied our method to the study of National Supported Work Demonstration, which also showed a superior performance of the proposed method. Results are shown in Web Appendix G.

6. Discussion

We proposed a class of estimators for the optimal treatment rule that we termed EARL. This class of methods is formed by applying a convex relaxation to the AIPWE of the marginal mean outcome. To reduce the risk of misspecification, it is possible to use flexible, e.g., nonparametric, models for the propensity score and the Q-function. However, we showed theoretically and empirically that such flexibility comes at the cost of additional variability and potentially poor small sample performance.

We demonstrated that extreme propensity scores may lead to a large variance in the augmented inverse probability weighted estimator. To alleviate this issue, weight stabilization could potentially help. In particular, we can consider a stabilized weight of the form

$$SW_a^m = W_a^m \Big/ \frac{I(A=a)}{\pi^m(a;\boldsymbol{X})}\,.$$

Using modified weight SW_a^m leads to consistent estimator of the optimal decision rule if positivity assumption holds, that is, Lemma 2.2 still holds under the modified weight.

Table 1: Coefficients for the estimated optimal decision rules by EARL with logistic loss (*: significant at 0.05 level).

	Coefficient	p-value
Intercept	2.466	-
Age	-0.001	0.905
Gender (Male = 1)	0.756	0.015*
Ethnicity (Hispanic = 1)	-1.045	0.144
Marital status (Single = 1)	-0.320	0.318
Race (White = 1)	-0.233	0.478
Body mass index	-0.063	0.037*
Disease type (UC or IC = 1)	0.309	0.234
Antibiotics drug usage (Yes = 1)	-0.156	0.563
Antidiarrheals drug usage (Yes = 1)	-0.580	0.167
Extra-intestinal manifestation (Yes = 1)	0.273	0.286
Baseline disease activity scores	0.050	0.427

Table 2: Agreements between the estimated optimal decision rule yield by different methods and the observed treatment. OWL-logit: OWL using logistic loss; EARL: EARL using logistic loss; EARL: EARL using exponential oss; EARL-hinge: EARL using hinge loss; EARL-sqhinge: EARL using squared hinge loss; QL: Q-learning.

	OWL-Logit	EARL-logit	EARL-exp	EARL-hinge	EARL-sqhinge	QL
OWL-Logit	1	0.642	0.821	0.639	0.639	0.577
EARL-logit		1	0.588	0.996	0.996	0.920
EARL-exp			1	0.591	0.591	0.529
EARL-hinge				1	1	0.916
EARL-sqhinge					1	0.916
QL						1
Observed	0.193	0.449	0.117	0.453	0.453	0.507

Alternatively, we may also consider an estimator which achieves the smallest variance among its class of doubly robust estimators when the propensity score model is correctly specified. Such an estimator can be derived following the techniques used in Cao et al. (2009).

There are several important ways this work might be extended. The first is to handle time-to-event outcomes wherein the observed data are subject to right-censoring. In this setting, efficient methods for augmentation to adjust for censoring might be folded into the EARL framework. Another extension is to multi-stage treatment rules, also known as, dynamic treatment regimes (Murphy, 2003; Robins, 2004; Moodie et al., 2007). A challenging component of this extension is that the variability of the AIPWE increases dramatically as the number of treatment stages increases. We believe that the convex relaxation may help in this setting not only in terms of computation but also by reducing variance.

Editor: Bayesian Optimization Special Issue

Abstract

Learning for control can acquire controllers for novel robotic tasks, paving the path for autonomous agents. Such controllers can be expert-designed policies, which typically require tuning of parameters for each task scenario. In this context, Bayesian optimization (BO) has emerged as a promising approach for automatically tuning controllers. However, sample-efficiency can still be an issue for high-dimensional policies on hardware. Here, we develop an approach that utilizes simulation to learn structured feature transforms that map the original parameter space into a domain-informed space. During BO, similarity between controllers is now calculated in this transformed space. Experiments on the ATRIAS robot hardware and simulation show that our approach succeeds at sample-efficiently learning controllers for multiple robots. Another question arises: What if the simulation significantly differs from hardware? To answer this, we create increasingly approximate simulators and study the effect of increasing simulation-hardware mismatch on the performance of Bayesian optimization. We also compare our approach to other approaches from literature, and find it to be more reliable, especially in cases of high mismatch. Our experiments show that our approach succeeds across different controller types, bipedal robot models and simulator fidelity levels, making it applicable to a wide range of bipedal locomotion problems.

Keywords: Bayesian Optimization, Bipedal Locomotion, Transfer Learning

1. Introduction

Machine learning can provide methods for learning controllers for robotic tasks. Yet, even with recent advances in this field, the problem of automatically designing and learning controllers for robots, especially bipedal robots, remains difficult. It is expensive to do learning experiments that require a large number of samples with physical robots. Specifically, legged robots are not robust to falls and failures, and are time-consuming to work with and repair. Furthermore, commonly used cost functions for optimizing controllers are noisy to evaluate, non-convex and non-differentiable. In order to find learning approaches that can be used on real robots, it is thus important to keep these considerations in mind.

Deep reinforcement learning approaches can deal with noise, discontinuities and non-convexity of the objective, but they are not data-efficient. These approaches could take on the order of a million samples to learn locomotion controllers (Peng et al., 2016), which would be infeasible on a real robot. For example, on the ATRIAS robot, 10,000 samples would take 7 days, in theory. But practically, the robot needs to be "reset" between trials and repaired in case of damage. Using structured expert-designed policies can help minimize damage to the robot and make the search for successful controllers feasible. However, the problem is black-box, non-convex and discontinuous. This eliminates approaches like PI^2 (Theodorou et al., 2010) which make assumptions about the dynamics of the system and PILCO (Deisenroth and Rasmussen, 2011) which assumes a continuous cost landscape. Evolutionary approaches like CMA-ES (Hansen, 2006) can still be prohibitively expensive, needing thousands of samples (Song and Geyer, 2015).

In comparison, Bayesian optimization (BO) is a sample-efficient optimization technique that is robust to non-convexity and noise. It has been recently used in a range of robotics problems, such as Calandra et al. (2016b), Marco et al. (2017) and Cully et al. (2015). However, sample-efficiency of conventional BO degrades in high dimensions, even for dimensionalities commonly encountered in locomotion controllers. Because of this, hardware-only optimization becomes intractable for flexible controllers and complex robots. One way of addressing this issue is to utilize simulation to optimize controller parameters. However, simulation-only optimization is vulnerable to learning policies that exploit the simulation and, because of that, perform well in simulation but poorly on the actual robot. This motivates the development of hybrid approaches that can incorporate simulation-based information into the learning method and then optimize with few samples on hardware.

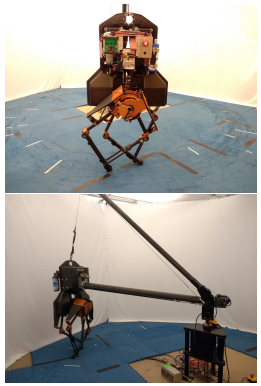

Figure 1: ATRIAS robot.

Towards this goal, our previous work in Antonova, Rai, and Atkeson (2016), Antonova et al. (2017), Rai et al. (2018) presents a framework that uses information from high-fidelity simulators to learn sample-efficiently on hardware. We use simulation to build informed feature transforms that are used to measure controller similarity during BO. Thus, during optimization on hardware, the similarity between controller parameters is informed by how they perform in simulation. With this, it becomes possible to quickly infer which regions of the input space are likely to perform well on hardware. This method has been tested on the ATRIAS biped robot (Figure 1) and shows considerable improvement in sample-efficiency over traditional BO.

In this article, we present in-depth explanations and empirical analysis of our previous work. Furthermore, for the first time, we present a procedure for systematically evaluating

robustness of such approaches to simulation-hardware mismatch. We extend our previous work incorporating mismatch estimates (Rai et al., 2018) to this setting. We also conduct extensive comparisons with competitive baselines from prior work, e.g. Cully et al. (2015).

The rest of this article is organized as follows: Section 2 provides background for BO, then gives an overview of related work on optimizing locomotion controllers. Section 3.1 describes the idea of incorporating simulation-based transforms into BO; Section 3.2 explains how we handle simulation-hardware mismatch. Sections 4.1-4.5 describe the robot and controllers we use for our experiments; Section 4.6 explains the motivation and construction of simulators with various kinds of simulation-hardware mismatch. Section 5 summarizes hardware experiments on the ATRIAS robot. Section 5.2 shows generalization to a different robot model in simulation. Section 5.3 presents empirical analysis of the impact of simulator quality on the performance of the proposed algorithms and alternative approaches.

2. Background and Related Work

This section gives a brief overview of Bayesian optimization (BO), the state-of-the-art research on optimizing locomotion controllers, and utilizing simulation information in BO.

2.1. Background on Bayesian Optimization

Bayesian optimization (BO) is a framework for online, black-box, gradient-free global search (Shahriari et al. (2016) and Brochu et al. (2010) provide a comprehensive introduction). The problem of optimizing controllers can be interpreted as finding controller parameters $\boldsymbol{x}^*$ that optimize some cost function $f(\boldsymbol{x})$. Here $\boldsymbol{x}$ contains parameters of a pre-structured policy; the cost $f(\boldsymbol{x})$ is a function of the trajectory induced by controller parameters $\boldsymbol{x}$. For brevity, we will refer to 'controller parameters $\boldsymbol{x}$' as 'controller $\boldsymbol{x}$'. We use BO to find controller $\boldsymbol{x}^*$, such that: $f(\boldsymbol{x}^*) = \min_{\boldsymbol{x}} f(\boldsymbol{x})$.

BO is initialized with a prior that expresses the *a priori* uncertainty over the value of $f(\boldsymbol{x})$ for each $\boldsymbol{x}$ in the domain. Then, at each step of optimization, based on data seen so far, BO optimizes an auxiliary function (called *acquisition function*) to select the next $\boldsymbol{x}$ to evaluate. The acquisition function balances exploration vs exploitation. It selects points for which the posterior estimate of the objective f is promising, taking into account both mean and covariance of the posterior. A widely used representation for the cost function f is a Gaussian process (GP):

$$f(\boldsymbol{x}) \sim \mathcal{GP}(\mu(\boldsymbol{x}), k(\boldsymbol{x}_i, \boldsymbol{x}_j))$$

The prior mean function $\mu(\cdot)$ is set to 0 when no domain-specific knowledge is provided. The kernel function $k(\cdot,\cdot)$ encodes similarity between inputs. If $k(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is large for inputs $\boldsymbol{x}_i, \boldsymbol{x}_j$, then $f(\boldsymbol{x}_i)$ strongly influences $f(\boldsymbol{x}_j)$. One of the most widely used kernel functions is the Squared Exponential (SE):

$$k_{SE}(\boldsymbol{x}_i, \boldsymbol{x}_j) = \sigma_k^2 \exp\big(-\tfrac{1}{2}(\boldsymbol{x}_i - \boldsymbol{x}_j)^T \operatorname{diag}(\boldsymbol{\ell})^{-2}(\boldsymbol{x}_i - \boldsymbol{x}_j)\big),$$

where σ_k^2, $\boldsymbol{\ell}$ are signal variance and a vector of length scales respectively. σ_k^2, $\boldsymbol{\ell}$ are referred to as 'hyperparameters' in the literature.

The SE kernel belongs to a broader class of Matérn kernels, which in general have more free parameters. In some cases, carefully choosing kernel parameters improves performance of BO (Snoek et al., 2012). However, domain-informed kernels can easily out-perform even

well-tuned Matérn kernels (Cully et al., 2015). SE and Matérn kernels are stationary: $k(\boldsymbol{x}_i, \boldsymbol{x}_j)$ depend only on $r = \boldsymbol{x}_i - \boldsymbol{x}_j \ \forall \boldsymbol{x}_{i,j}$. We aim to remove this limitation in a manner informed by simulation. In future work, incorporating other approaches that relax stationarity (e.g. Martinez-Cantin (2018)) could further improve BO.

2.2. Optimizing Locomotion Controllers

Parametric locomotion controllers can be represented as $\boldsymbol{u} = \pi_{\boldsymbol{x}}(\boldsymbol{s})$, where π is a policy structure that depends on parameters $\boldsymbol{x}$. For example, π can be parameterized by feedback gains on the center of mass (CoM), reference joint trajectories, etc. Vector $\boldsymbol{s}$ is the state of the robot, such as joint angles and velocities, used in closed-loop controllers. Vector $\boldsymbol{u}$ represents the desired control action, for example: torques, angular velocities or positions for each joint on the robot. The sequence of control actions yields a sequence of state transitions, which form the overall 'trajectory' $[\boldsymbol{s}_0, \boldsymbol{u}_1, \boldsymbol{s}_1, \boldsymbol{u}_2, \boldsymbol{s}_2, ...]$. This trajectory is used in the cost function to judge the quality of the controller $\boldsymbol{x}$. In our work, we use structured controllers designed by experts. State of the art research on walking robots featuring such controllers includes Feng et al. (2015) and Kuindersma et al. (2016). The overall optimization then includes manually tuning the parameters $\boldsymbol{x}$. An alternative to manual tuning is to use evolutionary approaches, like CMA-ES, as in Song and Geyer (2015). However, these require a large number of samples and can usually be conducted only in simulation. Optimization in simulation can produce controllers that perform well in simulation, but not on hardware. In comparison, BO is a sample-efficient technique which has become popular for direct optimization on hardware. Recent successes include manipulation (Englert and Toussaint, 2016) and locomotion (Calandra et al., 2016b).

BO for locomotion has been previously explored for several types of mobile robots. These include: snake robots (Tesch et al., 2011), AIBO quadrupeds (Lizotte et al., 2007), and hexapods (Cully et al., 2015). Tesch et al. (2011) optimize a 3-dimensional controller for a snake robot in 10-40 trials (for speeds up to $0.13m/s$). Lizotte et al. (2007) use BO to optimize gait parameters for a AIBO robot in 100-150 trials. Cully et al. (2015) learn 36 controller parameters for a hexapod. Even with hardware damage, they can obtain successful controllers for speeds up to $0.4m/s$ in 12-15 trials.

Hexapods, quadrupeds and snakes spend a large portion of their gaits with their center of mass within their support polygon (convex hull of the feet on the ground). Ignoring velocity, this is statically stable. In contrast, bipedal walking can be highly dynamic, especially for point-feet robots like ATRIAS. ATRIAS, like most bipeds, spends a significant time of its gait being "unstable", or dynamically stable. In our experiments on hardware, ATRIAS goes up to speeds of $1m/s$. All of this leads to a challenging optimization setting and discontinuous cost function landscape. Calandra et al. (2016b) use BO for optimizing gaits of a dynamic biped on a boom, needing 30-40 samples for finding walking gaits for a 4-dimensional controller. While this is promising, optimizing a higher-dimensional controller needed for complex robots would be even more challenging. If significant number of samples lead to unstable gaits and falls, they could damage the robot. Hence, it is important to develop methods that can learn complex controllers fast, without damaging the robot.

2.3. Incorporating Simulation Information into Bayesian Optimization

The idea of using simulation to speed up BO on hardware has been explored before. Information from simulation can be added as a prior to the GP used in BO, such as in Cully et al. (2015). While such methods can be successful, one needs to carefully tune the influence of simulation points over hardware points, especially when simulation is significantly different from hardware.

More generally, approaches such as Kandasamy et al. (2017) and Marco et al. (2017) address trading off computation vs simulation accuracy when selecting the source for the next trial/evaluation (with real world viewed as the most expensive source). Instead, we consider a setting with ample compute resources for simulation, but an extremely small number of experiments on a real robot. This is appropriate for bipedal locomotion with full-scale robots, since these can be expensive to run. Hence, our work does not fall into the 'multi-fidelity' BO paradigm, and we instead take a two step approach: pre-computing information needed for kernel transforms in the first stage, then running an ultra-sample efficient version of BO in the second stage on a real robot.

Recently, several approaches proposed incorporating Neural Networks (NNs) into the Gaussian process (GP) kernels (Wilson et al. (2016), Calandra et al. (2016a)). The strength of these approaches is that they can jointly update the GP and the NN. Calandra et al. (2016a) demonstrated how this added flexibility can handle discontinuities in the cost function landscape. However, these approaches do not directly address the problem of incorporating a large amount of data from simulation in hardware BO experiments.

Wilson et al. (2014) explored enhancing GP kernel with trajectories. Their Behavior Based Kernel (BBK) computes an estimate of a symmetric variant of the KL divergence between trajectories induced by two controllers, and uses this as a distance metric in the kernel. However, getting an estimate would require samples for each controller $\boldsymbol{x}_i, \boldsymbol{x}_j$ whenever $k(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is needed. This can be impractical, as it involves an evaluation of every controller considered. To overcome this, the authors suggest combining BBK with a model-based approach. But building an accurate model from hardware data might be an expensive process in itself.

Cully et al. (2015) utilize simulation by defining a behavior metric and collecting best performing points in simulation. This behavior metric then guides BO to quickly find controllers on hardware, and can even compensate for damage to the robot. The search on hardware is conducted in behavior space, and limited to pre-selected "successful" points from simulation. This helps make their search faster and safer on hardware. However, if an optimal point was not pre-selected, BO cannot sample it during optimization.

In our work, we utilize trajectories from simulation to build feature transforms that can be incorporated in the GP kernel used for BO. Our approaches incorporate trajectory/behavior information, but ensure that $k(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is computed efficiently during BO. Our work is related, in part, to input space warping, as described in Snoek et al. (2014), but we construct our transforms from simulated data. Our simulation-informed kernels bias the search towards regions that look promising, but are able to 'recover' and search in other parts of the space if simulation-hardware mismatch becomes apparent.

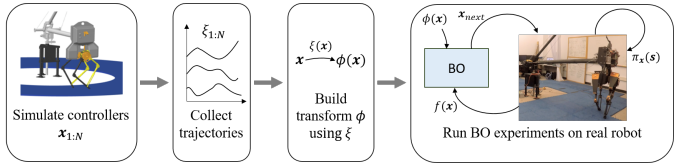

Figure 2: Overview of our proposed approach. Here, $\pi_{\boldsymbol{x}}(\boldsymbol{s})$ is the policy (Section 2.2); $\boldsymbol{x}$ is a vector of controller parameters; $\boldsymbol{s}$ is the state of the robot; $\xi(\boldsymbol{x})$ is a trajectory observed in simulation for $\boldsymbol{x}$; $\phi(\cdot)$ is the transform built using $\xi(\cdot)$; $f(\boldsymbol{x})$ is the cost of $\boldsymbol{x}$ evaluated on hardware. BO uses $\phi(\boldsymbol{x})$ and evaluated costs $f(\boldsymbol{x})$ to propose next promising controller x_{next}.

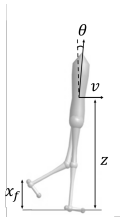
3. Proposed Approach: Bayesian Optimization with Informed Kernels

In this section, we offer in-depth explanation of approaches from our work in Antonova, Rai, and Atkeson (2016), Antonova et al. (2017), and Rai et al. (2018). This work proposes incorporating domain knowledge into BO with the help of simulation. We evaluate locomotion controllers in simulation, and collect their induced trajectories, which are then used to build an informed transform. This can be achieved by using a domain-specific feature transform (Section 3.1.1) or by learning to reconstruct short trajectory summaries (Section 3.1.2). This feature transform is used to construct an informed distance metric for BO, and helps BO discover promising regions faster. Figure 2 gives an overview. In Section 3.2 we discuss how to incorporate simulation-hardware mismatch in to the transform, ensuring that BO can benefit from inaccurate simulations as well.

3.1. Constructing Flexible Kernels using Simulation-based Transforms

High dimensional problems with discontinuous cost functions are very common with legged robots, where slight changes to some parameters can make the robot unstable. Both of these factors can adversely affect BO's performance, but informed feature transforms can help BO sample high-performing controllers even in such scenarios.



In this section, we demonstrate how to construct such transforms $\phi(\boldsymbol{x})$ utilizing simulations for a given controller $\boldsymbol{x}$. We then use ϕ to create an informed kernel $k_\phi(\boldsymbol{x}_i, \boldsymbol{x}_j)$ for BO on hardware:

$$\begin{aligned} \boldsymbol{t}_{ij} &= \phi(\boldsymbol{x}_i) - \phi(\boldsymbol{x}_j) \\ k_\phi(\boldsymbol{x}_i, \boldsymbol{x}_j) &= \sigma_k^2 \exp\Big(-\tfrac{1}{2} \boldsymbol{t}_{ij}^T \operatorname{diag}(\boldsymbol{\ell})^{-2} \boldsymbol{t}_{ij} \Big) \end{aligned} \tag{1}$$

Note that the functional form above is the same as that of Squared Exponential kernel, if considered from the point of view of the transformed space, with $\phi(\boldsymbol{x})$ as input. Using a low-dimensional ϕ could improve sample efficiency by reducing dimensionality. More notably, crucial gains arise when ϕ brings controllers that perform similar in simulation closer together, as compared to the original parameter space. For locomotion, this could bring failing controllers close together to occupy only a small portion of the transformed space, as illustrated in Rai et al. (2018). In essence, this means that the resultant kernel, though stationary in ϕ, is non-stationary in $\boldsymbol{x}$.

3.1.1. The Determinants of Gait Transform

We propose a feature transform for bipedal locomotion derived from physiological features of human walking called Determinants of Gaits (DoG) (Inman et al., 1953). ϕ_{DoG} was originally developed for human-like robots and controllers (Antonova, Rai, and Atkeson, 2016), and then generalized to be applicable to a wider range of bipedal locomotion controllers and robot morphologies (Rai et al., 2018). It is based on the features in Table 1.

M_1 (Swing leg retraction) – If the maximum ground clearance of the swing foot x_f is more than a threshold, $M_1 = 1$ (0 otherwise); ensures swing leg retraction.
M_2 (Center of mass height) – If CoM height z stays about the same at the start and end of a step, $M_2 = 1$ (0 otherwise); checks that the robot is not falling.
M_3 (Trunk lean) – If the average trunk lean θ is the same at the start and end of a step, $M_3 = 1$ (0 otherwise); ensures that the trunk is not changing orientation.
M_4 (Average walking speed) – Average forward speed v of a controller per step, $M_4 = v_{avg}$; M_4 helps distinguish controllers that perform similar on M_{1-3}.

Table 1: Illustration of the features used to construct DoG transform.

ϕ_{DoG} combines features M_{1-4} per step and scales them by the normalized simulation time to obtain the DoG score of controller $\boldsymbol{x}$:

$$score_{DoG} = \frac{t_{sim}}{t_{max}} \cdot \sum_{s=1}^{N} \sum_{k=1}^{4} M_{ks} \tag{2}$$

Here, subscript k identifies the feature metric, s is the step number, N is the total number of steps taken in simulation, t_{sim} is time at which simulation terminated (possibly due to a fall), t_{max} is total time allotted for simulation. Since larger number of steps lead to higher DoG, some controllers that chatter (step very fast before falling) could get misleadingly high scores; we scale the scores by $\frac{t_{sim}}{t_{max}}$ to prevent that. $\phi_{DoG}(\boldsymbol{x})$ for controller parameters $\boldsymbol{x}$ now becomes the computed $score_{DoG}$ of the resulting trajectories when $\boldsymbol{x}$ is simulated. ϕ_{DoG} essentially aids in (soft) clustering of controllers based on their behaviour in simulation. High scoring controllers are more likely to walk than low scoring ones. Since M_{1-4} are based on intuitive gait features, they are more likely to transfer between simulation and hardware, as compared to direct cost. The thresholds in M_{1-3} are chosen according to values observed in nominal human walking from Winter and Yack (1987).

3.1.2. Learning a Feature Transform with a Neural Network

While domain-specific feature transforms can be extremely useful and robust, they might be difficult to generate when a domain expert is not present. This motivates directly learning such feature transforms from trajectory data. In this section we describe our approach to train neural networks to reconstruct trajectory summaries (Antonova et al., 2017) that achieves this goal of minimizing expert involvement.

Trajectory summaries are a convenient choice for reparametrizing controllers into an easy to optimize space. For example, controllers that fall would automatically be far away from controllers that walk. If these trajectories can be extracted from a high-fidelity simulator, we would not have to evaluate each controller on hardware. However, conventional implementations of BO evaluate the kernel function for a large number of points per iteration, requiring thousands of simulations each iteration. To avoid this, a Neural Network (NN) can be trained to reconstruct trajectory summaries from a large set of pre-sampled data points. NN provides flexible interpolation, as well as fast evaluation (controller $\rightarrow$ trajectory summary). Furthermore, trajectories are agnostic to the specific cost used during BO. Thus the data collection can be done offline, and there is no need to re-run simulations in case the definition of the cost is modified.

We use the term 'trajectory' in a general sense, referring to several sensory states recorded during a simulation. To create trajectory summaries for the case of locomotion, we include measurements of: walking time (time before falling), energy used during walking, position of the center of mass and angle of the torso. With this, we construct a dataset for NN to fit: a Sobol grid of controller parameters ($\boldsymbol{x}_{1:N}$, $N \approx 0.5$ million) along with trajectory summaries $\xi_{\boldsymbol{x}_i}$ from simulation. NN is trained using mean squared loss:

NN input: $\boldsymbol{x}$ – a set of controller parameters

NN output: $\phi_{trajNN}(\boldsymbol{x}) = \hat{\xi}_{\boldsymbol{x}}$ – reconstructed trajectory summary

NN loss: $\frac{1}{2}\sum_{i=1}^{N} ||\hat{\xi}_{\boldsymbol{x}_i} - \xi_{\boldsymbol{x}_i}||^2$

The outputs $\phi_{trajNN}(\boldsymbol{x})$ are then used in the kernel for BO:

$$k_{trajNN}(\boldsymbol{x}_i, \boldsymbol{x}_j) = \sigma_k^2 \exp\left(-\frac{1}{2}\boldsymbol{t}_{ij}^T \operatorname{diag}(\boldsymbol{\ell})^{-2}\boldsymbol{t}_{ij}\right), \qquad \boldsymbol{t}_{ij} = \phi_{trajNN}(\boldsymbol{x}_i) - \phi_{trajNN}(\boldsymbol{x}_j) \tag{3}$$

Appendix A describes our data collection and training. We did not carefully select the sensory traces used in the trajectory summaries. Instead, we used the most obvious states, aiming for an approach that could be easily adapted to other domains. To apply this approach to a new setting, one could simply include information that is customarily tracked, or used in costs. For example, for a manipulator, the coordinates of the end effector(s) could be recorded at relevant points. Force-torque measurements could be included, if available.

3.2. Kernel Adjustment for Handling Simulation-Hardware Mismatch

Approaches described in previous sections could provide improvement for BO when a high-fidelity simulator is used in kernel construction. In Rai et al. (2018) we presented promising results of experimental evaluation on hardware. However, it is unclear how the performance changes when simulation-hardware mismatch becomes apparent.

In Rai et al. (2018), we also proposed a way to incorporate information about simulation-hardware mismatch into the kernel from the samples evaluated so far. We augment the simulation-based kernel to include this additional information about mismatch, by expanding the original kernel by an extra dimension that contains the predicted mismatch for each controller $\boldsymbol{x}$.

A separate Gaussian process is used to model the mismatch experienced on hardware, starting from an initial prior mismatch of 0: $g(\boldsymbol{x}) \sim \mathcal{GP}(0, k_{SE}(\boldsymbol{x}_i, \boldsymbol{x}_j))$. For any evaluated controller $\boldsymbol{x}_i$, we can compute the difference between $\phi(\boldsymbol{x}_i)$ in simulation and on hardware: $d_{\boldsymbol{x}_i} = \phi^{sim}(\boldsymbol{x}_i) - \phi^{hw}(\boldsymbol{x}_i)$. We can now use mismatch data $\{d_{\boldsymbol{x}_i} | i = 1...n\}$ to construct a model for the expected mismatch: $\bar{g}(\boldsymbol{x})$. In the case of using a GP-based model, $\bar{g}(\cdot)$ would denote the posterior mean. With this, we can predict simulation-hardware mismatch in the original space of controller parameters for unevaluated controllers. Combining this with

kernel k_ϕ we obtain an adjusted kernel:

$$\boldsymbol{\phi}_{\boldsymbol{x}}^{adj} = \begin{bmatrix} \phi^{sim}(\boldsymbol{x}) \\ \bar{g}(\boldsymbol{x}) \end{bmatrix}, \qquad \boldsymbol{t}_{ij}^{adj} = \boldsymbol{\phi}_{\boldsymbol{x}_i}^{adj} - \boldsymbol{\phi}_{\boldsymbol{x}_j}^{adj}$$
$$k_{\phi_{adj}}(\boldsymbol{x}_i, \boldsymbol{x}_j) = \sigma_k^2 \exp\Big(-\tfrac{1}{2} (\boldsymbol{t}_{ij}^{adj})^T \operatorname{diag}\Big(\begin{bmatrix} \boldsymbol{\ell_1} \\ \boldsymbol{\ell_2} \end{bmatrix}\Big)^{-2} \boldsymbol{t}_{ij}^{adj} \Big) \tag{4}$$

The similarity between points $\boldsymbol{x}_i, \boldsymbol{x}_j$ is now dictated by two components: representation in ϕ space and expected mismatch. This construction has an intuitive explanation: Suppose controller $\boldsymbol{x_i}$ results in walking when simulated, but falls during hardware evaluation. $k_{\phi_{adj}}$ would register a high mismatch for $\boldsymbol{x}_i$. Controllers would be deemed similar to $\boldsymbol{x}_i$ only if they have both similar simulation-based $\phi(\cdot)$ and similar estimated mismatch. Points with similar simulation-based $\phi(\cdot)$ and low predicted mismatch would still be 'far away' from the failed $\boldsymbol{x}_i$. This would help BO sample points that still have high chances of walking in simulation, but are in a different region of the original parameter space. In the next section, we present a more mathematically rigorous interpretation for $k_{\phi_{adj}}$.

3.2.1. Interpretation of Kernel with Mismatch Modeling

Let us consider a controller $\boldsymbol{x}_i$ evaluated on hardware. The difference between simulation-based and hardware-based feature transform for $\boldsymbol{x}_i$ is $d_{\boldsymbol{x}_i} = \phi^{sim}(\boldsymbol{x}_i) - \phi^{hw}(\boldsymbol{x}_i)$. The 'true' hardware feature transform for $\boldsymbol{x_i}$ is $\phi^{hw}(\boldsymbol{x_i}) = \phi^{sim}(\boldsymbol{x_i}) - d_{\boldsymbol{x_i}}$. After n evaluations on hardware, $\{d_{\boldsymbol{x}_i} | i = 1...n\}$ can serve as data for modeling simulation-hardware mismatch. In principle, any data-efficient model $g(\cdot)$ can be used, such as GP (a multi-output GP in case $\phi(\cdot) > 1D$). With this, we can obtain an adjusted transform: $\hat{\phi}^{hw}(\boldsymbol{x}) = \phi^{sim}(\boldsymbol{x}) - \bar{g}(\boldsymbol{x})$, where $\bar{g}(\cdot)$ is the output of the model fitted using $\{d_{\boldsymbol{x}_i} | i = 1, ...n\}$.

Suppose $\boldsymbol{x}_{new}$ has not been evaluated on hardware. We can use $\hat{\phi}^{hw}(\boldsymbol{x}_{new}) = \phi^{sim}(\boldsymbol{x}_{new}) - \bar{g}(\boldsymbol{x}_{new})$ as the adjusted estimate of what the output of ϕ should be, taking into account what we have learned so far about simulation-hardware mismatch.

Let's construct kernel $k_{\phi_{adj}}^{v_2}(\boldsymbol{x}_i, \boldsymbol{x}_j)$ that uses these hardware-adjusted estimates directly:

$$\begin{aligned} \boldsymbol{q}_{ij}^{adj} &= \hat{\phi}^{hw}(\boldsymbol{x}_i) - \hat{\phi}^{hw}(\boldsymbol{x}_j) \\ &= (\phi^{sim}(\boldsymbol{x}_i) - \bar{g}(\boldsymbol{x}_i)) - (\phi^{sim}(\boldsymbol{x}_j) - \bar{g}(\boldsymbol{x}_j)) \\ &= \underbrace{(\phi^{sim}(\boldsymbol{x}_i) - \phi^{sim}(\boldsymbol{x}_j))}_{\boldsymbol{v}_\phi} - \underbrace{(\bar{g}(\boldsymbol{x}_i) - \bar{g}(\boldsymbol{x}_j))}_{\boldsymbol{v}_g} \end{aligned}$$

$$\begin{aligned} k_{\phi_{adj}}^{v_2}(\boldsymbol{x}_i, \boldsymbol{x}_j) &= \sigma_{k_{v_0}}^2 \exp\Big(-\tfrac{1}{2} (\boldsymbol{q}_{ij}^{adj})^T \operatorname{diag}(\boldsymbol{\ell})^{-2} \boldsymbol{q}_{ij}^{adj} \Big) \\ &= \sigma^2 \exp\Big(-\tfrac{1}{2} \big[(\boldsymbol{v}_\phi - \boldsymbol{v}_g)^T \operatorname{diag}(\boldsymbol{\ell})^{-2} (\boldsymbol{v}_\phi - \boldsymbol{v}_g) \big] \Big) \\ &= \sigma^2 \exp\Big(-\tfrac{1}{2} \big[\boldsymbol{v}_\phi^T \operatorname{diag}(\boldsymbol{\ell})^{-2} \boldsymbol{v}_\phi + \boldsymbol{v}_g^T \operatorname{diag}(\boldsymbol{\ell})^{-2} \boldsymbol{v}_g - prod_{ij} \big] \Big) \\ &\qquad \text{where } prod_{ij} = 2 \boldsymbol{v}_\phi^T \operatorname{diag}(\boldsymbol{\ell})^{-2} \boldsymbol{v}_g \end{aligned}$$

Using $\exp(a + b + c) = \exp(c) \cdot \exp(a + b)$, we have:

$$k_{\phi_{adj}}^{v_2}(\boldsymbol{x}_i, \boldsymbol{x}_j) = \sigma^2 \exp(prod_{ij}) \exp\Big(-\tfrac{1}{2} \big[\boldsymbol{v}_\phi^T \operatorname{diag}(\boldsymbol{\ell})^{-2} \boldsymbol{v}_\phi + \boldsymbol{v}_g^T \operatorname{diag}(\boldsymbol{\ell})^{-2} \boldsymbol{v}_g \big] \Big)$$

Which can be written as:

$$k_{\phi_{adj}}^{v_2}(\boldsymbol{x}_i, \boldsymbol{x}_j) = \sigma^2 \exp(prod_{ij}) \exp\Big(-\tfrac{1}{2} (\boldsymbol{t}_{ij}^{adj})^T \operatorname{diag}\Big(\begin{bmatrix} \boldsymbol{\ell} \\ \boldsymbol{\ell} \end{bmatrix}\Big)^{-2} \boldsymbol{t}_{ij}^{adj} \Big)$$
$$\boldsymbol{t}_{ij}^{adj} = \begin{bmatrix} \boldsymbol{v}_\phi \\ \boldsymbol{v}_g \end{bmatrix} = \begin{bmatrix} \phi^{sim}(\boldsymbol{x}_i) - \phi^{sim}(\boldsymbol{x}_j) \\ \bar{g}(\boldsymbol{x}_i) - \bar{g}(\boldsymbol{x}_j) \end{bmatrix}$$

Compare this to $k_{\phi_{adj}}$ from Equation 4:

$$k_{\phi_{adj}}(\boldsymbol{x}_i, \boldsymbol{x}_j) = \sigma_k^2 \exp\Big(-\tfrac{1}{2} (\boldsymbol{t}_{ij}^{adj})^T \operatorname{diag}\Big(\begin{bmatrix} \boldsymbol{\ell_1} \\ \boldsymbol{\ell_2} \end{bmatrix}\Big)^{-2} \boldsymbol{t}_{ij}^{adj} \Big) \tag{5}$$

Now we see that $k_{\phi_{adj}}^{v_2}$ and $k_{\phi_{adj}}$ have a similar form. Hyperparameters $\boldsymbol{\ell_1}, \boldsymbol{\ell_2}$ provide flexibility in $k_{\phi_{adj}}$ as compared to having only vector $\boldsymbol{\ell}$ in $k_{\phi_{adj}}^{v_2}$. They can be adjusted manually or with Automatic Relevance Determination. For $k_{\phi_{adj}}^{v_2}$, the role of signal variance is captured by $\sigma^2 \exp(-prod_{ij})$. This makes the kernel nonstationary in the transformed ϕ space. Since $k_{\phi_{adj}}$ is already non-stationary in $\boldsymbol{x}$, it is unclear whether non-stationarity of $k_{\phi_{adj}}^{v_2}$ in the transformed ϕ space has any advantages.

The above discussion shows that $k_{\phi_{adj}}$ proposed in Rai et al. (2018) is motivated both intuitively and mathematically. It aims to use a transform that accounts for the hardware mismatch, without adding extra non-stationarity in the transformed space. While the above analysis shows the connection between $k_{\phi_{adj}}$ and $k_{\phi_{adj}}^{v_2}$, a more systematic empirical analysis would be beneficial as part of future work.

4. Robots, Simulators and Controllers Used

In this section we give a concise description of the robots, controllers and simulators used in experiments with BO for bipedal locomotion. Our approach is applicable to a wide range of bipedal robots and controllers, including state-of-the-art controllers (Feng et al., 2015). We work with two different types of controllers – a reactively stepping controller and a human-inspired neuromuscular controller (NMC). The reactively stepping controller is model-based: it uses inverse-dynamics models of the robot to compute desired motor torques. In contrast, NMC is model-free: it computes desired torques using hand-designed policies, created with biped locomotion dynamics in mind. These controllers exemplify two different and widely used ways of controlling bipedal robots. In addition to this, we show results on two different robot morphologies – a parallel bipedal robot ATRIAS, and a serial 7-link biped model. Our hardware experiments are conducted on ATRIAS; the 7-link biped is only used in simulation. Our success on both robots shows that the approaches developed in this paper are widely applicable to a range of bipedal robots and controllers.

4.1. ATRIAS Robot

Our hardware platform is an ATRIAS robot (Figure 1). ATRIAS is a parallel bipedal robot, weighing $\approx 64kg$. The legs are 4-segment linkages actuated by 2 Series Elastic Actuators (SEAs) in the sagittal plane and a DC motor in the lateral plane. Details can be found in Hubicki et al. (2016). In this work we focus on planar motion around a boom. ATRIAS is a highly dynamic system due to its point feet, with static stability only in double stance on the boom.

4.2. Planar 7-link Biped

The second robot used in our experiments is a 7-link biped (Thatte and Geyer, 2016). It has a trunk and segmented legs with ankles, with actuators in the hip, knees and ankles. The inertial properties of its links are similar to an average human (Winter and Yack, 1987). This 7-link model is a canonical simulator for testing bipedal walking algorithms, for example in Song and Geyer (2015). It is a simplified two-dimensional simulator for a large range of humanoid robots, like Atlas (Feng et al., 2015). We use this simulator to study the generalizability of our proposed approaches to systems different from ATRIAS.

4.3. Feedback Based Reactive Stepping Policy

We design a parametric controller for controlling the CoM height, torso angle and the swing leg by commanding desired ground reaction forces and swing foot landing location.

$$F_x = K_{pt}(\theta_{des} - \theta) - K_{dt}\dot{\theta} \qquad F_z = K_{pz}(z_{des} - z) - K_{dz}\dot{z} \qquad x_p = k(v - v_{tgt}) + Cd + 0.5vT$$

Here, F_x is the desired horizontal ground reaction force (GRF), K_{pt} and K_{dt} are the proportional and derivative feedback gains on the torso angle θ and velocity $\dot{\theta}$. F_z is the desired vertical GRF, K_{pz} and K_{dz} are the proportional and derivative gains on the CoM height z and vertical velocity $\dot{z}$. z_{des} and θ_{des} are the desired CoM height and torso lean. x_p is the desired foot landing location for the end of swing; v is the horizontal CoM velocity, k is the feedback gain that regulates v towards the target velocity v_{tgt}. C is a constant and d is the distance between the stance leg and the CoM; T is the swing time.

The desired GRFs are sent to ATRIAS inverse dynamics model that generates desired motor torques τ_f, τ_b. Details can be found in Rai et al. (2018). This controller assumes no double-support, and the swing leg takes off as soon as stance is detected. This leads to a highly dynamic gait, posing a challenging optimization problem.

To investigate the effects of increasing dimensionality on our optimization, we construct two controllers with different number of free parameters:

- *5-dimensional controller* : optimizing 5 parameters $[K_{pt}, K_{dt}, k, C, T]$ (z_{des}, θ_{des} and the feedback on z are hand tuned)
- *9-dimensional controller* : optimizing all 9 parameters of the high-level policy $[K_{pt}, K_{dt}, \theta_{des}, K_{pz}, K_{dz}, z_{des}, k, C, T]$

4.4. 16-dimensional Neuromuscular Controller

We use neuromuscular model policies, as introduced in Geyer and Herr (2010), as our controller for the 7-link planar human-like biped model. These policies use approximate models of muscle dynamics and human-inspired reflex pathways to generate joint torques, producing gaits that are similar to human walking.

Each leg is actuated by 7 muscles, which together produce torques about the hip, knee and ankle. Most of the muscle reflexes are length or force feedbacks on the muscle state aimed at generating a compliant leg, keeping knee from hyperextending and maintaining torso orientation in stance. The swing control has three main components – target leg angle, leg clearance and hip control due to reaction torques. Together with the stance control, this leads to a total of 16 controller parameters, described in details in Antonova et al. (2016).

Though originally developed for explaining human neural control pathways, this controller has recently been applied to prosthetics and bipeds, for example Thatte and Geyer (2016) and Van der Noot et al. (2015). This controller is capable of generating a variety of locomotion behaviours for a humanoid model – walking on rough ground, turning, running, and walking upstairs, making it a very versatile controller (Song and Geyer, 2015). This is a model-free controller as compared to the reactive-stepping controller, which was model-based.

4.5. 50-dimensional Virtual Neuromuscular Controller

Another model-free controller we use on ATRIAS is a modified version of Batts et al. (2015). VNMC maps a neuromuscular model, similar to the one described in Section 4.4 to the ATRIAS robot's topology and emulates it to generate desired motor torques. We adapt VNMC by removing some biological components while preserving its basic functionalities. The final version of the controller consists of 50 parameters including low-level control parameters, such as feedback gains, as well as high level parameters, such as desired step length and desired torso lean. Details can be found in Rai et al. (2018). When optimized using CMA-ES, it can control ATRIAS to walk on rough terrains with height changes of $\pm$20 cm in planar simulation (Batts et al., 2015).

4.6. Increasingly Inaccurate Simulators

To compare the performance of different methods that can be used to transfer information from simulation to hardware, we create a series of increasingly approximate simulators. These simulators emulate increasing mismatch between simulation and hardware and its effect on the information transfer. In this setting, the high-fidelity ATRIAS simulator (Martin et al., 2015), which was used in all the previous simulation experiments becomes the *"hardware"*. Next we make dynamics approximations to the original simulator, which are used commonly in simulators to decrease fidelity and increase simulation speed. For example, the complex dynamics of harmonic drives are approximated as a torque multiplication, and the boom is removed from the simulation, leading to a two-dimensional simulator. These approximate simulators now become the *"simulators"*. As the approximations in these simulators are increased, we expect the performance of methods that utilize simulation for optimization on hardware to deteriorate.

The details of the approximate simulators are described in the two paragraphs below:

1. Simulation with simplified gear dynamics : We replace the original high-fidelity gear model with a commonly used approximation for geared systems – multiplying the rotor torque by the gear ratio. This reduces the simulation time to about a third of the original simulator, but leads to an approximate gear dynamics model.

2. Simulation with no boom and simplified gear dynamics : The ATRIAS robot walks on a boom in our hardware experiments. In our second approximation, we remove the boom from the original simulator and constraint the motion of the robot to a 2-dimensional plane. This is a common approximation for two-dimensional robots. However, the boom leads to lateral forces on the robot, which have vertical force components that are not modelled anymore.

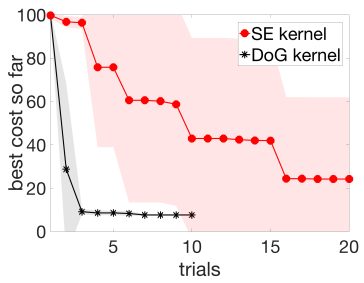
Figure 3: ATRIAS during BO with DoG-based kernel (video: `https://youtu.be/hpXNFREgaRA`)

The advantage of such an arrangement is that we can test the effect of un-modelled and wrongly modelled dynamics on information transfer between simulation and hardware. Even in our high-fidelity original simulator, there are several un-modelled components of the actual hardware. For example, the non-rigidness of the robot parts, misaligned motors and relative play between joints. In our experiments, we find that the 50-dimensional VNMC is a sensitive controller, with little hope of directly transferring from simulation to hardware. Anticipating this, we can now test several methods of compensating for this mismatch using our increasingly approximate simulators.

5. Experiments

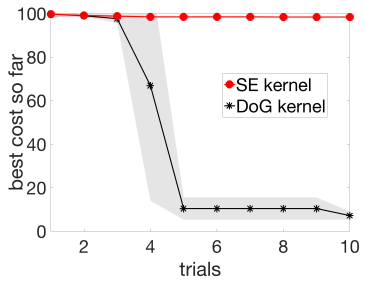
We will now present our experiments on optimizing controllers that are 5, 9, 16 and 50 dimensional. We split our experiments into three categories: hardware experiments on the ATRIAS robot, simulation experiments on the 7-link biped and experiments using simulators with different levels of mismatch. We demonstrate that our proposed approach is able to generalize to different controllers and robot structures and is also robust to simulation inaccuracies. The sections below present experimental results, while Appendix A gives further details on data collection, BO implementation and kernel generation.

5.1. Hardware Experiments on the ATRIAS Robot



In this section we describe experiments conducted on the ATRIAS robot (hardware from Section 4.1). These experiments were conducted around a boom. The cost function used in our experiments is a slight modification of the cost used in Song and Geyer (2015):

$$cost = \begin{cases} 100 - x_{fall}, \text{if fall} \\ ||v_{avg} - v_{tgt}||, \text{if walk} \end{cases} \quad (6)$$



where x_{fall} is distance covered before falling, v_{avg} is average speed per step and v_{tgt} contains target velocity profile, which can be variable. This cost function heavily penalizes falls, and encourages walking controllers to track target velocity.

We do multiple runs of each algorithm on the robot. Each run typically consists of 10 experiments on the robot. All BO runs start from scratch, with an uninformed GP prior. At the end of the run, the GP posterior has 10 data points, depending on the experiment. Each robot trial is designed to be between $30s$ to $60s$ long and the robot is reset to its "home" position between trials.

We will present two sets of hardware experiments in the following subsections. First we describe experiments with the DoG-based kernel on the 5 and 9 dimensional controllers

(a) BO for 5D controller. BO with SE finds walking points in 4/5 runs within 20 trials. BO with DoG-based kernel finds walking points in 5/5 runs within 3 trials.

(b) BO for 9D controller. BO with SE doesn't find walking points in 3 runs. BO with DoG-based kernel finds walking points in 3/3 runs within 5 trials.

Figure 4: BO for 5D and 9D controller on ATRIAS robot hardware. Plots show mean best cost so far. Shaded region shows ± one standard deviation. From Rai et al. (2018).

(first reported in Rai et al. (2018)). The second set describes a new set of experiments for optimizing a 9-dimensional controller using a Neural Network based kernel on hardware.

5.1.1. Experiments with a 5-dimensional controller and DoG-based kernel

In our first set of experiments on the robot, we investigated optimizing the 5-dimensional controller from Section 4.3. For these experiments we picked a challenging variable target speed profile: $0.4m/s$ (15 steps) - $1.0m/s$ (15 steps) - $0.2m/s$ (15 steps) - $0m/s$ (5 steps). The controller was stopped after the robot took 50 steps.

To evaluate the difficulty of this setting, we sampled 100 random points on hardware. 10% of these randomly sampled controllers could walk. In contrast, in simulation the success rate of random sampling was ≈27.5%. This indicates that the simulation was easier, which could be potentially detrimental to algorithms that rely heavily on simulation, because a large portion of controllers that walk in simulation fall on hardware. Nevertheless, using a DoG-based kernel offered significant improvements over a standard SE kernel (Figure 4a).

We conducted 5 runs of BO with DoG-based kernel and 5 runs of BO with SE, 10 trials for DoG-based kernel per run, and 20 for SE kernel. In total, this led to 150 experiments on the robot (excluding the 100 random samples, which were not used during BO). BO with DoG-based kernel found walking points in 100% of runs within 3 trials. In comparison, BO with SE found walking points in 10 trials in 60% runs, and in 80% runs in 20 trials (Figure 4a). Although BO could find walking controllers as early as the second trial (with no prior hardware information), it is worth noting that the optimization did not converge after only a few trials. Sampling more could possibly lead to better walking controllers, but our goal was to find the best controller with a budget of only 10 to 20 trials.

5.1.2. Experiments with a 9-dimensional controller and DoG-based kernel

Our next set of experiments optimized the 9-dimensional controller from Section 4.3. First, we sampled 100 random points for the variable speed profile described above, but this led

to no walking points. To ensure that we have a reasonable baseline we decided to simplify the speed profile for this setting: $0.4m/s$ for 30 steps. We evaluated 100 random points on hardware, and 3 walked for the easier speed profile. In comparison, the success rate in simulation was 8% for the tougher variable-speed profile, implying an even greater mismatch between hardware and simulation than the 5-dimensional controller. For experiments in Sections 5.1.1 and 5.1.2 the inertial measurement unit (IMU) of the robot was broken, and we replaced its functionality with external boom sensors. These were lower resolution than the IMU, leading to noisier readings and larger time delays. As a result, the system did not have a good estimation of vertical height of the CoM, leading to poor control authority. However, the IMU on ATRIAS is a very expensive fiber-optic IMU that is not commonly used on humanoid robots, and most robots use simple state estimation methods. So, this is a common setting for humanoid robots, even if it presents a challenge for the optimization methods.

We conducted 3 runs of BO with DoG-based kernel and BO with SE, 10 trials for DoG-based kernel per run, and 10 for SE. In total, this led to 60 experiments on the hardware (excluding the random samples, which were not used for BO). BO with DoG-based kernel found walking points in 5 trials in 3/3 runs. BO with SE did not find any walking points in 10 trials in all 3 runs. These results are shown in Figure 4b.

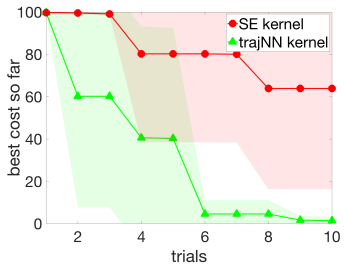
Based on these results, we concluded that BO with DoG-based kernel was indeed able to extract useful information from simulation and speed up learning on hardware, even when there was mismatch between simulation and hardware.

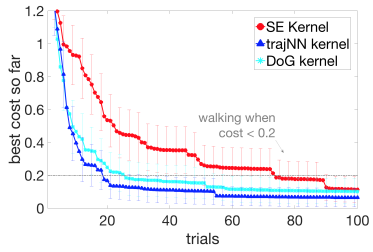
5.1.3. Experiments with a 9-dimensional controller and NN-based kernel

In the next set of experiments, we evaluated performance of the NN-based kernel described in Section 3.1.2. We optimize the 9-dimensional controller from Section 4.3.

The target of hardware experiments was to walk for 30 steps at $0.4m/s$, similar to Section 5.1.2.

For these experiments the IMU was repaired, leading to better state estimation on the robot. For a fair comparison, we re-ran experiments with the baseline for this setting and the baseline performed slightly better than the baseline of earlier experiments (because of improved sensing).





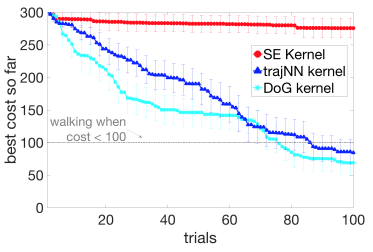


Figure 5: BO for 9D controller on ATRIAS robot hardware.

Figure 5 shows comparison of BO with NN-based kernel and SE kernels. We conducted 5 runs of both algorithms with 10 trials in each run, leading to a total of 100 robot trials. BO with the NN-based kernel found walking points in all 5 runs within 6 trials, while BO with SE kernel only found walking points in 2 of 5 runs in 10 trials. Hence, even without explicit hand-designed domain knowledge, like the DoG-based kernel, the NN-based kernel is able to extract useful information from simulation and successfully guide hardware experiments.

(a) Using smooth cost from Equation 7.

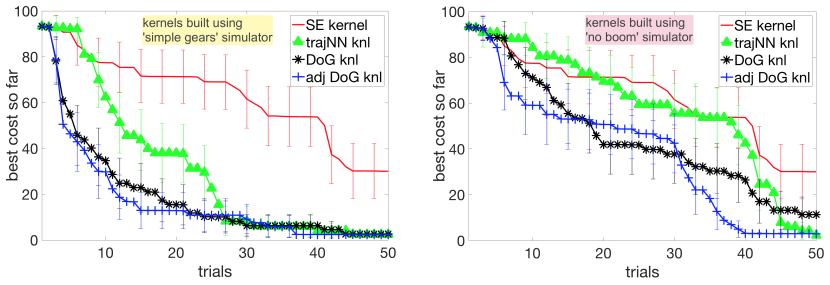
(b) Using non-smooth cost from Equation 8.

Figure 6: BO for the Neuromuscular controller. *trajNN* and *DoG* kernels were constructed with undisturbed model on flat ground. BO is run with mass/inertia disturbances on different rough ground profiles. Plots show means over 50 runs, 95% CIs. From Antonova et al. (2017).

5.2. Simulation Experiments on a 7-link Biped

This section describes simulation experiments with a 16-dimensional Neuromuscular controller (Section 4.4) on a 7-link biped model. These experiments, from Antonova et al. (2017), highlight the cost-agnostic nature of our approach by optimizing two very different costs.

Figure 6 shows BO with DoG-based kernel, NN-based kernel and SE kernel for two different costs from prior literature. The first cost promotes walking further and longer before falling, while penalizing deviations from the target speed (Antonova et al., 2016):



$$cost_{smooth} = 1/(1+t) + 0.3/(1+d) + 0.01(s - s_{tgt}), \tag{7}$$

where t is seconds walked, d is the final CoM position, s is speed and s_{tgt} is the desired walking speed ($1.3m/s$ in our case). The second cost function is similar to the cost used in Section 5. It penalizes falls explicitly, and encourages walking at desired speed and with lower cost of transport:

$$cost_{non\text{-}smooth} = \begin{cases} 300 - x_{fall}, \text{if fall} \\ 100||v_{avg} - v_{tgt}|| + c_{tr}, \text{if walk} \end{cases} \tag{8}$$

where x_{fall} is the distance covered before falling, v_{avg} is the average speed of walking, v_{tgt} is the target velocity, and c_{tr} captures the cost of transport. The changed constants is to account for a longer simulation time. Figure 6a shows that the NN-based kernel and the DoG-based kernel offer a significant improvement over BO with the SE kernel in sample efficiency when using the $cost_{smooth}$, with more than 90% of runs achieving walking after 25 trials. BO with the SE kernel takes 90 trials to get 90% success rate. Figure 6b shows that similar performance by the two proposed approaches is observed on the non-smooth cost. With the NN-based kernel, 70% of the runs find walking solutions after 100 trials, similar to the DoG-based kernel. However, optimizing non-smooth cost is very challenging for BO with the SE kernel: a walking solution is found only in 1 out of 50 runs after 100 trials.

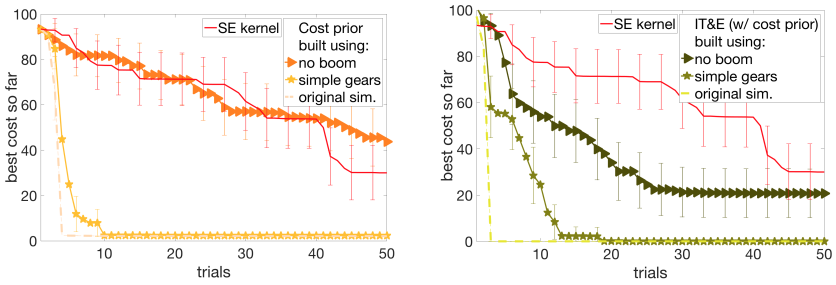
We attribute the difference in performance of the SE kernel on the two costs to the nature of the costs. If a point walks some distance d, Equation 7 reduces in terms of $\frac{1}{d}$ and Equation 8 reduces by $-d$. A sharper fall in the first cost encourages BO to exploit around points that walk some distance, quickly finding points that walk forever. BO with the second cost continues to explore, as the signal is too weak. However the success of both

(a) Informed kernels generated using simulator with simplified gear dynamics.

(b) Informed kernels generated using simplified gear dynamics, without boom model.

Figure 7: BO is run on the original simulator. Informed kernels perform well despite significant mismatch, when kernels are generated using simulator with simplified gear dynamics (left). In the case of severe mismatch, when the boom model is also removed, informed kernels still improve over baseline SE (right). Plots show best cost for mean over 50 runs for each algorithm, 95% CIs.

NN-based and DoG-based kernels on both costs shows that the same kernel can indeed be used for optimizing multiple costs robustly, without any further tuning needed.



5.3. Experiments with Increasing Simulation-Hardware Mismatch

In this section, we describe our experiments with increasing simulation-hardware mismatch and its effect on approaches that use information from simulation during hardware optimization. The quality of information transfer between simulation and hardware depends not only on the mismatch between the two, but also on the controller used. For a robust controller, small dynamics errors would not cause a significant deterioration in performance, while for a sensitive controller this might be much more detrimental.

In the rest of this section, we provide experimental analyses of settings with increasing simulated mismatch and their effect on optimization of the 50-dimensional VNMC from Section 4.5. We compare several approaches that improve sample-efficiency of BO and investigate if the improvement they offer is robust to mismatch between the simulated setting used for constructing kernel/prior and the setting on which BO is run.

First, we examine the performance of our proposed approaches with informed kernels: k_{DoG}, k_{trajNN} and $k_{DoG_{adj}}$. Figure 7a shows the case when informed kernels are generated using the simulator with simplified gear dynamics while BO is run on the original simulator. After 50 trials, all runs with informed kernels find walking solutions, while for SE only 70% have walking solutions.

Next, Figure 7b shows performance of k_{DoG}, k_{trajNN} and $k_{DoG_{adj}}$ when the kernels are constructed using a simulator with simplified dynamics and without a the boom. In this case the mismatch with the original simulator is larger than before and we see the advantage of using adjustment for DoG-based kernel: $k_{DoG_{adj}}$ finds walking points in all runs after 35 trials. k_{trajNN} also achieves this, but after 50 trials. k_{DoG} finds walking points in $\approx 90\%$

(a) BO with cost prior: straightforward approach useful for low-to-medium mismatch; but no improvement if mismatch is severe.

(b) Performance of IT&E algorithm (our implementation of Cully et al. (2015), adapted to bipedal locomotion).

Figure 8: BO using prior-based approaches. Mean over 50 runs for each algorithm, 95% CIs.

of the runs after 50 trials. The performance of SE stays the same, as it uses no prior information from any simulator.

This illustrates that while the original DoG-based kernel can recover from slight simulation-hardware mismatch, the adjusted DoG-kernel is required for higher mismatch. k_{trajNN} seems to recover from the mismatch, but might benefit from an adjusted version. We leave this to future work.

5.3.1. Comparisons of Prior-based and Kernel-based Approaches

In this section, we classify approaches that use simulation information in hardware optimization as prior-based or kernel-based. Prior-based approaches use costs from the simulation in the prior of the GP used in the BO. This can help BO a lot if the costs are similar between simulation and hardware, and the cost function is fixed. However, in the presence of large mismatch, controllers that perform well in simulation might fail on hardware. A prior-based method can be biased towards sampling promising points from simulation, resulting in worse performance than uninformed BO. Kernel-based approaches consist of methods that incorporate information from simulation into the kernel of the GP. These can be less sample-efficient as compared to prior-based method, but not as likely to be biased towards unpromising regions in the presence of mismatch. They also easily generalize to multiple costs, so that there is no need to re-run simulations for data collection if the cost is changed. This is important because a lot of these approaches can take several days of computation to generate a cost prior or informed kernel. For example, Cully et al. (2015) report taking 2 weeks on a 16-core computer to generate their map.

It is possible to also combine both prior-based and kernel-based methods, as in Cully et al. (2015). We classify these as 'prior-based' methods, since in our experiments prior outweighs the kernel effects for such cases. In our comparison with Cully et al. (2015), we implement a version with and without the prior points. We do not add a cost prior to BO using DoG-based kernel, as this would limit us to a particular cost and high-fidelity simulators, and both of these can be major obstacles in real robot experiments.

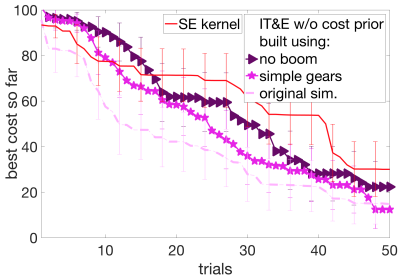


Figure 8a shows the performance when using simulation cost in the prior during BO. BO with a cost prior created using the original version of the simulator illustrates what would happen in the best case scenario. When the simulator with simplified gear dynamics is used for constructing the prior, we observe significant improvements over uninformed BO prior. However, when the prior is constructed from simplified gear dynamics and no boom setting, the approach performs slightly worse than uninformed BO. This shows that while an informed prior can be very helpful when created from a simulator close to hardware, it can hurt performance if simulator is significantly different from hardware.

Next, we discuss experiments with our implementation of Intelligent Trial and Error (IT&E) algorithm from Cully et al. (2015). This algorithm combines adding a cost prior from simulated evaluations with adding simulation information into the kernel. IT&E defines a behavior metric and tabulates best performing points from simulation on their corresponding behavior score. The behavior metric used in our experiments is duty-factor of each leg, which can go from 0 to 1.0. We discretize the duty factor into 21 cells of 0.05 increments, leading to a 21×21 grid. We collect the 5 highest performing controllers for each square in the behavior grid, creating a $21 \times 21 \times 5$ grid. Next, we generate 50 random combinations of a 21×21 grid, selecting 1 out of the 5 best controllers per grid cell. Care was taken to ensure that all 5 controllers had comparable costs in the simulator used for creating the map. Cost of each selected controller is added to the prior and BO is performed in the behavior space, like in Cully et al. (2015).

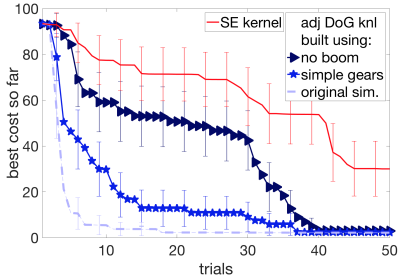

Figure 8b shows BO with IT&E constructed using different versions of the simulator. IT&E constructed using simplified gear dynamics simulator is slightly less sample-efficient than the straightforward 'cost prior' approach. When constructed with the simulator with no boom, IT&E is able to improve over uninformed BO. However, it only finds walking points in 77% of the runs in 50 trials in this case, as some of the generated maps contained no controllers that could walk on the 'hardware'. This is a shortcoming of the IT&E algorithm, as it eliminates a very large part of the search space and if the pre-selected space does not contain a walking point, no walking controllers can be sampled with BO. This problem could possibly be avoided by using a finer grid, or a different behavior metric. However tuning such hyper-parameters can turn out to be expensive, in computation and hardware experiment time.

To separate the effects of using simulation information in prior mean vs kernel, we evaluated a kernel-only version of IT&E algorithm (Figure 9a). It shows that the cost prior is crucial for the success of IT&E and performance deteriorates without it. Hence, it is not practical to use IT&E on a cost different than what it was generated for. Nonetheless, Figure 7 showed that BO with adjusted DoG kernel is able to handle both moderate and severe mismatch with kernel-only information, collected in Figure 9b.

Summarizing this section, we created two simulators with increasing modelling approximations, and studied the effect of using these to aid optimization on the original simulator. We found that while methods that use cost in the prior of BO can be very sample-efficient in low mismatch, their performance worsens as mismatch increases. IT&E, introduced in Cully et al. (2015), uses simulation information in both prior mean and kernel, and is very sample-efficient in cases of low mismatch. Even with high mismatch, it performed better than just prior-based BO but doesn't find walking controllers reliably. In comparison, adjusted DoG-based kernel performed well in all the tested scenarios, and can reliably improve sample-efficiency of BO even when the mismatch between simulation and hardware is high.

(a) BO using our implementation of IT&E without cost prior (from Cully et al. (2015)).

(b) BO using $k_{DoG_{adj}}$ constructed from simulators with various levels of mismatch.

6. Conclusion

In this paper, we presented and analyzed in detail our work from Antonova et al. (2016), Antonova et al. (2017) and Rai et al. (2018). These works introduce domain-specific feature transforms that can be used to optimize locomotion controllers on hardware efficiently. The feature transforms project the original controller space into a space where BO can discover promising regions quickly. We described a transform for bipedal locomotion designed with the knowledge of human walking and a neural network based transform that uses more general information from simulated trajectories. Our experiments demonstrate success at optimizing controllers on the ATRIAS robot. Further simulation-based experiments also indicate potential for other bipedal robots. For optimizing sensitive high-dimensional controllers, we proposed an approach to adjust simulation-based kernel using data seen on hardware. To study the performance of this, as well as compare our approach to other methods, we created a series of increasingly approximate simulators. Our experiments show that while several methods from prior literature can perform well with low simulation-hardware mismatch (sometimes even better than our proposed approach), they suffer when this mismatch increases. In such cases, our proposed kernels with hardware adjustment can yield reliable performance across different costs, simulators and robots.

Appendix A: Implementation Details

In this appendix we provide a summary of data collection and implementation details. Our implementation of BO was based on the framework in Gardner et al. (2014). We used Expected Improvement (EI) acquisition function (Mockus et al., 1978). We also experimented with Upper Confidence Bound (UCB) (Srinivas et al., 2010), but found that performance was not sensitive to the choice of acquisition function. Hyper-parameters for BO were initialized to default values: 0 for mean offset, 1.0 for kernel length scales and signal variance, 0.1 for σ_n (noise parameter). Hyperparameters were optimized using the marginal likelihood (Shahriari et al. (2016), Section V-A). For all algorithms, we started optimizing hyperparameters after a low-cost controller was found (to save compute resources and avoid premature hyperparameter optimization). The search space boundaries for controller parameters was designed with physical constraints of the ATRIAS robot in mind.

Kernel type	Controller dim	# Sim points	Sim duration	Kernel dim	Features in kernel
k_{DoG}	5	20K	3.5s	1	$score_{DoG}$
	9	100K	5s	1	$score_{DoG}$
	50	200K	5s	1	$score_{DoG}$
k_{trajNN}	9	100K	5s	4	t_{walk}, x_{end}, θ_{avg}, $v_{x,avg}$
	16	100K	5s	8	t_{walk}, x_{end}, θ_{end}, $v_{x,end}$ c_τ, y_{end}, $v_{y,end}$, $\dot{\theta}_{end}$
	50	200K	5s	13	t_{walk}, x_{end}, c_τ, $\boldsymbol{traj}_x$, $\boldsymbol{traj}_\theta$

Table 2: Simulation data collection details. $score_{DoG}$ was described in Section 3.1.1. For k_{trajNN}: t_{walk} is time walked in simulation before falling, x_{end} and y_{end} are the x and y positions of Center of Mass (CoM) at the end of the short simulation, θ is the torso angle, $\dot{\theta}$ is the torso velocity, v is the CoM speed (v_x is the horizontal and v_y is the vertical component), c_τ is the squared sum of torques applied; $\boldsymbol{traj}_x$, $\boldsymbol{traj}_\theta$ denote vectors with mean CoM and θ measurements every second.

k_{trajNN} discussed in Section 3.1.2 was constructed by training a fully connected neural network (NN) with 3 hidden layers, using L1 loss to reconstruct features encoded by trajectory summaries. For experiments with 16D controller in Section 5.2, for example, the hidden layers contained 512, 128, 32 units; NN was trained on 100K simulated examples to reconstruct 8D trajectory summaries (see next-to-last row of Table 2). We experimented with various hidden layer sizes for 9D and 50D controllers, but did not find the overall BO performance to be sensitive to size or other training parameters, like NN learning rate. This was likely because NN used to construct an informed kernel only needs to approximately learn to separate well-performing parts from failing parts of the control parameter space. This is the benefit of our choice not to put the output of NN directly into a GP posterior.

To create cost prior for experiments in Section 5.3 we collected 50,000 evaluations of 30s trials for a range of controller parameters. Then we conducted 50 runs, using random subsets of 35,000 evaluations to construct the prior. The numbers were chosen such that this approach used similar amount of computation as our kernel-based approaches. To accommodate GP prior with a large number of points we used a sparse GP construction provided by Rasmussen and Nickisch (2010).

Editor: Bayesian Optimization Special Issue

Abstract

Bayesian optimization (BO) based on Gaussian process models is a powerful paradigm to optimize black-box functions that are expensive to evaluate. While several BO algorithms provably converge to the global optimum of the unknown function, they assume that the hyperparameters of the kernel are known in advance. This is not the case in practice and misspecification often causes these algorithms to converge to poor local optima. In this paper, we present the first BO algorithm that is provably no-regret and converges to the optimum without knowledge of the hyperparameters. During optimization we slowly adapt the hyperparameters of stationary kernels and thereby expand the associated function class over time, so that the BO algorithm considers more complex function candidates. Based on the theoretical insights, we propose several practical algorithms that achieve the empirical sample efficiency of BO with online hyperparameter estimation, but retain theoretical convergence guarantees. We evaluate our method on several benchmark problems.

Keywords: Bayesian optimization, Unknown hyperparameters, Reproducing kernel Hilbert space (RKHS), Bandits, No regret

1. Introduction

The performance of machine learning algorithms often critically depends on the choice of tuning inputs, e.g., learning rates or regularization constants. Picking these correctly is a key challenge. Traditionally, these inputs are optimized using grid or random search (Bergstra and Bengio, 2012). However, as data sets become larger the computation time required to train a single model increases, which renders these approaches less applicable. Bayesian optimization (BO, Mockus (2012)) is an alternative method that provably determines good inputs within few evaluations of the underlying objective function. BO methods construct a statistical model of the underlying objective function and use it to evaluate inputs that are informative about the optimum. However, the theoretical guarantees, empirical performance, and data efficiency of BO algorithms critically depend on their own choice of hyperparameters and, in particular, on the prior distribution over the function space. Thus, we effectively shift the problem of tuning inputs one level up, to the tuning of hyperparameters of the BO algorithm.

In this paper, we use a Gaussian processes (GP, Rasmussen and Williams (2006)) for the statistical model. We present the first BO algorithm that does not require knowledge about the hyperparameters of the GP's stationary kernel and provably converges to the global optimum. To this end, we adapt the hyperparameters of the kernel and our BO algorithm, so that the associated function space grows over time. The resulting algorithm provably converges to the global optimum and retains theoretical convergence guarantees, even when combined with online estimation of hyperparameters.

Related work General BO has received a lot of attention in recent years. Typically, BO algorithms suggest inputs to evaluate by maximizing an acqusition function that measures informativeness about the optimum. Classical acquisition functions are the *expected improvement* over the best known function value encountered so far given the GP distribution (Mockus et al., 1978) and the *Upper Confidence Bound* algorithm, GP-UCB, which applies the 'optimism in the face of uncertainty' principle. The latter is shown to provably converge by Srinivas et al. (2012). Durand et al. (2018) extend this framework to the case of unknown measurement noise. A related method is *truncated variance reduction* by Bogunovic et al. (2016), which considers the reduction in uncertainty at candidate locations for the optimum. Hennig and Schuler (2012) propose *entropy search*, which approximates the distribution of the optimum of the objective function and uses the reduction of the entropy in this distribution as an acquisition function. Alternative information-theoretic methods are proposed by Hernández-Lobato et al. (2014); Wang and Jegelka (2017); Ru et al. (2018). Other alternatives are the *knowledge gradient* (Frazier et al., 2009), which is one-step Bayes optimal, and *information directed sampling* by Russo and Van Roy (2014), which considers a tradeoff between regret and information gained when evaluating an input. Kirschner and Krause (2018) extend the latter framework to heteroscedastic noise.

These BO methods have also been successful empirically. In machine learning, they are used to optimize the performance of learning methods (Brochu et al., 2010; Snoek et al., 2012). BO is also applicable more broadly; for example, in reinforcement learning to optimize a parametric policy for a robot (Calandra et al., 2014; Lizotte et al., 2007; Berkenkamp et al., 2016) or in control to optimize the energy output of a power plant (Abdelrahman et al., 2016). It also forms the backbone of Google vizier, a service for tuning black-box functions (Golovin et al., 2017).

Some of the previous BO algorithms provide theoretical guarantees about convergence to the optimum. These theoretical guarantees only hold when the kernel hyperparameters are known *a priori*. When this is not the case, hyperparameters are often inferred using either *maximum a posteriori* estimates or sampling-based inference (Snoek et al., 2012). Unfortunately, methods that estimate the hyperparameters online are known to get stuck in local optima (Bull, 2011). Instead, we propose to adapt the hyperparameters online in order to enlarge the function space over time, which allows us to provide guarantees in terms of convergence to the global optimum without knowing the hyperparameters. Wang and de

Freitas (2014) analyze this setting when a lower bound on the kernel lengthscales is known *a priori*. They decrease the lengthscales over time and bound the regret in terms of the known lower-bound on the lengthscales. Empirically, similar heuristics are used by Wang et al. (2016); Wabersich and Toussaint (2016). In contrast, this paper considers the case where the hyperparameters are *not known*. Moreover, the scaling of the hyperparameters in the previous two papers did not depend on the dimensionality of the problem, which can cause the function space to increase too quickly.

Considering larger function classes as more data becomes available is the core idea behind structural risk minimization (Vapnik, 1992) in statistical learning theory. However, there data is assumed to be sampled independently and identically distributed. This is not the case in BO, where new data is generated actively based on past information.

Our contribution In this paper, we present Adaptive GP-UCB (A-GP-UCB), the first algorithm that provably converges to the globally optimal inputs when BO hyperparameters are *unknown*. Our method expands the function class encoded in the model over time, but does so slowly enough to ensure sublinear regret and convergence to the optimum. Based on the theoretical insights, we propose practical variants of the algorithm with guaranteed convergence. Since our method can be used as an add-on module to existing algorithms with hyperparameter estimation, it achieves similar performance empirically, but avoids local optima when hyperparameters are misspecified. In summary, we:

- Provide theoretical convergence guarantees for BO with unknown hyperparameters;
- Propose several practical algorithms based on the theoretical insights;
- Evaluate the performance in practice and show that our method retains the empirical performance of heuristic methods based on online hyperparameter estimation, but leads to significantly improved performance when the model is misspecified initially.

The remainder of the paper is structured as follows. We state the problem in Sec. 2 and provide relevant background material in Sec. 3. We derive our main theoretical result in Sec. 4 and use insights gained from the theory to propose practical algorithms. We evaluate these algorithms experimentally in Sec. 5 and draw conclusions in Sec. 6. The technical details of the proofs are given in the appendix.

2. Problem Statement

In general, BO considers global optimization problems of the form

$$\mathbf{x}^* = \operatorname*{argmax}_{\mathbf{x}\in\mathcal{D}} f(\mathbf{x}), \tag{1}$$

where $\mathcal{D} \subset \mathbb{R}^d$ is a compact domain over which we want to optimize inputs $\mathbf{x}$, and $f\colon \mathcal{D} \to \mathbb{R}$ is an objective function that evaluates the reward $f(\mathbf{x})$ associated with a given input configuration $\mathbf{x}$. For example, in a machine learning application, $f(\mathbf{x})$ may be the validation loss and $\mathbf{x}$ may be the tuning inputs (e.g., regularization parameters) of the training algorithm. We do not have any significant prior knowledge about the structure of f. Specifically, we cannot assume convexity or that we have access to gradient information. Moreover, evaluations of f are corrupted by σ-sub-Gaussian noise, a general class of noise models that includes, for example, bounded or Gaussian noise.

Regret We aim to construct a sequence of input evaluations $\mathbf{x}_t$, that eventually maximizes the function value $f(\mathbf{x}_t)$. One natural way to prove this convergence is to show that an algorithm has sublinear regret. The instantaneous regret at iteration t is defined as $r_t = \max_{\mathbf{x}\in\mathcal{D}} f(\mathbf{x}) - f(\mathbf{x}_t) \geq 0$, which is the loss incurred by evaluating the function at $\mathbf{x}_t$ instead of at the *a priori unknown* optimal inputs. The cumulative regret is defined as $R_T = \sum_{0<t\leq T} r_t$, the sum of regrets incurred over T steps. If we can show that the cumulative regret is sublinear for a given algorithm, that is, $\lim_{t\to\infty} R_t \,/\, t = 0$, then eventually the algorithm evaluates the function at inputs that lead to close-to-optimal function values most of the time. We say that such an algorithm has *no-regret*. Intuitively, if the average regret approaches zero then, on average, the instantaneous regret must approach zero too, since r_t is strictly positive. This implies that there exists a $t > 0$ such that $f(\mathbf{x}_t)$ is arbitrarily close to $f(\mathbf{x}^*)$ and the algorithm converges. Thus, we aim to design an optimization algorithm that has sublinear regret.

Regularity assumptions Without further assumptions, it is impossible to achieve sublinear regret on (1). In the worst case, f could be discontinuous at every input in $\mathcal{D}$. To make the optimization problem in (1) tractable, we make regularity assumptions about f. In particular, we assume that the function f has low complexity, as measured by the norm in a reproducing kernel Hilbert space (RKHS, Christmann and Steinwart (2008)). An RKHS $\mathcal{H}_k$ contains well-behaved functions of the form $f(\mathbf{x}) = \sum_{i\geq 0} \alpha_i\, k(\mathbf{x}, \mathbf{x}_i)$, for given representer points $\mathbf{x}_i \in \mathbb{R}^d$ and weights $\alpha_i \in \mathbb{R}$ that decay sufficiently quickly. The kernel $k(\cdot,\cdot)$ determines the roughness and size of the function space and the induced RKHS norm $\|f\|_k = \sqrt{\langle f,\, f\rangle}$ measures the complexity of a function $f \in \mathcal{H}_k$ with respect to the kernel.

In the following, we assume that f in (1) has bounded RKHS norm $\|f\|_{k_\theta} \leq B$ with respect to a kernel k_θ that is parameterized by hyperparameters θ. We write $\mathcal{H}_\theta$ for the corresponding RKHS, $\mathcal{H}_{k_\theta}$. For known B and θ, no-regret BO algorithms for (1) are known, e.g., GP-UCB (Srinivas et al., 2012). In practice, these hyperparameters need to be tuned. In this paper, we consider the case where θ and B are unknown. We focus on stationary kernels, which measure similarity based on the distance of inputs, $k(\mathbf{x}, \mathbf{x}') = k(\mathbf{x} - \mathbf{x}')$. The most commonly used hyperparameters for these kernels are the lengthscales $\theta \in \mathbb{R}^d$, which scale the inputs to the kernel in order to account for different magnitudes in the different components of $\mathbf{x}$ and effects on the output value. That is, we scale the difference $\mathbf{x} - \mathbf{x}'$ by the lengthscales θ,

$$k_\theta(\mathbf{x}, \mathbf{x}') = k\left(\frac{[\mathbf{x}]_1 - [\mathbf{x}']_1}{[\theta]_1}, \ldots, \frac{[\mathbf{x}]_d - [\mathbf{x}']_d}{[\theta]_d}\right), \tag{2}$$

where $[\mathbf{x}]_i$ denotes the ith element of $\mathbf{x}$. Typically, these kernels assign larger similarity scores to inputs when the scaled distance between these two inputs is small. Another common hyperparameter is the prior variance of the kernel, a multiplicative constant that determines the magnitude of the kernel. We assume $k(\mathbf{x}, \mathbf{x}) = 1$ for all $\mathbf{x} \in \mathcal{D}$ without loss of generality, as any multiplicative scaling can be absorbed by the norm bound B.

In summary, our goal is to efficiently solve (1) via a BO algorithm with sublinear regret, where f lies in some RKHS $\mathcal{H}_\theta$, but neither the hyperparameters θ nor the norm-bound $\|f\|_{k_\theta}$ are known.

3. Background

In this section, we review Gaussian processes (GPs) and Bayesian optimization (BO).

3.1. Gaussian processes (GP)

Based on the assumptions in Sec. 2, we can use GPs to infer confidence intervals on f. The goal of GP inference is to infer a posterior distribution over the nonlinear map $f(\mathbf{x}) : D \to \mathbb{R}$ from an input vector $\mathbf{x} \in D$ to the function value $f(\mathbf{x})$. This is accomplished by assuming that the function values $f(\mathbf{x})$, associated with different values of $\mathbf{x}$, are random variables and that any finite number of these random variables have a joint Gaussian distribution (Rasmussen and Williams, 2006). A GP distribution is parameterized by a prior mean function and a covariance function or kernel $k(\mathbf{x}, \mathbf{x}')$, which defines the covariance of any two function values $f(\mathbf{x})$ and $f(\mathbf{x}')$ for $\mathbf{x}, \mathbf{x}' \in D$. In this work, the mean is assumed to be zero without loss of generality. The choice of kernel function is problem-dependent and encodes assumptions about the unknown function.

We can condition a $GP(0, k(\mathbf{x}, \mathbf{x}'))$ on a set of t past observations $\mathbf{y}_t = (y_1, \dots, y_t)$ at inputs $\mathcal{A}_t = \{\mathbf{x}_1, \dots, \mathbf{x}_t\}$ in order to obtain a posterior distribution on $f(\mathbf{x})$ for any input $\mathbf{x} \in D$. The GP model assumes that observations are noisy measurements of the true function value, $y_t = f(\mathbf{x}_t) + \omega_t$, where $\omega_t \sim \mathcal{N}(0, \sigma^2)$. The posterior distribution is again a $GP(\mu_t(\mathbf{x}), k_t(\mathbf{x}, \mathbf{x}'))$ with mean μ_t, covariance k_t, and variance σ_t, where

$$\mu_t(\mathbf{x}) = \mathbf{k}_t(\mathbf{x})(\mathbf{K}_t + \mathbf{I}\sigma^2)^{-1}\mathbf{y}_t, \tag{3}$$

$$k_t(\mathbf{x}, \mathbf{x}') = k(\mathbf{x}, \mathbf{x}') - \mathbf{k}_t(\mathbf{x})(\mathbf{K}_t + \mathbf{I}\sigma^2)^{-1}\mathbf{k}_t^{\mathrm{T}}(\mathbf{x}'), \tag{4}$$

$$\sigma_t^2(\mathbf{x}) = k_t(\mathbf{x}, \mathbf{x}). \tag{5}$$

The covariance matrix $\mathbf{K}_t \in \mathbb{R}^{t \times t}$ has entries $[\mathbf{K}_t]_{(i,j)} = k(\mathbf{x}_i, \mathbf{x}_j)$, $i, j \in \{1, \dots, t\}$, and the vector $\mathbf{k}_t(\mathbf{x}) = \big[k(\mathbf{x}, \mathbf{x}_1), \dots, k(\mathbf{x}, \mathbf{x}_t)\big]$ contains the covariances between the input $\mathbf{x}$ and the observed data points in $\mathcal{A}_t$. The identity matrix is denoted by $\mathbf{I}_t \in \mathbb{R}^{t \times t}$.

3.2. Learning RKHS functions with GPs

The GP framework uses a statistical model that makes different assumptions from the ones made about f in Sec. 2. In particular, we assume a different noise model, and samples from a $\mathrm{GP}(0, k(\mathbf{x}, \mathbf{x}'))$ are rougher than RKHS funtions and are not contained in $\mathcal{H}_k$. However, GPs and RKHS functions are closely related (Kanagawa et al., 2018) and it is possible to use GP models to infer reliable confidence intervals on f in (1).

Lemma 1 (Abbasi-Yadkori (2012); Chowdhury and Gopalan (2017)) *Assume that f has bounded RKHS norm $\|f\|_k \leq B$ and that measurements are corrupted by σ-sub-Gaussian noise. If $\beta_t^{1/2} = B + 4\sigma\sqrt{I(\mathbf{y}_t; f) + 1 + \ln(1/\delta)}$, then for all $\mathbf{x} \in D$ and $t \geq 0$ it holds jointly with probability at least $1 - \delta$ that $|\, f(\mathbf{x}) - \mu_t(\mathbf{x})\,| \leq \beta_t^{1/2}\sigma_t(\mathbf{x})$.*

Lemma 1 implies that, with high probability, the true function f is contained in the confidence intervals induced by the posterior GP distribution that uses the kernel k from Lemma 1 as a covariance function, scaled by an appropriate factor β_t. Here, $I(\mathbf{y}_t; f)$ denotes the mutual information between the GP prior on f and the t measurements $\mathbf{y}_t$. Intriguingly, for

GP models this quantity only depends on the inputs $\mathbf{x}_t$ and not the corresponding measurement y_t. Specifically, for a given set of measurements $\mathbf{y}_\mathcal{A}$ at inputs $\mathbf{x} \in \mathcal{A}$, the mutual information is given by

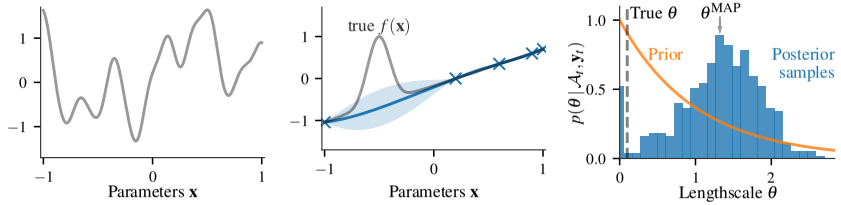
$$I(\mathbf{y}_\mathcal{A}; f) = 0.5 \log |\mathbf{I} + \sigma^{-2}\mathbf{K}_\mathcal{A}|, \tag{6}$$

where $\mathbf{K}_\mathcal{A}$ is the kernel matrix $[k(\mathbf{x}, \mathbf{x}')]_{\mathbf{x},\mathbf{x}' \in \mathcal{A}}$ and $|\cdot|$ is the determinant. Intuitively, the mutual information measures how informative the collected samples $\mathbf{y}_\mathcal{A}$ are about the function f. If the function values are independent of each other under the GP prior, they will provide large amounts of new information. However, if measurements are taken close to each other as measured by the kernel, they are correlated under the GP prior and provide less information.

3.3. Bayesian Optimization (BO)

BO aims to find the global maximum of an unknown function (Mockus, 2012). The framework assumes that evaluating the function is expensive in terms of time required or monetary costs, while other computational resources are comparatively inexpensive. In general, BO methods model the objective function f with a statistical model and use it to determine informative sample locations. A popular approach is to model the underlying function with a GP, see Sec. 3.1. GP-based BO methods use the posterior mean and variance predictions in (3) and (5) to compute the next sample location.

One commonly used algorithm is the GP-UCB algorithm by Srinivas et al. (2012). It uses confidence intervals on the function f, e.g., from Lemma 1, in order to select as next input the point with the largest plasuble function value according to the model,



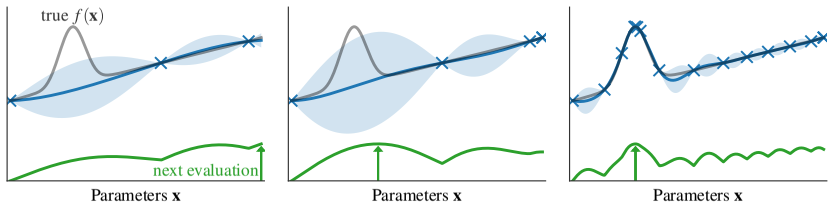
$$\mathbf{x}_{t+1} = \operatorname*{argmax}_{\mathbf{x} \in \mathcal{D}} \mu_t(\mathbf{x}) + \beta_t^{1/2}\sigma_t(\mathbf{x}). \tag{7}$$

Intuitively, (7) selects new evaluation points at locations where the upper bound of the confidence interval of the GP estimate is maximal. Repeatedly evaluating the function f at inputs $\mathbf{x}_{t+1}$ given by (7) improves the mean estimate of the underlying function and decreases the uncertainty at candidate locations for the maximum, so that the global maximum is provably found eventually (Srinivas et al., 2012). While (7) is also an optimization problem, it only depends on the GP model of f and solving it therefore does not require any expensive evaluations of f.

Regret bounds Srinivas et al. (2012) show that the GP-UCB algorithm has cumulative regret $R_t = \mathcal{O}(\sqrt{t\beta_t\gamma_t})$ for all $t \geq 1$ with the same $(1 - \delta)$ probability as the confidence intervals, e.g., in Lemma 1, hold. Here γ_t is the largest amount of mutual information that could be obtained by any algorithm from at most t measurements,

$$\gamma_t = \max_{\mathcal{A} \subset D, |\mathcal{A}| \leq t} I(\mathbf{y}_\mathcal{A}; f). \tag{8}$$

We refer to γ_t as the *information capacity*, since it can be interpreted as a measure of complexity of the function class associated with a GP prior. It was shown by Srinivas et al. (2012) that γ_t has a sublinear dependence on t for many commonly used kernels such as the Gaussian kernel. As a result, R_t has a sublinear dependence on t so that $R_t/t \to 0$ and therefore GP-UCB converges to function evaluations close to $f(\mathbf{x}^*)$. These regret bounds



(a) Sample from GP prior. (b) GP estimate (RKHS). (c) Lengthscale distribution.

Figure 1: A sample from the GP prior in Fig. 1a typically varies at a consistent rate over the input space. However, RKHS functions with the same kernel may be less consistent and can have bumps, as in Fig. 1b (gray). As a result, inferring the posterior lengthscales based on measurements (blue crosses in Fig. 1b) can lead to erroneous results. In Fig. 1c, most of the probability mass of the posterior lengthscales has concentrated around large lengthscales that encode smooth functions. Consequently, the GP's 2σ confidence intervals in Fig. 1b (blue shaded) based on the posterior samples do not contain the true function.

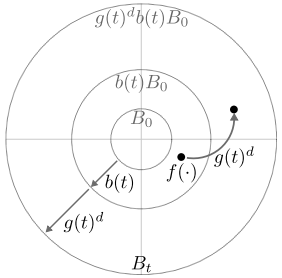
were extended to Thompson sampling, an algorithm that uses samples from the posterior GP as the acquisition function, by Chowdhury and Gopalan (2017).

Online hyperparameter estimation In the previous section, we have seen that the GP-UCB algorithm provably converges. However, it requires access to a RKHS norm bound $\|f\|_\theta \leq B$ under the correct kernel hyperparameters θ in order to construct reliable confidence intervals using Lemma 1. In practice, these are unknown and have to be estimated online, e.g., based on a prior distribution placed on θ. Unfortunately, it is well-known that online estimation of the inputs, be it via maximum a posteriori (MAP) or sampling methods, does not always converge to the optimum (Bull, 2011). The problem does not primarily lie with the inference scheme, but rather with the assumptions made by the GP. In particular, typical samples drawn from a GP with a stationary kernel tend to have a similar rate of change throughout the input space, see Fig. 1a. In contrast, the functions inside the RKHS, as specified in Sec. 2, can have different rates of change and are thus improbable under the GP prior. For example, the grey function in Fig. 1b is almost linear but has one bump that defines the global maximum, which makes this function an improbable sample under the GP prior even though it belongs to the RKHS induced by the same kernel. This property of GPs with stationary kernels means that, for inference, it is sufficient to estimate the lengthscales in a small part of the state-space in order to make statements about the function space globally. This is illustrated in Fig. 1c, where we show samples from the posterior distribution over the lengthscales based on the measurements obtained from the GP-UCB algorithm in Fig. 1b (blue crosses). Even though the prior distribution on the lengthscales θ is suggestive of short lengthscales, most of the posterior probability mass is concentrated around lengthscales that are significantly larger than the true ones. As a result, even under model averaging over the samples from the posterior distribution of the lengthscales, the GP confidence intervals do not contain the true function in Fig. 1b. This is not a problem of the inference method applied, but rather a direct consequence of

(a) Stuck in local optimum. (b) Expanding the function class. (c) Global optimum found.

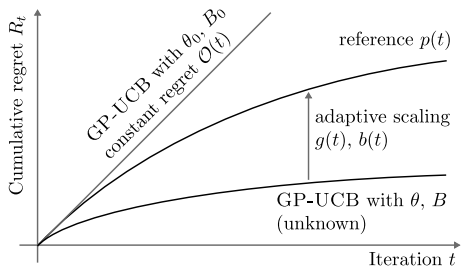
Figure 2: BO algorithms get stuck in local optima when the hyperpararameters of the model are misspecified. In Fig. 2a, the true function is not contained within the GP's confidence intervals (blue shaded), so that GP-UCB only collects data at the local optimum on the right (green arrow), see also Fig. 1. Our method expands the function class over time by scaling the hyperparameters, which encourages additional exploration in Fig. 2b. The function class grows slowly enough, so that the global optimum is provably found in Fig. 2c.

the probabilistic model that we have specified based on the stationary kernel, which does not consider functions with different rates of change to be likely.



4. The Adaptive GP-UCB Algorithm

In this section, we extend the GP-UCB algorithm to the case where neither the norm bound B nor the lengthscales θ are known. In this case, it is always possible that the local optimum is defined by a local bump based on a kernel with small lengthscales, which has not been encountered by the data points as in Fig. 1b. The only solution to avoid this problem is to keep exploring to eventually cover the input space $\mathcal{D}$ (Bull, 2011). We consider expanding the function space associated with the hyperparameters slowly over time, so that we obtain sublinear regret once the true function class has been identified. Intuitively, this can help BO algorithms avoid premature convergence to local optima caused by misspecified hyperparameters θ and B. For example, in Fig. 2a, the GP-UCB algorithm has converged to a local maximum. By decreasing the lengthscales, we increase the underlying function class, which means that the GP confidence intervals on the function increase. This enables GP-UCB to explore further so that the global optimum is found, as shown in Fig. 2c.



Specifically, we start with an initial guess θ_0 and B_0 for the lengthscales and norm bound on f, respectively. Over the iterations, we scale down the lengthscales and scale up the norm bound,

$$\theta_t = \frac{1}{g(t)}\,\theta_0, \qquad B_t = b(t)g(t)^d\,B_0, \tag{9}$$

where $g\colon \mathbb{N} \to \mathbb{R}_{>0}$ and $b\colon \mathbb{N} \to \mathbb{R}_{>0}$ with $b(0) = g(0) = 1$ are functions that can additionally depend on the data collected up to iteration t, $\mathcal{A}_t$ and $\mathbf{y}_t$. As $g(t)$ increases, the lengthscales θ_t of the kernel become shorter, which enlarges the underlying function space:

(a) Scaling of the norm bound.

(b) Cumulative regret with scaling.

Figure 3: The function f in Fig. 3a has RKHS norm $\|f\|_{\theta_0} > B_0$. To account for this, we expand the norm ball by $b(t)$ over time. When we scale down the lengthscales by $g(t)$, the norm of f in the resulting RKHS is larger, see Lemma 2. We account for this when defining the norm ball B_t in (9). In Fig. 3b, the GP-UCB algorithm based on the misspecified hyperparameters B_0 and θ_0 does not converge (constant regret). Our method scales the lengthscales and norm bound by $g(t)$ and $b(t)$, so that we eventually capture the true model. Scaling the hyperparameters beyond the true ones leads to additional exploration and thus larger cumulative regret than GP-UCB with the true, unknown hyperparameters θ and B. However, as long as the cumulative regret is upper bounded by a sublinear function p, ultimately the A-GP-UCB algorithm converges to the global optimum.

Lemma 2 *(Bull, 2011, Lemma 4) If $f \in \mathcal{H}_\theta$, then $f \in \mathcal{H}_{\theta'}$ for all $0 < \theta' \leq \theta$, and*

$$\|f\|^2_{\mathcal{H}_{\theta'}} \leq \left(\prod_{i=1}^{d} \frac{[\theta]_i}{[\theta']_i} \right) \|f\|^2_{\mathcal{H}_\theta} . \tag{10}$$

Lemma 2 states that when decreasing the lengthscales θ, the resulting function space contains the previous one. Thus, as $g(t)$ increases we consider larger RKHS spaces as candidate spaces for the function f. In addition, as we increase $b(t)$, we consider larger norm balls within the function space $\mathcal{H}_{\theta_t}$, which corresponds to more complex functions. However, it follows from (10) that, as we increase $g(t)$, we also increase the norm of any existing function in $\mathcal{H}_{\theta_0}$ by at most a factor of $g(t)^d$. This is illustrated in Fig. 3a: as we scale up the norm ball to $b(t)B_0$, we capture f under the initial lengthscales θ_0. However, by shortening the lengthscales by $g(t)$, the function f has a larger norm in the new function space $\mathcal{H}_{\theta_t} = \mathcal{H}_{\theta_0/g(t)}$. We account for this through the additional scaling factor $g(t)^d$ in the norm bound B_t in (9).

Theoretical analysis Based on the previous derivations together with Lemma 2, it is clear that, if $g(t)$ and $b(t)$ are monotonically increasing functions and $f \in \mathcal{H}_{\theta_{t^*}}$ with $\|f\|_{\theta_{t^*}} \leq B_{t^*}$ for some $t^* > 0$, then $f \in \mathcal{H}_{\theta_t}$ and $\|f\|_{\theta_t} \leq B_t$ for all $t \geq t^*$. That is, once the function f is contained within the norm ball of B_{t^*} for the lengthscales θ_{t^*}, then, for any further increase in $b(t)$ or $g(t)$, the function f is still contained in the candidate space $\{f \in \mathcal{H}_{\theta_t} \,|\, f \leq B_t\}$.

Based on this insight, we propose A-GP-UCB in Algorithm 1. At iteration t, A-GP-UCB sets the GP lengthscales to θ_t and selects new inputs $\mathbf{x}_{t+1}$ similar to the GP-UCB algorithm, but based on the norm bound B_t. We extend the analysis of GP-UCB and Lemma 1 to obtain our main result.

Theorem 1 *Assume that f has bounded RKHS norm $\|f\|^2_{k_\theta} \leq B$ in a RKHS that is parametrized by a stationary kernel $k_\theta(\mathbf{x}, \mathbf{x}')$ with unknown lengthscales θ. Based on an initial guess, θ_0 and B_0, define monotonically increasing functions $g(t) > 0$ and $b(t) > 0$ and run* A-GP-UCB *with $\beta_t^{1/2} = b(t)g(t)^d B_0 + 4\sigma\sqrt{I_{\theta_t}(\mathbf{y}_t; f) + 1 + \ln(1/\delta)}$ and GP lengthscales $\theta_t = \theta_0/g(t)$. Then, with probability at least $(1-\delta)$, we obtain a regret bound of*

$$R_t \leq 2B \max\left(g^{-1}\left(\max_i \frac{[\theta_0]_i}{[\theta]_i} \right), b^{-1}\left(\frac{B}{B_0} \right) \right) + \sqrt{C_1 t \beta_t I_{\theta_t}(\mathbf{y}_t; f)}, \tag{11}$$

where I_{θ_t} is the mutual information in (6) *based on the GP model with lengthscales θ_t and $C_1 = 8/\log(1+\sigma^{-2})$.*

The proof is given in the appendix. Intuitively, the regret bound in (11) splits the run of the algorithm into two distinct phases. In the first one, either the RKHS space $\mathcal{H}_{\theta_t}(\mathcal{D})$ or the norm bound B_t are too small to contain the true function f. Thus, the GP confidence intervals scaled by $\beta_t^{1/2}$ do not necessarily contain the true function f, as in Fig. 1b. In these iterations, we obtain constant regret that is bounded by $2B$, since $\|f\|_\infty \leq \|f\|_\theta \leq B$. After both g and b have grown sufficiently in order for the considered function space to contain the true function, the confidence bounds are reliable and we can apply the theoretical results of the GP-UCB algorithm. This is illustrated in Fig. 3b: If the initial hyperparameters θ_0 and B_0 are misspecified, the confidence intervals do not contain f and GP-UCB does not converge. We avoid this problem by increasing $b(t)$ and $g(t)$ over time, so that we eventually contain f in our function class. However, increasing the norm ball and decreasing the lengthscales beyond the true ones causes additional exploration and thus additional cumulative regret relative to GP-UCB with the true, unknown hyperparameters. This additional regret represents the cost of not knowing the hyperparameters in advance. As long as the overall regret remains bounded by a sublinear function $p(t)$, our method eventually converges to the global optimum. The regret bound in (11) depends on the true hyperparameters θ and B. However, the algorithm does not depend on them. Theorem 1 provides an instance-specific bound, since the mutual information depends on the inputs in $\mathcal{A}_t$. One can obtain a worst-case upper bound by bounding $I_{\theta_t}(\mathbf{y}_t; f) \leq \gamma_t(\theta_t)$, which is the worst-case mutual information as in (8), but based on the GP model with lengthscales θ_t. While Theorem 1 assumes that the noise properties are known, the results can be extended to estimate the noise similar to Durand et al. (2018).

For arbitrary functions $g(t)$ and $b(t)$, the candidate function space $\{f \in \mathcal{H}_{\theta_t} \,|\, f \leq B_t\}$ can grow at a faster rate than it contracts by selecting informative measurements y_t according to (7). In particular, in the regret term $\sqrt{C_1 t \beta_t \gamma_t}$ both β_t and γ_t depend on the scaling factors $g(t)$ and $b(t)$. If these factors grow at a faster rate than $\sqrt{t}$, the resulting algorithm does not enjoy sublinear regret. We have the following result that explicitly states the dependence of γ_t on the scaling factor $g(t)$.

Proposition 2 *Let k_θ be a stationary kernel parameterized by lengthscales θ as in* (2) *and define $\gamma_t(\theta)$ for lengthscales θ as in* (8)*. Define the lengthscales as $\theta_t = \theta_0/g(t)$ as in* (9)*.*

Algorithm 1 Adaptive GP-UCB(A-GP-UCB)

Input: Input space $\mathcal{D}$, $GP(0, k(\mathbf{x}, \mathbf{x}'))$, functions $g(t)$ and $b(t)$
Set $B_0 = 1$ and $\theta_0 = \text{diam}(\mathcal{D})$
for all $t = 0, 1, 2, \ldots$ **do**
  Set the GP kernel lengthscsales to $\theta_t = \theta_0 / g(t)$
  $\beta_t^{1/2} \leftarrow B(t) + 4\sigma\sqrt{I_{\theta_t}(\mathbf{y}_t; f) + 1 + \ln(1/\delta)}$ with $B(t) = b(t)g(t)^d B_0$
  Choose $\mathbf{x}_{t+1} = \text{argmax}_{\mathbf{x}\in\mathcal{D}}\ \mu_t(\mathbf{x}) + \beta_t^{1/2}\sigma_t(\mathbf{x})$
  Evaluate $y_{t+1} = f(\mathbf{x}_{t+1}) + \epsilon_{t+1}$
  Perform Bayesian update to obtain μ_{t+1} and σ_{t+1}

- *If* $k(\mathbf{x}, \mathbf{x}') = \exp(-\frac{1}{2}\|\mathbf{x} - \mathbf{x}'\|_2^2)$ *is the squared exponential (Gaussian) kernel, then*

$$\gamma_t(\theta_t) = \mathcal{O}\left(g(t)^d (\log t)^{d+1}\right) \tag{12}$$

- *If* $k(\mathbf{x}, \mathbf{x}') = \left(2^{1-\nu}/\Gamma(\nu)\right) r^\nu B_\nu(r)$ *is the Matérn kernel, where* $r = \sqrt{2\nu}\|\mathbf{x} - \mathbf{x}'\|_2$, B_ν *is the modified Bessel function with* $\nu > 1$, *and* Γ *is the gamma function. Then*

$$\gamma_t(\theta_t) = \mathcal{O}\left(g(t)^{2\nu+d} t^{\frac{d(d+1)}{2\nu+d(d+1)}} \log t\right) \tag{13}$$

Proposition 2 explicitly states the relationship between γ_t and $g(t)$. For the Gaussian kernel, if we scale down the lengthscales by a factor of two, the amount of mutual information that we can gather in the worst case, γ_t, grows by 2^d. Given the dependence of γ_t on $g(t)$, we can refine Theorem 1 to obtain concrete regret bounds for two commonly used kernels.

Corollary 3 *If, under the assumptions of Theorem 1,* $g(t)$ *and* $b(t)$ *grow unbounded, then we obtain the following, high-probability regret bounds for Algorithm 1:*

- *Squared exponential kernel:* $R_t \leq \mathcal{O}\left(b(t)\sqrt{t g(t)^{3d}\gamma_t(\theta_0)} + g(t)^d \gamma_t(\theta_0)\sqrt{t}\right)$;
- *Matérn kernel:* $R_t \leq \mathcal{O}\left(b(t)\sqrt{t g(t)^{2\nu+3d}\gamma_t(\theta_0)} + g(t)^{\nu+d}\gamma_t(\theta_0)\sqrt{t}\right)$.

If $b(t)$ and $g(t)$ grow unbounded, the first term of the cumulative regret in (11) can be upper bounded by a constant. The remaining result is obtained by plugging in β_t and the bounds from (8). Thus, any functions $g(t)$ and $b(t)$ that render the regret bounds in Corollary 3 sublinear allow the algorithm to converge, even though the true lengthscales and norm bound are unknown.

The specific choices of $b(t)$ and $g(t)$ matter for the regret bound in Theorem 1 in practice. Consider the one-dimensional case $d = 1$ for the Gaussian kernel. Given the true hyperparameters B and θ, if we set $g(t) = \theta_0/\theta$ and $b(t) = B/B_0$ to be constant, we recover the non-adaptive regret bounds of GP-UCB with known hyperparameters. If $g(t)$ depends on t and grows slowly, then the algorithm incurs constant regret during the initial rounds when the model is misspecified, while functions g that grow to values larger than the optimal ones lead to additional exploration and incur an additional $\mathcal{O}(b(t)g(t)^{3d/2}))$ factor in the cumulative regret in later rounds, as in Corollary 3. In the following section, we discuss appropriate choices for these functions in practice.

4.1. Choosing the scaling functions $g(t)$ and $b(t)$

It follows from Theorem 1 that A-GP-UCB achieves no-regret for any functions $g(t)$ and $b(t)$ that increase without bound and render (11) sublinear in t. Thus, the corresponding BO routine converges to the optimal value eventually. For example, $b(t) = g(t) = \log(t)$ satisfy this condition. However, the convergence guarantees in Theorem 1 are only meaningful once t has grown sufficiently so that the true function is contained in the confidence intervals. In practice, BO is often used with objective functions f that are expensive to evaluate, which imposes a hard constraint on the number of evaluations. For the regret bounds to be meaningful in this setting, we must choose functions g and b that grow fast enough to ensure that the constant regret period in (11) is small, yet slow enough that the effect of the sublinear regret is visible for small enough t. In the following, we propose two methods to choose $g(t)$ and $b(t)$ *adaptively*, based on the observations seen so far.

For convenience, we fix the relative magnitude of $g(t)$ and $b(t)$. In particular, we define $b(t) = 1 + \epsilon_b(t)$ and $g(t)^d = 1 + \epsilon_g(t)$ together with a weighting factor $\lambda = \epsilon_b(t)/\epsilon_g(t)$ that encodes whether we prefer to scale up the norm bound using $b(t)$ or decrease the lengthscales using $g(t)$. This allows us to reason about the overall magnitude of the scaling $h(t) = (1 + \epsilon_g(t))(1 + \epsilon_b(t)) \geq 1$, which can be uniquely decomposed into $g(t)$ and $b(t)$ given λ. For $\lambda = 0$ we have $g(t) = h(t)$, $b(t) = 1$ and the algorithm prefers to attribute an increase in $h(t)$ to $g(t)$ and shorten the lengthscales, while for $\lambda \to \infty$ the algorithm prefers to scale up the RKHS norm. The assumptions in Corollary 3 hold for any $\lambda \in (0, \infty)$ if $h(t)$ grows unbounded. Moreover, we have that $g(t)^d \leq h(t)$ and $b(t) \leq h(t)$.

Reference regret While any function $h(t)$ that grows unbounded and renders the cumulative regret in Theorem 1 sublinear makes our method to converge to the optimum eventually, we want to ensure that our method performs well in finite time too. For fixed hyperparameters with $h(t) = 1$, which implies $g(t) = b(t) = 1$, our algorithm reduces to GP-UCB with hyperparameters θ_0 and B_0 and the regret bound term $\sqrt{C_1\beta_t\gamma_t(\theta_0)}$ is sublinear, which is illustrated by the bottom curve in Fig. 3b. However, this does not imply no-regret if hyperparameters are misspecified as in Fig. 2a, since the first term in Theorem 1 is unbounded in this case. To avoid this, we must increase the scaling factor $h(t)$ to consider larger function classes.

We propose to define a sublinear reference regret $p(t)$, see Fig. 3b, and to scale $h(t)$ to match an estimate of the regret with respect to the current hyperparameters to this reference. As GP-UCB converges, the regret estimate with respect to the current hyperparameters levels off and drops below the reference $p(t)$. In these cases, we increase $h(t)$ to consider larger function classes and explore further. The choice of $p(t)$ thus directly specifies the amount of additional regret one is willing to incur for exploration. Specifically, given a regret estimate $\bar{R}_t(h)$ that depends on the data collected so far and the selected scaling h, we obtain $h(t)$ from matching the reference, $\bar{R}_t(h) = p(t)$, as

$$h^*(t) = \bar{R}_t^{-1}(p(t)), \qquad h(t) = \max(h^*(t),\, h(t-1)). \tag{14}$$

Here we explicitly enforce that $h(t)$ must be an increasing function. In the following, we consider estimators $\bar{R}_t$ that are increasing functions of h, so that (14) can be solved efficiently via a line search.

Whether choosing $h(t)$ according to (14) leads to a sublinear function depends on the regret estimator $\bar{R}_t$. However, it is always possible to upper bound the $h(t)$ obtained from (14) by a fixed sublinear function. This guarantees sublinear regret eventually. In the following, we consider two estimators that upper bound the cumulative regret experienced so far with respect to the hyperparameters suggested by $h(t)$.

Regret bound As a first estimator for the cumulative regret, we consider the regret bound on R_t in (11). We focus on the Gaussian kernel, but the arguments transfer directly to the case of the Matérn kernel. The term $\sqrt{C_1 t\, \beta_t\, I_{\theta_t}(\mathbf{y}_t; f)}$ bounds the regret with respect to the current function class specified by θ_t. In addition to the direct dependence on $b(t)g(t)^d$ in β_t, the regret bound also depends on $g(t)$ implicitly through the mutual information $I_{\theta_t}(\mathbf{y}_t; f)$, where $\theta_t = \theta_0/g(t)$. To make the dependence on $g(t)$ more explicit, we use Theorem 2 and rewrite the mutual information as $(g(t)/g(t-1))^d I_{\theta_{t-1}}(\mathbf{y}_t; f)$ instead. Note that the scaling factor was derived for γ_t, but remains a good indicator of increase in mutual information in practice. With this replacement we use

$$\bar{R}_t(h) = \sqrt{C_1 t\, \beta_t\, (b(t), g(t))\; g(t)^d I_{\theta_{t-1}}(\mathbf{y}_t; f)} \tag{15}$$

to estimate the regret, where the term $\beta_t(b, g)$ is as in Theorem 1, but with the mutual information similarly replaced with the explicit dependence on $g(t)$. Solving (14) together with (15) is computationally efficient, since computing $\bar{R}_t$ does not require inverting the kernel matrix.

One step predictions While (15) is fast to compute, it requires us to know the dependence of $\gamma_t(\theta_t)$ on $h(t)$. Deriving analytic bounds can be infeasible for many kernels. As an alternative, we estimate the regret one-step ahead directly. In particular, if the considered function class is sufficiently large and our confidence intervals hold at all time steps $t > 0$, then the one-step ahead cumulative regret R_{t+1} for our algorithm at iteration t is bounded from above by

$$\bar{R}_t = 2 \sum_{j=1}^{t} \beta_j^{1/2} \sigma_j(\mathbf{x}_{j+1}), \tag{16}$$

where each β_t and σ_t is based on the corresponding hyperparameters θ_t. In Theorem 1, R_{t+1} is further upper-bounded by (11). The regret estimate in (16) depends on $\mathbf{x}_{t+1}$, which is the next input that would be evaluated based on the UCB criterion with GP hyperparameters scaled according to $h(t)$. As the hyperparameters for previous iterations are fixed, the only term that depends on $h(t)$ is the bound on the instantaneous regret, $r_t \leq 2\beta_t \sigma_t(\mathbf{x}_{t+1})$. Unlike (15), (16) is not able to exploit the known dependence of γ_t on $h(t)$, so that it cannot reason about the long-term effects of changing $h(t)$. This means that, empirically, the cumulative regret may overshoot the reference regret, only to settle below it later.

Scaling $h(t)$ according to (16) provides an interesting perspective on the method by Wang and de Freitas (2014). They decrease the kernel lengthscales whenever $\sigma_t(\mathbf{x}_{t+1}) \leq \kappa$. In our framework, this corresponds to $p(t) = \sum_{j=1}^{t} 2\beta_j \max(\kappa, \sigma_j(\mathbf{x}_{j+1})) \geq \kappa t$, which is not sublinear. As a consequence, while they ultimately bound the cumulative regret using the smallest possible lengthscale, the choice for $p(t)$ forces too much exploration to achieve sublinear regret before the lower bound is reached. In contrast, if we choose $p(t)$ to be sublinear,

then the function class grows slowly enough to ensure more careful exploration. This allows us to achieve sublinear regret in the case when a lower bound on the hyperparameters it not known.

4.2. Practical Considerations and Discussion

In this section, we discuss additional practical considerations and show how to combine the theoretical results with online inference of the hyperparameters.

Online inference and exploration strategies The theoretical results presented in the previous sections extend to the case where the initial guess θ_0 of the GP's lengthscale is improved online using any estimator, e.g., with MAP estimation to obtain θ_t^{MAP}. Theoretically, as long as the change in θ_0 is bounded, the cumulative regret increases by at most a constant factor. In practice, this bound can always be enforced by truncating the estimated hyperparameters. Moreover, the scaling induced by online inference can be considered to be part of $g(t)$ according to Lemma 2, in which case the norm bound can be adapted accordingly. In practice, online inference improves performance drastically, as it is often difficult to specify an appropriate relative initial scaling of the lengthscales θ_0.

In more than one dimension, $d > 1$, there are multiple ways that MAP estimation can be combined with the theoretical results of the paper. The simplest one is to enforce an upper bound on the lengthscales based on $g(t)$,

$$\theta_t = \min(\theta_t^{\mathrm{MAP}},\, \theta_0 \,/\, g(t)), \tag{17}$$

where the min is taken elementwise. This choice is similar to the one by Wang et al. (2016). If all entries of θ_0 have the same magnitude, this scaling can be understood as encouraging additional exploration in the smoothest direction of the input space first. This often makes sense, since MAP estimates tend to assume functions that are too smooth, see Fig. 1. However, it can be undesirable in the case when the true function only depends on a subset of the inputs. In these cases, the MAP estimate would correctly eliminate these inputs from the input space by assigning long lengthscales, but the scaling in (17) would encourage additional exploration in these directions first. Note that eventually exploring the entire input space is unavoidable to avoid getting stuck in local optima (Bull, 2011).

An alternative approach is to instead scale down the MAP estimate directly,

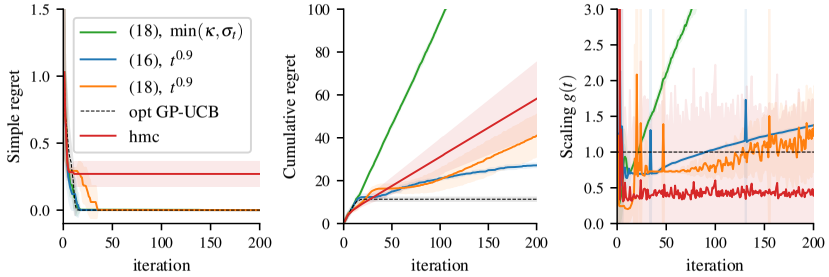
$$\theta_t = \theta_t^{\mathrm{MAP}} \,/\, \max(g(t),\, 1). \tag{18}$$

This scaling can be understood as evenly encouraging additional exploration in all directions. While (18) also explores in directions that have been eliminated by the MAP estimate, unlike (17) it simultaneously explores all directions relative to the MAP estimate. From a theoretical point of view, the choice of exploration strategy does not matter, as in the limit as $t \to \infty$ all lengthscales approach zero. In the one-dimensional case, the two strategies are equivalent. Both strategies use the MAP lengthscales for BO in the nominal case, but the $g(t)$ factor eventually scales down the lengthscales further. This ensures that our method only improves on the empirical performance of BO with MAP estimation.

In practice, maximum likelihood estimates for the inputs are often good enough when the underlying function resembles a sample from a GP. Thus, the approach presented in

this paper is most relevant when the underlying function has some 'nonstationarity'. In the literature, other approaches to deal with nonstationarity have been proposed. For example, Snoek et al. (2013) scale the input inputs through a beta function and infer its hyperparameters online. Our approach can easily be combined with any such method, as it works on top of any estimate provided by the underlying inference scheme. Moreover, in high-dimensional spaces one can combine our algorithm with methods to automatically identify a low-dimensional subspace of $\mathcal{D}$ (Djolonga et al., 2013; Wang et al., 2016).

In this paper, we have considered the kernel to be fixed, and only adapted the lengthscales and norm bound. However, often the kernel structure itself is a critical hyperparameter (Duvenaud et al., 2011). The strategy presented in this paper could be used to add rougher kernels over time or, for example, to adapt the ν input of the Matérn kernel, which determines its roughness.



Confidence intervals Empirically, β_t is often set to a constant rather than using the theoretical bounds in Lemma 1, which leads to (point-wise) confidence intervals when f is sampled from a GP model. In particular, typically measurement data is standardized to be zero mean and unit variance and β_t is set to two or three. This often works well in practice, but does not provide any guarantees. However, if one were to believe the resulting confidence bounds, our method can be used to avoid getting stuck in local optima, too. In this case on can set $h(t) = g(t)$ and apply our method as before.

General discussion Knowing how the sample complexity of the underlying BO algorithm depends on the lengthscales also has implications in practice. For example, Wang et al. (2016) and Wabersich and Toussaint (2016) suggest to scale down the lengthscales by a factor of 2 and roughly 1.1, respectively, although not at every iteration. As shown in Sec. 4, this scales the regret bound by a factor of g^d, which quickly grows with the number of dimensions. Exponentiating their factors with $1/d$ is likely to make their approaches more robust when BO is used in high-dimensional input spaces $\mathcal{D}$.

Lastly, in a comparison of multiple BO algorithms (acquisition functions) on a robotic platform, Calandra et al. (2014) conclude that the GP-UCB algorithm shows the best empirical performance for their problem. They use the theoretical version of the algorithm by Srinivas et al. (2012), in which β_t grows with an additional factor of $\mathcal{O}(\sqrt{\log(t^2)})$ relative to Lemma 1. In our framework with the bounds in Lemma 1, this is equivalent to scaling up the initial guess for the RKHS norm bound for f by the same factor at every iteration, which increases the function class considered by the algorithm over time. We conjecture that this increase of the function class over time is probably responsible for pushing the MAP estimate of the lengthscales out of the local minima, which in turn led to better empirical performance.

5. Experiments

In this section, we evaluate our proposed method on several benchmark problems. As baselines, we consider algorithms based on the UCB acquisition function. We specify a strong gamma prior that encourages short lengthscales, and consider both maximum a posteriori (MAP) point-estimates of the hyperparameters and a Hamiltonian Monte Carlo (HMC) approach that samples from the posterior distribution of the hyperparameters and

(a) Simple regret. (b) Cumulative regret. (c) Scaling $g(t)$.

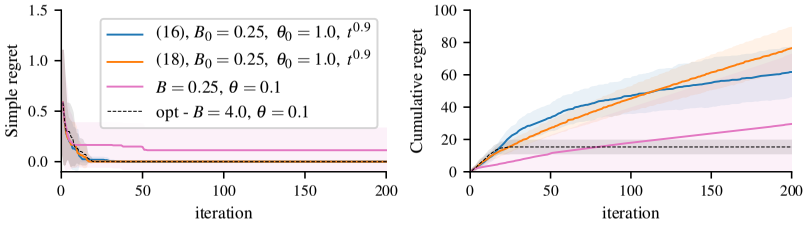


Figure 4: Mean and standard deviation of the empirical simple and cumulative regret over ten different random initializations for the function in Fig. 2. The HMC baseline (red) gets stuck in a local optimum and obtains constant regret in Fig. 4a. GP-UCB with the true hyperparameters (gray dashed) obtains the lowest cumulative regret in Fig. 4b. However, our methods (orange/blue) increase the function class over time, see Fig. 4c, and thus obtain sublinear regret without knowing the true hyperparameters.

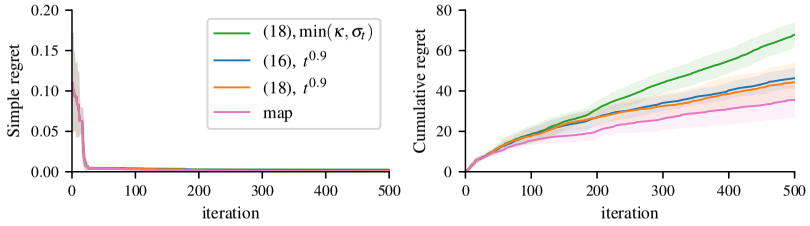
marginalizes them out. Unless otherwise specified, the initial lengthscales are set to $\theta_0 = \mathbf{1}$, the initial norm bound is $B_0 = 2$, the confidence bounds hold with probability at least $\delta = 0.9$, and the tradeoff factor between $b(t)$ and $g(t)$ is $\lambda = 0.1$.

We follow several best-practices in BO to ensure a fair comparison with the baselines. We rescale the input space $\mathcal{D}$ to the unit hypercube in order to ensure that both the initial lengthscales and the prior over lengthscales are reasonable for different problems. As is common in practice, the comparison baselines use the empirical confidence intervals suggested in Sec. 4.2, instead of the theoretical bounds in Lemma 1 that are used for our method. Lastly, we initialize all GPs with 2^d measurements that are collected uniformly at random within the domain $\mathcal{D}$. To measure performance, we use the cumulative regret that has been the main focus of this paper. In addition, we evaluate the different methods in terms of simple regret, which is the regret of the best inputs evaluated so far, $\max_{x \in \mathcal{D}} f(x) - \max_{t' <= t} f(\mathbf{x}_{t'})$. This metric is relevant when costs during experiments do not matter and BO is only used to determine high-quality inputs by the end of the optimization procedure.

5.1. Synthetic Experiments

Example function We first evaluate all proposed methods on the example function in Fig. 2, which lives inside the RKHS associated with a Gaussian kernel with $\theta = 0.1$ and has norm $\|f\|_{k_\theta} = 2$. We evaluate our proposed method for the sublinear reference function $p(t) = t^{0.9}$ together with maximum a posteriori hyperparameter estimation. We compare against both GP-UCB with the fixed, correct hyperparameters and HMC hyperparameter estimation. Additionally, we consider a modified variant of the method suggested by Wang and de Freitas (2014), see Sec. 4.1. Rather than scaling the lengthscales by a fixed constant, we conduct a line search to find the smallest possible scaling factor that ren-



(a) Simple regret. (b) Cumulative regret.

Figure 5: Simple and cumulative regret over 10 random seeds for samples from a GP with bounded RKHS norm. The GP-UCB algorithm with misspecified hyperparameters (magenta) fails to converge given only a wrong choice of B_0. In contrast, our methods (blue/orange) converge even though θ_0 is misspecified in addition.

ders $\sigma_t(\mathbf{x}_{t+1}) \geq \kappa = 0.1$. This is the most conservative variant of the algorithm. Note that we do not know a lower bound on the hyperparameters and therefore do not enforce it.

The results of the experiments are shown in Fig. 4. The simple regret plot in Fig. 4a shows that all methods based on hyperparameter adaptation evaluate close-to-optimal inputs eventually, and do so almost as quickly as GP-UCB based on the true hyperparameters (black, dashed). However, the method based on HMC hyperparameter estimation (red) considers functions that are too smooth and gets stuck in local optima, as in Fig. 2. This can also be seen in Fig. 4c, which plots the effective scaling $g(t)$ based on the combination of Bayesian hyperparameter estimation and hyperparameter adaptation through $h(t)$. The HMC hyperparameters consistenly over-estimate the lengthscales by a factor of roughly two. In contrast, while the MAP estimation leads to the wrong hyperparameters initially, the adaptation methods in (15) and (16) slowly increase the function class until the true lengthscales are found eventually. It can be seen that the one step estimate (16) (orange) is more noisy than the upper bound in (15) (blue).

While all adaptation methods determine good inputs quickly according to the simple regret, they perform differently in terms of the cumulative regret in Fig. 4b. As expected, the HMC method (red line) converges to a local optimum and experiences constant regret increase equal to the simple regret at every time step. The modified method of Wang and de Freitas (2014) (green line) expands the function class too aggressively and also achieves constant regret. Empirically, their method always explores and never repeatedly evaluates close-to-optimal inputs that would decrease cumulative regret. While the method works well in terms of simple regret, without a lower bound on the hyperparameters it never converges to sublinear regret. As expected from Theorem 1, GP-UCB based on the optimal hyperparameters achieves the lowest cumulative regret. Our two methods expand the function class over time, which allows them to converge to close-to-optimal inputs, even though MAP estimation estimates the hyperparameters wrongly initially. While the regret is sublinear, the additional exploration caused by $g(t)$ means that the cumulative regret is larger. This is the additional cost we incur for not knowing the hyperparameters in advance.

(a) Simple regret. (b) Cumulative regret.

Figure 6: Simple and cumulative regret over 5 random seeds for a logistic regression problem. All methods determine close-to-optimal parameters. However, our methods explore more to counteract misspecified hyperparameters.

Samples from a GP As a second experiment, we compare GP-UCB to A-GP-UCB on samples drawn from a GP when the norm bound B_0 is misspecified. Samples from a GP are not contained in the RKHS. To avoid this technical issue, we sample function values from the posterior GP at only a finite number of discrete gridpoints and interpolate between them using the kernel with the correct lengthscales θ. We rescale these functions to have RKHS norm of $B = 4$, but use $B_0 = 0.25$ as an initial guess for both BO algorithms and do not use any hyperparameter estimation. Even though we use the correct kernel lengthscales for GP-UCB, $\theta_0 = \theta = 0.1$, this discrepancy means that the true function is not contained in the initial confidence intervals. As before, for our method we use the reference regret $p(t) = t^{0.9}$ and additionally misspecify the lengthscales, $\theta_0 = 1$.

The results are shown in Fig. 5. GP-UCB with the correct hyperparameters (black, dashed) obtains the lowest cumulative regret. However, it fails to converge when hyperparameters are misspecified (magenta), since the confidence intervals are too small to encourage any exploration. In contrast, our methods (blue/orange) converge to close-to-optimal inputs as in the previous example.

5.2. Logistic Regression Experiment

Lastly, we use our method to tune a logistic regression problem on the MNIST data set (LeCun, 1998). As in the experiment in Klein et al. (2016), we consider four training inputs: the learning rate, the l_2 regularization constant, the batch size, and the dropout rate. We use the validation loss as the optimization objective.

The results are shown in Fig. 6. Even though the input space is fairly high-dimensional with $d = 4$, all algorithms determine close-to-optimal inputs quickly. In particular, MAP estimation determines that both the dropout rate and the batch size do not influence the validation loss significantly. Since the theoretical results in A-GP-UCB are compatible with MAP estimation, our approach achieves the same empirical performance, but has theoretical worst-case regret bounds. After convergence, the BO baselines repeatedly evaluate the same inputs, without gaining any new information. In contrast, our method continues to explore in order to potentially find better inputs. While it does not occur in this case, this allows us

to be more confident that the global optimum has been identified as t increases. For standard BO methods, there is no guarantee of convergence with misspecified hyperparameters.

6. Conclusion and Future Work

We introduced A-GP-UCB, a BO algorithm that is provably no-regret when hyperparameters are unknown. Our method adapts the hyperparameters online, which causes the underlying BO algorithm to consider larger function spaces over time. Eventually, the function space is large enough to contain the true function, so that our algorithm provably converges. We evaluated our method on several benchmark problems, confirming that, on the one hand, it provably converges even in cases where standard BO algorithms get stuck in local optima, and, on the other hand, enjoys competitive performance as standard BO algorithms that do not have theoretical guarantees in this setting.

The main idea behind our analysis is that adapting the hyperparameters increases the cumulative regret bound, but we do so slowly enough to converge eventually. This idea is fairly general and could also be applied to other no-regret algorithms. Another potential future direction is to investigate alternative strategies to select the scaling factors $b(t)$ and $g(t)$ and consider adapting other parameters such as the kernel structure.

Appendix A. Proof of Main Theorem

Lemma 3 *Let $f \in \mathcal{H}_{\theta_{t^*}}$ with $\|f\|_{\theta_{t^*}} \leq B_{t^*}$. Then, for any monotonically increasing functions $g(t) \geq 1$ and $b(t) \geq 1$ and for all $t \geq t^*$: $f \in \mathcal{H}_{\theta_t}$ with $\|f\|_{\theta_t} \leq B_t$*

Proof Lemma 2 together with monotonicity of g yields $\mathcal{H}_{\theta_t} \supseteq \mathcal{H}_{\theta_{t^*}}$ so that $f \in \mathcal{H}_{\theta_t}$ and

$$\|f\|_{\theta_t} \leq \prod_{1 \leq i \leq d} \frac{[\theta_{t^*}]_i}{[\theta_t]_i} \|f\|_{\theta_{t^*}} \leq \frac{g(t)^d}{g(t^*)^d} B_{t^*} = \frac{g(t)^d}{g(t^*)^d} g(t^*)^d b(t^*) B_0 = g(t)^d b(t^*) B_0 \leq B_t$$

■

Lemma 4 *Under the assumptions of Lemma 1, let θ_t be a predictable sequence of kernel hyperparameters such that $\|f\|_{k_{\theta_t}} \leq B_t$ and let the GP predictions μ_t and σ_t use the prior covariance k_{θ_t}. If $\beta_t^{1/2} = B_t + 4\sigma\sqrt{I_{\theta_t}(\mathbf{y}_t; f) + 1 + \ln(1/\delta)}$, then $|\, f(\mathbf{x}) - \mu_t(\mathbf{x}) \,| \leq \beta_t^{1/2} \sigma_t(\mathbf{x})$ holds for all $\mathbf{x} \in D$ and iterations $t \geq 0$ jointly with probability at least $1 - \delta$.*

Proof The proof is the same as the one by Abbasi-Yadkori (2012); Chowdhury and Gopalan (2017), except that the kernel is time-dependent. ■

We are now ready to prove the main result:

Proof [Theorem 1] We split the regret bound into two terms, $R_t = t_0\, r_c + r_s(t)$. In the initial rounds, where either $B_t \leq g(t)^d B_0$ or $\max_i [\theta]_i/[\theta]_0 > 1$, the regret is trivially bounded by $r_t \leq 2\|f\|_\infty \leq 2\|f\|_\theta \leq B$. Thus $r_c \leq 2B$. Let $t_0 \in (0, \infty]$ be the first iteration such that $f \in \mathcal{H}_{\theta_{t_0}}$ with $\|f\|_{\theta_{t_0}} \leq B_{t_0}$. From Lemma 3, we have that $f \in \mathcal{H}_{\theta_t}$ with $\|f\|_{\theta_t} \leq B_t$ for all $t \geq t_0$. Thus we can use Lemma 4 to conclude $|f - \mu_t(\mathbf{x})| \leq \beta_t^{1/2}\sigma_t(\mathbf{x})$ for all $\mathbf{x} \in \mathcal{D}$ and $t \geq t_0$ jointly with probability at least $(1-\delta)$. We use Lemmas 5.2-5.4 in Srinivas et al. (2012) to conclude that the second stage has a regret bound of $r_s^2(t) \leq C_1 \beta_t I(\mathbf{y}_t; f)$, which concludes the proof. ■

Appendix B. Bound on the information capacity γ_t

Theorem 4 (Theorem 8 in Srinivas et al. (2012)) *Suppose that $D \subset \mathbb{R}^d$ is compact, and $k(\mathbf{x}, \mathbf{x}')$ is a covariance function for which the additional assumption of Theorem 2 in Srinivas et al. (2012) hold. Moreover, let $B_k(T_*) = \sum_{s>T_*} \lambda_s$, where $\{\lambda_s\}$ is the operator spectrum of k with respect to the uniform distribution over D. Pick $\tau > 0$, and let $n_T = C_4 T^\tau (\log T)$ with $C_4 = 2\mathcal{V}(D)(2\tau+1)$. Then, the following bound holds true:*

$$\gamma_T \leq \frac{1/2}{1-e^{-1}} \max_{r \in \{1,\ldots,T\}} T_* \log\left(\frac{r n_T}{\sigma^2}\right) + C_4 \sigma^{-2}(1 - \frac{r}{T})(B_k(T_*) T^{\tau+1} + 1) \log T + \mathcal{O}(T^{1-\frac{\tau}{d}}). \tag{19}$$

Theorem 4 allows us to bound γ_t through the operator spectrum of the kernel with respect to the uniform distribution. We now consider this quantity for two specific kernels.

B.1. Bounds for the Squared Exponential Kernel

Lemma 5 *For all $x \in [0, x_{\max}^2]$ it holds that $\log(1+x^2) \geq \frac{\log(1+x_{\max}^2)}{x_{\max}^2} x^2$*

In this section, we use Theorem 4 to obtain concrete bounds for the Gaussian kernel. From Seeger et al. (2008), we obtain a bound on the eigenspectrum that is given by

$$\lambda_s \leq c B^{s^{1/d}}, \text{ where } c = \sqrt{\frac{2a}{A}}, \quad b = \frac{1}{2\theta_t^2}, \quad B = \frac{b}{A}, \quad \text{and} \quad A = a + b + \sqrt{a^2 + 2ab}.$$

The constant $a > 0$ parameterizes the distribution $\mu(\mathbf{x}) \sim \mathcal{N}(\mathbf{0}, (4a)^{-1}\mathbf{I}_d)$. As a consequence of $\theta_t > 0$, we have that $b \geq 0$, $0 < B < 1$, $c > 0$, and $A > 0$. In the following, we bound the eigenspectrum. The steps follow the outline of Seeger et al. (2008), but we provide more details and the dependence on the lengtscales θ_t is made explicit:

$$\begin{aligned} B_k(T_*) &= \sum_{s>T_*} \lambda_s \leq c \sum_{s \geq T_*+1} B^{s^{1/d}} = c \sum_{s \geq T_*+1} \exp\log(B^{s^{1/d}}) = c \sum_{s \geq T_*+1} \exp(s^{1/d} \log B), \\ &= c \sum_{s \geq T_*+1} \exp(-s^{1/d}\alpha) \leq c \int_{T_*}^\infty \exp(-\alpha s^{1/d})\, \mathrm{d}s, \end{aligned}$$

where $\alpha = -\log B$. Now substitute $s = \phi(t) = (t/\alpha)^d$. Then $\mathrm{d}s = \frac{dt^{d-1}}{\alpha}\,\mathrm{d}t$ and

$$B_k(T_*) \leq c \int_{\alpha T_*^{1/d}}^\infty \exp(-t) \frac{dt^{d-1}}{\alpha}\,\mathrm{d}t = cd\alpha^{-d}\Gamma(d, \alpha T_*^{1/d}),$$

where $\Gamma(d,\beta) = \int_\beta^\infty e^{-t} t^{d-1}\,dt = (d-1)! e^{-\beta} \sum_{k=0}^{d-1} \beta^k/k!$ for $d \in \mathbb{N}$ as in Gradshteĭn et al. (2007, (8.352.4)). Then, with $\beta = \alpha T_*^{1/d}$,

$$B_k(T_*) \leq cd\alpha^{-d}(d-1)! e^{-\beta} \sum_{k=0}^{d-1} \beta^k/k! = c(d!)\alpha^{-d} e^{-\beta} \sum_{k=0}^{d-1} (k!)^{-1} \beta^k.$$

Before we bound the information gain, let us determine how α^{-d} and c depend on the lengthscales. In particular, we want to quantify their upper bounds in terms of $g(t)$.

$$\begin{aligned} \alpha^{-d} &= \log^{-d}(1/B) = \log^{-d}\left(2\theta_t^2 A\right) = \log^{-d}\left(1 + 2\theta_t^2 a + 2\theta_t \sqrt{a^2 + \frac{a}{\theta_t^2}}\right) && (20) \\ &\leq \log^{-d}\left(1 + 2\theta_t^2 a\right) \leq \left(\frac{\log(1 + 2\theta_0^2 a)}{2\theta_0^2 a} 2\theta_t^2 a\right)^{-d} \qquad \text{by Lemma 5} && (21) \\ &= \mathcal{O}\left(\theta_t^{-2d}\right) = \mathcal{O}\left(g^{2d}(t)\right), && (22) \end{aligned}$$

where (21) follows from Lemma 5, since $g(t) \geq 1$ for all $t > 0$. Similarly,

$$c = \left(\frac{2a}{a + \frac{1}{2\theta_t^2} + \sqrt{a^2 + \frac{a}{\theta_t^2}}}\right)^{d/2} \leq \left(\frac{2a}{\frac{1}{2\theta_t^2}}\right) = \left(4a\theta_t^2\right)^{d/2} = \mathcal{O}(g(t)^{-d}). \tag{23}$$

As in Srinivas et al. (2012), we choose $T_* = (\log(T n_T)/\alpha)^d$, so that $\beta = \log(T n_T)$ and therefore does not depend on g_t. Plugging into (19), the first term of (19) dominates and

$$\gamma_T = \mathcal{O}\left(\left[\log(T^{d+1}(\log T))\right]^{d+1} c\alpha^{-d}\right)^{d/2} = \mathcal{O}\left((\log T)^{d+1} g(t)^d\right). \tag{24}$$

B.2. Matérn kernel

Following the proof for Theorem 2 in the addendum to Seeger et al. (2008), we have that

$$\lambda_s^{(T)} \leq C(1+\delta) s^{-(2\nu+d)/d} \;\forall s \geq s_0, \tag{25}$$

For the leading constant we have $C = C_3^{(2\nu+d)/d}$ with $\alpha = \frac{2\pi\theta_t}{\sqrt{2\nu}}$. Hiding terms that do not depend on α and therefore $g(t)$, we have

$$\begin{aligned} &C_t(\alpha,\nu) = \frac{\Gamma(\nu + d/2)}{\pi^{d/2}\Gamma(\nu)} \alpha^d = \mathcal{O}(g(t)^{-d}) \quad c_1 = \frac{1}{(2\pi)^d C_t(\alpha,\nu)} = \mathcal{O}(g(t)^d) \\ &C_2 = \frac{\alpha^{-d}}{2^d \pi^{d/2}\Gamma(d/2)} = \mathcal{O}(g(t)^d) \qquad C_3 = C_2 \frac{2\tilde{C}}{d} c_1^{\frac{-d}{2\nu+d}} = \mathcal{O}(g(t)^d g(t)^{\frac{-d^2}{2\nu+d}}) = \mathcal{O}(g(t)^d), \end{aligned}$$

so that $C = \mathcal{O}(g(t)^{2\nu+d})$. The second term in C_3 must be over-approximated as a consequence of the proof strategy. It follows that $B_k(T_*) = \mathcal{O}(g(t)^{2\nu d} T_*^{1-(2\nu+d)/d})$ and, as in Srinivas et al. (2012), that $\gamma_T = \mathcal{O}(T^{\frac{d(d+1)}{2\nu+d(d+1)}} (\log T) g(t)^{2\nu d})$.

Abstract

Ensemble methods are a powerful tool, often outperforming individual prediction models. Existing Bayesian ensembles either do not model the correlations between sources, or they are only capable of combining non-probabilistic predictions. We propose a new model, which overcomes these disadvantages. Transforming the probabilistic predictions with the inverse additive logistic transformation allows us to model the correlations with multivariate normal mixtures. We derive an efficient Gibbs sampler for the proposed model and implement a regularization method to make it more robust. We compare our method to related work and the classical linear opinion pool. Empirical evaluation on several toy and real-world data sets, including a case study on air-pollution forecasting, shows that the method outperforms other methods, while being robust and easy to use.

Keywords: correlated classifiers, ensemble, probabilistic models, additive logistic transformation, Bayesian inference

1. Introduction

Classifier combination (or ensemble learning) is an important area of applied machine learning and statistics. The idea behind these methods is that combining several prediction models should achieve better performance. Intuitively, if the models make different mistakes, we can combine them and overcome their individual drawbacks. Zhou (2012) highlights the importance of diversity between individual models and argues that understanding such diversity is an open problem in ensemble learning. A theoretical result on how the generalization error of a combination (weighted average of individual methods) decreases as the correlations between individual errors decrease can be found in Ueda and Nakano (1996). That ensembles achieve better performance in practice proved to be the case, as they are extensively used in various machine learning challenges and competitions to great effect—for example an ensemble method won the KDD Cup 2017 (SIGKDD, 2017). The classifiers in an ensemble can be trained on the same data, or on different data sets. In practice, one might want to combine predictions from various sources, for example, a classifier and expert predictions.

Our work was motivated by Kim and Ghahramani (2012) who proposed a Bayesian approach to combining classifiers—the independent Bayesian classifier combination (IBCC) and its dependent extension, the dependent Bayesian classifier combination (DBCC). Their method is able to combine categorical predictions of classifiers, humans, and other sources, not necessarily trained on the same data. They used Markov networks to model the dependencies between classifiers. One drawback of their method is that it can only be used to combine non-probabilistic (categorical) classifiers. Another drawback is that the method's time complexity grows exponentially in the number of classifiers. Simpson et al. (2013) applied the IBCC to a crowdsourcing problem. They observed that the sampler for IBCC can have difficulties with convergence, and proposed a variational IBCC. Additionally Simpson (2014) presented a simplification of Kim and Ghahramani's IBCC, which led to a more efficient Gibbs sampler for parameter inference. Venanzi et al. (2014) extended the IBCC specifically for crowdsourcing problems. They proposed CommunityBCC, where each source (worker) is assumed to belong to some community with a common confusion matrix. The method is able to model the dependencies implicitly through community membership. The results show that CommunityBCC outperforms IBCC on sparse data sets. Nazábal et al. (2016) extended the IBCC model to combine probabilistic models by modeling the predictions with the Dirichlet distribution, however they do not model correlations explicitly.

Another approach that is closely related to IBCC are supra-Bayesian methods, which rely on Bayes' rule to combine the information gathered from several experts and thus improve the predictions. They assume a multivariate normal (MVN) distribution of the predictions and are therefore able to model correlations. Lindley (1985) presented a method for combining probabilistic predictions of categorical data. The author proposed modeling of log-odds instead of original data to deal with the non-normality. The method also uses a common covariance matrix, independent of true labels. Due to the use of a MVN distribution and the assumption of a common covariance matrix the described method lacks flexibility to model the latent space well.

Hoeting et al. (1999) presented Bayesian model averaging that combines several probabilistic models, weighted by their posterior probability. However this approach assumes that one of the combining models is the true data generating model and that the models represent mutually exclusive situations. These assumptions can lead to severe loss of performance, as Cerquides and De Mántaras (2005) have shown.

Lacoste et al. (2014) proposed the agnostic Bayesian learning of ensembles, where they produced ensembles of predictors based on holdout estimations of their generalization performances. Their ideas are based on the inductive learning paradigm and they use Bayesian treatment to find the posterior probability of each hypothesis being the best. They defined the risk of each hypothesis as its expected loss and examined various priors over the joint risk. The inputs to the model can be probabilistic and they account for correlations between inputs. Agnostic Bayes differs from IBCC, its extensions, and supra-Bayesian methods, as it focuses on finding the best performing models and weighting them accordingly, as opposed to relying on finding a latent structure of the predictions.

We propose a new model based on the IBCC that is able to combine probabilistic predictions by learning the latent structure of the sources. We extend the IBCC to probabilistic predictions with a change of the model's distribution for the predictions. First we transform the predictions with the inverse of the additive logistic transformation and then model them with MVN mixtures to account for correlation explicitly. The correlation matrices grow quadratically in the number of classifiers and the number of classes. We construct

the model with a fully Bayesian framework and use Gibbs sampling (Casella and George, 1992) for parameter inference. Since the complexity of the model grows with the number of classifiers, we implement a regularization method, which makes the model more robust. Our method can also be viewed as an extension of the supra-Bayesian method, where we use mixtures of normals as the likelihood and condition the means and covariance matrices on the true label—increasing the method's flexibility.

We empirically evaluated our method on several toy and real-world data sets, and compared it to related methods. The results on toy data sets highlight that none of the ensembles works well for all data sets. Overall, our method compares favourably to related methods. Additionally, we provide a case study on combining predictions of air-pollutant concentration in Slovenia, where we show that our method is well suited for combining machine learning models with human expert predictions.

The paper is organized as follows. In Section 2 we formulate the problem, present our main methodological contribution, and provide a description of related work. We present the data sets, empirical results, and a case study in Section 3. We discuss the results and provide directions for future work in Section 4.

2. Methods

Let $\{t_i\}_{i=1}^{n}$ be our data set of n observations that can take one of m different values $t_i \in \{1, \ldots, m\}$. Additionally, we have r sources of probabilistic predictions and, for each source, a probabilistic prediction for each observation $\{p_i^{(1)}, \ldots, p_i^{(r)}\}_{i=1}^{n}$, where $p_i^{(k)} = \begin{bmatrix} p_{i1}^{(k)} & \cdots & p_{im}^{(k)} \end{bmatrix}^T$ is the $k-$th source's prediction for the $i-$th observation.

The task is to learn how to combine individual sources into more accurate probabilistic predictions, so that we are able to produce probabilistic predictions $\{\hat{p}_i\}_{i=1}^{n+n^*}$ for n observed and n^* future/unobserved data, represented with categorical random variables $\{T_i\}_{i=n+1}^{n+n^*}$, for which only the sources' predictions $\{p_i^{(1)}, \ldots, p_i^{(r)}\}_{i=n+1}^{n+n^*}$ are known.

2.1. MVN Mixture Conditional Likelihood Model (MM)

Aitchison (1982) proposed the modeling of correlated data on a simplex with the logit-normal distribution. The data on a simplex are considered as data drawn from a MVN distribution, transformed by the additive logistic transformation. This transformation transforms a vector $x \in \mathbb{R}^z$ into a vector $f(x) \in S^{z+1}$, where S^{z+1} represents a $(z+1)$-dimensional simplex. To model the correlations between probabilistic predictions we first transform each source's prediction with the inverse of the additive logistic transformation. Applying it to $\{p_i^{(1)}, \ldots, p_i^{(r)}\}_{i=1}^{n+n^*}$, we get $\{u_i^{(1)}, \ldots, u_i^{(r)}\}_{i=1}^{n+n^*}$, where $u_i^{(k)} = \begin{bmatrix} u_{i1}^{(k)} & \cdots & u_{i(m-1)}^{(k)} \end{bmatrix}^T$. Let $u_i = \begin{bmatrix} u_i^{(1)T} & \cdots & u_i^{(r)T} \end{bmatrix}$, be the concatenated vector of $u_i^{(k)}$s, where $k = 1, ..., r$. The dimension of u_i is then $r(m-1)$, the number of sources times the number of classes minus one. Then the vectors u_i, can be modeled by a MVN distribution, as described above. However, the transformation does not guarantee a MVN distribution of u_i and in practice multi-modal distributions can often arise. Therefore we model the transformed data with MVN mixtures of dimension $r(m-1)$.

Our generative model can be described as follows. The probabilistic predictions $p_i^{(k)} = \begin{bmatrix} p_{i1}^{(k)} & \cdots & p_{im}^{(k)} \end{bmatrix}^T$ are generated by applying the additive logistic transformation to realizations of MVN mixtures, whose parameters depend on the true label. The probability for a new observation to be in true label j is then proportional to the density of the corresponding MVN mixture. The true labels $\{t_i\}_{i=1}^{n}$ and $\{T_i\}_{i=n+1}^{n+n^*}$ are assumed to be generated by a categorical distribution with parameter ρ, and we set a Dirichlet prior on ρ, same as Nazábal et al. (2016). The mixture memberships g_i are assumed to be generated by a categorical distribution of dimension d. For the parameters of MVN distributions we set semi-conjugate MVN and inverse-Wishart priors. We write the likelihood and the priors as

$$u_i | t_i = j, g_i = h, \mu, \Sigma \sim \mathcal{N}_{r(m-1)}(\mu_{jh}, \Sigma_{jh}), \tag{1}$$
$$t_i | \rho \sim \text{Cat}(\rho), \tag{2}$$
$$\rho | \gamma_0 \sim \text{Dir}(\gamma_0), \tag{3}$$
$$g_i \sim \text{Cat}(\tau_0), \tag{4}$$
$$\mu_{jh} \sim \mathcal{N}_{r(m-1)}(\mu_0, \Sigma_0), \tag{5}$$
$$\Sigma_{jh} \sim \text{inv-Wishart}(\nu_0, S_0^{-1}), \tag{6}$$

where $\mu = \{\mu_{jh} : j = 1, ..., m \wedge h = 1, ..., d\}$, $\Sigma = \{\Sigma_{jh} : j = 1, ..., m \wedge h = 1, ..., d\}$. Figure 1 shows the proposed model in plate notation. Let vectors $u_i = \begin{bmatrix} u_i^{(1)T} & \cdots & u_i^{(r)T} \end{bmatrix}$ form the rows of matrix U. Our goal is to sample from

$$\int p(T, \rho, g, \mu, \Sigma | U, t) d\rho = p(T, g, \mu, \Sigma | U, t). \tag{7}$$

To simplify the sampling we marginalize over ρ. Therefore, we need to sample T, μ, Σ, and g. In the remainder of the section we derive full-conditional distributions for these variables and construct a Gibbs sampler. We infer the parameters μ, Σ, and g only on the data where the true label is known, however, the method would also allow inference over unlabelled data.

First we observe that full-conditional distributions of μ and Σ are conditionally independent of ρ and proportional to the product of likelihood and the respective prior. Let $U^{(jh)}$ be the matrix of observations where the true label is j and that belong to the $h-$th mixture. Using the standard formulas for semi-conjugate priors and using Eq. (1), (5), and (6), we get the following full-conditionals

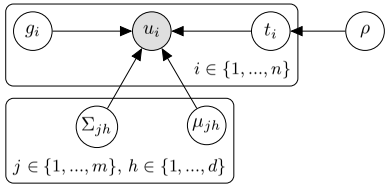

Figure 1: Bayesian plate notation for the proposed model. The transformed predictions u_i for the $i-$th observation are assumed to be generated conditional on the true label $t_i = j$ from the corresponding MVN distribution with parameters μ_{jh} and Σ_{jh}, which also depend on the latent group $g_i = h$. The true label is distributed categorically with parameter ρ. Priors are omitted for brevity.

$$\mu_{jh}|U, t, \rho, g, \Sigma \sim \mathcal{N}_{r(m-1)}(\mu^*, \Sigma^*), \tag{8}$$

$$\Sigma_{jh}|U, t, \rho, g, \mu \sim \text{inv-Wishart}(\nu^*, S^{*-1}), \tag{9}$$

$$\begin{aligned}
\mu^* &= \Sigma^*(\Sigma_0^{-1}\mu_0 + n_{jh}\Sigma_{jh}^{-1}\bar{u}^{(jh)}),\\
\Sigma^* &= (\Sigma_0^{-1} + n_{jh}\Sigma_{jh}^{-1})^{-1},\\
\nu^* &= \nu_0 + n_{jh},\\
S^* &= S_0 + \sum_{l=1}^{n_{jh}} (u_l^{(jh)} - \mu_{jh})(u_l^{(jh)} - \mu_{jh})^T,
\end{aligned}$$

where n_{jh} is the number of true labels equal to j in group h and $\bar{u}^{(jh)}$ are the column means of $U^{(jh)}$.

The mixture membership variable g is also conditionally independent of ρ. Using Eq. (1) and (4), the full-conditional of g is

$$\begin{aligned}
p(g|U, t, \rho, \mu, \Sigma) &\propto p(U|g, t, \rho, \mu, \Sigma)p(g, t, \rho, \mu, \Sigma)\\
&\propto \Big(\prod_{i=1}^{n} p(u_i|g_i, t_i, \rho, \mu, \Sigma)\Big)p(g)\\
&\propto \prod_{i=1}^{n} p(u_i|g_i, t_i, \mu, \Sigma)p(g_i).
\end{aligned} \tag{10}$$

For the predictive distribution of a new observation T_i, we do not have samples of g_i. Therefore we need to marginalize over g_i. Using Eq. (1), (2), and (3), the full-conditional for T is

$$\begin{aligned}
p(T_i = j|U, t, \rho, g, \mu, \Sigma) &\propto \int \sum_{l=1}^{d} p(T_i = j, g_i = l, U, t, \rho, g, \mu, \Sigma)d\rho\\
&\propto \int \sum_{l=1}^{d} p(u_i|T_i = j, g_i = l, t, \rho, g, \mu, \Sigma)p(T_i = j, g_i = l, t, \rho, g, \mu, \Sigma)d\rho\\
&\propto \int \sum_{l=1}^{d} p(u_i|\mu_{jl}, \Sigma_{jl})p(g_i = l|T_i = j, g)p(T_i = j, t, \rho)d\rho\\
&\propto \sum_{l=1}^{d} p(u_i|\mu_{jl}, \Sigma_{jl})p(g_i = l|T_i = j, g) \int p(T_i = j, \rho)p(t|\rho)p(\rho)d\rho,
\end{aligned} \tag{11}$$

where we integrate over all $\rho \in S^m$. The integral in Eq. (11) can be solved by observing that the expression is the multivariate beta function. Some algebra with gamma functions leads to $(\gamma_{0j} + n_j)$, where $n_j = \sum_{l=1}^{n} \mathrm{I}(t_l = j)$. Additionally let $n_{g_{jl}} = p(g_i = l|T_i = j, g) = |\{g_s = l \wedge t_s = j : s = 1, \ldots, n\}|/|\{t_s = j : s = 1, \ldots, n\}|$, which represents the probability of the new observation being in a specific mixture. Inserting this into Eq. (11) and using Eq. (8), (9), and (10) we construct a Gibbs sampler for Eq. (7)

$$\begin{aligned}
\mu_{jh}|U, t, \rho, g, \Sigma &\sim \mathcal{N}_{r(m-1)}(\mu^*, \Sigma^*),\\
\Sigma_{jh}|U, t, \rho, g, \mu &\sim \text{inv-Wishart}(\nu^*, S^{*-1}),\\
p(g_i = h|U, t_i = j, \rho, \mu, \Sigma) &\propto p(u_i|\mu_{jh}, \Sigma_{jh})\tau_{0h},\\
p(T_i = j|U, t, \rho, g, \mu, \Sigma) &\propto \sum_{l=1}^{d} n_{g_{jl}} p(u_i|\mu_{jl}, \Sigma_{jl})(\gamma_{0j} + n_j),
\end{aligned}$$

where we use the conditional independence of group memberships in Eq. (10) and sample each g_i separately. Due to an efficient group collapsing property, the number of mixture groups d can be set to some arbitrary high number and the model finds the suitable number automatically. Some groups tend to be closer together at the beginning. This causes the data points to interchange between groups and pairs of groups often merge into one, resulting in fewer mixture components.

If we constrain the covariance matrices Σ to be diagonal, the model is still able to find mixture-components where the correlations are relatively low. This way the correlations are still modelled, while the method becomes less complex. Therefore, we can exchange some flexibility for simplicity, which results in faster inference (inverse of the covariance matrices becomes trivial), while still remaining flexible enough to model the correlations well in most situations. We included this method in the empirical evaluation (MM-diag).

2.1.1. Regularization

To make the method more robust, we implemented regularization by discounting individual dimensions in transformed observation space U. Let λ^* be a vector of length $r(m-1)$ and

$\lambda_i^* \geq 0$. We modify Eq. (11) by changing $p(u_i|\mu_{jl}, \Sigma_{jl})$ to $p(u_i|\mu_{jl}, \Sigma_{jl} + \text{diag}(\lambda^*))$. Adding a positive number to an element on the diagonal increases the variance of the density, reducing the variance of the data in that dimension (and their covariance with all other dimensions). This effectively decreases the differences in density (between observations) in that dimension. That is, it reduces the influence of that dimension on the distribution of T_i.

For each Gibbs iteration, the λ^* for that iteration is determined before predicting for the unobserved data T using

$$p(\lambda|U, t, \rho, g, \mu, \Sigma) \propto p(t_i = j_i|U, t, \rho, g, \mu, \Sigma, \lambda)p(\lambda),$$

where j_i is the true class label for example i.
In general, we could make our predictions by integrating over λ. However, the posterior distribution for λ is intractable and in practice typically very difficult to sample from efficiently. For the purposes of this work, we use only the MAP estimate

$$\lambda^* = \arg\max_{\lambda} \log p(\lambda) + \sum_{i=1}^{n} \log p(t_i = j_i|U, t, \rho, g, \mu, \Sigma, \lambda).$$

2.2. Related Work

To empirically evaluate our method, we also implemented four Bayesian approaches to combining classifiers and the classical linear opinion pool.

2.2.1. Supra-Bayesian

Lindley (1985) presented the supra-Bayesian method for combining probabilistic predictions of a categorical variable of r experts. The method relies on Bayes' theorem to calculate the posterior distribution of predictions of the decision maker, given the predictions of the experts. Let $A_1, A_2, ..., A_m$ be the possible outcomes of the categorical variable and let $S_1, S_2, ..., S_r$ be classifiers. Let H be the decision maker's prior probability for the response and $q_{ij} = \log(\Pr_i(A_j))$ the log-probability assigned to true label A_j by the $i-$th classifier. Then the decision maker updates his probabilities via the Bayes' theorem

$$p(A_j|Q, H) \propto p(Q|A_j, H)p(A_j|H). \tag{12}$$

To model the correlations between given predictions, Lindley proposes a MVN distribution for $p(Q|A, H)$. Additionally, Lindley argues that the classifiers' belief in their prediction is independent of the label of their prediction, therefore the MVN distributions share a common covariance matrix between predictions for different labels. The author also proposes the modeling of log-odds instead of log-probabilities, as log-odds are expected to be distributed normally. We implemented a ML estimation of the multivariate parameters for Eq. (12), where the matrix Q represented log-odds.

Note that the described method is the one proposed by Lindley (1985) and that supra-Bayesian methods are a very general term for combination methods that rely on the Bayes' theorem. By selecting the appropriate likelihoods we arrive at IBCC and (unregularized) MM as special cases.

2.2.2. IBCC

IBCC (Kim and Ghahramani, 2012) assumes that the true labels t are generated by a categorical distribution with parameter κ. The prediction $c_i^{(k)}$ of individual classifier k is also generated by a categorical distribution with parameters $\pi_j^{(k)}$ for each possible value j of the true label. Let ν be the prior for κ and $\alpha_{0,j}^{(k)}$ prior for $\pi_j^{(k)}$. Kim and Ghahramani additionally put an exponential prior on $\alpha_{0,j}^{(k)}$, but Simpson (2014) observed that the model without this additional flexibility performs comparably well and derived the Gibbs sampler for κ, Π, and the true labels

$$p(\kappa|t, \nu_0) = \frac{1}{B(\nu)} \prod_{j=1}^{m} \kappa_j^{\nu_j},$$

$$p(\pi_j^{(k)}|t, c, \alpha_{0,j}^{(k)}) = \frac{1}{B(\alpha_{t_i}^{(k)})} \prod_{l=1}^{m} \left(\pi_{j,l}^{(k)}\right)^{\alpha_{j,l}^{(k)}},$$

$$p(t_i = j|\Pi, \kappa, c) \propto \kappa_j \prod_{k=1}^{r} \pi_{j,c_i^{(k)}}^{(k)},$$

where $\nu_j = \nu_{0,j} + \sum_{i=1}^{n+n^*} \delta(t_i - j)$ and $\alpha_{j,l}^{(k)} = \alpha_{0,j,l}^{(k)} + \sum_{i=1}^{n+n^*} \delta(t_i - j)\delta(c_i^{(k)} - l)$.

2.2.3. IBCC QPI

The IBCC method can be extended to allow for quasi-probabilistic inputs (QPI). Probabilistic classifiers provide us with probabilities of each outcome $p_i^{(k)} = \begin{bmatrix} p_{i1}^{(k)} & \cdots & p_{im}^{(k)} \end{bmatrix}^T$. For the IBCC to exploit probabilistic predictions, we can first take a sample from a categorical distribution with parameter $p_i^{(k)}$ for each source k. The categorical samples can then be represented as binary vectors, which are of appropriate form for the inputs of IBCC. We then take n_{tsamp} such samples and use them to create a new training set of size $n \times n_{\text{tsamp}}$.

For prediction, we use the same procedure. We sample according to the sources' probabilistic predictions. We retrieve the final prediction as the average probabilistic prediction over all samples. This allows the IBCC to take advantage of probabilistic predictions, instead of simply using the class with the highest probability, as the sources' predictions.

2.2.4. Agnostic Bayes

The agnostic Bayes approach (Lacoste et al., 2014) combines sources based on the probability of being the *best* source, where best is defined in terms of some task-dependent measure. The combined prediction is defined as

$$\hat{p}_i = \sum_{k=1}^{r} P(k^\star = k|p, t)p_i^{(k)},$$

where $P(k^\star = k|p, t)$ is the probability of source k being the best source, given the available data (all predictions p and observed values t). In our case of categorical target variables and

log-score performance measure, we can simplify $P(k^\star = k|p,t) = P(\forall k' \in 1..r : E[l^{(k)}] \geq E[l^{(k')}]|l) = P(k|l)$, where $E[l^{(k)}]$ is the $k-$th source's expected log-score and l all the observed log-scores (for this model, a sufficient statistic for p and t).

We draw samples from $P(k|l)$ with bootstrap inference (this was shown to be very effective in Lacoste et al. 2014, at least as effective as placing priors over joint risk and performing Bayesian inference). That is, we draw a replacement set of observations and compute the average log-score. This gives us the best source on this replacement set—one sample from $P(k|l)$. The process is repeated for several iterations to obtain a set of samples that approximate $P(k|l)$.

2.2.5. Linear Opinion Pool (LOP)

The linear opinion pool (Cooke et al., 1991) is the classical approach to combining predictions. The combined prediction $\hat{p}_i$ is expressed as a linear combination of individual sources

$$\hat{p}_i = X_i \beta,$$

where $X_i = \begin{bmatrix} p_i^{(r)} & p_i^{(r-1)} & \cdots & p_i^{(1)} & p_{\cdot}^{(0)} \end{bmatrix}$ and $\beta = \begin{bmatrix} \beta_r & \beta_{r-1} & \cdots & \beta_1 & \beta_0 \end{bmatrix}^T$.

The parameters β_i and $p_{\cdot}^{(0)}$ were fit by maximizing the likelihood, subject to $0 \leq \beta_i \leq 1$, $\sum_{i=0}^{r} \beta_i = 1$, $0 \leq p_{ij}^{(0)} \leq 1$, and $\sum_{j=1}^{m} p_{\cdot j}^{(0)} = 1$.

We also included a combination of LOP and MM, where the probabilistic predictions obtained by MM are added to the sources before LOP is applied (LOP+MM).

2.2.6. Discussion of Related Work

We can divide the methods for classifier combination into two groups. Methods that aim to estimate the performance of each classifier and then weigh their predictions by their performance (LOP, agnostic-Bayes, etc.). And methods that aim to learn the latent structure of the classifications and then provide probabilistic classifications (IBCC and extensions, supra-Bayesian, etc.).

The former are expected to perform poorly when there is a latent structure to learn, for example, biased classifiers or systematic errors in classifiers. On the other hand, these methods have an advantage that they are not expected to perform discernibly worse than the best source. The latter are the exact opposite—they can learn complex latent structure and perform better than the first group, but can also perform extremely poorly, discernibly worse than the best source. In Section 3 we present 5 toy data sets, which serve to show the differences in performance of these groups, depending on the structure of the data.

The main difference between IBCC and our method (MM) lies in the conditional likelihood for the true label. IBCC models sources' predictions with a multinomial distribution, while MM assumes a latent space of transformed predictions and models it with multivariate normal mixtures. The advantage of this is that it allows us to model both probabilistic predictions and correlations between sources, while the computational complexity is quadratic in the number of sources and outcomes (as opposed to DBCC, where it is exponential).

IBCC QPI is similar to MM in that it is able to exploit probabilistic nature of predictions, however it does not model correlations.

Nazábal et al. (2016) used a Dirichlet distribution to model probabilistic outputs of the sources. A similar (but not equivalent) model would result if we used diagonal covariances without mixtures in the proposed MM. Therefore the proposed MM improves on the drawbacks of Nazábal et al. as it allows for the modeling of correlations between sources, and additionally adds flexibility through the use of mixtures.

MM could also be interpreted as a regularized supra-Bayesian method with MVN-mixture likelihood. The modeling of log-odds described by Lindley (1985) is equivalent to the modeling of the transformed classifiers by MM. A major difference between the methods is that MM does not assume the same covariances over all true labels. Furthermore, each mixture component has its own covariance matrix, which further improves the flexibility of our method.

3. Empirical Evaluation

We empirically evaluated and compared the methods on several toy and real-world data sets. We estimated out-of-sample log-score using train-test splits. To compare the best-performing method with the rest, we used the differences between log-scores. Let a be the vector of length n_t of log-scores of the best performing method, b the vector of log-scores of another method, and $d = a - b$. If

$$\left| \frac{1}{n_t} \sum_{i=1}^{n_t} d_i \right| > 2 \sqrt{\frac{\text{VAR}[d]}{n_t}},$$

we argue that there is a discernible difference in performance. Details on how the data were generated and split are provided below.

For IBCC and its extension, we selected priors that assume each class has the same prior probability. We used the same priors ($\alpha_{0,j} = 1$) for all confusion matrices, which represents a weak belief that the models are random. For MM we selected vague priors that put prior belief that the mean values of transformed predictions are zero with large variances. However, MM has proved to be somewhat robust to the prior selection. We set the same priors for Bayesian methods over all data sets. For λ, we use uniform priors $\lambda_i \sim_{\text{iid}} \text{U}(0, 10^5)$. We set the maximum number of mixture components for MM to 15, however this number dynamically falls, depending on the problem, as we described in Section 2.1.

3.1. Data Sets

In this section we describe the data sets we used for empirical evaluation.

3.1.1. Toy Data Sets

Each of the 5 toy data sets is a combination of the same underlying data set and two sources of probabilistic predictions from a set of sources with different properties. The purpose of the toy data sets is to illustrate some of the shortcomings of the methods for combining categorical predictions.

The data set has a target variable with three possible outcomes. The target variable's value is generated for each sample i separately by first drawing the underlying probability vector p_i^* from Dirichlet$(1.5, 0.9, 0.6)$ and then drawing the target value from Categorical(p_i^*). We generated 500 samples for training and 5000 samples for testing.

We then generated the following sources of probabilities, based on the underlying probability vectors p^*:

- **Random 1 & 2:** The probabilities are drawn independently for each sample from Dirichlet$(1, 1, 1)$.
- **Good 1 & 2:** The probabilities are drawn independently for each sample from Dirichlet$(10p_i^*)$.
- **Permuted 1:** The probabilities are drawn independently for each sample from Dirichlet$(100p_i^*)$ and permuted (2, 3, 1). This results in a source that gives very accurate probabilities, but does not correctly assign them to the possible values of the target variable.
- **Permuted 2:** Identical to Good 2, but permuted (2, 3, 1).

The two sources, Source 1 and Source 2, were assigned as follows: **toy A** (Random 1, Random 2), **toy B** (Good 1, Random 1), **toy C** (Good 1, Good 2), **toy D** (Good 1, Permuted 1), and **toy E** (Good 1, Permuted 2).

3.1.2. Bookies

Each sample in this data set is a football game and the four sources of probabilistic predictions are four major online bookmakers. Probabilistic predictions were calculated by normalizing the reciprocals of odds offered for the outcome of the game (home, draw, away). Therefore, the target variable has 3 outcomes. The data set has 5434 samples, we used 2000 for training and 3434 for testing. Bookmakers are very good sources of probabilistic predictions (Forrest et al., 2005) and their predictions are highly correlated—the lowest correlation is 0.92. We do not expect any ensemble method to outperform the best source.

3.1.3. DNA

Two data sets were constructed using the StatLog DNA data set in a way similar to the experiments in Kim and Ghahramani (2012).

DNA A: 2000 samples were partitioned into 5 partitions, 400 samples each, and a C4.5 decision tree classifier was trained on each partition. These classifiers were used to classify the remaining 1186 samples, 400 of which were used for training and 786 for testing.

DNA B: 2000 samples were used to train 5 different classifiers: a multinomial logistic regression (Source 1), linear discriminant analysis (Source 2), a decision tree classifier (Source 3), a random forest classifier (Source 4), and a k-nearest-neighbour classifier (Source 5, k = 50). These classifiers were used to classify the remaining 1186 samples, 400 of which were used for training and 786 for testing.

3.2. Results

The results are shown in Table 1. No method clearly outperforms other methods over all data sets. LOP and MM perform well on most data sets. For LOP the exceptions are data sets with a more complex relationship between the sources' predictions and the outcome (toy D). And for MM the exceptions are the two simple toy data sets with a continuous relationship between the sources' predictions and the probability of the outcome (toy B, toy C). MM-diag performs worse than the MM on all data sets, however, the differences are small on average. A combination of LOP and MM nullifies the drawbacks of each individual method and performs the best on average. Toy D, with systematic errors in otherwise good sources, is a good example of a data set where the methods that rely on finding the best source are inferior to models that learn the latent structure, providing a good argument for the latter.

Agnostic Bayes will assign a lot of weight to the best source, unless it is difficult to discern the best source. The latter is in cases where there is not a lot of data, relative to the magnitude of the differences between the sources in terms of performance (toy A, DNA A). Therefore, as expected, it performs well when the most accurate source performs well (toy B, toy C, toy E, bookies), and performs poorly, when it does not (DNA B). Note that there is no correlation between the true labels and sources in the toy A data set—the best possible model would assign the same probabilities to all outcomes. Agnostic Bayes performs poorly because it tries to identify the best performing model, but none of the sources perform well. The same would happen to LOP if we did not include an intercept term.

IBCC performs poorly on the toy data sets but performs well on the DNA data sets. However, it is strictly outperformed by MM. The quasi-probabilistic IBCC outperforms the IBCC on DNA data sets and performs similarly on most of the toy data sets. Furthermore, it performs well on the toy A data set, where it is the best performing model, with the proposed MM showing a similar level of performance. IBCC QPI therefore proved to be better suited for probabilistic input than the IBCC, as expected. The supra-Bayesian approach of Lindley (1985), which can be viewed as a very simple case of the proposed approach, performs the worst on average, among all the Bayesian approaches.

As expected, all methods fail to outperform the best source on the bookies data set, which has very accurate and highly correlated sources. This relates heavily to the theoretical results mentioned in the introduction—the data set lacks diversity to exploit. Methods that do not model correlations perform exceptionally poorly. However, methods that weigh/select sources perform at least as good as the best source.

3.3. Case Study—Prediction of Air-Pollutant Concentration

Air pollution poses a great risk for public health (World Health Organization, 2014). Forecasting excessive air pollution is an important task, also regulated by a EU directive (European Council, 2008). In Slovenia, the Slovenian Environment Agency (ARSO) is tasked with forecasting daily average concentration of particulate matter (PM_{10}) and daily maximum concentration of tropospheric ozone (O_3) for the same day (in the morning) and the next day. Currently, models and human experts are used for this task. Faganeli Pucer et al. (2018) proposed a Bayesian methodology for this problem and empirically compared several machine learning methods and human experts. Gaussian processes performed the best on average, but the question remains whether an ensemble method can be used to improve on individual models. With that aim, we evaluate methods from Section 2 on four air-pollution data sets used in Faganeli Pucer et al. (2018).

The data sets consist of measurements of daily levels of PM_{10} and O_3 on several stations across Slovenia from 2013 to 2016. The data were provided by ARSO. According to reporting guidelines, PM_{10} levels are categorized into three categories: 0-35 $\mu g/m^3$, 35-50 $\mu g/m^3$, greater than 50 $\mu g/m^3$, and O_3 levels are categorized into four categories: 0-60 $\mu g/m^3$, 60-120 $\mu g/m^3$, 120-180 $\mu g/m^3$, greater than 180 $\mu g/m^3$.

Three prediction models—Bayesian lasso, random forests, and Gaussian processes—and human expert predictions were used to predict the levels for the same and next day, depending on covariates available at the current day. Expert predictions were non-probabilistic (categorical). The models were trained in a time-respecting manner (predictions for 2014 were obtained by training the models on data from 2013, predictions for 2015 were obtained by training the models on data from 2013 and 2014, etc.). We used two thirds of observations for training and the rest for testing.

The empirical results for the case study are shown in Table 2. The combination of MM and LOP performs the best over all data sets. MM and LOP are the only methods that show no discernible differences to LOP+MM over all data sets. This provides a strong argument for our method, compared to other methods which learn the latent structure of the data. MM also strictly outperforms MM-diag, as expected. IBCC QPI performs well on the PM_{10} data sets, however it does not outperform MM. Agnostic Bayes performs slightly better than the best source on all data sets, however it is discernibly worse than the best method on two data sets. The other methods are unable to outperform the best performing individual classifier on all data sets.

The major arguments for our method are twofold. First, it is a step forward in the state-of-the-art methods which rely on learning the latent structure of the data (IBCC, IBCC QPI, Supra). This can be seen as it is the only such method which is never discernibly worse than the best performing method. Second, LOP+MM performs the best on all data sets in the case study. It also outperforms LOP on all real-world data sets, which is discernibly better—it is highly unlikely that this is due to chance.

4. Conclusion

We proposed a new Bayesian method for combining probabilistic predictions, based on MVN mixtures. Our method improves on the IBCC (and DBCC) as it is able to model probabilistic classifiers, and on the work of Nazábal et al. (2016) as it also models the

correlations between the classifiers. We derived an efficient Gibbs sampler for our method, along with a regularization method for robustness.

The results on toy data sets highlighted that there is no single method that performs well over several diverse data sets. However, our method outperforms related Bayesian methods on all but one real-world data sets. The method proved to be especially useful in the case study, where we combined three machine learning methods and human expert predictions for air-pollutant concentration forecasting. This case study illustrates the main use-case for our method—a relatively small number of probabilistic or crisp (0/1) sources, which are potentially flawed (biased, etc.) and correlated. Our method is also very robust and requires practically no tuning. Additionally, a combination of linear opinion pool and our method proved to be very successful, outperforming all methods on all but one real-world data sets, and also being robust on the difficult toy data sets.

Our method still has some drawbacks, however. The original model is based on full covariance matrices, so the number of the parameters grows quadratically with the number of possible outcomes and the number of classifiers. While this is an improvement over the exponential growth in the number of classifiers of the DBCC model, it still leads to very complex models in high dimensions. One possibility of at least partially regulating this drawback is to constrain the covariance matrices to being diagonal—as in our empirical evaluation. Alternatively, we could assume the same covariance matrix over all mixture components in a true label, or assume the same variances/covariances over several predictions. We leave the analysis of possible constraints for future work. As part of future work, we will also explore if the predictive performance or robustness of the method could be improved by using Gaussian processes and/or variational autoencoders instead of multivariate normal mixtures to model the sources' transformed probabilities. Additionally, we could limit the computational complexity by using sparse Gaussian processes.

As is the case in other areas of learning, there is no single best method of combining probabilistic predictions. In some cases, the best approach is to combine the sources based on their predictive performance or to directly maximize the predictive performance of the combination, such as agnostic Bayes or the linear opinion pool. However, sometimes there are more complex relationships between classifiers and the target variable and methods that are able to learn these patterns will perform better. In such cases, our method is in several ways a superior alternative to existing Bayesian approaches. It is able to model complex relationships, while still being robust and easy to tune, thus providing us with a useful approach for combining probabilistic predictions.

Acknowledgments

The authors would like to acknowledge Jana Faganeli Pucer and the Slovenian Environment Agency (ARSO), who provided environmental pollution data sets. Our research was partially supported by the Slovenian Research Agency (ARRS project grant L1-7542 and research core funding P5-0410). Gregor Pirš is supported by the ARRS Young researcher grant.

Abstract

The multi-armed bandit problem forms the foundation for solving a wide range of online stochastic optimization problems through a simple, yet effective mechanism. One simply casts the problem as a gambler who repeatedly pulls one out of N slot machine arms, eliciting random rewards. Learning of reward probabilities is then combined with reward maximization, by carefully balancing reward exploration against reward exploitation. In this paper, we address a particularly intriguing variant of the multi-armed bandit problem, referred to as the *Stochastic Point Location (SPL)* problem. The gambler is here only told whether the optimal arm (point) lies to the "left" or to the "right" of the arm pulled, with the feedback being erroneous with probability $1 - \pi$. This formulation thus targets optimization in continuous action spaces with both *informative* and *deceptive* feedback. To tackle this class of problems, we formulate a compact and scalable Bayesian representation of the solution space that simultaneously captures both the location of the optimal arm as well as the probability of receiving correct feedback. We further introduce the accompanying Thompson Sampling guided Stochastic Point Location (TS-SPL) scheme for balancing exploration against exploitation. By learning π, TS-SPL also supports *deceptive* environments that are lying about the direction of the optimal arm. This, in turn, allows us to address the fundamental Stochastic Root Finding (SRF) problem. Empirical results demonstrate that our scheme deals with both deceptive and informative environments, significantly outperforming competing algorithms both for SRF and SPL.

Keywords: thompson sampling, searching on the line, probabilistic bisection search, deceptive environment, stochastic point location

1. Introduction

Research on the *Stochastic Point Location* (SPL) problem (Oommen, 1997) has delivered increasingly efficient schemes for locating the optimal point on a line. In all brevity, the optimal point must be found based on iteratively proposing candidate points, with each candidate revealing whether the optimal point lies to the candidate's left or to its right. The provided directions can be erroneous, and the goal is to locate the optimal point with as few non-optimal candidate proposals as possible. The SPL problem can also be cast as an agent that moves on a line, attempting to locate a particular location λ^*. The agent communicates with a teacher that notifies the agent whether its current location λ is greater or lower than λ^*. However, the teacher is of a stochastic nature and feeds the agent erroneous feedback with probability $1 - \pi$.

Despite the simplicity of the SPL problem, SPL schemes have provided novel solutions for a wide range of problems. Intriguing applications include the estimation of non-stationary binomial distributions (Yazidi et al., 2012b), communication network routing (Oommen et al., 2007), and meta-optimization (Oommen et al., 2009). Furthermore, recent research that addresses the related *Stochastic Root-Finding* (SRF) problem provides promising solutions for parameter estimation, transportation system optimization, as well as supply chain optimization (Chen and Schmeiser, 2001; Pasupathy and Kim, 2011).

State-of-the-art. Adaptive Step Searching (ASS) (Tao et al., 2013) is currently the leading approach to solving SPL problems, although it is outperformed by Hierarchical Stochastic Searching on the Line (HSSL) (Yazidi et al., 2012a) in highly volatile non-stationary environments (Tao et al., 2013). Optimal Computing Budget Allocation (OCBA) has also been applied to SPL (Zhang et al., 2015) and provides stable solutions while converging slightly slower than ASS. Unfortunately, these state-of-the-art schemes fail when noise increases beyond a certain degree, which happens when the majority of obtained directions mislead rather than guide. Indeed, by naively following the directions provided under such circumstances, one is systematically led away from the optimal point. We refer to these kinds of problem environments as *deceptive* environments, as opposed to *informative* ones, which are explained in more detail below.

To the best of the authors' knowledge, the pioneering CPL-AdS (Oommen et al., 2003) scheme was the first known approach handling deceptive SPL environments. CPL-AdS relies on two consecutive phases. In the first phase, a sequence of intelligently selected questions is used to classify the environment as either informative or deceptive. By spending a sufficient amount of time in this phase, the classification can be made arbitrarily accurate. In the second phase, a regular SPL scheme is applied, except that the directions obtained are reversed if the problem environment was classified as deceptive in the first phase. This means that the scheme may have to remain in the first phase for an extensive amount of time to ensure that the problem environment is correctly classified, otherwise, one risks being systematically misled in the second phase. These properties largely render CPL-AdS inappropriate for online or anytime problem solving.

Recently, HSSL has been extended by Zhang et al. to cover both informative and deceptive environments, using a Symmetric HSSL (SHSSL) scheme (Zhang et al., 2016). This scheme essentially runs two HSSL schemes in conjunction: one regular, which handles informative environments, and one that inverts all feedback from the environment, to handle deceptive environments. The hierarchy navigation capabilities of HSSL are then exploited to allow SHSSL to switch between the two HSSLs, depending on the nature of the environment. However, a significant limitation of HSSL, namely, that π must be larger than the conjugate of the golden ratio, carries over to SHSSL. Indeed, SHSSL fails to converge for $\pi \in [0.382, 0.682]$, which amounts to approximately 30% of the feasible values for π. This is in contrast to the approach we propose in this paper, as well as to CPL-AdS (Oommen

*. A preliminary version of some of the results of this paper appears in the Proceedings of AIAI'15.

et al., 2003), since both of these schemes operate along the whole range of π (apart from $\pi = 0.5$).

To cast further light on the challenges lined out above, we here introduce the *N-Door Puzzle* as a framework for modeling deception. We also propose an accompanying novel solution scheme — *Thompson Sampling guided Stochastic Point Location* (TS-SPL). The TS-SPL scheme handles both SPL and SRF problems, and is capable of *simultaneously* solving the problem as well as determining whether we are dealing with an informative or a deceptive environment. As we shall see, not only does this scheme handle an arbitrary level of noise, but it also outperforms current state-of-the-art techniques in both informative and deceptive environments.

The N-Door Puzzle. In the book "To Mock a Mockingbird" (Smullyan, 1988) the following puzzle is formulated: *"Someone was sentenced to death, but since the king loves riddles, he threw this guy into a room with two doors. One leading to death, one leading to freedom. There are two guards, each one guarding one door. One of the guards is a perfect liar, the other one will always tell the truth. The man is allowed to ask one guard a single yes-no question and then has to decide, which door to take. What single question can he ask to guarantee his freedom?"* To avoid spoiling the puzzle for the reader, we omit the solution here and note that asking a double negative question will often be the correct course of action for these types of puzzles.

The above puzzle can be generalized by increasing the number of doors. Instead of deciding between merely two doors, the prisoner now faces N doors, with a guard posted between each pair of doors. Only a single door leads to freedom, the remaining doors lead to death. Every day at sunrise, the prisoner is allowed to ask one of the guards whether the door leading to freedom is to the left or to the right of the guard. However, only a fixed proportion of the guards answers truthfully, the rest are compulsive liars. Further, the guards are randomly assigned a position at each sunrise, and thus, knowing who lies and who tells the truth is impossible. As an additional complication, depending on the mood of the king, the prisoner may be ordered to walk through a door of his choice at an arbitrary day. Therefore, to save his life, it is imperative that the prisoner determines as quickly as possible which door leads to freedom.

Specifically, let $\pi = \frac{\#\text{truthful guards}}{\#\text{guards}}$ be the fraction of truthful guards. Since the guards are randomly assigned a position each day, the probability of obtaining a truthful answer is governed by π. If $\pi < 0.5$ then the majority of the guards are compulsive liars, and the guards as an entity can be characterized as being *deceptive*. Conversely, if $\pi > 0.5$ then the majority of the guards are truthful and the guards can be seen as *informative*. For completeness, we mention that the puzzle is unsolvable for the case where π is exactly equal to $\frac{1}{2}$, since it is then impossible to obtain any information on neither the nature of the doors nor the guards.

Thompson Sampling. The Thompson Sampling (TS) principle was introduced by Thompson already in 1933 (Thompson, 1933) and now forms the basis for several state-of-the-art approaches to the Multi-Armed Bandit (MAB) problem — a fundamental sequential resource allocation problem that has challenged researchers for decades. At each time step in the MAB problem, one is offered to pull one out of N bandit arms, which in turn triggers a stochastic reward. Each arm has an underlying probability of providing a reward, however,

these probabilities are unknown to the decision maker. The challenge is thus to decide which of the arms to pull at each time step, to maximize the expected total number of rewards obtained (Bubeck and Cesa-Bianchi, 2012).

In all brevity, TS seeks to achieve the above goal by quickly shifting from exploring reward probabilities to maximizing the number of rewards obtained. This is achieved by recursively estimating the underlying reward probability of each arm, using Bayesian filtering of the rewards obtained so far. TS then simply selects the next arm to pull based on the Bayesian estimates of the reward probabilities (one reward probability density function per arm).

The arm selection strategy of TS is rather straightforward, yet surprisingly efficient. To determine which arm to pull, a single candidate reward probability is sampled from the probability density function of each arm. *The arm with the highest sample value is the one pulled next.* The outcome of pulling this arm is in turn used to perform the next Bayesian update of the arm's reward probability estimate. It is this simple scheme that makes TS select arms with frequency proportional to the posterior probability of being optimal, leading to quick convergence towards always selecting the optimal arm.

TS has turned out to be among the top performers for traditional MAB problems (Granmo, 2010; Chapelle and Li, 2011), supported by theoretical regret bounds (Agrawal and Goyal, 2012, 2013a; Dong and Van Roy, 2018). It has also been successfully applied to contextual MAB problems (Agrawal and Goyal, 2013b), constrained Gaussian process optimization (Glimsdal and Granmo, 2013), distributed quality of service control in wireless networks (Granmo and Glimsdal, 2013), cognitive radio optimization (Jiao et al., 2016), as well as a foundation for solving the maximum a posteriori estimation problem (Tolpin and Wood, 2015).

Pure Exploration Bandits. Throughout this paper we assume that each SPL problem potentially takes part in a larger system consisting of multiple SPL problems, and not necessarily operating in isolation. From existing applications in the literature, such as web crawler load balancing (Granmo et al., 2007), it is clear that the value of an SPL scheme does hinge upon its ability to cooperate and interact with other decision makers. Such cooperation demands predictable behaviour from the individual decision makers, as well as coordinated balancing of exploring new solution candidates against maintaining good solution candidates. Without such an ability, the system as a whole will not be able to systematically move towards the more promising areas of the search space, gradually focusing in on an optimal configuration. Therefore, in this paper we omit a direct comparison with schemes that rely on a "fixed sampling *then* decide" approach, such as unimodal bandits (Jia and Mannor, 2011). For the same reason, we will not investigate purely exploitative bandits (Even-Dar et al., 2006; Jamieson et al., 2014; Audibert and Bubeck, 2010; Gabillon et al., 2011; Karnin et al., 2013), bandits that have a predefined finite time horizon and whose performance is only measured at the end of that horizon. Such algorithms are free to explore without any negative impact, and this allows them to outperform traditional exploitation-exploration bandits such as TS and UCB in scenarios where exploitation is not required.[1]

1. There also exists a wide spectrum of techniques and schemes in the literature on the topic of searching with noise. See for instance (Pelc, 2002) for a comprehensive survey. These are unable to handle unknown and deceptive environments, with stochastic directional feedback, and are therefore not directly

Paper Contributions. In this paper, we introduce a novel scheme for solving the SPL problem, namely, TS-SPL. At the core of TS-SPL, we find a compact and scalable Bayesian representation of the SPL solution space. This Bayesian representation simultaneously captures both the location of the optimal point (bandit arm) as well as the probability of receiving correct feedback. We further introduce an accompanying scheme for balancing exploration against exploitation, based on TS. By learning π, TS-SPL also supports *deceptive* environments that are lying about the direction of the optimal arm. This, in turn, allows us to solve the fundamental SRF problem. More specifically, the contributions of the paper can be summarized as follows:

1. We introduce a novel TS-SPL scheme that represents the solution space of N-Door Puzzles, and thus SPL problems, in terms of a Bayesian model. As opposed to competing solutions that merely maintain and refine a single candidate solution, our Bayesian model encompasses the complete space of candidate solutions at every time instant.

2. We formulate a compact and scalable Bayesian representation of the solution space that simultaneously captures both the location of the optimal point (arm), as well as the probability of receiving correct feedback. This Bayesian representation of the problem opens up for efficient exploration and exploitation of the solution space with TS.

3. We link TS-SPL to so-called stochastic bisection search; and unify accompanying methods under the umbrella of TS.

4. Similarly, we enhance the Soft Generalized Binary Search (SGBS), Probabilistic Bisection Search (PBS) and Burnashev-Zigangirov Algorithm (BZ) by introducing novel parameter free solutions that take advantage of our Bayesian model of the N-door puzzle and the SPL problem. This approach eliminates previous reliance on knowing the exact degree of noise affecting the system to be optimized.

5. We provide the first unified empirical comparison of the key state-of-the-art SPL- and SRF solvers.

6. We finally demonstrate the empirical performance of TS-SPL for both SPL and SRF problems. TS-SPL outperforms the state-of-the-art algorithms in both informative and deceptive environments, except for the SGBS and BZ schemes with correctly specified observation noise.

Paper Outline. The paper is organized as follows. In Section 2, we present our scheme for TS guided SPL (TS-SPL). We first introduce the Bayesian model of the N-door puzzle. Based on the Bayesian model, we then formulate our TS-based scheme that balances solution space exploration against reward maximization. We further extend selected state-of-the-art solution schemes with our Bayesian N-door puzzle model. This extension removes the need for knowing the observation noise beforehand. In Section 3, we provide extensive empirical results comparing TS-SPL with state-of-the-art schemes for both SPL and SRF. We conclude in Section 4 and point to promising directions for further work.

comparable to SPL solution schemes. We have therefore not included this class of techniques in the present paper.

2. Thompson Sampling Guided Stochastic Point Location

In this section, we introduce the TS-SPL scheme. The scheme can be summarized as follows. At the core of TS-SPL we find a Bayesian model of the N-Door Puzzle. Formally, we represent an instance of the N-door puzzle as a tuple $(\lambda^*, \pi^*) \in D \times T$, where $D = \{d_1, \ldots, d_N\}$ is the set of doors and $T \in [0, 1]$ is the truthfulness of the guards. Let (λ^*, π^*) be the particular N-door puzzle faced. A novel aspect of TS-SPL is that instead of maintaining a single or a limited set of candidate solutions, we instead maintain a posterior distribution over the whole solution space, $(\lambda, \pi) \in D \times T$. This distribution is conditioned on the feedback already obtained up to time step n, allowing us to single in on (λ^*, π^*) as the number of time steps increases, ultimately converging to (λ^*, π^*).

Assuming no prior information, we assign a uniform distribution over $D \times T$, i.e., all puzzle instances are equally probable. By gradually refining the posterior distribution over $D \times T$, we can select guards to question in a goal-oriented manner. In all brevity, we sample a solution candidate (λ^c, π^c) from $D \times T$, selecting the guard to the left or to right of λ^c. The answer of the selected guard is then used to update our posterior distribution. By repeating this procedure, the expected probability of the underlying N-door puzzle instance (λ^*, π^*) increases monotonically, reducing the probability of other puzzle instances. In effect, given enough iterations, TS-SPL will correctly identify the door leading to freedom as the posterior probability of (λ^*, π^*) approaches unity.

2.1 Bayesian Model of the N-Door Puzzle

The main purpose of the Bayesian model is to facilitate the efficient calculation of a posterior distribution over the possible N-door puzzle instances, $D \times T$. Since the prisoner does not initially know which problem instance he is facing, and since the observations are stochastic, we cast D and T as two random variables. We further assume that D and T are independent of each other. Furthermore, the information we obtain from questioning the guards is represented as a set of random variables $Q = \{Q_1, \ldots, Q_n\}$, with each random variable Q_k representing the answer from question k. Finally, we assume that the outcomes of the individual questions $Q_k \in Q$ are independent when conditioned on D and P. For each question Q_k, we can then compute the probability of the answer ("left" or "right") that we received from the guard, as summarized in Table 1.

Guard to the left of door to freedom	$P(\text{left} \mid \text{guard, door}, t) = t$
	$P(\text{right} \mid \text{guard, door}, t) = 1 - t$
Guard to the right of door to freedom:	$P(\text{left} \mid \text{guard, door}, t) = 1 - t$
	$P(\text{right} \mid \text{guard, door}, t) = t$

Table 1: Conditional door probabilities

As an example, let us assume that the truthfulness of the guards is $t = 0.75$. If for instance the guard to the left of door d_4 replies that the door leading to freedom lies to his left, we can infer that all doors to the left have the likelihood of $t = 0.75$ of leading to freedom, and all the doors to the right have the likelihood $1 - t = 0.25$ of leading to freedom.

Applying Bayes Theorem to $P(Q|d,t)$, defined in Table 1, we are able to derive closed-form expressions for the posterior distributions of both D and T. The derivation of $P(d|Q)$, $d \in D$, follows [the derivation of $P(t|Q)$, $t \in T$, is analogous, and is left out here for the sake of brevity]:

$$P(d|Q) = \sum_{t \in T} P(d,t|Q) \tag{1}$$
$$\propto \sum_{t \in T} P(Q|d,t)P(d,t) \tag{2}$$
$$= \sum_{t \in T} P(Q|d,t)P(d)P(t) \tag{3}$$
$$= \sum_{t \in T} \hat{Q}Q^{+}P(d)P(t) \tag{4}$$

Above, $\hat{Q} = \prod_{k=1}^{n-1} P(Q_k|d,t)$ and $Q^{+} = P(Q_n|d,t)$. Further, (2) follows directly from Bayes Theorem. We obtain (3) as a result of the independence of D and T, and (4) from the independence between the questions in Q. This leads to the following two equations for updating our knowledge about both the door probabilities (5) and the truthfulness of the guards (6).

$$P(d|Q) \propto \sum_{t \in T} \hat{Q}Q^{+}P(d)P(t) \tag{5}$$

$$P(t|Q) \propto \sum_{d \in D} \hat{Q}Q^{+}P(d)P(t) \tag{6}$$

2.2 Guard Selection

We have now formally determined how we can transform information from the guards into a probability distribution over which door leads to freedom. However, as mentioned previously, we also face a trade-off between exploring different doors and zeroing in on the best door found so far. To handle this trade-off, we model the door selection as a so-called Global Information MAB (GI-MAB) (Atan et al., 2015).

To decide which door should be selected at each iteration, we solve the GI-MAB by utilizing the principle of TS. Here, the selection process is simply to select a random door proportional to the probability that this door is the one that leads to freedom. Once the door has been selected, we need to decide which of the guards to query: the guard to the left or to the right of the door selected. We do this by randomly selecting one of the guards, again proportional to the sum of the probabilities of the doors next to each guard. Let us assume for instance that we have three doors $d_k, 1 \leq k \leq 3$ with the probabilities of leading to freedom: $P(d_1) = 0.1, P(d_2) = 0.2, P(d_3) = 0.7$. Then, according to the TS principle, these are also the probabilities we use to sample a particular door. Note that since the answer obtained from each guard affects the complete probability distribution over D (the probability associated with every door is updated), we have a GI-MAB as opposed to a traditional MAB.

2.3 Improving State-of-the-Art Schemes with the Bayesian Model of the N-Door Puzzle

A main advantage of TS-SPL compared to similar schemes is the utilization of the Bayesian model that enables TS-SPL to operate without knowing the problem parameters in advance. Due to TS-SPL's close connection to the Probabilistic Bisection Search (PBS) (Horstein, 1963), Noisy Generalized Binary Search (NGBS) (Nowak, 2008) and the BZ algorithm (Burnashev and Zigangirov, 1974), we will here use our Bayesian TS-SPL model to also make these other schemes parameter free.

Probabilistic Bisection Search

The goal of PBS[2] (Waeber et al., 2013; Nowak, 2008) is to locate an unknown point $X^* \in [0,1]$. To acquire intelligence on the location of X^*, one queries an oracle of the relation between a point x and X^*. The oracle responds by informing whether x is on the left or the right side of X^*. If we assume that the oracle is always telling the truth, then the well-known deterministic bisection search, which halves the search space with each query, can be employed to efficiently find X^*. However, in PBS we assume that the Oracle provides correct answers with probability $p \in (0.5, 1.0]$ and erroneous ones with probability $1-p$.

The PBS can be traced back to Horstein (Horstein, 1963). In PBS a probability distribution is mapped over the search space and is gradually updated using a Bayesian methodology under the assumption that the environment noise p is known a priori. The search space is then continuously explored using the median of the posterior distribution as the point of interest. It has been shown that PBS has a geometric rate of convergence under the latter assumptions (Waeber et al., 2013).

As the noise p is assumed to be given, one can simply invoke (7) to calculate the posterior distribution:

$$P(d \mid Q) \propto P(Q \mid d)\ P(d). \tag{7}$$

Here, $P(Q \mid d)$ is the conditional probability of obtaining answer Q (point to the right). That is, for every location d to the left of X^*, the probability that the oracle directs the decision maker to the right is $P(Q \mid d) = p$. And conversely, $P(Q \mid d) = 1-p$ for d to the right of X^*.

To explicitly represent PBS' dependence on knowing p beforehand, we can cast (7) in terms of (5) and (6). The resulting model is identical to TS-SPL, with the major difference that PBS employs the median to explore the search space. We denote this new and improved scheme PBS-M.

We also observe that due to its simple nature, PBS is particularly well-suited for parallel computing environments (Pallone et al., 2014), as opposed to more traditional stochastic approximation methods (Kushner and Yin, 1987).

PowerTest-Probabilistic Bisection Search

In a recent paper, Frazier et al. (Frazier et al., 2019) demonstrated an alternative approach to removing the dependency of PBS on knowing the fixed noise probability p. Instead of

2. In this context this scheme also covers the Stochastic *Binary* Search

applying a Bayesian prior over p, as done in TS-SPL, they introduce a frequency-based approach, referred to as PowerTest-PBS (PT-PBS). PT-PBS is based on repeatedly sampling the underlying function $g(x)$ until a pre-specified confidence α is archived on a hypothesis test over the sign of the feedback of $g(x)$. They further demonstrated that the asymptotic convergence of PT-PBS is similar to that of Stochastic Approximation (SA).

Generalized Binary Search

The Generalized Binary Search (GBS) problem can be formulated as follows (Nowak, 2008, 2011). Consider a collection of unique binary-valued functions H defined on a domain X. Each $h \in H$ is defined as a mapping from X to $\{-1, 1\}$. Assume that there exists an optimal function $h^* \in H$ that produces the correct binary labeling for each $x \in X$. For each query $x \in X$, the value of $h^*(x)$ is observed, possibly corrupted by independent binary noise. The objective is then to determine the function h^* using as few queries as possible. In this paper, we restrict H to the class of threshold binary functions with the effect of turning the GBS into an informative N-door puzzle.

If the feedback is noiseless then the problem simplifies to the combinatorial problem of finding an optimal decision tree in the H space, a problem that Hyafil and Rivest showed to be NP-complete (Hyafil and Rivest, 1976; Nowak, 2011).

The Soft-Decision Generalized Binary Search (SDGB-Search) (Nowak, 2008, 2011) is the *state-of-art* algorithm for finding $h^*(x) \in H$ when the probability of binary noise is less than 1/2, that is, for informative environments.

Similar to TS-SPL, SDBG-search employs a probabilistic model that for time step n assigns a probability $p_n(h)$ to each $h \in H$. However, for each time-step, it decides which $x \in X$ is queried next based on a deterministic heuristic:

$$\arg\min_{x \in X} \sum_{h \in H} |p(h)h(x)| \tag{8}$$

SDGB uses the following equation to determine and update $p_n(h)$ at each time step:

$$p_{i+1}(h) \propto p_i(h)\beta^{(1-z_i(h))/2}(1-\beta)^{(1+z_i(h))/2}. \tag{9}$$

Here, $z_i(h) = h(x_i)y_i$ and $y_i \in \{-1, 1\}$ are the responses from $h^*(x_i)$. Simplifying (9), we observe that $z_i(h)$ represents an *AND* operator that takes on the value 1 if $h(x_i)$ is equal to $h^*(x_i)$ and -1 otherwise. Furthermore, we note that since $z_h(i) \in \{-1, 1\}$, then one of $1 - z_i(h)$ and $1 + z_i(h)$ will have to take the value 2, while the other takes the value 0.

By applying the transformation $\pi = 1 - \beta$, we can rewrite (9) as:

$$p_{i+1}(h) \propto= \begin{cases} p_i(h) \times \pi & \text{if } y_i = h^*(x_i) \\ p_i(h) \times (1-\pi) & \text{else} \end{cases} \tag{10}$$

.

This update scheme is identical to the one in PBS and thus suffers from the same limitation (noise probability is assumed to be known a priori). In the same manner as we enhanced PBS by employing our Bayesian TS-SPL scheme, we can make SDGB parameter-free using (5,6). In the following, we will denote this improved version of SDGB as SDGB-M.

Burnashev-Zigangirov Algorithm

The Burnashev-Zigangirov (BZ) algorithm (Burnashev and Zigangirov, 1974) is one of the most widely used algorithms for solving the discrete PBS problem and has in particular been used in active learning (Singh et al., 2006; Castro and Nowak, 2006). The BZ algorithm searches for a point θ^* that is located on a line. This line is discretized into m bins and we are only allowed to query the borders of the bins for the direction of θ^*. The BZ algorithm suffers from the same practical limitation as PBS and SDGB, namely a dependency on knowing the exact noise level.

We will now show how the BZ algorithm can be improved in a similar fashion as PBS and SDGB, leveraging our Bayesian model. Let $a_i(j)$ denote the probability of θ^* residing in bin I_i at time-step j. The probability mass function (pmf) of all the bins is therefore $\mathbf{a}(j) = \{a_1(j), a_2(j), \ldots, a_m(j)\}$ with its cumulative density function (cdf) denoted as $\mathbf{A}(j)$.

To decide which point to investigate next (i.e., decide a value for X_{j+1}), the BZ algorithm selects one of the two closest points to the median of $\mathbf{a}(j)$. We denote this point $k = k(j+1)$. The binary response variable $Y_{j+1} = \mathbb{1}\{X_{(j+1)} \geq \theta^*\}$ is observed with probability $1 - \alpha$, whereas $Y_{j+1} = \mathbb{1}\{X_{(j+1)} < \theta^*\}$ is observed with probability α (the noise probability).

To update the probability distribution over $\mathbf{a}(j)$, we introduce $\beta = 1 - \alpha$ and $\tau = 2A(k(j+1)) - 1$. For $i \leq k$, we then have

$$a_i(j+1) = a_i(j) \begin{cases} \frac{2\alpha}{1-\tau(\beta-\alpha)} & \text{if } Y_{j+1} = 0 \\ \frac{2\beta}{1+\tau(\beta-\alpha)} & \text{if } Y_{j+1} = 1 \end{cases}$$

and for $i > k$ we have:

$$a_i(j+1) = a_i(j) \begin{cases} \frac{2\beta}{1-\tau(\beta-\alpha)} & \text{if } Y_{j+1} = 0 \\ \frac{2\alpha}{1+\tau(\beta-\alpha)} & \text{if } Y_{j+1} = 1 \end{cases}$$

To make the BZ algorithm parameter-free, we first note that for any given noise $t \in T$, we have that $\beta = t$, $\alpha = 1 - t$, $\beta - \alpha = 2t - 1$, and $\tau = A_k(j) - (1 - A_k(j))$. After some simple algebraic manipulations, it turns out that the updating scheme of the BZ algorithm is identical to PBS except that:

1. The BZ algorithm calculates the normalizing factor as a part of the updating rule instead of using the likelihood value, and then later normalizes as PBS does.

2. The BZ algorithm samples on the interval edges while PBS samples the midpoints of each interval.

To obtain an enhanced parameter-free version of the BZ algorithm, we simply replace α as a pre-determined constant with a prior distribution that we marginalize out using (5) and (6). We denote the resulting scheme BZ-M.

3. Empirical Results

In this section, we evaluate the performance of TS-SPL empirically, in comparison with competing schemes. We investigate both the effect that the various parameter settings

have on the behavior, as well as the capability of TS-SPL to handle different applications, including SPL and SRF problems. Unless otherwise noted, the empirical results report the average of 10 000 independent trials.

For some of the applications we investigate here, we do not find any existing scheme that handles deceptive environments. Instead, the schemes we identified assume that feedback is on average informative. To make the comparison fair, we thus introduce TS-SPL-INF, which is configured with the precondition that the feedback is informative. This modification also serves to exemplify one of the advantages of our Bayesian approach — we can tailor the the prior distribution of the noisy probability for the task at hand. Note that this informed prior is equivalent to the priors we use for the other probability theory based schemes we introduced in this paper, namely, PBS-M and SDGB-M.

Further note that we apply a fixed set of parameter values across the whole suite of experiments, set to optimize overall performance. For SHSSL (Zhang et al., 2016) and HSSL (Yazidi et al., 2012a) we used a tree branching factor of $D = 8$, and for ASS (Tao et al., 2013) we set $N_{\max} = 256$ and $N_{\min} = 1$. For OCBA (Zhang et al., 2016), we set $n_0 = 15$ and $\theta = 1/256$. We additionally set the confidence γ of PT-PBS (Frazier et al., 2019) to 0.55 based on a comprehensive brute force search for the best value. The prior used for TS-SPL is uniform over the unit interval and is discretized as $|D| = 201$ and $|T| = 101$. For the informative schemes TS-SPL-INF, PGA-M, SGDB-M, BZ-M, we use the same prior for the doors as for TS-SPL, $|D| = 201$ however, we use a uniform prior over the interval $(0.5, 1]$ for truthfulness, with $|T| = 51$.

We will in the following subsections investigate (1) the effect of different priors on TS-SPL; (2) TS-SPL's ability to identify the nature of the underlying stochastic environment; (3) the ability to solve the SPL problem; and (4) performance on SRF problems – a particularly intriguing class of deceptive environments that arises naturally as a result of the properties of stochastic root finding.

3.1 Sensitivity to Discretization and Distribution of Prior

Although TS-SPL is a parameter free scheme, it depends on defining $D \times T$, the set of all possible N-Door Puzzles, and then formulating a prior distribution over this space. We here investigate to what degree the performance of TS-SPL is affected by the degree of discretization, that is, the cardinality of $D \times T$.

To measure performance, we count how many time steps passes before 95% of the probability mass is contained within the target interval I, that is, $P(I|\text{Observed History}) \geq 0.95$. We refer to this event as convergence of the learning process.

From Table 2, we observe that the cardinality of D, in fact, does affect the performance of TS-SPL. As $|D|$ increases, so does the time it takes before TS-SPL converges. However, it is evident that the relationship between convergence time and $|D|$ is non-linear. Indeed, the increase in convergence time is insignificant even when doubling the number of doors from 3200 to 6400. The behaviour reported in the table thus indicates a logarithmic relation between $|D|$ and convergence time.

To see how the cardinality $|T|$ of T affects performance, we increase $|T|$ from 50 to 3200, fixing $|D|$ to 100. From Table 3, it is clear that $|T|$ does not significantly affect performance.

$\lvert D\rvert$:	100	200	400	800	1600	3200	6400
Convergence Steps:	31.4	36.0	38.9	39.4	39.3	40.2	40.9

Table 2: Convergence steps for TS-SPL solving the N-Door Puzzle with $\lambda^* = 0.15$, $I = \{0.15 \pm 0.01\}$, $T = \{0.8\}$, and $\pi = 0.8$.

$\lvert T\rvert$:	50	100	200	400	800	1600	3200
Convergence Steps:	51.6	50.8	48.4	52.1	51.0	52.4	52.1

Table 3: Convergence steps for TS-SPL solving the N-Door Puzzle with $\lambda^* = 0.15$, $I = \{0.15 \pm 0.01\}$, $|D| = 101$, and $\pi = 0.8$.

Another advantage of our Bayesian scheme is the ability to incorporate prior information to guide the algorithm. On the other hand, specifying an incorrect prior can potentially deteriorate performance instead of enhancing it. In Table 4, we provide performance results from employing an informed prior over T and D. With the correct underlying values $\lambda^* = \pi = 0.85$, we specify three types of priors: Correct $\propto N(\mu = 0.85, \sigma = 0.3)$, Incorrect $\propto N(\mu = 0.15, \sigma = 0.3)$ and Flat (all solutions equally probable), denoted C, I, and F, respectively. We can see the effect of these different priors in Table 4. In brief, having a correct prior over the doors contributes more to convergence time than having a correct prior over the truthfulness of the guards. The disadvantage of setting an incorrectly biased prior is also evident, as the flat prior performs better than any combination involving a incorrectly biased prior.

3.2 Tracking the Truthfulness of the Environment

An interesting property of TS-SPL is its ability to provide a distribution over the truthfulness π of the environment. This can be a significant advantage because information on π can be leveraged in various ways. As an example, information on π can be used in the case of repeated trials, where the information from previous trials can be used as a prior in subsequent trials, greatly increasing convergence speed (cf. Section 3.1). Figure 1 plots the probability of each level of noise as the TS-SPL progresses with noise probability $\pi = 0.15$ (a highly deceptive environment). As seen, TS-SPL is capable of quickly estimating π accurately.

3.3 Stochastic Point Location

The N-Door Puzzle, as outlined in the introduction, is dependent on two variables λ^* and π^*, with λ^* specifying the door leading to freedom and π^* the truthfulness of the guards. Since the N-Door Puzzle does not pose any spatial requirements on the placements of the doors we can generate a mapping from the N-Door Puzzle to the SPL problem by uniformly placing the doors over the unit interval.

We here use so-called regret to measure performance because not all of the schemes evaluated in this section are Bayesian. Regret is further typical for evaluating multi-armed bandit algorithms Regret can be stated as the cumulative penalty from selecting sub-optimal

Door	Truthfulness	Convergence
F	F	36.4
F	C	35.7
F	I	41.2
C	F	30.2
C	C	30.0
C	I	40.5
I	F	46.4
I	C	45.2
I	I	113.1

Table 4: Convergence steps for TS-SPL solving the N-Door Puzzle with different priors: C - Correct Prior, F - Flat Prior, I - Incorrect prior. Here, $\lambda^* = 0.85$, $I = \{0.15 \pm 0.01\}$, $|T| = |D| = 101$, and $\pi = 0.85$.

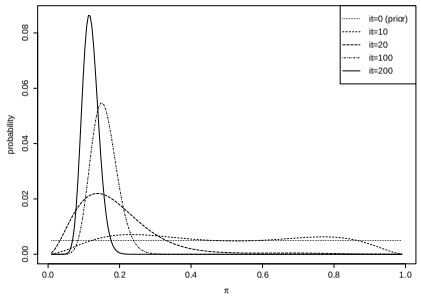

Figure 1: TS-SPL maintains a posterior distribution over π. Here, the true underlying value of π is 0.15. The figure shows the posterior distribution of π after various number of iterations during a single run of TS-SPL. As seen, TS-SPL obtains a sharply peaked posterior over π after only 20 iterations.

actions. In the case of SPL we define regret as the (unsigned) distance between the selected point x and the optimal point λ^*.

3.3.1 Informative SPL

We first evaluate the performance of TS-SPL and TS-SPL-INF on an informative SPL problem, in comparison with algorithms designed to handle informative environments. To the best of our knowledge this is the first time both the family of PBS based schemes and the family of SPL based schemes are compared.

The performance of the different schemes is summarized in Table 5. One significant observation is the performance difference between the Learning Automata (LA) based schemes (HSSL and SHSSL) and the Bayesian schemes. It is clear that performance-wise, Bayesian schemes significantly outperform the LA based schemes. However, it should be noted that the LA based schemes require less memory and run faster than the Bayesian ones due to their simplicity.

As seen in Table 5, the distance $|\frac{1}{2} - \lambda^*|$ is an important metric for how hard a particular SPL problem is to solve. This can be explained by the fact that most schemes start exploring from the center. Thus, if λ^* is far from the center, such a scheme needs more evidence before it starts exploring the peripheral regions of the search space. This is particularly apparent for PBS-M as its performance peaks in the case where $\lambda^* = 0.25$, even when faced with significant noise ($\pi = 0.65$).

Since PBS-M pursues the median of the probability distribution, we can say that PBS-M is conservative in its exploration. This is because it takes significant more evidence to move the point of exploration compared to TS-SPL. TS-SPL, on the other hand, has a tendency to explore too much. Indeed, as noted by Lattimore (Lattimore, 2015), using TS for exploration can lead to over-exploration when facing high variance distributions. In the low noise scenarios, however, NGBS-M is the most efficient scheme, exploring deterministically. For PT-PBS, we observe throughout all the experiments significantly worse performance than PBS-M. We thus omit the PT-PBS results for the remaining experiments, focusing on PBS-M instead.

Finally, from Table 6 we observe that TS-SPL-INF exhibits the lowest standard deviation overall, and is consequentially the scheme that consistently perform closest to its expected regret for every trial. This is in sharp contrast to PBS-M who outperform TS-SPL when it comes to average regret, but is unable to do so consistently. NGBS-M also displays significant variance in high noise scenarios.

3.3.2 SPL in Deceptive Environments

With the underlying π taking on values in the interval $[0, 1]$, we test TS-SPL, CPL-AdS (Oommen et al., 2003) and SHSSL (Zhang et al., 2016) for speed of convergence as well as accumulation of regret. However, since CPL-AdS operates in a two-phase manner, direct comparison with TS-SPL and SHSSL is inappropriate (the latter schemes also operate online). Oommen et al. states that this decision phase needs approximately 200 time steps (Oommen et al., 2003), and by this time TS-SPL is already close to converging to the actual solution. Table 7 further explores this difference. As seen, TS-SPL outperforms CPL-AdS by several orders of magnitude, also outperforming SHSSL.

	Avg Regret $\lambda^* = 0.25$	Avg Regret $\lambda^* = 0.85$	Avg Regret $\lambda^* = 0.95$
TS-SPL	29.2 / 9.8 / 5.1	36.4 / 12.9 / 6.2	57.3 / 20.3 / 10.1
TS-SPL-INF	22.2 / 7.3 / 3.7	**22.5** / 7.7 / 3.8	**23.9** / 8.7 / 4.3
PBS-M	**9.8** / 4.0 / 2.6	32.7 / 14.2 / 8.5	52.1 / 29.6 / 16.9
PT-PBS	245.4 / 247.5 / 247.4	548.2 / 751.5 / 785.2	551.4 / 815.0 / 828.4
BZ-M	23.5 / 5.9 / 2.2	27.5 / 6.3 / 2.5	35.1 / 9.6 / 3.4
NGBS-M	36.9 / **3.5** / **1.0**	48.9 / **4.5** / **1.5**	68.5 / **7.1** / **2.3**
ASS	45.8 / 17.0 / 6.7	30.4 / 8.9 / 3.6	38.8 / 11.7 / 3.9
OCBA	70.8 / 47.4 / 35.2	89.9 / 55.8 / 37.1	112.1 / 78.4 / 48.8
HSSL	117.3 / 23.1 / 8.2	111.7 / 16.7 / 4.8	131.5 / 19.1 / 5.3
SHSSL	152.2 / 32.6 / 11.8	151.8 / 23.5 / 6.5	175.1 / 26.1 / 7.3

Table 5: Average regret for the different schemes in an informative SPL. The result is reported in the format $a/b/c$, where a is the average regret for $\pi = 0.65$, b for $\pi = 0.75$, and c for $\pi = 0.85$. The number of time steps per trial is 1000.

	Std. dev. $\lambda^* = 0.25$	Std. dev. $\lambda^* = 0.85$	Std. dev. $\lambda^* = 0.95$
TS-SPL	16.8 / 5.9 / 2.6	20.5 / 6.5 / 3.1	30.9 / 10.3 / 4.6
TS-SPL-INF	**13.8** / **4.2** / 2.0	**14.2** / **4.4** / 2.5	**15.7** / **5.7** / 2.4
PBS-M	15.2 / 10.3 / 10.2	69.1 / 40.9 / 31.5	94.2 / 71.1 / 56.6
PT-PBS	20.1 / 19.0 / 13.6	145.6 / 31.0 / 22.8	192.1 / 60.5 / 55.8
BZ-M	30.4 / 8.9 / 3.1	40.8 / 9.8 / 4.9	48.8 / 15.3 / 5.3
NGBS-M	68.5 / 8.9 / **0.9**	83.7 / 13.6 / **1.4**	108.7 / 19.4 / **1.6**
ASS	51.6 / 22.4 / 10.1	47.8 / 15.7 / 5.4	62.3 / 23.1 / 4.6
OCBA	46.2 / 27.6 / 19.4	63.9 / 43.9 / 25.6	76.1 / 64.6 / 41.9
HSSL	71.7 / 16.1 / 4.6	83.6 / 16.1 / 4.2	94.8 / 19.4 / 4.5
SHSSL	89.7 / 23.5 / 6.2	108.5 / 23.4 / 5.8	126.5 / 27.7 / 6.4

Table 6: Standard deviation for the different schemes in an informative SPL. The result is reported in the format $a/b/c$, where a is the standard deviation for $\pi = 0.65$, b for $\pi = 0.75$, and c for $\pi = 0.85$. The number of time steps per trial is 1000.

	$\pi = 0.85$	$\pi = 0.15$
TS-SPL ($\lambda^* = 0.85$)	6.2	**6.2**
CPL-AdS ($\lambda^* = 0.85$)	501.6 / 354.9	842.8/502.3
PBS-M ($\lambda^* = 0.85$)	31.5	77.5
BZ-M ($\lambda^* = 0.85$)	4.9	352.5
NGBS-M ($\lambda^* = 0.85$)	**1.4**	191.2
SHSSL ($\lambda^* = 0.85$)	6.5	6.5

Table 7: Cumulative regret for the deceptive SPL problem after $N = 1000$ time steps. For CPL-AdS, we report both the total accumulated regret, as well as regret obtained after the nature of the environment has been decided.

Another interesting observation is that the performance of TS-SPL is symmetric around 0.5. Further note that SHSSL fails to converge for $\pi \in [0.382, 0.682]$, as stated earlier. Hence, SHSSL is effectively operating with a 30% smaller search space for π than both TS-SPL and CPL-AdS.

After modifying PBS, NGBS and BZ to support a Bayesian model of truthfulness, we can use the same prior that we apply in TS-SPL also for these schemes, leading to PBS-M, NGBS-M and BZ-M. The effect of this enhancement to existing schemes is summarized in Table 7. As clearly seen, the query selection method for these schemes is not suited to handle deceptive environments.

3.4 Stochastic Root-Finding

The deterministic root finding problem concerns locating a root x^* of a function $g(x)$, defined over an interval (a, b) [i.e., finding x^*, $g(x^*) = 0$]. We assume that $g(x)$ is unknown, however, an oracle returns the value of $g(x)$ at any point x queried. The problem is then how to determine the root x^* using as few queries as possible. One approach to solving the deterministic root finding problem is the Bisection Method. This approach halves the search space in each iteration by continually querying the oracle using the midpoint of the remaining search space.

If the response from the oracle is noisy, we obtain the SRF problem (Pasupathy and Kim, 2011). We define the SRF problem as follows. For any $x \in (0, 1)$, the oracle generates a sample $Y(x) = g(x) + w_{\text{noise}}$, where w_{noise} is a random variable with mean zero. Let $S(x)$ denote the sign of $Y(x)$: $S(x) = \text{sgn}[Y(x)]$. Notice that the noise w_{noise} may render $\text{sgn}[Y(x)]$ different from $\text{sgn}[g(x)]$. Thus, with noisy feedback, the Bisection Method may discard the wrong half of the search space. The challenge is then how to select a sequence of queries $x_1, x_2, \ldots, x_n$ to gather information on x^*, so that the final query x_n is close to x^*, $|x_n - x^*| < \epsilon$, despite the noise (Waeber et al., 2011). Note that in the SRF problems we investigate here, $S(x)$ returns $\text{sgn}[g(x)]$ with probability π and $-\text{sgn}[g(x)]$ with probability $1 - \pi$.

The traditional approach to solving SRF problems is to apply a variant of Stochastic Approximation (SA) (Robbins and Monro, 1951; Kiefer and Wolfowitz, 1952). Implementation-

wise SA methods[3] extend or modify the iterative Newton-Raphson algorithm to handle noise:

$$x_{n+1} = x_n - a_n Y_n(x_n)$$

where $\{a_n\}$ is a sequence of step lengths that decreases as n increases.

Approaches for applying SA to the SRF problem has been extensively studied in the literature. It is outside the scope of this article to give a full literature review, however, interested readers are referred to surveys in recent studies (Lai, 2003; Asmussen and Glynn, 2007; Pasupathy and Kim, 2011). As there exists a myriad of different SA approaches, we have selected one of the more fundamental ones to form a basis for contrasting the different schemes.

Note that the SA approach we use here requires that $g(x)$ is monotonic. This can be explained as follows. The main difference between SRF and SPL is that, unlike SPL, the SRF oracle does not directly provide feedback on the direction of the root x^* from the query location x. However, for monotonic $g(x)$, one can obtain this direction from the sign of $Y(x)$, $S(x) \in \{-1, 1\}$ and from the derivative $g'(x)$ of $g(x)$. If $g(x)$ is increasing and $S(x) = 1$, then the direction derived from the oracle is "to the left of x" [and "to the right" if $S(x) = -1$]. Conversely, if $g(x)$ is decreasing and $S(x) = 1$, then the direction obtained is "to the right of x" [and "to the left" if $S(x) = -1$].

TS-SPL, on the other hand, does not need to know the derivative of $g(x)$. Indeed, $g(x)$ does not even need to be monotonic. Instead, TS-SPL merely requires an arbitrary mapping of the sign $S(x)$ to a direction. One could, for instance, define positive to mean "left", $S(x) = 1 \Rightarrow$ *left*, and negative to mean "right", $S(x) = -1 \Rightarrow$ *right*. If it turns out that the opposite is the case, TS-SPL will recognize that the feedback is deceptive and still solve the problem. An informative scheme, on the other hand, will be misled in such a deceptive environment.

Informative SPL schemes can also be used for SRF problems. However, then we need an initial sampling step that decides the nature of the function $g(x)$. Learning whether the function $g(x)$ starts above zero and falls below zero, or vice versa, can be done by repeatedly querying a single point on the edge of the interval $(0, 1)$, obtaining multiple samples from either $S(x)$. In brief, by estimating $E[S(x)]$, we can decide the nature of $g(x)$. To gain insight into how many repeated samples are sufficient for estimating $E[S(x)]$ accurately, we employ the two sided Hoeffding's inequality $P(|\bar{X} - E[\bar{X}]| \geq \delta) \leq 2e^{-2n\delta^2}$. Here, $\bar{X}$ is the average of n queries at x and δ is a value such that $|\pi - \frac{1}{2}| \geq \delta$. Setting the rhs. equal to p and solving for n, we obtain $n \geq -\frac{\log(p/2)}{2\delta^2}$. Plugging in for $\delta = 0.05$ and $p = 0.99$ we obtain $\lceil n \rceil = 62$. Thus we are 99% sure of our estimate of $S(x)$, given that $|\pi - 0.5| \geq 0.05$.

The functions that we use to measure performance and compare schemes are illustrated in Figure 2. From Table 8, 9 and 10 it is clear that TS-SPL is the most efficient root solver among state-of-the-art schemes. We believe this largely comes from the fact that it simultaneously learns the nature of the oracle (informative or deceptive), as well as trying to locate the root x^*. In addition, there is the risk that the sampling procedure that the other schemes apply to determine which direction $g(x)$ is increasing may conclude with the wrong answer. If this happens, none of the schemes depending on the sampling will

3. The form of SA shown here is also referred to as Classical Stochastic Approximation (CSA) as it closely resembles the original form proposed by Robbins and Monro (Pasupathy and Schmeiser, 2010).

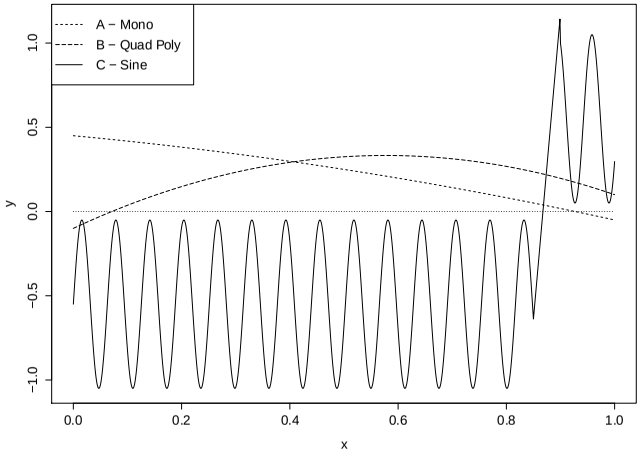

Figure 2: The three functions A, B and C for benchmarking stochastic root finding schemes.

Func A	Avg Regret. $\pi = 0.65$	Avg Regret. $\pi = 0.75$	Avg Regret $\pi = 0.85$
TS-SPL	46.0	17.1	8.6
TS-SPL-INF	55.2 (24.3)	39.1 (8.1)	35.0 (4.1)
PBS-M	55.1 (24.2)	40.3 (9.3)	35.2 (4.2)
NGBS-M	53.4 (22.4)	35.3 (4.3)	32.9 (1.9)
BZ-M	63.8 (32.8)	39.9 (8.9)	33.8 (2.8)
SA	**32.4**	**14.8**	**5.4**
ASS	80.4 (49.4)	38.7 (7.7)	33.5 (2.5)
HSSL	60.4 (29.4)	45.5 (14.6)	35.8 (4.8)
SHSSL	62.8	20.2	6.7
CPL-AdS	162.1 (107.9)	146.3 (97.4)	135.3 (90.1)

Table 8: Average residuals for the different schemes when finding the root of the monotonic function A under various noise levels. The root is $x^* = 0.07104$. The results are given in the format "average residuals (average residuals after sampling)" for each scheme. For CPL-AdS the sampling period is the estimation period (epoch 0) as defined by the scheme. The number of iterations per trial is 250.

Func B	Avg Regret. $\pi = 0.65$	Avg Regret. $\pi = 0.75$	Avg Regret $\pi = 0.85$
TS-SPL	47.1	**17.8**	**8.5**
TS-SPL-INF	53.8 (22.9)	39.5 (8.5)	35.1 (4.1)
PBS-M	**41.1** (10.2)	35.3 (4.31)	33.3 (2.3)
SGBS-M	50.6 (19.7)	35.7 (4.7)	33.0 (2.0)

SHSSL	75.4	30.8	12.7
CPL-AdS	117.9 (109.3)	116.7 (107.1)	144.9 (96.5)

Table 9: Average residuals for the different schemes when finding the root of the quadric function B under various noise levels. The root is $x^* = 0.9270$. The results are given in the format "average residuals (average residuals after sampling)" for each scheme. For CPL-AdS the sampling period is the estimation period (epoch 0) as defined by the scheme. The number of iterations per trial is 250.

Func C	Avg Regret. $\pi = 0.65$	Avg Regret. $\pi = 0.75$	Avg Regret $\pi = 0.85$
TS-SPL	**36.9**	**13.7**	**6.4**
TS-SPL-INF	52.8 (21.9)	38.8 (7.8)	34.9 (3.9)
PBS-M	49.6 (18.7)	39.2 (8.3)	34.3 (3.3)
SGBS-M	47.2 (16.2)	34.6 (3.6)	32.5 (1.6)
BZ-M	58.8 (27.9)	38.4 (7.4)	33.7 (2.7)
SA	149.0	178.0	185.0
ASS	54.3 (23.4)	39 (8.0)	33.5 (2.5)
HSSL	75.2 (44.3)	44.3 (13.4)	35.6 (4.6)
SHSSL	56.5	18.4	**6.4**
CPL-AdS	153.0 (101.6)	156.2 (103.7)	165.0 (109.6)

Table 10: Average residuals for the different schemes when finding the root of the sinusoidal function C under various noise levels. The root is $x^* = 0.8675$. The results are given in the format "average residuals (average residuals after sampling)" for each scheme. For CPL-AdS the sampling period is the estimation period (epoch 0) as defined by the scheme. The number of iterations per trial is 250.

converge towards the root x^*. A perhaps even stronger advantage of TS-SPL is that it can be applied to a wide range of functions without regards to the presence of local extrema. SA, on the other, only performs well for monotonic functions as exemplified in Table 8.

4. Conclusions and Further Work

In this paper, we investigated a novel reinforcement learning problem derived from the so-called "N-Door Puzzle". This puzzle has the fascinating property that it involves stochastic *compulsive liars*. Feedback is erroneous on average, systematically misleading the decision maker. This renders traditional reinforcement learning (RL) based approaches ineffective due to their dependency on *"on average"* correct feedback.

To solve the problem of deceptive feedback, we recast the problem as a challenging variant of the multi-armed bandit problem, referred to as the *Stochastic Point Location* (SPL) problem. In SPL, the decision maker is only told whether the optimal point on a line lies to the "left" or to the "right" of a current guess, with the feedback being erroneous with probability $1-\pi$. Solving this problem opens up for optimization in continuous action spaces with both *informative* and *deceptive* feedback.

Our solution to the above problem, introduced in the present paper, is based on a novel Bayesian representation of the solution space that is both compact and scalable. This model simultaneously captures both the location of the optimal point, as well as the probability of receiving correct feedback π. We further introduced an accompanying Thompson Sampling (TS) guided Stochastic Point Location (TS-SPL) scheme for balancing exploration against exploitation. By learning π, TS-SPL supports deceptive environments that are lying about the direction of the optimal point.

We used TS-SPL to solve the Stochastic Point Location (SPL) problem and outperformed all of the Learning Automata driven methods. However, by enhancing the Soft Generalized Binary Search (SGBS) scheme with our Bayesian representation of the solution space, SGBS was able to outperform TS-SPL under informative feedback. For deceptive SPL problems, TS-SPL outperformed all of the existing state-of-art schemes by several orders of magnitude, even when the latter schemes were supported by our Bayesian model.

We also applied TS-SPL to the *Stochastic Root Finding* (SRF) problem. We further demonstrated that SRF can be seen as a deceptive problem, allowing TS-SPL to outperform existing dedicated state-of-art SRF schemes by an order of magnitude. Thus, TS-SPL can be considered state-of-the-art for both deceptive SPL and for SRF, while yielding comparable results to the top performing schemes in the case of informative SPLs.

Despite the above performance gains, TS-SPL is based on Thompson Sampling, which is known to have a tendency to over-explore high variance reward distributions (Lattimore, 2015). In future work, it is therefore interesting to investigate mechanisms that eliminate or reduce this tendency, to further increase convergence speed.

Another important avenue for future work is the establishment of theoretical results, including proof of convergence, to corroborate the purely empirical findings presented in this paper. We suggest that a promising starting point for such an endeavour would be to combine the theoretical properties of TS (Agrawal and Goyal, 2012, 2013a; Dong and Van Roy, 2018) with the theoretical results of PBS (Waeber et al., 2013; Frazier et al., 2019), as they are closely related.

Abstract

Modern supervised machine learning algorithms involve hyperparameters that have to be set before running them. Options for setting hyperparameters are default values from the software package, manual configuration by the user or configuring them for optimal predictive performance by a tuning procedure. The goal of this paper is two-fold. Firstly, we formalize the problem of tuning from a statistical point of view, define data-based defaults and suggest general measures quantifying the tunability of hyperparameters of algorithms. Secondly, we conduct a large-scale benchmarking study based on 38 datasets from the OpenML platform and six common machine learning algorithms. We apply our measures to assess the tunability of their parameters. Our results yield default values for hyperparameters and enable users to decide whether it is worth conducting a possibly time consuming tuning strategy, to focus on the most important hyperparameters and to choose adequate hyperparameter spaces for tuning.

Keywords: machine learning, supervised learning, classification, hyperparameters, tuning, meta-learning

1. Introduction

Machine learning (ML) algorithms such as gradient boosting, random forest and neural networks for regression and classification involve a number of *hyperparameters* that have to be set before running them. In contrast to direct, first-level model parameters, which are determined during training, these second-level *tuning parameters* often have to be carefully optimized to achieve maximal performance. A related problem exists in many other algorithmic areas, e.g., control parameters in evolutionary algorithms (Eiben and Smit, 2011).

In order to select an appropriate hyperparameter *configuration* for a specific dataset at hand, users of ML algorithms can resort to default values of hyperparameters that are specified in implementing software packages or manually configure them, for example, based on recommendations from the literature, experience or trial-and-error.

Alternatively, one can use hyperparameter *tuning strategies*, which are data-dependent, second-level optimization procedures (Guyon et al., 2010), which try to minimize the expected generalization error of the inducing algorithm over a hyperparameter search space of considered candidate configurations, usually by evaluating predictions on an independent test set, or by running a resampling scheme such as cross-validation (Bischl et al., 2012). For a recent overview of tuning strategies, see, e.g., Luo (2016). These search strategies range from simple grid or random search (Bergstra and Bengio, 2012) to more complex, iterative procedures such as Bayesian optimization (Hutter et al., 2011; Snoek et al., 2012; Bischl et al., 2017b) or iterated F-racing (Birattari et al., 2010; Lang et al., 2017).

In addition to selecting an efficient tuning strategy, the set of tunable hyperparameters and their corresponding ranges, scales and potential prior distributions for subsequent sampling have to be determined by the user. Some hyperparameters might be safely set to default values, if they work well across many different scenarios. Wrong decisions in these areas can inhibit either the quality of the resulting model or at the very least the efficiency and fast convergence of the tuning procedure. This creates a burden for:

1. ML users—Which hyperparameters should be tuned and in which ranges?

2. Designers of ML algorithms—How do I define robust defaults?

We argue that many users, especially if they do not have years of practical experience in the field, here often rely on heuristics or spurious knowledge. It should also be noted that designers of fully automated tuning frameworks face at least very similar problems. It is not clear how these questions should be addressed in a data-dependent, automated, optimal and objective manner. In other words, the scientific community not only misses answers to these questions for many algorithms but also a systematic framework, methods and criteria, which are required to answer these questions.

With the present paper we aim at filling this gap and formalize the problem of parameter tuning from a statistical point of view, in order to simplify the tuning process for less experienced users and to optimize decision making for more advanced processes.

After presenting related literature in Section 2, we define theoretical measures for assessing the impact of tuning in Section 3. For this purpose we (i) define the concept of *default hyperparameters*, (ii) suggest measures for quantifiying the tunability of the whole algorithm and specific hyperparameters based on the differences between the performance of default hyperparameters and the performance of the hyperparameters when this hyperparameter is set to an optimal value. Then we (iii) address the tunability of hyperparameter combinations and joint gains, (iv) provide theoretical definitions for an appropriate hyperparameter space on which tuning should be executed and (v) propose procedures to estimate these quantities based on the results of a benchmark study with random hyperparameter configurations with the help of surrogate models. In sections 4 and 5 we illustrate these concepts and methods through an application. For this purpose we use benchmark results of six machine learning algorithms with different hyperparameters which were evaluated on 38 datasets from the OpenML platform. Finally, in the last Section 6 we conclude and discuss the results.

2. Related Literature

To the best of our knowledge, only a limited amount of articles address the problem of tunability and generation of tuning search spaces. Bergstra and Bengio (2012) compute the relevance of the hyperparameters of neural networks and conclude that some are important on all datasets, while others are only important on some datasets. Their conclusion is primarily visual and used as an argument for why random search works better than grid search when tuning neural networks.

A specific study for decision trees was conducted by Mantovani et al. (2016) who apply standard tuning techniques to decision trees on 102 datasets and calculate differences of accuracy between the tuned algorithm and the algorithm with default hyperparameter settings.

A different approach is proposed by Hutter et al. (2013), which aims at identifying the most important hyperparameters via forward selection. In the same vein, Fawcett and Hoos (2016) present an *ablation analysis* technique, which aims at identifying the hyperparameters that contribute the most to improved performance after tuning. For each of the considered hyperparameters, they compute the performance gain that can be achieved by changing its value from the initial value to the value specified in the target configuration which was determined by the tuning strategy. This procedure is iterated in a greedy forward search.

A more general framework for measuring the importance of single hyperparameters is presented by Hutter et al. (2014). After having used a tuning strategy such as sequential model-based optimization, a functional ANOVA approach is used for measuring the importance of hyperparameters.

These works concentrate on the importance of hyperparameters on single datasets, mainly to retrospectively explain what happened during an already concluded tuning process. Our main focus is the generalization across multiple datasets in order to facilitate better general understanding of hyperparameter effects and better decision making for future experiments. In a recent paper van Rijn and Hutter (2017) pose very similar questions to ours to assess the importance of hyperparameters across datasets. We compare it to our approach in Section 6.

Our framework is based on using surrogate models, also sometimes called empirical performance models, which allow estimating the performance of arbitrary hyperparameter configurations based on a limited number of prior experiments. The idea of surrogate models is far from new (Audet et al., 2000), as it constitutes the central idea of Bayesian optimization for hyperparameter search but is also used, for example, in Biedenkapp et al. (2017) for increasing the speed of an ablation analysis and by Eggensperger et al. (2018) for speeding up the benchmarking of tuning strategies.

3. Methods for Estimation of Defaults, Tunability and Ranges

In this section we introduce theoretical definitions for defaults, tunability and tuning ranges, then describe how to estimate them and finally discuss the topic of reparametrization.

3.1. General Notation

Consider a target variable Y, a feature vector X, and an unknown joint distribution P on (X, Y), from which we have sampled a dataset $\mathcal{T}$ of n observations. A machine learning (ML) algorithm now learns the functional relationship between X and Y by producing a prediction model $\hat{f}(X, \theta)$, controlled by the k-dimensional hyperparameter configuration $\theta = (\theta_1, ..., \theta_k)$ from the hyperparameter search space $\Theta = \Theta_1 \times ... \times \Theta_k$. In order to measure prediction performance pointwise between the true label Y and its prediction $\hat{f}(X, \theta)$, we define a loss function $L(Y, \hat{f}(X, \theta))$. We are naturally interested in estimating the expected risk of the inducing algorithm, w.r.t. θ on new data, also sampled from $\mathcal{P}$: $R(\theta) = E(L(Y, \hat{f}(X, \theta))|\mathcal{P})$. This mapping encodes, given a certain data distribution, a certain learning algorithm and a certain performance measure, the numerical quality for any hyperparameter configuration θ. Given m different datasets (or data distributions) $\mathcal{P}_1, ..., \mathcal{P}_m$, we arrive at m hyperparameter risk mappings

$$R^{(j)}(\theta) := E(L(Y, \hat{f}(X, \theta))|\mathcal{P}_j), \qquad j = 1, ..., m. \tag{1}$$

For now, we assume all $R^{(j)}(\theta)$ to be known, and show how to estimate them in Section 3.7.

3.2. Optimal Configuration per Dataset and Optimal Defaults

We first define the best hyperparameter configuration for dataset j as

$$\theta^{(j)\star} := \arg\min_{\theta \in \Theta} R^{(j)}(\theta). \tag{2}$$

Defaults settings are supposed to work well across many different datasets and are usually provided by software packages, in an often ad hoc or heuristic manner. We propose to define an optimal default configuration, based on an extensive number of empirical experiments on m different benchmark datasets, by

$$\theta^{\star} := \arg\min_{\theta \in \Theta} g(R^{(1)}(\theta), ..., R^{(m)}(\theta)). \tag{3}$$

Here, g is a summary function that has to be specified. Selecting the mean (or median as a more robust candidate) would imply minimizing the average (or median) risk over all datasets.

The measures $R^{(j)}(\theta)$ could potentially be scaled appropriately beforehand in order to make them more commensurable between datasets, e.g., one could scale all $R^{(j)}(\theta)$ to $[0, 1]$ by subtracting the result of a very simple baseline like a featureless dummy predictor and dividing this difference by the absolute difference between the risk of the best possible result (as an approximation of the Bayes error) and the result of the very simple baseline predictor. Or one could produce a statistical z-score by subtracting the mean and dividing by the standard deviation from all experimental results on the same dataset (Feurer et al., 2018).

The appropriateness of the scaling highly depends on the performance measure that is used. One could, for example, argue that the AUC does not have to be scaled by using the probabilistic interpretation of the AUC. Given a randomly chosen observation x belonging to class 1, and a randomly chosen observation x' belonging to class 0, the AUC is the probability that the evaluated classification algorithm will assign a higher score to x than to x'. Thus,

an improvement from 0.5 to 0.6 on one dataset could be seen as equally important to an improvement from 0.8 to 0.9 on another dataset. On the other hand, averaging the mean squared error on several datasets does not make a lot of sense, as the scale of the outcome of different regression problems can be very different. Then scaling or using another measure such as the R^2 is reasonable. As our main risk measure is the AUC, we do not use any scaling.[1]

3.3. Measuring Overall Tunability of a ML Algorithm

A general measure of the tunability of an algorithm per dataset can then be computed based on the difference between the risk of an overall reference configuration (e.g., either the software defaults or definition (3)) and the risk of the best possible configuration on that dataset:

$$d^{(j)} := R^{(j)}(\theta^\star) - R^{(j)}(\theta^{(j)\star}), \text{ for } j = 1, ..., m. \tag{4}$$

For each algorithm, this gives rise to an empirical distribution of performance differences over datasets, which might be directly visualized or summarized to an aggregated tunability measure d by using mean, median or quantiles.

3.4. Measuring Tunability of a Specific Hyperparameter

The best hyperparameter value for one parameter i on dataset j, when all other parameters are set to defaults from $\theta^\star := (\theta_1^\star, ..., \theta_k^\star)$, is denoted by

$$\theta_i^{(j)\star} := \underset{\theta \in \Theta, \theta_l = \theta_l^\star \forall l \neq i}{\arg\min} R^{(j)}(\theta). \tag{5}$$

A natural measure for tunability of the i-th parameter on dataset j is then the difference in risk between the above and our default reference configuration:

$$d_i^{(j)} := R^{(j)}(\theta^\star) - R^{(j)}(\theta_i^{(j)\star}), \text{ for } j = 1, ..., m, i = 1, ..., k. \tag{6}$$

Furthermore, we define $d_i^{(j),\text{rel}} = \frac{d_i^{(j)}}{d^{(j)}}$ as the fraction of performance gain, when we only tune parameter i compared to tuning the complete algorithm, on dataset j. Again, one can calculate the mean, the median or quantiles of these two differences over the n datasets, to get a notion of the overall tunability d_i of this parameter.

3.5. Tunability of Hyperparamater Combinations and Joint Gains

Let us now consider two hyperparameters indexed as i_1 and i_2. To measure the tunability with respect to these two parameters, we define

$$\theta_{i_1,i_2}^{(j)\star} := \underset{\theta \in \Theta, \theta_l = \theta_l^\star \forall l \notin \{i_1, i_2\}}{\arg\min} R^{(j)}(\theta), \tag{7}$$

1. We also tried out normalization (z-score) and got qualitatively similar results to the non-normalized results presented in Section 5.

i.e., the θ-vector containing the default values for all hyperparameters other than i_1 and i_2, and the optimal combination of values for the i_1-th and i_2-th components of θ.

Analogously to the previous section, we can now define the tunability of the set (i_1, i_2) as the gain over the reference default on dataset j as

$$d_{i_1,i_2}^{(j)} := R^{(j)}(\theta^*) - R^{(j)}(\theta_{i_1,i_2}^{(j)\star}). \tag{8}$$

The joint gain which can be expected when tuning not only one of the two hyperparameters individually, but both of them jointly, on a dataset j, can be expressed by

$$g_{i_1,i_2}^{(j)} := \min\{(R^{(j)}(\theta_{i_1}^{(j)\star})), (R^{(j)}(\theta_{i_2}^{(j)\star}))\} - R^{(j)}(\theta_{i_1,i_2}^{(j)\star}). \tag{9}$$

Furthermore, one could be interested in whether this joint gain could simply be reached by tuning both parameters i_1 and i_2 in a univariate fashion sequentially, either in the order $i_1 \to i_2$ or $i_2 \to i_1$, and what order would be preferable. For this purpose one could compare the risk of the hyperparameter value that results when tuning them together $R^{(j)}(\theta_{i_1,i_2}^{(j)\star})$ with the risks of the hyperparameter values that are obtained when tuning them sequentially, that means $R^{(j)}(\theta_{i_1 \to i_2}^{(j)\star})$ or $R^{(j)}(\theta_{i_2 \to i_1}^{(j)\star})$, which is done for example in Waldron et al. (2011).

Again, all these measures should be summarized across datasets, resulting in d_{i_1,i_2} and g_{i_1,i_2}. Of course, these approaches can be further generalized by considering combinations of more than two parameters.

3.6. Optimal Hyperparameter Ranges for Tuning

A reasonable hyperparameter space $\Theta^\star$ for tuning should include the optimal configuration $\theta^{(j)\star}$ for dataset j with high probability. We denote the p-quantile of the distribution of one parameter regarding the best hyperparameters on each dataset $(\theta^{(1)\star})_i, ..., (\theta^{(m)\star})_i$ as $q_{i,p}$. The hyperparameter tuning space can then be defined as

$$\Theta^\star := \{\theta \in \Theta | \forall i \in \{1, ..., k\} : \theta_i \geq q_{i,p_1} \wedge \theta_i \leq q_{i,p_2}\}, \tag{10}$$

with p_1 and p_2 being quantiles which can be set for example to the 5 % quantile and the 95 % quantile. This avoids focusing too much on outlier datasets and makes the definition of the space independent from the number of datasets.

The definition above is only valid for numerical hyperparameters. In case of categorical variables one could use similar rules, for example only including hyperparameter values that were at least once or in at least 10 % of the datasets the best possible hyperparameter setting.

3.7. Practical Estimation

In order to practically apply the previously defined concepts, two remaining issues need to be addressed: a) We need to discuss how to obtain $R^{(j)}(\theta)$; and b) in (2) and (3) a multivariate optimization problem (the minimization) needs to be solved.[2]

2. All other previous optimization problems are univariate or two-dimensional and can simply be addressed by simple techniques such as a fine grid search.

For a) we estimate $R^{(j)}(\theta)$ by using surrogate models $\hat{R}^{(j)}(\theta)$, and replace the original quantity by its estimator in all previous formulas. Surrogate models for each dataset j are based on a meta dataset. This is created by evaluating a large number of configurations of the respective ML method. The surrogate regression model then learns to map a hyperparameter configuration to estimated performance. For b) we solve the optimization problem—now cheap to evaluate, because of the surrogate models—through black-box optimization.

3.8. Reparametrization

All tunability measures mentioned above can possibly depend on and be influenced by a reparametrization of hyperparameters. For example, in the case of the elastic net the parameters λ and α could be reparametrized as $\lambda_1 = \alpha\lambda$ and $\lambda_2 = (1-\alpha)\lambda$. Formally, such a reparametrization could be defined as a (bijective) function $\phi : \Theta \to \tilde{\Theta}$, such that $\phi(\theta)$ maps an original configuration θ to a new representation $\tilde{\theta} = \phi(\theta)$ from $\tilde{\Theta}$, in a one-to-one manner. Then defaults (calculated by the approach in Section 3.2) are naturally transformed via $\tilde{\theta}^\star = \phi(\theta^\star)$ into the new space $\tilde{\Theta}$, but will stay logically the same. Moreover, the general tunability of the algorithm does (obviously) not change. Depending on the parameters that are involved in the reparametrization, the tunability of the parameters can change. If, for example, only one parameter is involved, all tunabilities remain the same. If two or more parameters are involved, the single tunabilities of the parameters could change but the tunability of the set of the transformed parameters remains the same.

One might define a reparametrization as ideal (in the sense of simplified tuning) if the tunability is concentrated on one (or only few) hyperparameter(s), so that only this parameter has to be optimized and all remaining hyperparameters can remain at their (optimal) default values, reducing a multivariate optimization problem to a 1-dimensional or at least lower dimensional one. Using the definition above, this would imply that the joint gain of the new parameter(s) is (close to) 0. For example, imagine that the optimal hyperparameter values per dataset of two hyperparameters θ_1 and θ_2 lie on the line of equation $\theta_1 = \theta_2$. A useful reparametrization would then be $\tilde{\theta}_1 = \theta_1 + \theta_2$ and the orthogonal $\tilde{\theta}_2 = \theta_1 - \theta_2$. It would then only be necessary to tune $\tilde{\theta}_1$, while $\tilde{\theta}_2$ would be set to the default value 0.

A more general formulation is possible if we use the definition of 3.4. We could, for example, search for a bijective and invertible function $\phi^\star(.)$, across a certain parameterized function space, such that the mean tunability is concentrated on and therefore maximal for the first parameter and minimal for the other parameters, i.e.:

$$\phi^\star := \arg\min_{\phi \in \Phi} \frac{1}{m} \sum_{j=1}^{m} \min_{\tilde{\theta} \in \tilde{\Theta}, \tilde{\theta}_l = \tilde{\theta}_l^\star \forall l \neq 1} R^{(j)} \left(\phi^{-1} \left(\tilde{\theta} \right) \right). \tag{11}$$

We could select a restricted function space for ϕ, e.g., restrict ourselves to the space of all linear (invertible) transformations $\{\phi : \mathbb{R}^k \to \mathbb{R}^k | \phi(x) = Ax, A \in \mathbb{R}^{k \times k}, \det(A) \neq 0\}$. If concentrating the whole tunability on only one parameter is not possible, we could try a similar approach by concentrating it on a combination of two hyperparameters.

Note that such a reparametrization is not always helpful. For example, imagine we have two binary parameters and transform them such that (i) one of them has 4 levels that correspond to all possible combinations of these two parameters and (ii) the other parameter is set to a fixed constant. This reparametrization would not be useful: all the tunability is contained in the first parameter, but there is no real advantage, as still four evaluations have to be executed in the tuning process to get the best hyperparameter combination.

Finally, note that it can also be useful to reparametrize a single hyperparameter for the purpose of tuning. Imagine, for example, that most of the optimal parameters on the different datasets are rather small and only a few are large. A transformation of this parameter such as a log-transformation may then be useful. This is very similar to using prior probabilities for tuning (based on results on previous datasets) which could be seen as a useful alternative to a reparametrization and which is already proposed in van Rijn and Hutter (2017).

4. Experimental Setup

In this section we give an overview about the experimental setup that is used for obtaining surrogate models, tunability measures and tuning spaces.

4.1. Datasets from the OpenML Platform

Recently, the OpenML project (Vanschoren et al., 2013) has been created as a flexible online platform that allows ML scientists to share their data, corresponding tasks and results of different ML algorithms. We use a specific subset of carefully curated classification datasets from the OpenML platform called *OpenML100* (Bischl et al., 2017a). For our study we only use the 38 binary classification tasks that do not contain any missing values.

4.2. ML Algorithms

The algorithms considered in this paper are common methods for supervised learning. We examine elastic net (`glmnet` R package), decision tree (`rpart`), k-nearest neighbors (`kknn`), support vector machine (`svm`), random forest (`ranger`) and gradient boosting (`xgboost`). For more details about the used software packages see Kühn et al. (2018b). An overview of their considered hyperparameters is displayed in Table 1, including respective data types, box-constraints and a potential transformation function.

In the case of `xgboost`, the underlying package only supports numerical features, so we opted for a dummy feature encoding for categorical features, which is performed internally by the underlying packages for `svm` and `glmnet`.

Some hyperparameters of the algorithms are dependent on others. We take into account these dependencies and, for example, only sample a value for `gamma` for the support vector machine if the radial kernel was sampled beforehand.

4.3. Performance estimation

Several measures are regarded throughout this paper, either for evaluating our considered classification models that should be tuned, or for evaluating our surrogate regression models. As no optimal measure exists, we will compare several of them. In the classification case, we consider AUC, accuracy and Brier score. In the case of surrogate regression, we consider R^2, which is directly proportional to the regular mean squared error but scaled to [0,1] and explains the gain over a constant model estimating the overall mean of all data points. We also compute Kendall's tau as a ranking based measure for regression.

Algorithm	Hyperparameter	Type	Lower	Upper	Trafo
glmnet					
(Elastic net)	alpha	numeric	0	1	-
	lambda	numeric	-10	10	2^x
rpart					
(Decision tree)	cp	numeric	0	1	-
	maxdepth	integer	1	30	-
	minbucket	integer	1	60	-
	minsplit	integer	1	60	-
kknn					
(k-nearest neighbor)	k	integer	1	30	-
svm					
(Support vector machine)	kernel	discrete	-	-	-
	cost	numeric	-10	10	2^x
	gamma	numeric	-10	10	2^x
	degree	integer	2	5	-
ranger					
(Random forest)	num.trees	integer	1	2000	-
	replace	logical	-	-	-
	sample.fraction	numeric	0.1	1	-
	mtry	numeric	0	1	$x \cdot p$
	respect.unordered.factors	logical	-	-	-
	min.node.size	numeric	0	1	n^x
xgboost					
(Gradient boosting)	nrounds	integer	1	5000	-
	eta	numeric	-10	0	2^x
	subsample	numeric	0.1	1	-
	booster	discrete	-	-	-
	max_depth	integer	1	15	-
	min_child_weight	numeric	0	7	2^x
	colsample_bytree	numeric	0	1	-
	colsample_bylevel	numeric	0	1	-
	lambda	numeric	-10	10	2^x
	alpha	numeric	-10	10	2^x

Table 1: Hyperparameters of the algorithms. p refers to the number of variables and n to the number of observations. The columns *Lower* and *Upper* indicate the regions from which samples of these hyperparameters are drawn. The transformation function in the trafo column, if any, indicates how the values are transformed according to this function. The exponential transformation is applied to obtain more candidate values in regions with smaller hyperparameters because for these hyperparameters the performance differences between smaller values are potentially bigger than for bigger values. The `mtry` value in `ranger` that is drawn from $[0, 1]$ is transformed for each dataset separately. After having chosen the dataset, the value is multiplied by the number of variables and afterwards rounded up. Similarly, for the `min.node.size` the value x is transformed by the formula $[n^x]$ with n being the number of observations of the dataset, to obtain a positive integer values with higher probability for smaller values (the value is finally rounded to obtain integer values).

The performance estimation for the different hyperparameter experiments is computed through 10-fold cross-validation. For the comparison of surrogate models 10 times repeated 10-fold cross-validation is used.

4.4. Random Bot sampling strategy for meta data

To reliably estimate our surrogate models we need enough evaluated configurations per classifier and dataset. We sample these points from independent uniform distributions where the respective support for each parameter is displayed in Table 1. Here, *uniform* refers to the untransformed scale, so we sample uniformly from the interval [*Lower*, *Upper*] of Table 1.

In order to properly facilitate the automatic computation of a large database of hyperparameter experiments, we implemented a so called OpenML bot. In an embarrassingly parallel manner it chooses in each iteration a random dataset, a random classification algorithm, samples a random configuration and evaluates it via cross-validation. A subset of 500000 experiments for each algorithm and all datasets are used for our analysis here.[3] More technical details regarding the random bot, its setup and results can be obtained in Kühn et al. (2018b), furthermore, for simple and permanent access the results of the bot are stored in a figshare repository (Kühn et al., 2018a).

4.5. Optimizing Surrogates to Obtain Optimal Defaults

Random search is also used for our black-box optimization problems in Section 3.7. For the estimation of the defaults for each algorithm we randomly sample 100000 points in the hyperparameter space as defined in Table 1 and determine the configuration with the minimal average risk. The same strategy with 100000 random points is used to obtain the best hyperparameter setting on each dataset that is needed for the estimation of the tunability of an algorithm. For the estimation of the tunability of single hyperparameters we also use 100000 random points for each parameter, while for the tunability of combination of hyperparameters we only use 10000 random points to reduce runtime as this should be enough to cover 2-dimensional hyperparameter spaces.

Of course one has to be careful with overfitting here, as our optimal defaults are chosen with the help of the same datasets that are used to determine the performance. Therefore, we also evaluate our approach via a "10-fold cross-validation across datasets". Here, we repeatedly calculate the optimal defaults based on 90% "training datasets" and evaluate the package defaults and our optimal defaults—the latter induced from the training datasets—on the surrogate models of the remaining 10% "test datasets", and compare their difference in performance.

4.6. The Problem of Hyperparameter Dependency

Some parameters are dependent on other superordinate hyperparameters and are only relevant if the parameter value of this superordinate parameter was set to a specific value. For example `gamma` in `svm` only makes sense if the `kernel` was set to "radial" or `degree` only makes sense if the kernel was set to "polynomial". Some of these subordinate parameters might be invalid/inactive in the reference default configuration, rendering it impossible to

3. Only 30 experiments are used for each dataset for `kknn`, because we only consider the parameter k.

univariately tune them in order to compute their tunability score. In such a case we set the superordinate parameter to a value which makes the subordinate parameter active, compute the optimal defaults for the rest of the parameters and compute the tunability score for the subordinate parameter with these defaults.

4.7. Software Details

All our experiments are executed in R and are run through a combination of custom code from our random bot (Kühn et al., 2018b), the `OpenML` R package (Casalicchio et al., 2017), `mlr` (Bischl et al., 2016) and `batchtools` (Lang et al., 2017) for parallelization. All results are uploaded to the OpenML platform and there publicly available for further analysis. `mlr` is also used to compare and fit all surrogate regression models. The fully reproducible R code for all computations and analyses of our paper can be found on the github page: `https://github.com/PhilippPro/tunability`. We also provide an interactive shiny app under `https://philipppro.shinyapps.io/tunability/`, which displays all results of the following section in a potentially more convenient, interactive fashion and which can simply be accessed through a web browser.

5. Results and Discussion

We calculate all results for AUC, accuracy and Brier score but mainly discuss AUC results here. Tables and figures for the other measures can be accessed in the appendix and in our interactive shiny application.

5.1. Surrogate Models

We compare different possible regression models as candidates for our surrogate models: the linear model (`lm`), a simple decision tree (`rpart`), k nearest-neighbors (`kknn`) and random forest (`ranger`)[4] All algorithms are run with their default settings. We calculate 10 times repeated 10-fold cross-validated regression performance measures R^2 and Kendall's tau per dataset, and average these across all datasets.[5] Results for AUC are displayed in Figure 1. A good overall performance is achieved by `ranger` with qualitatively similar results for other classification performance measures (see Appendix). In the following we use random forest as surrogate model because it performs reasonably well and is already an established algorithm for surrogate models in the literature (Eggensperger et al., 2014; Hutter et al., 2013).

5.2. Optimal Defaults and Tunability

Table 2 displays our mean tunability results for the algorithms as defined in formula (4) w.r.t. package defaults (`Tun.P` column) and our optimal defaults (`Tun.O`). The distribution of the tunability values of the optimal defaults can be seen in Figure 2 in the modified

4. We also tried `cubist` (Kuhn et al., 2016), which provided good results but the algorithm had some technical problems for some combinations of datasets and algorithms. We did not include gaussian process which is one of the standard algorithms for surrogate models as it cannot handle categorical variables.
5. In case of `kknn` four datasets did not provide results for one of the surrogate models and were not used.

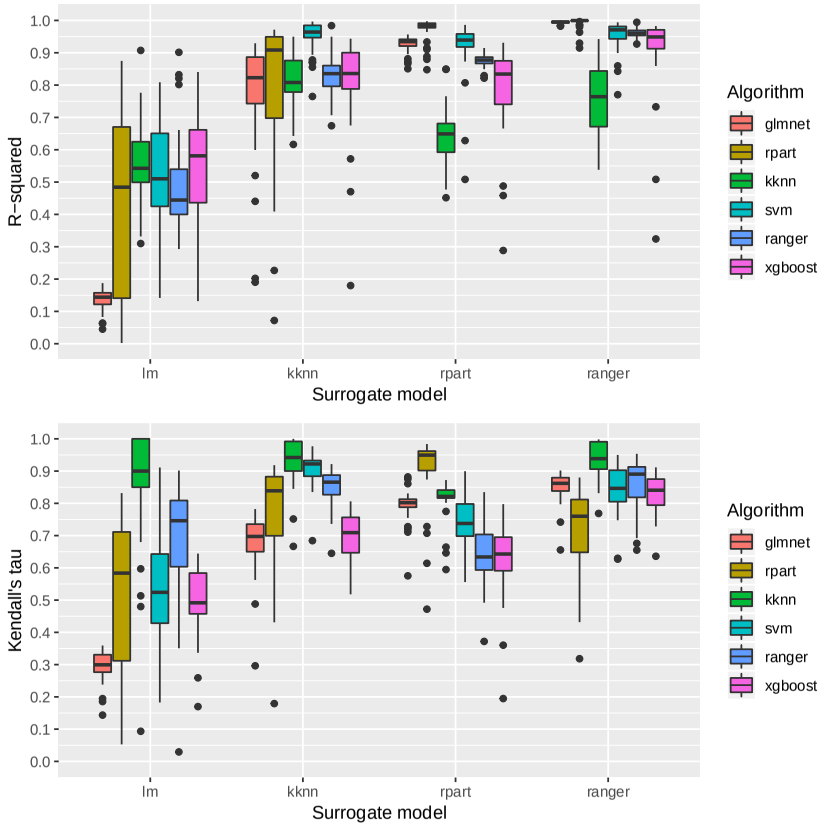

Figure 1: Average performances over the datasets of different surrogate models (target: AUC) for different algorithms (that were presented in 4.2). For an easier comparison of the surrogate models the same graph with exchanged x-axis and legend is available in the appendix in Figure 5.

Algorithm	Tun.P	Tun.O	Tun.O-CV	Improv	Impr-CV
glmnet	0.069 ± 0.019	0.024 ± 0.013	0.037 ± 0.015	0.045 ± 0.015	0.032 ± 0.015
rpart	0.038 ± 0.006	0.012 ± 0.004	0.016 ± 0.004	0.025 ± 0.006	0.022 ± 0.006
kknn	0.031 ± 0.006	0.006 ± 0.004	0.006 ± 0.004	0.025 ± 0.008	0.025 ± 0.008
svm	0.056 ± 0.011	0.042 ± 0.007	0.048 ± 0.008	0.014 ± 0.005	0.008 ± 0.007
ranger	0.010 ± 0.003	0.006 ± 0.001	0.007 ± 0.001	0.004 ± 0.003	0.003 ± 0.003
xgboost	0.043 ± 0.006	0.014 ± 0.006	0.017 ± 0.007	0.029 ± 0.003	0.026 ± 0.003

Table 2: Mean tunability (regarding AUC) with the package defaults (Tun.P) and the optimal defaults (Tun.O) as reference, cross-validated tunability (Tun.O-CV), average improvement (Improv) and cross-validated average improvement (Impr-CV) obtained by using optimal defaults compared to package defaults. The (cross-validated) improvement can be calculated by the (rounded) difference between Tun.P and Tun.O (Tun.O-CV). Standard error of the mean (SEM) is given behind the "±"-sign.

boxplots. Table 2 also displays the average improvement per algorithm when moving from package defaults to optimal defaults (`Improv`), which was positive overall. This also holds for `svm` and `ranger` although the package defaults are data dependent, which we currently cannot model (`gamma` $= 1/p$ for `svm` and `mtry` $= \sqrt{p}$ for `ranger`). As our optimal defaults are calculated based on all datasets, there is a risk of overfitting. So we perform a 5-fold cross-validation on dataset level, always calculating optimal defaults on $\frac{4}{5}$ of datasets and evaluating them on $\frac{1}{5}$ of the datasets. The results in the column `Impr-CV` in Table 2 show that the improvement compared to the package defaults is less pronounced but still positive for all algorithms.

From now on, when discussing tunability, we will only do this w.r.t. our optimal defaults.

Clearly, some algorithms such as `glmnet` and `svm` are much more tunable than the others, while `ranger` is the algorithm with the smallest tunability, which is in line with common knowledge in the web community. In the boxplots in Figure 2 for each ML algorithm, some values that are much bigger than the others are visible, which indicates that tuning has a much higher impact on some specific datasets.

5.3. Tunability of Specific Hyperparameters

In Table 3 the mean tunability (regarding the AUC) of single hyperparameters as defined in Equation (6) in Section 3.4 can be seen. Moreover, in Figure 3 the distributions of the tunability values of the hyperparameters are depicted in boxplots, which makes it possible to detect outliers and to examine skewness. The same results for the Brier score and accuracy can be found in the appendix. In the following analysis of our results, we will refer to tunability only with respect to optimal defaults.

For `glmnet` `lambda` seems to be more tunable than `alpha` regarding the AUC, especially for two datasets tuning seems to be crucial. For accuracy we observe the same pattern, while for Brier score `alpha` seems to be more tunable than `lambda` (see Figure 11 and Figure 13 in the appendix). We could not find any recommendation in the literature for

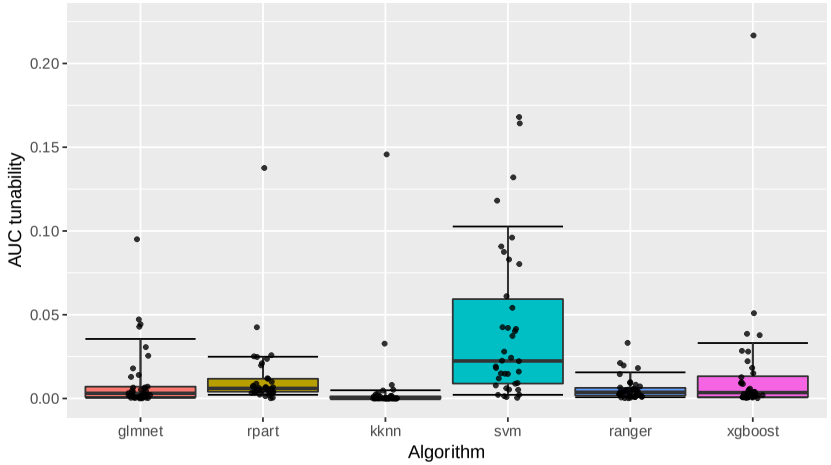

Figure 2: Boxplots of the tunabilities (AUC) of the different algorithms with respect to optimal defaults. The upper and lower whiskers (upper and lower line of the boxplot rectangle) are in our case defined as the 0.1 and 0.9 quantiles of the tunability scores. The 0.9 quantile indicates how much performance improvement can be expected on at least 10% of datasets. One outlier of `glmnet` (value 0.5) is not shown.

these two parameters. In `rpart` the `minbucket` and `minsplit` parameters seem to be the most important ones for tuning which is in line with the analysis of Mantovani et al. (2018). `k` in the `kknn` algorithm is very tunable w.r.t. package defaults, but not regarding optimal defaults. Note that the optimal default is 30 which is at the boundary of possible values, so possibly bigger values can provide further improvements. A classical suggestion in the literature (Lall and Sharma, 1996) is to use $\sqrt{n}$ as default value. This is in line with our results, as the number of observations is bigger than 900 in most of our datasets.

In `svm` the biggest gain in performance can be achieved by tuning the `kernel`, `gamma` or `degree`, while the `cost` parameter does not seem to be very tunable. To the best of our knowledge, this has not been noted in the literature yet. In `ranger` `mtry` is the most tunable parameter which is already common knowledge and is implemented in software packages such as `caret` (Kuhn, 2008). For `xgboost` there are two parameters that are quite tunable: `eta` and `booster`. The tunability of `booster` is highly influenced by an outlier as can be seen in Figure 3. The 5-fold cross-validated results can be seen in Table 10 of the appendix: they are quite similar to the non cross-validated results and for all parameters slightly higher.

Parameter	Def.P	Def.O	Tun.P	Tun.O	$q_{0.05}$	$q_{0.95}$

5.4. Tunability of Hyperparameter Combinations and Joint Gains

As an example, Table 4 displays the average tunability d_{i_1,i_2} of all 2-way hyperparameter combinations for `rpart`. Obviously, the increased flexibility in tuning a 2-way combination enables larger improvements when compared with the tunability of one of the respective individual parameters. In Table 5 the joint gain of tuning two hyperparameters g_{i_1,i_2} instead of only the best as defined in Section 3.5 can be seen. The parameters `minsplit` and `minbucket` have the biggest joint effect, which is not very surprising, as they are closely related: `minsplit` is the minimum number of observations that must exist in a node in order for a split to be attempted and `minbucket` the minimum number of observations in any terminal leaf node. If a higher value of `minsplit` than the default performs better on a dataset it is possibly not enough to set it higher without also increasing `minbucket`, so the strong relationship is quite clear. Again, further figures for other algorithms are available through the shiny app. Another remarkable example is the combination of `sample.fraction` and `min.node.size` in `ranger`: the joint gain is very low and tuning `sample.fraction` only seems to be enough, which is concordant to the results of Scornet (2018). Moreover, in `xgboost` the joint gain of `nrounds` and `eta` is relatively low, which is not surprising, as these parameters are highly connected with each other (when setting `nrounds` higher, `eta` should be set lower and vice versa).

5.5. Hyperparameter Space for Tuning

The hyperparameter space for tuning, as defined in Equation (10) in Section 3.6 and based on the 0.05 and 0.95 quantiles, is displayed in Table 3. All optimal defaults are contained in this hyperparameter space while some of the package defaults are not.

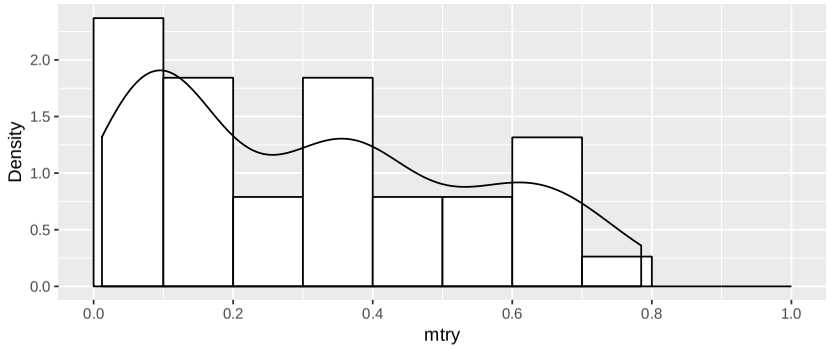

Figure 4: Density and histogram of best parameter values for `mtry` of random forest over all considered datasets.

As an example, Figure 4 displays the full histogram of the best values of `mtry` of the random forest over all datasets. Note that for quite a few datasets much higher values than the package defaults seem advantageous.

6. Conclusion and Discussion

Our paper provides concise and intuitive definitions for optimal defaults of ML algorithms and the impact of tuning them either jointly, tuning individual parameters or combinations, all based on the general concept of surrogate empirical performance models. Tunability values as defined in our framework are easily and directly interpretable as *how much performance can be gained by tuning this hyperparameter?*. This allows direct comparability of the tunability values across different algorithms.

In an extensive OpenML benchmark, we computed optimal defaults for elastic net, decision tree, k-nearest neighbors, SVM, random forest and xgboost and quantified their tunability and the tunability of their individual parameters. This—to the best of our knowledge—has never been provided before in such a principled manner. Our results are often in line with common knowledge from literature and our method itself now allows an analogous analysis for other or more complex methods.

Our framework is based on the concept of default hyperparameter values, which can be seen both as an advantage (default values are a valuable output of the approach) and as an inconvenience (the determination of the default values is an additional analysis step and needed as a reference point for most of our measures).

We now compare our method with van Rijn and Hutter (2017). In contrast to us, they apply the functional ANOVA framework from Hutter et al. (2014) on a surrogate random forest to assess the importance of hyperparameters regarding empirical performance of a support vector machine, random forest and adaboost, which results in numerical importance

scores for individual hyperparameters. Their numerical scores are - in our opinion - less directly interpretable, but they do not rely on defaults as a reference point, which one might see as an advantage. They also propose a method for calculating hyperparameter priors, combine it with the tuning procedure hyperband, and assess the performance of this new tuning procedure. In contrast, we define and calculate ranges for all hyperparameters. Setting ranges for the tuning space can be seen as a special case of a prior distribution - the uniform distribution on the specified hyperparameter space. Regarding the experimental setup, we compute more hyperparameter runs (around 2.5 million vs. 250000), but consider only the 38 binary classification datasets of OpenML100 while van Rijn and Hutter (2017) use all the 100 datasets which also contain multiclass datasets. We evaluate the performance of different surrogate models by 10 times repeated 10-fold cross-validation to choose an appropriate model and to assure that it performs reasonably well.

Our study has some limitations that could be addressed in the future: a) We only considered binary classification, where we tried to include a wider variety of datasets from different domains. In principle this is not a restriction as our methods can easily be applied to multiclass classification, regression, survival analysis or even algorithms not from machine learning whose empirical performance is reliably measurable on a problem instance. b) Uniform random sampling of hyperparameters might not scale enough for very high dimensional spaces, and a smarter sequential technique might be in order here, see Bossek et al. (2015) for an potential approach of sampling across problem instances to learn optimal mappings from problem characteristics to algorithm configurations. c) We currently are learning static defaults, which cannot depend on dataset characteristics (like number of features, or further statistical measures). Doing so might improve performance results of optimal defaults considerably, but would require a more complicated approach. A recent paper regarding this topic was published by van Rijn et al. (2018). d) Our approach still needs initial ranges to be set, in order to run our sampling procedure. Only based on these wider ranges we can then compute more precise, closer ranges.

Acknowledgments

We would like to thank Joaquin Vanschoren for support regarding the OpenML platform and Andreas Müller, Jan van Rijn, Janek Thomas and Florian Pfisterer for reviewing and useful comments. Thanks to Jenny Lee for language editing. Abstract

Recently, deep reinforcement learning (RL) methods have been applied successfully to multi-agent scenarios. Typically, the observation vector for decentralized decision making is represented by a concatenation of the (local) information an agent gathers about other agents. However, concatenation scales poorly to swarm systems with a large number of homogeneous agents as it does not exploit the fundamental properties inherent to these systems: (i) the agents in the swarm are interchangeable and (ii) the exact number of agents in the swarm is irrelevant. Therefore, we propose a new state representation for deep multi-agent RL based on mean embeddings of distributions, where we treat the agents as samples and use the empirical mean embedding as input for a decentralized policy. We define different feature spaces of the mean embedding using histograms, radial basis functions and neural networks trained end-to-end. We evaluate the representation on two well-known problems from the swarm literature — rendezvous and pursuit evasion — in a globally and locally observable setup. For the local setup we furthermore introduce simple communication protocols. Of all approaches, the mean embedding representation using neural network features enables the richest information exchange between neighboring agents, facilitating the development of complex collective strategies.

Keywords: deep reinforcement learning, swarm systems, mean embeddings, neural networks, multi-agent systems

1. Introduction

In swarm systems, many identical agents interact with each other to achieve a common goal. Typically, each agent in a swarm has limited capabilities in terms of sensing and manipulation so that the considered tasks need to be solved collectively by multiple agents.

A promising application where intelligent swarm systems take a prominent role is swarm robotics (Bayındır, 2016). Robot swarms are formed by a large number of cheap and easy to manufacture robots that can be useful in a variety of situations and tasks, such as search and rescue missions or exploration scenarios. A swarm of robots is inherently redundant towards loss of individual robots since usually none of the robots plays a specific role in the execution of the task. Because of this property, swarm-based missions are often favorable over single-robot missions (or, let alone, human missions) in hazardous environments. Behavior of natural swarms, such as foraging, formation control, collective manipulation, or the localization of a common 'food' source can be adapted to aid in these missions (Bayındır, 2016). Another field of application is routing in wireless sensor networks (Saleem et al., 2011) since each sensor in the network can be treated as an agent in a swarm.

A common method to obtain control strategies for swarm systems is to apply optimization-based approaches using a model of the agents or a graph abstraction of the swarm (Lin et al., 2004; Jadbabaie et al., 2003). Optimization-based approaches allow to compute optimal control policies for tasks that can be well modeled, such as rendezvous or consensus problems (Lin et al., 2007) and formation control (Ranjbar-Sahraei et al., 2012), or to learn pursuit strategies to capture an evader (Zhou et al., 2016). Yet, these approaches typically use simplified models of the agents / the task and often rely on unrealistic assumptions, such as operating in a connected graph (Dimarogonas and Kyriakopoulos, 2007) or having full observability of the system state (Zhou et al., 2016). Rule-based approaches use heuristics inspired by natural swarm systems, such as ants or bees (Handl and Meyer, 2007). Yet, while the resulting heuristics are often simple and can lead to complex swarm behavior, the obtained rules are difficult to adapt, even if the underlying task changes only slightly.

Recently, deep reinforcement learning (RL) strategies have become popular to solve multi-agent coordination problems. In RL, tasks are specified indirectly through a cost function, which is typically easier than defining a model of the task directly or a finding a heuristic for the controller. Having defined a cost function, the RL algorithm aims to find a policy that minimizes the expected cost. Applying deep reinforcement learning within the swarm setting, however, is challenging due to the large number of agents that need to be considered. Compared to single-agent learning, where the agent is confronted only with observations about its own state, each agent in a swarm can make observations of several other agents populating the environment and thus needs to process an entire set of information that is potentially varying in size. Accordingly, two main challenges can be identified in the swarm setting:

1. High state and observation dimensionality, caused by large system sizes.

2. Changing size of the available information set, either due to addition or removal of agents, or because the number of observed neighbors changes over time.

Most current multi-agent deep reinforcement learning methods either concatenate the information received from different agents (Lowe et al., 2017) or encode it in a multi-channel image, where the image channels contain different features based on a local view of an agent (Sunehag et al., 2017; Zheng et al., 2017). However, both types of methods bare major drawbacks. Since neural network policies assume a fixed input dimensionality, a concatenation of observations is unsuitable in the case changing agent numbers. Furthermore, a concatenation disregards the inherent permutation invariance of identical agents in a swarm system and scales poorly to large system sizes. Top-down image based representations alleviate the

issue of permutation invariance, however, the information obtained from neighboring agents is of mostly spatial nature. While additional information can be captured by adding more image channels, the dimensionality of the representation increases linearly with each feature. Furthermore, the discretization into pixels has limited accuracy due to quantization errors.

In this paper, we exploit the homogeneity of swarm systems and treat the state information perceived from neighboring agents as samples of a random variable. Based on this model, we then use mean feature embeddings (MFE) (Smola et al., 2007) to encode the current distribution of the agents. Each agent gets a local view of this distribution, where the information obtained from the neighbors is encoded in the mean embedding. Due to the sample-based view of the collected state information, we achieve a permutation invariant representation that is furthermore invariant to the number of agents in the swarm / the number of perceived neighbors.

Mean feature embeddings have so far been used mainly for kernel-based feature representations (Gretton et al., 2012), but they can be also applied to histograms or radial basis function (RBF) networks. The resulting models are closely related to the "invariant model" formulated by Zaheer et al. (2017). However, compared to the summation approach described in their paper, the averaging of feature activations proposed in our approach yields the desired invariance with respect to the observed agent number mentioned above. To the best of our knowledge, we are the first to use mean embeddings inside a deep reinforcement learning framework for swarm systems where both the feature space of the mean embedding as well as the policy are learned end-to-end.

We test our state representation on various rendezvous and pursuit evasion problems using Trust Region Policy Optimization (TRPO) (Schulman et al., 2015) as the underlying deep RL algorithm. In the rendezvous problem, the agents need to find a collective strategy that allows them to meet at some arbitrary location. In the pursuit evasion domain, a group of agents collectively tries to capture one or multiple evaders.

Policies are learned in a *centralized-learning / decentralized-execution fashion* fashion, meaning that during learning data from all agents is collected centrally and used to optimize the parameters as if there was only one agent. Nonetheless, each agent only has access to its own perception of the global system state to generate actions from the policy function. We compare our representation to several deep RL baselines as well as to optimization-based solutions, if available. Herein, we perform our experiments both in settings with global observability (i.e., all agents are neighbors) and in settings with local observability (i.e., agents are only locally connected). In the latter setting, we also evaluate different communication protocols (Hüttenrauch et al., 2018) that allow the agents to transmit additional information about their local graph structure. For example, an agent might transmit the number of neighbors within its current neighborhood. Previously, such additional information could not be encoded efficiently due to the poor scalability of the histogram-based approaches.

Our results show that agents using our representation can learn faster and obtain policies of higher quality, suggesting that the representation as mean embedding is an efficient encoding of the global state configuration for swarm-based systems. Moreover, mean embeddings are simple to implement inside existing neural network architectures and can be

applied to any deep RL algorithm, which makes the approach applicable in a wide variety of scenarios. The source code to reproduce our results can be found online.[1]

2. Related Work

The main contribution of this work lies in the development of a compact representation of state information in swarm systems, which can easily be used within deep multi-agent reinforcement learning (MARL) settings that contain homogeneous agent groups. In fact, our work is mostly orthogonal to other research in the field of MARL and the presented ideas can be incorporated into most existing approaches. To provide an overview, we begin with a brief survey of algorithms used in (deep) MARL, we revisit the basics of mean embedding theory, and we summarize some classic approaches to swarm control for the rendezvous and pursuit evasion task.

2.1. Deep RL

Recently, there has been increasing interest in deep reinforcement learning for swarms and multi-agent systems in general. For example, Zheng et al. (2017) provide a many-agent reinforcement learning platform based on a multi-channel image state representation, which uses Deep Q-Networks (DQN) (Mnih et al., 2015) to learn decentralized control strategies in large grid worlds with discrete actions. Gupta et al. (2017) show a comparison of centralized, concurrent and parameter sharing approaches to cooperative deep MARL, using TRPO (Schulman et al., 2015), DDPG (Lillicrap et al., 2015) and DQN. They evaluate each method on three tasks, one of which is a pursuit task in a grid world using bitmap-like images as state representation. A variant of DDPG for multiple agents in Markov games using a centralized action-value function is provided by Lowe et al. (2017). The authors evaluate the method on tasks like cooperative communication, navigation and others. The downside of a centralized action-value function is that the input space grows linearly with the number of agents, and hence, their approach scales poorly to large system sizes. A more scalable approach is presented by Yang et al. (2018). Employing mean field theory, the interactions within the population of agents are approximated by the interaction of a single agent with the average effect from the overall population, which has the effect that the action-value function input space stays constant. Experiments are conducted on a Gaussian squeeze problem, an Ising model, and a mixed cooperative-competitive battle game. Yet, the paper does not address the state representation problem for swarm systems.

Omidshafiei et al. (2017) investigate hysteretic Q-learning (Matignon et al., 2007) and distillation (Rusu et al., 2015). They use deep recurrent Q-networks (Hausknecht and Stone, 2015) to solve single and multi-task Dec-POMDP problems. Following this work, Palmer et al. (2017) add leniency (Panait et al., 2006) to the hysteretic approach to prevent "relative overgeneralization" of agents. The approach is evaluated on a coordinated multi-agent object transportation problem in a grid world with stochastic rewards.

Sunehag et al. (2017) tackle the "lazy agent" problem in cooperative MARL with a single team reward by training each agent with a learned additive decomposition of a value function based on the team reward. Experiments show an increase in performance on cooperative

1. `https://github.com/LCAS/deep_rl_for_swarms`

two-player games in a grid world. Rashid et al. (2018) further develop the idea with the insight that a full factorization of the value function is not necessary. Instead, they introduce a monotonicity constraint on the relationship between the global value function and each local value function. Results are presented on the StarCraft micro management domain.

Finally, Grover et al. (2018) show a framework to model agent behavior as a representation learning problem. They learn an encoder-decoder embedding of agent policies via imitation learning based on interactions and evaluate it on a cooperative particle world (Mordatch and Abbeel, 2018) and a competitive two-agent robo sumo environment (Al-Shedivat et al., 2018). The design of the policy function in the approach of Mordatch and Abbeel (2018) is similar to ours but the model uses a softmax pooling layer. However, instead of applying (model-free) reinforcement learning to optimize the parameters of the policy function, they build an end-to-end differentiable model of all agent and environment state dynamics and calculate the gradient of the return with respect to the parameters via backpropagation.

An application related to our approach can be found in the work by Gebhardt et al. (2018), where the authors use mean embeddings to learn a centralized controller for object manipulation with robot swarms. Here, the key idea is to directly embed the swarm configuration into a reproducing kernel Hilbert space, whereas our approach is based on embedding the agent's local view. Furthermore, using kernel-based feature spaces for the mean embedding scales poorly in the number of samples and in the dimensionality of the embedded information.

2.2. Optimization-Based Approaches for Swarm Systems

To provide a concise summary of the most relevant related work, we concentrate on optimization-based approaches that derive decentralized control strategies for the rendezvous and pursuit evasion problem considered in this paper. Ji and Egerstedt (2007) derive a control mechanism preserving the connectedness of a group of agents with limited communication abilities for the rendezvous and formation control problem. The method focuses on high-level control with single integrator linear state manipulation and provides no rules for agents that are not part of the agent graph. Similarly, Gennaro and Jadbabaie (2006) present a decentralized algorithm to maximize the connectivity (characterized by an exponential model) of a multi-agent system. The algorithm is based on the minimization of the second smallest eigenvalue of the Laplacian of the proximity graph. An approach providing a decentralized control strategy for the rendezvous problem for nonholonomic agents can be found in the work by Dimarogonas and Kyriakopoulos (2007). Using tools from nonsmooth Lyapunov theory and graph theory, the stability of the overall system is examined. A control strategy for the pursuit evasion problem with multiple pursuers and single evader that we investigate in more detail later in this paper was proposed Zhou et al. (2016). The authors derive decentralized control policies for the pursuers and the evader based on the minimization of Voronoi partitions. Again, the control mechanism is for high-level linear state manipulation. Furthermore, the method assumes visibility of the evader at all times. A survey on pursuit evasion in mobile robotics in general is provided by Chung et al. (2011).

2.3. Analytic Approaches

Another line of work concerned with the curse of dimensionality can be found in the area of multi-player reach-avoid games. Chen et al. (2017), for example, look at pairwise interactions between agents. This way, they are able to use the Hamilton-Jacobian-Isaacs approach to solve a partial differential equation in the joint state space of the players. Similar work can be found in (Chen et al., 2014a,b; Zhou et al., 2012).

3. Background

In this section, we give a short overview of Trust Region Policy Optimization and mean embeddings of distributions.

3.1. Trust Region Policy Optimization

Trust Region Policy Optimization is an algorithm to optimize control policies in single-agent reinforcement learning problems (Schulman et al., 2015). These problems are formulated as Markov decision processes (MDPs), which can be compactly written as a tuple $\langle \mathcal{S}, \mathcal{A}, P, R \rangle$. In an MDP, an agent chooses an action $a \in \mathcal{A}$ according to some policy $\pi(a \,|\, s)$ based on its current state $s \in \mathcal{S}$ and progresses to state $s' \in \mathcal{S}$ according to the transition dynamics P, i.e., $s' \sim P(s' \,|\, s, a)$. After each step, the agent receives a reward $r = R(s, a)$, provided by the reward function R, which judges the quality of its decision. The goal of the agent is to find a policy that maximizes the cumulative reward achieved over a certain period of time.

In TRPO, the policy is parametrized by a parameter vector θ containing the weights and biases of a neural network. In the following, we denote this parametrized policy as π_θ. The reinforcement learning objective is expressed as finding a new policy that maximizes the expected advantage function of the current policy π_{old}, i.e., $J^{\text{TRPO}} = \mathbb{E}\left[\frac{\pi_\theta}{\pi_{\theta_{\text{old}}}} A^{\pi_{\text{old}}}(s, a)\right]$, where $A^{\pi_{\text{old}}}(s, a) = Q^{\pi_{\text{old}}}(s, a) - V^{\pi_{\text{old}}}(s)$. Herein, the state-action value function $Q^{\pi_{\text{old}}}(s, a)$ is typically estimated via trajectory rollouts, while for the value function $V^{\pi_{\text{old}}}(s)$ linear or neural network baselines are used that are fitted to the Monte-Carlo returns, resulting in an estimate $\hat{A}(s, a)$ for the advantage function. The objective is to be maximized subject to a fixed constraint on the Kullback-Leibler (KL) divergence of the policy before and after the parameter update, which ensures that the updates to the policy parameters θ are bounded, in order to avoid divergence of the learning process. The overall optimization problem is summarized as

$$\begin{aligned} \underset{\theta}{\text{maximize}} \quad & \mathbb{E}\left[\frac{\pi_\theta}{\pi_{\theta_{\text{old}}}} \hat{A}(s, a)\right] \\ \text{subject to} \quad & \mathbb{E}[D_{\text{KL}}(\pi_{\theta_{\text{old}}} || \pi_\theta)] \leq \delta. \end{aligned}$$

The problem is approximately solved using conjugate gradient optimization, after linearizing the objective and quadratizing the constraint.

3.2. Mean Embeddings

Our work is inspired by the idea of embedding distributions into reproducing kernel Hilbert spaces (Smola et al., 2007) from where we borrow the concept of mean embeddings. A probability distribution $P(X)$ can be represented as an element in a reproducing kernel

Hilbert space by its expected feature map (i.e., the mean embedding),

$$\mu_X = \mathbb{E}_X[\phi(X)],$$

where $\phi(x)$ is a (possibly infinite dimensional) feature mapping. Given a set of observations $\{x_1, \ldots, x_m\}$, drawn i.i.d. from $P(X)$, the empirical estimate of the expected feature map is given by

$$\hat{\mu}_X = \frac{1}{m} \sum_{i=1}^{m} \phi(x_i).$$

Using characteristic kernel functions $k(x, x') = \langle \phi(x),\ \phi(x') \rangle$, such as Gaussian RBF or Laplace kernels, mean embeddings can be used, for example, in two-sample tests (Gretton et al., 2012) and independence tests (Gretton et al., 2008). A characteristic kernel is required to uniquely identify a distribution based on its mean embedding. However, this assumption can be relaxed to using finite feature spaces if the objective is merely to extract relevant information from a distribution such as, in our case, the information needed for the policy of the agents.

4. Deep Reinforcement Learning for Swarms

The reinforcement learning algorithm presented in the last section has been originally designed for single-agent learning. In order to apply this algorithm to the swarm setup, we switch to a different problem domain and show the implications on the learning algorithm. Policies in this context are then optimized in a centralized–learning / decentralized–execution fashion.

4.1. Problem Domain

The problem domain for our swarm system is best described as a swarm MDP environment (Šošić et al., 2017). The swarm MDP can be regarded as a special case of a decentralized partially observable Markov decision process (Dec-POMDP) (Bernstein et al., 2002) and is constructed in two steps. First, an agent prototype is defined as a tuple $\mathbb{A} = \langle \mathcal{S}, \mathcal{O}, \mathcal{A}, \pi \rangle$, determining the local properties of an agent in the system. Herein, $\mathcal{S}$ denotes the set of the agent's local states, $\mathcal{O}$ is the set of possible local observations, $\mathcal{A}$ is the set of actions available to the agent, and $\pi : \mathcal{O} \times \mathcal{A} \to [0, 1]$ is the agent's stochastic control policy. Based on this definition, the swarm MDP is constructed as $\langle N, \mathbb{A}, P, O, R \rangle$, where N is the number of agents in the system and $\mathbb{A}$ is the aforementioned agent prototype. The coupling of the agents is specified through a global state transition model $P : \mathcal{S}^N \times \mathcal{S}^N \times \mathcal{A}^N \to [0, \infty)$ and an observation model $O : \mathcal{S}^N \times \{1, \ldots, N\} \to \mathcal{O}$, which determines the local observation $\boldsymbol{o}^i \in \mathcal{O}$ for agent i at a given swarm state $\boldsymbol{s} \in \mathcal{S}^N$, i.e., $\boldsymbol{o}^i = O(\boldsymbol{s}, i)$. Finally, $R : \mathcal{S}^N \times \mathcal{A}^N \to \mathbb{R}$ is the global reward function, which encodes the cooperative task for the swarm by providing an instantaneous reward feedback $R(\boldsymbol{s}, \boldsymbol{a})$ according to the current swarm state $\boldsymbol{s}$ and the corresponding joint action assignment $\boldsymbol{a} \in \mathcal{A}^N$ of the agents. The specific state dynamics and observation models considered in this paper are described in Section 5.

The model encodes two important properties of swarm networks: First, all agents in the system are assumed to be identical, and accordingly, they are all assigned the same

decentralized policy π. This is an immediate consequence of the two-step construction of the model, which implies that all agents share the same internal architecture. Second, the agents are only partially informed about the global system state, as prescribed by the observation model O. Note that both the transition model and the observation model are assumed to be invariant to permutations of the agents in order to ensure the homogeneity of the system. For details, see (Šošić et al., 2017).

4.2. Local Observation Models

The local observation $\boldsymbol{o}^i$ introduced in the last section is a combination of observations o^i_{loc} an agent makes about local properties (like the agent's current velocity or its distance to a wall) and observations O^i of other agents. In order to describe the observation model used for the agents, we use an interaction graph representation of the swarm. This graph is given by nodes $V = \{v_1, v_2, \ldots, v_N\}$ corresponding to the agents in the swarm and an edge set $E \subset V \times V$, which we assume contains unordered pairs of the form $\{v_i, v_j\}$ indicating that agents i and j are neighbors. The interaction graph is denoted as $\mathcal{G} = (V, E)$. If both the set of nodes and the set of edges are not changing, we call $\mathcal{G}$ a static interaction graph; if either of the set undergoes changes, we instead refer to $\mathcal{G}$ as a dynamic interaction graph.

The set of neighbors of agent i in the graph $\mathcal{G}$ is given by

$$\mathcal{N}_{\mathcal{G}}(i) = \{j \,|\, \{v_i, v_j\} \in E\}.$$

Within this neighborhood, agent i can sense local information about other agents, for example distance or bearing to each neighbor. We denote the information agent i receives from agent j as $o^{i,j} = f(s^i, s^j)$, which is a function of the local states of agent i and agent j. The observation $o^{i,j}$ is available for agent i only if $j \in \mathcal{N}_{\mathcal{G}}(i)$. Hence, the complete state information agent i receives from all neighbors is given by the set $O^i = \left\{o^{i,j} \,|\, j \in \mathcal{N}_{\mathcal{G}}(i)\right\}$.

As the observations of other agents are summarized in form of sets $\{O^i\}$, we require an efficient encoding that can be used as input to a neural network policy. In particular, it must meet the following two properties:

- The encoding needs to be invariant to the indexing of the agents, respecting the unorderedness of the elements in the observation set. Only by exploiting the system's inherent homogeneity we can escape the curse of dimensionality.
- The encoding must be applicable to varying set sizes because the local graph structure might change dynamically. Even if each agent can observe the entire system at all times, the encoding should be applicable for different swarm sizes.

4.3. Local Communication Models

In addition to perceiving local state information of neighboring agents, the agents can also communicate information about the interaction graph $\mathcal{G}$ (Hüttenrauch et al., 2018). For example, agent j can transmit the number of perceived neighbors to agent i. Furthermore, the agents can also perform more complex operations on their local neighborhood graph. For example, they could compute the shortest distance to a target point (such as an evader) that is perceived by at least one agent within their local sub-graph. Hence, by using local

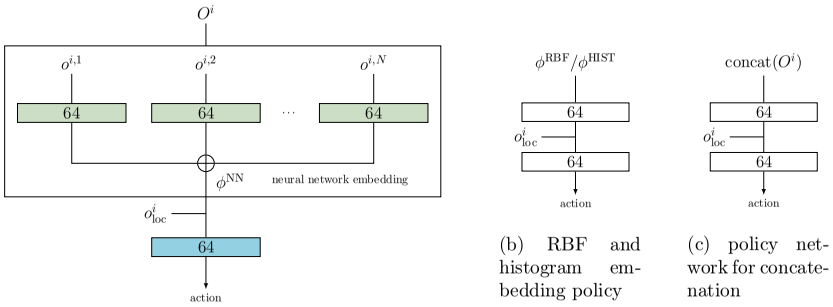
communication protocols, observation $o^{i,j}$ can contain information about both, the local states s^i and s^j as well as the graph $\mathcal{G}$, i.e., $o^{i,j} = f(s^i, s^j, \mathcal{G})$.

4.4. Mean Embeddings as State Representations for Swarms

In the simplest case, the local observation $o^{i,j}$ that agent i receives of agent j is composed of the distance and the bearing angle of agent i to agent j. However, $o^{i,j}$ can also contain more complex information, such as relative velocities or orientations. A straightforward way to represent the information set O^i is to concatenate the local quantities $\{o^{i,j}\}_j$ into a single observation vector. However, as mentioned before, this representation has various drawbacks as it ignores the permutation invariance inherent to a homogeneous agent network. Furthermore, it grows linearly with the number of agents in the swarm and is, therefore, limited to a fixed number of neighbors when used in combination with neural network policies.

To resolve these issues, we treat the elements in the information set O^i as samples from a distribution that characterizes the current swarm configuration, i.e., $o^{i,j} \sim p_i(\cdot \,|\, \mathbf{s})$. We can now use an empirical encoding of this distribution in order to achieve permutation invariance of the elements of O^i as well as flexibility to the size of O^i. As highlighted in Section 3.2, a simple way is to use a mean feature embedding, i.e.,

$$\hat{\mu}_{O^i} = \frac{1}{|O^i|} \sum_{o^{i,j} \in O^i} \phi(o^{i,j}),$$



where ϕ defines the feature space of the mean embedding. The input dimensionality to the policy is given by the dimensionality of the feature space of the mean embedding and, hence, it does not depend on the size of the information set O^i any more. This allows us to use the embedding $\hat{\mu}_{O^i}$ as input to a neural network used in deep RL. In the following sections, we describe different feature spaces that can be used for the mean embedding. Figure 1 illustrates the resulting policy architectures with further details given in Appendix F.

4.4.1. Neural Network Feature Embeddings

In line with the deep RL paradigm, we propose to use a neural network as feature mapping ϕ^{NN} whose parameters are determined by the reinforcement learning algorithm. Using a neural network to define the feature space allows us to handle high dimensional observations, which is not feasible with traditional approaches such as histograms (Hüttenrauch et al., 2018). In our experiments, a rather shallow architecture with one layer of RELU units already performed very well, but deeper architectures could be used for more complex applications. To the best of our knowledge, we present the first approach for using neural networks to define the feature space of a mean embedding.

4.4.2. Histograms

An alternative feature space are provided by histograms, which can be related to image-like representations. In this approach, we discretize the space of certain features, such as the distance and bearing to other agents, into a fixed number of bins. This way, we can collect information about neighboring agents in the form of a fixed-size multi-dimensional histogram. Herein, the histogram bins define a feature mapping ϕ^{HIST} using a one-hot-coding for each observed agent. A detailed description of this approach can be found in

(a) neural network embedding policy network

(b) RBF and histogram embedding policy

(c) policy network for concatenation

Figure 1: Illustration of (a) the neural network mean embedding policy, (b) the network architecture used for the RBF and histogram representation, and (c) for the simple concatenation of observations. The numbers inside the boxes denote the dimensionalities of the hidden layers. The color coding in (a) highlights which layers share the same weights. The plus sign denotes the mean of the feature activations.

our previous work (Hüttenrauch et al., 2018). While the approach works well in discrete environments where each cell is only occupied by a single agent, the representation can lead to blurring effects between agents in the continuous case. Moreover, the histogram approach does not scale well with the dimensionality of the feature space.

4.4.3. Radial Basis Functions

A specific problem of the histogram approach is the hard assignment of agents into bins, which results in abrupt changes in the observation space when a neighboring agent moves from one bin to another. A more fine-grained representation can be achieved by using RBF networks with a fixed number of basis functions evenly distributed over the observation space. The resulting feature mapping ϕ^{RBF} is then defined by the activations of each basis function and can be seen as a "soft-assigned" histogram. However, both representations (histogram and RBF) suffer from the curse of dimensionality, as the number of required basis functions typically increases exponentially with the number of dimensions of the observation vector.

4.5. Other Representation Techniques

Inspired by the work of Mordatch and Abbeel (2018), we also investigate a policy function that uses a softmax pooling layer instead of the mean embedding. The elements of the pooling layer $\psi = [\psi_1, \ldots, \psi_K]$ are given by

$$\psi_k = \frac{\sum_{o^{i,j} \in O^i} \exp\left(\alpha \phi_k(o^{i,j})\right) \phi_k(o^{i,j})}{\sum_{o^{i,j} \in O^i} \exp\left(\alpha \phi_k(o^{i,j})\right)}$$

for each feature dimension of $\phi = [\phi_1, \dots, \phi_K]$ with a temperature parameter α. Note that the representation becomes identical to our mean embedding for $\alpha = 0$, while setting $\alpha \gg 1$ results in max-pooling and $\alpha \ll -1$ corresponds to min-pooling. In our experiments, we choose $\alpha = 1$ as a trade-off between a mean embedding and max-pooling and additionally study the performance of max-pooling over each individual feature dimension.

4.6. Adaption of TRPO to the Homogeneous Swarm Setup

Gupta et al. (2017) present a parameter-sharing variant of TRPO that can be used in a multi-agent setup. During the learning phase, the algorithm collects experiences made by all agents and uses these experiences to optimize one policy with a single set of parameters θ. Since, in the swarm setup, we assume homogeneous agents that are potentially indistinguishable to each other, we omit the agent index introduced by Gupta et al. (2017). The optimization problem is expressed using advantage values based on all agents' observations. During execution, however, each agent has only access to its own perception. Hence, the terminology of centralized–learning / decentralized–execution is chosen.

During the trajectory roll-outs, we use a sub-sampling strategy to achieve a trade-off between the number of samples and the variability in advantage values seen by the learning algorithm. Our implementation is based on the OpenAI baselines version of TRPO with 10 MPI workers, where each worker samples 2048 time steps, resulting in $2048N$ samples. Subsequently, we randomly choose the data of 8 agents, yielding $2048 \times 10 \times 8 = 163840$ samples per TRPO iteration. The chosen number of samples worked well throughout our experiments and was not extensively tuned.

5. Experimental Results

Our experiments are designed to study the use of mean embeddings in a cooperative swarm setting. The three main aspects are:

1. How do the different mean embeddings (neural networks, histograms and RBF representation) compare when provided with the same state information content?

2. How does the mean embedding using neural networks perform when provided with additional state information while keeping the dimensionality of the feature space constant?

3. How does the mean embedding of neural network features compare against other pooling techniques?

In this section, we first introduce the swarm model used for our experiments and present the results of different evaluations afterwards. During a policy update, a fixed number of K trajectories are sampled, each yielding a return of $G_k = \sum_{t=1}^{T} r(t)$. The results are presented in terms of the average return, denoted as $\bar{G} = \frac{1}{K} \sum_{k=1}^{K} G_k$. Videos demonstrating the agents' behavior in the different tasks can be found online.[2]

2. http://computational-learning.net/deep_rl_for_swarms

5.1. Swarm Models

Our agents are modeled as unicycles (a commonly used agent model in mobile robotics; see, for example, Egerstedt and Hu, 2001), where the control parameters either manipulate the linear and angular velocities v and ω (single integrator dynamics) or the corresponding accelerations $\dot{v}$ and $\dot{\omega}$ (double integrator dynamics). In the single integrator case, the state of an agent is defined by its location $\boldsymbol{x} = (x, y)$ and orientation ϕ. In case of double integrator dynamics, the agent is additionally characterized by its current velocities. The exact state definition and kinematic models can be found in Appendix A. Note that these agent models are more complex than what is typically considered in optimization-based approaches, which mostly assume single integrator dynamics directly on $\boldsymbol{x}$. Depending on the task, we either opt for a closed state space where the limits act as walls, or a periodic toroidal state space where agents exceeding the boundaries reappear on the opposite side of the space. Either way, the state is bounded by $x_{\max} = y_{\max} = 100$.

We study two different observation scenarios for the agents, i.e., global observability and local observability. In the case of global observability, all agents are neighbors, i.e.

$$\mathcal{N}_{\mathcal{G}}(i) = \{j \in \{1, \dots, N\} \,|\, i \neq j\},$$

which corresponds to a fully connected static interaction graph. For the local observability case, we use Δ-disk proximity graphs, where edges are formed if the distance $d^{i,j} = \sqrt{(x^i - x^j)^2 + (y^i - y^j)^2}$ between agents i and j is less than a pre-defined cut-off distance d_c for communication, resulting in a dynamic interaction graph. The neighborhood set of the graph is then defined as

$$\mathcal{N}_{\mathcal{G}}(i) = \{j \in \{1, \dots, N\} \,|\, i \neq j,\ d^{i,j} \leq d_c\}.$$

For a detailed description of all observational features available to the agents in the tasks, see Appendices B and C.

5.2. Rendezvous

In the rendezvous problem, the goal is to minimize the distances between all agents. The reason why we choose this experiment is because a simple optimization-based baseline controller can be defined by the consensus protocol,

$$\dot{\boldsymbol{x}}^i = -\sum_{j \in \mathcal{N}(i)} (\boldsymbol{x}^i - \boldsymbol{x}^j),$$

where $\boldsymbol{x}^i = (x^i, y^i)$ denotes the location of agent i. To make the solution compatible to the double integrator agent model, we make use of a PD-controller (see Appendix A for details). The reward function for the problem can be found in Appendix E.1.

We evaluate different observation vectors $o^{i,j}$ which are fed into the policy. To compare the histogram and RBF embedding with the proposed neural network approach, we restrict the *basic* observation model (see below) to a set of two features: the distance $d^{i,j}$ between two agents and the corresponding bearing $\phi^{i,j}$. This restriction allows for a comparison to the optimization-based consensus protocol, which is based on displacements (an equivalent formulation of distance and bearing). To show that the neural network embeddings can

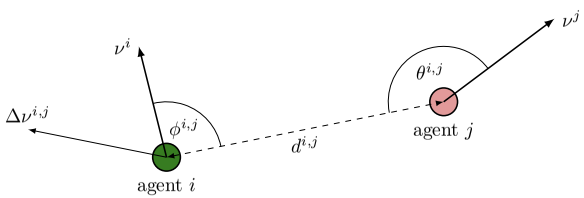


Figure 2: Illustration of two neighboring agents facing the direction of their velocity vectors ν^i and ν^j, along with the observed quantities, shown with respect to agent i. The observed quantities are the bearing $\phi^{i,j}$ to agent j, agent j's relative orientation $\theta^{i,j}$ to agent i, their distance $d^{i,j}$ and a relative velocity vector $\Delta\nu^{i,j} = \nu^i - \nu^j$. In this trivial example, agent i's observed neighborhood size as well as the neighborhood size communicated by agent j are $|\mathcal{N}(i)| = |\mathcal{N}(j)| = 1$.

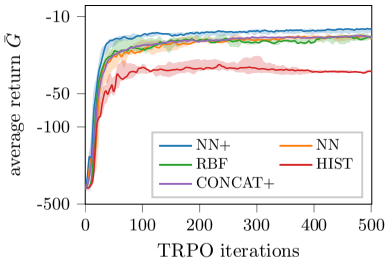
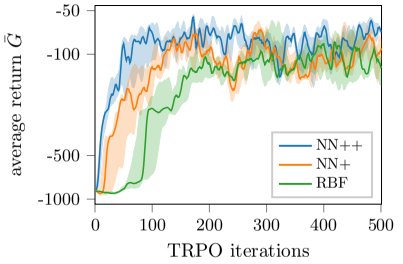
be used with more informative observations, we further introduce an *extended* set and a communication (*comm*) set. These sets may include relative orientations $\theta^{i,j}$ or relative velocities $\Delta\nu^{i,j}$ (depending on the agent dynamics), as well as the own neighborhood size and those of the neighbors. An illustration of these quantities can be found in Figure 2.

5.2.1. Global Observability



First, we study the rendezvous problem with 20 agents in the global observability setting with double integrator dynamics to illustrate the algorithm's ability to handle complex dynamics. To this end, we compare the performances of policies using histogram, RBF and neural network embeddings on the *basic* set, as well as neural network embeddings on the *extended* set. The observations $o^{i,j}$ in the *basic* set comprise the distance $d^{i,j}$ and bearing $\phi^{i,j}$. In the *extended* set, which is processed only via neural network embeddings, we additionally add neighboring agents' relative orientations $\theta^{i,j}$ and velocities $\Delta\nu^{i,j}$. The local properties o^i_{loc} consist of a shortest distance and orientation to the closest boundary, i.e., d^i_{wall} and ϕ^i_{wall}. The sets are summarized as follows:

$$\begin{aligned} \textit{Basic}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}}\} \\ \textit{Extended}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j},\ \theta^{i,j},\ \Delta\nu^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}}\}. \end{aligned}$$

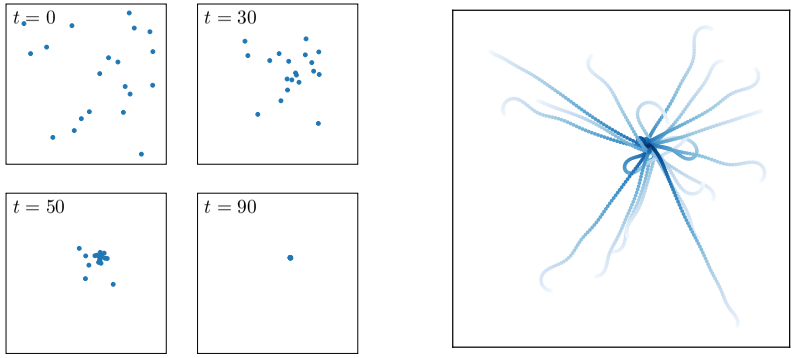


The results are shown in Figure 3a. On first sight, they reveal that all shown methods eventually find a successful strategy, with the histogram approach showing worst performance. Upon a closer look, it can be seen that the best solutions are found with the neural network embedding, in which case the learning algorithm also converges faster, demonstrating that this form of embedding serves as a suitable representation for deep RL. However, there are two important things to note:

- The differences between the approaches seem to be small due to the wide range of obtained reward values, but the NN+ method brings in fact a significant performance gain. Compared to the NN and RBF embedding, the performance of the learned NN+ policy is ∼10% better in terms of the average return of an episode (Figure 3a) and almost twice as good ($\sim 4 \times 10^{-2}$ versus $\sim 8 \times 10^{-2}$) in terms of the mean distance between agents at the steady state solution after around 200 time steps (Figure 5a). Furthermore, the NN+ embedding reaches the mean distance achieved by the NN and RBF embeddings roughly 20 to 30 time steps earlier, which corresponds to an improvement of ∼25%.

- Although the performance gain of NN+ can be partly explained by the use of the extended feature set, experiments with the same feature set using the histogram / RBF approach did *not* succeed to find solutions to the rendezvous problem; hence, the corresponding results are omitted. The reason is that the dimensionality of the input space scales exponentially for the histogram / RBF approach while only linearly for the neural network embedding, which results in a more compact feature representation that keeps the learning problem tractable.

(a) 20 agents with global observability



(b) 20 agents with local observability

Figure 3: Learning curves for the rendezvous task with different observation models. The curves show the median of the average return $\bar{G}$ based on the top five trials on a log scale. **Legend:** NN++: neural network mean embedding of *comm* set, NN+: neural network mean embedding of *extended* set, NN: neural network embedding of *basic* set, RBF: radial basis function embedding of *basic* set, HIST: histogram embedding of *basic* set, CONCAT+: simple concatenation of *extended* set.

Together, these two observations suggest that the neural network embedding provides a suitable learning architecture for deep RL, whereas the histogram / RBF approach is only suited for low-dimensional spaces.

Figure 4 shows a visualization of a policy using the neural network mean embedding of the *extended* set. After random initialization, the agents' locations quickly converge to a single point. Figure 5 shows performance evaluations of the best policies found with each of the mean embedding approaches. We plot the evolution of the mean distance between all agents over 1000 episodes with equal starting conditions. We also include the performance of the PD-controller defined in Appendix A. It can be seen in Figures 5a and 5c that the policies using the neural network embeddings decrease the mean distance most quickly and also find

(a) snapshots (b) full episode

Figure 4: Visualization of a learned policy for the pursuit evasion task. The policy is learned and executed by 10 agents using a neural network mean embedding of the *extended* set. Pursuers are illustrated in blue, the evader is highlighted in red. Visualization of a learned policy for the rendezvous task. The policy is learned and executed by 20 agents using a neural network mean embedding of the *extended* set.

the best steady-state solutions among all learning approaches. While the optimization-based solution (PD) eventually drives the mean distance to zero, a small error remains for the learning-based approaches. However, the learned policies are faster in reducing the distance and therefore show a better average reward. Although the optimization-based policy is guaranteed to find an optimal stationary solution, the approach is build for simpler dynamics and hence performs suboptimally in the considered scenario. Note, that the controller gains for this approach have been tuned manually to maximize performance.

In order to show the generalization abilities of the embeddings, we finally evaluate the obtained policies (except for the concatenation) with 100 agents. The results are displayed in Figure 5b. Again, the neural network embedding of the *extended* set is quickest in reducing the inter-agent distances, resulting in the best overall performance.

5.2.2. Local Observability

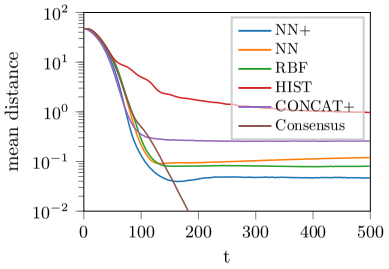
The local observability case is studied with 20 agents and a communication cut-off distance of $d_c = 40$. Due to the increased difficulty of the task, we resort to single integrator dynamics for this experiment. Again, we evaluate the *basic* and the *extended* set, which in this case contains the single integrator state information. Accordingly, we remove the relative velocities from the information sets. Moreover, we employ a local communication strategy that transmits the number of observed neighbors as additional information. Note that this information can be used by the agents to estimate in which direction the center of mass of the swarm is located.

While the received neighborhood sizes $\{|\mathcal{N}(j)|\}_{j\in\mathcal{N}(i)}$ are treated as part of agent i's local observation of the swarm, the own perceived neighborhood size $|\mathcal{N}(i)|$ is considered as part of the local features o^i_{loc}. The observation models for the local observability case are thus summarized as:

$$\begin{aligned}
\textit{Basic}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}}\} \\
\textit{Extended}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j},\ \theta^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}}\} \\
\textit{Comm}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j},\ \theta^{i,j},\ |\mathcal{N}(j)|\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}},\ |\mathcal{N}(i)|\}.
\end{aligned}$$

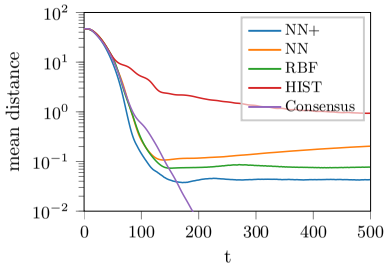
For the experiment, we limit our comparison to RBF embeddings (which showed best performance among all non-neural-network solutions) of the *basic* set and neural network embeddings of the *extended* set and the *comm* set. The results are illustrated in Figure 3b, which shows that the neural network embeddings lead to a quicker learning progress. Furthermore, by introducing the *comm* model, a higher return is achieved. Compared to the global observability case, however, the learning process exhibits an increased variance caused by the information loss in the reward signal (see Appendix E).

Figure 5c illustrates the performances of the learned policies. Again, the neural network embedding is quicker in reducing the inter-agent distances and converges to better steady-state solutions. In order to test the efficacy of the communication protocol, we further evaluate the learned policies with 10 agents. The results are displayed in Figure 5d. As expected, the performance decreases due to the lower chance of agents seeing each other but we still notice a benefit caused by the communication.



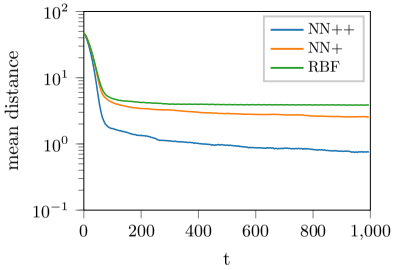
5.3. Pursuit Evasion with a Single Evader

Our implementation of the pursuit evasion scenario is based on the work by Zhou et al. (2016), from which we adopt the evader strategy. The strategy is based on Voronoi regions, which the pursuers try to minimize and the evader tries to maximize. While the original paper considers a closed world, we change the world type from closed to periodic, thereby making it impossible to trap the evader in a corner. In order to encourage a higher level of coordination between the agents, we set the evader's maximum velocity to twice the pursuers' maximum velocity. An episode ends once the evader is caught, i.e., if the distance of the closest pursuer is below a certain threshold. In all our experiments, the evader policy is fixed and not part of the learning process. The reward function for the problem is based on the shortest distance of the closest pursuer and can be found in Appendix E.2.

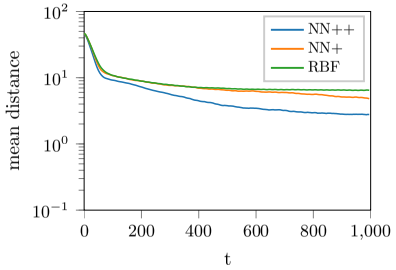


5.3.1. Global Observability

Again, we study the global observability case with ten agents. Since the pursuit of an evader is a more challenging task already, we reduce the movement complexity to single integrator dynamics. The *basic* and *extended* set are equal to those in the rendezvous experiment with single integrator dynamics, with additional information about the evader in the local properties o^i_{loc}. In here, we add the distance $d^{i,e}$ and bearing $\phi^{i,e}$ of agent i to the evader e. Accordingly, the observation sets are given as:



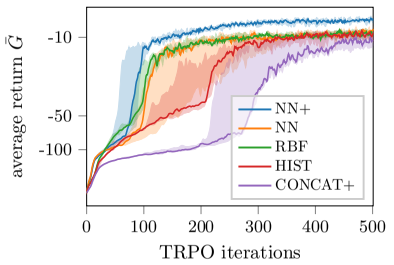
$$\begin{aligned}
\textit{Basic}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}},\ d^{i,e},\ \phi^{i,e}\} \\
\textit{Extended}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j},\ \theta^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}},\ d^{i,e},\ \phi^{i,e}\}.
\end{aligned}$$



(a) 20 agents (global observability)

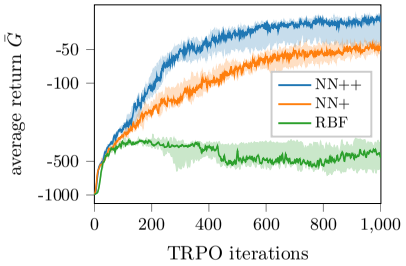
(b) 100 agents (global observability)

(c) 20 agents (local observability)



(d) 10 agents (local observability)

Figure 5: Comparison of the mean distance between agents in the rendezvous experiment achieved by the best learned policies and the consensus protocol. In (a) and (b), the policy is learned with 20 agents and executed by 20 and 100 agents, respectively. In (c) and (d), the policy is learned with 20 agents and executed by 20 and 10 agents. Results are averaged over 1000 episodes with identical starting conditions.



The results in Figure 6a reveal that successful strategies can be obtained with all methods. However, this time, a clear advantage can be seen for the policies using neural network mean embeddings of the *extended* set, both in terms of behavior quality and in the number of samples necessary to find the solution.

Figure 7 illustrates the strategy that such a policy exerts. After random initialization, the agents first spread in a way that leaves no possibility for the evader to increase its Voronoi region, thereby keeping the evader almost on the same spot. Once this configuration is reached, they surround the evader in a circular pattern and start to reduce the distance until one pursuer successfully reaches the distance threshold.

To investigate the performance of the best mean embedding policies (learned with 10 agents), we estimate the corresponding probabilities that the evader is caught within a certain time frame. For the sake of completeness, we also include the method proposed by Zhou

(b) full episode

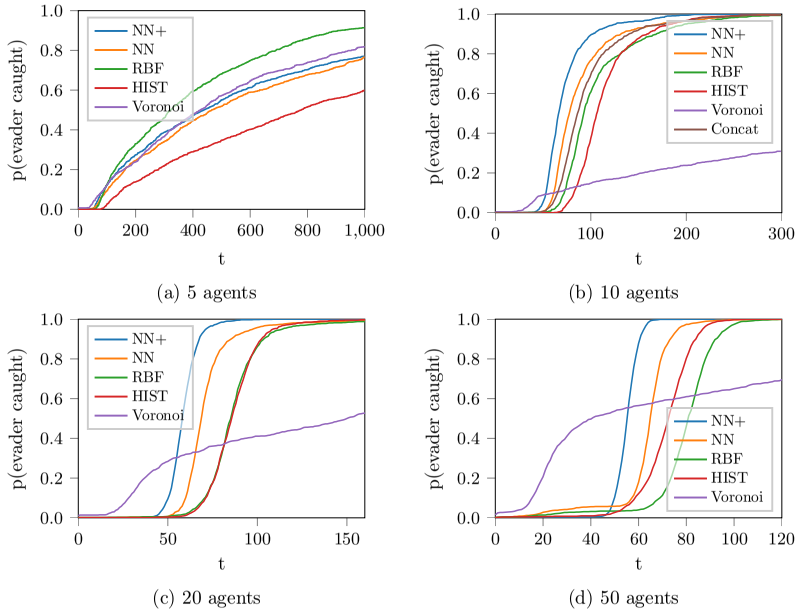
Figure 7: Visualization of a learned policy for the pursuit evasion task. The policy is learned and executed by 10 agents using a neural network mean embedding of the *extended* set. Pursuers are illustrated in blue, the evader is highlighted in red.

et al. (2016), which was originally not designed for a setup with a faster evader, though. The results are plotted in Figure 8 as the fraction of episodes ending at the respective time instant, averaged over 1000 episodes. The plot in Figure 8b reveals that the evader may be caught using all presented methods if the policies are executed for long time periods. As already indicated by the learning curves, using a neural network mean embedding representation yields the quickest capture among all methods. The additional information in the *extended* set further increases performance.

Next, we examine the generalization abilities of the learned policies, this time on scenarios with 5, 20 and 50 agents (Figures 8a,c,d). Increasing the amount of agents leads to a quicker capture for all methods; however, the best performance is still shown by the agents executing a neural network policy based on embeddings of the *extended* set. Interestingly, when using fewer agents than in the original setup (Figure 8a), all methods struggle to capture the evader. After inspection of the behavior, we found that the strategy of establishing a circle around the evader causes too large gaps between the agents through which the evader can escape.

5.3.2. Local Observability

The local observability case is studied with 20 agents and a communication cut-off distance of $d_c = 40$. Additionally, we introduce an observation radius $d_o = 20$ within which the pursuers can observe the distance and bearing to the evader. We reuse the *basic* and *extended* set from last section and modify the *comm* set to include the shortest path information of other agents in the neighborhood of agent i to the evader. This way, each agent i can compute a shortest path to the evader over a graph of connected agents, such that the path $P = (v^1, v^2, \dots, v^M)$ minimizes the sum $d^{i,e}_{\text{min}} = \sum_{m=1}^{M-1} d^{m,m+1}$ where v^1 represents agent i and v^M is the evader. The observation sets are given as:



$$
\begin{aligned}
\textit{Basic}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}},\ d^{i,e},\ \phi^{i,e}\} \\
\textit{Extended}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j},\ \theta^{i,j}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}},\ d^{i,e},\ \phi^{i,e}\} \\
\textit{Comm}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j},\ \theta^{i,j},\ d^{j,e}_{\text{min}}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}},\ d^{i,e},\ \phi^{i,e},\ d^{i,e}_{\text{min}}\}.
\end{aligned}
$$

Note that in this case the distance and bearing to an evader are only available if $d^{i,e} \leq d_o$. Furthermore, the correct shortest path is only available if an agent and the evader are in the same sub-graph, otherwise, a pre-defined value is fed into the policy.

Again, we limit the comparison for the local observability case to the more promising methods of neural network and RBF mean embeddings. The results in Figure 6b show that the performance gain of the neural network mean embeddings is even more noticeable than in the global observability case, with a clear advantage in the presence of the local communication protocols. The inspection of the termination probabilities in Figure 9 confirms that the neural network mean embedding results in a significantly improved policy.

5.4. Pursuit Evasion with Multiple Evaders

Lastly, we study a pursuit evasion scenario with multiple evaders, i.e., we assume that agent i receives observation samples $\{o^{i,e}\}$ from several evaders, which are processed using a second mean embedding to account for the variable set size. Where in the previous experiment

(a) 5 agents (b) 10 agents

(c) 20 agents (d) 50 agents

Figure 8: Performance comparison of the best learned policies and the optimization approach minimizing Voronoi regions in the pursuit evasion task with global observability. The curves show the probability that the evader is caught after t time steps. All policies are learned with 10 agents but executed with different agent numbers, as indicated below each subfigure. Results are averaged over 1000 episodes with identical starting conditions.

the agents had precise information about the evader in terms of distance and bearing, they now have to extract this information from the respective embedding. An additional level of difficulty results from the fact that the reward function no longer provides any guidance in terms of the distances to the evaders since it only counts the number of evaders caught in each time step (see Appendix E.3 for details).

We study a scenario with 50 pursuers and 5 evaders using the global observability setup in Section 5.3.1, except that we respawn caught evaders to a new random location instead of terminating the episode. The observation sets, containing the same type of information but arranged according to the inputs of the neural networks, are designed as follows:

$$
\begin{aligned}
\textit{Basic}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j}\} && o^{i,e} = \{d^{i,e},\ \phi^{i,e}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}}\} \\
\textit{Extended}: \quad & o^{i,j} = \{d^{i,j},\ \phi^{i,j},\ \theta^{i,j}\} && o^{i,e} = \{d^{i,e},\ \phi^{i,e}\} && o^i_{\text{loc}} = \{d^i_{\text{wall}},\ \phi^i_{\text{wall}}\}.
\end{aligned}
$$

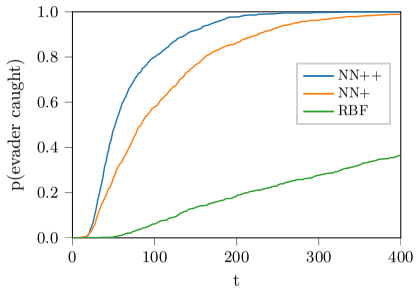


Figure 9: Performance comparison of the best policies in the pursuit evasion task with local observability. The curves show the probability that the evader is caught after t time steps. All policies are learned and executed by 20 agents. Results are averaged over 1000 episodes with identical starting conditions.

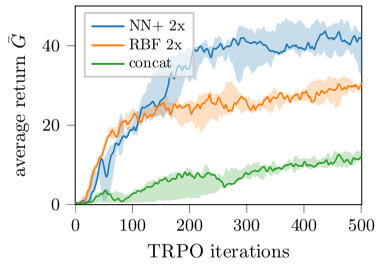

Figure 10a shows the learning curves for policies with neural network and RBF mean embeddings and for the concatenation approach. The return directly relates to the number of evaders caught during an episode. Again, the neural network mean embedding performs significantly better than the RBF embedding. The curves clearly indicate the positive influence of the additional information present in the *extended* set. With this amount of agents, the dimensionality of the concatenation has increased to a point where learning is no longer feasible.

5.5. Evaluation of Pooling Functions

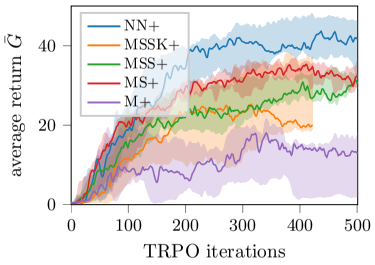

Figure 11 shows learning curves of policies based on mean embeddings, softmax pooling, and max-pooling (as described in Section 4.5) of features of the *extended* set for the rendezvous and pursuit evasion task with global observability.

In the rendezvous task (Figure 11a), all pooling techniques eventually manage to find a good solution. Policies using neural network mean embedding, however, on average converge more quickly while policies using max-pooling show slightly worse performance. Given its reduced computational complexity compared to the softmax-pooling, the mean embedding provides the most effective approach among all proposed architectures.

When examining the results of the pursuit evasion task (Figure 11b), we find that the algorithm produces two distinct solutions. A sub-optimal one, which is only able to circle the evader but is unable to catch it (a catch is realized if the distance of the closest pursuer to the evader is below a certain threshold), and a solution which additionally catches the evader after a short period of time. Therefore, we not only report the performance of the top 5 trials out of 16, but also provide the number of times the algorithm was able to discover the better of the two solution (Table 1). Once that the algorithm finds a good solution, the mean embedding and softmax solutions perform comparably well but the max-pooling approach shows a significantly worse performance. More importantly, however, the algorithm was

able to find the good solution more often using the mean embedding than using the other pooling approaches.

mean	sm	max
10/16	6/16	4/16

Table 1: Number of times the algorithm discovered policies that led to a successful catch.

5.6. Comparison to Moment-Based Representations

Finally, we compare the mean embedding of neural network features to a representation using statistics of the input. Figure 10b shows an evaluation on the pursuit evasion task with 50 agents and 5 evaders. Here, we use combinations of the empirical mean, standard deviation, skew and kurtosis of each feature of the *extended* set as the input to a policy function. The plot reveals that neural network mean embeddings can capture more relevant information about the characteristics of the distribution of agents than simple statistics of the elements in the *extended* set. Similar results were obtained for the other tasks although the differences in performance were less pronounced.

5.7. Computational Complexity

Unlike in classical optimization-based control, where the controller is derived from an assumed dynamics model, model-free reinforcement learning methods like TRPO find their control policies through interaction with the environment, without requiring explicit knowledge of the underlying system dynamics. While this comes at the cost of an additional exploration phase, learning-based approaches typically offer an increased flexibility in that the same control architecture can adapt to different tasks and environments, without being affected by potential model mismatches. More importantly, considering the final learned policy from a computational perspective, the synthesis of the control signal involves no additional conceptual steps compared to an optimization-based approach.

While a typical experiment with 20 agents in our setup takes between four and six hours of training on a machine with ten cores (sampling trajectories in parallel), a forward pass through the trained neural network to compute the instantaneous control signal takes only about 1 ms, which enables an execution in real time. Furthermore, all control strategies learned through our framework are decentralized, which allows an arbitrary system size scaling in a real swarm network, where the required computations are naturally distributed over all agents. When learning new policies, the memory requirements scale $\mathcal{O}(N(N-1))$ with the number of agents (assuming global observability) since we need to store the local views of all agents. However, decentralized execution after the policy is learned scales linearly in N per agent. An incremental online computation of the mean can be chosen if memory restrictions exist (Finch, 2009).

For comparison, the complexity of calculating Voronoi regions for the pursuit evasion policy scales $\mathcal{O}(N \log N)$ with the number of agents (Aurenhammer, 1991). Concerning the system sizes considered in our experiments, the resulting computation time of both policy types is in the same order of magnitude during task execution.

6. Conclusion

In this paper, we proposed the use of mean feature embeddings as state representations to overcome two major problems in deep reinforcement learning for swarms: the high and possibly changing dimensionality of information perceived by each agent. We introduced three different approaches to realize such embeddings — two manually designed approaches based on histograms / radial basis functions and an end-to-end learned neural network feature representation. We evaluated the approaches on different variations of the rendezvous and pursuit evasion problem and compared their performances to that of a naive feature concatenation method and classical approaches found in the literature. Our evaluation revealed that learning embeddings end-to-end using neural network features scales well with increasing agent numbers, leads to better performing policies, and often results in faster convergence compared to all other approaches. As expected, the naive concatenation approach fails for larger system sizes.

Acknowledgments

Appendix A. Agent Kinematics

In the single integrator case, the state of an agent is given by $s^i = [x^i, y^i, \phi^i] \in \mathcal{S} = \{[x, y, \phi] \in \mathbb{R}^3 : 0 \leq x \leq x_{\max},\ 0 \leq y \leq y_{\max},\ 0 \leq \phi < 2\pi\}$, and the linear velocity v and angular velocity ω can be directly controlled by the agent. The kinematic model is given by

$$\begin{aligned}\dot{x} &= v\cos\phi\\ \dot{y} &= v\sin\phi\\ \dot{\phi} &= \omega.\end{aligned}$$

In the double integrator case, the state is given by $s^i = [x^i, y^i, \phi^i, v^i, \omega^i] \in \mathcal{S} = \{[x, y, \phi, v, \omega] \in \mathbb{R}^5 : 0 \leq x \leq x_{\max},\ 0 \leq y \leq y_{\max},\ 0 \leq \phi < 2\pi, |v| \leq v_{\max}, |\omega| \leq \omega_{\max}\}$ and the agent can only indirectly change its velocity by acceleration. With the control inputs a_v and a_ω, the model is then given by

$$\begin{aligned}\dot{v} &= a_v\\ \dot{\omega} &= a_\omega\\ \dot{x} &= v\cos\phi\\ \dot{y} &= v\sin\phi\\ \dot{\phi} &= \omega.\end{aligned}$$

For the experiments, we use finite differences to model the system in discrete time.

Appendix B. Observation Model

Irrespective of the task, an agent i can sense the following properties about other agents $j \in \mathcal{N}(i)$ within its neighborhood:

$$
\begin{aligned}
d^{i,j} & && \text{distance to neighboring agents} \\
\phi^{i,j} &= \arctan(\frac{y^j - y^i}{x^j - x^i}) - \phi^i && \text{bearing to neighboring agents} \\
\theta^{i,j} &= \arctan(\frac{y^i - y^j}{x^i - x^j}) - \phi^j && \text{relative orientation} \\
\Delta v^{i,j} &= v^i \left[\cos\phi^i, \sin\phi^i\right] - v^j \left[\cos\phi^j, \sin\phi^j\right] && \text{relative velocity}
\end{aligned}
$$

Furthermore, each agent has access to the following local properties:

$$
\begin{aligned}
d^i_{\text{wall}} &= \min(x^i - x_{\min},\ y^i - y_{\min},\ x_{\max} - x^i, y_{\max} - y^i) && \text{distance to closest wall} \\
\phi^i_{\text{wall}} &= \varphi^i_{\text{wall}} - \phi^i && \text{orientation to closest wall} \\
v^i, \omega^i & && \text{own velocity}
\end{aligned}
$$

where φ^i_{wall} denotes the absolute bearing of agent i to the closest wall segment.

Appendix C. Task Specific Communication Protocols

In the rendezvous task, agent i additionally can sense information about neighborhood sizes:

$$
\begin{aligned}
|\mathcal{N}(i)| & && \text{own neighborhood size} \\
|\mathcal{N}(j)| : j \in \mathcal{N}(i) & && \text{neighborhood size of neighbor } j
\end{aligned}
$$

In pursuit evasion, we additionally have one or multiple evaders with states $s^e = [x^e, y^e] \in \{[x, y] \in \mathbb{R}^2 : 0 \le x \le x_{\max},\ 0 \le y \le y_{\max}\}$. Agents can sense the distance and bearing to an evader, given that the evader is within an observation distance d_o:

$$
\begin{aligned}
d^{i,e} &= \sqrt{(x^i - x^e)^2 + (y^i - y^e)^2} \quad \text{if } d^{i,e} \le d_o && \text{distance to evader} \\
\phi^{i,e} &= \arctan(\frac{y^e - y^i}{x^e - x^i}) - \phi^i \quad \text{if } d^{i,e} \le d_o && \text{bearing to evader}
\end{aligned}
$$

Furthermore, we assume that each agent i can compute a shortest path to the evader over a graph of connected agents, such that the path $P = (v^1, v^2 \ldots, v^M)$ minimizes the sum $\sum_{m=1}^{M-1} d^{m,m+1}$ where v^1 is agent i and v^M is the evader.

Appendix D. Controller for Double Integrator Dynamics

We use a simple PD-controller to transform the consensus protocol with high-level direct state manipulation to the unicycle model with double integrator dynamics. It is given by

$$
\begin{aligned}
a_v &= K_1(v_d - v) \\
a_\omega &= K_2(\phi_d - \phi) + D_2(\omega_d - \omega) \\
v_d &= \|\dot{\boldsymbol{x}}\| \\
\phi_d &= \arctan(\frac{\dot{y}}{\dot{x}}) \\
\omega_d &= 0,
\end{aligned}
$$

where the parameters K_1, K_2 and D_2 are tuned manually to give good performance on the problem.

Appendix E. Reward Functions

E.1. Rendezvous

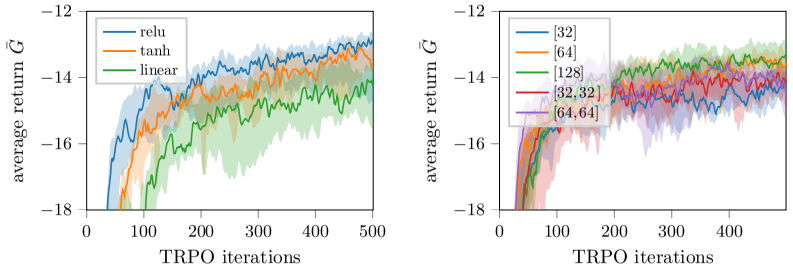
The reward function is defined in terms of the inter-agent distances $\{d^{i,j}\}$ as

$$
R(\boldsymbol{s}, \boldsymbol{a}) = \alpha \sum_{i=1}^{N} \sum_{j=i+1}^{N} \min(d^{i,j}, d_c) + \beta \|\boldsymbol{a}\|,
$$

where in the global observability case we set the cut-off distance $d_c = \max(x_{\max}, y_{\max})$ to the maximum possible inter-agent distance in the respective environment. The factor $\alpha = -\left(\frac{N(N-1)}{2} d_c\right)^{-1}$ serves as a reward normalization factor and $\beta = -1 \times 10^{-3}$ controls how strongly high action outputs of the policy are penalized.

E.2. Pursuit Evasion

For the case of a single evader, the pursuit evasion objective may be expressed in terms of the distance to the closest pursuer. More specifically, the reward function is given as



$$
R(\boldsymbol{s}, \boldsymbol{a}) = -\frac{1}{d_o} \min(d_{\min}, d_o),
$$

where $d_{\min} = \min(d^{1,e}, \ldots, d^{N,e})$. For the global observability case, we set d_o to the maximum possible distance of $d^{i,e}$.

E.3. Pursuit Evasion with Multiple Evaders

In the case of multiple evaders, we use a sparser reward function that counts how many evaders are caught per time step, with no additional guidance of inter-agent distances. An evader e is assumed to be caught if the closest pursuer's distance $d_{\min,e} = \min(d^{1,e}, \ldots, d^{N,e})$ is closer than a threshold distance $d_t = 3$. The reward function is given by

$$
R(\boldsymbol{s}, \boldsymbol{a}) = \sum_{e=1}^{E} \mathbf{1}_{[0,d_t]}(d_{\min,e}),
$$

where E is the number of evaders and

$$\mathbf{1}_{[a,b]}(x) = \begin{cases} 1 & \text{if } x \in [a,b] \\ 0 & \text{else} \end{cases}$$

is the indicator function.

Appendix F. Policy Architectures

This section briefly summarizes the chosen policy architectures. Illustrations can be found in Figure 1.

F.1. Neural Network Embedding Policy

We evaluated different layer sizes and activation functions on the rendezvous problem and show the results in Figure 12. In all other experiments, the neural network mean feature embedding for agent i, given by

$$\phi^{\text{NN}}(O^i) = \frac{1}{|O^i|} \sum_{o^{i,j} \in O^i} \phi(o^{i,j}),$$

is realized as the empirical mean of the outputs of a single layer feed-forward neural network,

$$\phi(o^{i,j}) = h(W o^{i,j} + b),$$

with 64 neurons and a RELU non-linearity h.

F.2. Histogram Embedding Policy

The histogram embedding is achieved with a two-dimensional histogram over the distance and bearing space to other agents. We use eight evenly spaced bins for each feature, resulting in a 64 dimensional feature vector.

F.3. RBF Embedding Policy

The RBF embedding is given by a vector $\phi^{\text{RBF}}(O^i) = \left[\psi_1(O^i), \ldots, \psi_{M^2}(O^i)\right]$ of M^2 contributions from $M = 8$ radial basis functions whose center points are evenly distributed in the distance and bearing space. With $o^{i,j} = [d^{i,j}, \phi^{i,j}]$, $\mu_m = [\mu_{d,m}, \mu_{\phi,m}]$, and $\sigma = [\sigma_d, \sigma_\phi]$ its components are given by

$$\psi_m(O^i) = \sum_{o^{i,j} \in O^i} \rho_m(o^{i,j}),$$

where we choose

$$\rho_m(o^{i,j}) = \exp\left(-\frac{1}{2}\left[\frac{(d^{i,j} - \mu_{d,m})^2}{\sigma_d^2} + \frac{(\phi^{i,j} - \mu_{\phi,m})^2}{\sigma_\phi^2}\right]\right).$$

The policy network structure used for both, the histogram and the RBF representations, is illustrated in Figure 1b.

F.4. Concatenation Policy

For the concatenation method, we first concatenate agent i's neighborhood observations contained in the set O^i and process them with one hidden layer of 64 neurons and a RELU non-linearity. The resulting feature vector is then concatenated with the local properties o^i_{loc} and fed into a second layer of same size. Finally, the output of the second layer is mapped to the action. The corresponding policy network structure can be seen in Figure 1c.

Abstract

Deep Learning has enabled remarkable progress over the last years on a variety of tasks, such as image recognition, speech recognition, and machine translation. One crucial aspect for this progress are novel neural architectures. Currently employed architectures have mostly been developed manually by human experts, which is a time-consuming and error-prone process. Because of this, there is growing interest in automated *neural architecture search* methods. We provide an overview of existing work in this field of research and categorize them according to three dimensions: search space, search strategy, and performance estimation strategy.

Keywords: Neural Architecture Search, AutoML, AutoDL, Search Space Design, Search Strategy, Performance Estimation Strategy

1. Introduction

The success of deep learning in perceptual tasks is largely due to its automation of the feature engineering process: hierarchical feature extractors are learned in an end-to-end fashion from data rather than manually designed. This success has been accompanied, however, by a rising demand for *architecture engineering*, where increasingly more complex neural architectures are designed manually. *Neural Architecture Search* (NAS), the process of automating architecture engineering, is thus a logical next step in automating machine learning. Already by now, NAS methods have outperformed manually designed architectures on some tasks such as image classification (Zoph et al., 2018; Real et al., 2019), object detection (Zoph et al., 2018) or semantic segmentation (Chen et al., 2018). NAS can be seen as subfield of AutoML (Hutter et al., 2019) and has significant overlap with hyperparameter optimization (Feurer and Hutter, 2019) and meta-learning (Vanschoren, 2019). We categorize methods for NAS according to three dimensions: search space, search strategy, and performance estimation strategy:

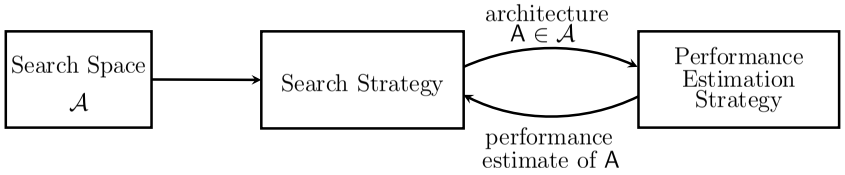

Figure 1: Abstract illustration of Neural Architecture Search methods. A search strategy selects an architecture A from a predefined search space $\mathcal{A}$. The architecture is passed to a performance estimation strategy, which returns the estimated performance of A to the search strategy.

- **Search Space.** The search space defines which architectures can be represented in principle. Incorporating prior knowledge about typical properties of architectures well-suited for a task can reduce the size of the search space and simplify the search. However, this also introduces a human bias, which may prevent finding novel architectural building blocks that go beyond the current human knowledge.
- **Search Strategy.** The search strategy details how to explore the search space (which is often exponentially large or even unbounded). It encompasses the classical exploration-exploitation trade-off since, on the one hand, it is desirable to find well-performing architectures quickly, while on the other hand, premature convergence to a region of suboptimal architectures should be avoided.
- **Performance Estimation Strategy.** The objective of NAS is typically to find architectures that achieve high predictive performance on unseen data. *Performance Estimation* refers to the process of estimating this performance: the simplest option is to perform a standard training and validation of the architecture on data, but this is unfortunately computationally expensive and limits the number of architectures that can be explored. Much recent research therefore focuses on developing methods that reduce the cost of these performance estimations.

We refer to Figure 1 for an illustration. The article is also structured according to these three dimensions: we start with discussing search spaces in Section 2, cover search strategies in Section 3, and outline performance estimation methods in Section 4. We conclude with an outlook on future directions in Section 5.

2. Search Space

The search space defines which neural architectures a NAS approach might discover in principle. We now discuss common search spaces from recent works.

A relatively simple search space is the space of *chain-structured neural networks*, as illustrated in Figure 2 (left). A chain-structured neural network architecture A can be written as a sequence of n layers, where the i'th layer L_i receives its input from layer $i-1$ and

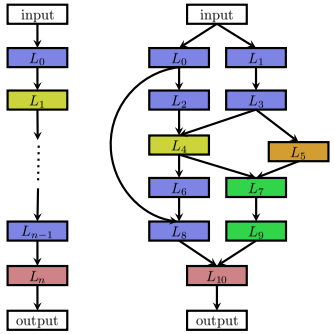

Figure 2: An illustration of different architecture spaces. Each node in the graphs corresponds to a layer in a neural network, e.g., a convolutional or pooling layer. Different layer types are visualized by different colors. An edge from layer L_i to layer L_j denotes that L_j receives the output of L_i as input. Left: an element of a chain-structured space. Right: an element of a more complex search space with additional layer types and multiple branches and skip connections.

its output serves as the input for layer $i+1$, i.e., $\mathsf{A} = L_n \circ \dots L_1 \circ L_0$. The search space is then parametrized by: (i) the (maximum) number of layers n (possibly unbounded); (ii) the type of operation every layer executes, e.g., pooling, convolution, or more advanced operations like depthwise separable convolutions (Chollet, 2016) or dilated convolutions (Yu and Koltun, 2016); and (iii) hyperparameters associated with the operation, e.g., number of filters, kernel size and strides for a convolutional layer (Baker et al., 2017a; Suganuma et al., 2017; Cai et al., 2018a), or simply number of units for fully-connected networks (Mendoza et al., 2016). Note that the parameters from (iii) are conditioned on (ii), hence the parametrization of the search space is not fixed-length but rather a conditional space.

Recent work on NAS (Brock et al., 2017; Elsken et al., 2017; Zoph et al., 2018; Elsken et al., 2019; Real et al., 2019; Cai et al., 2018b) incorporates modern design elements known from hand-crafted architectures, such as skip connections, which allow to build complex, *multi-branch networks*, as illustrated in Figure 2 (right). In this case the input of layer i can be formally described as a function $g_i(L_{i-1}^{out}, \dots, L_0^{out})$ combining previous layer outputs. Employing such a function results in significantly more degrees of freedom. Special cases of these multi-branch architectures are (i) the chain-structured networks (by setting $g_i(L_{i-1}^{out}, \dots, L_0^{out}) = L_{i-1}^{out}$), (ii) Residual Networks (He et al., 2016), where previous layer outputs are summed ($g_i(L_{i-1}^{out}, \dots, L_0^{out}) = L_{i-1}^{out} + L_j^{out}, j < i-1$) and (iii) DenseNets (Huang et al., 2017), where previous layer outputs are concatenated ($g_i(L_{i-1}^{out}, \dots, L_0^{out}) = concat(L_{i-1}^{out}, \dots, L_0^{out})$).

Motivated by hand-crafted architectures consisting of repeated motifs (Szegedy et al., 2016; He et al., 2016; Huang et al., 2017), Zoph et al. (2018) and Zhong et al. (2018a) propose to search for such motifs, dubbed *cells* or *blocks*, respectively, rather than for whole

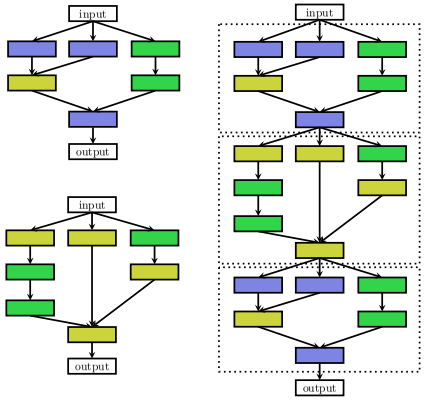

Figure 3: Illustration of the cell search space. Left: Two different cells, e.g., a normal cell (top) and a reduction cell (bottom) (Zoph et al., 2018). Right: an architecture built by stacking the cells sequentially. Note that cells can also be combined in a more complex manner, such as in multi-branch spaces, by simply replacing layers with cells.

architectures. Zoph et al. (2018) optimize two different kind of cells: a *normal cell* that preserves the dimensionality of the input and a *reduction cell* which reduces the spatial dimension. The final architecture is then built by stacking these cells in a predefined manner, as illustrated in Figure 3. This search space has three major advantages compared to the ones discussed above:

1. The size of the search space is drastically reduced since cells usually consist of significantly less layers than whole architectures. For example, Zoph et al. (2018) estimate a seven-times speed-up compared to their previous work (Zoph and Le, 2017) while achieving better performance.

2. Architectures built from cells can more easily be transferred or adapted to other data sets by simply varying the number of cells and filters used within a model. Indeed, Zoph et al. (2018) transfer cells optimized on CIFAR-10 to ImageNet and achieve state-of-the-art performance.

3. Creating architectures by repeating building blocks has proven a useful design principle in general, such as repeating an LSTM block in RNNs or stacking a residual block.

Consequently, this cell-based search space is also successfully employed by many recent works (Real et al., 2019; Liu et al., 2018a; Pham et al., 2018; Elsken et al., 2019; Cai et al., 2018b; Liu et al., 2019b; Zhong et al., 2018b). However, a new design-choice arises when

using a cell-based search space, namely how to choose the *macro-architecture*: how many cells shall be used and how should they be connected to build the actual model? For example, Zoph et al. (2018) build a sequential model from cells, in which each cell receives the outputs of the two preceding cells as input, while Cai et al. (2018b) employ the high-level structure of well-known manually designed architectures, such as DenseNet (Huang et al., 2017), and use their cells within these models. In principle, cells can be combined arbitrarily, e.g., within the multi-branch space described above, by simply replacing layers with cells. Ideally, both the macro-architecture and the micro-architecture (i.e., the structure of the cells) should be optimized jointly instead of solely optimizing the micro-architecture; otherwise, one may easily end up having to do manual macro-architecture engineering after finding a well-performing cell. One step in the direction of optimizing macro-architectures is the hierarchical search space introduced by Liu et al. (2018b), which consists of several levels of motifs. The first level consists of the set of primitive operations, the second level of different motifs that connect primitive operations via a directed acyclic graph, the third level of motifs that encode how to connect second-level motifs, and so on. The cell-based search space can be seen as a special case of this hierarchical search space where the number of levels is three, the second level motifs correspond to the cells, and the third level is the hard-coded macro-architecture.

The choice of the search space largely determines the difficulty of the optimization problem: even for the case of the search space based on a single cell with fixed macro-architecture, the optimization problem remains (i) non-continuous and (ii) relatively high-dimensional (since more complex models tend to perform better, resulting in more design choices).

We note that the architectures in many search spaces can be written as fixed-length vectors; e.g., the search space for each of the two cells by Zoph et al. (2018) can be written as a 40-dimensional[1] search space with categorical dimensions, each of which chooses between a small number of different building blocks and inputs. Unbounded search spaces can be constrained to have a (potentially very large, but finite) number of layers, which again gives rise to fixed-size search spaces with (potentially many) conditional dimensions.

In the next section, we discuss Search Strategies that are well-suited for these kinds of search spaces.

3. Search Strategy

Many different search strategies can be used to explore the space of neural architectures, including random search, Bayesian optimization, evolutionary methods, reinforcement learning (RL), and gradient-based methods. Historically, evolutionary algorithms were already used by many researchers to evolve neural architectures (and often also their weights) decades ago (see, e.g., Angeline et al., 1994; Stanley and Miikkulainen, 2002; Floreano et al., 2008; Stanley et al., 2009; Jozefowicz et al., 2015). Yao (1999) provides a literature review of work earlier than 2000.

1. Each of the 2 cells consists of 5 blocks. For each block, 2 inputs are chosen and for each of these inputs an operation to be applied to the input is chosen, resulting in a $2 \cdot 5 \cdot 2 \cdot 2 = 40$ dimensional representation. Note that originally there was another dimension for either summing or concatenating the operations within a block. However, this choice was discarded in the experiments of the paper and the outputs within a block were always summed.

Bayesian optimization celebrated several early successes in NAS since 2013, leading to state-of-the-art vision architectures (Bergstra et al., 2013), state-of-the-art performance for CIFAR-10 without data augmentation (Domhan et al., 2015), and the first automatically-tuned neural networks to win on competition data sets against human experts (Mendoza et al., 2016). NAS became a mainstream research topic in the machine learning community after Zoph and Le (2017) obtained competitive performance on the CIFAR-10 and Penn Treebank benchmarks with a search strategy based on reinforcement learning. While Zoph and Le (2017) used vast computational resources to achieve this result (800 GPUs for three to four weeks), after their work, a wide variety of methods have been published in quick succession to reduce the computational costs and achieve further improvements in performance.

To frame NAS as a *reinforcement learning* (RL) problem (Baker et al., 2017a; Zoph and Le, 2017; Zhong et al., 2018a; Zoph et al., 2018), the generation of a neural architecture can be considered to be the agent's action, with the action space identical to the search space. The agent's reward is based on an estimate of the performance of the trained architecture on unseen data (see Section 4). Different RL approaches differ in how they represent the agent's policy and how they optimize it: Zoph and Le (2017) use a recurrent neural network (RNN) policy to sequentially sample a string that in turn encodes the neural architecture. They initially trained this network with the REINFORCE policy gradient algorithm (Williams, 1992), but in their follow-up work (Zoph et al., 2018) use Proximal Policy Optimization (Schulman et al., 2017) instead. Baker et al. (2017a) use Q-learning to train a policy which sequentially chooses a layer's type and corresponding hyperparameters.

An alternative view of these approaches is as sequential decision processes in which the policy samples actions to generate the architecture sequentially, the environment's "state" contains a summary of the actions sampled so far, and the (undiscounted) reward is obtained only after the final action. However, since no interaction with an environment occurs during this sequential process (no external state is observed, and there are no intermediate rewards), we find it more intuitive to interpret the architecture sampling process as the sequential generation of a single action; this simplifies the RL problem to a stateless multi-armed bandit problem.

A related approach was proposed by Cai et al. (2018a), who frame NAS as a sequential decision process: in their approach the state is the current (partially trained) architecture, the reward is an estimate of the architecture's performance, and the action corresponds to an application of function-preserving mutations, dubbed network morphisms (Chen et al., 2016; Wei et al., 2017), see also Section 4, followed by a training phase of the network. In order to deal with variable-length network architectures, they use a bi-directional LSTM to encode architectures into a fixed-length representation. Based on this encoded representation, actor networks decide on the sampled action. The combination of these two components constitute the policy, which is trained end-to-end with the REINFORCE policy gradient algorithm. We note that this approach will not visit the same state (architecture) twice.

An alternative to using RL are *neuro-evolutionary* approaches that use evolutionary algorithms for optimizing the neural architecture. The first such approach for designing neural networks we are aware of dates back almost three decades: Miller et al. (1989)

use genetic algorithms to propose architectures and use backpropagation to optimize their weights. Many neuro-evolutionary approaches since then (Angeline et al., 1994; Stanley and Miikkulainen, 2002; Stanley et al., 2009) use genetic algorithms to optimize both the neural architecture and its weights; however, when scaling to contemporary neural architectures with millions of weights for supervised learning tasks, SGD-based weight optimization methods currently outperform evolutionary ones.[2] More recent neuro-evolutionary approaches (Real et al., 2017; Suganuma et al., 2017; Liu et al., 2018b; Real et al., 2019; Miikkulainen et al., 2017; Xie and Yuille, 2017; Elsken et al., 2019) therefore again use gradient-based methods for optimizing weights and solely use evolutionary algorithms for optimizing the neural architecture itself. Evolutionary algorithms evolve a population of models, i.e., a set of (possibly trained) networks; in every evolution step, at least one model from the population is sampled and serves as a parent to generate offsprings by applying mutations to it. In the context of NAS, mutations are local operations, such as adding or removing a layer, altering the hyperparameters of a layer, adding skip connections, as well as altering training hyperparameters. After training the offsprings, their fitness (e.g., performance on a validation set) is evaluated and they are added to the population.

Neuro-evolutionary methods differ in how they sample parents, update populations, and generate offsprings. For example, Real et al. (2017), Real et al. (2019), and Liu et al. (2018b) use tournament selection (Goldberg and Deb, 1991) to sample parents, whereas Elsken et al. (2019) sample parents from a multi-objective Pareto front using an inverse density. Real et al. (2017) remove the worst individual from a population, while Real et al. (2019) found it beneficial to remove the oldest individual (which decreases greediness), and Liu et al. (2018b) do not remove individuals at all. To generate offspring, most approaches initialize child networks randomly, while Elsken et al. (2019) employ Lamarckian inheritance, i.e, knowledge (in the form of learned weights) is passed on from a parent network to its children by using network morphisms. Real et al. (2017) also let an offspring inherit all parameters of its parent that are not affected by the applied mutation; while this inheritance is not strictly function-preserving it might also speed up learning compared to a random initialization. Moreover, they also allow mutating the learning rate which can be seen as a way for optimizing the learning rate schedule during NAS. We refer to Stanley et al. (2019) for a recent in-depth review on neuro-evolutionary methods.

Real et al. (2019) conduct a case study comparing RL, evolution, and random search (RS), concluding that RL and evolution perform equally well in terms of final test accuracy, with evolution having better anytime performance and finding smaller models. Both approaches consistently perform better than RS in their experiments, but with a rather small margin: RS achieved test errors of approximately 4% on CIFAR-10, while RL and evolution reached approximately 3.5% (after "model augmentation" where depth and number of filters was increased; the difference on the non-augmented space actually used for the search was approx. 2%). The difference was even smaller for Liu et al. (2018b), who reported a test error of 3.9% on CIFAR-10 and a top-1 validation error of 21.0% on ImageNet for RS, compared to 3.75% and 20.3% for their evolution-based method, respectively.

2. Some recent work shows that evolving even millions of weights is competitive to gradient-based optimization when only high-variance estimates of the gradient are available, e.g., for reinforcement learning tasks (Salimans et al., 2017; Such et al., 2017; Chrabaszcz et al., 2018). Nonetheless, for supervised learning tasks gradient-based optimization is by far the most common approach.

Bayesian Optimization (BO, see, e.g., (Shahriari et al., 2016)) is one of the most popular methods for hyperparameter optimization, but it has not been applied to NAS by many groups since typical BO toolboxes are based on Gaussian processes and focus on low-dimensional continuous optimization problems. Swersky et al. (2013) and Kandasamy et al. (2018) derive kernel functions for architecture search spaces in order to use classic GP-based BO methods. In contrast, several works use tree-based models (in particular, tree Parzen estimators (Bergstra et al., 2011), or random forests (Hutter et al., 2011)) to effectively search high-dimensional conditional spaces and achieve state-of-the-art performance on a wide range of problems, optimizing both neural architectures and their hyperparameters jointly (Bergstra et al., 2013; Domhan et al., 2015; Mendoza et al., 2016; Zela et al., 2018). While a full comparison is lacking, there is preliminary evidence that these approaches can also outperform evolutionary algorithms (Klein et al., 2018).

Negrinho and Gordon (2017) and Wistuba (2017) exploit the tree-structure of their search space and use *Monte Carlo Tree Search*. Elsken et al. (2017) propose a simple yet well performing *hill climbing* algorithm that discovers high-quality architectures by greedily moving in the direction of better performing architectures without requiring more sophisticated exploration mechanisms.

While the methods above employ a discrete search space, Liu et al. (2019b) propose a *continuous relaxation* to enable direct gradient-based optimization: instead of fixing a single operation o_i (e.g., convolution or pooling) to be executed at a specific layer, the authors compute a convex combination from a set of operations $\{o_1, \dots, o_m\}$. More specifically, given a layer input x, the layer output y is computed as $y = \sum_{i=1}^{m} \alpha_i o_i(x), \alpha_i \geq 0, \sum_{i=1}^{m} \alpha_i = 1$, where the convex coefficients α_i effectively parametrize the network architecture. Liu et al. (2019b) then optimize both the network weights and the network architecture by alternating gradient descent steps on training data for weights and on validation data for architectural parameters such as α. Eventually, a discrete architecture is obtained by choosing the operation i^* with $i^* = \arg\max_i \alpha_i$ for every layer. Instead of optimizing a weighting α of possible operations, Xie et al. (2019); Cai et al. (2019) propose to optimize a parametrized distribution over the possible operations. Shin et al. (2018) and Ahmed and Torresani (2018) also employ gradient-based optimization of neural architectures, however focusing on optimizing layer hyperparameters or connectivity patterns, respectively.

4. Performance Estimation Strategy

The search strategies discussed in Section 3 aim at finding a neural architecture A that maximizes some performance measure, such as accuracy on unseen data. To guide their search process, these strategies need to estimate the performance of a given architecture A they consider. The simplest way of doing this is to train A on training data and evaluate its performance on validation data. However, training each architecture to be evaluated from scratch frequently yields computational demands in the order of thousands of GPU days for NAS (Zoph and Le, 2017; Real et al., 2017; Zoph et al., 2018; Real et al., 2019). This naturally leads to developing methods for speeding up performance estimation, which we will now discuss. We refer to Table 4 for an overview of existing methods.

Performance can be estimated based on *lower fidelities* of the actual performance after full training (also denoted as proxy metrics). Such lower fidelities include shorter training

Speed-up method	How are speed-ups achieved?	References
Lower fidelity estimates	Training time reduced by training for fewer epochs, on subset of data, downscaled models, downscaled data, ...	Li et al. (2017), Zoph et al. (2018), Zela et al. (2018), Falkner et al. (2018), Real et al. (2019), Runge et al. (2019)
Learning Curve Extrapolation	Training time reduced as performance can be extrapolated after just a few epochs of training.	Swersky et al. (2014), Domhan et al. (2015), Klein et al. (2017a), Baker et al. (2017b)
Weight Inheritance/ Network Morphisms	Instead of training models from scratch, they are warm-started by inheriting weights of, e.g., a parent model.	Real et al. (2017), Elsken et al. (2017), Elsken et al. (2019), Cai et al. (2018a,b)
One-Shot Models/ Weight Sharing	Only the one-shot model needs to be trained; its weights are then shared across different architectures that are just subgraphs of the one-shot model.	Saxena and Verbeek (2016), Pham et al. (2018), Bender et al. (2018), Liu et al. (2019b), Cai et al. (2019), Xie et al. (2019)

Table 1: Overview of different methods for speeding up performance estimation in NAS.

times (Zoph et al., 2018; Zela et al., 2018), training on a subset of the data (Klein et al., 2017b), on lower-resolution images (Chrabaszcz et al., 2017), or with less filters per layer and less cells (Zoph et al., 2018; Real et al., 2019). While these low-fidelity approximations reduce the computational cost, they also introduce bias in the estimate as performance will typically be underestimated. This may not be problematic as long as the search strategy only relies on ranking different architectures and the relative ranking remains stable. However, recent results indicate that this relative ranking can change dramatically when the difference between the cheap approximations and the "full" evaluation is too big (Zela et al., 2018), arguing for a gradual increase in fidelities (Li et al., 2017; Falkner et al., 2018).

Another possible way of estimating an architecture's performance builds upon learning curve extrapolation (Swersky et al., 2014; Domhan et al., 2015; Klein et al., 2017a; Baker et al., 2017b; Rawal and Miikkulainen, 2018). Domhan et al. (2015) propose to extrapolate initial learning curves and terminate those predicted to perform poorly to speed up the architecture search process. Swersky et al. (2014), Klein et al. (2017a), Baker et al. (2017b), and Rawal and Miikkulainen (2018) also consider architectural hyperparameters for predicting which partial learning curves are most promising. Training a surrogate model for predicting the performance of novel architectures is also proposed by Liu et al. (2018a), who do not employ learning curve extrapolation but support predicting performance based on architectural/cell properties and extrapolate to architectures/cells with larger size than seen during training. The main challenge for predicting the performances of neural architectures is that, in order to speed up the search process, good predictions in a relatively large search space need to be made based on relatively few evaluations.

Another approach to speed up performance estimation is to initialize the weights of novel architectures based on weights of other architectures that have been trained before. One way of achieving this, dubbed *network morphisms* (Wei et al., 2016), allows modifying an architecture while leaving the function represented by the network unchanged, resulting in methods that only require a few GPU days (Elsken et al., 2017; Cai et al., 2018a,b; Jin et al., 2018). This allows increasing the capacity of networks successively and retaining high performance without requiring training from scratch. Continuing training for a few epochs can also make use of the additional capacity introduced by network morphisms. An advantage of these approaches is that they allow search spaces without an inherent upper bound on the architecture's size (Elsken et al., 2017); on the other hand, strict network morphisms can only make architectures larger and may thus lead to overly complex architectures. This can be attenuated by employing approximate network morphisms that allow shrinking architectures (Elsken et al., 2019).

One-Shot Architecture Search (see Figure 4) treats all architectures as different subgraphs of a supergraph (the one-shot model) and shares weights between architectures that have edges of this supergraph in common (Saxena and Verbeek, 2016; Brock et al., 2017; Pham et al., 2018; Liu et al., 2019b; Bender et al., 2018; Cai et al., 2019; Xie et al., 2019). Only the weights of a single one-shot model need to be trained (in one of various ways), and architectures (which are just subgraphs of the one-shot model) can then be evaluated without any separate training by inheriting trained weights from the one-shot model. This greatly speeds up performance estimation of architectures, since no training is required (only evaluating performance on validation data), again resulting in methods that only require a few GPU days. The one-shot model typically incurs a large bias as it underestimates the actual performance of the best architectures severely; nevertheless, it allows ranking architectures, which would be sufficient if the estimated performance correlates strongly with the actual performance. However, it is currently not clear if this is actually the case (Bender et al., 2018; Sciuto et al., 2019).

Different one-shot NAS methods differ in how the one-shot model is trained: ENAS (Pham et al., 2018) learns a RNN controller that samples architectures from the search space and trains the one-shot model based on approximate gradients obtained through REINFORCE. DARTS (Liu et al., 2019b) optimizes all weights of the one-shot model jointly with a continuous relaxation of the search space, obtained by placing a mixture of candidate operations on each edge of the one-shot model. Instead of optimizing real-valued weights on the operations as in DARTS, SNAS (Xie et al., 2019) optimizes a distribution over the candidate operations. The authors employ the concrete distribution (Maddison et al., 2017; Jang et al., 2017) and reparametrization (Kingma and Welling, 2014) to relax the discrete distribution and make it differentiable, enabling optimization via gradient descent. To overcome the necessity of keeping the entire one-shot model in the GPU memory, ProxylessNAS (Cai et al., 2019) "binarizes" the architectural weights, masking out all but one edge per operation. The probabilities for an edge being either masked out or not are then learned by sampling a few binarized architectures and using BinaryConnect (Courbariaux et al., 2015) to update the corresponding probabilities. Bender et al. (2018) only train the one-shot model once and show that this is sufficient when deactivating parts of this model stochastically during training using path dropout.

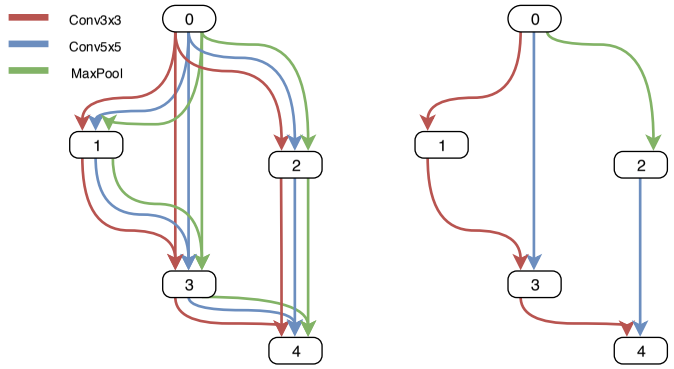

Figure 4: Illustration of one-shot architecture search. Simple network with an input node (denoted as 0), three hidden nodes (denoted as 1,2,3) and one output node (denoted as 4). Instead of applying a single operation (such as a 3x3 convolution) to a node, the one-shot model (left) contains several candidate operations for every node, namely 3x3 convolution (red edges), 5x5 convolution (blue edges) and MaxPooling (green edges) in the above illustration. Once the one-shot model is trained, its weights are shared across different architectures, which are simply subgraphs of the one-shot model (right). Figure inspired by Liu et al. (2019b).

While the previously mentioned approaches optimize a distribution over architectures during training, the approach of Bender et al. (2018) can be seen as using a fixed distribution. The high performance obtainable by the latter indicates that the combination of weight sharing and a fixed (carefully chosen) distribution might (perhaps surprisingly) be the only required ingredients for one-shot NAS. Related to these approaches is meta-learning of hypernetworks that generate weights for novel architectures and thus requires only training the hypernetwork but not the architectures themselves (Brock et al., 2017; Zhang et al., 2019). The main difference here is that weights are not strictly shared but generated by the shared hypernetwork (conditional on the sampled architecture).

A general limitation of one-shot NAS is that the supergraph defined a priori restricts the search space to its subgraphs. Moreover, approaches which require that the entire supergraph resides in GPU memory during architecture search will be restricted to relatively small supergraphs and search spaces accordingly, and are thus typically used in combination with cell-based search spaces. While approaches based on weight sharing have substantially reduced the computational resources required for NAS (from thousands to a few GPU days), it is currently not well understood which biases they introduce into the search if the sampling distribution of architectures is optimized along with the one-shot model instead of fixing it (Bender et al., 2018). For instance, an initial bias in exploring certain parts of the search space more than others might lead to the weights of the one-shot model being better adapted for these architectures, which in turn would reinforce the bias of the search to these parts of the search space. This might result in premature convergence of NAS or little correlation between the one-shot and true performance of an architecture (Sciuto et al., 2019). In general, a more systematic analysis of biases introduced by different performance estimators would be a desirable direction for future work.

5. Future Directions

In this section, we discuss several current and future directions for research on NAS. Most existing work has focused on NAS for image classification. On the one hand, this provides a challenging benchmark since a lot of manual engineering has been devoted to finding architectures that perform well in this domain and are not easily outperformed by NAS. On the other hand, it is relatively easy to define a well-suited search space by exploiting knowledge from manual engineering. This in turn makes it unlikely that NAS will find architectures that substantially outperform existing ones considerably since the found architectures cannot differ fundamentally. We thus consider it important to go beyond image classification problems by applying NAS to less explored domains. Notable first steps in this direction have been taken in image restoration (Suganuma et al., 2018), semantic segmentation (Chen et al., 2018; Nekrasov et al., 2018; Liu et al., 2019a), transfer learning (Wong et al., 2018), machine translation (So et al., 2019), reinforcement learning (Runge et al., 2019)[3], as well as optimizing recurrent neural networks (Greff et al., 2015; Jozefowicz et al., 2015; Zoph and Le, 2017; Rawal and Miikkulainen, 2018), e.g., for language or music modeling. Further promising application areas for NAS would be generative adversarial networks or sensor fusion.

An additional promising direction is to develop NAS methods for multi-task problems (Liang et al., 2018; Meyerson and Miikkulainen, 2018) and for multi-objective problems (Elsken et al., 2019; Dong et al., 2018; Zhou et al., 2018), in which measures of resource efficiency are used as objectives along with the predictive performance on unseen data. We highlight that multi-objective NAS is closely related to network compression (Han et al., 2016; Cheng et al., 2018): both aim at finding well-performing but efficient architectures. Hence, some compression methods can also be seen as NAS methods (Han et al., 2015; Liu et al., 2017; Gordon et al., 2018; Liu et al., 2019c; Cao et al., 2019) and vice versa (Saxena and Verbeek, 2016; Liu et al., 2019b; Xie et al., 2019).

Likewise, it would be interesting to extend RL/bandit approaches, such as those discussed in Section 3, to learn policies that are conditioned on a state that encodes task properties/resource requirements (i.e., turning the setting into a contextual bandit). A similar direction was followed by Ramachandran and Le (2018) in extending one-shot NAS to generate different architectures depending on the task or instance on-the-fly. Moreover, applying NAS to searching for architectures that are more robust to adversarial examples (Cubuk et al., 2017) is an intriguing recent direction.

Related to this is research on defining more general and flexible search spaces. For instance, while the cell-based search space provides high transferability between different image classification tasks, it is largely based on human experience on image classification and does not generalize easily to other domains where the hard-coded hierarchical structure (repeating the same cells several times in a chain-like structure) does not apply (e.g.,

3. Many authors have optimized some architectural choices of deep reinforcement learning algorithms before. Runge et al. (2019) used the largest and most versatile space of policy network architectures so far (e.g., including both convolutional and recurrent building blocks), but a full study of NAS for RL is yet missing.

semantic segmentation or object detection). A search space which allows representing and identifying more general hierarchical structure would thus make NAS more broadly applicable, see Liu et al. (2018b, 2019a) for first work in this direction. Moreover, common search spaces are also based on predefined building blocks, such as different kinds of convolutions and pooling, but do not allow identifying novel building blocks on this level; going beyond this limitation might substantially increase the power of NAS.

The comparison of different methods for NAS and even the reproducibility of published results[4] is complicated by the fact that measurements of an architecture's performance depend on many factors other than the architecture itself. While most authors report results on the CIFAR-10 data set, experiments often differ with regard to search space, computational budget, data augmentation, training procedures, regularization, and other factors. For example, for CIFAR-10, performance substantially improves when using a cosine annealing learning rate schedule (Loshchilov and Hutter, 2017), data augmentation by CutOut (Devries and Taylor, 2017), by MixUp (Zhang et al., 2017) or by a combination of factors (Cubuk et al., 2018), and regularization by Shake-Shake regularization (Gastaldi, 2017) or ScheduledDropPath (Zoph et al., 2018). It is therefore conceivable that improvements in these ingredients have a larger impact on reported performance numbers than the better architectures found by NAS. We thus consider the definition of common benchmarks to be crucial for a fair comparison of different NAS methods. A first step in this direction is the benchmark proposed by Ying et al. (2019), where a search space consisting of approximately 423,000 unique convolutional architectures is considered. Each element of this space was pre-trained and evaluated multiple times, resulting in a data set containing training, validation and test accuracies as well as training times and model sizes for different training budgets for multiple runs. Different search strategies can hence be compared with low computational resources on this benchmark by simply querying the pre-computed data set. In a smaller previous study, Klein et al. (2018) pre-evaluated the joint space of neural architectures and hyperparameters. It would also be interesting to evaluate NAS methods not in isolation but as part of a full open-source AutoML system, where also hyperparameters (Mendoza et al., 2016; Real et al., 2017; Zela et al., 2018), and data augmentation pipeline (Cubuk et al., 2018) are optimized along with NAS.

While NAS has achieved impressive performance, so far it provides little insights into why specific architectures work well and how similar the architectures derived in independent runs would be. Identifying common motifs, providing an understanding why those motifs are important for high performance, and investigating if these motifs generalize over different problems would be desirable.

Acknowledgments

We would like to thank Arber Zela, Esteban Real, Gabriel Bender, Kenneth Stanley, Thomas Pfeil and the anonymous reviewers for feedback on this survey. This work has partly been supported by the European Research Council (ERC) under the European Unions Horizon 2020 research and innovation programme under grant no. 716721.

4. We refer to Li and Talwalkar (2019) for a detailed discussion on reproducibility for NAS.

Near Optimal Frequent Directions for Sketching Dense and Sparse Matrices

Editor: Kilian Weinberger

Abstract

Given a large matrix $A \in \mathbb{R}^{n\times d}$, we consider the problem of computing a sketch matrix $B \in \mathbb{R}^{\ell\times d}$ which is significantly smaller than but still well approximates A. We consider the problems in the streaming model, where the algorithm can only make one pass over the input with limited working space, and we are interested in minimizing the *covariance error* $\|A^TA - B^TB\|_2$. The popular Frequent Directions algorithm of Liberty (2013) and its variants achieve optimal space-error tradeoffs. However, whether the running time can be improved remains an unanswered question. In this paper, we almost settle the question by proving that the time complexity of this problem is equivalent to that of matrix multiplication up to lower order terms. Specifically, we provide new space-optimal algorithms with faster running times and also show that the running times of our algorithms can be improved if and only if the state-of-the-art running time of matrix multiplication can be improved significantly.

Keywords: Matrix Sketching, Frequent Directions, Streaming Algorithms

1. Introduction

For large-scale matrix computations, exact algorithms are often too slow, so a large body of work focuses on designing fast randomized approximation algorithms. Matrix sketching is a commonly used algorithmic technique for solving linear algebra problems over massive data matrices, e.g., Sarlos (2006); Clarkson and Woodruff (2013); Avron et al. (2013); Chierichetti et al. (2017). In the sketch-and-solve framework, given a large matrix, we first compute a small sketch using a lightweight algorithm, and then do more expensive computations on the sketch instead of on the original matrix. Thus, the key is how to efficiently compute sketch matrices that are small but still preserve vital properties of the input matrix.

In real-world applications, data often arrives in a streaming fashion and it is often impractical or impossible to store the entire data set in the main memory. This paper studies online streaming algorithms for maintaining matrix sketches with small *covariance errors*. In the *streaming model*, the rows of the input matrix arrive one at a time; algorithm is only allowed to make one pass over the stream with severely limited working space, and is required to maintain a sketch continuously. This problem has received lots of attention recently (Liberty, 2013; Ghashami and Phillips, 2014; Woodruff, 2014a; Ghashami et al., 2016; Wei et al., 2016).

The popular *Frequent Directions* algorithms (Liberty, 2013; Ghashami et al., 2016) achieve optimal tradeoffs between space usage and approximation error (Woodruff, 2014a), which have found lots of applications in online learning, e.g., Boutsidis et al. (2015); Karnin and Liberty (2015); Leng et al. (2015); Huang and Kasiviswanathan (2015); Luo et al. (2016); Calandriello et al. (2017), and other important problems (Song et al., 2015; Ye et al., 2016; Kim et al., 2016; Cohen et al., 2017). However, in contrast to the space complexity, it is unclear whether their running times can be improved; one might hope to get linear (in sparsity) time algorithms, which is possible for many matrix problems (see e.g., Clarkson and Woodruff (2013)). This paper is motivated by the following question:

- *Is there an input sparsity time Frequent Directions, which achieves the same optimal space-error tradeoff?*

1.1. Problem Definitions

Given a matrix $A \in \mathbb{R}^{n\times d}$, the problem is to compute a much smaller matrix $B \in \mathbb{R}^{\ell\times d}$, which has low *covariance error*, i.e., $\|A^TA - B^TB\|_2$.

Definition 1 (Covariance Sketch) *For any $0 < \alpha < 1$, and integer $0 \le k \le \mathsf{rank}(A)$, we will call B an (α, k)-*cov*-sketch of A, if the covariance error*[1]

$$\|A^TA - B^TB\|_2 \le \alpha\|A - [A]_k\|_F^2. \tag{1}$$

Here $\|\cdot\|_2$ and $\|\cdot\|_F$ are the *spectral norm* and *Frobenius norm* of matrices; $[A]_k$ is the best rank-k approximation to A. We will use $\pi_B^k(A)$ to denote the projection of A on the top-k singular vectors of B, i.e. $\pi_B^k(A) = AVV^T$, where the columns of V are the top-k right singular vectors of B.

Definition 2 (Projection Error) *The projection error of B with respect to A is defined as $\|A - \pi_B^k(A)\|_F^2$.*

Note $\pi_B^k(A)$ is a rank-k matrix, thereby the projection error is at least $\|A - [A]_k\|_F^2$. It is proved in Ghashami and Phillips (2014) that one can obtain relative projection error from small covariance error. We include a proof of the next lemma in Appendix A.1.

Lemma 3 (Covariance Error to Projection Error (Ghashami and Phillips, 2014))

$$\|A - \pi_B^k(A)\|_F^2 \le \|A - [A]_k\|_F^2 + 2k\cdot\|A^TA - B^TB\|_2.$$

Therefore, any $(\frac{\varepsilon}{2k}, k)$-cov-sketch B has projection error

$$\|A - \pi_B^k(A)\|_F^2 \le (1+\varepsilon)\|A - [A]_k\|_F^2. \tag{2}$$

We will often refer to $(\frac{\varepsilon}{2k}, k)$-cov-sketches as (ε, k)-proj-sketches.

(ε, k)-proj-sketches actually satisfy a more general property, called *Projection-Cost Preserving* property. Specially, suppose B is an (ε, k)-proj-sketch of a matrix A, then

$$\|B - BQQ^T\|_F^2 = (1\pm\varepsilon)\|A - AQQ^T\|_F^2,$$

1. for $k = 0$, we define $[A]_0 = \mathbf{0}$

for all rank-k orthonormal matrices Q (see Feldman et al. (2013); Cohen et al. (2015, 2017) for more details). One immediate application of projection-cost preserving sketches is constrained low rank approximations, which can be formulated as the following optimization problem:

$$\min_{X:\mathsf{rank}(X)\leq k, X\in\mathcal{S}} \|A - AXX^T\|_F^2,$$

where $\mathcal{S}$ is some constraint; special cases include sparse PCA, nonnegative PCA, and k-means clustering (Feldman et al., 2013; Cohen et al., 2015). Given any projection-cost preserving sketch B of A, one can solve the above optimization problem with respect to B to obtain an approximate solution, which significantly reduces the computational costs when B is much smaller than A.

Modern data matrices are often large and sparse, so we will always assume n and d are very large and $\mathsf{nnz}(A) \ll nd$, where $\mathsf{nnz}(A)$ in the number of nonzero entries in A. Moreover, we assume that each entry of A is representable by $O(\log(nd))$ bits. To simplify the analysis, we assume the entries of A are integers of magnitude at most $\mathrm{poly}(nd)$; the general case can be reduced to this, see e.g., Boutsidis et al. (2016).

1.2. Previous Results

In the row-wise update streaming model, Liberty's *Frequent Directions* (FD) algorithm (Liberty, 2013), with an improved analysis by Ghashami and Phillips (2014), maintains an (α, k)-cov-sketch $B \in \mathbb{R}^{\ell\times d}$ at any time, where $\ell = O(k + \alpha^{-1})$. The algorithm uses $O(d\ell)$ space and runs in $O(nd\ell)$ time. For sparse matrices, the running time of FD is improved to $O(\mathsf{nnz}(A)\ell\log d + \mathsf{nnz}(A)\log n + n\ell^2)$ by Ghashami et al. (2016). Setting $\alpha = \varepsilon/2k$ (or $\ell = O(k/\varepsilon)$) and by Lemma 3, B is a (ε, k)-proj-sketch. Now, B contains $O(k/\varepsilon)$ rows, and the space and running time become $O(dk/\varepsilon)$ and $O(\mathsf{nnz}(A)k\varepsilon^{-1}\cdot\log d + \mathsf{nnz}(A)\log n + nk^2\varepsilon^{-2})$ respectively. The $\log d$ factor in the leading term was removed by Luo et al. (2016). It was shown by Woodruff (Woodruff, 2014a) that the space used by FD is optimal for both covariance error and projection error. A natural question is if the running time can be improved. In particular,

- *Is there an input sparsity time algorithm, i.e., in time* $O(\mathsf{nnz}(A) + (n+d)\cdot\mathrm{poly}(k\alpha^{-1}))$, *which achieves the same guarantee as* FD?

1.3. Our Contributions

This paper almost settles the above question. Our main contributions are summarized as follows.

1. We give a new space-optimal streaming algorithm with $O(ndk) + \tilde{O}(d\alpha^{-3})$ running time to compute (α, k)-cov-sketches for dense matrices, which improves the original FD algorithm for small α. The running time is optimal up to lower order terms, provided matrix multiplication cannot be improved significantly.

2. Based on our fast algorithm for sketching dense matrices, we then give a new space-optimal streaming algorithm with $O(\mathsf{nnz}(A)k + nk^3) + \tilde{O}(d\alpha^{-3})$ running time to compute (α, k)-cov-sketches for sparse matrices. We separate the dependence of $1/\alpha$ from $\mathsf{nnz}(A)$, which improves the results of Ghashami et al. (2016) for small α. Therefore, to compute an (ε, k)-proj-sketch, our algorithm only needs $O(\mathsf{nnz}(A)k)$ time (ignoring lower order terms) as opposed to $O(\mathsf{nnz}(A)k\varepsilon^{-1}\cdot\log d)$ in Ghashami et al. (2016) (see Table 1).

3. We show that $o(\mathsf{nnz}(A)k)$ time is likely very difficult to achieve, as it will imply a breakthrough in fast matrix multiplication. Specifically, we prove that, under mild assumptions, the time complexity for computing an $(O(1), k)$-cov-sketch $B \in \mathbb{R}^{O(k)\times d}$ of A in the streaming model is equivalent to the time complexity of left multiplying A by an arbitrary matrix $C \in \mathbb{R}^{k\times n}$.

	Time	
	(α, k)-cov	(ε, k)-proj
FD (Liberty, 2013)	$O(ndk + nd/\alpha)$	$O(ndk/\varepsilon)$
FFDdense (**new**)	$O(ndk)$	$O(ndk)$
Sparse FD(Ghashami et al., 2016)	$O(\mathsf{nnz}(A)k\log d + \mathsf{nnz}(A)\log d/\alpha)$	$O(\mathsf{nnz}(A)k\log d/\varepsilon)$
FFDsparse (**new**)	$O(\mathsf{nnz}(A)k)$	$O(\mathsf{nnz}(A)k)$
Lower bounds (**new**)	$\Omega(\mathsf{nnz}(A)k)$	$\Omega(\mathsf{nnz}(A)k)$

Table 1: Running times and lower bounds for streaming (α, k)-cov-sketch and (ε, k)-proj-sketch algorithms. Lower order terms are omitted and the lower bounds are conditional.

1.4. Other Related Work

The problem of computing (α, k)-cov-sketches was also studied in the sliding window streaming model (Wei et al., 2016) and distributed models (Ghashami et al., 2014; Huang et al., 2017; Zhang et al., 2017). A closely related problem, namely *approximate PCA*, was studied in Kannan et al. (2014); Liang et al. (2014); Boutsidis et al. (2016); Zhang et al. (2015). Clarkson and Woodruff (2009) studied other streaming numerical linear algebra problems.

1.5. Matrix Preliminaries and Notations

We always use n for the number rows and d for the dimension of each row. For a d-dimensional vector x, $\|x\|$ is the ℓ_2 norm of x. We use x_i to denote the ith entry of x, and $\mathsf{Diag}(x) \in \mathbb{R}^{d\times d}$ is a diagonal matrix such that the ith diagonal entry is x_i. For a matrix $A \in \mathbb{R}^{n\times d}$ with $n > d$, we use A_i to denote the ith row of A and $a_{i,j}$ for the (i,j)-th entry of A. $\mathsf{nnz}(A)$ is the number of non-zero entries in A and $\mathsf{rows}(A)$ is the number of rows in A. We write the (reduced) singular value decomposition of A as $(U, \Sigma, V) = \mathsf{SVD}(A)$. The computation time of standard SVD algorithms is $O(nd^2)$. We use $\|A\|_2$ or $\|A\|$ to denote the spectral norm of A, which is the largest singular value of A, and $\|A\|_F$ for the *Frobenius Norm*, which is $\sqrt{\sum_{i,j} a_{i,j}^2}$. For $k \leq \mathsf{rank}(A)$, we use $[A]_k$ to denote the best rank k approximation of A. We define $[A]_0 = \mathbf{0}$. $[A; B]$ is the matrix formed by concatenating the rows of A and B. We use $\tilde{O}()$ to hide $\mathrm{polylog}(ndk)$ factors.

1.6. Tools

Frequent Directions. We will use the Frequent Directions (FD) algorithm by Liberty (Liberty, 2013), denoted as $\mathsf{FD}(A, \alpha, k)$; and the main result is summarized in the following theorem.

Theorem 4 (Liberty (2013)) *Given $A \in \mathbb{R}^{n\times d}$, in one pass, $\mathsf{FD}(A, \alpha, k)$ processes A in $O(nd(k + \alpha^{-1}))$ time and $O(d(k + \alpha^{-1}))$ space. It maintains a matrix $B \in \mathbb{R}^{O(k+\alpha^{-1})\times d}$ such that $\|A^TA - B^TB\|_2 \le \alpha\|A - [A]_k\|_F^2$.*

Row sampling. We provide a result about row sampling, which is analogous to a result from Drineas et al. (2006). The difference is that they use *sampling with replacement*, i.e., each row of B is an iid sample from the rows of A. On the other hand, we use *Bernoulli sampling*, i.e., sample each A_i independently with some probability q_i, and B is the set of sampled rows. *Bernoulli sampling* can easily be combined with FD in the streaming model. The proof is essentially the same as that for sampling with replacement, which can be found in Appendix.

Theorem 5 *For any $A \in \mathbb{R}^{n\times d}$ and $F > 0$, we sample each row A_i with probability $p_i \ge \frac{\|A_i\|^2}{\alpha^2 F}$; if it is sampled, scale it by $1/\sqrt{p_i}$. Let B be the (rescaled) sampled rows, then w.p. 0.99, $\|A^TA - B^TB\|_2 \le 10\alpha\sqrt{F}\|A\|_F$ and $\|B\|_F \le 10\|A\|_F$. The expected number of rows sampled is $O(\frac{\|A\|_F^2}{\alpha^2 F})$ if $p_i = O(\frac{\|A_i\|^2}{\alpha^2 F})$ for each i.*

Input-sparsity time subspace embedding. We will use fast subspace embeddings (Clarkson and Woodruff, 2013) to speedup computation. There are various approaches to achieve input-sparsity time subspace embedding with different guarantees; the following result suffices for our purpose, the proof of which can be found in Woodruff (2014b) (Lemma 4.2 and Remark 4.1).

Theorem 6 (Subspace Embedding) *Given any $A \in \mathbb{R}^{n\times d}$, there exist (random) matrices $J \in \mathbb{R}^{O(k)\times t_1}$ and $C \in \mathbb{R}^{t_1\times d}$, with $t_1 = \min(d, O(k^2))$, such that, with probability 0.99, the column space of $S = AC^TJ^T$ contains an $O(1)$-approximate rank-k approximation to A. More precisely, there exists X with $\mathsf{rank}(X) \le k$ such that*

$$\|A - SX\|_F^2 \le O(1)\|A - [A]_k\|_F^2,$$

Moreover, C only contains $O(d)$ nonzero entries and $S = AC^TJ^T$ can be computed in time $O(\mathsf{nnz}(A)) + O(nk^3)$.

One can choose J to be a matrix with iid Gaussian random variables and C to be a count-sketch matrix (Clarkson and Woodruff, 2013)

2. Algorithm for Dense Matrices

Theorem 7 ($\mathsf{FFDdense}(A, \alpha, k)$) *Given a matrix $A \in \mathbb{R}^{n\times d}$, $0 < \alpha < 1$ and $0 \le k \le d$, $\mathsf{FFDdense}(A, \alpha, k)$ processes A in one pass using $O(ndk) + \tilde{O}(d\alpha^{-3})$ time and $O(dk + d\alpha^{-1}))$ space, and maintains a matrix $B^{O(k+\alpha^{-1})\times d}$. With probability 0.99, it holds that $\|A^TA - B^TB\|_2 \le \alpha\|A - [A]_k\|_F^2$.*

Overview of the algorithm. To speed up FD, we will use the idea of adaptive random sampling. Let us first review the standard FD algorithm. Given an integer parameter $\ell \le d$, the algorithm always maintains a matrix B with at most 2ℓ rows at any time. When a new row v arrives, it processes the row using $\mathsf{FDShrink}(B, v, \ell)$ (Algorithm 3). In this procedure, we first append a after B; if B has no more than 2ℓ rows we do nothing, and otherwise do a $\mathsf{DenseShrink}$ operation (Algorithm 1) on B, which halves the number of rows in B (after removing zero rows). It was proved by Liberty (2013) and Ghashami and Phillips (2014) that for $\ell = k + \alpha^{-1}$, we have

$$\|A^TA - B^TB\|_2 \le \alpha\|A - [A]_k\|_F^2.$$

Since each SVD computation in $\mathsf{DenseShrink}$ takes $O(d\ell^2)$ time and there are totally n/ℓ SVD computations (SVD is applied every ℓ rows), the running time is $O(nd\ell) = O(nd(k + \alpha^{-1}))$. Our goal is to separate nd from α^{-1} in the running time.

Algorithm 1 $\mathsf{DenseShrink}$

Input: $B \in \mathbb{R}^{2\ell\times d}$.

1: Compute $[U, \Sigma, V] = \mathsf{SVD}(B)$, and $\sigma = \Sigma_{\ell,\ell}$.
2: $\hat{\Sigma} = \sqrt{\max(\Sigma^2 - \sigma^2 I_{2\ell}, 0)}$
3: **return** $B = \hat{\Sigma}V^T$

Algorithm 2 $\mathsf{DenseShrinkR}$

Input: $B \in \mathbb{R}^{2\ell\times d}$.

1: Compute $[U, \Sigma, V] = \mathsf{SVD}(B)$, and $\sigma = \Sigma_{\ell,\ell}$.
2: $\hat{\Sigma} = \sqrt{\max(\Sigma^2 - \sigma^2 I_{2\ell}, 0)}$
3: $\bar{\Sigma} = \sqrt{\Sigma^2 - \hat{\Sigma}^2}$ ▶ $\Sigma^2 = \bar{\Sigma}^2 + \hat{\Sigma}^2$
4: **return** $B = \hat{\Sigma}V^T$, $\bar{\Sigma}$ and V^T

Algorithm 3 $\mathsf{FDShrink}$

Input: $B \in \mathbb{R}^{\ell'\times d}$, $\mathbf{v} \in \mathbb{R}^d$, and an integer ℓ ▶ it always holds that $\ell' < 2\ell$.

1: $B = [B; \mathbf{v}]$
2: **If** $\ell' + 1 = 2\ell$, **then** $B = \mathsf{DenseShrink}(B, \ell)$.
3: **return** B

To achieve this, we first compute a coarse approximation using FD by invoking $B = \mathsf{FD}(A, k, \frac{1}{2k})$, which takes $O(ndk)$ time. The key idea here is that in each $\mathsf{DenseShrink}$ operation, after shrinking B, we also return the residual; we call this modified shrinking operation $\mathsf{DenseShrinkR}$ (see Algorithm 2). Let C be the matrix which is the concatenation of all residuals return from $\mathsf{DenseShrinkR}$. We will show $A^TA = B^TB + C^TC$ and $\|C\|_F^2 \le \|A - [A]_k\|_F^2$. We then refine the answer by computing an approximation to C. Since the norm of C is small, random sampling suffices. To save space, the sampled rows will be fed to a standard FD algorithm. See Algorithm 4 for detailed description of the algorithm.

Algorithm 4 FFDdense

Input: $A \in \mathbb{R}^{n\times d}$, $0 < \alpha < 1$, and integer $k \le d$.

1: $F = 0$, $\ell = 3k$, $Q =$ **empty**, $B =$ **empty**
2: **for** $i = 1$ **to** n **do**
3: Append A_i after B
4: **if** $\mathsf{rows}(B) = 2\ell$ **then**
5: $[B, \Sigma, V] = \mathsf{DenseShrinkR}(B)$ ▶ *Here $\ell = 3k$, thus $B = \mathsf{FD}(A, \frac{1}{2k}, k)$*
6: $F = F + \|\Sigma\|_F^2$, ▶ *Next: subsample $C := \Sigma V$, and then compress the sampled rows using standard* FD
7: **for** $j = 1$ **to** 2ℓ **do**
8: $p_j = \frac{\Sigma_j^2}{\alpha^2 F}$
9: Sample C_j with probability p_j.
10: **if** C_j is sampled **then**
11: Set $\mathbf{v} = \frac{C_j}{\sqrt{p_j}}$.
12: $Q = \mathsf{FDShrink}([Q; \mathbf{v}], \frac{1}{\alpha})$ ▶ *Invoking* FD *with $k = 0$*
13: **end if**
14: **end for**
15: **end if**
16: **end for**
17: **return** $[B; Q]$

Correctness. We note that, at the end of Algorithm 4, $B = \mathsf{FD}(A, \frac{1}{2k}, k)$, so $\|A^TA - B^TB\|_2 \le \|A - [A]_k\|_F^2/2k$, or equivalently

$$\max_{x:\|x\|=1} \big|\, \|Ax\|^2 - \|Bx\|^2 \,\big| \le \|A - [A]_k\|_F^2/2k. \tag{3}$$

Let $\Sigma^{(i)}$, $V^{(i)}$, and $B^{(i)}$ be the value of Σ, V, and B respectively returned by ith $\mathsf{DenseShrinkR}$ operation (line 5). Let $C^{(i)} = \Sigma^{(i)}V^{(i)}$. We use $B'^{(i)}$ to denote the value of B right before the ith $\mathsf{DenseShrinkR}$ operation (or the input of the ith $\mathsf{DenseShrinkR}$ operation). From Algorithm 2, we have that

$$B'^{(i)T}B'^{(i)} = B^{(i)T}B^{(i)} + V^{(i)T}\Sigma^{(i)2}V^{(i)} = B^{(i)T}B^{(i)} + C^{(i)T}C^{(i)}.$$

Let $A^{(i)}$ be the rows of A arrived between the $(i-1)$th and the ith $\mathsf{DenseShrinkR}$ operation, which means $B'^{(i)} = [B^{(i-1)}; A^{(i)}]$, and thus

$$B'^{(i)T}B'^{(i)} = B^{(i-1)T}B^{(i-1)} + A^{(i)T}A^{(i)}.$$

Combined with the previous equality, we get

$$A^{(i)T}A^{(i)} + B^{(i-1)T}B^{(i-1)} - B^{(i)T}B^{(i)} = C^{(i)T}C^{(i)}.$$

Let t be the total number of iterations. We define $B^{(0)} = 0$, and $C = [C^{(1)}; \cdots; C^{(t)}]$. Summing the above equality over $i = 1, \cdots, t$, we have

$$\begin{aligned} C^TC = \sum_i C^{(i)T}C^{(i)} &= \sum_i \left(A^{(i)T}A^{(i)} + B^{(i-1)T}B^{(i-1)} - B^{(i)T}B^{(i)}\right) \\ &= A^TA - B^TB. \end{aligned}$$

It follows that

$$\|C\|_F^2 \;=\; \mathsf{trace}(C^TC) = \mathsf{trace}(A^TA) - \mathsf{trace}(B^TB) = \|A\|_F^2 - \|B\|_F^2.$$

Now we bound $\|A\|_F^2 - \|B\|_F^2$ using similar ideas as in Ghashami and Phillips (2014). Let w_j be the jth singular vector of A, we have

$$\begin{aligned} \|C\|_F^2 &= \|A\|_F^2 - \|B\|_F^2 \\ &= \sum_{j=1}^{k} \|Aw_j\|^2 + \sum_{j=k+1}^{d} \|Aw_j\|^2 - \|B\|_F^2 \\ &\le \sum_{j=1}^{k} \|Aw_j\|^2 + \|A - [A]_k\|_F^2 - \sum_{j=1}^{k} \|Bw_j\|^2 \quad \text{because } \sum_{j=1}^{k} \|Bw_j\|^2 \le \|B\|_F^2 \\ &\le \|A - [A]_k\|_F^2 + k \cdot \|A - [A]_k\|_F^2/2k \quad \text{by Eq (3)} \\ &= 1.5\|A - [A]_k\|_F^2. \end{aligned} \tag{4}$$

In the algorithm, each row of C is sampled with probability $\frac{\|C_j\|^2}{\alpha^2 F}$, where F is the current squared F-norm of C. Let C_s be the sampled rows. Given Eq (4), we can prove the following using Theorem 5

$$\|C^TC - C_s^TC_s\|_2 \le \alpha\|A - [A]_k\|_F^2, \text{ and } \|C_s\|_F^2 = O(1) \cdot \|A - [A]_k\|_F^2.$$

At the end of the algorithm, $Q = \mathsf{FD}(C_s, \alpha, 0)$, then

$$\|C_s^TC_s - Q^TQ\|_2 \le \alpha\|C_s\|_F^2 \le O(\alpha) \cdot \|A - [A]_k\|_F^2.$$

Applying triangle inequality, we have $\|C^TC - Q^TQ\|_2 \le O(\alpha) \cdot \|A - [A]_k\|_F^2$, and thus

$$\|A^TA - B^TB - Q^TQ\|_2 = \|C^TC - Q^TQ\|_2 \le O(\alpha) \cdot \|A - [A]_k\|_F^2,$$

which proves the correctness.

Space and running time. The space is dominated by maintaining $B = \mathsf{FD}(A, 1/2k, k)$ and $Q = \mathsf{FD}(C_s, \alpha, 0)$, which is $O(dk + d/\alpha)$ in total.

The running time of computing B is $O(ndk)$, and the running time for Q is $O(\mathsf{rows}(C_s)d/\alpha)$. To bound $\mathsf{rows}(C_s)$, we divide the stream into epochs, where F roughly doubles in each epoch. This means the total number of epochs is bounded by $O(\log(nd))$, since we assume each real number in the input can be represented by $O(\log(nd))$ bits. We emphasize that a rigorous analysis on this will be more subtle; see discussions in the proof of Lemma 15 below. Applying Theorem 5 on the submatrix in each epoch, it is easy to check the expected number of rows sampled in each epoch is $O(1/\alpha^2)$, so $\mathsf{rows}(C_s) = O(\frac{\log(nd)}{\alpha^2})$. Thus the total running time is $O(ndk) + \tilde{O}(d\alpha^{-3})$. We remark that the residual return by $\mathsf{DenseShrinkR}$ is in the form of $C = \Sigma V^T$, where Σ is diagonal and V has orthonormal columns. Therefore, the row norms of C are simply the diagonals of Σ.

3. Algorithm for Sparse Matrices

For sketching sparse matrices, we will use a subroutine (see Algorithm 5) for computing weak low rank approximations based on fast subspace embeddings. In this subroutine, the input matrix is an $\ell \times d$ matrix A and two additional matrices J and C, where J has $O(k)$ rows and C has d columns. In our applications, J, C will always be the subspace embedding matrices from Theorem 6. The algorithm outputs an $O(k) \times \ell$ matrix Z with orthonormal rows.

Algorithm 5 Weak Low Rank Approximation (LRA)

Input: $A \in \mathbb{R}^{\ell \times d}$, $J \in \mathbb{R}^{O(k) \times w}$ and $C \in \mathbb{R}^{w \times d}$

1: Compute $S = AC^T J^T$
2: Compute $Z \in \mathbb{R}^{O(k) \times \ell}$ whose rows form an orthonormal basis for the column space of S
3: **return** Z

The following lemma is a simple corollary of Theorem 6.

Lemma 8 *If J, C are the subspace embedding matrices from Theorem 6 with $w = \min(d, O(k^2))$ and Z is the output of Algorithm 5, then with probability* 0.99

$$\|A - Z^T ZA\|_F^2 \leq O(1)\|A - [A]_k\|_F^2.$$

Moreover, Z can be computed in $O(\mathsf{nnz}(A) + \ell k^3)$ time and $O(\ell k^2)$ extra space.

Proof From Theorem 6, there exists X with $\mathsf{rank}(X) \leq k$ such that

$$\|A - Z^T X\|_F^2 \leq O(1)\|A - [A]_k\|_F^2.$$

Hence,

$$\begin{aligned}\|A - Z^T ZA\|_F^2 &\leq \|A - Z^T ZA\|_F^2 + \|Z^T ZA - Z^T X\|_F^2 \\ &= \|A - Z^T X\|_F^2 \quad \text{Pythagorean theorem} \\ &\leq O(1)\|A - [A]_k\|_F^2.\end{aligned}$$

Note that S can be computed in time $O(\mathsf{nnz}(A) + \ell k^3)$ and Z can be computed from S in $O(\ell k^2)$ time. The space usage is dominated by storing the intermediate result AC^T, which is $O(\ell k^2)$. ■

3.1. Overview of Our Algorithm

Our approach is quite different from Ghashami et al. (2016). Their main idea is to use fast approximate SVD (Musco and Musco, 2015) in the original FD, which leads to suboptimal time. Our approach is summarized as follows.

1. Decompose $A^T A = A'^T A' + R^T R$, such that A' contains small number of rows and $\|A' - [A']_k\|_F^2 = O(1) \cdot \|A - [A]_k\|_F^2$. Moreover, $\|R\|_F^2 = O(1) \cdot \|A - [A]_k\|_F^2$.

2. Compute a sketch B of A' using fast FD algorithm for dense matrices (Theorem 7), which satisfies that $\|A'^T A' - B^T B\|_2 \leq \alpha\|A' - [A']_k\|_F^2 \leq \alpha\|A - [A]_k\|_F^2$.

3. Compute a sketch matrix C of R such that $\|R^T R - C^T C\|_2 \leq \alpha\|R\|_F^2 \leq O(\alpha) \cdot \|A - [A]_k\|_F^2$, which can be done via random sampling (Theorem 5) combined with FD.

4. The final sketch is $S = [B; C]$.

Note that $S = [B; C]$ approximate $[A'; R]$ in the sense that

$$\begin{aligned}\|A'^T A' + R^T R - B^T B - C^T C\|_2 &\leq \|A'^T A' - B^T B\|_2 + \|R^T R - C^T C\|_2 \\ &\leq O(\alpha) \cdot \|A - [A]_k\|_F^2.\end{aligned}$$

From step (1), we have $A^T A = A'^T A' + R^T R$, and thus $[B; C]$ is a good approximation of A. Next we briefly describe how to implement this in one pass and small space.

To achieve (1), we use the following new idea. Let $Z \in \mathbb{R}^{O(k) \times d}$ be an orthonormal matrix satisfying $\|A - Z^T ZA\|_F^2 \leq O(1)\|A - [A]_k\|_F^2$. Let $A' = ZA$ and $R = (I - Z^T Z)A$. It is easy to check that A' and R satisfy the requirement of (1). In the streaming model, we divide A into blocks, each of which contains roughly dk non-zero entries, and thus there are at most $t = \frac{nnz(A)}{dk}$ blocks. We use the above idea for each of the blocks and concatenate the results together. More precisely, for each block $A^{(i)} \in \mathbb{R}^{\ell_i \times d}$, we use an input-sparsity time algorithm (Algorithm 5 and Lemma 8) to compute a matrix $Z^{(i)} \in \mathbb{R}^{O(k) \times \ell_i}$ such that

$$\|A^{(i)} - Z^{(i)T} Z^{(i)} A^{(i)}\|_F^2 \leq O(1)\|A^{(i)} - [A^{(i)}]_k\|_F^2.$$

Let $A'^{(i)} = Z^{(i)} A^{(i)}$, and $R^{(i)} = (I - Z^{(i)T} Z^{(i)})A^{(i)}$. We then set $A' = [A'^{(1)}; \cdots; A'^{(t)}]$ and $R = [R^{(1)}; \cdots; R^{(t)}]$, and prove that A' and R satisfy the requirement of (1), where A' only has $t \times O(k) = O(\frac{\mathsf{nnz}(A)}{d})$ rows (since each block of A' has $O(k)$ rows). Here we do not compute R explicitly, as we will sample a subset of the rows from R. Note that the running time of this step is dominated by computing $Z^{(i)} A^{(i)}$, which is $O(\mathsf{nnz}(A^{(i)})k)$, and thus $O(\mathsf{nnz}(A)k)$ in total.

To compute B of step (2), we may use the standard $\mathsf{FD}(A', \alpha, k)$ (Theorem 4). Since A' has at most $O(\frac{\mathsf{nnz}(A)}{d})$ rows, B can be computed in $O(\mathsf{nnz}(A)(k + \alpha^{-1}))$ time. However, it still has an $\mathsf{nnz}(A)\alpha^{-1}$ term. So, we apply our faster FD algorithm for dense matrices (Theorem 7) on A', which only takes $O(\mathsf{nnz}(A)k) + \tilde{O}(d\alpha^{-3})$ time.

In order to compute a sketch C of R in step (3), we first subsample the rows of R using streaming Bernoulli sampling. One difficulty is that R could be dense, and it may take nd time to compute the row norms. Fortunately, each $R^{(i)}$ is of special form, and we are able to design a fast algorithm to compute its row norms (Algorithm 7). Let Q be the sampled rows, with $\mathsf{rows}(Q) = \tilde{O}(1/\alpha^2)$, and note that each row of Q can be computed in time $O(kd)$ as $Z^{(i)} A^{(i)}$ has already been computed in step (1). We finally use $\mathsf{FD}(Q, \alpha, 0)$ to compute a sketch matrix C of Q in time $\tilde{O}(d\alpha^{-3})$. In all, the running time is roughly $O(\mathsf{nnz}(A)k) + \tilde{O}(d\alpha^{-3} + dk\alpha^{-2})$.

3.2. Our Algorithm

Algorithm 6 FFDsparse

Input: $A \in \mathbb{R}^{n\times d}$, $\alpha \in (0,1)$, and integers $k \le d$.

$F = \eta$, $F' = 0$, $B = \mathbf{0}$, $Q = \mathbf{0}$ ▶ η will be determined in Lemma 15

Divide the rows of A into continuous blocks $A^{(1)}, \cdots, A^{(t)}$: we will put new rows into the current block until: a) the number of non-zero entries exceeds dk, or b) the number of rows is $\frac{d}{k}$. When either a) or b) happens, we start a new block. Note that the total number of blocks $t \le \frac{\mathsf{nnz}(A)}{dk} + \frac{nk}{d}$.

Choose subspace embedding matrices J, C (Theorem 6) ▶ J, C are fixed for all blocks

for $i = 1$ **to** t **do**

  Compute $Z^{(i)} = \mathsf{LRA}(A^{(i)}, J, C)$ (Algorithm 5). Let $\ell_i = \mathsf{rows}(A^{(i)})$.

  Compute $A'^{(i)} = Z^{(i)} A^{(i)}$.

  $w = \mathsf{RowNorms}(A^{(i)}, Z^{(i)})$ ▶ w contains the row norms of $A^{(i)} - Z^{(i)T} Z^{(i)} A^{(i)}$ (Algorithm 7)

  $F' = F' + \|w\|^2$, and if $F' \ge 2F$, $F = F'$.
  ▶ We always have $F = O(1) \cdot \sum_i \|(I - Z^{(i)T} Z^{(i)}) A^{(i)}\|_F^2$

  Let $p \in \mathbb{R}^{\ell_i}$ such that $p_j = \frac{w_j^2}{\alpha^2 F}$ for $j = 1, \cdots, \ell_i$. Let $x \in \mathbb{R}^{\ell_i}$ be a random vector with independent entries: For each j, $x_j = 1/p_j$ w.p. p_j, and $x_j = 0$ w.p. $1 - p_j$.

  Let $R^{(i)} = (I - Z^{(i)T} Z^{(i)}) A^{(i)}$ and $Q^{(i)} = \mathsf{Diag}(x) \cdot R^{(i)}$ (no need to compute $R^{(i)}$ explicitly).

  $B = \mathsf{FFDdense}([B; A'^{(i)}], \alpha, k)$. ▶ Sketching $A' = [A'^{(1)}; \cdots; A'^{(t)}]$ using Theorem 7

  $C = \mathsf{FD}([C; Q^{(i)}], \alpha, 0)$. ▶ Sketching $Q = [Q^{(1)}; \cdots; Q^{(t)}]$ using FD.

end for

return $[B; C]$

Theorem 9 (FFDsparse) *Given any matrix $A \in \mathbb{R}^{n\times d}$, $0 < \alpha < 1$ and $0 \le k \le d$, $\mathsf{FFDsparse}(A, \alpha, k)$ (Algorithm 6) maintains a matrix S in a streaming fashion, such that, with probability 0.9,*

$$\|A^T A - S^T S\|_2 \le \alpha \|A - [A]_k\|_F^2.$$

The algorithm uses $O(d(k + \alpha^{-1}))$ space and $O(\mathsf{nnz}(A)k + nk^3) + \tilde{O}(d\alpha^{-3} + dk\alpha^{-2})$ time.

By Lemma 3, we also have the following result.

Theorem 10 *Given any matrix $A \in \mathbb{R}^{n\times d}$, $0 < \varepsilon < 1$ and $0 < k \le d$, there is a streaming algorithm which maintains a strong (ε, k)-proj-sketch $S \in \mathbb{R}^{O(k/\varepsilon)\times d}$. The algorithm uses $O(dk/\varepsilon)$ space and runs in $O(\mathsf{nnz}(A)k + nk^3) + \tilde{O}(dk^3\varepsilon^{-3}))$ time.*

3.3. Proof of Theorem 9

The detail of our fast algorithm for sparse matrix is described in Algorithm 6. We let $A' = [A'^{(1)}; \cdots; A'^{(t)}]$, $R = [R^{(1)}; \cdots; R^{(t)}]$, and $Q = [Q^{(1)}; \cdots; Q^{(t)}]$. We use $w^{(i)}$ to denote the vector w in ith iteration. We need some technical lemmas.

Lemma 11 *With probability at least 0.99, we have (1) $\|A' - [A']_k\|_F^2 \le \|A - [A]_k\|_F^2$; (2) $\|R\|_F^2 \le O(1) \cdot \|A - [A]_k\|_F^2$.*

Proof We divide A and A' into blocks as defined in Algorithm 6, i.e. $A = [A^{(1)}; \cdots; A^{(t)}]$ and $A' = [A'^{(1)}; \cdots; A^{(t)}]$. For each i, we have $A'^{(i)} = Z^{(i)} A^{(i)}$ for some matrix $Z^{(i)}$ with $O(k)$ orthonormal rows.

Let P be the projection matrix onto the subspace spanned by the top-k right singular vectors of A. So we have

$$\begin{aligned}
\|A' - [A']_k\|_F^2 &\le \|A' - A'P\|_F^2 && \text{since } P \text{ is of rank } k \\
&= \sum_{i=1}^{t} \|A'^{(i)} - A'^{(i)} P\|_F^2 \\
&= \sum_{i=1}^{t} \|Z^{(i)} A^{(i)} - Z^{(i)} A^{(i)} P\|_F^2 \\
&\le \sum_{i=1}^{t} \|A^{(i)} - A^{(i)} P\|_F^2 && Z^{(i)} \text{ is a orthonormal} \\
&= \|A - AP\|_F^2 = \|A - [A]_k\|_F^2, && \text{by definition of } P
\end{aligned}$$

which proves (1).

As defined in Algorithm 6, $R^{(i)} = (I - Z^{(i)T} Z^{(i)}) A^{(i)}$, where $Z^{(i)} = \mathsf{LRA}(A^{(i)}, J, C)$. Since $\|A^{(i)} - Z^{(i)T} Z^{(i)} A^{(i)}\|_F^2 \le O(1) \cdot \|A^{(i)} - [A^{(i)}]_k\|_F^2$ for each i (by Lemma 8), one gets

$$\begin{aligned}
\|R\|_F^2 = \sum_{i=1}^{t} \|R^{(i)}\|_F^2 &= \sum_{i=1}^{t} \|(I - Z^{(i)T} Z^{(i)}) A^{(i)}\|_F^2 \\
&\le O(1) \cdot \sum_{i=1}^{t} \|A^{(i)} - [A^{(i)}]_k\|_F^2 \\
&\le O(1) \cdot \|A - [A]_k\|_F^2
\end{aligned}$$

which proves (2). One caveat: the above argument needs $\|A^{(i)} - Z^{(i)T}Z^{(i)}A^{(i)}\|_F^2 \le O(1) \cdot \|A^{(i)} - [A^{(i)}]_k\|_F^2$ to hold for all i simultaneously. To achieve this, one could use a similar idea as in Boutsidis et al. (2016) to first boost the success probability in Lemma 8 and then apply a union bound, but this results in an extra log factor in the time complexity.

Thus, we use a different argument to bypass this. Let $S = AC^TJ^T$ and write S in the block form as $S = [S^{(1)}; \cdots; S^{(t)}]$.

Note that $S^{(i)} = A^{(i)}C^TJ^T$ and the rows of $Z^{(i)}$ form an orthonormal basis for the column space of $S^{(i)}$, thus for each i

$$\begin{aligned}
&\min_{X:\mathsf{rank}(X)\le k} \|A^{(i)} - S^{(i)}X\|_F^2 = \min_{X:\mathsf{rank}(X)\le k} \|A^{(i)} - Z^{(i)T}X\|_F^2 \\
&= \min_{X:\mathsf{rank}(X)\le k} \|A^{(i)} - Z^{(i)T}Z^{(i)}A^{(i)} + Z^{(i)T}Z^{(i)}A^{(i)} - Z^{(i)T}X\|_F^2 \\
&= \min_{X:\mathsf{rank}(X)\le k} \left(\|A^{(i)} - Z^{(i)T}Z^{(i)}A^{(i)}\|_F^2 + \|Z^{(i)T}Z^{(i)}A^{(i)} - Z^{(i)T}X\|_F^2\right) \quad \text{by Pythagorean} \\
&\ge \|A^{(i)} - Z^{(i)T}Z^{(i)}A^{(i)}\|_F^2
\end{aligned}$$

Therefore, we get

$$\begin{aligned}
\min_{X:\mathsf{rank}(X)\le k} \|A - SX\|_F^2 &= \min_{X:\mathsf{rank}(X)\le k} \sum_{i=1}^t \|A^{(i)} - S^{(i)}X\|_F^2 \\
&\ge \sum_{i=1}^t \min_{X:\mathsf{rank}(X)\le k} \|A^{(i)} - S^{(i)}X\|_F^2. \\
&\ge \sum_{i=1}^t \|A^{(i)} - Z^{(i)T}Z^{(i)}A^{(i)}\|_F^2 \qquad (5)
\end{aligned}$$

One the other hand, by Theorem 6, with probability 0.99

$$\min_{X:\mathsf{rank}(X)\le k} \|A - SX\|_F^2 \le O(1)\|A - [A]_k\|_F^2. \qquad (6)$$

Combining (5) and (6), we finally get

$$\|R\|_F^2 = \sum_{i=1}^t \|R^{(i)}\|_F^2 = \sum_{i=1}^t \|A^{(i)} - Z^{(i)T}Z^{(i)}A^{(i)}\|_F^2 \le O(1)\|A - [A]_k\|_F^2.$$

Note that, in the above proof, we only require one probabilistic event, i.e., (6), to happen, and thus avoid the union bound argument. This finish the proof of part (2). ■

Lemma 12 *$A^TA = R^TR + A'^TA'$; and with probability 0.99, it holds that $\|A^TA - A'^TA'\|_F \le O(1) \cdot \|A - [A]_k\|_F^2$.*

Proof To prove the first part, we only need to prove $A^{(i)T}A^{(i)} = R^{(i)T}R^{(i)} + A'^{(i)T}A'^{(i)}$ holds for all i. Recall that $A'^{(i)} = Z^{(i)}A^{(i)}$. For each i, we have

$$\begin{aligned}
R^{(i)T}R^{(i)} &= A^{(i)T}(I - Z^{(i)T}Z^{(i)}) \cdot (I - Z^{(i)T}Z^{(i)})A^{(i)} \\
&= A^{(i)T}(I - Z^{(i)T}Z^{(i)})A^{(i)} \qquad \text{since } (I - Z^{(i)T}Z^{(i)}) \text{ is a projection} \\
&= A^{(i)T}A^{(i)} - A'^{(i)T}A'^{(i)}.
\end{aligned}$$

This proves the first part, from which, we also get

$$\|A^TA - A'^TA'\|_F = \|R^TR\|_F \le \|R\|_F^2,$$

where the inequality is from the submultiplicative property of the Frobenius norm. Then the second part follows from Lemma 11. ■

Lemma 13 *If the entries of A are integers bounded in magnitude by $\mathrm{poly}(nd)$ and $\mathsf{rank}(A) \ge 1.1k$, then $\|A - [A]_k\|_F^2 \ge 1/\mathrm{poly}(nd)$.*

Proof The lemma directly follows from a result of Clarkson and Woodruff (2009), and here we use the restated version from Boutsidis et al. (2016).

Lemma 14 (Lemma 37 of Boutsidis et al. (2016)) *If an $n \times d$ matrix A has integer entries bounded in magnitude by γ, and has rank ρ, then the k-th largest singular value of A satisfies*

$$\sigma_k \ge (nd\gamma^2)^{-k/2(\rho-k)}.$$

■

Lemma 15 *We set $\eta = \mathrm{poly}^{-1}(nd)$ (see line 1 of Algorithm 6), then with probability at least 0.99, it holds that*

$$\|Q\|_F^2 = O(\|R\|_F^2),\ \|R^TR - Q^TQ\|_2 = O(\alpha) \cdot \|A - [A]_k\|_F^2,$$

$$\text{and } \mathsf{rows}(Q) = O(\log(nd)/\alpha^2).$$

Proof Let us first assume $\mathsf{rank}(A) \ge 1.1k$. Each row R_i of R is sampled with probability $\Theta(\frac{\|R_i\|^2}{\alpha^2 F})$, with F initialized to be η. We have $\eta \le \|A - [A]_k\|_F^2$ (by Lemma 13). When $\|R\|_F^2 \ge \eta$, the sampling probability for each row is at least $\Omega(\frac{\|R_i\|^2}{\alpha^2\|R\|_F^2})$ (since F is at most a constant approximation to $\|R\|_F^2$ at any time), so the first two parts directly follow from Theorem 5 and Lemma 11. Otherwise if $\|R\|_F^2 \le \eta \le \|A - [A]_k\|_F^2$, then the probability for sampling each row is $\Omega(\frac{\|R_i\|^2}{\alpha^2\eta}) = \Omega(\frac{\|R_i\|^2}{\alpha^2\|A-[A]_k\|_F^2})$ and the first two parts follow from Theorem 5.

To bound the number of rows sampled, we divide the stream into epochs, where F roughly doubles in each epoch. So the total number of epochs is bounded by $O(\log \frac{\|R\|_F}{\eta})$, as the final value of F is at most $O(\|R\|_F^2)$. Recall that we assume each entry of A is an integer bounded in magnitude by $\mathrm{poly}(nd)$, which implies the number of epochs is

$$O(\log \frac{\|R\|_F^2}{\eta}) \le O\left(\log\left(\|A\|_F^2 \cdot \mathrm{poly}(nd)\right)\right) = O(\log(nd)).$$

The number of rows sampled in each epoch is at most $O(1/\alpha^2)$: let $a_1, \cdots, a_t$ be the rows of R in the epoch, and thus $\sum_j \|a_j\|^2 \le O(F)$ (since the epoch ends if F doubles); each row

a_j is sampled with probability $\Theta(\frac{\|a_j\|^2}{\alpha^2 F})$, which implies the total number of rows sampled is $O(1/\alpha^2)$. This proves the third part.

The case $\mathsf{rank}(A) \le 1.1k$ is easier: we can set the rank parameter k a little larger (say $k' = 2k$) in our algorithm so that R is always $\mathbf{0}$ by Lemma 11, and thus $\mathsf{rows}(Q) = 0$. In this case, our algorithm is essentially exact. ■

Correctness. By union bound, with probability 0.9, all the above lemmas hold simultaneously, and we assume this happens. Since $C = \mathsf{FD}(Q, \alpha, 0)$, by Theorem 4 and Lemma 15, we have

$$\|Q^TQ - C^TC\|_2 \le \alpha\|Q\|_F^2 \le O(\alpha)\cdot\|R\|_F^2. \tag{7}$$

Since $B = \mathsf{FFDdense}(A', \alpha, k)$, by Theorem 7, we have

$$\|A'^TA' - B^TB\|_2 \le \alpha\|A' - [A']_k\|_F^2 \le \alpha\|A - [A]_k\|_F^2, \tag{8}$$

where the last inequality is from Lemma 11. Let $S = [B; C]$,

$$\begin{aligned}
&\|A^TA - S^TS\|_2 = \|A^TA - B^TB - C^TC\|_2\\
&\le \|A^TA - A'^TA' - C^TC\|_2 + \|A'^TA' - B^TB\|_2\\
&\le \|A^TA - A'^TA' - C^TC\|_2 + \alpha\|A - [A]_k\|_F^2 \qquad \text{by (8)}\\
&= \|R^TR - C^TC\|_2 + \alpha\|A - [A]_k\|_F^2\\
&\le \|R^TR - Q^TQ\|_2 + \|Q^TQ - C^TC\|_2 + \alpha\|A - [A]_k\|_F^2 \quad \text{triangle inequality}\\
&\le O(\alpha)\cdot\|A - [A]_k\|_F^2 + O(\alpha)\cdot\|R\|_F^2 + \alpha\|A - [A]_k\|_F^2 \qquad \text{by (7) and Lemma 15}\\
&\le O(\alpha)\cdot\|A - [A]_k\|_F^2, \qquad \text{by Lemma 11}
\end{aligned}$$

which proves the error bound after adjusting α by a constant.

Running time. Let ℓ_i be the number of rows in ith block $A^{(i)}$. The time to compute $Z^{(i)}$ using Lemma 8 is $O(\mathsf{nnz}(A^{(i)}) + \ell_i k^2)$. Hence the total time used on this step is

$$\sum_i O(\mathsf{nnz}(A^{(i)}) + \ell_i k^2) = O(\mathsf{nnz}(A) + nk^2).$$

The step to compute the matrix multiplication $A'^{(i)} = Z^{(i)}A^{(i)}$ takes $O(\mathsf{nnz}(A^{(i)})k)$ time, since Z has $O(k)$ rows. So the total time spent on this step is $O(\mathsf{nnz}(A)k)$. By definition, there are at most $O(\frac{\mathsf{nnz}(A)}{dk} + \frac{nk}{d})$ blocks. Moreover, after left multiplied by $Z^{(i)}$, each block contributes $O(k)$ rows to A', and thus the total number of rows in A' is at most $O(\frac{\mathsf{nnz}(A)}{d} + \frac{nk^2}{d})$. Computing B by invoking $B = \mathsf{FFDdense}(A', \alpha, k)$ needs $O(\mathsf{rows}(A')dk) + \tilde{O}(d/\alpha^3) = O(\mathsf{nnz}(A)k + nk^3) + \tilde{O}(d/\alpha^3)$ time. Finally, each row of Q can be computed in time $O(dk)$ given A' (which has been computed in line 6). Invoking $C = \mathsf{FD}(Q, \alpha, 0)$ needs $\tilde{O}(d/\alpha^3 + dk/\alpha^2)$ since $\mathsf{rows}(Q) = \tilde{O}(1/\alpha^2)$ by Lemma 15. So far, the total time is $O(\mathsf{nnz}(A)k + nk^3) + \tilde{O}(d\alpha^{-3} + dk\alpha^{-2})$.

The time for naively computing the row norms of R is high. One may use Johnson-Lindenstrauss transforms (Johnson and Lindenstrauss, 1984) to reduce the running time,

since constant approximations are good enough. By standard arguments, it is not hard to verify that the running time will be $O(\mathsf{nnz}(A)\log n)$ with JL transforms. If $k = \Omega(\log n)$, this term is absorbed by the leading term $O(\mathsf{nnz}(A)k)$; if $k = o(\log n)$, however, this becomes the dominating part. We next provide an algorithm, which computes the *exact* row norms of $A - Z^TZA$ in time $O(\mathsf{nnz}(A)k)$. Using this algorithm, the total time of $\mathsf{FFDsparse}$ is $O(\mathsf{nnz}(A)k + nk^3) + \tilde{O}(d\alpha^{-3} + dk\alpha^{-2})$.

Faster algorithm for computing row norms.

Lemma 16 *Given any $A \in \mathbb{R}^{n\times d}$ and $Z \in \mathbb{R}^{O(k)\times n}$, the exact row norms of $A - Z^TZA$ can be computed in time $O(\mathsf{nnz}(A)k + dk^2 + nk^2)$ and in space $O(nk + dk)$.*

Proof The algorithm is presented in Algorithm 7. We first compute ZA in $\mathsf{nnz}(A)k$ time,

Algorithm 7 RowNorms

Input: $A \in \mathbb{R}^{n\times d}$, $Z \in \mathbb{R}^{O(k)\times\ell}$
1: Compute $S = ZA$
2: Compute $[U, \Sigma, V] = \mathsf{SVD}(S)$
3: Compute $L = Z^TU\Sigma$
4: **for** $i = 1$ **to** n **do**
5: Compute $\mathbf{a}^{(1)} = A_iV$
6: Compute $w_i = \left\|\mathbf{a}^{(1)} - L_i\right\|^2 + \|A_i\|^2 - \|\mathbf{a}^{(1)}\|^2$
7: **end for**
8: **return** $w = [w_1, \cdots, w_n]$

then perform SVD on ZA: $ZA = U\Sigma V^T$. Since ZA is a $O(k)\times d$ matrix, this takes $O(dk^2)$ time. Next compute $L = Z^TU\Sigma$, which takes $O(\mathsf{rows}(A)k^2)$ time. Let $\mathbf{a}$ be the ith row in A. We compute $\mathbf{a}^{(1)} = \mathbf{a}V$ (in $O(\mathsf{nnz}(a)k)$ time), and set $\mathbf{b} = \mathbf{a} - \mathbf{a}^{(1)}V^T$ (we don't compute $\mathbf{b}$ explicitly). Then decompose $\mathbf{a}$ into two orthogonal parts as

$$\mathbf{a} = \mathbf{a}^{(1)}V^T + \mathbf{b}.$$

The ith row of $A - Z^TZA$ is

$$\mathbf{a} - L_iV^T = \left(\mathbf{a}^{(1)} - L_i\right)V^T + \mathbf{b}.$$

Note that V^T and $\mathbf{b}$ are orthogonal, and thus

$$\|\mathbf{a} - L_iV^T\|^2 = \|\left(\mathbf{a}^{(1)} - L_i\right)V^T\|^2 + \|\mathbf{b}\|^2 = \left\|\mathbf{a}^{(1)} - L_i\right\|^2 + \|\mathbf{a}\|^2 - \|\mathbf{a}^{(1)}\|^2,$$

which can be computed in time $O(\mathsf{nnz}(\mathbf{a}) + k)$. In all, the total time to compute all the row norms in $A - Z^TZA$ is

$$\mathsf{nnz}(A)k + dk^2 + \mathsf{rows}(A)k^2 + \sum_{i=1}^{\mathsf{rows}(A)} O(\mathsf{nnz}(A_i) + k) = O(\mathsf{nnz}(A)k + dk^2 + \mathsf{rows}(A)k^2).$$

■

Therefore, the time to compute all the row norms in the jth block $A^{(j)} - Z^T Z A^{(j)}$ is $O(\mathsf{nnz}(A^{(j)})k + dk^2 + \mathsf{rows}(A^{(j)})k^2)$, and the total time over all block is thus

$$\sum_{j=1}^{t} O(\mathsf{nnz}(A^{(i)})k + dk^2 + \mathsf{rows}(A^{(i)})k^2) = O(\mathsf{nnz}(A)k + nk^3),$$

where we use the fact that $t = O(\frac{\mathsf{nnz}(A)}{dk} + \frac{nk}{d})$.

Space. For space, we need a buffer to store a new block of A, the size of which is at most $dk + d$, as $\mathsf{nnz}(A^{(i)})$ is at most $dk + d$. When using Algorithm 5, the input matrix always has at most $\frac{d}{k}$ rows, so we need $O(dk)$ space to compute and store each $Z^{(i)}$ (Lemma 8). $A'^{(i)}$ is of dimension $O(k) \times d$, which needs $O(dk)$ space to compute and store. According to Lemma 16, the space needed to compute the row norms of each $R^{(i)}$ is $O(\ell_i k + dk) = O(dk)$, since $\ell_i \leq \frac{d}{k}$ for all i. From Theorem 7, the space used by $\mathsf{FFDdense}(A', \alpha, k)$ is $O(d(k+\alpha^{-1}))$. Note that, in line 12 of Algorithm 6, the rows of $Q^{(i)}$ can be computed one by one and fed to FD directly, and thus compute $C = \mathsf{FD}(Q, \alpha, 0)$ uses $O(d/\alpha)$ space by theorem 4. In all, the total space usage is bounded by $O(d(k + \alpha^{-1}))$.

4. On the Equivalence Between Frequent Directions and Matrix Multiplication

In this section, we show that, under mild assumptions, the time complexity of Frequent Directions is essentially equivalent to that of matrix multiplication modulo lower order terms.

Let $\mathcal{A}$ be an algorithm for multiplying a matrix $A \in \mathbb{R}^{n\times d}$ with an arbitrary k by n matrix; and $T(\mathsf{nnz}(A), k, n, d)$ be the running time. In this section we will assume T is non-decreasing in the first parameter $\mathsf{nnz}(A)$. Moreover, T is additive in the first parameter, i.e., $T(a, k, n, d) + T(b, k, n, d) = T(a + b, k, n, d)$ for any non-negative a and b.

4.1. Faster Matrix Multiplication Implies Faster FD

This direction follows from our $\mathsf{FFDsparse}$ algorithm.

Theorem 17 *Let $\mathcal{A}$ be an algorithm for multiplying a matrix $A \in \mathbb{R}^{n\times d}$ with an arbitrary k by n matrix and assume its running time is $T(\mathsf{nnz}(A), k, n, d)$. If T is additive and non-decreasing in the first parameter $\mathsf{nnz}(A)$, then Algorithm 6 can be implemented in time $T(\mathsf{nnz}(A), O(k), \frac{d}{k}, d) + O(nk^3) + \tilde{O}(d\alpha^{-3} + dk\alpha^{-2})$.*

Proof First, we note that the time complexity of our algorithm for sketching sparse matrices is dominated by computing $Z^{(i)}A^{(i)}$ (Line 6 in Algorithm 6) for $i = 1, 2, \cdots, t$, where $Z^{(i)}$ contains $O(k)$ rows. Using $\mathcal{A}$, this takes $T(\mathsf{nnz}(A^{(i)}), O(k), \frac{d}{k}, d)$ time, since the number of rows in $A^{(i)}$ is at most d/k in the algorithm. By the additive assumption, the total time is

$$\sum_{i=1}^{t} T(\mathsf{nnz}(A^{(i)}), O(k), \frac{d}{k}, d) = T(\mathsf{nnz}(A), O(k), \frac{d}{k}, d).$$

■

4.2. Faster FD Implies Faster Matrix Multiplication

In this subsection, we prove the other direction by showing that the running time of FD is lower bounded by matrix multiplication. The proof is based on the idea of Musco and Woodruff (2017). In particular, we show that the existence an algorithms which computes an $(O(1), k)$-cov-sketch in time $o(\mathsf{nnz}(A)k)$ implies a breakthrough in matrix multiplication, which is likely very difficult. In fact, the lower bound holds even for offline algorithms without constraints on working space.

Theorem 18 *Assume there is an algorithm $\mathcal{A}$, which, given any $A \in \mathbb{R}^{n\times d}$ with polynomially bounded integer entries, returns $B \in \mathbb{R}^{O(k)\times d}$ in time $T(\mathsf{nnz}(A), k, n, d)$ such that*

$$\|A^T A - B^T B\|_2 \leq \Delta \|A - [A]_k\|_F^2,$$

for some constant error parameter Δ. If T is additive and non-decreasing in the first parameter, then there is a $T(\mathsf{nnz}(M), k, n, d) + T(nk, k, n, d) + O(dk^2)$ time algorithm for multiplying arbitrary polynomially bounded integer matrices $M^T \in \mathbb{R}^{(d-k)\times n}$, $C \in \mathbb{R}^{n\times k}$.

Proof For any matrices $M \in \mathbb{R}^{n\times(d-k)}$ and $C \in \mathbb{R}^{n\times k}$ with integer entries in $[-U, U]$, let $A \in \mathbb{R}^{n\times d}$ be the matrix which is a concatenation of the columns of M and wC, i.e., $A = [M, wC]$. Here w is large number will be determined later. We have $\|A - [A]_k\|_F^2 \leq \|M\|_F^2 \leq ndU^2$ and

$$A^T A = \begin{bmatrix} M^T M & wM^T C \\ wC^T M & w^2 C^T C \end{bmatrix}.$$

We assume $\mathcal{A}$ is an algorithm with running time T, which can compute a sketch matrix $B \in \mathbb{R}^{O(k)\times d}$ of A such that

$$\|A^T A - B^T B\|_2 \leq \Delta \|A - [A]_k\|_F^2 \leq \Delta U^2 nd,$$

for some constant error parameter Δ.

The spectral norm of a matrix N is the largest singular value, which can be equivalently defined as $\|N\|_2 = \max_{x,y:\|x\|=\|y\|=1} x^T N y$, thereby $N_{i,j} = e_i^T N e_j \leq \|N\|_2$ for all i, j. It follows that $(A^T A - B^T B)_{i,j} \leq \Delta U^2 nd$, meaning the corresponding block of $B^T B$ is an entry-wise approximation to $wM^T C$ within additive error $\Delta U^2 nd$.

Now if w is a large integer, say $w = \lceil 3\Delta U^2 nd \rceil$, we can recover $M^T C$ from $B^T B$ exactly by rounding the numbers in $B^T B$ to their nearest integer multiple of w (as $M^T C$ is an integer matrix). Note $B^T B$ can be computed in time $O(dk^2)$ given B and the rounding can be done in $O(dk)$, so using $\mathcal{A}$, the exact integer matrix multiplication $M^T C$ can be computed in time

$$T(\mathsf{nnz}(A), k, n, d) + O(dk^2) = T(\mathsf{nnz}(M), k, n, d) + T(nk, k, n, d) + O(dk^2).$$

Here we used the fact that $\mathsf{nnz}(wC) \leq nk$ and the assumption that T is linear in the first parameter. We remark that all the integers in our reduction are at most $\mathrm{poly}(nd)$ in magnitude, as long as $U = \mathrm{poly}(nd)$, so our reduction works for any M, C with polynomially bounded entries. ■

Therefore, if $T = o(\mathsf{nnz}(A)k) = o(\mathsf{nnz}(M)k + nk^2)$, then $M^T C$ can be computed in time $o(\mathsf{nnz}(M)k) + O(nk^2 + dk^2)$, which will be a breakthrough in fast matrix multiplication.

5. Conclusion

This paper studies the problem of computing covariance sketches for matrices in the streaming model. Based on several novel algorithmic techniques, we provide new space-optimal algorithms with improved running time. We also prove that, under mild assumptions, the time complexity of Frequent Directions is essentially equivalent to that of matrix multiplication up to lower order terms. In particular, this implies that the running times of FFDdense and FFDsparse cannot be significantly improved unless the state-of-the-art matrix multiplication algorithms can, and vice versa. Thus, this paper almost settles the time complexity of this problem.

Appendix A. Omitted Proofs

A.1. Covariance error to projection error

Lemma 19 $\|A - \pi_B^k(A)\|_F^2 \le \|A - [A]_k\|_F^2 + 2k \cdot \|A^TA - B^TB\|_2$.

Proof For any x with $\|x\| = 1$, we have

$$\left| \|Ax\|^2 - \|Bx\|^2 \right| = \left| x^T(A^TA - B^TB)x \right| \le \|A^TA - B^TB\|_2 \tag{9}$$

Let u_i and w_i be the ith right singular vector of B and A respectively

$$\begin{aligned}
&\|A - \pi_B^k(A)\|_F^2 = \|A\|_F^2 - \|\pi_B^k(A)\|_F^2 \\
&= \|A\|_F^2 - \sum_{i=1}^{k} \|Au_i\|^2 \quad \text{Pathagorean theorem} \\
&\le \|A\|_F^2 - \sum_{i=1}^{k} \|Bu_i\|^2 + k \cdot \|A^TA - B^TB\|_2 \quad \text{by Eq. (9)} \\
&\le \|A\|_F^2 - \sum_{i=1}^{k} \|Bw_i\|^2 + k \cdot \|A^TA - B^TB\|_2 \quad \text{because } \sum_{i=1}^{k} \|Bw_i\|^2 \le \sum_{i=1}^{k} \|Bu_i\|^2 \\
&\le \|A\|_F^2 - \sum_{i=1}^{k} \|Aw_i\|^2 + 2k \cdot \|A^TA - B^TB\|_2 \quad \text{by Eq. (9)} \\
&= \|A - [A]_k\|_F^2 + 2k \cdot \|A^TA - B^TB\|_2.
\end{aligned}$$

■

A.2. Row sampling

Theorem 20 *For any $A \in \mathbb{R}^{n\times d}$ and $F > 0$, we sample each row A_i with probability $p_i \ge \frac{\|A_i\|^2}{\alpha^2 F}$; if it is sampled, scale it by $1/\sqrt{p_i}$. Let B be the (rescaled) sampled rows, then w.p. 0.99, $\|A^TA - B^TB\|_2 \le 10\alpha\sqrt{F}\|A\|_F$, and $\|B\|_F \le 10\|A\|_F$. The expected number of rows sampled is $O(\frac{\|A\|_F^2}{\alpha^2 F})$ if $p_i = O(\frac{\|A_i\|^2}{\alpha^2 F})$ for each i.*

Proof Since spectral norm is no larger than the Frobenius norm, it is sufficient to prove $\|A^TA - B^TB\|_F \le 10\alpha\sqrt{F}\|A\|_F$.

For each $j \in [n]$, let

$$x_j = \begin{cases} 1 & \text{if the } j\text{th rows of } A \text{ is sampled} \\ 0 & \text{otherwise.} \end{cases}$$

We have $(A^TA)_{i,j} = \sum_{t=1}^{n} a_{t,i}a_{t,j}$, while

$$(B^TB)_{i,j} = \sum_{t=1}^{n} \frac{x_t^2 \cdot a_{t,i}a_{t,j}}{p_t}.$$

So $\mathsf{E}[(B^TB)_{i,j}] = (A^TA)_{i,j}$. We also have

$$\mathsf{Var}[(B^TB)_{i,j}] = \mathsf{Var}\left[\sum_{t=1}^{n} \frac{x_t^2 \cdot a_{t,i}a_{t,j}}{p_t}\right] = \sum_{t=1}^{n} \frac{a_{t,i}^2 a_{t,j}^2 \cdot \mathsf{Var}\left[x_t^2\right]}{p_t^2} \leq \sum_{t=1}^{n} \frac{a_{t,i}^2 a_{t,j}^2}{p_t},$$

where we use the fact $\mathsf{Var}[x_t^2] = p_t(1-p_t) \leq p_t$. So we have

$$\mathsf{E}\left[\left((A^TA)_{i,j} - (B^TB)_{i,j}\right)^2\right] = \mathsf{Var}[(B^TB)_{i,j}] \leq \sum_{t=1}^{n} \frac{a_{t,i}^2 a_{t,j}^2}{p_t}.$$

Therefore,

$$\begin{aligned}
\mathsf{E}\left[\|A^TA - B^TB\|_F^2\right] &= \sum_{i,j} \mathsf{E}\left[\left((A^TA)_{i,j} - (B^TB)_{i,j}\right)^2\right] \\
&\leq \sum_{i,j}\sum_{t=1}^{n} \frac{a_{t,i}^2 a_{t,j}^2}{p_t} \\
&= \sum_{t=1}^{n} \frac{\|A_t\|^2\|A_t\|^2}{p_t} \\
&= \sum_{t=1}^{n} \alpha^2 F\|A_t\|^2 = \alpha^2 F\|A\|_F^2.
\end{aligned} \tag{10}$$

We adjust α by a constant, and using Markov's inequality

$$\mathsf{Pr}\left[\|A^TA - B^TB\|_F^2 \geq 100\alpha^2 F\|A\|_F^2\right] \leq 0.01,$$

which is equivalent to

$$\mathsf{Pr}\left[\|A^TA - B^TB\|_F \geq 10\alpha\sqrt{F}\|A\|_F\right] \leq 0.01.$$

The success probability can be boosted by a similar argument as in Drineas et al. (2006) via McDiarmid's inequality (see e.g. Boucheron et al. (2013)).

It is not hard to verify that

$$\mathsf{E}\left[\|B\|_F^2\right] = \|A\|_F^2.$$

So by another Markov inequality, we prove the second part. ■

Abstract

A crucial issue in heterogeneous domain adaptation (HDA) is the ability to learn a feature mapping between different types of features across domains. Inspired by language translation, a word translated from one language corresponds to only a few words in another language, we present an efficient method named *Sparse Heterogeneous Feature Representation (SHFR)* in this paper for multi-class HDA to learn a sparse feature transformation between domains with multiple classes. Specifically, we formulate the problem of learning the feature transformation as a compressed sensing problem by building multiple binary classifiers in the target domain as various measurement sensors, which are decomposed from the target multi-class classification problem. We show that the estimation error of the learned transformation decreases with the increasing number of binary classifiers. In other words, for adaptation across heterogeneous domains to be successful, it is necessary to construct a sufficient number of incoherent binary classifiers from the original multi-class classification problem. To achieve this, we propose to apply the error correcting output correcting (ECOC) scheme to generate incoherent classifiers. To speed up the learning of the feature transformation across domains, we apply an efficient batch-mode algorithm to solve the resultant nonnegative sparse recovery problem. Theoretically, we present a generalization error bound of our proposed HDA method under a multi-class setting. Lastly, we conduct extensive experiments on both synthetic and real-world datasets to demonstrate the superiority of our proposed method over existing state-of-the-art HDA methods in terms of prediction accuracy and training efficiency.

Keywords: Heterogeneous domain adaptation, multi-class classification, compressed sensing.

1. Introduction

In many applications, it is often expensive or time consuming to annotate sufficient labeled training data to build machine learning-based information systems. There may therefore be only a few labeled training data in the domain of interest but many labeled training data in another domain that is referred to as a source domain. Because of the differences between domains, a model trained on the labeled data in the source domain cannot be applied directly to the target domain. To address this problem, domain adaptation that aims to adapt a model from a source domain to a target domain with little or no additional human supervision has been proposed (Blitzer et al., 2006; Jiang and Zhai, 2007; Huang et al., 2007; Pan et al., 2008, 2011). Apart from thorough theoretical studies (Ben-David et al., 2006; Ben-David et al., 2010), domain adaptation techniques have been successfully applied to various applications, such as WiFi localization (Pan et al., 2008, 2011), Natural Language Processing applications (Daumé III, 2007; Jiang and Zhai, 2007), sentiment analysis (Blitzer et al., 2007b; Pan et al., 2010; Seah et al., 2011; Zhou et al., 2014, 2016a), object categorization (Duan et al., 2009; Gong et al., 2012; Hoffman et al., 2013), object detection (Donahue et al., 2013; Hoffman et al., 2014) and information retrieval (Zhou et al., 2016b, 2018).

Most existing domain adaptation works are based on the assumption that different domain data can be represented by the same feature space of the same dimensionality (Pan and Yang, 2010). However, this assumption may not hold in many real-world scenarios. For instance, in a cross-language (e.g., English/Spanish) text classification task (Prettenhofer and Stein, 2010), the feature spaces are referred to as vocabularies in different languages, and the features across domains are neither in the same feature space nor of the same dimensionality. To relax this assumption, there has been an increased focus on domain adaptation across heterogeneous feature spaces, which is referred to as Heterogeneous Domain Adaptation (HDA) (Dai et al., 2008; Yang et al., 2009). Besides cross-language text classification, many other real-world applications can be formulated as an HDA problem, such as an image classification task using auxiliary text data (Zhu et al., 2011), where the heterogeneous features are referred to as pixels and bags of textual words, respectively, image classification by using auxiliary images with different sets of features (Saenko et al., 2010; Kulis et al., 2011), where the heterogeneous features are referred to as different computer vision features, and so on.

Existing HDA approaches can be classified into two main categories. In the first category, two dense feature mappings $\mathbf{P}$ and $\mathbf{Q}$ can be learned to transform the source domain data $\mathbf{X}_S$ and target domain data $\mathbf{X}_T$, respectively, to a new latent common feature space such that the difference between the mapped domain data $\mathbf{P}\mathbf{X}_S$ and $\mathbf{Q}\mathbf{X}_T$ is reduced (Shi et al., 2010; Prettenhofer and Stein, 2010; Wang and Mahadevan, 2011; Duan et al., 2012). For example, Shi et al. (2010) proposed a heterogeneous spectral mapping (HeMap) method to learn dense orthogonal mappings based on spectral embedding without using any label information. The resultant optimization problem is a standard eigen-decomposition problem. However, this approach is known to suffer from the scalability issue. Wang and Mahadevan (2011) proposed a manifold alignment method known as DAMA to align heterogeneous features into a latent space based on manifold regularization. Unfortunately, DAMA only works on data that has a manifold structure. This limits its transferability to data on which the manifold assumption is satisfied. Furthermore, the use of DAMA results in a generalized eigen-decomposition problem of a series of matrices whose sizes depend on the dimensionality of the data. Duan et al. (2012) proposed a Heterogeneous Feature Augmentation (HFA) method to augment heterogeneous features with homogeneous common features learned using a maximum-

margin approach from both source and target domains. However, the proposed model results in an expensive semidefinite program (SDP) problem.

In the second category, a dense feature mapping $\mathbf{G}$ can be learned to transform heterogeneous data from one domain to the other domain directly so that the difference between $\mathbf{G}\mathbf{X}_S$ and $\mathbf{X}_T$ can be minimized or the alignment between $\mathbf{G}\mathbf{X}_S$ and $\mathbf{X}_T$ can be maximized. Harel and Mannor (2011) proposed a method named MOMAP to learn dense rotation matrices to match data distributions between the source and target domains. The resultant optimization problem is solved through singular value decomposition (SVD) for each class in an independent way. Kulis et al. (2011) proposed an asymmetric regularized cross-domain transformation (ARC-t) method to learn asymmetric transformation across domains based on metric learning. Similar to DAMA, ARC-t also utilizes the label information to construct the similarity and dissimilarity constraints between instances from the source and target domains, respectively. However, the computational complexities of ARC-t and its kernelized version depend quadratically on the feature dimensions and the data size, respectively.

Though most existing HDA methods have shown promising results, they still suffer from the following three major limitations.

1. **Dense Feature Mappings.** Existing methods tend to recover dense feature mappings, which is not tenable without sufficient constraints. As we will show, dense feature mappings may inevitably lose interpretability and contain significant amount of noise, which may affect the classification performance.

2. **Multi-class problem.** To address multi-class classification problems, most existing HDA methods (Dai et al., 2008; Wang and Mahadevan, 2011; Duan et al., 2012) simply adopt the one-vs-all strategy to learn multiple binary classifiers independently. Unfortunately, this strategy fails to fully explore the underlying structure among multiple classes. Consequently, this heuristic scheme is unable to guarantee good performance for multi-class HDA problems.

3. **High Computational Cost.** Since the size of the feature mapping $\mathbf{G}$ scales with the product of the dimensionality of the source and target domains, the computational cost to estimate the mapping is extremely high, especially for high-dimensional source and target data, e.g. MOMAP, HeMap, DAMA, ARC-t. To address this computational issue, Duan et al. (2012) and Kulis et al. (2011) proposed kernelized versions to learn the feature mapping. However, the kernelized methods still suffer from high computational cost on large-scale data in terms of the number of data instances.

2. Motivations and Contributions

In this work, we propose a **Sparse Heterogeneous Feature Representation** (SHFR) approach to address the above issues under following assumptions.

2.1 Motivations

1. **Sparse feature representation:** The feature mapping $\mathbf{G}$ between two domains is row-sparse, i.e., each target domain feature can be represented by a small subset of the source domain features.

2. **Class-invariance transformation:** Instances belonging to different classes share the same feature mapping $\mathbf{G}$.

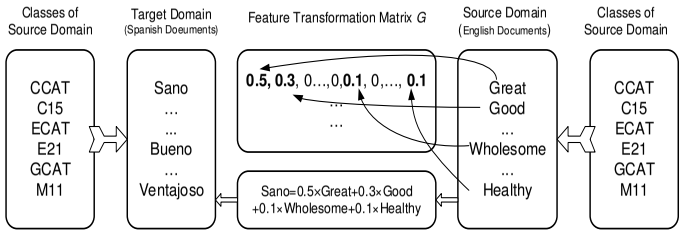

Figure 1: Illustration of the sparse feature representation matrix.

The above two assumptions are common in real-world multilingual text categorization applications. Recall that the sparsity assumption of the feature mapping across domains implies that each feature in one domain can only be represented by a small subset of features in another domain. Here, we still use the multi-language (i.e., English/Spanish) text classification problem as a motivating example. Typically, the word "Sano" in Spanish has a similar meaning to the words "Great", "Good", "Wholesome", and "healthy" in English, but not to all English words. Therefore, by assuming that the feature mapping across domains is linear, a feature or word in the Spanish domain can be represented by a linear combination of only several features or words in the English domain. As illustrated in Figure 2.1, the sparse matrix $\mathbf{G}$ denotes the feature mapping from the English domain to the Spanish domain. Based on the sparse matrix $\mathbf{G}$, the word "Sano" in Spanish can be represented sparsely by only four words in English as "Sano$''$ $=$ $0.5\times$ "Great$''+0.3\times$ "Good$''+0.1\times$ "Wholesome$''+0.1\times$ "Healthy$''$. This sparsity characteristic, which also facilitates a significant reduction in computational cost on very high-dimensional data, has not been explored in existing HDA methods. The feature mapping of the word "Sano" is invariant for different classes, for example, "CCAT" and "C15". To encode the *class-invariance* property into the feature mapping, we propose to learn a common $\mathbf{G}$ underlying all the classes which has a similar spirit to multi-task feature learning (Argyriou et al., 2007) and domain-invariant feature learning (Gong et al., 2013). We first decompose a multi-class classification problem into multiple binary classification tasks, and then jointly optimize all the binary classification tasks and the feature mapping $\mathbf{G}$, such that $\mathbf{G}$ is class-invariant to all the binary classification tasks.

2.2 Our Contributions

Based on these observations, we propose a new approach to learning a feature mapping for HDA with application to cross-lingual multi-class text categorization. To estimate this a feature mapping, we leverage the weight vectors of the binary classifiers learned in the source and target domains. We then formulate the problem of learning the feature mapping between domains as a Compressed Sensing (CS) problem, which aims to recover a sparse signal from a small number of measurements with respect to an underdetermined linear system by taking advantage of the sparseness or compressibility of the signal (Donoho, 2006; Candès et al., 2006). The main contributions of this paper are as follows:

1. We propose a **Sparse Heterogeneous Feature Representation** (SHFR) approach to learn a sparse transformation for HDA by exploring the common underlying structures between multiple classes.

2. Our major finding is that, based on the CS theory, a sparse feature mapping can be learned if and only if a sufficient number of classifiers are provided. Based on this analysis, we propose to generate sufficient classifiers under the **Error Correcting Output Correcting** (ECOC) scheme to accurately estimate the sparse feature mapping.

3. To reduce the high computational cost, we propose a **batch-mode** pursuit algorithm to efficiently solve the resultant nonnegative lasso problem of SHFR. The computational cost of SHFR is independent of the data size and the dimensionality of the source domain data, and scales linearly only with size of the dimensionality of the target domain data.

4. This paper is the first to present a **generalization error bound** for multi-class HDA which is dependent on the number of tasks as well as the degree of sparsity of the feature mapping $\mathbf{G}$.

The remainder of the paper is organized as follows. In Section 3, we first present how to formulate an HDA problem as a compressed sensing problem, and describe the detail of the proposed method, SHFR. We then theoretically analyze a generalization error bound for SHFR in Section 4, and develop a batch-mode algorithm in Section 5 to efficiently solve the resultant compressed sensing problem. In Section 6, we conduct extensive experiments on both toy and real-world datasets to demonstrate the effectiveness and efficiency of SHFR. We conclude this paper and discuss future work in Section 7.

3. Sparse Heterogeneous Feature Representation

We study the HDA problem with one source domain and one target domain under the multi-class setting. Let $\{(\mathbf{x}_{S_i}, y_{S_i})\}_{i=1}^{n_S}$ denote a set of labeled training instances of the source domain, where $\mathbf{x}_{S_i} \in \mathbb{R}^{d_S}$ denotes the i-th instance, and $y_{S_i} \in \{1, 2, \cdots, c\}$ denotes its label. Let $\{(\mathbf{x}_{T_i}, y_{T_i})\}_{i=1}^{n_T}$ be a set of labeled training instances of the target domain, where $n_T \ll n_S$, $\mathbf{x}_{T_i} \in \mathbb{R}^{d_T}$, and $y_{T_i} \in \{1, 2, \cdots, c\}$.

Given a binary task $t \in \{1, 2, \cdots, n_c\}$, we assume that the classifiers for both source and target domain are linear, which can be written as $f^t(\mathbf{x}) = \mathbf{w}^{t\top}\mathbf{x}$, where $\mathbf{w}^t$ is the weight vector of the t-th classifier. Since there are sufficient labeled data in the source domain, i.e., $\{(\mathbf{x}_{S_i}, y_{S_i})\}_{i=1}^{n_S}$, we can learn a robust set of weight vectors $\{\mathbf{w}_S^t\}_{t=1}^{n_c}$ for the source classifiers of the binary tasks decomposed from the multi-class classification problem. Similarly, we can build a corresponding set of weight vectors $\{\mathbf{w}_T^t\}_{t=1}^{n_c}$ with limited labeled data $\{(\mathbf{x}_{T_i}, y_{T_i})\}_{i=1}^{n_T}$ for the target domain.

3.1 Feature Mapping for HDA

Recall that, for HDA problems, the feature dimensions of the source and target domains may not be equal, i.e., $d_S \neq d_T$. To make effective learning across heterogeneous domains possible, a transformation matrix $\mathbf{G} \in \mathbb{R}^{d_T \times d_S}$ was introduced in ARC-t (Kulis et al., 2011; Saenko et al., 2010) to learn the similarity $\mathbf{x}_{T_i}^\top \mathbf{G}\mathbf{x}_{S_i}$ between a source instance $\mathbf{x}_{S_i} \in \mathbb{R}^{d_S}$ and a target instance $\mathbf{x}_{T_i} \in \mathbb{R}^{d_T}$. Data points can be transformed from the source feature space to the target feature

space via $\mathbf{x}_{T_i} = \mathbf{G}\mathbf{x}_{S_i}$, or equivalently, the target domain data can be mapped into the source domain via $\mathbf{G}^\top$ (Saenko et al., 2010). To learn the transformation matrix $\mathbf{G}$, corresponding pairs across domains are usually supposed to be given in advance (Qi et al., 2011) or generated based on the label information in both the source and target domains (Saenko et al., 2010). However, in practice, instance-correspondences between domains are usually missing, or the constructed instance correspondences using label information are not precise. Therefore, instead of learning the transformation by using the input raw data directly, we adapt an idea from a multi-task learning method (Ando and Zhang, 2005)[1], and propose to learn the feature mapping across heterogeneous features based on the source and target predictive structures, i.e., $\{\mathbf{w}_S^t\}$'s and $\{\mathbf{w}_T^t\}$'s.

We can either learn the transformation matrix $\mathbf{G} \in \mathbb{R}^{d_T \times d_S}$ by maximizing the dependency between the transformed weight vectors of source classifiers and the weight vectors of target classifiers via

$$\max_{\mathbf{G}} \mathbf{w}_T^{t\top} \mathbf{G}\mathbf{w}_S^t,$$

or by minimizing the distance between these two vectors via

$$\min_{\mathbf{G}} \|\mathbf{w}_T^t - \mathbf{G}\mathbf{w}_S^t\|.$$

For simplicity in theoretical analysis, we adopt the latter objective to learn the transformation $\mathbf{G}$. Given a binary task $t \in \{1, \cdots, n_c\}$ and a transformation $\mathbf{G} \in \mathbb{R}^{d_T \times d_S}$, the relationship between the weight vectors of the source and target classifiers can be modeled as follows,

$$\mathbf{w}_T^t - \mathbf{G}\mathbf{w}_S^t = \mathbf{w}_\Delta^t,$$

where $\mathbf{w}_\Delta^t$ is referred to as a "delta" weight vector, and its ℓ_2-norm $\|\mathbf{w}_\Delta^t\|_2$ is used to measure the difference between the target weight vector $\mathbf{w}_T^t$ and the transformed source weight vector $\mathbf{G}\mathbf{w}_S^t$. Note that the relationship is linear. This is because, in this paper, we focus on the application of HDA on cross-language text categorization, where using a linear form to model the relationship of predictive structures between domains is more suitable for high-dimensional text data. For modeling a nonlinear relationship between the source and target predictive structures, which may be more useful in other application areas, e.g., image classification or speech recognition, it is possible to apply an explicit nonlinear feature mapping $\phi(\mathbf{x})$ to both the source and target domain data before training the weight vectors for each domain.

3.2 Proposed Formulation

In order to use the robust source domain weight vector $\mathbf{w}_S^t$ to make predictions on the target domain data, the difference between the source and target domains after transformation should be minimized. We therefore propose to learn the transformation $\mathbf{G}$ by minimizing $\|\mathbf{w}_\Delta^t\|_2$. As mentioned in Section 2, the feature mapping $\mathbf{G}$ should be class-invariant and sparse, and for multi-language text classification and many other real-world applications, the feature mapping $\mathbf{G}$ between feature spaces should be nonnegative. The motivation of adding the nonnegative constraint on the feature mapping $\mathbf{G}$ is similar to that of applying nonnegative matrix factorization (NMF) (Lee and Seung,

1. Multi-task learning aims to simultaneously learn the classifiers for multiple tasks by sharing parameters between all the tasks, where each task has only limited labeled data. In contrast, the goal of HDA is to learn a classifier only for a target domain with limited target label data by leveraging the models learned from the source domain.

2001) to text mining. Here, we aim to approximate "input vectors", i.e., target features, by a nonnegative linear combination of a set of nonnegative "basis vectors", i.e., source features, through the mapping $\mathbf{G}$. This is also similar to multiple kernel learning (MKL) (Lanckriet et al., 2004; Gönen and Alpaydın, 2011), where the target kernel is represented by the nonnegative linear combination of base kernels. In the context of multi-lingual text classification, the nonnegative entries in $\mathbf{G}$ can be deemed as explicit "soft" global co-occurrences between the source and target wordbooks, while without the nonnegative constraint on $\mathbf{G}$, it is difficult to interpret the physical or semantic meaning behind $\mathbf{G}$.

Let $\mathbf{G} = [\mathbf{g}_1, \mathbf{g}_2, \cdots, \mathbf{g}_{d_T}]^\top$, by imposing the ℓ_1-regularization and the nonnegative constraint on $\mathbf{g}_i$, the learning of $\mathbf{G}$ can be formulated as the following nonnegative LASSO problem (Yuan and Lin, 2007; Slawski and Hein, 2011),

$$\begin{aligned} \min_{\mathbf{G}} \quad & \frac{1}{n_c}\sum_{t=1}^{n_c}\|\mathbf{w}_T^t - \mathbf{G}\mathbf{w}_S^t\|_2^2 + \sum_{i}^{d_T}\lambda_i\|\mathbf{g}_i\|_1, \\ s.t. \quad & \mathbf{g}_i \succeq \mathbf{0}, \end{aligned} \tag{1}$$

where $\lambda_i > 0$ is the trade-off parameter for the regularization term on each $\mathbf{g}_i$. In (1), the first term in the objective aims to minimize the difference between $\mathbf{w}_T^t$ and $\mathbf{G}\mathbf{w}_S^t$ over all the n_c tasks, the second term in the objective is to enforce the sparsity on each row of $\mathbf{G}$, and the constraints are used to preserve nonnegative linear relations between the source and target predictive structures.

Note that in practice, once the source domain classifiers in terms of the weight vectors $\{\mathbf{w}_S^t\}_{t=1}^{n_c}$ are learned offline, the source domain training data can be discarded. For a new domain of interest, i.e., the target domain, the weight vectors $\{\mathbf{w}_T^t\}_{t=1}^{n_c}$ can first be learned with a few labeled training data, and then $\mathbf{G}$ can be learned with $\{\mathbf{w}_S^t\}_{t=1}^{n_c}$ instead of the original source domain training data, which significantly reduces the learning complexity. This learning scheme is typically different from most of the existing HDA methods that require the original source domain training data to be available to learn the feature mapping across domains. More discussion on the complexity issue can be found in Section 5.1. As $\mathbf{G}$ is learned through all the binary classification tasks, knowledge can be transferred from the easy tasks to the difficult ones. In Section 4.2, we theoretically show that as long as a significant number of base binary tasks are not badly designed, the generalization error of the target classification model is guaranteed to be small.

To solve the optimization problem (1), we can first rewrite it in the following equivalent form,

$$\begin{aligned} \min_{\mathbf{g}_i} \quad & \frac{1}{n_c}\sum_{t=1}^{n_c}\sum_{i=1}^{d_T}(w_{T_i}^t - \mathbf{w}_S^{t\top}\mathbf{g}_i)^2 + \sum_{i}^{d_T}\lambda_i\|\mathbf{g}_i\|_1, \\ s.t. \quad & \mathbf{g}_i \succeq \mathbf{0}, \end{aligned} \tag{2}$$

where $w_{T_i}^t$ is the i-th element of the vector $\mathbf{w}_T^t$. If we exchange the summation sequences in the first term, the above optimization problem can be reformulated as the following CS problem,

$$\begin{aligned} \min_{\mathbf{g}_i} \quad & \sum_{i}^{d_T}\left(\frac{1}{n_c}\|\mathbf{b}_i - \mathbf{D}\mathbf{g}_i\|_2^2 + \lambda_i\|\mathbf{g}_i\|_1\right), \\ s.t. \quad & \mathbf{g}_i \succeq \mathbf{0}, \end{aligned} \tag{3}$$

where $\mathbf{b}_i$ is the concatenated row vector containing $\{w_{T_i}^t\}_{t=1}^{n_c}$, and $\mathbf{D} = [\mathbf{w}_S^1\ \mathbf{w}_S^2\ \cdots\ \mathbf{w}_S^{n_c}]^\top \in \mathbb{R}^{n_c \times d_S}$.

This type of CS problem has been well studied, and a number of algorithms have been proposed to solve it, such as nonnegative least squares (NNLS) (Cantarella and Piatek, 2004), accelerated proximal gradient algorithm (APG) (Toh and Yun, 2010), and orthogonal matching pursuit (OMP) (Zhang, 2009). In this work, we propose an efficient batch-mode algorithm to solve it, which is introduced in detail in Section 5. After the sparse transformation $\mathbf{G}$ has been learned, we can reuse the source domain classifiers to predict its label for any unseen test data $\mathbf{x}_T^*$ from the target domain via

$$y_T^* = F(\{(\mathbf{G}\mathbf{w}_S^t)^\top\mathbf{x}_T^*\}_{t=1}^{n_c}),$$

where $F(\cdot)$ is a decision function that combines the predictive results of all the n_c source classifiers to make a final prediction.

4. Generalization Error Bound for HDA

In the past decade, theoretical analysis for domain adaptation has been widely studied (Blitzer et al., 2007a; Mansour et al., 2009; Ben-David et al., 2010), and has focused on understanding conditions and assumptions of domain adaptation. However, most previous theoretical works were restricted by the assumption that the data from the source and target domains are represented in the same feature space and therefore cannot be applied directly to analyze the generalization error of our proposed method, SHFR, under the HDA setting. In this section, we analyze the theoretical guarantee of SHFR in detail. In contrast to existing generalization error analysis for homogeneous domain adaptation, we derive the generalization error bound for SHFR mainly from the perspectives of ECOC and compressed sensing.

4.1 Estimation Error Bound for Sparse Feature Mapping

Recall that the optimization problem (3) is composed of d_T lasso problems. In general, we have $n_c < d_S$ for relatively high-dimensional data, therefore (3) is an underdetermined linear system (Donoho, 2006). However, based on the compressed sensing theory, if $\mathbf{g}_i$ is sparse, it is possible to obtain a solution with sufficient measurements and a matrix $\mathbf{D}$ that satisfies certain conditions (Donoho, 2006; Candès et al., 2006). In particular, one such condition is the sparse Riesz condition or RIP condition, which requires that any two columns of $\mathbf{D}$ should be as perfectly incoherent as possible (Donoho, 2006; Zhang and Huang, 2008; Candès et al., 2006).

For simplicity in presentation, let k_i denote the number of non-sparse entries of $\mathbf{g}_i$ (or non-sparsity degree), and $\widehat{\mathbf{g}}_i$ denote an estimator of $\mathbf{g}_i$. According to Theorem 3 and Remark 4 in (Zhang and Huang, 2008), under some restricted conditions, the estimation error $||\mathbf{g}_i - \widehat{\mathbf{g}}_i||_2$ for each independent subproblem can be bounded by $O\left(\sqrt{\frac{k_i \log d_S}{n_c}}\right)$, where d_S denotes the dimensionality of the source domain data and n_c is the number of tasks. Hence, we can obtain the following lemma.

Lemma 1 *Under the sparse Riesz condition, the estimation error $\|\Delta\mathbf{G}_{CS}\|_F = \|\mathbf{G} - \widehat{\mathbf{G}}\|_F$ in (1) is bounded by $O\left(d_T\sqrt{\frac{k\log d_S}{n_c}}\right)$, where k, d_S, d_T, n_c, $\widehat{\mathbf{G}}$ denote the largest row non-sparsity degree of $\mathbf{G}$, the dimensionality of the source and target domain data, the number of tasks, and the estimator of $\mathbf{G}$, respectively.*

Note that besides the sparse Riesz condition, Lemma 1 also holds under some other restricted conditions, such as the RIP condition (Zhang and Huang, 2008; Candès et al., 2006). Both the sparse Riesz condition and the RIP condition require that any two columns of $\mathbf{D}$ should be as incoherent as possible (Donoho, 2006; Zhang and Huang, 2008; Candès et al., 2006). However, although the RIP condition for randomly designed matrices has been thoroughly investigated (Baraniuk et al., 2008), it is more difficult to investigate it for deterministically designed matrices in general. In contrast, the sparse Riesz condition for a deterministically designed matrix holds with high probability if the following condition is satisfied (see Proposition 1 in (Zhang and Huang, 2008)):

$$\max_{|A|=k} \inf_{\alpha \geq 1} \left\{ \sum_{j \in A} \left(\sum_{i \in A, i \neq j} |\rho_{ji}|^{\alpha/(\alpha-1)} \right)^{\alpha-1} \right\}^{1/\alpha} \leq \delta < 1,$$

where k denotes the non-sparsity degree and $\rho_{ji} = \mathbf{d}_j' \mathbf{d}_i / n_c$.

Remark 2 *Note that ρ_{ji} can be deemed as the correlation between the columns $\mathbf{d}_j$ and $\mathbf{d}_i$. Therefore, the sparse Riesz condition for a deterministically designed matrix can be evaluated by the correlations between the columns of the dictionary matrix. The smaller the summary of correlations $\sum |\rho_{ji}|$ (or δ) is, the more likely it is that the sparse Riesz condition for $\mathbf{D}$ will hold.*

According to Lemma 1 and Remark 2, to reduce the reconstruction error of the feature mapping $\mathbf{G}$, it is necessary to 1) construct as many classifiers as possible to increase the number of measurements, i.e., n_c needs to be large enough, and 2) ensure the columns of $\mathbf{D}$ constructed from the classifiers are incoherent, i.e., $\mathbf{D}$ is incoherent. For a multi-class classification problem with labels $\{1, 2, \cdots, c\}$, c binary classifiers can be generated using the one-vs-all strategy (Dietterich and Bakiri, 1995). However, when c is small, this strategy is not able to generate sufficient binary classifiers. Alternatively, the one-vs-one strategy may be used to generate $c(c-1)/2$ binary classifiers. The classifiers generated in this way may have large redundancy, however, i.e., some classifiers may be highly correlated to each other. To address this issue, we propose to use the Error Correcting Output Codes (ECOC) scheme (Dietterich and Bakiri, 1995; Zhou et al.) to generate sufficient binary classifiers for estimating the feature mapping $\mathbf{G}$. As will be shown empirically in Section 6.5, greater incoherence for $\mathbf{D}$ over the one-vs-all or one-vs-one strategy can be guaranteed with a proper design of the ECOC coding matrix.

4.2 Generalization Error Analysis of HDA Based on ECOC

By using the ECOC scheme, the multi-class hypothesis h is composed of a set of binary classifiers $\{\widehat{\mathbf{G}}\mathbf{w}_S^t\}_{t=1}^{n_c}$. However, in contrast to the one-vs-all scheme, ECOC is more general and consists of two steps: encoding, i.e., to design a coding matrix M to induce binary classifiers, and decoding, i.e., to combine the results of all the binary classifiers to make predictions based on the coding matrix. In order to analyze the generalization error bound of SHFR for multi-class HDA based on ECOC, we need to first analyze the principles of ECOC for multi-class classification.

As discussed in Dietterich and Bakiri (1995); Allwein et al. (2001), the prediction performance of a multi-class classification model learned based on the ECOC scheme depends on the design of the coding matrix. Given a coding matrix $M = \{-1, 0, +1\}^{c \times n_c}$, each class is associated with a row of the matrix M, and each binary classifier is associated with a column of the matrix M. If

an entry $M(i, j) = +1$, it implies that in the classifier f^j, class i is considered as a positive class, while if $M(i, j) = -1$, it implies that in the classifier f^j, the class i is considered as a negative class, otherwise, the class i is not taken into account for training and testing. In this way, either the one-vs-all scheme or the one-vs-one scheme can be considered as a special case of the ECOC scheme.

As pointed out by Dietterich and Bakiri (1995), a coding matrix is good if each codeword, i.e., each row, is well-separated in the Hamming distance from each of the other codewords, and each bit-position function f^k, i.e., each column, is uncorrelated with the functions to be learned for the other bit positions f^j, $j \neq k$. The power of a coding matrix M for multi-class classification can be measured by the minimum Hamming distance between any pair of its codewords (Allwein et al., 2001), denoted by $\Delta_{min}(M)$. For instance, for the one-vs-all code, $\Delta_{min}(M) = 2$, and for the one-vs-one code, $\Delta_{min}(M) = \left(\binom{c}{2} - 1 \right)/2 + 1$. For a random matrix with components chosen over $\{-1, 0, 1\}$, the expected value of $\Delta_{min}(M)$ for any distinct pair of rows is $n_c/2$.

Here, we first follow the proof procedure on error analysis for multi-class classification described in Allwein et al. (2001) to analyze the condition of a testing error by the ECOC decoding. After that, we derive the generalization error bound for the proposed SHFR with the ECOC scheme.

Given a coding matrix $M \in \{-1, 0, +1\}^{c \times n_c}$, each row corresponds to a class and each column corresponds to a binary task. For some $t \in \{1, 2, \cdots, n_c\}$, we denote $\mathbf{w}_S^t$ and h_S^t as the source domain weight vector and the hypothesis of the t-th task defined by the coding matrix M, respectively. We denote $\widehat{\mathbf{G}}\mathbf{w}_S^t$ and h_T^t as the estimated target domain weight vector and hypothesis of the t-th task, respectively. We also define the loss function,

$$L(z) = (1 - z)_+ = \max\{1 - z, 0\}, \tag{4}$$

in terms of the margin z. For example, given a target domain instance $\mathbf{x}_{T_i}$ with its label y_{T_i}, the corresponding margin $z_{T_i}^t$ for t-th task is defined as

$$z_{T_i}^t = M(y_{T_i}, t) h_T^t(\mathbf{x}_{T_i}) = M(y_{T_i}, t)((\widehat{\mathbf{G}}\mathbf{w}_S^t)^\top \mathbf{x}_{T_i}). \tag{5}$$

For instance, SVM seeks to minimize the margin-based loss under L_2 norm regularization as follows,

$$\min_{\mathbf{w}} \frac{1}{2}\|\mathbf{w}\|_2^2 + C \sum_{i=1}^{m} (1 - y_i \mathbf{w}^\top \mathbf{x}_i)_+, \tag{6}$$

where we denote margin $z = y_i \mathbf{w}^\top \mathbf{x}_i$. When the prediction is correct and $M(y_{T_i}, t) \neq 0$ for $\mathbf{x}_{T_i}$, then the margin $z_{T_i}^t > 0$, which results in $0 \leq L(z) < 1$; when the prediction is wrong and $M(y_{T_i}, t) \neq 0$ for $\mathbf{x}_{T_i}$, then the margin $z_{T_i}^t < 0$, which results in $L(z) > 1$; when $M(y_{T_i}, t) = 0$, then the margin $\mathbf{z}_{T_i}^t = 0$, which results in $L(z) = 1$. We define the $L(z)$ loss-based decoding scheme for prediction as follows:

$$d_L(M(r, :), h(\mathbf{x}_{T_i})) = \sum_{t=1}^{n_c} L(M(r, t) h_T^t(\mathbf{x}_{T_i})). \tag{7}$$

The predicted label $\hat{y} \in \{1, 2, \cdots, c\}$ is given by $\hat{y} = \arg\min_r d_L(M(r), h(\mathbf{x}_{T_i}))$.

To understand the error correction ability of ECOC, we first define the distance between the codes in any distinct pair of rows, $M(r_1,:)$ and $M(r_2,:)$, in the coding matrix M as

$$d(M(r_1,:),M(r_2,:)) = \sum_{s=1}^{n_c} d(M(r_1,s),M(r_2,s)), \tag{8}$$

where $d(M(r_1,s),M(r_2,s)) = \frac{1-sign(M(r_1,s)M(r_2,s))}{2}$.

We define $\rho = \min_{r_1 \neq r_2} d(M(r_1,:),M(r_2,:))$ as the minimum distance between any two rows in the coding matrix M, which is pre-calculated before the training.

Proposition 3 *Given a coding matrix $M \in \{-1,0,+1\}^{c\times n_c}$, a set of hypothesis outputs $h^1(\mathbf{x}),\cdots,h^{n_c}(\mathbf{x})$ on a test instance $\mathbf{x}$ generated by n_c base classifiers, and a convex loss function $L(z)$ in terms of the margin z, if $\mathbf{x}$ is misclassified by the loss-based ECOC decoding, then*

$$\sum_{t=1}^{n_c} L(M(y,t)h^t(\mathbf{x})) \geq \rho L(0), \tag{9}$$

where $M(y,t)$ denotes the corresponding label generated by the coding matrix M of ground truth. In other words, the loss of the vector of predictions $f(\mathbf{x})$ is greater than $\rho L(0)$.

Proof Suppose that the loss-based ECOC decoding incorrectly classifies a test instance $\mathbf{x}$ with the ground-truth label y. Then should then exist a label $r \neq y$ such that

$$d_L(M(y,:),h(\mathbf{x})) \geq d_L(M(r,:),h(\mathbf{x})).$$

By using the definitions of the loss function and margin introduced in (4) and (5), we denote

$$z^t = M(y,t)h^t(\mathbf{x}),$$
$$z'^t = M(r,t)h^t(\mathbf{x}),$$

By using the definitions of d_L in (7), we have

$$\sum_{t=1}^{n_c} L(z^t) \geq \sum_{t=1}^{n_c} L(z'^t). \tag{10}$$

Let $S_\Delta = \{t : M(r,t) \neq M(y,t) \wedge M(r,t) \neq 0 \wedge M(y,t) \neq 0\}$ be the set of columns of M whose r-th and y-th row entries are different and nonzero, and let $S_0 = \{t : M(r,t) = 0 \vee M(y,t) = 0\}$ be the set of columns whose r-th or y-th row entry is zero.

If $t \notin S_\Delta \cup S_0$, then $z^t = z'^t$, and (10) implies that

$$\sum_{t\in S_\Delta\cup S_0} L(z^t) \geq \sum_{t\in S_\Delta\cup S_0} L(z'^t),$$

which, in turn, implies that

$$\begin{aligned}\sum_{t=1}^{n_c} L(z^t) \geq & \sum_{t\in S_\Delta\cup S_0} L(z^t)\\ \geq & \frac{1}{2}\sum_{t\in S_\Delta\cup S_0}(L(z^t)+L(z'^t))\\ = & \frac{1}{2}\sum_{t\in S_\Delta}(L(z^t)+L(z'^t)) + \frac{1}{2}\sum_{t\in S_0}(L(z^t)+L(z'^t)).\end{aligned} \tag{11}$$

If $t \in S_\Delta$, then $z'^t = -z^t$ and $(L(-z^t)+L(z^t))/2 \geq L(0)$ due to convexity. If $t \in S_0$, then either $z^t = 0$ or $z'^t = 0$. Hence, we obtain that $L(z'^t)+L(z^t) \geq L(0)$, and the second term of (11) is at least $L(0)|S_0|/2$. Therefore,

$$\begin{aligned}\sum_{t=1}^{n_c} L(z^t) \geq & \frac{1}{2}\sum_{t\in S_\Delta}(L(z^t)+L(z'^t)) + \frac{1}{2}\sum_{t\in S_0}(L(z^t)+L(z'^t))\\ \geq & L(0)\left(|S_\Delta| + \frac{|S_0|}{2}\right)\\ = & L(0)d(M(r,:),M(y,:))\\ \geq & \rho L(0),\end{aligned} \tag{12}$$

where (12) is obtained from the fact that

$$\begin{aligned}d(M(r_1,s),M(r_2,s)) &= \frac{1-sign(M(r_1,s)M(r_2,s))}{2}\\ &= \begin{cases}0 & if\ \ M(r,t)=M(y,t)\wedge M(r,t)\neq 0\wedge M(y,t)\neq 0\\ \frac{1}{2} & if\ \ M(r,t)=0\vee M(y,t)=0\\ 1 & if\ \ M(r,t)\neq M(y,t)\wedge M(r,t)\neq 0\wedge M(y,t)\neq 0.\end{cases}\end{aligned}$$

This completes the proof. ■

Remark 4 *From Proposition 3, it can be seen that misclassification on a test instance $(\mathbf{x},y)$ implies that $\sum_{t=1}^{n_c} L(M(y,t)h^t(\mathbf{x})) \geq \rho L(0)$. In other words, the prediction codes are not required to be exactly the same as ground-truth codes for all the base classifications. As long as the loss is smaller than $\rho L(0)$, ECOC can rectify the error committed by some base classifiers, and is still able to make an accurate prediction. This error-correcting ability is very important, especially when the labeled data is insufficient in the target domain. This proposition holds for any convex margin-based loss function $L(z)$. In this paper, we use hinge loss defined in (4), then $L(0) = 1$.*

Theorem 5 *Let ϵ be the averaged loss of the target domain hypotheses $h_T^1,\ldots,h_T^{n_c}$ on the target test data $\{\{(\mathbf{x}_{T_i},M(y_{T_i},t))\}_{i=n_T+1}^{n_{Te}}\}_{t=1}^{n_c}$ with respect to the coding matrix $M \in \{-1,0,+1\}^{c\times n_c}$, where c is the cardinality of the label set. Let the convex loss function be $L(z) = |1-z|_+$. The multi-class HDA generalization error of SHFR using sparse random encoding and loss-based decoding is then at most $\frac{\epsilon n_c}{\rho}$.*

Proof According to Proposition 3, the loss for any misclassified testing instance $\mathbf{x}_T$ satisfies

$$\rho L(0) \leq \sum_{t=1}^{n_c} L(M(y_T,t)h_T^t(\mathbf{x}_T)).$$

Let a be the number of incorrect predictions for a test sample of size n_{Te}, then we can obtain the following inequality,

$$a\rho L(0) \leq a\sum_{t=1}^{n_c} L(M(y_T,t)h_T^t(\mathbf{x}_T)) \leq n_{Te}\sum_{t=1}^{n_c} L(M(y_T,t)h_T^t(\mathbf{x}_T)). \tag{13}$$

Then we have

$$a \leq \frac{n_{Te}\sum_{t=1}^{n_c} L(M(y_T,t)h_T^t(\mathbf{x}_T))}{\rho L(0)} = \frac{n_{Te}\epsilon n_c}{\rho}, \tag{14}$$

where $\epsilon = \frac{\sum_{t=1}^{n_c} L(M(y_T,t)h_T^t(\mathbf{x}_T))}{n_c}$ and $L(0) = |1-0|_+ = 1$.
Therefore, the generalization error rate is bounded by $\frac{\epsilon n_c}{\rho L(0)}$. The proof is completed. ■
