Remark 6 *The above error bound is usually small in the setting studied in this paper for the following reasons. When sufficient classifiers are generated using ECOC and* $\mathbf{G}$ *satisfies the sparsity assumption, the reconstruction error is small and bounded according to the compressive sensing theory. On the other hand, the loss* $L(M(y_T,t)h_T^t(\mathbf{x}_T))$ *for some* $\{h_T^t\}$*s, which rely on* $\mathbf{G}$*, may be large due to there being limited target domain data. The data-independent term* n_c *is usually predefined and the minimum distance* ρ *is determined correspondingly, as* ρ *monotonically increases with* n_c *according to (8). Given the predefined ECOC coding matrix, as long as the averaged loss* ϵ *is small, according to Theorem 5, target classifier is still able to make a precise prediction. In other words, SHFR is only unable to achieve satisfactory performance in terms of classification accuracy if most or all of the binary classifiers generated using ECOC trained on the target domain data are poorly designed.*

In summary, we show that the multi-class HDA generalization error of SHFR based on the ECOC scheme has a linear relationship with the average loss over all generated binary classifiers when using random encoding and loss-based decoding methods. In addition to theoretical analysis, García-Pedrajas and Ortiz-Boyer (2011) conducted comprehensive experiments and concluded that ECOC and one-vs-one are superior to other multi-class classification schemes, and are the best choices for either powerful learners or simple learners. Furthermore, Montazer et al. (2012) claimed that, of several multi-class classification schemes, sparse ECOC is better than dense ECOC, while dense ECOC is better than one-vs-one, and one-vs-all is the worst. Ghani (2000) proved a theoretical bound that a randomly-construct binary matrix is not well row-separated with probability at most $1/c^4$, where c is the number of classes. Therefore, in our experiments, we adopt the sparse and random ECOC scheme for multi-class HDA problems.

4.3 Robust Transformation Learning using ECOC

The robustness of ECOC is another important motivation for using ECOC in SHFR. Recall that the error-correcting codes can be viewed as a compact form of voting, and a certain number of incorrect votes can be corrected through the corrected votes (Dietterich and Bakiri, 1995). Given a total number of T classifiers, the voting-based methods guarantee to make a correct decision as long as there are $\lfloor \frac{T}{2} + 1 \rfloor$ correct classifiers (Dietterich, 2000), where $\lfloor\ \rfloor$ is the *floor* function that returns the largest integer not greater than the input of the function. In other words, even though there are misclassifications due to incorrect base classifiers, good performance can still be achieved in terms of the final classification accuracy by using the ECOC scheme. It has been shown in previous research that although bit error is unavoidable in real-world applications, it is still possible to make correct decisions using the error-correcting codes with a sufficient number of good learners (Ghani, 2000).

This property is particularly important for the proposed multi-class HDA method, SHFR, since some of the learned binary classifiers in the target domain may not be accurate due to insufficient label information. SHFR with ECOC is able to learn a robust transformation matrix $\mathbf{G}$ even when some target binary classifiers are not precise. The robustness of SHFR with ECOC will be verified empirically in Section 6, where we demonstrate that even with inaccurate target classifiers, the class-invariant $\mathbf{G}$ learned by SHFR with the ECOC scheme can still dramatically enhance prediction accuracy for the target domain. By combining all the above theoretical analyses, we can conclude that the generalization error of our proposed method SHFR for multi-class HDA problems is small and bounded with a proper ECOC coding matrix design.

5. Efficient Batch Decoding for SHFR

In this section, we present an algorithm to solve the proposed optimization problem (3) of SHFR in detail. Recall that problem (3) contains d_T LASSO problems with nonnegative constraints, which can be solved by adapting existing algorithms like NNLS solvers (Cantarella and Piatek, 2004; Slawski and Hein, 2011) or LASSO solvers, e.g., APG (Toh and Yun, 2010) and OMP (Zhang, 2009). However, the time complexity of these methods is $O(n_c d_S)$ for each LASSO problem, which makes problem (3) intractable when the source domain data is of very high dimensionality and the number of LASSO problems d_T is very large.

Recall that each of the optimization problems (3) can be cast as the following problem

$$\begin{aligned} \min_{\mathbf{g}_i} \quad & \frac{1}{n_c}\|\mathbf{b}_i - \mathbf{D}\mathbf{g}_i\|_2^2 + \lambda_i\|\mathbf{g}_i\|_1, \\ s.t. \quad & \mathbf{g}_i \succeq \mathbf{0}, \end{aligned} \tag{15}$$

where $\mathbf{b}_i \in \mathbb{R}^{n_c \times 1}$ is the concatenated row vector containing $w_{T_i}^t$ for all the n_c tasks, and $\mathbf{D} = [\mathbf{w}_S^1\ \mathbf{w}_S^2\ \cdots\ \mathbf{w}_S^{n_c}]^\top \in \mathbb{R}^{n_c \times d_S}$. For simplicity and without loss of clarity, we drop the subscript i from $\mathbf{g}_i$ and $\mathbf{b}_i$ in our discussion. Given any $\mathbf{g}$, let

$$\boldsymbol{\xi} = \mathbf{b} - \mathbf{D}\mathbf{g} \tag{16}$$

be the residual. Problem (15) can then be equivalently reformulated as the following problem

$$\begin{aligned} \min_{\mathbf{g}\succeq\mathbf{0},\boldsymbol{\xi}} \quad & \lambda||\mathbf{g}||_1 + \frac{1}{2}||\boldsymbol{\xi}||^2, \\ s.t. \quad & \boldsymbol{\xi} = \mathbf{b} - \mathbf{D}\mathbf{g}. \end{aligned} \tag{17}$$

Solving this problem directly can be very expensive when the source domain data is of very high dimensionality. Following Tan et al. (2015a), we propose to solve problem (15) via a matching pursuit method, called matching pursuit LASSO (MPL), as shown in Algorithm 1.

In Algorithm 1, the residual $\boldsymbol{\xi}^0$ is initialized by $\boldsymbol{\xi}^0 = \mathbf{b}$ since $\mathbf{g}^0 = \mathbf{0}$. At the t-th step, we first choose a set of B components in $\mathbf{g}$ with the B largest values in $\mathbf{D}^\top\boldsymbol{\xi}_t$, and merge their indices $\mathcal{J}_t$ into the active set $\mathcal{I}_t$. We then solve a reduced problem whose scale is only $O(n_c|\mathcal{I}_t|)$:

$$\begin{aligned} \min_{\mathbf{g}\succeq\mathbf{0},\boldsymbol{\xi}} \quad & \lambda||\mathbf{g}||_1 + \frac{1}{2}||\boldsymbol{\xi}||^2, \\ s.t. \quad & \boldsymbol{\xi} = \mathbf{b} - \mathbf{D}\mathbf{g}, \mathbf{g}_{\mathcal{I}_t^c} = \mathbf{0}, \end{aligned} \tag{18}$$

Algorithm 1 Matching pursuit LASSO for solving the nonnegative LASSO problem.

Initialize the residual $\boldsymbol{\xi}^0 = \mathbf{b}$, $\mathcal{I}_0 = \emptyset$, and let $t = 1$.
1: Compute $\mathbf{q} = \mathbf{D}^\top \boldsymbol{\xi}^{t-1}$, choose the B largest q_j, and record their indices by $\mathcal{J}_t$.
2: Let $\mathcal{I}_t = \mathcal{I}_{t-1} \cup \mathcal{J}_t$.
3: Let $\mathbf{g}_{\mathcal{I}_t^c} = \mathbf{0}$, and solve the subproblem (18) to update $\mathbf{g}_{\mathcal{I}_t}$.
4: Compute $\boldsymbol{\xi}^t = \mathbf{b} - \mathbf{D}\mathbf{g}_{\mathcal{I}_t}$.
5: Terminate if the stopping condition is achieved. Otherwise, let $t = t + 1$ and go to step 1.

where $\mathcal{I}_t$ denotes the index set of the selected columns from $\mathbf{D}$ and $\mathcal{I}_t^c$ is the corresponding complementary set of $\mathcal{I}_t$. This subproblem can be solved efficiently using a projected proximal gradient (PG) method. Note that the number B in Step 1 is a small positive integer, e.g., $B = 1$. Due to the nonnegative constraints $\mathbf{g} \succeq 0$, we find the elements with the B largest value in $\mathbf{D}^\top \boldsymbol{\xi}$ rather than $|\mathbf{D}^\top \boldsymbol{\xi}|$.

Batch-mode MPL. In Algorithm 1, solving each subproblem has a complexity of $O(kn_c)$, where k denotes the degree of the sparsity, namely $k = |\mathcal{I}_t|$, while computing $\mathbf{D}^\top \boldsymbol{\xi}$ has a complexity of $O(d_S n_c)$. Note that problem (3) has d_T sub-problems as in (15). Therefore, computing $\mathbf{D}^\top \boldsymbol{\xi}$ will dominate the whole complexity of the decoding if both n_c and d_T are very large.

To address the above computational burden imposed by $\mathbf{D}^\top \boldsymbol{\xi}$, we propose a batch-mode MPL (BMPL) algorithm. Note that $\mathbf{D}^\top \boldsymbol{\xi} = \mathbf{D}^\top(\mathbf{b} - \mathbf{D}\mathbf{g}) = \mathbf{D}^\top \mathbf{b} - \mathbf{D}^\top \mathbf{D}\mathbf{g}$. We can pre-compute $\boldsymbol{\beta} = \mathbf{D}^\top \mathbf{b}$ and $\mathbf{Q} = \mathbf{D}^\top \mathbf{D}$, and store them in the memory. Since $\mathbf{g}_{\mathcal{I}_t^c} = \mathbf{0}$ for the t-th iteration, we have $\mathbf{D}^\top \boldsymbol{\xi}^t = \mathbf{D}^\top \mathbf{b} - [\mathbf{D}^\top \mathbf{D}_{\mathcal{I}_t}]\mathbf{g}_{\mathcal{I}_t} = \boldsymbol{\beta} - \mathbf{Q}_{\mathcal{I}_t}\mathbf{g}_{\mathcal{I}_t}$, where $\mathbf{Q}_{\mathcal{I}_t}$ denotes the columns of $\mathbf{Q}$ indexed by $\mathcal{I}_t$. The computation cost for $\mathbf{D}^\top \boldsymbol{\xi}$ is thus reduced to $O(kn_c)$, which saves considerable computation cost when $k \ll d_S$. Note that $\boldsymbol{\beta}$ and $\mathbf{Q}$ are shared by all the LASSO tasks, thus they only need to be calculated once. With this strategy, the overall computational cost of solving (3) when d_S is large is significantly reduced to $O(d_T n_c k)$ (Tan et al., 2015a,b).

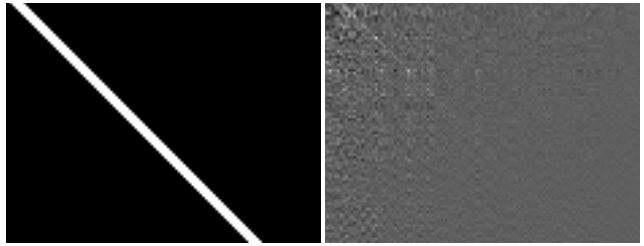
5.1 Complexity Comparison

We use linear SVMs to build the base classifiers for the source and target domains, which are obtained using the Liblinear solver (Fan et al., 2008) and pre-trained offline. The learning of $\mathbf{G}$ is not related to the number of training instances. According to the analysis in Section 5, the computational cost of SHFR is $O(d_T n_c k)$, where the sparsity degree $k \ll d_S$. Compared to state-of-the-art HDA methods, our proposed method is much more efficient. The MOMAP method transforms the problem into c separate singular value decomposition (SVD) problems resulting in complexity of $O(4d_S^2 d_T + 8d_S d_T^2 + 9d_T^3)$. The HeMap method is based on standard eigen-decomposition, whose complexity is $O(n_S + n_T)^3$. The ARC-t method solves an optimization problem that contains $n_S n_T$ constraints by applying an alternating projection method (e.g., Bregman's algorithm (Censor and Zenios, 1997)), resulting in complexity of $d_S d_T n_S n_T$. The HFA method adopts an alternating projection method to solve a semidefinite program (SDP), where the transformation matrix to be learned is in $\mathbb{R}^{(n_S+n_T)\times(n_S+n_T)}$, resulting in time complexity bounded by $O(n_S + n_T)^3$. Therefore, ARC-t and HFA perform inefficiently when the data size is large. DAMA first constructs a series of combinatorial Laplacian matrices in $\mathbb{R}^{(d_S+d_T)\times(d_S+d_T)}$, and then solves a generalized eigen-decomposition problem of time complexity bounded by $O(d_S + d_T)^3$. DAMA is therefore

Table 1: Complexity comparison of HDA methods.

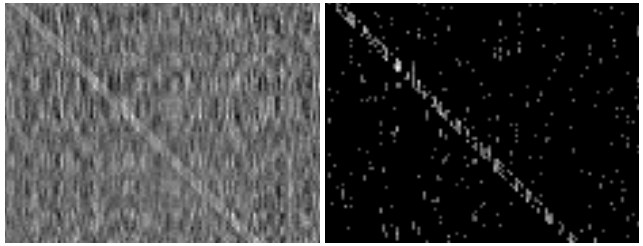
Methods	Complexity
MOMAP (Harel and Mannor, 2011)	$O(4d_S^2 d_T + 8d_S d_T^2 + 9d_T^3)$
HeMap (Shi et al., 2010)	$O(n_S + n_T)^3$
DAMA (Wang and Mahadevan, 2011)	$O(d_S + d_T)^3$
ARC-t (Kulis et al., 2011)	$O(d_S d_T n_S n_T)$
HFA (Duan et al., 2012)	$O(n_S + n_T)^3$
SHFR (our proposed method)	$O(d_T n_c k)$

computationally very expensive when the data dimensionality is high. The comparison in terms of time complexity between different methods is summarized in Table 1.



6. Experiments

In this section, we conduct experiments on both toy and real-world datasets to verify the effectiveness and efficiency of our proposed method SHFR for multi-class HDA. The parameter settings of our proposed method and other baseline methods are as follows. For ARC-t and HFA, which require the use of kernel functions to measure data similarity, we use the RBF kernel for learning the transformation. Parameter tuning is still an open research issue, as cross-validation is not applicable to HDA problems due to the limited size of labeled data in the target domain. We therefore tune the parameters of the comparison methods on a predefined range and report their best results on the test data. We use linear SVMs as the base classifiers, the regularization parameter C of which is cross-validated from the range of $\{0.01, 0.1, 1, 10, 100\}$ on the source domain data, and we use it for all the comparison methods. For our proposed method SHFR, we empirically set the maximum number of iterations to 20, $\lambda = 0.01$ and $B = 2$ in the BGMP algorithm, and generate the ECOC as long as possible for each dataset.



6.1 Experiments on Synthetic Datasets

We first compare the performance of different HDA methods in terms of recovering a ground-truth feature mapping $\mathbf{G}$ on a 20-class toy dataset. To generate the toy dataset, we first randomly generate 150 instances of 150 features for each class from different Gaussian distributions to form a source domain $\mathbf{X}_S \in \mathbb{R}^{150\times 3{,}000}$. We then construct the ground-truth sparse feature mapping $\mathbf{G} \in \mathbb{R}^{100\times 150}$ using the following method: for each row i, we set $\mathbf{G}_{ij} = 1/5$, where $j = i, i+1, \cdots, i+5$, and $\mathbf{G}_{ij} = 0$ otherwise. This generation of $\mathbf{G}$ implies that each target domain feature is represented by five source domain features. The ground-truth feature mapping is displayed in Figure 2(a), where the dark area represents the zero entries and the bright area denotes nonzero values of $\mathbf{G}$. Lastly, we construct the target domain data $\mathbf{X}_T \in \mathbb{R}^{100\times 3{,}000}$ by using $\mathbf{X}_T = \mathbf{G}\mathbf{X}_S$. When conducting the experiment, we randomly select five instances per class from the target domain data $\mathbf{X}_T$ as the labeled training data, and apply different HDA methods on them together with all 3,000 source domain labeled data to recover the feature mapping $\mathbf{G}$.

In this experiment, the HDA methods, DAMA and ARC-t, are adopted as the baselines. For ease of comparison, we present the recovered matrix $\mathbf{G}$ for each of the three methods in Figures 2(b)-2(d). From Figure 2(b), we observe that DAMA fails to recover the structure of $\mathbf{G}$, while ARC-t

(a) Ground Truth (b) DAMA

(c) ARC-t (d) SHFR

Figure 2: Illustration of the recovered feature mappings using different methods on the toy data. Black represents 0 and white represents 1.

shows better performance as can be seen in Figure 2(c). However, the $\mathbf{G}$s recovered by these two methods are not sparse. In contrast, SHFR can perfectly recover the sparse $\mathbf{G}$ with little noise as shown in Figure 2(d). These experimental results demonstrate that by explicitly adding sparsity constraints, SHFR is able to recover the feature mapping $\mathbf{G}$ more accurately.

6.2 Experiments on Real-world Datasets

We conduct experiments on three real-world datasets, Multilingual Reuters Collection, BBC Collection, and Cross-lingual Sentiment Dataset, to verify the effectiveness and efficiency of SHFR. The reported results are averaged over 10 independent data-split procedures.

6.2.1 DATASETS AND EXPERIMENTAL SETUP

Multilingual Reuters Collection[2] is a text dataset with over 11,000 news articles from six categories in five languages, i.e., English, French, German, Italian and Spanish, which are represented by a bag-of-words weighted by TF-IDF. Following the setting in Duan et al. (2012), we use Spanish as the target domain and the other four languages as source domains, which results in four multi-class HDA problems. For each class, we randomly select 100 instances from the source domain

2. http://multilingreuters.iit.nrc.ca/ReutersMultiLingualMultiView.htm

and 10 instances from the target domain for training. We randomly select 10,000 instances from the target domain as the test data. Note that the original data is of very high dimensionality, and the baseline methods cannot handle such high-dimensional features. To conduct comparison experiments, we first perform PCA with 60% energy preserved on the TF-IDF features. We then obtain 1,131 features for the the English documents, 1,230 features for the French documents, 1,417 features for the German documents, 1,041 features for the Italian documents, and 807 features for the Spanish documents. In contrast to the baseline methods, we use original features for SHFR since it can efficiently handle high-dimensional data.

BBC Collection[3] was collected for multi-view learning, and each instance is represented by three views. It was constructed from a single-view BBC corpora by splitting news articles into related "views" of text. We consider **View 3** as the target domain, and **View 1** and **View 2** as source domains. Similar to the pre-processing on the Reuters dataset, we perform PCA on the original data to reduce dimensions such that other baselines can be applied. The reduced dimensions for **View 1**, **View 2** and **View 3** are 203, 205 and 418, respectively. We randomly select 70% source domain instances and 10 target domain instances for each class for training. The remaining target domain instances are considered to be the test data.

Cross-lingual Sentiment Dataset[4] consists of Amazon product reviews of three product categories: books, DVDs and music. These reviews are written in four languages: English, German, French, and Japanese. We treat English reviews as the source domain data and the other language reviews as the target data domain data. After performing PCA, the reviews are of 715, 929, 964, and 874 features for English, German, French and Japanese, respectively. We randomly select 1,500 source domain instances and 10 target domain instances per class for training, and use the rest 5,970 target domain instances for testing.

6.2.2 OVERALL COMPARISON RESULTS

Comparison results between SHFR and other baselines on the three real-world datasets are reported in Tables 2-4. From the tables, we observe that the SVMs conducted on a small number of target domain data only, denoted by SVM-T, using either one-vs-one or one-vs-all strategy, perform the worst on average. Moreover, the results of SVM-T using one-vs-one and one-vs-all, respectively, are not consistent. For instance, on the BBC dataset in Table 3, SVM-T using the one-vs-all strategy performs much better than SVM-T using the one-vs-one strategy, while on the sentiment dataset in Table 4, SVM-T using the one-vs-one strategy performs much better than SVM-T using the one-vs-all strategy. The reason is that the size of the labeled training data is too limited to train a precise and stable classifier in the target domain. Compared to one-vs-all and one-vs-one, SVM-T with ECOC shows much more stable performance and superior results on most problems, which is because of the error correcting ability of ECOC when the labeled data is limited. The performance in terms of classification accuracy of the HDA baseline methods, DAMA, ARC-t and HFA, are comparable on the three datasets except for the BBC dataset, where DAMA performs much worse than the other two methods. This may be because the performance of DAMA is sensitive to the intrinsic manifold structure of the data. If the manifold assumption does not hold on the data, the performance of DAMA drops significantly. Our proposed SHFR method using either the one-vs-one or ECOC scheme performs best on the three datasets. SHFR can further improve the performance

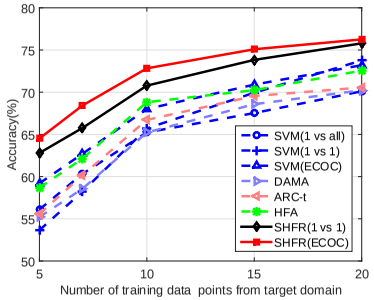
in terms of classification accuracy, compared to one-vs-one, using the ECOC scheme. The superior performance benefits from both the global transformation of $\mathbf{G}$ and the error correcting ability of ECOC. As discussed in Section 4.1, the recovered feature mapping $\mathbf{G}$ tends to be more accurate with more constructed binary tasks.

6.3 Impact on Training Sample Size of the Target Domain

We verify the impact of the size of labeled training sample in the target domain to the overall HDA performance in terms of classification accuracy. We vary the number of target domain training instances from five to 20. In this experiment, we only report the results on the Reuters dataset, where we use English as the source domain and Spanish as the target domain. The experimental results are shown in Figure 3. From the figure, we observe that SHFR consistently outperforms the baseline methods under different numbers of labeled training instance in the target domain. In particular, SHFR shows significantly better performance than the baseline methods when the size of the target domain labeled data is smaller than 10.

Based on Theorem 5, the overall generalization error of SHFR depends on the accuracy of the binary classifiers generated based on ECOC. To empirically demonstrate this point, we report the



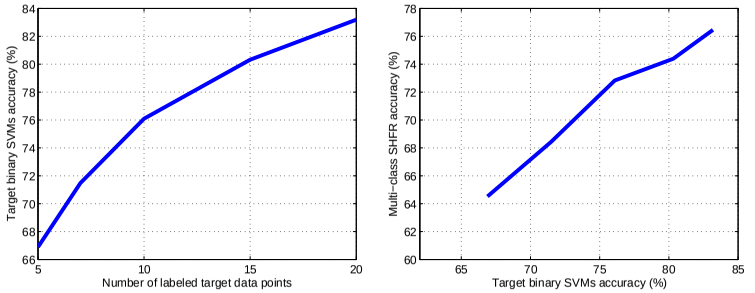


Figure 3: Comparison of different HDA methods under varying size of target labeled data.

(a) Averaged binary accuracy v.s. target data size. (b) Multiclass accuracy v.s. averaged binary accuracy.

Figure 4: Relationships between binary base classifiers and multi-class SHFR (ECOC).

averaged accuracy of all binary classifiers generated based on ECOC on the Reuters dataset under varying numbers of labeled training instances in the target domain in Figure 4(a). We also report the overall multi-class prediction accuracy versus the averaged accuracy of all binary classifiers in Figure 4(b). From the figures, we see that more labeled target data leads to more precise target binary classifiers, and thus leads to improvement in multi-class HDA classification in terms of accuracy. In particular, we observe from Figure 4(b) that the multi-class classification accuracy is proportional to the averaged binary task accuracy. The reason is that more precise target binary classifiers generally induce better alignment between the target and source classifiers.

6.4 Impact on Dimensionality of the Target Domain

In this experiment, we aim to compare the performance of different HDA methods under varying dimensionality of the target domain data. Here, we only report experimental results on the English-Spanish HDA task on the Reuters dataset. We first select 5,000 of the most-frequent features in the English domain as the source domain. We vary the dimensionality of the Spanish domain, i.e.,

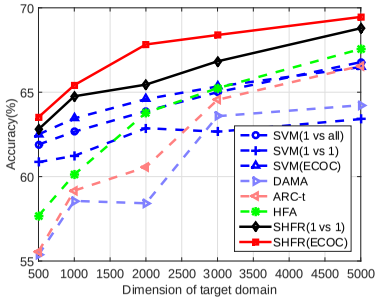

Figure 5: Comparison of different HDA methods under varying dimensions of target labeled data.

Table 5: Comparison in correlation $\sum_{ji} |\rho_{ji}|$.

Coding Scheme	English	French	German	Italian
1 vs all	0.8532 ± 0.1358	0.7557 ± 0.1289	0.2738 ± 0.0245	0.9331 ± 0.5701
1 vs 1	0.3374 ± 0.0290	0.2509 ± 0.0576	0.1168 ± 0.0110	0.3322 ± 0.1679
ECOC	0.1349 ± 0.0142	0.1478 ± 0.0225	0.0732 ± 0.0145	0.1725 ± 0.1047

the target domain, in the range of $\{500, 1000, 2000, 3000, 5000\}$ by selecting the most-frequent features of this domain. The results are shown in the Figure 5, from which we observe that SHFR consistently outperforms other baselines, especially when the dimensionality of the target domain data is low.

6.5 Incoherent Dictionary $\mathbf{D}$ Construction

In this experiment, we adopt the summation of absolute value of all pairs of columns in the dictionary $\mathbf{D}$ to evaluate $\mathbf{D}$'s coherence degree, i.e., $\sum_{ji} |\rho_{ji}|$. In other words, the smaller the value of $\sum_{ji} |\rho_{ji}|$ is, the more incoherent the dictionary is (Zhang and Huang, 2008). The results of different coding schemes on the Reuters dataset are summarized in Table 5. From the table, we observe that ECOC can be used to significantly reduce the coherence degree to enable better construction of the dictionary for the formulated compressed sensing problem.

6.6 Error Correction through Learning a Global $\mathbf{G}$

As discussed in Section 4, the weight vectors of the binary classifiers constructed in the target domain, i.e., $\{\mathbf{w}_T\}$s, may be unreliable due to the lack of target labeled data, which may affect the estimation of $\mathbf{G}$. To verify that SHFR can correct the bias of some binary classifiers, we conduct comparison experiments between SVM-T and SHFR in terms of classification accuracy on each binary task on the Reuters dataset. The results are shown in Table 6, where each column corresponds to a binary task, indexed by $k \in \{1, \cdots, 15\}$. From the table, we observe that the predictions of SVM-T on some binary tasks are inaccurate due to the limited number of labeled data. The accuracy is even below 50% (numbers in boldface). However, by learning the transformation $\mathbf{G}$ jointly among all the binary tasks, we are able to reduce the bias of the weak binary classifiers,

Table 6: Comparison results on each binary task in terms of classification accuracy (%).

Binary Classifiers	1	2	3	4	5	6	7	8
SVM-T	74.42	67.98	85.67	82.53	**43.32**	75.95	66.30	73.92

and increase accuracy by more than 30% on average. Experiments on the other two datasets return similar results, where the performance in terms of accuracy of the binary classifiers obtained through $\mathbf{G}$ is increased by 26.53% on the BBC dataset and 3.01% on the Sentiment dataset on average, compared to the results generated by SVM-T.

The experimental results in Table 6 also verify why SHFR outperforms ARC-t in the experiments shown in Tables 2-4 and Figure 3. ARC-t aims to align the target data with the source data via a transformation $\mathbf{G}$ that is learned from similarity and dissimilarity constraints. The constraints are constructed from a large number of source domain labeled data and a few target domain labeled data. In the multi-class setting, the number of similarity constraints to be constructed when the number of classes is large is much smaller than the number of dissimilarity constraints due to the limited number of target domain labeled data. In contrast to ARC-t, SHFR tries to align the target classifiers with the source classifiers using transformation $\mathbf{G}$, which is shared by all the induced binary tasks or classifiers. In other words, $\mathbf{G}$ is estimated through all classifiers. By borrowing the idea from multi-task feature learning which jointly optimizes all classifiers to learn a global feature transformation $\mathbf{G}$, is still possible to estimate a stable and precise $\mathbf{G}$ for multi-class HDA. Furthermore, as discussed in Section 4.3, ECOC with a well designed coding matrix is powerful for correcting error, as shown in Table 6.

6.7 Impact of Dichotomizer Size on Classification Error

As proven in Section 4, the generalization error of SHFR for multi-class HDA depends on the averaged loss over all the tasks, which relies on two factors: the number of classifiers (or measurements) and the degree of sparsity on $\mathbf{G}$. When $\mathbf{G}$ is sparse and the constructed binary classifiers are sufficient, it is possible to recover a precise $\mathbf{G}$ by using the dictionary constructed by $\mathbf{w}_S$. To demonstrate how the generalization error of SHFR changes under varying numbers of classifiers or dichotomizers, we conduct experiments on the Reuters dataset.

Experimental results are showed in Figure 6. From this figure we observe that when more dichotomizers are constructed, the predictions are more accurate in the target domain. This verifies that having more dichotomizers provides more information to recover the feature mapping $\mathbf{G}$. Furthermore, the standard deviation decreases with the increasing number of dichotomizers; however, as observed from the figure, multi-class accuracy no longer increases when the number of classifiers reaches 31. There are two reasons for this observation: 1) the redundancy in information among the constructed binary classifiers prevents improvement in estimating $\mathbf{G}$, and 2) according to García-Pedrajas and Ortiz-Boyer (2011), when there are many dichotomizers, the minimum distance in ECOC becomes small, which decreases the error correction ability. In general, SHFR obtains bet-

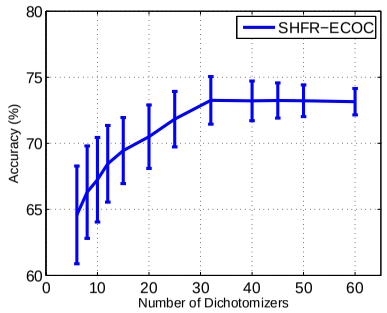

Figure 6: Accuracy vs dichotomizer (or task) size.

Table 7: Impact of Nonnegative Constraints and L_1 Norm Regularization: comparison between the results of different solvers in terms of classification accuracy (%). Results of SHFR are significantly better than the other baselines except for the cases denoted with *, judged by the t-test with a significance level at 0.05.

ter and more stable performance in terms of classification accuracy with an increasing number of dichotomizers.

6.8 Impacts of Nonnegative Constraints and ℓ_1 Norm Regularization

As discussed in Section 4, similar to the motivation of NMF, the nonnegative constraints on $\mathbf{G}$ are to approximate the "input vectors" (i.e., target features) by nonnegative linear combinations of nonnegative "basis vectors" (i.e., source features). The idea of nonnegative linear relationship can also be found in multiple kernel learning, where the target kernel is approximated by the nonnegative linear combination of base kernels. To verify the impact of the nonnegative constraints on $\mathbf{G}$, we add a baseline for comparison by moving the nonnegative constraints from the the optimization problem of SHFR, which is denoted by SHFR-LASSO. In this case, the model is reduced to a typical lasso problem.

Regarding the ℓ_1 norm regularization term in SHFR, note that some studies in the literature have shown that Non-Negative Least Squares (NNLS) can indeed achieve sparse recovery of nonnegative signals in a noiseless setting (Bruckstein et al., 2008; Donoho and Tanner, 2010; Wang and Tang, 2009; Wang et al., 2011). However, the noiseless assumption does not hold in practice. As mentioned by Slawski et al. (2013), apart from sign constraints, NNLS only consists of a fitting term, and thus is prone to overfitting, especially when the training data is high-dimensional. The ℓ_1-norm regularizer is therefore necessary to prevent over-adaptation to noisy data and enforce desired structural properties of the solution, which is similar to the idea of adding sparsity to the vector of coefficients of a predictive model (Slawski et al., 2013). In our proposed optimization problem (1), it is insufficient to achieve desirable solution of $\mathbf{G}$ without the ℓ_1-norm term in the objective since both $\mathbf{w}_S^t$ and $\mathbf{w}_T^t$ are of high dimensionality, and some of $\{\mathbf{w}_T^t\}$'s are not precise. As stated in Theorem 1 in Slawski and Hein (2011), exact sparsity, i.e., ℓ_1-norm, is not needed when the matrix satisfies the self-regularizing property, which is not applicable to our optimization problem as $\mathbf{G}$ does not have this property. Using the ℓ_1-norm ensures that a more sparse solution can be achieved by using nonnegative constraints. To verify the impact of the ℓ_1-norm on $\mathbf{G}$, we add another baseline for comparison by moving the ℓ_1-norm from the the optimization problem of SHFR, which is denoted by SHFR-NNLS. In this case, the model is reduced to an NNLS problem. In this paper, we adopt the NNLS solver proposed by Cantarella and Piatek (2004) to solve it.[5]

The results on the three multilingual datasets are summarized in Table 7. We observe from the table that SHFR-LASSO performs the worst and SHFR-NNLS enhances its performances through the nonnegative constraint. This is probably because the feature mapping $\mathbf{G}$ is learned globally and the features are naturally nonnegative for text classification. As SHFR explicitly imposes both nonnegativity and sparsity in learning the transformation $\mathbf{G}$, it can further enhance the performance compared to SHFR-NNLS by avoiding over adapting the noise in the high-dimensional data.

6.9 Experiments on Removing Negative Alignment

We have observed from Table 6 that the accuracy of SHFR for some constructed binary tasks is slightly less than the accuracy of SVM-T after learning and using the transformation $\mathbf{G}$, which can be referred to as *negative transfer* (Pan and Yang, 2010). The problem of negative transfer in SHFR mainly occurs for the following two reasons:

1. *Negative alignment* between the source and target classifiers, which happens when the classification accuracy of the corresponding target classifier is below 50%. This is because some initial target classifiers are less accurate due to the limited number of target domain labeled data.

2. The transformation $\mathbf{G}$ is class-invariant, therefore $\mathbf{G}$ is enforced to generalize well on all classifiers. In this case, $\mathbf{G}$ may correct the bias of some weak classifiers, but may also smooth the strength of good classifiers.

In this experiment, we study how the performance of SHFR is affected by removing negative alignments, and how SHFR performs if only good target classifiers whose accuracy is above 50%

5. In practice, the nonnegative lasso problem has been well studied and applied to many applications such as dimensionality reduction (Wang and Ye, 2014) and index tracking (Wu et al., 2014). Nevertheless, how to solve the nonnegative lasso problem is not the focus of our paper. In this paper, we address it by modifying the algorithm proposed by Tan et al. (2015a,b), which has demonstrated superior performance over many state-of-the-art solvers.

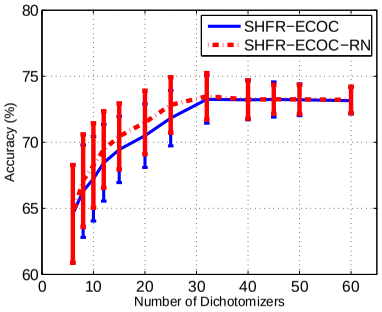
Table 8: Comparison results on each binary task after removing negative alignment in terms of classification accuracy (%).

Binary Classifiers	1	2	3	4	5	6	7	8
SVM-T	74.42	67.98	85.67	82.53	**43.32**	75.95	66.30	73.92
SHFR-RN	85.39	83.26	86.45	92.43	83.79	78.19	77.45	81.28
Difference	10.97	15.28	0.87	9.90	40.47	2.24	11.15	7.36
Binary Classifiers	9	10	11	12	13	14	15	
SVM-T	**42.78**	76.56	78.32	65.43	72.74	**46.56**	**49.71**	
SHFR-RN	84.15	78.45	92.14	82.12	84.58	82.72	88.61	
Difference	41.37	1.89	13.82	16.69	11.84	36.16	38.90	

are used. We investigate whether dropping negative alignments improves accuracy on all the binary tasks as well as the final multi-class HDA classification problem. Experimental results are shown in Table 8 and Figure 7. Compared to the results in Table 6, we discover from Table 8 that by removing the negative alignments we can improve all binary classification performances in terms of accuracy, and thus avoid negative transfers. We sort the binary tasks created from ECOC according to the accuracy on the test data and remove the poorly designed tasks. From Figure 7, we observe that when the number of dichotomizers is small (e.g., less than 30), SHFR with negative alignment removed achieves better performance in terms of multi-class classification accuracy. However, in practice, it is difficult to evaluate target classifiers due to the limit number of target domain labeled data. Interestingly, we can also find from Figure 7 that when the number of dichotomizers or tasks is sufficient, the classification accuracy of SHFR with or without removing negative alignments converges to the same value. This is because sub-class partition in ECOC often leads to higher binary accuracy when creating many dichotomizers or tasks. In this case, there are fewer binary target classifiers whose accuracy is below 50%. Therefore, we can conclude that SHFR with negative alignments removed enhances the performance in terms of classification accuracy when there are insufficient classifiers. In the multi-class HDA setting, however, the difficulty in alignment evaluation makes this post-processing impractical. Fortunately, SHFR can achieve the same performance as SHFR-RNs when there are sufficient dichotomizers or tasks, which makes SHFR more practicable for the multi-class HDA problem.

6.10 Training Time Comparison

Lastly, to verify the computational efficiency of SHFR, we conduct two experiments to compare the training time in learning the feature mapping between SHFR and other baselines under varying numbers of data dimensions and data instances. These experiments are conducted on a toy dataset, where the dimensions of the source and target data are constructed to be the same. In the first experiment, shown in Figure 8(a), we fix the number of training data (including both source and target domain data) to 3,000 and vary the data dimensions in the range of $\{100, 200, 500, 1000, 2000, 5000\}$. We observe that SHFR performs faster than all the baselines, and its training time increases slowly with the number of data dimensions. This is because the time complexity of SHFR has a linear relationship with the target domain dimensions. We can also see that the training time of DAMA increases dramatically when the number of data dimensions increases. In contrast, the training time of HFA and ARC-t does not increase much when the number of data dimensions increases. This



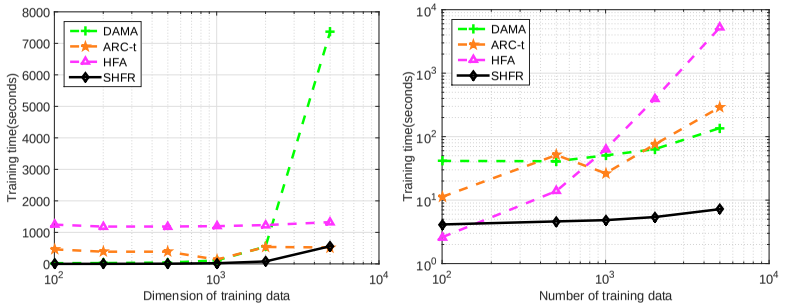


Figure 7: Accuracy v.s. dichotomizers size on removing tasks with negative alignment.

(a) Training time v.s. data dimensions (b) Training time v.s. data size

Figure 8: Time complexity comparison

is because these two methods adopt the kernel technique such that the computational time depends on the number of data instances instead of the data dimensions. In the second experiment, shown in Figure 8(b), we fix the data dimension to 1,000 and vary the number of training instances in the range of $\{100, 500, 1000, 2000, 5000\}$. From the figure, we observe that the training time of SHFR changes slightly when the number of training instances increases. However, the training time of ARC-t and HFA increases polynomially when the number of training instances increases. These two experiments verify the superiority of SHFR in computational efficiency compared with the baseline methods.

7. Conclusion and Future Work

In this paper, we propose a **sparse heterogeneous feature representation** (SHFR) method for learning sparse transformation between heterogeneous features for HDA by exploring the common underlying structures of multiple classes between the source and target domains for multi-class

HDA. SHFR encodes the sparsity and class-invariance properties in learning the feature mapping. Learning feature mapping can be cast as a Compressed Sensing (CS) problem for SHFR. Based on the CS theory, we show that the number of binary learning tasks affects the multi-class HDA performance. In addition, the proposed method has superior scalability over other methods. Extensive experiments demonstrate the effectiveness, efficiency, and stability of SHFR.

In future, we would like to investigate how to extend the proposed method by exploring the nonlinear feature transformation between image and text feature representations.

Abstract

State-of-the-art first- and second-order optimization methods are able to achieve either fast global linear convergence rates or quadratic convergence, but not both of them. In this work, we propose an interpolation between first- and second-order methods for regularized empirical risk minimization that exploits the problem structure to efficiently combine multiple update directions. Our method attains both optimal global linear convergence rate for first-order methods, and local quadratic convergence. Experimental results show that our method outperforms state-of-the-art first- and second-order optimization methods in terms of the number of data accesses, while is competitive in training time.

1. Introduction

Consider the general problem

$$\min_{\boldsymbol{w}\in\mathbb{R}^n} \quad f(\boldsymbol{w}), \tag{1}$$

where $f(\boldsymbol{w})$ is convex and continuously differentiable. Most iterative optimization methods generate iterates by using the first- and second-order derivatives. After a new step is generated, the previous steps and related calculation results are usually considered outdated and thus discarded. In this work, we show that we can reuse previous descent directions in later iterations to reduce computation and to achieve both linear and quadratic convergence.

The idea behind our proposed method is simple. We store all previous directions, and approximately solve the subproblem

$$\min_{\boldsymbol{t}\in\mathbb{R}^m} \quad f(\boldsymbol{w}+P\boldsymbol{t}), \tag{2}$$

where the columns of $P = [\boldsymbol{p}_1, \ldots, \boldsymbol{p}_m]$ form an orthonormal basis of the span of the previous update directions. The resulting direction $P\boldsymbol{t}$ is then used to update the current iterate $\boldsymbol{w}$ for the next iteration. Utilizing all previous directions obtained from the first iteration on seems to be computationally and spatially expensive, especially in the later stage of this method. However, we note that for regularized empirical risk minimization (ERM) of linear models, the method comes with little additional cost by wisely caching the inner products between these $\boldsymbol{p}_i$ and the training data. We will exemplify how to use this caching strategy to significantly accelerate the computation in our method for ERM. Experimental results show that our method outperforms state of the art.

There are other optimization methods that also reuse previous update directions. For example, the heavy-ball method (Polyak, 1964), the (nonlinear) conjugate gradient method (Fletcher and Reeves, 1964), and Nesterov's accelerated gradient method (Nesterov, 1983, 2013) reuse the previous direction $\boldsymbol{w}_k - \boldsymbol{w}_{k-1}$ together with the current gradient to decide the update direction at the k-th iteration. On the other hand, quasi-Newton methods such as BFGS (Dennis and Moré, 1977) and L-BFGS (Liu and Nocedal, 1989) store previous gradients to construct an approximation of the Hessian. More details of these methods and empirical comparisons are provided in later sections.

This paper is organized as follows. We describe the details of our algorithm in Section 2. We prove global linear convergence and local quadratic convergence. Section 3 illustrates important techniques for accelerating the computation when solving ERM problems. We then extend the proposed method to a more general framework and obtain a better linear convergence rate in Section 4. Related works are discussed in Section 5. Experimental results in Section 6 show that our method outperforms state-of-the-art methods empirically in terms of the number of data accesses, and is competitive in terms of training time. We then consider some interesting extensions in Section 7. Section 8 concludes the paper.

Programs used for experiments and a supplementary file including additional results can be found at `http://www.csie.ntu.edu.tw/~cjlin/papers/commdir/`.

2. Common-directions Method

Before starting the description of our algorithm, we first specify the type of problems we consider. For all our theoretical results except Theorem 6, we require that $f(\boldsymbol{w})$ satisfies Assumption 1.

Assumption 1 *The objective function $f(\boldsymbol{w})$ is differentiable, ρ Lipschitz smooth and σ strongly convex with some constants $\rho \geq \sigma > 0$.*[1] *That is,*

$$\|\nabla f(\boldsymbol{u}) - \nabla f(\boldsymbol{v})\| \leq \rho\|\boldsymbol{u}-\boldsymbol{v}\|, \quad \forall \boldsymbol{u}, \boldsymbol{v} \in \mathbb{R}^n, \tag{3}$$

and

$$f(\boldsymbol{u}) - f(\boldsymbol{v}) - \nabla f(\boldsymbol{v})^\top(\boldsymbol{u}-\boldsymbol{v}) \geq \frac{\sigma}{2}\|\boldsymbol{u}-\boldsymbol{v}\|^2, \quad \forall \boldsymbol{u}, \boldsymbol{v} \in \mathbb{R}^n. \tag{4}$$

For some theoretical results, we further need that $f(\boldsymbol{w})$ satisfies Assumption 2.

1. The requirement $\rho \geq \sigma$ comes from the conditions (3) and (4).

Algorithm 1: A framework for the common-directions method

Given $\boldsymbol{w}_0$, compute $\nabla f(\boldsymbol{w}_0)$;
$P = [\nabla f(\boldsymbol{w}_0)/\|\nabla f(\boldsymbol{w}_0)\|]$;
for *k=0,1,... in the outer loop* **do**
  if $\nabla f(\boldsymbol{w}_k) = \mathbf{0}$, or some stopping condition is satisfied **then**
    stop;
  end
  Let $\boldsymbol{t}_k = -(P^\top \nabla^2 f(\boldsymbol{w}_k) P)^{-1} P^\top \nabla f(\boldsymbol{w}_k)$;
  Backtracking line search on $f(\boldsymbol{w}_k + \theta P \boldsymbol{t}_k)$ by Algorithm 2 to obtain θ_k;
  $\boldsymbol{w}_{k+1} = \boldsymbol{w}_k + \theta_k P \boldsymbol{t}_k$;
  Compute $\nabla f(\boldsymbol{w}_{k+1})$;
  Let $\boldsymbol{p} = \nabla f(\boldsymbol{w}_{k+1}) - P(P^\top \nabla f(\boldsymbol{w}_{k+1}))$;
  if $\boldsymbol{p} \neq \mathbf{0}$ **then**
    $P = [P,\ \boldsymbol{p}/\|\boldsymbol{p}\|]$;
  end
end

Algorithm 2: Backtracking line search

Given $\beta \in (0,1)$, $\lambda > 0$, the current iterate $\boldsymbol{w}$, a descent direction $P\boldsymbol{t}$;
Let $\theta := 1$;
while $f(\boldsymbol{w}) - f(\boldsymbol{w} + \theta P \boldsymbol{t}) < \frac{\lambda}{2}\theta^2 \|P\boldsymbol{t}\|^2$ **do**
  $\theta := \beta\theta$;
end

Assumption 2 *The objective function $f(\boldsymbol{w})$ is twice-differentiable, and the Hessian of $f(\boldsymbol{w})$ is M Lipschitz continuous with some constant $M > 0$. That is,*

$$\|\nabla^2 f(\boldsymbol{u}) - \nabla^2 f(\boldsymbol{v})\| \leq M\|\boldsymbol{u} - \boldsymbol{v}\|, \quad \forall \boldsymbol{u}, \boldsymbol{v} \in \mathbb{R}^n.$$

When minimizing a function, we usually only work on derivatives of the current iterate. For example, a gradient descent step can be derived from searching along the negative gradient direction, and a Newton step can be expressed by the current gradient and Hessian. However, after obtaining the update direction, stale derivatives are usually discarded, which can be inefficient. A simple idea is to store all previous directions $\boldsymbol{p}_j$ in $P = [\boldsymbol{p}_1, \ldots, \boldsymbol{p}_m]$ and consider working on the linear span of $\boldsymbol{p}_j$. If possible, we search for the best linear combination $P\boldsymbol{t}$ such that $f(\boldsymbol{w} + P\boldsymbol{t})$ is the smallest; see the sub-problem (2). However, in practice (2) may be difficult to be solved, so following past optimization development, we consider the second-order Taylor approximation of $f(\boldsymbol{w})$ as

$$\tilde{f}(\boldsymbol{u} \mid \boldsymbol{w}) \equiv f(\boldsymbol{w}) + \nabla f(\boldsymbol{w})^\top (\boldsymbol{u} - \boldsymbol{w}) + \frac{1}{2}(\boldsymbol{u} - \boldsymbol{w})^\top \nabla^2 f(\boldsymbol{w})(\boldsymbol{u} - \boldsymbol{w}), \tag{5}$$

where $\nabla^2 f(\boldsymbol{w})$ is the Hessian at $\boldsymbol{w}$. Then, a descent direction $\boldsymbol{d} = P\boldsymbol{t}$ can be found by optimizing $\tilde{f}$ along all the directions $\boldsymbol{p}_j$

$$\min_{\boldsymbol{t}} \quad \tilde{f}(\boldsymbol{w} + \sum_{j=1}^{m} t_j \boldsymbol{p}_j \mid \boldsymbol{w}) = (P^\top \nabla f(\boldsymbol{w}))^\top \boldsymbol{t} + \frac{1}{2}\boldsymbol{t}^\top (P^\top \nabla^2 f(\boldsymbol{w}) P)\boldsymbol{t}. \tag{6}$$

Problem (6) can be solved by the following linear system.

$$(P^\top \nabla^2 f(\boldsymbol{w}) P)\boldsymbol{t} = -P^\top \nabla f(\boldsymbol{w}).$$

Say we have stored m previous directions in $P \in \mathbb{R}^{m \times n}$, where $m \ll n$. Problem (6) has m variables but if instead we consider the Newton direction by solving the problem in (5), the number of variables is n. Therefore, solving (6) should be easier than finding a Newton direction if the construction of $P\nabla^2 f(\boldsymbol{w})P^\top$ is not too expensive. In Section 3, we will show that when the Hessian is structured, the subproblem (6) can be solved easily.

From the above concept, we propose the common-directions method. In each iteration of this method, given the orthonormal basis P of the span of the past directions, we solve the subproblem (6) with respect to $\boldsymbol{t}$ to obtain the update direction $P\boldsymbol{t}$. A line search along $P\boldsymbol{t}$ is performed to guarantee the strict decrease of the function value. After updating the iterate $\boldsymbol{w}$, a new direction $-\nabla f(\boldsymbol{w})$ is then taken to enlarge the orthonormal basis P by Gram-Schmidt orthogonalization. A description of the common-directions method is given in Algorithm 1, and the line-search sub-routine is described in Algorithm 2. Note that other choices of the directions being added to P are also possible, but for the ease of description and analysis, we confine our choice to the current steepest descent direction.

We define the following quantities before stating and proving the theorems. We denote the condition number of f by

$$\kappa \equiv \frac{\rho}{\sigma},$$

and define an ϵ-accurate solution of f to be a point $\boldsymbol{w}$ such that

$$f(\boldsymbol{w}) - f(\boldsymbol{w}^*) \leq \epsilon,$$

where $\boldsymbol{w}^*$ is the optimal solution of f. Note that under Assumption 1, problem (1) possesses a unique optimal solution. The following theorems present theoretical convergence of the proposed method. In particular, we show that the line search sub-routine has finite termination, and our method is globally linearly convergent and locally quadratically convergent.

Theorem 3 *Under Assumption 1, every time being called by Algorithm 1, Algorithm 2 terminates within $\lceil \log_\beta(\beta\sigma/(\rho+\lambda)) \rceil$ steps, and Algorithm 1 converges Q-linearly with iteration complexity $O(\kappa^3 \log(1/\epsilon))$ to achieve an ϵ-accurate solution. Further, if Algorithm 2 always stops at step size 1, the iteration complexity becomes $O(\kappa \log(1/\epsilon))$.*

In practice, we observed that the common-direction method usually accepts step size 1.

Theorem 4 *Under Assumptions 1 and 2, Algorithm 1 converges quadratically after certain iteration.*

The proofs are presented in Appendix A.

3. Application on Regularized Empirical Risk Minimization Problems

For most optimization problems, computing the $n \times n$ Hessian matrix, or its inverse, whose cost is $O(n^3)$, is much more expensive than obtaining the function value and the n-dimensional gradient vector. To tackle this problem, different approaches have been considered, and in some cases the problem structure can be utilized to reduce the cost. We are interested in solving machine learning problems, and thus we will focus our discussion on differentiable regularized ERM problems. More specifically, given training feature-label pairs $(\boldsymbol{x}_i, y_i)$, $i = 1, \ldots, l$, with $\boldsymbol{x}_i \in \mathbb{R}^n$, $y_i \in \mathbb{R}$, and a parameter $C > 0$, we consider L2-regularized ERM problems

$$\min_{\boldsymbol{w}\in\mathbb{R}^n} \quad f(\boldsymbol{w}), \quad \text{where } f(\boldsymbol{w}) \equiv \frac{1}{2}\boldsymbol{w}^\top\boldsymbol{w} + C\sum_{i=1}^{l}\xi(y_i; \boldsymbol{w}^\top\boldsymbol{x}_i), \tag{7}$$

and ξ is a loss function convex in $\boldsymbol{w}^\top\boldsymbol{x}_i$. The first term in (7) makes f be σ strongly convex with $\sigma \geq 1$, and the choice of loss functions ensures that $\nabla f(\boldsymbol{w})$ is Lipschitz continuous, though the corresponding constant ρ may be unknown. Therefore, Assumption 1 is satisfied.

For problem (7), by defining

$$X \equiv \begin{pmatrix} \boldsymbol{x}_1^\top \\ \vdots \\ \boldsymbol{x}_l^\top \end{pmatrix},$$

we can write the gradient as

$$\nabla f(\boldsymbol{w}) = \boldsymbol{w} + X^\top \boldsymbol{v}_{\boldsymbol{w}}, \text{ where } (v_{\boldsymbol{w}})_i = C\frac{\partial}{\partial z}\xi(y_i; z)\mid_{z=\boldsymbol{w}^\top\boldsymbol{x}_i}, i = 1, \ldots, l, \tag{8}$$

and if $f(\boldsymbol{w})$ is twice-differentiable, the Hessian is

$$\nabla^2 f(\boldsymbol{w}) \equiv I + X^\top D_{\boldsymbol{w}} X, \tag{9}$$

where I is the identity matrix and $D_{\boldsymbol{w}}$ is a diagonal matrix with

$$(D_{\boldsymbol{w}})_{ii} \equiv C\frac{\partial^2}{\partial z^2}\xi(y_i; z)\mid_{z=\boldsymbol{w}^\top\boldsymbol{x}_i}, i = 1, \ldots, l. \tag{10}$$

The structure of (9) allows efficient computations to use the Hessian in various ways. Our method utilizes it to incorporate the Hessian-vector products with low cost as discussed in the following sections.

Some problems of the form (7), such as logistic regression and ridge regression, also satisfy Assumption 2. The loss of ridge regression is

$$\xi(y_i; \boldsymbol{w}^\top\boldsymbol{x}_i) = (y_i - \boldsymbol{w}^\top\boldsymbol{x}_i)^2.$$

It is clearly twice-differentiable with the diagonal matrix $D_{\boldsymbol{w}}$ defined in (10) being the identity matrix. Clearly, this loss satisfies Assumption 2 with any $M \geq 0$ as the Hessian is a constant. The loss of logistic regression is

$$\xi(y_i; \boldsymbol{w}^\top\boldsymbol{x}_i) = \log(1 + \exp(-y_i\boldsymbol{w}^\top\boldsymbol{x}_i)),$$

where $y_i \in \{-1, 1\}$. Because its third derivative is upper-bounded, by applying first-order Taylor expansion on the Hessian, one can see that Assumption 2 holds. On the other hand, problems that satisfy Assumption 1 only, like squared-hinge loss support vector classification/regression (Boser et al., 1992; Vapnik, 1995), can also be solved by our algorithm, although in this case we can only expect linear convergence.[2]

3.1. Subproblem of Common Directions

At the k-th iteration, given the matrix $P_k = [\boldsymbol{p}_1, \boldsymbol{p}_2, \ldots, \boldsymbol{p}_m] \in \mathbb{R}^{n\times m}$ with orthogonal columns, we consider solving (6) along $P_k\boldsymbol{t}$

$$\min_{\boldsymbol{t}\in\mathbb{R}^m} \quad \tilde{f}(\boldsymbol{w}_k + P_k\boldsymbol{t} \mid \boldsymbol{w}_k). \tag{11}$$

The gradient and the Hessian of (11) with respect to the variable $\boldsymbol{t}$ at $\boldsymbol{t} = \boldsymbol{0}$ are respectively

$$\nabla_{\boldsymbol{t}}\tilde{f}(\boldsymbol{w}_k + P_k\boldsymbol{t})\mid_{\boldsymbol{t}=\boldsymbol{0}} = P_k^\top\nabla f(\boldsymbol{w}_k) \tag{12}$$

and

$$\nabla^2_{\boldsymbol{t},\boldsymbol{t}}\tilde{f}(\boldsymbol{w}_k + P_k\boldsymbol{t})\mid_{\boldsymbol{t}=\boldsymbol{0}} = P_k^\top\nabla^2 f(\boldsymbol{w}_k)P_k = P_k^\top(I + X^\top D_{\boldsymbol{w}_k}X)P_k = I + P_k^\top X^\top D_{\boldsymbol{w}_k}XP_k. \tag{13}$$

Observe the term XP_k. The trick to make the computation efficient is to store this term in memory to avoid repetitive computations of $X\boldsymbol{p}_j$ for all previous directions $\boldsymbol{p}_j$. If XP_k, $\nabla f(\boldsymbol{w}_k)$, and $D_{\boldsymbol{w}_k}$ are available, the construction of (12)-(13) involves the following cost.

- $P_k^\top\nabla f(\boldsymbol{w}_k)$: $O(mn)$,
- $(XP_k)^\top D_{\boldsymbol{w}_k}(XP_k)$: $O(lm^2)$.

The optimal solution $\boldsymbol{t}$ of (11) can be obtained by solving the following linear system

$$\left(I + P_k^\top X^\top D_{\boldsymbol{w}_k}XP_k\right)\boldsymbol{t} = -P_k^\top\nabla f(\boldsymbol{w}_k) \tag{14}$$

in $O(m^3)$ cost. Note that the Hessian with respect to $\boldsymbol{t}$ is always invertible because the term I in (13) ensures its positive definiteness.

Let $\boldsymbol{t}_k$ be the solution of (14). We show that to obtain necessary information for the next iteration, it is sufficient to maintain XP_{k+1} and $X\boldsymbol{w}_{k+1}$. To have the new function value, from (7) we mainly need to compute $X\boldsymbol{w}_{k+1}$. If $X\boldsymbol{w}_k$ is available and the full direction $(XP_k)\boldsymbol{t}_k$ is taken, by

$$X\boldsymbol{w}_{k+1} = X\boldsymbol{w}_k + \theta(XP_k)\boldsymbol{t}_k, \tag{15}$$

with $\theta = 1$, in $O(lm)$ cost $X\boldsymbol{w}_{k+1}$ is obtained. In practice, a step size θ is decided by line search, which involves some minor cost as shown in Section 3.2. The vector $X\boldsymbol{w}_{k+1}$ is also used to construct $\boldsymbol{v}_{\boldsymbol{w}_{k+1}}$ needed for gradient calculation. Then from (8),

$$\nabla f(\boldsymbol{w}_{k+1}) = \boldsymbol{w}_{k+1} + X^\top\boldsymbol{v}_{\boldsymbol{w}_{k+1}}$$

2. If the objective function is not twice differentiable, we can use the generalized Hessian (Mangasarian, 2002) to replace the Hessian in the Newton step, as Assumption 1 guarantees the existence of generalized Hessian.

takes $O(\#\text{nnz})$ cost, where #nnz is the number of non-zero elements in X. We then apply the Gram-Schmidt procedure to check if a new column should be added to P_{k+1}. In practice this procedure is computed by

$$\boldsymbol{p}_{m+1} = (I - P_k P_k^T)\nabla f(\boldsymbol{w}_{k+1}) = \nabla f(\boldsymbol{w}_{k+1}) - P_k(P_k^\top \nabla f(\boldsymbol{w}_{k+1})).$$

The cost is $O(mn)$. If $\boldsymbol{p}_{m+1} \neq \boldsymbol{0}$, to maintain XP_{m+1} after $\boldsymbol{p}_{m+1}$ is added, we must compute $X\boldsymbol{p}_{m+1}$, which costs $O(\#\text{nnz})$. Details of the algorithm is shown in Algorithm 3.

In summary, the cost per iteration is

$$O(lm^2 + mn + m^3 + \#\text{nnz}). \tag{16}$$

Because usually we have $n \gg m$ and $l \gg m$ from the first iteration till reaching a good enough solution, in general #nnz is still the dominant term in (16). Therefore, each of our iterations does not cost much more than a typical iteration in an optimization method that often involves the $O(\#\text{nnz})$ cost.

Further, for the same set of directions P_k, we could solve the subproblem (11) and update $\boldsymbol{w}_k$ multiple times in order to approximately solve (2). Note that the update of $\boldsymbol{w}_k$ does not need to go through the data matrix X. The reason is that the $D_{\boldsymbol{w}}$ matrix and the $\boldsymbol{v}_{\boldsymbol{w}}$ vector rely on $\boldsymbol{w}_k$ only through the inner products $\boldsymbol{w}_k^\top \boldsymbol{x}_i$, and this is a linear combination of XP_k, and thus we can compute it without additional inner product computations with the data matrix X. This idea of solving (11) multiple times will be exploited in Section 4 to achieve the optimal linear convergence rate for first-order methods.

3.2. Line Search on Common Directions

Once the solution $\boldsymbol{t}$ of (14) has been obtained, in $O(mn)$ cost we get the descent direction

$$\boldsymbol{d} = P_k \boldsymbol{t}. \tag{17}$$

Next, we conduct line search in Algorithm 2 for the step size θ in

$$f(\boldsymbol{w}_k + \theta\boldsymbol{d}) = \frac{1}{2}\|\boldsymbol{w}_k + \theta\boldsymbol{d}\|^2 + C\sum_{i=1}^{l} \xi(y_i; \boldsymbol{w}_k^\top \boldsymbol{x}_i + \theta \boldsymbol{d}^\top \boldsymbol{x}_i).$$

The sufficient decrease condition is

$$C\sum_{i=1}^{l} \xi(y_i; \boldsymbol{w}_k^\top \boldsymbol{x}_i) - \theta \boldsymbol{w}_k^\top \boldsymbol{d} - \frac{\theta^2}{2}\|\boldsymbol{d}\|^2 - C\sum_{i=1}^{l} \xi(y_i; \boldsymbol{w}_k^\top \boldsymbol{x}_i + \theta \boldsymbol{d}^\top \boldsymbol{x}_i) \geq \frac{\lambda}{2}\theta^2 \|\boldsymbol{d}\|^2.$$

Because XP_k is maintained, after obtaining $X\boldsymbol{d}$ in $O(lm)$ time by

$$X\boldsymbol{d} = (XP_k)\boldsymbol{t}, \tag{18}$$

and calculating $\boldsymbol{w}_k^\top \boldsymbol{d}$, $\boldsymbol{w}_k^\top \boldsymbol{w}_k$, $\boldsymbol{d}^\top \boldsymbol{d}$ in $O(n)$ time, each line search step would only cost $O(l)$ because $\boldsymbol{w}_k^\top \boldsymbol{x}_i$ is already available in our calculation for the gradient and the Hessian. Thus, we could perform line search in

$$O(lm + mn + l \times \#(\text{line search steps})) \text{ time}. \tag{19}$$

By Theorem 3, #(line search) is bounded by a constant, and thus the complexity does not grow infinitely. After finishing the line search procedure, we already have $\boldsymbol{w}_k^\top \boldsymbol{x}_i + \theta \boldsymbol{d}^\top \boldsymbol{x}_i$ as the next $\boldsymbol{w}_{k+1}^\top \boldsymbol{x}_i$ as shown in (15).

Algorithm 3: The common-directions method for solving the ERM problem (7)

Given $\boldsymbol{w}_0$, compute $\boldsymbol{z} = X\boldsymbol{w}_0$;
Use $\boldsymbol{z}$ to calculate $\boldsymbol{v}_{\boldsymbol{w}_0}$ and $D_{\boldsymbol{w}_0}$ in (8) and (10);
Compute $\nabla f(\boldsymbol{w}_0) = \boldsymbol{w}_0 + X^\top \boldsymbol{v}_{\boldsymbol{w}_0}$ from (8);
$P = [\nabla f(\boldsymbol{w}_0)/\|\nabla f(\boldsymbol{w}_0)\|], U = XP$;
for *k=0,1,... in the oute loop* **do**
  if $\nabla f(\boldsymbol{w}_k) = \boldsymbol{0}$, or some stopping condition is satisfied **then**
    stop;
  end
  Obtain $\boldsymbol{t}$ by solving (14) with $\boldsymbol{t} = [I + U^\top D_{\boldsymbol{w}_k} U]^{-1}[-P^\top \nabla f(\boldsymbol{w}_k)]$;
  Compute $\hat{\boldsymbol{z}} = U\boldsymbol{t}$;
  Backtracking line search on $f(\boldsymbol{w}_k + \theta P\boldsymbol{t})$ by Algorithm 2 to obtain θ using the values of $\boldsymbol{z}$ and $\hat{\boldsymbol{z}}$ to compute $\xi(y_i; \boldsymbol{z} + \theta\hat{\boldsymbol{z}})$;
  $\boldsymbol{w}_{k+1} = \boldsymbol{w}_k + \theta P\boldsymbol{t}$;
  $\boldsymbol{z} = \boldsymbol{z} + \theta\hat{\boldsymbol{z}}$;
  Use $\boldsymbol{z}$ to calculate $\boldsymbol{v}_{\boldsymbol{w}_{k+1}}$ and $D_{\boldsymbol{w}_{k+1}}$;
  Compute $\nabla f(\boldsymbol{w}_{k+1}) = \boldsymbol{w}_{k+1} + X^\top \boldsymbol{v}_{\boldsymbol{w}_{k+1}}$ from (8);
  Let $\boldsymbol{p} = \nabla f(\boldsymbol{w}_{k+1}) - P(P^\top \nabla f(\boldsymbol{w}_{k+1}))$;
  if $\boldsymbol{p} \neq \boldsymbol{0}$ **then**
    $P = [P,\ \boldsymbol{p}/\|\boldsymbol{p}\|], U = [U,\ X\boldsymbol{p}/\|\boldsymbol{p}\|]$;
  end
end

3.3. Total Cost of the Algorithm

Based on the analysis in Sections 3.1 and 3.2, the total cost is

$$O(lm^2 + mn + m^3 + \#\text{nnz} + l \times \#(\text{line search steps})) \times \text{iterations}. \tag{20}$$

In Section 5, we will compare the cost with that of some existing approaches.

4. Common-directions Method with Multiple Inner Iterations

In Section 2, we considered solving the second-order Taylor approximation of $f(\boldsymbol{w}_k + P_k\boldsymbol{t})$ with respect to the coefficients $\boldsymbol{t}$ to get a good combination along the directions of P_k. Now we further extend the idea to directly minimize $f(\boldsymbol{w}_k + P_k\boldsymbol{t})$. We first describe the general framework, and then discuss how it can be applied to the special case of solving regularized ERM problems.

4.1. General Framework

We can consider the following convex optimization problem

$$\min_{\boldsymbol{t}} \quad f(\boldsymbol{w}_k + P_k\boldsymbol{t}), \tag{21}$$

and apply any optimization algorithm to solve it. When applying iterative algorithms, we terminate the optimization procedure after the solution is considered good enough.

Therefore, usually (21) is only solved approximately. In particular, the method discussed in Section 2 can be viewed as using only one Newton iteration to loosely solve (21). Because of two levels of iterations, we refer to the process of approximately solving (21) as an outer iteration, while each step in the process as an inner iteration.

Among the different methods to solve (21), we apply multiple inner Newton steps on the variable $\boldsymbol{t}$. That is, we repeatedly minimize the second-order Taylor expansion of (21).

$$\min_{\Delta \boldsymbol{t} \in \mathbb{R}^m} \quad \tilde{f}(\boldsymbol{w}_k + P_k\boldsymbol{t} + P_k\Delta\boldsymbol{t} \mid \boldsymbol{w}_k + P_k\boldsymbol{t}).$$

Because

$$\begin{aligned}&\tilde{f}(\boldsymbol{w}_k + P_k\boldsymbol{t} + P_k\Delta\boldsymbol{t} \mid \boldsymbol{w}_k + P_k\boldsymbol{t})\\ &= f(\boldsymbol{w}_k + P_k\boldsymbol{t}) + (P_k^\top \nabla f(\boldsymbol{w}_k + P_k\boldsymbol{t}))^\top \Delta\boldsymbol{t} + \frac{1}{2}\Delta\boldsymbol{t}^\top P_k^\top \nabla f(\boldsymbol{w}_k + P_k\boldsymbol{t}) P_k \Delta\boldsymbol{t},\end{aligned}$$

this amounts to solving the following linear system for $\Delta\boldsymbol{t}$.

$$(P_k^\top \nabla^2 f(\boldsymbol{w}_k + P_k\boldsymbol{t}) P_k)\Delta\boldsymbol{t} = -P_k^\top \nabla f(\boldsymbol{w}_k + P_k\boldsymbol{t}). \tag{22}$$

Each time the solution of the linear system will be our update direction, and then we will conduct backtracking line search to ensure the sufficient function decrease. The detailed algorithm is described in Algorithm 4, where we can see that $\boldsymbol{w}_k + P_k\boldsymbol{t}$ is the iterate updated in the inner iterations.

We now show that this general framework has better global convergence rate than the one discussed in Section 2.

Theorem 5 *Under Assumption 1 and a proper inner stopping condition, given any $\epsilon > 0$, Algorithm 4 converges R-linearly and obtains an ϵ-accurate solution in $O(\sqrt{\kappa}\log(1/\epsilon))$ iterations.*

The proof is in Appendix B.

It has been shown in Nesterov (2003) that $O(\sqrt{\kappa}\log(1/\epsilon))$ is the optimal iteration complexity for methods whose directions are obtained from the span of $\nabla f(\boldsymbol{w}_0), \nabla f(\boldsymbol{w}_1), \cdots$. The inner stopping condition used in proving Theorem 5 is not easy to implement in practice. It is possible to devise a practical one to ensure that this optimal linear convergence rate can be guaranteed. However, as we will see in the empirical results in Section 6, the setting of using a single inner iteration in approximately solving (21) tends to outperform that of using multiple inner iterations in terms of overall training time. In light of this understanding, we do not further explore practical inner stopping conditions.

Another interesting property of Algorithm 4 is that if the optimal solution of (21) is obtained at each outer iteration, then the algorithm can reach the optimum of (7) in finite steps even if neither Assumption 1 nor 2 is satisfied.

Theorem 6 *If at each iteration of Algorithm 4, the optimal solution of* (21) *is obtained, the optimum of* (1) *is reached within n iterations.*

The proof is in Appendix C.

These two theorems show that our algorithm can be treated as an analogy of the linear conjugate gradient method to general nonlinear optimization problems. See more details in Section 5.1

Algorithm 4: Common-directions method with multiple inner iterations

Given $\boldsymbol{w}_0$, compute $\nabla f(\boldsymbol{w}_0)$;
$P = [\nabla f(\boldsymbol{w}_0)/\|\nabla f(\boldsymbol{w}_0)\|]$;
for *k=0,1,... in the outer loop* **do**
  if $\nabla f(\boldsymbol{w}_k) = \boldsymbol{0}$, or some stopping condition is satisfied **then**
    stop;
  end
  $\boldsymbol{w} = \boldsymbol{w}_k$;
  while an inner stopping condition is not satisfied **do** `// inner loop`
    Obtain $\Delta\boldsymbol{t}$ by solving (22) with

$$(P^\top \nabla^2 f(\boldsymbol{w}) P)\Delta\boldsymbol{t} = -P^\top \nabla f(\boldsymbol{w});$$

    Backtracking line search on $f(\boldsymbol{w} + \theta P\Delta\boldsymbol{t})$ by Algorithm 2 to obtain θ;
    $\boldsymbol{w} = \boldsymbol{w} + \theta P\Delta\boldsymbol{t}$;
  end
  $\boldsymbol{w}_{k+1} = \boldsymbol{w}$;
  Compute $\nabla f(\boldsymbol{w}_{k+1})$;
  Let $\boldsymbol{p} = \nabla f(\boldsymbol{w}_{k+1}) - P(P^\top \nabla f(\boldsymbol{w}_{k+1}))$;
  if $\boldsymbol{p} \neq \boldsymbol{0}$ **then**
    $P = [P, \boldsymbol{p}/\|\boldsymbol{p}\|]$;
  end
end

4.2. Application on Regularized ERM Problems

For general problems, Algorithm 4 may not be beneficial because the cost of one inner iteration of solving (21) is similar to that of conducting an outer iteration of Algorithm 1, while (1) rather than (21) is what we actually would like to solve. However, for solving the regularized ERM problems (7), we show that one inner iteration of the while-loop in Algorithm 5 can be significantly cheaper than one outer iteration of Algorithm 3. We note that in the complexity analysis (16) for Algorithm 3, the dominant term $O(\#\text{nnz})$ is unavoidable for calculating $\nabla f(\boldsymbol{w}_{k+1})$. A crucial difference here is that this $O(\#\text{nnz})$ term is not needed. In Algorithm 3, the whole $\nabla f(\boldsymbol{w}_{k+1})$ vector is used for the Gram-Schmidt procedure in checking if P_k should be augmented. Instead, here P_k remains the same throughout inner iterations and all we need is $P_k^\top \nabla f(\boldsymbol{w}_k + P_k\boldsymbol{t})$ in (22). When we apply Algorithm 4 to regularized ERM problems, the linear system (22) has the following form.

$$(I + P_k^\top X^\top D_{\boldsymbol{w}_k + P_k\boldsymbol{t}} X P_k)\Delta\boldsymbol{t} = -(P_k^\top(\boldsymbol{w}_k + P_k\boldsymbol{t}) + P_k^\top X^\top \boldsymbol{v}_{\boldsymbol{w}_k + P_k\boldsymbol{t}}). \tag{23}$$

If

$$XP_k \ \text{ and } \ X(\boldsymbol{w}_k + P_k\boldsymbol{t}), \tag{24}$$

are maintained, the right-hand side can be easily calculated by

- $\boldsymbol{v}_{\boldsymbol{w}_k + P_k\boldsymbol{t}}$: $O(l)$,

- $P_k^\top(\boldsymbol{w}_k + P_k\boldsymbol{t})$: $O(mn)$,
- $(P_k^\top X^\top)\boldsymbol{v}_{\boldsymbol{w}_k+P_k\boldsymbol{t}}$: $O(lm)$.

Interestingly, for other operations in Algorithm 3, it has been shown that the two values in (24) can be easily maintained. Here we follow the same setting. A detailed procedure is in Algorithm 5. In summary, the cost per inner iteration is

$$O(lm^2 + mn + m^3). \tag{25}$$

In compared with the cost per outer iteration in Algorithm 3, here we do not have the #nnz term. The main difference comes from that in (23), we use the available XP_k to calculate

$$(P_k^\top X^\top)\boldsymbol{v}_{\boldsymbol{w}_k+P_k\boldsymbol{t}},$$

but in an outer iteration of Algorithm 3, $\nabla f(\boldsymbol{w}_{k+1})$ is calculated by

$$X^\top \boldsymbol{v}_{\boldsymbol{w}_{k+1}},$$

which costs $O(\#\text{nnz})$. Therefore, because in general #nnz is larger than (25), an inner iteration here is cheaper than an outer one in Algorithm 3.

5. Related Works

We compare our algorithm with linear conjugate gradient method for solving a linear system, as well as popular nonlinear optimization methods. The methods being discussed include those considering a linear combination of multiple directions to form the update direction, and those utilizing the Hessian matrix in various ways.

5.1. Linear Conjugate Gradient Method

Linear conjugate gradient (CG) method iteratively solves the following linear system.

$$A\boldsymbol{x} = \boldsymbol{b}, \tag{26}$$

where $A \in \mathbb{R}^{n\times n}$ is symmetric and positive-definite, and $\boldsymbol{b} \in \mathbb{R}^n$. Alternatively, CG can be viewed as an optimization method for the following problem.

$$\min_{\boldsymbol{x}} \quad \frac{1}{2}\boldsymbol{x}^\top A\boldsymbol{x} - \boldsymbol{b}^\top \boldsymbol{x}. \tag{27}$$

The idea behind linear CG is that at each iteration, we generate a new update direction $\boldsymbol{p}_k$ that is conjugate to the existing ones such that

$$\boldsymbol{p}_i^\top A\boldsymbol{p}_j = 0, \ \ \forall i \neq j.$$

Then an exact line search is conducted to decide the next iterate. At each iteration, a matrix-vector product $A\boldsymbol{v}$ for some vector $\boldsymbol{v}$ is conducted to generate the desired step, and this matrix-vector product is the computational dominant part at each CG iteration.

Algorithm 5: Common-directions method with multiple inner iterations for the ERM problem (7)

Given $\boldsymbol{w}_0$, compute $\boldsymbol{z} = X\boldsymbol{w}_0$;
Use $\boldsymbol{z}$ to compute $\boldsymbol{v}_{\boldsymbol{w}_0}$ and $D_{\boldsymbol{w}_0}$ in (8) and (10);
Compute $\nabla f(\boldsymbol{w}_0) = \boldsymbol{w}_0 + X^\top \boldsymbol{v}_{\boldsymbol{w}_0}$ from (8);
$P = [\nabla f(\boldsymbol{w}_0)/\|\nabla f(\boldsymbol{w}_0)\|]$, $U = XP$;
for *k=0,1,... in the outer loop* **do**
  if $\nabla f(\boldsymbol{w}_k) = \boldsymbol{0}$, or some stopping condition is satisfied **then**
    stop;
  end
  $\boldsymbol{w} = \boldsymbol{w}_k, \boldsymbol{v}_{\boldsymbol{w}} = \boldsymbol{v}_{\boldsymbol{w}_k}, D_{\boldsymbol{w}} = D_{\boldsymbol{w}_k}$;
  while an inner stopping condition is not satisfied **do** `// inner loop`
    Obtain $\Delta\boldsymbol{t}$ by solving (23) with

$$\Delta\boldsymbol{t} = (I + U^\top D_{\boldsymbol{w}} U)^{-1}(-P^\top \boldsymbol{w} + U^\top \boldsymbol{v}_{\boldsymbol{w}});$$

    Compute $\hat{\boldsymbol{z}} = U\Delta\boldsymbol{t}$;
    Backtracking line search on $f(\boldsymbol{w} + \theta P\Delta\boldsymbol{t})$ by Algorithm 2 to obtain θ, using the values of $\boldsymbol{z}$ and $\hat{\boldsymbol{z}}$ to compute $\xi(y_i; \boldsymbol{z} + \theta\hat{\boldsymbol{z}})$;
    $\boldsymbol{w} = \boldsymbol{w} + \theta P\Delta\boldsymbol{t}$;
    $\boldsymbol{z} = \boldsymbol{z} + \theta(XP)\Delta\boldsymbol{t}$;
    Use $\boldsymbol{z}$ to compute $\boldsymbol{v}_{\boldsymbol{w}}$ and $D_{\boldsymbol{w}}$ in (8) and (10);
  end
  $\boldsymbol{w}_{k+1} = \boldsymbol{w}, \boldsymbol{v}_{\boldsymbol{w}_{k+1}} = \boldsymbol{v}_{\boldsymbol{w}}, D_{\boldsymbol{w}_{k+1}} = D_{\boldsymbol{w}}$;
  Compute $\nabla f(\boldsymbol{w}_{k+1}) = \boldsymbol{w}_{k+1} + X^\top \boldsymbol{v}_{\boldsymbol{w}_{k+1}}$ from (8);
  $\boldsymbol{p} = \nabla f(\boldsymbol{w}_{k+1}) - P(P^\top \nabla f(\boldsymbol{w}_{k+1}))$;
  if $\boldsymbol{p} \neq \boldsymbol{0}$ **then**
    $P = [P_k, \boldsymbol{p}/\|\boldsymbol{p}\|]$, $U = [U, X\boldsymbol{p}/\|\boldsymbol{p}\|]$;
  end
end

Therefore, the cost per iteration of CG is simply the cost of a matrix-vector product and several $O(n)$ operations on the vectors.

There are two nice properties of linear CG. First, when viewed as a solver for (26), it obtains the exact solution in n steps. Second, when viewed as a solver for (27), its iteration complexity for an ϵ-accurate solution is $O(\sqrt{\kappa}\log(1/\epsilon))$. See, for example, Chapter 5.1 of Nocedal and Wright (2006). Because the method proposed in Section 4 possesses the same two properties in Theorems 5 and 6, it can be viewed as an extension of linear CG to general nonlinear convex optimization.

5.2. First-order Methods and Momentum

For nonlinear convex optimization, the simplest first-order method is gradient descent. In gradient descent, the update direction is always the negative gradient $-\nabla f(\boldsymbol{w})$. It has been

shown in many standard convex optimization books such as Boyd and Vandenberghe (2004); Nocedal and Wright (2006); Nesterov (2003) that with a proper choice of the step size, to obtain an ϵ-accurate solution for a given $\epsilon > 0$, gradient descent requires $O(\kappa \log(1/\epsilon))$ iterations. However, this is far from the aforementioned optimal convergence rate $O(\sqrt{\kappa}\log(1/\epsilon))$ for methods that have their update directions in the span of all previous gradients.

Methods like the heavy-ball method (Polyak, 1964) and nonlinear CG try to improve the convergence by using the "momentum." These methods possess update rules in the form

$$\boldsymbol{w}_{k+1} = \boldsymbol{w}_k - \alpha_k \nabla f(\boldsymbol{w}_k) + \beta_k(\boldsymbol{w}_k - \boldsymbol{w}_{k-1}), \tag{28}$$

where α_k and β_k vary in different methods, and the term $\boldsymbol{w}_k - \boldsymbol{w}_{k-1}$ is the so-called momentum. By induction we can easily see that $\boldsymbol{w}_k - \boldsymbol{w}_{k-1}$ in (28) is a linear combination of $\nabla f(\boldsymbol{w}_0), \nabla f(\boldsymbol{w}_1), \ldots, \nabla f(\boldsymbol{w}_{k-1})$, and therefore these methods fall in the category of picking the update direction from the span of the previous gradients. Nonlinear CG has many different variants that consider different strategies based on $\boldsymbol{w}_k$, $\boldsymbol{w}_{k-1}$, $\nabla f(\boldsymbol{w}_k)$, $\nabla f(\boldsymbol{w}_{k-1})$ and even $\nabla^2 f(\boldsymbol{w}_k)$, and all of them reduce to linear CG when the problem is (27). Interested readers are referred to Hager and Zhang (2006) and the references therein. When f is quadratic and strongly convex, it can be shown that both the heavy-ball method with proper parameters (Lessard et al., 2016) and nonlinear CG methods can achieve the optimal convergence rate for first-order methods,[3] but for non-quadratic functions, the situation is different. Some variants of nonlinear CG can be shown to converge asymptotically, but the rate is unclear (Hager and Zhang, 2006, Theorem 5.1). On the other hand, Ghadimi et al. (2014) showed that for problems satisfying Assumption 1, with properly chosen parameters, the heavy-ball method converges globally R-linearly. If in addition the problem is twice-differentiable, Polyak (1987) showed that when the iterate is close enough to the optimum, the local R-linear convergence rate of the heavy-ball method matches the optimal linear convergence rate of first-order methods for a specific choice of α_k and β_k.

Nesterov's accelerated gradient (Nesterov, 1983) considers two sequences $\{\boldsymbol{w}_k\}$ and $\{\boldsymbol{s}_k\}$ with the following update rules.

$$\begin{aligned}\boldsymbol{w}_{k+1} &\equiv \boldsymbol{s}_k - \frac{1}{\rho}\nabla f(\boldsymbol{s}_k),\\ \boldsymbol{s}_{k+1} &= (1 + \frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1})\boldsymbol{w}_{k+1} - \frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\boldsymbol{w}_k.\end{aligned}$$

Interestingly, this method uses only the previous gradients in a deterministic way with κ to be the only data-dependent value, but it can guarantee the optimal iteration complexity of first-order methods for problems satisfying Assumption 1. A problem in this method is that we need to know the values ρ and σ in advance, and these values may not be available. To solve this problem, a variant of Nesterov's accelerated gradient is proposed in Nesterov (2013). This algorithm estimates these parameters at each iteration via an iterative procedure similar to backtracking line search, and achieves the same iteration complexity with little additional cost. Note that for all these first-order methods, the main bottleneck is the computation of the gradients, and the cost is proportional to the number of different gradients computed per iteration.

3. Section 1 of Hager and Zhang (2006) suggests that nonlinear CG methods reduce to linear CG when f is quadratic, and the convergence rate follows what we described in Section 5.1.

Our method can be viewed as a generalization of these approaches, in the sense that the same search space for the update direction is considered. The major difference is that these momentum methods are restricted to some deterministic or pre-specified ways of combination, while our method considers combining multiple directions with adaptive weights according to the data that can and will change over iterations. Another difference is that we utilize higher-order derivatives to decide the combination coefficient, so quadratic convergence in Theorem 4 can be obtained.

5.3. Methods Utilizing Multiple Directions

The cutting plane method (Kelley, 1960) and the bundle method (Teo et al., 2010) use all gradients obtained from the first iteration on. They differ from our method from using the previous gradients to construct a piecewise linear function to approximate (the hard-to-compute part of) the actual function.[4] Therefore, the purpose of using previous gradients in these methods and that of ours are different. An advantage of the cutting plane method and the bundle method is the ability to deal with nonsmooth problems by using subgradients. When being applied to problems satisfying Assumption 1, the bundle method converges linearly (Teo et al., 2010). However, optimizing a piecewise linear function with a growing number of pieces is more expensive than dealing with one smooth function. Our method considers easier-to-solve subproblems at each iteration. Moreover, our method converges quadratically while the bundle method and the cutting plane method do not have this property.

Quasi-Newton methods also consider previous momentums and gradients, but the purpose is to approximate the real Hessian matrix via these vectors in order to achieve superlinear convergence. Among different quasi-Newton methods, the BFGS method (Dennis and Moré, 1977) and its limited-memory variant, L-BFGS (Liu and Nocedal, 1989), are the most widely used ones. It is known that the BFGS method admits local superlinear convergence and converges globally; see, for example, (Nocedal and Wright, 2006, Chapter 6). By applying a proper line search procedure, L-BFGS has global linear convergence for problems satisfying Assumption 1.[5] Note that because older information are discarded, L-BFGS does not have superlinear convergence, but it has the advantage of less spatial cost and is more suitable for large-scale problems.

At the k-th iteration for any $k \geq 1$, given the current iterate $\boldsymbol{w}_k$, BFGS solves the following quadratic problem.

$$\min_{\boldsymbol{p}_k} \quad \nabla f(\boldsymbol{w}_k)^\top \boldsymbol{p}_k + \frac{1}{2}(\boldsymbol{p}_k)^\top B_k \boldsymbol{p}_k, \tag{29}$$

where B_k is a positive definite symmetric approximation of $\nabla^2 f(\boldsymbol{w}_k)$ such that

$$B_k^{-1} = (I - \mu_{k-1}\boldsymbol{u}_{k-1}\boldsymbol{s}_{k-1}^\top)^\top B_{k-1}^{-1}(I - \mu_{k-1}\boldsymbol{u}_{k-1}\boldsymbol{s}_{k-1}^\top) + \mu_{k-1}\boldsymbol{s}_{k-1}\boldsymbol{s}_{k-1}^\top, \tag{30}$$

4. It is known in functional analysis that any convex function can be approximated by piecewise linear functions to any precision.

5. Note that the proof that L-BFGS converges globally linearly utilized the property of using a bounded number of historical vectors and thus does not apply to BFGS.

with

$$\mu_{k-1} \equiv \frac{1}{\boldsymbol{u}_{k-1}^\top \boldsymbol{s}_{k-1}}, \quad \boldsymbol{s}_{k-1} = \boldsymbol{w}_k - \boldsymbol{w}_{k-1}, \quad \boldsymbol{u}_{k-1} = \nabla f(\boldsymbol{w}_k) - \nabla f(\boldsymbol{w}_{k-1}).$$

Note that although B_0 can be decided arbitrarily, the most common choice is

$$B_0 = \beta I \tag{31}$$

for some $\beta > 0$. The solution of (29) is clearly

$$\boldsymbol{p}_k = -B_k^{-1} \nabla f(\boldsymbol{w}_k). \tag{32}$$

If (31) is used, this operation can be conducted cheaply with only $O(kn)$ cost by a sequence of vector-vector operations obtained from expanding (30).[6] After deciding $\boldsymbol{p}_k$, a line search procedure is conducted to find a suitable step size θ_k to ensure that the sequence $\{\boldsymbol{w}_k\}$ converges to the optimal solution of f.

With the choice of (31), by induction the vector

$$\boldsymbol{s}_k = \alpha_{k+1} \boldsymbol{p}_k \tag{33}$$

is a linear combination of $\nabla f(\boldsymbol{w}_0), \ldots, \nabla f(\boldsymbol{w}_k)$ for all k.[7] Thus, we can see that $\boldsymbol{p}_k \in \mathtt{span}\{\nabla f(\boldsymbol{w}_0), \ldots, f(\boldsymbol{w}_k)\}$ and thus the BFGS algorithm only utilizes the previous gradients, but is able to achieve superlinear convergence. Interestingly, our algorithm utilizes the same information as BFGS, but because we also consider the Hessian to search for the best update direction in $\mathtt{span}\{\nabla f(\boldsymbol{w}_0), \ldots, \nabla f(\boldsymbol{w}_k)\}$, our method is better than BFGS for being able to achieve quadratic convergence.

A major drawback of the BFGS algorithm is that it requires storing many vectors (or an $O(n^2)$ dense matrix) in memory. The memory consumption can be prohibitively expensive after iterations. This issue also happens in our method, but we notice that in practice, it is not severe. One reason is that the memory capacity is large enough to store the required information unless the number of iterations is high, and both our method and BFGS converge fast enough such that the memory capacity is not reached. For extremely large data, the memory issue may be faced, but this issue is less problematic in our method than in BFGS. The reason is that at each iteration of BFGS, two new vectors are added to memory, while in our method, at most one vector is added.

To handle the memory consumption problem of BFGS, its limited-memory variant, L-BFGS (Liu and Nocedal, 1989), is proposed. L-BFGS uses a different setting of B_k^{-1}. Given an integer $m > 0$, at the k-th iteration, L-BFGS only uses $\boldsymbol{s}_i, \boldsymbol{u}_i, i = k-m, k-m+1, \ldots, k-1$ and $\nabla f(\boldsymbol{w}_k)$ to construct the approximate Hessian inverse. For L-BFGS, in the recursive computation of (30), the matrix B_{k-m}^{-1} can be replaced by any matrix. According

6. If B_0 has neither sparsity nor some special structures, the cost of computing (32) at each iteration is $O(n^2)$ by directly maintaining (30), and it does not fall in the category of algorithms that only use gradients anymore because the vector $B_0^{-1}\nabla f(\boldsymbol{w})$ is considered.
7. By continually expanding (32) using (31) and (30), we can see that $\boldsymbol{p}_k$ is a linear combination of $\boldsymbol{s}_i, \boldsymbol{u}_i, i = 1, \ldots, k-1$ and $\nabla f(\boldsymbol{w}_k)$. By induction, if all $\boldsymbol{s}_i$ are linear combinations of previous gradients, then with the definition of $\boldsymbol{u}_i$, $\boldsymbol{p}_k$ is also a linear combination of previous gradients. The induction is finished by that $\boldsymbol{s}_k$ is a multiple of $\boldsymbol{p}_k$ in (33).

to (Nocedal and Wright, 2006, Chapter 7), a choice that has been shown to be practically effective is

$$\frac{\boldsymbol{s}_{k-1}^T \boldsymbol{u}_{k-1}}{\|\boldsymbol{u}_{k-1}\|^2} I. \tag{34}$$

This is also the choice we use in our implementation for empirical comparisons. As mentioned earlier, L-BFGS has only linear but not superlinear convergence. Nevertheless, it might outperform BFGS practically because the computation cost per iteration and the memory access amount are both lower. Moreover, it is shown in Bubeck et al. (2015) that L-BFGS outperforms those methods mentioned in Section 5.2 empirically, although the coefficient of its linear convergence is not clear.

5.4. Newton Method

At each iteration, given the current iterate $\boldsymbol{w}$, the Newton method obtains the update direction by solving

$$\min_{\boldsymbol{p} \in \mathbb{R}^n} \quad \boldsymbol{p}^\top \nabla f(\boldsymbol{w}) + \frac{1}{2} \boldsymbol{p}^\top \nabla^2 f(\boldsymbol{w}) \boldsymbol{p}. \tag{35}$$

To obtain the solution of (35), the following n by n linear system is solved.

$$\nabla^2 f(\boldsymbol{w}) \boldsymbol{p} = -\nabla f(\boldsymbol{w}) \quad \Rightarrow \quad \boldsymbol{p} = -\nabla^2 f(\boldsymbol{w})^{-1} \nabla f(\boldsymbol{w}). \tag{36}$$

Then a line search procedure is conducted to ensure the sufficient function decrease. It is known that for twice-differentiable functions satisfying Assumption 2, the Newton method with line search has local quadratic convergence (Boyd and Vandenberghe, 2004; Nocedal and Wright, 2006). However, The computational cost per Newton iteration for directly solving the linear system (36) is as expensive as $O(n^3)$. Moreover, solving (36) precisely may not be beneficial when the current iterate is far from optimum. Therefore, truncated Newton methods that utilize, for example, the iterative linear CG method we discussed in Section 5.1 to approximately solve (36) is often used. In general, the computational cost per CG iteration is $O(n^2)$ for conducting the Hessian-vector product provided the Hessian is available. When we only want to solve the problem approximately, usually the required CG iteration is much smaller than n, making the computation of a truncated Newton step much cheaper than that of a full Newton step. It is known that truncated Newton steps combined with a line search procedure or trust region techniques retain local quadratic convergence for problems satisfying Assumption 2 and have superlinear convergence for problems satisfying Assumption 1, if the residual of the solution to (36) goes to zero as the number of truncated Newton iterations goes to infinity. See, for example, Lin and Moré (1999) and (Nocedal and Wright, 2006, Theorem 7.2).

As mentioned above, the cost of directly computing the Hessian-vector product is $O(n^2)$ both spatially and computationally if we store the Hessian matrix explicitly. However, as Keerthi and DeCoste (2005); Lin et al. (2008) proposed, for ERM problems in (7), if we calculate the product between Hessian and a given vector $\boldsymbol{v}$ by

$$\nabla^2 f(\boldsymbol{w}) \boldsymbol{v} = (I + X^\top D_{\boldsymbol{w}} X) \boldsymbol{v} = \boldsymbol{v} + \left(X^\top \left(D_{\boldsymbol{w}} \left(X \boldsymbol{v} \right) \right) \right), \tag{37}$$

this computation costs only $O(\#\text{nnz} + n)$ per CG iteration, where #nnz is at most ln but is usually much smaller for sparse data. Further, no storage space is needed for the

operation in (37). On the other hand, explicitly forming the Hessian matrix in this case costs $O(\#\text{nnz}^2)$. Therefore, for regularized ERM problems, the CG approach without explicitly computing the Hessian matrix is more preferable. In this sense, truncated Newton methods costs

$$O((\#\text{nnz} + n) \times \text{CG iterations}) \tag{38}$$

per Newton iteration. A comparison between (38) and (20) shows that by a careful utilization of the problem structure of ERM, we have a cheaper cost of running one Newton iteration to approximately minimize a sub-problem over a subspace. The cost of our Newton iteration is only about that of one CG iteration here. We will examine the relative training speed between the truncated Newton method and our algorithm by experiments in Section 6.

6. Experiments

We examine the empirical speed of our algorithm for solving two L2-regularized ERM problems. The first one is logistic regression, in which $\xi(\cdot)$ in (7) is defined by

$$\xi(y; z) \equiv \log\left(1 + \exp\left(-yz\right)\right),$$

and the second one is the squared-hinge loss problem, where $\xi(\cdot)$ is

$$\xi(y; z) \equiv \max\left\{1 - yz, 0\right\}^2.$$

In both cases, $y \in \{-1, 1\}$. We first compare the approach of conducting only one inner iteration discussed in Section 2 with that of conducting multiple inner iterations illustrated in Section 4 using the logistic regression problems. The relative efficiency between our methods and the methods reviewed in Section 5 is then examined on both loss functions.

6.1. Experiment Settings

We consider the data sets listed in Table 1 with three different choices of parameters $C = \{10^{-3}, 1, 10^3\}$ to examine the situation of different condition numbers. All data sets except yahoo-japan and yahoo-korea are publicly available.[8] We use the relative distance to the optimal objective value, which is defined below, to compare different optimization approaches.

$$\left|\frac{f(\boldsymbol{w}) - f(\boldsymbol{w}^*)}{f(\boldsymbol{w}^*)}\right|,$$

where $\boldsymbol{w}^*$ is the optimal solution obtained by running our algorithm long enough. All experiments are conducted on a 64-bit machine with Intel Xeon 2.0 GHz CPU (E5504), 4MB cache, and 32GB memory.

We consider two different criteria for comparison. The first one is the empirical training time. This is the most important criterion in single-machine training for most users. We also consider the number of data passes, which is proportional to the number of iterations[9] and is thus an indicator of iteration complexity. This criterion can also serve as a training time estimate for scenarios that the cost is highly dependent to the number of passes through the data, such as distributed machine learning, or disk-level classification (Yu et al., 2012). In addition, this criterion excludes the effect of implementation differences.

8. http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets.
9. For the Newton method, this is the number of inner iterations in CG plus the number of Newton iterations.

6.2. Using Single or Multiple Inner Iterations

We compare on logistic regression problems the performance of the two variants of our algorithms, namely the approach of using only a single inner iteration and the variant of using multiple inner iterations, in Figures 1-6. Note that the result of KDD2010-b with $C = 10^3$ is not shown because the training time is too long. For the backtracking line search procedure in Algorithm 2, we set $\beta = 0.4, \lambda = 0.25$. The solution to the linear system (14) is obtained by a Cholesky factorization with partial pivoting. For the multiple inner iteration variant, we use the following heuristic stopping condition for the inner loop in Algorithm 4.

$$\|P_k \nabla f(\boldsymbol{w})\| \leq \min(0.1\|\nabla f(\boldsymbol{w}_k)\|, \|\nabla f(\boldsymbol{w}_k)\|^2).$$

We can see that the two approaches perform quite similarly in both criteria, while the single inner iteration approach is slightly better in the training time. The figures of data passes indicate that using a single inner iteration has similar function value decrease per iteration to using multiple inner iterations, so the additional cost of multiple inner iterations sometimes results in slightly longer training time. Therefore, we use the single iteration variant in later experiments of comparing with existing algorithms.

6.3. Comparison Between Different Methods

We compare the following different algorithms for training L2-regularized smooth empirical risk minimization problems.

- CommDir: our common-directions method with single inner iteration.

- Line search truncated Newton method (NEWTON): at each Newton iteration, (35) is approximately solved by linear CG, until CG generates an approximate solution $\boldsymbol{p}$ of (35) that satisfies
$$\|\nabla f(\boldsymbol{w}) - \nabla^2 f(\boldsymbol{w})\boldsymbol{p}\| \leq 0.1\|\nabla f(\boldsymbol{w})\|.$$
We follow the discussion in Section 5 to efficiently compute the Hessian-vector products in $O(n + \#\text{nnz})$ time. The implementation is modified from that in LIBLINEAR (Fan et al., 2008).

- L-BFGS: We implement the L-BFGS algorithm by considering different numbers of history states $m = 5, 10, 15, 20, 30$.[10] For the first step, where no historical information is available, we follow the implementation by the authors of Liu and Nocedal (1989) to take the initial step size for the gradient direction as $1/\|\nabla f(\boldsymbol{w}_0)\|$. For later iterations, we take the matrix defined in (34) as B_{k-m}^{-1}. In general $m = 30$ performs the best, so we report results of using this number of states.

- BFGS: we use our L-BFGS implementation and set m to infinity to obtain a BFGS solver.

- Nesterov's accelerated gradient (AG): we consider the approach proposed by Nesterov (2013) that adaptively estimates the parameters σ and ρ by a procedure similar to backtracking line search. We take the initial estimation to be $\sigma = 1$ and $\rho = 1/Cl$.

For NEWTON, L-BFGS and BFGS that require a line search procedure to ensure the convergence, we follow our method to apply Algorithm 2 with the same parameters $\beta = 0.4$ and $\lambda = 0.25$ used in Section 6.2. We exploit the trick discussed in Section 3.2 to efficiently conduct this line search procedure. Note that for all methods except AG, evaluating $X^T\boldsymbol{v}_{\boldsymbol{w}}$ in (8) for gradient at each iteration requires one data pass, and the line search procedure requires another one to maintain $X\boldsymbol{w}$. For NEWTON, each CG iteration requires one data pass. For AG, each inner iteration for adaptively estimating σ and ρ requires two data passes to compute related values. All algorithms are implemented in C++.

The results on logistic regression problems are shown in Figures 7-9 for running time and Figures 10-12 for number of data passes. Note that the result of KDD2010-b with $C = 10^3$ is not shown because the training time is too long. We can see that our method has the fewest data passes in all settings and all data sets. This observation suggests the usefulness of our method in the scenario that the data passes are expensive. The number of data passes is significantly reduced because we use the ideas in Section 3 to store the inner products XP_k to avoid redundant data accesses. In terms of training time, our method is among the fastest. The exceptions are a9a and rcv1t whose l are much larger than n, and the largest data set KDD2010-b, which from Table 1 is highly sparse. From the result of data passes, we see that our method requires fewer iterations than other methods, in the cost of the $O(lm^2 + mn)$ operations per iteration in addition to the $O(\#\text{nnz})$ cost required by all methods to conduct one data pass; see (20). When $O(lm^2 + mn) \ll O(\#\text{nnz})$, this additional cost is negligible and hence the advantage of fewer iterations dominates.

10. We also tried the implementation by the authors of Liu and Nocedal (1989) at `http://users.iems.northwestern.edu/~nocedal/lbfgs.html`, but found that it is not as efficient as ours. Note that their implementation does not utilize the efficient line search procedure discussed in Section 3.2.

However, when n is relatively small, or when the data set is highly sparse, the $O(lm^2 + mn)$ cost is significant in compared with $O(\#\text{nnz})$, so our method may be slower for these data sets.

We then show results on squared-hinge loss problems in Figures 13-15 for running time and in Figures 16-18 for data passes. Similar trends of superiority of our method in data passes are still observed in squared-hinge loss problems, but in general the squared-hinge loss problems are harder to optimize for all methods. A possible reason is that logistic loss is infinitely continuously differentiable but squared-hinge loss is only once continuously differentiable. This difficulty in optimization of squared-hinge loss problems is reflected in running time as well. Since our common-directions method has cost that grows superlinearly with the number of iterations passed, its relative running time performance is also worse on squared-hinge loss problems than that on logistic regression problems.

The comparison here between NEWTON and L-BFGS is inconsistent with that in Lin et al. (2008). A further investigation showed that the major difference is from the choice of m. In Lin et al. (2008), $m = 5$ is used, while we observe that setting larger m like 30 here in most cases leads to faster convergence in terms of time, as long as the memory capacity is not an issue. Another minor difference is that each line search iteration of L-BFGS in the experiments of Lin et al. (2008) requires one data pass while we use the idea of caching inner products to accelerate the line search in our experiments. Moreover, in Lin et al. (2008), instead of line search, a trust region approach is considered for the truncated Newton method.

An interesting observation in our experimental results is the impressive performance of BFGS. Although BFGS has better theoretical convergence than L-BFGS, in practice people tend to use L-BFGS because BFGS consumes too much memory. Our experiments indicate that with larger memory and better computation power nowadays, BFGS becomes feasible and can outperform L-BFGS in some cases. However, it is also observed that when both the number of iterations to converge and n are large, such as the cases of webspam and url with $C = 1000$, BFGS still suffers from the memory problem.

7. Discussion

As shown in our experiments, our method has a smaller number of data passes than all other methods. This property implies that our method has at least two potential applications for solving extremely large-scale ERM problems. The first one is disk-level classification when the data cannot fit into memory, and the second one is distributed machine learning. In both tasks, each data pass involves expensive operations like intensive disk I/O or between-machine communication. With fewer data passes, our method is suitable for these tasks to tackle the bottleneck.

Each data pass in disk-level classification requires expensive disk I/O to access data because we cannot store all of them in memory. Existing methods for disk-level classification (Yu et al., 2012; Chang and Roth, 2011) consider solving the dual problem with techniques involving shuffling and partitioning data into blocks. Each block can be fully loaded into memory and these methods work on one block at a time. The random shuffling step gives better convergence, but requires lengthy pre-processing time because of heavy disk I/O. In contrast, our method does not require the random shuffling of data.

To reduce the number of data passes, Chang and Roth (2011) considered caching important instances in memory. Our method also uses ideas similar to caching, while the information being kept in memory is not some training instances, but the inner products XP_k. The number of these inner products is roughly the same as the number of iterations, which is usually not too large. Therefore, the memory consumption of our method tends to be smaller, and hence our method can cache more important information to reduce the data I/O.

For distributed machine learning that uses multiple machines, each data pass requires an expensive communication of a vector proportional to the data size to synchronize information among machines. Usually this step is the bottleneck of distributed machine learning. With fewer data passes and thus fewer rounds of communication, our method can be expected to have shorter training time than other algorithms in distributed environments.

8. Conclusions

In this paper, we propose a new optimization algorithm that utilizes the Hessian information to combine different update directions. Theoretically, our method has global linear and local quadratic convergence, while the cost per iteration is not expensive for solving ERM problems. Empirically, extensive experimental results show that for solving ERM problems, our method is competitive with state-of-the-art methods in terms of training time, but outperforms them in terms of data passes. After the first version of this paper, we have studied possible choices of common directions other than the gradients for distributed training in Lee et al. (2017).

Acknowledgments

The implementation of Nesterov's accelerated gradient is modified from an unreleased C# experimental code provided by Lin Xiao. C.-J. Lin was supported in part by the Ministry of Science and Technology of Taiwan via the grants 107-2221-E-002-167-MY3.

Appendix A. Analysis of Common-directions Method with Single Inner Iteration

We will show that under Assumptions 1, Algorithm 1 converges linearly by Theorem 3. If in addition Assumption 2 is satisfied, Algorithm 1 converges quadratically by Theorem 4.

Lemma 7 *Let P be an n by m real matrix such that $P^\top P = I$. Then*

$$\|P^\top \boldsymbol{v}\| \le \|\boldsymbol{v}\|, \ \forall \boldsymbol{v} \in \mathbb{R}^n.$$

Further, equality holds if and only if

$$\boldsymbol{v} \in \mathtt{span}(P) \equiv \{P\boldsymbol{t} \mid \forall \boldsymbol{t} \in \mathbb{R}^m\}.$$

Proof Note that $\boldsymbol{v}$ can be decomposed as

$$\boldsymbol{v} = PP^\top \boldsymbol{v} + (I - PP^\top)\boldsymbol{v}. \tag{39}$$

Taking norm at both sides and applying $P^\top P = I$, there is

$$\|\boldsymbol{v}\|^2 = \|P^\top \boldsymbol{v}\|^2 + \|(I - PP^\top)\boldsymbol{v}\|^2 \ge \|P^\top \boldsymbol{v}\|^2. \tag{40}$$

Thus, the first result follows. For the second result, we know that $\boldsymbol{v}$ is in the span of P if and only if its orthogonal projection to the span of P is itself. Therefore,

$$\boldsymbol{v} \in \mathtt{span}(P) \iff \boldsymbol{v} = PP^\top \boldsymbol{v}.$$

Combining this with (39), we obtain

$$\boldsymbol{v} \in \mathtt{span}(P) \implies (I - PP^\top)\boldsymbol{v} = \boldsymbol{0} \implies \|P^\top \boldsymbol{v}\| = \|\boldsymbol{v}\|.$$

Similarly, with (40), we have

$$\|P^\top \boldsymbol{v}\| = \|\boldsymbol{v}\| \implies \|(I - PP^\top)\boldsymbol{v}\| = 0 \implies \boldsymbol{v} \in \mathtt{span}(P).$$

Thus, the second result follows from the above two statements. ■

Lemma 8 *For every iteration k of Algorithm 1, we have*

$$P_k^\top P_k = I, \tag{41}$$

and

$$\|P_k^\top \nabla f(\boldsymbol{w}_k)\| = \|\nabla f(\boldsymbol{w}_k)\|. \tag{42}$$

Proof The augmenting of P in Algorithm 1 is simply the Gram-Schmidt process, and thus (41) holds. Further, from the fact that $(I - P_{k-1}P_{k-1}^\top)\nabla f(\boldsymbol{w}_k)$ is used to generate P_k, we have that $\nabla f(\boldsymbol{w}_k) \in \mathtt{span}(P_k)$, so (42) follows from Lemma 7. ■

Lemma 9 *Under Assumption 1,*

$$\sigma I \preceq P_k^\top \nabla^2 f(\boldsymbol{w}_k) P_k \preceq \rho I. \tag{43}$$

Proof Assumption 1 indicates that

$$\sigma I \preceq \nabla^2 f(\boldsymbol{w}) \preceq \rho I, \ \forall \boldsymbol{w}. \tag{44}$$

Combining (44) and (41) in Lemma 8, one has that for any $\boldsymbol{t}$,

$$\begin{aligned} \boldsymbol{t}^\top P_k^\top \nabla^2 f(\boldsymbol{w}_k) P_k \boldsymbol{t} &\ge \sigma \|P_k \boldsymbol{t}\|^2 = \sigma \|\boldsymbol{t}\|^2, \\ \boldsymbol{t}^\top P_k^\top \nabla^2 f(\boldsymbol{w}_k) P_k \boldsymbol{t} &\le \rho \|P_k \boldsymbol{t}\|^2 = \rho \|\boldsymbol{t}\|^2, \end{aligned} \tag{45}$$

which then imply (43). ■

Lemma 10 *Under Assumption 1,*

$$\frac{1}{2\rho}\|\nabla f(\boldsymbol{w})\|^2 \le f(\boldsymbol{w}) - f^* \le \frac{1}{2\sigma}\|\nabla f(\boldsymbol{w})\|^2, \tag{46}$$

where f^* is the optimal objective value.

Proof The first inequality is from Nesterov (2003, Theorem 2.1.5) together with that

$$\nabla f(\boldsymbol{w}^*) = \mathbf{0},$$

where $\boldsymbol{w}^*$ is the optimal solution. The second inequality follows from Nesterov (2003, Theorem 2.1.10). ■

Proof of Theorem 3

We will show that the update direction does not deviate from the steepest descent direction too much, and the line search procedure will then ensure the sufficient decrease of the function value for linear convergence. Let

$$\boldsymbol{t} = -(P_k^\top \nabla^2 f(\boldsymbol{w}_k) P_k)^{-1} P_k^\top \nabla f(\boldsymbol{w}_k). \tag{47}$$

Note that $(P_k^\top \nabla^2 f(\boldsymbol{w}_k) P_k)$ is invertible because of Lemma 9.

We first show that the step size produced in the line search procedure in Algorithm 2 is lower-bounded. From (44) via Assumption 1, for any $\bar{\theta} > 0$, we have

$$f(\boldsymbol{w}_k + \bar{\theta} P_k \boldsymbol{t}) \leq f(\boldsymbol{w}_k) + \bar{\theta} \nabla f(\boldsymbol{w}_k)^\top P_k \boldsymbol{t} + \frac{\rho}{2} \bar{\theta}^2 \|P_k \boldsymbol{t}\|^2. \tag{48}$$

If

$$-\bar{\theta} \nabla f(\boldsymbol{w}_k)^\top P_k \boldsymbol{t} - \frac{\rho}{2} \bar{\theta}^2 \|P_k \boldsymbol{t}\|^2 \geq \frac{\lambda}{2} \bar{\theta}^2 \|P_k \boldsymbol{t}\|^2, \tag{49}$$

then with (48) the stopping condition of Algorithm 2 is satisfied. For $\bar{\theta} > 0$, (49) is equivalent to

$$\bar{\theta} \leq \frac{-\nabla f(\boldsymbol{w}_k)^\top P_k \boldsymbol{t}}{\|P_k \boldsymbol{t}\|^2} \frac{2}{\rho + \lambda}. \tag{50}$$

From (41) of Lemma 8,

$$\|P_k \boldsymbol{t}\| = \|\boldsymbol{t}\|. \tag{51}$$

Thus, by the definition of $\boldsymbol{t}$ in (47) and Lemma 9,

$$\frac{-\nabla f(\boldsymbol{w}_k)^\top P_k \boldsymbol{t}}{\|P_k \boldsymbol{t}\|^2} = \frac{\boldsymbol{t}^\top (P_k^\top \nabla^2 f(\boldsymbol{w}_k) P_k) \boldsymbol{t}}{\|\boldsymbol{t}\|^2} \geq \sigma, \tag{52}$$

whenever $\nabla f(\boldsymbol{w}_k) \neq \mathbf{0}$. Then we have that (49), or equivalently (50), holds whenever

$$\bar{\theta} \leq \frac{2\sigma}{\rho + \lambda}.$$

This ensures the finite termination of Algorithm 2 and guarantees that the generated step size θ_k satisfies

$$\theta_k \geq \min(1, \frac{2\beta\sigma}{\rho + \lambda}) \geq \frac{\beta\sigma}{\rho + \lambda}, \tag{53}$$

where the second inequality is from $\beta < 1$, $\lambda > 0$, and $\sigma \leq \rho$. Therefore, the line-search procedure terminates after at most $\lceil \log_\beta(\beta\sigma/(\rho + \lambda)) \rceil$ steps.

Next we prove the linear convergence. By (51), the definition of $\boldsymbol{t}$ in (47), Lemma 9, and (42) of Lemmas 8, we have

$$\begin{aligned} &\|P_k \boldsymbol{t}\|^2 = \|\boldsymbol{t}\|^2 \\ &= \nabla f(\boldsymbol{w}_k)^\top P_k (P_k^\top \nabla^2 f(\boldsymbol{w}_k) P_k)^{-2} P_k^\top \nabla f(\boldsymbol{w}_k) \\ &\geq \frac{1}{\rho^2} \|P_k^\top \nabla f(\boldsymbol{w}_k)\| = \frac{1}{\rho^2} \|\nabla f(\boldsymbol{w}_k)\|^2. \end{aligned}$$

With this inequality and Lemma 10, the line search stopping condition implies

$$\begin{aligned} f(\boldsymbol{w}_{k+1}) - f^* &\leq f(\boldsymbol{w}_k) - f^* - \frac{\lambda \theta_k^2}{2} \|P_k \boldsymbol{t}\|^2 \\ &\leq f(\boldsymbol{w}_k) - f^* - \frac{\lambda \theta_k^2}{2\rho^2} \|\nabla f(\boldsymbol{w}_k)\|^2 \leq (1 - \frac{\lambda \theta_k^2 \sigma}{\rho^2})(f(\boldsymbol{w}_k) - f^*). \end{aligned} \tag{54}$$

Plugging in the lower bound (53) of the step-size θ_k to (54), we have the linear convergence

$$f(\boldsymbol{w}_{k+1}) - f^* \leq (1 - \frac{\lambda \beta^2 \sigma^3}{(\rho + \lambda)^2 \rho^2})(f(\boldsymbol{w}_k) - f^*).$$

This non-asymptotic linear convergence holds for any λ. Specifically, if we take $\lambda = \rho$, then we have the iteration complexity

$$O(\frac{\rho^3}{\sigma^3} \log(\frac{1}{\epsilon})),$$

Further, if Algorithm 2 always stops at step size $\theta_k = 1$, the rate (54) becomes

$$f(\boldsymbol{w}_{k+1}) - f^* \leq (1 - \frac{\lambda \sigma}{\rho^2})(f(\boldsymbol{w}_k) - f^*).$$

In this case, picking $\lambda = \rho$ recovers the iteration complexity of gradient descent methods (Nesterov, 2003)

$$O\left(\frac{\rho}{\sigma} \log\left(\frac{1}{\epsilon}\right)\right).$$

Thus, all the results are established. ■

Proof of Theorem 4

If $\nabla f(\boldsymbol{w}_0) = \mathbf{0}$, then the initial point is the optimal solution, and there is nothing to prove. Therefore, because $\nabla f(\boldsymbol{w}_0)/\|\nabla f(\boldsymbol{w}_0)\| \neq \mathbf{0}$ is included in P_0, we start our discussion with $\text{rank}(P_k) \geq 1$. The procedure of adding columns to P_k in Algorithm 1 ensures that $\text{rank}(P_k)$ is a monotonically increasing and bounded sequence with

$$1 \leq \text{rank}(P_k) \leq n, \ \forall k \in \mathbb{N}.$$

Thus, there exists a k_0 such that

$$\text{rank}(P_k) = \text{rank}(P_{k_0}), \ \forall k \geq k_0.$$

Together with $\boldsymbol{w}_{k+1} = \boldsymbol{w}_k + \theta_k P_k \boldsymbol{t}_k$ in Algorithm 1, this implies

$$\boldsymbol{w}_k - \boldsymbol{w}_0 \in \texttt{span}(P_{k_0}),\ \forall k \geq 0.$$

From Theorem 3, we know that $f(\boldsymbol{w}_k)$ converges to $f(\boldsymbol{w}^*)$. This property and the strong convexity of f imply that $\boldsymbol{w}_k$ also converges to $\boldsymbol{w}^*$ globally because

$$f(\boldsymbol{w}_k) - f(\boldsymbol{w}^*) \geq \frac{\sigma}{2}\|\boldsymbol{w}_k - \boldsymbol{w}^*\|^2.$$

Therefore, we have $\boldsymbol{w}^* - \boldsymbol{w}_0 \in \texttt{span}(P_{k_0})$. This means that the minimization procedure takes update directions wholly in the space $\texttt{span}(P_{k_0})$, and each step in the algorithm is equivalent to applying the Newton method with line search in the subspace. Consider the following equivalent reformulation

$$\boldsymbol{w}_k = \boldsymbol{w}_0 + P_{k_0}\hat{\boldsymbol{t}}_k, \boldsymbol{w}^* = \boldsymbol{w}_0 + P_{k_0}\hat{\boldsymbol{t}}^*, \forall k \geq k_0.$$

Our method after the k_0-th iteration is equivalent to applying the Newton method over the variables $\hat{\boldsymbol{t}}$. That is, the following optimization problem is solved

$$\min_{\hat{\boldsymbol{t}}} \quad f(\boldsymbol{w}_0 + P_{k_0}\hat{\boldsymbol{t}}). \tag{55}$$

From Lemma 9, (55) possesses a unique optimal solution $\hat{\boldsymbol{t}}^*$. See also (47), which has the form of the Newton direction of (55). Note that for $g(\boldsymbol{t}) \equiv f(\boldsymbol{w}_0 + P_{k_0}\boldsymbol{t})$, Assumption 2 is still satisfied because with $\|P_{k_0}\| = 1$,

$$\begin{aligned}&\|\nabla^2 g(\boldsymbol{t}_1) - \nabla^2 g(\boldsymbol{t}_2)\| = \|P_{k_0}^\top(\nabla^2 f(\boldsymbol{w}_0 + P_{k_0}\boldsymbol{t}_1) - \nabla^2 f(\boldsymbol{w}_0 + P_{k_0}\boldsymbol{t}_2))P_{k_0}\| \\ &\leq \|P_{k_0}\|^2 M\|P_{k_0}(\boldsymbol{t}_1 - \boldsymbol{t}_2)\| \leq M\|\boldsymbol{t}_1 - \boldsymbol{t}_2\|.\end{aligned}$$

Further, the line search process is scale-invariant because the columns in P_{k_0} are orthogonal due to the Schmidt process. Thus, the quadratic convergence of $\hat{\boldsymbol{t}}_k$ follows from that of the Newton method for problems satisfying Assumption 2 (Nocedal and Wright, 2006, Theorem 3.5).

$$\|\hat{\boldsymbol{t}}_{k+1} - \hat{\boldsymbol{t}}^*\| = O(\|\hat{\boldsymbol{t}}_k - \hat{\boldsymbol{t}}^*\|^2).$$

Because columns in P_{k_0} are orthogonal to each other, we have that

$$\|P_{k_0}(\hat{\boldsymbol{t}}_{k+1} - \hat{\boldsymbol{t}}^*)\| = \|(\hat{\boldsymbol{t}}_{k+1} - \hat{\boldsymbol{t}}^*)\| = O(\|\hat{\boldsymbol{t}}_k - \hat{\boldsymbol{t}}^*\|^2) = O(\|P_{k_0}(\hat{\boldsymbol{t}}_k - \hat{\boldsymbol{t}}^*)\|^2).$$

Therefore, quadratic convergence for the original variables $\boldsymbol{w}_k$ holds. ■

Appendix B. Proof of Theorem 5

We first prove that, if every iteration of Algorithm 4 reaches the optimal solution of (21), then the optimal convergence rate is guaranteed. The main idea of this proof follows from the convergence rate proof of Nesterov's accelerated gradient (Nesterov, 1983) in Bubeck (2015, Theorem 3.17).

Let $\boldsymbol{w}_k$ be the iterate obtained from Algorithm 4 at the k-th iteration. Define

$$\phi_{k+1}(\boldsymbol{w}) \equiv (1-\alpha)\,\phi_k(\boldsymbol{w}) + \alpha\left(f(\boldsymbol{w}_k) + \nabla f(\boldsymbol{w}_k)^\top(\boldsymbol{w} - \boldsymbol{w}_k) + \frac{\sigma}{2}\|\boldsymbol{w} - \boldsymbol{w}_k\|^2\right), k \geq 0, \tag{56}$$

$$\text{with}\ \ \alpha \equiv \sqrt{\frac{\sigma}{\rho}} \in (0,1], \qquad \text{and} \qquad \phi_0(\boldsymbol{w}) \equiv \frac{\sigma}{2}\|\boldsymbol{w} - \boldsymbol{w}_0\|^2 + f(\boldsymbol{w}_0). \tag{57}$$

We will first show that, by induction,

$$\nabla^2\phi_k(\boldsymbol{w}) = \sigma I,\ \forall k. \tag{58}$$

The claim holds trivially at $k = 0$ from (57). Now suppose the claim (58) holds for some $k \geq 0$. For the $(k+1)$-th iteration, by (56) we have

$$\nabla^2\phi_{k+1}(\boldsymbol{w}) = (1-\alpha)\nabla^2\phi_k(\boldsymbol{w}) + \alpha\sigma I = \sigma I.$$

Thus, the induction on (58) is established.

Now we examine the recurrence relation in ϕ_k. Because $\phi_0(\boldsymbol{w})$ and the recurrence (56) are all strongly convex quadratic, we have $\phi_k(\boldsymbol{w})$ is also a strongly convex quadratic by induction. Let $\boldsymbol{v}_k$ be a constant that minimizes ϕ_k, which implies $\nabla\phi_k(\boldsymbol{v}_k) = \boldsymbol{0}$. By (58) and the Taylor expansion, we obtain

$$\begin{aligned}\phi_k(\boldsymbol{w}) &= \phi_k(\boldsymbol{v}_k) + \nabla\phi_k(\boldsymbol{v}_k)^\top(\boldsymbol{w} - \boldsymbol{v}_k) + \frac{\sigma}{2}\|\boldsymbol{w} - \boldsymbol{v}_k\|^2 \\ &= \phi_k(\boldsymbol{v}_k) + \frac{\sigma}{2}\|\boldsymbol{w} - \boldsymbol{v}_k\|^2,\ \forall \boldsymbol{w}.\end{aligned} \tag{59}$$

Further, let $\boldsymbol{v}_{k+1}$ be the minimizer of ϕ_{k+1}. Using the derivative of (56) together with (59), we have

$$\begin{aligned}&\nabla\phi_{k+1}(\boldsymbol{v}_{k+1}) \\ &= (1-\alpha)\nabla\phi_k(\boldsymbol{v}_{k+1}) + \alpha(\nabla f(\boldsymbol{w}_k) + \sigma(\boldsymbol{v}_{k+1} - \boldsymbol{w}_k)) \\ &= (1-\alpha)\sigma(\boldsymbol{v}_{k+1} - \boldsymbol{v}_k) + \alpha(\nabla f(\boldsymbol{w}_k) + \sigma(\boldsymbol{v}_{k+1} - \boldsymbol{w}_k)) = \boldsymbol{0}.\end{aligned}$$

Thus, we obtain a recurrent definition of $\boldsymbol{v}_{k+1}$:

$$\begin{aligned}\boldsymbol{v}_0 &= \boldsymbol{w}_0, \\ \boldsymbol{v}_{k+1} &= (1-\alpha)\boldsymbol{v}_k + \alpha\boldsymbol{w}_k - \frac{\alpha}{\sigma}\nabla f(\boldsymbol{w}_k).\end{aligned} \tag{60}$$

From (60), we have

$$\boldsymbol{v}_{k+1} - \boldsymbol{v}_k = -\alpha(\boldsymbol{v}_k - \boldsymbol{w}_k) - \frac{\alpha}{\sigma}\nabla f(\boldsymbol{w}_k), \tag{61}$$

$$\boldsymbol{v}_{k+1} - \boldsymbol{w}_k = (1-\alpha)(\boldsymbol{v}_k - \boldsymbol{w}_k) - \frac{\alpha}{\sigma}\nabla f(\boldsymbol{w}_k). \tag{62}$$

Next, we obtain a recurrent relation of $\phi_{k+1}(\boldsymbol{v}_{k+1})$.

$$\begin{aligned}\phi_{k+1}(\boldsymbol{v}_{k+1}) = \; & (1-\alpha)\left(\phi_k(\boldsymbol{v}_k) + \frac{\sigma}{2}\|\boldsymbol{v}_{k+1}-\boldsymbol{v}_k\|^2\right) \\ & + \alpha\left(f(\boldsymbol{w}_k) + \nabla f(\boldsymbol{w}_k)^\top(\boldsymbol{v}_{k+1}-\boldsymbol{w}_k) + \frac{\sigma}{2}\|\boldsymbol{v}_{k+1}-\boldsymbol{w}_k\|^2\right) \quad (63) \\ = \; & (1-\alpha)\phi_k(\boldsymbol{v}_k) + \alpha f(\boldsymbol{w}_k) \\ & + \alpha(1-\alpha)\left(\nabla f(\boldsymbol{w}_k)^\top(\boldsymbol{v}_k-\boldsymbol{w}_k) + \frac{\sigma}{2}\|\boldsymbol{v}_k-\boldsymbol{w}_k\|^2\right) - \frac{1}{2\rho}\|\nabla f(\boldsymbol{w}_k)\|^2, \quad (64)\end{aligned}$$

where (63) is by (56) and (59), and (64) is by (61), (62), and applying the definition $\alpha = \sqrt{\sigma/\rho}$ to the coefficient of $\|\nabla f(\boldsymbol{w}_k)\|^2$. Note that $\{\phi_k\}$ is called the estimation sequence in Nesterov (1983).

Now we show by induction that, for $\boldsymbol{w}_k$ minimizing (21) exactly,

$$\min_{\boldsymbol{w}\in\mathbb{R}^n} \quad \phi_k(\boldsymbol{w}) = \phi_k(\boldsymbol{v}_k) \geq f(\boldsymbol{w}_k), \; \forall k \geq 0. \quad (65)$$

First, (65) holds trivially at $k=0$ from the definition (57). Assume (65) holds at the k-th iteration. At the $(k+1)$-th iteration, (64) and (65) imply

$$\phi_{k+1}(\boldsymbol{v}_{k+1}) \geq f(\boldsymbol{w}_k) + \alpha(1-\alpha)\left(\nabla f(\boldsymbol{w}_k)^\top(\boldsymbol{v}_k-\boldsymbol{w}_k) + \frac{\sigma}{2}\|\boldsymbol{v}_k-\boldsymbol{w}_k\|^2\right) - \frac{1}{2\rho}\|\nabla f(\boldsymbol{w}_k)\|^2. \quad (66)$$

By the definition of P_k and induction on (60), both $\boldsymbol{v}_k$ and $\boldsymbol{w}_k$ belong to $\boldsymbol{w}_0 + \texttt{span}(P_{k-1})$. Thus, the optimality of $\boldsymbol{w}_k$ on

$$\min_{\boldsymbol{t}} \quad f(\boldsymbol{w}_{k-1} + P_{k-1}\boldsymbol{t})$$

implies that

$$P_{k-1}^\top \nabla f(\boldsymbol{w}_k) = \boldsymbol{0}. \quad (67)$$

Thus

$$\nabla f(\boldsymbol{w}_k)^\top(\boldsymbol{v}_k - \boldsymbol{w}_k) = 0. \quad (68)$$

This result, (66), and $\alpha \in (0,1]$ from (57) then lead to

$$\phi_{k+1}(\boldsymbol{v}_{k+1}) \geq f(\boldsymbol{w}_k) - \frac{1}{2\rho}\|\nabla f(\boldsymbol{w}_k)\|^2. \quad (69)$$

Further,

$$\begin{aligned} & f(\boldsymbol{w}_k) - \frac{1}{2\rho}\|\nabla f(\boldsymbol{w}_k)\|^2 = f(\boldsymbol{w}_k) - \frac{1}{\rho}\|\nabla f(\boldsymbol{w}_k)\|^2 + \frac{\rho}{2}\frac{1}{\rho^2}\|\nabla f(\boldsymbol{w}_k)\|^2 \\ \geq \; & f(\boldsymbol{w}_k - \frac{1}{\rho}\nabla f(\boldsymbol{w}_k)) \quad (70) \\ \geq \; & f(\boldsymbol{w}_{k+1}). \quad (71)\end{aligned}$$

The inequality (70) comes from the Taylor expansion of $f(\boldsymbol{w}_k - \nabla f(\boldsymbol{w}_k)/\rho)$ and (44):

$$\begin{aligned} f(\boldsymbol{w}_k - \frac{1}{\rho}\nabla f(\boldsymbol{w}_k)) &= f(\boldsymbol{w}_k) - \frac{1}{\rho}\|\nabla f(\boldsymbol{w}_k)\|^2 + \frac{1}{2\rho^2}\nabla f(\boldsymbol{w}_k)^\top \nabla^2 f(\tilde{\boldsymbol{w}})\nabla f(\boldsymbol{w}_k) \\ &\leq f(\boldsymbol{w}_k) - \frac{1}{\rho}\|\nabla f(\boldsymbol{w}_k)\|^2 + \frac{1}{2\rho}\|\nabla f(\boldsymbol{w}_k)\|^2, \end{aligned}$$

where $\tilde{\boldsymbol{w}}$ is between $\boldsymbol{w}_k$ and $\boldsymbol{w}_k - \frac{1}{\rho}\nabla f(\boldsymbol{w}_k)$. For (71), it holds because $\nabla f(\boldsymbol{w}_k) \in \texttt{span}(P_k)$ and $\boldsymbol{w}_{k+1}$ is a minimizer of f over $\boldsymbol{w}_0 + \texttt{span}(P_k)$. Combining (69) and (71), we have (65) holds at iteration $k+1$. Therefore, (65) holds for every $k \geq 0$ by induction.

Now, we arrive at the final steps. From (65), (56), and the strong convexity of f in Assumption 1, we have

$$\begin{aligned} & f(\boldsymbol{w}_{k+1}) - f(\boldsymbol{w}^*) \\ \leq \; & \min_{\boldsymbol{w}} \quad \phi_{k+1}(\boldsymbol{w}) - f(\boldsymbol{w}^*) \\ \leq \; & \phi_{k+1}(\boldsymbol{w}^*) - f(\boldsymbol{w}^*) \quad (72) \\ = \; & (1-\alpha)\phi_k(\boldsymbol{w}^*) + \alpha(f(\boldsymbol{w}_k) + \nabla f(\boldsymbol{w}_k)^\top(\boldsymbol{w}^*-\boldsymbol{w}_k) + \frac{\sigma}{2}\|\boldsymbol{w}^*-\boldsymbol{w}_k\|^2) - f(\boldsymbol{w}^*) \\ \leq \; & (1-\alpha)\phi_k(\boldsymbol{w}^*) + \alpha f(\boldsymbol{w}^*) - f(\boldsymbol{w}^*) \\ = \; & (1-\alpha)(\phi_k(\boldsymbol{w}^*) - f(\boldsymbol{w}^*)) \quad (73) \\ \leq \; & (1-\alpha)^{k+1}(\phi_0(\boldsymbol{w}^*) - f(\boldsymbol{w}^*)). \quad (74)\end{aligned}$$

Note that (74) comes from repeating the steps between (72) and (73). By taking logarithm at both sides, we have proven that Algorithm 4 achieves the optimal rate when (21) is solved exactly.

Next we discuss the situation when (21) is approximately solved. In the above proof we can see that having a $\boldsymbol{w}_{k+1}$ that satisfies (65) is sufficient for proving the linear convergence. Because (65) comes from (66)-(69) and (71),[11] we can consider running inner iterations in Algorithm 4 until the following inner stopping condition is satisfied.

$$\begin{cases} \nabla f(\boldsymbol{w}_{k+1})^\top(\boldsymbol{v}_{k+1}-\boldsymbol{w}_{k+1}) + \frac{\sigma}{2}\|\boldsymbol{v}_{k+1}-\boldsymbol{w}_{k+1}\|^2 \geq 0, & (75a) \\ f(\boldsymbol{w}_{k+1}) \leq f(\boldsymbol{w}_k - \frac{1}{\rho}\nabla f(\boldsymbol{w}_k)). & (75b)\end{cases}$$

Denote $\boldsymbol{t}_k^*$ as the exact solution of (21) and let

$$\boldsymbol{w}_{k+1}^* \equiv \boldsymbol{w}_k + P_k\boldsymbol{t}_k^*.$$

From the discussion in (68) and (71), clearly $\boldsymbol{w}_{k+1}^*$ satisfies (75). The remaining task is to prove that (75) can be achieved in a finite number of iterations. If $\boldsymbol{w}_{k+1}^*$ strictly satisfies inequalities in (75), then by the continuity of f and ∇f, there is a neighborhood of $\boldsymbol{w}_{k+1}^*$ in which every point satisfies (75). Because inner iterations lead to the convergence to $\boldsymbol{w}_{k+1}^*$, the inner loop must terminate finitely. On the other hand, we can easily rule out situations where $\boldsymbol{w}_{k+1}^*$ satisfies one of the conditions in (75) as an equality. When (75a) becomes an equality under $\boldsymbol{w}_{k+1}^*$, (68) implies that

$$\boldsymbol{w}_{k+1}^* = \boldsymbol{v}_{k+1}.$$

When (75b) becomes an equality, the strong convexity of $f(\boldsymbol{w}_k + P_k\boldsymbol{t})$ on $\boldsymbol{t}$, which follows from Lemma 9, implies that the optimum $\boldsymbol{w}_{k+1}^*$ of $\min_{\boldsymbol{t}} f(\boldsymbol{w}_k + P_k\boldsymbol{t})$ is unique. This property, the fact that $\nabla f(\boldsymbol{w}_k)$ lies in the column space of P_k, and the equality in (75b) imply that

$$\boldsymbol{w}_{k+1}^* = \boldsymbol{w}_k - \frac{1}{\rho}\nabla f(\boldsymbol{w}_k).$$

11. Note that we ensure (75) holds for every k, so (75a) with k rather than $k+1$ is what we use for (66).

Therefore, before starting the inner loop of Algorithm 4, we can first check if $\boldsymbol{v}_{k+1}$ or $\boldsymbol{w}_k - (1/\rho)\nabla f(\boldsymbol{w}_k)$ satisfies (75). If one of them satisfies both inequalities, then we can take this vector as $\boldsymbol{w}_{k+1}$ without going into the loop. Otherwise, neither $\boldsymbol{v}_{k+1}$ nor $\boldsymbol{w}_k - (1/\rho)\nabla f(\boldsymbol{w}_k)$ is $\boldsymbol{w}^*_{k+1}$, so $\boldsymbol{w}^*_{k+1}$ must strictly satisfy inequalities in (75).

Therefore, after a finite number of inner iterations we can always find an iterate $\boldsymbol{w}_{k+1}$ satisfying (75). This condition ensures (69) and (71) hold. Therefore, (65) is established.

Appendix C. Proof of Theorem 6

At the k-th iteration, if (21) is solved exactly, the optimality condition (67) implies that any column in P_k is orthogonal to $\nabla f(\boldsymbol{w}_{k+1})$. Therefore, if $\nabla f(\boldsymbol{w}_{k+1}) \neq \boldsymbol{0}$, the new gradient will augment P_{k+1} by one column. By induction, if $\nabla f(\boldsymbol{w}_{k'}) \neq \boldsymbol{0}$, $\forall k' = 0, \ldots, k-1$, then P_k has k orthogonal columns. Because each column of P_k is in $\mathbb{R}^n$, there can be at most n orthogonal directions in P_k. Therefore, when $k \geq n$, $\texttt{span}(P_k) = R^n$ and the solution of (21) is equivalent to the solution of (1). Thus, the optimum is reached within n iterations.

Abstract

We study the performance of kernel methods on the acoustic modeling task for automatic speech recognition, and compare their performance to deep neural networks (DNNs). To scale the kernel methods to large data sets, we use the random Fourier feature method of Rahimi and Recht (2007). We propose two novel techniques for improving the performance of kernel acoustic models. First, we propose a simple but effective feature selection method which reduces the number of random features required to attain a fixed level of performance. Second, we present a number of metrics which correlate strongly with speech recognition performance when computed on the heldout set; we attain improved performance by using these metrics to decide when to stop training. Additionally, we show that the linear bottleneck method of Sainath et al. (2013a) improves the performance of our kernel models significantly, in addition to speeding up training and making the models more compact. Leveraging these three methods, the kernel methods attain token error rates between 0.5% better and 0.1% worse than fully-connected DNNs across four speech recognition data sets, including the TIMIT and Broadcast News benchmark tasks.

Keywords: kernel methods, deep neural networks, acoustic modeling, automatic speech recognition, feature selection, logistic regression

1. Introduction

Large-scale non-linear classification is an important and challenging problem in machine learning. In recent years, deep learning techniques have significantly advanced state-of-the-art performance on classification problems in various domains, including automatic speech recognition (ASR) (Seide et al., 2011a; Hinton et al., 2012; Mohamed et al., 2012; Xiong et al., 2017; Saon et al., 2017), computer vision (Krizhevsky et al., 2012; Simonyan and Zisserman, 2015; He et al., 2016), and natural language processing (NLP) (Mikolov et al., 2013; Sutskever et al., 2014; Andor et al., 2016). Deep neural networks (DNNs) are able to gracefully scale to large data sets, and can successfully leverage this additional data to achieve strong empirical performance. In contrast, kernel methods, which are attractive due to their high capacity, as well as for their theoretical learning guarantees and tractability (Schölkopf and Smola, 2002), do not scale well. In particular, with data sets of size N, the $\Theta(N^2)$ size of the kernel matrix makes training prohibitively slow, while the typical $\Theta(N)$ size of the resulting models (Steinwart, 2003) makes their deployment impractical.

An important technique for scaling kernel methods to large data sets is to use approximation. Kernel approximation methods construct explicit feature maps whose dot-products approximate the kernel function, and then learn linear models with these features. Notable approximation methods include the Nyström method (Williams and Seeger, 2000), and random Fourier features (RFFs) (Rahimi and Recht, 2007). Although these methods make it possible to apply kernel methods to large-scale tasks, there have been very few published attempts applying these methods to the challenging large-scale tasks on which deep learning techniques have truly shined.[1]

The primary contribution of this paper is to demonstrate, in a large-scale setting where deep learning techniques have been known to dominate, that kernel approximation methods can effectively compete with fully-connected DNNs. More specifically:

- We benchmark the performance of kernel approximation methods (RFFs) relative to fully-connected DNNs on the acoustic modeling problem for automatic speech recognition, on four data sets with millions of training points and hundreds/thousands of classes.[2]
- We propose three methods for improving the performance of the kernel acoustic models: a feature selection method, new early stopping criteria for training, and the use of a linear bottleneck layer (Sainath et al., 2013a). We show that using these techniques, the kernel methods attain token error rates (TER)[3] between 0.5% better and 0.1% worse than fully-connected DNNs on the four data sets.

This contribution is important for both practical and theoretical reasons. From a practical perspective, it suggests that kernel methods can be competitive with deep learning

1. See related work section for discussion.
2. We use the IARPA Babel Program Cantonese (IARPA-babel101-v0.4c) and Bengali (IARPA-babel103b-v0.4b) limited language packs, a 50-hour subset of Broadcast News (BN-50) (Kingsbury, 2009), and TIMIT (Garofolo et al., 1993).
3. For our Cantonese data set, 'token error rate' corresponds to 'character error rate.' For our Bengali and Broadcast News data sets, it corresponds to 'word error rate.' For TIMIT, it corresponds to 'phone error rate.'

methods on large-scale tasks. From a theoretical perspective, it adds to our understanding of DNNs and non-linear classification. There is a large open question of why DNNs work, which is being actively investigated from various directions, including optimization (Dauphin et al., 2014; Choromanska et al., 2015; Anandkumar and Ge, 2016; Agarwal et al., 2017; Xie et al., 2017; Pennington and Bahri, 2017), representational power and efficiency (Cybenko, 1989; Hornik et al., 1989; Bengio et al., 2007; Bianchini and Scarselli, 2014; Montúfar et al., 2014; Ba and Caruana, 2014), and generalization performance (Bartlett, 1996; Neyshabur et al., 2015; Zhang et al., 2017; Arpit et al., 2017). The fact that kernel methods can match DNNs on a task this large and challenging gives an important new perspective.

As discussed above, we propose three methods to improve the performance of the kernel acoustic models. First, we propose a simple feature selection algorithm, which effectively reduces the number of random features required to attain a fixed level of performance. We iteratively select features from large pools of random features, using learned weights in the selection criterion. This has two clear benefits: (1) the subsequent training on the selected features is considerably faster than training on the entire pool of random features, and (2) the resulting model is also much smaller. For certain kernels, this feature selection approach—which is applied at the level of the random features—can be regarded as a non-linear method for feature selection at the level of the input features. We use this observation to motivate the design of a new kernel function, the "sparse Gaussian kernel," which performs well in conjunction with the feature selection algorithm.

Second, we present several frame-level metrics which correlate strongly with the TER. We show that we can attain notable gains in TER for both kernels and DNNs by monitoring these metrics on the heldout set during training to determine when to stop training.

Lastly, we demonstrate the importance of using a linear bottleneck (Sainath et al., 2013a) in the parameter matrix of our kernel models. Not only does this method improve the performance of our kernel models significantly, it also makes training faster, and reduces the size of the models learned.

In this paper we unify and extend the previous works of Lu et al. (2016) and May et al. (2016). The most significant additions are as follows: (1) we show that we can attain improved performance by combining the methods from both papers; (2) we present a more extensive set of experiments, including results on the TIMIT benchmark task, and a detailed ablation study to reveal the marginal improvements from each method; (3) we present a larger set of metrics which correlate strongly with TER, and show that we can attain improved performance by using these metrics during training to decide when to decay the learning rate and stop training.

The rest of the paper is organized as follows. We review related work in Section 2. We provide some background for kernel approximation methods, as well as for acoustic modeling, in Section 3. We present our feature selection algorithm in Section 4. In Section 5, we present several novel metrics which correlate strongly with TER, and discuss how they can be used during training to improve TER performance. In Section 6, we report extensive experiments comparing DNNs and kernel methods, including results using the methods discussed above. We conclude in Section 7.

2. Related Work

Scaling up kernel methods has been a long-standing and actively studied problem (Platt, 1998; DeCoste and Schölkopf, 2002; Tsang et al., 2005; Bottou et al., 2007; Clarkson, 2010). Approximating kernels by constructing explicit finite-dimensional feature representations, where dot products between these representations approximate the kernel function, has emerged as a powerful technique (e.g., Williams and Seeger, 2000; Rahimi and Recht, 2007). The Nyström method constructs these feature maps, for arbitrary kernels, via a low-rank decomposition of the kernel matrix (Williams and Seeger, 2000). For shift-invariant kernels, the RFF technique of Rahimi and Recht (2007) uses random projections to generate the features. Random projections can also be used to approximate a wider range of kernels (Kar and Karnick, 2012; Vedaldi and Zisserman, 2012; Hamid et al., 2014; Pennington et al., 2015). Many recent works aim to make RFFs more computationally efficient. One line of work attempts to reduce the time and memory needed to compute the RFFs by imposing structure on the random projection matrix (Le et al., 2013; Yu et al., 2015). It is also possible to use doubly-stochastic methods to speed-up stochastic gradient training of models based on the random features (Dai et al., 2014). For kernels with sparse feature expansions, Sonnenburg and Franc (2010) show how to scale kernel SVMs to data sets with up to 50 million training samples by using sparse vector operations for parameter updates.

Despite much progress in kernel approximation, there have been very few applications of these methods to challenging large-scale problems, or comparisons with DNNs on these tasks. Notable exceptions are the following: on image recognition problems, it has been shown that random Fourier features (Rahimi and Recht, 2007) can be used to replace the fully connected layers in the convolutional neural network (CNN) known as AlexNet (Krizhevsky et al., 2012), and achieve comparable performance on the ImageNet 2012 data set (Dai et al., 2014; Yang et al., 2015). Although these results suggest that kernel methods can replace the fully-connected layers of neural networks, the hybrid CNN-kernel model makes it difficult to disentangle the relative importance of these two components. In ASR, the only existing work applying kernel approximation methods has been quite limited in scope (Huang et al., 2014), using the relatively easy and small-scale TIMIT data set.[4] A detailed evaluation of kernel methods on large-scale ASR tasks, together with a thorough comparison with DNNs, has not been performed. Our work fills this gap, tackling challenging large-scale acoustic modeling problems, where deep neural networks achieve strong performance. Additionally, we provide a number of important improvements to the kernel methods, which boost their performance significantly.

One contribution of our work is to introduce a feature selection method that works well in conjunction with random Fourier features in the context of large-scale multi-class classification problems. Recent work on feature selection methods with random Fourier features, for binary classification and regression problems, includes the Sparse Random Features algorithm of Yen et al. (2014). This algorithm is a coordinate descent method for smooth convex optimization problems in the infinite space of non-linear features; each step involves solving a batch ℓ_1-regularized convex optimization problem over randomly generated non-linear features. Here, the ℓ_1-regularization may cause the learned solution

4. Here, we are excluding the results presented in this paper, some of which have already been published (May et al., 2016; Lu et al., 2016).

to only depend on a subset of the generated features. A drawback of this approach is the computational burden of fully solving many batch optimization problems, which is prohibitive for large data sets. In our attempts to implement an online variant of this method using the forward-backward splitting (FOBOS) algorithm of Duchi and Singer (2009) (using ℓ_1/ℓ_2 mixed-norm regularization for the multi-class setting), we observed that very strong regularization was required to obtain any intermediate sparsity, which in turn severely hurt prediction performance. Our approach for selecting random features is more efficient, and more directly ensures sparsity, than regularization. The basic idea behind our approach is to iteratively train a model over a batch of random features, and to then replace the features whose corresponding rows in the parameter matrix have small ℓ_2 norm. This method bears some similarity to the methods of pruning neural networks which eliminate parameters whose magnitudes are below a certain threshold (Ström, 1997; Han et al., 2015); a difference is that in our method we eliminate entire *rows* of the parameter matrix instead of individual entries.

Another improvement we propose alters the frame-level training of the acoustic model to improve the speech recognition performance of the final model. A set of methods, typically referred to as *sequence training* techniques, share our goal of tuning the acoustic model for the purpose of improving its recognition performance. There are a number of different sequence training criteria which have been proposed, including maximum mutual information (MMI) (Bahl et al., 1986; Valtchev et al., 1997), boosted MMI (BMMI) (Povey et al., 2008), minimum phone error (MPE) (Povey and Woodland, 2002), or minimum Bayes risk (MBR) (Kaiser et al., 2000; Gibson and Hain, 2006; Povey and Kingsbury, 2007). These methods, though originally proposed for training Gaussian mixture model (GMM) acoustic models, can also be used for neural network acoustic models (Kingsbury, 2009; Veselý et al., 2013). Nonetheless, all of these methods are quite computationally expensive and are typically initialized with an acoustic model trained via the frame-level cross-entropy criterion. Our method, by contrast, is very simple, only making a small change to the frame-level training process. Furthermore, it can be used in conjunction with the above-mentioned sequence training techniques by providing a better initial model. Recently, Povey et al. (2016) showed that it is possible to train an acoustic model using *only* sequence-training methods, with the lattice-free version of the MMI criterion. In a similar vein, there has been significant work on end-to-end training of ASR systems, which removes the need for frame-level training of acoustic models altogether (Graves et al., 2006; Amodei et al., 2016; Chan et al., 2016; Chiu et al., 2018). For future work, we would like to see how much kernel models can benefit from the various sequence training methods mentioned above, relative to DNNs.

Recent years have seen huge improvements in the performance of state-of-the-art speech recognition systems. The most important factors leading to this success have been the following: sequence training (Povey et al., 2008, 2016), speaker adaptation through the use of i-vectors (Dehak et al., 2011), training on large data sets (van den Berg et al., 2017; Saon et al., 2017), and improved deep architectures for both language modeling (Mikolov et al., 2010; Sundermeyer et al., 2012; Saon et al., 2017), and acoustic modeling. For acoustic modeling, CNNs (Krizhevsky et al., 2012; Sainath et al., 2013c; Soltau et al., 2014; Simonyan and Zisserman, 2015; Sercu and Goel, 2016; He et al., 2016; Saon et al., 2017) along with Long Short Term Memory (LSTM) networks (Sak et al., 2014; Saon et al., 2017), have been developed to leverage the time-frequency structure of the speech signal,

and achieve better performance than fully-connected feed-forward DNNs. The most recent state-of-the-art systems (Xiong et al., 2017; Saon et al., 2017) use an ensemble of LSTMs and CNNs for acoustic modeling. In Saon et al. (2016) they show an improvement of 1.3% in WER on the Switchboard data set when switching from a sigmoid DNN architecture to an LSTM, while in Xiong et al. (2017) they see that a ResNet CNN (He et al., 2016) improves upon a ReLU DNN by 1.6%.

In the context of these recent advances, our results showing competitive performance with fully-connected DNNs are significant, for a number of reasons. First of all, while no longer being state-of-the-art, fully-connected DNNs still attain strong performance on the acoustic modeling task. Second, fully-connected DNNs remain an important class of models, which are used widely (e.g., Andor et al., 2016). Furthermore, fully-connected layers are an important building block within more complex deep learning architectures (Simonyan and Zisserman, 2015; He et al., 2016). Additionally, we believe it should be important to the research community to discover when and why deep architectures are necessary, while simultaneously working to explore which other families of models might be able to compete; we think kernel methods are an important family of models to consider, as they lend themselves to simpler interpretation, and cleaner theoretical analysis, relative to DNNs. For future work, we would like to develop specialized kernel methods to better leverage the structure in the speech signal, in a manner similar to CNNs and LSTMs.

This work also contributes to the debate on the relative strengths of deep and shallow models. Kernel models can generally be seen as shallow models, given that they involve learning a linear model on top of a fixed transformation of the data. Furthermore, as explained in Section 3.3, many types of kernels (including popular kernels like the Gaussian kernel and the Laplacian kernel) can actually be seen as a special case of a shallow neural network. Conversely, any neural network can be understood as a kernel model, in which the kernel function itself is learned. Classic results show that both deep and shallow neural networks, as well as kernel methods, are "universal approximators," meaning that they can approximate any real-valued continuous function with bounded support to an arbitrary degree of precision (Cybenko, 1989; Hornik et al., 1989; Micchelli et al., 2006). However, a number of papers have argued that there exist functions which deep neural networks can express with exponentially fewer parameters than shallow neural networks (Montúfar et al., 2014; Bianchini and Scarselli, 2014). Other papers have argued that kernel methods may require a number of training samples which is exponential in the intrinsic dimension of the data manifold to generalize well, a problem known as the *curse of dimensionality* (Härdle et al., 2004; Bengio et al., 2007). In Ba and Caruana (2014), the authors show that the performance of shallow neural networks can be improved considerably by training them to match the outputs of deep neural networks. In showing that kernel methods can compete with DNNs on large-scale speech recognition tasks, this paper adds credence to the argument that shallow models can compete with deep networks.

3. Background

In this section, we provide background on kernels and how to approximate them with random Fourier features (Rahimi and Recht, 2007), on acoustic modeling (using neural networks and kernels), and on the linear bottleneck method of Sainath et al. (2013a).

3.1. Kernel Methods and Random Fourier Features

Kernel methods, broadly speaking, are a set of machine learning techniques which either explicitly or implicitly map data from the input space $\mathcal{X}$ to some feature space $\mathcal{H}$, in which a linear model is learned. A kernel function $K\colon \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is then defined[5] as the function which takes as input $\boldsymbol{x}, \boldsymbol{x}' \in \mathcal{X}$, and returns the dot-product of the corresponding points in $\mathcal{H}$. If we let $\boldsymbol{\phi}\colon \mathcal{X} \to \mathcal{H}$ denote the map into the feature space, then $K(\boldsymbol{x}, \boldsymbol{x}') = \langle \boldsymbol{\phi}(\boldsymbol{x}), \boldsymbol{\phi}(\boldsymbol{x}') \rangle$. Standard kernel methods avoid inference in $\mathcal{H}$, because it is generally a very high-dimensional, or even infinite-dimensional, space. Instead, they solve the dual problem by using the N-by-N kernel matrix containing the values of the kernel function applied to all pairs of N training points. This method of working in the dual space is known as the "kernel trick," and it provides a nice computational advantage when $\dim(\mathcal{H})$ is far greater than N. However, when N is very large, the $\Theta(N^2)$ size of the kernel matrix makes training impractical.

Rahimi and Recht (2007) address this problem by leveraging Bochner's Theorem, a classical result in harmonic analysis, to provide a way to approximate any positive-definite shift-invariant kernel K with finite-dimensional features, known as random Fourier features. A kernel function K is shift-invariant if and only if $K(\boldsymbol{x}, \boldsymbol{x}') = \hat{K}(\boldsymbol{x} - \boldsymbol{x}')\ \forall \boldsymbol{x}, \boldsymbol{x}' \in \mathcal{X}$ for some function $\hat{K}\colon \mathbb{R}^d \to \mathbb{R}$. We now present Bochner's Theorem:

Theorem 1 *(Bochner's theorem, adapted from Rahimi and Recht (2007)): A continuous shift-invariant kernel $K(\boldsymbol{x}, \boldsymbol{x}') = \hat{K}(\boldsymbol{x} - \boldsymbol{x}')$ on $\mathbb{R}^d$ is positive-definite if and only if $\hat{K}$ is the Fourier transform of a non-negative measure $\mu(\boldsymbol{\omega})$.*

Thus, for any positive-definite shift-invariant kernel $\hat{K}(\boldsymbol{\delta})$, we have that

$$\hat{K}(\boldsymbol{\delta}) = \int_{\mathbb{R}^d} \mu(\boldsymbol{\omega}) e^{-j\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{\delta}}\, d\boldsymbol{\omega}, \tag{1}$$

where

$$\mu(\boldsymbol{\omega}) = (2\pi)^{-d} \int_{\mathbb{R}^d} \hat{K}(\boldsymbol{\delta}) e^{j\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{\delta}}\, d\boldsymbol{\delta} \tag{2}$$

is the inverse Fourier transform[6] of $\hat{K}(\boldsymbol{\delta})$, and where $j = \sqrt{-1}$. By Bochner's theorem, $\mu(\boldsymbol{\omega})$ is a non-negative measure. As a result, if we let $Z = \int_{\mathbb{R}^d} \mu(\boldsymbol{\omega}) d\boldsymbol{\omega}$, then $p(\boldsymbol{\omega}) = \frac{1}{Z}\mu(\boldsymbol{\omega})$ is a proper probability distribution, and we get that

$$\frac{1}{Z}\hat{K}(\boldsymbol{\delta}) = \int_{\mathbb{R}^d} p(\boldsymbol{\omega}) e^{-j\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{\delta}}\, d\boldsymbol{\omega}.$$

For simplicity, we will assume that $\hat{K}$ is properly-scaled, meaning that $Z = 1$. Now, the above equation allows us to rewrite this integral as an expectation:

$$\hat{K}(\boldsymbol{\delta}) = \hat{K}(\boldsymbol{x} - \boldsymbol{x}') = \int_{\mathbb{R}^d} p(\boldsymbol{\omega}) e^{j\boldsymbol{\omega}^{\mathrm{T}}(\boldsymbol{x}-\boldsymbol{x}')}\, d\boldsymbol{\omega} = \mathbb{E}_{\boldsymbol{\omega}}\left[e^{j\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}} e^{-j\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}'}\right]. \tag{3}$$

5. It is also possible to define the kernel function prior to defining the feature map; then, for positive-definite kernel functions, Mercer's theorem guarantees that a corresponding feature map $\boldsymbol{\phi}$ exists such that $K(\boldsymbol{x}, \boldsymbol{x}') = \langle \boldsymbol{\phi}(\boldsymbol{x}), \boldsymbol{\phi}(\boldsymbol{x}') \rangle$.
6. There are various ways of defining the Fourier transform and its inverse. We use the convention specified in Equations (1) and (2), which is consistent with Rahimi and Recht (2007).

Kernel name	$K(\boldsymbol{x}, \boldsymbol{y})$	$p(\boldsymbol{\omega})$	Density name
Gaussian	$e^{-\|\boldsymbol{x}-\boldsymbol{x}'\|_2^2/2\sigma^2}$	$(2\pi(1/\sigma^2))^{-d/2} e^{-\frac{\|\boldsymbol{\omega}\|_2^2}{2(1/\sigma)^2}}$	Normal$(\mathbf{0}_d, \frac{1}{\sigma^2}\mathbb{1}_d)$
Laplacian	$e^{-\lambda\|\boldsymbol{x}-\boldsymbol{x}'\|_1}$	$\prod_{i=1}^{d} \frac{1}{\lambda\pi(1+(\boldsymbol{\omega}_i/\lambda)^2)}$	Cauchy$(\mathbf{0}_d, \lambda)$

Table 1: Gaussian and Laplacian Kernels, together with their sampling distributions $p(\boldsymbol{\omega})$.

This can be further simplified as

$$\hat{K}(\boldsymbol{x} - \boldsymbol{x}') = \mathbb{E}_{\boldsymbol{\omega},b}\left[\sqrt{2}\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x} + b) \cdot \sqrt{2}\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}' + b)\right],$$

where $\boldsymbol{\omega}$ is drawn from $p(\boldsymbol{\omega})$, and b is drawn uniformly from $[0, 2\pi]$. See Appendix B for details on why this specific functional form is correct.

This motivates a sampling-based approach for approximating the kernel function. Concretely, we draw $\{\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_D\}$ independently from the distribution $p(\boldsymbol{\omega})$, and $\{b_1, \ldots, b_D\}$ independently from the uniform distribution on $[0, 2\pi]$. We then use these parameters to approximate the kernel as follows:

$$K(\boldsymbol{x}, \boldsymbol{x}') \approx \frac{1}{D}\sum_{i=1}^{D} \sqrt{2}\cos(\boldsymbol{\omega}_i^{\mathrm{T}}\boldsymbol{x} + b_i) \cdot \sqrt{2}\cos(\boldsymbol{\omega}_i^{\mathrm{T}}\boldsymbol{x}' + b_i) = z(\boldsymbol{x})^{\mathrm{T}} z(\boldsymbol{x}'),$$

where $z_i(\boldsymbol{x}) = \sqrt{\frac{2}{D}}\cos(\boldsymbol{\omega}_i^{\mathrm{T}}\boldsymbol{x} + b_i)$ is the i^{th} element of the D-dimensional random vector $z(\boldsymbol{x})$. In Table 1, we list two popular (properly-scaled) positive-definite kernels with their respective inverse Fourier transforms.

Using these random feature maps in conjunction with linear learning algorithms can yield huge gains in efficiency relative to standard kernel methods on large data sets. Learning with a representation $z(\cdot) \in \mathbb{R}^D$ is relatively efficient provided that D is far less than the number of training samples N. For example, in our experiments (Section 6), we have 2 million to 16 million training samples, while $D \approx 25{,}000$ often leads to good performance.

3.2. Neural Networks Acoustic Models

Neural network acoustic models provide a conditional probability distribution $p(y|\boldsymbol{x})$ over C possible acoustic states, conditioned on an acoustic frame $\boldsymbol{x}$ encoded in some feature representation. The acoustic states correspond to context-dependent phoneme states (Dahl et al., 2012), and in modern speech recognition systems, the number of such states is on the order of 10^3 to 10^4. The acoustic model is used within probabilistic systems for decoding speech signals into word sequences. Typically, the probability model used is a hidden Markov model (HMM), where the model's emission and transition probabilities are provided by an acoustic model together with a language model. We use Bayes' rule to compute the probability $p(\boldsymbol{x}|y)$ of emitting a certain acoustic feature vector $\boldsymbol{x}$ from state y, given the output $p(y|\boldsymbol{x})$ of the neural network:

$$p(\boldsymbol{x}|y) \quad = \quad \frac{p(y|\boldsymbol{x})p(\boldsymbol{x})}{p(y)}.$$

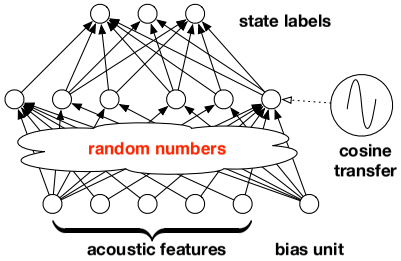

Figure 1: Kernel acoustic model seen as a shallow neural network.

Note that $p(x)$ can be ignored at inference time because it doesn't affect the relative scores assigned to different word sequences, and $p(y)$ is simply the prior probability of HMM state y. The Viterbi algorithm can then be used to determine the most likely word sequence (see Gales and Young (2007) for an overview of using HMMs for speech recognition).

3.3. Kernel Acoustic Models

To train kernel acoustic models, we use random Fourier features and simply plug the random feature vector $z(\boldsymbol{x})$ (for an acoustic frame $\boldsymbol{x}$) into a multinomial logistic regression model:

$$p(y|\boldsymbol{x}) = \frac{\exp\left(\langle \boldsymbol{\theta}_y,\ z(\boldsymbol{x})\rangle\right)}{\sum_{y'} \exp\left(\langle \boldsymbol{\theta}_{y'},\ z(\boldsymbol{x})\rangle\right)}. \tag{4}$$

The label y can take any value in $\{1, 2, \ldots, C\}$, each corresponding to a context-dependent phonetic state label, and the parameter matrix $\Theta = [\boldsymbol{\theta}_1|\ldots|\boldsymbol{\theta}_C]$ is learned. Note that we also include a bias term in our model by appending a 1 to $z(\boldsymbol{x})$ in the equation above.

The model in Equation (4) can be seen as a shallow neural network, with the following properties: (1) the parameters from the inputs (i.e., acoustic feature vectors) to the hidden units are set randomly, and are not learned; (2) the hidden units use $\cos(\cdot)$ as their activation function; (3) the parameters from the hidden units to the output units are learned (can be optimized with convex optimization); and (4) the softmax function is used to normalize the outputs of the network. See Figure 1 for a visual representation of this model architecture. Note that although using sinusoidal activation functions has been proposed previously (Goodfellow et al., 2016), their use has remained quite rare in the deep learning context.

3.4. Linear Bottleneck

When the number of random features D and the number of phonetic state labels C are large, the $D \times C$ size of the kernel acoustic model parameter matrix Θ can lead to memory and computation issues during training. We can significantly reduce the number of parameters in Θ by using a low-rank factorization $\Theta = UV$; this is called a "linear bottleneck" (Sainath et al., 2013a). This strictly decreases the capacity of the resulting model, while unfortunately rendering the optimization problem non-convex. This method can be understood

as a regularization technique, which typically improves the generalization performance of a trained model, as we will show in Section 6.

It is important to note that one can also replace a parameter matrix with a low-rank decomposition after training has completed, for example, using singular value decomposition (Xue et al., 2013). However, in the context of our work it is necessary to impose the low-rank decomposition during training, given GPU memory constraints.

4. Random Feature Selection

In this section, we first motivate and describe our proposed feature selection algorithm. We then introduce a new "sparse Gaussian kernel," which performs well in conjunction with the feature selection algorithm.

4.1. Proposed Feature Selection Algorithm

Our proposed random feature selection method, shown in Algorithm 1, is iterative. In each iteration, a model is trained on a set of features using a single pass of stochastic gradient descent (SGD) on a subset of the training data. Then, the features whose corresponding rows in the parameter matrix have the smallest ℓ_2 norms are discarded and replaced with a new set of random features.

This feature selection method has the following advantages: The overall computational cost is mild, as it requires just T passes of SGD through subsets of the data of size R (equivalent to TR/N full SGD epochs). In fact, in our experiments, we find it sufficient to use $R = O(D)$. Moreover, the method is able to explore a large number of non-linear features, while maintaining a compact model. If the number of features s_t selected in iteration t grows linearly each iteration ($s_t = Dt/T$), then the learning algorithm is exposed to $D(T+1)/2$ random features throughout the feature selection process; this s_t sequence is the selection schedule we use in all our experiments. We show in Section 6 that the acoustic models trained on the selected features generally outperform models trained on random features.

It is important to note the similarities between this method, and the FOBOS method with ℓ_1/ℓ_2-regularization (Duchi and Singer, 2009). In the FOBOS method, one solves the ℓ_1/ℓ_2-regularized problem in a stochastic fashion by alternating between taking unregularized stochastic gradient descent (SGD) steps, and then "shrinking" the rows of the parameter matrix; each time the parameters are shrunk, the rows whose ℓ_2-norms are below a threshold are set to 0. After training completes, the solution will likely have some rows which are all zero, at which point the features corresponding to those rows can be discarded. In our method, on the other hand, we take many consecutive unregularized SGD steps, and only thereafter do we choose to discard the rows whose ℓ_2-norm is below a threshold. As mentioned in the related work section, our attempts at using FOBOS for feature selection failed, because the magnitude of the regularization parameter needed to produce a sparse model was so large that it dominated the learning process; as a result, the learned models performed badly, and the selected features were essentially random.

Algorithm 1 Random feature selection

  for $i \in \{1, \ldots, D\} \backslash S$ **do**
    $\boldsymbol{\omega}_i \sim p(\boldsymbol{\omega})$.
    $b_i \sim \mathcal{U}(0, 2\pi)$.
  end for
  if $t \neq T$ **then**
    Initialize parameter matrix Θ.[7]
    Learn weights $\Theta \in \mathbb{R}^{D \times C}$ using a single pass of SGD over R randomly selected training examples, using the projection vectors $(\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_D)$, and the biases $(b_1, \ldots, b_D)$, to generate the random Fourier features.
    $S := \{i \mid \Theta_i$ is amongst the s_t rows of Θ with highest ℓ_2 norm$\}$.[8]
  end if
end for
return The selected projection vectors $(\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_D)$, and the selected biases $(b_1, \ldots, b_D)$.

One disadvantage of this method is that the selection criterion may misrepresent the features' actual predictive utilities. For instance, the presence of some random feature may increase or decrease the weights for other random features relative to what they would be if that feature were not present. An alternative would be to consider features in isolation, and add features one at a time (as in stagewise regression methods and boosting), but this would be significantly more computationally expensive. For example, it would require $O(D)$ passes through the data, relative to $O(T)$ passes, which would be prohibitive for large D values. We find empirically that the influence of the additional random features in the selection criterion is tolerable, and it is still possible to select useful features with this method.

4.2. A Sparse Gaussian Kernel

In Section 6 we will show that our proposed feature selection algorithm improves the performance of the Laplacian kernel models significantly more than the Gaussian kernel models. In this section, we leverage this insight in order to design a new kernel, the "sparse Gaussian kernel," which we will show also benefits significantly from the feature selection process.

Recall from Table 1 that for the Laplacian kernel, the sampling distribution used for the random Fourier features is the multivariate Cauchy density. Because the Cauchy distribution is fat-tailed, a d-dimensional Cauchy vector will typically contain some entries

7. See Section 6.3 for details on how Θ is initialized.
8. In the case where we are using a linear bottleneck to decompose the parameter matrix Θ into UV, we perform the SGD training using this decomposition. After we complete the training in a given iteration, we compute $\Theta = UV$, and then select features based on the ℓ_2 norms of the rows of Θ.

much larger than the rest. This property of the sampling distribution implies that many of the random features generated via projections with random Cauchy vectors will effectively concentrate on only a few of the input features. We can thus regard such random features as being non-linear combinations of a small number of the original input features. Thus, the proposed feature selection method effectively picks out useful non-linear interactions between small sets of input features.

We can also directly construct sparse non-linear combinations of the input features. Instead of relying on the properties of the Cauchy distribution, we can actually choose a small number k of coordinates $F \subseteq \{1, 2, \ldots, d\}$, say, uniformly at random, and then choose the random vector so that it is always zero in positions outside of F. Compared to the random Fourier feature approximation to the Laplacian kernel, the random vectors chosen in this way are truly sparse. From a systems perspective, this sparsity can reduce the memory required for the random projection matrix, and make the random features more efficient to compute (if efficient sparse matrix operations are used).

Note that random Fourier features with such sparse sampling distributions in fact correspond to shift-invariant kernels that are rather different from the Laplacian kernel. For instance, if the non-zero entries of $\boldsymbol{\omega}$ are drawn i.i.d. from $\mathcal{N}(0, \sigma^{-2})$, then the corresponding kernel is

$$K(\boldsymbol{x}, \boldsymbol{x}') = \binom{d}{k}^{-1} \sum_{\substack{F \subseteq \{1, \ldots, d\}, \\ |F| = k}} \exp\left(-\frac{\|\boldsymbol{x}_F - \boldsymbol{x}'_F\|_2^2}{2\sigma^2}\right), \tag{5}$$

where $\boldsymbol{x}_F$ is a vector composed of the elements $\boldsymbol{x}_i$ for $i \in F$. We call this kernel the "sparse Gaussian kernel." Note that this kernel puts equal emphasis on all input feature subsets F of size k. However, the feature selection process may effectively bias the distribution of the feature subsets to concentrate on some small family $\mathcal{F}$ of input feature subsets.

5. New Early Stopping Criteria

A challenge for training acoustic models is that the training criterion (e.g., cross-entropy) does not perfectly correlate with the true objective (TER). To partially address this problem, in this section we present several new metrics which we observe correlate with TER significantly better than cross-entropy does. In Section 6 we then show that we can attain improved TER performance by monitoring these metrics on the heldout set during training to decide when to decay the learning rate and stop training. Note that the reason we use these metrics as proxies for the TER, instead of directly using the TER, is that it is very expensive to compute the TER on the development set.

The common thread which unites all the metrics we will present is that they do not penalize very incorrect examples (meaning, examples for which a model assigns a probability very close to 0 to the correct label) as strongly as cross-entropy does. Notice, for instance, that the cross-entropy loss can approach infinity on a single incorrect example. Our metrics are more lenient. We present them now:

1. **Entropy Regularized Log Loss (ERLL)**:[9] This loss rewards models for being confident (low entropy), by considering a weighted sum of the cross entropy loss (CE) and the average entropy (ENT) of the model on the heldout data. Specifically, for any $\beta \in \mathbb{R}$, we define the loss as

$$CE + \beta \cdot ENT = -\frac{1}{N}\sum_{i=1}^{N}\sum_{y=1}^{C}[\mathbb{I}(y = y_i) + \beta \cdot p(y|\boldsymbol{x}_i)] \log p(y|\boldsymbol{x}_i).$$

   This metric encourages models to be more confident, even if it means having a worse cross-entropy loss as a result.

2. **Capped Log Loss**: For any value of $\lambda \geq 0$, we define the "capped log loss" as

$$-\frac{1}{N}\sum_{i=1}^{N}\log(p(y_i|\boldsymbol{x}_i) + \lambda).$$

   Effectively, this loss ensures that no single example contributes more than $-\frac{1}{N}\log(\lambda)$ to the loss. If λ is a small positive number, this loss is very similar to the normal log loss for values of $p(y_i|\boldsymbol{x}_i)$ close to 1, while affecting the loss dramatically for values close to 0 (for example, when $p(y_i|\boldsymbol{x}_i) < \lambda$).

3. **Top-k Log Loss**: For this loss, assume that the heldout examples $(\boldsymbol{x}_i, y_i)$ are sorted in descending order of their $p(y_i|\boldsymbol{x}_i)$ values. Then, for any positive integer $k \leq N$, we can define the "Top-k Log Loss" as

$$-\frac{1}{k}\sum_{i=1}^{k}\log p(y_i|\boldsymbol{x}_i).$$

   This metric judges a model based on how well it does on the k heldout examples to which it assigns highest probabilities.

Notice that for $\beta = 0$, $\lambda = 0$, and $k = N$, these metrics all simplify to the standard cross-entropy loss. In Figure 2, we show plots of the empirical correlations of these metrics with TER values, as a function of each metric's "hyperparameters," based on models we have trained. More specifically, we fully train a large number of kernel and DNN models; we then evaluate the TER performance of these models on the development set, as well as compute the heldout performance of these models in terms of the three metrics described above (for various settings of β, λ, and k). The precise set of models we used are those in Tables 4 and 5. We train models on four data sets: the Cantonese and Bengali data sets for the IARPA Babel program, a 50-hour subset of the broadcast news data set (BN-50), and the TIMIT benchmark task (see Section 6.1 for data set details). We then compute the empirical correlations between the TER values and the different metrics, and plot them as a function of each metric's hyperparameter. Note that for the top-k log loss, we plot the correlation with TER as a function of the fraction $1 - \frac{k}{N}$ of the heldout data set which is *ignored*.

9. In Lu et al. (2016) this metric was called "entropy regularized perplexity" (ERP) for $\beta = 1$.

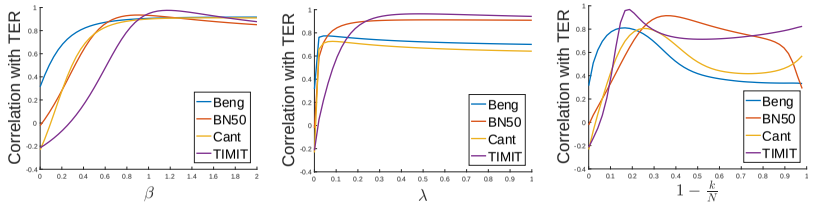

Figure 2: Empirical correlations of (left to right) heldout entropy regularized log loss, capped log loss, and top-k log loss with TER on the development set, as a function of β, λ, and $1 - \frac{k}{N}$, respectively.

As can be seen from these plots, for certain ranges of values of the metric hyperparameters, the correlation of these metrics with TER is quite high. For example, for $\beta = 1$, the correlations between entropy regularized log loss and TER are 0.91, 0.93, 0.90, and 0.95 for Bengali, BN-50, Cantonese, and TIMIT respectively. This is compared to correlations of 0.31, -0.02, -0.23, and -0.21 for the cross-entropy objective.

One conjecture for why these metrics attain higher correlation with ASR performance than heldout cross-entropy is because there is inherent noise in the labels on which the acoustic models are trained. The labels are noisy because they are generated via a forced alignment between the correct transcription and the audio using a GMM/HMM acoustic model, as discussed in Section 6.1. Thus, by not penalizing a model's mistakes on the incorrect labels as harshly, and instead focusing on the model's performance on the clean labels, these metrics better capture the quality of the model for the downstream ASR task. Better understanding this phenomenon is an interesting area for future work.

Because of the high correlation between these metrics and ASR performance, we propose to monitor these metrics on the heldout set during training to decide when to decay the learning rate and stop training (details in Section 6.3). In Section 6.4 we present results using this learning rate decay method with the ERLL metric with $\beta = 1$, and show that it leads to improvements in TER for both kernel and DNN models. We note that we could have also used the other metrics for this purpose, but chose to use ERLL with $\beta = 1$ since we observed that it attained high correlation values with TER across all four data sets.

6. Experiments

We now present our empirical results comparing the performance of fully-connected DNNs with kernel approximation methods for acoustic modeling, across four data sets. We leverage the three methods we have discussed—feature selection, the new early stopping criterion, and linear bottlenecks—and show that using these three methods the kernel models perform very similarly to the DNNs across the four test sets, attaining token error rates between 0.5% better and 0.1% worse than the DNNs.

In this section, we first provide a description of the data sets we use, and our evaluation criteria. We then give an overview of our training procedure, and provide details regarding

hyperparameter choices. We then present our experimental results comparing the performance of kernel approximation methods to DNNs. Lastly, we discuss the impact of the number of random features on performance, and take a deeper look at the dynamics of the feature selection process.

6.1. Data Sets

We train DNN and kernel acoustic models, as described in Section 3, on four data sets: the IARPA Babel Program Cantonese (IARPA-babel101-v0.4c) and Bengali (IARPA-babel103b-v0.4b) limited language packs, a 50 hour subset of the Broadcast News data set (BN-50) (Kingsbury, 2009; Sainath et al., 2011), and the TIMIT benchmark data set (Garofolo et al., 1993). Each data set is partitioned in four: a training set, a heldout set, a development set, and a test set. We use the heldout set to tune the hyperparameters of our training procedure (e.g., the learning rate). We then run decoding on the development set using IBM's Attila speech recognition toolkit (Soltau et al., 2010), to select a small subset of models which perform best in terms of TER (the best kernel and DNN model per data set). We tune the acoustic model weight on the development set to optimize the relative contributions of the language model and the acoustic model to the final score assigned to a given word sequence. Finally, we evaluate the TER performance on the test set using the selected group of models (using, for each model, the best acoustic model weight on the development set), to get a fair comparison between the methods we are using. Having a separate development set helps us avoid the risk of over-fitting to the test set.

The Bengali and Cantonese Babel data sets both include training and development sets of approximately 20 hours, and an approximately 5 hour test set. We designate about 10% of the training data as a heldout set. The training, heldout, development, and test sets all contain different speakers. Babel data is challenging because it is two-person conversations between people who know each other well (family and friends) recorded over telephone channels (in most cases with mobile telephones) from speakers in a wide variety of acoustic environments, including moving vehicles and public places. As a result, it contains many natural phenomena such as mispronunciations, disfluencies, laughter, rapid speech, background noise, and channel variability. An additional challenge in Babel is that the only data available for training language models is the acoustic transcripts, which are comparatively small.

For the Broadcast News data set, we use 45 hours of audio for training, and 5 hours as a heldout set. For the development set, we use the EARS Dev-04f data set (as described by Kingsbury, 2009), which consists of approximately three hours of broadcast news from various news shows. We use the DARPA EARS RT-03 English Broadcast News Evaluation Set (Fiscus et al., 2003) as our test set, consisting of 72 five minute conversations.

The TIMIT data set contains recordings of 630 speakers, of various English dialects, each reciting ten sentences, for a total of 5.4 hours of speech. The training set (from which the heldout set is then taken) consists of data from 462 speakers each reciting 8 sentences (SI and SX sentences). The development set consists of speech from 50 speakers. For evaluation, we use the "core test set," which consists of 192 utterances total from 24 speakers (SA sentences are excluded). For reference, we use the exact same features, labels,

Data set	Train	Heldout	Dev	Test	# features	# classes
Beng.	21 hr (7.7M)	2.8 hr (1.0M)	20 hr (7.1M)	5 hr (1.7M)	360	1000
BN-50	45 hr (16M)	5 hr (1.8M)	2 hr (0.7M)	2.5 hr (0.9M)	360	5000
Cant.	21 hr (7.5M)	2.5 hr (0.9M)	20 hr (7.2M)	5 hr (1.8M)	360	1000
TIMIT	3.2 hr (2.3M)	0.3 hr (0.2M)	0.15 hr (0.1M)	0.15 hr (0.1M)	440	147

Table 2: Data set details. We report the size of each data set partition in terms of the number of hours of speech, and in terms of the number of acoustic frames (in parentheses).

and divisions of the data set as Huang et al. (2014) and Chen et al. (2016), which allows direct comparison of our results with theirs (Table 8).

The acoustic features, representing 25 ms acoustic frames with context, are real-valued dense vectors. A 10 ms shift is used between adjacent frames (except on TIMIT, where a 5 ms shift is used). For the Cantonese, Bengali, and Broadcast News data sets we use a standard 360-dimensional speaker-adapted representation used by IBM (Kingsbury et al., 2013); these feature vectors correspond to the concatenation of nine 40-dimensional vectors corresponding to the four frames before and after the current frame. For the TIMIT experiments, we use 40-dimensional feature space maximum likelihood linear regression (fMLLR) features (Gales, 1998), and concatenate the five neighboring frames in either direction, for a total of eleven frames and 440 features.

The state labels are obtained via forced alignment using a GMM/HMM system. This forced alignment is necessary because there is a mismatch between the ground truth available for training (a word sequence transcribing each utterance) and the actual labels needed for training (precise assignment of HMM states to frames). The Cantonese and Bengali data sets each have 1000 labels, corresponding to quinphone context-dependent HMM states clustered using decision trees. For Broadcast News, there are 5000 such states. The TIMIT data set has 147 context-independent labels, corresponding to the beginning, middle, and end of 49 phonemes.

The language models we use are all n-gram language models estimated using modified Kneser-Ney smoothing, with n values of 2, 4, 3, and 3 for Bengali, Broadcast News, Cantonese, and TIMIT, respectively. The TIMIT language model is a phone-level model. The Bengali and Cantonese language models are particularly small (approximately 60,000 bigrams and 136,000 trigrams, respectively), trained using only the provided audio transcripts. The Broadcast News model is small as well, containing only 3.3 million 4-grams.

In Table 2 we provide details on all the data sets, as well as on their number of features and classes. All our data sets have millions of training points, significantly exceeding the size of typical machine learning tasks tackled by kernel methods. Additionally, the large number of output classes for our data sets presents a scalability challenge, given that the size of the kernel models scales linearly with the number of output classes (if no bottleneck is used).

6.2. Evaluation Metrics

We use five metrics to evaluate the DNN and kernel acoustic models:

1. **Cross-entropy (CE)**: Given examples, $\{(\boldsymbol{x}_i, y_i), i = 1 \dots N\}$, the cross-entropy is defined as
$$-\frac{1}{N}\sum_{i=1}^{N} \log p(y_i|\boldsymbol{x}_i). \quad (6)$$

2. **Average Entropy (ENT)**: The average entropy of a model is defined as
$$-\frac{1}{N}\sum_{i=1}^{N}\sum_{y=1}^{C} p(y|\boldsymbol{x}_i) \log p(y|\boldsymbol{x}_i).$$
If a model has low average entropy, it is generally confident in its predictions.

3. **Entropy Regularized Log Loss (ERLL)**: Defined in Section 5. We use $\beta = 1$ unless specified otherwise.

4. **Classification Error (ERR)**: The classification error is defined as
$$\frac{1}{N}\sum_{i=1}^{N} \mathbb{1}\left[y_i \neq \arg\max_{y \in 1,2,\dots,C} p(y|\boldsymbol{x}_i)\right].$$

5. **Token Error Rate (TER)**: We feed the predictions of the acoustic models, which correspond to probability distributions over the phonetic states, to the rest of the ASR pipeline and calculate the misalignment between the decoder's outputs and the ground-truth transcriptions. For Bengali and BN-50, we measure the error in terms of the word error rate (WER), for Cantonese we use the character error rate (CER), and for TIMIT we use the phone error rate (PER). We use the term "token error rate" (TER) to refer, for each data set, to its corresponding metric.

6.3. Details of Acoustic Model Training

We train all our kernel models with either the Laplacian, the Gaussian, or the sparse Gaussian (Section 4.2) kernels. These kernel models typically have three hyperparameters: the kernel bandwidth (σ for the Gaussian kernels, λ for the Laplacian kernel; see Table 1), the number of random projections, and the initial learning rate. We try various numbers of random features, ranging from 5000 to 400,000. Using more random features leads to a better approximation of the kernel function, as well as to more powerful models, though there are diminishing returns as the number of features increases. The sparse Gaussian kernel additionally has the hyperparameter k which specifies the sparsity of each random projection vector $\boldsymbol{\omega}_i$. For all experiments, we use $k = 5$.

For all DNNs, we tune hyperparameters related to both the architecture and the optimization. This includes the number of layers, the number of hidden units in each layer, and the learning rate. We perform 1 epoch of layer-wise discriminative pre-training (Seide et al., 2011b; Kingsbury et al., 2013), and then train the entire network jointly using SGD. We find that four hidden layers is generally the best setting for our DNNs, so all the DNN results we present in this paper use this setting; in Table 3 we show how depth affects recognition performance on the Broadcast News data set. Additionally, all our DNNs use

	1000	2000	4000
3	17.5	16.8	16.7
4	17.1	**16.4**	16.5
5	16.9	16.5	16.7
6	17.0	16.5	16.6

Table 3: Effect of depth and width on DNN TER (development set): This table shows TER results for DNNs with 1000, 2000, or 4000 hidden units per layer, and 3-6 layers, on the Broadcast News development set. All of these models were trained using a linear bottleneck for the output parameter matrix, and using ERLL for learning rate decay. The best result is in bold.

the tanh activation function. We vary the number of hidden units per layer (1000, 2000, or 4000). We use this same set of DNN architectures for all our data sets.

For both DNN and kernel models, we use stochastic gradient descent (SGD) as our optimization algorithm for minimizing the training cross-entropy objective. We use mini-batches of size of 250 or 256 samples during training, and we use the heldout set to tune the other hyperparameters. We use the learning rate decay scheme described in (Morgan and Bourlard, 1990; Sainath et al., 2013a,b), which monitors performance on the heldout set to decide when to decay the learning rate. This method divides the learning rate in half at the end of an SGD epoch if the heldout cross-entropy doesn't improve by at least 1%; additionally, if the heldout cross-entropy gets *worse*, it reverts the model back to its state at the beginning of the epoch. Instead of using the heldout cross-entropy, in some of our experiments we use the heldout ERLL to decide when to decay the learning rate. We terminate training once we have divided the learning rate 10 times.

As mentioned in Section 3.4, one effective way of reducing the number of parameters in our models is use a linear bottleneck, which is a low-rank factorization of the output parameter matrix (Sainath et al., 2013a). We use bottlenecks of size 1000, 250, 250, and 100 for BN-50, Bengali, Cantonese, and TIMIT, respectively. We train models both with and without this technique; the only exception is that we are unable to train BN-50 kernel models without the bottleneck of size 1000, due to memory constraints on our GPUs.

We initialize our DNN parameters uniformly at random within $[-\frac{\sqrt{6}}{\sqrt{d_{in}+d_{out}}}, \frac{\sqrt{6}}{\sqrt{d_{in}+d_{out}}}]$, as suggested by Glorot and Bengio (2010); here, d_{in} and d_{out} refer to the dimensionality of the input and output of a DNN layer, respectively. For our kernel models, we initialize the random projection matrix as discussed in Section 3, and we initialize the parameter matrix Θ as the zero matrix. When using a linear bottleneck to decompose the parameter matrix, we initialize the resulting two matrices randomly, like we do for our DNNs.

For each iteration of random feature selection, we draw a random subsample of the training data of size $R = 10^6$ (except when $D \geq 10^5$, in which case we use $R = 2\times10^6$, to ensure a safe R to D ratio), but ultimately we use all N training examples once the random features are selected. Thus, each iteration of feature selection has equivalent computational cost to a R/N fraction of an SGD epoch (roughly 1/7 or 2/7 for $D < 10^5$ and $D \geq 10^5$ respectively, on the Babel speech data sets). We use $T = 50$ iterations of feature selection,

and in iteration t, we select $s_t = t \cdot (D/T) = 0.02Dt$ random features. Thus, the total computational cost we incur for feature selection is equivalent to approximately seven (or fourteen) epochs of training on the Babel data sets. For the Broadcast News data set, it corresponds to the cost of approximately six full epochs of training (for $D \geq 10^5$).

All our training code is written in MATLAB, leveraging its GPU features, and executed on Amazon EC2 machines.

6.4. Results

In this section, we report the results from our experiments comparing kernel methods to DNNs on ASR tasks. We first discuss the ablation study showing the marginal improvements to the kernel model performance attained by feature selection, the new early stopping criterion, and the linear bottlenecks; we show analogous results for DNNs for the early stopping and linear bottleneck methods. We then compare for each data set the performance of the best kernel and DNN models from these detailed experiments; the most important result from these comparisons, shown in Table 7, is that the kernel models are competitive with the DNNs, attaining TER values between 0.5% better and 0.1% worse than the DNNs across our four test sets.

For our detailed experiments, for both DNN and kernel methods we train models with and without linear bottlenecks, and with and without using ERLL to determine the learning rate decay. For our kernel methods, we additionally train models with and without using feature selection. We run experiments with all three kernels (Laplacian, Gaussian, sparse Gaussian) and we use 100,000 random features on all data sets except for TIMIT, where we are able to use 200,000 random features (because the output dimensionality is lower). As mentioned in the previous section, for our DNN experiments, we train models with four hidden layers,[10] using the tanh activation function, and using either 1000, 2000, or 4000 hidden units per layer. We focus on comparing the performance of these methods in terms of TER, but we also report results for other metrics. Unless specified otherwise, all TER results are on the development set, and all cross-entropy, entropy, classification error, and ERLL results are on the heldout set.

In Tables 4 and 5, we show the TER results for our DNN and kernel models, respectively, across all data sets. There are many things to notice about these results. For our DNN models, linear bottlenecks almost always lower TER values, though in a few cases they have no effect on TER. Using ERLL to determine when to decay the learning rate generally helps lower TER values for our DNNs, but in a few cases it actually hurts (Cantonese with 4000 hidden units, and TIMIT with 2000 and 4000). The DNNs with 4000 hidden units typically attain the best results, though on a couple of data sets they are matched or narrowly beaten by the 2000 models.

For our kernel models, we see that incorporating a linear bottleneck brings large drops in TER across the board.[11] Performing feature selection generally improves TER as well; we see that it improves TER considerably for the Laplacian kernel, and modestly for the sparse Gaussian kernel. For the Gaussian kernel, it typically helps, though there are several

10. As mentioned in Section 6.3, we find that this is generally the best setting.
11. Recall that we are unable to train BN-50 kernel models *without* using a bottleneck because the resulting models would not fit on our GPUs.

instances in which feature selection hurts TER (see Section 6.6 for discussion). Second, we see that using heldout ERLL to determine when to decay the learning rate helps all our kernel models attain lower TER values. Next, we see that without using feature selection, the sparse Gaussian kernel has the best performance across the board. After we include feature selection, it performs very comparably to the Laplacian kernel with feature selection. It is interesting to note that without using feature selection, the Gaussian kernel is generally better than the Laplacian kernel; however, with feature selection, the Laplacian kernel surpasses the Gaussian kernel (see Section 6.6). In general, the kernel function which performed best, across the majority of settings, was the sparse Gaussian kernel.

To further improve the performance of the kernel models, we train models with up to 400k features on Broadcast News, our most challenging data set. Due to the large computational expense of training these models, we only trained a few, and only used the Laplacian and sparse Gaussian kernels, as these attained the best performance after feature selection, in terms of TER. We report results in Table 6. All of these models were trained with a linear bottleneck of size 1000, and using ERLL for learning rate decay. We include results using 100k random features in this table for comparison. As we can observe, our best kernel model on BN-50 now attains a TER of 16.4%, which is equal to the performance of our best DNN model. Furthermore, we continue to see improvements in the performance of our kernel models, even as we increase the number of features beyond 100k; for the Laplacian kernel we get a gain of 0.3% in TER when increasing from 100k to 400k (both with and without feature selection), while for the sparse Gaussian kernel we get gains of 0.2% and 0.4%, with and without feature selection (respectively). To date, these are the largest models we have trained, though it seems likely we could continue getting performance improvements with even larger models.

In Table 7, we compare for each data set the performance of the best DNN model with the best kernel model, across six metrics. Importantly, for each metric (except for test set TER), we find the kernel and DNN model which performs best for that specific metric; this is in contrast to picking the kernel and DNN models which are best in terms of TER, and reporting all metrics on these models. For Broadcast News, we consider the kernel models from Table 6 with 200k and 400k random features, along with those in Table 5, in the process of finding the best performing models. In terms of heldout cross-entropy, the kernels outperformed the DNNs on Cantonese and TIMIT, while the DNNs beat the kernels on Bengali and BN-50. With regard to classification error, the kernels beat the DNNs on all data sets except for Bengali. In terms of the average heldout entropy of the models, the DNNs were consistently more confident in their predictions (lower entropy) than the kernels. Significantly, we observe that the best development set TER results for our DNN and kernel models are quite comparable; on Cantonese and TIMIT, the kernel models outperform the DNNs by 0.4% absolute, on Broadcast News the kernels exactly match the DNNs, while on Bengali the DNNs do better by 0.1%.

We now discuss the results on the test sets. First of all, to avoid overfitting to the test sets, for each data set we only performed test set evaluations for the DNN and kernel models which performed best in terms of the development set TER. The final row of Table 7 thus contains all the test results we collected.[12] As one can see, the relative test performance

12. The only exception is on the Broadcast News data set. Prior to training the best performing 400k model, we had already evaluated the best 100k model, which attained a TER of 11.9% on the test set.

Table 7: Table comparing the Best DNN ('D') and kernel ('K') results, across four data sets and six metrics. The first four metrics are on the heldout set, the fifth is on the development set, and the last metric is reported on the test set. For BN50, the large models from Table 6 are included in the set of models from which the best performing model is picked (for each metric). See Section 6.2 for metric definitions.

	Test TER (DNN)	Test TER (Kernel)
Huang et al. (2014)	20.5	21.3
Chen et al. (2016)	N/A	20.9
This work	20.5	**20.4**

Table 8: Table comparing the Best DNN and kernel results from this work to those from Huang et al. (2014) and Chen et al. (2016), on the TIMIT test set.

of the DNN and kernel models is quite similar to the development set results; the DNNs perform better by 0.5% on Cantonese, 0.1% on TIMIT and Broadcast News, and perform worse by 0.1% on Bengali. For direct comparison on the TIMIT data set, we include in Table 8 the test results for the best DNN and kernel models from Huang et al. (2014) and Chen et al. (2016). As mentioned in Section 6.1, we use the same features, labels, data set partitions (train/heldout/dev/test), and decoding script as these papers, and thus our results are directly comparable. We achieve a 0.9% absolute improvement in TER with our kernel model relative to Huang et al. (2014), and 0.5% improvement relative to Chen et al. (2016); furthermore, our best DNN matches the performance of the best performing DNN from Huang et al. (2014). We believe the most significant of all these results is that the kernels (narrowly) beat the DNNs on Broadcast News, our largest and most challenging data set, and one which has been used extensively in large scale speech recognition research. In Appendix A, we include more detailed tables comparing the various models we trained across all the metrics from Section 6.2.

6.5. Importance of the Number of Random Features

We will now illustrate the importance of the number of random features D on model performance. For this purpose, we trained kernel models on the BN-50 data set using $D \in \{5000, 10000, 25000, 50000, 100000\}$ for the three kernel functions, with and without feature selection, with a linear bottleneck of size 1000, and using heldout cross-entropy for learning rate decay. In Figure 3, we show how increasing the number of features dramat-

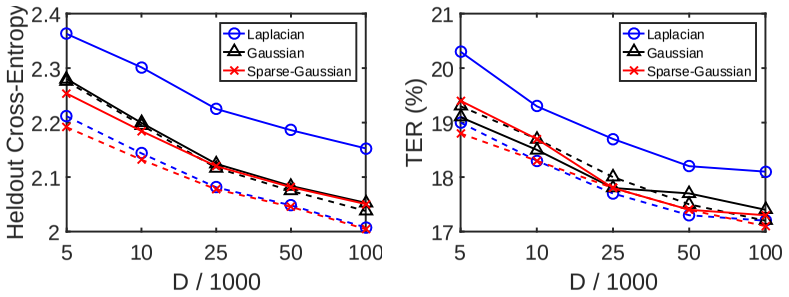

Figure 3: Heldout cross-entropy and development set TER performance of kernel acoustic models on BN-50, as a function of the number of random features D. Dashed lines mean feature selection was performed, while solid lines mean it was not.

ically improves the performance of the learned model, both in terms of cross-entropy and TER; there are diminishing returns, however, with small improvements in TER when increasing D from 50,000 to 100,000. Interestingly, we can also observe in these plots that the benefits from feature selection (gap between the dashed and solid lines) are large for the Laplacian kernel, modest for the sparse Gaussian kernel, and insignificant for the Gaussian kernel. We provide insight into why these trends occur in the following section.

6.6. Dynamics of Random Feature Selection

We now explore the feature selection dynamics. We first show that features selected in early iterations are likely to be selected in all subsequent iterations, demonstrating that the selection criterion is consistent. Second, we show that the feature selection process can be seen as way of learning to upweight important input features. This effect is pronounced for the Laplacian and sparse Gaussian kernels, but not for the Gaussian kernel, helping to explain why the former methods benefit from feature selection more than the latter.

In Figure 4, we plot the fraction of the s_t features selected in iteration t that remain in the model after all T iterations ("survival rate"). We show results for kernel models trained on the Cantonese data set, without using linear bottlenecks, and using heldout cross-entropy for learning rate decay. In nearly all iterations and for all kernels, over half of the selected features survive to the final model. For instance, over 90% of the Laplacian kernel features selected at iteration 10 survive the remaining 40 rounds of selection. For comparison, we plot the expected survival rate if at each iteration the features were chosen uniformly at random; for $s_t = Dt/T$, the expected survival rate for features selected at iteration t is $T!/(t! \cdot T^{T-t})$, which is exponentially small in T when $t \leq \beta T$ for any fixed $\beta < 1$.[13] For example, at $t = 10$ the expected survival rate is approximately 9×10^{-11} with $T = 50$. Thus, our selection criterion is orders of magnitude more consistent than random selection.

13. This can be shown using Stirling's formula. See Jameson (2015) for a useful review.

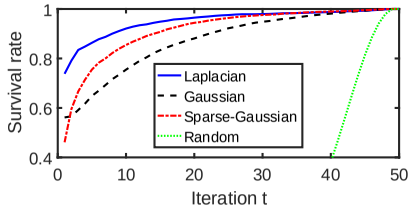

Figure 4: Fraction of the s_t features selected in iteration t that are in the final model (survival rate) for kernel models trained on the Cantonese data set.

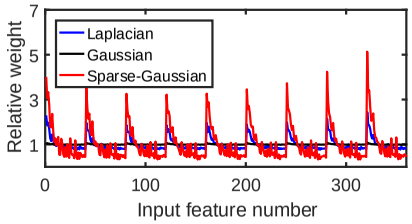

Figure 5: The relative weight of each input feature in the projection matrix Ω after feature selection completes, for kernel models trained on the Cantonese data set.

Finally, we consider how the feature selection process can be seen as a way of learning to assign more weight to the more important input features. Consider the final matrix of random vectors $\Omega := [\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_D] \in \mathbb{R}^{d \times D}$ after feature selection, for the Cantonese models from Figure 4. A coarse measure of how much influence an input feature $i \in \{1, 2, \ldots, d\}$ has in the final feature map is the relative "weight" of the i-th row of Ω. In Figure 5, we plot $\sum_{j=1}^{D} |\Omega_{i,j}|/Z$ for each input feature $i \in \{1, 2, \ldots, d\}$, where $Z = \frac{1}{d} \sum_{i,j} |\Omega_{i,j}|$ is a normalization term.[14] There is a strong periodic effect as a function of the input feature number. An examination of the feature pipeline from Kingsbury et al. (2013) reveals that this is because these features vectors are the concatenation of nine 40-dimensional acoustic feature vectors, where each set of 40 features is ordered by a measure of discriminative quality (via linear discriminant analysis). Thus, it is expected that the features with low $(i-1)$ mod 40 value may be more useful than the others; indeed, this is evident in the plot. Note that this effect exists, but is extremely weak, for the Gaussian kernel. We believe this is because Gaussian random vectors in $\mathbb{R}^d$ are likely to have all their entries be bounded in magnitude by $O(\sqrt{\log(d)})$. This observation helps explain why feature selection significantly improves the Laplacian and sparse Gaussian models, but not the Gaussian models.

14. For the Laplacian kernel, we discard the largest element in each of the d rows of Ω, because there are sometimes outliers which dominate the entire sum for their row.

7. Conclusion

In this paper, we explore the performance of kernel methods on large-scale ASR tasks, leveraging the kernel approximation technique of Rahimi and Recht (2007). We propose two new methods (feature selection, new early stopping criteria) which lead to large improvements in the performance of kernel acoustic models. We further show that using a linear bottleneck (Sainath et al., 2013a) to decompose the parameter matrices of these kernel models leads to significant improvements in performance as well. We validate these findings on four data sets, including the Broadcast News and TIMIT benchmark tasks. Using all these methods together, the kernel methods attain comparable speech recognition performance to DNNs across the four test sets; on Cantonese, TIMIT, and Broadcast News, the kernel models outperform the DNNs by 0.5%, 0.1%, and 0.1% TER absolute, respectively, whereas on Bengali, the DNN does better by 0.1% TER.

For future work, we are interested in continuing to test the limits of kernel methods on challenging empirical tasks. For example, can kernel methods be adapted to compete with convolutional and recurrent neural networks?

Appendix A. Detailed Empirical Results

In this appendix, we include tables comparing the models we trained in terms of four different metrics (CE, ENT, ERR, and ERLL). The notation is the same as in Tables 4 and 5. For both DNN and kernel models, 'NT' specifies that no "tricks" were used during training (no bottleneck, did not use ERLL for learning rate decay). A 'B' specifies that a linear bottleneck was used for the output parameter matrix, while an 'R' specifies that ERLL was used for learning rate decay (so 'BR' means both were used). For kernel models, '+FS' specifies that feature selection was performed for the corresponding row. The best result for each metric and data set is in bold.

Some important things to take note of in these tables:

- The linear bottleneck typically causes large drops in the average entropy of kernel models, while not having as strong or consistent an effect on cross-entropy. For DNNs, the bottleneck typically causes increases in cross-entropy, and relatively modest decreases in entropy.
- Using ERLL to determine learning rate decay typically causes increases in cross-entropy, and decreases in entropy, with the decrease in entropy typically being larger than the increase in cross-entropy. As a result, the ERLL is typically lower for models that use this method (with the exception of TIMIT DNN models).
- Feature selection typically results in large drops in cross-entropy, especially for Laplacian and sparse Gaussian kernels, while its effect on entropy is quite small. It thus helps lower heldout ERLL across the board, as well as TER in the vast majority of cases.

Table 16: DNN: Metric ERR

Appendix B. Derivation of Functional Form for Random Fourier Features

In this appendix, we will prove that for a properly-scaled (i.e., $Z = 1$) positive-definite shift-invariant kernel k,

$$k(\boldsymbol{x}, \boldsymbol{x}') = \mathbb{E}_{\boldsymbol{\omega},b}\left[\sqrt{2}\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x} + b) \cdot \sqrt{2}\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}' + b)\right], \tag{7}$$

where $\boldsymbol{\omega}$ is drawn from $p(\boldsymbol{\omega})$, the inverse Fourier transform of k, and b is drawn uniformly from $[0, 2\pi]$. We begin this proof using Equation (3) from Section 3.1:

$$\begin{aligned}
k(\boldsymbol{x}, \boldsymbol{x}') &= \int_{R^d} p(\boldsymbol{\omega}) e^{j\boldsymbol{\omega}^{\mathrm{T}}(\boldsymbol{x}-\boldsymbol{x}')}\, d\boldsymbol{\omega} \\
&= \mathbb{E}_{\boldsymbol{\omega}}\left[e^{j\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}} e^{-j\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}'}\right] \\
&= \mathbb{E}_{\boldsymbol{\omega}}\left[\left(\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}) + j\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\right)\left(\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}') - j\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\right)\right] \\
&= \mathbb{E}_{\boldsymbol{\omega}}\left[\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}') + \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\right] \\
&\quad + j \cdot \mathbb{E}_{\boldsymbol{\omega}}\left[\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}') - \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\right] \\
&= \mathbb{E}_{\boldsymbol{\omega}}\left[\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}') + \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\right] \qquad (8)
\end{aligned}$$

Note the Equation (8) is true because we know that $k(\boldsymbol{x}, \boldsymbol{x}')$ is a real-valued function, and thus the imaginary part of the expectation must disappear. We now show that the right-hand side of Equation (7) is equal to this same expression:

$$\begin{aligned}
&\mathbb{E}_{\boldsymbol{\omega},b}\left[\sqrt{2}\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x} + b) \cdot \sqrt{2}\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}' + b)\right] \\
&\quad = 2 \cdot \mathbb{E}_{\boldsymbol{\omega},b}\Bigg[\left(\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(b) - \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\sin(b)\right) \cdot \\
&\qquad\qquad \left(\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\cos(b) - \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\sin(b)\right)\Bigg] \qquad (9) \\
&\quad = 2 \cdot \mathbb{E}_{\boldsymbol{\omega},b}\Big[\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\cos^2(b) \\
&\qquad\qquad - \cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\cos(b)\sin(b) \\
&\qquad\qquad - \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\cos(b)\sin(b) \\
&\qquad\qquad + \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\sin^2(b)\Big] \\
&\quad = 2 \cdot \mathbb{E}_{\boldsymbol{\omega}}\left[\frac{1}{2}\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}') + \frac{1}{2}\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\right] \qquad (10) \\
&\quad = \mathbb{E}_{\boldsymbol{\omega}}\left[\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\cos(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}') + \sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x})\sin(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}')\right] \\
&\quad = k(\boldsymbol{x}, \boldsymbol{x}')
\end{aligned}$$

Equation (9) is true by the cosine sum of angles formula, and Equation (10) is true because $\mathbb{E}_b\left[\cos^2(b)\right] = \mathbb{E}_b\left[\sin^2(b)\right] = \int_0^{2\pi} \frac{1}{2\pi}\sin^2(b) = \frac{1}{2}$, and because $\mathbb{E}_b\left[\sin(b)\cos(b)\right] = 0$. This concludes the proof. ■

Abstract

In nonparametric regression, the derivative estimation has attracted much attention in recent years due to its wide applications. In this paper, we propose a new method for the derivative estimation using the locally weighted least absolute deviation regression. Different from the local polynomial regression, the proposed method does not require a finite variance for the error term and so is robust to the presence of heavy-tailed errors. Meanwhile, it does not require a zero median or a positive density at zero for the error term in comparison with the local median regression. We further show that the proposed estimator with random difference is asymptotically equivalent to the (infinitely) composite quantile regression estimator. In other words, running one regression is equivalent to combining infinitely many quantile regressions. In addition, the proposed method is also extended to estimate the derivatives at the boundaries and to estimate higher-order derivatives. For the equidistant design, we derive theoretical results for the proposed estimators, including the asymptotic bias and variance, consistency, and asymptotic normality. Finally, we conduct simulation studies to demonstrate that the proposed method has better performance than the existing methods in the presence of outliers and heavy-tailed errors, and analyze the Chinese house price data for the past ten years to illustrate the usefulness of the proposed method.

Keywords: composite quantile regression, differenced method, LowLAD, LowLSR, outlier and heavy-tailed error, robust nonparametric derivative estimation

1. Introduction

The derivative estimation is an important problem in nonparametric regression and it has applications in a wide range of fields. For instance, when analyzing human growth data (Müller, 1988; Ramsay and Silverman, 2002) or maneuvering target tracking data (Li and Jilkov, 2003, 2010), the first- and second-order derivatives of the height as a function of time are two important parameters, with the first-order derivative representing the speed and the second-order derivative representing the acceleration. The derivative estimates are also needed in change-point problems, e.g., for exploring the structures of curves (Chaudhuri and Marron, 1999; Gijbels and Goderniaux, 2005), for detecting the extremum of derivatives (Newell et al., 2005), for characterizing submicroscopic nanoparticle from scattering data (Charnigo et al., 2007, 2011a), for comparing regression curves (Park and Kang, 2008), for detecting abrupt climate changes (Matyasovszky, 2011), and for inferring the cell growth rates (Swain et al., 2016).

In the existing literature, one usually obtains the derivative estimates as a by-product by taking the derivative of a nonparametric fit of the regression function. There are three main approaches for the derivative estimation: smoothing spline, local polynomial regression, and differenced estimation. For smoothing spline, the derivatives are estimated by taking derivatives of the spline estimation of the regression function (Stone, 1985; Zhou and Wolfe, 2000). For local polynomial regression, a polynomial using the Taylor expansion is fitted locally by the kernel method (Ruppert and Wand, 1994; Fan and Gijbels, 1996; Delecroix and Rosa, 1996). These two methods both require an estimate of the regression function. As pointed out in Wang and Lin (2015), when the regression function estimator achieves the optimal rate of convergence, the corresponding derivative estimators may fail to achieve the rate. In other words, minimizing the mean square error of the regression function estimator does not necessarily guarantee the derivatives be optimally estimated (Wahba and Wang, 1990; Charnigo et al., 2011b).

For the differenced estimation, Müller et al. (1987) and Härdle (1990) proposed a cross-validation method to estimate the first-order derivative without estimating the regression function. Unfortunately, their method may not perform well in practice as the variance of their estimator is proportional to n^2 when the design points are equally spaced. Observing this shortcoming, Charnigo et al. (2011b) and De Brabanter et al. (2013) proposed a variance-reducing estimator for the derivative function called the empirical derivative that is essentially a linear combination of the symmetric difference quotients. They further derived the order of the asymptotic bias and variance, and established the consistency of the empirical derivative. Wang and Lin (2015) represented the empirical derivative as a local constant estimator in locally weighted least squares regression (LowLSR), and proposed a new estimator for the derivative function to reduce the estimation bias in both valleys and peaks of the true derivative function. More recently, Dai et al. (2016) generalized equidistant design to non-equidistant design, and Liu and De Brabanter (2018) further generalized the existing work to random design.

The aforementioned differenced derivative estimators are all based on the least squares (LS) method. Although elegant, the least squares method is not robust to outliers (Huber and Ronchetti, 2009). To overcome this problem, various robust methods have been proposed in the literature to improve the estimation of the regression function, see, for ex-

ample, kernel M-smoother (Härdle and Gasser, 1984), local least absolute deviation (LAD) (Fan and Hall, 1994; Wang and Scott, 1994), and locally weighted least squares (Cleveland, 1979; Ruppert and Wand, 1994) among others. In contrast, little attention has been paid to improving the derivative estimation except for the parallel developments of the above remedies (Härdle and Gasser, 1985; Welsh, 1996; Boente and Rodriguez, 2006), so call for a better solution.

In this paper, we propose a locally weighted least absolute deviation (LowLAD) method by combining the differenced method and the L_1 regression systematically. Over a neighborhood centered at a fixed point, we first obtain a sequence of linear regression representation in which the derivative is the intercept term. We then estimate the derivative by minimizing the sum of weighted absolute errors. By repeating this local fitting over a grid of points, we can obtain the derivative estimates on a discrete set of points. Finally, the entire derivative function is obtained by applying the local polynomial regression or the cubic spline interpolation.

The rest of the paper is organized as follows. Section 2 presents the motivation, the first-order derivative estimator and its theoretical properties, including the asymptotic bias and variance, consistency, and asymptotic normality. Section 3 studies the relation between the LowLAD estimator and the existing estimators. In particular, we show that the LowLAD estimator with random difference is asymptotically equivalent to the (infinitely) composite quantile regression estimator. Section 4 derives the first-order derivative estimation at the boundaries of the domain, and Section 5 generalizes the proposed method to estimate the higher-order derivatives. In Section 6 we conduct extensive simulation studies to assess the finite-sample performance of the proposed estimators and compare them with the existing competitors; we also apply our method to a real data set to illustrate its usefulness in practice. Finally, we conclude the paper with some discussions in Section 7, and provide the proofs of the theoretical results in six Appendices.

A word on notation: $\doteq$ means that the higher-order terms are omitted, and $\approx$ means an approximate result with up to two decimal digits.

2. First-Order Derivative Estimation

Combining the differenced method and the L_1 regression, we propose the LowLAD regression to estimate the first-order derivative. The new method inherits the advantage of the differenced method and also the robustness of the L_1 method.

2.1. Motivation

Consider the nonparametric regression model

$$Y_i = m(x_i) + \epsilon_i, \quad 1 \le i \le n, \tag{1}$$

where $x_i = i/n$ is the design point, Y_i is the response variable, $m(\cdot)$ is an unknown regression function, and ϵ_i are independent and identically distributed (iid) random errors with a continuous density $f(\cdot)$.

We first define first-order symmetric (about i) difference quotient (Charnigo et al., 2011b; De Brabanter et al., 2013) as

$$Y_{ij}^{(1)} = \frac{Y_{i+j} - Y_{i-j}}{x_{i+j} - x_{i-j}}, \quad 1 \le j \le k, \tag{2}$$

where k is a positive integer, and then decompose $Y_{ij}^{(1)}$ into two parts as

$$Y_{ij}^{(1)} = \frac{m(x_{i+j}) - m(x_{i-j})}{2j/n} + \frac{\epsilon_{i+j} - \epsilon_{i-j}}{2j/n}, \quad 1 \le j \le k. \tag{3}$$

On the right hand side of (3), the first term contains the bias information of the true derivative, and the second term contains the variance information. By Wang and Lin (2015), the first-order derivative estimation based on the third-order Taylor expansion usually outperforms the estimation based on the first-order Taylor expansion due to bias correction. For the same reason, we assume that $m(\cdot)$ is three times continuously differentiable on $[0, 1]$. By the Taylor expansion, we obtain

$$\frac{m(x_{i+j}) - m(x_{i-j})}{2j/n} = m^{(1)}(x_i) + \frac{m^{(3)}(x_i)}{6}\frac{j^2}{n^2} + o\left(\frac{j^2}{n^2}\right), \tag{4}$$

where the estimation bias is contained in the remainder term of the Taylor expansion.

By (3) and (4), we have

$$Y_{ij}^{(1)} = m^{(1)}(x_i) + \frac{m^{(3)}(x_i)}{6}\frac{j^2}{n^2} + \frac{\epsilon_{i+j} - \epsilon_{i-j}}{2j/n} + o\left(\frac{j^2}{n^2}\right). \tag{5}$$

In Proposition 11 (see Appendix A), we show that the median of $\epsilon_{i+j} - \epsilon_{i-j}$ is always zero, no matter whether the median of ϵ_i is zero or not. As a result, for any fixed $k = o(n)$, we have

$$\text{Median}[Y_{ij}^{(1)}] = m^{(1)}(x_i) + \frac{m^{(3)}(x_i)}{6}d_j^2 + o\left(d_j^2\right), \quad 1 \le j \le k, \tag{6}$$

where $d_j = j/n$. We treat (6) as a linear regression with d_j^2 and $Y_{ij}^{(1)}$ as the independent and dependent variables, respectively. In the presence of heavy-tailed errors, we propose to estimate $m^{(1)}(x_i)$ as the intercept of the linear regression using the LowLAD method.

2.2. Estimation Methodology

In order to derive the estimation bias, we further assume that $m(\cdot)$ is five times continuously differentiable, that is, the regression function is two degrees smoother than our postulated model due to the equidistant design. Following the paradigm of Draper and Smith (1981) and Wang and Scott (1994), we discard the higher-order terms of $m(\cdot)$ and assume locally that the approximate model is

$$Y_{ij}^{(1)} = \beta_{i1} + \beta_{i3}d_j^2 + \beta_{i5}d_j^4 + \zeta_{ij},$$

where $\beta_i = (\beta_{i1}, \beta_{i3}, \beta_{i5})^T = (m^{(1)}(x_i), m^{(3)}(x_i)/6, m^{(5)}(x_i)/120)^T$ are the unknown coefficients of the true underlying quintic function, and $\zeta_{ij} = (\epsilon_{i+j} - \epsilon_{i-j})/(2j/n)$ with

Median$[\zeta_{ij}]=0$. Under the assumption of the approximate model, β_{i1} can be estimated as

$$\min_b \sum_{j=1}^{k} w_j \left|Y_{ij}^{(1)} - (b_{i1}+b_{i3}d_j^2+b_{i5}d_j^4)\right| = \min_b \sum_{j=1}^{k} \left|\tilde{Y}_{ij}^{(1)} - (b_{i1}d_j+b_{i3}d_j^3+b_{i5}d_j^5)\right|,$$

where $w_j=d_j$ are the weights, $b=(b_{i1},b_{i3},b_{i5})^T$, and $\tilde{Y}_{ij}^{(1)}=(Y_{i+j}-Y_{i-j})/2$. Accordingly, the approximate model can be rewritten as

$$\tilde{Y}_{ij}^{(1)} = \beta_{i1}d_j+\beta_{i3}d_j^3+\beta_{i5}d_j^5+\tilde{\zeta}_{ij},$$

where $\tilde{\zeta}_{ij}=(\epsilon_{i+j}-\epsilon_{i-j})/2$ are iid random errors with Median$[\tilde{\zeta}_{ij}]=0$ and a continuous, symmetric density $g(\cdot)$ which is positive in a neighborhood of zero (see Appendix A).

Rather than the best L_1 quintic fitting, we search for the best L_1 cubic fitting to $\tilde{Y}_{ij}^{(1)}$. Specifically, we estimate the model by LowLAD:

$$(\hat{\beta}_{i1},\hat{\beta}_{i3}) = \arg\min_b \sum_{j=1}^{k} \left|\tilde{Y}_{ij}^{(1)} - b_{i1}d_j - b_{i3}d_j^3\right|$$

with $b=(b_{i1},b_{i3})^T$, and define the LowLAD estimator of $m^{(1)}(x_i)$ as

$$\hat{m}_{\text{LowLAD}}^{(1)}(x_i) = \hat{\beta}_{i1}. \tag{7}$$

The following theorem states the asymptotic behavior of $\hat{\beta}_{i1}$.

Theorem 1 *Assume that ϵ_i are iid random errors with a continuous bounded density $f(\cdot)$. Then as $k\to\infty$ and $k/n\to 0$, $\hat{\beta}_{i1}$ in (7) is asymptotically normally distributed with*

$$\text{Bias}[\hat{\beta}_{i1}] = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4}+o\left(\frac{k^4}{n^4}\right), \quad \text{Var}[\hat{\beta}_{i1}] = \frac{75}{16g(0)^2}\frac{n^2}{k^3}+o\left(\frac{n^2}{k^3}\right),$$

where $g(0)=2\int_{-\infty}^{\infty}f^2(x)\mathrm{d}x$. The optimal k that minimizes the asymptotic mean square error (AMSE) is

$$k_{opt} \approx 3.26\left(\frac{1}{g(0)^2 m^{(5)}(x_i)^2}\right)^{1/11} n^{10/11},$$

and, consequently, the minimum AMSE is

$$\text{AMSE}[\hat{\beta}_{i1}] \approx 0.19\left(\frac{m^{(5)}(x_i)^6}{g(0)^{16}}\right)^{1/11} n^{-8/11}.$$

In the local median regression (see Section 3.1 below for its definition), the density $f(\cdot)$ is usually assumed to have a zero median and a positive $f(0)$ value. While in Theorem 1, we only require a continuity condition on the density $f(\cdot)$. In addition, the variance of the LowLAD estimator depends on $g(0)=2\int_{-\infty}^{\infty}f^2(x)\mathrm{d}x$ which is always positive, while the variance of the local median estimator relies on a single value $f(0)$ only. In this sense, the LowLAD estimator is more robust than the local median estimator.

2.3. LowLAD with Random Difference

To further improve the estimation efficiency, we propose the LowLAD with random difference referred to as RLowLAD. First, define the first-order random difference sequence as

$$Y_{ijl} = Y_{i+j}-Y_{i+l}, \quad -k\le j,l\le k,$$

where we implicitly exclude j and l being 0 to be comparable to the LowLAD estimator. Second, define the RLowLAD estimator as

$$\hat{m}_{\text{RLowLAD}}^{(1)}(x_i) = \hat{\beta}_{i1}^{\text{RLowLAD}}, \tag{8}$$

where

$$\begin{aligned}&(\hat{\beta}_{i1}^{\text{RLowLAD}},\hat{\beta}_{i2}^{\text{RLowLAD}},\hat{\beta}_{i3}^{\text{RLowLAD}},\hat{\beta}_{i4}^{\text{RLowLAD}})\\ &= \arg\min_b \sum_{j=-k}^{k}\sum_{l=-k,l<j}^{k}\left|Y_{ijl} - b_{i1}(d_j-d_l) - b_{i2}(d_j^2-d_l^2) - b_{i3}(d_j^3-d_l^3) - b_{i4}(d_j^4-d_l^4)\right|\end{aligned}$$

with the true value $\beta_i=(\beta_{i1},\beta_{i2},\beta_{i3},\beta_{i4})^T=(m^{(1)}(x_i),m^{(2)}(x_i)/2,m^{(3)}(x_i)/6,m^{(4)}(x_i)/24)^T$ and $b=(b_{i1},b_{i2},b_{i3},b_{i4})^T$.

Theorem 2 *Under the assumptions of Theorem 1, the bias and variance of the RLowLAD estimator in (8) are, respectively,*

$$\text{Bias}[\hat{\beta}_{i1}^{\text{RLowLAD}}] = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4}+o\left(\frac{k^4}{n^4}\right), \quad \text{Var}[\hat{\beta}_{i1}^{\text{RLowLAD}}] = \frac{75}{24g(0)^2}\frac{n^2}{k^3}+o\left(\frac{n^2}{k^3}\right).$$

By replacing the symmetric difference with the random difference, we improve the estimation accuracy with the variance from $\frac{75}{16g(0)^2}\frac{n^2}{k^3}$ to $\frac{75}{24g(0)^2}\frac{n^2}{k^3}$. While the cost is to increase the computation complexity from $O(n)$ to $O(n^2)$.

3. Comparison with Existing First-Order Derivative Estimators

We first review some existing methods for the first-order derivative estimation which are based on either the least squares regression or the quantile regression. Both methods can be used to estimate the first-order derivative of $m(\cdot)$ due to the special structure of model (1). Note that $\mathrm{E}[Y_i|x_i]=m(x_i)+\mathrm{E}[\epsilon_i]$, and $\mathrm{Q}_\tau(Y_i|x_i)=m(x_i)+\mathrm{Q}_\tau(\epsilon_i)$ because ϵ_i is independent of x_i, where $\mathrm{Q}_\tau(\epsilon_i)$ is the τth unconditional quantile of ϵ_i. Although $\mathrm{E}[Y_i|x_i]$ may not equal to $\mathrm{Q}_\tau(Y_i|x_i)$, their derivatives must be the same as the corresponding derivatives of $m(x_i)$. To make the existing estimators comparable to our LowLAD and RLowLAD estimators, we use the uniform kernel and the same order Taylor expansion throughout this section.

3.1. LS, LowLSR and LAD Estimators

In Fan and Gijbels (1996), the first-order derivative is estimated by the least squares method:

$$(\hat{\alpha}_{i0}^{\text{LS}},\hat{\alpha}_{i1}^{\text{LS}},\hat{\alpha}_{i2}^{\text{LS}},\hat{\alpha}_{i3}^{\text{LS}},\hat{\alpha}_{i4}^{\text{LS}}) = \arg\min_\alpha \sum_{j=-k}^{k}\left(Y_{i+j}-\alpha_{i0}-\alpha_{i1}d_j-\alpha_{i2}d_j^2-\alpha_{i3}d_j^3-\alpha_{i4}d_j^4\right)^2,$$

where $\alpha = (\alpha_{i0}, \alpha_{i1}, \alpha_{i2}, \alpha_{i3}, \alpha_{i4})^T$. For ease of comparison, we exclude the point $j = 0$ so that the same Y_i's are used as in the LowLAD estimation. Define the least squares (LS) estimator as

$$\hat{m}^{(1)}_{\rm LS}(x_i) = \hat{\alpha}^{\rm LS}_{i1}. \tag{9}$$

Corollary 3 *Under the assumptions of Theorem 1, the bias and variance of the LS estimator in* (9) *are, respectively,*

$$\mathrm{Bias}[\hat{\alpha}^{\rm LS}_{i1}] = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4} + o\left(\frac{k^4}{n^4}\right), \quad \mathrm{Var}[\hat{\alpha}^{\rm LS}_{i1}] = \frac{75\sigma^2}{8}\frac{n^2}{k^3} + o\left(\frac{n^2}{k^3}\right).$$

To obtain the optimal convergence rate of the derivative estimation, Wang and Lin (2015) proposed the LowLSR estimator:

$$\hat{m}^{(1)}_{\rm LowLSR}(x_i) = \hat{\alpha}^{\rm LowLSR}_{i1}, \tag{10}$$

where

$$(\hat{\alpha}^{\rm LowLSR}_{i1}, \hat{\alpha}^{\rm LowLSR}_{i3}) = \arg\min_{\alpha_{i1},\alpha_{i3}} \sum_{j=1}^{k} \left(\tilde{Y}^{(1)}_{ij} - \alpha_{i1} d_j - \alpha_{i3} d_j^3\right)^2.$$

Corollary 4 *Under the assumptions of Theorem 1, the bias and variance of the LowLSR estimator in* (10) *are, respectively,*

$$\mathrm{Bias}[\hat{\alpha}^{\rm LowLSR}_{i1}] = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4} + o\left(\frac{k^4}{n^4}\right), \quad \mathrm{Var}[\hat{\alpha}^{\rm LowLSR}_{i1}] = \frac{75\sigma^2}{8}\frac{n^2}{k^3} + o\left(\frac{n^2}{k^3}\right).$$

Wang and Scott (1994) proposed the local polynomial least absolute deviation (LAD) estimator:

$$\hat{m}^{(1)}_{\rm LAD}(x_i) = \hat{\beta}^{\rm LAD}_{i1}, \tag{11}$$

where

$$(\hat{\beta}^{\rm LAD}_{i0}, \hat{\beta}^{\rm LAD}_{i1}, \hat{\beta}^{\rm LAD}_{i2}, \hat{\beta}^{\rm LAD}_{i3}, \hat{\beta}^{\rm LAD}_{i4}) = \arg\min_{b} \sum_{j=-k}^{k} \left|Y_{i+j} - b_{i0} - b_{i1} d_j^1 - b_{i2} d_j^2 - b_{i3} d_j^3 - b_{i4} d_j^4\right|$$

with $b = (b_{i0}, b_{i1}, b_{i2}, b_{i3}, b_{i4})^T$.

Corollary 5 *Under the assumptions of Theorem 1, the bias and variance of the LAD estimator in* (11) *are, respectively,*

$$\mathrm{Bias}[\hat{\beta}^{\rm LAD}_{i1}] = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4} + o\left(\frac{k^4}{n^4}\right), \quad \mathrm{Var}[\hat{\beta}^{\rm LAD}_{i1}] = \frac{75}{32 f(0)^2}\frac{n^2}{k^3} + o\left(\frac{n^2}{k^3}\right).$$

There is one key difference between the LS method and the LAD method. For the LS method, the LS estimator and the LowLSR estimator are asymptotically equivalent; while for the LAD method, the asymptotic variances of the LAD estimator and the LowLAD estimator are very different, although their asymptotic biases are the same. We provide the reasons for this key difference in Appendix F.

3.2. Quantile Regression Estimators

Quantile regression (Koenker and Bassett, 1978; Koenker, 2005) exploits the distribution information of the error term to improve the estimation efficiency. Following the composite quantile regression (CQR) in Zou and Yuan (2008), Kai et al. (2010) proposed the local polynomial CQR estimator. In general, the local polynomial CQR estimator of $m^{(1)}(x_i)$ is defined as

$$\hat{m}^{(1)}_{\rm CQR}(x_i) = \hat{\gamma}^{\rm CQR}_{i1}, \tag{12}$$

where

$$\begin{aligned}&(\left\{\hat{\gamma}^{\rm CQR}_{i0h}\right\}_{h=1}^{q}, \hat{\gamma}^{\rm CQR}_{i1}, \hat{\gamma}^{\rm CQR}_{i2}, \hat{\gamma}^{\rm CQR}_{i3}, \hat{\gamma}^{\rm CQR}_{i4})\\ &= \arg\min_{\gamma} \sum_{h=1}^{q} \left(\sum_{j=-k}^{k} \rho_{\tau_h}(Y_{i+j} - \gamma_{i0h} - \gamma_{i1} d_j^1 - \gamma_{i2} d_j^2 - \gamma_{i3} d_j^3 - \gamma_{i4} d_j^4)\right),\end{aligned}$$

with $\gamma = \left(\{\gamma_{i0h}\}_{h=1}^{q}, \gamma_{i1}, \gamma_{i2}, \gamma_{i3}, \gamma_{i4}\right)^T$, $\rho_\tau(x) = \tau x - xI(x < 0)$ is the check function, and $\tau_h = h/(q+1)$.

Corollary 6 *Under the assumptions of Theorem 1, the bias and variance of the CQR estimator in* (12) *are, respectively,*

$$\mathrm{Bias}[\hat{\gamma}^{\rm CQR}_{i1}] = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4} + o\left(\frac{k^4}{n^4}\right), \quad \mathrm{Var}[\hat{\gamma}^{\rm CQR}_{i1}] = \frac{75 R_1(q)}{8}\frac{n^2}{k^3} + o\left(\frac{n^2}{k^3}\right),$$

where $R_1(q) = \sum_{l=1}^{q}\sum_{l'=1}^{q} \tau_{ll'} / \{\sum_{l=1}^{q} f(c_l)\}^2$, $c_l = F^{-1}(\tau_l)$, *and* $\tau_{ll'} = \min\{\tau_l, \tau_{l'}\} - \tau_l \tau_{l'}$. *As* $q \to \infty$,

$$R_1(q) \to \frac{1}{12(E[f(\epsilon)])^2} = \frac{1}{3g(0)^2}, \quad \mathrm{Var}[\hat{\gamma}^{\rm CQR}_{i1}] = \frac{75}{24 g(0)^2}\frac{n^2}{k^3} + o\left(\frac{n^2}{k^3}\right).$$

Zhao and Xiao (2014) proposed the weighted quantile average (WQA) estimator for the regression function in nonparametric regression, an idea originated from Koenker (1984). We now extend the WQA method to estimate $m^{(1)}(x_i)$ using the local polynomial quantile regression. Specifically, we define

$$\hat{m}^{(1)}_{\rm WQA}(x_i) = \sum_{h=1}^{q} w_h \hat{\gamma}^{\rm WQA}_{i1h}, \tag{13}$$

where $\sum_{h=1}^{q} w_h = 1$, and

$$\begin{aligned}&(\hat{\gamma}^{\rm WQA}_{i0h}, \hat{\gamma}^{\rm WQA}_{i1h}, \hat{\gamma}^{\rm WQA}_{i2h}, \hat{\gamma}^{\rm WQA}_{i3h}, \hat{\gamma}^{\rm WQA}_{i4h})\\ &= \arg\min_{\gamma_h} \left(\sum_{j=-k}^{k} \rho_{\tau_h}(Y_{i+j} - \gamma_{i0h} - \gamma_{i1h} d_j^1 - \gamma_{i2h} d_j^2 - \gamma_{i3h} d_j^3 - \gamma_{i4h} d_j^4)\right)\end{aligned}$$

with $\gamma_h = (\gamma_{i0h}, \gamma_{i1h}, \gamma_{i2h}, \gamma_{i3h}, \gamma_{i4h})^T$.

Corollary 7 *Under the assumptions of Theorem 1, the bias and variance of the WQA estimator in* (13) *are, respectively,*

$$\text{Bias}[\hat{m}^{(1)}_{\text{WQA}}(x_i)] = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4} + +o\left(\frac{k^4}{n^4}\right), \quad \text{Var}[\hat{m}^{(1)}_{\text{WQA}}(x_i)] = \frac{75R_2(q|\mathbf{w})}{8}\frac{n^2}{k^3} + o\left(\frac{n^2}{k^3}\right),$$

where $R_2(q|\mathbf{w}) = \mathbf{w}^T\mathbf{H}\mathbf{w}$ *with* $\mathbf{w} = (w_1, \cdots, w_q)^T$, *and* $\mathbf{H} = \left\{\frac{\tau_{l,l'}}{f(c_l)f(c_{l'})}\right\}_{1\le l,l'\le q}$. *The optimal weights are given by* $\mathbf{w}^* = \frac{\mathbf{H}^{-1}e_q}{e_q^T\mathbf{H}^{-1}e_q}$, *where* $e_q = (1, \ldots, 1)^T_{q\times 1}$, *and* $R_2(q|\mathbf{w}^*) = (e_q^T\mathbf{H}^{-1}e_q)^{-1}$. *As* $q \to \infty$, *under the regularity assumptions in Theorem 6.2 of Zhao and Xiao (2014), the variance of the optimal CQR is*

$$\text{Var}[\hat{m}^{(1)}_{\text{WQA}}(x_i)] = \frac{75I(f)^{-1}}{8}\frac{n^2}{k^3} + o\left(\frac{n^2}{k^3}\right),$$

where $I(f)$ *is the Fisher information of* f.

	LS	LowLSR	LAD	CQR	WQA	LowLAD	RLowLAD
s^2	σ^2	σ^2	$\frac{1}{4f(0)^2}$	$R_1(q)$	$R_2(q)$	$\frac{1}{2g(0)^2}$	$\frac{1}{3g(0)^2}$
Asymptotic s^2	σ^2	σ^2	$\frac{1}{4f(0)^2}$	$\frac{1}{3g(0)^2}$	$I(f)^{-1}$	$\frac{1}{2g(0)^2}$	$\frac{1}{3g(0)^2}$

Table 1: s^2 in the variances $\frac{75n^2}{8k^3}s^2$ of the existing first-order derivative estimators.

For the LS, LowLSR, LAD, CQR, WQA, LowLAD and RLowLAD estimators with the same k, their asymptotic biases are all the same. In contrast, their asymptotic variances are $\frac{75n^2}{8k^3}s^2$ with s^2 being $\sigma^2, \sigma^2, \frac{1}{4f(0)^2}, R_1(q), R_2(q)$, $\frac{1}{2g(0)^2}$ and $\frac{1}{3g(0)^2}$, as listed in Table 1. From the kernel interpretation of the differenced estimator by Wang and Yu (2017), we expect an equivalence between the LS and LowLSR estimators. As $q \to \infty$, we have $R_1(q) \to 1/\{3g(0)^2\}$ and $R_2(q) \to I(f)^{-1}$, and hence the WQA estimator is the most efficient estimator as q becomes large. Nevertheless, it requires the error density function to be known in advance to carry out the most efficient WQA estimator. Otherwise, a two-step procedure is needed, where the first step estimates the error density. For a fixed q, the three quantile-based estimators (i.e., LAD, CQR, WQA) depend only on the density values of $f(\cdot)$ at finite quantile points, whose behaviors are uncertain and may not be reliable. In contrast, our new estimators rely on $g(0) = 2E[f(x)]$, which includes all information on the density $f(\cdot)$ and hence is more robust.

3.3. Relationship Among the CQR, WQA and RLowLAD Estimators

From the asymptotic variances, we can see that the RLowLAD estimator is asymptotically equivalent to the infinitely CQR estimator. Why can this happen? Intuitively, they use the same information in different ways. First, in infinitely CQR, all local data (i.e., data at all quantiles) are employed to estimate the same parameter $m^{(1)}(x_i)$, which is the same as in RLowLAD. Second, in infinitely CQR, we first use data horizontally (at fixed τ) and then combine data vertically (across τ), while in RLowLAD, we first combine data vertically since

the distribution of the error term of Y_{ijl} is $\int f\left(F^{-1}(\tau)\right)d\tau$, and then run a single regression horizontally (at $\tau = 0.5$). It is interesting (and may be also surprising) to see that these two different ways of using information have the same efficiency. The RLowLAD estimation is more powerful in practice by noticing that a single differencing in Y_{ijl} is equivalent to combining all (infinitely many) quantiles.

It should be emphasized that the ways of combining the infinitely many quantiles in CQR and WQA are different. Suppose we use the equal weights $\mathbf{w}_E = \left(\frac{1}{q}, \cdots, \frac{1}{q}\right)^T$ in WQA. Such a weighting scheme is parallel to CQR where an equal weight is imposed on each check function. Then from Theorem 2 of Kai et al. (2010), $R_2(q|\mathbf{w}_E) \to 1$ as $q \to \infty$; while $R_1(q) \to \frac{1}{3g(0)^2}$. From Table 2 of Kai et al. (2010), $\frac{1}{3g(0)^2} < 1$ for most distributions (except $N(0,1)$). Why can this difference happen? Note that

$$\left\{\hat{\gamma}^{\text{WQA}}_{ih}\right\}_{h=1}^{q} = \arg\min_{\gamma_1,\cdots,\gamma_q}\left(\sum_{h=1}^{q}\sum_{j=-k}^{k}\rho_{\tau_h}(Y_{i+j} - \gamma_{i0h} - \gamma_{i1h}d_j^1 - \gamma_{i2h}d_j^2 - \gamma_{i3h}d_j^3 - \gamma_{i4h}d_j^4)\right)$$

where $\hat{\gamma}^{\text{WQA}}_{ih} = (\hat{\gamma}^{\text{WQA}}_{i0h}, \hat{\gamma}^{\text{WQA}}_{i1h}, \hat{\gamma}^{\text{WQA}}_{i2h}, \hat{\gamma}^{\text{WQA}}_{i3h}, \hat{\gamma}^{\text{WQA}}_{i4h})^T$, so the CQR estimator is a constrained WQA estimator with the constraints being that the slopes at different quantiles must be the same. On the other hand, the WQA estimator can be interpreted as a minimum distance estimator,

$$\arg\min_{\gamma}\left(\hat{\gamma}^{\text{WQA}}_{i1} - \gamma e_q\right)^T\mathbf{W}\left(\hat{\gamma}^{\text{WQA}}_{i1} - \gamma e_q\right) = \frac{e_q^T\mathbf{W}\hat{\gamma}^{\text{WQA}}_{i1}}{e_q^T\mathbf{W}e_q} = \mathbf{w}^T\hat{\gamma}^{\text{WQA}}_{i1},$$

where $\hat{\gamma}^{\text{WQA}}_{i1} = \left(\hat{\gamma}^{\text{WQA}}_{i11}, \cdots, \hat{\gamma}^{\text{WQA}}_{i1q}\right)^T$, $\mathbf{W}$ is a symmetric weight matrix, and $\mathbf{w} = \frac{\mathbf{W}e_q}{e_q^T\mathbf{W}e_q}$. When $\mathbf{W} = \mathbf{I}_q$, the $q \times q$ identity matrix, we get the equally-weighted WQA estimator; when $\mathbf{W} = \mathbf{H}^{-1}$, we get the optimally weighted WQA estimator; and when

$$\mathbf{W} = a\mathbf{I}_q + (1-a)\mathbf{H}^{-1} \neq \mathbf{I}_q,$$

we get an estimator that is asymptotically equivalent to the CQR estimator, where

$$a = \frac{-(q-B)(1-BC) + \sqrt{(q^2-AB)(1-BC)}}{A - (2q-B)(1-BC) - q^2C} \neq 1$$

with $A = e_q^T\mathbf{H}e_q = q^2R_2(q|\mathbf{w}_E)$, $B = R_2(q|\mathbf{w}^*)^{-1}$ and $C = R_1(q)$. For example, if $\varepsilon \sim N(0,1)$, then when $q = 5$, $a = -0.367$; when $q = 9$, $a = -0.165$; when $q = 19$, $a = -0.067$; and when $q = 99$, $a = -0.011$. This is why imposing constraints directly on the objective function (i.e., the CQR estimator) or on the resulting estimators (i.e., the WQA estimator) would generate different estimators. The RLowLAD estimator and the CQR estimator have the same asymptotic variance because both of them impose constraints directly on the objective function.

3.4. Asymptotic Relative Efficiency

In this subsection, we study the Asymptotic Relative Efficiency (ARE) of the RLowLAD estimator with respect to the LowLSR and LAD estimators by comparing their asymptotic variances and AMSEs.

Since all estimators have the same bias, the comparison of their variances becomes important. We define the variance ratios of the LowLSR and LAD estimators relative to the RLowLAD estimator as

$$\mathrm{R}_{\mathrm{LowLSR}} = \frac{\mathrm{Var}(\hat{m}_{\mathrm{LowLSR}^{(1)}})}{\mathrm{Var}(\hat{m}^{(1)}_{\mathrm{RLowLAD}})} = 3\sigma^2 g(0)^2,$$
$$\mathrm{R}_{\mathrm{LAD}} = \frac{\mathrm{Var}(\hat{m}^{(1)}_{\mathrm{LAD}})}{\mathrm{Var}(\hat{m}^{(1)}_{\mathrm{RLowLAD}})} = \frac{3g(0)^2}{4f(0)^2}.$$

In addition, the overall performance of an estimator is usually measured by its AMSE, so we define the AREs based on AMSE as

$$\mathrm{ARE}_{\mathrm{LowLSR}} = \frac{\mathrm{AMSE}(\hat{m}^{(1)}_{\mathrm{LowLSR}})}{\mathrm{AMSE}(\hat{m}^{(1)}_{\mathrm{RLowLAD}})},$$
$$\mathrm{ARE}_{\mathrm{LAD}} = \frac{\mathrm{AMSE}(\hat{m}^{(1)}_{\mathrm{LAD}})}{\mathrm{AMSE}(\hat{m}^{(1)}_{\mathrm{RLowLAD}})}.$$

The LowLSR estimator has the AMSE

$$\mathrm{AMSE}(\hat{m}^{(1)}_{\mathrm{LowLSR}}) = \left\{\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4}\right\}^2 + \frac{75\sigma^2}{8}\frac{n^2}{k^3},$$

and the optimal k minimizing the AMSE is

$$k^{opt}_{\mathrm{LowLSR}} = \left\{\frac{893025\sigma^2}{(m^{(5)}(x_i))^2}\right\}^{1/11} n^{10/11}$$

Similarly, we have

$$k^{opt}_{\mathrm{RLowLAD}} = \left\{\frac{893025}{3g(0)^2(m^{(5)}(x_i))^2}\right\}^{1/11} n^{10/11} = R^{-1/11}_{\mathrm{LowLSR}} k^{opt}_{\mathrm{LowLSR}}.$$

As $n \to \infty$, we can show

$$\mathrm{ARE}_{\mathrm{LowLSR}} = {\mathrm{R}_{\mathrm{LowLSR}}}^{8/11},$$
$$\mathrm{ARE}_{\mathrm{LAD}} = {\mathrm{R}_{\mathrm{LAD}}}^{8/11}.$$

Since the variance ratio and ARE have a close relationship, we only report the variance ratios. We consider eight distributions for the random errors: the normal distribution $N(0, 1^2)$, the Laplace (double exponential) distribution, the Logistic distribution, the t distribution with 3 degrees of freedom, the mixed normal distribution $0.9N(0, 1^2)+0.1N(0, 3^2)$ and $0.9N(0, 1^2)+0.1N(0, 10^2)$, the Cauchy distribution, the mixed double gamma distribution $0.9Gamma(0, 1) + 0.1Gamma(1, 1)$ and $0.9Gamma(0, 1) + 0.1Gamma(3, 1)$, and the bimodal distribution $0.5N(-1, 1) + 0.5N(1, 1)$ and $0.5N(-3, 1) + 0.5N(3, 1)$, which were adopted in the robust location estimation by Koenker and Bassett (1978) and the variable selection by Zou and Yuan (2008).

	$f(0)$	$g(0)$	σ^2	$\mathrm{R}_{\mathrm{LowLSR}}$	$\mathrm{R}_{\mathrm{LAD}}$
$N(0,1)$	0.40	0.56	1	0.95	1.5
$0.9N(0,1)+0.1N(0,3^2)$	0.37	0.50	1.8	1.37	1.38
$0.9N(0,1)+0.1N(0,10^2)$	0.36	0.47	10.9	7.28	1.27
$t(3)$	0.37	0.46	3	1.90	1.17
Laplace	0.50	0.50	2	1.50	0.75
Logistic	0.25	0.33	3.29	1.10	1.33
Cauchy	0.32	0.32	∞	∞	0.75
$0.9Gamma(0,1)+0.1Gamma(1,1)$	0.50	0.45	1.1	1.63	0.68
$0.9Gamma(0,1)+0.1Gamma(3,1)$	0.46	0.42	1.3	2.44	0.68
$0.5N(-1,1)+0.5N(1,1)$	0.15	0.39	2	0.89	5.18
$0.5N(-3,1)+0.5N(3,1)$	4.92×10^{-5}	0.28	10	2.39	2.46×10^{7}

Table 2: Variance ratios for different error distributions.

Table 2 lists the variance ratios for these eight error distributions which are derived in Appendix E. From Table 2, a few interesting results can be drawn. First of all, the variance of the RLowLAD estimator is usually smaller and more robust than that of the LowLSR and LAD estimators in most cases. Secondly, the LAD estimator is not robust since it relies on the density value at one point 0, so when facing the bimodal errors the variance is huge. Thirdly, the minimum value of $\mathrm{R}_{\mathrm{LowLSR}}$ in Table 2 is 0.89. Actually, there is an exact lower bound for $\mathrm{R}_{\mathrm{LowLSR}}$ as stated in Theorem 4 of Kai et al. (2010). For completeness, we repeat their Theorem 4 in the following Lemma 8.

Lemma 8 *Let $\mathcal{F}$ denote the class of error distributions with mean 0 and variance 1. Then*

$$\inf_{f\in\mathcal{F}} \mathrm{R}_{\mathrm{LowLSR}}(f) \approx 0.86.$$

The lower bound is reached if and only if the error follows the rescaled beta$(2, 2)$ distribution. Thus,

$$\inf_{f\in\mathcal{F}} \mathrm{ARE}_{\mathrm{LowLSR}}(f) = \mathrm{R}^{8/11}_{\mathrm{LowLSR}} \approx 0.90.$$

In other words, the potential efficiency loss of the RLowLAD estimator relative to the LowLSR estimator is at most 10%.

In Appendix E, we further illustrate the trade-off between the sharp-peak and heavy-tailed errors using three error distributions.

4. Derivative Estimation at Boundaries

At the left boundary with $2 \le i \le k$, the bias and variance of the LowLAD estimator are $-m^{(5)}(x_i)(i-1)^4/(504n^4)$ and $75n^2/(16g(0)^2(i-1)^3)$, respectively. At the endpoint $i = 1$, the LowLAD estimator is not well defined. Similar results hold for the estimation at the right boundary with $n-k+1 \le i \le n-1$. In this section, we propose an asymmetrical LowLAD method (As-LowLAD) to reduce the estimation variance as well as to improve the finite-sample performance at the boundaries.

Assume that $m(\cdot)$ is twice continuously differentiable on $[0,1]$ and Median$[\epsilon_i]=0$. For $1\le i\le k$, we define the asymmetric lag-j first-order difference quotients as

$$Y_{ij}^{<1>}=\frac{Y_{i+j}-Y_i}{x_{i+j}-x_i},\quad -(i-1)\le j\le k,\quad j\neq 0.$$

By decomposing $Y_{ij}^{<1>}$ into two parts, we have

$$\begin{aligned}Y_{ij}^{<1>}&=\frac{m(x_{i+j})-m(x_i)}{j/n}+\frac{\epsilon_{i+j}-\epsilon_i}{j/n}\\&=m^{(1)}(x_i)+(-\epsilon_i)d_j^{-1}+\frac{\epsilon_{i+j}}{j/n}+\frac{m^{(2)}(x_i)}{2!}\frac{j}{n}+o\left(\frac{j}{n}\right),\end{aligned}$$

where ϵ_i is fixed as j changes. Thus, Median$(Y_{ij}^{<1>}|\epsilon_i)=m^{(1)}(x_i)+(-\epsilon_i)d_j^{-1}+\frac{m^{(2)}(x_i)}{2!}\frac{j}{n}$. Ignoring the last term, we can rewrite the above model as

$$Y_{ij}^{<1>}=\beta_{i1}+\beta_{i0}d_j^{-1}+\delta_{ij}+o(1),\quad -(i-1)\le j\le k,\quad j\neq 0,$$

where $(\beta_{i0},\beta_{i1})^T=(-\epsilon_i,m^{(1)}(x_i))^T$, $\delta_{ij}=\frac{\epsilon_{i+j}}{j/n}$. By the LowLAD method, the regression coefficients can be estimated as

$$\begin{aligned}\left(\hat\beta_{i0},\hat\beta_{i1}\right)&=\arg\min_b\sum_{j=-(i-1)}^{k}\left|Y_{ij}^{<1>}-b_{i1}-b_{i0}d_j^{-1}\right|w_j\\&=\arg\min_b\sum_{j=-(i-1)}^{k}\left|\tilde Y_{ij}^{<1>}-b_{i0}-b_{i1}d_j\right|,\end{aligned}\tag{14}$$

where $w_j=d_j$, $b=(b_{i0},b_{i1})^T$, and $\tilde Y_{ij}^{<1>}=Y_{i+j}-Y_i$. The As-LowLAD estimator of $m^{(1)}(x_i)$ is $\hat\beta_{i1}$.

Similarly to Theorem 1, we can prove the asymptotic normality for $\hat\beta_{i1}$. The following theorem states its asymptotic bias and variance.

Theorem 9 *Assume that ϵ_i are iid random errors with median 0 and a continuous, positive density $f(\cdot)$ in a neighborhood of zero. Furthermore, assume that $m(\cdot)$ is twice continuously differentiable on $[0,1]$. Then for each $1\le i\le k$, the leading terms of the bias and variance of $\hat\beta_{i1}$ in (14) are, respectively,*

$$\begin{aligned}\mathrm{Bias}[\hat\beta_{i1}]&=\frac{m^{(2)}(x_i)}{2}\frac{k^4+2k^3i-2ki^3-i^4}{n(k^3+3k^2i+3ki^2+i^3)},\\\mathrm{Var}[\hat\beta_{i1}]&=\frac{3}{f(0)^2}\frac{n^2}{k^3+3k^2i+3ki^2+i^3}.\end{aligned}$$

For the estimation at the boundaries, Wang and Lin (2015) proposed a one-side LowLSR (OS-LowLSR) estimator of the first-order derivative, with the bias and variance being $m^{(2)}(x_i)k/(2n)$ and $12\sigma^2n^2/k^3$, respectively. In contrast, if we consider the one-side LowLAD (OS-LowLAD) estimator of the first-order derivative, its bias and variance are $m^{(2)}(x_i)k/(2n)$ and $3n^2/(f(0)^2k^3)$, respectively. Note that the two biases are the same, while the variances are different with the former related to σ^2 and the latter related to $f(0)$. Note also that different from the LowLAD estimator at the interior point, the variance of the OS-LowLAD estimator involves $f(0)$ rather than $g(0)$.

Theorem 9 shows that our estimator has a smaller bias than the OS-LowLSR and OS-LowLAD estimators. In the special case $i=k$, the bias disappears (in fact it reduces to the higher-order term $O(k^2/n^2)$). With normal errors, when $1<i<\lfloor 0.163k\rfloor$, the order of variances of the three estimators is $\mathrm{Var}(\hat m^{(1)}_{\mathrm{OS-LAD}}(x_i))>\mathrm{Var}(\hat m^{(1)}_{\mathrm{AS-LAD}}(x_i))>\mathrm{Var}(\hat m^{(1)}_{\mathrm{OS-LSR}}(x_i))$, where for a real number x, $\lfloor x\rfloor$ means the largest integer less than x; when $\lfloor 0.163k\rfloor<i<k$, the order of variances of the three estimators is $\mathrm{Var}(\hat m^{(1)}_{\mathrm{OS-LSR}}(x_i))>\mathrm{Var}(\hat m^{(1)}_{\mathrm{OS-LAD}}(x_i))>\mathrm{Var}(\hat m^{(1)}_{\mathrm{AS-LAD}}(x_i))$. As i approaches k, the variance of the As-LowLAD estimator is reduced to one-eighth of the variance of the OS-LowLAD estimator, and is much smaller than the variance of the OS-LowLSR estimator.

Up to now, we have the first-order derivative estimators $\{\hat m^{(1)}(x_i)\}_{i=1}^n$ on the discrete points $\{x_i\}_{i=1}^n$. To estimate the first-order derivative function, we suggest two strategies for different noise levels of the derivative data: the cubic spline interpolation in Knott (2000) for 'good' derivative estimators, and the local polynomial regression in Brown and Levine (2007) and De Brabanter et al. (2013) for 'bad' derivative estimators. Here, the terms 'good' and 'bad' indicate small and large estimation variances of the derivative estimators, respectively.

5. Second- and Higher-Order Derivative Estimation

In this section, we generalize our robust method for the first-order derivative estimation to the second- and higher-order derivatives estimation.

5.1. Second-Order Derivative Estimation

Define the second-order difference quotients as

$$Y_{ij}^{(2)}=\frac{Y_{i-j}-2Y_i+Y_{i+j}}{j^2/n^2},\quad 1\le j\le k,\tag{15}$$

and assume that $m(\cdot)$ is six times continuously differentiable. Then we can decompose (15) into two parts and simplify it by the Taylor expansion as

$$\begin{aligned}Y_{ij}^{(2)}&=\frac{m(x_{i-j})-2m(x_i)+m(x_{i+j})}{j^2/n^2}+\frac{\epsilon_{i-j}-2\epsilon_i+\epsilon_{i+j}}{j^2/n^2}\\&=m^{(2)}(x_i)+\frac{m^{(4)}(x_i)}{12}\frac{j^2}{n^2}+\frac{m^{(6)}(x_i)}{360}\frac{j^4}{n^4}+o\left(\frac{j^4}{n^4}\right)+\frac{\epsilon_{i-j}-2\epsilon_i+\epsilon_{i+j}}{j^2/n^2}.\end{aligned}$$

Since i is fixed as j varies, the conditional expectation of $Y_{ij}^{(2)}$ given ϵ_i is

$$\mathrm{E}[Y_{ij}^{(2)}|\epsilon_i]=m^{(2)}(x_i)+\frac{m^{(4)}(x_i)}{12}\frac{j^2}{n^2}+\frac{m^{(6)}(x_i)}{360}\frac{j^4}{n^4}+o\left(\frac{j^4}{n^4}\right)+(-2\epsilon_i)\frac{n^2}{j^2}.$$

This results in the true regression model as

$$Y_{ij}^{(2)} = \alpha_{i2} + \alpha_{i4} d_j^2 + \alpha_{i6} d_j^4 + o\left(d_j^4\right) + \alpha_{i0} d_j^{-2} + \delta_{ij}, \quad 1 \le j \le k,$$

where $\alpha_i = (\alpha_{i0}, \alpha_{i2}, \alpha_{i4}, \alpha_{i6})^T = (-2\epsilon_i, m^{(2)}(x_i), m^{(4)}(x_i)/12, m^{(6)}(x_i)/360)^T$, and the errors $\delta_{ij} = \frac{\epsilon_{i+j} + \epsilon_{i-j}}{j^2/n^2}$. If ϵ_i has a symmetric density about zero, then $\tilde{\delta}_{ij} = \frac{j^2}{n^2}\delta_{ij} = \epsilon_{i+j} + \epsilon_{i-j}$ has median 0 (see Appendix D). Following the similar procedure as in the first-order derivative estimation, our LowLAD estimator of $m^{(2)}(x_i)$ is defined as

$$\hat{m}^{(2)}_{\text{LowLAD}}(x_i) = \hat{\alpha}_{i2}, \tag{16}$$

where

$$\begin{aligned}(\hat{\alpha}_{i0}, \hat{\alpha}_{i2}, \hat{\alpha}_{i4})^T &= \arg\min_a \sum_{j=1}^{k} \left|Y_{ij}^{(2)} - (a_{i2} + a_{i4} d_j^2 + a_{i0} d_j^{-2})\right| W_j \\ &= \arg\min_a \sum_{j=1}^{k} \left|\tilde{Y}_{ij}^{(2)} - (a_{i0} + a_{i2} d_j^2 + a_{i4} d_j^4)\right|\end{aligned}$$

with $a = (a_{i0}, a_{i2}, a_{i4})^T$, $W_j = d_j^2$, and $\tilde{Y}_{ij}^{(2)} = Y_{i-j} - 2Y_i + Y_{i+j}$. The following theorem shows that $\hat{m}^{(2)}_{\text{LowLAD}}(x_i)$ behaves similarly as $\hat{m}^{(1)}_{\text{LowLAD}}(x_i)$.

Theorem 10 *Assume that ϵ_i are iid random errors whose density $f(\cdot)$ is continuous and symmetric about zero. Then as $k \to \infty$ and $k/n \to 0$, $\hat{\alpha}_{i2}$ in (16) is asymptotically normally distributed with*

$$\text{Bias}[\hat{\alpha}_{i2}] = -\frac{m^{(6)}(x_i)}{792}\frac{k^4}{n^4} + o\left(\frac{k^4}{n^4}\right), \quad \text{Var}[\hat{\alpha}_{i2}] = \frac{2205}{16h(0)^2}\frac{n^4}{k^5} + o\left(\frac{n^4}{k^5}\right),$$

where $h(0) = \int_{-\infty}^{\infty} f^2(x)\mathrm{d}x$. The optimal k that minimizes the AMSE is

$$k_{opt} \approx 3.93 \left(\frac{1}{h(0)^2 m^{(6)}(x_i)^2}\right)^{1/13} n^{12/13},$$

and, consequently, the minimum AMSE is

$$\text{AMSE}[\hat{\alpha}_{i2}] \approx 0.24 \left(\frac{m^{(6)}(x_i)^{10}}{h(0)^{16}}\right)^{1/13} n^{-8/13}.$$

5.2. Higher-Order Derivative Estimation

We now propose a robust method for estimating the higher-order derivatives $m^{(l)}(x_i)$ with $l > 2$ via a two-step procedure. In the first step, we construct a sequence of symmetric difference quotients in which the higher-order derivative is the intercept of the linear regression derived by the Taylor expansion, and in the second step, we estimate the higher-order derivative using the LowLAD method.

When l is odd, let $d = (l+1)/2$. We linearly combine $m(x_{i\pm j})$ subject to

$$\sum_{h=1}^{d}[a_{jd+h} m(x_{i+jd+h}) + a_{-(jd+h)} m(x_{i-(jd+h)})] = m^{(l)}(x_i) + O\left(\frac{j}{n}\right), \quad 0 \le j \le k,$$

where k is a positive integer. We can derive a total of $2d$ equations through the Taylor expansion to solve out the $2d$ unknown parameters. Define

$$Y_{ij}^{(l)} = \sum_{h=1}^{d}[a_{jd+h} Y_{i+jd+h} + a_{-(jd+h)} Y_{i-(jd+h)}],$$

and consider the linear regression

$$Y_{ij}^{(l)} = m^{(l)}(x_i) + \delta_{ij}, \quad 0 \le j \le k,$$

where $\delta_{ij} = \sum_{h=1}^{d}[a_{i,jd+h}\epsilon_{i+jd+h} + a_{i,-(jd+h)}\epsilon_{i-(jd+h)}] + O(j/n)$.

When l is even, let $d = l/2$. We linearly combine $m(x_{i\pm j})$ subject to

$$b_j m(x_i) + \sum_{h=1}^{d}[a_{jd+h} m(x_{i+jd+h}) + a_{-(jd+h)} m(x_{i-(jd+h)})] = m^{(l)}(x_i) + O\left(\frac{j}{n}\right), \quad 0 \le j \le k,$$

where k is a positive integer. We can derive a total of $2d+1$ equations through the Taylor expansion to solve out the $2d+1$ unknown parameters. Define

$$Y_{ij}^{(l)} = b_j Y_i + \sum_{h=1}^{d}[a_{jd+h} Y_{i+jd+h} + a_{-(jd+h)} Y_{i-(jd+h)}],$$

and consider the linear regression

$$Y_{ij}^{(l)} = m^{(l)}(x_i) + b_j\epsilon_i + \delta_{ij}, \quad 0 \le j \le k,$$

where $\delta_{ij} = \sum_{h=1}^{d}[a_{i,jd+h}\epsilon_{i+jd+h} + a_{i,-(jd+h)}\epsilon_{i-(jd+h)}] + O(j/n)$.

When k is large, we suggest to keep the j^2/n^2 term as in (6) to reduce the estimation bias. If $\sum_{h=1}^{d}[a_{i,jd+h}\epsilon_{i+jd+h} + a_{i,-(jd+h)}\epsilon_{i-(jd+h)}]$ has median zero, then we can obtain the higher-order derivative estimators by the LowLAD method and deduce their asymptotic properties by similar arguments as in the previous sections. To save space, we omit the technical details in this paper.

6. Simulation Studies and Empirical Application

In this section, we conduct simulations to evaluate the finite-sample performance of our first- and second-order derivative estimators and compare them with some existing estimators. We also apply our method to a real data set to illustrate its usefulness in practice.

6.1. First-Order Derivative Estimators

We first consider the following three regression functions:

$$m_0(x) = (x) = \sqrt{x(1-x)}\sin((2.1\pi)/(x+0.05)), \quad x \in [0.25, 1],$$
$$m_1(x) = \sin(2\pi x) + \cos(2\pi x) + \log(4/3 + x), \quad x \in [-1, 1],$$
$$m_2(x) = 32e^{-8(1-2x)^2}(1-2x), \quad x \in [0, 1].$$

These three functions were also considered in Hall (2010) and De Brabanter et al. (2013).

For normal errors, we consider the function $m_0(x)$ and compare the LowLAD, RLowLAD and LowLSR estimators. The data set of size 300 is generated from model (1) with errors $\epsilon_i \overset{iid}{\sim} N(0, 0.1^2)$ and is plotted in Figure 1(a). Figure 1 (2) displays the LowLAD (RLowLAD) estimator (use the R package 'L1pack' in Osorio (2015)) and the LowLSR estimator with $k \in \{6, 12, 25, 30, 50\}$. When k is small (see Figure 1(b) and 1(c)), both estimators are noise-corrupted versions of the true first-order derivatives; as k becomes larger (see Figure 1(d)-(f)), our estimator provides a similar performance as the LowLSR estimator. Furthermore, by combining the left part of Figure 1(d), the middle part of 1(e) and the right part of 1(f), more accurate derivative estimators can be obtained for practical use.

In addition, note that the three estimators have the same variation trend, whereas the LowLAD estimator has a slightly large oscillation and the RLowLAD estimator has a similar performance compared to the LowLSR estimator. These simulation results coincide with the theoretical results: the three estimators have the same bias, which explains the same variation trend; the variance ratios are $\mathrm{Var}(\hat{m}^{(1)}_{\mathrm{LowLSR}})/\mathrm{Var}(\hat{m}^{(1)}_{\mathrm{LowLAD}}) \approx 0.64$ and $\mathrm{Var}(\hat{m}^{(1)}_{\mathrm{LowLSR}})/\mathrm{Var}(\hat{m}^{(1)}_{\mathrm{RLowLAD}}) \approx 0.95$, which explains the oscillation performance.

Next, we consider the non-normal errors: 90% of the errors come from $\epsilon \sim N(0, \sigma^2)$ with $\sigma = 0.1$, and the remaining 10% come from $\epsilon \sim N(0, \sigma_0^2)$ with $\sigma_0 = 1$ or 10 corresponding to the low or high contamination level. Figures 3 and 4 present the finite-sample performance of the first-order derivative estimators for the regression functions m_1 and m_2, respectively. They show that the estimated curves of the first-order derivative based on LowLAD fit the true curves more accurately than LowLSR in the presence of heavy-tailed errors. The heavier the tail, the more significant the improvement.

We also compute the mean absolute errors to further assess the performance of the four methods, i.e., LowLAD, RLowLAD, LowLSR and LAD. Since the oscillation of a periodic function depends on its frequency and amplitude, we consider the sine function in the following form as the regression function,

$$m_3(x) = A\sin(2\pi f x), \quad x \in [0, 1].$$

The errors are generated in the above contaminated way. We consider two sample sizes: $n = 100$ and 500, two standard deviations: $\sigma = 0.1$ and 0.5, two contaminated standard deviations: $\sigma_0 = 1$ and 10, two frequencies: $f = 0.5$ and 1, and two amplitudes: $A = 1$ and 10.

We use the following adjusted mean absolute error (AMAE) as the criterion of performance evalution:

$$\mathrm{AMAE}(k) = \frac{1}{n-2k}\sum_{i=k+1}^{n-k}\left|\hat{m}^{(1)}(x_i) - m^{(1)}(x_i)\right|.$$

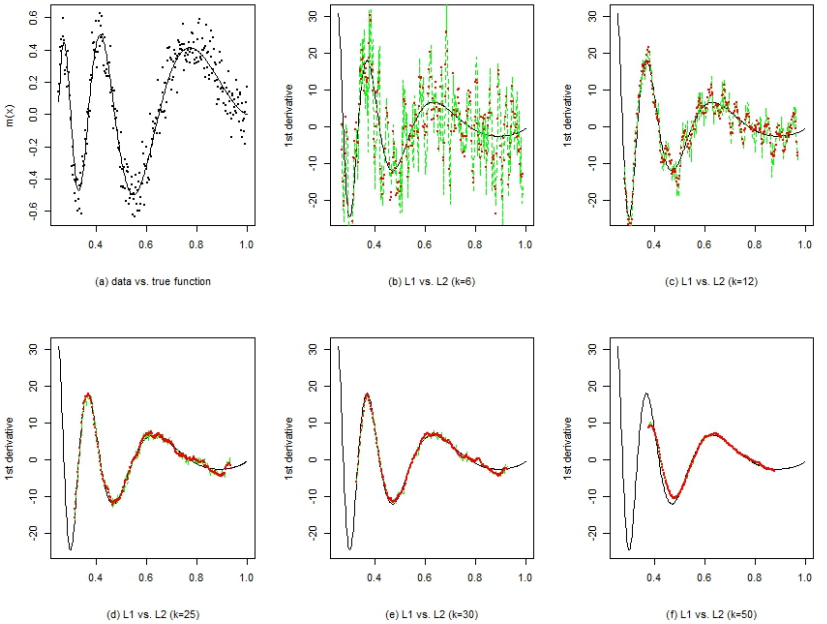

Figure 1: The comparison between the LowLAD and LowLSR estimators. (a) Simulated data set of size 300 from model (1) with equidistant $x_i \in [0.25, 1]$, $\epsilon_i \overset{iid}{\sim} N(0, 0.1^2)$, and the true regression function $m_0(x)$ (bold line). (b)-(f) The first-order LowLAD derivative estimators (green points) and the first-order LowLSR derivative estimators (red dashed line) for $k \in \{6, 9, 12, 25, 30, 50\}$. As a reference, the true first-order derivative fucntion is also plotted (bold line).

Due to the heavy computation (for example, it needs more than 48 hours for the case $n = 500$ and $k = n/5 = 100$ based on 1000 repetitions on our personal computer), we choose $k = n/5$ uniformly.

Table 3 reports the simulation results based on 1000 repetitions. The numbers outside and inside the parentheses represent the mean and standard deviation of the AMAE, respectively. It is evident that RLowLAD performs uniformly better than LowLAD and performs the best for most of cases. In particular for the cases with $\sigma_0 = 2\sigma$, the contamination is very light and thus LowLSR is better than LowLAD; while for the cases with $\sigma_0 = 10\sigma$, the contamination is very heavy and thus LowLSR is worse than LowLAD. These simulation results coincide with the theoretical results.

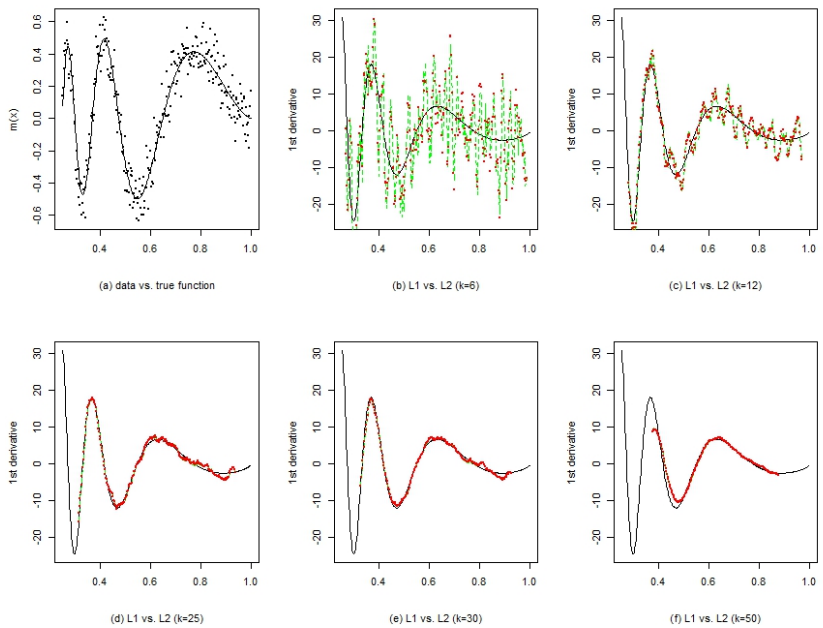

Figure 2: The comparison between the RLowLAD and LowLSR estimators for the same data set as in Figure 1

6.2. Second-Order Derivative Estimators

To assess the finite-sample performance of the second-order derivative estimators, we consider the same regression functions as in Section 6.1. Figures 5 and 6 present the estimated curves of the second-order derivatives of m_1 and m_2, respectively. It shows that our LowLAD estimator fits the true curves more accurately than the LowLSR estimator in all settings.

We further compare LowLAD with two other well-known methods: the local polynomial regression with $p = 5$ (use R package 'locpol' in Cabrera (2012)) and the penalized smoothing splines with $norder = 6$ and $method = 4$ (use R package 'pspline' in Ramsay and Ripley (2013)). For simplicity, we consider the simple version of m_3 with $A = 5$ and $f = 1$:

$$m_4(x) = 5\sin(2\pi x), \quad x \in [0, 1].$$

We let $n = 500$, and generate the errors in the same way as in Section 6.1. With 1000 repetitions, the simulation results are reported in Figures 7 and 8 which indicate that our

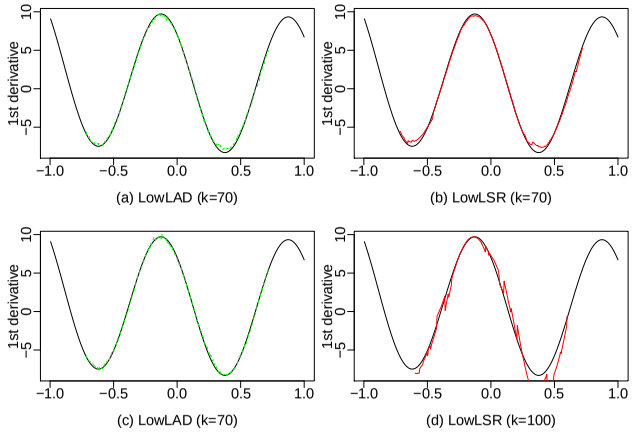

Figure 3: (a-b) The true first-order derivative function (bold line), LowLAD (green line) and LowLSR estimators (red line). Model (1) with equidistant $x_i \in [-1, 1]$, regression function m_1, and $\epsilon \sim 90\%N(0, 0.1^2) + 10\%N(0, 1^2)$. (c-d) The same designs as in (a-b) except $\epsilon \sim 90\%N(0, 0.1^2) + 10\%N(0, 10^2)$.

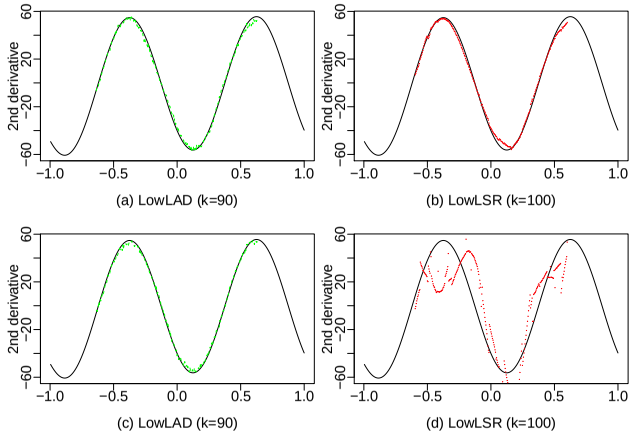

Figure 4: (a-d) The true first-order derivative function (bold line), LowLAD (green line) and LowLSR estimators (red line). The same designs as in Figure 3 except the regression function being m_2.

robust estimator is superior to the existing methods in the presence of sharp-peak and heavy-tailed errors.

6.3. House Price of China in Latest Ten Years

In reality, there are many data sets recorded by year, month, week, day, hour, minute, etc. For example, human growth is usually recorded by year, and temperature is recorded by hour, day or month. In this section, we apply RLowLAD to the data set of house price in two cities of China, i.e., Beijing and Jinan. We collect these monthly data from the web: http://www.creprice.cn/ (see Figure 9), which last from January 2008 to July 2018 and have size 127. We analyze this date set in two steps. Firstly, we apply our method to estimate the first-order derivative with $k = 8$ for RLowLAD and $k = 6$ for lower-order RLowLAD, where the lower-order means that we conduct the Taylor expansion to order 2 instead of order 4. Secondly, we define the relative growth rate as the ratio between the RLowLAD estimator and the house price at the same month, and then plot the relative growth rates in Figures 10 and 11. In the last ten years, the house price goes through tricycle fast increasing, and the monthly growth rate is larger than 0 most of the time with the maximum value at about 0.05.

7. Conclusion and Extensions

In this paper, we propose a robust differenced method for estimating the first- and higher-order derivatives of the regression function in nonparametric models. The new method consists of two main steps: first construct a sequence of symmetric difference quotients, and second estimate the derivatives using the LowLAD regression. The main contributions are as follows:

(1) Unlike LAD, our proposed LowLAD has the unique property of *double robustness* (or *robustness*[2]. Specifically, it is robust not only to heavy-tailed error distributions (like LAD), but also to low density of the error term at a specific quantile (LAD needs a high value of the error density at median; otherwise, the relative efficiency of LAD can be arbitrarily small compared with LowLAD). Following Theorem 1, the asymptotic variance of the LowLAD estimator includes the term $g(0) = 2\int_{-\infty}^{\infty} f^2(x)dx = 2\int_{-\infty}^{\infty} f(F^{-1}(\tau))d\tau$, which implies that we are able to utilize the information of the whole error density. While for the LAD estimator, its variance depends on a single value $f(0)$ only. In this sense, the LowLAD estimator is more robust than the LAD estimator.

(2) Our proposed LowLAD does not require the error distribution to have a zero median, and so is more flexible than LAD. To be more specific, our symmetric differenced errors are guaranteed to have a zero median and a positive symmetric density in a neighborhood of zero, regardless of whether or not the distribution of the original error is symmetric. While for LAD, we must require the error distribution to have a zero median, and consequently, the practical usefulness of LAD will be rather limited.

(3) More surprisingly, as an extension of LowLAD, our proposed RLowLAD based on random difference is asymptotically equivalent to the infinitely composite quantile regression (CQR) estimator. *In other words, running one RLowLAD regression is equivalent to combining infinitely many quantile regressions.*

(4) Lastly, it is also worthwhile to mention that the differences between LowLAD and LAD are strikingly distinct from the differences between LowLSR and LS. For the same data and the same tuning parameter k, we have LS = LowLSR, whereas LAD $\neq$ LowLAD. What is more, RLowLAD is able to further improve the estimation efficiency compared with LowLAD, while RLowLSR, the LS counterpart of RLowLAD, is not able to improve efficiency relative to LowLSR.

LowLAD is a new idea to explore the information of density function by combining first-order difference and LAD. We can adopt the third-order symmetric difference $\{(Y_{i+j} - Y_{i-j}) + (Y_{i+l} - Y_{i-l})\}$ or the third-order random difference $\{(Y_{i+j} + Y_{i+l}) - (Y_{i+u} + Y_{i+v})\}$, even higher-order difference, to explore the information of density function. Whether and how to achieve the Cramer-Rao Lower bound deserves further study. These questions would be investigated in a separate paper.

In this paper, we focus on the derivative estimation with fixed designs and iid errors. With minor technical extensions, the proposed method can be extended to random designs with heteroskedastic errors. Further extensions to linear model, high-dimensional model for variable selection, semiparametric model, and change-point detection are also possible.

Appendix A. Proof of Theorem 1

Proposition 11 *If ϵ_i are iid with a continuous, positive density $f(\cdot)$ in a neighborhood of the median, then $\tilde{\zeta}_{ij} = (\epsilon_{i+j} - \epsilon_{i-j})/2$ (j=1,..., k) are iid with median 0 and a continuous, positive, symmetric density $g(\cdot)$, where*

$$g(x) = 2\int_{-\infty}^{\infty} f(2x+\epsilon)f(\epsilon)\mathrm{d}\epsilon.$$

Proof of Proposition 11 The distribution of $\tilde{\zeta}_{ij} = (\epsilon_{i+j} - \epsilon_{i-j})/2$ is

$$\begin{aligned} F_{\tilde{\zeta}_{ij}}(x) &= P((\epsilon_{i+j} - \epsilon_{i-j})/2 \leq x) \\ &= \iint_{\epsilon_{i+j} \leq 2x+\epsilon_{i-j}} f(\epsilon_{i+j})f(\epsilon_{i-j})\mathrm{d}\epsilon_{i+j}\mathrm{d}\epsilon_{i-j} \\ &= \int_{-\infty}^{\infty}\{\int_{-\infty}^{2x+\epsilon_{i-j}} f(\epsilon_{i+j})\mathrm{d}\epsilon_{i+j}\}f(\epsilon_{i-j})\mathrm{d}\epsilon_{i-j} \\ &= \int_{-\infty}^{\infty} F(2x+\epsilon_{i-j})f(\epsilon_{i-j})\mathrm{d}\epsilon_{i-j}. \end{aligned}$$

Then the density of $\tilde{\zeta}_{ij}$ is

$$g(x) \triangleq \frac{\mathrm{d}F_{\tilde{\zeta}_{ij}}(x)}{\mathrm{d}x} = 2\int_{-\infty}^{\infty} f(2x+\epsilon_{i-j})f(\epsilon_{i-j})\mathrm{d}\epsilon_{i-j}.$$

The density $g(\cdot)$ is symmetric due to

$$\begin{aligned} g(-x) &= 2\int_{-\infty}^{\infty} f(-2x+\epsilon_{i-j})f(\epsilon_{i-j})\mathrm{d}\epsilon_{i-j} \\ &= 2\int_{-\infty}^{\infty} f(\epsilon_{i-j})f(\epsilon_{i-j}+2x)\mathrm{d}\epsilon_{i-j} \\ &= g(x). \end{aligned}$$

Therefore, we have

$$\begin{aligned} F_{\tilde{\zeta}_{ij}}(0) &= \int_{-\infty}^{\infty} F(\epsilon_{i-j})f(\epsilon_{i-j})\mathrm{d}\epsilon_{i-j} = \frac{1}{2}F^2(\epsilon_{i-j})\,|_{-\infty}^{\infty} = \frac{1}{2}, \\ g(0) &= 2\int_{-\infty}^{\infty} f^2(\epsilon_{i-j})\mathrm{d}\epsilon_{i-j}. \end{aligned}$$

■

Proof of Theorem 1 Rewrite the objective function as

$$S_n(b) = \frac{1}{n}\sum_j f_n\left(\tilde{Y}_{ij}|b\right),$$

where

$$f_n\left(\tilde{Y}_{ij}|b\right) = \left|\tilde{Y}_{ij}^{(1)} - b_{i1}d_j - b_{i3}d_j^3\right|\frac{1}{h}1(0 < d_j \leq h)$$

with $b = (b_{i1}, b_{i3})^T$ and $h = k/n$. Define $X_j = \left(d_j, d_j^3\right)^T$ and $H = \mathrm{diag}\{h, h^3\}$. Note that $\arg\min_b S_n(b) = \arg\min_b [S_n(b) - S_n(\beta)]$, where $\beta = \left(m^{(1)}(x_i), m^{(3)}(x_i)/6\right)^T$.

We first show that $H\left(\widehat{\beta} - \beta\right) = o_p(1)$, where $\widehat{\beta} = (\hat{\beta}_{i1}, \hat{\beta}_{i3})^T$. We use Lemma 4 of Porter and Yu (2015) to show the consistency. Essentially, we need to show that

(i) $\sup_{b\in\mathcal{B}} |S_n(b) - S_n(\beta) - \mathrm{E}[S_n(b) - S_n(\beta)]| \xrightarrow{p} 0$,

(ii) $\inf_{\|H(b-\beta)\|>\delta} \mathrm{E}[S_n(b) - S_n(\beta)] > \varepsilon$ for n large enough, where $\mathcal{B}$ is a compact parameter space for β, and δ and ε are fixed positive small numbers.

We use Lemma 2.8 of Pakes and Pollard (1989) to show (i), where

$$\mathcal{F}_n = \left\{f_n\left(\tilde{Y}|b\right) - f_n\left(\tilde{Y}|\beta\right) : b \in \mathcal{B}\right\}.$$

Note that $\mathcal{F}_n$ is Euclidean (see, e.g., Definition 2.7 of Pakes and Pollard (1989) for the definiton of an Euclidean-class of functions) by applying Lemma 2.13 of Pakes and Pollard (1989), where $\alpha = 1$, $f(\cdot, t_0) = 0$, $\phi(\cdot) = \|X_j\|\frac{1}{h}1(0 < d_j \leq h)$ and the envelope function is $F_n(\cdot) = M\phi(\cdot)$ for some finite constant M. Since $\mathrm{E}[F_n] = \mathrm{E}\left[\|X_j\|\frac{1}{h}1(0 < d_j \leq h)\right] = O(h) < \infty$, Lemma 2.8 of Pakes and Pollard (1989) implies

$$\sup_{b\in\mathcal{B}} |S_n(b) - S_n(\beta) - E[S_n(b) - S_n(\beta)]| \xrightarrow{p} 0.$$

As to $\inf_{\|H(b-\beta)\|>\delta} E[S_n(b) - S_n(\beta)]$, by Proposition 1 of Wang and Scott (1994),

$$\begin{aligned} &\mathrm{E}[S_n(b) - S_n(\beta)] \\ \doteq &\frac{1}{n}\sum_j g(0)\left[X_j^T H^{-1}H(b-\beta)\right]^2\frac{1}{h}1(0 < d_j \leq h) \\ &-\frac{1}{n}\sum_j 2g(0)\left[\frac{m(d_{i+j}) - m(d_{i-j})}{2} - X_j^T\beta\right]\left[X_j^T H^{-1}H(b-\beta)\right]\frac{1}{h}1(0 < d_j \leq h) \\ \gtrsim &\delta^2 - h^5\delta, \end{aligned}$$

where $\doteq$ means that the higher-order terms are omitted, and $\gtrsim$ means the left side is bounded blow by a constant times the right side.

We then derive the asymptotic distribution of $\sqrt{nh}H\left(\widehat{\beta} - \beta\right)$ by applying the empirical process technique. First, the first order conditions can be written as

$$\frac{1}{n}\sum_j \mathrm{sign}\left(\tilde{Y}_{ij}^{(1)} - Z_j^T H\widehat{\beta}\right)Z_j\frac{\sqrt{h}}{h}1(0 < d_j \leq h) = o_p(1),$$

which is denoted as

$$\frac{1}{n}\sum_j f_n'(\tilde{Y}_{ij}^{(1)}|\widehat{\beta}) \triangleq S_n'\left(\widehat{\beta}\right) = o_p\left(1\right),$$

where $Z_j = H^{-1}X_j$. By Example 2.9 of Pakes and Pollard (1989), $\mathcal{F}_n'$ forms an Euclidean-class of functions with envelope $F_n' = \|Z_j\|\frac{\sqrt{h}}{h}1(0 < d_j \le h)$, where $\mathcal{F}_n' = \left\{f_n'(\tilde{Y}_{ij}^{(1)}|b) : b \in \mathcal{B}\right\}$, and $E\left[F_n'^2\right] < \infty$. So by Lemma 2.17 of Pakes and Pollard (1989) and $H\left(\widehat{\beta}-\beta\right) = o_p(1)$,

$$\mathbb{G}_n\left(f_n'(\tilde{Y}_{ij}^{(1)}|\widehat{\beta})\right) = \mathbb{G}_n\left(f_n'(\tilde{Y}_{ij}^{(1)}|\beta)\right) + o_p(1),$$

where $\mathbb{G}_n\left(f\right) = \sqrt{n}\left(P_n - P\right)f$ is the standardized empirical process, and P_n is the empirical measure of the original data. Since

$$\sqrt{n}\sum_j\left(\mathrm{E}\left[f_n'(\tilde{Y}_{ij}^{(1)}|\widehat{\beta})\right] - \mathrm{E}\left[f_n'(\tilde{Y}_{ij}^{(1)}|\beta)\right]\right) \doteq -\sqrt{nh}\frac{2g(0)}{nh}\sum_j Z_j Z_j^T H\left(\widehat{\beta}-\beta\right),$$

and

$$\frac{1}{nh}\sum_j \mathrm{sign}\left(\tilde{Y}_{ij}^{(1)} - Z_j^T H\beta\right)Z_j 1(0 < d_j \le h)$$

$$-\frac{1}{nh}\sum_j \mathrm{sign}\left(\tilde{Y}_{ij}^{(1)} - \frac{m\left(d_{i+j}\right) - m(d_{i-j})}{2}\right)Z_j 1(0 < d_j \le h) \doteq \frac{2g(0)}{nh}\sum_j Z_j d_j^5 \frac{m^{(5)}(x_i)}{5!},$$

we have

$$\sqrt{nh}\left(H\left(\widehat{\beta}-\beta\right) - \left[\frac{1}{nh}\sum_j Z_j Z_j^T\right]^{-1}\frac{1}{nh}\sum_j Z_j d_j^5\frac{m^{(5)}(x_i)}{5!}\right)$$

$$\doteq \frac{1}{2g(0)}\left[\frac{1}{nh}\sum_j Z_j Z_j^T\right]^{-1}\frac{1}{\sqrt{nh}}\sum_j \mathrm{sign}\left(\tilde{\zeta}_{ij}^{(1)}\right)Z_j 1(0 < d_j \le h).$$

In other words,

$$2g(0)V_k\left(\widehat{\beta}-\beta - V_k^{-2}\sum_{j=1}^k X_j d_j^5\frac{m^{(5)}(x_i)}{5!}\right) \doteq V_k^{-1}\sum_{j=1}^k \mathrm{sign}\left(\tilde{\zeta}_{ij}^{(1)}\right)X_j,$$

where $V_k = (\sum_{j=1}^k X_j X_j^T)^{1/2}$ is a symmetric positive definite matrix. By Cramér-Wold device and Lyapunov CLT, we complete the proof of asymptotic normality.

The bias of $\hat{\beta}_{i1}$ is

$$\mathrm{Bias}[\hat{\beta}_{i1}] \doteq [1,0]\left(\sum_j X_j X_j^T\right)^{-1}\sum_{j=1}^k X_j d_j^5\frac{m^{(5)}(x_i)}{5!} = -\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4}.$$

and the variance is

$$\mathrm{Var}[\hat{\beta}_{i1}] \doteq \frac{1}{4g(0)^2}[1,0]\left(\sum_j X_j X_j^T\right)^{-1}\begin{bmatrix}1\\0\end{bmatrix} \approx \frac{75}{16g(0)^2}\frac{n^2}{k^3}.$$

Combining the squared bias and the variance, we obtain the AMSE

$$\mathrm{AMSE}[\hat{\beta}_{i1}] = \frac{m^{(5)}(x_i)^2}{504^2}\frac{k^8}{n^8} + \frac{75}{16g(0)^2}\frac{n^2}{k^3}. \tag{17}$$

To minimize (17) with respect to k, we take the first-order derivative of (17) and yield the gradient as

$$\frac{\mathrm{dAMSE}[\hat{\beta}_{i1}]}{\mathrm{d}k} = \frac{m^{(5)}(x_i)^2}{31752}\frac{k^7}{n^8} - \frac{225}{16g(0)^2}\frac{n^2}{k^4}.$$

Our optimization problem is to solve $\frac{\mathrm{dAMSE}[\hat{\beta}_{i1}]}{\mathrm{d}k} = 0$. So we obtain

$$k_{opt} = \left(\frac{893025}{2g(0)^2 m^{(5)}(x_i)^2}\right)^{1/11} n^{10/11} \approx 3.26\left(\frac{1}{g(0)^2 m^{(5)}(x_i)^2}\right)^{1/11} n^{10/11},$$

and

$$\mathrm{AMSE}[\hat{\beta}_{i1}] \approx 0.19(m^{(5)}(x_i)^6/g(0)^{16})^{1/11}n^{-8/11}.$$

Appendix B. Proof of Theorem 2

Rewrite the objective function as a U-process,

$$S_n\left(b\right) = \sum_{l<j} f_n\left(Y_{i+j}, Y_{i+l}|b\right),$$

where

$$f_n\left(Y_{i+j}, Y_{i+l}|b\right) = \left|Y_{i+j} - Y_{i+l} - b_1(d_j - d_l) - b_{i2}(d_j^2 - d_l^2) - b_3(d_j^3 - d_l^3) - b_4(d_j^4 - d_l^4)\right| \cdot \frac{1}{h^2}1(0 < |d_j| \le h)1(0 < |d_l| \le h)$$

with $b = (b_{i1}, b_{i2}, b_{i3}, b_{i4})^T$ and $h = k/n$. Define $U_n = \frac{2}{n(n-1)}S_n\left(b\right)$, $H = \mathrm{diag}\left\{h, h^2, h^3, h^4\right\}$ and $X_{jl} = \left(d_j - d_l, d_j^2 - d_l^2, d_j^3 - d_l^3, d_j^4 - d_l^4\right)^T$. Note that $\arg\min_b S_n\left(b\right) = \arg\min_b U_n(b) = \arg\min_b\left[U_n(b) - U_n\left(\beta\right)\right]$, where $\beta = \left(m^{(1)}(x_i), m^{(2)}(x_i)/2!, m^{(3)}(x_i)/3!, m^{(4)}(x_i)/4!\right)^T$.

We first show that $H\left(\widehat{\beta}-\beta\right) = o_p(1)$, where $\widehat{\beta} = (\hat{\beta}_{i1}^{\mathrm{RLowLAD}}, \hat{\beta}_{i2}^{\mathrm{RLowLAD}}, \hat{\beta}_{i3}^{\mathrm{RLowLAD}}, \hat{\beta}_{i4}^{\mathrm{RLowLAD}})^T$. We use Lemma 4 of Porter and Yu (2015) to show the consistency. Essentially, we need to show that

(i) $\sup_{b\in\mathcal{B}}\left|U_n\left(b\right) - U_n\left(\beta\right) - \mathrm{E}\left[U_n\left(b\right) - U_n\left(\beta\right)\right]\right| \xrightarrow{p} 0,$

(ii) $\inf_{\|H(b-\beta)\|>\delta} \mathrm{E}\left[U_n(b) - U_n(\beta)\right] > \varepsilon$ for n large enough, where $\mathcal{B}$ is a compact parameter space for β, and δ and ε are fixed positive small numbers.

We use Theorem A.2 of Ghosal et al. (2000) to show (i), where

$$\mathcal{F}_n = \left\{ f_n\left(Y_{i+j}, Y_{i+l}|b\right) - f_n\left(Y_{i+j}, Y_{i+l}|\beta\right) : b \in \mathcal{B} \right\}.$$

Note that $\mathcal{F}_n$ forms an Euclidean-class of functions by applying Lemma 2.13 of Pakes and Pollard (1989), where $\alpha = 1$, $f(\cdot, t_0) = 0$, $\phi(\cdot) = \|X_{jl}\| \frac{1}{h^2} 1(|d_j| \leq h) 1(|d_l| \leq h)$ and the envelope function is $F_n(\cdot) = M\phi(\cdot)$ for some finite constant M. It follows that

$$N\left(\varepsilon \|F_n\|_{Q,2}, \mathcal{F}_n, L_2(Q)\right) \lesssim \varepsilon^{-C}$$

for any probability measure Q and some positive constant C, where $\lesssim$ means the left side is bounded by a constant times the right side. Hence,

$$\frac{1}{n}\mathrm{E}\left[\int_0^\infty \log N\left(\varepsilon, \mathcal{F}_n, L_2\left(U_2^n\right)\right) d\varepsilon\right] \lesssim \frac{1}{n}\sqrt{\mathrm{E}\left[F_n^2\right]} \int_0^\infty \log \frac{1}{\varepsilon} d\varepsilon = O\left(\frac{1}{n}\right),$$

where U_2^n is the random discrete measure putting mass $\frac{1}{n(n-1)}$ on each of the points (Y_{i+j}, Y_{i+l}). Next, by Lemma A.2 of Ghosal et al. (2000), the projections

$$\overline{f}_n\left(Y_{i+j}|b\right) = \int f_n\left(Y_{i+j}, Y_{i+l}|b\right) dF_{Y_{i+l}}(Y_{i+l})$$

satisfy

$$\sup_Q N\left(\varepsilon \left\|\overline{F}_n\right\|_{Q,2}, \overline{\mathcal{F}}_n, L_2(Q)\right) \lesssim \varepsilon^{-2C},$$

where $\overline{\mathcal{F}}_n = \left\{ \overline{f}_n\left(Y_{i+j}|b\right) - \overline{f}_n\left(Y_{i+j}|\beta\right) : b \in \mathcal{B} \right\}$, and $\overline{F}_n$ is an envelope of $\overline{\mathcal{F}}_n$. Thus

$$\frac{1}{\sqrt{n}}\mathrm{E}\left[\int_0^\infty \log N\left(\varepsilon, \overline{\mathcal{F}}_n, L_2\left(P_n\right)\right) d\varepsilon\right] \lesssim \frac{1}{\sqrt{n}}\sqrt{E\left[\overline{F}_n^2\right]} \int_0^\infty \log \frac{1}{\varepsilon} d\varepsilon = O\left(\frac{1}{\sqrt{n}}\right).$$

By Theorem A.2 and Markov's inequality, $\sup_{b\in\mathcal{B}} \left|U_n(b) - U_n(\beta) - \mathrm{E}\left[U_n(b) - U_n(\beta)\right]\right| \xrightarrow{p} 0$.

As to $\inf_{\|H(b-\beta)\|>\delta} E\left[U_n(b) - U_n(\beta)\right]$, by Proposition 1 of Wang and Scott (1994),

$$\begin{aligned}
&\mathrm{E}\left[U_n(b) - U_n(\beta)\right] \\
\doteq &\frac{2}{n(n-1)} \sum_{l<j} \frac{g(0)}{2} \left[X_{jl}^T H^{-1} H\left(b-\beta\right)\right]^2 \frac{1}{h^2} 1(0 < |d_j| \leq h) 1(0 < |d_l| \leq h) \\
&- \frac{2}{n(n-1)} \sum_{l<j} g(0) \left[m\left(d_{i+j}\right) - m(d_{i+l}) - X_{jl}^T\beta\right] \left[X_{jl}^T H^{-1} H\left(b-\beta\right)\right] \\
&\frac{1}{h^2} 1(0 < |d_j| \leq h) 1(0 < |d_l| \leq h) \\
\gtrsim &\delta^2 - h^5\delta.
\end{aligned}$$

We then derive the asymptotic distribution of $\sqrt{nh}H\left(\widehat{\beta} - \beta\right)$. First, by Theorem A.1 of Ghosal et al. (2000), we approximate the first order conditions by an empirical process. Second, we derive the asymptotic distribution of $\sqrt{nh}H\left(\widehat{\beta} - \beta\right)$ by applying the empirical process technique.

First, the first order conditions can be written as

$$\frac{2}{n(n-1)} \sum_{l<j} \mathrm{sign}\left(Y_{i+j} - Y_{i+l} - Z_{jl}^T H\widehat{\beta}\right) Z_{jl} \frac{\sqrt{h}}{h^2} 1(0 < |d_j| \leq h) 1(0 < |d_l| \leq h) = o_p(1),$$

which is denoted as

$$\frac{2}{n(n-1)} \sum_{l<j} f_n'(Y_{i+j}, Y_{i+l}|\widehat{\beta}) \triangleq \frac{2}{n(n-1)} S_n'\left(\widehat{\beta}\right) = o_p(1),$$

where $Z_{jl} = H^{-1}X_{jl}$. By Example 2.9 of Pakes and Pollard (1989), $\mathcal{F}_n'$ forms an Euclidean-class of functions with envelope $F_n' = \|Z_{jl}\| \frac{\sqrt{h}}{h^2} 1(|d_j| \leq h) 1(|d_l| \leq h)$, where

$$\mathcal{F}_n' = \left\{ f_n'(Y_{i+j}, Y_{i+l}|b) : b \in \mathcal{B} \right\},$$

so

$$N\left(\varepsilon \left\|F_n'\right\|_{Q,2}, \mathcal{F}_n', L_2(Q)\right) \lesssim \varepsilon^{-V}$$

for any probability measure Q and some positive constant V. By Theorem A.1 and the discussion following Theorem A.1 and A.2 in Ghosal et al. (2000), it follows that

$$\begin{aligned}
&n\mathrm{E}\left[\sup_{f_n'\in\mathcal{F}_n'} \left|U_2^n f_n' - 2P_n\left[\overline{E}_2\left[f_n'(Y_{i+j}, Y_{i+l}|b)\right]\right] - \overline{E}\left[f_n'(Y_{i+j}, Y_{i+l}|b)\right]\right|\right] \\
\lesssim &E\left[\int_0^\infty \log N\left(\varepsilon, \mathcal{F}_n', L_2\left(U_2^n\right)\right) d\varepsilon\right] \lesssim \int_0^1 \log\left(\varepsilon^{-V}\right) d\varepsilon \sqrt{\mathrm{E}\left[\left(F_n'\right)^2\right]} \lesssim h^{-1/2},
\end{aligned}$$

where $\overline{E}_2[\cdot]$ takes expectation on Y_{i+l} and also averages over d_l, and $\overline{E}[\cdot]$ takes expectation on (Y_{i+j}, Y_{i+l}) and also averages over (d_j, d_l). As a result,

$$\sqrt{n} \sup_{f_n'\in\mathcal{F}_n'} \left|U_2^n f_n' - 2P_n\left[\overline{E}_2[\cdot]\left[f_n'(Y_{i+j}, Y_{i+l}|b)\right]\right] + \overline{E}\left[f_n'(Y_{i+j}, Y_{i+l}|b)\right]\right| = o_p(1),$$

which implies

$$\sqrt{n}\left(2P_n\left[\overline{E}_2\left[f_n'(Y_{i+j}, Y_{i+l}|\widehat{\beta})\right]\right] - \overline{E}\left[f_n'(Y_{i+j}, Y_{i+l}|\widehat{\beta})\right]\right) = o_p(1),$$

where

$$\begin{aligned}
&\overline{E}_2\left[f_n'(Y_{i+j}, Y_{i+l}|b)\right] \\
= &\frac{\sqrt{h}}{nh^2} \sum_l \left[2F_\epsilon\left(Y_{i+j} - m(d_{i+l}) - Z_{jl}^T Hb\right) - 1\right] Z_{jl} 1(0 < |d_j| \leq h) 1(0 < |d_l| \leq h)
\end{aligned}$$

with $F_\epsilon(\cdot)$ being the cumulative distribution function of ϵ. In other words,

$$2\mathbb{G}_n\left(\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]\right)+\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]=o_p(1).$$

By Lemma 2.13 of Pakes and Pollard (1989), $\mathcal{F}_{1n}'=\left\{\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|b)\right]:b\in\mathcal{B}\right\}$ is Euclidean with envelope $F_{1n}=\frac{\sqrt{h}}{nh^2}\sum_l\|Z_{jl}\|1(0<|d_j|\le h)1(0<|d_l|\le h)$, so by Lemma 2.17 of Pakes and Pollard (1989) and $H\left(\widehat{\beta}-\beta\right)=o_p(1)$,

$$\mathbb{G}_n\left(\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]\right)=\mathbb{G}_n\left(\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\right)+o_p(1).$$

As a result,

$$\begin{aligned}
&2\mathbb{G}_n\left(\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\right)+\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]\\
=&2\sqrt{n}P_n\left(\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\right)-2\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\\
+&\sqrt{n}\left(\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]-\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\right)+\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\\
=&2\sqrt{n}P_n\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l})\right]+2\sqrt{n}P_n\left(\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]-\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l})\right]\right)\\
+&\sqrt{n}\left(\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]-\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\right)-\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\\
=&2\sqrt{n}P_n\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l})\right]+\sqrt{n}\left(\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]-\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\right)\\
+&\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\\
=&o_p(1),
\end{aligned}$$

where

$$\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l})\right]=\frac{\sqrt{h}}{nh^2}\sum_l\left[2F_\epsilon(\epsilon_{i+j})-1\right]Z_{jl}1(0<|d_j|\le h)1(0<|d_l|\le h)$$

satisfies $E\left[\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l})\right]\right]=0$, and the second to last equality is from

$$\sqrt{n}P_n\left(\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]-\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l})\right]\right)\doteq\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right].$$

Since

$$\begin{aligned}
\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|b)\right]=&\frac{\sqrt{h}}{n^2h^2}\sum_{l,j}Z_{jl}1(0<|d_j|\le h)1(0<|d_l|\le h)\\
&\cdot\left[2\int F_\epsilon\left(\epsilon+m(d_{i+j})-m(d_{i+l})-Z_{jl}^THb\right)-1\right]f(\epsilon)\,d\epsilon,
\end{aligned}$$

we have

$$\sqrt{n}\left(\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\widehat{\beta})\right]-\overline{E}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\right)\doteq-\sqrt{nh}g(0)\left(\frac{1}{n^2h^2}\sum_{l,j}Z_{jl}Z_{jl}^T\right)H\left(\widehat{\beta}-\beta\right),$$

$$\sqrt{nE}\left[f_n'(Y_{i+j},Y_{i+l}|\beta)\right]\doteq\sqrt{nh}g(0)\frac{1}{n^2h^2}\sum_{l,j}Z_{jl}\left(d_j^5-d_l^5\right)\frac{m^{(5)}(x_i)}{5!}.$$

In summary,

$$\begin{aligned}
&\sqrt{nh}\left(H\left(\widehat{\beta}-\beta\right)-\left(\frac{1}{n^2h^2}\sum_{l,j}Z_{jl}Z_{jl}^T\right)^{-1}\left(\frac{1}{n^2h^2}\sum_{l,j}Z_{jl}\left(d_j^5-d_l^5\right)\right)\frac{m^{(5)}(x_i)}{5!}\right)\\
\doteq&2g(0)^{-1}\left(\frac{1}{n^2h^2}\sum_{l,j}Z_{jl}Z_{jl}^T\right)^{-1}\sqrt{n}P_n\overline{E}_2\left[f_n'(Y_{i+j},Y_{i+l})\right],
\end{aligned}$$

Thus, the asymptotic bias is

$$e^TH^{-1}\left(\frac{1}{n^2h^2}\sum_{l,j}Z_{jl}Z_{jl}^T\right)^{-1}\left(\frac{1}{n^2h^2}\sum_{l,j}Z_{jl}\left(d_j^5-d_l^5\right)\right)\frac{m^{(5)}(x_i)}{5!}=-\frac{m^{(5)}(x_i)}{504}\frac{k^4}{n^4},$$

and the asymptotic variance is

$$\frac{4}{kg(0)^2}e^TH^{-1}G^{-1}VG^{-1}H^{-1}e=\frac{75}{24g(0)^2}\frac{n^2}{k^3},$$

where $e=(1,0,0,0)^T$, $G=\frac{1}{k^2}\sum_{l,j}Z_{jl}Z_{jl}^T$, and $V=\frac{1}{3k}\sum_{j=-k}^k(\frac{1}{k}\sum_{l=-k}^kZ_{jl})(\frac{1}{k}\sum_{l=-k}^kZ_{jl})^T$ with $\mathrm{Var}\left(2F_\epsilon\left(\epsilon_{i+j}\right)-1\right)=1/3$.

Appendix C. Proof of Theorem 9

Proof of Theorem 9 Following the proof of Theorem 1, the leading term of the bias is

$$\mathrm{Bias}[\hat{\beta}_{i11}]=\frac{m^{(2)}(x_i)}{2}\frac{k^4+2k^3i-2ki^3-i^3}{n(k^3+3k^2i+3ki^2+i^3)},$$

and the leading term of the variance is

$$\mathrm{Var}[\hat{\beta}_{i11}]=\frac{3}{f(0)^2}\frac{n^2}{k^3+3k^2i+3ki^2+i^3}.$$

■

Appendix D. Proof of Theorem 10

Proposition 12 *If the errors ϵ_i are iid with a symmetric (about 0), continuous, positive density function $f(\cdot)$, then $\tilde{\delta}_{ij}=\epsilon_{i+j}+\epsilon_{i-j}$ (j=1, ..., k) are iid with $Median[\tilde{\delta}_{ij}]=0$ and a continuous, positive density $h(\cdot)$ in a neighborhood of 0, where*

$$h(x)=\int_{-\infty}^{\infty}f(x-\epsilon)f(\epsilon)\mathrm{d}\epsilon.$$

Proof of Proposition 12 The distribution of $\tilde{\delta}_{ij} = \epsilon_{i+j} + \epsilon_{i-j}$ is

$$\begin{aligned}
F_{\tilde{\delta}_{ij}}(x) =& P(\epsilon_{i+j} + \epsilon_{i-j} \le x) \\
=& \iint_{\epsilon_{i+j} \le x - \epsilon_{i-j}} f(\epsilon_{i+j}) f(\epsilon_{i-j}) \mathrm{d}\epsilon_{i+j} \mathrm{d}\epsilon_{i-j} \\
=& \int_{-\infty}^{\infty} \{ \int_{-\infty}^{x-\epsilon_{i-j}} f(\epsilon_{i+j}) \mathrm{d}\epsilon_{i+j} \} f(\epsilon_{i-j}) \mathrm{d}\epsilon_{i-j} \\
=& \int_{-\infty}^{\infty} F(x - \epsilon_{i-j}) f(\epsilon_{i-j}) \mathrm{d}\epsilon_{i-j}.
\end{aligned}$$

Then the density of $\tilde{\delta}_{ij}$ is

$$h(x) \triangleq \frac{\mathrm{d}F_{\tilde{\delta}_{ij}}(x)}{\mathrm{d}x} = \int_{-\infty}^{\infty} f(x - \epsilon_{i-j}) f(\epsilon_{i-j}) \mathrm{d}\epsilon_{i-j}.$$

By the symmetry of the density function, we have

$$\begin{aligned}
F_{\tilde{\delta}_{ij}}(0) =& \int_{-\infty}^{\infty} F(-\epsilon_{i-j}) f(\epsilon_{i-j}) \mathrm{d}\epsilon_{i-j} \\
=& \int_{-\infty}^{\infty} (1 - F(\epsilon_{i-j})) f(\epsilon_{i-j}) \mathrm{d}\epsilon_{i-j} \\
=& (F - \frac{1}{2} F^2(\epsilon_{i-j})) \mid_{-\infty}^{\infty} \\
=& \frac{1}{2}, \\
h(0) =& \int_{-\infty}^{\infty} f^2(\epsilon_{i-j}) \mathrm{d}\epsilon_{i-j}.
\end{aligned}$$

■

Proof of Theorem 10 Following the proof of Theorem 1, the asymptotic bias is

$$\mathrm{Bias}[\hat{\alpha}_{i2}] = -\frac{m^{(6)}(x_i)}{792} \frac{k^4}{n^4} + o\left(\frac{k^4}{n^4}\right),$$

and the asymptotic variance of $\hat{\alpha}_{i1}$ is

$$\mathrm{Var}[\hat{\alpha}_{i2}] = \frac{2205}{64h(0)^2} \frac{n^4}{k^5} + o\left(\frac{n^4}{k^5}\right).$$

Combining the squared bias and the variance, we obtain the AMSE as

$$\mathrm{AMSE}[\hat{\alpha}_{i2}] = \frac{m^{(6)}(x_i)^2}{792^2} \frac{k^8}{n^8} + \frac{2205}{64h(0)^2} \frac{n^4}{k^5}. \tag{18}$$

To minimize (18) with respect to k, we take the first-order derivative of (18) and yield the gradient as

$$\frac{\mathrm{dAMSE}[\hat{\alpha}_{i2}]}{\mathrm{d}k} = \frac{m^{(6)}(x_i)^2}{78408} \frac{k^7}{n^8} - \frac{11025}{16h(0)^2} \frac{n^4}{k^6}.$$

Now the optimization problem is to solve $\frac{\mathrm{dAMSE}[\hat{\alpha}_{i2}]}{\mathrm{d}k} = 0$. So we obtain

$$k_{opt} = \left(\frac{108056025}{8h(0)^2 m^{(6)}(x_i)^2}\right)^{1/13} n^{12/13} \approx 3.54 \left(\frac{1}{h(0)^2 m^{(6)}(x_i)^2}\right)^{1/13} n^{12/13},$$

and

$$\mathrm{AMSE}[\hat{\alpha}_{i2}] \approx 0.29 (m^{(6)}(x_i)^{10} / h(0)^{16})^{1/13} n^{-8/13}.$$

■

Appendix E. Variance Ratios for Popular Distributions

Variance Ratios for Eight Error Distributions

In this subsection, we investigate the variance ratio of the RLowLAD estimator with respect to the LowLSR and LAD estimators for eight error distributions.

From the main text,

$$\mathrm{R}_{\mathrm{LowLSR}}(f) = 3\sigma^2 g(0)^2, \quad \mathrm{R}_{\mathrm{LAD}}(f) = \frac{3g(0)^2}{4f(0)^2}.$$

Example 1: Normal distribution. The error density function is $f(\epsilon) = \frac{1}{\sqrt{2\pi}} \exp(-\epsilon^2/2)$, which implies

$$f(0) = \frac{1}{\sqrt{2\pi}}, \quad g(0) = 2\int_{-\infty}^{\infty} \frac{1}{2\pi} e^{-\epsilon^2} \mathrm{d}\epsilon = \frac{1}{\sqrt{\pi}}.$$

Due to $\sigma^2 = 1$, we have

$$\mathrm{R}_{\mathrm{LowLSR}}(f) = 3/\pi \approx 0.95, \quad \mathrm{R}_{\mathrm{LAD}}(f) = 1.50.$$

In other words, the RLowLAD estimator is almost as efficient as the LowLSR estimator for the normal distribution.

Example 2: Mixed normal distribution. The error density function is

$$f(\epsilon; \alpha, \sigma_0) = (1 - \alpha) \frac{1}{\sqrt{2\pi}} e^{-\epsilon^2/2} + \alpha \frac{1}{\sqrt{2\pi}\sigma_0} e^{-\epsilon^2/(2\sigma_0^2)}$$

with $0 < \alpha \le 1/2$ and $\sigma_0 > 1$, which implies

$$\begin{aligned}
f(0;\alpha,\sigma_0) =&(1-\alpha)\frac{1}{\sqrt{2\pi}} + \alpha\frac{1}{\sqrt{2\pi}\sigma_0},\\
g(0;\alpha,\sigma_0) =&2\int_{-\infty}^{\infty} f^2(\epsilon)\mathrm{d}\epsilon\\
=&2\left\{(1-\alpha)^2\int_{-\infty}^{\infty}\frac{1}{2\pi}\mathrm{e}^{-\epsilon^2}\mathrm{d}\epsilon + 2\alpha(1-\alpha)\int_{-\infty}^{\infty}\frac{1}{2\pi\sigma_0}\mathrm{e}^{-(\frac{\epsilon^2}{2}+\frac{\epsilon^2}{2\sigma_1^2})}\mathrm{d}\epsilon\right.\\
&\left.+\alpha^2\int_{-\infty}^{\infty}\frac{1}{2\pi\sigma_0^2}\mathrm{e}^{-\frac{x^2}{\sigma_0^2}}\mathrm{d}\epsilon\right\}\\
=&2\left\{(1-\alpha)^2\frac{1}{2\sqrt{\pi}} + 2\alpha(1-\alpha)\frac{1}{\sqrt{2\pi}\sqrt{1+\sigma_0^2}} + \alpha^2\frac{1}{2\sqrt{\pi}\sigma_0}\right\},\\
\mathrm{Var}(\epsilon_i) =&(1-\alpha)+\alpha\sigma_0^2 \triangleq \sigma^2.
\end{aligned}$$

Thus,

$$\begin{aligned}
\mathrm{R}_{\mathrm{LowLSR}}(\alpha,\sigma_0) =&12\left\{(1-\alpha)+\alpha\sigma_0^2\right\}\left\{(1-\alpha)^2\frac{1}{2\sqrt{\pi}} + 2\alpha(1-\alpha)\frac{1}{\sqrt{2\pi}\sqrt{1+\sigma_0^2}} + \alpha^2\frac{1}{2\sqrt{\pi}\sigma_0}\right\}^2,\\
\mathrm{R}_{\mathrm{LAD}}(\alpha,\sigma_0) =&\frac{3\left\{(1-\alpha)^2\frac{1}{2\sqrt{\pi}} + 2\alpha(1-\alpha)\frac{1}{\sqrt{2\pi}\sqrt{1+\sigma_0^2}} + \alpha^2\frac{1}{2\sqrt{\pi}\sigma_0}\right\}^2}{\left\{(1-\alpha)\frac{1}{\sqrt{2\pi}} + \alpha\frac{1}{\sqrt{2\pi}\sigma_0}\right\}^2}.
\end{aligned}$$

In particular,

$$\begin{aligned}
\mathrm{R}_{\mathrm{LowLSR}}(0.1,3) \approx&1.80, \quad \mathrm{R}_{\mathrm{LowLSR}}(0.1,10) \approx 10.90,\\
\mathrm{R}_{\mathrm{LAD}}(0.1,3) \approx&1.38, \quad \mathrm{R}_{\mathrm{LAD}}(0.1,10) \approx 1.27.
\end{aligned}$$

Example 3: t distribution. The error density function is

$$f(\epsilon;\nu) = \frac{\Gamma((\nu+1)/2)}{\sqrt{\nu\pi}\Gamma(\nu/2)}\left(1+\frac{\epsilon^2}{\nu}\right)^{-(\nu+1)/2)}$$

with the degree of freedom $\nu > 2$, which implies

$$\begin{aligned}
f(0) =&\frac{\Gamma((\nu+1)/2)}{\sqrt{\nu\pi}\Gamma(\nu/2)},\\
g(0) =&2\int_{-\infty}^{\infty}\frac{1}{\nu\pi}\left(\frac{\Gamma((\nu+1)/2)}{\Gamma(\nu/2)}\right)^2\left(1+\frac{\epsilon^2}{\nu}\right)^{-(\nu+1)}\mathrm{d}\epsilon = \frac{2}{\sqrt{\nu\pi}}\left(\frac{\Gamma((\nu+1)/2)}{\Gamma(\nu/2)}\right)^2\frac{\Gamma(\nu+1/2)}{\Gamma(\nu+1)}.
\end{aligned}$$

Due to $\sigma^2 = \nu/(\nu-2)$, we have

$$\begin{aligned}
\mathrm{R}_{\mathrm{LowLSR}}(\nu) =&\frac{12}{(\nu-2)\pi}\left(\frac{\Gamma((\nu+1)/2)}{\Gamma(\nu/2)}\right)^4\left(\frac{\Gamma(\nu+1/2)}{\Gamma(\nu+1)}\right)^2,\\
\mathrm{R}_{\mathrm{LAD}}(\nu) =&3\left(\frac{\Gamma((\nu+1)/2)}{\Gamma(\nu/2)}\right)^2\left(\frac{\Gamma(\nu+1/2)}{\Gamma(\nu+1)}\right)^2.
\end{aligned}$$

For $\nu = 3$,

$$\mathrm{R}_{\mathrm{LowLSR}}(3) = 75/(4\pi^2) \approx 1.90, \quad \mathrm{R}_{\mathrm{LAD}}(3) = 75/64 \approx 1.17.$$

Example 4: Laplace (double exponential) distribution. The error density function is $f(\epsilon) = \frac{1}{2}\exp(-|\epsilon|)$, which implies

$$f(0) = \frac{1}{2}, \quad g(0) = 2\int_{-\infty}^{\infty}\frac{1}{4}e^{-2|\epsilon|}\mathrm{d}\epsilon = \frac{1}{2}.$$

Due to $\sigma^2 = 2$, we have

$$\mathrm{R}_{\mathrm{LowLSR}}(f) = 1.50, \quad \mathrm{R}_{\mathrm{LAD}}(f) = 0.75.$$

Example 5: Logistic distribution. The error density function is $f(\epsilon) = \exp(\epsilon)/(\exp(\epsilon)+1)^2$, which implies

$$f(0) = \frac{1}{4}, \quad g(0) = 2\int_{-\infty}^{\infty}\frac{e^{2\epsilon}}{(\exp(\epsilon)+1)^4}\mathrm{d}\epsilon = \frac{1}{3}.$$

Due to $\sigma^2 = \pi^2/3$, we have

$$\mathrm{R}_{\mathrm{LowLSR}}(f) = \pi^2/9 \approx 1.10, \quad \mathrm{R}_{\mathrm{LAD}}(f) = 4/3 \approx 1.33.$$

Example 6: Cauchy distribution. The error density function is $f(\epsilon) = 1/(\pi(1+\epsilon^2))$, which implies

$$f(0) = \frac{1}{\pi}, \quad g(0) = \frac{1}{\pi}, \quad \mathrm{Var}(\epsilon) = \infty.$$

Thus,

$$\mathrm{R}_{\mathrm{LowLSR}}(f) = \infty, \quad \mathrm{R}_{\mathrm{LAD}}(f) = 0.75.$$

Example 7: Mixed double Gamma distribution. The error density function is

$$f(\epsilon;\alpha,k) = (1-\alpha)\frac{1}{2}e^{-|\epsilon|} + \alpha\frac{1}{2\Gamma(k+1)}|\epsilon|^k e^{-|\epsilon|}$$

with parameter $k > 0$ and the mixed ratio α, which implies

$$\begin{aligned}
f(0;\alpha,k) =&\frac{1-\alpha}{2} + \frac{\alpha}{2\Gamma(k+1)},\\
g(0;\alpha,k) =&2\int_{-\infty}^{\infty} f^2(\epsilon;\alpha,k)\mathrm{d}\epsilon\\
=&\int_{-\infty}^{\infty}\frac{(1-\alpha)^2}{2}e^{-2|\epsilon|} + \frac{(1-\alpha)\alpha}{\Gamma(k+1)}|\epsilon|^k e^{-2|\epsilon|} + \frac{\alpha^2}{2\Gamma(k+1)^2}|\epsilon|^{2k}e^{-2|\epsilon|}\mathrm{d}\epsilon\\
=&\frac{(1-\alpha)^2}{2} + \frac{\alpha(1-\alpha)}{2^k} + \frac{\alpha^2\Gamma(2k+1)}{2^{2k+1}\Gamma^2(k+1)},\\
\mathrm{Var}(\epsilon|\alpha,k) =&1+\alpha k.
\end{aligned}$$

Thus,

$$\mathrm{R}_{\mathrm{LowLSR}}(\alpha,k) =3(1+\alpha k)\left\{\frac{(1-\alpha)^2}{2}+\frac{\alpha(1-\alpha)}{2^k}+\frac{\alpha^2\Gamma(2k+1)}{2^{2k+1}\Gamma^2(k+1)}\right\},$$
$$\mathrm{R}_{\mathrm{LAD}}(\alpha,k) = 3\left\{\frac{(1-\alpha)^2}{2}+\frac{\alpha(1-\alpha)}{2^k}+\frac{\alpha^2\Gamma(2k+1)}{2^{2k+1}\Gamma^2(k+1)}\right\}^2\Bigg/\left\{4\left(\frac{1-\alpha}{2}+\frac{\alpha}{2\Gamma(k+1)}\right)^2\right\}.$$

In particular,

$$\begin{aligned}\mathrm{R}_{\mathrm{LowLSR}}(0.1,3)\approx&1.63,\quad \mathrm{R}_{\mathrm{LowLSR}}(0.1,10)\approx 2.44,\\ \mathrm{R}_{\mathrm{LAD}}(0.1,3)\approx&0.68,\quad \mathrm{R}_{\mathrm{LAD}}(0.1,10)\approx 0.68.\end{aligned}$$

Example 8: Bimodal distribution (mixed normal distribution with different locations). The error density function is

$$f(\epsilon;\mu)=0.5\frac{1}{\sqrt{2\pi}}e^{-(\epsilon-\mu)^2/2}+0.5\frac{1}{\sqrt{2\pi}}e^{-(\epsilon+\mu)^2/2}$$

with $\mu>0$, which implies

$$f(0;\mu)=\frac{e^{-\mu^2}}{\sqrt{2\pi}},\quad g(0;\mu)=\frac{1+e^{-\mu^2}}{2\sqrt{\pi}},\quad \sigma^2=1+\mu^2.$$

Thus,

$$\mathrm{R}_{\mathrm{LowLSR}}(\mu)=3(1+\mu^2)\frac{1+e^{-\mu^2}}{2\sqrt{\pi}},\quad \mathrm{R}_{\mathrm{LAD}}(\mu)=3\left(\frac{1+e^{-\mu^2}}{2\sqrt{\pi}}\right)^2\Bigg/\left(4\left(\frac{e^{-\mu^2}}{\sqrt{2\pi}}\right)^2\right).$$

In particular,

$$\begin{aligned}\mathrm{R}_{\mathrm{LowLSR}}(1)\approx&0.89,\quad \mathrm{R}_{\mathrm{LowLSR}}(3)\approx 2.39,\\ \mathrm{R}_{\mathrm{LAD}}(1)\approx&5.18,\quad \mathrm{R}_{\mathrm{LAD}}(3)\approx 2.46\times 10^7.\end{aligned}$$

Variance Ratio Functions for Three Error Distributions

To further illustrate the trade-off between the sharp-peak and heavy-tailed errors, we consider three of the above examples: Examples 2, 3, and 8.

For the mixed normal distribution, we list in Table 4 the critical value of σ_0 such that the LowLAD (or RLowLAD) and LowLSR estimators have the same variance. When σ_0 is smaller than the critical value, the LowLAD (or RLowLAD) estimator is more efficient than the LowLSR estimator. The overall comparison curve is given in Figure 12. Since LowLAD and RLowLAD have a close relationship, we consider only RLowLAD in the following comparisons. Another critical σ_0 curve comparing RLowLAD and LAD is provided in Figure 13. When σ_0 is larger than the critical value, the RLowLAD estimator is more efficient than the LAD estimator.

For the $t(\nu)$ distribution, the variance ratio function between LowLSR and RLowLAD is shown in Figure 14. We see that the ratio between LowLSR and RLowLAD is greater than 1 for small degrees of freedom (from 3 to 18). As ν increases, the ratio converges to $3/\pi\approx 0.95$. This phenomenon is expected because the T distribution converges to the normal distribution as $\nu\to\infty$, and the variance ratio for the normal distribution is 0.95. Figure 15 shows the ratio between LAD and RLowLAD, where we see that this ratio is greater than 1 for all degrees of freedom. As ν increases, the ratio converges to 1.50. This is expected from the stirling formula $\Gamma(\nu)=\sqrt{2\pi}e^{-\nu}\nu^{\nu-1/2}$, which implies $\mathrm{R}_{\mathrm{LAD}}(f)\to 1.50$ as $\nu\to\infty$.

For the bimodal distribution, the variance ratio function between LowLSR and RLowLAD is given in Figure 16. As μ increases, the ratio becomes smaller and achieves the minimum value 0.89 at point 1.12, and then becomes larger and tends to ∞. The variance ratio function between LAD and RLowLAD is shown in Figure 17. As μ increases, the ratio diverges fast to ∞.

Appendix F. One Key Difference between LS and LAD Methods

For the LS method, the LS estimator and the LowLSR estimator are asymptotically equivalent; while for the LAD method, the asymptotic variances of the LAD estimator and the LowLAD estimator are very different, although their asymptotic biases are the same. To understand this discrepancy, we show that the objective functions of the LS and LowLSR estimation are asymptotically equivalent while those of the LAD and LowLAD estimation are not. Note that the objective function of the LowLSR estimation is equivalent to

$$\begin{aligned}&4\textstyle\sum_{j=1}^k\left(\tilde{Y}_{ij}^{(1)}-\alpha_{i1}d_j-\alpha_{i3}d_j^3\right)^2\\ =&\textstyle\sum_{j=1}^k\left(Y_{i+j}-Y_{i-j}-2\alpha_{i1}d_j-2\alpha_{i3}d_j^3\right)^2\\ =&\textstyle\sum_{j=1}^k\left(Y_{i+j}-Y_{i-j}-(\alpha_{i0}-\alpha_{i0})-\alpha_{i1}\left(d_j-d_{-j}\right)-\alpha_{i2}\left(d_j^2-d_{-j}^2\right)-\alpha_{i3}\left(d_j^3-d_{-j}^3\right)-\alpha_{i4}\left(d_j^4-d_{-j}^4\right)\right)^2\\ =&\textstyle\sum_{j=1}^k\left(Y_{i+j}-\alpha_{i0}-\alpha_{i1}d_j-\alpha_{i2}d_j^2-\alpha_{i3}d_j^3-\alpha_{i4}d_j^4\right)^2\\ +&\textstyle\sum_{j=1}^k\left(Y_{i-j}-\alpha_{i0}-\alpha_{i1}d_{-j}-\alpha_{i2}d_{-j}^2-\alpha_{i3}d_{-j}^3-\alpha_{i4}d_{-j}^4\right)^2\\ -&2\textstyle\sum_{j=1}^k\left(Y_{i+j}-\alpha_{i0}-\alpha_{i1}d_j-\alpha_{i2}d_j^2-\alpha_{i3}d_j^3-\alpha_{i4}d_j^4\right)\left(Y_{i-j}-\alpha_{i0}-\alpha_{i1}d_{-j}-\alpha_{i2}d_{-j}^2-\alpha_{i3}d_{-j}^3-\alpha_{i4}d_{-j}^4\right),\end{aligned}$$

where $d_{-j}=-j/n$. It can be shown that the cross term in the last equality is a higher-order term and is negligible, and the first two terms constitute exactly the objective function of the least squares estimation. More specifically, we can show that

$$\begin{aligned}\hat{m}_{\mathrm{LS}}^{(1)}(x_i)-m^{(1)}(x_i)-\mathrm{Bias}&\doteq(0,1,0,0,0)\left(\textstyle\sum_{j=-k}^k X_jX_j'\right)^{-1}\textstyle\sum_{j=-k}^k X_j\epsilon_{i+j}\\ &=\textstyle\sum_{j=-k}^k D_j\epsilon_{i+j}\end{aligned}$$

with $X_j=\left(1,d_j,d_j^2,d_j^3,d_j^4\right)^T$ and

$$D_j=n\frac{j(75k^4+150k^3-75k+25)-j^3\left(105k^2+105k-35\right)}{k(8k^6+28k^5+14k^4-35k^3-28k^2+7k+6)}=-D_{-j},$$

and

$$\begin{aligned}
&\hat{m}^{(1)}_{\text{LowLSR}}(x_i) - m^{(1)}(x_i) - \text{Bias} \\
&\doteq (1,0)\left[\begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}\left(\sum_{j=1}^k X_j X_j'\right)\begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}^T\right]^{-1} \\
&\cdot \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}\sum_{j=1}^k X_j \tfrac{\epsilon_{i+j}-\epsilon_{i-j}}{2} \\
&= \sum_{j=1}^k 2D_j \tfrac{\epsilon_{i+j}-\epsilon_{i-j}}{2} = \sum_{j=-k}^k D_j \epsilon_{i+j}.
\end{aligned}$$

The influence functions of $\hat{m}^{(1)}_{\text{LS}}(x_i)$ and $\hat{m}^{(1)}_{\text{LowLSR}}(x_i)$ are exactly the same, so the contribution of the cross term is null.

On the contrary, the objective function of the LowLAD estimator is equivalent to

$$\begin{aligned}
&2\sum_{j=1}^k \left|\tilde{Y}^{(1)}_{ij} - \beta_{i1}d_j - \beta_{i3}d_j^3\right| \\
&= \sum_{j=1}^k \left|Y_{i+j} - Y_{i-j} - (\beta_{i0}-\beta_{i0}) - \beta_{i1}(d_j - d_{-j}) - \beta_{i2}\left(d_j^2 - d_{-j}^2\right) - \beta_{i3}\left(d_j^3 - d_{-j}^3\right) - \beta_{i4}\left(d_j^4 - d_{-j}^4\right)\right| \\
&= \sum_{j=1}^k \left|Y_{i+j} - \beta_{i0} - \beta_{i1}d_j - \beta_{i2}d_j^2 - \beta_{i3}d_j^3 - \beta_{i4}d_j^4\right| + \sum_{j=1}^k \left|Y_{i-j} - \beta_{i0} - \beta_{i1}d_{-j} - \beta_{i2}d_{-j}^2 - \beta_{i3}d_{-j}^3 - \beta_{i4}d_{-j}^4\right| \\
&\quad + \text{extra term},
\end{aligned}$$

where the extra term is equal to

$$\begin{aligned}
&-2\max\left(\text{sign}\left(Y_{i+j} - \beta_{i0} - \beta_{i1}d_j - \beta_{i2}d_j^2 - \beta_{i3}d_j^3 - \beta_{i4}d_j^4\right)\right. \\
&\left.\cdot\text{sign}\left(Y_{i-j} - \beta_{i0} - \beta_{i1}d_{-j} - \beta_{i2}d_{-j}^2 - \beta_{i3}d_{-j}^3 - \beta_{i4}d_{-j}^4\right), 0\right) \\
&\cdot \min\left(\left|Y_{i+j} - \beta_{i0} - \beta_{i1}d_j - \beta_{i2}d_j^2 - \beta_{i3}d_j^3 - \beta_{i4}d_j^4\right|, \left|Y_{i-j} - \beta_{i0} - \beta_{i1}d_{-j} - \beta_{i2}d_{-j}^2 - \beta_{i3}d_{-j}^3 - \beta_{i4}d_{-j}^4\right|\right),
\end{aligned}$$

and cannot be neglected, where $sign(x) = 1$ if $x > 0$ and $sign(x) = -1$ if $x < 0$. More specifically, we can show that

$$\begin{aligned}
&\hat{m}^{(1)}_{\text{LAD}}(x_i) - m^{(1)}(x_i) - \text{Bias} \\
&\doteq (0,1,0,0,0)\left(2f(0)\sum_{j=-k}^k X_j X_j'\right)^{-1}\sum_{j=-k}^k X_j \text{sign}(\epsilon_{i+j}) \\
&= \tfrac{1}{2f(0)}\sum_{j=-k}^k D_j \text{sign}(\epsilon_{i+j}) = \tfrac{1}{f(0)}\sum_{j=1}^k D_j \tfrac{\text{sign}(\epsilon_{i+j})-\text{sign}(\epsilon_{i-j})}{2},
\end{aligned}$$

and

$$\begin{aligned}
&\hat{m}^{(1)}_{\text{LowLAD}}(x_i) - m^{(1)}(x_i) - \text{Bias} \\
&\doteq (1,0)\left[2g(0)\begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}\left(\sum_{j=1}^k X_j X_j'\right)\begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}^T\right]^{-1} \\
&\cdot \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}\sum_{j=1}^k X_j \text{sign}\left(\tfrac{\epsilon_{i+j}-\epsilon_{i-j}}{2}\right) \\
&= \tfrac{1}{g(0)}\sum_{j=1}^k D_j \text{sign}\left(\tfrac{\epsilon_{i+j}-\epsilon_{i-j}}{2}\right).
\end{aligned}$$

So the contribution of the extra term to the influence function is

$$D_j\left[\frac{\text{sign}\left(\frac{\epsilon_{i+j}-\epsilon_{i-j}}{2}\right)}{g(0)} - \frac{\text{sign}(\epsilon_{i+j})-\text{sign}(\epsilon_{i-j})}{2f(0)}\right] = \frac{D_j}{g(0)}\begin{cases} \text{sign}(\epsilon_{i+j}-\epsilon_{i-j}), & \text{if } \epsilon_{i+j}\epsilon_{i-j} > 0, \\ \left(1 - \frac{g(0)}{f(0)}\right)\text{sign}(\epsilon_{i+j}), & \text{if } \epsilon_{i+j}\epsilon_{i-j} < 0, \end{cases}$$

which is not null, where we neglect the event that $\epsilon_{i+j}\epsilon_{i-j} = 0$ because the probability of such an event is zero.

Abstract

The higher order singular value decomposition (HOSVD) of tensors is a generalization of matrix SVD. The perturbation analysis of HOSVD under random noise is more delicate than its matrix counterpart. Recently, polynomial time algorithms have been proposed where statistically optimal estimates of the singular subspaces and the low rank tensors are attainable in the Euclidean norm. In this article, we analyze the sup-norm perturbation bounds of HOSVD and introduce estimators of the singular subspaces with sharp deviation bounds in the sup-norm. We also investigate a low rank tensor denoising estimator and demonstrate its fast convergence rate with respect to the entry-wise errors. The sup-norm perturbation bounds reveal unconventional phase transitions for statistical learning applications such as the exact clustering in high dimensional Gaussian mixture model and the exact support recovery in sub-tensor localizations. In addition, the bounds established for HOSVD also elaborate the one-sided sup-norm perturbation bounds for the singular subspaces of unbalanced (or fat) matrices.

Keywords: HOSVD, Entry-wise perturbation, Gaussian noise, High dimensional clustering.

1. Introduction

A tensor is a multi-array of more than 2 dimensions, which can be viewed as a higher order generalization of matrices. Data of tensor types has been widely available in many fields, such as image and video processing (see Liu et al. (2013), Westin et al. (2002), Hildebrand and Rüegsegger (1997), Li and Li (2010), Vasilescu and Terzopoulos (2002)); latent variable modelling (see Anandkumar et al. (2014), Cichocki et al. (2015), Chaganty and Liang (2013)); genomic signal processing (Omberg et al. (2007), Muralidhara et al. (2011) and Ponnapalli et al. (2011)) and references therein. It is demanding to handle these datasets in order to take the most advantages of the tensor structures. The task is challenging due to the highly non-convexity of tensor related optimization problems. For instance, computing the tensor operator norm is generally NP-hard (see, e.g., Hillar and Lim (2013)) while it can be implemented fast for matrices.

The higher order singular value decomposition (HOSVD) is one machinery to deal with tensors which generalizes the matrix SVD to higher order tensors, see Zheng and Tomioka (2015), De Lathauwer et al. (2000b), Bergqvist and Larsson (2010), Chen and Saad (2009) and Kolda and Bader (2009). The conceptual simplicity and computational efficiency make HOSVD popular. It has been successfully applied to various statistical learning tasks, for instance, face recognition (see Vasilescu and Terzopoulos (2002)), genomic signal processing (see Muralidhara et al. (2011)) and more examples in a survey paper (Acar and Yener (2009)). Basically, the HOSVD unfolds a higher order tensor into matrices and treat it with standard matrix techniques to obtain the principal singular subspaces in each dimension (see more details in Section 2). Although the HOSVD shows appealing effectiveness, there are several fundamental theoretic mysteries yet to be uncovered.

One particularly important question is related to the perturbation of HOSVD when a low rank tensor is contaminated by stochastic noise. The difficulty comes from both methodological and theoretical aspects. The computation of HOSVD is essentially reduced to matrix SVD which can be implemented efficiently. This naive estimator is actually statistically sub-optimal. It is well-known that further power iterations can ameliorate the naive spectral initializations and thus deliver statistically optimal estimators, see more details in Richard and Montanari (2014), Zhang and Xia (2018), Hopkins et al. (2015), Liu et al. (2017) and references therein. Another intriguing phenomenon is on the phase transitions of the signal-to-noise ratio (SNR). Actually, the SNR exhibits distinct computational and statistical phase transitions, while the differences do not exist for matrix SVD. In particular, there is a gap on SNR between statistical optimality and computational optimality for HOSVD, see Zhang and Xia (2018). For introductory simplicity [1], we focus on the third-order tensors. Suppose that an unknown tensor $\mathbf{A} \in \mathbb{R}^{d\times d\times d}$ with multilinear ranks (r, r, r) is planted in a noisy observation $\mathbf{Y}$ with

$$\mathbf{Y} = \mathbf{A} + \mathbf{Z} \in \mathbb{R}^{d\times d\times d}. \tag{1}$$

The noise tensor $\mathbf{Z}$ has i.i.d. entries with $Z(i,j,k) \sim \mathcal{N}(0,\sigma^2)$ for $i,j,k \in [d]$ and noise variance $\sigma^2 > 0$. Here, we denote by $[d] := \{1,\dots,d\}$. The signal strength $\underline{\Lambda}(\mathbf{A})$ is defined as the smallest nonzero singular values of the matrices unfolded from $\mathbf{A}$ (see definitions in Section 3.3). Let $\mathbf{U},\mathbf{V},\mathbf{W} \in \mathbb{R}^{d\times r}$ denote the singular vectors of $\mathbf{A}$ in the corresponding dimensions. It was proved (see Zheng and Tomioka (2015), Zhang and Xia (2018) and Liu et al. (2017)) that if the signal strength $\underline{\Lambda}(\mathbf{A}) \geq D_1\sigma d^{3/4}$ for a large enough constant

$D_1 > 0$, the following bound holds

$$r^{-1/2}\max\Big\{\big\|\hat{\mathbf{U}}\hat{\mathbf{U}}^\top - \mathbf{U}\mathbf{U}^\top\big\|_{\ell_2}, \big\|\hat{\mathbf{V}}\hat{\mathbf{V}}^\top - \mathbf{V}\mathbf{V}^\top\big\|_{\ell_2}, \big\|\hat{\mathbf{W}}\hat{\mathbf{W}}^\top - \mathbf{W}\mathbf{W}^\top\big\|_{\ell_2}\Big\} = O_p\Big(\frac{\sigma d^{1/2}}{\underline{\Lambda}(\mathbf{A})} + \frac{\sigma d^{3/2}}{\underline{\Lambda}^2(\mathbf{A})}\Big),$$

where $\hat{\mathbf{U}}, \hat{\mathbf{V}}, \hat{\mathbf{W}}$ represent the naive SVD obtained from noisy tensor $\mathbf{Y}$ and $\|\cdot\|_{\ell_2}$ denotes the Euclidean norm. Power iterations (also called higher order orthogonal iterations, see De Lathauwer et al. (2000a)) can improve the estimate (denoted by $\widetilde{\mathbf{U}}, \widetilde{\mathbf{V}}, \widetilde{\mathbf{W}}$) to

$$r^{-1/2}\max\Big\{\big\|\widetilde{\mathbf{U}}\widetilde{\mathbf{U}}^\top - \mathbf{U}\mathbf{U}^\top\big\|_{\ell_2}, \big\|\widetilde{\mathbf{V}}\widetilde{\mathbf{V}}^\top - \mathbf{V}\mathbf{V}^\top\big\|_{\ell_2}, \big\|\widetilde{\mathbf{W}}\widetilde{\mathbf{W}}^\top - \mathbf{W}\mathbf{W}^\top\big\|_{\ell_2}\Big\} = O_p\Big(\frac{\sigma d^{1/2}}{\underline{\Lambda}(\mathbf{A})}\Big), \quad (2)$$

which is statistically optimal (see Zhang and Xia (2018)). Moreover, it is demonstrated in Zhang and Xia (2018), built on a hardness conjecture of the hyper-graphical planted clique detection problem, that if $\underline{\Lambda}(\mathbf{A}) = o\big(\sigma d^{3/4}\big)$, then all polynomial time algorithms deliver trivial estimates of $\mathbf{U}, \mathbf{V}, \mathbf{W}$ in general.

One focus of this article is on estimating the linear forms of tensor singular vectors in model (1). More specifically, let $\mathbf{U} = \big(\mathbf{u}_1, \ldots, \mathbf{u}_r\big) \in \mathbb{R}^{d\times r}$ be $\mathbf{A}$'s singular vectors in certain mode, our goal is to estimate $\langle \mathbf{u}_j, \mathbf{x}\rangle$ for fixed $\mathbf{x} \in \mathbb{R}^d$ and $j = 1, \ldots, r$. Through choosing $\mathbf{x}$ all over the canonical basis vectors in $\mathbb{R}^d$, we end up with an estimate of $\mathbf{u}_j$ whose component-wise perturbation bound can be attained. Unlike the ℓ_2-norm perturbation bound, the ℓ_∞ bound can characterize the entry-wise sign consistency and entry-wise significance (i.e. entry-wise magnitude) of singular vectors. The component-wise signs of singular vectors are critical in numerous applications such as community detection (see Florescu and Perkins (2015), Newman (2004), Mitra (2009) and Jin (2015)). The entry-wise significance is advantageous in sub-matrix localizations, see Cai et al. (2015), Ma and Wu (2015) and references therein. In Section 4, we show that the sup-norm perturbation bounds reveal unconventional phase transitions for the exact clustering in high dimensional Gaussian mixture model. Put it simply, algorithms based on the sup-norm bounds require weaker SNR conditions than algorithms driven by the ℓ_2-norm bounds to guarantee exact clustering. Furthermore, it enables us to construct a low rank denoising estimator of $\mathbf{A}$ so that entry-wise denoising is fulfilled. To the best of our knowledge, ours is the first result concerning the low rank tensor denoising with sharp entry-wise deviation bounds. In Section 4, we show that a simple algorithm based on the ℓ_∞ bounds can exactly recover the supports for sub-tensor localizations (see Remark 13).

To better highlight our contributions, suppose that $\mathbf{A}$ is an orthogonally decomposable third order tensor with (in particular, the CP decomposition of orthogonally decomposable tensors)

$$\mathbf{A} = \sum_{k=1}^{r} \lambda_k\big(\mathbf{u}_k \otimes \mathbf{v}_k \otimes \mathbf{w}_k\big), \quad \lambda_1 \geq \ldots \geq \lambda_r > 0 \quad (3)$$

where $\mathbf{U} = (\mathbf{u}_1, \ldots, \mathbf{u}_r), \mathbf{V} = (\mathbf{v}_1, \ldots, \mathbf{v}_r)$ and $\mathbf{W} = (\mathbf{w}_1, \ldots, \mathbf{w}_r)$ are $d \times r$ matrices containing orthonormal columns. The k-th eigengap is written as $\bar{g}_k\big(\mathcal{M}_1(\mathbf{A})\big) = \bar{g}_k\big(\mathcal{M}_2(\mathbf{A})\big) = \bar{g}_k\big(\mathcal{M}_3(\mathbf{A})\big) = \min\big(\lambda_{k-1} - \lambda_k, \lambda_k - \lambda_{k+1}\big)$ where $\mathcal{M}_j(\mathbf{A})$ represents the matrices from unfoldings of $\mathbf{A}$ (see Section 2). We preset $\lambda_0 = +\infty$ and $\lambda_{r+1} = 0$ for notational consistency. We show that, if $\bar{g}_k\big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\big) \geq D_1\big(\sigma\lambda_1 d^{1/2} + \sigma^2 d^{3/2}\big)$ for a large enough absolute constant $D_1 > 0$, then the following bound holds for any $\mathbf{x} \in \mathbb{R}^d$,

$$\Big|\langle \hat{\mathbf{u}}_k, \mathbf{x}\rangle - (1+b_k)^{1/2}\langle \mathbf{u}_k, \mathbf{x}\rangle\Big| = O_p\Big(\|\mathbf{x}\|_{\ell_2}\frac{\lambda_1\sigma + d\sigma^2}{\bar{g}_k\big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\big)}\Big) = O_p\Big(\frac{\|\mathbf{x}\|_{\ell_2}}{d^{1/2}}\Big). \quad (4)$$

where $b_k \in [-1/2, 0]$ is a constant which does not depend on $\mathbf{x}$. The $d \times r$ matrix $\hat{\mathbf{U}} = (\hat{\mathbf{u}}_1, \cdots, \hat{\mathbf{u}}_k)$ represent the empirical left singular vectors of mode-1 unfolding of $\mathbf{Y}$ satisfying model (1).

In the special case that $r = 1$ (rank one spiked tensor PCA model, see Richard and Montanari (2014)) such that $\underline{\Lambda}(\mathbf{A}) = \bar{g}_1\big(\mathcal{M}_1(\mathbf{A})\big) = \lambda_1$, we get from (4) that

$$\Big|\langle \hat{\mathbf{u}}_1, \mathbf{x}\rangle - (1+b_1)^{1/2}\langle \mathbf{u}_1, \mathbf{x}\rangle\Big| = O_p\Big(\frac{\sigma}{\underline{\Lambda}(\mathbf{A})} + \frac{\sigma^2 d}{\underline{\Lambda}^2(\mathbf{A})}\Big)\|\mathbf{x}\|_{\ell_2}. \quad (5)$$

By taking $\mathbf{x}$ over the canonical basis vectors in $\mathbb{R}^d$, the bounds in (5) imply that

$$\big\|\hat{\mathbf{u}}_1 - (1+b_1)^{1/2}\mathbf{u}_1\big\|_{\ell_\infty} = O_p\Big(\Big(\frac{\log d}{d}\Big)^{1/2}\Big) \quad (6)$$

under the eigen-gap condition $\underline{\Lambda}(\mathbf{A}) = \lambda_1 \gg \sigma d^{3/4}$. It is the standard requirement in tensor PCA. [2] Based on (6), we propose a low rank tensor estimator (denoted by $\hat{\mathbf{A}}$) under the same SNR requirements such that

$$\|\hat{\mathbf{A}} - \mathbf{A}\|_{\ell_\infty} = O_p\Big(\Big(\frac{\sigma^2 d}{\lambda_1} + \sigma\Big)\big(\|\mathbf{u}_1\|_{\ell_\infty}\|\mathbf{v}_1\|_{\ell_\infty} + \|\mathbf{u}_1\|_{\ell_\infty}\|\mathbf{w}_1\|_{\ell_\infty} + \|\mathbf{v}_1\|_{\ell_\infty}\|\mathbf{w}_1\|_{\ell_\infty}\big)\Big). \quad (7)$$

Equation (7) shows that the entry-wise denoising bound of the novel estimator $\hat{\mathbf{A}}$ is determined by the coherences of the singular vectors $\mathbf{u}_1, \mathbf{v}_1$ and $\mathbf{w}_1$. In particular, if $\mathbf{u}_1, \mathbf{v}_1, \mathbf{w}_1$ are incoherent so that $\max\{\|\mathbf{u}_1\|_{\ell_\infty}, \|\mathbf{v}_1\|_{\ell_\infty}, \|\mathbf{w}_1\|_{\infty}\} = O\big(\frac{1}{\sqrt{d}}\big)$, then equation (7) implies that

$$\|\hat{\mathbf{A}} - \mathbf{A}\|_{\ell_\infty} = O_p\Big(\frac{\sigma^2}{\lambda_1} + \frac{\sigma}{d}\Big).$$

Our main contribution is on the theoretical front. The HOSVD is essentially the standard SVD computed on an unbalanced matrix where the column size is much larger than the row size. The perturbation tools, such as Wedin's $\sin\Theta$ theorem (Wedin (1972)), characterize the ℓ_2 bounds through the larger dimension, even when the left singular space lies in a low dimensional space. At the high level, the HOSVD is connected to the one-sided spectral analysis (see, e.g.,Zheng and Tomioka (2015), Wang (2015), Cai and Zhang (2016) and references therein) which provide sharp perturbation bounds in ℓ_2-norm. There are recent bounds (see Fan et al. (2016) and Cape et al. (2017)) in ℓ_∞-norm developed under

2. We shall point out that a similar result on matrix SVD has appeared in Koltchinskii and Xia (2016) which is sub-optimal for tensors or unbalanced matrices. Indeed, the result in Koltchinskii and Xia (2016) is established under the eigengap condition $\lambda_1 \geq D_1\sigma d$.

additional constraint (incoherent singular subspaces) and structural noise (sparse noise). To obtain a sharp ℓ_∞-norm bound, we borrow the instruments invented by Koltchinskii and Lounici (2016) and extensively applied in Koltchinskii and Xia (2016). Our framework starts from a second order method of estimating the singular subspaces, which improves the eigengap condition than the first order method. Similar techniques have been proposed for tensor completion (Xia and Yuan (2019)) and tensor PCA (Zheng and Tomioka (2015) and Liu et al. (2017)). The success of this seemingly natural treatment hinges upon delicate dealing with the correlations among higher order terms. We benefit from these ℓ_∞-norm perturbation bounds by proposing a low rank estimator for tensor denoising where the entry-wise deviation error is guaranteed by the tensor incoherence conditions.

We organize our paper as follows. Tensor notations and preliminaries on HOSVD are explained in Section 2. Our main theoretical contributions are presented in Section 3 which includes the ℓ_∞-norm bound of the singular subspace perturbation and the entry-wise accuracy of a low rank tensor denoising estimator. In Section 4, we apply our theoretical results on applications including high dimensional clustering and sub-tensor localizations to manifest the advantages of utilizing ℓ_∞ bounds, where algorithms driven by the ℓ_∞-norm bounds are designed. Results of numerical experiments are displayed in Section 4.3. The proofs are provided in Section 6.

2. Preliminaries on Tensor and HOSVD

2.1. Notations

We first review some notations that will be used through the paper. We use boldfaced upper-case letters to denote tensors or matrices, and use the same letter in normal font with indices to denote its entries. We use boldfaced lower-case letters to represent vectors, and the same letter in normal font with indices to represent its entries. For notationally simplicity, our main context is focused on third-order tensors, while our results can be easily generalized to higher order tensors.

Given a third-order tensor $\mathbf{A} \in \mathbb{R}^{d_1\times d_2\times d_3}$, define a linear mapping $\mathcal{M}_1 : \mathbb{R}^{d_1\times d_2\times d_3} \mapsto \mathbb{R}^{d_1\times(d_2d_3)}$ such that

$$\mathcal{M}_1(\mathbf{A})\big(i_1,(i_2-1)d_3+i_3\big) = A(i_1,i_2,i_3), \quad i_1\in[d_1], i_2\in[d_3], i_3\in[d_3]$$

which is conventionally called the unfolding (or matricization) of tensor $\mathbf{A}$. It is also called the mode-1 unfolding of $\mathbf{A}$. The columns of matrix $\mathcal{M}_1(\mathbf{A})$ are called the mode-1 fibers of $\mathbf{A}$. The corresponding matricizations $\mathcal{M}_2(\mathbf{A})$ and $\mathcal{M}_3(\mathbf{A})$ can be defined in a similar fashion. The multilinear ranks of $\mathbf{A}$ are then defined by:

$$r_1(\mathbf{A}) := \mathrm{rank}\big(\mathcal{M}_1(\mathbf{A})\big), \quad r_2(\mathbf{A}) := \mathrm{rank}\big(\mathcal{M}_2(\mathbf{A})\big), \quad r_3(\mathbf{A}) := \mathrm{rank}\big(\mathcal{M}_3(\mathbf{A})\big)$$

Note that $r_1(\mathbf{A}), r_2(\mathbf{A}), r_3(\mathbf{A})$ are unnecessarily equal with each other in general. We write $\mathbf{r}(\mathbf{A}) := \big(r_1(\mathbf{A}), r_2(\mathbf{A}), r_3(\mathbf{A})\big)$ which are also called the Tucker ranks of $\mathbf{A}$.

The marginal product $\times_1 : \mathbb{R}^{r_1\times r_2\times r_3}\times\mathbb{R}^{d_1\times r_1}\mapsto\mathbb{R}^{d_1\times r_2\times r_3}$ is given by

$$\mathbf{C}\times_1\mathbf{U} = \Big(\sum_{j_1=1}^{r_1} C(j_1,j_2,j_3)U(i_1,j_1)\Big)_{i_1\in[d_1],j_2\in[r_2],j_3\in[r_3]},$$

and $\times_2$ and $\times_3$ are defined similarly. Therefore, we write the multilinear product of tensors $\mathbf{C}\in\mathbb{R}^{r_1\times r_2\times r_3}, \mathbf{U}\in\mathbb{R}^{d_1\times r_1}, \mathbf{V}\in\mathbb{R}^{d_2\times r_2}$ and $\mathbf{W}\in\mathbb{R}^{d_3\times r_3}$ as

$$\mathbf{C}\cdot(\mathbf{U},\mathbf{V},\mathbf{W}) = \mathbf{C}\times_1\mathbf{U}\times_2\mathbf{V}\times_3\mathbf{W}\in\mathbb{R}^{d_1\times d_2\times d_3}.$$

We use $\|\cdot\|$ to denote the operator norm of matrices and $\|\cdot\|_{\ell_2}$ and $\|\cdot\|_{\ell_\infty}$ to denote ℓ_2 and ℓ_∞ norms of vectors, or vectorized matrices and tensors.

2.2. HOSVD and Eigengaps

For a tensor $\mathbf{A}\in\mathbb{R}^{d_1\times d_2\times d_3}$ with multilinear ranks $\mathbf{r}(\mathbf{A}) = \big(r_1(\mathbf{A}), r_2(\mathbf{A}), r_3(\mathbf{A})\big)$, let $\mathbf{U}\in\mathbb{R}^{d_1\times r_1(\mathbf{A})}, \mathbf{V}\in\mathbb{R}^{d_2\times r_2(\mathbf{A})}$ and $\mathbf{W}\in\mathbb{R}^{d_3\times r_3(\mathbf{A})}$ be the left singular vectors of $\mathcal{M}_1(\mathbf{A}), \mathcal{M}_2(\mathbf{A})$ and $\mathcal{M}_3(\mathbf{A})$ respectively, which can be computed efficiently via matricization followed by thin singular value decomposition. The higher order singular value decomposition (HOSVD) refers to the decomposition

$$\mathbf{A} = \mathbf{C}\times_1\mathbf{U}\times_2\mathbf{V}\times_3\mathbf{W} \tag{8}$$

where the $r_1(\mathbf{A})\times r_2(\mathbf{A})\times r_3(\mathbf{A})$ core tensor $\mathbf{C}$ is obtained by $\mathbf{C} := \mathbf{A}\times_1\mathbf{U}^\top\times_2\mathbf{V}^\top\times_3\mathbf{W}^\top$.

Suppose that a noisy version of $\mathbf{A}$ is observed as in model (1) so that

$$\mathbf{Y} = \mathbf{A} + \mathbf{Z}$$

where $\mathbf{Z}\in\mathbb{R}^{d_1\times d_2\times d_3}$ is an unknown noise tensor with i.i.d. entries satisfying $Z(i,j,k)\sim\mathcal{N}(0,\sigma^2)$. By observing $\mathbf{Y}$, our goal is to estimate $\mathbf{U},\mathbf{V}$ and $\mathbf{W}$. An immediate approach is to compute HOSVD of $\mathbf{Y}$. To this end, let $\hat{\mathbf{U}}\in\mathbb{R}^{d_1\times r_1}, \hat{\mathbf{V}}\in\mathbb{R}^{d_2\times r_2}, \hat{\mathbf{W}}\in\mathbb{R}^{d_3\times r_3}$ be the corresponding top singular vectors of $\mathcal{M}_1(\mathbf{Y}), \mathcal{M}_2(\mathbf{Y})$ and $\mathcal{M}_3(\mathbf{Y})$. The key factor characterizing the perturbation bounds of $\hat{\mathbf{U}},\hat{\mathbf{V}}$ and $\hat{\mathbf{W}}$ is the so-called eigengap.

Since the computing of $\hat{\mathbf{U}}$ is essentially via the matrix SVD on $\mathcal{M}_1(\mathbf{A})$, it suffices to consider the eigengaps of matrices. Given a rank r matrix $\mathbf{M}\in\mathbb{R}^{m_1\times m_2}$ with SVD:

$$\mathbf{M} = \sum_{k=1}^{r}\lambda_k\big(\mathbf{g}_k\otimes\mathbf{h}_k\big)$$

where $\mathbf{M}$'s singular values are $\lambda_1\ge\lambda_2\ge\ldots\ge\lambda_r>0$ and $\{\mathbf{g}_1,\ldots,\mathbf{g}_r\}$ are the corresponding left singular vectors and $\{\mathbf{h}_1,\ldots,\mathbf{h}_r\}$ are $\mathbf{M}$'s corresponding right singular vectors. We further introduce $\lambda_0=+\infty$ and $\lambda_{r+1}=0$. The k-th eigengap of matrix $\mathbf{M}$ is then defined by

$$\bar{g}_k(\mathbf{M}) := \min\big(\lambda_k-\lambda_{k+1},\lambda_{k-1}-\lambda_k\big), \quad \forall\ 1\le k\le r.$$

Recall that $\mathbf{U},\hat{\mathbf{U}}\in\mathbb{R}^{d_1\times r_1}$ are the top-r_1 left singular vectors of $\mathcal{M}_1(\mathbf{A})$ and $\mathcal{M}_1(\mathbf{Y})$ respectively. By Davis-Kahan Theorem (Davis and Kahan (1970)) or Wedin's $\sin\Theta$ theorem (Wedin (1972)), we get

$$\|\hat{\mathbf{U}}\hat{\mathbf{U}}^\top-\mathbf{U}\mathbf{U}^\top\| = O\Big(\frac{\|\mathcal{M}_1(\mathbf{Z})\|}{\bar{g}_{r_1}\big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\big)}\Big), \tag{9}$$

which is generally sub-optimal especially when $\mathcal{M}_1(\mathbf{Z})\in\mathbb{R}^{d_1\times(d_2d_3)}$ is unbalanced such that $d_2d_3\gg d_1$. Sharper bounds in ℓ_2-norm concerning one sided perturbation have been derived

in Zheng and Tomioka (2015), Wang (2015) and Cai and Zhang (2016). In this paper, we derive sharp perturbation bounds of $\hat{\mathbf{U}}, \hat{\mathbf{V}}, \hat{\mathbf{W}}$ in ℓ_∞-norm which illustrate unconventional phase transitions for various statistical learning applications. More generally, we will investigate the perturbation bounds of linear forms $\langle \hat{\mathbf{u}}_k, \mathbf{x} \rangle$ for any fixed vector $\mathbf{x} \in \mathbb{R}^{d_1}$. Similar results can be obtained for singular vectors $\hat{\mathbf{V}}$ and $\hat{\mathbf{W}}$.

3. Main Results

3.1. Second Order Method for One-sided Spectral Analysis

The ℓ_∞-norm perturbation bounds for singular subspaces of balanced matrices has been developed in Koltchinskii and Xia (2016). Recall that $\mathbf{u}_k$ denotes the k-th left singular vector of $\mathcal{M}_1(\mathbf{A})$ and $\hat{\mathbf{u}}_k$ denotes the k-th left singular vector of $\mathcal{M}_1(\mathbf{Y})$ where $\mathcal{M}_1(\mathbf{A})$ is of size $d_1 \times (d_2 d_3)$. The operator norm $\|\mathcal{M}_1(\mathbf{Z})\|$ is generally determined by the larger dimension $(d_1 \vee d_2 d_3)$, see Section 6. It turns out that the machinery in Koltchinskii and Xia (2016) is sub-optimal concerning the SNR requirement. Indeed, the eigengap requirement in Koltchinskii and Xia (2016) becomes $\bar{g}_k\big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\big) \gg \sigma\big(d_1 \vee d_2 d_3\big)^{1/2}$, which shall is unnecessarily strong in view of the recent results in Zheng and Tomioka (2015), Cai and Zhang (2016), Zhang and Xia (2018) and Liu et al. (2017).

To bridge such gaps, we conduct a second order spectral analysis for $\hat{\mathbf{U}}$. The key observation is that the top left singular vectors of $\mathcal{M}_1(\mathbf{Y})$ are also the top eigenvectors of $\mathcal{M}_1(\mathbf{Y})\mathcal{M}_1^\top(\mathbf{Y})$. The second order method seeks the eigenspace perturbation on $\mathcal{M}_1(\mathbf{Y})\mathcal{M}_1^\top(\mathbf{Y})$ instead of singular space perturbation on $\mathcal{M}_1(\mathbf{Y})$. Clearly, we have

$$\mathcal{M}_1(\mathbf{Y})\mathcal{M}_1^\top(\mathbf{Y}) = \mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A}) + \mathbf{\Gamma} \in \mathbb{R}^{d_1 \times d_1}$$

where $\mathbf{\Gamma} = \mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{Z}) + \mathcal{M}_1(\mathbf{Z})\mathcal{M}_1^\top(\mathbf{A}) + \mathcal{M}_1(\mathbf{Z})\mathcal{M}_1^\top(\mathbf{Z})$. Note that $\mathbf{U}$ are the leading eigenvectors of $\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})$ and $\hat{\mathbf{U}}$ are the top-r_1 eigenvectors of $\mathcal{M}_1(\mathbf{Y})\mathcal{M}_1^\top(\mathbf{Y})$. Moreover, the following relation on eigengaps is obvious:

$$\bar{g}_{r_1}\Big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\Big) \geq \bar{g}_{r_1}^2\big(\mathcal{M}_1(\mathbf{A})\big).$$

The advantage of second order method comes from the observation that even though $\mathbb{E}\big\|\mathcal{M}_1(\mathbf{Z})\mathcal{M}_1^\top(\mathbf{Z})\big\|$ is of the order $\sigma^2(d_1 \vee d_2 d_3)$, the symmetric matrix $\mathcal{M}_1(\mathbf{Z})\mathcal{M}_1^\top(\mathbf{Z})$ is concentrated at $d_2 d_3 \sigma^2 \mathbf{I}_{d_1}$ such that (see more details in Section 6)

$$\big\|\mathcal{M}_1(\mathbf{Z})\mathcal{M}_1^\top(\mathbf{Z}) - \sigma^2 d_2 d_3 \mathbf{I}_{d_1}\big\| = O_p\Big(\sigma^2\big(d_1 d_2 d_3\big)^{1/2}\Big).$$

Note that subtracting by an identity matrix does not affect the eigen-structure. The second order method introduces the additional term $\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{Z})$ whose operator norm is bounded by $O_p\big(\sigma\sqrt{d_1}\big\|\mathcal{M}_1(\mathbf{A})\big\|\big)$, which creates a constraint on the condition number of $\mathcal{M}_1(\mathbf{A})$. However, in order to characterize sharp perturbation bounds of linear forms $\langle \hat{\mathbf{u}}_k, \mathbf{x} \rangle$, we need to pay more attention to dealing with correlations among the higher order terms than the first order method in Koltchinskii and Xia (2016). We note that the idea of second order method is already existing in the literature (see, e.g., Zheng and Tomioka (2015) for the ℓ_2-norm perturbation bounds). The second order moment method is only the starting point of our technical analysis which significantly reduces the SNR requirements.

Our most fundamental contribution is about the sup-norm characterization of the empirical singular vectors. Basically, we observe that the empirical singular vectors are biased and the bias is nicely aligned with the true singular vectors. After subtracting the bias, the empirical singular vectors exhibit the so-called *delocalization* property where all the entry-wise perturbations have comparable magnitudes. Such *delocalization* property is universal meaning that no conditions on the true singular vectors are needed. In Section 4, we show that the sup-norm perturbation bounds indeed reveal unconventional phase transitions in statistical learning applications such as the exact clustering in high dimensional Gaussian mixture models and the exact support recovery in sub-tensor localizations.

3.2. Perturbation of Linear Forms of Singular Vectors

In this section, we present our main theorem characterizing the perturbation of linear forms $\langle \hat{\mathbf{u}}_k, \mathbf{x} \rangle$ for any $\mathbf{x} \in \mathbb{R}^{d_1}$, where $\hat{\mathbf{u}}_k$ is the k-th left singular vector of $\mathcal{M}_1(\mathbf{Y})$. Our results have similar implications as the previous work Koltchinskii and Xia (2016), meaning that the bias $\mathbb{E}\hat{\mathbf{u}}_k\hat{\mathbf{u}}_k^\top - \mathbf{u}_k\mathbf{u}_k^\top$ is well aligned with $\mathbf{u}_k\mathbf{u}_k^\top$. Therefore, after correcting the bias term, we are able to obtain a sharper estimation of linear forms $\langle \mathbf{u}_k, \mathbf{x} \rangle$. To this end, we denote the condition number of the matrix $\mathcal{M}_1(\mathbf{A})$ by

$$\kappa\big(\mathcal{M}_1(\mathbf{A})\big) = \frac{\lambda_{\max}\big(\mathcal{M}_1(\mathbf{A})\big)}{\lambda_{\min}\big(\mathcal{M}_1(\mathbf{A})\big)}$$

where $\lambda_{\max}(\cdot)$ and $\lambda_{\min}(\cdot)$ return the largest and smallest nonzero singular values, respectively. Since $\hat{\mathbf{u}}_k$ is up to the switch of signs, we choose $\hat{\mathbf{u}}_k$ in the following theorems, remarks and corollaries so that $\big\langle \hat{\mathbf{u}}_k, \mathbf{u}_k \big\rangle > 0$.

Theorem 1 *Let*[3] $\mathbf{M} := \mathcal{M}_1(\mathbf{A})$ *and* $\delta(d_1, d_2, d_3) := \sigma d_1^{1/2}\|\mathbf{M}\| + \sigma^2(d_1 d_2 d_3)^{1/2}$ *and suppose* $d_2 d_3 e^{-d_1/2} \leq 1$. *There exist absolute constants* $D_1, D_2 > 0$ *such that the following fact holds. Let* $\mathbf{u}_k$ *be* $\mathbf{M}$*'s* k*-th left singular vector with multiplicity* 1. *If* $\bar{g}_k\big(\mathbf{M}\mathbf{M}^\top\big) \geq D_1\delta(d_1, d_2, d_3)$, *there exist a constant* $b_k \in [-1/2, 0]$ *with* $|b_k| \leq \frac{\sqrt{2}\delta(d_1,d_2,d_3)}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}$ *such that for any* $\mathbf{x}$, *the following bound holds with probability at least* $1 - e^{-t}$,

$$\begin{aligned}&\big|\langle \hat{\mathbf{u}}_k, \mathbf{x} \rangle - (1 + b_k)^{1/2}\langle \mathbf{u}_k, \mathbf{x} \rangle\big| \\ &\quad\leq D_2\bigg(t^{1/2}\frac{\sigma\|\mathbf{M}\| + \sigma^2(d_2 d_3)^{1/2}}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)} + \frac{\sigma^2 d_1}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big(\frac{\delta(d_1, d_2, d_3)}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big)\bigg)\|\mathbf{x}\|_{\ell_2} \qquad (10)\end{aligned}$$

for all $\log 8 \leq t \leq d_1$. *In particular, if* $\mathbf{x} = \pm\mathbf{u}_k$, *then with the same probability,*

$$\begin{aligned}\big|\big|\langle \hat{\mathbf{u}}_k, \mathbf{u}_k \rangle\big| - 1\big| &\leq \big|\sqrt{1 + b_k} - 1\big| \\ &\quad + D_2\bigg(t^{1/2}\frac{\sigma\|\mathbf{M}\| + \sigma^2(d_2 d_3)^{1/2}}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)} + \frac{\sigma^2 d_1}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big(\frac{\delta(d_1, d_2, d_3)}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big)\bigg).\end{aligned}$$

By Theorem 1, it is easy to check that the condition $\bar{g}_k\big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\big) \geq D_1\delta(d_1, d_2, d_3)$ holds whenever

$$\bar{g}_k\big(\mathcal{M}_1(\mathbf{A})\big) \geq D_1\Big(\sigma(d_1 d_2 d_3)^{1/4} + \sigma d_1^{1/2}\kappa\big(\mathcal{M}_1(\mathbf{A})\big)\Big).$$

3. Observe that if we set $d_3 = 1$ and consider the case with $d_1 \ll d_2$, then Theorem 1 elaborates the one-sided perturbation bounds in ℓ_∞-norm for singular vectors of unbalanced (or fat) matrices.

If $\kappa\big(\mathcal{M}_1(\mathbf{A})\big) \le \big(\frac{d_2d_3}{d_1}\big)^{1/4}$, the above bound becomes $\bar{g}_k\big(\mathcal{M}_1(\mathbf{A})\big) \gg \sigma(d_1d_2d_3)^{1/4}$ which is a standard requirement in tensor SVD or PCA, see Zheng and Tomioka (2015), Zhang and Xia (2018), Hopkins et al. (2015) and Richard and Montanari (2014). By taking $\mathbf{x}$ over the standard basis vectors in $\mathbb{R}^{d_1}$ and choosing $t \ge D_3 \log d_1$, we end up with a ℓ_∞-norm perturbation bound for empirical singular vector $\hat{\mathbf{u}}_k$.

Corollary 2 *Under the conditions in Theorem 1, there exists a universal constant $D_1 > 0$ such that the following bound holds with probability at least $1 - \frac{1}{d_1}$,*

$$\big\|\hat{\mathbf{u}}_k - (1+b_k)^{1/2}\mathbf{u}_k\big\|_{\ell_\infty} \le D_1\bigg(\Big(\frac{\log d_1}{d_1}\Big)^{1/2} + \Big(\frac{d_1}{d_2d_3}\Big)^{1/2}\bigg).$$

If $d_1 \asymp d_2 \asymp d_3 \asymp d$, we obtain

$$\mathbb{P}\Big(\big\|\hat{\mathbf{u}}_k - (1+b_k)^{1/2}\mathbf{u}_k\big\|_{\ell_\infty} \ge D_1\Big(\frac{\log d}{d}\Big)^{1/2}\Big) \le \frac{1}{d}$$

which has an analogous form to the perturbation bound in Koltchinskii and Xia (2016) implying a famous *delocalization* phenomenon in random matrix theory, see Rudelson and Vershynin (2015) and Vu and Wang (2015) and references therein.

Remark 3 *Let's compare with the ℓ_2-norm bound in Zheng and Tomioka (2015) in the case that rank $r = 1$, $d_1 = d_2 = d_3 = d$ and signal strength $\bar{g}_1(\mathbf{M}\mathbf{M}^\top) = \lambda^2$. By (Zheng and Tomioka, 2015, Theorem 1), if $\lambda \gg \sigma d^{3/4}$, then*

$$\|\hat{\mathbf{u}}_1 - \mathbf{u}_1\|_{\ell_2} = O_p\Big(\frac{d^{1/2}\sigma}{\lambda} + \frac{\sigma^2 d^{3/2}}{\lambda^2}\Big). \tag{11}$$

By Theorem 1, if $\lambda \gg \sigma d^{3/4}$, then we get

$$\big\|\hat{\mathbf{u}}_1 - (1+b_1)^{1/2}\mathbf{u}_1\big\|_{\ell_\infty} = O_p\Big(\frac{\sigma\log^{1/2} d}{\lambda} + \frac{\sigma^2 d\log^{1/2} d}{\lambda^2}\Big) \tag{12}$$

for a constant $b_1 \in [-1/2, 0]$ depending on $\mathbf{u}_1$ and λ only. By (12) and (11), we observe that, after subtracting the bias, the entry-wise deviation of the empirical left singular vector $\hat{\mathbf{u}}_1$ is about $\sqrt{\frac{\log d}{d}}$ of the ℓ_2-norm perturbation bound of $\hat{\mathbf{u}}_1$. It means that, after subtracting the bias, the deviations of all $\hat{\mathbf{u}}_1$'s entries have comparable magnitudes, namely the so-called delocalization property. Interestingly, if $|u_1(j)| \gg \frac{1}{\sqrt{d}}$, then eq. (12) implies that $\hat{u}_1(j)$ has the same sign as $u_1(j)$ as long as $\lambda \gg \sigma d^{3/4}$. This sign consistency is crucial for guaranteeing the exact clustering of high dimensional mixture model, see more details in Section 4.

The bias b_k is usually unknown and we borrow the idea in Koltchinskii and Xia (2016) to estimate b_k based on two independent samples. It happens in the application of tensor decomposition for gene expression data where usually multiple independent copies are available, see more details in Hore et al. (2016).

Suppose that two independent noisy version of $\mathbf{A} \in \mathbb{R}^{d_1\times d_2\times d_3}$ are observed with $\mathbf{Y}^{(1)} = \mathbf{A} + \mathbf{Z}^{(1)}$ and $\mathbf{Y}^{(2)} = \mathbf{A} + \mathbf{Z}^{(2)}$ where $\mathbf{Z}^{(1)}$ and $\mathbf{Z}^{(2)}$ have i.i.d. centered Gaussian entries with

variance σ^2 as in (1). Let $\hat{\mathbf{u}}_k^{(1)}$ and $\hat{\mathbf{u}}_k^{(2)}$ denote the k-th left singular vector of $\mathcal{M}_1\big(\mathbf{Y}^{(1)}\big)$ and $\mathcal{M}_1\big(\mathbf{Y}^{(2)}\big)$, respectively. The signs of $\hat{\mathbf{u}}_k^{(1)}$ and $\hat{\mathbf{u}}_k^{(2)}$ are chosen such that $\langle\hat{\mathbf{u}}_k^{(1)}, \hat{\mathbf{u}}_k^{(2)}\rangle \ge 0$. Define the estimator of b_k by

$$\hat{b}_k := \langle\hat{\mathbf{u}}_k^{(1)}, \hat{\mathbf{u}}_k^{(2)}\rangle - 1.$$

Define the scaled version of empirical singular vector $\widetilde{\mathbf{u}}_k := \frac{\hat{\mathbf{u}}_k}{(1+\hat{b}_k)^{1/2}}$, which is not necessarily a unit vector.

Theorem 4 *Under the assumptions in Theorem 1, there exists an absolute constant $D_1 > 0$ such that for any $\mathbf{x} \in \mathbb{R}^{d_1}$, the follow bound holds with probability at least $1 - e^{-t}$ for all $\log 8 \le t \le d_1$,*

$$\big|\hat{b}_k - b_k\big| \le D_1\bigg(t^{1/2}\frac{\sigma\|\mathbf{M}\| + \sigma^2(d_2d_3)^{1/2}}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)} + \frac{\sigma^2 d_1}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big(\frac{\delta(d_1,d_2,d_3)}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big)\bigg)$$

and

$$\big|\langle\widetilde{\mathbf{u}}_k - \mathbf{u}_k, \mathbf{x}\rangle\big| \le D_1\bigg(t^{1/2}\frac{\sigma\|\mathbf{M}\| + \sigma^2(d_2d_3)^{1/2}}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)} + \frac{\sigma^2 d_1}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big(\frac{\delta(d_1,d_2,d_3)}{\bar{g}_k(\mathbf{M}\mathbf{M}^\top)}\Big)\bigg)\|\mathbf{x}\|_{\ell_2}$$

where $\mathbf{M} = \mathcal{M}_1(\mathbf{A})$.

Remark 5 *By Theorem 4, if $d/2 \le \min_k d_k \le \max_k d_k \le 2d$, we get*

$$\mathbb{P}\Big(\|\widetilde{\mathbf{u}}_k - \mathbf{u}_k\|_{\ell_\infty} \ge D_1\Big(\frac{\log d}{d}\Big)^{1/2}\Big) \le \frac{1}{d}.$$

3.3. Low Rank Tensor Denoising and Entry-wise Deviation Bound

In this section, we study a low rank estimate of $\mathbf{A}$ through the projection of $\mathbf{Y}$. Let $\widetilde{\mathbf{U}} = (\tilde{\mathbf{u}}_1, \ldots, \tilde{\mathbf{u}}_{r_1}) \in \mathbb{R}^{d_1\times r_1}$ be scaled singular vectors each of which is computed as in Theorem 4. Similarly, let $\widetilde{\mathbf{V}} \in \mathbb{R}^{d_2\times r_2}$ and $\widetilde{\mathbf{W}} \in \mathbb{R}^{d_3\times r_3}$ be the corresponding scaled singular vectors computed from $\mathcal{M}_2(\mathbf{Y})$ and $\mathcal{M}_3(\mathbf{Y})$. Define the low rank estimate

$$\widetilde{\mathbf{A}} := \mathbf{Y} \times_1 \mathbf{P}_{\widetilde{\mathbf{U}}} \times_2 \mathbf{P}_{\widetilde{\mathbf{V}}} \times_3 \mathbf{P}_{\widetilde{\mathbf{W}}}$$

where $\mathbf{P}_{\widetilde{\mathbf{U}}}$ represents the scaled projector $\mathbf{P}_{\widetilde{\mathbf{U}}} := \widetilde{\mathbf{U}}\widetilde{\mathbf{U}}^\top$. Clearly, $\mathrm{rank}(\widetilde{\mathbf{A}}) = (r_1, r_2, r_3)$ which serves as a low rank estimate of $\mathbf{A}$. We characterize the entry-wise accuracy of $\widetilde{\mathbf{A}}$, namely, the upper bound of $\|\widetilde{\mathbf{A}} - \mathbf{A}\|_{\ell_\infty}$ in terms of the coherence of $\mathbf{U}, \mathbf{V}$ and $\mathbf{W}$. Our $\|\widetilde{\mathbf{A}} - \mathbf{A}\|_{\ell_\infty}$ bound relies on the simultaneous ℓ_∞-norm perturbation bounds of $\{\tilde{\mathbf{u}}_{k_1}\}_{k_1=1}^{r_1}$, $\{\tilde{\mathbf{v}}_{k_2}\}_{k_2=1}^{r_2}$ and $\{\tilde{\mathbf{w}}_{k_3}\}_{k_3=1}^{r_3}$. We impose the following conditions on the eigengaps: for a large enough constant $D_1 > 0$,

$$\bar{g}_{k_1}\big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\big) \ge D_1\Big(\sigma d_1^{1/2}\overline{\Lambda}(\mathbf{A}) + \sigma^2(d_1d_2d_3)^{1/2}\Big), \quad 1 \le k_1 \le r_1, \tag{13}$$

$$\bar{g}_{k_2}\big(\mathcal{M}_2(\mathbf{A})\mathcal{M}_2^\top(\mathbf{A})\big) \ge D_1\Big(\sigma d_2^{1/2}\overline{\Lambda}(\mathbf{A}) + \sigma^2(d_1d_2d_3)^{1/2}\Big), \quad 1 \le k_2 \le r_2, \tag{14}$$

$$\bar{g}_{k_3}\big(\mathcal{M}_3(\mathbf{A})\mathcal{M}_3^\top(\mathbf{A})\big) \geq D_1\Big(\sigma d_3^{1/2}\overline{\Lambda}(\mathbf{A}) + \sigma^2(d_1d_2d_3)^{1/2}\Big), \quad 1 \leq k_3 \leq r_3, \tag{15}$$

where we denote by

$$\overline{\Lambda}(\mathbf{A}) := \max\big\{\lambda_{\max}\big(\mathcal{M}_1(\mathbf{A})\big), \lambda_{\max}\big(\mathcal{M}_2(\mathbf{A})\big), \lambda_{\max}\big(\mathcal{M}_3(\mathbf{A})\big)\big\}.$$

Similarly, we define

$$\underline{\Lambda}(\mathbf{A}) := \min\Big\{\lambda_{\min}\big(\mathcal{M}_1(\mathbf{A})\big),\ \lambda_{\min}\big(\mathcal{M}_2(\mathbf{A})\big),\ \lambda_{\min}\big(\mathcal{M}_3(\mathbf{A})\big)\Big\}$$

and the overall eigengap

$$\bar{g}_{\min}\big(\mathbf{A}\big) := \min\Big\{\bar{g}_{k_1}^{1/2}\big(\mathcal{M}_1(\mathbf{A})\mathcal{M}_1^\top(\mathbf{A})\big), \bar{g}_{k_2}^{1/2}\big(\mathcal{M}_2(\mathbf{A})\mathcal{M}_2^\top(\mathbf{A})\big), \bar{g}_{k_3}^{1/2}\big(\mathcal{M}_3(\mathbf{A})\mathcal{M}_3^\top(\mathbf{A})\big) \\ , 1 \leq k_1 \leq r_1, 1 \leq k_2 \leq r_2, 1 \leq k_3 \leq r_3\Big\}.$$

By definition, it is clear that $\underline{\Lambda}(\mathbf{A}) \geq \bar{g}_{\min}(\mathbf{A})$.

Theorem 6 *Suppose conditions (13) (14) (15) hold and assume that for all $i \in [d_1], j \in [d_2], k \in [d_3]$,*

$$\|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2} \leq \mu_{\mathbf{U}}\sqrt{\frac{r_1}{d_1}}, \quad \|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2} \leq \mu_{\mathbf{V}}\sqrt{\frac{r_2}{d_2}}, \quad \|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2} \leq \mu_{\mathbf{W}}\sqrt{\frac{r_3}{d_3}}$$

for some constants $\mu_{\mathbf{U}}, \mu_{\mathbf{V}}, \mu_{\mathbf{W}} \geq 0$. Suppose that $\frac{d}{2} \leq \min_{1\leq k\leq 3} d_k \leq \max_{1\leq k\leq 3} d_k \leq 2d$ and $\frac{r}{2} \leq \min_{1\leq k\leq 3} r_k \leq \max_{1\leq k\leq 3} r_k \leq 2r$. Then, there exists an absolute constant $D_2 > 0$ such that, with probability at least $1 - \frac{1}{d}$,

$$\big\|\tilde{\mathbf{A}} - \mathbf{A}\big\|_{\ell_\infty} \\ \leq D_2\sigma r^3\Big(\frac{\widetilde{\kappa}(\mathbf{A})\sigma}{\bar{g}_{\min}(\mathbf{A})} + \frac{\widetilde{\kappa}^2(\mathbf{A})}{d}\Big)\big(\mu_{\mathbf{U}}\mu_{\mathbf{V}} + \mu_{\mathbf{U}}\mu_{\mathbf{W}} + \mu_{\mathbf{V}}\mu_{\mathbf{W}}\big)\log^{3/2} d$$

where $\widetilde{\kappa}(\mathbf{A}) = \overline{\Lambda}(\mathbf{A})/\bar{g}_{\min}(\mathbf{A})$.

Remark 7 *To highlight the contribution of Theorem 6, let $r = O(1)$ and $\widetilde{\kappa}(\mathbf{A}) = O(1)$. Note that if the coherence constants $\mu_{\mathbf{U}}, \mu_{\mathbf{V}}, \mu_{\mathbf{W}} = d^{(\frac{3}{4}-\varepsilon)/2}$ for $\varepsilon \in (0, 3/4)$, i.e., $\mathbf{U}, \mathbf{V}, \mathbf{W}$ can be almost spiked, under the minimal eigengap $\bar{g}_{\min}(\mathbf{A}) \gg \sigma d^{3/4}$, we obtain*

$$\|\tilde{\mathbf{A}} - \mathbf{A}\|_{\ell_\infty} = O_p\Big(\frac{\sigma}{d^\varepsilon}\log^{3/2} d\Big).$$

It worths to point out that the minimax optimal bound of estimating $\mathbf{A}$ in ℓ_2-norm is $O\big(\sigma d^{1/2}\big)$, see Zhang and Xia (2018). Theorem 6 is more interesting when $\mathbf{A}$ is incoherent such that $\mu_{\mathbf{U}}, \mu_{\mathbf{V}}, \mu_{\mathbf{W}} = O(1)$ where we can conclude that

$$\|\tilde{\mathbf{A}} - \mathbf{A}\|_{\ell_\infty} = O_p\Big(\Big(\frac{\sigma^2}{\bar{g}_{\min}(\mathbf{A})} + \frac{\sigma}{d}\Big)\log^{3/2} d\Big) = O_p\Big(\frac{\sigma}{d^{3/4}}\log^{3/2} d\Big). \tag{16}$$

By (16), if the entry $|A(j_1, j_2, j_3)| \gg \frac{\sigma\log^{3/2} d}{d^{3/4}}$, then the entry $\tilde{A}(j_1, j_2, j_3)$ maintains the same sign as $A(j_1, j_2, j_3)$. In Section 4 and Remark 13, we show that the sup-norm bound of $\tilde{\mathbf{A}} - \mathbf{A}$ is useful for the exact support recovery of sub-tensor localizations, under minimal signal strength requirements (that is the support size).

4. Applications

In this section, we review two applications of ℓ_∞-norm perturbation bound. In these applications, we note that it is unnecessary to estimate the bias b_k. We show that the sup-norm perturbation bounds reveal unconventional phase transitions in these statistical learning applications. Meanwhile, novel yet simple statistical algorithms can be designed based on the sup-norm perturbation bounds.

4.1. High Dimensional Clustering

Many statistical and machine learning tasks are associated with clustering high dimensional data, see McCallum et al. (2000), Parsons et al. (2004), Fan and Fan (2008), Hastie et al. (2009), Friedman (1989) and references therein. We consider a two-class Gaussian mixture model such that each data point $\mathbf{y}_i \in \mathbb{R}^p$ can be represented by

$$\mathbf{y}_i = -\ell_i\boldsymbol{\beta} + (1 - \ell_i)\boldsymbol{\beta} + \boldsymbol{\varepsilon}_i \in \mathbb{R}^p \tag{17}$$

where the associated label $\ell_i \in \{0, 1\}$ for $i = 1, 2, \ldots, n$ is unknown and the noise vector $\boldsymbol{\varepsilon}_i \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_p)$. The vector $\boldsymbol{\beta} \in \mathbb{R}^p$ is unknown with $p \gg n$. We denote the true clusters by

$$\mathcal{N}_0 := \{1 \leq i \leq n : \ell_i = 0\} \quad \text{and} \quad \mathcal{N}_1 := \{1 \leq i \leq n : \ell_i = 1\}.$$

Given the data matrix

$$\mathbf{Y} = \big(\mathbf{y}_1, \ldots, \mathbf{y}_n\big)^\top \in \mathbb{R}^{n\times p}$$

, our goal is to cluster the n data points into two disjoint groups. Let $n_{k+1} := \mathrm{Card}\big(\mathcal{N}_k\big)$ for $k = 0, 1$ such that $n_1 + n_2 = n$. Observe that $\mathbb{E}\mathbf{Y}$ has rank 1 and its leading left singular vector $\mathbf{u} \in \mathbb{R}^n$ with

$$u(i) = \frac{1 - \ell_i}{n^{1/2}} - \frac{\ell_i}{n^{1/2}}, \quad 1 \leq i \leq n.$$

The signs of $\mathbf{u}$ immediately suggest the cluster memberships of each data points. Moreover, the leading singular value of $\mathbb{E}\mathbf{Y}$ is $n^{1/2}\|\boldsymbol{\beta}\|_{\ell_2}$. Let $\hat{\mathbf{u}}$ denote the leading left singular vector of $\mathbf{Y}$. By Corollary 2, if $\|\boldsymbol{\beta}\|_{\ell_2} \geq D_1\big(1 \vee (p/n)^{1/4}\big)$ such that $|(1 + b_k)^{-1/2} - 1| \leq 1/2$, then there exists an event $\mathcal{E}$ with $\mathbb{P}(\mathcal{E}) \geq 1 - \frac{1}{n}$ so that on event $\mathcal{E}$,

$$\big\|\hat{\mathbf{u}} - (1 + b_k)^{1/2}\mathbf{u}\big\|_{\ell_\infty} \leq D_2\Big(\frac{1}{\|\boldsymbol{\beta}\|_{\ell_2}} + \frac{(p/n)^{1/2}}{\|\boldsymbol{\beta}\|_{\ell_2}^2}\Big)\Big(\frac{1}{\|\boldsymbol{\beta}\|_{\ell_2}^2} + \sqrt{\frac{\log n}{n}}\Big).$$

On event $\mathcal{E}$, if $\|\boldsymbol{\beta}\|_{\ell_2} \geq D_1\Big(n^{1/6} \vee p^{1/8} \vee \big(p\log(n)/n\big)^{1/4}\Big)$, then we get

$$\|\hat{\mathbf{u}} - \mathbf{u}\|_{\ell_\infty} \leq \|\hat{\mathbf{u}} - (1 + b_k)^{1/2}\mathbf{u}\|_{\ell_\infty} + \big|(1 + b_k)^{-1/2} - 1\big|\|\mathbf{u}\|_{\ell_\infty} \\ \leq \|\hat{\mathbf{u}} - (1 + b_k)^{1/2}\mathbf{u}\|_{\ell_\infty} + \frac{1}{2n^{1/2}} \leq \frac{3}{4n^{1/2}} \tag{18}$$

implying that if $\ell_i = \ell_j$, then $\mathrm{sign}\big(\hat{u}(i)\big) = \mathrm{sign}\big(\hat{u}(j)\big)$ for all $1 \leq i, j \leq n$. Therefore, we propose a simple clustering algorithm by entry-wise signs of $\hat{\mathbf{u}}$ in Algorithm 1.

By the bound (18), Algorithm 1 can guarantee exact clustering as follows.

Algorithm 1 High dimensional bi-clustering by entry-wise signs.

Input: Data matrix $\mathbf{Y} \in \mathbb{R}^{n\times p}$
Calculate the leading left singular vector of $\mathbf{Y}$, denoted by $\hat{\mathbf{u}} \in \mathbb{R}^n$
Initiate $\hat{\mathcal{N}}_0 = \{\}$ and $\hat{\mathcal{N}}_1 = \{\}$
for $i = 1, \cdots, n$ **do**
  if $\hat{u}(i) \geq 0$ **then**
    $\hat{\mathcal{N}}_0 \leftarrow \hat{\mathcal{N}}_0 \cup \{i\}$
  else
    $\hat{\mathcal{N}}_1 \leftarrow \hat{\mathcal{N}}_1 \cup \{i\}$
  end if
end for
Output: $\hat{\mathcal{N}}_0$ and $\hat{\mathcal{N}}_1$.

Theorem 8 *Suppose model (17) holds with noise vector $\boldsymbol{\varepsilon} \sim \mathcal{N}(0, \mathbf{I}_p)$. Let $\hat{\mathcal{N}}_0$ and $\hat{\mathcal{N}}_1$ be the output of Algorithm 1. There exists an absolute constant $D_1 > 0$ such that if $\|\boldsymbol{\beta}\|_{\ell_2} \geq D_1\Big(n^{1/6} \vee p^{1/8} \vee \big(p\log(n)/n\big)^{1/4}\Big)$, then with probability at least $1 - \frac{1}{n}$,*

$$\hat{\mathcal{N}}_0 = \mathcal{N}_0 \quad \text{or} \quad \hat{\mathcal{N}}_0 = \mathcal{N}_1.$$

The proof of Theorem 8 is straightforward based on eq. (18). We note that eq. (18) also implies that it is unnecessary to estimate b_k in this application, since scaling switch the entry-wise signs simultaneously and thus maintains the clustering outputs.

Remark 9 *Theorem 8 reveal unconventional phase transition thresholds for the exact clustering of Gaussian mixture model (17). Indeed, by Theorem 8, the sup-norm based clustering algorithm (Algorithm 1) will exactly recover the memberships with high probability when the signal strength satisfies*

$$\|\boldsymbol{\beta}\|_{\ell_2} \gg \Big(n^{1/6} \vee p^{1/8} \vee \big(p\log(n)/n\big)^{1/4}\Big).$$

In comparison, the ℓ_2-norm based clustering algorithm in Cai and Zhang (2016) and Zheng and Tomioka (2015) requires

$$\|\boldsymbol{\beta}\|_{\ell_2} \gg \big(n^{1/2} \vee p^{1/4}\big)$$

for exact clustering. Clearly, with respect to exact recovery, the sup-norm based clustering algorithm requires much weaker SNR conditions.

Remark 10 *The above framework can be directly generalized to Gaussian mixture model with k-clusters. Suppose that the j-th cluster has mean vector $\boldsymbol{\beta}_j$ and size n_j, then without loss of generality, the data matrix $\mathbf{Y} = \mathbf{M} + \mathbf{Z}$*

$$\mathbf{M} = \big(\underbrace{\boldsymbol{\beta}_1, \cdots, \boldsymbol{\beta}_1}_{n_1}, \cdots, \underbrace{\boldsymbol{\beta}_j, \cdots, \boldsymbol{\beta}_j}_{n_j}, \cdots, \underbrace{\boldsymbol{\beta}_k, \cdots, \boldsymbol{\beta}_k}_{n_k}\big)^\top \in \mathbb{R}^{N\times p}$$

with $N = \sum_{j=1}^k n_j$ and $\mathbf{Z} \in \mathbb{R}^{N\times p}$ having i.i.d. standard Gaussian entries. Observe that $\mathrm{rank}(\mathbf{M}) \leq k$, it suffices to consider the top-k left singular vectors of $\mathbf{M}$. However, it

requires nontrivial effort to investigate the eigengaps of $\mathbf{M}$ without further assumptions on $\{\boldsymbol{\beta}_j\}_{j=1}^k$. In the case that $n_j = n$ and $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_k$ are mutually orthogonal such that $\|\boldsymbol{\beta}_1\|_{\ell_2} \geq \ldots \geq \|\boldsymbol{\beta}_k\|_{\ell_2}$, then $\mathbf{M}$'s top-k singular values are $\lambda_j = \sqrt{n_j}\|\boldsymbol{\beta}_j\|_{\ell_2}, 1 \leq j \leq k$. Clearly, the non-zero entries of $\mathbf{M}$'s top-k left singular vectors provide the cluster membership of each data points. By Theorem 1, if $\Delta_j \geq C_1\sqrt{k}\|\boldsymbol{\beta}_1\|_{\ell_2} + C_2(kp/n)^{1/2}$ where $\Delta_j = \min\{\big(\|\boldsymbol{\beta}_j\|_{\ell_2}^2 - \|\boldsymbol{\beta}_{j+1}\|_{\ell_2}^2\big), \big(\|\boldsymbol{\beta}_{j-1}\|_{\ell_2}^2 - \|\boldsymbol{\beta}_j\|_{\ell_2}^2\big)\}$, then

$$\|\hat{\mathbf{u}}_j - \sqrt{1+b_j}\mathbf{u}_j\|_{\ell_\infty} = O_p\Big(\big(\frac{\|\boldsymbol{\beta}_1\|_{\ell_2}}{\Delta_j} + \frac{(p/n)^{1/2}}{\Delta_j}\big)\big(\frac{k^{3/2}}{\Delta_j} + \sqrt{\frac{k\log n}{n}}\big)\Big)$$

for all $1 \leq j \leq k$.

4.2. Sub-tensor Localization

In gene expression association analysis (see Hore et al. (2016), Xiong et al. (2012), Kolar et al. (2011) and Ben-Dor et al. (2003)) and planted clique detection (see Brubaker and Vempala (2009), Anandkumar et al. (2013) and Gauvin et al. (2014)), the goal is equivalent to locating a sub-tensor whose entries are statistically more significant than the others. One simple model characterizing this type of tensor data is as

$$\mathbf{Y} = \lambda \mathbf{1}_{C_1} \otimes \mathbf{1}_{C_2} \otimes \mathbf{1}_{C_3} + \mathbf{Z} \in \mathbb{R}^{d_1\times d_2\times d_3} \tag{19}$$

with $C_k = \cup_{j=1}^{s_k} C_k^{(j)} \subset [d_k]$ where $\big\{C_k^{(1)}, \ldots, C_k^{(s_k)}\big\}$ are disjoint subsets of $[d_k]$ for $k = 1, 2, 3$, i.e., there are $s_k \geq 1$ dense blocks in the k-th direction. Then, in total, there are $s_1s_2s_3$ dense blocks in $\mathbb{E}\mathbf{Y}$. The vector $\mathbf{1}_{C_k} \in \mathbb{R}^{d_k}$ is a zero-or-one vector whose entry equals 1 only when the index belongs to $\mathbf{C}_k$. The noise tensor $\mathbf{Z}$ has i.i.d. entries such that $Z(i,j,k) \sim \mathcal{N}(0,1)$. Given the noisy observation $\mathbf{Y}$, the goal is to locate the unknown subsets $\{C_1^{(j)}\}_{j=1}^{s_1}, \{C_2^{(j)}\}_{j=1}^{s_2}$ and $\{C_3^{(j)}\}_{j=1}^{s_3}$. The appealing scenario is $\lambda = O(1)$, since otherwise the signal is so strong that the problem can be easily solved by just looking at each entry. The tensor $\mathbb{E}\mathbf{Y}$ has rank 1 with leading singular value $\lambda|C_1|^{1/2}|C_2|^{1/2}|C_3|^{1/2}$ and corresponding singular vectors

$$\mathbf{u} = \frac{1}{|C_1|^{1/2}}\mathbf{1}_{C_1}, \quad \mathbf{v} = \frac{1}{|C_2|^{1/2}}\mathbf{1}_{C_2} \quad \text{and} \quad \mathbf{w} = \frac{1}{|C_3|^{1/2}}\mathbf{1}_{C_3},$$

where $|C|$ denotes the cardinality of C. By Theorem 1, if $\lambda \geq D_1\frac{(d_1d_2d_3)^{1/4}}{|C_1|^{1/2}|C_2|^{1/2}|C_3|^{1/2}}$ for a large enough constant $D_1 > 0$ and $d_{\max} \leq (d_1d_2d_3)^{1/2}$ where $d_{\max} := (d_1 \vee d_2 \vee d_3)$, then with probability at least $1 - \frac{1}{d_{\max}}$, we obtain

$$\begin{aligned}&\|\hat{\mathbf{u}} - (1+b_1)^{1/2}\mathbf{u}\|_{\ell_\infty}\\ &\quad\leq \frac{D_1\log^{1/2} d_{\max}}{\lambda|C_1|^{1/2}|C_2|^{1/2}|C_3|^{1/2}} + \frac{D_1(d_2d_3\log d_{\max})^{1/2}}{\lambda^2|C_1||C_2||C_3|} + \frac{D_1d_1}{\lambda^2|C_1||C_2||C_3|}\Big(\frac{(d_1d_2d_3)^{1/2}}{\lambda^2|C_1||C_2||C_3|}\Big),\end{aligned} \tag{20}$$

where $b_1 \in [-0.5, 0]$ is a constant depending on $\mathbf{u}, \mathbf{v}, \mathbf{w}$ and λ only. Similar bounds can be also derived for $\hat{\mathbf{v}}$ and $\hat{\mathbf{w}}$. By eq. (20), we propose a simple algorithm (Algorithm 2) for the

Algorithm 2 Sub-tensor localizations by entry-wise magnitudes.

Input: Data matrix $\mathbf{Y} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$

Calculate the leading left singular vectors of $\{\mathcal{M}_k(\mathbf{Y})\}_{k=1}^3$, denoted by $\hat{\mathbf{u}} \in \mathbb{R}^{d_1}, \hat{\mathbf{v}} \in \mathbb{R}^{d_2}$ and $\hat{\mathbf{w}} \in \mathbb{R}^{d_3}$, respectively.

Take entry-wise magnitudes $\{|\hat{u}(j_1)|\}_{j_1=1}^{d_1}$ and arrange them in a non-increasing order,

Record the top-$|C_1|$ locations and denote them by $\hat{C}_1$;

Take entry-wise magnitudes $\{|\hat{v}(j_2)|\}_{j_2=1}^{d_2}$ and arrange them in a non-increasing order,

Record the top-$|C_2|$ locations and denote them by $\hat{C}_2$;

Take entry-wise magnitudes $\{|\hat{w}(j_3)|\}_{j_3=1}^{d_3}$ and arrange them in a non-increasing order,

Record the top-$|C_3|$ locations and denote them by $\hat{C}_3$;

Output: $\hat{C}_1$, $\hat{C}_2$ and $\hat{C}_3$.

support recovery of sub-tensor model (19). By bound (20), we can immediately guarantee the exact support recovery by Algorithm 2. The proof is straightforward and is omitted here.

Theorem 11 *Suppose model (19) holds and $(d_1 + d_2 + d_3) \leq 2(d_1 d_2 d_3)^{1/2}$. There exist absolute constants $D_1, D_2 > 0$ such that if $\lambda \geq D_1 \frac{(d_1 d_2 d_3)^{1/4}}{(|C_1||C_2||C_3|)^{1/2}}$ and*

$$\max\left\{\sqrt{\frac{|C_1|}{d_1}}, \sqrt{\frac{|C_2|}{d_2}}, \sqrt{\frac{|C_3|}{d_3}}\right\} \cdot \frac{(d_1 d_2 d_3 \log d_{\max})^{1/2}}{\lambda^2 |C_1||C_2||C_3|} \leq \frac{1}{D_2},$$

then, with probability at least $1 - \frac{1}{d_1+d_2+d_3}$, we get

$$\hat{C}_1 = C_1 \quad \text{and} \quad \hat{C}_2 = C_2 \quad \text{and} \quad \hat{C}_3 = C_3$$

where $\{\hat{C}_k\}_{k=1}^3$ are the output of Algorithm 2.

Note that in Algorithm 2 and Theorem 11, it is also unnecessary to estimate the bias b_1 because we are interested in the top-$|C_1|$ largest entries of $|\hat{\mathbf{u}}|$ and scaling does not affect the ordering of the entry-wise magnitudes.

Remark 12 *The phase transition of Algorithm 2 and model (19) is intriguing. Note that the support localizations are trivial when $\lambda \gg 1$. Therefore, we only focus on the case $\lambda = 1$. Now, let $|C_1| \asymp |C_2| \asymp |C_3| = K$ and $d_1 \asymp d_2 \asymp d_3 = d$. By Theorem 11, we conclude that Algorithm 2 can exactly recover the supports C_1, C_2, C_3 with high probability if the support size $K \gg d^{\frac{1}{2}}$. Meanwhile, by the lower bound arguments in Zhang and Xia (2018), we know that if $K \ll d^{\frac{1}{2}}$, then there exist no polynomial time algorithms which can recover C_1 consistently. Put it differently, phase transition occurs at the threshold $O(d^{\frac{1}{2}})$ such that if $K \ll d^{\frac{1}{2}}$, the problem is unsolvable by polynomial time algorithms; if $K \gg d^{\frac{1}{2}}$, the problem can be perfectly solved by Algorithm 2. In comparison, the ℓ_2-norm based algorithms can only guarantee the consistency of support recovery when $K \gg d^{\frac{1}{2}}$, rather than the exact recovery.*

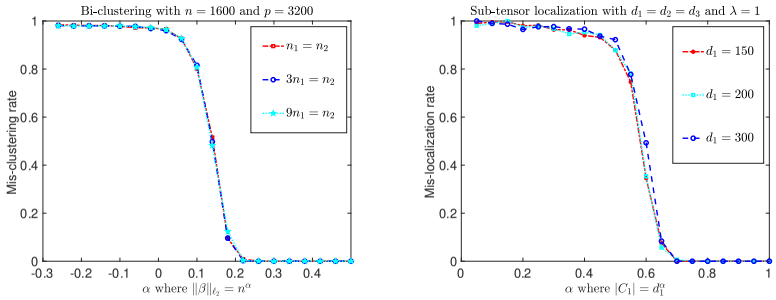
Remark 13 *We could also investigate the entry-wise denoising of model (19). Suppose that $|C_1| \asymp |C_2| \asymp |C_3| = K$ and $d_1 \asymp d_2 \asymp d_3 = d$. We denote by $\mathbf{A} = \mathbf{1}_{C_1} \otimes \mathbf{1}_{C_2} \otimes \mathbf{1}_{C_3}$ where we fix $\lambda = 1$ and we focus only on the support sizes $\{|C_k|\}_{k=1}^3$. Let $\hat{\mathbf{u}}, \hat{\mathbf{v}}$ and $\hat{\mathbf{w}}$ be the empirical singular vectors as in Algorithm 2. Define the projection estimator*

$$\hat{\mathbf{A}} = \mathbf{Y} \times_1 (\hat{\mathbf{u}}\hat{\mathbf{u}}^\top) \times_2 (\hat{\mathbf{v}}\hat{\mathbf{v}}^\top) \times_3 (\hat{\mathbf{w}}\hat{\mathbf{w}}^\top).$$

Similarly as in Theorem 6, we can show that there exists a constant $b \in [\sqrt{2}/4, 1]$ such that with probability at least $1 - \frac{1}{d}$,

$$\|\hat{\mathbf{A}} - b \cdot \mathbf{A}\|_{\ell_\infty} \leq D_1 \cdot \Big(\frac{1}{K} + \frac{d}{K^{5/2}}\Big) \log^{3/2} d \tag{21}$$

for some absolute constant $D_1 > 0$. Recall from model (19) that $A(j_1, j_2, j_3) = 1$ if $(j_1, j_2, j_3) \in C_1 \times C_2 \times C_3$. From eq. (21), we conclude that if $K \geq D_2\big(\sqrt{d} + d^{0.4} \log^{0.6} d\big)$ for a large enough absolute constant $D_2 > 0$ (note that the threshold $\sqrt{d}$ comes from SNR requirement as in eq. (20)), then



$$\big|\hat{A}(j_1, j_2, j_3)\big| > |\hat{A}(j_1', j_2', j_3')|$$

for all $(j_1, j_2, j_3) \in C_1 \times C_2 \times C_3$ and $(j_1', j_2', j_3') \notin C_1 \times C_2 \times C_3$. As a result, we can choose the locations of $\hat{\mathbf{A}}$'s entries with the largest-$|C_1||C_2||C_3|$ magnitudes and recover $\mathbf{A}$'s supports exactly.

4.3. Numerical Experiments

We present simulation results of experiments for the applications in Section 4. For high dimensional clustering in model (17), we randomly sample a vector $\boldsymbol{\beta} \in \mathbb{R}^p$ with $p = 3200$. For a fixed $\boldsymbol{\beta}$, we sample $n_1 = n/2 = 800$ random vectors from distribution $\mathcal{N}(\boldsymbol{\beta}, \mathbf{I}_p)$ and $n_2 = n/2 = 800$ random vectors from distribution $\mathcal{N}(-\boldsymbol{\beta}, \mathbf{I}_p)$. Then, we calculate the top left singular vector of $\mathbf{Y}$ as in (17) and apply Algorithm 1 to cluster the 1600 points into two disjoint groups. For each $\boldsymbol{\beta}$, we repeat the experiments for 50 times and the average mis-clustering rate is recorded. The signal strengths are chosen so that $\|\boldsymbol{\beta}\|_{\ell_2} = n^\alpha$ with $\alpha = 0.06 * k - 0.5$ for $1 \leq k \leq 20$. The average mis-clustering rates with respect to signal strengths are displayed in Figure (1a). Moreover, in Figure (1a), we also compare the average mis-clustering rates when two clusters have different sizes such as $3n_1 = n_2 = 1200$ and $9n_1 = n_2 = 1440$. As shown in Figure (1a), there exists a threshold around $\alpha = 0.18$ such that the mis-clustering rates by Algorithm 1 decreases extremely fast when the signal strength exceeds the threshold. Meanwhile, Figure (1a) also shows that the size balances of two clusters does not affect the threshold. Both these numerical observations from Figure (1a) are consistent with the theoretic guarantees from Theorem 8.

For sub-tensor localizations in model (19), we fix $\lambda = 1$ because the support localization task is trivial if $\lambda \gg 1$. Similarly as in Remark 12, it then suffices to investigate the efficiency of Algorithm 2 with respect to the support sizes. For simplicity, we choose $d_1 = d_2 = d_3$ and $C_1 = C_2 = C_3 = [|C_1|]$, that is, the sub-tensor is in the bottom-left-front corner of $\mathbb{E}\mathbf{Y}$. For each $d_1 = 150, d_1 = 200$ and $d_1 = 300$, we show the average mis-localization rates by Algorithm 2 with respect to the support size $|C_1|$. The average mis-localization rates are

(a) *Mis-clustering rates of Algorithm 1* **(b)** *Mis-localization rates of Algorithm 2*

Figure 1: *Simulation results for the performances of Algorithm 1 and Algorithm 2. In Figure (1a), the phase transition happens around the signal strength $\|\boldsymbol{\beta}\|_{\ell_2} \approx n^{0.18}$ which coincides with Theorem 8. Figure (1a) shows that Algorithm 1 can exactly recover the true clusters when signal strength exceeds the aforementioned threshold. Figure (1a) also shows that the efficiency of Algorithm 1 is unaffected when two clusters have unbalanced sizes. In Figure (1b), the phase transition happens when the support C_1 has size around $d_1^{0.6}$. It shows that Algorithm 2 can exactly locate the sub-tensor when the support size exceeds the aforementioned threshold.*

calculated from 50 independent experiments. The support sizes are chosen as $|C_1| = \lceil d_1^{\alpha} \rceil$ with $0.06 \le \alpha \le 1$. The results of mis-localization rates are displayed in Figure (1b). Indeed, Figure (1b) shows that the mis-localization rates by Algorithm 2 starts to decrease extremely fast when the support size is around $|C_1| \asymp d_1^{0.6}$. The exponent 0.6 is somewhat larger than the threshold 0.5 claimed in Remark 12. Note that the dimension size d is moderately large (only 300) in our simulations due to the heavy computational cost.

5. Acknowledgements

The authors would like to thank the action editor and three anonymous referees for their insightful suggestions which significantly improve the readability of the article.

6. Proofs

For notational brevity, we write $A \lesssim B$ if there exists an absolute constant D_1 such that $A \le D_1 B$. A similar notation would be $\gtrsim$ and $A \asymp B$ means that $A \lesssim B$ and $A \gtrsim B$ simultaneously. If the constant D_1 depends on some parameter γ, we shall write $\lesssim_\gamma, \gtrsim_\gamma$ and $\asymp_\gamma$.

Recall that the HOSVD is translated directly from SVD on $\mathcal{M}_1(\mathbf{A})$ and the matrix perturbation model $\mathcal{M}_1(\mathbf{Y}) = \mathcal{M}_1(\mathbf{A}) + \mathcal{M}_1(\mathbf{Z})$. Without loss of generality, it suffices to focus on matrices with unbalanced sizes. In the remaining context, we write $\mathbf{A}, \mathbf{Z}, \mathbf{Y} \in \mathbb{R}^{m_1 \times m_2}$ instead of $\mathcal{M}_1(\mathbf{A}), \mathcal{M}_1(\mathbf{Z}), \mathcal{M}_1(\mathbf{Y}) \in \mathbb{R}^{m_1 \times m_2}$, where $m_1 = d_1$ and $m_2 = d_2 d_3$ such

that $m_1 \ll m_2$. The second order spectral analysis begins with

$$\mathbf{Y}\mathbf{Y}^\top = \mathbf{A}\mathbf{A}^\top + \mathbf{\Gamma}, \quad \text{where} \quad \mathbf{\Gamma} = \mathbf{A}\mathbf{Z}^\top + \mathbf{Z}\mathbf{A}^\top + \mathbf{Z}\mathbf{Z}^\top.$$

Suppose that $\mathbf{A}$ has the thin singular value decomposition

$$\mathbf{A} = \sum_{k=1}^{r_1} \lambda_k (\mathbf{u}_k \otimes \mathbf{h}_k) \in \mathbb{R}^{m_1 \times m_2}$$

where $\{\mathbf{h}_1, \ldots, \mathbf{h}_{r_1}\} \subset \mathrm{span}\{\mathbf{v}_j \otimes \mathbf{w}_k^\top : j \in [r_2], k \in [r_3]\}$ are the right singular vectors of $\mathbf{A}$. Moreover, $\mathbf{A}\mathbf{A}^\top$ admits the eigen-decomposition:

$$\mathbf{A}\mathbf{A}^\top = \sum_{k=1}^{r_1} \lambda_k^2 (\mathbf{u}_k \otimes \mathbf{u}_k).$$

In an identical fashion, denote the eigen-decomposition of $\mathbf{Y}\mathbf{Y}^\top$ by

$$\mathbf{Y}\mathbf{Y}^\top = \sum_{k=1}^{m_1} \hat{\lambda}_k^2 (\hat{\mathbf{u}}_k \otimes \hat{\mathbf{u}}_k).$$

Even though Theorem 1 and Theorem 4 are stated when the singular value λ_k has multiplicity 1, we present more general results in this section. Note that when there are repeated singular values, the singular vectors are not uniquely defined. In this case, let $\mu_1 > \mu_2 > \ldots > \mu_s > 0$ be distinct singular values of $\mathbf{A}$ with $s \le r_1$. Denote $\Delta_k := \{j : \lambda_j = \mu_k\}$ for $1 \le k \le s$ and $\nu_k := \mathrm{Card}(\Delta_k)$ the multiplicity of μ_k. Let $\mu_{s+1} = 0$ which is a trivial eigenvalue of $\mathbf{A}\mathbf{A}^\top$ with multiplicity $m_1 - r_1$. Then, the spectral decomposition of $\mathbf{A}\mathbf{A}^\top$ can be represented as

$$\mathbf{A}\mathbf{A}^\top = \sum_{k=1}^{s+1} \mu_k^2 \mathbf{P}_k^{uu}$$

where the spectral projector $\mathbf{P}_k^{uu} := \sum_{j \in \Delta_k} \mathbf{u}_j \otimes \mathbf{u}_j$ which is uniquely defined. Correspondingly, define the empirical spectral projector based on eigen-decomposition of $\mathbf{Y}\mathbf{Y}^\top$,

$$\hat{\mathbf{P}}_k^{uu} := \sum_{j \in \Delta_k} \hat{\mathbf{u}}_j \otimes \hat{\mathbf{u}}_j.$$

We develop a sharp concentration bound for bilinear forms $\langle \hat{\mathbf{P}}_k^{uu} \mathbf{x}, \mathbf{y} \rangle$ for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{m_1}$. Observe that $\mathbf{Y}\mathbf{Y}^\top$ has an identical eigen-space as $\mathbf{Y}\mathbf{Y}^\top - m_2\sigma^2\mathbf{I}_{m_1}$. Let $\hat{\mathbf{\Gamma}} := \mathbf{\Gamma} - m_2\sigma^2\mathbf{I}_{m_1}$ and the spectral analysis shall be realized on $\mathbf{A}\mathbf{A}^\top + \hat{\mathbf{\Gamma}}$.

Several preliminary facts are introduced as follows. It is clear that the k-th eigengap is $\bar{g}_k(\mathbf{A}\mathbf{A}^\top) := \min\left(\mu_{k-1}^2 - \mu_k^2, \mu_k^2 - \mu_{k+1}^2\right)$ for $1 \le k \le s$, where we set $\mu_0 = +\infty$. The proof of Lemma 14 is provided in the Appendix.

Lemma 14 *For any deterministic matrix $\mathbf{B} \in \mathbb{R}^{m_3 \times m_2}$, the following bounds hold*

$$\begin{aligned} \mathbb{E}\|\mathbf{B}\mathbf{Z}^\top\| &\lesssim \sigma\|\mathbf{B}\|\left(m_1^{1/2} + m_3^{1/2} + (m_1 m_3)^{1/4}\right) \\ \left\|\mathbb{E}\mathbf{Z}\mathbf{Z}^\top - m_2\sigma^2\mathbf{I}_{m_1}\right\| &\lesssim \sigma^2 (m_1 m_2)^{1/2}. \end{aligned} \tag{22}$$

For any $t>0$, the following inequalities hold with probability at least $1-e^{-t}$,

$$\|\mathbf{B}\mathbf{Z}^\top\| \lesssim \sigma\|\mathbf{B}\|\Big(m_1^{1/2}+m_3^{1/2}+(m_1m_3)^{1/4}+t^{1/2}+(m_1t)^{1/4}\Big) \tag{23}$$
$$\big\|\mathbf{Z}\mathbf{Z}^\top-m_2\sigma^2\mathbf{I}_{m_1}\big\| \lesssim \sigma^2 m_2^{1/2}\big(m_1^{1/2}+t^{1/2}\big).$$

6.1. Proof of Theorem 1

To this end, define

$$\mathbf{C}_k^{uu} := \sum_{s\neq k}\frac{1}{\mu_s^2-\mu_k^2}\mathbf{P}_s^{uu}$$

and

$$\mathbf{P}_k^{hh} := \sum_{j\in\Delta_k}\mathbf{h}_j\otimes\mathbf{h}_j.$$

Theorem 1 is decomposed into two separate parts. Theorem 15 provides the concentration bound for $\big|\langle\mathbf{P}_k\mathbf{x},\mathbf{y}\rangle-\mathbb{E}\langle\mathbf{P}_k\mathbf{x},\mathbf{y}\rangle\big|$ by Gaussian isoperimetric inequality and the proof is postponed to the Appendix. In Theorem 17, we characterize the bias $\mathbb{E}\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu}$.

Theorem 15 *Let $\delta(m_1,m_2) := \mu_1\sigma m_1^{1/2}+\sigma^2(m_1m_2)^{1/2}$ and suppose that $\bar{g}_k(\mathbf{A}\mathbf{A}^\top)\geq D_1\delta(m_1,m_2)$ for a large enough constant $D_1>0$. Then, for any $\mathbf{x},\mathbf{y}\in\mathbb{R}^{m_1}$, there exists an absolute constant $D_2>0$ such that for all $\log 8\leq t\lesssim m_1$, the following bound holds with probability at least $1-e^{-t}$,*

$$\big|\langle\hat{\mathbf{P}}_k^{uu}\mathbf{x},\mathbf{y}\rangle-\mathbb{E}\langle\hat{\mathbf{P}}_k^{uu}\mathbf{x},\mathbf{y}\rangle\big| \leq D_2t^{1/2}\bigg(\frac{\sigma\mu_1+\sigma^2m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

The following spectral representation formula is needed whose proof can be found in Koltchinskii and Lounici (2016).

Lemma 16 *The following bound holds*

$$\|\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu}\| \leq \frac{4\|\hat{\mathbf{\Gamma}}\|}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}.$$

Moreover, $\hat{\mathbf{P}}_k^{uu}$ can be represented as

$$\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu} = \mathbf{L}_k(\hat{\mathbf{\Gamma}})+\mathbf{S}_k(\hat{\mathbf{\Gamma}})$$

where $\mathbf{L}_k(\hat{\mathbf{\Gamma}})=\mathbf{P}_k^{uu}\hat{\mathbf{\Gamma}}\mathbf{C}_k^{uu}+\mathbf{C}_k^{uu}\hat{\mathbf{\Gamma}}\mathbf{P}_k^{uu}$ and

$$\|\mathbf{S}_k(\hat{\mathbf{\Gamma}})\| \leq 14\bigg(\frac{\|\hat{\mathbf{\Gamma}}\|}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg)^2.$$

Theorem 17 *Let $\delta(m_1,m_2) := \mu_1\sigma m_1^{1/2}+\sigma^2(m_1m_2)^{1/2}$ and suppose that $\bar{g}_k(\mathbf{A}\mathbf{A}^\top)\geq D_1\delta(m_1,m_2)$ for a large enough constant $D_1>0$ and $m_2e^{-m_1/2}\leq 1$. Then there exists an absolute constant $D_2>0$ such that*

$$\big\|\mathbb{E}\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu}-\mathbf{P}_k^{uu}\big(\mathbb{E}\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu}\big)\mathbf{P}_k^{uu}\big\| \leq D_2\nu_k\frac{\sigma^2m_1+\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg(\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg).$$

Proof [Proof of Theorem 1] Combining Theorem 15 and Theorem 17, we conclude that for any $\mathbf{x},\mathbf{y}\in\mathbb{R}^{m_1}$ with probability at least $1-e^{-t}$ for all $\log 8\leq t\leq m_1$,

$$\begin{aligned}&\big|\langle\hat{\mathbf{P}}_k^{uu}\mathbf{x},\mathbf{y}\rangle-\langle\mathbf{P}_k^{uu}\mathbf{x},\mathbf{y}\rangle-\langle\mathbf{P}_k^{uu}(\mathbb{E}\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu})\mathbf{P}_k^{uu}\mathbf{x},\mathbf{y}\rangle\big|\\ &\qquad\lesssim\bigg(t^{1/2}\frac{\sigma\mu_1+\sigma^2m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}+\frac{\sigma^2m_1\delta(m_1,m_2)}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\bigg)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\end{aligned}$$

where we used the fact $\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\leq 1$ and $\nu_k=1$ (since $\bar{g}_k(\mathbf{M}\mathbf{M}^\top)>0$). Since $\nu_k=1$ such that $\mathbf{P}_k^{uu}=\mathbf{u}_k\otimes\mathbf{u}_k$ and $\hat{\mathbf{P}}_k^{uu}=\hat{\mathbf{u}}_k\otimes\hat{\mathbf{u}}_k$, we can write

$$\mathbf{P}_k^{uu}(\mathbb{E}\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu})\mathbf{P}_k^{uu} = b_k\mathbf{P}_k^{uu}$$

where

$$b_k = \mathbb{E}\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle^2-1\in[-1,0].$$

Moreover, a simple fact is $b_k\leq\mathbb{E}\|\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu}\|\lesssim\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}$ by Wedin's sinΘ theorem (Wedin (1972)). If $\bar{g}_k(\mathbf{A}\mathbf{A}^\top)\geq D\delta(m_1,m_2)$ for a large enough constant $D>0$, we can ensure $b_k\in[-1/2,0]$. Then, with probability at least $1-e^{-t}$,

$$\big|\big\langle\big(\hat{\mathbf{P}}_k^{uu}-(1+b_k)\mathbf{P}_k^{uu}\big)\mathbf{x},\mathbf{y}\big\rangle\big|\lesssim\bigg(t^{1/2}\frac{\sigma\mu_1+\sigma^2m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}+\frac{\sigma^2m_1\delta(m_1,m_2)}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\bigg)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

By choosing $\mathbf{x}=\mathbf{y}=\mathbf{u}_k$, we obtain for all $\log 8\leq t\leq m_1$,

$$\mathbb{P}\bigg(\big|\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle^2-(1+b_k)\big|\gtrsim t^{1/2}\frac{\sigma\mu_1+\sigma^2m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}+\frac{\sigma^2m_1\delta(m_1,m_2)}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\bigg)\leq e^{-t}.$$

Denote this event by $\mathcal{E}_1$. Observe that if the constant $D>0$ is large enough and $m_1\ll m_2$, we conclude that on event $\mathcal{E}_1$, $\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle^2\geq\frac{1}{4}$. Then, on event $\mathcal{E}_1$,

$$\begin{aligned}&\big|\langle\hat{\mathbf{u}}_k,\mathbf{x}\rangle-\sqrt{1+b_k}\langle\mathbf{u}_k,\mathbf{x}\rangle\big|\\ &\leq\Big|\frac{1+b_k}{\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle}-\sqrt{1+b_k}\Big|\big|\langle\mathbf{u}_k,\mathbf{x}\rangle\big|\\ &+\frac{1}{\big|\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle\big|}\Big|\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle\langle\hat{\mathbf{u}}_k,\mathbf{x}\rangle-(1+b_k)\langle\mathbf{u}_k,\mathbf{x}\rangle\Big|\\ &=\frac{\sqrt{1+b_k}\big|1+b_k-\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle^2\big|\big|\langle\mathbf{u}_k,\mathbf{x}\rangle\big|}{\big|\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle\big|\big(\sqrt{1+b_k}+\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle\big)}+\frac{1}{\big|\langle\hat{\mathbf{u}}_k,\mathbf{u}_k\rangle\big|}\big|\big\langle\big(\hat{\mathbf{P}}_k^{uu}-(1+b_k)\mathbf{P}_k^{uu}\big)\mathbf{u}_k,\mathbf{x}\big\rangle\big|\\ &\lesssim t^{1/2}\frac{\sigma\mu_1+\sigma^2m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}+\frac{\sigma^2m_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg(\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg)\|\mathbf{x}\|_{\ell_2},\end{aligned}$$

which concludes the proof after replacing $\mathbf{A}$ with $\mathcal{M}_1(\mathbf{A})$ and μ_1 with $\|\mathcal{M}_1(\mathbf{A})\|$. ■

Proof [Proof of Theorem 17] Recall the representation formula of $\hat{\mathbf{P}}_k^{uu}$ in Lemma 16 that

$$\mathbb{E}\hat{\mathbf{P}}_k^{uu} = \mathbf{P}_k^{uu}+\mathbb{E}\mathbf{S}_k(\hat{\mathbf{\Gamma}})$$

where $\hat{\mathbf{\Gamma}} := \mathbf{A}\mathbf{Z}^\top + \mathbf{Z}\mathbf{A}^\top + \mathbf{Z}\mathbf{Z}^\top - m_2\sigma^2\mathbf{I}_{m_1}$. To this end, define

$$\widetilde{\mathbf{\Gamma}} := \hat{\mathbf{\Gamma}} - \big(\mathbf{Z}\mathbf{P}_k^{hh}\mathbf{Z}^\top - \nu_k\sigma^2\mathbf{I}_{m_1}\big)$$

such that we can write $\mathbb{E}\hat{\mathbf{P}}_k^{uu} = \mathbf{P}_k^{uu} + \mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) + \Big(\mathbb{E}\mathbf{S}_k(\hat{\mathbf{\Gamma}}) - \mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\Big)$. We derive an upper bound on $\big\|\mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbb{E}\mathbf{S}_k(\hat{\mathbf{\Gamma}})\big\|$ and the proof can be found in the Appendix. Lemma 18 implies that our analysis can be proceeded by replacing $\hat{\mathbf{\Gamma}}$ with $\widetilde{\mathbf{\Gamma}}$.

Lemma 18 *There exists a universal constant $D_1 > 0$ such that if $m_2 e^{-m_1/2} \le 1$, then*

$$\big\|\mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbb{E}\mathbf{S}_k(\hat{\mathbf{\Gamma}})\big\| \le D_1\frac{\sigma\mu_1 + \sigma^2 m_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big).$$

Let $\delta_t = \mathbb{E}\|\hat{\mathbf{\Gamma}}\| + D_1\sigma\mu_1 t^{1/2} + D_2\sigma^2 m_2^{1/2}t^{1/2}$ for $0 < t \le m_1$ to be determined later and large enough constants $D_1, D_2 > 0$ such that $\mathbb{P}\big(\|\hat{\mathbf{\Gamma}}\| \ge \delta_t\big) \le e^{-t}$. We write

$$\begin{aligned}
&\mathbb{E}\hat{\mathbf{P}}_k^{uu} - \mathbf{P}_k^{uu} - \mathbf{P}_k^{uu}\mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}\\
&\quad= \mathbb{E}\mathbf{S}_k(\hat{\mathbf{\Gamma}}) - \mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\\
&\quad+ \mathbb{E}\Big(\mathbf{P}_k^{uu}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp + (\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu} + (\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp\Big)\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\big)\\
&\quad+ \mathbb{E}\Big(\mathbf{P}_k^{uu}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp + (\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu} + (\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp\Big)\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\| > \delta_t\big). \quad (24)
\end{aligned}$$

We prove an upper bound for $\mathbb{E}\langle\mathbf{x}, (\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}\mathbf{y}\rangle\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\big)$ for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{m_1}$. Similar to the approach in Koltchinskii and Xia (2016), under the assumption $\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t$, $\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})$ is represented in the following analytic form,

$$\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) = -\frac{1}{2\pi i}\oint_{\gamma_k}\sum_{r\ge 2}(-1)^r\Big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\Big)^r\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)d\eta$$

where γ_k is a circle on the complex plane with center μ_k^2 and radius $\frac{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}{2}$, and $\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)$ is the resolvent of the operator $\mathbf{A}\mathbf{A}^\top$ with $\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta) = (\mathbf{A}\mathbf{A}^\top - \eta\mathbf{I}_{m_1})^{-1}$ which can be explicitly written as

$$\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta) := (\mathbf{A}\mathbf{A}^\top - \eta\mathbf{I}_{m_1})^{-1} = \sum_s\frac{1}{\mu_s^2 - \eta}\mathbf{P}_s^{uu}.$$

We also denote

$$\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta) := \mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta) - \frac{1}{\mu_k^2 - \eta}\mathbf{P}_k^{uu} = \sum_{s\ne k}\frac{1}{\mu_s^2 - \eta}\mathbf{P}_s^{uu}.$$

It is easy to check that

$$\begin{aligned}
&(\mathbf{P}_k^{uu})^\perp\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^r\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{P}_k^{uu}\\
&\quad= (\mathbf{P}_k^{uu})^\perp\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^r\frac{1}{\mu_k^2 - \eta}\mathbf{P}_k^{uu}\\
&\quad= \Big(\frac{1}{(\mu_k^2 - \eta)^2}\sum_{s=2}^r\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\big(\mathbf{P}_k^{uu}\widetilde{\mathbf{\Gamma}}\big)\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\Big)\\
&\quad+ \frac{1}{\mu_k^2 - \eta}\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^r\mathbf{P}_k^{uu},
\end{aligned}$$

where we used the formula $(a+b)^r = b^r + \sum_{s=1}^r b^{s-1}a(a+b)^{r-s}$. As a result,

$$\begin{aligned}
&(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}\\
&= -\sum_{r\ge 2}(-1)^r\frac{1}{2\pi i}\oint_{\gamma_k}\Big(\frac{1}{(\mu_k^2 - \eta)^2}\sum_{s=2}^r\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\big(\mathbf{P}_k^{uu}\widetilde{\mathbf{\Gamma}}\big)\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\\
&\quad+ \frac{1}{\mu_k^2 - \eta}\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^r\mathbf{P}_k^{uu}\Big)d\eta. \quad (25)
\end{aligned}$$

For any $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{m_1}$, we shall derive an upper bound for

$$\mathbb{E}\Big\langle\mathbf{x}, \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\big(\mathbf{P}_k^{uu}\widetilde{\mathbf{\Gamma}}\big)\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}\Big\rangle\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\big), \quad s = 2, \ldots, r.$$

Recall that $\mathrm{rank}(\mathbf{P}_k^{uu}) = \nu_k$ and $\mathbf{P}_k^{uu} = \sum_{j\in\Delta_k}\mathbf{u}_j \otimes \mathbf{u}_j$. Then,

$$\begin{aligned}
&\Big\langle\mathbf{x}, \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\big(\mathbf{P}_k^{uu}\widetilde{\mathbf{\Gamma}}\big)\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}\Big\rangle\\
&\qquad= \sum_{j\in\Delta_k}\Big\langle\mathbf{x}, \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\big(\mathbf{u}_j \otimes \mathbf{u}_j\widetilde{\mathbf{\Gamma}}\big)\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}\Big\rangle\\
&\qquad= \sum_{j\in\Delta_k}\big\langle\widetilde{\mathbf{\Gamma}}\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}, \mathbf{u}_j\big\rangle\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\mathbf{u}_j, \mathbf{x}\big\rangle.
\end{aligned}$$

Observe that

$$\begin{aligned}
\big|\big\langle\widetilde{\mathbf{\Gamma}}\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}, \mathbf{u}_j\big\rangle\big| \le&\|\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\|^{r-s}\|\widetilde{\mathbf{\Gamma}}\|^{r-s+1}\|\mathbf{y}\|_{\ell_2}\\
\le&\Big(\frac{2}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{(r-s)}\|\widetilde{\mathbf{\Gamma}}\|^{r-s+1}\|\mathbf{y}\|_{\ell_2}.
\end{aligned}$$

Therefore,

$$\begin{aligned}
&\mathbb{E}\Big\langle\mathbf{x}, \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\big(\mathbf{P}_k^{uu}\widetilde{\mathbf{\Gamma}}\big)\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}\Big\rangle\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big)\\
&= \sum_{j\in\Delta_k}\mathbb{E}\big\langle\widetilde{\mathbf{\Gamma}}\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}, \mathbf{u}_j\big\rangle\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\mathbf{u}_j, \mathbf{x}\big\rangle\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big)\\
&\le \sum_{j\in\Delta_k}\mathbb{E}^{1/2}\Big|\big\langle\widetilde{\mathbf{\Gamma}}\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}, \mathbf{u}_j\big\rangle\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big)\Big|^2\\
&\qquad\qquad\times\mathbb{E}^{1/2}\Big|\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}\mathbf{u}_j, \mathbf{x}\big\rangle\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big)\Big|^2\\
&\le \Big(\frac{2\delta_t}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{r-s}\delta_t\|\mathbf{y}\|_{\ell_2}\sum_{j\in\Delta_k}\mathbb{E}^{1/2}\Big|\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\mathbf{u}_j, \mathbf{x}\big\rangle\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big)\Big|^2. \quad (26)
\end{aligned}$$

It then remains to bound, for each $j \in \Delta_k$,

$$\mathbb{E}^{1/2}\Big|\Big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\mathbf{u}_j, \mathbf{x}\Big\rangle\Big|^2\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big).$$

Recall that we can write

$$\widetilde{\mathbf{\Gamma}} = \mathbf{A}\mathbf{Z}^\top + \mathbf{Z}\mathbf{A}^\top + \mathbf{Z}\sum_{k'\neq k}\mathbf{P}^{hh}_{k'}\mathbf{Z}^\top - \sigma^2(m_2-\nu_k)\mathbf{I}_{m_1}$$

and correspondingly

$$\widetilde{\mathbf{\Gamma}}\mathbf{u}_j = \mathbf{A}\mathbf{Z}^\top\mathbf{u}_j + \mathbf{Z}\mathbf{A}^\top\mathbf{u}_j + \mathbf{Z}\sum_{k'\neq k}\mathbf{P}^{hh}_{k'}\mathbf{Z}^\top\mathbf{u}_j - \sigma^2(m_2-\nu_k)\mathbf{u}_j.$$

We write

$$\begin{aligned}
&\Big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\mathbf{u}_j, \mathbf{x}\Big\rangle \\
&\quad = \Big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}\mathbf{A}^\top\mathbf{u}_j, \mathbf{x}\Big\rangle && (27)\\
&\quad + \Big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{A}\mathbf{Z}^\top\mathbf{u}_j, \mathbf{x}\Big\rangle && (28)\\
&\quad + \Big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\Big(\mathbf{Z}\sum_{k'\neq k}\mathbf{P}^{hh}_{k'}\mathbf{Z}^\top\mathbf{u}_j - \sigma^2(m_2-\nu_k)\mathbf{u}_j\Big), \mathbf{x}\Big\rangle. && (29)
\end{aligned}$$

The upper bounds of (27), (28), and (29) shall be obtained separately via different representations.

Bound of $\mathbb{E}^{1/2}\big|\big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}\mathbf{A}^\top\mathbf{u}_j, \mathbf{x}\big\rangle\big|^2\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big)$. Observe that $\mathbf{A}^\top\mathbf{u}_j = \mu_k\mathbf{h}_j \in \mathbb{R}^{m_2}$ for $j \in \Delta_k$ such that

$$\mathbf{Z}\mathbf{A}^\top\mathbf{u}_j = \mu_k\mathbf{Z}\mathbf{h}_j = \mu_k\sum_{i=1}^{m_1}\langle \mathbf{z}_i, \mathbf{h}_j\rangle\mathbf{e}_i$$

where $\{\mathbf{e}_1, \ldots, \mathbf{e}_{m_1}\}$ denote the canonical basis vectors in $\mathbb{R}^{m_1}$ and $\{\mathbf{z}_1^\top, \ldots, \mathbf{z}_{m_1}^\top\}$ denote the rows of $\mathbf{Z}$. Therefore,

$$\begin{aligned}
&\big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}\mathbf{A}^\top\mathbf{u}_j, \mathbf{x}\big\rangle \\
&\qquad = \mu_k\sum_{i=1}^{m_1}\langle \mathbf{z}_i, \mathbf{h}_j\rangle\big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{e}_i, \mathbf{x}\big\rangle.
\end{aligned}$$

It is clear that $\langle \mathbf{z}_i, \mathbf{h}_j\rangle, i = 1, \ldots, m_1$ are i.i.d. and $\langle \mathbf{z}_i, \mathbf{h}_j\rangle \sim \mathcal{N}(0, \sigma^2)$. Recall that $\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta) = \sum_{k'\neq k}\frac{\mathbf{P}^{uu}_{k'}}{\mu_{k'}^2-\eta}$, implying that $\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)$ can be viewed as a linear combination of operators

$$(\mathbf{P}^{uu}_{t_1}\widetilde{\mathbf{\Gamma}}\mathbf{P}^{uu}_{t_2})(\mathbf{P}^{uu}_{t_2}\widetilde{\mathbf{\Gamma}}\mathbf{P}^{uu}_{t_3})\ldots(\mathbf{P}^{uu}_{t_{s-2}}\widetilde{\mathbf{\Gamma}}\mathbf{P}^{uu}_{t_{s-1}})$$

where $t_1, \ldots, t_{s-1} \neq k$. For each $\mathbf{P}^{uu}_{t_1}\widetilde{\mathbf{\Gamma}}\mathbf{P}^{uu}_{t_2}$, we have

$$\mathbf{P}^{uu}_{t_1}\widetilde{\mathbf{\Gamma}}\mathbf{P}^{uu}_{t_2} = \mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{Z}^\top\mathbf{P}^{uu}_{t_2} + \mathbf{P}^{uu}_{t_1}\mathbf{Z}\mathbf{A}^\top\mathbf{P}^{uu}_{t_2} + \mathbf{P}^{uu}_{t_1}\big(\mathbf{Z}\sum_{k'\neq k}\mathbf{P}^{hh}_{k'}\mathbf{Z}^\top\big)\mathbf{P}^{uu}_{t_2} - \sigma^2(m_2-\nu_k)\mathbf{P}^{uu}_{t_1}\mathbf{P}^{uu}_{t_2}.$$

Clearly, $\mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{Z}^\top$ is a function of random vectors $\mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{z}_i, i = 1, \ldots, m_1$; $\mathbf{Z}\mathbf{A}^\top\mathbf{P}^{uu}_{t_2}$ is a function of random vectors $\mathbf{P}^{uu}_{t_2}\mathbf{A}\mathbf{z}_i, i = 1, \ldots, m_1$; $\mathbf{Z}\sum_{k'\neq k}\mathbf{P}^{hh}_{k'}\mathbf{Z}^\top = \mathbf{Z}\sum_{k'\neq k}(\mathbf{P}^{hh}_{k'})^2\mathbf{Z}^\top$ is a function of random vectors $\mathbf{P}^{hh}_{k'}\mathbf{z}_i, i = 1, \ldots, m_1$. The following facts are obvious

$$\mathbb{E}\langle \mathbf{z}_i, \mathbf{h}_j\rangle\mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{z}_i = \mathbf{P}^{uu}_{t_1}\mathbf{A}(\mathbb{E}\mathbf{z}_i\otimes\mathbf{z}_i)\mathbf{h}_j = \sigma^2\mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{h}_j = \sigma^2\mu_k\mathbf{P}^{uu}_{t_1}\mathbf{u}_j = \mathbf{0}, \quad \forall t_1 \neq k$$

and

$$\mathbb{E}\langle \mathbf{z}_i, \mathbf{h}_j\rangle\mathbf{P}^{hh}_{k'}\mathbf{z}_i = \mathbf{P}^{hh}_{k'}(\mathbb{E}\mathbf{z}_i\otimes\mathbf{z}_i)\mathbf{h}_j = \sigma^2\mathbf{P}^{hh}_{k'}\mathbf{h}_j = \mathbf{0}, \quad \forall k' \neq k.$$

Since $\big\{\langle \mathbf{z}_i, \mathbf{h}_j\rangle, i = 1, \ldots, m_1\big\}$ are Gaussian random variables and $\big\{\mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{z}_i, \mathbf{P}^{hh}_{k'}\mathbf{z}_i, i = 1, \ldots, m_1\big\}$ are (complex) Gaussian random vectors, uncorrelations indicate that $\big\{\langle \mathbf{z}_i, \mathbf{h}_j\rangle : i = 1, \ldots, m_1\big\}$ are independent with $\big\{\mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{z}_i, \mathbf{P}^{hh}_{k'}\mathbf{z}_i : t_1 \neq k, k' \neq k, i = 1, \ldots, m_1\big\}$. We conclude that $\big\{\langle \mathbf{z}_i, \mathbf{h}_j\rangle : i = 1, \ldots, m_1\big\}$ are independent with

$$\big\{\big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{e}_i, \mathbf{x}\big\rangle, i = 1, \ldots, m_1\big\}.$$

To this end, define the complex random variables

$$\omega_i(\mathbf{x}) = \big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{e}_i, \mathbf{x}\big\rangle = \omega_i^{(1)}(\mathbf{x}) + \omega_i^{(2)}(\mathbf{x})\mathrm{Im} \in \mathbb{C}, \quad i = 1, \ldots, m_1$$

where Im denotes the imaginary number. Then,

$$\begin{aligned}
&\big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}\mathbf{A}^\top\mathbf{u}_j, \mathbf{x}\big\rangle \\
&\qquad = \mu_k\sum_{i=1}^{m_1}\langle \mathbf{z}_i, \mathbf{h}_j\rangle\omega_i^{(1)}(\mathbf{x}) + \Big(\mu_k\sum_{i=1}^{m_1}\langle \mathbf{z}_i, \mathbf{h}_j\rangle\omega_i^{(2)}(\mathbf{x})\Big)\mathrm{Im} \\
&\qquad =: \kappa_1(\mathbf{x}) + \kappa_2(\mathbf{x})\mathrm{Im} \in \mathbb{C}.
\end{aligned}$$

Conditioned on $\big\{\mathbf{P}^{uu}_{t_1}\mathbf{A}\mathbf{z}_i, \mathbf{P}^{hh}_{k'}\mathbf{z}_i : t_1 \neq k, k' \neq k, i = 1, \ldots, m_1\big\}$, we get

$$\mathbb{E}\kappa_1^2(\mathbf{x}) = \mu_k^2\sigma^2\sum_{i=1}^{m_1}\Big(\omega_i^{(1)}(\mathbf{x})\Big)^2$$

and

$$\mathbb{E}\kappa_1(\mathbf{x})\kappa_2(\mathbf{x}) = \mu_k^2\sigma^2\sum_{i=1}^{m_1}\omega_i^{(1)}(\mathbf{x})\omega_i^{(2)}(\mathbf{x})$$

implying that the centered Gaussian random vector $(\kappa_1(\mathbf{x}), \kappa_2(\mathbf{x}))$ has covariance matrix:

$$\Big(\mu_k^2\sigma^2\sum_{i=1}^{m_1}\omega_i^{(k_1)}(\mathbf{x})\omega_i^{(k_2)}(\mathbf{x})\Big)_{k_1,k_2=1,2}.$$

Finally,

$$\begin{aligned}
&\mathbb{E}^{1/2}\big|\big\langle \big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}\mathbf{A}^\top\mathbf{u}_j, \mathbf{x}\big\rangle\big|^2\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big) \\
&\quad = \mathbb{E}^{1/2}\big(\kappa_1^2(\mathbf{x}) + \kappa_2^2(\mathbf{x})\big)\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big) \\
&\quad = \sigma\mu_k\mathbb{E}^{1/2}\Big(\sum_{i=1}^{m_1}\big(\omega_i^{(1)}(\mathbf{x})\big)^2 + \big(\omega_i^{(2)}(\mathbf{x})\big)^2\Big)\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big) \\
&\quad = \sigma\mu_k\mathbb{E}^{1/2}\sum_{i=1}^{m_1}\big|\omega_i(\mathbf{x})\big|^2\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le \delta_t\Big).
\end{aligned}$$

Moreover,

$$\sum_{i=1}^{m_1}\big|\omega_i(\mathbf{x})\big|^2=\sum_{i=1}^{m_1}\big|\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\mathbf{x},\mathbf{e}_j\big\rangle\big|^2\le\big\|\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\mathbf{x}\big\|_{\ell_2}^2$$
$$\le\|\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\|^{2(s-1)}\|\widetilde{\mathbf{\Gamma}}\|^{2(s-2)}\|\mathbf{x}\|_{\ell_2}^2\le\Big(\frac{2}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{2(s-1)}\|\widetilde{\mathbf{\Gamma}}\|^{2(s-2)}\|\mathbf{x}\|_{\ell_2}^2.$$

As a result,

$$\mathbb{E}^{1/2}\big|\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}\mathbf{A}^\top\mathbf{u}_j,\mathbf{x}\big\rangle\big|^2\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t\Big)$$
$$\le\sigma\mu_k\mathbb{E}^{1/2}\Big(\frac{2}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{2(s-1)}\|\widetilde{\mathbf{\Gamma}}\|^{2(s-2)}\|\mathbf{x}\|_{\ell_2}^2\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t\Big)$$
$$\le\frac{\sigma\mu_k}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{s-2}\|\mathbf{x}\|_{\ell_2}.$$

Bound of $\mathbb{E}^{1/2}\big|\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{A}\mathbf{Z}^\top\mathbf{u}_j,\mathbf{x}\big\rangle\big|^2\mathbf{1}(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t)$. With a little abuse on the notations, we denote by $\mathbf{z}_1,\ldots,\mathbf{z}_{m_2}\in\mathbb{R}^{m_1}$ the corresponding columns of $\mathbf{Z}$ in this paragraph. Then,

$$\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{A}\mathbf{Z}^\top\mathbf{u}_j,\mathbf{x}\big\rangle=\sum_{i=1}^{m_2}\langle\mathbf{z}_i,\mathbf{u}_j\rangle\Big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{A}\mathbf{e}_i,\mathbf{x}\Big\rangle.$$

Similarly, $\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)$ can be represented as linear combination of operators

$$\big(\mathbf{P}_{t_1}^{uu}\widetilde{\mathbf{\Gamma}}\mathbf{P}_{t_2}^{uu}\big)\big(\mathbf{P}_{t_2}^{uu}\widetilde{\mathbf{\Gamma}}\mathbf{P}_{t_3}^{uu}\big)\ldots\big(\mathbf{P}_{t_{s-2}}^{uu}\widetilde{\mathbf{\Gamma}}\mathbf{P}_{t_{s-1}}^{uu}\big),\quad t_1,\ldots,t_{s-1}\ne k.$$

To this end, we write

$$\mathbf{P}_{t_1}^{uu}\widetilde{\mathbf{\Gamma}}\mathbf{P}_{t_2}^{uu}=\mathbf{P}_{t_1}^{uu}\mathbf{A}\mathbf{Z}^\top\mathbf{P}_{t_2}^{uu}+\mathbf{P}_{t_1}^{uu}\mathbf{Z}\mathbf{A}^\top\mathbf{P}_{t_2}^{uu}+\mathbf{P}_{t_1}^{uu}\big(\mathbf{Z}\sum_{k'\ne k}\mathbf{P}_{k'}^{hh}\mathbf{Z}^\top\big)\mathbf{P}_{t_2}^{uu}-\sigma^2(m_2-\nu_k)\mathbf{P}_{t_1}^{uu}\mathbf{P}_{t_2}^{uu}.$$

Observe that $\mathbf{P}_{t_1}^{uu}\mathbf{A}\mathbf{Z}^\top\mathbf{P}_{t_2}^{uu}$, $\mathbf{P}_{t_1}^{uu}\mathbf{Z}\mathbf{A}^\top\mathbf{P}_{t_2}^{uu}$ and $\mathbf{P}_{t_1}^{uu}\big(\mathbf{Z}\sum_{k'\ne k}\mathbf{P}_{k'}^{hh}\mathbf{Z}^\top\big)\mathbf{P}_{t_2}^{uu}$ are functions of random vectors $\{\mathbf{P}_{t_1}^{uu}\mathbf{z}_i,\mathbf{P}_{t_2}^{uu}\mathbf{z}_i:t_1,t_2\ne k,i=1,\ldots,m_2\}$. Moreover,

$$\mathbb{E}\langle\mathbf{z}_i,\mathbf{u}_j\rangle\mathbf{P}_{t_1}^{uu}\mathbf{z}_i=\mathbf{P}_{t_1}^{uu}\big(\mathbb{E}\mathbf{z}_i\otimes\mathbf{z}_i\big)\mathbf{u}_j=\sigma^2\mathbf{P}_{t_1}^{uu}\mathbf{u}_j=\mathbf{0},\quad\forall\ t_1\ne k$$

which implies that $\{\langle\mathbf{z}_i,\mathbf{u}_j\rangle:i=1,\ldots,m_2\}$ and $\Big\{\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{A}\mathbf{e}_i,\mathbf{x}\big\rangle:i=1,\ldots,m_2\Big\}$ are independent. Following an identical analysis as above, we get

$$\mathbb{E}^{1/2}\big|\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{A}\mathbf{Z}^\top\mathbf{u}_j,\mathbf{x}\big\rangle\big|^2\mathbf{1}(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t)\le\frac{\sigma\mu_1}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{s-2}\|\mathbf{x}\|_{\ell_2}.$$

Bound of $\mathbb{E}^{1/2}\Big|\Big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\big(\mathbf{Z}\sum_{k'\ne k}\mathbf{P}_{k'}^{hh}\mathbf{Z}^\top\big)\mathbf{u}_j,\mathbf{x}\Big\rangle\Big|^2\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t\big)$. Note that we used the fact $\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{u}_j=\mathbf{0}$ in (29). Again, let $\{\mathbf{z}_1,\ldots,\mathbf{z}_{m_2}\}\subset\mathbb{R}^{m_1}$ denote the corresponding columns of $\mathbf{Z}$. We write

$$\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\big(\mathbf{Z}\sum_{k'\ne k}\mathbf{P}_{k'}^{hh}\mathbf{Z}^\top\big)\mathbf{u}_j,\mathbf{x}\big\rangle$$
$$=\sum_{i=1}^{m_2}\langle\mathbf{z}_i,\mathbf{u}_j\rangle\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}\big(\sum_{k'\ne k}\mathbf{P}_{k'}^{hh}\big)\mathbf{e}_i,\mathbf{x}\big\rangle.$$

In a similar fashion, we show that $\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\mathbf{Z}$ is a function of random vectors $\big\{\mathbf{P}_t^{uu}\mathbf{z}_i:t\ne k,i=1,\ldots,m_2\big\}$ which are independent with $\big\{\langle\mathbf{z}_i,\mathbf{u}_j\rangle:i=1,\ldots,m_2\big\}$. Then,

$$\mathbb{E}^{1/2}\Big|\Big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\big(\mathbf{Z}\sum_{k'\ne k}\mathbf{P}_{k'}^{hh}\mathbf{Z}^\top\big)\mathbf{u}_j,\mathbf{x}\Big\rangle\Big|^2\mathbf{1}(\|\widetilde{\mathbf{\Gamma}}\|\le\delta)$$
$$\le\mathbb{E}^{1/2}\sigma^2\|\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\|^{2(s-1)}\|\widetilde{\mathbf{\Gamma}}\|^{2(s-2)}\|\mathbf{Z}\sum_{k'\ne k}\mathbf{P}_{k'}^{hh}\|^2\|\mathbf{x}\|_{\ell_2}^2\mathbf{1}(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t)$$
$$\lesssim\frac{\sigma^2m_2^{1/2}}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{\delta_t}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{s-2}\|\mathbf{x}\|_{\ell_2}.$$

where we used the fact $\mathbb{E}^{1/2}\big\|(\sum_{k'\ne k}\mathbf{P}_{k'}^{hh})\mathbf{Z}^\top\big\|^2\lesssim\sigma m_2^{1/2}$ from Lemma 14.

Finalize the proof of Theorem. Combining the above bounds into (28), (27) and (29), we conclude that

$$\mathbb{E}^{1/2}\Big|\big\langle\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-2}\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\mathbf{u}_j,\mathbf{x}\big\rangle\Big|^2\mathbf{1}(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t)$$
$$\lesssim\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{s-2}\|\mathbf{x}\|_{\ell_2}.$$

Continue from (26) and we end up with

$$\mathbb{E}\langle\mathbf{x},\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{s-1}(\mathbf{P}_k^{uu}\widetilde{\mathbf{\Gamma}})\big(\mathbf{R}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^{r-s}\mathbf{P}_k^{uu}\mathbf{y}\rangle\mathbf{1}(\|\widetilde{\mathbf{\Gamma}}\|\le\delta_t)$$
$$\lesssim\nu_k\delta_t\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{r-2}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

Plug the bounds into (25),

$$\big|\mathbb{E}\big\langle(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}\mathbf{y},\mathbf{x}\big\rangle\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\le\delta_t\|\big)\big|$$
$$\lesssim\sum_{r\ge2}\frac{\pi\bar g_k(\mathbf{A}\mathbf{A}^\top)}{2\pi}\Big(\frac{2}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^2(r-1)\nu_k\delta_t\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{r-2}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}$$
$$\le D_1\nu_k\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\sum_{r\ge2}(r-1)\Big(\frac{2\delta_t}{\bar g_k(\mathbf{A}\mathbf{A}^\top)}\Big)^{r-1}$$

where we used the fact $\oint_{\gamma_k}\big(\widetilde{\mathbf{R}}_{\mathbf{A}\mathbf{A}^\top}(\eta)\widetilde{\mathbf{\Gamma}}\big)^r\mathbf{P}_k^{uu}d\eta=\mathbf{0}$. By the inequality $\sum_{r\geq 1}rq^r=\frac{q}{(1-q)^2},\forall q<1$ and the fact $D_1\delta_t\leq\bar{g}_k(\mathbf{A}\mathbf{A}^\top)$ for some large constant $D_1>0$ and $t\leq m_1$, we conclude with

$$\begin{aligned}&\big|\mathbb{E}\big\langle(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}\mathbf{y},\mathbf{x}\big\rangle\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\leq\delta_t\|\big)\big|\\&\qquad\lesssim\nu_k\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2},\quad\forall\mathbf{x},\mathbf{y}\in\mathbb{R}^{m_1}\end{aligned}$$

implying that

$$\Big\|\mathbb{E}(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|\leq\delta_t\big)\Big\|\lesssim\nu_k\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big).$$

The same bound holds for

$$\big\|\mathbb{E}\mathbf{P}_k^{uu}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|\leq\delta_t\big)\big\|\quad\text{and}\quad\big\|\mathbb{E}(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|\leq\delta_t\big)\big\|,$$

following the same arguments. As a result,

$$\begin{aligned}&\Big\|\mathbb{E}\Big((\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}+\mathbf{P}_k^{uu}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp+(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp\Big)\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|\leq\delta_t\big)\Big\|\\&\qquad\lesssim\nu_k\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta_t}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big).\end{aligned}\tag{30}$$

By choosing $t=m_1$ such that $\mathbb{P}(\|\widetilde{\mathbf{\Gamma}}\|\geq\delta_{m_1})\leq e^{-m_1/2}$, we get

$$\begin{aligned}&\Big\|\mathbb{E}\Big((\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}+\mathbf{P}_k^{uu}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp+(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp\Big)\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|>\delta_{m_1}\big)\Big\|\\&\leq\mathbb{E}\Big\|\Big((\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}+\mathbf{P}_k^{uu}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp+(\mathbf{P}_k^{uu})^\perp\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})(\mathbf{P}_k^{uu})^\perp\Big)\Big\|\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|>\delta_{m_1}\big)\\&\leq\mathbb{E}\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\|\mathbf{1}\big(\|\widetilde{\mathbf{\Gamma}}\|>\delta_{m_1}\big)\leq\mathbb{E}^{1/2}\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\|^2\mathbb{P}^{1/2}\big(\|\widetilde{\mathbf{\Gamma}}\|>\delta_{m_1}\big)\\&\lesssim\Big(\frac{\delta_{m_1}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)^2\mathbb{P}^{1/2}\big(\|\widetilde{\mathbf{\Gamma}}\|>\delta_{m_1}\big)\lesssim\Big(\frac{\delta_{m_1}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)^2e^{-m_1/2},\end{aligned}$$

which is clearly dominated by (30). Substitute the above bounds into (24) and we get

$$\begin{aligned}\Big\|\mathbb{E}\hat{\mathbf{P}}_k^{uu}-\mathbf{P}_k^{uu}-\mathbf{P}_k^{uu}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})\mathbf{P}_k^{uu}\Big\|&\leq\|\mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}})-\mathbf{S}_k(\hat{\mathbf{\Gamma}})\|+D_1\nu_k\frac{\sigma^2m_2^{1/2}+\sigma\mu_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)\\&\leq D_2\nu_k\frac{\sigma^2m_2^{1/2}+\sigma^2m_1+\sigma\mu_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{2\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big).\end{aligned}$$

■

6.2. Proof of Theorem 4

The proof of Theorem 4 is identical to the proof of Corollary 1.5 in Koltchinskii and Xia (2016) and will be skipped here.

6.3. Proof of Theorem 6

It suffices to prove the upper bound of $\big|\widetilde{A}(i,j,k)-A(i,j,k)\big|$ for $i\in[d_1],j\in[d_2],k\in[d_3]$. To this end, denote by $\mathbf{e}_i$ the i-th canonical basis vectors. Observe that

$$\begin{aligned}\big\langle\widetilde{\mathbf{A}}-\mathbf{A},\mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle=&\Big\langle\mathbf{A}\times_1\mathbf{P}_{\widetilde{\mathbf{U}}}\times_2\mathbf{P}_{\widetilde{\mathbf{V}}}\times_3\mathbf{P}_{\widetilde{\mathbf{W}}}-\mathbf{A},\mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\Big\rangle\\&+\Big\langle\mathbf{Z}\times_1\mathbf{P}_{\widetilde{\mathbf{U}}}\times_2\mathbf{P}_{\widetilde{\mathbf{V}}}\times_3\mathbf{P}_{\widetilde{\mathbf{W}}},\mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\Big\rangle.\end{aligned}$$

Some preliminary facts shall be concluded from Theorem 1. By Theorem 4, there exists an event $\mathcal{E}_2$ with $\mathbb{P}\big(\mathcal{E}_2\big)\geq 1-\frac{1}{d^2}$ on which

$$\big\|\mathbf{e}_i^\top\big(\widetilde{\mathbf{U}}-\mathbf{U}\big)\big\|_{\ell_2}\leq r^{1/2}\big\|\mathbf{e}_i^\top\big(\widetilde{\mathbf{U}}-\mathbf{U}\big)\big\|_{\ell_\infty}\lesssim\frac{\sigma\overline{\Lambda}(\mathbf{A})r^{1/2}+\sigma^2dr^{1/2}}{\bar{g}_{\min}^2(\mathbf{A})}\log^{1/2}d$$

and

$$\big\|\widetilde{\mathbf{U}}^\top\mathbf{U}-\mathbf{I}_{r_1}\big\|\leq\|\widetilde{\mathbf{U}}^\top\mathbf{U}-\mathbf{I}_{r_1}\|_{\mathrm{F}}\lesssim r\|\widetilde{\mathbf{U}}^\top\mathbf{U}-\mathbf{I}_{r_1}\|_{\ell_\infty}\lesssim\frac{\sigma\overline{\Lambda}(\mathbf{A})r+\sigma^2dr}{\bar{g}_{\min}^2(\mathbf{A})}\log^{1/2}d.$$

The following decomposition is straightforward,

$$\begin{aligned}&\mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}},\mathbf{P}_{\widetilde{\mathbf{V}}},\mathbf{P}_{\widetilde{\mathbf{W}}}\big)-\mathbf{A}\\&\quad=\mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}}-\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\mathbf{W}}\big)+\mathbf{A}\cdot\big(\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\widetilde{\mathbf{V}}}-\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\mathbf{W}}\big)\\&\quad+\mathbf{A}\cdot\big(\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\widetilde{\mathbf{W}}}-\mathbf{P}_{\mathbf{W}}\big)+\mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}}-\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\widetilde{\mathbf{V}}}-\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\mathbf{W}}\big)\\&\quad+\mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}}-\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\widetilde{\mathbf{W}}}-\mathbf{P}_{\mathbf{W}}\big)+\mathbf{A}\cdot\big(\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\widetilde{\mathbf{V}}}-\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\widetilde{\mathbf{W}}}-\mathbf{P}_{\mathbf{W}}\big)\\&\quad+\mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}}-\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\widetilde{\mathbf{V}}}-\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\widetilde{\mathbf{W}}}-\mathbf{P}_{\mathbf{W}}\big)\end{aligned}$$

Recall that $\mathbf{A}=\mathbf{C}\cdot(\mathbf{U},\mathbf{V},\mathbf{W})$ and we get

$$\begin{aligned}&\Big\langle\mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}}-\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\mathbf{W}}\big),\mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\Big\rangle\\&\qquad=\mathbf{e}_i^\top\Big(\widetilde{\mathbf{U}}\big(\widetilde{\mathbf{U}}^\top\mathbf{U}\big)-\mathbf{U}\Big)\mathcal{M}_1(\mathbf{C})\big(\mathbf{V}\otimes\mathbf{W}\big)^\top(\mathbf{e}_j\otimes\mathbf{e}_k).\end{aligned}$$

Observe that

$$\mathbf{e}_i^\top\Big(\widetilde{\mathbf{U}}\big(\widetilde{\mathbf{U}}^\top\mathbf{U}\big)-\mathbf{U}\Big)=\mathbf{e}_i^\top\big(\widetilde{\mathbf{U}}-\mathbf{U}\big)\big(\widetilde{\mathbf{U}}^\top\mathbf{U}\big)+\mathbf{e}_i^\top\mathbf{U}\big(\widetilde{\mathbf{U}}^\top\mathbf{U}-\mathbf{I}_{r_1}\big)$$

implying that on event $\mathcal{E}_2$,

$$\begin{aligned}&\Big\|\mathbf{e}_i^\top\Big(\widetilde{\mathbf{U}}\big(\widetilde{\mathbf{U}}^\top\mathbf{U}\big)-\mathbf{U}\Big)\Big\|_{\ell_2}\\&\quad\leq\big\|(\widetilde{\mathbf{U}}-\mathbf{U})^\top\mathbf{e}_i\big\|_{\ell_2}\|\widetilde{\mathbf{U}}^\top\mathbf{U}\|+\big\|\widetilde{\mathbf{U}}^\top\mathbf{U}-\mathbf{I}_{r_1}\big\|\|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2}\\&\quad\lesssim\frac{\sigma\overline{\Lambda}(\mathbf{A})r^{1/2}+\sigma^2dr^{1/2}}{\bar{g}_{\min}^2(\mathbf{A})}\log^{1/2}d+\|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2}\frac{\sigma\overline{\Lambda}(\mathbf{A})r+\sigma^2dr}{\bar{g}_{\min}^2(\mathbf{A})}\log^{1/2}d\\&\quad\lesssim\frac{\sigma\overline{\Lambda}(\mathbf{A})r+\sigma^2dr}{\bar{g}_{\min}^2(\mathbf{A})}\log^{1/2}d,\end{aligned}$$

where we used the facts $\|\widetilde{\mathbf{U}}^\top \mathbf{U}\| \le \|\widetilde{\mathbf{U}}\|\|\mathbf{U}\| \le (1+b_k)^{-1/2} = O(1)$ and

$$\|\mathbf{U}^\top \mathbf{e}_i\|_{\ell_2} = \big\langle \mathbf{U}\mathbf{U}^\top, \mathbf{e}_i \otimes \mathbf{e}_i \big\rangle^{1/2} \le 1.$$

Therefore, on event $\mathcal{E}_2$,

$$\begin{aligned}&\big|\big\langle \mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \\ &\qquad \lesssim \overline{\Lambda}(\mathbf{A})\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\log^{1/2} d\bigg)\|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2}\|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2}.\end{aligned}$$

Similar bounds hold for

$$\big|\big\langle \mathbf{A}\cdot\big(\mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\widetilde{\mathbf{V}}} - \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \quad\text{and}\quad \big|\big\langle \mathbf{A}\cdot\big(\mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\widetilde{\mathbf{W}}} - \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big|.$$

Following the same method, we can show that on event $\mathcal{E}_2$,

$$\begin{aligned}&\big|\big\langle \mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\widetilde{\mathbf{V}}} - \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \\ &\qquad \lesssim \overline{\Lambda}(\mathbf{A})\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\log^{1/2} d\bigg)^2\|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2}\end{aligned}$$

and

$$\begin{aligned}&\big|\big\langle \mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\widetilde{\mathbf{V}}} - \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\widetilde{\mathbf{W}}} - \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \\ &\qquad \lesssim \overline{\Lambda}(\mathbf{A})\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\log^{1/2} d\bigg)^3.\end{aligned}$$

We conclude that on event $\mathcal{E}_2$,

$$\begin{aligned}&\big|\big\langle \mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}}, \mathbf{P}_{\widetilde{\mathbf{V}}}, \mathbf{P}_{\widetilde{\mathbf{W}}}\big) - \mathbf{A}, \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \\ &\lesssim \overline{\Lambda}(\mathbf{A})\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\log^{1/2} d\bigg)\Big(\|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2}\|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2} \\ &\quad + \|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2}\|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2} + \|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2}\|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2}\Big) \\ &\quad + \overline{\Lambda}(\mathbf{A})\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\log^{1/2} d\bigg)^2\Big(\|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2} + \|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2} + \|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2}\Big) \\ &\quad + \overline{\Lambda}(\mathbf{A})\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\log^{1/2} d\bigg)^3.\end{aligned}$$

Recall that for all $i \in [d_1], j \in [d_2], k \in [d_3]$

$$\|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2} \le \mu_{\mathbf{U}}\sqrt{\frac{r}{d}}, \quad \|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2} \le \mu_{\mathbf{V}}\sqrt{\frac{r}{d}}, \quad \|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2} \le \mu_{\mathbf{W}}\sqrt{\frac{r}{d}}$$

and conditions (13) (14) (15) imply

$$\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\log^{1/2} d \lesssim r\Big(\frac{\log d}{d}\Big)^{1/2}.$$

We end up with a simpler bound on event $\mathcal{E}_2$,

$$\begin{aligned}&\big|\big\langle \mathbf{A}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}}, \mathbf{P}_{\widetilde{\mathbf{V}}}, \mathbf{P}_{\widetilde{\mathbf{W}}}\big) - \mathbf{A}, \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \\ &\qquad \lesssim \sigma r^3\bigg(\frac{\sigma\widetilde{\kappa}(\mathbf{A})}{\bar{g}_{\min}(\mathbf{A})} + \frac{\widetilde{\kappa}^2(\mathbf{A})}{d}\bigg)(\mu_{\mathbf{U}}\mu_{\mathbf{V}} + \mu_{\mathbf{U}}\mu_{\mathbf{W}} + \mu_{\mathbf{V}}\mu_{\mathbf{W}})\log^{3/2} d\end{aligned} \tag{31}$$

where $\widetilde{\kappa}(\mathbf{A}) = \overline{\Lambda}(\mathbf{A})/\bar{g}_{\min}(\mathbf{A})$.

Next, we prove the upper bound of $\big|\big\langle \mathbf{Z}\cdot(\mathbf{P}_{\widetilde{\mathbf{U}}}, \mathbf{P}_{\widetilde{\mathbf{V}}}, \mathbf{P}_{\widetilde{\mathbf{W}}}), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big|$ and we proceed with the same decomposition. Observe that

$$\begin{aligned}\big\langle \mathbf{Z}\cdot(\mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle =& \big\langle \mathbf{Z}, (\mathbf{P}_{\mathbf{U}}\mathbf{e}_i)\otimes(\mathbf{P}_{\mathbf{V}}\mathbf{e}_j)\otimes(\mathbf{P}_{\mathbf{W}}\mathbf{e}_k)\big\rangle \\ \sim& \mathcal{N}\Big(0, \sigma^2\|\mathbf{P}_{\mathbf{U}}\mathbf{e}_i\|^2_{\ell_2}\|\mathbf{P}_{\mathbf{V}}\mathbf{e}_j\|^2_{\ell_2}\|\mathbf{P}_{\mathbf{W}}\mathbf{e}_k\|^2_{\ell_2}\Big)\end{aligned}$$

The standard concentration inequality of Gaussian random variables yields that with probability at least $1 - \frac{1}{d^2}$,

$$\begin{aligned}\big|\big\langle \mathbf{Z}\cdot(\mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \lesssim& \sigma\|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2}\|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2}\|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2}\log^{1/2} d \\ \lesssim& \sigma\Big(\frac{r}{d}\Big)^{3/2}\mu_{\mathbf{U}}\mu_{\mathbf{V}}\mu_{\mathbf{W}}\log^{1/2} d.\end{aligned}$$

Similarly, with probability at least $1 - \frac{1}{d^2}$,

$$\begin{aligned}&\big|\big\langle \mathbf{Z}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \\ &\quad = \big|\mathbf{e}_i^\top\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}\big)\mathcal{M}_1(\mathbf{Z})\big(\mathbf{V}\otimes\mathbf{W}\big)\big((\mathbf{V}^\top\mathbf{e}_j)\otimes(\mathbf{W}^\top\mathbf{e}_k)\big)\big| \\ &\quad \le \|(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}})\mathbf{e}_i\|_{\ell_2}\big\|\mathcal{M}_1(\mathbf{Z})(\mathbf{V}\otimes\mathbf{W})\big\|\|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2}\|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2} \\ &\quad \lesssim \sigma d^{1/2}\|(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}})\mathbf{e}_i\|_{\ell_2}\|\mathbf{V}^\top\mathbf{e}_j\|_{\ell_2}\|\mathbf{W}^\top\mathbf{e}_k\|_{\ell_2}\end{aligned}$$

where we used Lemma 14 for the upper bound of $\big\|\mathcal{M}_1(\mathbf{Z})(\mathbf{V}\otimes\mathbf{W})\big\|$. Moreover, since $\mu_{\mathbf{U}} \ge 1$,

$$\begin{aligned}\big\|\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}\big)\mathbf{e}_i\big\|_{\ell_2} \le& \|(\widetilde{\mathbf{U}} - \mathbf{U})\mathbf{e}_i\|_{\ell_2} + \|\widetilde{\mathbf{U}} - \mathbf{U}\|_{\ell_2}\|\mathbf{U}^\top\mathbf{e}_i\|_{\ell_2} \\ \lesssim& \frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\mu_{\mathbf{U}}\log^{1/2} d.\end{aligned}$$

Denote the above event by $\mathcal{E}_3$. On $\mathcal{E}_2 \cap \mathcal{E}_3$,

$$\big|\big\langle \mathbf{Z}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \lesssim \frac{\sigma r}{d^{1/2}}\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\bigg)\mu_{\mathbf{U}}\mu_{\mathbf{V}}\mu_{\mathbf{W}}\log^{1/2} d.$$

Similar bounds can be attained for

$$\big|\big\langle \mathbf{Z}\cdot\big(\mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\widetilde{\mathbf{V}}} - \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \quad\text{and}\quad \big|\big\langle \mathbf{Z}\cdot\big(\mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\widetilde{\mathbf{W}}} - \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big|.$$

In an identical fashion, on event $\mathcal{E}_2 \cap \mathcal{E}_3$,

$$\begin{aligned}&\big|\big\langle \mathbf{Z}\cdot\big(\mathbf{P}_{\widetilde{\mathbf{U}}} - \mathbf{P}_{\mathbf{U}}, \mathbf{P}_{\widetilde{\mathbf{V}}} - \mathbf{P}_{\mathbf{V}}, \mathbf{P}_{\mathbf{W}}\big), \mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\big\rangle\big| \\ &\qquad \lesssim \sigma r^{1/2}\bigg(\frac{\sigma\overline{\Lambda}(\mathbf{A})r + \sigma^2 dr}{\bar{g}^2_{\min}(\mathbf{A})}\bigg)^2\mu_{\mathbf{U}}\mu_{\mathbf{V}}\mu_{\mathbf{W}}\log d.\end{aligned}$$

and

$$\begin{aligned}&\left|\left\langle \mathbf{Z}\cdot\left(\mathbf{P}_{\widetilde{\mathbf{U}}}-\mathbf{P}_{\mathbf{U}},\mathbf{P}_{\widetilde{\mathbf{V}}}-\mathbf{P}_{\mathbf{V}},\mathbf{P}_{\widetilde{\mathbf{W}}}-\mathbf{P}_{\mathbf{W}}\right),\mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\right\rangle\right|\\&\lesssim\sigma d^{1/2}\left(\frac{\sigma\overline{\Lambda}(\mathbf{A})r+\sigma^2dr}{\bar{g}^2_{\min}(\mathbf{A})}\right)^3\mu_{\mathbf{U}}\mu_{\mathbf{V}}\mu_{\mathbf{W}}\log^{3/2}d.\end{aligned}$$

Observe by conditions (13) (14) (15) that

$$\frac{\sigma\overline{\Lambda}(\mathbf{A})r+\sigma^2dr}{\bar{g}^2_{\min}(\mathbf{A})}\lesssim\frac{r}{d^{1/2}}.$$

We conclude on event $\mathcal{E}_2\cap\mathcal{E}_3$ with

$$\left|\left\langle \mathbf{Z}\cdot\left(\mathbf{P}_{\widetilde{\mathbf{U}}},\mathbf{P}_{\widetilde{\mathbf{V}}},\mathbf{P}_{\widetilde{\mathbf{W}}}\right),\mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\right\rangle\right|\lesssim\frac{\sigma r^2}{d^{1/2}}\left(\frac{\sigma\overline{\Lambda}(\mathbf{A})r+\sigma^2dr}{\bar{g}^2_{\min}(\mathbf{A})}\right)\mu_{\mathbf{U}}\mu_{\mathbf{V}}\mu_{\mathbf{W}}\log^{3/2}d.\tag{32}$$

By combining (31) and (32), we get on event $\mathcal{E}_2\cap\mathcal{E}_3$,

$$\begin{aligned}&\left|\left\langle\widetilde{\mathbf{A}}-\mathbf{A},\mathbf{e}_i\otimes\mathbf{e}_j\otimes\mathbf{e}_k\right\rangle\right|\\&\lesssim\sigma r^3\left(\frac{\sigma\widetilde{\kappa}(\mathbf{A})}{\bar{g}_{\min}(\mathbf{A})}+\frac{\widetilde{\kappa}^2(\mathbf{A})}{d}\right)(\mu_{\mathbf{U}}\mu_{\mathbf{V}}+\mu_{\mathbf{U}}\mu_{\mathbf{W}}+\mu_{\mathbf{V}}\mu_{\mathbf{W}})\log^{3/2}d\\&+\frac{\sigma r^2}{d^{1/2}}\left(\frac{\sigma\overline{\Lambda}(\mathbf{A})r+\sigma^2dr}{\bar{g}^2_{\min}(\mathbf{A})}\right)\mu_{\mathbf{U}}\mu_{\mathbf{V}}\mu_{\mathbf{W}}\log^{3/2}d\\&\lesssim\sigma r^3\left(\frac{\sigma\widetilde{\kappa}(\mathbf{A})}{\bar{g}_{\min}(\mathbf{A})}+\frac{\widetilde{\kappa}^2(\mathbf{A})}{d}\right)(\mu_{\mathbf{U}}\mu_{\mathbf{V}}+\mu_{\mathbf{U}}\mu_{\mathbf{W}}+\mu_{\mathbf{V}}\mu_{\mathbf{W}})\log^{3/2}d,\end{aligned}$$

where the last inequality is due to fact $\bar{g}_{\min}(\mathbf{A})\gtrsim\sigma d^{3/4}$ and $\max\left\{\mu_{\mathbf{U}},\mu_{\mathbf{V}},\mu_{\mathbf{W}}\right\}\lesssim\sqrt{d}$.

Appendix A. Proof of Lemma 14

Let $\mathbf{z}_i \in \mathbb{R}^{m_1}, i = 1, \ldots, m_2$ denote the columns of $\mathbf{Z}$. Then, we write

$$\mathbf{Z}\mathbf{Z}^\top - \sigma^2 m_2 \mathbf{I}_{m_1} = \sum_{i=1}^{m_2} \big(\mathbf{z}_i \otimes \mathbf{z}_i - \sigma^2 \mathbf{I}_{m_1}\big).$$

Similarly, let $\tilde{\mathbf{z}}_j^\top \in \mathbb{R}^{m_2}, j = 1, \ldots, m_1$ denote the rows of $\mathbf{Z}$ and observe that $\|\mathbf{B}\mathbf{Z}^\top\| = \|\mathbf{B}\mathbf{Z}^\top\mathbf{Z}\mathbf{B}^\top\|^{1/2}$ and

$$\mathbf{B}\mathbf{Z}^\top\mathbf{Z}\mathbf{B}^\top = \sum_{j=1}^{m_1} \Big(\big(\mathbf{B}\tilde{\mathbf{z}}_j\big) \otimes \big(\mathbf{B}\tilde{\mathbf{z}}_j\big) - \sigma^2 \mathbf{B}\mathbf{B}^\top\Big).$$

The inequalities (28) and (23) are on the concentration of sample covariance operator, where a sharp bound has been derived in Koltchinskii and Lounici (2017) and will be skipped here.

Appendix B. Proof of Theorem 15

Since $\mathbb{E}\hat{\mathbf{\Gamma}} = \mathbf{0}$, we immediately get $\mathbb{E}\mathbf{L}_k(\hat{\mathbf{\Gamma}}) = \mathbf{0}$. Then,

$$\big\langle \mathbf{x}, \hat{\mathbf{P}}_k^{uu}\mathbf{y}\big\rangle - \mathbb{E}\big\langle \mathbf{x}, \hat{\mathbf{P}}_k^{uu}\mathbf{y}\big\rangle = \big\langle \mathbf{x}, \mathbf{L}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\big\rangle + \big\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\big\rangle - \mathbb{E}\big\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\big\rangle.$$

Lemma 19 *For any $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{m_1}$, there exists an absolute constant $D_1 > 0$ such that for all $0 \le t \le m_1$, with probability at least $1 - e^{-t}$,*

$$\big|\big\langle \mathbf{x}, \mathbf{L}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\big\rangle\big| \le D_1 t^{1/2}\bigg(\frac{\sigma\mu_1 + \sigma^2 m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

Proof Recall that

$$\hat{\mathbf{\Gamma}} = \mathbf{A}\mathbf{Z}^\top + \mathbf{Z}\mathbf{A}^\top + \mathbf{Z}\mathbf{Z}^\top - m_2\sigma^2\mathbf{I}_{m_1}.$$

Then, we write $\big\langle \mathbf{x}, \mathbf{L}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\big\rangle$ as

$$\begin{aligned}\big\langle \mathbf{x}, \mathbf{L}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\big\rangle =& \big\langle \hat{\mathbf{\Gamma}}\mathbf{P}_k^{uu}\mathbf{x}, \mathbf{C}_k^{uu}\mathbf{y}\big\rangle + \big\langle \hat{\mathbf{\Gamma}}\mathbf{C}_k^{uu}\mathbf{x}, \mathbf{P}_k^{uu}\mathbf{y}\big\rangle \\ =& \big\langle (\mathbf{A}\mathbf{Z}^\top + \mathbf{Z}\mathbf{A}^\top + \mathbf{Z}\mathbf{Z}^\top - m_2\sigma^2\mathbf{I}_{m_1})\mathbf{P}_k^{uu}\mathbf{x}, \mathbf{C}_k^{uu}\mathbf{y}\big\rangle \\ &+ \big\langle (\mathbf{A}\mathbf{Z}^\top + \mathbf{Z}\mathbf{A}^\top + \mathbf{Z}\mathbf{Z}^\top - m_2\sigma^2\mathbf{I}_{m_1})\mathbf{C}_k^{uu}\mathbf{x}, \mathbf{P}_k^{uu}\mathbf{y}\big\rangle.\end{aligned}$$

It suffices to consider the following terms separately for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{m_1}$:

$$\big\langle \mathbf{Z}\mathbf{A}^\top\mathbf{x}, \mathbf{y}\big\rangle, \quad \big\langle \mathbf{A}\mathbf{Z}^\top\mathbf{x}, \mathbf{y}\big\rangle, \quad \big\langle \big(\mathbf{Z}\mathbf{Z}^\top - m_2\sigma^2\mathbf{I}_{m_1}\big)\mathbf{x}, \mathbf{y}\big\rangle.$$

It is straightforward to check that $\langle \mathbf{Z}\mathbf{A}^\top\mathbf{x}, \mathbf{y}\rangle$ is a normal random variable with zero mean and variance

$$\mathbb{E}\langle \mathbf{Z}\mathbf{A}^\top\mathbf{x}, \mathbf{y}\rangle^2 = \mathbb{E}\langle \mathbf{Z}, \mathbf{y} \otimes (\mathbf{A}^\top\mathbf{x})\rangle^2 = \sigma^2\|\mathbf{y} \otimes (\mathbf{A}^\top\mathbf{x})\|_{\ell_2}^2 = \sigma^2\|\mathbf{y}\|_{\ell_2}^2\|\mathbf{A}^\top\mathbf{x}\|_{\ell_2}^2,$$

where we used the fact that $\mathbf{Z}$ is a $m_1 \times m_2$ matrix with i.i.d. $\mathcal{N}(0, \sigma^2)$ entries. Therefore,

$$\mathbb{E}\langle \mathbf{Z}\mathbf{A}^\top\mathbf{P}_k^{uu}\mathbf{x}, \mathbf{C}_k^{uu}\mathbf{y}\rangle^2 \le \frac{\sigma^2\mu_k^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}^2\|\mathbf{y}\|_{\ell_2}^2,$$

where we used the facts $\|\mathbf{C}_k\| \le \frac{1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}$ and $\|\mathbf{A}^\top\mathbf{P}_k^{uu}\| \le \mu_k$. By the standard concentration inequality of Gaussian random variables, we get for all $t \ge 0$,

$$\mathbb{P}\bigg(\big|\langle \mathbf{Z}\mathbf{A}^\top\mathbf{P}_k^{uu}\mathbf{x}, \mathbf{C}_k^{uu}\mathbf{y}\rangle\big| \ge 2t^{1/2}\frac{\sigma\mu_k}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\bigg) \le e^{-t}.$$

Similarly, for all $t \ge 0$,

$$\mathbb{P}\bigg(\big|\langle \mathbf{Z}\mathbf{A}^\top\mathbf{C}_k^{uu}\mathbf{x}, \mathbf{P}_k^{uu}\mathbf{y}\rangle\big| \ge 2t^{1/2}\frac{\sigma\mu_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\bigg) \le e^{-t}.$$

We next turn to the bound of $\big|\big\langle \big(\mathbf{Z}\mathbf{Z}^\top - m_2\sigma^2\mathbf{I}_{m_1}\big)\mathbf{P}_k^{uu}\mathbf{x}, \mathbf{C}_k^{uu}\mathbf{y}\big\rangle\big|$. Recall that $\mathbf{P}_k^{uu}\mathbf{C}_k^{uu} = \mathbf{0}$ implying that it suffices to consider $\big\langle \mathbf{Z}\mathbf{Z}^\top\mathbf{P}_k^{uu}\mathbf{x}, \mathbf{C}_k^{uu}\mathbf{y}\big\rangle$. Let $\mathbf{z}_1, \ldots, \mathbf{z}_{m_2} \in \mathbb{R}^{m_1}$ denote the columns of $\mathbf{Z}$ such that $\mathbf{z}_i \in \mathcal{N}\big(\mathbf{0}, \sigma^2\mathbf{I}_{m_1}\big)$ for $1 \le i \le m_2$. Write

$$\big\langle \mathbf{Z}\mathbf{Z}^\top(\mathbf{P}_k^{uu}\mathbf{x}), \mathbf{C}_k^{uu}\mathbf{y}\big\rangle = \sum_{i=1}^{m_2}\big\langle \mathbf{z}_i, \mathbf{P}_k^{uu}\mathbf{x}\big\rangle\big\langle \mathbf{z}_i, \mathbf{C}_k^{uu}\mathbf{y}\big\rangle.$$

Observe that $\mathbb{E}\big(\mathbf{P}_k^{uu}\mathbf{z}_i\big) \otimes \big(\mathbf{C}_k^{uu}\mathbf{z}_i\big) = \mathbf{0}$ implying that $\big\langle \mathbf{z}_i, \mathbf{P}_k^{uu}\mathbf{x}\big\rangle$ is independent of $\big\langle \mathbf{z}_i, \mathbf{C}_k^{uu}\mathbf{y}\big\rangle$. By concentration inequalities of Gaussian random variables, for all $t \ge 0$,

$$\begin{aligned}\mathbb{P}\bigg(\big|\big\langle \mathbf{Z}\mathbf{Z}^\top(\mathbf{P}_k^{uu}\mathbf{x}), \mathbf{C}_k^{uu}\mathbf{y}\big\rangle\big| \ge 2t^{1/2}\|\mathbf{y}\|_{\ell_2}&\frac{\sigma\big(\sum_{i=1}^{m_2}\langle \mathbf{z}_i, \mathbf{P}_k^{uu}\mathbf{x}\rangle^2\big)^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)} \\ &\Big|\Big\{\langle \mathbf{z}_i, \mathbf{P}_k^{uu}\mathbf{x}\rangle : i = 1, \ldots, m_2\Big\}\bigg) \le e^{-t}.\end{aligned}$$

By (Vershynin, 2010, Prop 5.16), the following bound holds with probability at least $1-e^{-t}$,

$$\Big|\sum_{i=1}^{m_2}\langle \mathbf{z}_i, \mathbf{P}_k^{uu}\mathbf{x}\rangle^2 - \sigma^2 m_2\|\mathbf{x}\|_{\ell_2}^2\Big| \lesssim \sigma\Big(m_2^{1/2}t^{1/2}+t\Big)\|\mathbf{x}\|_{\ell_2}.$$

If $t \lesssim m_1 \le m_2$, we conclude that there exists an absolute constant $D_1>0$ such that

$$\mathbb{P}\bigg(\Big|\big\langle \mathbf{Z}\mathbf{Z}^\top(\mathbf{P}_k^{uu}\mathbf{x}), \mathbf{C}_k^{uu}\mathbf{y}\big\rangle\Big| \ge D_1\frac{\sigma^2 m_2^{1/2}t^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\bigg) \le e^{-t}.$$

To sum up, for all $0\le t\lesssim m_1$, the following bound holds with probability at least $1-e^{-t}$,

$$\big|\big\langle \mathbf{x}, \mathbf{L}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\big\rangle\big| \lesssim t^{1/2}\bigg(\frac{\sigma\mu_1+\sigma^2 m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\bigg)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}$$

which concludes the proof. ■

It remains to derive the upper bound of $\big|\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle - \mathbb{E}\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle\big|$.The following lemma is due to Koltchinskii and Lounici (2016).

Lemma 20 *Let $\delta(m_1,m_2) := \sigma\mu_1 m_1^{1/2} + \sigma^2(m_1m_2)^{1/2}$ and suppose that $\delta(m_1,m_2) \le \frac{1-\gamma}{2(1+\gamma)}\bar{g}_k(\mathbf{A}\mathbf{A}^\top)$ for some $\gamma\in(0,1)$. There exists a constant $D_\gamma>0$ such that, for all symmetric $\widehat{\mathbf{\Gamma}}_1, \hat{\mathbf{\Gamma}}_2 \in \mathbb{R}^{m_1\times m_1}$ satisfying the condition $\max\big\{\|\hat{\mathbf{\Gamma}}_1\|, \|\hat{\mathbf{\Gamma}}_2\|\big\} \le (1+\gamma)\delta(m_1,m_2)$,*

$$\|\mathbf{S}_k(\hat{\mathbf{\Gamma}}_1) - \mathbf{S}_k(\hat{\mathbf{\Gamma}}_2)\| \le D_\gamma\frac{\delta(m_1,m_2)}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\hat{\mathbf{\Gamma}}_1-\hat{\mathbf{\Gamma}}_2\|.$$

Define function $\varphi(\cdot):\mathbb{R}_+\mapsto[0,1]$ such that $\varphi(t)=1$ for $0\le t\le 1$ and $\varphi(t)=0$ for $t\ge(1+\gamma)$ and φ is linear in between. Then, function φ is Lipschitz on $\mathbb{R}_+$ with constant $\frac{1}{\gamma}$. To illustrate the dependence of $\hat{\mathbf{\Gamma}}$ on $\mathbf{Z}$, we write $\hat{\mathbf{\Gamma}}(\mathbf{Z})$ instead of $\hat{\mathbf{\Gamma}}$. To this end, fix $\mathbf{x},\mathbf{y}\in\mathbb{R}^{m_1}$ and constants $\delta_1,\delta_2>0$ and define the function

$$F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}) := \Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z})\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z})\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}\|}{\delta_2}\Big).$$

where we view $\mathbf{Z}$ as a point in $\mathbb{R}^{m_1\times m_2}$ rather than a random matrix.

Lemma 21 *For any $\delta_1 \le \frac{1-\gamma}{2(1+\gamma)}\bar{g}_k(\mathbf{A}\mathbf{A}^\top)$ for some $\gamma\in(0,1)$ and $\delta_2>0$, there exists an absolute constant $C_\gamma>0$ such that*

$$\big|F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_1) - F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_2)\big| \le C_\gamma\frac{\delta_1}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\Big(\mu_1+\delta_2+\frac{\delta_1}{\delta_2}\Big)\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}$$

Proof [Proof of Lemma 21] Since $\varphi(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z})\|}{\delta_1})\varphi(\frac{\|\mathbf{Z}\|}{\delta_2}) \ne 0$ only if $\|\hat{\mathbf{\Gamma}}(\mathbf{Z})\| \le (1+\gamma)\delta_1$ and $\|\mathbf{Z}\|\le(1+\gamma)\delta_2$, Lemma 16 implies that

$$\big|F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z})\big| = \Big|\Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z})\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z})\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}\|}{\delta_2}\Big)\Big| \le 14(1+\gamma)^2\frac{\delta_1^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}.$$

Case 1. If $\max\big\{\big\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big\|, \big\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\big\|\big\} \le (1+\gamma)\delta_1$ and $\max\big\{\|\mathbf{Z}_1\|,\|\mathbf{Z}_2\|\big\}\le(1+\gamma)\delta_2$.

By the Lipschitzity of function φ, Lemma 20 and definition of $\hat{\mathbf{\Gamma}}(\mathbf{Z})$, it is easy to check

$$\begin{aligned}
&|F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_1) - F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_2)|\\
&\quad\le\|\mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big) - \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\big)\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\\
&\quad+\frac{14(1+\gamma)^2\delta_1}{\gamma\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\big\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)-\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\big\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2} + \frac{14(1+\gamma)^2\delta_1^2}{\delta_2\gamma\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\\
&\quad\le D_\gamma\frac{\delta_1}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)-\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2} + \frac{14(1+\gamma)^2\delta_1^2}{\delta_2\gamma\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\\
&\quad\le D_\gamma\frac{\delta_1}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\Big(\mu_1+\delta_2+\frac{\delta_1}{\delta_2}\Big)\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.
\end{aligned}$$

Case 2. If $\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\| \le (1+\gamma)\delta_1$, $\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\| \ge (1+\gamma)\delta_1$ and $\max\big\{\|\mathbf{Z}_1\|,\|\mathbf{Z}_2\|\big\} \le (1+\gamma)\delta_2$. Since $\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\| \ge (1+\gamma)\delta_1$, we have $\varphi\big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\|}{\delta_1}\big)=0$ and $F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_2)=0$. Then,

$$\begin{aligned}
&\big|F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_1) - F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_2)\big|\\
&\quad=\Big|\Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}_1\|}{\delta_2}\Big)\Big|\\
&\quad=\Big|\Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}_1\|}{\delta_2}\Big) - \Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}_1\|}{\delta_2}\Big)\Big|\\
&\quad\le\big\|\mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\big\|\frac{1}{\delta_1\gamma}\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)-\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\\
&\quad\le\frac{(1+\gamma)^2\delta_1^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)\delta_1\gamma}\big(2\mu_1+2(1+\gamma)\delta_2\big)\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\\
&\quad\le D_\gamma\frac{\delta_1}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}(\mu_1+\delta_2)\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.
\end{aligned}$$

Case 3. If $\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\| \le (1+\gamma)\delta_1$, $\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\| \ge (1+\gamma)\delta_1$, $\|\mathbf{Z}_1\| \le (1+\gamma)\delta_2$, $\|\mathbf{Z}_2\| \ge (1+\gamma)\delta_2$. It can be proved similarly as *Case 2.*

Case 4. If $\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\| \le (1+\gamma)\delta_1$, $\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\| \ge (1+\gamma)\delta_1$, $\|\mathbf{Z}_1\| \ge (1+\gamma)\delta_2$, $\|\mathbf{Z}_2\| \ge (1+\gamma)\delta_2$. It is a trivial case since $F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_1) = F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_2) = 0$.

Case 5. If $\max\big\{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\|, \|\hat{\mathbf{\Gamma}}(\mathbf{Z}_2)\|\big\} \le (1+\gamma)\delta_1$, $\|\mathbf{Z}_1\| \le (1+\gamma)\delta_2$, $\|\mathbf{Z}_2\| \ge (1+\gamma)\delta_2$. Again, we have $F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_2) = 0$. Then,

$$\begin{aligned}
&\big|F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_1) - F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}_2)\big|\\
&\quad=\Big|\Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}_1\|}{\delta_2}\Big)\Big|\\
&\quad=\Big|\Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}_1\|}{\delta_2}\Big) - \Big\langle \mathbf{x}, \mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\mathbf{y}\Big\rangle\varphi\Big(\frac{\|\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\|}{\delta_1}\Big)\varphi\Big(\frac{\|\mathbf{Z}_2\|}{\delta_2}\Big)\Big|\\
&\quad\le\big\|\mathbf{S}_k\big(\hat{\mathbf{\Gamma}}(\mathbf{Z}_1)\big)\big\|\frac{1}{\delta_2\gamma}\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2} \le \frac{(1+\gamma)^2\delta_1^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)\delta_2\gamma}\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\\
&\quad\le D_\gamma\frac{\delta_1}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\frac{\delta_1}{\delta_2}\|\mathbf{Z}_1-\mathbf{Z}_2\|\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.
\end{aligned}$$

All the other cases shall be handled similarly and we conclude the proof. ■

Note that $\|\mathbf{Z}_1 - \mathbf{Z}_2\| \le \|\mathbf{Z}_1 - \mathbf{Z}_2\|_{\ell_2}$, Lemma 21 indicates that $F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z})$ is Lipschitz with constant

$$D_\gamma \frac{\delta_1}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\Big(\mu_1 + \delta_2 + \frac{\delta_1}{\delta_2}\Big)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

Lemma 22 *Let $\delta(m_1,m_2) := \sigma\mu_1 m_1^{1/2} + \sigma^2(m_1m_2)^{1/2}$ and suppose that $\mathbb{E}\|\hat{\mathbf{\Gamma}}\| \le \frac{1-\gamma}{2}\bar{g}_k(\mathbf{A}\mathbf{A}^\top)$ for some $\gamma \in (0,1)$. There exists some constant D_γ such that for any $\mathbf{x},\mathbf{y} \in \mathbb{R}^{m_1}$ and all $\log 8 \le t \le m_1$, the following inequality holds with probability at least $1 - e^{-t}$,*

$$\big|\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle - \mathbb{E}\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle\big| \le D_\gamma t^{1/2}\frac{\sigma\mu_1 + \sigma^2 m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

Proof [Proof of Lemma 22] Choose $\delta_1 = \delta_1(m_1,m_2)$ and $\delta_2 = \delta_2(m_1,m_2)$ as follows where $\log 8 \le t \le m_1$ is to be determined:

$$\begin{aligned}\delta_1(m_1,m_2) :&= \delta_1(m_1,m_2,t) := \mathbb{E}\|\widetilde{\mathbf{\Gamma}}\| + D_1 t^{1/2}(\sigma\mu_1 + \sigma^2 m_2^{1/2})\\ \delta_2(m_1,m_2) :&= \delta_2(m_1,m_2,t) := \mathbb{E}\|\mathbf{Z}\| + D_2\sigma t^{1/2}\end{aligned}$$

and the constants $D_1, D_2 > 0$ are chosen such that $\mathbb{P}\big(\|\hat{\mathbf{\Gamma}}\| \ge \delta_1(m_1,m_2,t)\big) \le e^{-t}$ and $\mathbb{P}\big(\|\mathbf{Z}\| \ge \delta_2(m_1,m_2,t)\big) \le e^{-t}$. Let $M := \mathrm{Med}(\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle)$ denote its median.

Case 1. If $D_1 t^{1/2}(\mu_1\sigma + \sigma^2 m_2^{1/2}) \le \frac{\gamma}{4}\bar{g}_k(\mathbf{A}\mathbf{A}^\top)$. Then, $\delta_1 \le (1-\frac{\gamma}{2})\frac{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}{2} = \frac{1-2\gamma'}{1+2\gamma'}\frac{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}{2}$ for some $\gamma' \in (0,1/2)$. By Lemma 21, $F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\cdot)$ satisfies the Lipschitz condition. By definition of $F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z})$, we have $F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}) = \langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle$ on the event $\{\|\hat{\mathbf{\Gamma}}\| \le \delta_1, \|\mathbf{Z}\| \le \delta_2\}$. By Lemma 14 and $t \ge \log 8$,

$$\begin{aligned}&\mathbb{P}\Big\{F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}) \ge M\Big\}\\ &\quad\ge \mathbb{P}\Big\{F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}) \ge M, \quad \|\hat{\mathbf{\Gamma}}\| \le \delta_1, \quad \|\mathbf{Z}\| \le \delta_2\Big\}\\ &\quad\ge \mathbb{P}\Big\{\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle \ge M\Big\} - \mathbb{P}\{\|\hat{\mathbf{\Gamma}}\| \le \delta_1, \|\mathbf{Z}\| \le \delta_2\}\\ &\quad\ge \mathbb{P}\Big\{\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle \ge M\Big\} - \mathbb{P}\Big\{\|\hat{\mathbf{\Gamma}}\| \le \delta_1\Big\} - \mathbb{P}\Big\{\|\mathbf{Z}\| \le \delta_2\Big\}\\ &\quad\ge \frac{1}{2} - \frac{1}{8} - \frac{1}{8} = 1/4,\end{aligned}$$

and similarly,

$$\mathbb{P}\Big\{F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}) \le M)\Big\} \ge 1/4.$$

It follows from Gaussian isoperimetric inequality (see (Koltchinskii and Xia, 2016, Lemma 2.6)) and Lemma 21 that with some constant $D_\gamma > 0$, for all $t \ge \log 8$ with probability at least $1 - e^{-t}$,

$$\big|F_{\delta_1,\delta_2,\mathbf{x},\mathbf{y}}(\mathbf{Z}) - M\big| \le D_\gamma \frac{\sigma\delta_1 t^{1/2}}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\Big(\mu_1 + \delta_2 + \frac{\delta_1}{\delta_2}\Big)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

Since $t \le m_1 \le m_2$, it is easy to check by Lemma 14 that $\delta_1 \asymp \sigma\mu_1 m_1^{1/2} + \sigma^2(m_1m_2)^{1/2}$ and $\delta_2 \asymp \sigma m_2^{1/2}$. Moreover, $\mathbb{P}\big\{\|\hat{\mathbf{\Gamma}}\| \le \delta_1, \|\mathbf{Z}\| \le \delta_2\big\} \ge 1 - 2e^{-t}$. As a result, with probability at least $1 - e^{-3t}$,

$$\big|\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle - M\big| \le D_\gamma \frac{\sigma\mu_1 t^{1/2} + \sigma^2 m_2^{1/2} t^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}. \tag{33}$$

Case 2. If $D_1 t^{1/2}(\sigma\mu_1 + \sigma^2 m_2^{1/2}) > \frac{\gamma}{4}\bar{g}_k(\mathbf{A}\mathbf{A}^\top)$. It implies that

$$\mathbb{E}\|\hat{\mathbf{\Gamma}}\| \le D_1\frac{(1-\gamma)}{\gamma}t^{1/2}(\sigma\mu_1 + \sigma^2 m_2^{1/2}),$$

and $\delta_1 \le D_\gamma t^{1/2}(\sigma\mu_1 + \sigma^2 m_2^{1/2})$. By Lemma 14 and Lemma 16, with probability at least $1 - e^{-t}$,

$$|\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle| \le \|\mathbf{S}_k(\hat{\mathbf{\Gamma}})\| \le D_\gamma t\frac{(\sigma\mu_1 + \sigma^2 m_2^{1/2})^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2},$$

which immediately yields that

$$M \le D_\gamma\frac{(\sigma\mu_1 + \sigma^2 m_2^{1/2})^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.$$

The above inequalities imply that with probability at least $1 - e^{-t}$ for $\log 8 \le t \le m_1$,

$$\begin{aligned}|\langle \mathbf{x}, \mathbf{S}_k(\hat{\mathbf{\Gamma}})\mathbf{y}\rangle - M| \le& D_\gamma t\frac{(\sigma\mu_1 + \sigma^2 m_2^{1/2})^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}\\ \le& D_\gamma\frac{\sigma\mu_1 t^{1/2} + \sigma^2 m_2^{1/2} t^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}.\end{aligned} \tag{34}$$

Therefore, bounds (33) and (34) hold in both cases. The rest of the proof is quite standard by integrating the exponential tails and will be skipped here, see Koltchinskii and Xia (2016). ■

Proof [Proof of Theorem 15] By Lemma 19 and Lemma 22, if $D_1\delta(m_1,m_2) \le \bar{g}_k(\mathbf{A}\mathbf{A}^\top)$ for a large enough constant $D_1 > 0$ such that $\gamma \le 1/2$, we conclude that for all $\log 8 \le t \le m_1$, with probability at least $1 - 2e^{-t}$,

$$\big|\langle \mathbf{x}, \hat{\mathbf{P}}_k\mathbf{y}\rangle\big| \le Dt^{1/2}\frac{\sigma\mu_1 + \sigma^2 m_2^{1/2}}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\|\mathbf{x}\|_{\ell_2}\|\mathbf{y}\|_{\ell_2}$$

which concludes the proof after adjusting the constant D accordingly. ■

Appendix C. Proof of Lemma 18

Observe that for any $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{m_1}$ with $\|\mathbf{x}\|_{\ell_2} = \|\mathbf{y}\|_{\ell_2} = 1$ and $\delta_t = \mathbb{E}\|\hat{\mathbf{\Gamma}}\| + D_1\sigma\mu_1 t^{1/2} + D_2\sigma^2 m_2^{1/2} t^{1/2}$ with $t \le m_1$ and some $\gamma \in (0, 1/2]$,

$$\begin{aligned}
\Big|\mathbb{E}\big\langle \mathbf{x}, \big(\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\big)\mathbf{y}\big\rangle\Big| &\le \mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\| \\
&= \mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\|\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big)\mathbf{1}\Big(\|\hat{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big) \\
&+ \mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\|\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big)\mathbf{1}\Big(\|\hat{\mathbf{\Gamma}}\| > (1+\gamma)\delta_t\Big) \\
&+ \mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\|\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| > (1+\gamma)\delta_t\Big)\mathbf{1}\Big(\|\hat{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big) \\
&+ \mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\|\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| > (1+\gamma)\delta_t\Big)\mathbf{1}\Big(\|\hat{\mathbf{\Gamma}}\| > (1+\gamma)\delta_t\Big)
\end{aligned}$$

where the constants $D_1, D_2 > 0$ are chosen such that $\max\big\{\mathbb{P}\big(\|\widetilde{\mathbf{\Gamma}}\| \ge \delta_t\big), \mathbb{P}\big(\|\hat{\mathbf{\Gamma}}\| \ge \delta_t\big)\big\} \le e^{-t}$. By Lemma 20,

$$\begin{aligned}
&\mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\|\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big)\mathbf{1}\Big(\|\hat{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big) \\
&\quad\le D_\gamma \frac{\delta_t}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\mathbb{E}\|\widetilde{\mathbf{\Gamma}} - \hat{\mathbf{\Gamma}}\| \le D_\gamma \frac{\delta_t}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\mathbb{E}\|\mathbf{Z}\mathbf{P}_k^{hh}\mathbf{Z}^\top - \nu_k\sigma^2\mathbf{I}_{m_1}\|.
\end{aligned}$$

By writing $\mathbf{P}_k^{hh} := \sum_{j\in\Delta_k}\mathbf{h}_j \otimes \mathbf{h}_j$, we obtain

$$\begin{aligned}
\mathbf{Z}\mathbf{P}_k^{hh}\mathbf{Z}^\top - \sigma^2\nu_k\mathbf{I}_{m_1} &= \sum_{j\in\Delta_k}(\mathbf{Z}\mathbf{h}_j)\otimes(\mathbf{Z}\mathbf{h}_j) - \sigma^2\nu_k\mathbf{I}_{m_1} \\
&= \nu_k\Big(\frac{1}{\nu_k}\sum_{j\in\Delta_k}(\mathbf{Z}\mathbf{h}_j)\otimes(\mathbf{Z}\mathbf{h}_j) - \sigma^2\mathbf{I}_{m_1}\Big).
\end{aligned}$$

where $\nu_k = \mathrm{Card}(\Delta_k)$. The vectors $\mathbf{Z}\mathbf{h}_j \sim \mathcal{N}(0, \sigma^2\mathbf{I}_{m_1})$ and $\{\mathbf{Z}\mathbf{h}_j : \ldots, j \in \Delta_k\}$ are independent. By Koltchinskii and Lounici (2017),

$$\mathbb{E}\Big\|\frac{1}{\nu_k}\sum_{j\in\Delta_k}(\mathbf{Z}\mathbf{h}_j)\otimes(\mathbf{Z}\mathbf{h}_j) - \sigma^2\mathbf{I}_{m_1}\Big\| \lesssim \sigma^2\Big(\sqrt{\frac{m_1}{\nu_k}} \vee \frac{m_1}{\nu_k}\Big).$$

Since $\nu_k \le m_1$, we conclude with

$$\begin{aligned}
\mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\|\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big)\mathbf{1}\Big(\|\hat{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_t\Big) \\
\lesssim_\gamma \frac{\delta_t}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{m_1\sigma^2}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big).
\end{aligned} \tag{35}$$

Choose $t = m_1$, by Lemma 16 and Lemma 14,

$$\begin{aligned}
&\mathbb{E}\Big\|\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbf{S}_k(\hat{\mathbf{\Gamma}})\Big\|\mathbf{1}\Big(\|\hat{\mathbf{\Gamma}}\| \le (1+\gamma)\delta_{m_1}\Big)\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| > (1+\gamma)\delta_{m_1}\Big) \\
&\quad\le D_\gamma\frac{\delta_{m_1}^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\mathbb{E}\frac{\|\widetilde{\mathbf{\Gamma}}\|^2}{\bar{g}_k^2(\mathbf{A}\mathbf{A}^\top)}\mathbf{1}\Big(\|\widetilde{\mathbf{\Gamma}}\| > (1+\gamma)\delta_{m_1}\Big) \\
&\quad\lesssim_\gamma \frac{\delta_{m_1}^2}{\bar{g}_k^4(\mathbf{A}\mathbf{A}^\top)}e^{-m_1/2}\mathbb{E}^{1/2}\|\widetilde{\mathbf{\Gamma}}\|^4 \lesssim \frac{\delta_{m_1}^4}{\bar{g}_k^4(\mathbf{A}\mathbf{A}^\top)}e^{-m_1/2} \\
&\quad\lesssim \frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{\sigma\mu_1 + \sigma^2 m_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big)
\end{aligned}$$

which is clearly dominated by (35) for $t = m_1$ and $m_2 e^{-m_1/2} \le 1$. The other terms are bounded in a similar fashion. To sum up, we obtain

$$\|\mathbb{E}\mathbf{S}_k(\widetilde{\mathbf{\Gamma}}) - \mathbb{E}\mathbf{S}_k(\hat{\mathbf{\Gamma}})\| \lesssim \frac{\sigma\mu_1 + \sigma^2 m_1}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big(\frac{\delta(m_1,m_2)}{\bar{g}_k(\mathbf{A}\mathbf{A}^\top)}\Big).$$

Abstract

We consider revenue maximization in online auction/pricing problems. A seller sells an identical item in each period to a new buyer, or a new set of buyers. For the online pricing problem, both when the arriving buyer bids or only responds to the posted price, we design algorithms whose regret bounds *scale with the best fixed price in-hindsight*, rather than the range of the values. Under the bidding model, we further show our algorithms achieve a revenue convergence rate that matches the offline sample complexity of the single-item single-buyer auction. We also show regret bounds that are *scale free*, and match the offline sample complexity, when comparing to a benchmark that requires a lower bound on the market share. We further expand our results beyond pricing to multi-buyer auctions, and obtain online learning algorithms for auctions, with convergence rates matching the known sample complexity upper bound of online single-item multi-buyer auctions.

These results are obtained by generalizing the classical learning from experts and multi-armed bandit problems to their *multi-scale* versions. In this version, the reward of each action is in a different range, and the regret with respect to a given action scales with its own range, rather than the maximum range. We obtain almost optimal multi-scale regret bounds by introducing a new Online Mirror Descent (OMD) algorithm whose mirror map is the multi-scale version of the negative entropy function. We further generalize to the bandit setting by introducing the stochastic variant of this OMD algorithm.

Keywords: online learning, multi-scale learning, auction theory, bandit information, sample complexity. †

1. Introduction

Consider the following revenue maximization problem in a repeated setting, called the *online posted pricing* problem. In each period, the seller has a single item to sell, and a new prospective buyer. The seller offers to sell the item to the buyer at a given price; the buyer buys the item if and only if the price is below his private valuation for the item. The private valuation of the buyer itself is never revealed to the seller. How should a monopolistic seller iteratively set the prices if he wishes to maximize his revenue? What if he also cares about the market share, i.e., the fraction of time periods at which the item is sold?[1]

Estimating price sensitivities and demand models in order to optimize revenue and market share is one of the bedrock of revenue management. The emergence of online marketplaces has enabled sellers to costlessly change prices, as well as collect huge amounts of data. This has renewed the interest in understanding best practices for data driven pricing. The extreme case of this when the price is updated for each buyer is the online pricing problem described above; one can always use this for less frequent price updates. Moreover this problem is intimately related to the classical experimentation and estimation procedures.

This problem has been studied from an *online learning* perspective, as a variant of the *multi-armed bandit* problem. In this variant, there is an arm for each possible price (presumably after an appropriate discretization). The revenue of each arm p is either p or zero, depending on whether the value of the arriving buyer is at least equal to the price p or smaller than the price p, respectively. The total revenue of a pricing algorithm is then compared to the total revenue of the best fixed posted price in hindsight. The difference between the two, called the *regret*, is then bounded from above. No assumption is made on the distribution of values; the regret bounds are required to hold for the *worst case* sequence of values. Blum et al. (2004) assume that the buyer valuations are in $[1, h]$, and show the following multiplicative plus additive bound on the regret: for any $\epsilon \in (0, 1)$, the regret is at most ϵ times the revenue of the optimal price, plus $O(\epsilon^{-2} h \log h \log\log h)$. Blum and Hartline (2005) show that the additive factor can be made to be $O(\epsilon^{-3} h \log\log h)$, trading off a $\log h$ factor for an extra ϵ^{-1} factor.

An undesirable aspect of these bounds is that they scale *linearly with* h; this is particularly problematic when h is an estimate and we might set it to be a generous upper bound on the range of prices we wish to consider. A typical use case is when the same algorithm is used for many different products, with widely varying price ranges. We may not be able to manually tune the range for each product separately.

One might wonder if this dependence on h is unavoidable, as it seems to be reflected by the existing lower bounds for this problem in the literature (lower bounds are discussed later in the introduction with more details). Interestingly, in all of these lower-bound instances the best fixed price is equal to h itself; Therefore, it is not clear whether this dependency on h is required for instances where h is only a pessimistic upper-bound on the best fixed price. We now ask the following question:

> **Question**: *do online learning algorithms exist for the online posted pricing problem, such that their regrets are proportional to the best fixed price instead of the highest value?*

1. As we will see later in the paper, we consider designing pricing algorithms that have vanishing revenue regret with respect to all prices, or only prices with a given minimum market share.

Standard off-the-shelf bounds, e.g., those obtained by using classic results on full information online learning (Arora et al., 2012) or bandit information online learning (Auer et al., 1995; Bubeck, 2011), allow regret to depend on the loss of the best arm instead of the worst case loss. However, even such bounds still depend linearly on the maximum range of all the losses, and thus they would not allow to replace h by the best fixed price.

Fortunately, in the online pricing problem the reward function of the arms is well structured. In particular, as a neat observation, the reward of the arm p is upper-bounded by p (and not only the maximum value). Can we use this structure in our favor to improve the standard regret bounds? We answer this question in the affirmative by the means of reducing the problem to a pure learning problem termed as *mutli-scale online learning*. Notably, this structural observation is the same structural observation that enabled the improved bounds of Blum and Hartline (2005) over the prior work at the time.

1.1. Multi-scale online learning

The main technical ingredients in our results are variants of the classical problems of learning from expert advice and multi-armed bandit. We introduce the multi-scale versions of these problems, where each action has its reward bounded in a different range. We assume these ranges are known in advance by any online algorithm. Here, we seek to design online learning algorithms that guarantee *multi-scale regret* bounds, i.e. their regrets with respect to each certain action scales with the range of that particular action, instead of the maximum possible range. These guarantees are in contrast with the regret bounds of the standard versions, which scale with the maximum range.

> **Main result (informal):** *we give algorithms for the full information and bandit information versions of the multi-scale online learning problem with information theoretically optimal (or almost optimal) multi-scale regret guarantees.*

While we use these bounds mostly for designing online auctions and pricing mechanisms, we expect such bounds to be of independent interest.

The main idea behind our algorithms is to use a tailored variant of *online (stochastic) mirror descent (OSMD)* (Bubeck, 2011). In this tailored version, the algorithm uses a *weighted negative entropy* as the Legendre function (also known as the *mirror map*), where the weight of each term i (corresponding to arm i) is actually equal to the range of that arm. More formally, assuming the range of arm i is equal to c_i (i.e., reward of arm i is in $[0, c_i]$), our mirror descent algorithms (Algorithm 1 for full information, and Algorithm 3 for the bandit information) use the following mirror map:

$$F(x) = \sum_{\text{arms } i} c_i \cdot x_i \ln(x_i)$$

Intuitively speaking, these algorithms take into account different ranges for different arms by first normalizing the reward of each arm by its range (i.e. divide the reward of arm i by its corresponding range c_i), and then projecting the updated weights by performing a *smooth multi-scale projection* into the simplex. This projection is an instance of the more general Bregman projection (Bubeck, 2011) for the special case of weighted negative entropy as the mirror map. The mirror descent framework then gives regret bounds in terms of a

"local norm" as well as an "initial divergence", which we then bound differently for each version of the problem. In the technical sections we highlight how the subtle variations arise as a result of different techniques used to bound these two terms.

While our algorithms have the style of the multiplicative weights update (up to a normalization of the rewards), the smooth projection step at each iteration makes them drastically different. To shed some insight on this projection step, which plays an important role in our analysis, consider a very special case of the problem where the reward of each arm i is deterministically equal to c_i. The multiplicative weights algorithm picks arm i with a probability proportional to $\exp(c_i)$. However, as it is clear from the description of Algorithm 1, our algorithm uniformly scales the weight of each arm first. Then, in the projection step the weight of each arm i is multiplied by $\exp(-\frac{\lambda^*}{c_i})$ for some parameter λ^*. Hence, arm i will be sampled with a probability proportional to $\exp(-\frac{\lambda^*}{c_i})$ (which is a smooth approximation to $i^* = \text{argmax } c_i$, but in a different way compared to the vanilla multiplicative weights).

The multi-scale versions exhibit subtle variations that do not appear in the standard versions. First of all, our applications to auctions and pricing have non-negative rewards, and this actually makes a difference. For both the expert and the bandit versions, the minimax regret bounds for non-negative rewards are *provably better* than those when rewards could be negative. Further, for the bandit version with non-negative rewards, we can prove a better bound (in terms of the dependency on time horizon T) if we only require the bound to hold with respect to the *best* action, rather than *all* actions (which was the requirement of the vanilla version of our definition for a multi-scale regret bound). The various regret bounds and comparison to standard bounds are summarized in Tables 1.

	Standard regret bound $O(\cdot)$	Multi-scale bound (this paper)	
		Upper bound $O(\cdot)$	Lower bound $\Omega(\cdot)$
Experts/non-negative	$c_{\max}\sqrt{T\log(k)}$ *	$c_i\sqrt{T\log(kT)}$	$c_i\sqrt{T\log(k)}$
Bandits/non-negative	$c_{\max}\sqrt{Tk}$ †	$c_i T^{\frac{2}{3}}(k\log(kT))^{\frac{1}{3}}$	$c_i\sqrt{TK}$
		$c_{i^*}\sqrt{Tk\log(k)}$, i^* is the best action	-
Experts/symmetric	$c_{\max}\sqrt{T\log(k)}$ *	$c_i\sqrt{T\log(k\cdot\frac{c_{\max}}{c_{\min}})}$	$c_i\sqrt{T\log(k)}$
Bandits/symmetric	$c_{\max}\sqrt{Tk}$ †	$c_i\sqrt{Tk\cdot\frac{c_{\max}}{c_{\min}}\log(kT\cdot\frac{c_{\max}}{c_{\min}})}$	$c_i\sqrt{Tk\cdot\frac{c_{\max}}{c_{\min}}}$

* Freund and Schapire (1995); † Audibert and Bubeck (2009).

Table 1: Pure-additive regret bounds for non-negative rewards, i.e. when reward of any action i at any time is in $[0, c_i]$, and symmetric range rewards, i.e. when reward of any action i at any time is in $[-c_i, c_i]$ (suppose T is the time horizon, A is the action set, and k is the number of actions).

1.2. The implications for online auctions and pricing

As a direct application of our multi-scale online learning framework, somewhat surprisingly,

Second contribution: *we show that we can get regret proportional to the best fixed price instead of the highest value for the online posted pricing problem.*

(i.e., we can replace h by the best fixed price, which is used in the definition of the benchmark). In particular, we show that the additive bound can be made to be $O(\epsilon^{-2}p^* \log h)$, where p^* is the best fixed price in hindsight. This allows us to use a very generous estimate for h and let the algorithm adapt to the actual range of prices; we only lose a $\log h$ factor. The algorithm balances exploration probabilities of different prices carefully and automatically zooms in on the relevant price range. This does not violate known lower bounds, since in those instances p^* is close to h.

Bar-Yossef et al. (2002), Blum et al. (2004), and Blum and Hartline (2005) also consider the "full information" version of the problem, or what we call the *online (single buyer) auction* problem, where the valuations of the buyers are revealed to the algorithm after the buyer has made a decision. Such information may be available in a context where the buyers have to bid for the items, and are awarded the item if their bid is above a hidden price. In this case, the additive term can be improved to $O(\epsilon^{-1}h \log(\epsilon^{-1}))$, which is tight. Once again, by a reduction to multi-scale online learning, *we show that h can be replaced with p^**; in particular, we show that the additive term can be made to be $O(\epsilon^{-1}p^* \log(h\epsilon^{-1}))$.

1.3. Purely multiplicative bounds and sample complexity

The regret bounds mentioned above can be turned into a purely multiplicative factor in the following way: for any $\epsilon > 0$, the algorithm is guaranteed to get a $1 - O(\epsilon)$ fraction of the best fixed price revenue, provided the number of periods $T \geq E/\epsilon$, where E is the additive term in the regret bounds above. This follows from the observation that a revenue of T is a lower bound on the best fixed price revenue. Define the number of periods required to get a $1 - \epsilon$ multiplicative approximation (as a function of ϵ) to be the *convergence rate* of the algorithm.

A $1 - \epsilon$ multiplicative factor is also the target in the recent line of work, on the *sample complexity* of auctions, started by Balcan et al. (2008); Elkind (2007); Dhangwatnotai et al. (2014); Cole and Roughgarden (2014). (We give a more comprehensive discussion of this line of work in Section 1.4.) Here, *i.i.d.* samples of the valuations are given from a *fixed but unknown distribution*, and the goal is to find a price such that its revenue with respect to the hidden distribution is a $1 - \epsilon$ fraction of the optimum revenue for this distribution. The sample complexity is the minimum number of samples needed to guarantee this (as a function of ϵ).

The sample complexity and the convergence rate (for the full information setting) are closely related to each other. The sample complexity is always smaller than the convergence rate: the problem is easier because of the following.

1. The valuations are i.i.d. in the case of sample complexity, whereas they can be arbitrary (worst case) in the case of convergence rate.

2. Sample complexity corresponds to an offline problem: you get all the samples at once. Convergence rate corresponds to an online problem: you need to decide what to do on a given valuation without knowing what valuations arrive in the future.

This is formalized in terms of an *online to offline reduction* [folklore] which shows that a convergence rate upper bound can be automatically translated to a sample complexity upper bound. This lets us convert sample complexity lower bounds into lower bounds on the convergence rate, and in turn into lower bounds on the additive error E in an additive plus multiplicative regret bound. For example, the additive error for the online auction problem (and hence also for the posted pricing problem[2]) cannot be $o(h\epsilon^{-1})$ (Huang et al., 2015b). Moreover, it is insightful to compare convergence rates we show with *the best known sample complexity upper bound; proving better convergence rates would mean improving these bounds as well.*

A natural target convergence rate for a problem is therefore the corresponding sample complexity, but achieving this is not always trivial. In particular, we consider an interesting version of the sample complexity bound for auctions, for which no analogous convergence rate bound is known in the literature. This version takes into account *both revenue and market share*, and gets sample complexity bounds that are *scale free*; there is no dependence on h, which means it works for unbounded valuations! For any $\delta \in (0, 1)$, the best fixed price benchmark is relaxed to ignore those prices whose market share (which is equivalent to the probability of sale) is below a δ fraction; as δ increases the benchmark is lower. This is a meaningful benchmark since in many cases revenue is not the only goal, even if you are a monopolist. A more reasonable goal is to maximize revenue subject to the constraint that the market share is above a certain threshold. What is more, this gives a sample complexity of $O(\epsilon^{-2}\delta^{-1} \log(\delta^{-1}\epsilon^{-1}))$ (Huang et al., 2015b). In fact δ can be set to h^{-1} without loss of generality, when the values are in $[1, h]$,[3] and the above bound then matches the sample complexity with respect to the best fixed price revenue. In addition, this bound gives a precise interpolation: as the target market share δ increase, the number of samples needed decreases almost linearly.

Third contribution: *we show an average revenue convergence rate that almost matches the above sample complexity, for the full information setting, i.e. number of rounds required for this convergence matches the number of i.i.d. samples required for an offline algorithm to attain the same near-optimality guarantee.*

We have a mild dependence on h; the rate is proportional to $\log \log h$. Further, we also show a near optimal convergence rate for the online posted pricing problem.[4]

Multiple buyers: All of our results in the full information (online auction) setting extend to the multiple buyer model. In this model, in each time period, a new set of n buyers competes for a single item. The seller runs a truthful auction that determines the winning buyer and his payment. The benchmark here is the set of all "Myerson-type" mechanisms. These are mechanisms that are optimal when each period has n buyers of potentially different types, and the value of each buyer is drawn independently from a type dependent

2. We conjecture that the lower bound for the posted pricing problem should be worse by a factor of ϵ^{-1}, since one needs to explore about ϵ^{-1} different prices.
3. When the values are in $[1, h]$, we can guarantee a revenue of T by posting a price of 1, and to beat this, any other price (and in particular a price of h) would have to sell at least T/h times.
4. Unfortunately, we cannot yet guarantee that our online algorithm itself gets a market share of δ, although we strongly believe that it does. Showing such bounds on the market share of the algorithm is an important avenue for future research.

distribution. In fact, our convergence rates also imply new sample complexity bounds for these problems (except that they are not computationally efficient).

The various bounds and comparisons to previous work are summarized in Tables 2 & 3.

Table 2: Number of rounds/samples needed to get a $1-\epsilon$ approximation to the best offline price/mechanism. Sample complexity is for the offline case with i.i.d. samples from an unknown distribution. Convergence rate is for the online case with a worst case sequence. Sample complexity is always no larger than the convergence rate. Lower bounds hold for sample complexity too, except for the online posted pricing problem for which there is no sample complexity version. The additive plus multiplicative regret bounds are converted to convergence rates by dividing the additive error by ϵ. In the last row, n is the number of buyers. In the last column, p^* denotes the optimal price.

1.4. Other related work

The online pricing problem, also called *dynamic pricing*, is a much studied topic, across disciplines such as operations research and management science (Talluri and Van Ryzin, 2006), economics (Segal, 2003), marketing, and of course computer science. The multi-armed bandit approach to pricing is particularly popular. See den Boer (2015) for a recent survey on various approaches to the problem.

Kleinberg and Leighton (2003) consider the online pricing problem, under the assumption that the values are in $[0,1]$, and considered purely additive factors. They showed that the minimax additive regret is $\tilde{\Theta}(T^{2/3})$, where T is the number of periods. This is similar in spirit to regret bounds that scale with h, since one has to normalize the values so that they are in $[0,1]$. The finer distinction about the magnitude of the best fixed price is absent in this work. Recently, Syrgkanis (2017) also consider the online auction problem, with an emphasis on a notion of "oracle based" computational efficiency. He assume the values are all in $[0,1]$ and do not consider the scaling issue that we do; this makes their contribution orthogonal to ours.

Starting with Dhangwatnotai et al. (2014); Elkind (2007), there has been a spate of recent results analyzing the sample complexity of pricing and auction problems. Cole and Roughgarden (2014) and Devanur et al. (2016) consider multiple buyer auctions with regular distributions (with unbounded valuations) and give sample complexity bounds that are polynomial in n and ϵ^{-1}, where n is the number of buyers. Morgenstern and Roughgarden (2015) consider arbitrary distributions with values bounded by h, and gave bounds that are polynomial in n, h, and ϵ^{-1}. Roughgarden and Schrijvers (2016); Huang et al. (2015b) give further improvements on the single- and multi-buyer versions respectively; Tables 2 and 3 give a comparison of these results with our bounds, for the problems we consider. The dynamic pricing problem has also been studied when there are a given number of copies of the item to sell (limited supply) (Agrawal and Devanur, 2014; Babaioff et al., 2015; Badanidiyuru et al., 2013; Besbes and Zeevi, 2009). There are also variants where the seller interacts with the same buyer repeatedly, and the buyer can strategize to influence his utility in the future periods (Amin et al., 2013).

Foster et al. (2017) also consider the multi-scale online learning problem motivated by a model selection problem. They consider additive bounds, for the symmetric case, for full information, but not bandit feedback. Their regret bounds are not comparable to ours in general; our bounds are better for the pricing/auction applications we consider, and their bounds are better for their application.

Organization We start in Section 2 by showing regret upper bounds for the multi-scale experts problem with non-negative rewards (Theorem 1). The corresponding upper bounds for the bandit version are in section 3 (Theorem 12). In Section 4 we show how the multi-scale regret bounds (Theorems 1 and 12) imply the corresponding bounds for the auction/pricing problems (Theorems 16 and 17). Finally, the regret (upper and lower) bounds for the symmetric range are discussed in Section 5 (Theorems 18, 20, 21, and 23).

2. Full Information Multi-scale Online Learning

We consider a variety of online algorithmic problems that are all parts of the *multiscale online learning* framework. We start by defining this framework, in which different actions have different ranges. We exploit this structure and express our results in terms of *action-specific* regret bounds for this general problem. To obtain these results, we use a variant of online mirror descent and propose a multiplicative-weight update style learning algorithm for our problem, termed as *Multi-Scale Multiplicative-Weight (MSMW)* algorithm.

Next, we investigate the single buyer auction problem (or equivalently the full-information single buyer dynamic pricing problem) as a canonical application, and show how to get mul-

tiplicative cum additive approximations here by the help of the multi-scale online learning framework. To show the tightness of our bounds, we compare the convergence rate of our dynamic pricing with the sample complexity of a closely related offline problem, i.e. the near optimal Bayesian revenue maximization from samples (Cole and Roughgarden, 2014).

2.1. The framework

Our full-information multi-scale online learning framework is basically the classical learning from expert advice problem. The main difference is that the *range* of rewards of different experts could be different. More formally, suppose there is a set of actions A.[5] The online problem proceeds in T rounds, where in each round $t \in [T]$:[6]

- The adversary picks a reward function $\mathbf{g}(t)$, where $g_i(t)$ is the reward of action i.
- The algorithm picks an action $i_t \in A$ simultaneously.
- Then the algorithm gets the reward $g_{i_t}(t)$ and observes the entire reward function $\mathbf{g}(t)$.

The total reward of the algorithm is denoted by

$$G_{\text{ALG}} := \sum_{t=1}^{T} g_{i_t}(t).$$

The standard "best fixed action" benchmark is

$$G_{\text{MAX}} := \max_{i \in A} \sum_{t=1}^{T} g_i(t).$$

We further assume that the action set is countable, either finite or infinite (will discuss this later). Without loss of generality, if the action set is of size k, we identify $A = [k]$. The reward $\mathbf{g}(t)$ is such that for all $i \in A$, $g_i(t) \in [0, c_i]$, where $c_i \in \mathbb{R}_+$ is the *range* of action i.

2.2. Multi-scale regret bounds

We prove action-specific regret bounds, which we call also *multi-scale regret guarantees*. Towards this end, we define the following quantities.

$$G_i := \sum_{t \in [T]} g_i(t) \ , \tag{1}$$

$$\text{REGRET}_i := G_i - G_{\text{ALG}} \ . \tag{2}$$

The regret bound w.r.t. action i, i.e., an upper bound on $\mathbb{E}[\text{REGRET}_i]$, depends on the range c_i, as well as any *prior* distribution $\boldsymbol{\pi}$ over the action set A; this way, we can handle countably many actions. Let $c_{\min} = \inf_{i \in A} c_i$ and $c_{\max} = \sup_{i \in A} c_i$ (if applicable) be the minimum and the maximum range. We first state a version of the regret bound which is parameterized by $\epsilon > 0$; such bounds are stronger than $\sqrt{T}$ type bounds which are more standard.

5. We use the terms experts, arms and actions interchangeably in this paper.
6. We use the notation $[n] := \{1, 2, \ldots, n\}$, for any $n \in \mathbb{N}$.

Theorem 1 (Main Result) *There exists an algorithm for the full-information multi-scale online learning problem that takes as input any distribution $\boldsymbol{\pi}$ over A, the ranges c_i, $\forall\, i \in A$ and a parameter $0 < \epsilon \leq 1$, and satisfies:*

$$\forall i \in A: \quad \mathbb{E}[\text{REGRET}_i] \leq \epsilon \cdot G_i + O\left(\frac{1}{\epsilon} \log\left(\frac{1}{\epsilon \pi_i}\right) \cdot c_i\right) \tag{3}$$

Compare this to what you get by using the standard analysis for the experts problem (Arora et al., 2012), where the second term in the regret bound is $O\big(\frac{1}{\epsilon}\log(k) \cdot c_{\max}\big)$. Choosing $\boldsymbol{\pi}$ to be the uniform distribution in the above theorem gives $O\big(\frac{1}{\epsilon}\log\left(\frac{k}{\epsilon}\right) \cdot c_i\big)$. Also, one can compare the pure-additive version of this bound with the classic pure-additive regret bound $O\big(c_{\max} \cdot \sqrt{T\log(k)}\big)$ for the experts problem by setting $\epsilon = \sqrt{\frac{\log(kT)}{T}}$ (Corollary 2).

Corollary 2 *There exists an algorithm for the full-information multi-scale online learning problem that takes as input the ranges c_i, $\forall\ i \in A$, and satisfies:*

$$\forall i \in A: \quad \mathbb{E}[\text{REGRET}_i] \leq O\left(c_i \cdot \sqrt{T \log(kT)}\right) \tag{4}$$

Remark 3 *We should assert that in a multi-scale regret guarantee, we provide a separate regret bound for each action, where the bound on the regret of action i only scales linearly with c_i. This type of guarantee should "not" be mistaken as a bound on the worst action.*

Here is the map of the rest of this section. In Section 2.3 we propose an algorithm that exploits the reward structure, and later in Section 2.4 we show how this algorithm is an online mirror descent with weighted negative entropy as its mirror map. For reward-only instances, we prove the regret bound in Section 2.5. We finally turn our attention to the single buyer online auction problem in Section 2.6.

2.3. Multi-Scale Multiplicative-Weight (MSMW) algorithm

We achieve our regret bound in Theorem 1 by using the MSMW algorithm (Algorithm 1). The main idea behind this algorithm is to take into account different ranges for different experts, and therefore:

1. We normalize the reward of each expert accordingly, i.e. divide the reward of expert i by its corresponding range c_i;
2. We project the updated weights by performing a *smooth multi-scale projection* into the simplex: the algorithm finds a λ^* such that multiplying the current weight of each expert i by $\exp\left(-\frac{\lambda^*}{c_i}\right)$ makes a probability distribution over the experts. It then uses this resulting probability distribution for sampling the next expert.

2.4. Equivalence to online mirror descent with weighted negative entropy

While it is possible to analyze the regret of the MSMW algorithm (Algorithm 1) by using first principles, we take a different approach (the elementary analysis can still be found in the appendix, Section A.2). We show how this algorithm is indeed an instance of the Online Mirror Descent (OMD) algorithm for a particular choice of the *Legendre function* (also known as *the mirror map*).

Algorithm 1 MSMW

input initial distribution $\boldsymbol{\mu}$ over A, learning rate $0 < \eta \leq 1$.

  Find λ^* (e.g., binary search) s.t. $\sum_{i \in A} w_i(t+1) \cdot \exp(-\frac{\lambda^*}{c_i}) = 1$.
  $\forall i \in A: \quad p_i(t+1) \leftarrow w_i(t+1) \cdot \exp(-\frac{\lambda^*}{c_i})$.
end for

2.4.1. Preliminaries on online mirror descent.

Fix an open convex set $\mathcal{D}$ and its closure $\bar{\mathcal{D}}$, which in our case are $(0, +\infty)^A$ and $[0, +\infty)^A$ respectively, and a closed-convex action set $\mathcal{A} \subset \bar{\mathcal{D}}$, which in our case is Δ_A, i.e. the set of all probability distributions over experts in A. At the heart of an OMD algorithm there is a *Legendre* function $F : \bar{\mathcal{D}} \to \mathbb{R}$, i.e. a strictly convex function that admits continuous first order partial derivatives on $\mathcal{D}$ and $\lim_{x \to \bar{\mathcal{D}} \setminus \mathcal{D}} \|\nabla F(x)\| = +\infty$, where $\nabla F(.)$ denotes the gradient map of F. One can think of OMD as a member of *projected gradient descent* algorithms, where the *gradient update* happens in the *dual space* $\nabla F(\mathcal{D})$ rather than in primal $\mathcal{D}$, and the *projection* is defined by using the *Bregman divergence* associated with F rather than ℓ_2-distance (see Figure 2.4.1).

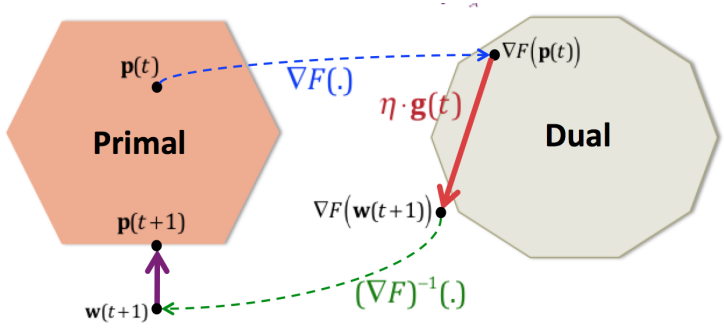

Figure 1: Online Mirror Descent (OMD): moving to the dual space by gradient map *(blue)*, gradient update in the dual space *(red)*, applying the inverse gradient map *(green)*, and finally projecting back to the simplex using Bregman projection *(purple)*.

Definition 4 (Bregman Divergence (Bubeck, 2011)) *Given a Legendre function F over Δ_A, the Bregman divergence associated with F, denoted as $D_F : \Delta_A \times \Delta_A \to \mathbb{R}$, is defined by*

$$D_F(x, y) = F(x) - F(y) - (x - y)^T \nabla F(y)$$

Definition 5 (Online Mirror Descent (Bubeck, 2011)) *Suppose F is a Legendre function. At every time $t \in [T]$, the online mirror descent algorithm with Legendre function F selects an expert drawn from distribution $\mathbf{p}(t)$, and then updates $\mathbf{w}(t)$ and $\mathbf{p}(t)$ given rewards $\mathbf{g}(t)$ by:*

Gradient update:

$$\nabla F(\mathbf{w}(t+1)) = \nabla F(\mathbf{p}(t)) + \eta \cdot \mathbf{g}(t) \Rightarrow \mathbf{w}(t+1) = (\nabla F)^{-1}(\nabla F(\mathbf{p}(t)) + \eta \cdot \mathbf{g}(t)) \quad (5)$$

Bregman projection:

$$\mathbf{p}(t+1) = \underset{\mathbf{p} \in \Delta_A}{argmin}\, (D_F(\mathbf{p}, \mathbf{w}(t+1))) \quad (6)$$

where $\eta > 0$ is called the learning rate of OMD.

We use the following standard regret bound of OMD (Refer to Bubeck (2011) for a thorough discussion on OMD. For completeness, a proof is also provided in the appendix, Section A.3). Roughly speaking, this lemma upper-bounds the regret by the summation of two separate terms: "local norm" (the first term), which captures the total deviation between $\mathbf{p}(t)$ and $\mathbf{w}(t+1)$, and "initial divergence" (the second term), which captures how much the initial distribution is far from the target distribution.

Lemma 6 *For any learning rate parameter $0 < \eta \leq 1$ and any benchmark distribution $\mathbf{q}$ over A, the OMD algorithm with Legendre function $F(.)$ admits the following:*

$$\sum_{t \in [T]} \mathbf{g}(t) \cdot (\mathbf{q} - \mathbf{p}(t)) \leq \frac{1}{\eta} \sum_{t \in [T]} D_F(\mathbf{p}(t), \mathbf{w}(t+1)) + \frac{1}{\eta} D_F(\mathbf{q}, \mathbf{p}(1)) \quad (7)$$

2.4.2. MSMW algorithm as an OMD

For our application, we focus on a particular choice of Legendre function that captures different learning rates proportional to c_i^{-1} for different experts, as we saw earlier in Algorithm 1. We start by defining the *weighted negative entropy* function.

Definition 7 *Given expert-ranges $\{c_i\}_{i \in A}$, the* weighted negative entropy *is defined by*

$$F(x) = \sum_{i \in A} c_i \cdot x_i \ln(x_i) \quad (8)$$

Corollary 8 *It is straightforward to see $F(x) = \sum_{i \in A} c_i \cdot x_i \ln(x_i)$ is a non-negative Legendre function over $\mathbb{R}_+^A$. Moreover, $\nabla F(x)_i = c_i(1 + \ln(x_i))$ and $D_F(x, y) = \sum_{i \in A} c_i \cdot (x_i \ln(\frac{x_i}{y_i}) - x_i + y_i)$.*

We now have the following lemma that shows Algorithm 1 is indeed an OMD algorithm.

Lemma 9 *The MSMW algorithm, i.e. Algorithm 1, is equivalent to an OMD algorithm associated with the weighted negative entropy $F(x) = \sum_{i \in A} c_i \cdot x_i \ln(x_i)$ as its Legendre function.*

Proof Look at the gradient update step of OMD, as in Equation (5), with Legendre function $F(x) = \sum_{i\in A} c_i \cdot x_i \ln(x_i)$. By using Corollary 8 we have

$$\nabla F(\mathbf{w}(t+1)) = \nabla F(\mathbf{p}(t)) + \eta \cdot \mathbf{g}(t) \Rightarrow c_i(1+\ln(w_i(t+1))) = c_i(1+\ln(p_i(t))) + \eta \cdot g_i(t)\ ,$$

and therefore, $w_i(t+1) = p_i(t) \cdot \exp(\eta \cdot \frac{g_i(t)}{c_i})$. Moreover, for the Bregman projection step we have

$$\mathbf{p}(t+1) = \operatorname*{argmin}_{\mathbf{p}\in\Delta_A} \left(D_F(\mathbf{p}, \mathbf{w}(t+1))\right) = \operatorname*{argmin}_{\mathbf{p}\in\Delta_A} \left(\sum_{i\in A} c_i \cdot (p_i \ln(\frac{p_i}{w_i(t+1)}) - p_i + w_i(t+1))\right) \tag{9}$$

This is a convex minimization over a convex set. To find a closed form solution, we look at the Lagrangian dual function $\mathcal{L}(\mathbf{p}, \lambda) \triangleq \sum_{i\in A} c_i \cdot (p_i \ln(\frac{p_i}{w_i(t+1)}) - p_i + w_i(t+1)) + \lambda(\sum_{i\in A} p_i - 1)$ and the Karush-Kuhn-Tucker (KKT) conditions $\nabla\mathcal{L}(\mathbf{p}^*, \lambda^*) = \mathbf{0}$. We have

$$c_i \cdot \ln(\frac{p_i^*}{w_i(t+1)}) + \lambda^* = 0 \Rightarrow p_i^* = w_i(t+1) \cdot \exp(-\frac{\lambda^*}{c_i}) \tag{10}$$

As $\sum_{i\in A} p_i^* = 1$, λ^* should be the unique number s.t. $\sum_{i\in A} w_i(t+1) \cdot \exp(-\frac{\lambda^*}{c_i}) = 1$, and then $p_i(t+1) = w_i(t+1) \cdot \exp(-\frac{\lambda^*}{c_i})$. So, Algorithm 1 is equivalent to OMD with weighted negative entropy as its Legendre function. ■

By combining Lemma 6, Corollary 8 and finally Lemma 9 we prove the following regret bound for the MSMW algorithm. We encourage the reader to also look at the appendix, Section A.2, for an extra proof using first principles.

Proposition 10 *For any initial distribution $\boldsymbol{\mu}$ over A, and any learning rate parameter $0 < \eta \leq 1$, and any benchmark distribution $\mathbf{q}$ over A, the MSMW algorithm satisfies:*

$$\sum_{i\in A} q_i \cdot G_i - \mathbb{E}\left[G_{\text{ALG}}\right] \leq \eta \sum_{t\in[T]} \sum_{i\in A} p_i(t) \frac{(g_i(t))^2}{c_i} + \frac{1}{\eta} \cdot \sum_{i\in A} c_i \left(q_i \ln\left(\frac{q_i}{\mu_i}\right) - q_i + \mu_i\right)\ .$$

Proof We have:

$$\sum_{i\in A} q_i \cdot G_i - \mathbb{E}\left[G_{\text{ALG}}\right] = \sum_{t\in[T]} \mathbf{q}\cdot\mathbf{g}(t) - \sum_{t\in[T]} \mathbf{p}(t)\cdot\mathbf{g}(t) = \sum_{t\in[T]} \mathbf{g}(t)\cdot\left(\mathbf{q}-\mathbf{p}(t)\right) \tag{11}$$

By applying the regret bound of OMD (Lemma 6) to upper-bound the RHS, we have

$$\sum_{i\in A} q_i \cdot G_i - \mathbb{E}\left[G_{\text{ALG}}\right] \leq \frac{1}{\eta} \sum_{t\in[T]} D_F(\mathbf{p}(t), \mathbf{w}(t+1)) + \frac{1}{\eta} D_F(\mathbf{q}, \mathbf{p}(1)) \tag{12}$$

To bound the first term in regret, a.k.a *local norm*, we have:

$$\begin{aligned} D_F(\mathbf{p}(t), \mathbf{w}(t+1)) &= \sum_{i\in A} c_i \cdot (p_i(t) \ln(\frac{p_i(t)}{w_i(t+1)}) - p_i(t) + w_i(t+1)) \\ &= \sum_{i\in A} c_i \cdot p_i(t)(-\eta \cdot \frac{g_i(t)}{c_i} - 1 + exp(\eta \cdot \frac{g_i(t)}{c_i})) \end{aligned} \tag{13}$$

Note that $\eta \cdot \frac{g_i(t)}{c_i} \in [-1, 1]$ because $g_i(t) \in [-c_i, c_i]$ and $0 < \eta \leq 1$. By $\exp(x) - x - 1 \leq x^2$ for $-1 \leq x \leq 1$ and that $\eta g_i(t) \in [-c_i, c_i]$, the above is upper bounded by $\eta^2 \sum_{i\in A} p_i(t) \frac{(g_i(t))^2}{c_i}$. We can also rewrite the second term in regret. In fact, if we set $\mathbf{p}(1) = \boldsymbol{\mu}$, then

$$\frac{1}{\eta} \cdot D_F(\mathbf{q}, \mathbf{p}(1)) = \frac{1}{\eta} \cdot \sum_{i\in A} c_i \left(q_i \ln\left(\frac{q_i}{\mu_i}\right) - q_i + \mu_i\right)$$

By summing the upper-bounds $\eta^2 \sum_{i\in A} p_i(t) \frac{(g_i(t))^2}{c_i}$ on each term of local norm in (13) for $t \in [T]$ and putting all the pieces together, we get the desired bound. ■

2.5. Regret analysis for non-negative rewards

Theorem 1 *There exists an algorithm for the full-information multi-scale online learning problem that takes as input any distribution $\boldsymbol{\pi}$ over A, the ranges c_i, $\forall\, i \in A$ and a parameter $0 < \epsilon \leq 1$, and satisfies:*

$$\forall i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] \leq \epsilon \cdot G_i + O\left(\frac{1}{\epsilon} \log\left(\frac{1}{\epsilon\pi_i}\right) \cdot c_i\right) \tag{14}$$

Proof Suppose $i_{\min}$ is an action with the minimum c_i. Let $\boldsymbol{\mu} = (1-\eta)\cdot\mathbf{1}_{i_{\min}} + \eta\cdot\boldsymbol{\pi}$, and let $\mathbf{q} = (1-\eta)\cdot\mathbf{1}_i + \eta\cdot\boldsymbol{\pi}$ in Proposition 10. If $i \neq i_{\min}$, we get that (note that $\mu_j = q_j$ for any $j \neq i, i_{\min}$):

$$\begin{aligned} (1-\eta)\cdot G_i + \eta \cdot \sum_{j\in A} \pi_j \cdot G_j - \mathbb{E}\left[G_{\text{ALG}}\right] \leq \eta \cdot \mathbb{E}\left[G_{\text{ALG}}\right] &+ \frac{1}{\eta} \cdot c_i \cdot \left(q_i \ln\left(\frac{q_i}{\mu_i}\right) - q_i + \mu_i\right) \\ &+ \frac{1}{\eta} \cdot c_{i_{\min}} \cdot \left(q_{i_{\min}} \ln\left(\frac{q_{i_{\min}}}{\mu_{i_{\min}}}\right) - q_{i_{\min}} + \mu_{i_{\min}}\right) \end{aligned}$$

By $1 \geq q_i > \mu_i \geq \eta\pi_i$, the second term on the RHS is upper bounded as:

$$\frac{1}{\eta} \cdot c_i \cdot \left(q_i \ln\left(\frac{q_i}{\mu_i}\right) - q_i + \mu_i\right) \leq \frac{1}{\eta} \cdot c_i \cdot \ln\left(\frac{1}{\eta\pi_i}\right)$$

Similarly, by $1 \geq \mu_{i_{\min}} > q_{i_{\min}} \geq 0$, the third term on the RHS is upper bounded as

$$\frac{1}{\eta} \cdot c_{i_{\min}} \cdot \left(q_{i_{\min}} \ln\left(\frac{q_{i_{\min}}}{\mu_{i_{\min}}}\right) - q_{i_{\min}} + \mu_{i_{\min}}\right) \leq \frac{1}{\eta} \cdot c_{i_{\min}} \leq \frac{1}{\eta} \cdot c_i$$

Finally, note that $G_j \geq 0$ for all $j \in A$ in reward-only instances. So the LHS is lower bounded by

$$(1-\eta)\cdot G_i - \mathbb{E}\left[G_{\text{ALG}}\right] = (1-\eta)\cdot \text{REGRET}_i - \eta\cdot\mathbb{E}\left[G_{\text{ALG}}\right].$$

Putting all this together, we get that

$$\mathbb{E}\left[\text{REGRET}_i\right] \leq \frac{2\eta}{1-\eta} \cdot \mathbb{E}\left[G_{\text{ALG}}\right] + O\left(\frac{1}{\eta} \ln\left(\frac{1}{\eta\pi_i}\right) \cdot c_i\right) \leq 3\eta \cdot \mathbb{E}\left[G_{\text{ALG}}\right] + O\left(\frac{1}{\eta} \ln\left(\frac{1}{\eta\pi_i}\right) \cdot c_i\right)\ .$$

The theorem then follows by choosing $\eta = \frac{\epsilon}{3}$ and rearranging terms. ■

2.6. A canonical application: online single buyer auction

The setup. The simple auction design problem that we consider is as follows. There is a seller with infinite identical copies of an item. Buyers arrive over time. At each round, the seller picks a *price* and the arriving buyer reports her *value*. If the value is no less than the price, the trade happens; money goes to the seller and the copy of the item goes to the arriving buyer. The goal is to maximize the revenue of the seller.

Formally, we look at this problem as an instance of the full information multi-scale online learning framework; The action set is $A = [1, h]$. [7] The reward function is such that at round t the adversary (i.e. the arriving buyer) picks a value $v(t) \in [1, h]$ and for any price $p \in A$ picked by the seller (i.e. the algorithm), the reward is $g_p(t) := p \cdot \mathbf{1}(v(t) \geq p)$. This is a full information setting, because the value $v(t)$ is revealed to the algorithm after each round t.

The additive/multiplicative approximation. In order to obtain a $(1-\epsilon)$-approximation of the optimal revenue, i.e. the revenue of the best fixed price p^* in hindsight, it suffices to consider prices of the form $(1+\epsilon)^j$ for $0 \leq j \leq \lfloor \log_{1+\epsilon} h \rfloor = O(\frac{\log h}{\epsilon})$. As a result, we reduce the online single buyer auction problem to the multi-scale online learning with full information and finite actions. The action set has $k = O(\frac{\log h}{\epsilon})$ actions whose ranges form a geometric sequence $(1+\epsilon)^j$, $0 \leq j < k$.

Recall the definition of G_{MAX} in Section 2.1, and let p^* be the best fixed price in hindsight, which is the price that achieves G_{MAX}. We now show how to get a multiplicative cum additive approximation for this problem with G_{MAX} as the benchmark, à la Blum et al. (2004); Blum and Hartline (2005). The main improvement over these results is that the additive term scales with the best price rather than h.

Theorem 11 *There is an algorithm for the online single buyer auction problem that takes as input a parameter $\epsilon > 0$, and satsify $G_{\text{ALG}} \geq (1-\epsilon)G_{\text{MAX}} - O(E)$, where:*

$$E = \frac{p^* \log(\log h/\epsilon)}{\epsilon} .$$

Also, even if h is not known up front, there is an (slightly modified) algorithm that achieves a similar approximation guarantee for online single buyer auction with:

$$E = \frac{p^* \log(p^*/\epsilon)}{\epsilon} .$$

Proof
[Part 1: known h] Recall the above formulation of the problem as an online learning problem with full information. The proof then follows by Theorem 1, letting $\boldsymbol{\pi}$ to be the uniform distribution over the $k = O(\log h/\epsilon)$ actions, i.e., discretized prices.

[Part 2: unknown h] When h is not known up front, we consider a variant of our algorithm (Algorithm 2) that picks the next price in each round t from the set of *relevant prices* (denoted by $\mathcal{P}$), updates this set if necessary, and then updates the weights of prices in this set as in Algorithm 1. The main new idea here is to update the set of prices $\mathcal{P}$ so that it only includes prices that are at most the highest value we have seen so far (let the highest seen value be 1 at the beginning). Now, for the sake of analysis, consider a hypothetical algorithm (called $\texttt{ALG}^H$) that considers a countably infinite action space comprising all prices of the form $(1+\epsilon)^j$, for $j \geq 0$. We first show this hypothetical algorithm $\texttt{ALG}^H$ satisfies the required approximation guarantee in Theorem 11. We then show the expected revenue of Algorithm 2 is at least the expected revenue of $\texttt{ALG}^H$ (minus a constant that is negligible in our bound), and hence the final proof.

The proof of the regret bound of Theorem 1 works when we have countably many actions (although we cannot implement such algorithms directly). Now, consider simulating $\texttt{ALG}^H$ and let the prior distribution $\boldsymbol{\pi}$ be such that for any price $p = (1+\epsilon)^j$, $\pi_p = \epsilon(\epsilon+2)(1+\epsilon)^{-2(j+1)} = \frac{\epsilon(\epsilon+2)}{(1+\epsilon)^2} \cdot \frac{1}{p^2}$ (this choice will become more clear later in the proof; in short we need π_p to be proportional to $\frac{1}{p^2}$). The approximation guarantee in Theorem 11 then follows by Theorem 1. We now argue the followings:

- For any round t, unless the value in that round is a new highest value, Algorithm 2 gets weakly higher revenue than $\texttt{ALG}^H$. This is because the probability that Algorithm 2 plays any relevant price in $\mathcal{P}$ (that has a non-zero gain in this round) is weakly higher than that in $\texttt{ALG}^H$.

- For any price $p = (1+\epsilon)^j$, consider the first time a value at least p shows up. Algorithm 2 suffers a loss of at most $p \cdot \pi_p$ compared to $\texttt{ALG}^H$, due to $\texttt{ALG}^H$'s probability of playing p in that round, where π_p is the probability of playing p in the initial distribution. This is because the probability that $\texttt{ALG}^H$ plays p in this round is at most π_p as p has not got any positive gains before this round.

- Then, by choosing π_p to be inversely proportional to p^2, we can show that Algorithm 2 has an additive loss of $\sum_p \frac{\beta}{p} = \frac{\epsilon+2}{\epsilon+1} = O(1)$ compared to$\texttt{ALG}^H$, where $\beta = \left(\sum_p \frac{1}{p^2}\right)^{-1} = \frac{\epsilon(2+\epsilon)}{(1+\epsilon)^2}$ is the normalization constant of the initial distribution $\boldsymbol{\pi}$. This finishes the proof.

■

Algorithm 2 Online single buyer auction (for unknown h)

input learning rate $0 < \eta \leq 1$, price discretization parameter $0 < \epsilon \leq 1$.
initialize the set of relevant prices $\mathcal{P} = \{1\}$. Let $\alpha_1(1) = 1$.
for $t = 1, \ldots, T$ **do**
  Randomly pick a price in $\mathcal{P}$ drawn from $\boldsymbol{\alpha}(t)$, and observe $\mathbf{g}(t)$.
  Update $\mathcal{P}$ to be all the prices $(1+\epsilon)^j$ that are at most the highest value until time t.
  $\forall p \in \mathcal{P}: \quad w_p(t+1) \leftarrow \alpha_p(t) \cdot \exp(\eta \cdot \frac{g_p(t)}{p})$.
  Find λ^* (e.g., binary search) s.t. $\sum_{p \in \mathcal{P}} w_p(t+1) \cdot \exp(-\frac{\lambda^*}{p}) = 1$.
  $\forall p \in \mathcal{P}: \quad \alpha_p(t+1) \leftarrow w_p(t+1) \cdot \exp(-\frac{\lambda^*}{p})$.
end for

Bounds on the sample complexity of auctions for single buyer problem (Huang et al., 2015a) imply that the first bound in this theorem is tight up to log factors: the lower bound

7. Here, we allow an infinite action set. Later, we show how to discretize to get around this issue.

is $h\epsilon^{-1}$ in an instance where p^* is actually equal to h. Also, the best upper bound known is by Blum et al. (2004); Blum and Hartline (2005), which is

$$E = \frac{h\log(1/\epsilon)}{\epsilon} .$$

We conclude that Theorem 11 generalizes the known tight sample complexity upper-bound for the offline single buyer Bayesian revenue maximization to the online adversarial setting.

3. Multi-Scale Online Learning with Bandit Feedback

In this section, we look at the bandit feedback version of multi-scale online learning framework proposed in Section 2.1. Essentially, the only difference here is that after the algorithm picks an arm i_t at time t, it only observes the obtained reward, i.e. $g_{i_t}(t)$, and *does not* observe the entire reward function $\mathbf{g}(t)$.

Inspired by the online stochastic mirror descent algorithm (Bubeck, 2011) we introduce *Bandit-MSMW* algorithm. Our algorithm follows the standard bandit route of using unbiased estimators for the rewards in a full information strategy (in this case MSMW). We also mix the MSMW distribution with an extra uniform exploration, and use a tailored initial distribution to obtain the desired mutli-scale regret bounds.

3.1. Bandit multi-scale regret bounds

For the bandit version, we can get similar regret guarantees as in Section 2.2 for the full-information variant, but only for the *best* action. If we require the regret bound to hold for all actions, then we can only get a weaker bound, where the second term has ϵ^{-2} instead of ϵ^{-1}. The difference between the bounds for the bandit and the full information setting is essentially a factor of k, which is unavoidable.

Theorem 12 *There exists an algorithm for the online multi-scale problem with bandit feedback that takes as input the ranges c_i, $\forall\ i \in A$, and a parameter $0 < \epsilon \leq 1$, and satisfies,*

- *for $i^* = \arg\max_{i\in A} G_i$,*

$$\mathbb{E}\left[\text{REGRET}_{i^*}\right] \leq \epsilon \cdot G_{i^*} + O\left(\tfrac{1}{\epsilon} k \log\left(\tfrac{k}{\epsilon}\right) \cdot c_{i^*}\right). \tag{15}$$

- *for all $i \in A$,*

$$\mathbb{E}\left[\text{REGRET}_{i}\right] \leq \epsilon \cdot G_{i} + O\left(\tfrac{1}{\epsilon^2} k \log\left(\tfrac{k}{\epsilon}\right) \cdot c_{i}\right). \tag{16}$$

Also, one can compute the pure-additive versions of the bounds in Theorems 12 by setting $\epsilon = \sqrt{\frac{k\log(kT)}{T}}$ and $\epsilon = (\frac{k\log(kT)}{T})^{\frac{1}{3}}$ resepctively (Corollary 13), and compare with the pure-additive regret bound $O\big(c_{\max}\cdot\sqrt{Tk}\big)$ for the adversarial multi-armed bandit problem (Audibert and Bubeck, 2009; Auer et al., 1995).

Corollary 13 *There exist algorithms for the online multi-scale bandits problem that satisfies,*

- *For $i^* = \arg\max_{i\in A} G_i$,*

$$\mathbb{E}\left[\text{REGRET}_{i^*}\right] \leq O\left(c_{i^*}\cdot\sqrt{Tk\log(kT)}\right) \tag{17}$$

- *For all $i \in A$,*

$$\mathbb{E}\left[\text{REGRET}_{i}\right] \leq O\left(c_i \cdot T^{\frac{2}{3}}(k\log(kT))^{\frac{1}{3}}\right) \tag{18}$$

Here is a map of this section. In Section 3.2 we propose our bandit algorithm and prove its general regret guarantee for non-negative rewards. Then in Section 3.3 we show how to get a multi-scale style regret guarantee for the best arm c_{i^*}, and a weaker guarantee for all arms $\{c_i\}_{i\in A}$.

3.2. Bandit Multi-Scale Multiplicative Weight (Bandit-MSMW) algorithm

We present our Bandit algorithm (Algorithm 3) when the set of actions A is finite (with $|A| = k$). Let η be the learning rate and γ be the exploration probability. We show the following regret bound.

Algorithm 3 Bandit-MSMW

input exploration parameter $\gamma > 0$, learning rate $\eta > 0$.
initialize $\mathbf{p}(1) = (1-\gamma)\mathbf{1}_{i_{\min}} + \frac{\gamma}{k}\mathbf{1}$, where $i_{\min}$ is the arm with minimum range $c_{i_{\min}}$.
for $t = 1, \ldots, T$ **do**
  Let $\tilde{\mathbf{p}}(t) = (1-\gamma)\mathbf{p}(t) + \frac{\gamma}{k}\mathbf{1}$.
  Randomly pick an expert i_t drawn from $\tilde{\mathbf{p}}(t)$, and observe $g_{i_t}(t)$.
  Let $\tilde{\mathbf{g}}(t)$ be such that

$$\tilde{g}_i(t) = \begin{cases} \frac{g_i(t)}{\tilde{p}_i(t)} & \text{if } i = i_t; \\ 0 & \text{otherwise.} \end{cases}$$

  $\forall i \in A: \quad w_i(t+1) \leftarrow p_i(t)\cdot\exp(\frac{\eta}{c_i}\cdot\tilde{g}_i(t))$.
  Find λ^* (e.g., binary search) s.t. $\sum_{i\in A} w_i(t+1)\cdot\exp(-\frac{\lambda^*}{c_i}) = 1$.
  $\forall i \in A: \quad p_i(t+1) \leftarrow w_i(t+1)\cdot\exp(-\frac{\lambda^*}{c_i})$.
end for

Lemma 14 *For any exploration probability $0 < \gamma \leq \frac{1}{2}$ and any learning rate parameter $0 < \eta \leq \frac{\gamma}{k}$, the Bandit-MSMW algorithm achieves the following regret bound when the gains are non-negative :*

$$\forall i \in A : \mathbb{E}\left[\text{REGRET}_i\right] \leq O\left(\tfrac{1}{\eta}\log\left(\tfrac{k}{\gamma}\right)\cdot c_i + \eta\textstyle\sum_{j\in A} G_j + \gamma\cdot G_i\right)$$

Proof We further define:

$$\widetilde{G}_{\text{ALG}} \triangleq \textstyle\sum_{t\in[T]} g_{i_t}(t) = \sum_{t\in[T]} \tilde{\mathbf{p}}(t)\cdot\tilde{\mathbf{g}}(t) ,$$
$$\widetilde{G}_j \triangleq \textstyle\sum_{t\in[T]} \tilde{g}_j(t) .$$

In expectation over the randomness of the algorithm, we have:

1. $\mathbb{E}[G_{\text{ALG}}] = \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]$; and

2. $G_j = \mathbb{E}\left[\widetilde{G}_j\right]$ for any $j \in A$.

Hence, to upper bound $\mathbb{E}[\text{REGRET}_i] = G_i - \mathbb{E}[G_{\text{ALG}}]$, it suffices to upper bound $\mathbb{E}\left[\widetilde{G}_i - \widetilde{G}_{\text{ALG}}\right]$. By the definition of the probability that the algorithm picks each arm, i.e., $\tilde{\mathbf{p}}(t)$, we have:

$$\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \geq (1-\gamma)\textstyle\sum_{t\in[T]} \mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\ .$$

Hence, we have for any initial distribution $\mathbf{q}$ over A:

$$\begin{aligned}\sum_{j\in A} q_j\cdot\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \leq\ & \mathbb{E}\left[\textstyle\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\right] + \tfrac{\gamma}{1-\gamma}\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]\\ \leq\ & \mathbb{E}\left[\textstyle\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\right] + 2\gamma\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]\ . \quad (19)\end{aligned}$$

Next, we upper bound the 1st term on the RHS. Note that $\mathbf{p}(t)$'s are the probabilities of choosing experts by MSMW when the experts have rewards $\tilde{\mathbf{g}}(t)$'s. By Proposition 10, we have for any benchmark distribution $\mathbf{q}$ over S, the Bandit-MSMW algorithm satisfies:

$$\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t) \leq \eta\sum_{t\in[T]}\sum_{j\in A}\frac{p_j(t)}{c_j}\cdot\left(\tilde{g}_j(t)\right)^2 + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right)\ . \quad (20)$$

For any $t\in[T]$ and any $j\in A$, by the definition of $\tilde{g}_j(t)$, it equals $\frac{g_j(t)}{\tilde{p}_j(t)}$ with probability $\tilde{p}_j(t)$, and equals 0 otherwise. Thus, if we fix the random coin flips in the first $t-1$ rounds and, thus, fix $\tilde{\mathbf{p}}(t)$, and take expectation over the randomness in round t, we have:

$$\mathbb{E}\left[\frac{p_j(t)}{c_j}\cdot\left(\tilde{g}_j(t)\right)^2\right] = \frac{p_j(t)}{c_j}\cdot\tilde{p}_j(t)\cdot\left(\frac{g_j(t)}{\tilde{p}_j(t)}\right)^2 = \frac{p_j(t)}{\tilde{p}_j(t)}\frac{(g_j(t))^2}{c_j}\ .$$

Further note that since $\tilde{p}_j(t)\geq(1-\gamma)p_j(t)$, and $g_j(t)\leq c_j$, the above is upper bounded by $\frac{1}{1-\gamma}g_j(t)\leq 2g_j(t)$. By putting all together with (20), we have for any $0<\eta\leq\frac{\gamma}{n}$:

$$\begin{aligned}\mathbb{E}\left[\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\right] \leq\ & \eta\sum_{t\in[T]}\sum_{j\in A} 2g_j(t) + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right)\\ =\ & 2\eta\sum_{j\in A} G_j + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right)\end{aligned}$$

Combining with (19), we have:

$$\sum_{j\in A} q_j\cdot\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \leq 2\eta\sum_{j\in A} G_j + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right) + 2\gamma\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]$$

Let $\mathbf{q} = (1-\gamma)\mathbf{1}_i + \frac{\gamma}{k}\mathbf{1}$. Recall that $\mathbf{p}(1) = (1-\gamma)\mathbf{1}_{i_{\min}} + \frac{\gamma}{k}\mathbf{1}$ (recall $i_{\min}$ is the arm with minimum range $c_{i_{\min}}$). Similar to the discussion for the expert problem in Section 2.5, the 2nd term on the RHS is upper bounded by $O\left(\frac{1}{\eta}\log\left(\frac{k}{\gamma}\right)\cdot c_i\right)$. Hence, we have:

$$\sum_{j\in A} q_j\cdot\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \leq 2\eta\sum_{j\in A} G_j + O\left(\frac{1}{\eta}\log\left(\frac{k}{\gamma}\right)\cdot c_i\right) + 2\gamma\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]\ . \quad (21)$$

Further, the LHS is lower bounded as:

$$(1-\gamma)\mathbb{E}\left[\widetilde{G}_i\right] + \frac{\gamma}{k}\sum_{j\in A}\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \geq (1-\gamma)\mathbb{E}\left[\widetilde{G}_i\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]\ .$$

The lemma then follows by putting this lower-bound of LHS of (21) back to the equation and rearranging terms. ■

3.3. Regret bounds for non-negative rewards - proof of Theorem 12

Letting $\gamma = \epsilon$ and $\eta = \frac{\gamma}{k} = \frac{\epsilon}{k}$ in Lemma 14, we get that the expected regret w.r.t. an action $i\in A$ is bounded by:

$$O\left(\epsilon\cdot G_i + \tfrac{\epsilon}{k}\textstyle\sum_{j\in A} G_j + c_i\cdot\frac{k}{\epsilon}\ln\left(\frac{k}{\epsilon}\right)\right)\ .$$

When $i = i^*$ (best arm), regret is bounded by $O\left(\epsilon\cdot G_{i^*} + c_i^*\cdot\frac{k}{\epsilon}\ln\left(\frac{k}{\epsilon}\right)\right)$, as desired.

For the regret w.r.t. an arbitrary action, note that $\mathbb{E}[G_{\text{ALG}}] \geq \frac{\gamma}{k}\sum_{j\in A} G_j$. Thus, the regret bound w.r.t. an action $i\in A$ in Lemma 14 is further upper bounded by:

$$O\left(\tfrac{1}{\eta}\log\left(\tfrac{k}{\gamma}\right)\cdot c_i + \left(\tfrac{\eta k}{\gamma} + \gamma\right)\cdot\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]\right)$$

The theorem then follows by letting $\gamma = \epsilon$ and $\eta = \frac{\gamma^2}{k} = \frac{\epsilon^2}{k}$.

4. More Applications of Multi-scale Learning for Auctions and Pricing

In this section, we consider applying the multi-scale online learning framework, developed in Section 2 and Section 3, to design several other online auctions and pricings be the single buyer auction (discussed in Section 2.6). Besides the single buyer auction, the problems that we consider are as follows.

- **Online posted pricing:** The same as the online single buyer auction of Section 2.6, but in the bandit setting. The algorithm only learns the indicator function $\mathbf{1}(v(t)\geq p_t)$ where p_t is the price it picks in round t.

- **Online multi buyer auction:** The action set is the set of all "Myerson-type" mechanisms for n buyers, for some $n\in\mathbb{N}$. (See Definition 15.) The adversary picks a valuation vector $\mathbf{v}(t)\in[1,h]^n$ and the reward of a mechanism M is its revenue when the valuation of the buyers is given by $\mathbf{v}(t)$; this is denoted by $\text{REV}_M(\mathbf{v}(t))$. The algorithm sees the full vector of valuations $\mathbf{v}(t)$.

4.1. Auctions and pricing as multi-scale online learning problems

We now show how to reduce the above problems to special cases of multi-scale online learning.

Online multi buyer auction In multi buyer auctions, we consider the set of all discretized Myerson-type auctions as the action space. We start by defining Myerson-type auctions:

Definition 15 (Myerson-type auctions) *A* Myerson-type auction *is defined by n non-decreasing virtual value mappings $\phi_1, \ldots, \phi_n : [1, h] \mapsto [-\infty, h]$. Given a value profile $v_1, \ldots, v_n$, the item is given to the bidder j with the largest non-negative virtual value $\phi_j(v_j)$. Then, bidder j pays the minimum value that would keep him as the the winner.*

Myerson (1981) shows that when the bidders' values are drawn from independent (but not necessarily identical) distributions, the revenue-optimal auction is a Myerson-type auction. Devanur et al. (2016, Lemma 5) observe that to obtain a $1-\epsilon$ approximation, it suffices to consider the set of discretized Myerson-type auctions that treat each bidder's value as if it is equal to the closest power of $1+\epsilon$ from below. As a result, it suffices to consider the set of discretized Myerson-type auctions, each of which is defined by the virtual values of $(1+\epsilon)^j$'s, i.e., by $O(n \log h/\epsilon)$ real numbers $\phi_\ell((1+\epsilon)^j)$, for $\ell \in [n]$, and $0 \le j \le \lfloor \log_{1+\epsilon} h \rfloor$. Furthermore, first Elkind (2007) and later on Devanur et al. (2016); Gonczarowski and Nisan (2017) note that a discretized Myerson-type auction is in fact completely characterized by the total ordering of $\phi_\ell((1+\epsilon)^j)$'s;[8] their actual values do not matter. Indeed, both the allocation rule and the payment rule are determined by the ordering of virtual values. As a result, our action space is a finite set with at most $O((n \log h/\epsilon)!)$ actions. The range of an action, i.e., a discretized Myerson-type auction, is the largest price ever charged by the auction, i.e., the largest value v of the form $(1+\epsilon)^j$ such that there exists $\ell \in [n]$, $\phi_\ell(v) > \phi_\ell((1+\epsilon)^{-1} v)$.

4.2. Multiplicative/additive approximations

Similar to Section 2.6, we show how to get a multiplicative cum additive approximations for these problems with G_{MAX} as the benchmark. Recall the definition of G_{MAX} in Section 2.1 and let p^* be the best fixed price on hindsight, which is the price that achieves G_{MAX}.

Theorem 16 *There are algorithms for the online posted pricing and the online multi buyer auction problems that take as input a parameter $\epsilon > 0$, and satsify $G_{\text{ALG}} \ge (1-\epsilon) G_{\text{MAX}} - O(E)$, where respectively (for the two problems mentioned above)*

$$E = \frac{p^* \log h \log(\log h/\epsilon)}{\epsilon^2}, \quad \text{and} \quad \frac{hn \log h \log(n \log h/\epsilon)}{\epsilon^2}.$$

Even if h is not known up front, we can still get the similar approximation guarantee for the online multi buyer auction with:

$$E = \frac{hn \log h \log(n \log h/\epsilon)}{\epsilon^2}.$$

8. Cai et al. (2012) also generalizes this observation to multi-dimensional types.

We conjecture that our bound for the online posted pricing problem is tight up to logarithmic factors, and leave resolving this as an open problem. The second bound is not comparable to the best sample complexity for the multi buyer auction problem by Roughgarden and Schrijvers (2016); it is better than theirs for large ϵ (when $1/\epsilon \le o(nh)$), and is worse for smaller ϵ (when $1/\epsilon \ge \omega(nh)$). Also, compare the first bound to the corresponding upper bound for the pricing problem by Blum and Hartline (2005), which is

$$\min\left\{\frac{h \log h \log\log h}{\epsilon^2}, \frac{h \log\log h}{\epsilon^3}\right\}.$$

Essentially, the main improvement over this result is that the additive term scales with the best price rather than h.

Proof [of Theorem 16]

Online posted pricing. Recall the formulation of the problem as an online learning problem with bandit feedback in Section 4.1. This part then follows by Theorem 12 with $k = O(\log h/\epsilon)$ actions.

Online multiple buyer auction. Recall the formulation of the problem as an online learning problem with full information in Section 4.1. The proof then follows by Theorem 1, where we let $\boldsymbol{\pi}$ be the uniform distribution over the $k = O((n \log h/\epsilon)!)$ actions, i.e., Myerson-type auctions.

When h is not known up front, similar to the proof of Theorem 11, we consider a hypothetical algorithm with countably infinite action space A as follows. For any $p = (1+\epsilon)^j$, $j \ge 0$, let the $k_p = O((n \log p/\epsilon)!)$ Myerson-type auctions for values in $[1, p]$ be in A; we assume these auctions treat any values greater than p as if they were p. Further, we choose the prior distribution $\boldsymbol{\pi}$ such that the probability mass of each auction for range $[1, p]$ is equal to $\frac{\epsilon(\epsilon+2)}{(1+\epsilon)^2} \cdot \frac{1}{p^2} \cdot \frac{1}{k_p}$. The approximation guarantee then follows by Theorem 1. To implement this algorithm, we use the same trick as in the proof Theorem 11 by running a modified algorithm that only considers auctions for all ranges $[1, p]$ where p is no larger than the highest value seen so far among all the buyers (i.e. a multi-buyer auction version of Algorithm 2). The rest of the proof that shows the revenue loss of this algorithm compared to the hypothetical algorithm is negligible is similar to the proof of Theorem 11 (and hence omitted for brevity).

■

4.3. Competing with δ-guarded benchmarks

For the single buyer auction/pricing problem, we define a δ-guarded benchmark, for any $\delta \in [0, 1]$. This benchmark is restricted to only those prices that sell the item in at least a δ fraction of the rounds.

$$G_{\text{MAX}}(\delta) := \max\left\{\textstyle\sum_{t=1}^T g_p(t) : p \in A, \sum_{t=1}^T \mathbf{1}(v_t \ge p) \ge \delta T\right\}.$$

As observed in Footnote 3, one can replace δ with $1/h$ and get the corresponding guarantees for G_{MAX} rather than $G_{\text{MAX}}(\delta)$. However, the main point of these results is to show a graceful improvement of the bounds as δ is chosen to be larger.

Multiple buyers: For the multi buyer auction problem, we define the δ-guarded benchmark as follows. For any sequence of value vectors $\mathbf{v}(1), \mathbf{v}(2), \ldots, \mathbf{v}(T)$, let $\bar{V}$ denote the largest value such that there are at least δT distinct $t \in [T]$ with $\max_{i\in[n]} v_i(t) \geq \bar{V}$. Define the δ-guarded benchmark to be

$$G_{\text{MAX}}(\delta) = \max_M \sum_{t=1}^{T} Rev_M \left(\min(\bar{V}\vec{\mathbf{1}}, \mathbf{v}(t))\right),$$

where the "min" is taken coordinate-wise, and the "max" is over all Myerson-type mechanisms. In other words, here is how we can describe the δ-guarded benchmark: for each Myerson-type auction M, after identifying the value cap $\bar{V}$, we cut all the values that are above $\bar{V}$ by this quantity, and then run M. The benchmark is then the revenue of the best Myerson-type auction under these modified values.

We focus on purely multiplicative approximation factors when competing with $G_{\text{MAX}}(\delta)$. In particular, for any given $\epsilon > 0$, we are interested in a $1-\epsilon$ approximation. We state our results in terms of the *convergence rate*. We say that $T(\epsilon, \delta)$ is the convergence rate of an algorithm if for all time horizon $T \geq T(\epsilon, \delta)$, we are guaranteed that $G_{\text{ALG}} \geq (1-\epsilon)G_{\text{MAX}}(\delta)$. Our main results are as follows.

Theorem 17 *There are algorithms for the online single buyer auction, online posted pricing, and the online multi buyer auction problems with convergence rates respectively of*

$$O\left(\frac{\log(\log h/\epsilon)}{\epsilon^2\delta}\right), \quad O\left(\frac{\log h}{\epsilon^4\delta}\right), \quad \text{and } O\left(\frac{n\log(1/\epsilon\delta)\log(n\log(1/\epsilon\delta)/\epsilon)}{\epsilon^3\delta} + \frac{\log(\log h/\epsilon)}{\epsilon^2\delta}\right).$$

Even if h is not known upfront, we can still get the following similar convergence rates for online single buyer auction and online multi buyer auction respectively:

$$O\left(\frac{\log(p^*/\epsilon)}{\epsilon^2\delta}\right), \quad \text{and} \quad O\left(\frac{n\log(1/\epsilon\delta)\log(n\log(1/\epsilon\delta)/\epsilon)}{\epsilon^3\delta} + \frac{\log(h/\epsilon)}{\epsilon^2\delta}\right).$$

Once again, we compare to the sample compexity bounds: our first is within a $\log\log h$ factor of the best sample complexity upper bound in Huang et al. (2015b). The lower bound for the online single buyer auction is $\Omega(\delta^{-1}\epsilon^{-2})$, which is also the best lower bound known for the pricing and the multi-buyer problem.[9]

For the online posted pricing problem, we conjecture that the right dependence on ϵ should be ϵ^{-3}. No sample complexity bounds for the multi-buyer problem were known before; in fact we introduce the definition of a δ-guarded benchmark for this problem.

Proof [of Theorem 17] *Online single buyer auction.* By Theorem 1, letting $\boldsymbol{\pi}$ be the uniform distribution over the $k = O(\log h/\epsilon)$ actions, i.e., discretized prices, we have that for any price p (recall that $c_p = p$):

$$G_{\text{ALG}} \geq (1-\epsilon)\cdot G_p - O\left(\tfrac{\log(\log h/\epsilon)}{\epsilon}\cdot p\right).$$

For the δ-guarded optimal price p^* (i.e., subject to selling in at least δT rounds), we have $G_{p^*} \geq \delta T \cdot p^*$. Therefore, when $T \geq O\left(\log(\log h/\epsilon)/\epsilon^2\delta\right)$, the additive term of the above approximation guarantee is at most $\epsilon \cdot G_{p^*}$. So the theorem holds.

9. Cole and Roughgarden (2014) show that at least a linear dependence on n is necessary when the values are drawn from a regular distribution, but as is, their lower bound needs unbounded valuations. The lower bound probably holds for "large enough h" but it is not clear if it holds for all h.

The treatment for the case when h is not known up front is essentially the same as in Theorem 16 and Theorem 11. As a hypothetical algorithm useful for analysis, we consider an algorithm (similar to Algorithm 1) with a countably infinite action space comprising all prices of the form $(1+\epsilon)^j$, for $j \geq 0$. Then, let the prior distribution $\boldsymbol{\pi}$ be such that for any price $p = (1+\epsilon)^j$, $\pi_p = \epsilon(\epsilon+2)(1+\epsilon)^{-2(j+1)} = \frac{\epsilon(eps+2))}{(1+\epsilon)^2}\cdot\frac{1}{p^2}$. The rest of the proof and how to implement is the same as in the proof of Theorem 11 (i.e. Algorithm 2).

Online posted pricing. Recall the above formulation of the problem as an online learning problem with bandit feedback. By Theorem 12 with $k = O(\log h/\epsilon)$ actions, we have that for any price p:

$$G_{\text{ALG}} \geq (1-\epsilon)\cdot G_p - O\left(\tfrac{\log h\log(\log h/\epsilon)}{\epsilon^3}\cdot p\right).$$

Again, for the δ-guarded optimal price p^* (i.e., subject to selling in at least δT rounds), we have $G_{p^*} \geq \delta T \cdot p^*$. Therefore, when $T \geq O\left(\log h\log\left(\log h/\epsilon\right)/\epsilon^4\delta\right)$, the additive term of the above approximation guarantee is at most $\epsilon \cdot G_{p^*}$. So the theorem holds.

Online multi buyer auction. Suppose i^* is the δ-guarded best Myerson-type auction. Recall that $\bar{V}$ is the largest value such that there are at least δT distinct $v(t)$'s with $\max_{\ell\in[n]} v_\ell(t) \geq \bar{V}$. So we may assume without loss of generality that i^* does not distinguish values greater than $\bar{V}$. Hence:

$$c_{i^*} \leq \bar{V}. \tag{22}$$

Further, note that running a second-price auction with anonymous reserve $\bar{V}$ is a Myerson-type auction (e.g., mapping values less than $\bar{V}$ to virtual value $-\infty$ and values greater than or equal to $\bar{V}$ to virtual value $\bar{V}$), and it gets revenue at least $\delta T\cdot\bar{V}$. So we have that:

$$G_{p^*} \geq \delta T\cdot\bar{V}. \tag{23}$$

Finally, the above implies that to obtain a $1-\epsilon$ approximation, it suffices to consider prices that are at least $\epsilon\delta\bar{V}$. Hence, it suffices to consider Myerson-type auctions that, for a given $\bar{V}$, do not distinguish among values greater than $\bar{V}$, and do not distinguish among values smaller than $\epsilon\delta\bar{V}$. There are $O(\log h/\epsilon)$ different values of $\bar{V}$. Further, given $\bar{V}$, there are only $O(\log(1/\epsilon\delta)/\epsilon)$ distinct values to be considered and, thus, there are at most $O((n\log(1/\epsilon\delta)/\epsilon)!)$ distinct Myerson-type auctions of this kind. Hence, the total number of distinct Myerson-type actions that we need to consider is at most:

$$k = O\left(\frac{\log h}{\epsilon}\cdot\left(\frac{n\log(1/\epsilon\delta)}{\epsilon}\right)!\right).$$

Letting $\boldsymbol{\pi}$ be the uniform distribution over the k actions in Theorem 1, we have that (recall Eqn. (22)):

$$G_{\text{ALG}} \geq (1-\epsilon)\cdot G_{i^*} - O\left(\frac{n\log(1/\epsilon\delta)\log(n\log(1/\epsilon\delta)/\epsilon)}{\epsilon^2} + \frac{\log(\log h/\epsilon)}{\epsilon}\right)\cdot\bar{V}.$$

When $T \geq O\left(\frac{n\log(1/\epsilon\delta)\log(n\log(1/\epsilon\delta)/\epsilon)}{\epsilon^3\delta} + \frac{\log(\log h/\epsilon)}{\epsilon^2\delta}\right)$, the additive term of the above approximation guarantee is at most $\epsilon\cdot G_{i^*}$ due to Eqn. (23). So the theorem holds.

Again, the treatment for the case when h is not known up front is similar to that in Theorem 16. When h is not known up front, we consider a hypothetical algorithm with a countably infinite action space A as follows. For any $\bar{V} = (1+\epsilon)^j$, $j \geq 0$, let the $k' = O((n \log(1/\epsilon\delta)/\epsilon)!)$ Myerson-type auctions that do not distinguish among values greater than $\bar{V}$, and do not distinguish among values smaller than $\epsilon\delta\bar{V}$ be in A. Further, we choose the prior distribution $\boldsymbol{\pi}$ such that the probability mass of each Myerson-type auction for a given $\bar{V}$ is equal to $\frac{\epsilon}{1+\epsilon} \cdot \frac{1}{\bar{V}} \cdot \frac{1}{k'}$. The approximation guarantee then follows by Theorem 1 and essentially the same argument as the known h case. Implementation is similar to the proof of Theorem 16 and Theorem 11 (i.e. a multi-buyer auction version of Algorithm 2). The rest of the proof that shows the revenue loss of this algorithm compared to the hypothetical algorithm is negligible is similar to the proof of Theorem 16 (and hence omitted for brevity). ■

Remark Devanur et al. (2016) show that when the values are drawn from independent regular distributions, the ϵ-guarded optimal price is a $1-\epsilon$ approximation of the unguarded optimal price. So our convergence rate for the online multi buyer auction problem in Theorem 1 implies a $\tilde{O}(n\epsilon^{-4})$ sample complexity modulo a mild $\log\log h$ dependency on the range, almost matching the best known sample complexity upper bound for regular distributions.

5. Multi-scale Online Learning with Symmetric Range

In this section, we consider multi-scale online learning when the rewards are in a symmetric range, i.e. for all $i \in A$ and $t \in [T]$, $g_i(t) \in [-c_i, c_i]$. The standard analysis for the experts and the bandit problems holds even if the range of $g_i(t)$ is $[-c_i, c_i]$, instead of $[0, c_i]$. In contrast, there are subtle differences on the best achievable multi-scale regret bounds between the non-negative and the symmetric range, which we explore in this section. We look at both the full information and bandit setting, and prove action-specific regret upper bounds. We then prove a tight lower-bound in Section 5.3 for the full information case, and an almost tight lower-bound in Section 5.5 for the bandit setting.

5.1. Multi-scale regret bounds for symmetric ranges

We first show the following upper bound for the full information setting when the range is symmetric. This bound follows the same style of action-specific regret bounds as in Theorem 1. More detailed discussion on how the choice of initial distribution $\boldsymbol{\pi}$ affects the bound is deferred to the appendix, Section A.1 (recall that the initial distribution $\boldsymbol{\pi}$ is the distribution over actions that is used in the first round of Algorithm 1).

Theorem 18 *There exists an algorithm for the multi-scale experts problem with symmetric range that takes as input any distribution $\boldsymbol{\pi}$ over A, the ranges c_i, $\forall\, i \in A$, and a parameter $0 < \epsilon \leq 1$, and satisfies:*

$$\forall i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] \leq \epsilon \cdot \mathbb{E}\left[\sum_{t\in[T]} \left|g_t(i)\right|\right] + O\left(\frac{1}{\epsilon}\log\left(\frac{1}{\pi_i}\cdot\frac{c_i}{c_{\min}}\right)\cdot c_i\right). \tag{24}$$

Similar to Section 2.1, we can compute the pure-additive version of the bound in Theorem 18 by setting $\epsilon = \sqrt{\frac{\log(k\cdot\frac{c_{\max}}{c_{\min}})}{T}}$, as in Corollary 2.

Corollary 19 *There exists an algorithm for the online multi-scale experts problem with symmetric range that takes as input the ranges c_i, $\forall\, i \in A$, and satisfies:*

$$\forall i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] \leq O\left(c_i \cdot \sqrt{T\log(k\cdot\tfrac{c_{\max}}{c_{\min}})}\right) \tag{25}$$

If we compare the above regret bound with the standard $O(c_{\max}\sqrt{T\log k})$ regret bound for the experts problem, we see that we replace the dependency on $c_{\max}$ in the standard bound with $c_i\sqrt{\log(\frac{c_{\max}}{c_{\min}})}$. It is natural to ask whether we could get rid of the dependence on $\log(c_i/c_{\min})$ and show a regret bound of $O(c_i\sqrt{T\log k})$, like we did for non-negative rewards. However, the next theorem shows that this dependence on $\log(c_i/c_{\min})$ in the above bound is necessary, in a weak sense: where the constant in the $O(\cdot)$ is universal and does not depend on the ranges c_i. This is because the lower bound only holds for "small" values of the horizon T, which nonetheless grows with the $\{c_i\}$s.[10]

Theorem 20 *There exists an action set of size k, and ranges $c_i, \forall i \in [k]$, and time horizon T, such that for all algorithms for the online multi-scale experts problem with symmetric range, there is a sequence of T gain vectors such that*

$$\exists i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] > \tfrac{c_i}{4} \cdot \sqrt{T\log(k\cdot\tfrac{c_{\max}}{c_{\min}})}$$

We then show the following upper bound for the bandit setting when the range is symmetric. This bound also follows the same style of action-specific regret bounds as in Theorem 12.

Theorem 21 *There exists an algorithm for the multi-scale bandits problem with symmetric range that takes as input the ranges c_i, $\forall\, i \in A$, and a parameter $0 < \epsilon \leq 1/2$, and satisfies:*

$$\forall i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] \leq O\big(\epsilon T + \tfrac{k}{\epsilon}\tfrac{c_{\max}}{c_{\min}}\log\left(\tfrac{k}{\epsilon}\tfrac{c_{\max}}{c_{\min}}\right)\big)\cdot c_i. \tag{26}$$

Also, similar to Section 2.1, we can compute the pure-additive version of the bound in Theorem 21 by setting $\epsilon = \sqrt{\frac{k\frac{c_{\max}}{c_{\min}}\log(kT\cdot\frac{c_{\max}}{c_{\min}})}{T}}$, as in Corollary 2. This bound is comparable to the standard regret bound of $O(c_{\max}\sqrt{kT\log k})$ (Auer et al., 1995) for the adversarial multi-armed bandits problem.

Corollary 22 *There exists an algorithm for the online multi-scale bandits problem with symmetric range that satisfies:*

$$\forall i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] \leq O\left(c_i \cdot \sqrt{Tk\cdot\tfrac{c_{\max}}{c_{\min}}\log(kT\cdot\tfrac{c_{\max}}{c_{\min}})}\right). \tag{27}$$

Once again, for the bandit problem, the following theorem shows that this bound cannot be improved beyond logarithmic factors (to get a guarantee like that of Theorem 12, for instance).

Theorem 23 *There exists an action set of size k, and ranges $c_i, \forall i \in [k]$, such that for all algorithms for the online multi-scale bandit problem with symmetric range, for all sufficiently large time horizon T, there is a sequence of T gain vectors such that*

$$\exists i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] > \frac{c_i}{8\sqrt{2}} \cdot \sqrt{Tk\cdot\frac{c_{\max}}{c_{\min}}}.$$

10. For this reason we chose not to include this bound in Table 1.

5.2. Upper bound for experts with symmetric range - Proof of Theorem 18

Recall the proof of Proposition 10. The proof only requires $g_i(t) \in [-c_i, c_i]$ for all $i \in A, t \in [T]$. Choosing q to be $\mathbf{1}_i$, a vector with a 1-entry in i^{th} coordinate and 0-entries elsewhere for an action $i \in A$, and noting that

$$\sum_{t\in[T]} \sum_{i\in A} p_i(t) \frac{(g_i(t))^2}{c_i} \leq \sum_{t\in[T]} \sum_{i\in A} p_i(t) \cdot \left|g_i(t)\right| ,$$

we get the following regret bound as a corollary of Proposition 10.

Corollary 24 *For any initial distribution μ over A, and any learning rate parameter $0 < \eta \leq 1$, the MSMW algorithm achieves the following regret bound:*

$$\forall i \in A: \quad \mathbb{E}\left[\text{REGRET}_i\right] \leq \eta \cdot \mathbb{E}\left[\sum_{t\in[T]} \left|g_i(t)\right|\right] + \frac{1}{\eta} c_i \cdot \log\left(\frac{1}{\mu_i}\right) + \frac{1}{\eta} \sum_{j\in A} \mu_j c_j \tag{28}$$

Now, we can prove the multi-scale regret upper-bound in Theorem 18 using Corollary 24.

Proof [of Theorem 18] The proof follows by choosing an appropriate initial distribution μ in Corollary 24. By Corollary 24, we have:

$$\mathbb{E}\left[\text{REGRET}_i\right] \leq \eta \cdot \mathbb{E}\left[\sum_{t\in[T]} \left|g_i(t)\right|\right] + \frac{1}{\eta} c_i \cdot \log(\frac{1}{\mu_i}) + \frac{1}{\eta} \sum_{j\in A} \mu_j c_j$$

Let $i_{\min}$ be an action with the minimum range $c_{i_{\min}} = c_{\min}$. Consider an initial distribution $\mu_j = \pi_j \frac{c_{\min}}{c_j}$ for all $j \neq i_{\min}$, and $\mu_{i_{\min}} = 1 - \sum_{j\neq i_{\min}} \mu_j$, i.e., putting all remaining probability mass on action $i_{\min}$. Then, the third term on the RHS is upper bounded by:

$$\sum_{j\in A} \mu_j c_j = \sum_{j\neq i_{\min}} \mu_j c_j + \mu_{i_{\min}} c_{i_{\min}} = \sum_{j\neq i_{\min}} \pi_j c_{\min} + \mu_{i_{\min}} c_{\min} \leq 2c_{\min} \leq 2c_i \ .$$

For $i \neq i_{\min}$, by the definition of μ_i, we have:

$$\begin{aligned}\mathbb{E}\left[\text{REGRET}_i\right] &\leq \eta \cdot \mathbb{E}\left[\sum_{t\in[T]} \left|g_i(t)\right|\right] + \frac{1}{\eta} c_i \cdot \log(\frac{1}{\pi_i} \cdot \frac{c_i}{c_{\min}}) + \frac{1}{\eta} \cdot 2c_{\min} \\ &= \eta \cdot \mathbb{E}\left[\sum_{t\in[T]} \left|g_i(t)\right|\right] + O\left(\frac{1}{\eta} \log\left(\frac{1}{\pi_i} \cdot \frac{c_i}{c_{\min}}\right) \cdot c_i\right) \ .\end{aligned}$$

So the theorem follows by choosing $\eta = \epsilon$. For $i = i_{\min}$, note that $\mu_j \leq \pi_j$ for all $j \neq i_{\min}$ and, thus, $\mu_{i_{\min}} = 1 - \sum_{j\neq i_{\min}} \mu_j \geq 1 - \sum_{j\neq i_{\min}} \pi_j = \pi_{i_{\min}} = \pi_{i_{\min}} \frac{c_{\min}}{c_{i_{\min}}}$. The theorem then holds following the same calculation as in the $j \neq i_{\min}$ case. ■

5.3. Lower bound for experts with symmetric range - proof of Theorem 20

We first show that for any online learning algorithm, and any sufficiently large $h > 1$, there is an instance that has two experts with $c_1 = 1$ and $c_2 = h$ with $T = \Theta(\log h)$ rounds, such that either

$$\mathbb{E}\left[\text{REGRET}_1\right] > \tfrac{1}{2}T + \sqrt{h} \ , \qquad \text{or} \qquad \mathbb{E}\left[\text{REGRET}_2\right] > \tfrac{1}{2}Th + \tfrac{1}{5}h\log_2 h \ .$$

We will construct this instance with $T = \frac{1}{2}\log_2 h - 1$ rounds adaptively that always has gain 0 for action 1 and gain either h or $-h$ for action 2. The proof of the theorem then

follows as $c_{\min} = 1$, $c_{\max} = h$, $T = \frac{1}{2}\log_2 h - 1$, and $k = 2$ in this instance. Let q_t denote the probability that the algorithm picks action 2 in round t after having the same rewards 1 and h for the two actions respectively in the first $t-1$ rounds. We will first show that (1) if the algorithm has small regret with respect to action 1, then q_t must be upper bounded since the adversary may let action 2 have cost $-h$ in any round t in which q_t is too large. Then, we will show that (2) since q_t is upper bounded for any $1 \leq t \leq T$, the algorithm must have large regret with respect to action 2.

We proceed with the upper bounding q_t's. Concretely, we will show the following lemma.

Lemma 25 *Suppose $\mathbb{E}\left[\text{REGRET}_1\right] \leq \frac{1}{2}T + \sqrt{h}$. Then, for any $1 \leq t \leq T$, we have $q_t \leq \frac{2^t}{\sqrt{h}}$.*

Proof We will prove by induction on t. Consider the base case $t = 1$. Suppose for contradiction that $q_1 > \frac{2}{\sqrt{h}}$. Then, consider an instance in which action 2 always has gain. In this case, the expected gain of the algorithm (even if it always correctly picks action 1 in the remaining instance) is at most $q_1 \cdot (-h) < -2\sqrt{h}$. This is a contradiction to the assumption that $\mathbb{E}\left[\text{REGRET}_1\right] \leq \frac{1}{2}T + \sqrt{h} < 2\sqrt{h}$.

Next, suppose the lemma holds for all rounds prior to round t. Then, the expected gain of algorithm in the first $t-1$ rounds if arm 2 has gain H is

$$\sum_{\ell=1}^{t-1} q_\ell \cdot h \leq \sum_{\ell=1}^{t-1} 2^\ell \sqrt{h} = \left(2^t - 2\right)\sqrt{h} \ .$$

Suppose for contradiction that $q_t > \frac{2^t}{\sqrt{h}}$. Then, consider an instance in which action 2 has gain H in the first $t-1$ rounds and $-H$ afterwards. In this case, the expected gain of the algorithm (even if it always correctly picks action 1 after round t) is at most

$$\left(2^t - 2\right)\sqrt{h} + q_t(-h) < \left(2^t - 2\right)\sqrt{h} + 2^t\sqrt{h} < -2\sqrt{h} \ .$$

This is a contradiction to the assumption that $\mathbb{E}\left[\text{REGRET}_1\right] \leq \frac{1}{2}T + \sqrt{h} < 2\sqrt{h}$. ■

Consider an instance in which action 2 always has gain H. Suppose that $\mathbb{E}\left[\text{REGRET}_1\right] \leq \frac{1}{2}T + \sqrt{h}$. As an immediate implication of the above lemma, the algorithm is that the expected gain of the algorithm is upper bounded by:

$$\sum_{t=1}^{T} q_t h \leq \sum_{t=1}^{T} 2^t\sqrt{h} < 2^{T+1}\sqrt{h} = h \ .$$

Note that in this instance $\mathbb{E}\left[G_2\right] = T \cdot h$. Thus, the regret w.r.t. action 2 is at least $(T-1)h$, which is greater than $\frac{1}{2} \cdot \mathbb{E}\left[G_2\right] + \frac{1}{5}h\log_2 h$ for sufficiently large h.

5.4. Upper bound for bandits with symmetric range - Proof of Theorem 21

We start by presenting the following regret bound, whose proof is an alteration of that for Lemma 14 under symmetric range. Next, we prove Theorem 21.

Lemma 26 *For any exploration rate $0 < \gamma \leq \min\{\frac{1}{2}, \frac{c_{\min}}{c_{\max}}\}$ and any learning rate $0 < \eta \leq \frac{\gamma}{k}$, the Bandit-MSMW algorithm (Algorithm 3) achieves the following regret bound:*

$$\forall i \in A : \mathbb{E}\left[\text{REGRET}_i\right] \leq O\left(\frac{1}{\eta}\log\left(\frac{k}{\gamma}\right)\cdot c_i + \gamma T \cdot c_{\max}\right)$$

Proof We further define:

$$\widetilde{G}_{\text{ALG}} \triangleq \sum_{t\in[T]} g_{i_t}(t) = \sum_{t\in[T]} \tilde{\mathbf{p}}(t)\cdot\tilde{\mathbf{g}}(t)\ ,$$
$$\widetilde{G}_j \triangleq \sum_{t\in[T]} \tilde{g}_j(t)\ .$$

In expectation over the randomness of the algorithm, we have:

1. $\mathbb{E}\left[G_{\text{ALG}}\right] = \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]$; and
2. $G_j = \mathbb{E}\left[\widetilde{G}_j\right]$ for any $j \in A$.

Hence, to upper bound $\mathbb{E}\left[\text{REGRET}_i\right] = G_i - \mathbb{E}\left[G_{\text{ALG}}\right]$, it suffices to upper bound $\mathbb{E}\left[\widetilde{G}_i - \widetilde{G}_{\text{ALG}}\right]$.

By the definition of the probability that the algorithm picks each arm, i.e., $\tilde{\mathbf{p}}(t)$, and that reward of each round is at least $-c_{\max}$, we have that:

$$\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \geq (1-\gamma)\sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t) - \gamma T c_{\max}\ .$$

Hence, for any benchmark distribution $\mathbf{q}$ over A, we have that:

$$\begin{aligned}\textstyle\sum_{j\in A} q_j\cdot\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] &\leq \mathbb{E}\left[\textstyle\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\right] + \tfrac{\gamma}{1-\gamma}\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] + \tfrac{\gamma}{1-\gamma}Tc_{\max}\\ &\leq \mathbb{E}\left[\textstyle\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\right] + 2\gamma\mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] + 2\gamma T c_{\max}\\ &\leq \mathbb{E}\left[\textstyle\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\right] + 4\gamma T c_{\max}\ . \qquad (29)\end{aligned}$$

where the 2nd inequality is due to $\gamma \leq \frac{1}{2}$, and the 3rd inequality follows by that $c_{\max}$ is the largest possible reward per round.

Next, we upper bound the 1st term on the RHS of (29). Note that $\mathbf{p}(t)$'s are the probability of choosing experts by MSMW when the experts have rewards $\tilde{\mathbf{g}}(t)$'s. By Proposition 10, we have that for any benchmark distribution $\mathbf{q}$ over S, the Bandit-MSMW algorithm satisfies that:

$$\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t) \leq \eta\sum_{t\in[T]}\sum_{j\in A}\frac{p_j(t)}{c_j}\cdot\left(\tilde{g}_j(t)\right)^2 + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right)\ . \qquad (30)$$

For any $t \in [T]$ and any $j \in A$, by the definition of $\tilde{g}_j(t)$, it equals $\frac{g_j(t)}{\tilde{p}_j(t)}$ with probability $\tilde{p}_j(t)$, and equals 0 otherwise. Thus, if we fix the random coin flips in the first $t-1$ rounds and, thus, fix $\tilde{\mathbf{p}}(t)$, and take expectation over the randomness in round t, we have that:

$$\mathbb{E}\left[\frac{p_j(t)}{c_j}\cdot\left(\tilde{g}_j(t)\right)^2\right] = \frac{p_j(t)}{c_j}\cdot\tilde{p}_j(t)\cdot\left(\frac{g_j(t)}{\tilde{p}_j(t)}\right)^2 = \frac{p_j(t)}{\tilde{p}_j(t)}\frac{(g_j(t))^2}{c_j}\ .$$

Further note that $\tilde{p}_j(t) \geq (1-\gamma)p_j(t)$, and $|g_j(t)| \leq c_j$, the above is upper bounded by $\frac{1}{1-\gamma}|g_j(t)| \leq 2|g_j(t)| \leq 2c_{\max}$. Putting together with (30), we have that for any $0 < \eta \leq \frac{\gamma}{n}$:

$$\begin{aligned}\mathbb{E}\left[\sum_{j\in A} q_j\cdot\widetilde{G}_j - \sum_{t\in[T]}\mathbf{p}(t)\cdot\tilde{\mathbf{g}}(t)\right] &\leq \eta\sum_{t\in[T]}\sum_{j\in A} 2c_{\max} + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right)\\ &= 2\eta T k c_{\max} + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right)\end{aligned}$$

Combining with (29), we have (recall that $\eta \leq \frac{\gamma}{k}$):

$$\begin{aligned}\sum_{j\in A} q_j\cdot\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] &\leq 2\eta T k c_{\max} + \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right) + 4\gamma T c_{\max}\\ &\leq \frac{1}{\eta}\sum_{j\in A} c_j\left(q_j\ln\left(\frac{q_j}{p_j(1)}\right) - q_j + p_j(1)\right) + 6\gamma T c_{\max}\end{aligned}$$

Let $\mathbf{q} = (1-\gamma)\mathbf{1}_i + \frac{\gamma}{k}\mathbf{1}$. Recall that $\mathbf{p}(1) = (1-\gamma)\mathbf{1}_{i_{\min}} + \frac{\gamma}{k}\mathbf{1}$ (recall $i_{\min}$ is the arm with minimum range $c_{i_{\min}}$). Similar to the discussion for the expert problem in Section 2.5, the 1st term on the RHS is upper bounded by $O\left(\frac{1}{\eta}\log\left(\frac{k}{\gamma}\right)\cdot c_i\right)$. Hence, we have:

$$\sum_{j\in A} q_j\cdot\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \leq O\left(\frac{1}{\eta}\log\left(\frac{k}{\gamma}\right)\cdot c_i\right) + 6\gamma T c_{\max}\ . \qquad (31)$$

Further, the LHS is lower bounded as:

$$(1-\gamma)\mathbb{E}\left[\widetilde{G}_i\right] + \frac{\gamma}{k}\sum_{j\in A}\mathbb{E}\left[\widetilde{G}_j\right] - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right] \geq (1-\gamma)\mathbb{E}\left[\widetilde{G}_i\right] - \gamma T c_{\max} - \mathbb{E}\left[\widetilde{G}_{\text{ALG}}\right]\ .$$

The lemma then follows by putting it back to (31) and rearranging terms. ■

Proof [of Theorem 21] Let $\gamma = \epsilon\frac{c_{\min}}{c_{\max}}$ and $\eta = \frac{\gamma}{k}$ in Lemma 26. Theorem follows noting that $\gamma c_{\max} = \epsilon c_{\min} \leq \epsilon c_i$. ■

5.5. Lower-bound for bandits with symmetric range - Proof of Theorem 23

We first show that for any online multi-scale bandits algorithm problem, and there is an instance that has two arms with $c_1 = 1$ and $c_2 = h$ for some sufficiently large h, a sufficiently large T, and $\epsilon = \sqrt{\frac{h}{256T}}$, such that either

$$\mathbb{E}\left[\text{REGRET}_1\right] > \epsilon T + \tfrac{1}{256\epsilon}h\ , \qquad \text{or} \qquad \mathbb{E}\left[\text{REGRET}_2\right] > \epsilon T h + \tfrac{1}{256\epsilon}h^2$$

We will prove the existence of this instance by looking at the stochastic setting, i.e., the gain vectors $\mathbf{g}(t)$'s are i.i.d. for $1 \leq t \leq T$. We consider two instances, both of which admit

a fixed gain of 0 for action 1. In the first instance, the gain of action 2 is h with probability $\frac{1}{2} - 2\epsilon$, and $-h$ otherwise. Hence, the expected gain of playing action 2 is $-4\epsilon h$ per round in instance 1. In the second instance, the gain of action 2 is h with probability $\frac{1}{2} + 2\epsilon$, and $-h$ otherwise. Hence, the expected gain of playing action two is $4\epsilon h$ per round in instance 2. Note this proves the theorem, as $c_{\min} = 1$, $c_{\max} = h$, $k = 2$ and and $T = \frac{h}{256\epsilon^2}$.

Suppose for contradiction that the algorithm satisfies:

$$\mathbb{E}\left[\text{REGRET}_1\right] \leq \epsilon T + \tfrac{1}{256\epsilon} h = \tfrac{1}{128\epsilon} h \quad , \quad \mathbb{E}\left[\text{REGRET}_2\right] \leq \epsilon h T + \tfrac{1}{256\epsilon} h^2 = \tfrac{1}{128\epsilon} h^2 \ .$$

Let N_1 denote the expected number of times that the algorithm plays action 2 in instance 1. Then, the expected regret with respect to action 1 in instance 1 is $N_1 \cdot 4\epsilon h$. By the assumption that $\mathbb{E}\left[\text{REGRET}_1\right] \leq \frac{1}{128\epsilon} h$, we have $N_1 \leq \frac{1}{512\epsilon^2}$.

Next, by standard calculation, we get that the Kullback-Leibler (KL) divergence of the observed rewards in a single round in the two instances is 0 if action 1 is played and is at most $64\epsilon^2$ (for $0 < \epsilon < 0.1$) if action 2 is played. So the KL divergence of the observed reward sequences in the two instances is at most $64\epsilon^2 \cdot N_1 \leq \frac{1}{8}$.

Then, we use a standard inequality about KL divergences. For any measurable function $\psi : X \mapsto \{1, 2\}$, we have $\Pr_{X \sim \rho_1}\big(\psi(X) = 2\big) + \Pr_{X \sim \rho_2}\big(\psi(X) = 1\big) \geq \frac{1}{2}\exp\big(-KL(\rho_1, \rho_2)\big)$. For any $1 \leq t \leq T$, let ρ_1 and ρ_2 be the distribution of observed rewards up to a round t in the two instances, and let $\psi(X)$ be the action played by the algorithm. By this inequality and the above bound on the KL divergence between the observed rewards in the two instances, we get that in each round, the probability that the algorithm plays action 2 in instance 1, plus the probability that the algorithm plays action 1 in instance 2, is at least $\frac{1}{2}\exp\left(-\frac{1}{8}\right) > \frac{2}{5}$ in any round t. Thus, the expected number of times that the algorithm plays action 1 in instance 2 from round 1 to T, denoted as N_2, is at least $N_2 \geq \frac{2}{5} \cdot T - N_1 \geq \frac{1}{3} \cdot T$, where the second inequality holds for sufficiently large h. Therefore, the expected regret w.r.t. action 2 in instance 2 is at least: $4\epsilon h \cdot \frac{1}{3} \cdot T = \frac{4}{3}\epsilon h T > \frac{1}{128\epsilon} h^2$. This is a contradiction to our assumption that $\mathbb{E}\left[\text{REGRET}_2\right] \leq \frac{1}{128\epsilon} h^2$.

6. Conclusion

Revenue management has emerged as a competitive toolbox of strategies for increasing the profit of web-based markets. In particular, dynamic pricing, and dynamic auction design as its less mature relative, have become prevalent market mechanisms in nearly all industries. In this paper, we studied these problems from the perspective of online learning. For the online auction for single buyer, we showed regret bounds that scale with the best fixed price, rather than the range of the values (with a generalization to learning auctions). Moreover, we demonstrated a connection between the optimal regret bounds for this problem and offline sample complexity lower-bounds of approximating optimal revenue, studied in Cole and Roughgarden (2014); Huang et al. (2015a). Using this connection, we showed our regret bounds are almost optimal as they match these information theoretic lower-bounds. We further generalized our result to online pricing (bandit feedback) and online auction with multiple-buyers.

The key to our development and improved regret bounds for online auction design is generalizing the classical learning from experts and multi-armed bandit problems to their "multi-scale versions", where the reward of each action is in a different range. Here the objective is to design online learning algorithms whose regret with respect to a given action scales with its own range, rather than the maximum range. We showed how a variant of online mirror descent solves this learning problem.

Appendix A. Other Deferred Proofs and Discussions

A.1. Discussion on choice of $\boldsymbol{\pi}$ for bandit symmetric range

We now describe how the choice of initial distribution $\boldsymbol{\pi}$ affects the bound given in Theorem 18.

- When the action set is finite, we can choose $\boldsymbol{\pi}$ to be the uniform distribution to get the term
$$O\big(\frac{1}{\epsilon}\log(kc_i/c_{\min})\cdot c_i\big)$$
This recovers the standard bound by setting $c_i = c_{\max}$ for all $i \in A$.
- We can choose $\pi_i = \frac{c_i}{\sum_{j\in A} c_j}$ to get $O\big(\frac{1}{\epsilon}\log(\sum_{j\in A} c_j/c_{\min})\cdot c_i\big)$. In particular, if the c_i's form an arithmetic progression with a constant difference then this is just $O\big(\frac{\log k}{\epsilon}\cdot c_i\big)$.

A.2. Elementary proof of Proposition 10 from first principles

Based on the update rule of Algorithm 1, we have $g_i(t) = \frac{c_i}{\eta}\log(\frac{w_i(t+1)}{p_i(t)})$ for any $i \in A$. Therefore:

$$\begin{aligned}
\mathbf{g}(t)\cdot\big(\mathbf{q}-\mathbf{p}(t)\big) &= \sum_{i\in A} g_i(t)\big(q_i - p_i(t)\big)\\
&= \sum_{i\in A}\frac{c_i}{\eta}\cdot\log\big(\frac{w_i(t+1)}{p_i(t)}\big)\cdot\big(q_i-p_i(t)\big)\\
&= \frac{1}{\eta}\left(\sum_{i\in S} c_i\cdot q_i\cdot\log\big(\frac{w_k(t+1)}{p_k(t)}\big) + \sum_{i\in A} c_i\cdot p_i(t)\cdot\log\big(\frac{p_i(t)}{w_i(t+1)}\big)\right)\\
&= \frac{1}{\eta}\Big(\sum_{i\in S} c_i\cdot q_i\cdot\log\big(\frac{w_k(t+1)}{p_k(t+1)}\big) + \sum_{i\in S} c_i\cdot q_i\cdot\log\big(\frac{p_k(t+1)}{p_k(t)}\big)\\
&\qquad + \sum_{i\in A} c_i\cdot p_i(t)\cdot\log\big(\frac{p_i(t)}{w_i(t+1)}\big)\Big) \qquad (32)
\end{aligned}$$

Now, note that due to the normalization step of Algorithm 1, for any $i \in S$ we have:

$$c_i\cdot\log(\frac{w_i(t+1)}{p_i(t+1)}) = \lambda = \sum_{j\in A} c_j\cdot p_j(t+1)\cdot\frac{\lambda}{c_j} = \sum_{j\in A} c_j\cdot p_j(t+1)\cdot\log(\frac{w_j(t+1)}{p_j(t+1)})$$

So the first summation in (32) is equal to:

$$\begin{aligned}
\sum_{i\in S} c_i\cdot q_i\cdot\log\big(\frac{w_k(t+1)}{p_k(t+1)}\big) &= \sum_{i\in S} q_i\cdot\sum_{j\in A} c_j\cdot p_j(t+1)\cdot\log(\frac{w_j(t+1)}{p_j(t+1)})\\
&= \sum_{j\in A} c_j\cdot p_j(t+1)\cdot\log(\frac{w_j(t+1)}{p_j(t+1)})\\
&= \sum_{i\in A} c_i\cdot p_i(t+1)\cdot\log(\frac{w_i(t+1)}{p_i(t+1)}) \qquad (33)
\end{aligned}$$

Combining Eqn. (32) and (33), we have:

$$\begin{aligned}
\mathbf{g}(t)\cdot\big(\mathbf{q}-\mathbf{p}(t)\big) &= \frac{1}{\eta}\sum_{i\in A} c_i\cdot\left(p_i(t)\cdot\log(\frac{p_i(t)}{w_i(t+1)}) + p_i(t+1)\cdot\log(\frac{w_i(t+1)}{p_i(t+1)})\right)\\
&\quad + \frac{1}{\eta}\sum_{i\in S} c_i\cdot q_i\cdot\log\big(\frac{p_i(t+1)}{p_i(t)}\big)
\end{aligned}$$

The 2nd part is a telescopic sum when we sum over t. We will upper bound the 1st part as follows. By $\log(x) \le (x-1)$, we get that:

$$\begin{aligned}
&\sum_{i\in A} c_i\cdot\left(p_i(t)\cdot\log(\frac{p_i(t)}{w_i(t+1)}) + p_i(t+1)\cdot\log(\frac{w_i(t+1)}{p_i(t+1)})\right)\\
&\quad\le \sum_{i\in A} c_i\cdot\left(p_i(t)\cdot\log(\frac{p_i(t)}{w_i(t+1)}) - p_i(t+1) + w_i(t+1)\right)\\
&\quad= \sum_{i\in A} c_i\cdot\big(p_i(t)-p_i(t+1)\big) + \sum_{i\in A} c_i\cdot\left(p_i(t)\cdot\log(\frac{p_i(t)}{w_i(t+1)}) - p_i(t) + w_i(t+1)\right)
\end{aligned}$$

Again, the 1st part is a telescopic sum when we sum over t. We will further work on the 2nd part. By the relation between $w_i(t+1)$ and $p_i(t)$, we get that:

$$\sum_{i\in A} c_i\cdot\left(p_i(t)\cdot\log(\frac{p_i(t)}{w_i(t+1)}) - p_i(t) + w_i(t+1)\right) = \sum_{i\in A} c_i\cdot p_i(t)\left(-\eta\cdot\frac{g_i(t)}{c_i} - 1 + \exp(\eta\cdot\frac{g_i(t)}{c_i})\right)$$

Note that $\eta\cdot\frac{g_i(t)}{c_i} \in [-1,1]$ because $g_i(t) \in [-c_i, c_i]$ and $0 < \eta \le 1$. By $\exp(x) - x - 1 \le x^2$ for $-1 \le x \le 1$ and that $\eta g_i(t) \in [-c_i, c_i]$, the above is upper bounded by $\eta^2\sum_{i\in A} p_i(t)\frac{(g_i(t))^2}{c_i}$. Putting together, we get that:

$$\mathbf{g}(t)\cdot\big(\mathbf{q}-\mathbf{p}(t)\big) \le \frac{1}{\eta}\sum_{i\in S} c_i\cdot\left(q_i\cdot\log\big(\frac{p_i(t+1)}{p_i(t)}\big) + p_i(t) - p_i(t+1)\right) + \eta\sum_{i\in A} p_i(t)\frac{(g_i(t))^2}{c_i}$$

Summing over t, we have:

$$\mathbf{g}(t)\cdot\big(\mathbf{q}-\mathbf{p}(t)\big) \le \frac{1}{\eta}\sum_{i\in S} c_i\cdot\left(q_i\cdot\log\big(\frac{p_i(T+1)}{p_i(1)}\big) + p_i(1) - p_i(T+1)\right) + \eta\sum_{t\in[T]}\sum_{i\in A} p_i(t)\frac{(g_i(t))^2}{c_i}$$

Finally, by $\log(x) \le (x-1)$, we get that $q_i\log\big(\frac{p_i(T+1)}{q_i}\big) \le p_i(T+1) - q_i$. Hence, we have:

$$\mathbf{g}(t)\cdot\big(\mathbf{q}-\mathbf{p}(t)\big) \le \frac{1}{\eta}\sum_{i\in S} c_i\cdot\left(q_i\cdot\log\big(\frac{q_i}{p_i(1)}\big) + p_i(1) - q_i\right) + \eta\sum_{t\in[T]}\sum_{i\in A} p_i(t)\frac{(g_i(t))^2}{c_i}$$

The proposition then follows by our choice of the initial distribution.

A.3. Proof of OMD regret bound

In order to prove the OMD regret bound, we need some properties of Bregman divergence.

Lemma 27 (Properties of Bregman divergence (Bubeck, 2011)) *Suppose $F(\cdot)$ is a Legendre function and $D_F(\cdot,\cdot)$ is its associated Bregman divergence as defined in Definition 4. Then:*

- *$D_F(x,y) > 0$ if $x \neq y$ as F is strictly convex, and $D_F(x,x) = 0$.*
- *$D_F(.,y)$ is a convex function for any choice of y.*
- *(*Pythagorean theorem*) If $\mathcal{A}$ is a convex set, $a \in \mathcal{A}$, $b \notin \mathcal{A}$ and $c = \underset{x\in\mathcal{A}}{argmin}(D_F(x,b))$, then*

$$D_F(a,c) + D_F(c,b) \leq D_F(a,b)$$

Given Lemma 27, we are now ready to prove Lemma 6.

Proof [Proof of Lemma 6] To obtain the OMD regret bound, we have:

$$\begin{aligned}
\mathbf{q}\cdot\mathbf{g}(t) - \mathbf{p}(t)\cdot\mathbf{g}(t) &= \frac{1}{\eta}(\mathbf{q}-\mathbf{p}(t))\cdot(\nabla F(\mathbf{w}(t+1)) - \nabla F(\mathbf{p}(t))) \\
&= \frac{1}{\eta}(D_F(qb,\mathbf{p}(t)) + D_F(\mathbf{p}(t),\mathbf{w}(t+1)) - D_F(qb,\mathbf{w}(t+1))) \\
&\overset{(1)}{\leq} \frac{1}{\eta}D_F(\mathbf{p}(t),\mathbf{w}(t+1)) + \frac{1}{\eta}\left(D_F(\mathbf{q},\mathbf{p}(t)) - D_F(\mathbf{q},\mathbf{p}(t+1))\right) \qquad (34)
\end{aligned}$$

where in (1) we use $D_F(\mathbf{p}(t+1),\mathbf{w}(t+1)) \geq 0$ and $D_F(\mathbf{q},\mathbf{p}(t+1)) + D_F(\mathbf{p}(t+1),\mathbf{w}(t+1)) \leq D_F(\mathbf{q},\mathbf{w}(t+1))$ due to Pythagorean theorem (Lemma 27). By summing up both hand sides of (34) for $t = 1,\cdots,T$ we have:

$$\sum_{t\in[T]} \mathbf{g}(t)\cdot\big(\mathbf{q}-\mathbf{p}(t)\big) \leq \frac{1}{\eta}\sum_{t\in[T]} D_F(\mathbf{p}(t),\mathbf{w}(t+1)) + \frac{1}{\eta}D_F(\mathbf{q},\mathbf{p}(1)) \qquad (35)$$

Abstract

We prove new upper and lower bounds on the VC-dimension of deep neural networks with the ReLU activation function. These bounds are tight for almost the entire range of parameters. Letting W be the number of weights and L be the number of layers, we prove that the VC-dimension is $O(WL\log(W))$, and provide examples with VC-dimension $\Omega(WL\log(W/L))$. This improves both the previously known upper bounds and lower bounds. In terms of the number U of non-linear units, we prove a tight bound $\Theta(WU)$ on the VC-dimension. All of these bounds generalize to arbitrary piecewise linear activation functions, and also hold for the pseudodimensions of these function classes.

Combined with previous results, this gives an intriguing range of dependencies of the VC-dimension on depth for networks with different non-linearities: there is no dependence for piecewise-constant, linear dependence for piecewise-linear, and no more than quadratic dependence for general piecewise-polynomial.

Keywords: VC-dimension, pseudodimension, neural networks, ReLU activation function, statistical learning theory

1. Introduction

Deep neural networks underlie many of the recent breakthroughs in applied machine learning, particularly in image and speech recognition. These successes motivate a renewed study of these networks' theoretical properties.

Classification is one of the learning tasks in which deep neural networks have been particularly successful, e.g., for image recognition. A natural foundational question that arises is: what are the generalization guarantees of these networks in a statistical learning framework? An established way to address this question is by considering the VC-dimension, which characterizes uniform convergence of misclassification frequencies to probabilities (see Vapnik and Chervonenkis, 1971), and asymptotically determines the sample complexity of PAC learning with such classifiers (see Blumer, Ehrenfeucht, Haussler, and Warmuth, 1989).

Definition 1 (growth function, VC-dimension, shattering) *Let H denote a class of functions from $\mathcal{X}$ to $\{0,1\}$ (the hypotheses, or the classification rules). For any non-negative integer m, we define the* growth function *of H as*

$$\Pi_H(m) \coloneqq \max_{x_1,\ldots,x_m\in\mathcal{X}} |\{(h(x_1),\ldots,h(x_m)) : h\in H\}|\,.$$

If $|\{(h(x_1),\ldots,h(x_m)) : h\in H\}| = 2^m$, we say H shatters *the set $\{x_1,\ldots,x_m\}$. The Vapnik-Chervonenkis dimension of H, denoted* $\mathrm{VCdim}(H)$*, is the size of the largest shattered set, i.e. the largest m such that $\Pi_H(m) = 2^m$. If there is no largest m, we define $\mathrm{VCdim}(H) = \infty$.*

For a class of real-valued functions, such as those generated by neural networks, a natural measure of complexity that implies similar uniform convergence properties is the pseudodimension, introduced by Pollard (1990) (see, e.g., Anthony and Bartlett (1999, Theorem 19.2)).

Definition 2 (pseudodimension) *Let $\mathcal{F}$ be a class of functions from $\mathcal{X}$ to $\Re$. The pseudodimension of $\mathcal{F}$, written* $\mathrm{Pdim}(\mathcal{F})$*, is the largest integer m for which there exists $(x_1,\ldots,x_m,y_1,\ldots,y_m)\in\mathcal{X}^m\times\Re^m$ such that for any $(b_1,\ldots,b_m)\in\{0,1\}^m$ there exists $f\in\mathcal{F}$ such that*

$$\forall i : f(x_i) > y_i \iff b_i = 1$$

For a class $\mathcal{F}$ of real-valued functions, we define $\mathrm{VCdim}(\mathcal{F}) \coloneqq \mathrm{VCdim}(\mathrm{sgn}(\mathcal{F}))$, where

$$\mathrm{sgn}(\mathcal{F}) \coloneqq \{\mathrm{sgn}(f) : f\in\mathcal{F}\}$$

and $\mathrm{sgn}(x) = \mathbf{1}[x > 0]$. For any class $\mathcal{F}$, clearly $\mathrm{VCdim}(\mathcal{F}) \le \mathrm{Pdim}(\mathcal{F})$. If $\mathcal{F}$ is the class of functions generated by a neural network $\mathcal{N}$ with a fixed architecture and fixed activation functions (see Section 1.3 for definitions), then it is not hard to see that indeed $\mathrm{Pdim}(\mathcal{F}) \le \mathrm{VCdim}(\mathcal{F}')$, where $\mathcal{F}'$ is the class of functions generated by a certain neural network with one more parameter and one more layer than $\mathcal{N}$ (see Anthony and Bartlett (1999, Theorem 14.1) for a proof). Therefore, all the results of this paper automatically apply to the pseudodimensions of neural networks as well, after appropriate adjustments.

The main contribution of this paper is to prove nearly-tight bounds on the VC-dimension of deep neural networks in which the non-linear activation function is a piecewise linear function with a constant number of pieces. For simplicity we will henceforth refer to such networks as "piecewise linear networks". The activation function that is the most commonly used in practice is the *rectified linear unit*, also known as *ReLU* (see LeCun, Bengio, and

*. An extended abstract appeared in Proceedings of the Conference on Learning Theory (COLT) 2017: http://proceedings.mlr.press/v65/harvey17a.html; the upper bound was presented at the 2016 ACM Conference on Data Science: http://ikdd.acm.org/Site/CoDS2016/keynotes.html. This version includes all the proofs and a refinement of the upper bound, Theorem 7.

Hinton, 2015; Goodfellow, Bengio, and Courville, 2016). The ReLU function is defined as $\sigma(x) = \max\{0, x\}$, so it is clearly piecewise linear.

It is particularly interesting to understand how the VC-dimension is affected by the various attributes of the network: the number W of parameters (i.e., weights and biases), the number U of non-linear units (i.e., nodes), and the number L of layers. Among all networks with the same size (number of weights), is it true that those with more layers have larger VC-dimension?

Such a statement is indeed true, and previously known; however, a tight characterization of how depth affects VC-dimension was unknown prior to this work.

1.1. Our results

Our first main result is a new VC-dimension lower bound that holds even for the restricted family of ReLU networks.

Theorem 3 (Main lower bound) *There exists a universal constant C such that the following holds. Given any W, L with $W > CL > C^2$, there exists a ReLU network with $\leq L$ layers and $\leq W$ parameters with VC-dimension $\geq WL\log(W/L)/C$.*

Remark 4 *Our construction can be augmented slightly to give a neural network with linear threshold and identity activation functions with the same guarantees.*

Remark 5 *Our goal in this paper is to give asymptotic lower and upper bounds. However, one may wonder what is the smallest depth for which we can give a positive lower bound for the VC-dimension. Our Theorem 11 gives a positive lower bound as soon as the number of layers is at least 8 (which corresponds to $k = 1$ in that theorem).*

The proof appears in Section 2. Prior to our work, the best known lower bounds were $\Omega(WL)$ (see Bartlett, Maiorov, and Meir, 1998, Theorem 2) and $\Omega(W \log W)$ (see Maass, 1994, Theorem 1). We strictly improve both bounds to $\Omega(WL\log(W/L))$.

Our proof of Theorem 3 uses the "bit extraction" technique, which was also used by Bartlett et al. (1998) to give an $\Omega(WL)$ lower bound. We refine this technique to gain the additional logarithmic factor that appears in Theorem 3.

Unfortunately there is a barrier to refining this technique any further. Our next theorem shows the hardness of computing the mod function, implying that the bit extraction technique cannot yield a stronger lower bound than Theorem 3. Further discussion of this connection may be found in Remark 14.

Theorem 6 *Assume there exists a piecewise linear network with W parameters and L layers that computes a function $f : \Re \to \Re$, with the property that $|f(x) - (x \bmod 2)| < 1/2$ for all $x \in \{0, 1, \ldots, 2^m - 1\}$. Then we have $m = O(L\log(W/L))$.*

The proof of this theorem appears in Section 3. One interesting aspect of the proof is that it does not use Warren's lemma (Warren, 1968), which is a mainstay of VC-dimension upper bounds (see Goldberg and Jerrum, 1995; Bartlett et al., 1998; Anthony and Bartlett, 1999).

Our next main result is an upper bound on the VC-dimension of neural networks with piecewise polynomial activation functions.

Theorem 7 (Main upper bound) *Consider a neural network architecture with W parameters and U computation units arranged in L layers, so that each unit has connections only from units in earlier layers. Let k_i denote the number of units at the ith layer. Suppose that all non-output units have piecewise-polynomial activation functions with $p + 1$ pieces and degree no more than d, and the output unit has the identity function as its activation function.*

If $d = 0$, let W_i denote the number of parameters (weights and biases) at the inputs to units in layer i; if $d > 0$, let W_i denote the total number of parameters (weights and biases) at the inputs to units in all the layers ***up to layer*** *i (i.e., in layers $1, 2, \ldots, i$). Define the* effective depth *as*

$$\bar{L} \coloneqq \frac{1}{W}\sum_{i=1}^{L} W_i,$$

and let

$$R \coloneqq \sum_{i=1}^{L} k_i(1 + (i-1)d^{i-1}) \leq U + U(L-1)d^{L-1}. \tag{1}$$

For the class $\mathcal{F}$ of all (real-valued) functions computed by this network and $m \geq \bar{L}W$, we have

$$\Pi_{\mathrm{sgn}(\mathcal{F})}(m) \leq \prod_{i=1}^{L} 2\left(\frac{2emk_ip(1 + (i-1)d^{i-1})}{W_i}\right)^{W_i},$$

and if $U > 2$ then

$$\mathrm{VCdim}(\mathcal{F}) \leq L + \bar{L}W\log_2(4epR\log_2(2epR)) = O(\bar{L}W\log(pU) + \bar{L}LW\log d).$$

In particular, if $d = 0$, then

$$\mathrm{VCdim}(\mathcal{F}) \leq L + W\log_2(4epU\log_2(2epU)) = O(W\log(pU));$$

and if $d = 1$, then

$$\mathrm{VCdim}(\mathcal{F}) \leq L + \bar{L}W\log_2\left(4ep\sum_{i=1}^{L} ik_i\log_2\left(\sum_{i=1}^{L} 2epik_i\right)\right) = O(\bar{L}W\log(pU)).$$

Remark 8 *The average depth $\bar{L}$ is always between 1 and L, and captures how the parameters are distributed in the network: it is close to 1 if they are concentrated near the output (or if the activation functions are piecewise-constant), while it is of order L if the parameters are concentrated near the input, or are spread out throughout the network. Hence, this suggests that edges and vertices closer to the input have a larger effect in increasing the VC-dimension, a phenomenon not observed before; and indeed our lower bound construction in Theorem 3 (as well as the lower bound construction from Bartlett et al. (1998)) considers a network with most of the parameters near the input.*

Remark 9 *If we have $\sum_{i=1}^{L} k_i \leq \sum_{i=1}^{L} W_i$, which holds for most network architectures used in practice, the upper bound on the growth function can be simplified into*

$$\Pi_{\mathrm{sgn}(\mathcal{F})}(m) \leq \left(4emp(1 + (L-1)d^{L-1})\right)^{\sum W_i}.$$

The proofs of Theorem 7 and Remark 9 appear in Section 4. Prior to our work, the best known upper bounds were $O(W^2)$ (see Goldberg and Jerrum, 1995, Section 3.1) and $O(WL\log W+WL^2)$ (see Bartlett et al., 1998, Theorem 1), both of which hold for piecewise polynomial activation functions with a bounded number of pieces (for the remainder of this section, assume that $p = O(1)$ throughout); we strictly improve the second bound to $O(WL\log W)$ for the special case of piecewise linear functions ($d = 1$). Recall that ReLU is an example of a piecewise linear activation function. For the case $d = 0$, an $O(W\log U)$ bound for the VC-dimension was already proved using different techniques by Cover (1968) and by Baum and Haussler (1989, Corollary 2). Our Theorem 7 implies all of these upper bounds (except the $O(W^2)$ upper bound of Goldberg and Jerrum) using a unified technique, and gives a slightly more refined picture of the dependence of the VC-dimension on the distribution of parameters in a deep network.

To compare our upper and lower bounds, let $d(W, L)$ denote the largest VC-dimension of a piecewise linear network with W parameters and L layers. Theorems 3 and 7 imply there exist constants c, C such that

$$c \cdot WL\log(W/L) \;\le\; d(W, L) \;\le\; C \cdot WL\log W\,. \tag{2}$$

For neural networks arising in practice it would certainly be the case that L is significantly smaller than $W^{0.99}$, in which case our results determine the asymptotic bound $d(W, L) = \Theta(WL\log W)$. On the other hand, in the regime $L = \Theta(W)$, which is merely of theoretical interest, we also now have a tight bound $d(W, L) = \Theta(WL)$, obtained by combining Theorem 3 with results of Goldberg and Jerrum (1995). There is now only a very narrow regime, say $W^{0.99} \ll L \ll W$, in which the bounds of (2) are not asymptotically tight, and they differ only in the logarithmic factor.

Our final result is an upper bound for VC-dimension in terms of W and U (the number of non-linear units, or nodes). This bound is tight in the case $d = 1$ and $p = 2$, as discussed in Remark 12.

Theorem 10 *Consider a neural network with W parameters and U units with activation functions that are piecewise polynomials with at most p pieces and of degree at most d. Let $\mathcal{F}$ be the set of (real-valued) functions computed by this network. Then* $\mathrm{VCDim}(\mathrm{sgn}(\mathcal{F})) = O(WU\log((d+1)p))$.

The proof of this result appears in Section 5. The best known upper bound before our work was $O(W^2)$, implicitly proven for bounded d and p by Goldberg and Jerrum (1995, Section 3.1). Our theorem improves this to the tight result $O(WU)$.

We can summarize the tightest known results on the VC-dimension of neural networks with piecewise polynomial activation functions as follows: for classes $\mathcal{F}$ of functions computed by the class of networks with L layers, W parameters, and U units with the following non-linearities, we have the following bounds on VC-dimension:

Piecewise constant. $\mathrm{VCdim}(\mathcal{F}) = \Theta(W\log W)$ (Cover (1968) and Baum and Haussler (1989) showed the upper bound and Maass (1994) showed the lower bound).

Piecewise linear. $c \cdot WL\log(W/L) \;\le\; \mathrm{VCdim}(\mathcal{F}) \;\le\; C \cdot WL\log W$ (this paper).

Piecewise polynomial. $\mathrm{VCdim}(\mathcal{F}) = O(WL^2 + WL\log W)$ (Bartlett et al., 1998), and $\mathrm{VCdim}(\mathcal{F}) = O(WU)$ (this paper), and $\mathrm{VCdim}(\mathcal{F}) = \Omega(WL\log(W/L))$ (this paper). We note that closing the gap here requires fundamentally new techniques (see Remark 14).

1.2. Related work

For a general overview on theoretical properties of neural networks, we refer the reader to the monograph by Anthony and Bartlett (1999). There are various methods, other than the VC-dimension, for bounding the generalization error of neural networks; see Jakubovitz, Giryes, and Rodrigues (2018) for a recent survey.

In the reset of this section, we review some previous work studying the impact of depth on the representational power of neural networks. It has long been known that two-layer networks with a variety of activation functions can approximate arbitrary continuous functions on compact sets (Hornik, 1991). Sontag (1992) showed that three-layer networks of linear threshold units can approximate inverses of continuous functions, whereas two-layer networks cannot. There are several recent papers that aim to understand which functions can be expressed using a neural network of a given depth and size. There are technical similarities between our work and these. Two striking papers considered the problem of approximating a deep neural network with a shallower network. Telgarsky (2016) shows that there is a ReLU network with L layers and $U = \Theta(L)$ units such that any network approximating it with only $O(L^{1/3})$ layers must have $\Omega(2^{L^{1/3}})$ units; this phenomenon holds even for real-valued functions. Eldan and Shamir (2016) show an analogous result for a high-dimensional 3-layer network that cannot be approximated by a 2-layer network except with an exponential blow-up in the number of nodes.

Very recently, several authors have shown that deep neural networks are capable of approximating broad classes of functions. Safran and Shamir (2017) show that a sufficiently non-linear C^2 function on $[0, 1]^d$ can be approximated with ϵ error in L_2 by a ReLU network with $O(\mathrm{polylog}(1/\epsilon))$ layers and weights, but any such approximation with $O(1)$ layers requires $\Omega(1/\epsilon)$ weights. Yarotsky (2017) shows that any C^n-function on $[0, 1]^d$ can be approximated with ϵ error in L_∞ by a ReLU network with $O(\log(1/\epsilon))$ layers and $O((\frac{1}{\epsilon})^{d/n}\log(1/\epsilon))$ weights. Liang and Srikant (2017) show that a sufficiently smooth univariate function can be approximated with ϵ error in L_∞ by a network with ReLU and threshold gates with $\Theta(\log(1/\epsilon))$ layers and $O(\mathrm{polylog}(1/\epsilon))$ weights, but that $\Omega(\mathrm{poly}(1/\epsilon))$ weights would be required if there were only $o(\log(1/\epsilon))$ layers; they also prove analogous results for multivariate functions. Lastly, Cohen, Sharir, and Shashua (2016) draw a connection to tensor factorizations to show that, for a certain family of arithmetic circuits (in particular, without ReLU non-linearities), the set of functions computable by a shallow network have measure zero among those computable by a deep networks. For more recent results on representation power of neural networks, see Grohs, Perekrestenko, Elbrächter, and Bölcskei (2019) and the references therein.

1.3. Notation

A neural network is defined by an *activation function* $\psi : \Re \to \Re$, a directed acyclic graph, and a set of parameters: a weight for each edge of the graph, and a bias for each node of

the graph. Let W denote the number of parameters (weights and biases) of the network, U denote the number of computation units (nodes), and L denote the length of the longest path in the graph. We will say that the neural network has L layers.

Layer 0 consists of nodes with in-degree 0. We call these nodes input nodes and they simply output the real value given by the corresponding input to the network. We assume that the graph has a single sink node; this is the unique node in layer L, which we call the output layer. This output node can have predecessors in any layer $\ell < L$. For $1 \le \ell < L$, a node is in layer ℓ if it has a predecessor in layer $\ell - 1$ and no predecessor in any layer $\ell' \ge \ell$. (Note that for example there could be an edge connecting a node in layer 1 with a node in layer 3.) In the jargon of neural networks, layers 1 through $L-1$ are called *hidden* layers.

The computation of a neural network proceeds as follows. For $i = 1, \ldots, L$, the input into a computation unit u at layer i is $w^\top x + b$, where x is the (real) vector corresponding to the outputs of the computational units with a directed edge to u, w is the corresponding vector of edge weights, and b is the bias parameter associated with u. For layers $1, \ldots, L-1$, the output of u is $\psi(w^\top x + b)$. For the output layer, we replace ψ with the identity, so the output is simply $w^\top x + b$. Since we consider VC-dimension, we will always take the sign of the output of the network, to make the output lie in $\{0, 1\}$ for binary classification.

A piecewise polynomial function with p pieces is a function f for which there exists a partition of $\Re$ into disjoint intervals (pieces) $I_1, \ldots, I_p$ and corresponding polynomials $f_1, \ldots, f_p$ such that if $x \in I_i$ then $f(x) = f_i(x)$. A piecewise linear function is a piecewise polynomial function in which each f_i is linear. The most common activation function used in practice is the rectified linear unit (ReLU) where $I_1 = (-\infty, 0]$, $I_2 = (0, \infty)$ and $f_1(x) = 0, f_2(x) = x$. We denote this function by $\sigma(x) := \max\{0, x\}$. The set $\{1, 2, \ldots, n\}$ is denoted $[n]$.

2. Proof of Theorem 3

The proof of our main lower bound uses the "bit extraction" technique from Bartlett et al. (1998), who proved an $\Omega(WL)$ lower bound. We refine this technique in a key way — we partition the input bits into blocks and extract multiple bits at a time instead of a single bit at a time. This yields a more efficient bit extraction network, and hence a stronger VC-dimension lower bound.

We show the following result, which immediately implies Theorem 3.

Theorem 11 *Let r, m, n be positive integers, and let $k = \lceil m/r \rceil$. There exists a ReLU network with $3 + 5k$ layers, $2 + n + 4m + k((11 + r)2^r + 2r + 2)$ parameters, $m + n$ input nodes and $m + 2 + k(5 \times 2^r + r + 1)$ computational nodes with VC-dimension $\ge mn$.*

Remark 12 *Choosing $r = 1$ gives a network with $W = O(m + n)$, $U = O(m)$ and VC-dimension $\Omega(mn) = \Omega(WU)$. This implies that the upper bound $O(WU)$ given in Theorem 10 is tight.*

To prove Theorem 3, assume W, L, and W/L are sufficiently large, and set $r = \log_2(W/L)/2$, $m = rL/8$, and $n = W - 5m2^r$ in Theorem 11. The rest of this section is devoted to proving Theorem 11.

Let $S_n \subseteq \Re^n$ denote the standard basis. We shatter the set $S_n \times S_m$. Given an arbitrary function $f : S_n \times S_m \to \{0, 1\}$, we build a ReLU neural network that takes as input $(x_1, x_2) \in S_n \times S_m$ and outputs $f(x_1, x_2)$. Define n numbers $a_1, a_2, \ldots, a_n \in \{\frac{0}{2^m}, \frac{1}{2^m}, \ldots, \frac{2^m-1}{2^m}\}$ so that the ith digit of the binary representation of a_j equals $f(e_j, e_i)$. These numbers will be used as the parameters of the network, as described below.

Given input $(x_1, x_2) \in S_n \times S_m$, assume that $x_1 = e_j$ and $x_2 = e_i$. The network must output the ith bit of a_j. This "bit extraction approach" was used in Bartlett et al. (1998, Theorem 2) to give an $\Omega(WL)$ lower bound for the VC-dimension. We use a similar approach but we introduce a novel idea: we split the bit extraction into blocks and extract r bits at a time instead of a single bit at a time. This allows us to prove a lower bound of $\Omega(WL \log(W/L))$. One can ask, naturally, whether this approach can be pushed further. Our Theorem 6 implies that the bit extraction approach cannot give a lower bound better than $\Omega(WL \log(W/L))$ (see Remark 14).

The first layer of the network "selects" a_j, and the remaining layers "extract" the ith bit of a_j. In the first layer we have a single computational unit that calculates

$$a_j = (a_1, \ldots, a_n)^\top x_1 = \sigma\left((a_1, \ldots, a_n)^\top x_1\right).$$

This part uses 1 layer, 1 computation unit, and $1 + n$ parameters.

The rest of the network extracts all bits of a_j and outputs the ith bit. The extraction is done in k steps, where in each step we extract the r most significant bits and zero them out. We will use the following building block for extracting r bits.

Lemma 13 *Suppose positive integers r and m are given. There exists a ReLU network with 5 layers, $5 \times 2^r + r + 1$ units and $11 \times 2^r + r2^r + 2r + 2$ parameters that given the real number $b = 0.b_1 b_2 \ldots b_m$ (in binary representation) as input, outputs the $(r+1)$-dimensional vector $(b_1, b_2, \ldots, b_r, 0.b_{r+1} b_{r+2} \ldots b_m)$.*

Figure 1 shows a schematic of the ReLU network in the above lemma.

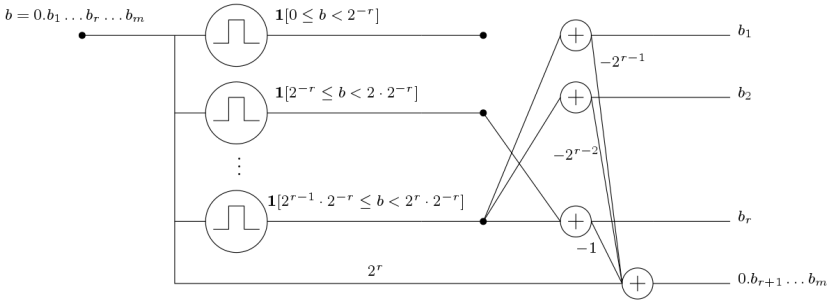

Figure 1: The ReLU network used to extract the most significant r bits of a number. Unlabeled edges indicate a weight of 1 and missing edges indicate a weight of 0.

Proof Partition $[0,1)$ into 2^r even subintervals. Observe that the values of $b_1,\dots,b_r$ are determined by knowing which such subinterval b lies in. We first show how to design a two-layer ReLU network that computes the indicator function for an interval to any arbitrary precision. Using 2^r of these networks in parallel allows us to determine which subinterval b lies in and hence, determine the bits $b_1,\dots,b_r$.

For any $a \le b$ and $\varepsilon > 0$, observe that the function $f(x) \coloneqq \sigma(1-\sigma(a/\varepsilon - x/\varepsilon)) + \sigma(1-\sigma(x/\varepsilon - b/\varepsilon)) - 1$ has the property that, $f(x) = 1$ for $x \in [a,b]$, and $f(x) = 0$ for $x \notin (a-\varepsilon, b+\varepsilon)$, and $f(x) \in [0,1]$ for all x. Thus we can use f to approximate the indicator function for $[a,b]$, to any desired precision. Moreover, this function can be computed with 3 layers, 5 units, and 11 parameters as follows. First, computing $\sigma(a/\varepsilon - x/\varepsilon)$ can be done with 1 unit, 1 layer, and 2 parameters. Computing $\sigma(1-\sigma(a/\varepsilon - x/\varepsilon))$ can be done with 1 additional unit, 1 additional layer, and 2 additional parameters. Similarly, $\sigma(1-\sigma(x/\varepsilon - b/\varepsilon))$ can be computed with 2 units, the same 2 layers, and 4 parameters. Computing the sum can be done with 1 additional layer, 1 additional unit, and 3 additional parameters. In total, computing f can be done with 3 layers, 5 units, and 11 parameters. We will choose $\varepsilon = 2^{-m-2}$ because we are working with m-digit numbers.

Thus, the values $b_1,\dots,b_r$ can be generated by adding the corresponding indicator variables. (For instance, $b_1 = \sum_{k=2^{r-1}}^{2^r-1} \mathbf{1}[b \in [k\cdot 2^{-r}, (k+1)\cdot 2^{-r})]$.) Finally, the remainder $0.b_{r+1}b_{r+2}\dots b_m$ can be computed as $0.b_{r+1}b_{r+2}\dots b_m = 2^r b - \sum_{k=1}^{r} 2^{r-k} b_k$.

Now we count the number of layers and parameters: we use 2^r small networks that work in parallel for producing the indicators, each has 3 layers, 5 units and 11 parameters. To produce $b_1,\dots,b_r$ we need an additional layer, $r\times(2^r+1)$ additional parameters, and r additional units. For producing the remainder we need 1 more layer, 1 more unit, and $r+2$ more parameters. ■

We use $\lceil m/r \rceil$ of these blocks to extract the bits of a_j, denoted by $a_{j,1},\dots,a_{j,m}$. Extracting $a_{j,i}$ is now easy, noting that if $x,y \in \{0,1\}$ then $x \wedge y = \sigma(x+y-1)$. So, since $x_2 = e_i$, we have

$$a_{j,i} = \sum_{t=1}^{m} x_{2,t} \wedge a_{j,t} = \sum_{t=1}^{m} \sigma(x_{2,t} + a_{j,t} - 1) = \sigma\left(\sum_{t=1}^{m} \sigma(x_{2,t} + a_{j,t} - 1)\right).$$

This calculation needs 2 layers, $1+m$ units, and $1+4m$ parameters.

Remark 14 *Theorem 6 implies an inherent barrier to proving lower bounds using the "bit extraction" approach from Bartlett et al. (1998). Recall that this technique uses n binary numbers with m bits to encode a function $f\colon S_n \times S_m \to \{0,1\}$ to show an $\Omega(mn)$ lower bound for VC-dimension, where S_k denotes the set of standard basis vectors in $\Re^k$. The network begins by selecting one of the n binary numbers, and then extracting a particular bit of that number. Bartlett et al. (1998) shows that it is possible to take $m = \Omega(L)$ and $n = \Omega(W)$, thus proving a lower bound of $\Omega(WL)$ for the VC-dimension. In Theorem 3 we showed we can increase m to $\Omega(L\log(W/L))$, improving the lower bound to $\Omega(WL\log(W/L))$. Theorem 6 implies that to extract just the least significant bit, one is forced to have $m = O(L\log(W/L))$; on the other hand, we always have $n \le W$. Hence there is no way to improve the VC-dimension lower bound by more than a constant via the bit extraction technique. In particular, for general piecewise polynomial networks, closing the gap between the $O(WL^2 + WL\log W)$ of Bartlett et al. (1998) and $\Omega(WL\log W/L)$ of this paper will require a different technique.*

3. Proof of Theorem 6

For a piecewise polynomial function $\Re \to \Re$, *breakpoints* are the boundaries between the pieces. So if a function has p pieces, it has $p-1$ breakpoints.

Lemma 15 *Let $f_1,\dots,f_k : \Re \to \Re$ be piecewise polynomials of degree D, and suppose the union of their breakpoints has size B. Let $\psi : \Re \to \Re$ be a piecewise polynomial of degree d with b breakpoints. Let $w_1,\dots,w_k \in \Re$ be arbitrary. The function $g(x) \coloneqq \psi(\sum_i w_i f_i(x))$ is piecewise polynomial of degree Dd with at most $(B+1)(2+bD)-1$ breakpoints.*

Proof Without loss of generality, assume that $w_1 = \cdots = w_k = 1$. The function $\sum_i f_i$ has $B+1$ pieces. Consider one such interval $\mathcal{I}$. We will prove that it will create at most $2+bD$ pieces in g. In fact, if $\sum_i f_i$ is constant on $\mathcal{I}$, g will have 1 piece on $\mathcal{I}$. Otherwise, for any point y, the equation $\sum_i f_i(x) = y$ has at most D solutions on $\mathcal{I}$. Let $y_1,\dots,y_b$ be the breakpoints of ψ. Suppose we move along the curve $(x, \sum_i f_i(x))$ on $\mathcal{I}$. Whenever we hit a point (t, y_i) for some t, one new piece is created in g. So at most bD new pieces are created. In addition, we may have two pieces for the beginning and ending of $\mathcal{I}$. This gives a total of $2+bD$ pieces per interval, as required. Finally, note that the number of breakpoints is one fewer than the number of pieces. ■

Theorem 6 follows immediately from the following theorem.

Theorem 16 *Assume there exists a neural network with W parameters and L layers that computes a function $f : \Re \to \Re$, with the property that $|f(x) - (x \bmod 2)| < 1/2$ for all $x \in \{0,1,\dots,2^m-1\}$. Also suppose the activation functions are piecewise polynomials of degree at most $d \ge 1$, and have at most $p \ge 1$ pieces. Then we have*

$$m \le L\log_2(13pd^{(L+1)/2}\cdot W/L).$$

In the special case of piecewise linear functions, this gives $m = O(L\log(W/L))$.

Proof For a node v of the network, let $\gamma(v)$ count the number of directed paths from the input node to v. Applying Lemma 15 iteratively gives that for a node v at layer $i \ge 1$, the number of breakpoints is bounded by $(6p)^i d^{i(i-1)/2}\gamma(v) - 1$. Let o denote the output node. Hence, o has at most $(6p)^L d^{L(L-1)/2}\gamma(o)$ pieces. The output of node o is piecewise polynomial of degree at most d^L. On the other hand, as we increase x from 0 to 2^m-1, the function $x \bmod 2$ flips 2^m-1 many times, which implies the output of o becomes equal to $1/2$ at least 2^m-1 times, thus we get

$$(6p)^L d^{L(L-1)/2}\gamma(o) \times d^L \ge 2^m - 1. \tag{3}$$

Let us now relate $\gamma(o)$ with W and L. Suppose that, for $i \in [L]$, there are W_i edges between layer i and previous layers. By the AM-GM inequality,

$$\gamma(o) \leq \prod_i (1+W_i) \leq \left(\sum_i \frac{1+W_i}{L}\right)^L \leq (2W/L)^L. \tag{4}$$

Combining Eqs. (3) and (4) gives the theorem. ■

Telgarsky (2016) showed how to construct a function f which satisfies $f(x) = (x \bmod 2)$ for $x \in \{0, 1, \ldots, 2^m - 1\}$ using a neural network with $O(m)$ layers and $O(m)$ parameters. By choosing $m = k^3$, Telgarsky showed that any function g computable by a neural network with $\Theta(k)$ layers and $O(2^k)$ nodes must necessarily have $\|f - g\|_1 > c$ for some constant $c > 0$.

Our theorem above implies a qualitatively similar statement. In particular, if we choose $m = k^{1+\varepsilon}$, then for any function g computable by a neural network with $\Theta(k)$ layers and $O(2^{k^\varepsilon})$ parameters, there must exist $x \in \{0, 1, \ldots, 2^m - 1\}$ such that $|f(x) - g(x)| > 1/2$.

4. Proof of Theorem 7

The proof of this theorem is very similar to the proof of the upper bound for piecewise polynomial networks from Bartlett et al. (1998, Theorem 1) but optimized in a few places. The main technical tool in the proof is a bound on the growth function of a polynomially parametrized function class, due to Goldberg and Jerrum (1995). It uses an argument involving counting the number of connected components of semi-algebraic sets. The form stated here is Bartlett et al. (1998, Lemma 1), which is a slight improvement of a result of Warren (1968) (the proof can be found in Anthony and Bartlett (1999, Theorem 8.3)).

Lemma 17 *Suppose $W \leq M$ and let $P_1, \ldots, P_M$ be polynomials of degree at most D in W variables. Define*

$$K := \left|\left\{(\operatorname{sgn}(P_1(a)), \ldots, \operatorname{sgn}(P_M(a))) : a \in \Re^W\right\}\right|,$$

i.e., K is the number of possible sign vectors attained by the polynomials. Then we have $K \leq 2(2eMD/W)^W$.

Proof [of Theorem 7]. For input $x \in \mathcal{X}$ and parameter vector $a \in \Re^W$, let $f(x, a)$ denote the output of the network. Then $\mathcal{F}$ is simply the class of functions $\{x \mapsto f(x, a) : a \in \Re^W\}$.

Fix $x_1, x_2, \ldots, x_m$ in $\mathcal{X}$. We view the parameters of the network, denoted a, as a collection of W real variables. We wish to bound

$$K := \left|\left\{(\operatorname{sgn}(f(x_1, a)), \ldots, \operatorname{sgn}(f(x_m, a))) : a \in \Re^W\right\}\right|.$$

In other words, K is the number of sign patterns that the neural network can output for the sequence of inputs $(x_1, \ldots, x_m)$. We will prove geometric upper bounds for K, which will imply upper bounds for $\Pi_{\operatorname{sgn}(\mathcal{F})}(m)$.

For any partition $\mathcal{S} = \{P_1, P_2, \ldots, P_N\}$ of the parameter domain $\Re^W$, clearly we have

$$K \leq \sum_{i=1}^N \left|\left\{(\operatorname{sgn}(f(x_1, a)), \ldots, \operatorname{sgn}(f(x_m, a))) : a \in P_i\right\}\right|. \tag{5}$$

We choose the partition in such a way that within each region P_i, the functions $f(x_j, \cdot)$ are all fixed polynomials of bounded degree, so that each term in this sum can be bounded via Lemma 17.

The partition is constructed iteratively layer by layer, through a sequence $\mathcal{S}_0, \mathcal{S}_1, \ldots, \mathcal{S}_{L-1}$ of successive refinements, with the following properties:

1. We have $|\mathcal{S}_0| = 1$ and, for each $n \in [L-1]$,
$$\frac{|\mathcal{S}_n|}{|\mathcal{S}_{n-1}|} \leq 2\left(\frac{2emk_np(1+(n-1)d^{n-1})}{W_n}\right)^{W_n}. \tag{6}$$
2. For each $n \in \{1, \ldots, L\}$, each element S of $\mathcal{S}_{n-1}$, each $j \in [m]$, and each unit u in the nth layer, when a varies in S, the net input to u is a fixed polynomial function in W_n variables of a, of total degree no more than $1 + (n-1)d^{n-1}$ (this polynomial may depend on S, j and u).

We may define $\mathcal{S}_0 = \{\Re^W\}$, which satisfies property 2 above, since the input to any node in layer 1 is of the form $w^T x_j + b$, which is an affine function of w, b.

Now suppose that $\mathcal{S}_0, \ldots, \mathcal{S}_{n-1}$ have been defined, and we want to define $\mathcal{S}_n$. For any $h \in [k_n], j \in [m]$, and $S \in \mathcal{S}_{n-1}$, let $p_{h,x_j,S}(a)$ denote the function describing the net input of the hth unit in the nth layer, in response to x_j, when $a \in S$. By the induction hypothesis this is a polynomial with total degree no more than $1 + (n-1)d^{n-1}$, and depends on at most W_n many variables.

Let $\{t_1, \ldots, t_p\}$ denote the set of breakpoints of the activation function. For any fixed $S \in \mathcal{S}_{n-1}$, by Lemma 17, the collection of polynomials

$$\left\{p_{h,x_j,S}(a) - t_i : h \in [k_n], j \in [m], i \in [p]\right\}$$

attains at most

$$\Pi := 2(2e(k_nmp)(1+(n-1)d^{n-1})/W_n)^{W_n}$$

distinct sign patterns when $a \in \Re^W$. Thus, one can partition $\Re^W$ into this many regions, such that all these polynomials have the same signs within each region. We intersect all these regions with S to obtain a partition of S into at most Π subregions. Performing this for all $S \in \mathcal{S}_{n-1}$ gives our desired partition $\mathcal{S}_n$. Thus, the required property 1 (inequality (6)) is clearly satisfied.

Fix some $S' \in \mathcal{S}_n$. Notice that, when a varies in S', all the polynomials

$$\left\{p_{h,x_j,S}(a) - t_i : h \in [k_n], j \in [m], i \in [p]\right\}$$

have the same sign, hence the *input* of each nth layer unit lies between two breakpoints of the activation function, hence the *output* of each nth layer unit in response to an x_j

is a fixed polynomial in W_n variables of degree no more than $d(1+(n-1)d^{n-1}) \le nd^n$. This implies that the *input* of every $(n+1)$th layer unit in response to an x_j is a fixed polynomial function of W_{n+1} variables of degree no more than $1+nd^n$. (When $d=0$, this affine function depends only on the W_{n+1} parameters in layer $n+1$; for $d>0$, it is a polynomial function of all parameters up to layer $n+1$.)

Proceeding in this way we obtain a partition $\mathcal{S}_{L-1}$ of $\Re^W$ such that for each $S \in \mathcal{S}_{L-1}$, the network output in response to any x_j is a fixed polynomial of a of degree no more than $1+(L-1)d^{L-1}$ (recall that the last node just outputs its input), and hence by Lemma 17 again,

$$|\{(\mathrm{sgn}(f(x_1,a)),\ldots,\mathrm{sgn}(f(x_m,a))) : a \in S\}| \le 2\left(\frac{2em(1+(L-1)d^{L-1})}{W_L}\right)^{W_L}.$$

On the other hand, applying (6) iteratively gives

$$|\mathcal{S}_{L-1}| \le \prod_{i=1}^{L-1} 2\left(\frac{2emk_ip(1+(i-1)d^{i-1})}{W_i}\right)^{W_i},$$

and thus using (5), and since the points $x_1,\ldots,x_m$ were chosen arbitrarily, we obtain

$$\begin{aligned}
\Pi_{\mathrm{sgn}(\mathcal{F})}(m) &\le \prod_{i=1}^{L} 2\left(\frac{2emk_ip(1+(i-1)d^{i-1})}{W_i}\right)^{W_i} \\
&\le 2^L\left(\frac{2emp\sum k_i(1+(i-1)d^{i-1})}{\sum W_i}\right)^{\sum W_i} && \text{(weighted AM-GM)} \\
&= 2^L\left(\frac{2empR}{\sum W_i}\right)^{\sum W_i} && \text{(definition of } R \text{ in (1))} \qquad (7)
\end{aligned}$$

For the bound on the VC-dimension, from the definition of VC-dimension we find

$$2^{\mathrm{VCdim}(\mathcal{F})} = \Pi_{\mathrm{sgn}(\mathcal{F})}(\mathrm{VCdim}(\mathcal{F})) \le 2^L\left(\frac{2epR\cdot\mathrm{VCdim}(\mathcal{F})}{\sum W_i}\right)^{\sum W_i}$$

Notice that $U>2$ implies $2eR \ge 16$, hence Lemma 18 below gives

$$\mathrm{VCdim}(\mathcal{F}) \le L + (\sum W_i)\log_2(4epR\log_2(2epR)) = O(\bar{L}W\log(pU) + \bar{L}LW\log d),$$

completing the proof. ■

Lemma 18 *Suppose that $2^m \le 2^t(mr/w)^w$ for some $r \ge 16$ and $m \ge w \ge t \ge 0$. Then, $m \le t + w\log_2(2r\log_2 r)$.*

Proof We would like to show that $2^x > 2^t(xr/w)^w$ for all $x > t + w\log_2(2r\log_2 r) =: m$. Let $f(x) := x - t - w\log_2(xr/w)$. To show that $f(x)>0$ for all $x>m$, we need only show that $f(m)\ge 0$ and $f'(x)>0$ for all $x \ge m$. First, $f(m)\ge 0$ if and only if

$$w\log_2(2r\log_2 r) - w\log_2(mr/w) \ge 0,$$

if and only if

$$(2r\log_2 r) - (mr/w) \ge 0,$$

if and only if

$$2\log_2 r - (t + w\log_2(2r\log_2 r))/w \ge 0,$$

if and only if

$$2\log_2 r - t/w - \log_2(2r\log_2 r) \ge 0,$$

if and only if

$$r^2/2\log_2 r \ge 2^{t/w},$$

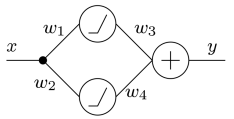
which holds since $r \ge 16$ and $t/w \le 1$. Finally, for $x \ge m$, we have $f'(x) \ge 0$ if and only if

$$1 - w/(x\ln(2)) \ge 0$$

if and only if

$$x \ge w/\ln 2,$$

which holds since $r \ge 16$ implies $x \ge m \ge w\log_2(2r\log_2 r) > w/\ln 2$. ■



Proof [of Remark 9]. Note that $\sum k_i \le \sum W_i$ implies $L \le \sum W_i$, hence from (7) we have

$$\begin{aligned}
\Pi_{\mathrm{sgn}(\mathcal{F})}(m) &\le 2^L\left(\frac{2empR}{\sum W_i}\right)^{\sum W_i} \\
&\le \left(\frac{4emp(1+(L-1)d^{L-1})\sum k_i}{\sum W_i}\right)^{\sum W_i} && (L \le \textstyle\sum W_i) \\
&\le \left(4emp(1+(L-1)d^{L-1})\right)^{\sum W_i} && (\textstyle\sum k_i \le \sum W_i).
\end{aligned}$$

■

5. Proof of Theorem 10

The idea of the proof is that the sign of the output of a neural network can be expressed as a Boolean formula where each predicate is a polynomial inequality. For example, consider the following toy network, where the activation function of the hidden units is a ReLU.

The sign of the output of the network is $\mathrm{sgn}(y) = \mathrm{sgn}(w_3\sigma(w_1x) + w_4\sigma(w_2x))$. Define the following Boolean predicates: $p_1 = (w_1x > 0)$, $p_2 = (w_2x > 0)$, $q_1 = (w_3w_1x > 0)$, $q_2 = (w_4w_2x > 0)$, and $q_3 = (w_3w_1x + w_4w_2x > 0)$. Then, we can write

$$\mathrm{sgn}(y) = (\neg p_1 \wedge \neg p_2 \wedge 0) \vee (p_1 \wedge \neg p_2 \wedge q_1) \vee (\neg p_1 \wedge p_2 \wedge q_2) \vee (p_1 \wedge p_2 \wedge q_3).$$

A theorem of Goldberg and Jerrum states that any class of functions that can be expressed using a relatively small number of distinct polynomial inequalities has small VC-dimension.

Theorem 19 (Theorem 2.2 of Goldberg and Jerrum (1995)) *Let k, n be positive integers and $f : \Re^n \times \Re^k \to \{0,1\}$ be a function that can be expressed as a Boolean formula containing s distinct atomic predicates where each atomic predicate is a polynomial inequality or equality in $k+n$ variables of degree at most d. Let $\mathcal{F} = \{f(\cdot, w) : w \in \Re^k\}$. Then* $\mathrm{VCDim}(\mathcal{F}) \leq 2k \log_2(8eds)$.

Proof [of Theorem 10]. Consider a neural network with W weights and U computation units, and assume that the activation function ψ is piecewise polynomial of degree at most d with p pieces. To apply Theorem 19, we will express the sign of the output of the network as a Boolean function consisting of less than $2(1+p)^U$ atomic predicates, each being a polynomial inequality of degree at most $\max\{U+1, 2d^U\}$.

Since the neural network graph is acyclic, it can be topologically sorted. For $i \in [U]$, let u_i denote the ith computation unit in the topological ordering. The input to each computation unit u lies in one of the p pieces of ψ. For $i \in [U]$ and $j \in [p]$, we say "u_i is in state j" if the input to u_i lies in the jth piece.

For u_1 and any j, the predicate "u_1 is in state j" is a single atomic predicate which is the quadratic inequality indicating whether its input lies in the corresponding interval. So, the state of u_1 can be expressed as a function of p atomic predicates. Conditioned on u_1 being in a certain state, the state of u_2 can be determined using p atomic predicates, which are polynomial inequalities of degree at most $2d+1$. Consequently, the state of u_2 can be determined using $p + p^2$ atomic predicates, each of which is a polynomial of degree at most $2d+1$. Continuing similarly, we obtain that for each i, the state of u_i can be determined using $p(1+p)^{i-1}$ atomic predicates, each of which is a polynomial of degree at most $d^{i-1} + \sum_{j=0}^{i-1} d^j$. Consequently, the state of all nodes can be determined using less than $(1+p)^U$ atomic predicates, each of which is a polynomial of degree at most $d^{U-1} + \sum_{j=0}^{U-1} d^j \leq \max\{U+1, 2d^U\}$ (the output unit is linear). Conditioned on all nodes being in certain states, the sign of the output can be determined using one more atomic predicate, which is a polynomial inequality of degree at most $\max\{U+1, 2d^U\}$.

In total, we have less than $2(1+p)^U$ atomic polynomial-inequality predicates and each polynomial has degree at most $\max\{U+1, 2d^U\}$. Thus, by Theorem 19, we get an upper bound of $2W \log_2(16e \cdot \max\{U+1, 2d^U\} \cdot (1+p)^U) = O(WU \log((1+d)p))$ for the VC-dimension. ■

Abstract

In this paper we provide a finite-sample and an infinite-sample representer theorem for the concatenation of (linear combinations of) kernel functions of reproducing kernel Hilbert spaces. These results serve as mathematical foundation for the analysis of machine learning algorithms based on compositions of functions. As a direct consequence in the finite-sample case, the corresponding infinite-dimensional minimization problems can be recast into (nonlinear) finite-dimensional minimization problems, which can be tackled with nonlinear optimization algorithms. Moreover, we show how concatenated machine learning problems can be reformulated as neural networks and how our representer theorem applies to a broad class of state-of-the-art deep learning methods.

Keywords: deep kernel learning, representer theorem, artificial neural networks, multi-layer kernel, regularized least-squares regression

1. Introduction

The interpolation or regression of given function values is one of the main tasks in modern data mining and machine learning applications. Due to the famous representer theorem for empirical risk minimization in reproducing kernel Hilbert spaces (RKHS), see e.g. Schölkopf and Smola (2002); Steinwart and Christmann (2008); Kimeldorf and Wahba (1970), various algorithms based on finite linear combinations of kernel translates have gained much popularity in the last decade, like, for example, support vector machines (SVMs) and Tikhonov-regularized least-squares in RKHS. In general, these methods work very well if the underlying problem fits the chosen reproducing kernel space H, e.g. if the given input values stem from a function $g \in H$. However, if H contains for instance only smooth functions but g has a kink or a jump, the interpolant or regressor, respectively, in H might not represent a good approximation to the true function g anymore. Then, if it is not known how to choose an appropriate kernel K of H a priorily, one usually relies on so-called multiple kernel learning (MKL) algorithms, which try to determine the optimal kernel adaptively, see e.g. Bach et al. (2004). But while most of these methods allow to learn a suitable kernel by simply constructing a linear or convex combination of a given set of input kernels, they still do not achieve considerably better results than standard a-priori kernel choices for many applications, see Gönen and Alpaydin (2011).

In recent years, promising new variants of kernel learning methods, namely deep kernel learning and multi-layer-MKL (MLMKL) algorithms have been developed. They have proven to be very successful in regression and classification tasks. Here, motivated by multi-layer feed-forward neural networks, a kernel function is concatenated with one or more nonlinear functions in order to achieve a highly flexible new kernel function, see e.g. Cho and Saul (2009); Damianou and Lawrence (2013); Rebai et al. (2016); Strobl and Visweswaran (2013); Wilson et al. (2016); Zhuang et al. (2011). The main idea behind this approach is to combine the flexibility of deep neural networks, in which the feature detection in the data set is done completely automatically, with the approximation power of kernel methods, in which a feature map is determined by the chosen kernel. This way, the neural network architecture learns the optimal kernel that best represents important features of the data for the task at hand. While first steps towards creating a mathematical framework to analyze deep neural networks—especially for image classification tasks—have been made in e.g. Mallat (2016); Mhaskar et al. (2017); Montavon et al. (2017), deep approximation theory for kernel based approaches is still missing at large. Moreover, the underlying nonlinear minimization problem is usually tackled by simple gradient descent and heuristic backpropagation algorithms without a thorough theoretical analysis of its properties. An initial cornerstone for the analysis of chained kernel approximations has been provided by Dinuzzo (2011), where two-layer kernel networks were considered and their relation to MKL was established. However, an analysis of deeper kernel networks and their connection to MLMKL has not been considered so far.

In this paper, we consider the problem of optimal concatenated approximation in reproducing kernel Hilbert spaces, which will directly lead to a variant of multi-layer kernel learning problems and will extend the results achieved in Dinuzzo (2011). For this class, we will prove a representer theorem, which allows us to reduce the nonlinear, potentially infinite-dimensional optimization problem to a finite-dimensional one. Consequently, standard nonlinear optimization techniques can be used to tackle this problem. At least to our knowledge, this is the first derivation of a representer theorem for concatenated function approximation in the literature. It is also valid for certain types of hidden layer neural networks and deep SVMs.

The remainder of this paper is organized as follows: In Section 2, we briefly review the interpolation and the regression problem in an (possibly infinite-dimensional) RKHS and discuss how the classical representer theorem allows to recast these problems into finite-dimensional linear equation systems. In Section 3, we introduce the optimal *concatenated* approximation problem for arbitrary loss functions and regularizers. We derive a representer theorem for this problem in the multi-layer case and discuss its relation to deep learning and multi-layer multiple kernel learning methods. Furthermore, we exemplarily derive algorithms for interpolation and least-squares regression in the two-layer case from it. The latter will be a natural generalization of the RLS2 method developed in Dinuzzo (2011), which only deals with a linear outer kernel. Section 4 illustrates the application of our concatenated interpolation and regression algorithms to two simple examples and serves as a proof of concept. Finally, we conclude with a summary and an outlook in Section 5.

2. Interpolation and regression in reproducing kernel Hilbert spaces

In this section we shortly review interpolation and least-squares regression problems, respectively, in an RKHS. To this end, we consider the standard representer theorem and show how it helps to find an interpolant/regressor.

2.1. Interpolation

Let $\Omega \subset \mathbb{R}^d$ be an open domain and let the pairwise disjoint points $X := \{\boldsymbol{x}_1, \dots, \boldsymbol{x}_N\} \subset \Omega$ and the values $Y := \{y_1, \dots, y_N\} \subset \mathbb{R}$ be given. Let furthermore $H := H(\Omega, \mathbb{R})$ be a reproducing kernel Hilbert space of real-valued functions on Ω. The minimal norm interpolant is

$$f^*_{X,Y} := \arg\min_{f \in H} \|f\|_H \quad \text{such that} \quad f(\boldsymbol{x}_i) = y_i \quad \forall\, i = 1, \dots, N. \tag{1}$$

The classical representer theorem, see e.g. Schölkopf and Smola (2002); Steinwart and Christmann (2008) for scalar-valued functions and Micchelli and Pontil (2005) for vector-valued functions, now states that $f^*_{X,Y}$ can be written as a *finite* linear combination of kernel evaluations in the data, namely

$$f^*_{X,Y}(\boldsymbol{x}) = \sum_{i=1}^{N} \alpha_i^* K(\boldsymbol{x}_i, \boldsymbol{x}), \tag{2}$$

where $K : \Omega \times \Omega \to \mathbb{R}$ denotes the reproducing kernel of H and $\alpha_i^* \in \mathbb{R}, i = 1, \dots, N$, are the corresponding coefficients. For details on RKHS, see Aronszajn (1950). Therefore, the solution to the possibly infinite-dimensional optimization problem (1) resides in the N-dimensional span of the functions $K(\boldsymbol{x}_i, \cdot), i = 1, \dots, N$. To compute the coefficients, we simply have to solve the system

$$\boldsymbol{M}_{X,X} \boldsymbol{\alpha}^* = \boldsymbol{y} \tag{3}$$

of linear equations with

$$\boldsymbol{M}_{X,X} := \begin{pmatrix} K(\boldsymbol{x}_1, \boldsymbol{x}_1) & \dots & K(\boldsymbol{x}_1, \boldsymbol{x}_N) \\ \vdots & \ddots & \vdots \\ K(\boldsymbol{x}_N, \boldsymbol{x}_1) & \dots & K(\boldsymbol{x}_N, \boldsymbol{x}_N) \end{pmatrix}, \quad \boldsymbol{\alpha}^* := \begin{pmatrix} \alpha_1^* \\ \vdots \\ \alpha_N^* \end{pmatrix} \quad \text{and } \boldsymbol{y} := \begin{pmatrix} y_1 \\ \vdots \\ y_N \end{pmatrix}. \tag{4}$$

Note that this $N \times N$ system admits a unique solution if the kernel K is strictly positive definite. For example, for Sobolev kernels it can be shown that the condition number of the system matrix $\boldsymbol{M}_{X,X}$ only grows moderately with the size N provided that the data points are quasi-uniformly distributed, see de Marchi and Schaback (2010). Moreover, for infinitely smooth kernel functions (e.g. Gaussian kernels or multiquadrics) it can be necessary to perform an appropriate basis change before solving the above equation system, see e.g. Wendland (2005).

2.2. Least-squares regression

In real-world applications, the values $y_i, i = 1, \dots, N$ are usually not exactly given, but are perturbed by some noise term. Therefore, a direct interpolation might no longer be appropriate. In this case, one considers the corresponding regularized least-squares regression

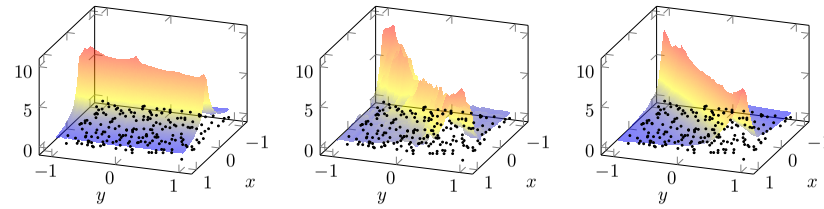
problem

$$f^\lambda_{X,Y} := \arg\min_{f \in H} \lambda \|f\|_H^2 + \sum_{j=1}^{N} |f(\boldsymbol{x}_i) - y_i|^2, \tag{5}$$

where the side condition in (1) is substituted by a penalty term. Here, the Lagrange multiplier λ weights the importance of the norm minimization against the function evaluation error. Again, the representer theorem Micchelli and Pontil (2005); Schölkopf and Smola (2002); Steinwart and Christmann (2008) tells us that $f^\lambda_{X,Y}$ is of the form (2), i.e.

$$f^\lambda_{X,Y}(\boldsymbol{x}) = \sum_{i=1}^{N} \alpha_i^\lambda K(\boldsymbol{x}_i, \boldsymbol{x}).$$

This time the coefficients $\alpha_i^\lambda, i = 1, \dots, N$, are determined by



$$(\boldsymbol{M}_{X,X} + \lambda \boldsymbol{I})\, \boldsymbol{\alpha}^\lambda = \boldsymbol{y}, \tag{6}$$

where $\boldsymbol{I}$ denotes the $N \times N$ identity matrix. The size of the Lagrange parameter $\lambda > 0$ now also influences the condition number of the system matrix, i.e. the larger λ is, the smaller the condition number becomes.

3. Interpolation and regression with compositions of reproducing kernel Hilbert spaces

As already mentioned in the introduction, the standard interpolation and regression algorithms in RKHS work well if the samples y_i are (perturbed) evaluations of a function $g \in H$, where the reproducing kernel space H is known in the first place. However, if the appropriate RKHS H is unknown, it is advisable to resort to multiple kernel learning methods or multi-layer multiple kernel learning methods.

We now explain this aspect in more detail and, to this end, motivate a first two-dimensional, two-layer approach with an example: Let the kernel K of H be a tensor-product of two univariate Matérn Sobolev kernels of order one on $\mathbb{R}$, see Section 4 for a definition of this kernel. The corresponding function space H is often also called Sobolev space of "mixed smoothness" of order one and it is of special importance for e.g. sparse grid discretizations, see Bungartz and Griebel (2004), and quasi Monte Carlo quadrature, see Hinrichs et al. (2016). Now, let us consider the continuous function $g_1(x, y) := (0.1 + |x|)^{-1}$, which has a kink that is perpendicular to the x-axis. It can easily be shown that $g_1 \in H$ and, therefore, the interpolant of g_1 by a function from H resembles a good approximation to g_1, see Figure 1(a). If we now look at $g_2(x, y) := (0.1 + |x - y|)^{-1}$, which has a kink along the diagonal with $x = y$, then $g_2 \notin H$. Therefore, the interpolant of g_2 by a function in H is a rather bad approximation to g_2. This can be seen in Figure 1(b). However, if we let R^{-1} be a rotation by 45°, then $g_2 \circ R^{-1} \in H$ would have an axis-aligned kink like g_1. To use this fact when interpolating g_2, we can simply look for the best interpolant in $\{f \circ R \mid f \in H\}$ in (1) instead of $f \in H$. This example is illustrated in Figure 1(c). As we can see, the interpolant in Figure 1(c) is a much better representative for g_2 than the one in Figure 1(b). This example illustrates that, already in the very simple case of employing a concatenation with a rotation, a two-layer approach can be a good choice to overcome

(a) $y_i = g_1(\boldsymbol{x}_i), f \in H$ (b) $y_i = g_2(\boldsymbol{x}_i), f \in H$ (c) $y_i = g_2(\boldsymbol{x}_i), f \in \{h \circ R \mid h \in H\}$

Figure 1: Solutions to (1) in the two-variate tensor-product Matérn-kernel Sobolev space H of order one, see also Fasshauer and Ye (2011), with 200 uniform samples $\boldsymbol{x}_i, i = 1, \ldots, 200$ (marked in black), shown in the domain $[-1, 1]^2$. (a) depicts the solution $f \in H$ for values y_i sampled from g_1, whereas (b) shows the optimal solution for y_i sampled from g_2. (c) presents the best interpolant of type $f \circ R$, where $f \in H$ and R is a rotation by 45° for y_i sampled from g_2. For reasons of comparability, we restricted our representation to $[-1, 1]^2$ here, although some data points were mapped outside of this domain by applying the rotation R and the kernel was defined on the whole $\mathbb{R}^2$.

the restrictions of a standard kernel learning algorithm. Let us remark that already this motivating example exhibits a fundamentally different setting from the one considered in Dinuzzo (2011) because of the nonlinearity of the outer kernel. While the RLS2 algorithm introduced there can be interpreted as an MKL variant, where a convex combination of given kernel functions is computed, we are looking for an inner function, which transforms the domain in such a way that it is optimal for the (possibly nonlinear) outer kernel.

Now, instead of just considering one layer of simple rotations as in the above example, we allow for a fully flexible multi-layer kernel learning approach, where we employ arbitrary functions from reproducing kernel Hilbert spaces in each layer. This approach can successfully deal with a much broader class of interpolation and regression problems, see also Rebai et al. (2016); Zhuang et al. (2011). To this end, we consider *concatenated* machine learning problems. We introduce a new representer theorem for the case of multiple concatenations of functions from RKHS, which allows us to derive the related, finite-dimensional, nonlinear optimization problem.

3.1. A representer theorem for concatenated kernel learning

In this section, we show how a *concatenated representer theorem* can be derived for a very general class of problem types and an arbitrary number $L \in \mathbb{N}$ of concatenations. For more details on vector-valued reproducing kernel Hilbert spaces, we refer the reader to Micchelli and Pontil (2005). For a two-layer variant of this theorem, we refer to Dinuzzo (2011).

Theorem 1 *Let $\mathcal{H}_1, \ldots, \mathcal{H}_L$ be reproducing kernel Hilbert spaces of functions with finite-dimensional domains D_l and ranges $R_l \subseteq \mathbb{R}^{d_l}$ with $d_l \in \mathbb{N}$ for $l = 1, \ldots, L$ such that $R_l \subseteq D_{l-1}$ for $l = 2, \ldots, L$, $D_L = \Omega$ and $R_1 \subseteq \mathbb{R}$. Let furthermore $\mathcal{L} : \mathbb{R}^2 \to [0, \infty]$ be an arbitrary loss function and let $\Theta_1, \ldots, \Theta_L : [0, \infty) \to [0, \infty)$ be strictly monotonically increasing functions. Then, a set of minimizers $(f_l)_{l=1}^L$ with $f_l \in \mathcal{H}_l$ of*

$$J(f_1, \ldots, f_L) \coloneqq \sum_{i=1}^{N} \mathcal{L}\left(y_i, f_1 \circ \ldots \circ f_L(\boldsymbol{x}_i)\right) + \sum_{l=1}^{L} \Theta_l\left(\|f_l\|_{\mathcal{H}_l}^2\right) \tag{7}$$

fulfills $f_l \in \tilde{V}_l \subset \mathcal{H}_l$ for all $l = 1, \ldots, L$ with

$$\tilde{V}_l = \operatorname{span}\left\{K_l\left(f_{l+1} \circ \ldots \circ f_L\left(\boldsymbol{x}_i\right), \cdot\right) \boldsymbol{e}_{k_l} \mid i = 1, \ldots, N \text{ and } k_l = 1, \ldots, d_l\right\},$$

where K_l denotes the reproducing kernel of $\mathcal{H}_l$ and $\boldsymbol{e}_{k_l} \in \mathbb{R}^{d_l}$ is the k_l-th unit vector.

Proof We denote by $\Pi_{\tilde{V}_l}$ and $\Pi_{\tilde{V}_l}^{\perp}$ the projector onto $\tilde{V}_l$ and its orthogonal complement in $\mathcal{H}_l$, respectively, for $l = 1, \ldots, L$. First, we note that

$$\begin{aligned}
f_l \circ f_{l+1} \circ \ldots \circ f_L(\boldsymbol{x}_i) &= \sum_{k=1}^{d_l} \left(\Pi_{\tilde{V}_l}\left(f_l\right) + \Pi_{\tilde{V}_l^{\perp}}\left(f_l\right), K_l\left(f_{l+1} \circ \ldots \circ f_L(\boldsymbol{x}_i), \cdot\right) \boldsymbol{e}_k\right)_{\mathcal{H}_l} \cdot \boldsymbol{e}_k \\
&= \sum_{k=1}^{d_l} \left(\Pi_{\tilde{V}_l}\left(f_l\right), K_l\left(f_{l+1} \circ \ldots \circ f_L(\boldsymbol{x}_i), \cdot\right) \boldsymbol{e}_k\right)_{\mathcal{H}_l} \cdot \boldsymbol{e}_k \\
&= \sum_{k=1}^{d_l} \left(\boldsymbol{e}_k^T \Pi_{\tilde{V}_l}\left(f_l\right)\left(f_{l+1} \circ \ldots \circ f_L(\boldsymbol{x}_i)\right)\right) \cdot \boldsymbol{e}_k \\
&= \Pi_{\tilde{V}_l}\left(f_l\right)\left(f_{l+1} \circ \ldots \circ f_L(\boldsymbol{x}_i)\right)
\end{aligned}$$

for all $i = 1, \ldots, N$ and $l = 1, \ldots, L$. Since this holds for each function in the chain, we can iterate this process to obtain

$$f_l \circ f_{l+1} \circ \ldots \circ f_L(\boldsymbol{x}_i) = \Pi_{\tilde{V}_l}\left(f_l\right) \circ \Pi_{\tilde{V}_{l+1}}\left(f_{l+1}\right) \circ \ldots \circ \Pi_{\tilde{V}_L}\left(f_L\right)\left(\boldsymbol{x}_i\right) \tag{8}$$

for each $l = 1, \ldots, L$. Therefore, we have

$$\begin{aligned}
J(f_1, \ldots, f_L) = &\sum_{i=1}^{N} \mathcal{L}\left(y_i, \Pi_{\tilde{V}_1}(f_1) \circ \ldots \circ \Pi_{\tilde{V}_L}(f_L)(\boldsymbol{x}_i)\right) \\
&+ \sum_{l=1}^{L} \Theta_l\left(\|\Pi_{\tilde{V}_l}(f_l)\|_{\mathcal{H}_l}^2 + \|\Pi_{\tilde{V}_l^{\perp}}(f_l)\|_{\mathcal{H}_l}^2\right) \geq J(\Pi_{\tilde{V}_1}(f_1), \ldots, \Pi_{\tilde{V}_L}(f_L))
\end{aligned}$$

and equality only holds if $f_l \in \tilde{V}_l$ for each $l = 1, \ldots, L$ because of the strict monotonicity of each Θ_l. This completes the proof. ■

Note that theorem 1 also holds for

$$J(f_1, \ldots, f_L) \coloneqq \mathcal{L}\left(y_1, f_1 \circ \ldots \circ f_L(\boldsymbol{x}_1), \ldots, y_N, f_1 \circ \ldots f_L(\boldsymbol{x}_N)\right) + \sum_{l=1}^{L} \Theta_l\left(\|f_l\|_{\mathcal{H}_l}^2\right)$$

with arbitrary loss $\mathcal{L} : \left(\mathbb{R}^2\right)^N \to [0, \infty]$. However, the version we proved above is more consistent with the remainder of this paper. Furthermore, because of (8), we could also

state an even more general version of Theorem 1 where the loss function $\mathcal{L}$ not only depends on the point evaluations $f_1 \circ \ldots \circ f_L(\boldsymbol{x}_i)$ for $i = 1, \ldots, N$, but also on the intermediate values $f_l \circ \ldots \circ f_L(\boldsymbol{x}_i)$ for any $l = 2, \ldots, L$. However, for the sake of readability, we proceed with (7). Theorem 1 now states that

$$(f_1, \ldots, f_L) = \underset{\substack{\bar{f}_l \in \mathcal{H}_l \\ l=1,\ldots,L}}{\arg\min}\, J(\bar{f}_1, \ldots, \bar{f}_L) = \underset{\substack{\bar{f}_l \in \tilde{V}_l \\ l=1,\ldots,L}}{\arg\min}\, J(\bar{f}_1, \ldots, \bar{f}_L) \tag{9}$$

with J from (7). This means that the (possibly) infinite-dimensional optimization problem

$$\underset{\substack{\bar{f}_l \in \mathcal{H}_l \\ l=1,\ldots,L}}{\arg\min}\, J(\bar{f}_1, \ldots, \bar{f}_L)$$

can be recast into the finite-dimensional optimization problem

$$\underset{\substack{\bar{f}_l \in \tilde{V}_l \\ l=1,\ldots,L}}{\arg\min}\, J(\bar{f}_1, \ldots, \bar{f}_L).$$

In this way, our representer theorem is a direct extension of the classical representer theorem, see Section 2 and Schölkopf and Smola (2002), to concatenated functions. We obtain that the solution to (9) is given by a linear combination of at most N basis functions in each layer. Therefore, the overall number of degrees of freedom in the underlying optimization problem (9) is given by

$$\#\text{dof} = \sum_{l=1}^{L} \dim\left(\tilde{V}_l\right) = \sum_{l=1}^{L} N \cdot d_l = N \cdot \left(1 + \sum_{l=2}^{L} d_l\right).$$

According to Theorem 1, we can write f_1 as

$$f_1(\cdot) = \sum_{j=1}^{N} \alpha_j K_1\left(f_2 \circ \ldots \circ f_L(\boldsymbol{x}_j), \cdot\right)$$

for some coefficients $\alpha_j \in \mathbb{R}$. Therefore, the concatenated function $h(\cdot) = f_1 \circ \ldots \circ f_L(\cdot)$, which we are interested in, can be expressed as

$$h(\cdot) = \sum_{j=1}^{N} \alpha_j \mathcal{K}^L(\boldsymbol{x}_j, \cdot)$$

with the deep kernel

$$\mathcal{K}^L(\boldsymbol{x}, \boldsymbol{y}) = K_1\left(f_2 \circ \ldots \circ f_L(\boldsymbol{x}), f_2 \circ \ldots \circ f_L(\boldsymbol{y})\right). \tag{10}$$

Due to the definition of $\tilde{V}_l$ for $l = 1, \ldots, L$, the corresponding f_l is defined recursively. In general, it is thus not possible to simply write down a closed formula for $\mathcal{K}^L$ for arbitrary

L. To illustrate the structure of the kernel $\mathcal{K}^L$, we therefore consider a two-layer example with $L = 2$ in the following. In this case, we obtain $\tilde{V}_2 = \text{span}\{K_2(\boldsymbol{x}_i, \cdot)\boldsymbol{e}_{k_2} \mid i = 1, \ldots, N \text{ and } k_2 = 1, \ldots, d_2\}$. From Theorem 1, we know that

$$f_2(\cdot) = \sum_{i=1}^{N} \sum_{k_2=1}^{d_2} c_{i,k_2} K_2(\boldsymbol{x}_i, \cdot)\boldsymbol{e}_{k_2}$$

for certain coefficients $c_{i,k_2} \in \mathbb{R}$. Furthermore, we have that $f_1 \in \tilde{V}_1 = \text{span}\{K_1(f_2(\boldsymbol{x}_i), \cdot) \mid i = 1, \ldots, N\}$ and thus

$$f_1(\cdot) = \sum_{j=1}^{N} \alpha_j K_1\left(\sum_{i=1}^{N} \sum_{k_2=1}^{d_2} c_{i,k_2} K_2(\boldsymbol{x}_i, \boldsymbol{x}_j)\boldsymbol{e}_{k_2}, \cdot\right).$$

The concatenated function is then given by $h(\cdot) := f_1 \circ f_2(\cdot) = \sum_{j=1}^{N} \alpha_j \mathcal{K}^2(\boldsymbol{x}_j, \cdot)$ with the composition kernel

$$\mathcal{K}^2(\boldsymbol{x}, \boldsymbol{y}) = K_1\left(\sum_{i=1}^{N} \sum_{k_2=1}^{d_2} c_{i,k_2} K_2(\boldsymbol{x}_i, \boldsymbol{x})\boldsymbol{e}_{k_2}, \sum_{i=1}^{N} \sum_{k_2=1}^{d_2} c_{i,k_2} K_2(\boldsymbol{x}_i, \boldsymbol{y})\boldsymbol{e}_{k_2}\right). \tag{11}$$

Therefore, instead of considering the infinite-dimensional optimization problem of finding $f_1 \in \mathcal{H}_1$ and $f_2 \in \mathcal{H}_2$ that minimize

$$J(f_1, f_2) = \sum_{i=1}^{N} \mathcal{L}\left(y_i, f_1(f_2(\boldsymbol{x}_i))\right) + \Theta_1\left(\|f_1\|_{\mathcal{H}_1}^2\right) + \Theta_2\left(\|f_2\|_{\mathcal{H}_2}^2\right),$$

we can restrict ourselves to finding the $N + N \cdot d_2$ coefficients α_j, c_{i,k_2} for $i, j = 1, \ldots, N$ and $k_2 = 1, \ldots, d_2$.

Note at this point that the problem of finding these coefficients is highly nonlinear and becomes more complicated for a larger number of layers L. While the corresponding problem of optimizing the outermost coefficients, i.e. α_j for $j = 1, \ldots, N$ in our example, is still convex if the loss $\mathcal{L}$ and the penalty terms Θ_1, Θ_2 are convex, the optimization of the inner coefficients, i.e. c_{i,k_2} for $i = 1, \ldots, N$ and $k_2 = 1, \ldots, d_2$, is usually not convex anymore and can have many local minima. Here, finding a global minimum is an issue because standard (iterative) optimization methods strongly depend on the chosen initial value and usually just deliver some local minimum.

If the optimization functional J is smooth, one can rely on a Newton-type minimizer such as BFGS to solve the underlying optimization problem. However, if one deals with nonsmooth loss functionals or penalty terms, one should resort to specifically designed stochastic gradient algorithms which fit the problem at hand, see e.g. Reddi et al. (2016).

It remains to note that our representer theorem covers much more than just interpolation or least-squares regression algorithms. In the same fashion as the standard representer theorem in Schölkopf and Smola (2002), it can directly be applied to more involved settings such as regression with a concatenation of support vector machines for instance. To this end, just choose $\mathcal{L}$ to be the ε-insensitive loss function and $\Theta_1(x) = \ldots = \Theta_L(x) = x$. Furthermore, the choice of the additive penalties $\Theta_1, \ldots, \Theta_L$ in (7) is rather arbitrary and one could think of more complex interactions between the penalties for each function $f_l, l = 1, \ldots, L$, as long as the arguments in the proof of Theorem 1 remain valid.

3.2. An infinite-sample representer theorem for concatenated kernel learning

After deriving the representer theorem 1 for the case of multi-layer kernel approximations, we now extend our results to the case of infinitely many samples. This has to be understood in analogy to the results in chapter 5 of Steinwart and Christmann (2008), where such an infinite-sample representer theorem is provided for the single-layer case. Although such a result can usually not directly be applied to a practical problem unless the distribution of the data points is known, it can serve as a cornerstone for the analysis of robustness with respect to a measure change and can lead to a-priori convergence results, see Steinwart and Christmann (2008). We will restrict the loss function to be an L-times differentiable Nemitski loss for the following theorem. For a definition, we refer to Steinwart and Christmann (2008) or our appendix, where we define an even more general type of *Nemitski vector loss*. Note that, when we refer to convexity or differentiability of Nemitski losses or reproducing kernels, this should always be understood with respect to the second argument, i.e. $\mathrm{d}K(\boldsymbol{x},\boldsymbol{z})$ should be understood as $\frac{\partial}{\partial \boldsymbol{z}}K(\boldsymbol{x},\boldsymbol{z})$. In the following, we denote by $\mathcal{B}(X,Y)$ the space of bounded linear operators from X to Y, endowed with the standard operator norm.

Theorem 2 *Let $\mathcal{H}_1,\dots,\mathcal{H}_L$ and the domains and ranges of their elements be as in theorem 1 and let $\lambda_1,\dots,\lambda_L>0$. Let, furthermore, the kernel K_l of $\mathcal{H}_l$ fulfill $K_l\in C^1(D_l\times D_l)$ together with*

$$\sup_{\boldsymbol{x}\in D_l}\|K_l(\boldsymbol{x},\boldsymbol{x})\|_2\leq c_l \quad \text{and} \quad \sup_{\boldsymbol{x},\boldsymbol{z}\in D_l}\|\mathrm{d}K_l(\boldsymbol{x},\boldsymbol{z})\|_{\mathcal{B}\left(D_l,\mathbb{R}^{d_l\times d_l}\right)}\leq c_l \tag{12}$$

for some $c_l<\infty$ and all $l=1,\dots,L$. Let $\mathbb{P}$ be a distribution on $\Omega\times R_1$ and let $\mathcal{L}:R_1\times\mathbb{R}\to[0,\infty)$ be a convex, $\mathbb{P}$-integrable and 1-times differentiable (w.r.t. the second variable) Nemitski loss such that the absolute value of the derivative is also a $\mathbb{P}$-integrable Nemitski loss, which fulfills

$$\left|\mathcal{L}^{(k)}(y,z)\right|\leq b_k(y)+h_k(|z|) \quad \text{for all } (y,z)\in R_1\times\mathbb{R}$$

for some $L_{1,\mathbb{P}_{R_1}}$-integrable[1] $b_k:R_1\to[0,\infty)$ and some increasing $h_k:[0,\infty)\to[0,\infty)$ for $k=0,1$. Then, if we assume that a set of minimizers $(f_l)_{l=1}^L$ with $f_l\in\mathcal{H}_l$ of

$$J(f_1,\dots,f_L):=\int_{\Omega\times R_1}\mathcal{L}\left(y,f_1\circ\ldots\circ f_L(\boldsymbol{x})\right)\,\mathrm{d}\mathbb{P}(\boldsymbol{x},y)+\sum_{l=1}^{L}\lambda_l\|f_l\|_{\mathcal{H}_l}^2 \tag{13}$$

exists, it fulfills the Bochner-type integral equation

$$f_l(\cdot)=-\frac{1}{2\lambda_i}\int_{\Omega\times R_1}K_l\left(\cdot,f_{l+1}\circ\ldots\circ f_L(\boldsymbol{x})\right)A_{f_l,f_{l+1},\dots,f_L}(\boldsymbol{x},y)\,\mathrm{d}\mathbb{P}(\boldsymbol{x},y) \tag{14}$$

for some $A_{f_l,f_{l+1},\dots,f_L}\in L_{1,\mathbb{P}}(\Omega\times R_1;R_l)$ for all $l=1,\dots,L$.

Proof The proof works layer-wise and it is an extension of the proof of theorem 5.8 of Steinwart and Christmann (2008) to the multi-layer case and to Nemitski vector loss functions, see also definition 5. Let $g_i\in\mathcal{H}_i$ be arbitrary for all $i=1,\dots,L$. Let $G_1:\Omega\times R_1\to R_2\times R_1$ be defined by $G_1(\boldsymbol{x},y)=(g_2\circ\ldots\circ g_L(\boldsymbol{x}),y)$. Obviously, G_1 is a measurable map and we can define the pushforward $G_{1,\star}(\mathbb{P})$ of $\mathbb{P}$ onto $R_2\times R_1$. With this we obtain

$$\int_{\Omega\times R_1}\mathcal{L}\left(y,g_1\circ\ldots\circ g_L(\boldsymbol{x})\right)\,\mathrm{d}\mathbb{P}(\boldsymbol{x},y)=\int_{R_2\times R_1}\mathcal{L}\left(y,g_1(\boldsymbol{\xi})\right)\,\mathrm{d}G_{1,\star}(\mathbb{P})(\boldsymbol{\xi},y).$$

Now, with the functional $J_{g_2,\dots,g_L}:\mathcal{H}_1\to[0,\infty)$ defined by

$$J_{g_2,\dots,g_L}(g_1):=\int_{R_2\times R_1}\mathcal{L}\left(y,g_1(\boldsymbol{\xi})\right)\,\mathrm{d}G_{1,\star}(\mathbb{P})(\boldsymbol{\xi},y)+\lambda_1\|g_1\|_{\mathcal{H}_1}^2,$$

we can reformulate the minimization problem as

$$\min_{g_1\in\mathcal{H}_1,\dots,g_L\in\mathcal{H}_L}J(g_1,\dots,g_L)=\min_{g_2\in\mathcal{H}_2,\dots,g_L\in\mathcal{H}_L}\left(\min_{g_1\in\mathcal{H}_1}J_{g_2,\dots,g_L}(g_1)\right)+\sum_{l=2}^{L}\lambda_l\|g_l\|_{\mathcal{H}_l}^2.$$

Since G_1 leaves the second argument unchanged, it directly follows from the $\mathbb{P}$-integrability that $\mathcal{L}$ is also a $G_{1,\star}(\mathbb{P})$-integrable Nemitski loss. Therefore, the application of the infinite-sample representer theorem 5.8 in Steinwart and Christmann (2008) states that the minimizer $g_1^\star$ of $J_{g_2,\dots,g_L}$ can be written as

$$\begin{aligned}g_1^\star(\cdot)&=-\frac{1}{2\lambda_1}\int_{R_2\times R_1}\mathcal{L}^{(1)}\left(y,g_1^\star(\boldsymbol{\xi})\right)K_1(\cdot,\boldsymbol{\xi})\,\mathrm{d}G_{1,\star}(\mathbb{P})(\boldsymbol{\xi},y)\\&=-\frac{1}{2\lambda_1}\int_{\Omega\times R_1}\mathcal{L}^{(1)}\left(y,g_1^\star\circ g_2\circ\ldots\circ g_L(\boldsymbol{x})\right)K_1(\cdot,g_2\circ\ldots\circ g_L(\boldsymbol{x}))\,\mathrm{d}\mathbb{P}(\boldsymbol{x},y),\end{aligned}$$

where $\mathcal{L}^{(1)}$ denotes the first derivative of $\mathcal{L}$ w.r.t. the second argument. For the choice $g_i=f_i$ for $i=2,\dots,L$, we obtain the minimizer $f_1=g_1^\star$. Note that f_1 is continuous and $\|f_1\|_\infty:=\sup_{\boldsymbol{x}\in D_1}|f_1(\boldsymbol{x})|<\infty$ since $\mathcal{H}_1\hookrightarrow C(D_1)$ follows directly by (12). Therefore, (14) is true for $l=1$ since

$$\begin{aligned}|A_{f_1,\dots,f_L}(\cdot)|:=&\left|\mathcal{L}^{(1)}\left(y,f_1\circ f_2\circ\ldots\circ f_L(\cdot)\right)\right|\leq b_1(y)+h_1\left(|f_1\circ f_2\circ\ldots\circ f_L(\cdot)|\right)\\&\leq b_1(y)+h_1\left(\|f_1\|_\infty\right)\end{aligned}$$

is in $L_{1,\mathbb{P}}$ since $b_1\in L_{1,\mathbb{P}_{R_1}}(R_1)$.

To tackle the next layer, we define $\tilde{\mathcal{L}}:R_1\times R_2\to[0,\infty)$ by

$$\tilde{\mathcal{L}}(y,\boldsymbol{z}):=\mathcal{L}(y,f_1(\boldsymbol{z})).$$

We proceed by showing that $\tilde{\mathcal{L}}$ is a $\mathbb{P}$-integrable and 1-times differentiable Nemitski vector loss. Then we show that we can use analogous techniques as in Steinwart and Christmann (2008)—but for vector-valued functions—to ensure the representation (14) for $l=2$. These arguments can then be iterated until we reach the innermost layer and the proof is completed. Since the details are quite technical, we outsourced them into appendix A. ■

Theorem 2 states that the solution f_l in the l-th layer of (13) is an element of the range of

1. Here, $\mathbb{P}_{R_1}$ denotes the marginal distribution of $\mathbb{P}$ w.r.t. the second variable.

the integral operator defined by the kernel $K_l\left(\cdot, f_{l+1} \circ \ldots \circ f_L(\cdot)\right) : D_l \times \Omega \to \mathbb{R}^{d_l \times d_l}$. Note that the statement of theorem 1 can be derived by choosing a sum of finitely many Dirac measures $\delta_{\boldsymbol{x}_i, y_i}$ as $\mathbb{P}$ in theorem 2. In this special case, the result boils down to f_l being in the span of the kernel evaluations in the data points.

Note furthermore that—in contrast to the finite sample case—f_l is defined as a convolution with the asymmetric kernel in (14). This can be interpreted as a smoothing step for many kernel choices. In this sense, we can expect the solutions f_l of (13) to employ a higher degree of smoothness than in the case of (7), where the solutions are only finite linear combinations of kernels. However, this of course comes at the cost of the regularity condition on the kernels in the requirements of theorem 2.

3.3. Relation to neural networks and deep learning

We now come back to the finite sample case in this section and discuss the relation of our representer theorem 1 to two of the most common approaches in deep learning with kernels, namely multi-layer multiple kernel learning (MLMKL) and deep kernel networks (DKN), see e.g. Cho and Saul (2009); Damianou and Lawrence (2013); Rebai et al. (2016); Strobl and Visweswaran (2013); Wilson et al. (2016); Zhuang et al. (2011). For reasons of simplicity, we restrict ourselves to the two-layer case $L = 2$ here.

3.3.1. Relation to hidden layer neural networks

Let us first illustrate how our approach can be encoded as a hidden layer feed-forward neural network. The idea behind artificial neural networks is the same as for multi-layer kernel learning, namely using concatenations of functions to compute good approximations. More precisely, the so-called universal approximation theorem states that already a two-layer neural network can approximate any continuous function arbitrarily well, see Cybenko (1989); Hornik (1991). For more details on artificial neural networks and deep learning, we refer the reader to Goodfellow et al. (2016).

As mentioned in the two-layer case above, we are aiming to find a function $h(\cdot) = f_1 \circ f_2(\cdot) = \sum_{j=1}^{N} \alpha_j \mathcal{K}^2(\boldsymbol{x}_j, \cdot)$ with $f_1 \in \mathcal{H}_1$ and $f_2 \in \mathcal{H}_2$ and associated K_1 and K_2, respectively, where the kernel $\mathcal{K}^2$ is given by (11). The construction of h can be easily encoded as a feed-forward neural network with one hidden layer if K_1 is a radial basis function (RBF) kernel for instance[2]. We illustrate[3] the case $d_2 = 1$ with an RBF kernel $K_1(z_1, z_2) = a(|z_1 - z_2|)$ for some function $a : \mathbb{R} \to \mathbb{R}$ in Figure 2. The first layer is split into the input layer with values $K_2(\boldsymbol{x}_i, \boldsymbol{x})$ for $i = 1, \ldots, N$ and an artificial "always on" layer with neuron-clusters that supply the constant values $K_2(\boldsymbol{x}_i, \boldsymbol{x}_j)$ with weights $-c_j$ for $i, j = 1, \ldots, N$. Note that the i-th cluster $K_2(\boldsymbol{x}_i, \boldsymbol{x}_j)$ of the "always on" layer is only connected to the i-th neuron of the hidden layer. Note furthermore that the inputs $K_2(\boldsymbol{x}_i, \boldsymbol{x})$ can also easily be computed by a neural network with fixed weights if K_2 is a radial basis

2. For many other types of kernels, e.g. tensor products of RBF kernels, one can still construct a more complex Sigma-Pi neural network for the computation of the output values.
3. Note that we only choose $d_2 = 1$ for illustrative reasons. For $d_2 > 1$, a neural network can be built analogously with an additional hidden layer to compute the norm of the difference of d_2-dimensional vectors. However, this additional layer, which just computes $\|\boldsymbol{x} - \boldsymbol{y}\|_2$ for given $\boldsymbol{x}$ and $\boldsymbol{y}$, has fixed weights and does not play any role for the optimization of the neural network.

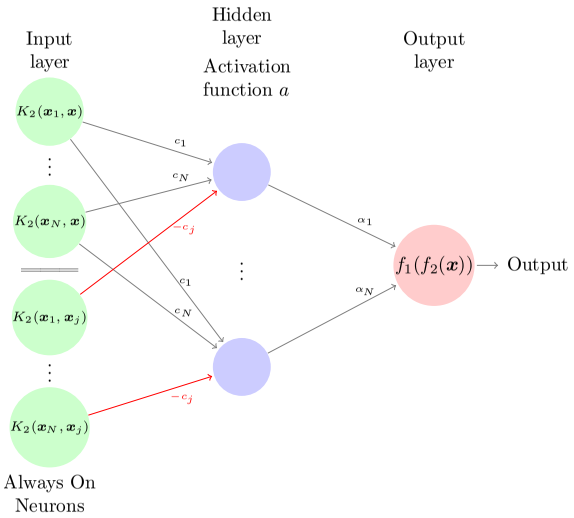


Figure 2: A hidden layer, feed-forward neural network to simulate the concatenation of two functions f_1 and f_2 from reproducing kernel Hilbert spaces. For reasons of readability, we choose $d_2 = 1$ and write $c_i := c_{i,1}$. The outer kernel is $K_1(z_1, z_2) = a(|z_1 - z_2|)$. Note that the i-th artificial "always on" neuron-cluster in the lower half of the first layer is written as $K_2(\boldsymbol{x}_i, \boldsymbol{x}_j)$, which stands for N single neurons with values $K_2(\boldsymbol{x}_i, \boldsymbol{x}_1), \ldots, K_2(\boldsymbol{x}_i, \boldsymbol{x}_N)$. The cluster $K_2(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is only connected to the i-th neuron of the hidden layer with weights $-c_j$ (red lines). This means that the value $\sum_{j=1}^{N} -c_j K_2(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is forwarded to the i-th neuron of the hidden layer.

kernel. If we consider a "deeper" concatenation, we would need a deeper neural network with additional layers, i.e. for $f_1 \circ \ldots \circ f_L$, we need $L - 1$ hidden layers.

3.3.2. Relation to multi-layer multiple kernel learning

The common idea in MLMKL methods is to learn a kernel $\tilde{K}$, which consists of a chain of linear combinations of functions and an inner kernel, e.g.

$$\tilde{K}(\boldsymbol{x}, \boldsymbol{y}) = \sum_{\ell=1}^{n_1} \nu_{1,\ell} k_{1,\ell} \left(\sum_{i=1}^{n_2} \nu_{2,i} K_{2,i}(\boldsymbol{x}, \boldsymbol{y}) \right)$$

in the two-layer case, where $k_{1,\ell}$ are real-valued functions for $\ell = 1, \ldots, n_1$ and $K_{2,i}$ are different scalar-valued kernels for $i = 1, \ldots, n_2$. Note that the functions $k_{1,\ell}$ are chosen such that $\tilde{K}$ is still a kernel. In the case of linear $k_{1,\ell}$, Dinuzzo (2011) has shown that the resulting algorithm becomes a standard MKL procedure and can be interpreted as a two-layer kernel network with a linear outer kernel. However, for arbitrary $k_{1,\ell}$ this is not

the case and we are dealing with a true MLMKL approach. The specific MLMKL algorithm then aims to find the optimal values for the coefficients $\nu_{1,\ell}, \nu_{2,i}$ in order to determine the best $\tilde{K}$ for a regression of the given data X and Y with e.g. a support vector regression algorithm. Note that the kernels and the k-functions are usually chosen heuristically, e.g. as polynomials, Gaussians, sigmoidals, etc., see Rebai et al. (2016); Zhuang et al. (2011).

To apply our result to the two-layer MKL method above, let us consider the case $n_1 = 1$ and $n_2 = N$. We set $\nu_{1,1} = 1$ without loss of generality. We let the outer function $k_{1,1}(z) = a(|z|)$ be the radial basis function used for the outer kernel (i.e. middle layer) in Figure 2. Furthermore, we set

$$K_{2,i}(\boldsymbol{x}, \boldsymbol{y}) := K_2(\boldsymbol{x}_i, \boldsymbol{x}) - K_2(\boldsymbol{x}_i, \boldsymbol{y}).$$

Note that the $K_{2,i}$ are no longer kernels anymore in this setting. However, they are now directly connected to our concatenated function learning approach since

$$\begin{aligned}\tilde{K}(\boldsymbol{x}, \boldsymbol{y}) &= k_{1,1}\left(\sum_{i=1}^{N} \nu_{2,i} K_{2,i}(\boldsymbol{x}, \boldsymbol{y})\right) = a\left(\left|\sum_{i=1}^{N} \nu_{2,i} K_2(\boldsymbol{x}_i, \boldsymbol{x}) - \nu_{2,i} K_2(\boldsymbol{x}_i, \boldsymbol{y})\right|\right) \\ &= K_1\left(\sum_{i=1}^{N} \nu_{2,i} K_2(\boldsymbol{x}_i, \boldsymbol{x}), \sum_{i=1}^{N} \nu_{2,i} K_2(\boldsymbol{x}_i, \boldsymbol{y})\right) = \mathcal{K}^2(\boldsymbol{x}, \boldsymbol{y})\end{aligned}$$

from (11) with $c_i = \nu_{2,i}$ and the kernels K_1 and K_2 used in Figure 2. Altogether, we thus see that an MLMKL algorithm with these parameters already determines the optimal solution (provided that the right hand side of (9) is solved exactly) among all functions of type $h = f_1 \circ f_2$ with $f_1 \in \mathcal{H}_1$ and $f_2 \in \mathcal{H}_2$ according to Theorem 1. This way, our representer theorem for concatenated functions directly applies to a special case of MLMKL networks. Note however that a generalization of our arguments to more layers, i.e. $L > 2$, is not straightforward for MLMKL.

3.3.3. Relation to deep kernel learning approaches

The class of DKN methods consists of algorithms which build a kernel by nonlinearly transforming the input vectors before applying an outer kernel function. This is in contrast to the MLMKL approach, where only the innermost function is a two-variate kernel and its evaluations are modified by some nonlinear outer functions. The models in this class range from simple feature map powers for some function Ψ, i.e.

$$\tilde{K}(x, y) = \underbrace{\Psi \circ \ldots \circ \Psi}_{L-1 \text{ times}}(\boldsymbol{x}) \cdot \underbrace{\Psi \circ \ldots \circ \Psi}_{L-1 \text{ times}}(\boldsymbol{y}),$$

see Cho and Saul (2009), to more general variants like

$$\tilde{K}(x, y) = K\left(f_2 \circ \ldots \circ f_L(\boldsymbol{x}), f_2 \circ \ldots \circ f_L(\boldsymbol{y})\right)$$

with nonlinear functions $f_2, \ldots, f_L$, see Wilson et al. (2016). If we assume that $f_l \in \mathcal{H}_l$ for $l = 2, \ldots, L$ stem from reproducing kernel Hilbert spaces with associated kernels K_l, we can apply Theorem 1 to this approach and obtain that each f_l can be written as a finite linear combination of evaluations of the kernel K_l. Thus, we can directly apply our representer theorem for L-layer DKN algorithms.

3.4. The two-layer interpolation problem

After analyzing the general multi-layer kernel concatenation problem in Theorem 1, we now have a closer, more detailed look at the main component of it, namely the *concatenation of two functions*. To this end, we specifically consider the interpolation problem for $L = 2$. This simple, illustrative setting gives further insights into the way concatenation works in machine learning problems.

3.4.1. Definition of the problem

We slightly adapt our notation to this special case to obtain a direct relation to the single-layer interpolation problem from Section 2. To this end, let $D := d_2$ and consider the domain $\Phi := D_1 \subseteq \mathbb{R}^D$ together with the two function spaces

$$\begin{aligned} H(\Phi, \mathbb{R}) &:= \mathcal{H}_1 \subset C(\Phi) := \{f : \Phi \to \mathbb{R} \mid f \text{ continuous}\} && \text{– “outer” space,} \\ \boldsymbol{H}(\Omega, \Phi) &:= \mathcal{H}_2 \subset \left\{\boldsymbol{g} = (g_1, \ldots, g_D)^T : \Omega \to \Phi \mid \boldsymbol{g} \text{ continuous}\right\} && \text{– “inner” space.}\end{aligned}$$

Both spaces are supposed to be reproducing kernel Hilbert spaces, i.e. there is an (outer) kernel $K := K_1 : \Phi \times \Phi \to \mathbb{R}$ for $H(\Phi, \mathbb{R})$ such that

$$\begin{aligned} K(\boldsymbol{x}, \cdot) &\in H(\Phi, \mathbb{R}) && \text{for all } \boldsymbol{x} \in \Omega, \\ f(\boldsymbol{x}) &= (f, K(\boldsymbol{x}, \cdot))_{H(\Phi,\mathbb{R})} && \text{for all } \boldsymbol{x} \in \Omega \text{ and all } f \in H(\Phi, \mathbb{R}).\end{aligned}$$

The function space $\boldsymbol{H}(\Omega, \Phi)$ is assumed to be a vector-valued RKHS, i.e. there is an (inner) kernel $\boldsymbol{K} : \Omega \times \Omega \to \mathbb{R}^{D \times D}$ such that

$$\begin{aligned} \boldsymbol{K}(\boldsymbol{x}, \cdot)\, \boldsymbol{c} &\in \boldsymbol{H}(\Omega, \Phi) && \text{for all } \boldsymbol{x} \in \Omega \text{ and all } \boldsymbol{c} \in \mathbb{R}^D, \\ \boldsymbol{c}^T \boldsymbol{g}(\boldsymbol{x}) &= (\boldsymbol{g}, \boldsymbol{K}(\boldsymbol{x}, \cdot)\, \boldsymbol{c})_{\boldsymbol{H}(\Omega,\Phi)} && \text{for all } \boldsymbol{x} \in \Omega, \text{ all } \boldsymbol{c} \in \mathbb{R}^D \text{ and all } \boldsymbol{g} \in \boldsymbol{H}(\Omega, \Phi).\end{aligned}$$

To formulate the concatenated interpolation problem in the spirit of (1), we have to define an appropriate functional and propose an appropriate search set for the minimization task. To this end, we consider the functional $J : H(\Phi, \mathbb{R}) \times \boldsymbol{H}(\Omega, \Phi) \to \mathbb{R}$ given by

$$J(f, \boldsymbol{g}) := \|f\|^2_{H(\Phi,\mathbb{R})} + \|\boldsymbol{g}\|^2_{\boldsymbol{H}(\Omega,\Phi)},$$

which penalizes the norms of both the outer and the inner function, and the admissible set

$$\mathcal{A}_{X,Y} := \{(f, \boldsymbol{g}) \in H(\Phi, \mathbb{R}) \times \boldsymbol{H}(\Omega, \Phi) \mid f \circ \boldsymbol{g}(\boldsymbol{x}_j) = y_j \ 1 \le j \le N\},$$

i.e. the set of all concatenations of functions from $H(\Phi, \mathbb{R})$ and $\boldsymbol{H}(\Omega, \Phi)$ which interpolate the data. With this notation, we can define the following variational optimization problem

$$J(f, \boldsymbol{g}) \to \min \quad \text{for } (f, \boldsymbol{g}) \in \mathcal{A}_{X,Y} \tag{P}$$

As explained in Section 2, the solution $f^*_{X,Y}$ to the standard interpolation problem (1) can be computed by solving the system (3) of linear equations for a given set of fixed and pairwise disjoint input data points $X := \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N\}$. Therefore, if we assume for a moment the inner function $\boldsymbol{g}$ in (P) to be fixed and $Z := \boldsymbol{g}(X) = \{\boldsymbol{z}_i = \boldsymbol{g}(\boldsymbol{x}_i) \mid i = 1, \ldots, N\}$,

then we obtain that the solution $f^*_{Z,Y}$ to (1) with data points Z is the only admissible minimizer of the concatenated interpolation problem (P), i.e.

$$f^*_{Z,Y} = \underset{f\in\{h\in H(\Phi,\mathbb{R})\mid(h,\boldsymbol{g})\in\mathcal{A}_{X,Y}\}}{\arg\min} \|f\|^2_{H(\Phi,\mathbb{R})}.$$

Note that the coefficients $\boldsymbol{\alpha}^* \in \mathbb{R}^N$ of $f^*_{Z,Y} = \sum_{i=1}^N \alpha_i^* K(\boldsymbol{z}_i,\cdot)$ can be computed by solving the system

$$\boldsymbol{M}_{Z,Z}\boldsymbol{\alpha}^* = \boldsymbol{y}$$

and the value of the optimal energy, i.e. the squared norm, is given by

$$\left\|f^*_{Z,Y}\right\|^2_{H(\Phi,\mathbb{R})} = \boldsymbol{\alpha}^{*T}\boldsymbol{M}_{Z,Z}\boldsymbol{\alpha}^* = \boldsymbol{y}^T\boldsymbol{M}^{-1}_{Z,Z}\boldsymbol{y}.$$

3.4.2. Application of the representer theorem

In order to rewrite the concatenated interpolation problem (P) into an unconstrained minimization problem by applying the above result, we first have to discuss what happens if $\boldsymbol{g}(\boldsymbol{x}_j) = \boldsymbol{g}(\boldsymbol{x}_k)$ for two indices $j \neq k$. If equality holds also for the corresponding values from Y, i.e. $y_j = y_k$, we can simply remove the pair $(x_j, y_j) \in X \times Y$ from the input data and with it also the corresponding condition from the admissible set. However, if $y_j \neq y_k$, there cannot be an $f \in H(\Phi,\mathbb{R})$ such that $(f,\boldsymbol{g}) \in \mathcal{A}_{X,Y}$. In this case, we simply set $J(f,\boldsymbol{g}) = \infty$. Using this convention, we can recast (P) into the unrestricted optimization problem

$$J\left(f^*_{\boldsymbol{g}(X),Y},\boldsymbol{g}\right) = \boldsymbol{y}^T\boldsymbol{M}^{-1}_{\boldsymbol{g}(X),\boldsymbol{g}(X)}\boldsymbol{y} + \|\boldsymbol{g}\|^2_{\boldsymbol{H}(\Omega,\Phi)} \to \min \quad \text{for } \boldsymbol{g}\in\boldsymbol{H}(\Omega,\Phi). \tag{uP}$$

Therefore, we only have to consider the minimization with respect to $\boldsymbol{g} \in \boldsymbol{H}(\Omega,\Phi)$ since the optimal outer function $f^*_{\boldsymbol{g}(X),Y}$ is completely determined by the inner function values $\boldsymbol{g}(X)$ and Y.

Note that the side condition $\boldsymbol{g}(\boldsymbol{x}_j) \neq \boldsymbol{g}(\boldsymbol{x}_k)$ for $j \neq k$ can also be enforced by adding a penalty term of type $\sum_{i<j} W\left(\|\boldsymbol{g}(\boldsymbol{x}_i) - \boldsymbol{g}(\boldsymbol{x}_j)\|_2^2\right)$ to J, where W is a smooth function with $W(0) = \infty$, e.g. $W(x) = \coth(x)$. This can also remedy the problem of small condition numbers of $\boldsymbol{M}_{\boldsymbol{g}(X),\boldsymbol{g}(X)}$ for large sample sizes since it maximizes distances between the point evaluations of $\boldsymbol{g}$. Adding this to (uP), we obtain

$$J_\gamma\left(f^*_{\boldsymbol{g}(X),Y},\boldsymbol{g}\right) := J\left(f^*_{\boldsymbol{g}(X),Y},\boldsymbol{g}\right) + \gamma \sum_{1\le i<j\le N} \coth\left(\|\boldsymbol{g}(\boldsymbol{x}_i) - \boldsymbol{g}(\boldsymbol{x}_j)\|_2^2\right) \tag{15}$$
$$\to \min \quad \text{for } \boldsymbol{g}\in\boldsymbol{H}(\Omega,\Phi).$$

However, since using $J_0 = J$ in our experiments in Section 4 works out already well and the side condition does not seem to affect the results for moderate sample sizes, we restrict ourselves to the problem (uP) in the following.

Although the above considerations seem to simplify the concatenated interpolation problem, we still have to solve a highly nonlinear optimization problem over the (possibly) infinite-dimensional RKHS $\boldsymbol{H}(\Omega,\Phi)$. Nonetheless, by applying Theorem 1 to the unrestricted concatenated interpolation problem (uP), we can restrict the search space $\boldsymbol{H}(\Omega,\Phi)$ to the span of the kernel translates in the input data.

Corollary 3 *Let $V_X := \operatorname{span}\{\boldsymbol{K}(\boldsymbol{x}_i,\cdot)\boldsymbol{e}_j \mid i = 1,\dots,N \text{ and } j = 1,\dots,D\}$, where $\boldsymbol{e}_j$ denotes the j-th unit vector in $\mathbb{R}^D$. Then, the solution $\boldsymbol{g}^*$ to the unconstrained concatenated interpolation problem* (uP) *fulfills $\boldsymbol{g}^* \in V_X$.*

Proof We apply Theorem 1 with $L = 2$, $\Theta_1(x) = \Theta_2(x) = x$ and

$$\mathcal{L}(y_i, f\circ\boldsymbol{g}(\boldsymbol{x}_i)) = \begin{cases} 0 & \text{if } f\circ\boldsymbol{g}(\boldsymbol{x}_i) = y_i \\ \infty & \text{else,}\end{cases}$$

which exactly resembles the interpolation problem (uP). ■

Due to Corollary 3, we can recast the unrestricted concatenated interpolation problem (uP) into

$$J\left(f^*_{\boldsymbol{g}(X),Y},\boldsymbol{g}\right) = \boldsymbol{y}^T\boldsymbol{M}^{-1}_{\boldsymbol{g}(X),\boldsymbol{g}(X)}\boldsymbol{y} + \|\boldsymbol{g}\|^2_{\boldsymbol{H}(\Omega,\Phi)} \to \min \text{ for } \boldsymbol{g}\in V_X \subset \boldsymbol{H}(\Omega,\Phi). \tag{uP-X}$$

This is a nonlinear, finite-dimensional and unrestricted optimization problem. We fix the basis $\{\boldsymbol{K}(\boldsymbol{x}_j,\cdot)\boldsymbol{e}_\ell \mid (j,\ell)\in\mathcal{I}\}$ with $\mathcal{I} := \{(j,\ell) \in \mathbb{N}^2 \mid 1\le j\le N, 1\le\ell\le D\}$ to solve (uP-X). Then, the optimal solution can be written as

$$\boldsymbol{g}^*(\cdot) = \sum_{(j,\ell)\in\mathcal{I}} c^*_{j,\ell}\boldsymbol{K}(\boldsymbol{x}_j,\cdot)\boldsymbol{e}_\ell. \tag{16}$$

In order to express the minimization problem (uP-X) with respect to the coefficients $\boldsymbol{c}^* = \left(c^*_{1,1},\dots,c^*_{N,D}\right)^T$, we introduce $\boldsymbol{Q}_{X,X}(\boldsymbol{c}) := \boldsymbol{M}_{\boldsymbol{g}(X),\boldsymbol{g}(X)}$, i.e.

$$\boldsymbol{Q}_{X,X}(\boldsymbol{c}) = \left(K\left(\sum_{(j,\ell)\in I} c_{j,\ell}\boldsymbol{K}(\boldsymbol{x}_j,\boldsymbol{x}_n)\boldsymbol{e}_\ell, \sum_{(j,\ell)\in I} c_{j,\ell}\boldsymbol{K}(\boldsymbol{x}_j,\boldsymbol{x}_m)\boldsymbol{e}_\ell\right)\right)_{1\le n,m\le N} \tag{17}$$

and the corresponding quadratic form

$$\mathcal{Q}: \mathbb{R}^{ND}\to\mathbb{R}, \quad \boldsymbol{c}\mapsto \boldsymbol{y}^T\boldsymbol{Q}_{X,X}(\boldsymbol{c})^{-1}\boldsymbol{y}.$$

Furthermore, to express $\|\boldsymbol{g}^*\|^2_{\boldsymbol{H}(\Omega,\Phi)}$ with respect to $\boldsymbol{c}^*$, we need

$$\mathcal{N}: \mathbb{R}^{ND}\to\mathbb{R}, \quad \boldsymbol{c}\mapsto \sum_{j,k=1}^N \begin{pmatrix} c_{j,1}\\ \vdots \\ c_{j,D}\end{pmatrix}^T \boldsymbol{K}(\boldsymbol{x}_j,\boldsymbol{x}_k) \begin{pmatrix} c_{k,1}\\ \vdots \\ c_{k,D}\end{pmatrix}. \tag{18}$$

Finally, we obtain the finite-dimensional optimization problem

$$\boldsymbol{c}^* = \underset{\boldsymbol{c}\in\mathbb{R}^{ND}}{\arg\min} \underbrace{\mathcal{Q}(\boldsymbol{c})}_{\|f^*_{\boldsymbol{g}(X),Y}\|^2_{H(\Phi,\mathbb{R})}} + \underbrace{\mathcal{N}(\boldsymbol{c})}_{\|\boldsymbol{g}\|^2_{\boldsymbol{H}(\Omega,\Phi)}}. \tag{Int}$$

3.4.3. Solving the minimization problem

The unconstrained problem (Int) is highly nonlinear because the coefficients $c_{j,\ell}$ are transformed by the outer kernel function K. It can be tackled by any suitable iterative optimization algorithm. If the kernels K and $\boldsymbol{K}$ are differentiable, a quasi-Newton approach is appropriate. If this is not the case, a derivative-free optimizer should be chosen.

Note that we can restrict the minimization in (Int) to a compact subset of $\mathbb{R}^{ND}$ without loss of generality. To this end, let $\underline{\boldsymbol{K}} \in \mathbb{R}^{ND\times ND}$ be the $N \times N$ matrix of matrices $\boldsymbol{K}(\boldsymbol{x}_i, \boldsymbol{x}_j) \in \mathbb{R}^{D\times D}$ and note that

$$\mathcal{Q}(\boldsymbol{c}) + \mathcal{N}(\boldsymbol{c}) \geq 0 + \lambda_{\min}\left(\underline{\boldsymbol{K}}\right) \cdot \|\boldsymbol{c}\|_2^2 \overset{\|\boldsymbol{c}\|_2\to\infty}{\longrightarrow} \infty,$$

where $\lambda_{\min}\left(\underline{\boldsymbol{K}}\right) > 0$ denotes the smallest eigenvalue of $\underline{\boldsymbol{K}}$. Therefore, we can restrict our search to the compact set $A := \left\{\boldsymbol{c} \in \mathbb{R}^{ND} \mid \|\boldsymbol{c}\|_2 \leq C\right\}$ for a large enough $C > 0$. Unfortunately, we cannot directly obtain the existence of a minimizer from this since (Int) is not continuous. However, if we add a smooth term

$$\begin{aligned}\mathcal{P}^\gamma(\boldsymbol{c}) &= \gamma \sum_{1\leq m<n\leq N} \coth\left(\|\boldsymbol{g}(\boldsymbol{x}_m) - \boldsymbol{g}(\boldsymbol{x}_n)\|_2^2\right) \\ &= \gamma \sum_{1\leq m<n\leq N} \coth\left(\left\|\sum_{(j,\ell)\in\mathcal{I}} c_{j,\ell}\left(\boldsymbol{K}\left(\boldsymbol{x}_j, \boldsymbol{x}_m\right) - \boldsymbol{K}\left(\boldsymbol{x}_j, \boldsymbol{x}_n\right)\right)\boldsymbol{e}_\ell\right\|_2^2\right),\end{aligned}$$

which is equivalent to (15), for $\gamma > 0$, we can deduce the existence of a minimizer with the direct method from the calculus of variations. To this end, note that for a minimizing sequence $(\boldsymbol{c}_i)_{i=1}^\infty$ of $\mathcal{Q} + \mathcal{N} + \mathcal{P}^\gamma$, there necessarily exist $i_0 \in \mathbb{N}$ and $C_0 > 0$ such that all mutual squared distances $\|\boldsymbol{g}(\boldsymbol{x}_m) - \boldsymbol{g}(\boldsymbol{x}_n)\|_2^2$ with $1 \leq m < n \leq N$ are larger than C_0 for all $\boldsymbol{c}_i$ with $i > i_0$. Therefore, we can restrict the minimization to the compact subdomain

$$A \cap \left\{\boldsymbol{c} \in \mathbb{R}^{ND} \mid \|\boldsymbol{g}(\boldsymbol{x}_m) - \boldsymbol{g}(\boldsymbol{x}_n)\|_2^2 \geq C_0 \ \text{ for } 1 \leq m < n \leq N\right\},$$

on which $\mathcal{Q}+\mathcal{N}+\mathcal{P}^\gamma$ is continuous, and the existence of a minimizer follows. Nevertheless, as we explained above, the critical condition $\mathcal{P}^\gamma(\boldsymbol{c}) = \infty$ is practically never met for moderate data set sizes and, therefore, it is safe to assume that there also exists a minimizer for (Int). Note however that, depending on the kernels and the data at hand, there usually might exist many minimizers and the solution to (Int) might not be unique. To reduce the chance of getting stuck in a local minimum, we propose to restart the minimization procedure several times with different starting values for $\boldsymbol{c}^*$.

Since we will be dealing with differentiable kernel functions in Section 4 and since the derivatives of these kernels can be computed explicitly, we propose a BFGS minimization algorithm to solve (Int). To this end, note that the only derivatives we need are essentially the derivative of the inverse of $\boldsymbol{Q}_{X,X}(\boldsymbol{c})$, i.e.

$$\frac{\partial}{\partial c_{m,n}}\boldsymbol{Q}_{X,X}^{-1}(\boldsymbol{c}) = -\boldsymbol{Q}_{X,X}^{-1}(\boldsymbol{c})\frac{\partial}{\partial c_{m,n}}\boldsymbol{Q}_{X,X}(\boldsymbol{c})\boldsymbol{Q}_{X,X}^{-1}(\boldsymbol{c}),$$

and the derivative of $\boldsymbol{Q}_{X,X}(\boldsymbol{c})$. The latter consists of the derivative of the outer kernel K, which is known analytically for all kernel choices that we discuss in Section 4, and

$$\frac{\partial}{\partial c_{m,n}}\boldsymbol{g}(\boldsymbol{x}) = \frac{\partial}{\partial c_{m,n}}\sum_{(j,\ell)\in\mathcal{I}} c_{j,\ell}\boldsymbol{K}\left(\boldsymbol{x}_j, \boldsymbol{x}\right)\boldsymbol{e}_\ell = \boldsymbol{K}\left(\boldsymbol{x}_m, \boldsymbol{x}\right)\boldsymbol{e}_n$$

for each $(m, n) \in \mathcal{I}$. The overall computational cost complexity for one BFGS step, i.e. the evaluation of $\mathcal{Q}, \mathcal{N}$ and their derivatives, is bounded by $\mathcal{O}\left(N^3D + (ND)^2\right)$.

3.5. Two-layer Least-squares regression

After the discussion of the two-layer interpolation problem in the last section, we now consider the regularized two-layer least-squares problem in more detail. This is a natural extension of the two-layer least-squares problem RLS2 considered in Dinuzzo (2011) to the case of nonlinear outer kernels.

3.5.1. Definition of the problem

For concatenated, regularized least-squares regression, the minimization task changes to

$$J_{\lambda,\mu}\left(f, \boldsymbol{g}\right) := \sum_{j=1}^N \left|f \circ \boldsymbol{g}\left(\boldsymbol{x}_j\right) - y_j\right|^2 + \lambda\left\|f\right\|_{H(\Phi,\mathbb{R})}^2 + \mu\left\|\boldsymbol{g}\right\|_{\boldsymbol{H}(\Omega,\Phi)}^2 \qquad \text{(R)}$$
$$\to \min \ \text{ for } f \in H\left(\Phi, \mathbb{R}\right), g \in \boldsymbol{H}\left(\Omega, \Phi\right)$$

with $\lambda, \mu > 0$, which is in the same fashion as the standard least-squares regression problem (5).

Analogously to our considerations in Section 3.4, we find that, for fixed inner points $Z = \boldsymbol{g}(X) \subset \Phi$, the function $f_{Z,Y}^\lambda$, see (5), is the solution of the problem

$$\sum_{j=1}^N \left|f(\boldsymbol{z}_j) - y_j\right|^2 + \lambda\left\|f\right\|_{H(\Phi,\mathbb{R})}^2 \to \min \ \text{ for } f \in H\left(\Phi, \mathbb{R}\right).$$

The corresponding coefficients $\boldsymbol{\alpha}^\lambda \in \mathbb{R}^N$ with respect to the basis $\{K(\boldsymbol{z}_j, \cdot) \mid j = 1, \ldots, N\}$ are computed by solving

$$\left(\boldsymbol{M}_{Z,Z} + \lambda\boldsymbol{I}\right)\boldsymbol{\alpha}^\lambda = \boldsymbol{y}.$$

Therefore, each of the terms of the optimal energy can be expressed as

$$\begin{aligned}\left\|f_{Z,Y}^\lambda\right\|_{H(\Phi,\mathbb{R})}^2 &= {\boldsymbol{\alpha}^\lambda}^T\boldsymbol{M}_{Z,Z}\boldsymbol{\alpha}^\lambda = \boldsymbol{y}^T\left(\boldsymbol{M}_{Z,Z} + \lambda\boldsymbol{I}\right)^{-1}\boldsymbol{M}_{Z,Z}\left(\boldsymbol{M}_{Z,Z} + \lambda\boldsymbol{I}\right)^{-1}\boldsymbol{y}, \\ \sum_{j=1}^N\left|f_{Z,Y}^\lambda\left(\boldsymbol{z}_j\right) - y_j\right|^2 &= \left\|\boldsymbol{M}_{Z,Z}\boldsymbol{\alpha}^\lambda - \boldsymbol{y}\right\|_2^2 = \left\|\left(\boldsymbol{I} - \boldsymbol{M}_{Z,Z}\left(\boldsymbol{M}_{Z,Z} + \lambda\boldsymbol{I}\right)^{-1}\right)\boldsymbol{y}\right\|_2^2.\end{aligned}$$

3.5.2. Application of the representer theorem

Analogously to (uP), we can use

$$J_{\lambda,\mu}\left(f^{\lambda}_{\boldsymbol{g}(X),Y},\boldsymbol{g}\right) = \lambda \boldsymbol{y}^T \left(\boldsymbol{M}_{\boldsymbol{g}(X),\boldsymbol{g}(X)} + \lambda \boldsymbol{I}\right)^{-1} \boldsymbol{M}_{\boldsymbol{g}(X),\boldsymbol{g}(X)} \left(\boldsymbol{M}_{\boldsymbol{g}(X),\boldsymbol{g}(X)} + \lambda \boldsymbol{I}\right)^{-1} \boldsymbol{y} + \mu \left\|\boldsymbol{g}\right\|^2_{\boldsymbol{H}(\Omega,\Phi)} + \left\| \left(\boldsymbol{I} - \boldsymbol{M}_{\boldsymbol{g}(X),\boldsymbol{g}(X)} \left(\boldsymbol{M}_{\boldsymbol{g}(X),\boldsymbol{g}(X)} + \lambda \boldsymbol{I}\right)^{-1}\right) \boldsymbol{y} \right\|^2_2 \tag{19}$$

to reformulate (R) as

$$J_{\lambda,\mu}\left(f^{\lambda}_{\boldsymbol{g}(X),Y},\boldsymbol{g}\right) \to \min \text{ for } \boldsymbol{g} \in \boldsymbol{H}(\Omega,\Phi). \tag{uR}$$

Corollary 4 *The solution $\boldsymbol{g}^{\lambda,\mu}$ to the unconstrained concatenated regression problem* (uR) *fulfills $\boldsymbol{g}^{\lambda,\mu} \in V_X$.*

Proof We apply Theorem 1 with $L = 2$, $\Theta_1(x) = \lambda \cdot x$, $\Theta_2(x) = \mu \cdot x$ and

$$\mathcal{L}\left(y_i, f \circ \boldsymbol{g}(\boldsymbol{x}_i)\right) = \left|f \circ \boldsymbol{g}\left(\boldsymbol{x}_i\right) - y_i\right|^2,$$

which resembles the regression problem (R). ■

Hence, as for interpolation, we obtain a representer theorem for concatenated least-squares regression, which allows us to replace the infinite-dimensional optimization problem (R) with the finite-dimensional problem

$$J_{\lambda,\mu}\left(f^{\lambda}_{\boldsymbol{g}(X),Y},\boldsymbol{g}\right) \to \min \text{ for } \boldsymbol{g} \in V_X \subset \boldsymbol{H}(\Omega,\Phi). \tag{uR-X}$$

Finally, we want to express (uR-X) in terms of the coefficients $\boldsymbol{c}^{\lambda,\mu} = \left(c^{\lambda,\mu}_{1,1}, \ldots, c^{\lambda,\mu}_{N,D}\right)^T$ of $\boldsymbol{g}^{\lambda,\mu}$ with respect to the basis $\{\boldsymbol{K}(\boldsymbol{x}_j,\cdot)\,\boldsymbol{e}_\ell \mid (j,\ell) \in \mathcal{I}\}$. To this end, we set $\boldsymbol{A} := \left(\boldsymbol{Q}_{X,X}(\boldsymbol{c}) + \lambda \boldsymbol{I}\right)^{-1}$ and define the quadratic forms

$$\begin{aligned}
\mathcal{Q}^{\lambda} &: \mathbb{R}^{ND} \to \mathbb{R}, \quad \boldsymbol{c} \mapsto \lambda \cdot \boldsymbol{y}^T \boldsymbol{A} \boldsymbol{Q}_{X,X}(\boldsymbol{c})\, \boldsymbol{A} \boldsymbol{y}, \\
\mathcal{N}^{\mu} &: \mathbb{R}^{ND} \to \mathbb{R}, \quad \boldsymbol{c} \mapsto \mu \cdot \mathcal{N}(\boldsymbol{c}) \quad \text{and} \\
\mathcal{C}^{\lambda} &: \mathbb{R}^{ND} \to \mathbb{R}, \quad \boldsymbol{c} \mapsto \boldsymbol{y}^T \left(\boldsymbol{I} - \boldsymbol{Q}_{X,X}(\boldsymbol{c})\, \boldsymbol{A}\right)^T \left(\boldsymbol{I} - \boldsymbol{Q}_{X,X}(\boldsymbol{c})\, \boldsymbol{A}\right) \boldsymbol{y}
\end{aligned}$$

with the help of (17) and (18). Subsequently, we arrive at the optimization problem

$$\boldsymbol{c}^{\lambda,\mu} = \underset{\boldsymbol{c} \in \mathbb{R}^{ND}}{\arg\min}\, \mathcal{Q}^{\lambda}(\boldsymbol{c}) + \mathcal{N}^{\mu}(\boldsymbol{c}) + \mathcal{C}^{\lambda}(\boldsymbol{c}), \tag{Reg}$$

which is the equivalent to (uR-X).

3.5.3. Solving the minimization problem

Note that the existence of a minimizer follows by similar arguments as in the previous section for the interpolation problem, i.e.

$$\mathcal{Q}^{\lambda}(\boldsymbol{c}) + \mathcal{N}^{\mu}(\boldsymbol{c}) + \mathcal{C}^{\lambda}(\boldsymbol{c}) \geq \mu \cdot \lambda_{\min}\left(\underline{\boldsymbol{K}}\right) \cdot \left\|\boldsymbol{c}\right\|^2_2 \overset{\|\boldsymbol{c}\|_2 \to \infty}{\longrightarrow} \infty$$

and we can thus restrict the search for a minimizer to a compact subset of $\mathbb{R}^{ND}$. For regression we need the inverse of $\boldsymbol{Q}_{X,X}(\boldsymbol{c}) + \lambda \boldsymbol{I}$ to compute $\mathcal{Q}^{\lambda}$, which is positive definite for every $\lambda > 0$ and, therefore, there are no pathological cases as in the interpolation setting. Thus, the functions $\mathcal{Q}^{\lambda}, \mathcal{N}^{\mu}, \mathcal{C}^{\lambda}$ are continuous and the minimization of (Reg) over a compact subset of $\mathbb{R}^{ND}$ has a minimizer. Nevertheless, also in this case the minimizer is not necessarily unique.

While the optimization for the coefficients in the RLS2 algorithm proposed in Dinuzzo (2011) boils down to a simplex-constrained linear least-squares problem, we have to deal with a high degree of nonlinearity here. Nevertheless, if the kernel functions are differentiable, we can again—as in the interpolation case—employ a BFGS algorithm with several restarts to approximately find the optimal coefficients $\boldsymbol{c}^{\lambda,\mu}$. To this end, note that $\mathcal{Q}^{\lambda}$ and $\mathcal{N}^{\mu}$ can be computed similarly as $\mathcal{Q}$ and $\mathcal{N}$ in the interpolation case. Furthermore, also the derivative of $\mathcal{C}^{\lambda}$ can be computed with the same techniques since we essentially only need the derivatives of $\boldsymbol{Q}_{X,X}(\boldsymbol{c})$ and $\left(\boldsymbol{Q}_{X,X}(\boldsymbol{c}) + \lambda \boldsymbol{I}\right)^{-1}$. While the number of terms is larger than in the interpolation case, the asymptotic computational runtime is still bounded by $\mathcal{O}\left(N^3 D + (ND)^2\right)$. Furthermore, the condition number of the matrix $\boldsymbol{Q}_{X,X}(\boldsymbol{c}) + \lambda \boldsymbol{I}$ is smaller than the one of $\boldsymbol{Q}_{X,X}$, which had to be inverted for interpolation. Therefore, computing $\mathcal{Q}^{\lambda}(\boldsymbol{c})$ with an iterative solver for the application of $\left(\boldsymbol{Q}_{X,X}(\boldsymbol{c}) + \lambda \boldsymbol{I}\right)^{-1}$ needs fewer computational steps than computing $\mathcal{Q}(\boldsymbol{c})$ in the interpolation case.

Finally, let us remark that for both interpolation and least-squares regression there exists another possibility to obtain a finite-dimensional optimization problem from (P) and (R), respectively, without using the representer theorem. We could discretize the functions $f_1 \in \mathcal{H}_1$ and $f_2 \in \mathcal{H}_2$ by $\tilde{f}_1 \in V_1$ and $\tilde{f}_2 \in V_2$ with finite-dimensional spaces V_1, V_2, see e.g. Bohn and Griebel (2017) for an error analysis of this scenario for single-layer regression. However, when following this approach, the choice of the specific discretization can severely influence the results of the minimization. Furthermore, we are limited by the size of the dimensions of the discretization spaces V_1, V_2, which influences the computational costs for solving the underlying optimization problem.

4. The effects of concatenated learning

This section serves to illustrate the main operating principle behind the concatenated interpolation and regression algorithms presented in the previous section. Note that our brief considerations in this section are not meant to provide a thorough numerical analysis of the performance of the algorithms but are rather thought to aid the understanding of their internal mechanisms. For benchmarks of highly performant variants of our basic algorithms on real-world data we refer the interested reader to Damianou and Lawrence (2013); Rebai et al. (2016); Zhuang et al. (2011).

4.1. Kernel choice

For reasons of simplicity, we will stick to the two-layer case and to outer function spaces $H(\Phi, \mathbb{R})$ with associated kernel K which are defined on the whole space $\mathbb{R}^D$. This way, the image Φ of the inner function space is automatically contained in the domain of the outer function space. Furthermore, if not stated otherwise, we assume that the matrix-valued kernel $\boldsymbol{K} : \Omega \times \Omega \to \mathbb{R}^{D\times D}$ of the inner RKHS can be written as

$$\boldsymbol{K}(\boldsymbol{x}, \boldsymbol{y}) = K_{\mathcal{I}}(\boldsymbol{x}, \boldsymbol{y}) \cdot \operatorname{diag}(\boldsymbol{a}) \tag{20}$$

for some weight vector $\boldsymbol{a} \in \mathbb{R}^D_+$. Here, $\operatorname{diag}(\boldsymbol{a})$ denotes the diagonal matrix $\boldsymbol{A}$ with $\boldsymbol{A}_{ii} = \boldsymbol{a}_i$ and $K_{\mathcal{I}} : \Omega \times \Omega \to \mathbb{R}$ is a scalar-valued kernel function.

Possible outer and inner kernel functions K and $K_{\mathcal{I}}$ are the polynomial kernel

$$K_{\mathrm{Poly},p}(\boldsymbol{x}, \boldsymbol{y}) := \left(\boldsymbol{x}^T \boldsymbol{y} + 1\right)^p,$$

the Gaussian kernel

$$K_{\mathrm{Gauss},\sigma}(\boldsymbol{x}, \boldsymbol{y}) := \exp\left(-\frac{\|\boldsymbol{x} - \boldsymbol{y}\|^2}{2\sigma^2}\right)$$

and the tensor-product Matérn kernel

$$K_{\mathrm{TensorMatérn},s}(\boldsymbol{x}, \boldsymbol{y}) := \prod_{i=1}^{d} \kappa_{\frac{2s-1}{2}}\left(|x_i - y_i|\right) \cdot |x_i - y_i|^{\frac{2s-1}{2}}.$$

where κ_α denotes the modified (hyperbolic) Bessel function of the second kind with parameter α. Note that the latter characterizes the Sobolev space of dominating mixed smoothness of order $s \in \mathbb{N}$, see e.g. Fasshauer and Ye (2011); Griebel and Harbrecht (2014) for a bivariate version. These Sobolev spaces play an important role for hyperbolic cross or sparse grid approximations for instance, see e.g. Bungartz and Griebel (2004). Note that the Gaussian kernel is already a tensor product kernel by nature.

4.2. Experiment design

Let us choose $\Omega = [-1, 1]^2$. We will evaluate our method for the two test functions

$$\begin{aligned} h_1 : \Omega \to \mathbb{R} \qquad & h_1(x, y) := (0.1 + |x - y|)^{-1} \\ h_2 : \Omega \to \mathbb{R} \qquad & h_2(x, y) := \begin{cases} 1 & \text{if } x \cdot y > \frac{3}{20} \\ 0 & \text{else} \end{cases}. \end{aligned}$$

The function h_1 employs a kink-like structure along the diagonal of the domain, while h_2 represents an indicator function with a jump. Neither of these two functions is an element of a reproducing kernel space spanned by any of the above kernel functions for arbitrary parameters $p, s \in \mathbb{N}, \sigma \in (0, \infty)$. Therefore they cannot be approximated too well by a single-layer method. The approximation of such functions with kinks or jumps by (a composition of) smooth functions plays an important role in applications from econometrics, finance or two-phase flow problems for example.

We choose $D = d = 2$, i.e. $\Omega, \Phi \subset \mathbb{R}^2$, and $\boldsymbol{a} = (1\ 1)^T$. Then, we independently draw $N = 100$ random equidistributed points $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N\} \subset \Omega$ and set $y_i := h_*(\boldsymbol{x}_i) + \varepsilon_i$ for all $i = 1, \ldots, N$ for the function $h_* \in \{h_1, h_2\}$. Here, ε_i are additive noise perturbations which are drawn i.i.d. according to a centered Gaussian distribution with standard deviation 0.01. To solve (Int) or (Reg), respectively, we use a BFGS algorithm with random initialization of the coefficient vector $\boldsymbol{c}$ of the inner function, see also (16). As the goal functions employ many local minima, we run the algorithm sufficiently many times to achieve a good approximation to the global minimum. It turned out that 64 runs were sufficient for our case of 100 data points in 2 dimensions. From the 64 runs we pick the vector $\boldsymbol{c}$ (and with this the functions f and $\boldsymbol{g}$) for which the smallest goal function value in (Int) or (Reg), respectively, is achieved.

To be able to compare our computed $f(g(\cdot))$, which approximates the true solution $f^*_{\boldsymbol{g}(X),Y}\left(\boldsymbol{g}^*(\cdot)\right)$ or $f^{\lambda}_{\boldsymbol{g}(X),Y}\left(\boldsymbol{g}^{\lambda,\mu}(\cdot)\right)$, respectively, to the result of a standard kernel interpolation/regression, we also calculate the interpolant/regressor $w \in \left\{f^*_{X,Y}, f^{\lambda}_{X,Y}\right\}$. This resembles the solution to (1) or (5), respectively, for the reproducing kernel Hilbert space $H(\Omega, \mathbb{R})$ which employs the same kernel type and parameters as $H(\Phi, \mathbb{R})$ but on the domain Ω instead of Φ. We then define $\boldsymbol{t}_i, i = 1, \ldots, n_t$, as the points of a uniform grid of meshwidth $\frac{1}{50}$ over $\Omega = [-1, 1]^2$, i.e. $n_t = 101^2$, and consider the *pointwise error*

$$\left|\left(f \circ \boldsymbol{g} - h_*\right)(\boldsymbol{t}_i)\right| \quad \text{and} \quad \left|\left(w - h_*\right)(\boldsymbol{t}_i)\right|,$$

which we visualize in a two-dimensional contour plot.

4.2.1. Interpolation

We first compare the results for two-layer interpolation, see (Int), with the results for single-layer interpolation, see (1). To this end, we choose an outer Matérn kernel $K = K_{\mathrm{TensorMatérn},s}$ with $s = 1$ and an inner polynomial kernel $K_{\mathcal{I}} = K_{\mathrm{Poly},p}$ with $p = 1$ or $p = 2$. In Figure 3 we display the pointwise errors. We observe that there is a visible improvement in the error when dealing with two-layer interpolation instead of single-layer interpolation. While the benefits of two-layer interpolation are already observable for the test function h_2, they become even more obvious for h_1. As explained in the beginning of Section 3, the fact that the kink of h_1 is not parallel to a coordinate axis poses a problem when dealing with the tensor-product kernel. Since a linear transformation (rotation) would suffice to remedy this problem, the polynomial kernel of degree $p = 1$ already suffices to obtain a better error behavior. Therefore, $p = 2$ can already lead to a small overfitting effect as we observe in Figure 3. Nevertheless, the error is still significantly better than in the single-layer case. In the case of h_2, however, we have a jump along two nonlinear curves. Here, $p = 2$ seems to be more appropriate to deal with this problem. Overall, we come to the conclusion that interpolation in reproducing kernel Hilbert spaces can significantly benefit from a two-layer approach if the reproducing kernel at hand does not suit the underlying function.

4.2.2. Regression

Now we have a look at solving the least-squares regression problem (Reg). To determine the optimal parameters λ and μ, we run a 5-fold cross-validation on the input data for all possible choices $\lambda, \mu \in \{2^{-2t+1} \mid t = 1, \ldots, 10\}$. Subsequently, we use the parameter pair (λ, μ) for which the smallest function value of (Reg) is achieved and run the regression

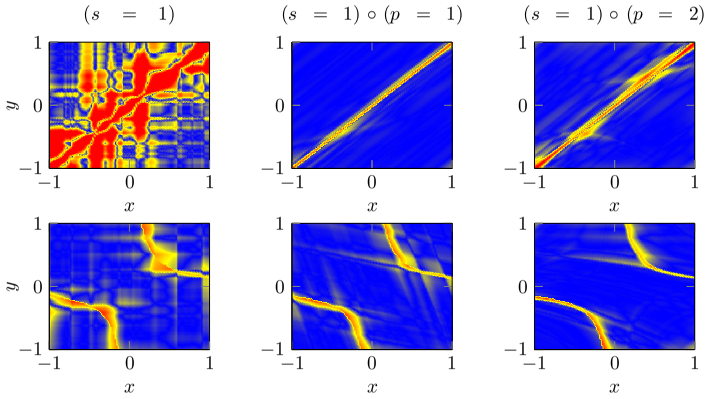

Figure 3: The pointwise error for standard interpolation with $w = f^*_{X,Y}$ (left) and for concatenated interpolation with outer kernel $K_{\text{TensorMatérn},1}$ and inner kernel $K_{\text{Poly},1}$ (mid) or $K_{\text{Poly},2}$ (right), respectively. We plotted both, the error for h_1 (top) and h_2 (bottom). The color scale ranges from blue (0% error) to red (more than 10% error), where the percentage has to be understood with respect to the $\|\cdot\|_{L_\infty}$ norm of h_1 or h_2, respectively.

algorithm on the whole input data set to obtain our final results. We compare the two-layer case with the single-layer regression, see also (5), with the parameter λ, which achieves the smallest error, i.e. we compare to the best possible single-layer solution.

Since the results for interpolation and least-squares regression with the same kernel choices as above happen to be similar, we employ an outer kernel of Gaussian type $K = K_{\text{Gauss},\sigma}$ with $\sigma = 0.1$ instead of Matérn type here. For the inner kernel we again choose $K_{\mathcal{I}} = K_{\text{Poly},p}$ with $p = 1, 2$. As we observe in Figure 4, there is a significant improvement of the two-layer approach over the single-layer one. Note that we deliberately employ the kernel width $\sigma = 0.1$, which appears to be too small for single-layer regression. However, the two-layer approach seems to remedy this bad choice automatically by adjusting the inner transformation accordingly. In this regard, the algorithm can also be understood as an implicit hyperparameter tuner.

4.2.3. Linear outer kernel

In this section, we again want to emphasize the difference of our approach, which allows for nonlinear outer kernels, to the MKL-type RLS2 algorithm of Dinuzzo (2011), where only a linear outer kernel is considered and the inner kernel is given by a diagonal matrix with its entries being different scalar-valued (nonlinear) kernels. To this end, we run our two-layer least-squares regression approach for the following two settings:

(1) Outer polynomial kernel $K = K_{\text{Poly},1}$ of order 1, inner mixture kernel $\boldsymbol{K}(\boldsymbol{x}, \boldsymbol{y})$,

(2) Outer Matérn kernel $K = K_{\text{TensorMatérn},1}$ of order 1, inner mixture kernel $\boldsymbol{K}(\boldsymbol{x}, \boldsymbol{y})$.

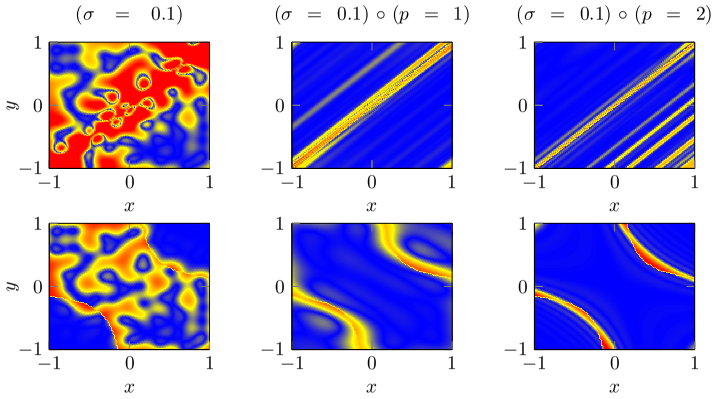

Figure 4: The pointwise error for standard least-squares with $w = f^{\lambda}_{X,Y}$ (left) and for concatenated least-squares with outer kernel $K_{\text{Gauss},0.1}$ and inner kernel $K_{\text{Poly},1}$ (mid) or $K_{\text{Poly},2}$ (right), respectively. We plotted both, the error for h_1 (top) and h_2 (bottom). The color scale ranges from blue (0% error) to red (more than 10% error), where the percentage has to be understood with respect to the $\|\cdot\|_{L_\infty}$ norm of h_1 or h_2, respectively.

For the inner mixture kernel, we deviate from (20) and from $D = 2$ here. To this end, we set $D = 5$ and use a diagonal kernel $\boldsymbol{K}$ with different scalar-valued kernels as entries. For the five scalar-valued kernels we choose three Gaussian kernels $K_{\text{Gauss},\sigma}$ with $\sigma = 0.1, 1, 10$ and two polynomial kernels $K_{\text{Poly},p}$ with $p = 1, 2$. Setting (1) serves to represent the RLS2 algorithm[4], where similar choices for the inner kernel have been made, see Dinuzzo (2011). To determine the optimal parameters $\lambda, \mu \in \{10^{-2t+1} \mid t = 1, \ldots, 6\}$, we again run a 5-fold crossvalidation[5]. The results can be found in figure 5. As we have already seen for interpolation, the structure of the function h_1 admits a good representation by a two-layer kernel discretization of type (2). However, despite the quite generic choice of the inner kernel in setting (1), the two-layer kernel approach with a linear outer kernel is not able to find a good representation of the function. This shows that a nonlinear choice for the outer kernel can be necessary to find suitable approximations by the two-layer algorithm. Although the results do not differ that much for h_2, we again see that there is a slight advantage in approximating with a nonlinear outer kernel.

4. Note however that we did not use a diagonal scaling of the linear kernel and our optimization algorithm is different from the one used in Dinuzzo (2011), which is adjusted to the problem with a linear outer kernel.

5. Note that we scan a coarser (but wider) range than in the previous section, which seemed to be appropriate here.

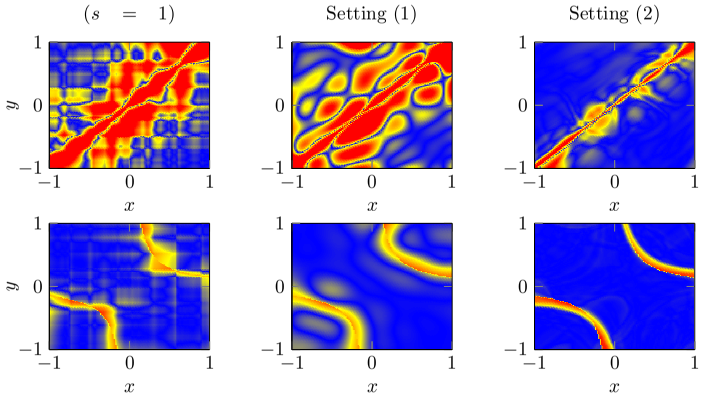

Figure 5: The pointwise error for standard least-squares with Matérn kernel and $w = f^{\lambda}_{X,Y}$ (left) and for concatenated least-squares with setting (1) (mid) and setting (2) (right) from section 4.2.3. We plotted both, the error for h_1 (top) and h_2 (bottom). The color scale ranges from blue (0% error) to red (more than 10% error), where the percentage has to be understood with respect to the $\|\cdot\|_{L_\infty}$ norm of h_1 or h_2, respectively.

4.3. Transformation by the inner function

To get a better impression on how the two-layer algorithms work, we exemplarily inspect the inner function $\boldsymbol{g}$ in the case of interpolation with $K = K_{\text{TensorMatérn},s}$ for $s = 1$ and $K_{\mathcal{I}} = K_{\text{Poly},p}$ for $p = 1$ or $p = 2$, i.e. for the setting from Section 4.2.1. To this end, we depict isotropic grid points in $\Omega = [-1, 1]^2$ and have a look at how these points are transformed by $\boldsymbol{g}$ in Figure 6.

We observe that for h_1 in both cases $p = 1$ and $p = 2$, the inner function aligns the kink almost perpendicular to the y-axis. Therefore, one can easily characterize the kink by the y-coordinate after the inner transformation. This reduces the original two-dimensional kink description $x - y = 0$ to just the one-dimensional description $y = 0$. While the function with the kink along the diagonal does not reside in the tensor-product Matérn space of order 1, which corresponds to the outer kernel in this example, a function with a kink parallel to one of the coordinate axes does. Therefore, the inner function $\boldsymbol{g}$ transforms the domain in such a way that the result resides in the RKHS to which the outer function belongs.

Considering the test function h_2, we see that a linear inner transformation, i.e. $p = 1$, essentially just rotates and shears the domain and does not change the alignment of the jump very much. However, in the case $p = 2$, the inner function $\boldsymbol{g}$ manages to transform the domain in such a way that the jump is now almost parallel to the y-axis. We observe that the pointwise errors in Figure 3 really benefit from this transformation and the jump is resolved almost perfectly. Overall, we see that the inner function $\boldsymbol{g}$ tries to align the features of the original test function in such a way that they can be easily resolved by the outer function f.

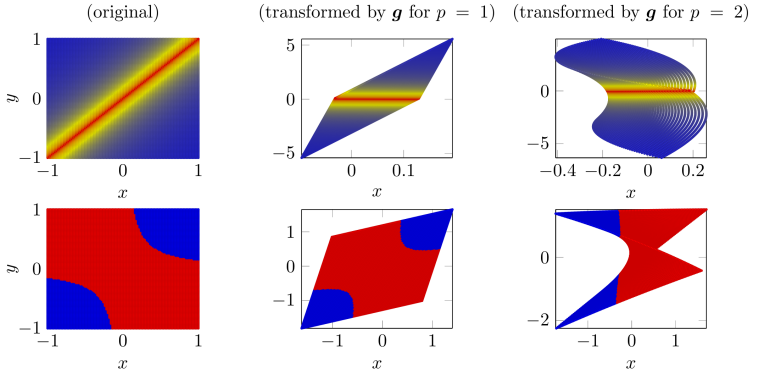

Figure 6: The transformation of the isotropic grid points (left) by the inner function with $p = 1$ (mid) and $p = 2$ (right). The underlying problem is interpolation of h_1 (top) and h_2 (bottom) for the outer kernel $K_{\text{TensorMatérn},1}$ and the inner kernel $K_{\text{Poly},p}$. The color scale represents the values of h_1 or h_2, respectively.

5. Conclusion

In this paper, we presented both a finite- and an infinite-sample representer theorem for concatenated machine learning problems. In the finite-sample case, the statement essentially boils down to the fact that the a priori infinite-dimensional optimization problem, which appears when dealing with function compositions from reproducing kernel Hilbert spaces, can be recast into a finite-dimensional optimization problem, where we only have to deal with at most N kernel translates in each layer of the composition. Here, N denotes the number of input data points. In the infinite-sample case, we derived an analogous result stating that the solution in each layer is an element of the image space of the integral operator defined by the corresponding kernel evaluated at the innermost functions. We introduced a simple neural network architecture, which represents the concatenated functions we are dealing with. Furthermore, we established a connection between our representer theorem and two types of state-of-the-art deep learning algorithms, namely multi-layer multiple kernel learning and deep kernel networks. Finally, we presented a detailed analysis on a two-layer interpolation and a two-layer least-squares regression algorithm, which can directly be derived from our representer theorem. We illustrated the operating principles of these algorithms with the help of two artificial test functions and explained why the two-layer approach is able to remedy the shortcomings of a single-layer variant. Furthermore, we highlighted that the use of a nonlinear outer kernel, instead of a linear one as in Dinuzzo (2011), can be inevitable to obtain good two-layer approximations. Nevertheless, the nonlinearity of the outer layer makes the numerical treatment of the underlying optimization problem more difficult.

While we presented specific two-layer ($L = 2$) algorithms and applied them to two-dimensional ($d = 2$) toy problems for illustrative reasons, our representer theorems can also be applied in the high-dimensional case with an arbitrary number of layers. Note

furthermore that, apart from interpolation and least-squares regression, also more general choices of the loss function $\mathcal{L}$ and the regularizers Θ_l are allowed in (7). Therefore, one can also think of multi-layer support vector machines for instance. The construction of such efficient deep kernel learning algorithms for high-dimensional problems and a thorough analysis of the interplay between the number of layers L and the dimension d will be future work.

Appendix A. Remainder of the proof of theorem 2

To continue the proof of theorem 2, we note that we already showed that f_1 has the desired structure (14). Let us assume we have shown (14) for all $f_1, \dots, f_{l-1}$ for an $l \in \{2, \dots, L\}$. To obtain (14) for f_l, we proceed in the same fashion as in the first part of the proof in section 3.2. To this end, we now define $J_{g_{l+1},\dots,g_L} : \mathcal{H}_l \to [0,\infty)$ by

$$J_{g_{l+1},\dots,g_L}(g_l) := \int_{R_{l+1}\times R_1} \tilde{\mathcal{L}}_l\left(y, g_l(\boldsymbol{\xi})\right) \, \mathrm{d}G_{l,\star}(\mathbb{P})(\boldsymbol{\xi}, y) + \lambda_l \|g_l\|^2_{\mathcal{H}_l},$$

where $\tilde{\mathcal{L}}_l(y, \boldsymbol{z}) := \mathcal{L}(y, f_1 \circ \ldots \circ f_{l-1}(\boldsymbol{z}))$ and $G_{l,\star}(\mathbb{P})$ is the pushforward of $\mathbb{P}$ onto $R_{l+1} \times R_1$ defined by $G_l(\boldsymbol{x}, y) = (g_{l+1} \circ \ldots \circ g_L(\boldsymbol{x}), y)$. Then it holds

$$\begin{aligned}
&\min_{g_l \in \mathcal{H}_l, \dots, g_L \in \mathcal{H}_L} J(f_1, f_2, \dots, f_{l-1}, g_l, g_{l+1}, \dots, g_L) \\
&= \min_{g_{l+1} \in \mathcal{H}_{l+1}, \dots, g_L \in \mathcal{H}_L} \left(\min_{g_l \in \mathcal{H}_l} J_{g_{l+1},\dots,g_{l+1}}(g_l) \right) + \sum_{i=l+1}^{L} \lambda_i \|g_i\|^2_{\mathcal{H}_i}
\end{aligned}$$

and we need to show that a minimizer of $J_{g_{l+1},\dots,g_L}$ admits a representation of type (14). To this end, we begin by defining a Nemitski vector loss function and we subsequently prove that these loss functions admit the representation we need.

Definition 5 *Let $\mathcal{L} : R_1 \times D \to [0,\infty)$ for some domain $D \subset \mathbb{R}^d$. Let $\mathbb{P}_{R_1}$ denote the marginal distribution of $\mathbb{P}$ w.r.t. the second variable. We call $\mathcal{L}$ a $\mathbb{P}$-integrable Nemitski vector loss, if there exist $b : R_1 \to [0,\infty)$ with $b \in L_{1,\mathbb{P}_{R_1}}(R_1)$ and a measurable, increasing $h : [0,\infty) \to [0,\infty)$ such that*

$$\mathcal{L}(y, \boldsymbol{z}) \le b(y) + h(\|\boldsymbol{z}\|) \quad \text{for all } (y, \boldsymbol{z}) \in R_1 \times D.$$

If $\mathcal{L}$ is k-times differentiable w.r.t. the second variable for all $y \in R_1$, we call it a k-times differentiable Nemitski vector loss.

Lemma 6 *Let $l \in \{2, \dots, L\}$ and let $\mathbb{P}^l$ be a distribution[6] on $R_{l+1} \times R_1$ and let $\mathcal{L}^\star$ be a $\mathbb{P}^l$-integrable and 1-differentiable Nemitski vector loss on $R_1 \times R_l$ such that the derivative w.r.t. the second argument $\nabla_2 \mathcal{L}$ fulfills*

$$\|\nabla_2 \mathcal{L}^\star(y, \boldsymbol{z})\| \le b^\star(y) + h^\star(\|\boldsymbol{z}\|) \quad \text{for all } (y, \boldsymbol{z}) \in R_1 \times R_l$$

for some $b^\star \in L_{1,\mathbb{P}^l_{R_1}}(R_1)$ and a measurable, increasing $h^\star : [0,\infty) \to [0,\infty)$. Then, the functional $\mathcal{R}_{l,\mathbb{P}^l} : \mathcal{H}_l \to [0,\infty)$ defined by

$$\mathcal{R}_{l,\mathbb{P}^l}(f) := \int_{R_{l+1}\times R_1} \mathcal{L}^\star(y, f(\boldsymbol{z})) \, \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y)$$

is Frechet differentiable and the derivative $\mathrm{d}\mathcal{R}_{l,\mathbb{P}^l} : \mathcal{H}_l \to \mathcal{B}(\mathcal{H}_l, \mathbb{R})$ is given by

$$\mathrm{d}\mathcal{R}_{l,\mathbb{P}^l}(f)(g) = \int_{R_{l+1}\times R_1} \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot g(\boldsymbol{z}) \, \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y). \tag{21}$$

Furthermore, a critical point of $J^\star : \mathcal{H}_l \to [0,\infty)$ defined by

$$J^\star(f) := \mathcal{R}_{l,\mathbb{P}^l}(f) + \lambda_l \|f\|^2_{\mathcal{H}_l}$$

is given by

$$f(\cdot) = -\frac{1}{2\lambda_l} \int_{R_{l+1}\times R_1} K_l(\cdot, \boldsymbol{z}) \cdot \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z})) \, \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y). \tag{22}$$

Proof We have

$$\begin{aligned}
&\lim_{\|g\|_{\mathcal{H}_l} \to 0} \frac{\mathcal{R}_{l,\mathbb{P}^l}(f+g) - \mathcal{R}_{l,\mathbb{P}^l}(f) - \int_{R_{l+1}\times R_1} \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot g(\boldsymbol{z}) \, \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y)}{\|g\|_{\mathcal{H}_l}} \\
&= \lim_{\|g\|_{\mathcal{H}_l} \to 0} \int_{R_{l+1}\times R_1} \frac{\mathcal{L}^\star(y, f(\boldsymbol{z}) + g(\boldsymbol{z})) - \mathcal{L}^\star(y, f(\boldsymbol{z})) - \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot g(\boldsymbol{z})}{\|g\|_{\mathcal{H}_l}} \, \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y) \\
&\overset{(*)}{=} \int_{R_{l+1}\times R_1} \lim_{\|g\|_{\mathcal{H}_l} \to 0} \frac{\mathcal{L}^\star(y, f(\boldsymbol{z}) + g(\boldsymbol{z})) - \mathcal{L}^\star(y, f(\boldsymbol{z})) - \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot g(\boldsymbol{z})}{\|g\|_{\mathcal{H}_l}} \, \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y) \\
&= 0,
\end{aligned}$$

where the last equation follows from the differentiability of $\mathcal{L}^\star$ and $(*)$ follows by the dominated convergence theorem since the integrand is bounded by

$$\begin{aligned}
&\left| \frac{\mathcal{L}^\star(y, f(\boldsymbol{z}) + g(\boldsymbol{z})) - \mathcal{L}^\star(y, f(\boldsymbol{z})) - \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot g(\boldsymbol{z})}{\|g\|_{\mathcal{H}_l}} \right| \\
&= \left| \frac{\nabla_2 \mathcal{L}^\star(y, cf(\boldsymbol{z}) + (1-c)g(\boldsymbol{z}))^T \cdot g(\boldsymbol{z}) - \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot g(\boldsymbol{z})}{\|g\|_{\mathcal{H}_l}} \right| \\
&\le 2b^\star(y) + h^\star(\|cf(\boldsymbol{z}) + (1-c)g(\boldsymbol{z})\|) + h^\star(\|f(\boldsymbol{z})\|)
\end{aligned}$$

6. Note that we set $R_{L+1} := D_L = \Omega$.

for some $c \in [0,1]$ due to the mean value theorem. Since the last line is bounded by $2b^\star(y) + 2h^\star(\|f(\boldsymbol{z})\| + 1)$ independently of g for any g with $\|g\|_{\mathcal{H}_l} \leq 1$, the dominated convergence theorem can be applied, which proves (21).

Since a critical point f of $J^\star$ fulfills

$$0 = \mathrm{d}J^\star(f)(g) = \mathrm{d}\mathcal{R}_{l,\mathbb{P}^l}(f)(g) + 2\lambda_l \langle f, g\rangle_{\mathcal{H}_l},$$

for all $g \in \mathcal{H}_l$, we obtain

$$\begin{aligned}
\langle f, g\rangle_{\mathcal{H}_l} =& -\frac{1}{2\lambda_l}\mathrm{d}\mathcal{R}_{l,\mathbb{P}^l}(f)(g) \\
=& -\frac{1}{2\lambda_l}\int_{R_{l+1}\times R_1} \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot g(\boldsymbol{z})\ \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y) \\
=& -\frac{1}{2\lambda_l}\int_{R_{l+1}\times R_1} \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T \cdot \sum_{i=1}^{d_l} \langle g, K_l(\cdot, \boldsymbol{z})\boldsymbol{e}_i\rangle_{\mathcal{H}_l} \cdot \boldsymbol{e}_i\ \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y) \\
=& -\frac{1}{2\lambda_l}\sum_{i=1}^{d_l}\left\langle \int_{R_{l+1}\times R_1} \nabla_2 \mathcal{L}^\star(y, f(\boldsymbol{z}))^T K_l(\cdot, \boldsymbol{z})\boldsymbol{e}_i\ \mathrm{d}\mathbb{P}^l(\boldsymbol{z}, y), g\right\rangle_{\mathcal{H}_l} \cdot \boldsymbol{e}_i
\end{aligned}$$

with the reproducing property of K_l, which is equivalent to the Bochner-type integral formulation (22). This finishes the proof. ■

Now, we can apply lemma 6 with $\mathbb{P}^l = G_{l,\star}(\mathbb{P})$ and $\mathcal{L}^\star = \tilde{\mathcal{L}}_l$, which shows that a critical point $g_l^\star$ of $J_{g_{l+1},\ldots,g_L}$ can be written as

$$\begin{aligned}
g_l^\star(\cdot) =& -\frac{1}{2\lambda_l}\int_{R_{l+1}\times R_1} K_l(\cdot, \boldsymbol{\xi}) \cdot \nabla_2 \tilde{\mathcal{L}}_l(y, g_l^\star(\boldsymbol{\xi}))\ \mathrm{d}G_{l,\star}(\mathbb{P})(\boldsymbol{\xi}, y) \qquad (23) \\
=& -\frac{1}{2\lambda_l}\int_{\Omega\times R_1} K_l(\cdot, g_{l+1}\circ\ldots\circ g_L(\boldsymbol{x})) \cdot \nabla_2 \tilde{\mathcal{L}}_l(y, g_l^\star \circ g_{l+1}\circ\ldots\circ g_L(\boldsymbol{x}))\ \mathrm{d}\mathbb{P}(\boldsymbol{x}, y),
\end{aligned}$$

which is of type (14). Therefore, it just remains to show that $\tilde{\mathcal{L}}_l$ fulfills the prerequisites of lemma 6 and that $A_{f_l, f_{l+1},\ldots,f_L}(\boldsymbol{x}, y) := \nabla_2 \tilde{\mathcal{L}}_l(y, f_l \circ f_{l+1}\circ\ldots\circ f_L(\boldsymbol{x})) \in L_{1,\mathbb{P}}$.

Lemma 7 *$\tilde{\mathcal{L}}_l$ is a $G_{l,\star}(\mathbb{P})$-integrable and 1-differentiable Nemitski loss and the derivative w.r.t. the second argument fulfills*

$$\left\|\nabla_2 \tilde{\mathcal{L}}_l(y, \boldsymbol{z})\right\| \leq \tilde{b}(y) + \tilde{h}(\|\boldsymbol{z}\|) \quad \text{for all } (y, \boldsymbol{z}) \in R_1 \times R_l \qquad (24)$$

for a $\tilde{b} \in L_{1,G_{l,\star}(\mathbb{P})_{R_1}}(R_1)$ and a measurable, increasing $\tilde{h} : [0,\infty) \to [0,\infty)$.

Proof Since

$$|\tilde{\mathcal{L}}_l(y, \boldsymbol{z})| = |\mathcal{L}(y, f_1\circ\ldots\circ f_{l-1}(\boldsymbol{z}))| \leq b_0(y) + h_0(f_1\circ\ldots\circ f_{l-1}(\boldsymbol{z})) \leq b_0(y) + h_0(\|f_1\|_\infty),$$

$\tilde{\mathcal{L}}_l$ is a $G_{l,\star}(\mathbb{P})$-integrable Nemitski-loss. Here, we again used that $f_1 \in \mathcal{H}_1 \hookrightarrow C(D_1)$ because of (12). Since $f_1, \ldots, f_{l-1}$ are differentiable because the respective kernels are in C^1, $\tilde{\mathcal{L}}_l$ is

also 1-differentiable by the chain rule. It remains to show (24). To this end, note that the chain rule gives us

$$\begin{aligned}
&\nabla_2 \tilde{\mathcal{L}}_l(y, \boldsymbol{z})(\cdot) = \frac{\partial}{\partial \boldsymbol{z}}\left(\mathcal{L}\left(y, f_1\circ\ldots\circ f_{l-1}(\boldsymbol{z})\right)\right) \\
&= \mathcal{L}^{(1)}(y, f_1\circ\ldots\circ f_{l-1}(\boldsymbol{z})) \cdot \mathrm{d}f_1(f_2\circ\ldots\circ f_{l-1}(\boldsymbol{z}))\left(\mathrm{d}f_2(f_3\circ\ldots\circ f_{l-1}(\boldsymbol{z}))\left(\ldots \mathrm{d}f_{l-1}(\boldsymbol{z})(\cdot)\right)\right),
\end{aligned}$$

which leads to

$$\begin{aligned}
\|\nabla_2 \tilde{\mathcal{L}}_l(y, \boldsymbol{z})\| \leq& \left(b_1(y) + h_1(|f_1\circ\ldots\circ f_{l-1}(\boldsymbol{z})|)\right) \cdot \prod_{i=1}^{l-1}\sup_{\boldsymbol{x}_i \in D_i} \|\mathrm{d}f_i(\boldsymbol{x}_i)\|_{\mathcal{B}(D_i,R_i)} \\
\leq& \left(b_1(y) + h_1(\|f_1\|_\infty)\right) \cdot \prod_{i=1}^{l-1}\sup_{\boldsymbol{x}_i \in D_i} \|\mathrm{d}f_i(\boldsymbol{x}_i)\|_{\mathcal{B}(D_i,R_i)}. \qquad (25)
\end{aligned}$$

Because of our assumption that we already showed (14) for $f_1, \ldots, f_{l-1}$ and because of (12), we get by the dominated convergence theorem that

$$\sup_{\boldsymbol{x}_i \in D_i} \|\mathrm{d}f_i(\boldsymbol{x}_i)\|_{\mathcal{B}(D_i,R_i)} \leq \frac{1}{2\lambda_i} c_i \|A_{f_i,\ldots,f_L}\|_{L_{1,\mathbb{P}}}$$

for all $i = 1, \ldots, l-1$. Therefore, by setting $\tilde{b}(y) := c \cdot b_1(y)$ and choosing a constant $\tilde{h} := c \cdot h_1(\|f_1\|_\infty)$ with $c := \prod_{i=1}^{l-1} \frac{1}{2\lambda_i} c_i \|A_{f_i,\ldots,f_L}\|_{L_{1,\mathbb{P}}} < \infty$, we obtain (24). ■

Applying lemma 6 and lemma 7 shows us that f_l fulfills the integral equation (23). To conclude the proof of theorem 2, we note that

$$A_{f_l, f_{l+1},\ldots,f_L}(\boldsymbol{x}, y) := \nabla_2 \tilde{\mathcal{L}}_l(y, f_l \circ f_{l+1}\circ\ldots\circ f_L(\boldsymbol{x})) \in L_{1,\mathbb{P}},$$

which directly follows from (25) and the fact that $b_1 \in L_{1,\mathbb{P}_{R_1}}$. This finally shows that f_l admits a representation of type (14). Since the argument is valid for each $l = 2, \ldots, L$ and we already proved (14) for $l = 1$ in section 3.2, this finishes the proof of theorem 2.

Abstract

We design an active learning algorithm for cost-sensitive multiclass classification: problems where different errors have different costs. Our algorithm, COAL, makes predictions by regressing to each label's cost and predicting the smallest. On a new example, it uses a set of regressors that perform well on past data to estimate possible costs for each label. It queries only the labels that *could be* the best, ignoring the sure losers. We prove COAL can be efficiently implemented for any regression family that admits squared loss optimization; it also enjoys strong guarantees with respect to predictive performance and labeling effort. We empirically compare COAL to passive learning and several active learning baselines, showing significant improvements in labeling effort and test cost on real-world datasets.

Keywords: Active Learning, Cost-sensitive Learning, Structured Prediction, Statistical Learning Theory, Oracle-based Algorithms.

1. Introduction

The field of active learning studies how to efficiently elicit relevant information so learning algorithms can make good decisions. Almost all active learning algorithms are designed for binary classification problems, leading to the natural question: How can active learning address more complex prediction problems? Multiclass and importance-weighted classification require only minor modifications but we know of no active learning algorithms that enjoy theoretical guarantees for more complex problems.

One such problem is cost-sensitive multiclass classification (CSMC). In CSMC with K classes, passive learners receive input examples x and cost vectors $c \in \mathbb{R}^K$, where $c(y)$ is the cost of predicting label y on x.[1] A natural design for an *active* CSMC learner then is to adaptively query the costs of only a (possibly empty) subset of labels on each x. Since measuring label complexity is more nuanced in CSMC (e.g., is it more expensive to query three costs on a single example or one cost on three examples?), we track both the number of examples for which at least one cost is queried, along with the total number of cost queries issued. The first corresponds to a fixed human effort for inspecting the example. The second captures the additional effort for judging the cost of each prediction, which depends on the number of labels queried. (By querying a label, we mean querying the cost of predicting that label given an example.)

In this setup, we develop a new active learning algorithm for CSMC called Cost Overlapped Active Learning (COAL). COAL assumes access to a set of regression functions, and, when processing an example x, it uses the functions with good past performance to compute the range of possible costs that each label might take. Naturally, COAL only queries labels with large cost range, akin to uncertainty-based approaches in active regression (Castro et al., 2005), but furthermore, it only queries labels that could possibly have the smallest cost, avoiding the uncertain, but surely suboptimal labels. The key algorithmic innovation is an efficient way to compute the cost range realized by good regressors. This computation, and COAL as a whole, only requires that the regression functions admit efficient squared loss optimization, in contrast with prior algorithms that require 0/1 loss optimization (Beygelzimer et al., 2009; Hanneke, 2014).

Among our results, we prove that when processing n (unlabeled) examples with K classes and a regression class with pseudo-dimension d (See Definition 1),

1. The algorithm needs to solve $\mathcal{O}(Kn^5)$ regression problems over the function class (Corollary 4). Thus COAL runs in polynomial time for convex regression sets.

2. With no assumptions on the noise in the problem, the algorithm achieves generalization error $\tilde{\mathcal{O}}(\sqrt{Kd/n})$ and requests $\tilde{\mathcal{O}}(n\theta_2\sqrt{Kd})$ costs from $\tilde{\mathcal{O}}(n\theta_1\sqrt{Kd})$ examples (Theorems 5 and 9) where θ_1, θ_2 are the disagreement coefficients (Definition 8)[2]. The worst case offers minimal improvement over passive learning, akin to active learning for binary classification.

3. With a Massart-type noise assumption (Assumption 3), the algorithm has generalization error $\tilde{\mathcal{O}}(Kd/n)$ while requesting $\tilde{\mathcal{O}}(Kd(\theta_2 + K\theta_1)\log n)$ labels from $\tilde{\mathcal{O}}(Kd\theta_1 \log n)$ examples (Corollary 6, Theorem 10). Thus under favorable conditions, COAL requests *exponentially fewer* labels than passive learning.

We also derive generalization and label complexity bounds under a milder Tsybakov-type noise condition (Assumption 4). Existing lower bounds from binary classification (Hanneke, 2014) suggest that our results are optimal in their dependence on n, although these lower bounds do not directly apply to our setting. We also discuss some intuitive examples highlighting the benefits of using COAL.

CSMC provides a more expressive language for success and failure than multiclass classification, which allows learning algorithms to make the trade-offs necessary for good performance and broadens potential applications. For example, CSMC can naturally express

1. Cost here refers to prediction cost and not labeling effort or the cost of acquiring different labels.
2. $\tilde{\mathcal{O}}(\cdot)$ suppresses logarithmic dependence on n, K, and d.

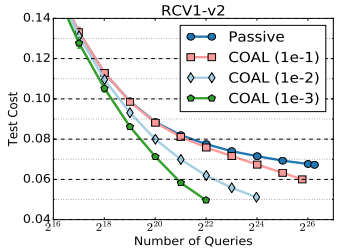

Figure 1: Empirical evaluation of COAL on Reuters text categorization dataset. Active learning achieves *better* test cost than passive, with a factor of 16 fewer queries. See Section 7 for details.

partial failure in hierarchical classification (Silla Jr. and Freitas, 2011). Experimentally, we show that COAL substantially outperforms the passive learning baseline with orders of magnitude savings in the labeling effort on a number of hierarchical classification datasets (see Figure 1 for comparison between passive learning and COAL on Reuters text categorization).

CSMC also forms the basis of learning to avoid cascading failures in joint prediction tasks like structured prediction and reinforcement learning (Daumé III et al., 2009; Ross and Bagnell, 2014; Chang et al., 2015). As our second application, we consider learning to search algorithms for joint or structured prediction, which operate by a reduction to CSMC. In this reduction, evaluating the cost of a class often involves a computationally expensive "roll-out," so using an active learning algorithm inside such a passive joint prediction method can lead to significant computational savings. We show that using COAL within the Aggravate algorithm (Ross and Bagnell, 2014; Chang et al., 2015) reduces the number of roll-outs by a factor of $\frac{1}{4}$ to $\frac{3}{4}$ on several joint prediction tasks.

Our code is publicly available as part of the Vowpal Wabbit machine learning library.[3]

2. Related Work

Active learning is a thriving research area with many theoretical and empirical studies. We recommend the survey of Settles (2012) for an overview of more empirical research. We focus here on theoretical results.

Our work falls into the framework of *disagreement-based active learning*, which studies general hypothesis spaces typically in an agnostic setup (see Hanneke (2014) for an excellent survey). Existing results study binary classification, while our work generalizes to CSMC, assuming that we can accurately predict costs using regression functions from our class. One difference that is natural for CSMC is that our query rule checks the range of predicted costs for a label.

The other main difference is that we use a square loss oracle to search the version space. In contrast, prior work either explicitly enumerates the version space (Balcan et al., 2006; Zhang and Chaudhuri, 2014) or uses a 0/1 loss *classification* oracle for the search (Dasgupta et al., 2007; Beygelzimer et al., 2009, 2010; Huang et al., 2015). In most instantiations, the oracle solves an NP-hard problem and so does not directly lead to an efficient algorithm, although practical implementations using heuristics are still quite effective. Our approach instead uses a squared-loss *regression* oracle, which can be implemented efficiently via convex optimization and leads to a polynomial time algorithm.

In addition to disagreement-based approaches, much research has focused on plug-in rules for active learning in binary classification, where one estimates the class-conditional regression function (Castro and Nowak, 2008; Minsker, 2012; Hanneke and Yang, 2012; Carpentier et al., 2017). Apart from Hanneke and Yang (2012), these works make smoothness assumptions and have a nonparametric flavor. Instead, Hanneke and Yang (2012) assume a calibrated surrogate loss and abstract realizable function class, which is more similar to our setting. While the details vary, our work and these prior results employ the same algorithmic recipe of maintaining an implicit version space and querying in a suitably-defined disagreement region. Our work has two notable differences: (1) our algorithm operates in an oracle computational model, only accessing the function class through square loss minimization problems, (2) our results apply to general CSMC, which exhibit significant differences from binary classification. See Subsection 6.1 for further discussion.

Focusing on linear representations, Balcan et al. (2007); Balcan and Long (2013) study active learning with distributional assumptions, while the selective sampling framework from the online learning community considers adversarial assumptions (Cavallanti et al., 2011; Dekel et al., 2010; Orabona and Cesa-Bianchi, 2011; Agarwal, 2013). These methods use query strategies that are specialized to linear representations and do not naturally generalize to other hypothesis classes.

Supervised learning oracles that solve NP-hard optimization problems in the worst case have been used in other problems including contextual bandits (Agarwal et al., 2014; Syrgkanis et al., 2016) and structured prediction (Daumé III et al., 2009). Thus we hope that our work can inspire new algorithms for these settings as well.

Lastly, we mention that square loss regression has been used to estimate costs for passive CSMC (Langford and Beygelzimer, 2005), but, to our knowledge, using a square loss oracle for active CSMC is new.

Advances over Krishnamurthy et al. (2017). Active learning for CSMC was introduced recently in Krishnamurthy et al. (2017) with an algorithm that also uses cost ranges to decide where to query. They compute cost ranges by using the regression oracle to perform a binary search for the maximum and minimum costs, but this computation results in a sub-optimal label complexity bound. We resolve this sub-optimality with a novel cost range computation that is inspired by the multiplicative weights technique for solving linear programs. This algorithmic improvement also requires a significantly more sophisticated statistical analysis for which we derive a novel uniform Freedman-type inequality for classes with bounded pseudo-dimension. This result may be of independent interest.

Krishnamurthy et al. (2017) also introduce an online approximation for additional scalability and use this algorithm for their experiments. Our empirical results use this same online approximation and are slightly more comprehensive. Finally, we also derive general-

3. `http://hunch.net/~vw`

ization and label complexity bounds for our algorithm in a setting inspired by Tsybakov's low noise condition (Mammen and Tsybakov, 1999; Tsybakov, 2004).

Comparison with Foster et al. (2018). In a follow-up to the present paper, Foster et al. (2018) build on our work with a regression-based approach for contextual bandit learning, a problem that bears some similarities to active learning for CSMC. The results are incomparable due to the differences in setting, but it is worth discussing their techniques. As in our paper, Foster et al. (2018) maintain an implicit version space and compute maximum and minimum costs for each label, which they use to make predictions. They resolve the sub-optimality in Krishnamurthy et al. (2017) with epoching, which enables a simpler cost range computation than our multiplicative weights approach. However, epoching incurs an additional $\log(n)$ factor in the label complexity, and under low-noise conditions where the overall bound is $\mathcal{O}(\text{polylog}(n))$, this yields a polynomially worse guarantee than ours.

3. Problem Setting and Notation

We study cost-sensitive multiclass classification (CSMC) problems with K classes, where there is an instance space $\mathcal{X}$, a label space $\mathcal{Y} = \{1, \ldots, K\}$, and a distribution $\mathcal{D}$ supported on $\mathcal{X} \times [0,1]^K$.[4] If $(x, c) \sim \mathcal{D}$, we refer to c as the *cost-vector*, where $c(y)$ is the cost of predicting $y \in \mathcal{Y}$. A classifier $h : \mathcal{X} \to \mathcal{Y}$ has expected cost $\mathbb{E}_{(x,c)\sim\mathcal{D}}[c(h(x))]$ and we aim to find a classifier with minimal expected cost.

Let $\mathcal{G} \triangleq \{g : \mathcal{X} \mapsto [0,1]\}$ denote a set of base regressors and let $\mathcal{F} \triangleq \mathcal{G}^K$ denote a set of vector regressors where the y^{th} coordinate of $f \in \mathcal{F}$ is written as $f(\cdot; y)$. The set of classifiers under consideration is $\mathcal{H} \triangleq \{h_f \mid f \in \mathcal{F}\}$ where each f defines a classifier $h_f : \mathcal{X} \mapsto \mathcal{Y}$ by

$$h_f(x) \triangleq \operatorname*{argmin}_y f(x; y). \tag{1}$$

When using a set of regression functions for a classification task, it is natural to assume that the expected costs under $\mathcal{D}$ can be predicted by some function in the set. This motivates the following realizability assumption.

Assumption 1 (Realizability) *Define the Bayes-optimal regressor $f^\star$, which has $f^\star(x; y) \triangleq \mathbb{E}_c[c(y)|x], \forall x \in \mathcal{X}$ (with $\mathcal{D}(x) > 0$), $y \in \mathcal{Y}$. We assume that $f^\star \in \mathcal{F}$.*

While $f^\star$ is always well defined, note that the cost itself may be noisy. In comparison with our assumption, the existence of a zero-cost classifier in $\mathcal{H}$ (which is often assumed in active learning) is stronger, while the existence of $h_{f^\star}$ in $\mathcal{H}$ is weaker but has not been leveraged in active learning.

We also require assumptions on the complexity of the class $\mathcal{G}$ for our statistical analysis. To this end, we assume that $\mathcal{G}$ is a compact convex subset of $L_\infty(\mathcal{X})$ with finite pseudo-dimension, which is a natural extension of VC-dimension for real-valued predictors.

Definition 1 (Pseudo-dimension) *The pseudo-dimension* $\text{Pdim}(\mathcal{F})$ *of a function class $\mathcal{F} : \mathcal{X} \to \mathbb{R}$ is defined as the VC-dimension of the set of threshold functions $\mathcal{H}^+ \triangleq \{(x, \xi) \mapsto \mathbf{1}\{f(x) > \xi\} : f \in \mathcal{F}\} \subset \mathcal{X} \times \mathbb{R} \to \{0, 1\}$.*

4. In general, labels just serve as indices for the cost vector in CSMC, and the data distribution is over (x, c) pairs instead of (x, y) pairs as in binary and multiclass classification.

Assumption 2 *We assume that $\mathcal{G}$ is a compact convex set with* $\text{Pdim}(\mathcal{G}) = d < \infty$.

As an example, linear functions in some basis representation, e.g., $g(x) = \sum_{i=1}^d w_i \phi_i(x)$, where weights w_i are bounded in some norm, have pseudodimension d. In fact, our result can be stated entirely in terms of covering numbers, and we translate to pseudo-dimension using the fact that such classes have "parametric" covering numbers of the form $(1/\varepsilon)^d$. Thus, our results extend to classes with "nonparametric" growth rates as well (e.g., Holder-smooth functions), although we focus on the parametric case for simplicity. Note that this is a significant departure from Krishnamurthy et al. (2017), which assumed that $\mathcal{G}$ was finite.

Our assumption that $\mathcal{G}$ is a compact convex set introduces a computational challenging of managing this infinitely large set. To address this challenge, we follow the trend in active learning of leveraging existing algorithmic research on supervised learning (Dasgupta et al., 2007; Beygelzimer et al., 2010, 2009) and access $\mathcal{G}$ exclusively through a *regression oracle*. Given an importance-weighted dataset $D = \{x_i, c_i, w_i\}_{i=1}^n$ where $x_i \in \mathcal{X}, c_i \in \mathbb{R}, w_i \in \mathbb{R}_+$, the regression oracle computes

$$\textsc{Oracle}(D) \in \operatorname*{argmin}_{g\in\mathcal{G}} \sum_{i=1}^n w_i (g(x_i) - c_i)^2. \tag{2}$$

Since we assume that $\mathcal{G}$ is a compact convex set it is amenable to standard convex optimization techniques, so this imposes no additional restriction. However, in the special case of linear functions, this optimization is just least squares and can be computed in closed form. Note that this is fundamentally different from prior works that use a 0/1-loss minimization oracle (Dasgupta et al., 2007; Beygelzimer et al., 2010, 2009), which involves an NP-hard optimization in most cases of interest.

Remark 2 *Our assumption that $\mathcal{G}$ is convex is only for computational tractability, as it is crucial in the efficient implementation of our query strategy, but is not required for our generalization and label complexity bounds. Unfortunately recent guarantees for learning with non-convex classes (Liang et al., 2015; Rakhlin et al., 2017) do not immediately yield efficient active learning strategies. Note also that Krishnamurthy et al. (2017) obtain an efficient algorithm without convexity, but this yields a suboptimal label complexity guarantee.*

Given a set of examples and queried costs, we often restrict attention to regression functions that predict these costs well and assess the uncertainty in their predictions given a new example x. For a subset of regressors $G \subset \mathcal{G}$, we measure uncertainty over possible cost values for x with

$$\gamma(x, G) \triangleq c_+(x, G) - c_-(x, G), \qquad c_+(x, G) \triangleq \max_{g\in G} g(x), \qquad c_-(x, G) \triangleq \min_{g\in G} g(x). \tag{3}$$

For vector regressors $F \subset \mathcal{F}$, we define the *cost range* for a label y given x as $\gamma(x, y, F) \triangleq \gamma(x, G_F(y))$ where $G_F(y) \triangleq \{f(\cdot, y) \mid f \in F\}$ are the base regressors induced by F for y. Note that since we are assuming realizability, whenever $f^\star \in F$, the quantities $c_+(x, G_F(y))$ and $c_-(x, G_F(y))$ provide valid upper and lower bounds on $\mathbb{E}[c(y)|x]$.

To measure the labeling effort, we track the number of examples for which even a single cost is queried as well as the total number of queries. This bookkeeping captures settings

Algorithm 1 Cost Overlapped Active Learning (COAL)

1: Input: Regressors $\mathcal{G}$, failure probability $\delta \leq 1/e$.
2: Set $\psi_i = 1/\sqrt{i}$, $\kappa = 3$, $\nu_n = 324(d\log(n) + \log(8Ke(d+1)n^2/\delta))$.
3: Set $\Delta_i = \kappa \min\{\frac{\nu_n}{i-1}, 1\}$.
4: **for** $i = 1, 2, \ldots, n$ **do**
5: $g_{i,y} \leftarrow \arg\min_{g\in\mathcal{G}} \widehat{R}_i(g; y)$. (See (5)).
6: Define $f_i \leftarrow \{g_{i,y}\}_{y=1}^K$.
7: (Implicitly define) $\mathcal{G}_i(y) \leftarrow \{g \in \mathcal{G}_{i-1}(y) \mid \widehat{R}_i(g; y) \leq \widehat{R}_i(g_{i,y}; y) + \Delta_i\}$.
8: Receive new example x. $Q_i(y) \leftarrow 0, \forall y \in \mathcal{Y}$.
9: **for** every $y \in \mathcal{Y}$ **do**
10: $\widehat{c_+}(y) \leftarrow \textsc{MaxCost}((x, y), \psi_i/4)$ and $\widehat{c_-}(y) \leftarrow \textsc{MinCost}((x, y), \psi_i/4)$.
11: **end for**
12: $Y' \leftarrow \{y \in \mathcal{Y} \mid \widehat{c_-}(y) \leq \min_{y'} \widehat{c_+}(y')\}$.
13: **if** $|Y'| > 1$ **then**
14: $Q_i(y) \leftarrow 1$ if $y \in Y'$ and $\widehat{c_+}(y) - \widehat{c_-}(y) > \psi_i$.
15: **end if**
16: Query costs of each y with $Q_i(y) = 1$.
17: **end for**

where the editorial effort for inspecting an example is high but each cost requires minimal further effort, as well as those where each cost requires substantial effort. Formally, we define $Q_i(y) \in \{0, 1\}$ to be the indicator that the algorithm queries label y on the i^{th} example and measure

$$L_1 \triangleq \sum_{i=1}^{n} \bigvee_{y} Q_i(y), \text{ and } L_2 \triangleq \sum_{i=1}^{n} \sum_{y} Q_i(y). \tag{4}$$

4. Cost Overlapped Active Learning

The pseudocode for our algorithm, Cost Overlapped Active Learning (COAL), is given in Algorithm 1. Given an example x, COAL queries the costs of some of the labels y for x. These costs are chosen by (1) computing a set of good regression functions based on the past data (i.e., the version space), (2) computing the range of predictions achievable by these functions for each y, and (3) querying each y that could be the best label *and* has substantial uncertainty. We now detail each step.

To compute an approximate version space we first find the regression function that minimizes the empirical risk for each label y, which at round i is:

$$\widehat{R}_i(g; y) \triangleq \frac{1}{i-1} \sum_{j=1}^{i-1} (g(x_j) - c_j(y))^2 Q_j(y). \tag{5}$$

Recall that $Q_j(y)$ is the indicator that we query label y on the j^{th} example. Computing the minimizer requires one oracle call. We implicitly construct the version space $\mathcal{G}_i(y)$ in Line 7 as the surviving regressors with low square loss regret to the empirical risk minimizer. The

tolerance on this regret is Δ_i at round i, which scales like $\tilde{\mathcal{O}}(d/i)$, where recall that d is the pseudo-dimension of the class $\mathcal{G}$.

COAL then computes the maximum and minimum costs predicted by the version space $\mathcal{G}_i(y)$ on the new example x. Since the true expected cost is $f^\star(x; y)$ and, as we will see, $f^\star(\cdot; y) \in \mathcal{G}_i(y)$, these quantities serve as a confidence bound for this value. The computation is done by the MaxCost and MinCost subroutines which produce approximations to $c_+(x, \mathcal{G}_i(y))$ and $c_-(x, \mathcal{G}_i(y))$ respectively (See (3)).

Finally, using the predicted costs, COAL issues (possibly zero) queries. The algorithm queries any *non-dominated* label that has a large *cost range*, where a label is non-dominated if its estimated minimum cost is smaller than the smallest maximum cost (among all other labels) and the cost range is the difference between the label's estimated maximum and minimum costs.

Intuitively, COAL queries the cost of every label which cannot be ruled out as having the smallest cost on x, but only if there is sufficient ambiguity about the actual value of the cost. The idea is that labels with little disagreement do not provide much information for further reducing the version space, since by construction all regressors would suffer similar square loss. Moreover, only the labels that could be the best need to be queried at all, since the cost-sensitive performance of a hypothesis h_f depends only on the label that it predicts. Hence, labels that are dominated or have small cost range need not be queried.

Similar query strategies have been used in prior works on binary and multiclass classification (Orabona and Cesa-Bianchi, 2011; Dekel et al., 2010; Agarwal, 2013), but specialized to linear representations. The key advantage of the linear case is that the set $\mathcal{G}_i(y)$ (formally, a different set with similar properties) along with the maximum and minimum costs have closed form expressions, so that the algorithms are easily implemented. However, with a general set $\mathcal{G}$ and a regression oracle, computing these confidence intervals is less straightforward. We use the MaxCost and MinCost subroutines, and discuss this aspect of our algorithm next.

4.1. Efficient Computation of Cost Range

In this section, we describe the MaxCost subroutine which uses the regression oracle to approximate the maximum cost on label y realized by $\mathcal{G}_i(y)$, as defined in (3). The minimum cost computation requires only minor modifications that we discuss at the end of the section.

Describing the algorithm requires some additional notation. Let $\tilde{\Delta}_j \triangleq \Delta_j + \widehat{R}_j(g_{j,y}; y)$ be the right hand side of the constraint defining the version space at round j, where $g_{j,y}$ is the ERM at round j for label y, $\widehat{R}_j(\cdot; y)$ is the risk functional, and Δ_j is the radius used in COAL. Note that this quantity can be efficiently computed since $g_{j,y}$ can be found with a single oracle call. Due to the requirement that $g \in \mathcal{G}_{i-1}(y)$ in the definition of $\mathcal{G}_i(y)$, an equivalent representation is $\mathcal{G}_i(y) = \bigcap_{j=1}^{i} \{g : \widehat{R}_j(g; y) \leq \tilde{\Delta}_j\}$. Our approach is based on the observation that given an example x and a label y at round i, finding a function $g \in \mathcal{G}_i(y)$ which predicts the maximum cost for the label y on x is equivalent to solving the minimization problem:

$$\text{minimize}_{g\in\mathcal{G}} (g(x) - 1)^2 \quad \text{such that} \quad \forall 1 \leq j \leq i, \widehat{R}_j(g; y) \leq \tilde{\Delta}_j. \tag{7}$$

Algorithm 2 MaxCost

Input: (x, y), tolerance TOL, (implicitly) risk functionals $\{\widehat{R}_j(\cdot; y)\}_{j=1}^i$.
Compute $g_{j,y} = \operatorname{argmin}_{g\in\mathcal{G}} \widehat{R}_j(g; y)$ for each j.
Let $\Delta_j = \kappa \min\{\frac{\nu_n}{j-1}, 1\}$, $\tilde{\Delta}_j = \widehat{R}_j(g_{j,y}; y) + \Delta_j$ for each j.
Initialize parameters: $c_\ell \leftarrow 0, c_h \leftarrow 1, T \leftarrow \frac{\log(i+1)(12/\Delta_i)^2}{\text{TOL}^4}, \eta \leftarrow \sqrt{\log(i+1)/T}$.
while $|c_\ell - c_h| > \text{TOL}^2/2$ **do**
  $c \leftarrow \frac{c_h - c_\ell}{2}$
  $\mu^{(1)} \leftarrow \mathbf{1} \in \mathbb{R}^{i+1}$. ▷ Use MW to check feasibility of Program (9).
  for $t = 1, \ldots, T$ **do**
    Use the regression oracle to find

$$g_t \leftarrow \operatorname*{argmin}_{g\in\mathcal{G}} \mu_0^{(t)}(g(x)-1)^2 + \sum_{j=1}^{i} \mu_j^{(t)} \widehat{R}_j(g; y) \tag{6}$$

    If the objective in (6) for g_t is at least $\mu_0^{(t)} c + \sum_{j=1}^i \mu_j^{(t)} \tilde{\Delta}_j$, $c_\ell \leftarrow c$, go to 5.
    Update

$$\mu_j^{(t+1)} \leftarrow \mu_j^{(t)} \left(1 - \eta \frac{\tilde{\Delta}_j - \widehat{R}_j(g_t; y)}{\Delta_j + 1}\right), \quad \mu_0^{(t+1)} \leftarrow \mu_0^{(t)} \left(1 - \eta \frac{c - (g_t(x)-1)^2}{2}\right).$$

  end for
  $c_h \leftarrow c$.
end while
Return $\widehat{c_+}(y) = 1 - \sqrt{c_\ell}$.

Given this observation, our strategy will be to find an approximate solution to the problem (7) and it is not difficult to see that this also yields an approximate value for the maximum predicted cost on x for the label y.

In Algorithm 2, we show how to efficiently solve this program using the regression oracle. We begin by exploiting the convexity of the set $\mathcal{G}$, meaning that we can further rewrite the optimization problem (7) as

$$\text{minimize}_{P\in\Delta(\mathcal{G})} \mathbb{E}_{g\sim P}\left[(g(x)-1)^2\right] \quad \text{such that} \quad \forall 1 \le j \le i, \mathbb{E}_{g\sim P}\left[\widehat{R}_j(g; y)\right] \le \tilde{\Delta}_j. \tag{8}$$

The above rewriting is effectively cosmetic as $\mathcal{G} = \Delta(\mathcal{G})$ by the definition of convexity, but the upshot is that our rewriting results in both the objective and constraints being linear in the optimization variable P. Thus, we effectively wish to solve a linear program in P, with our computational tool being a regression oracle over the set $\mathcal{G}$. To do this, we create a series of feasibility problems, where we repeatedly guess the optimal objective value for the problem (8) and then check whether there is indeed a distribution P which satisfies all the constraints and gives the posited objective value. That is, we check

$$?\exists P \in \Delta(\mathcal{G}) \text{ such that } \mathbb{E}_{g\sim P}(g(x)-1)^2 \le c \text{ and } \forall 1 \le j \le i, \mathbb{E}_{g\sim P}\widehat{R}_j(g; y) \le \tilde{\Delta}_j. \tag{9}$$

If we find such a solution, we increase our guess, and otherwise we reduce the guess and proceed until we localize the optimal value to a small enough interval.

It remains to specify how to solve the feasibility problem (9). Noting that this is a linear feasibility problem, we jointly invoke the Multiplicative Weights (MW) algorithm and the regression oracle in order to either find an approximately feasible solution or certify the problem as infeasible. MW is an iterative algorithm that maintains weights μ over the constraints. At each iteration it (1) collapses the constraints into one, by taking a linear combination weighted by μ, (2) checks feasibility of the simpler problem with a single constraint, and (3) if the simpler problem is feasible, it updates the weights using the slack of the proposed solution. Details of steps (1) and (3) are described in Algorithm 2.

For step (2), the simpler problem that we must solve takes the form

$$?\exists P \in \Delta(\mathcal{G}) \text{ such that } \mu_0 \mathbb{E}_{g\sim P}(g(x)-1)^2 + \sum_{j=1}^{i} \mu_j \mathbb{E}_{g\sim P}\widehat{R}_j(g; y) \le \mu_0 c + \sum_{j=1}^{i} \mu_j \tilde{\Delta}_j.$$

This program can be solved by a single call to the regression oracle, since all terms on the left-hand-side involve square losses while the right hand side is a constant. Thus we can efficiently implement the MW algorithm using the regression oracle. Finally, recalling that the above description is for a fixed value of objective c, and recalling that the maximum can be approximated by a binary search over c leads to an oracle-based algorithm for computing the maximum cost. For this procedure, we have the following computational guarantee.

Theorem 3 *Algorithm 2 returns an estimate $\widehat{c_+}(x; y)$ such that $c_+(x; y) \le \widehat{c_+}(x; y) \le c_+(x; y) + \text{TOL}$ and runs in polynomial time with $\mathcal{O}(\max\{1, i^2/\nu_n^2\}\log(i)\log(1/\text{TOL})/\text{TOL}^4)$ calls to the regression oracle.*

The minimum cost can be estimated in exactly the same way, replacing the objective $(g(x)-1)^2$ with $(g(x)-0)^2$ in Program (7). In COAL, we set $\text{TOL} = 1/\sqrt{i}$ at iteration i and have $\nu_n = \tilde{\mathcal{O}}(d)$. As a consequence, we can bound the total oracle complexity after processing n examples.

Corollary 4 *After processing n examples,* COAL *makes $\tilde{\mathcal{O}}(K(d^3 + n^5/d^2))$ calls to the square loss oracle.*

Thus COAL can be implemented in polynomial time for any set $\mathcal{G}$ that admits efficient square loss optimization. Compared to Krishnamurthy et al. (2017) which required $\mathcal{O}(n^2)$ oracle calls, the guarantee here is, at face value, worse, since the algorithm is slower. However, the algorithm enforces a much stronger constraint on the version space which leads to a much better statistical analysis, as we will discuss next. Nevertheless, these algorithms that use batch square loss optimization in an iterative or sequential fashion are too computational demanding to scale to larger problems. Our implementation alleviates this with an alternative heuristic approximation based on a sensitivity analysis of the oracle, which we detail in Section 7.

5. Generalization Analysis

In this section, we derive generalization guarantees for COAL. We study three settings: one with minimal assumptions and two low-noise settings.

Our first low-noise assumption is related to the Massart noise condition (Massart and Nédélec, 2006), which in binary classification posits that the Bayes optimal predictor is bounded away from 1/2 for all x. Our condition generalizes this to CSMC and posits that the expected cost of the best label is separated from the expected cost of all other labels.

Assumption 3 *A distribution $\mathcal{D}$ supported over (x, c) pairs satisfies the* Massart noise condition *with parameter $\tau > 0$, if for all x (with $\mathcal{D}(x) > 0$),*

$$f^\star(x; y^\star(x)) \leq \min_{y \neq y^\star(x)} f^\star(x; y) - \tau,$$

where $y^\star(x) \triangleq \mathit{argmin}_y f^\star(x; y)$ is the true best label for x.

The Massart noise condition describes favorable prediction problems that lead to sharper generalization and label complexity bounds for COAL. We also study a milder noise assumption, inspired by the Tsybakov condition (Mammen and Tsybakov, 1999; Tsybakov, 2004), again generalized to CSMC. See also Agarwal (2013).

Assumption 4 *A distribution $\mathcal{D}$ supported over (x, c) pairs satisfies the* Tsbyakov noise condition *with parameters (τ_0, α, β) if for all $0 \leq \tau \leq \tau_0$,*

$$\mathbb{P}_{x \sim \mathcal{D}}\left[\min_{y \neq y^\star(x)} f^\star(x; y) - f^\star(x; y^\star(x)) \leq \tau\right] \leq \beta \tau^\alpha,$$

where $y^\star(x) \triangleq \mathit{argmin}_y f^\star(x; y)$.

Observe that the Massart noise condition in Assumption 3 is a limiting case of the Tsybakov condition, with $\tau = \tau_0$ and $\alpha \to \infty$. The Tsybakov condition states that it is polynomially unlikely for the cost of the best label to be close to the cost of the other labels. This condition has been used in previous work on cost-sensitive active learning (Agarwal, 2013) and is also related to the condition studied by Castro and Nowak (2008) with the translation that $\alpha = \frac{1}{\kappa - 1}$, where $\kappa \in [0, 1]$ is their noise level.

Our generalization bound is stated in terms of the noise level in the problem so that they can be readily adapted to the favorable assumptions. We define the noise level using the following quantity, given any $\zeta > 0$.

$$P_\zeta \triangleq \mathbb{P}_{x \sim \mathcal{D}}\left[\min_{y \neq y^\star(x)} f^\star(x; y) - f^\star(x; y^\star(x)) \leq \zeta\right]. \tag{10}$$

P_ζ describes the probability that the expected cost of the best label is close to the expected cost of the second best label. When P_ζ is small for large ζ the labels are well-separated so learning is easier. For instance, under a Massart condition $P_\zeta = 0$ for all $\zeta \leq \tau$.

We now state our generalization guarantee.

Theorem 5 *For any $\delta < 1/e$, for all $i \in [n]$, with probability at least $1 - \delta$, we have*

$$\mathbb{E}_{x,c}[c(h_{f_{i+1}}(x)) - c(h_{f^\star}(x))] \leq \min_{\zeta > 0}\left\{\zeta P_\zeta + \frac{32 K \nu_n}{\zeta i}\right\},$$

where ν_n, f_i are defined in Algorithm 1, and h_{f_i} is defined in (1).

In the worst case, we bound P_ζ by 1 and optimize for ζ to obtain an $\tilde{\mathcal{O}}(\sqrt{Kd\log(1/\delta)/i})$ bound after i samples, where recall that d is the pseudo-dimension of $\mathcal{G}$. This agrees with the standard generalization bound of $O(\sqrt{\mathrm{Pdim}(\mathcal{F})\log(1/\delta)/i})$ for VC-type classes because $\mathcal{F} = \mathcal{G}^K$ has $O(Kd)$ statistical complexity. However, since the bound captures the difficulty of the CSMC problem as measured by P_ζ, we can obtain sharper results under Assumptions 3 and 4 by appropriately setting ζ.

Corollary 6 *Under Assumption 3, for any $\delta < 1/e$, with probability at least $1 - \delta$, for all $i \in [n]$, we have*

$$\mathbb{E}_{x,c}[c(h_{f_{i+1}}(x)) - c(h_{f^\star}(x))] \leq \frac{32 K \nu_n}{i\tau}.$$

Corollary 7 *Under Assumption 4, for any $\delta < 1/e$, with probability at least $1 - \delta$, for all $\frac{32K\nu_n}{\beta\tau_0^{\alpha+2}} \leq i \leq n$, we have*

$$\mathbb{E}_{x,c}[c(h_{f_{i+1}}(x)) - c(h_{f^\star}(x))] \leq 2\beta^{\frac{1}{\alpha+2}}\left(\frac{32K\nu_n}{i}\right)^{\frac{\alpha+1}{\alpha+2}}.$$

Thus, Massart and Tsybakov-type conditions lead to a faster convergence rate of $\tilde{\mathcal{O}}(1/n)$ and $\tilde{\mathcal{O}}(n^{-\frac{\alpha+1}{\alpha+2}})$. This agrees with the literature on active learning for classification (Massart and Nédélec, 2006) and can be viewed as a generalization to CSMC. Both generalization bounds match the optimal rates for binary classification under the analogous low-noise assumptions (Massart and Nédélec, 2006; Tsybakov, 2004). We emphasize that COAL obtains these bounds as is, without changing any parameters, and hence COAL is *adaptive* to favorable noise conditions.

6. Label Complexity Analysis

Without distributional assumptions, the label complexity of COAL can be $\mathcal{O}(n)$, just as in the binary classification case, since there may always be confusing labels that force querying. In line with prior work, we introduce two *disagreement coefficients* that characterize favorable distributional properties. We first define a set of good classifiers, the *cost-sensitive regret* ball:

$$\mathcal{F}_{\mathrm{csr}}(r) \triangleq \left\{f \in \mathcal{F} \;\middle|\; \mathbb{E}\left[c(h_f(x)) - c(h_{f^\star}(x))\right] \leq r\right\}.$$

We also recall our earlier notation $\gamma(x, y, F)$ (see (3) and the subsequent discussion) for a subset $F \subseteq \mathcal{F}$ which indicates the range of expected costs for (x, y) as predicted by the regressors corresponding to the classifiers in F. We now define the disagreement coefficients.

Definition 8 (Disagreement coefficients) *Define*

$$\mathit{DIS}(r, y) \triangleq \left\{x \mid \exists f, f' \in \mathcal{F}_{csr}(r), h_f(x) = y \neq h_{f'}(x)\right\}.$$

Then the disagreement coefficients are defined as:

$$\theta_1 \triangleq \sup_{\psi, r>0} \frac{\psi}{r} \mathbb{P}\left(\exists y \mid \gamma(x, y, \mathcal{F}_{csr}(r)) > \psi \wedge x \in DIS(r, y)\right),$$

$$\theta_2 \triangleq \sup_{\psi, r>0} \frac{\psi}{r} \sum_y \mathbb{P}\left(\gamma(x, y, \mathcal{F}_{csr}(r)) > \psi \wedge x \in DIS(r, y)\right).$$

Intuitively, the conditions in both coefficients correspond to the checks on the *domination* and *cost range* of a label in Lines 12 and 14 of Algorithm 1. Specifically, when $x \in \mathrm{DIS}(r, y)$, there is confusion about whether y is the optimal label or not, and hence y is not dominated. The condition on $\gamma(x, y, \mathcal{F}_{\mathrm{csr}}(r))$ additionally captures the fact that a small cost range provides little information, even when y is non-dominated. Collectively, the coefficients capture the probability of an example x where the good classifiers disagree on x in both predicted costs and labels. Importantly, the notion of good classifiers is via the algorithm-independent set $\mathcal{F}_{\mathrm{csr}}(r)$, and is only a property of $\mathcal{F}$ and the data distribution.

The definitions are a natural adaptation from binary classification (Hanneke, 2014), where a similar disagreement region to $\mathrm{DIS}(r, y)$ is used. Our definition asks for confusion about the optimality of a specific label y, which provides more detailed information about the cost-structure than simply asking for any confusion among the good classifiers. The $1/r$ scaling is in agreement with previous related definitions (Hanneke, 2014), and we also scale by the cost range parameter ψ, so that the favorable settings for active learning can be concisely expressed as having θ_1, θ_2 bounded, as opposed to a complex function of ψ.

The next three results bound the labeling effort (4), in the high noise and low noise cases respectively. The low noise assumptions enable significantly sharper bounds. Before stating the bounds, we recall that L_1 corresponds to the number of examples where at least one cost is queried, while L_2 is the total number of costs queried across all examples.

Theorem 9 *With probability at least $1 - \delta$, the label complexity of the algorithm over n examples is at most*

$$L_1 = \mathcal{O}\left(n\theta_1 \sqrt{K\nu_n} + \log(1/\delta)\right),$$
$$L_2 = \mathcal{O}\left(n\theta_2 \sqrt{K\nu_n} + K\log(1/\delta)\right).$$

Theorem 10 *Assume the Massart noise condition holds. With probability at least $1 - \delta$ the label complexity of the algorithm over n examples is at most*

$$L_1 = \mathcal{O}\left(\frac{K\log(n)\nu_n}{\tau^2}\theta_1 + \log(1/\delta)\right), \qquad L_2 = \mathcal{O}\left(KL_1\right)$$

Theorem 11 *Assume the Tsybakov noise condition holds. With probability at least $1 - \delta$ the label complexity of the algorithm over n examples is at most*

$$L_1 = \mathcal{O}\left(\theta_1^{\frac{\alpha}{\alpha+1}}(K\nu_n)^{\frac{\alpha}{\alpha+2}} n^{\frac{2}{\alpha+2}} + \log(1/\delta)\right), \qquad L_2 = \mathcal{O}\left(KL_1\right)$$

In the high-noise case, the bounds scales with $n\theta$ for the respective coefficients. In comparison, for binary classification the leading term is $\tilde{\mathcal{O}}\left(n\theta \mathrm{error}(h_{f^\star})\right)$ which involves a

different disagreement coefficient and which scales with the error of the optimal classifier $h_{f^\star}$ (Hanneke, 2014; Huang et al., 2015). Qualitatively the bounds have similar worst-case behavior, demonstrating minimal improvement over passive learning, but by scaling with $\mathrm{error}(h_{f^\star})$ the binary classification bound reflects improvements on benign instances. For the special case of multiclass classification, we are able to recover the dependence on $\mathrm{error}(h_{f^\star})$ and the standard disagreement coefficient with a simple modification to our proof, which we discuss in detail in the next subsection.

On the other hand, in both low noise cases the label complexity scales sublinearly with n. With bounded disagreement coefficients, this improves over the standard passive learning analysis where all labels are queried on n examples to achieve the generalization guarantees in Theorem 5, Corollary 6, and Corollary 7 respectively. In particular, under the Massart condition, both L_1 and L_2 bounds scale with $\theta \log(n)$ for the respective disagreement coefficients, which is an *exponential improvement* over the passive learning analysis. Under the milder Tsybakov condition, the bounds scale with $\theta^{\frac{\alpha}{\alpha+1}} n^{\frac{2}{\alpha+2}}$, which improves polynomially over passive learning. These label complexity bounds agree with analogous results from binary classification (Castro and Nowak, 2008; Hanneke, 2014; Hanneke and Yang, 2015) in their dependence on n.

Note that $\theta_2 \leq K\theta_1$ always and it can be much smaller, as demonstrated through an example in the next section. In such cases, only a few labels are ever queried and the L_2 bound in the high noise case reflects this additional savings over passive learning. Unfortunately, in low noise conditions, we do not benefit when $\theta_2 \ll K\theta_1$. This can be resolved by letting ψ_i in the algorithm depend on the noise level τ, but we prefer to use the more robust choice $\psi_i = 1/\sqrt{i}$ which still allows COAL to partially adapt to low noise and achieve low label complexity.

The main improvement over Krishnamurthy et al. (2017) is demonstrated in the label complexity bounds under low noise assumptions. For example, under Massart noise, our bound has the optimal $\log(n)/\tau^2$ rate, while the bound in Krishnamurthy et al. (2017) is exponentially worse, scaling with n^β/τ^2 for $\beta \in (0, 1)$. This improvement comes from explicitly enforcing monotonicity of the version space, so that once a regressor is eliminated it can never force COAL to query again. Algorithmically, computing the maximum and minimum costs with the monotonicity constraint is much more challenging and requires the new subroutine using MW.

6.1. Recovering Hanneke's Disagreement Coefficient

In this subsection we show that in many cases we can obtain guarantees in terms of Hanneke's disagreement coefficient (Hanneke, 2014), which has been used extensively in active learning for binary classification. We also show that, for multiclass classification, the label complexity scales with the error of the optimal classifier $h^\star$, a refinement on Theorem 9. The guarantees require no modifications to the algorithm and enable a precise comparison with prior results. Unfortunately, they do not apply to the general CSMC setting, so they have not been incorporated into our main theorems.

We start with defining Hanneke's disagreement coefficient (Hanneke, 2014). Define the *disagreement ball* $\widetilde{\mathcal{F}}(r) \triangleq \{f \in \mathcal{F} : \mathbb{P}[h_f(x) \neq h_{f^\star}(x)] \leq r\}$ and the disagreement region

$\widetilde{\mathrm{DIS}}(r) \triangleq \{x \mid \exists f, f' \in \widetilde{\mathcal{F}}(r), h_f(x) \neq h_{f'}(x)\}$. The coefficient is defined as

$$\theta_0 \triangleq \sup_{r>0} \frac{1}{r} \mathbb{P}\left[x \in \widetilde{\mathrm{DIS}}(r)\right]. \tag{11}$$

This coefficient is known to be $O(1)$ in many cases, for example when the hypothesis class consists of linear separators and the marginal distribution is uniform over the unit sphere (Hanneke, 2014, Chapter 7). In comparison with Definition 8, the two differences are that θ_1, θ_2 include the cost-range condition and involve the cost-sensitive regret ball $\mathcal{F}_{\mathrm{csr}}(r)$ rather than $\widetilde{\mathcal{F}}(r)$. As $\widetilde{\mathcal{F}}(r) \subset \mathcal{F}_{\mathrm{csr}}(r)$, we expect that θ_1 and θ_2 are typically larger than θ_0, so bounds in terms of θ_0 are more desirable. We now show that such guarantees are possible in many cases.

The low noise case. For general CSMC, low noise conditions admit the following:

Proposition 12 *Under Massart noise, with probability at least $1-\delta$ the label complexity of the algorithm over n examples is at most $L_1 = \mathcal{O}\left(\frac{\log(n)\nu_n}{\tau^2}\theta_0 + \log(1/\delta)\right)$. Under Tsybakov noise, the label complexity is at most $L_1 = \mathcal{O}\left(\theta_0 n^{\frac{2}{\alpha+2}} (\log(n)\nu_n)^{\frac{\alpha}{\alpha+2}} + \log(1/\delta)\right)$. In both cases we have $L_2 = O(KL_1)$.*

That is, for any low noise CSMC problem, COAL obtains a label complexity bound in terms of Hanneke's disagreement coefficient θ_0 directly. Note that this adaptivity requires no change to the algorithm. Proposition 12 enables a precise comparison with disagreement-based active learning for binary classification. In particular, this bound matches the guarantee for CAL (Hanneke, 2014, Theorem 5.4) with the caveat that our measure of statistical complexity is the pseudodimension of the $\mathcal{F}$ instead of the VC-dimension of the hypothesis class. As a consequence, under low noise assumptions, COAL has favorable label complexity in all examples where θ_0 is small.

The high noise case. Outside of the low noise setting, we can introduce θ_0 into our bounds, but only for multiclass classification, where we always have $c \triangleq \mathbf{1} - e_y$ for some $y \in [K]$. Note that $f(x; y)$ is now interpreted as a prediction for $1 - P(y|x)$, so that the least cost prediction $y^\star(x)$ corresponds to the most likely label. We also obtain a further refinement by introducing $\mathrm{error}(h_{f^\star}) \triangleq \mathbb{E}_{(x,c)}[c(h_{f^\star}(x))]$.

Proposition 13 *For multiclass classification, with probability at least $1-\delta$, the label complexity of the algorithm over n examples is at most*

$$L_1 = 4\theta_0 n \cdot \mathit{error}(h_{f^\star}) + \mathcal{O}\left(\theta_0\left(\sqrt{Kn\nu_n \cdot \mathit{error}(h_{f^\star})} + K\kappa\nu_n \log(n)\right) + \log(1/\delta)\right).$$

This result exploits two properties of the multiclass cost structure. First we can relate $\mathcal{F}_{\mathrm{csr}}(r)$ to the disagreement ball $\widetilde{\mathcal{F}}(r)$, which lets us introduce Hanneke's disagreement coefficient θ_0. Second, we can bound P_ζ in Theorem 5 in terms of $\mathrm{error}(h_{f^\star})$. Together the bound is comparable to prior results for active learning in binary classification (Hsu, 2010; Hanneke and Yang, 2012; Hanneke, 2014), with a slight generalization to the multiclass setting. Unfortunately, both of these refinements do not apply for general CSMC.

Summary. In important special cases, COAL achieves label complexity bounds directly comparable with results for active learning in binary classification, scaling with θ_0 and $\mathrm{error}(h_{f^\star})$. In such cases, whenever θ_0 is bounded — for which many examples are known — COAL has favorable label complexity. However, in general CSMC without low-noise assumptions, we are not able to obtain a bound in terms of these quantities, and we believe a bound involving θ_0 does not hold for COAL. We leave understanding natural settings where θ_1 and θ_2 are small, or obtaining sharper guarantees as intriguing future directions.

6.2. Three Examples

We now describe three examples to give more intuition for COAL and our label complexity bounds. Even in the low noise case, our label complexity analysis does not demonstrate all of the potential benefits of our query rule. In this section we give three examples to further demonstrate these advantages.

Our first example shows the benefits of using the domination criterion in querying, in addition to the cost range condition. Consider a problem under Assumption 3, where the optimal cost is predicted perfectly, the second best cost is τ worse and all the other costs are substantially worse, but with variability in the predictions. Since all classifiers predict the correct label, we get $\theta_1 = \theta_2 = 0$, so our label complexity bound is $\mathcal{O}(1)$. Intuitively, since every regressor is certain of the optimal label and its cost, we actually make zero queries. On the other hand, all of the suboptimal labels have large cost ranges, so querying based solely on a cost range criteria, as would happen with an active regression algorithm (Castro et al., 2005), leads to a large label complexity.

A related example demonstrates the improvement in our query rule over more naïve approaches where we query either no label or all labels, which is the natural generalization of query rules from multiclass classification (Agarwal, 2013). In the above example, if the best and second best labels are confused occasionally θ_1 may be large, but we expect $\theta_2 \ll K\theta_1$ since no other label can be confused with the best. Thus, the L_2 bound in Theorem 9 is a factor of K smaller than with a naïve query rule since COAL only queries the best and second best labels. Unfortunately, without setting ψ_i as a function of the noise parameters, the bounds in the low noise cases do not reflect this behavior.

The third example shows that both θ_0 and θ_1 yield pessimistic bounds on the label complexity of COAL in some cases. The example is more involved, so we describe it in detail. We focus on statistical issues, using a finite regressor class $\mathcal{F}$. Note that our results on generalization and label complexity hold in this setting, replacing $d\log(n)$ with $\log|\mathcal{F}|$, and the algorithm can be implemented by enumerating $\mathcal{F}$. Throughout this example, we use $\tilde{O}(\cdot)$ to further suppress logarithmic dependence on n.

Let $\mathcal{X} \triangleq \{x_1, \ldots, x_M\}$, $\mathcal{Y} \triangleq \{0, 1\}$, and consider functions $\mathcal{F} \triangleq \{f^\star, f_1, \ldots, f_M\}$. We have $f^\star(x) \triangleq (1/4, 1/2), \forall x \in \mathcal{X}$ and $f_i(x_i) \triangleq (1/4, 0)$ and $f_i(x_j) \triangleq (1/4, 1)$ for $i \neq j$. The marginal distribution is uniform and the true expected costs are given by $f^\star$ so that the problem satisfies the Massart noise condition with $\tau = 1/4$. The key to the construction is that f_is have high square loss on labels that they do not predict.

Observe that as $\mathbb{P}[h_{f_i}(x) \neq h_{f^\star}(x)] = 1/M$ and $h_{f_i}(x_i) \neq h_{f^\star}(x_i)$ for all i, the probability of disagreement is 1 until all f_i are eliminated. As such, we have $\theta_0 = M$. Similarly, we have $\mathbb{E}[c(h_{f_i}(x)) - c(h_{f^\star}(x))] = \frac{1}{4M}$ and $\gamma(x, 1, \mathcal{F}_{\mathrm{csr}}(\frac{1}{4M})) = 1$, so $\theta_1 = 4M$. Therefore, the

bounds in Theorem 10 and Proposition 12 are both $\tilde{O}(M \log |\mathcal{F}|) = \tilde{O}(|\mathcal{F}|)$. On the other hand, since $(f_i(x_j, 1) - f^\star(x_j, 1))^2 = 1/4$ for all $i, j \in [M]$, COAL eliminates every f_i once it has made a total of $\tilde{O}(\log |\mathcal{F}|)$ queries to label $y = 1$. Thus the label complexity is actually just $\tilde{O}(\log |\mathcal{F}|)$, which is exponentially better than the disagreement-based analyses. Thus, COAL can perform much better than suggested by the disagreement-based analyses, and an interesting future direction is to obtain refined guarantees for cost-sensitive active learning.

7. Experiments

We now turn to an empirical evaluation of COAL. For further computational efficiency, we implemented an approximate version of COAL using: 1) a relaxed version space $\mathcal{G}_i(y) \leftarrow \{g \in \mathcal{G} \mid \widehat{R}_i(g; y) \le \widehat{R}_i(g_{i,y}; y) + \Delta_i\}$, which does not enforce monotonicity, and 2) *online optimization*, based on online linear least-squares regression. The algorithm processes the data in one pass, and the idea is to (1) replace $g_{i,y}$, the ERM, with an approximation $g^o_{i,y}$ obtained by online updates, and (2) compute the minimum and maximum costs via a sensitivity analysis of the online update. We describe this algorithm in detail in Subsection 7.1. Then, we present our experimental results, first for simulated active learning (Subsection 7.2) and then for learning to search for joint prediction (Subsection 7.3).

7.1. Finding Cost Ranges with Online Approximation

Consider the maximum and minimum costs for a fixed example x and label y at round i, all of which may be suppressed. We ignore all the constraints on the empirical square losses for the past rounds. First, define $\widehat{R}(g, w, c; y) \triangleq \widehat{R}(g; y) + w(g(x) - c)^2$, which is the risk functional augmented with a fake example with weight w and cost c. Also define

$$\underline{g}_w \triangleq \arg\min_{g \in \mathcal{G}} \widehat{R}(g, w, 0; y), \qquad \overline{g}_w \triangleq \arg\min_{g \in \mathcal{G}} \widehat{R}(g, w, 1; y),$$

and recall that $g_{i,y}$ is the ERM given in Algorithm 1. The functional $\widehat{R}(g, w, c; y)$ has a monotonicity property that we exploit here, proved in Appendix C.

Lemma 14 *For any c and for $w' \ge w \ge 0$, define $g = \operatorname{argmin}_g \widehat{R}(g, w, c)$ and $g' = \operatorname{argmin}_g \widehat{R}(g, w', c)$. Then*

$$\widehat{R}(g') \ge \widehat{R}(g) \text{ and } (g'(x) - c)^2 \le (g(x) - c)^2.$$

As a result, an alternative to MinCost and MaxCost is to find

$$\underline{w} \triangleq \max\{w \mid \widehat{R}(\underline{g}_w) - \widehat{R}(g_{i,y}) \le \Delta_i\}, \tag{12}$$

$$\overline{w} \triangleq \max\{w \mid \widehat{R}(\overline{g}_w) - \widehat{R}(g_{i,y}) \le \Delta_i\}, \tag{13}$$

and return $\underline{g}_{\underline{w}}(x)$ and $\overline{g}_{\overline{w}}(x)$ as the minimum and maximum costs. We use two steps of approximation here. Using the definition of $\overline{g}_w$ and $\underline{g}_w$ as the minimizers of $\widehat{R}(g, w, 1; y)$ and $\widehat{R}(g, w, 0; y)$ respectively, we have

$$\widehat{R}(\underline{g}_w) - \widehat{R}(g_{i,y}) \le w \cdot g_{i,y}(x)^2 - w \cdot \underline{g}_w(x)^2,$$
$$\widehat{R}(\overline{g}_w) - \widehat{R}(g_{i,y}) \le w \cdot (g_{i,y}(x) - 1)^2 - w \cdot (\overline{g}_w(x) - 1)^2.$$

We use this upper bound in place of $\widehat{R}(g_w) - \widehat{R}(g_{i,y})$ in (12) and (13). Second, we replace $g_{i,y}$, $\underline{g}_w$, and $\overline{g}_w$ with approximations obtained by online updates. More specifically, we replace $g_{i,y}$ with $g^o_{i,y}$, the current regressor produced by all online linear least squares updates so far, and approximate the others by

$$\underline{g}_w(x) \approx g^o_{i,y}(x) - w \cdot s(x, 0, g^o_{i,y}), \qquad \overline{g}_w(x) \approx g^o_{i,y}(x) + w \cdot s(x, 1, g^o_{i,y}),$$

where $s(x, y, g^o_{i,y}) \ge 0$ is a *sensitivity* value that approximates the change in prediction on x resulting from an online update to $g^o_{i,y}$ with features x and label y. The computation of this sensitivity value is governed by the actual online update where we compute the derivative of the change in the prediction as a function of the importance weight w for a hypothetical example with cost 0 or cost 1 and the same features. This is possible for essentially all online update rules on importance weighted examples, and it corresponds to taking the limit as $w \to 0$ of the change in prediction due to an update, divided by w. Since we are using linear representations, this requires only $\mathcal{O}(s)$ time per example, where s is the average number of non-zero features. With these two steps, we obtain approximate minimum and maximum costs using

$$g^o_{i,y}(x) - \underline{w}^o \cdot s(x, 0, g^o_{i,y}), \qquad g^o_{i,y}(x) + \overline{w}^o \cdot s(x, 1, g^o_{i,y}),$$

where

$$\underline{w}^o \triangleq \max\{w \mid w\left(g^o_{i,y,}(x)^2 - (g^o_{i,y}(x) - w \cdot s(x, 0, g^o_{i,y}))^2\right) \le \Delta_i\}$$
$$\overline{w}^o \triangleq \max\{w \mid w\left((g^o_{i,y,}(x) - 1)^2 - (g^o_{i,y}(x) + w \cdot s(x, 1, g^o_{i,y}) - 1)^2\right) \le \Delta_i\}.$$

The online update guarantees that $g^o_{i,y}(x) \in [0, 1]$. Since the minimum cost is lower bounded by 0, we have $\underline{w}^o \in \left(0, \frac{g^o_{i,y}(x)}{s(x,0,g^o_{i,y})}\right]$. Finally, because the objective $w(g^o_{i,y}(x))^2 - w(g^o_{i,y}(x) - w \cdot s(x, 0, g^o_{i,y}))^2$ is increasing in w within this range (which can be seen by inspecting the derivative), we can find $\underline{w}^o$ with binary search. Using the same techniques, we also obtain an approximate maximum cost.

7.2. Simulated Active Learning

We performed simulated active learning experiments with three datasets. ImageNet 20 and 40 are sub-trees of the ImageNet hierarchy covering the 20 and 40 most frequent classes, where each example has a single zero-cost label, and the cost for an incorrect label is the tree-distance to the correct one. The feature vectors are the top layer of the Inception neural network (Szegedy et al., 2015). The third, RCV1-v2 (Lewis et al., 2004), is a multilabel text-categorization dataset, which has 103 labels, organized as a tree with a similar tree-distance cost structure as the ImageNet data. Some dataset statistics are in Table 1.

We compare our online version of COAL to passive online learning. We use the cost-sensitive one-against-all (csoaa) implementation in Vowpal Wabbit[5], which performs online linear regression for each label separately. There are two tuning parameters in our implementation. First, instead of Δ_i, we set the radius of the version space to $\Delta'_i = \frac{\kappa \nu_{i-1}}{i-1}$ (i.e. the $\log(n)$ term in the definition of ν_n is replaced with $\log(i)$) and instead tune the constant

κ. This alternate "mellowness" parameter controls how aggressive the query strategy is. The second parameter is the learning rate used by online linear regression[6].

For all experiments, we show the results obtained by the best learning rate for each mellowness on each dataset, which is tuned as follows. We randomly permute the training data 100 times and make one pass through the training set with each parameter setting. For each dataset let $\text{perf}(mel, l, q, t)$ denote the test performance of the algorithm using mellowness mel and learning rate l on the t^{th} permutation of the training data under a query budget of $2^{(q-1)} \cdot 10 \cdot K, q \geq 1$. Let $\text{query}(mel, l, q, t)$ denote the number of queries actually made. Note that $\text{query}(mel, l, q, t) < 2^{(q-1)} \cdot 10 \cdot K$ if the algorithm runs out of the

6. We use the default online learning algorithm in Vowpal Wabbit, which is a scale-free (Ross et al., 2013) importance weight invariant (Karampatziakis and Langford, 2011) form of AdaGrad (Duchi et al., 2010).

Table 2: Best learning rates for each learning algorithm and each dataset.

training data before reaching the q^{th} query budget[7]. To evaluate the trade-off between test performance and number of queries, we define the following performance measure:

$$\text{AUC}(mel, l, t) = \frac{1}{2} \sum_{q=1}^{q_{\max}} \Big(\text{perf}(mel, l, q+1, t) + \text{perf}(mel, l, q, t) \Big) \cdot \log_2 \frac{\text{query}(mel, l, q+1, t)}{\text{query}(mel, l, q, t)}, \tag{14}$$

where $q_{\max}$ is the minimum q such that $2^{(q-1)} \cdot 10$ is larger than the size of the training data. This performance measure is the area under the curve of test performance against number of queries in $\log_2$ scale. A large value means the test performance quickly improves with the number of queries. The best learning rate for mellowness mel is then chosen as

$$l^\star(mel) \triangleq \arg\max_l \text{median}_{1 \leq t \leq 100} \quad \text{AUC}(mel, l, t).$$

The best learning rates for different datasets and mellowness settings are in Table 2.

In the top row of Figure 2, we plot, for each dataset and mellowness, the number of queries against the median test cost along with bars extending from the 15^{th} to 85^{th} quantile. Overall, COAL achieves a better trade-off between performance and queries. With proper mellowness parameter, active learning achieves similar test cost as passive learning with a factor of 8 to 32 fewer queries. On ImageNet 40 and RCV1-v2 (reproduced in Figure 1), active learning achieves *better* test cost with a factor of 16 fewer queries. On RCV1-v2, COAL queries like passive up to around $256k$ queries, since the data is very sparse, and linear regression has the property that the cost range is maximal when an example has a new unseen feature. Once COAL sees all features a few times, it queries much more efficiently than passive. These plots correspond to the label complexity L_2.

In the bottom row, we plot the test error as a function of the number of examples for which at least one query was requested, for each dataset and mellowness, which experimentally corresponds to the L_1 label complexity. In comparison to the top row, the improvements offered by active learning are slightly less dramatic here. This suggests that our algorithm queries just a few labels for each example, but does end up issuing at least one query on most of the examples. Nevertheless, one can still achieve test cost competitive with passive learning using a factor of 2-16 less labeling effort, as measured by L_1.

We also compare COAL with two active learning baselines. Both algorithms differ from COAL only in their query rule. AllOrNone queries either all labels or no labels using both domination and cost-range conditions and is an adaptation of existing multiclass active learners (Agarwal, 2013). NoDom just uses the cost-range condition, inspired by active

7. In fact, we check the test performance only in between examples, so $\text{query}(mel, l, q, t)$ may be larger than $2^{(q-1)} \cdot 10 \cdot K$ by an additive factor of K, which is negligibly small.

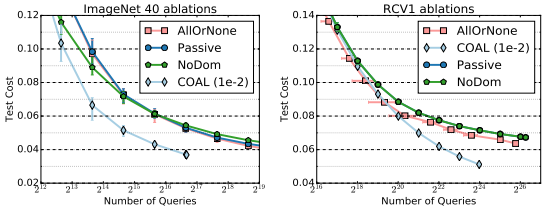

Figure 3: Test cost versus number of queries for COAL, in comparison with active and passive baselines on the ImageNet40 and RCV1-v2 dataset. On RCV1-v2, passive learning and NoDom are nearly identical.

regression (Castro et al., 2005). The results for ImageNet 40 and RCV1-v2 are displayed in Figure 3, where we use the AUC strategy to choose the learning rate. We choose the mellowness by visual inspection for the baselines and use 0.01 for COAL[8]. On ImageNet 40, the ablations provide minimal improvement over passive learning, while on RCV1-v2, AllOrNone does provide marginal improvement. However, on both datasets, COAL substantially outperforms both baselines and passive learning.

While not always the best, we recommend a mellowness setting of 0.01 as it achieves reasonable performance on all three datasets. This is also confirmed by the learning-to-search experiments, which we discuss next.

7.3. Learning to Search

We also experiment with COAL as the base leaner in *learning-to-search* (Daumé III et al., 2009; Chang et al., 2015), which reduces joint prediction problems to CSMC. A joint prediction example defines a search space, where a sequence of decisions are made to generate the structured label. We focus here on sequence labeling tasks, where the input is a sentence and the output is a sequence of labels, specifically, parts of speech or named entities.

Learning-to-search solves such problems by generating the output one label at a time, conditioning on all past decisions. Since mistakes may lead to compounding errors, it is natural to represent the decision space as a CSMC problem, where the classes are the "actions" available (e.g., possible labels for a word) and the costs reflect the long term loss of each choice. Intuitively, we should be able to avoid expensive computation of long term loss on decisions like "is 'the' a DETERMINER?" once we are quite sure of the answer. Similar ideas motivate adaptive sampling for structured prediction (Shi et al., 2015).

We specifically use Aggravate (Ross and Bagnell, 2014; Chang et al., 2015; Sun et al., 2017), which runs a learned policy to produce a backbone sequence of labels. For each position in the input, it then considers all possible deviation actions and executes an oracle for the rest of the sequence. The loss on this complete output is used as the cost for the

8. We use 0.01 for AllOrNone and 10^{-3} for NoDom.

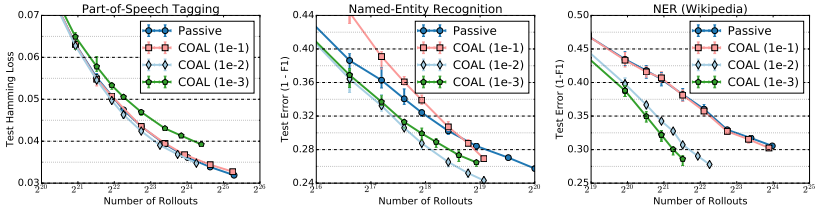

Figure 4: Learning to search experiments with COAL. Accuracy vs. number of rollouts for active and passive learning as the CSMC algorithm in learning-to-search.

deviating action. Run in this way, Aggravate requires $len \times K$ roll-outs when the input sentence has len words and each word can take one of K possible labels.

Since each roll-out takes $\mathcal{O}(len)$ time, this can be computationally prohibitive, so we use active learning to reduce the number of roll-outs. We use COAL and a passive learning baseline inside Aggravate on three joint prediction datasets (statistics are in Table 1). As above, we use several mellowness values and the same AUC criteria to select the best learning rate (see Table 2). The results are in Figure 4, and again our recommended mellowness is 0.01.

Overall, active learning reduces the number of roll-outs required, but the improvements vary on the three datasets. On the Wikipedia data, COAL performs a factor of 4 fewer rollouts to achieve similar performance to passive learning and achieves substantially better test performance. A similar, but less dramatic, behavior arises on the NER task. On the other hand, COAL offers minimal improvement over passive learning on the POS-tagging task. This agrees with our theory and prior empirical results (Hsu, 2010), which show that active learning may not always improve upon passive learning.

8. Proofs

In this section we provide proofs for the main results, the oracle-complexity guarantee and the generalization and label complexity bounds. We start with some supporting results, including a new uniform freedman-type inequality that may be of independent interest. The proof of this inequality, and the proofs for several other supporting lemmata are deferred to the appendices.

8.1. Supporting Results

A deviation bound. For both the computational and statistical analysis of COAL, we require concentration of the square loss functional $\widehat{R}_j(\cdot; y)$, uniformly over the class $\mathcal{G}$. To describe the result, we introduce the central random variable in the analysis:

$$M_j(g; y) \triangleq Q_j(y) \left[(g(x_j) - c_j(y))^2 - (f^\star(x_j; y) - c_j(y))^2 \right], \tag{15}$$

where (x_j, c_j) is the j^{th} example and cost presented to the algorithm and $Q_j(y) \in \{0,1\}$ is the query indicator. For simplicity we often write M_j when the dependence on g and y is clear from context. Let $\mathbb{E}_j[\cdot]$ and $\mathrm{Var}_j[\cdot]$ denote the expectation and variance conditioned on all randomness up to and including round $j-1$.

Theorem 15 *Let $\mathcal{G}$ be a function class with $\mathrm{Pdim}(\mathcal{G}) = d$, let $\delta \in (0,1)$ and define $\nu_n \triangleq 324(d\log(n) + \log(8Ke(d+1)n^2/\delta))$. Then with probability at least $1-\delta$, the following inequalities hold simultaneously for all $g \in \mathcal{G}$, $y \in [K]$, and $i < i' \in [n]$.*

$$\sum_{j=i}^{i'} M_j(g;y) \le \frac{3}{2}\sum_{j=i}^{i'} \mathbb{E}_j M_j(g;y) + \nu_n, \tag{16}$$

$$\frac{1}{2}\sum_{j=i}^{i'} \mathbb{E}_j M_j(g;y) \le \sum_{j=i}^{i'} M_j(g;y) + \nu_n. \tag{17}$$

This result is a uniform Freedman-type inequality for the martingale difference sequence $\sum_i M_i - \mathbb{E}_i M_i$. In general, such bounds require much stronger assumptions (e.g., sequential complexity measures (Rakhlin and Sridharan, 2017)) on $\mathcal{G}$ than the finite pseudo-dimension assumption that we make. However, by exploiting the structure of our particular martingale, specifically that the dependencies arise *only* from the query indicator, we are able to establish this type of inequality under weaker assumptions. The result may be of independent interest, but the proof, which is based on arguments from Liang et al. (2015), is quite technical and deferred to Appendix A. Note that we did not optimize the constants.

The Multiplicative Weights Algorithm. We also use the standard analysis of multiplicative weights for solving linear feasibility problems. We state the result here and, for completeness, provide a proof in Appendix B. See also Arora et al. (2012); Plotkin et al. (1995) for more details.

Consider a linear feasibility problem with decision variable $v \in \mathbb{R}^d$, explicit constraints $\langle a_i, v\rangle \le b_i$ for $i \in [m]$ and some implicit constraints $v \in S$ (e.g., v is non-negative or other simple constraints). The MW algorithm either finds an approximately feasible point or certifies that the program is infeasible assuming access to an oracle that can solve a simpler feasibility problem with just one explicit constraint $\sum_i \mu_i \langle a_i, v\rangle \le \sum_i \mu_i b_i$ for any non-negative weights $\mu \in \mathbb{R}^m_+$ and the implicit constraint $v \in S$. Specifically, given weights μ, the oracle either reports that the simpler problem is infeasible, or returns any feasible point v that further satisfies $\langle a_i, v\rangle - b_i \in [-\rho_i, \rho_i]$ for parameters ρ_i that are known to the MW algorithm.

The MW algorithm proceeds iteratively, maintaining a weight vector $\mu^{(t)} \in \mathbb{R}^m_+$ over the constraints. Starting with $\mu_i^{(1)} = 1$ for all i, at each iteration, we query the oracle with the weights $\mu^{(t)}$ and the oracle either returns a point v_t or detects infeasibility. In the latter case, we simply report infeasibility and in the former, we update the weights using the rule

$$\mu_i^{(t+1)} \leftarrow \mu_i^{(t)} \times \left(1 - \eta\frac{b_i - \langle a_i, v_t\rangle}{\rho_i}\right).$$

Here η is a parameter of the algorithm. The intuition is that if v_t satisfies the i^{th} constraint, then we down-weight the constraint, and conversely, we up-weight every constraint that is

violated. Running the algorithm with appropriate choice of η and for enough iterations is guaranteed to approximately solve the feasibility problem.

Theorem 16 (Arora et al. (2012); Plotkin et al. (1995)) *Consider running the MW algorithm with parameter $\eta = \sqrt{\log(m)/T}$ for T iterations on a linear feasibility problem where oracle responses satisfy $\langle a_i, v\rangle - b_i \in [-\rho_i, \rho_i]$. If the oracle fails to find a feasible point in some iteration, then the linear program is infeasible. Otherwise the point $\bar{v} \triangleq \frac{1}{T}\sum_{t=1}^T v_t$ satisfies $\langle a_i, \bar{v}\rangle \le b_i + 2\rho_i\sqrt{\log(m)/T}$ for all $i \in [m]$.*

Other Lemmata. Our first lemma evaluates the conditional expectation and variance of M_j, defined in (15), which we will use heavily in the proofs. Proofs of the results stated here are deferred to Appendix C.

Lemma 17 (Bounding variance of regression regret) *We have for all $(g,y) \in \mathcal{G}\times\mathcal{Y}$,*

$$\mathbb{E}_j[M_j] = \mathbb{E}_j\left[Q_j(y)(g(x_j) - f^\star(x_j;y))^2\right], \qquad \operatorname*{Var}_j[M_j] \le 4\mathbb{E}_i[M_j].$$

The next lemma relates the cost-sensitive error to the random variables M_j. Define

$$\mathcal{F}_i = \left\{f \in \mathcal{G}^K \mid \forall y, f(\cdot;y) \in \mathcal{G}_i(y)\right\},$$

which is the version space of vector regressors at round i. Additionally, recall that P_ζ captures the noise level in the problem, defined in (10) and that $\psi_i = 1/\sqrt{i}$ is defined in the algorithm pseudocode.

Lemma 18 *For all $i > 0$, if $f^\star \in \mathcal{F}_i$, then for all $f \in \mathcal{F}_i$*

$$\mathbb{E}_{x,c}[c(h_f(x)) - c(h_{f^\star}(x))] \le \min_{\zeta>0}\left\{\zeta P_\zeta + \mathbb{1}\left(\zeta \le 2\psi_i\right)2\psi_i + \frac{4\psi_i^2}{\zeta} + \frac{6}{\zeta}\sum_y \mathbb{E}_i\left[M_i\right]\right\}.$$

Note that the lemma requires that both $f^\star$ and f belong to the version space $\mathcal{F}_i$.

For the label complexity analysis, we will need to understand the cost-sensitive performance of all $f \in \mathcal{F}_i$, which requires a different generalization bound. Since the proof is similar to that of Theorem 5, we defer the argument to appendix.

Lemma 19 *Assuming the bounds in Theorem 15 hold, then for all i, $\mathcal{F}_i \subset \mathcal{F}_{csr}(r_i)$ where $r_i \triangleq \min_{\zeta>0}\left\{\zeta P_\zeta + \frac{44K\Delta_i}{\zeta}\right\}$.*

The final lemma relates the query rule of COAL to a hypothetical query strategy driven by $\mathcal{F}_{\text{csr}}(r_i)$, which we will subsequently bound by the disagreement coefficients. Let us fix the round i and introduce the shorthand $\widehat{\gamma}(x_i,y) = \widehat{c}_+(x_i,y) - \widehat{c}_-(x_i,y)$, where $\widehat{c}_+(x_i,y)$ and $\widehat{c}_-(x_i,y)$ are the approximate maximum and minimum costs computed in Algorithm 1 on the i^{th} example, which we now call x_i. Moreover, let Y_i be the set of non-dominated labels at round i of the algorithm, which in the pseudocode we call Y'. Formally, $Y_i = \{y \mid \widehat{c}_-(x_i,y) \le \min_{y'}\widehat{c}_+(x_i,y')\}$. Finally recall that for a set of vector regressors $F \subset \mathcal{F}$, we use $\gamma(x,y,F)$ to denote the cost range for label y on example x witnessed by the regressors in F.

Lemma 20 *Suppose that the conclusion of Lemma 19 holds. Then for any example x_i and any label y at round i, we have*

$$\widehat{\gamma}(x_i, y) \leq \gamma(x_i, y, \mathcal{F}_{csr}(r_i)) + \psi_i.$$

Further, with $y_i^\star = \operatorname{argmin}_y f^\star(x_i; y), \bar{y}_i = \operatorname{argmin}_y \widehat{c}_+(x_i, y)$, and $\tilde{y}_i = \operatorname{argmin}_{y \neq y_i^\star} \widehat{c}_-(x_i, y)$,

$$y \neq y_i^\star \wedge y \in Y_i \Rightarrow f^\star(x_i; y) - f^\star(x_i; y_i^\star) \leq \gamma(x_i, y, \mathcal{F}_{csr}(r_i)) + \gamma(x_i, y_i^\star, \mathcal{F}_{csr}(r_i)) + \psi_i/2,$$
$$|Y_i| > 1 \wedge y_i^\star \in Y_i \Rightarrow f^\star(x_i; \tilde{y}_i) - f^\star(x_i; y_i^\star) \leq \gamma(x_i, \tilde{y}_i, \mathcal{F}_{csr}(r_i)) + \gamma(x_i, y_i^\star, \mathcal{F}_{csr}(r_i)) + \psi_i/2.$$

8.2. Proof of Theorem 3

The proof is based on expressing the optimization problem (7) as a linear optimization in the space of distributions over $\mathcal{G}$. Then, we use binary search to re-formulate this as a series of feasibility problems and apply Theorem 16 to each of these.

Recall that the problem of finding the maximum cost for an (x, y) pair is equivalent to solving the program (7) in terms of the optimal g. For the problem (7), we further notice that since $\mathcal{G}$ is a convex set, we can instead write the minimization over g as a minimization over $P \in \Delta(\mathcal{G})$ without changing the optimum, leading to the modified problem (8).

Thus we have a linear program in variable P, and Algorithm 2 turns this into a feasibility problem by guessing the optimal objective value and refining the guess using binary search. For each induced feasibility problem, we use MW to certify feasibility. Let $c \in [0, 1]$ be some guessed upper bound on the objective, and let us first turn to the MW component of the algorithm. The program in consideration is

$$?\exists P \in \Delta(G) \text{ s.t. } \mathbb{E}_{g\sim P}(g(x_i) - 1)^2 \leq c \text{ and } \forall j \in [i], \mathbb{E}_{g\sim P}\widehat{R}_j(g; y) \leq \tilde{\Delta}_j. \tag{18}$$

This is a linear feasibility problem in the infinite dimensional variable P, with $i + 1$ constraints. Given a particular set of weights μ over the constraints, it is clear that we can use the regression oracle over g to compute

$$g_\mu = \arg\min_{g\in\mathcal{G}} \mu_0(g(x_i) - 1)^2 + \sum_{j\in[i]} \mu_j \mathbb{E}_{g\sim P}\widehat{R}_j(g; y). \tag{19}$$

Observe that solving this simpler program provides one-sided errors. Specifically, if the objective of (19) evaluated at g_μ is larger than $\mu_0 c + \sum_{j\in[i]} \mu_j \tilde{\Delta}_j$ then there cannot be a feasible solution to problem (18), since the weights μ are all non-negative. On the other hand if g_μ has small objective value it does not imply that g_μ is feasible for the original constraints in (18).

At this point, we would like to invoke the MW algorithm, and specifically Theorem 16, in order to find a feasible solution to (18) or to certify infeasibility. Invoking the theorem requires the ρ_j parameters which specify how badly g_μ might violate the j^{th} constraint. For us, $\rho_j \triangleq \kappa$ suffices since $\hat{R}_j(g; y) - \hat{R}_j(g_{j,y}; y) \in [0, 1]$ (since $g_{j,y}$ is the ERM) and $\Delta_j \leq \kappa$. Since $\kappa \geq 2$ this also suffices for the cost constraint.

If at any iteration, MW detects infeasibility, then our guessed value c for the objective is too small since no function satisfies both $(g(x_i) - 1)^2 \leq c$ and the empirical risk constraints in (18) simultaneously. In this case, in Line 10 of Algorithm 2, our binary search procedure

increases our guess for c. On the other hand, if we apply MW for T iterations and find a feasible point in every round, then, while we do not have a point that is feasible for the original constraints in (18), we will have a distribution P_T such that

$$\mathbb{E}_{P_T}(g(x_i) - 1)^2 \leq c + 2\kappa\sqrt{\frac{\log(i+1)}{T}} \text{ and } \forall j \in [i], \mathbb{E}_{P_T}\widehat{R}_j(g; y) \leq \tilde{\Delta}_j + 2\kappa\sqrt{\frac{\log(i+1)}{T}}.$$

We will set T toward the end of the proof.

If we do find an approximately feasible solution, then we reduce c and proceed with the binary search. We terminate when $c_h - c_\ell \leq \tau^2/2$ and we know that problem (18) is approximately feasible with c_h and infeasible with c_ℓ. From c_h we will construct a strictly feasible point, and this will lead to a bound on the true maximum $c_+(x, y, \mathcal{G}_i)$.

Let $\bar{P}$ be the approximately feasible point found when running MW with the final value of c_h. By Jensen's inequality and convexity of $\mathcal{G}$, there exists a single regressor that is also approximately feasible, which we denote $\bar{g}$. Observe that $g^\star$ satisfies all constraints with strict inequality, since by (20) we know that $\widehat{R}_j(g^\star; y) - \widehat{R}_j(g_{j,y}; y) \leq \Delta_j/\kappa < \Delta_j$. We create a strictly feasible point g_ζ by mixing $\bar{g}$ with $g^\star$ with proportion $1 - \zeta$ and ζ for

$$\zeta = \frac{4\kappa}{\Delta_i}\sqrt{\frac{\log(i+1)}{T}},$$

which will be in $[0, 1]$ when we set T. Combining inequalities, we get that for any $j \in [i]$

$$\begin{aligned}(1-\zeta)\widehat{R}_j(\bar{g}; y) + \zeta\widehat{R}_j(g^\star; y) &\leq \widehat{R}_j(g_{j,y}; y) + (1-\zeta)\left(\Delta_j + 2\kappa\sqrt{\frac{\log(i+1)}{T}}\right) + \zeta\left(\frac{\Delta_j}{\kappa}\right) \\ &\leq \widehat{R}_j(g_{j,y}; y) + \Delta_j - \left(\frac{\zeta\Delta_j(\kappa-1)}{\kappa} - 2\kappa\sqrt{\frac{\log(i+1)}{T}}\right) \\ &\leq \widehat{R}_j(g_{j,y}; y) + \Delta_j,\end{aligned}$$

and hence this mixture regressor g_ζ is exactly feasible. Here we use that $\kappa \geq 2$ and that Δ_i is monotonically decreasing. With the pessimistic choice $g^\star(x_i) = 0$, the objective value for g_ζ is at most

$$\begin{aligned}(g_\zeta(x_i) - 1)^2 &\leq (1-\zeta)(\bar{g}(x_i) - 1)^2 + \zeta(g^\star(x_i) - 1)^2 \leq (1-\zeta)\left(c_h + 2\kappa\sqrt{\frac{\log(i+1)}{T}}\right) + \zeta \\ &\leq c_\ell + \tau^2/2 + \left(2\kappa + \frac{4\kappa}{\Delta_i}\right)\sqrt{\frac{\log(i+1)}{T}}.\end{aligned}$$

Thus g_ζ is *exactly* feasible and achieves the objective value above, which provides an upper bound on the maximum cost. On the other hand c_ℓ provides a lower bound. Our setting of $T = \frac{\log(i+1)(8\kappa^2/\Delta_i)^2}{\tau^4}$ ensures that that this excess term is at most τ^2, since $\Delta_i \leq 1$. Note that since $\tau \leq [0, 1]$, this also ensures that $\zeta \in [0, 1]$. With this choice of T, we know that $c_\ell \leq (c_+(y) - 1)^2 \leq c_\ell + \tau^2$, which implies that $c_+(y) \in [1 - \sqrt{c_\ell + \tau^2}, 1 - \sqrt{c_\ell}]$. Since $\sqrt{c_\ell + \tau^2} \leq \sqrt{c_\ell} + \tau$, we obtain the guarantee.

As for the oracle complexity, since we start with $c_\ell = 0$ and $c_h = 1$ and terminate when $c_h - c_\ell \le \tau^2/2$, we perform $\mathcal{O}(\log(1/\tau^2))$ iterations of binary search. Each iteration requires $T = \mathcal{O}\left(\max\{1, i^2/\nu_n^2\}\frac{\log(i)}{\tau^4}\right)$ rounds of MW, each of which requires exactly one oracle call. Hence the oracle complexity is $\mathcal{O}\left(\max\{1, i^2/\nu_n^2\}\frac{\log(i)\log(1/\tau)}{\tau^4}\right)$. ■

8.3. Proof of the Generalization Bound

Recall the central random variable $M_j(g; y)$, defined in (15), which is the excess square loss for function g on label y for the j^{th} example, if we issued a query. The idea behind the proof is to first apply Theorem 15 to argue that all the random variables $M_j(g; y)$ concentrate uniformly over the function class $\mathcal{G}$. Next for a vector regressor f, we relate the cost-sensitive risk to the excess square loss via Lemma 18. Finally, using the fact that $g_{i,y}$ minimizes the empirical square loss at round i, this implies a cost-sensitive risk bound for the vector regressor $f_i = (g_{i,y})$ at round i.

First, condition on the high probability event in Theorem 15, which ensures that the empirical square losses concentrate. We first prove that $f^\star \in \mathcal{F}_i$ for all $i \in [n]$. At round i, by (17), for each y and for any g we have

$$0 \le \frac{1}{2}\sum_{j=1}^{i} \mathbb{E}_j M_j(g; y) \le \sum_{j=1}^{i} M_j(g; y) + \nu_n.$$

The first inequality here follows from the fact that $\mathbb{E}_j M_j(g; y)$ is a quadratic form by Lemma 17. Expanding $M_j(g; y)$, this implies that

$$\widehat{R}_{i+1}(f^\star(\cdot; y); y) \le \widehat{R}_{i+1}(g; y) + \frac{\nu_n}{i}.$$

Since this bound applies to all $g \in \mathcal{G}$ it proves that $f^\star \in \mathcal{F}_{i+1}$ for all i, using the definition of Δ_i and κ. Trivially, we know that $f^\star \in \mathcal{F}_1$. Together with the fact that the losses are in $[0, 1]$ and the definition of Δ_i, the above analysis yields

$$\widehat{R}_i(f^\star(\cdot; y); y) \le \widehat{R}_i(g; y) + \frac{\Delta_i}{\kappa}. \tag{20}$$

This implies that $f^\star(\cdot; y)$ strictly satisfies the inequalities defining the version space, which we used in the MW proof.

We next prove that $f_{i+1} \in \mathcal{F}_j$ for all $j \in [i]$. Fix some label y and to simplify notation, we drop dependence on y. If $g_{i+1} \notin \mathcal{G}_{t+1}$ for some $t \in \{0, \dots, i\}$ then, first observe that we must have t large enough so that $\nu_n/t \le 1$. In particular, since $\Delta_{t+1} = \kappa \min\{1, \nu_n/t\}$ and we always have $\hat{R}_{t+1}(g_{i+1}; y) \le \hat{R}_{t+1}(g_{t+1}; y) + 1$ due to boundedness, we do not evict any functions until $\nu_n/t \le 1$. For $t \ge \nu_n$, we get

$$\begin{aligned}
\sum_{j=1}^{t} M_j &= t\left(\widehat{R}_{t+1}(g_{i+1}) - \widehat{R}_{t+1}(g^\star)\right) \\
&= t\left(\widehat{R}_{t+1}(g_{i+1}) - \widehat{R}_{t+1}(g_{t+1}) + \widehat{R}_{t+1}(g_{t+1}) - \widehat{R}_{t+1}(g^\star)\right) \\
&\ge \kappa\nu_n - \nu_n = (\kappa - 1)\nu_n.
\end{aligned}$$

The inequality uses the radius of the version space and the fact that by assumption $g_{i+1} \notin \mathcal{G}_{t+1}$, so the excess empirical risk is at least $\Delta_{t+1} = \kappa\nu_n/t$ since we are considering large t. We also use (20) on the second term. Moreover, we know that since g_{i+1} is the empirical square loss minimizer for label y after round i, we have $\sum_{j=1}^{i} M_j(g_{i+1}; y) \le 0$. These two facts together establish that

$$\sum_{j=t+1}^{i} M_j(g_{i+1}) \le (1 - \kappa)\nu_n.$$

However, by Theorem 15 on this intermediary sum, we know that

$$0 \le \frac{1}{2}\sum_{j=t+1}^{i} \mathbb{E}_j M_j(g_{i+1}) \le \sum_{j=t+1}^{i} M_j(g_{i+1}) + \nu_n < (2 - \kappa)\nu_n < 0$$

using the definition of κ. This is a contradiction, so we must have that $g_{i+1} \in \mathcal{G}_j$ for all $j \in \{1, \dots, i\}$. The same argument applies for all y and hence we can apply Lemma 18 on all rounds to obtain

$$\begin{aligned}
&i\big(\mathbb{E}_{x,c}[c(h_{f_{i+1}}(x)) - c(h_{f^\star}(x))]\big) \\
&\le \min_{\zeta > 0}\left\{ i\zeta P_\zeta + \sum_{j=1}^{i}\left(\mathbb{1}\left(\zeta \le 2\psi_j\right) 2\psi_j + \frac{4\psi_j^2}{\zeta} + \frac{6}{\zeta}\sum_y \mathbb{E}_j\left[M_j(f_{i+1}; y)\right]\right)\right\}.
\end{aligned}$$

We study the four terms separately. The first one is straightforward and contributes ζP_ζ to the instantaneous cost sensitive regret. Using our definition of $\psi_j = 1/\sqrt{j}$ the second term can be bounded as

$$\sum_{j=1}^{i} \mathbb{1}\left(\zeta < 2\psi_j\right) 2\psi_j = \sum_{j=1}^{\lceil 4/\zeta^2 \rceil} \frac{2}{\sqrt{j}} \le 4\sqrt{\lceil 4/\zeta^2 \rceil} \le \frac{12}{\zeta}.$$

The inequality above, $\sum_{i=1}^{n} \frac{1}{\sqrt{i}} \le 2\sqrt{n}$, is well known. For the third term, using our definition of ψ_j gives

$$\sum_{j=1}^{i} \frac{4\psi_j^2}{\zeta} = \frac{4}{\zeta}\sum_{j=1}^{i} \frac{1}{j} \le \frac{4}{\zeta}(1 + \log(i)).$$

Finally, the fourth term can be bounded using (17), which reveals

$$\sum_{j=1}^{i} \mathbb{E}_j[M_j] \le 2\sum_{j=1}^{i} M_j + 2\nu_n$$

Since for each y, $\sum_{j=1}^{i} M_j(f_{i+1}; y) \le 0$ for the empirical square loss minimizer (which is what we are considering now), we get

$$\frac{6}{\zeta}\sum_y \sum_{j=1}^{i} \mathbb{E}_j[M_j(f_{i+1}; y)] \le \frac{12}{\zeta} K\nu_n.$$

And hence, we obtain the generalization bound

$$\mathbb{E}_{x,c}[c(x;h_{f_{i+1}}(x)) - c(x;h_{f^\star}(x))] \le \min_{\zeta>0}\left\{\zeta P_\zeta + \frac{1}{\zeta i}\left(4\log(i) + 16 + 12K\nu_n\right)\right\}$$
$$\le \min_{\zeta>0}\left\{\zeta P_\zeta + \frac{32K\nu_n}{\zeta i}\right\}. \qquad \blacksquare$$

Proof of Corollary 6. Under the Massart noise condition, set $\zeta = \tau$ so that $P_\zeta = 0$ and we immediately get the result. $\blacksquare$

Proof of Corollary 7. Set $\zeta = \min\left\{\tau_0, \left(\frac{32K\nu_n}{i\beta}\right)^{\frac{1}{\alpha+2}}\right\}$, so that for i sufficiently large the second term is selected and we obtain the bound. $\blacksquare$

8.4. Proof of the Label Complexity bounds

The proof for the label complexity bounds is based on first relating the version space $\mathcal{F}_i$ at round i to the cost-sensitive regret ball $\mathcal{F}_{\text{csr}}$ with radius r_i. In particular, the containment $\mathcal{F}_i \subset \mathcal{F}_{\text{csr}}(r_i)$ in Lemma 19 implies that our query strategy is more aggressive than the query strategy induced by $\mathcal{F}_{\text{csr}}(r_i)$, except for a small error introduced when computing the maximum and minimum costs. This error is accounted for by Lemma 20. Since the probability that $\mathcal{F}_{\text{csr}}$ will issue a query is intimately related to the disagreement coefficient, this argument leads to the label complexity bounds for our algorithm.

Proof of Theorem 9. Fix some round i with example x_i, let $\mathcal{F}_i$ be the vector regressors used at round i and let $\mathcal{G}_i(y)$ be the corresponding regressors for label y. Let $\bar{y}_i = \operatorname{argmin}_y \widehat{c_+}(x_i, y), y_i^\star = \operatorname{argmin}_y f^\star(x_i; y)$, and $\tilde{y}_i = \operatorname{argmin}_{y\neq y_i^\star} \widehat{c_-}(x_i, y)$. Assume that Lemma 19 holds. The L_2 label complexity is

$$\sum_y Q_i(y) = \sum_y \mathbf{1}\{|Y_i| > 1 \wedge y \in Y_i\}\mathbf{1}\{\widehat{\gamma}(x_i, y) > \psi_i\}$$
$$\le \sum_y \mathbf{1}\{|Y_i| > 1 \wedge y \in Y_i\}\mathbf{1}\{\gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) > \psi_i/2\}.$$

For the former indicator, observe that $y \in Y_i$ implies that there exists a vector regressor $f \in \mathcal{F}_i \subset \mathcal{F}_{\text{csr}}(r_i)$ such that $h_f(x_i) = y$. This follows since the domination condition means that there exists $g \in \mathcal{G}_i(y)$ such that $g(x_i) \le \min_{y'} \max_{g'\in\mathcal{G}_i(y')} g'(x_i)$. Since we are using a factored representation, we can take f to use g on the y^{th} coordinate and use the maximizers for all the other coordinates. Similarly, there exists another regressor $f' \in \mathcal{F}_i$ such that $h_{f'}(x_i) \neq y$. Thus this indicator can be bounded by the disagreement coefficient

$$\sum_y Q_i(y) \le \sum_y \mathbf{1}\{\exists f, f' \in \mathcal{F}_{\text{csr}}(r_i) \mid h_f(x_i) = y \neq h_{f'}(x_i)\}\mathbf{1}\{\gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) > \psi_i/2\}$$
$$= \sum_y \mathbf{1}\{x \in \text{DIS}(r_i, y) \wedge \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) \ge \psi_i/2\}.$$

We will now apply Freedman's inequality on the sequence $\{\sum_y Q_i(y)\}_{i=1}^n$, which is a martingale with range K. Moreover, due to non-negativity, the conditional variance is at most

K times the conditional mean, and in such cases, Freedman's inequality reveals that with probability at least $1-\delta$

$$X \le \mathbb{E}X + 2\sqrt{R\mathbb{E}X\log(1/\delta)} + 2R\log(1/\delta) \le 2\mathbb{E}X + 3R\log(1/\delta),$$

where X is the non-negative martingale with range R and expectation $\mathbb{E}X$. The last step is by the fact that $2\sqrt{ab} \le a + b$.

For us, Freedman's inequality implies that with probability at least $1-\delta/2$

$$\sum_{i=1}^n \sum_y Q_i(y) \le 2\sum_i \mathbb{E}_i \sum_y Q_i(y) + 3K\log(2/\delta)$$
$$\le 2\sum_i \mathbb{E}_i \sum_y \mathbf{1}\{x \in \text{DIS}(r_i, y) \wedge \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) \ge \psi_i/2\} + 3K\log(2/\delta)$$
$$\le 4\sum_i \frac{r_i}{\psi_i}\theta_2 + 3K\log(2/\delta).$$

The last step here uses the definition of the disagreement coefficient θ_2. To wrap up the proof we just need to upper bound the sequence, using our choices of $\psi_i = 1/\sqrt{i}$, $r_i = 2\sqrt{44K\Delta_i}$, and $\Delta_i = \kappa\min\{1, \frac{\nu_n}{i-1}\}$. With simple calculations this is easily seen to be at most

$$8n\theta_2\sqrt{88K\kappa\nu_n} + 3K\log(2/\delta).$$

Similarly for L_1 we can derive the bound

$$L_1 \le \sum_i \mathbb{1}\left(\exists y \mid \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) \ge \psi_i/2 \wedge x \in \text{DIS}(r_i, y)\right),$$

and then apply Freedman's inequality to obtain that with probability at least $1-\delta/2$

$$L_1 \le 2\sum_{i=1}^n \frac{2r_i}{\psi_i}\theta_1 + 3\log(2/\delta) \le 8\theta_1 n\sqrt{88K\kappa\nu_n} + 3\log(2/\delta). \qquad \blacksquare$$

Proof of Theorem 10. Using the same notations as in the bound for the high noise case we first express the L_2 label complexity as

$$\sum_y Q_i(y) = \sum_y \mathbf{1}\{|Y_i| > 1, y \in Y_i\}Q_i(y).$$

We need to do two things with the first part of the query indicator, so we have duplicated it here. For the second, we will use the derivation above to relate the query rule to the disagreement region. For the first, by Lemma 20, for $y \neq y_i^\star$, we can derive the bound

$$\mathbf{1}\{f^\star(x_i; y) - f^\star(x_i; y_i^\star) \le \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) + \gamma(x_i, y_i^\star, \mathcal{F}_{\text{csr}}(r_i)) + \psi_i/2\}$$
$$\le \mathbf{1}\{\tau - \psi_i/2 \le \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) + \gamma(x_i, y_i^\star, \mathcal{F}_{\text{csr}}(r_i))\}.$$

For $y = y_i^\star$, we get the same bound but with $\tilde{y}_i$, also by Lemma 20. Focusing on just one of these terms, say where $y \neq y_i^\star$ and any round where $\tau \geq \psi_i$, we get

$$\begin{aligned}
&\mathbf{1}\{\tau - \psi_i/2 \leq \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) + \gamma(x_i, y_i^\star, \mathcal{F}_{\text{csr}}(r_i))\}Q_i(y) \\
&\leq \mathbf{1}\{\tau/2 \leq \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) + \gamma(x_i, y_i^\star, \mathcal{F}_{\text{csr}}(r_i))\}Q_i(y) \\
&\leq \mathbf{1}\{\tau/4 \leq \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i))\}Q_i(y) + \mathbf{1}\{\tau/4 \leq \gamma(x_i, y_i^\star, \mathcal{F}_{\text{csr}}(r_i))\}Q_i(y) \\
&\leq D_i(y) + D_i(y_i^\star),
\end{aligned}$$

where for shorthand we have defined $D_i(y) \triangleq \mathbf{1}\{\tau/4 \leq \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) \wedge x_i \in \text{DIS}(r_i, y)\}$. The derivation for the first term is straightforward. We obtain the disagreement region for $y_i^\star$ since the fact that we query y (i.e. $Q_i(y)$) implies there is f such that $h_f(x_i) = y$, so this function witnesses disagreement to $y_i^\star$.

The term involving $y_i^\star$ and $\tilde{y}_i$ is bounded in essentially the same way, since we know that when $|Y_i| > 1$, there exists two function $f, f' \in \mathcal{F}_i$ such that $h_f(x_i) = \tilde{y}_i$ and $h_{f'}(x_i) = y_i^\star$. In total, we can bound the L_2 label complexity at any round i such that $\tau \geq \psi_i$ by

$$L_2 \leq D_i(\tilde{y}_i) + D_i(y_i^\star) + \sum_{y \neq y_i^\star} (D_i(y) + D_i(y_i^\star)) \leq K D_i(y_i^\star) + 2\sum_y D_i(y)$$

For the earlier rounds, we simply upper bound the label complexity by K. Since the range of this random variable is at most $3K$, using Freedman's inequality just as in the high noise case, we get that with probability at least $1 - \delta/2$

$$\begin{aligned}
L_2 &\leq \sum_{i=1}^n K\mathbf{1}\{\tau \leq \psi_i\} + 2\sum_{i=2}^n \mathbb{E}_i\left[K D_i(y_i^\star) + 2\sum_y D_i(y)\right] + 9K\log(2/\delta) \\
&\leq K\lceil 1/\tau^2 \rceil + \frac{8}{\tau}(K\theta_1 + \theta_2)\sum_{i=2}^n r_i + 9K\log(2/\delta).
\end{aligned}$$

The first line here is the application of Freedman's inequality. In the second, we evaluate the expectation, which we can relate to the disagreement coefficients θ_1, θ_2. Moreover, we use the setting $\psi_i = 1/\sqrt{i}$ to evaluate the first term. As a technicality, we remove the index $i = 1$ from the second summation, since we are already accounting for queries on the first round in the first term. The last step is to evaluate the series, for which we use the definition of $r_i = \min_{\zeta > 0}\{\zeta P_\zeta + 44K\Delta_i/\zeta\}$ and set $\zeta = \tau$, the Massart noise level. This gives $r_i = 44K\Delta_i/\tau$. In total, we get

$$L_2 \leq K\lceil 1/\tau^2 \rceil + \frac{352K\kappa\nu_n}{\tau^2}(K\theta_1 + \theta_2)\log(n) + 9K\log(2/\delta).$$

As $\theta_2 \leq K\theta_1$ always, we drop θ_2 from the above expression to obtain the stated bound.

For L_1 we use a very similar argument. First, by Lemmas 19 and 20

$$L_1 \leq \sum_{i=1}^n \mathbf{1}\{|Y_i| > 1 \wedge \exists y \in Y_i, \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) \geq \psi_i/2\}.$$

Again by Lemma 20, we know that

$$|Y_i| > 1 \wedge y \in Y_i \Rightarrow \exists f, f' \in \mathcal{F}_{\text{csr}}(r_i), h_f(x_i) = y \neq h_{f'}(x_i).$$

Moreover, one of the two classifiers can be $f^\star$, and so, when $\tau \geq \psi_i$, we can deduce

$$\begin{aligned}
&\Rightarrow f^\star(x_i, y) - f^\star(x_i, y_i^\star) \leq \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) + \gamma(x_i, y_i^\star, \mathcal{F}_{\text{csr}}(r_i)) + \psi_i/2 \\
&\Rightarrow \tau/4 \leq \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) \wedge \tau/4 \leq \gamma(x_i, y_i^\star, \mathcal{F}_{\text{csr}}(r_i)).
\end{aligned}$$

Combining this argument, we bound the L_1 label complexity as

$$L_1 \leq \sum_{i=1}^n \mathbf{1}\{\tau \leq \psi_i\} + \sum_{i=2}^n \mathbf{1}\{\exists y \mid x_i \in \text{DIS}(\mathcal{F}_{\text{csr}}(r_i), y) \wedge \gamma(x_i, y, \mathcal{F}_{\text{csr}}(r_i)) \geq \tau/4\}. \quad (21)$$

Applying Freedman's inequality just as before gives

$$L_1 \leq \lceil 1/\tau^2 \rceil + 2\sum_{i=2}^n \frac{4r_i}{\tau}\theta_1 + 2\log(2/\delta) \leq \lceil 1/\tau^2 \rceil + \frac{352K\kappa\nu_n}{\tau^2}\theta_1\log(n) + 2\log(2/\delta),$$

with probability at least $1 - \delta/2$. ■

Proof of Theorem 11. For the Tsybakov case, the same argument as in the Massart case gives that with probability at least $1 - \delta/2$

$$L_2 \leq K\lceil 1/\tau^2 \rceil + \frac{8}{\tau}(K\theta_1 + \theta_2)\sum_{i=2}^n r_i + 2n\beta\tau^\alpha + 9K\log(2/\delta).$$

The main difference here is the term scaling with $n\tau^\alpha$ which arises since we do not have the deterministic bound $f^\star(x_i, y) - f^\star(x_i, y_i^\star) \geq \tau$ as we used in the Massart case, but rather this happens except with probability $\beta\tau^\alpha$ (provided $\tau \leq \tau_0$). Now we must optimize ζ in the definition of r_i and then τ.

For ζ the optimal setting is $(44K\Delta_i/\beta)^{\frac{1}{\alpha+2}}$ which gives $r_i \leq 2\beta^{\frac{1}{\alpha+2}}(44K\Delta_i)^{\frac{\alpha+1}{\alpha+2}}$. Since we want to set $\zeta \leq \tau_0$, this requires $i \geq 1 + \frac{44K\kappa\nu_n}{\beta\tau_0^{\alpha+2}}$. For these early rounds we will simply pay K in the label complexity, but this will be dominated by other higher order terms. For the later rounds, we get

$$\sum_{i=2}^n r_i \leq 2\beta^{\frac{1}{\alpha+2}}(44K\kappa\nu_n)^{\frac{\alpha+1}{\alpha+2}}\sum_{i=2}^n\left(\frac{1}{i-1}\right)^{\frac{\alpha+1}{\alpha+2}} \leq 2(\alpha+2)(44K\kappa\nu_n)^{\frac{\alpha+1}{\alpha+2}}(\beta n)^{\frac{1}{\alpha+2}}.$$

This bound uses the integral approximation $\sum_{i=2}^n (i-1)^{-\frac{\alpha+1}{\alpha+2}} \leq 1 + \int_1^{n-1} x^{-\frac{\alpha+1}{\alpha+2}}dx \leq (\alpha+2)n^{\frac{1}{\alpha+2}}$. At this point, the terms involving τ in our bound are

$$K\lceil 1/\tau^2 \rceil + \frac{16}{\tau}(K\theta_1 + \theta_2)(\alpha+2)(44K\kappa\nu_n)^{\frac{\alpha+1}{\alpha+2}}(\beta n)^{\frac{1}{\alpha+2}} + 2n\beta\tau^\alpha.$$

We set $\tau = (8(\alpha+2)(K\theta_1+\theta_2))^{\frac{1}{\alpha+1}}(44K\kappa\nu_n)^{\frac{1}{\alpha+2}}(\beta n)^{\frac{-1}{\alpha+2}}$ by optimizing the second two terms which gives a final bound of

$$L_2 \leq \mathcal{O}\left((K\theta_1+\theta_2)^{\frac{\alpha}{\alpha+1}}(K\nu_n)^{\frac{\alpha}{\alpha+2}}n^{\frac{2}{\alpha+2}} + K\log(1/\delta)\right).$$

This follows since the $1/\tau^2$ term agrees in the n dependence and is lower order in other parameters, while the unaccounted for querying in the early rounds is independent of n. The bound of course requires that $\tau \leq \tau_0$, which again requires n large enough. Note we are treating α and β as constants and we drop θ_2 from the final statement.

The L_1 bound requires only slightly different calculations. Following the derivation for the Massart case, we get

$$\begin{aligned} L_1 &\leq \lceil 1/\tau^2 \rceil + \frac{8\theta_1}{\tau}\sum_{i=2}^{n} r_i + 2n\beta\tau^\alpha + 2\log(2/\delta) \\ &\leq \lceil 1/\tau^2 \rceil + \frac{16\theta_1(\alpha+2)}{\tau}\left(44K\kappa\nu_n\right)^{\frac{\alpha+1}{\alpha+2}}(\beta n)^{\frac{1}{\alpha+2}} + 2n\beta\tau^\alpha + 2\log(2/\delta), \end{aligned}$$

not counting the lower order term for the querying in the early rounds. Here we set $\tau = (8(\alpha+2)\theta_1)^{\frac{1}{\alpha+1}}\left(44K\kappa\nu_n\right)^{\frac{1}{\alpha+2}}(\beta n)^{\frac{-1}{\alpha+2}}$ to obtain

$$L_1 \leq \mathcal{O}\left(\theta_1^{\frac{\alpha}{\alpha+1}}(K\nu_n)^{\frac{\alpha}{\alpha+2}}n^{\frac{2}{\alpha+2}} + \log(1/\delta)\right). \qquad \blacksquare$$

Proof of Proposition 12: Massart Case. Observe that with Massart noise, we have $\mathcal{F}_{\mathrm{csr}}(r) \subset \widetilde{\mathcal{F}}(r/\tau)$, which implies that

$$\begin{aligned} \mathbb{E}\mathbf{1}\left\{\exists y \mid x \in \mathrm{DIS}(r,y) \wedge \gamma(x,y,\mathcal{F}_{\mathrm{csr}}(r)) \geq \tau/4\right\} &\leq \mathbb{E}\mathbf{1}\left\{x \in \widetilde{\mathrm{DIS}}(r/\tau)\right\} \\ &\leq \frac{r}{\tau}\sup_{r>0}\frac{1}{r}\mathbb{E}\mathbf{1}\left\{x \in \widetilde{\mathrm{DIS}}(r)\right\}. \end{aligned}$$

Thus we may replace θ_1 with θ_0 in the proof of the L_1 label complexity bound above. $\blacksquare$

Proof of Proposition 12: Tsybakov Case. The proof is identical to Theorem 11 except we must introduce the alternative coefficient θ_0. To do so, define $\mathcal{X}(\tau) \triangleq \{x \in \mathcal{X} : \min_{y \neq y^\star(x)} f^\star(x,y) - f^\star(x,y^\star(x)) \geq \tau\}$, and note that under the Tsybakov noise condition, we have $\mathbb{P}[x \notin \mathcal{X}(\tau)] \leq \beta\tau^\alpha$ for all $0 \leq \tau \leq \tau_0$. For such a value of τ we have

$$\begin{aligned} \mathbb{P}[h_f(x) \neq h_{f^\star}(x)] &\leq \mathbb{E}\mathbf{1}\{x \in \mathcal{X}(\tau) \wedge h_f(x) \neq h_{f^\star}(x)\} + \mathbb{P}[x \notin \mathcal{X}(\tau)] \\ &\leq \frac{1}{\tau}\mathbb{E}c(h_f(x)) - c(h_{f^\star}(x)) + \beta\tau^\alpha. \end{aligned}$$

We use this fact to prove that $\mathcal{F}_{\mathrm{csr}}(r) \subset \widetilde{\mathcal{F}}(2r/\tau)$ for τ sufficiently small. This can be seen from above by noting that if $f \in \mathcal{F}_{\mathrm{csr}}(r)$ then the right hand side is $\frac{r}{\tau} + \beta\tau^\alpha$, and if $\tau \leq (r/\beta)^{\frac{1}{1+\alpha}}$ the containment holds. Therefore, we have

$$\begin{aligned} \mathbb{E}\mathbf{1}\left\{\exists y \mid x \in \mathrm{DIS}(r,y) \wedge \gamma(x,y,\mathcal{F}_{\mathrm{csr}}(r)) \geq \tau/4\right\} &\leq \mathbb{E}\mathbf{1}\left\{\exists y \mid x \in \mathrm{DIS}(r,y)\right\} \\ &\leq \mathbb{E}\mathbf{1}\left\{x \in \widetilde{\mathrm{DIS}}(2r/\tau)\right\} \\ &\leq \frac{2r}{\tau}\cdot\sup_{r>0}\mathbb{E}\mathbf{1}\left\{x \in \widetilde{\mathrm{DIS}}(r)\right\}. \end{aligned}$$

Thus, provided $\tau \leq (r_n/\beta)^{\frac{1}{\alpha+1}}$, we can replace θ_1 with θ_0 in the above argument. This gives

$$\begin{aligned} L_1 &\leq \lceil 1/\tau^2 \rceil + \frac{4\theta_0}{\tau}\sum_{i=2}^{n} r_i + 2n\beta\tau^\alpha + 2\log(2/\delta) \\ &\leq \lceil 1/\tau^2 \rceil + \frac{8\theta_0(\alpha+2)}{\tau}\left(44K\kappa\nu_n\right)^{\frac{\alpha+1}{\alpha+2}}(\beta n)^{\frac{1}{\alpha+2}} + 2n\beta\tau^\alpha + 2\log(2/\delta). \end{aligned}$$

As above, we have taken $r_i = 2\beta^{\frac{1}{\alpha+2}}(44K\Delta_i)^{\frac{\alpha+1}{\alpha+2}}$ and approximated the sum by an integral. Since $\Delta_n = \kappa\nu_n/(n-1)$, we can set $\tau = 2^{\frac{\alpha+1}{\alpha+2}}(44K\kappa\nu_n)^{\frac{1}{\alpha+2}}(\beta n)^{-\frac{1}{\alpha+2}}$. This is a similar choice to what we used in the proof of Theorem 11 except that we are not incorporating θ_0 into the choice of τ, and it yields a final bound of $\mathcal{O}\left(\theta_0 n^{\frac{2}{\alpha+2}}\nu_n^{\frac{\alpha}{\alpha+2}} + \log(1/\delta)\right)$. $\blacksquare$

Proof of Proposition 13. First we relate θ_1 to θ_0 in the multiclass case. For $f \in \mathcal{F}_{\mathrm{csr}}(r)$, we have

$$\begin{aligned} \mathbb{P}[h_f(x) \neq h_{f^\star}(x)] &\leq \mathbb{P}[h_f(x) \neq y] + \mathbb{P}[h_{f^\star}(x) \neq y] = \mathbb{E}c(h_f(x)) - c(h_{f^\star}(x)) \\ &\leq 2\mathrm{error}(h_{f^\star}) + r \end{aligned}$$

Therefore for any $r > 0$ and any x,

$$\mathbf{1}\{\exists y \mid x \in \mathrm{DIS}(r,y) \wedge \gamma(x,y,\mathcal{F}_{\mathrm{csr}}(r)) \geq \psi/2\} \leq \mathbf{1}\{x \in \widetilde{\mathrm{DIS}}(r_i + 2\mathrm{error}(h_{f^\star}))\}.$$

Applying this argument in the L_1 derivation above, we obtain

$$\begin{aligned} L_1 &\leq 2\sum_i \mathbb{E}_i\mathbf{1}\{x \in \widetilde{\mathrm{DIS}}(r_i + 2\mathrm{error}(h_{f^\star}))\} + 3\log(2/\delta) \\ &\leq 2\sum_i (r_i + 2\mathrm{error}(h_{f^\star}))\theta_0 + 3\log(2/\delta). \end{aligned}$$

We now bound r_i via Lemma 19. In multiclass classification, the fact that $c = \mathbf{1} - e_y$ for some y implies that $f^\star(x,y)$ is one minus the probability that the true label is y. Thus $f^\star(x,y) \in [0,1]$, $\sum_y f^\star(x,y) = K-1$, and for any x we always have

$$\min_{y \neq y^\star(x)} f^\star(x,y) - f^\star(x,y^\star(x)) \geq 1 - 2f^\star(x,y^\star(x)).$$

Hence, we may bound P_ζ, for $\zeta \leq 1/2$, as follows

$$\begin{aligned} P_\zeta &= \mathbb{P}_{x\sim\mathcal{D}}\left[\min_{y \neq y^\star(x)} f^\star(x,y) - f^\star(x,y^\star(x)) \leq \zeta\right] \leq \mathbb{P}_{x\sim\mathcal{D}}\left[1 - 2f^\star(x,y^\star(x)) \leq \zeta\right] \\ &\leq \mathbb{E}_x f^\star(x,y^\star(x)) \cdot \frac{2}{1-\zeta} \leq 4\mathrm{error}(h_{f^\star}). \end{aligned}$$

Now apply Lemma 19 with $\zeta = \min\{1/2, \sqrt{44K\Delta_i/\mathrm{error}(h_{f^\star})}\}$, and we obtain

$$r_i \leq \sqrt{44K\Delta_i\mathrm{error}(h_{f^\star})} + 264K\Delta_i.$$

Using the definition of Δ_i the final L_1 label complexity bound is

$$L_1 \leq 4\theta_0 n\cdot\mathrm{error}(h_{f^\star}) + \mathcal{O}\left(\theta_0\left(\sqrt{Kn\kappa\nu_n\cdot\mathrm{error}(h_{f^\star})} + K\kappa\nu_n\log(n)\right) + \log(1/\delta)\right). \qquad \blacksquare$$

9. Discussion

This paper presents a new active learning algorithm for cost-sensitive multiclass classification. The algorithm enjoys strong theoretical guarantees on running time, generalization error, and label complexity. The main algorithmic innovation is a new way to compute the maximum and minimum costs predicted by a regression function in the version space. We also design an online algorithm inspired by our theoretical analysis that outperforms passive baselines both in CSMC and structured prediction.

On a technical level, our algorithm uses a square loss oracle to search the version space and drive the query strategy. This contrasts with many recent results using argmax or 0/1-loss minimization oracles for information acquisition problems like contextual bandits (Agarwal et al., 2014). As these involve NP-hard optimizations in general, an intriguing question is whether we can use a square loss oracle for other information acquisition problems. We hope to answer this question in future work.

Appendix A. Proof of Theorem 15

In the proof, we mostly work with the empirical ℓ_1 covering number for $\mathcal{G}$. At the end, we translate to pseudo-dimension using a lemma of Haussler.

Definition 21 (Covering numbers) *Given class $\mathcal{G} \subset \mathcal{X} \to \mathbb{R}$, $\alpha > 0$, and sample $X = (x_1, \ldots, x_n) \in \mathcal{X}^n$, the covering number $\mathcal{N}_1(\alpha, \mathcal{H}, X)$ is the minimum cardinality of a set $V \subset \mathbb{R}^n$ such that for any $g \in \mathcal{G}$, there exists a $(v_1, \ldots, v_n) \in V$ with $\frac{1}{n}\sum_{i=1}^n |g(x_i) - v_i| \leq \alpha$.*

Lemma 22 (Covering number and Pseudo-dimension (Haussler, 1995)) *Given a hypothesis class $\mathcal{G} \subset \mathcal{X} \to \mathbb{R}$ with $\mathrm{Pdim}(\mathcal{G}) \leq d$, for any $X \in \mathcal{X}^n$ we have*

$$\mathcal{N}_1(\alpha, \mathcal{G}, X) \leq e(d+1)\left(\frac{2e}{\alpha}\right)^d.$$

Fixing i and y, and working toward (16) we seek to bound

$$\mathbb{P}\left(\sup_{g\in\mathcal{G}} \sum_{j=1}^{i} M_j(g;y) - \frac{3}{2}\mathbb{E}_j[M_j(g;y)] \geq \tau\right). \tag{22}$$

The bound on the other tail is similar. In this section, we sometimes treat the query rule as a function which maps an x to a query decision. We use the notation $\mathbf{Q}_j : \mathcal{X} \to \{0,1\}$ to denote the query function used after seeing the first $j-1$ examples. Thus, our query indicator Q_j is simply the instantiation $\mathbf{Q}_j(x_j)$. In this section, we work with an individual label y and omit the explicit dependence in all our arguments and notation. For notational convenience, we use $z_j = (x_j, c_j, Q_j)$ and with $g^\star(\cdot) = f^\star(\cdot; y)$, we define

$$\xi_j = g^\star(x_j) - c_j \quad \text{and} \quad \ell(g, x) = (g(x) - g^\star(x)). \tag{23}$$

Note that ξ_j is a centered random variable, independent of everything else. We now introduce some standard concepts from martingale theory for the proof of Theorem 15.

Definition 23 (Tangent sequence) *For a dependent sequence $z_1, \ldots, z_i$ we use $z'_1, \ldots, z'_i$ to denote a* tangent sequence, *where $z'_j|z_{1:j-1} \stackrel{d}{=} z_j|z_{1:j-1}$, and, conditioned on $z_1, \ldots, z_i$, the random variables $z'_1, \ldots, z'_i$ are independent.*

In fact, in our case we have $z'_j = (x'_j, c'_j, Q'_j)$ where $(x'_j, c'_j) \sim \mathcal{D}$ and $Q'_j : \mathcal{X} \to \{0,1\}$ is identical to Q_j. We use $M'_j(g)$ to denote the empirical excess square loss on sample z'_j. Note that we will continue to use our previous notation of $\mathbb{E}_j$ to denote conditioning on $z_1, \ldots, z_{j-1}$. We next introduce one more random process, and then proceed with the proof.

Definition 24 (Tree process) *A* tree process *$\mathcal{Q}$ is a binary tree of depth i where each node is decorated with a value from $\{0,1\}$. For a Rademacher sequence $\epsilon \in \{-1,1\}^i$ we use $\mathcal{Q}_i(\epsilon)$ to denote the value at the node reached when applying the actions $\epsilon_1, \ldots, \epsilon_{i-1}$ from the root, where $+1$ denotes left and -1 denotes right.*

The proof follows a fairly standard recipe for proving uniform convergence bounds, but has many steps that all require minor modifications from standard arguments. We compartmentalize each step in various lemmata:

1. In Lemma 25, we introduce a ghost sample and replace the conditional expectation $\mathbb{E}_j[\cdot]$ in (22) with an empirical term evaluated on an *tangent sequence*.
2. In Lemma 26, we perform symmetrization and introduce Rademacher random variables and the associated tree process.
3. In Lemma 27 we control the symmetrized process for finite $\mathcal{G}$.
4. In Lemma 28, we use the covering number to discretize $\mathcal{G}$.

We now state and prove the intermediate results.

Lemma 25 (Ghost sample) *Let $Z = (z_1, \dots, z_i)$ be the sequence of (x, c, Q) triples and let $Z' = (z'_1, \dots, z'_i)$ be a tangent sequence. Then for $\beta_0 \geq \beta_1 > 0$ if $\tau \geq \frac{4(1+\beta_1)^2}{(\beta_0-\beta_1)}$, then*

$$\mathbb{P}_Z\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i} M_j(g) - (1+2\beta_0)\mathbb{E}_j M_j(g) \geq \tau\right]$$
$$\leq 2\mathbb{P}_{Z,Z'}\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i} M_j(g) - M'_j(g) - 2\beta_1 Q_j(x'_j)\ell^2(g,x'_j) \geq \frac{\tau}{2}\right],$$
$$\mathbb{P}_Z\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i}(1-2\beta_0)\mathbb{E}_j M_j(g) - M_j(g) \geq \tau\right]$$
$$\leq 2\mathbb{P}_{Z,Z'}\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i} M'_j(g) - M_j(g) - 2\beta_1 Q_j(x'_j)\ell^2(g,x'_j) \geq \frac{\tau}{2}\right].$$

Proof We derive the first inequality, beginning with the right hand side and working toward a lower bound. The main idea is to condition on Z and just work with the randomness in Z'. To this end, let $\hat{g}$ achieve the supremum on the left hand side, and define the events

$$E = \left\{\sum_{j=1}^{i} M_j(\hat{g}) - (1+2\beta_0)\mathbb{E}_j M_j(\hat{g}) \geq \tau\right\}$$
$$E' = \left\{\sum_{i=1}^{n} M'_j(\hat{g}) + 2\beta_1 Q_j(x'_j)\ell^2(\hat{g},x'_j) - (1+2\beta_0)\mathbb{E}_j M'_j(\hat{g}) \leq \tau/2\right\}.$$

Starting from the right hand side, by adding and subtracting $(1+2\beta_0)\mathbb{E}_j M_j(\hat{g})$ we get

$$\mathbb{P}_{Z,Z'}\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i} M_j(g) - M'_j(g) - 2\beta_1 Q_j(x'_j)\ell^2(g,x'_j) \geq \tau/2\right]$$
$$\geq \mathbb{P}_{Z,Z'}\left[\sum_{j=1}^{i} M_j(\hat{g}) - M'_j(\hat{g}) - 2\beta_1 Q_j(x'_j)\ell^2(\hat{g},x'_j) \geq \tau/2\right]$$
$$\geq \mathbb{P}_{Z,Z'}\left[E\bigcap E'\right] = \mathbb{E}_Z\left[\mathbf{1}\{E\}\times\mathbb{P}_{Z'}[E'|Z]\right].$$

Since we have defined $\hat{g}$ to achieve the supremum, we know that

$$\mathbb{E}_Z\mathbf{1}\{E\} = \mathbb{P}_Z\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i} M_j(g) - (1+2\beta_0)\mathbb{E}_j M_j(g) \geq \tau\right].$$

which is precisely the left hand side of the desired inequality. Hence we need to bound the $\mathbb{P}_{Z'}[E'|Z]$ term. For this term, we note that

$$\mathbb{P}_{Z'}[E'|Z] = \mathbb{P}_{Z'}\left[\sum_{i=1}^{n} M'_j(\hat{g}) + 2\beta_1 Q_j(x'_j)\ell^2(\hat{g},x'_j) - (1+2\beta_0)\mathbb{E}_j M'_j(\hat{g}) \leq \tau/2 \mid Z\right]$$
$$\overset{(a)}{=} \mathbb{P}_{Z'}\left[\sum_{i=1}^{n} M'_j(\hat{g}) + 2\beta_1\mathbb{E}_j M'_j(\hat{g}) - (1+2\beta_0)\mathbb{E}_j M'_j(\hat{g}) \leq \tau/2 \mid Z\right]$$
$$= \mathbb{P}_{Z'}\left[\sum_{i=1}^{n}\left(M'_j(\hat{g}) - \mathbb{E}_j M'_j(\hat{g})\right) + 2\left(\beta_1-\beta_0\right)\mathbb{E}_j M'_j(\hat{g})\right) \leq \tau/2 \mid Z\right].$$

Here, (a) follows since $\mathbb{E}_j[M'_j(g) \mid Z] = Q_j(x'_j)\ell^2(g,x'_j)$ for any g by Lemma 17. Since we are conditioning on Z, $\hat{g}$ is also not a random function and the same equality holds when we take expectation over Z', even for $\hat{g}$. With this, we can now invoke Chebyshev's inequality:

$$\mathbb{P}_{Z'}[E'|Z] = 1 - \mathbb{P}_{Z'}\left[\sum_{j=1}^{i} M'_j(\hat{g}) + 2\beta_1 Q_j(x'_j)\ell^2(\hat{g},x'_j) - (1+2\beta_0)\mathbb{E}_j M'_j(\hat{g}) \geq \tau/2 \,\middle|\, Z\right]$$
$$\geq 1 - \frac{\mathrm{Var}\left[\sum_{j=1}^{i} M'_j(\hat{g}) + 2\beta_1 Q_j(x'_j)\ell(\hat{g},x'_j)\middle| Z\right]}{\left(\tau/2 + 2(\beta_0-\beta_1)\sum_i \mathbb{E}_j[Q_j(x'_j)\ell^2(\hat{g},x'_j)\middle| Z]\right)^2}.$$

Since we are working conditional on Z, we can leverage the independence of Z' (recall Definition 23) to bound the variance term.

$$\mathrm{Var}\left[\sum_{j=1}^{i} M'_j(g) + 2\beta_1 Q_j(x'_j)\ell^2(\hat{g},x'_j)\middle| Z\right]$$
$$\leq \sum_{j=1}^{i}\mathbb{E}_j\left[M'_j(\hat{g})^2 + (2\beta_1)^2 Q_j(x'_j)\ell^4(\hat{g},x'_j) + 4\beta_1 M'_j(\hat{g})Q_j(x'_j)\ell^2(\hat{g},x'_j)\right]$$
$$\leq 4(1+\beta_1)^2\sum_{j=1}^{i}\mathbb{E}_j Q_j(x'_j)\ell^2(\hat{g},x'_j).$$

Here we use that $\mathrm{Var}[X] \leq \mathbb{E}[X^2]$ and then we use that $\ell^2 \leq \ell$ since the loss is bounded in $[0,1]$ along with Lemma 17. Returning to the application of Chebyshev's inequality, if we expand the quadratic in the denominator and drop all but the cross term, we get the bound

$$\mathbb{P}'_Z[E'|Z] \geq 1 - \frac{2(1+\beta_1)^2}{\tau(\beta_0-\beta_1)} \geq 1/2,$$

where the last step uses the requirement on τ. This establishes the first inequality.

For the second inequality the steps are nearly identical. Let $\hat{g}$ achieve the supremum on the left hand side and define

$$E = \left\{ \sum_{j=1}^{i} (1-2\beta_0)\mathbb{E}_j M_j(\hat{g}) - M_j(\hat{g}) \geq \tau \right\}$$
$$E' = \left\{ \sum_{j=1}^{i} (1-2\beta_0)\mathbb{E}_j M'_j(\hat{g}) - M'_j(\hat{g}) + 2\beta_1 Q_j(x'_j)\ell^2(\hat{g}, x'_j) \leq \tau/2 \right\}.$$

Using the same argument, we can lower bound the right hand side by

$$\mathbb{P}\left[\sup_{g\in\mathcal{G}} \sum_{j=1}^{i} M'_j(g) - M_j(g) - 2\beta_1 Q_j(x'_j)\ell^2(g, x'_j) \geq \tau/2 \right] \geq \mathbb{E}_Z\left[\mathbf{1}\{E\} \times \mathbb{P}_{Z'}\left[E' \middle| Z\right]\right]$$

Applying Chebyshev's inequality yields the same expression as for the other tail. ■

Lemma 26 (Symmetrization) *Using the same notation as in Lemma 25, we have*

$$\mathbb{P}_{Z,Z'}\left[\sup_{g\in\mathcal{G}} \sum_{j=1}^{i} M_j(g) - M'_j(g) - 2\beta_1 Q_j(x'_j)\ell^2(g, x'_j) \geq \tau \right]$$
$$\leq 2\mathbb{E} \sup_{\mathcal{Q}} \mathbb{P}_\epsilon \left[\sup_{g\in\mathcal{G}} \sum_{j=1}^{i} \epsilon_j \mathcal{Q}_j(\epsilon)((1+\beta_1)\ell(g, x_j)^2 + 2\xi_j \ell(g, x_j)) - \beta_1 \mathcal{Q}_j(\epsilon)\ell(g, x_j)^2 \geq \tau/2 \right].$$

the same bound holds on the lower tail with $(1-\beta_1)$ *replacing* $(1+\beta_1)$.

Proof For this proof, we think of Q_j as a binary variable that is dependent on $z_1, \ldots, z_{j-1}$ and x_j. Similarly Q'_j depends on $z_1, \ldots, z_{j-1}$ and x'_j. Using this notation, and decomposing the square loss, we get

$$M_j(g) = Q_j\left[(g(x_j) - c_j)^2 - (g^\star(x_j) - c_j)^2\right] = Q_j\ell^2(g, x_j) + 2Q_j\xi_j\ell(g, x_j).$$

As such, we can write

$$M_j(g) - M'_j(g) - 2\beta_1 Q'_j\ell^2(g, x'_j) = \underbrace{(1+\beta_1)Q_j\ell^2(g, x_j) + 2Q_j\xi_j\ell(g, x_j)}_{\triangleq T_{1,j}} - \underbrace{\beta_1 Q_j\ell^2(g, x_j)}_{\triangleq T_{2,j}}$$
$$- \underbrace{(1+\beta_1)Q'_j\ell^2(g, x'_j) - 2Q'_j\xi'_j\ell(g, x'_j)}_{\triangleq T'_{1,j}} - \underbrace{\beta_1 Q'_j\ell^2(g, x'_j)}_{\triangleq T'_{2,j}}.$$

Here we have introduce the short forms $T_{1,j}, T_{2,j}$ and the primed version just to condense the derivations. Overall we must bound

$$\mathbb{P}\left[\sup_{g\in\mathcal{G}} \sum_{j=1}^{i} T_{1,j} - T_{2,j} - T'_{1,j} - T'_{2,j} \geq \tau \right] = \mathbb{E}\mathbf{1}\left\{ \sup_{g\in\mathcal{G}} \sum_{j=1}^{i} T_{1,j} - T_{2,j} - T'_{1,j} - T'_{2,j} \geq \tau \right\}.$$

Observe that in the final term $T_{1,i}, T'_{1,i}$ are random variables with identical conditional distribution, since there are no further dependencies and (x_i, ξ_i, Q_i) are identically distributed to (x'_i, ξ'_i, Q'_i). As such, we can symmetrize the i^{th} term by introducing the Rademacher random variable $\epsilon_i \in \{-1, +1\}$ to obtain

$$\mathbb{E}_{Z,Z'}\mathbb{E}_{\epsilon_i}\mathbf{1}\left\{ \sup_{g\in\mathcal{G}} \sum_{j=1}^{i-1} T_{1,j} - T_{2,j} + \epsilon_i(T_{1,i} - T'_{1,i}) - \sum_{j=1}^{i}(T_{2,j} + T'_{2,j}) \geq \tau \right\}$$
$$\leq \mathbb{E}_{Z,Z'} \sup_{Q_i, Q'_i} \mathbb{E}_{\epsilon_i}\mathbf{1}\left\{ \sup_{g\in\mathcal{G}} \sum_{j=1}^{i-1} T_{1,j} - T_{2,j} + \epsilon_i(T_{1,i} - T'_{1,i}) - \sum_{j=1}^{i}(T_{2,j} + T'_{2,j}) \geq \tau \right\}.$$

Here in the second step, we have replace the expectation over Q_i, Q'_i with supremum, which breaks the future dependencies for the $(i-1)^{\text{st}}$ term. Note that while we still write $\mathbb{E}_{Z,Z'}$, we are no longer taking expectation over Q_i, Q'_i here. The important point is that since x_j, ξ_j are all i.i.d., the only dependencies in the martingale are through Q_js and by taking supremum over Q_i, Q'_i, swapping the role of $T_{1,i-1}$ and $T'_{1,i-1}$ no longer has any future effects. Thus we can symmetrize the $(i-1)^{\text{st}}$ term. Continuing in this way, we get

$$\mathbb{E}\mathbb{E}_{\epsilon_{i-1}} \sup_{Q_i, Q'_i} \mathbb{E}_{\epsilon_i}\mathbf{1}\left\{ \sup_{g\in\mathcal{G}} \sum_{j=1}^{i-2} T_{1,j} - T_{2,j} + \sum_{j=i-1}^{i} \epsilon_j(T_{1,j} - T'_{1,j}) - \sum_{j=1}^{i}(T_{2,j} + T'_{2,j}) \geq \tau \right\}$$
$$\leq \mathbb{E}\left\langle \sup_{Q_j, Q'_j} \mathbb{E}_{\epsilon_j} \right\rangle_{j=1}^{i} \mathbf{1}\left\{ \sup_{g\in\mathcal{G}} \sum_{j=1}^{i} \epsilon_j(T_{1,j} - T'_{1,j}) - \sum_{j=1}^{i}(T_{2,j} + T'_{2,j}) \geq \tau \right\}.$$

Here in the final expression the outer expectation is just over the variables x_j, x'_j, ξ_j, ξ'_j and the bracket notation denotes interleaved supremum and expectation. Expanding the definitions of $T_{1,i}, T_{2,i}$, we currently have

$$\mathbb{E}\left\langle \sup_{Q_j, Q'_j} \mathbb{E}_{\epsilon_j} \right\rangle_{j=1}^{i} \mathbf{1}\left\{ \sup_{g\in\mathcal{G}} \sum_{j=1}^{i} \epsilon_j\left[(1+\beta_1)Q_j\ell^2(g, x_j) + 2Q_j\xi_j\ell(g, x_j)\right] - \sum_{j=1}^{i} \beta_1 Q_j\ell^2(g, x_j) \right.$$
$$\left. - \sum_{j=1}^{i} \epsilon_j\left[(1+\beta_1)Q'_j\ell^2(g, x'_j) + 2Q'_j\xi'_j\ell(g, x'_j)\right] - \sum_{j=1}^{i} \beta_1 Q'_j\ell^2(g, x'_j) \geq \tau \right\}.$$

Next we use the standard trick of splitting the supremum over g into a supremum over two functions g, g', where g' optimizes the primed terms. This provides an upper bound, but moreover if we replace τ with $\tau/2$ we can split the indicator into two and this becomes

$$2\mathbb{E}\left\langle \sup_{Q_j} \mathbb{E}_{\epsilon_j} \right\rangle_{j=1}^{i} \mathbf{1}\left\{ \sup_{g\in\mathcal{G}} \sum_{j=1}^{i} \epsilon_j Q_j\left[(1+\beta_1)\ell^2(g, x_j) + 2\xi_j\ell(g, x_j)\right] - \beta_1 Q_j\ell^2(g, x_j) \geq \tau/2 \right\}$$
$$= 2\mathbb{E} \sup_{\mathcal{Q}} \mathbb{P}_\epsilon\left[\sup_{g\in\mathcal{G}} \sum_{j=1}^{i} \epsilon_j \mathcal{Q}_j(\epsilon)\left[(1+\beta_1)\ell^2(g, x_j) + 2\xi_j\ell(g, x_j)\right] - \beta_1 \mathcal{Q}_j(\epsilon)\ell^2(g, x_j) \geq \tau/2 \right].$$

The tree process $\mathcal{Q}$ arises here because the interleaved supremum and expectation is equivalent to choosing a binary tree decorated with values from $\{0,1\}$ and then navigating the tree using the Rademacher random variables ϵ. The bound for the other tail is proved in the same way, except $(1+\beta_1)$ is replaced by $(1-\beta_1)$. ■

The next lemma is more standard, and follows from the union bound and the bound on the Rademacher moment generating function.

Lemma 27 (Finite class bound) *For any $x_{1:i}, \xi_{1:i}, \mathcal{Q}$, and for finite $\mathcal{G}$, we have*

$$\mathbb{P}_\epsilon\left[\max_{g\in\mathcal{G}}\sum_{j=1}^{i}\epsilon_j\mathcal{Q}_j(\epsilon)\left[(1+\beta_1)\ell^2(g,x_j)+2\xi_j\ell(g,x_j)\right]-\beta_1\mathcal{Q}_j(\epsilon)\ell^2(g,x_j)\geq\tau\right]$$
$$\leq|\mathcal{G}|\exp\left(\frac{-2\beta_1\tau}{(3+\beta_1)^2}\right).$$

The same bound applies for the lower tail.

Proof Applying the union bound and the Chernoff trick, we get that for any $\lambda>0$ the LHS is bounded by

$$\sum_g\exp(-\tau\lambda)\mathbb{E}_\epsilon\exp\left\{\lambda\left[\sum_{j=1}^{i}\underbrace{\epsilon_j\mathcal{Q}_j(\epsilon)\left[(1+\beta_1)\ell^2(g,x_j)+2\xi_j\ell(g,x_j)\right]-\beta_1\mathcal{Q}_i(\epsilon)\ell^2(g,x_j)}_{\triangleq T_{3,j}}\right]\right\}$$
$$=\sum_g\exp(-\tau\lambda)\mathbb{E}_{\epsilon_{1:i-1}}\exp\left\{\lambda\sum_{j=1}^{i-1}T_{3,j}\right\}\times\mathbb{E}_{\epsilon_i|\epsilon_{1:i-1}}\exp(\lambda T_{3,i}).$$

Let us examine the i^{th} term conditional on $\epsilon_{1:i-1}$. Conditionally on $\epsilon_{1:i-1}$, $\mathcal{Q}_i(\epsilon)$ is no longer random, so we can apply the MGF bound for Rademacher random variables to get

$$\mathbb{E}_{\epsilon_i|\epsilon_{1:i-1}}\exp\left\{\lambda\epsilon_i\mathcal{Q}_i(\epsilon)\left[(1+\beta_1)\ell^2(g,x_i)+2\xi_i\ell(g,x_i)\right]-\lambda\beta_1\mathcal{Q}_i(\epsilon)\ell^2(g,x_i)\right\}$$
$$\leq\exp\left\{\frac{\lambda^2}{2}\mathcal{Q}_i(\epsilon)\left[(1+\beta_1)\ell^2(g,x_i)+2\xi_i\ell(g,x_i)\right]^2-\lambda\beta_1\mathcal{Q}_i(\epsilon)\ell^2(g,x_i)\right\}$$
$$\leq\exp\left\{\lambda^2\mathcal{Q}_i(\epsilon)\frac{(3+\beta_1)^2}{2}\ell^2(g,x_i)-\lambda\beta_1\mathcal{Q}_i(\epsilon)\ell^2(g,x_i)\right\}\leq 1.$$

Here the first inequality is the standard MGF bound on Rademacher random variables $\mathbb{E}\exp(a\epsilon)\leq\exp(a^2/2)$. In the second line we expand the square and use that $\ell,\xi\in[-1,1]$ to upper bound all the terms. Finally, we use the choice of $\lambda=\frac{2\beta_1}{(3+\beta_1)^2}$. Repeating this argument from i down to 1, finishes the proof of the upper tail. The same argument applies for the lower tail, but we actually get $(3-\beta_1)^2$ in the denominator, which is of course upper bounded by $(3+\beta_1)^2$, since $\beta_1>0$. ■

Lemma 28 (Discretization) *Fix $x_1,\ldots,x_i$ and let $V\subset\mathbb{R}^i$ be a cover of $\mathcal{G}$ at scale α on points $x_1,\ldots,x_i$. Then for any $\mathcal{Q}$*

$$\mathbb{P}_\epsilon\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i}\epsilon_j\mathcal{Q}_j(\epsilon)\left[(1+\beta_1)\ell^2(g,x_j)+2\xi_j\ell(g,x_j)\right]-\beta_1\mathcal{Q}_j(\epsilon)\ell^2(g,x_j)\geq\tau\right]\leq$$
$$\mathbb{P}_\epsilon\left[\sup_{v\in V}\sum_{j=1}^{i}\epsilon_j\mathcal{Q}_j(\epsilon)\left[(1+\beta_1)\ell^2(v,x_j)+2\xi_j\ell(v,x_j)\right]-\beta_1\mathcal{Q}_j(\epsilon)\ell^2(v,x_j)\geq\tau-4i(1+\beta)\alpha\right].$$

The same bound holds for the lower tail with $1-\beta_1$. Here $\ell(v,x_j)=(v_j-g^\star(x_j))$.

Proof Observe first that if v is the covering element for g, then we are guaranteed that

$$\frac{1}{i}\sum_{j=1}^{i}|\ell(g,x_j)-\ell(v,x_j)|=\frac{1}{i}\sum_{j=1}^{i}|g(x_j)-v_j|\leq\alpha,$$
$$\frac{1}{i}\sum_{j=1}^{i}|\ell^2(g,x_j)-\ell^2(v,x_j)|=\frac{1}{i}\sum_{j=1}^{i}|(g(x_j)-v_j)(g(x_j)+v_j-2g^\star(x_j)|\leq 2\alpha,$$

since $g,v,g^\star\in[0,1]$. Thus, adding and subtracting the corresponding terms for v, and applying these bounds, we get a residual term of $i\alpha(2(1+\beta_1)+2+2\beta_1)=4i\alpha(1+\beta_1)$. ■

Proof of Theorem 15. Finally we can derive the deviation bound. We first do the upper tail, $M_j-\mathbb{E}_jM_j$. Set $\beta_0=1/4,\beta_1=1/8$ and apply Lemmas 25 and 26 to (22).

$$\mathbb{P}\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i}M_j(g)-\frac{3}{2}\mathbb{E}_jM_j(g)\geq\tau\right]$$
$$\leq 2\mathbb{P}\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i}M_j(g)-M_j'(g)-\frac{1}{4}Q_j(x_j')\ell^2(g,x_j')\geq\tau/2\right]$$
$$\leq 4\mathbb{E}\sup_{\mathcal{Q}}\mathbb{P}_\epsilon\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i}\epsilon_j\mathcal{Q}_j(\epsilon)\left(\frac{9}{8}\ell^2(g,x_j)+2\xi_j\ell(g,x_j)\right)-\frac{1}{8}\mathcal{Q}_j(\epsilon_i)\ell^2(g,x_j)\geq\frac{\tau}{4}\right].$$

Now let $V(X)$ be the cover for $\mathcal{G}$ at scale $\alpha=\frac{\tau}{32i(9/8)}=\frac{\tau}{36i}$, which makes $\tau/4-4i(1+\beta_1)\alpha=\frac{\tau}{8}$. Thus we get the bound

$$\leq 4\mathbb{E}_{X,\xi}\sup_{\mathcal{Q}}\mathbb{P}_\epsilon\left[\sup_{h\in\mathcal{H}(X)}\sum_{j=1}^{i}\epsilon_j\mathcal{Q}_j(\epsilon)\left(\frac{9}{8}\ell^2(h,x_j)+2\xi_j\ell(h,x_j)\right)-\frac{1}{8}\mathcal{Q}_j(\epsilon_i)\ell^2(h,x_j)\geq\frac{\tau}{8}\right]$$
$$\leq 4\mathbb{E}_X|V(X)|\exp\left(\frac{-2(1/8)(\tau/8)}{(3+1/8)^2}\right)=2\exp(-2\tau/625)\mathbb{E}_X\mathcal{N}\left(\frac{\tau}{36i},\mathcal{G},X\right).$$

This entire derivation requires that $\tau\geq\frac{4(9/8)^2}{(1/8)^2}=324$.

The lower tail bound is similar. By Lemmas 25 and 26, with $\beta_0 = 1/4$ and $\beta_1 = 1/8$,

$$\begin{aligned}
&\mathbb{P}\left[\sup_{g\in\mathcal{G}}\sum_{i=1}^{n}\frac{1}{2}\mathbb{E}_j M_j(g) - M_j(g) \geq \tau\right] \\
&\leq 2\mathbb{P}\left[\sup_{g\in\mathcal{G}}\sum_{i=1}^{n}\frac{1}{2}\mathbb{E}_j M_j(g) - M_j(g) - 2(1/8)Q_j(x'_j)\ell^2(g,x'_j) \geq \frac{\tau}{2}\right] \\
&\leq 4\mathbb{E}\sup_{\mathcal{Q}}\mathbb{P}_\epsilon\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i}\epsilon_j\mathcal{Q}_j(\epsilon)\left[\frac{7}{8}\ell^2(g,x_j) + 2\xi_j\ell(g,x_j)\right] - \frac{1}{8}\sum_{j=1}^{i}\mathcal{Q}_i(\epsilon)\ell^2(g,x_j) \geq \frac{\tau}{4}\right] \\
&\leq 4\mathbb{E}\sup_{\mathcal{Q}}\mathbb{P}_\epsilon\left[\sup_{g\in\mathcal{G}}\sum_{j=1}^{i}\epsilon_j\mathcal{Q}_j(\epsilon)\left[\frac{9}{8}\ell^2(g,x_j) + 2\xi_j\ell(g,x_j)\right] - \frac{1}{8}\sum_{j=1}^{i}\mathcal{Q}_i(\epsilon)\ell^2(g,x_j) \geq \frac{\tau}{4}\right].
\end{aligned}$$

This is the intermediate term we had for the upper tail, so we obtain the same bound.

To wrap up the proof, apply Haussler's Lemma 22, to bound the covering number

$$\mathbb{E}_X\mathcal{N}\left(\frac{\tau}{36i}, \mathcal{G}, X\right) \leq e(d+1)\left(\frac{72ie}{\tau}\right)^d.$$

Finally take a union bound over all pairs of starting and ending indices $i < i'$, all labels y, and both tails to get that the total failure probability is at most

$$8Ke(d+1)\exp\left(-2\tau/625\right)\sum_{i<i'\in[n]}\left(\frac{72e(i'-i)}{\tau}\right)^d.$$

The result now follows from standard approximations. Specifically we use the fact that we anyway require $\tau \geq 324$ to upper bound that $1/\tau^d$ term, use $(i'-i)^d \leq n^d$ and set the whole expression to be at most δ.

Appendix B. Multiplicative Weights

For completeness we prove Theorem 16 here. For this section only let $q^{(t)} \propto p^{(t)}$ be the distribution used by the algorithm at round t. If the program is feasible, then there exists a point that is also feasible against every distribution q. By contraposition, if on iteration t, the oracle reports infeasibility against $q^{(t)}$, then the original program must be infeasible.

Now suppose the oracle always finds v_t that is feasible against $q^{(t)}$. This implies

$$0 \leq \sum_{t=1}^{T}\sum_{i=1}^{n} q_i^{(t)}(b_i - \langle a_i, v_t\rangle).$$

Define $\ell_t(i) = \frac{b_i - \langle a_i, v_t\rangle}{\rho_i}$ which is in $[-1,1]$ by assumption. We compare this term to the corresponding term for a single constraint i. Using the standard potential-based analysis,

with $\Phi^{(t)} = \sum_i p_i^{(t)}$, we get

$$\begin{aligned}
\Phi^{(T+1)} = \sum_{i=1}^{m} p_i^{(T)}\left(1 - \eta\ell_T(i)\right) &\leq \Phi^{(T)}\exp\left(-\eta\sum_{i=1}^{m} q_i^{(T)}\ell_T(i)\right) \\
&\leq m\exp\left(-\eta\sum_{t=1}^{T}\sum_{i=1}^{m} q_i^{(t)}\ell_t(i)\right).
\end{aligned}$$

For any i, we also have

$$\Phi^{(T+1)} \geq \prod_{t=1}^{T}(1 - \eta\ell_t(i)).$$

Thus, taking taking logarithms and re-arranging we get

$$0 \leq \sum_{t=1}^{T}\sum_{i=1}^{m} q_i^{(t)}\ell_t(i) \leq \frac{\log(m)}{\eta} + \frac{1}{\eta}\sum_{t=1}^{T}\log\left(\frac{1}{1-\eta\ell_t(i)}\right) \leq \frac{\log m}{\eta} + \sum_{t=1}^{T}\ell_t(i) + \eta T.$$

Here we use standard approximations $\log(1/(1-x)) \leq x + x^2$ (which holds for $x \leq 1/2$) along with the fact that $|\ell_t(i)| \leq 1$. Using the definition of $\ell_t(i)$ we have hence proved that

$$\sum_{t=1}^{T}\langle a_i, v_t\rangle \leq Tb_i + \frac{\rho_i\log m}{\eta} + \rho_i\eta T.$$

Now with our choice of $\eta = \sqrt{\log(m)/T}$ we get the desired bound. If $\eta \geq 1/2$ then the result is trivial by the boundedness guarantee on the oracle.

Appendix C. Proofs of Lemmata

Proof [Proof of Lemma 14] By the definitions,

$$\begin{aligned}
\widehat{R}(g') + w'(g'(x)-c)^2 = \widehat{R}(g', w', c) &\leq \widehat{R}(g) + w'(g(x)-c)^2 \\
&= \widehat{R}(g) + w(g(x)-c)^2 + (w'-w)(g(x)-c)^2 \\
&\leq \widehat{R}(g') + w(g'(x)-c)^2 + (w'-w)(g(x)-c)^2.
\end{aligned}$$

Rearranging shows that $(w'-w)(g'(x)-c)^2 \leq (w'-w)(g(x)-c)^2$. Since $w' \geq w$, we have $(g'(x)-c)^2 \leq (g(x)-c)^2$, which is the second claim. For the first, the definition of g gives

$$\widehat{R}(g) + w(g(x)-c)^2 \leq \widehat{R}(g') + w(g'(x)-c)^2.$$

Rearranging this inequality gives, $\widehat{R}(g') - \widehat{R}(g) \geq w((g(x)-c)^2 - (g'(x)-c)^2) \geq 0$, which yields the result. ∎

Proof [Proof of Lemma 17] We take expectation of M_j over the cost conditioned on a fixed example $x_j = x$ and a fixed query outcome $Q_j(y)$:

$$\begin{aligned}\mathbb{E}[M_j \mid x_j = x, Q_j(y)] &= Q_j(y) \times \mathbb{E}_c[g(x)^2 - f^\star(x;y)^2 - 2c(y)(g(x) - f^\star(x;y)) \mid x_j = x] \\ &= Q_j(y)\big(g(x)^2 - f^\star(x;y)^2 - 2f^\star(x;y)(g(x) - f^\star(x;y))\big) \\ &= Q_j(y)(g(x) - f^\star(x;y))^2.\end{aligned}$$

The second equality is by Assumption 1, which implies $\mathbb{E}[c(y) \mid x_j = x] = f^\star(x;y)$. Taking expectation over x_j and $Q_j(y)$, we have

$$\mathbb{E}_j[M_j] \;=\; \mathbb{E}_j\left[Q_j(y)(g(x_j) - f^\star(x_j;y))^2\right].$$

For the variance:

$$\begin{aligned}\operatorname*{Var}_j[M_j] \le \mathbb{E}_j[M_j^2] &= \mathbb{E}_j\left[Q_j(y)(g(x_j) - f^\star(x_j;y))^2(g(x_j) + f^\star(x_j;y) - 2c(y))^2\right] \\ &\le 4 \cdot \mathbb{E}_j\left[Q_j(y)(g(x_j) - f^\star(x_j;y))^2\right] = 4\mathbb{E}_j[M_j].\end{aligned}$$

This concludes the proof. ■

Proof [Proof of Lemma 18] Fix some $f \in \mathcal{F}_i$, and let $\hat{y} = h_f(x)$ and $y^\star = h_{f^\star}(x)$ for shorthand, but note that both depend on x. Define

$$S_\zeta(x) = \mathbb{1}\left(f^\star(x,\hat{y}) \le f^\star(x,y^\star) + \zeta\right), \qquad S'_\zeta(x) = \mathbb{1}\left(\min_{y \neq y^\star} f^\star(x,y) \le f^\star(x,y^\star) + \zeta\right).$$

Observe that for fixed ζ, $S_\zeta(x)\mathbb{1}(\hat{y} \neq y^\star) \le S'_\zeta(x)$ for all x. We can also majorize the complementary indicator to obtain the inequality

$$S^C_\zeta(x) \le \frac{f^\star(x,\hat{y}) - f^\star(x,y^\star)}{\zeta}.$$

We begin with the definition of realizability, which gives

$$\begin{aligned}\mathbb{E}_{x,c}[c(h_f(x)) - c(h_{f^\star}(x)] &= \mathbb{E}_x\left[(f^\star(x,\hat{y}) - f^\star(x,y^\star))\,\mathbb{1}(\hat{y} \neq y^\star)\right] \\ &= \mathbb{E}_x\left[\left(S_\zeta(x) + S^C_\zeta(x)\right)(f^\star(x,\hat{y}) - f^\star(x,y^\star))\,\mathbb{1}(\hat{y} \neq y^\star)\right] \\ &\le \zeta\mathbb{E}_x S'_\zeta(x) + \mathbb{E}_i\left[S^C_\zeta(x)\mathbb{1}(\hat{y} \neq y^\star)(f^\star(x,\hat{y}) - f^\star(x,y^\star))\right].\end{aligned}$$

The first term here is exactly the ζP_ζ term in the bound. We now focus on the second term, which depends on our query rule. For this we must consider three cases.

Case 1. If both $\hat{y}$ and $y^\star$ are not queried, then it must be the case that both have small cost ranges. This follows since $f \in \mathcal{F}_i$ and $h_f(x) = \hat{y}$ so $y^\star$ does not dominate $\hat{y}$. Moreover, since the cost ranges are small on both $\hat{y}$ and $y^\star$ and since we know that $f^\star$ is well separated under event $S^C_\zeta(x)$, the relationship between ζ and ψ_i governs whether we make a mistake or not. Specifically, we get that $S^C_\zeta(x)\mathbb{1}(\hat{y} \neq y^\star)\,\mathbb{1}(\text{no query}) \le \mathbb{1}(\zeta \le 2\psi_i)$ at round i. In other words, if we do not query and the separation is big but we make a mistake, then it must mean that the cost range threshold ψ_i is also big.

Using this argument, we can bound the second term as,

$$\begin{aligned}&\mathbb{E}_i\left[S^C_\zeta(x)\mathbb{1}(\hat{y} \neq y^\star)(1 - Q_i(\hat{y}))(1 - Q_i(y^\star))(f^\star(x,\hat{y}) - f^\star(x,y^\star))\right] \\ &\le \mathbb{E}_i\left[S^C_\zeta(x)\mathbb{1}(\hat{y} \neq y^\star)(1 - Q_i(\hat{y}))(1 - Q_i(y^\star))2\psi_i\right] \\ &\le \mathbb{E}_i\left[\mathbb{1}(\zeta \le 2\psi_i)\,2\psi_i\right] = \mathbb{1}(\zeta \le 2\psi_i)\,2\psi_i.\end{aligned}$$

Case 2. If both $\hat{y}$ and $y^\star$ are queried, we can relate the second term to the square loss,

$$\begin{aligned}&\mathbb{E}_i\left[S^C_\zeta(x)Q_i(\hat{y})Q_i(y^\star)(f^\star(x,\hat{y}) - f^\star(x,y^\star))\right] \\ &\le \frac{1}{\zeta}\mathbb{E}_i\left[Q_i(\hat{y})Q_i(y^\star)(f^\star(x,\hat{y}) - f^\star(x,y^\star))^2\right] \\ &\le \frac{1}{\zeta}\mathbb{E}_i\left[Q_i(\hat{y})Q_i(y^\star)(f^\star(x,\hat{y}) - f(x,\hat{y}) + f(x,y^\star) - f^\star(x,y^\star))^2\right] \\ &\le \frac{2}{\zeta}\mathbb{E}_i\left[Q_i(\hat{y})(f^\star(x,\hat{y}) - f(x,\hat{y}))^2 + Q_i(y^\star)(f(x,y^\star) - f^\star(x,y^\star))^2\right] \\ &\le \frac{2}{\zeta}\sum_y \mathbb{E}_i\left[Q_i(y)(f^\star(x,y) - f(x,y))^2\right] = \frac{2}{\zeta}\sum_y \mathbb{E}_i\left[M_i(f;y)\right].\end{aligned}$$

Passing from the second to third line here is justified by the fact that $f^\star(x,\hat{y}) \ge f^\star(x,y^\star)$ and $f(x,\hat{y}) \le f(x,y^\star)$ so we added two non-negative quantities together. The last step uses Lemma 17. While not written, we also use the event $\mathbb{1}(\hat{y} \neq y^\star)$ to save a factor of 2.

Case 3. The last case is if one label is queried and the other is not. Both cases here are analogous, so we do the derivation for when $y(x)$ is queried but $y^\star(x)$ is not. Since in this case, $y^\star(x)$ is not dominated ($h_f(x)$ is never dominated provided $f \in \mathcal{F}_i$), we know that the cost range for $y^\star(x)$ must be small. Using this fact, and essentially the same argument as in case 2, we get

$$\begin{aligned}&\mathbb{E}_i\left[S^C_\zeta(x)Q_i(\hat{y})(1 - Q_i(y^\star))(f^\star(x,\hat{y}) - f^\star(x,y^\star))\right] \\ &\le \frac{1}{\zeta}\mathbb{E}_i\left[Q_i(\hat{y})(1 - Q_i(y^\star))(f^\star(x,\hat{y}) - f^\star(x,y^\star))^2\right] \\ &\le \frac{2}{\zeta}\mathbb{E}_i\left[Q_i(\hat{y})(f^\star(x,\hat{y}) - f(x,\hat{y}))^2 + (1 - Q_i(y^\star))(f(x,y^\star) - f^\star(x,y^\star))^2\right] \\ &\le \frac{2\psi_i^2}{\zeta} + \frac{2}{\zeta}\mathbb{E}_i\left[Q_i(\hat{y})(f^\star(x,\hat{y}) - f(x,\hat{y}))^2\right] \le \frac{2\psi_i^2}{\zeta} + \frac{2}{\zeta}\sum_y \mathbb{E}_i\left[M_i(f;y)\right].\end{aligned}$$

We also obtain this term for the other case where $y^\star$ is queried but $\hat{y}$ is not.

To summarize, adding up the contributions from these cases (which is an over-estimate since at most one case can occur and all are non-negative), we get

$$\mathbb{E}_{x,c}[c(h_f(x)) - c(h_{f^\star}(x)] \le \zeta P_\zeta + \mathbb{1}(\zeta \le 2\psi_i)\,2\psi_i + \frac{4\psi_i^2}{\zeta} + \frac{6}{\zeta}\sum_y \mathbb{E}_i\left[M_i(f;y)\right].$$

This bound holds for any ζ, so it holds for the minimum. ■

Proof [Proof of Lemma 19] The proof here is an easier version of the generalization bound proof for f_i. First, condition on the high probability event in Theorem 15, under which we already showed that $f^\star \in \mathcal{F}_i$ for all $i \in [n]$. Now fix some $f \in \mathcal{F}_i$. Since by the monotonicity property defining the sets $\mathcal{G}_i$, we must have $f \in \mathcal{F}_j$ for all $1 \le j \le i$, we can immediately apply Lemma 18 on all rounds to bound the cost sensitive regret by

$$\frac{1}{i-1}\sum_{j=1}^{i-1}\min_{\zeta>0}\left\{\zeta P_\zeta + \mathbf{1}\{\zeta \le 2\psi_j\}2\psi_j + \frac{4\psi_j^2}{\zeta} + \frac{6}{\zeta}\sum_y \mathbb{E}_j[M_j(f;y)]\right\}.$$

As in the generalization bound, the first term contributes ζP_ζ, the second is at most $\frac{12}{\zeta}$ and the third is at most $4/\zeta(1+\log(i-1))$. The fourth term is slightly different. We still apply (17) to obtain

$$\begin{aligned}\frac{1}{i-1}\sum_{j=1}^{i-1}\mathbb{E}_j[M_j(f;y)] &\le \frac{2}{i-1}\sum_{j=1}^{i-1}M_j(f;y) + \frac{2\nu_n}{i-1}\\ &= 2\left(\widehat{R}_i(f;y) - \widehat{R}_i(g_{i,y};y) + \widehat{R}_i(g_{i,y};y) - \widehat{R}_i(f^\star;y)\right) + \frac{2\nu_n}{i-1}\\ &\le 2\Delta_i + \frac{2\nu_n}{i-1} = \frac{2(\kappa+1)\nu_n}{i-1}.\end{aligned}$$

We use this bound for each label. Putting terms together, the cost sensitive regret is

$$\min_{\zeta>0}\left\{\zeta P_\zeta + \frac{12}{\zeta} + \frac{4(1+\log(i-1))}{\zeta} + \frac{12K(\kappa+1)\nu_n}{\zeta(i-1)}\right\} \le \min_{\zeta>0}\left\{\zeta P_\zeta + \frac{44\kappa K\nu_n}{\zeta(i-1)}\right\}.$$

This proves containment, since this upper bounds the cost sensitive regret of every $f \in \mathcal{F}_i$. ■

Proof [Proof of Lemma 20] The first claim is straightforward, since $\mathcal{F}_i \subset \mathcal{F}_{\text{csr}}(r_i)$ and since we set the tolerance parameter in the calls to MaxCost and MinCost to $\psi_i/4$. Specifically,

$$\widehat{\gamma}(x_i,y) \le \gamma(x_i,y,\mathcal{F}_i) + \psi_i/2 \le \gamma(x_i,y,\mathcal{F}_{\text{csr}}(r_i)) + \psi_i/2.$$

For the second claim, suppose $y \neq y_i^\star$. Then

$$\begin{aligned}y \in Y_i &\Rightarrow \widehat{c_-}(x_i,y) \le \widehat{c_+}(x_i,\bar{y}_i)\\ &\Rightarrow \widehat{c_-}(x_i,y) \le \widehat{c_+}(x_i,y_i^\star)\\ &\Rightarrow c_-(x_i,y,\mathcal{F}_{\text{csr}}(r_i)) \le c_+(x_i,y_i^\star,\mathcal{F}_{\text{csr}}(r_i)) + \psi_i/2\\ &\Rightarrow f^\star(x_i;y) - \gamma(x_i,y,\mathcal{F}_{\text{csr}}(r_i)) \le f^\star(x_i;y_i^\star) + \gamma(x_i,y_i^\star,\mathcal{F}_{\text{csr}}(r_i)) + \psi_i/2.\end{aligned}$$

This argument uses the tolerance setting $\psi_i/4$, Lemma 19 to translate between the version space and the cost-sensitive regret ball, and finally the fact that $f^\star \in \mathcal{F}_{\text{csr}}(r_i)$ since it has zero cost-sensitive regret. This latter fact lets us lower (upper) bound the minimum (maximum) cost by $f^\star$ prediction minus (plus) the cost range.

For $y_i^\star$ we need to consider two cases. First assume $y_i^\star = \bar{y}_i$. Since by assumption $|Y_i| > 1$, it must be the case that $\widehat{c_-}(x_i,\tilde{y}_i) \le \widehat{c_+}(x_i,y_i^\star)$ at which point the above derivation produces the desired implication. On the other hand, if $y_i^\star \neq \bar{y}_i$ then $\widehat{c_+}(x_i,\bar{y}_i) \le \widehat{c_+}(x_i,y_i^\star)$, but this also implies that $\widehat{c_-}(x_i,\tilde{y}_i) \le \widehat{c_+}(x_i,y_i^\star)$, since minimum costs are always smaller than maximum costs, and $\bar{y}_i$ is included in the search defining $\tilde{y}_i$. ■

Abstract

Proximal distance algorithms combine the classical penalty method of constrained minimization with distance majorization. If $f(\boldsymbol{x})$ is the loss function, and C is the constraint set in a constrained minimization problem, then the proximal distance principle mandates minimizing the penalized loss $f(\boldsymbol{x}) + \frac{\rho}{2}\operatorname{dist}(\boldsymbol{x}, C)^2$ and following the solution $\boldsymbol{x}_\rho$ to its limit as ρ tends to ∞. At each iteration the squared Euclidean distance $\operatorname{dist}(\boldsymbol{x}, C)^2$ is majorized by the spherical quadratic $\|\boldsymbol{x} - P_C(\boldsymbol{x}_k)\|^2$, where $P_C(\boldsymbol{x}_k)$ denotes the projection of the current iterate $\boldsymbol{x}_k$ onto C. The minimum of the surrogate function $f(\boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{x} - P_C(\boldsymbol{x}_k)\|^2$ is given by the proximal map $\operatorname{prox}_{\rho^{-1}f}[P_C(\boldsymbol{x}_k)]$. The next iterate $\boldsymbol{x}_{k+1}$ automatically decreases the original penalized loss for fixed ρ. Since many explicit projections and proximal maps are known, it is straightforward to derive and implement novel optimization algorithms in this setting. These algorithms can take hundreds if not thousands of iterations to converge, but the simple nature of each iteration makes proximal distance algorithms competitive with traditional algorithms. For convex problems, proximal distance algorithms reduce to proximal gradient algorithms and therefore enjoy well understood convergence properties. For nonconvex problems, one can attack convergence by invoking Zangwill's theorem. Our numerical examples demonstrate the utility of proximal distance algorithms in various high-dimensional settings, including a) linear programming, b) constrained least squares, c) projection to the closest kinship matrix, d) projection onto a second-order cone constraint, e) calculation of Horn's copositive matrix index, f) linear complementarity programming, and g) sparse principal components analysis. The proximal distance algorithm in each case is competitive or superior in speed to traditional methods such as the interior point method and the alternating direction method of multipliers (ADMM). Source code for the numerical examples can be found at `https://github.com/klkeys/proxdist`.

1. Introduction

The solution of constrained optimization problems is part science and part art. As mathematical scientists explore the largely uncharted territory of high-dimensional nonconvex problems, it is imperative to consider new methods. The current paper studies a class of optimization algorithms that combine Courant's penalty method of optimization (Beltrami, 1970; Courant, 1943) with the notion of a proximal operator (Bauschke and Combettes, 2011; Moreau, 1962; Parikh and Boyd, 2013). The classical penalty method turns constrained minimization of a function $f(\boldsymbol{x})$ over a closed set C into unconstrained minimization. The general idea is to seek the minimum point of a penalized version $f(\boldsymbol{x}) + \rho q(\boldsymbol{x})$ of $f(\boldsymbol{x})$, where the penalty $q(\boldsymbol{x})$ is nonnegative and vanishes precisely on C. If one follows the solution vector $\boldsymbol{x}_\rho$ as ρ tends to ∞, then in the limit one recovers the constrained solution. The penalties of choice in the current paper are squared Euclidean distances $\operatorname{dist}(\boldsymbol{x}, C)^2 = \inf_{\boldsymbol{y} \in C} \|\boldsymbol{x} - \boldsymbol{y}\|^2$.

The formula

$$\operatorname{prox}_f(\boldsymbol{y}) \;=\; \operatorname{argmin}_{\boldsymbol{x}} \left[f(\boldsymbol{x}) + \frac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|^2 \right] \tag{1}$$

defines the proximal map of a function $f(\boldsymbol{x})$. Here $\|\cdot\|$ is again the standard Euclidean norm, and $f(\boldsymbol{x})$ is typically assumed to be closed and convex. Projection onto a closed convex set C is realized by choosing $f(\boldsymbol{x})$ to be the $0/\infty$ indicator $\delta_C(\boldsymbol{x})$ of C. It is possible to drop the convexity assumption if $f(\boldsymbol{x})$ is nonnegative or coercive. In so doing, $\operatorname{prox}_f(\boldsymbol{y})$ may become multi-valued. For example, the minimum distance from a nonconvex set to an exterior point may be attained at multiple boundary points. The point $\boldsymbol{x}$ in the definition (1) can be restricted to a subset S of Euclidean space by replacing $f(\boldsymbol{x})$ by $f(\boldsymbol{x}) + \delta_S(\boldsymbol{x})$, where $\delta_S(\boldsymbol{x})$ is the indicator of S.

One of the virtues of exploiting proximal operators is that they have been thoroughly investigated. For a large number of functions $f(\boldsymbol{x})$, the map $\operatorname{prox}_{cf}(\boldsymbol{y})$ for $c > 0$ is either given by an exact formula or calculable by an efficient algorithm. The known formulas tend to be highly accurate. This is a plus because the classical penalty method suffers from ill conditioning for large values of the penalty constant. Although the penalty method seldom delivers exquisitely accurate solutions, moderate accuracy suffices for many problems.

There are ample precedents in the optimization literature for the proximal distance principle. Proximal gradient algorithms have been employed for many years in many contexts, including projected Landweber, alternating projection onto the intersection of two or more closed convex sets, the alternating-direction method of multipliers (ADMM), and fast iterative shrinkage thresholding algorithms (FISTA) (Beck and Teboulle, 2009; Combettes and Pesquet, 2011; Landweber, 1951). Applications of distance majorization are more recent (Chi et al., 2014; Lange and Keys, 2014; Xu et al., 2017). The overall strategy consists of replacing the distance penalty $\operatorname{dist}(\boldsymbol{x}, C)^2$ by the spherical quadratic $\|\boldsymbol{x} - \boldsymbol{y}_k\|^2$, where $\boldsymbol{y}_k$ is the projection of the kth iterate $\boldsymbol{x}_k$ onto C. To form the next iterate, one then sets

$$\boldsymbol{x}_{k+1} \;=\; \operatorname{prox}_{\rho^{-1}f}(\boldsymbol{y}_k) \quad \text{with} \quad \boldsymbol{y}_k \;=\; P_C(\boldsymbol{x}_k).$$

The MM (majorization-minimization) principle guarantees that $\boldsymbol{x}_{k+1}$ decreases the penalized loss. We call the combination of Courant's penalty method with distance majorization the *proximal distance principle*. Algorithms constructed according to the principle are *proximal distance algorithms*.

The current paper extends and deepens our previous preliminary treatments of the proximal distance principle. Details of implementation such as Nesterov acceleration matter in performance. We have found that squared distance penalties tend to work better than exact penalties. In the presence of convexity, it is now clear that every proximal distance algorithm reduces to a proximal gradient algorithm. Hence, convergence analysis can appeal to a venerable body of convex theory. This does not imply that the proximal distance algorithm is limited to convex problems. In fact, its most important applications may well be to nonconvex problems. A major focus of this paper is on practical exploration of the proximal distance algorithm.

In addition to reviewing the literature, the current paper presents some fresh ideas. Among the innovations are: a) recasting proximal distance algorithms with convex losses as concave-convex programs, b) providing new perspectives on convergence for both convex and nonconvex proximal distance algorithms, c) demonstrating the virtue of folding constraints into the domain of the loss, and d) treating in detail seven interesting examples. It is noteworthy that some our new convergence theory is pertinent to more general MM algorithms.

It is our sincere hope to enlist other mathematical scientists in expanding and clarifying this promising line of research. The reviewers of the current paper have correctly pointed out that we do not rigorously justify our choices of the penalty constant sequence ρ_k. The recent paper by Li et al. (2017) may be a logical place to start in filling this theoretical gap. They deal with the problem of minimizing $f(\boldsymbol{x})$ subject to $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ through the quadratic penalized objective $f(\boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}\|^2$. For the right choices of the penalty sequence ρ_k, their proximal gradient algorithm achieves a $O(k^{-1})$ rate of convergence for $f(\boldsymbol{x})$ strongly convex. As a substitute, we explore the classical problem of determining how accurately the solution $\boldsymbol{y}_\rho$ of the problem $\min_{\boldsymbol{x}} f(\boldsymbol{x}) + \frac{\rho}{2} q(\boldsymbol{x})^2$ approximates the solution $\boldsymbol{y}$ of the constrained problem $\min_{\boldsymbol{x} \in C} f(\boldsymbol{x})$. Polyak (1971) demonstrates that $f(\boldsymbol{y}) - f(\boldsymbol{y}_\rho) = O(\rho^{-1})$ for a penalty function $q(\boldsymbol{x})$ that vanishes precisely on C. Polyak's proof relies on strong differentiability assumptions. Our proof for the case $q(\boldsymbol{x}) = \operatorname{dist}(\boldsymbol{x}, C)$ relies on convexity and is much simpler.

As a preview, let us outline the remainder of our paper. Section 2 briefly sketches the underlying MM principle. We then show how to construct proximal distance algorithms from the MM principle and distance majorization. The section concludes with the derivation of a few broad categories proximal distance algorithms. Section 3 covers convergence theory for convex problems, while Section 4 provides a more general treatment of convergence for nonconvex problems. To avoid breaking the flow of our exposition, all proofs are relegated to the Appendix. Section 5 discusses our numerical experiments on various convex and nonconvex problems. Section 6 closes by indicating some future research directions.

2. Derivation

The derivation of our proximal distance algorithms exploits the majorization-minimization (MM) principle (Hunter and Lange, 2004; Lange, 2010). In minimizing a function $f(\boldsymbol{x})$, the MM principle exploits a surrogate function $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$ that majorizes $f(\boldsymbol{x})$ around the current iterate $\boldsymbol{x}_k$. Majorization mandates both domination $g(\boldsymbol{x} \mid \boldsymbol{x}_k) \geq f(\boldsymbol{x})$ for all feasible $\boldsymbol{x}$ and tangency $g(\boldsymbol{x}_k \mid \boldsymbol{x}_k) = f(\boldsymbol{x}_k)$ at the anchor $\boldsymbol{x}_k$. If $\boldsymbol{x}_{k+1}$ minimizes $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$, then the

descent property $f(\boldsymbol{x}_{k+1}) \leq f(\boldsymbol{x}_k)$ follows from the string of inequalities and equalities

$$f(\boldsymbol{x}_{k+1}) \;\leq\; g(\boldsymbol{x}_{k+1} \mid \boldsymbol{x}_k) \;\leq\; g(\boldsymbol{x}_k \mid \boldsymbol{x}_k) \;=\; f(\boldsymbol{x}_k).$$

Clever selection of the surrogate $g(\boldsymbol{x} \mid \boldsymbol{x}_{k+1})$ can lead to a simple algorithm with an explicit update that requires little computation per iterate. The number of iterations until convergence of an MM algorithm depends on how tightly $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$ hugs $f(\boldsymbol{x})$. Constraint satisfaction is built into any MM algorithm. If maximization of $f(\boldsymbol{x})$ is desired, then the objective $f(\boldsymbol{x})$ should dominate the surrogate $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$ subject to the tangency condition. The next iterate $\boldsymbol{x}_{k+1}$ is then chosen to maximize $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$. The minorization-maximization version of the MM principle guarantees the ascent property.

The constraint set C over which the loss $f(\boldsymbol{x})$ is minimized can usually be expressed as an intersection $\cap_{i=1}^m C_i$ of closed sets. It is natural to define the penalty

$$q(\boldsymbol{x}) \;=\; \frac{1}{2}\sum_{i=1}^m \alpha_i \operatorname{dist}(\boldsymbol{x}, C_i)^2$$

using a convex combination of the squared distances. The neutral choice $\alpha_i = \frac{1}{m}$ is one we prefer in practice. Distance majorization gives the surrogate function

$$\begin{aligned} g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) &= f(\boldsymbol{x}) + \frac{\rho}{2}\sum_{i=1}^m \alpha_i \|\boldsymbol{x} - P_{C_i}(\boldsymbol{x}_k)\|^2 \\ &= f(\boldsymbol{x}) + \frac{\rho}{2}\Big\|\boldsymbol{x} - \sum_{i=1}^m \alpha_i P_{C_i}(\boldsymbol{x}_k)\Big\|^2 + c_k \end{aligned}$$

for an irrelevant constant c_k. If we put $\boldsymbol{y}_k = \sum_{i=1}^m \alpha_i P_{C_i}(\boldsymbol{x}_k)$, then by definition the minimum of the surrogate $g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k)$ occurs at the proximal point

$$\boldsymbol{x}_{k+1} \;=\; \operatorname{prox}_{\rho^{-1} f}(\boldsymbol{y}_k). \tag{2}$$

We call this MM algorithm the proximal distance algorithm. The penalty $q(\boldsymbol{x})$ is generally smooth because

$$\nabla \frac{1}{2}\operatorname{dist}(\boldsymbol{x}, C)^2 \;=\; \boldsymbol{x} - P_C(\boldsymbol{x})$$

at any point $\boldsymbol{x}$ where the projection $P_C(\boldsymbol{x})$ is single valued (Borwein and Lewis, 2006; Lange, 2016). This is always true for convex sets and almost always true for nonconvex sets. For the moment, we will ignore the possibility that $P_C(\boldsymbol{x})$ is multi-valued.

For the special case of projection of an external point $\boldsymbol{z}$ onto the intersection C of the closed sets C_i, one should take $f(\boldsymbol{x}) = \frac{1}{2}\|\boldsymbol{z} - \boldsymbol{x}\|^2$. The proximal distance iterates then obey the explicit formula

$$\boldsymbol{x}_{k+1} \;=\; \frac{1}{1+\rho}(\boldsymbol{z} + \rho \boldsymbol{y}_k).$$

Linear programming with arbitrary convex constraints is another example. Here the loss is $f(\boldsymbol{x}) = \boldsymbol{v}^t \boldsymbol{x}$, and the update reduces to

$$\boldsymbol{x}_{k+1} \;=\; \boldsymbol{y}_k - \frac{1}{\rho}\boldsymbol{v}.$$

If the proximal map is impossible to calculate, but $f(\boldsymbol{x})$ is L-smooth ($\nabla f(\boldsymbol{x})$ is Lipschitz with constant L), then one can substitute the standard majorization

$$f(\boldsymbol{x}) \leq f(\boldsymbol{x}_k) + \nabla f(\boldsymbol{x}_k)^t(\boldsymbol{x}-\boldsymbol{x}_k) + \frac{L}{2}\|\boldsymbol{x}-\boldsymbol{x}_k\|^2$$

for $f(\boldsymbol{x})$. Minimizing the sum of the loss majorization plus the penalty majorization leads to the MM update

$$\begin{aligned}\boldsymbol{x}_{k+1} &= \frac{1}{L+\rho}[-\nabla f(\boldsymbol{x}_k) + L\boldsymbol{x}_k + \rho\boldsymbol{y}_k] \\ &= \boldsymbol{x}_k - \frac{1}{L+\rho}[\nabla f(\boldsymbol{x}_k) + \rho\nabla q(\boldsymbol{x}_k)]. \end{aligned} \tag{3}$$

This is a gradient descent algorithm without an intervening proximal map.

In moderate-dimensional problems, local quadratic approximation of $f(\boldsymbol{x})$ can lead to a viable algorithm. For instance, in generalized linear statistical models, Xu et al. (2017) suggest replacing the observed information matrix by the expected information matrix. The latter matrix has the advantage of being positive semidefinite. In our notation, if $\boldsymbol{A}_k \approx d^2 f(\boldsymbol{x}_k)$, then an approximate quadratic surrogate is

$$f(\boldsymbol{x}_k) + \nabla f(\boldsymbol{x}_k)^t(\boldsymbol{x}-\boldsymbol{x}_k) + \frac{1}{2}(\boldsymbol{x}-\boldsymbol{x}_k)^t\boldsymbol{A}_k(\boldsymbol{x}-\boldsymbol{x}_k) + \frac{\rho}{2}\|\boldsymbol{x}-\boldsymbol{y}_k\|^2.$$

The natural impulse is to update $\boldsymbol{x}$ by the Newton step

$$\boldsymbol{x}_{k+1} = \boldsymbol{x}_k - (\boldsymbol{A}_k + \rho\boldsymbol{I})^{-1}[\nabla f(\boldsymbol{x}_k) - \rho\boldsymbol{y}_k]. \tag{4}$$

This choice does not necessarily decrease $f(\boldsymbol{x})$. Step halving or another form of backtracking restores the descent property.

A more valid concern is the effort expended in matrix inversion. If $\boldsymbol{A}_k$ is dense and constant, then extracting the spectral decomposition $\boldsymbol{V}\boldsymbol{D}\boldsymbol{V}^t$ of $\boldsymbol{A}$ reduces formula (4) to

$$\boldsymbol{x}_{k+1} = \boldsymbol{x}_k - \boldsymbol{V}(\boldsymbol{D}+\rho\boldsymbol{I})^{-1}\boldsymbol{V}^t[\nabla f(\boldsymbol{x}_k) - \rho\boldsymbol{y}_k],$$

which can be implemented as a sequence of matrix-vector multiplications. Alternatively, one can take just a few terms of the series

$$(\boldsymbol{A}_k + \rho\boldsymbol{I})^{-1} = \rho^{-1}\sum_{j=0}^{\infty}(-\rho^{-1}\boldsymbol{A}_k)^j$$

when ρ is sufficiently large. For a generalized linear model, parameter updating involves solving the linear system

$$(\boldsymbol{Z}^t\boldsymbol{W}_k\boldsymbol{Z} + \rho\boldsymbol{I})\boldsymbol{x} = \boldsymbol{Z}^t\boldsymbol{W}_k^{1/2}\boldsymbol{v}_k + \rho\boldsymbol{y}_k \tag{5}$$

for $\boldsymbol{W}_k$ a diagonal matrix with positive diagonal entries. This task is equivalent to minimizing the least squares criterion

$$\left\|\begin{pmatrix}\boldsymbol{W}_k^{1/2}\boldsymbol{Z} \\ \sqrt{\rho}\boldsymbol{I}\end{pmatrix}\boldsymbol{x} - \begin{pmatrix}\boldsymbol{v}_k \\ \sqrt{\rho}\boldsymbol{y}_k\end{pmatrix}\right\|^2. \tag{6}$$

In the unweighted case, extracting the singular value decomposition $\boldsymbol{Z} = \boldsymbol{U}\boldsymbol{S}\boldsymbol{V}^T$ facilitates solving the system of equations (5). The svd decomposition is especially cheap if there is a substantial mismatch between the number rows and columns of $\boldsymbol{Z}$. For sparse $\boldsymbol{Z}$, the conjugate gradient algorithm adapted to least squares (Paige and Saunders, 1982b) is subject to much less ill conditioning than the standard conjugate gradient algorithm. Indeed, the algorithm LSQR and its sparse version LSMR (Fong and Saunders, 2011) perform well even when the matrix $(\boldsymbol{Z}^t\boldsymbol{W}_k^{1/2}, \sqrt{\rho}\boldsymbol{I})^t$ is ill conditioned.

The proximal distance principle also applies to unconstrained problems. For example, consider the problem of minimizing a penalized loss $\ell(\boldsymbol{x}) + p(\boldsymbol{A}\boldsymbol{x})$. The presence of the linear transformation $\boldsymbol{A}\boldsymbol{x}$ in the penalty complicates optimization. The strategy of parameter splitting introduces a new variable $\boldsymbol{y}$ and minimizes $\ell(\boldsymbol{x}) + p(\boldsymbol{y})$ subject to the constraint $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}$. If $P_M(\boldsymbol{z})$ denotes projection onto the manifold

$$M = \{\boldsymbol{z} = (\boldsymbol{x}, \boldsymbol{y}) : \boldsymbol{A}\boldsymbol{x} = \boldsymbol{y}\},$$

then the constrained problem can be solved approximately by minimizing the function

$$\ell(\boldsymbol{x}) + p(\boldsymbol{y}) + \frac{\rho}{2}\operatorname{dist}(\boldsymbol{z}, M)^2$$

for large ρ. If $P_M(\boldsymbol{z}_k)$ consists of two subvectors $\boldsymbol{u}_k$ and $\boldsymbol{v}_k$ corresponding to $\boldsymbol{x}_k$ and $\boldsymbol{y}_k$, then the proximal distance updates are

$$\boldsymbol{x}_{k+1} = \operatorname{prox}_{\rho^{-1}\ell}(\boldsymbol{u}_k) \quad \text{and} \quad \boldsymbol{y}_{k+1} = \operatorname{prox}_{\rho^{-1}p}(\boldsymbol{v}_k).$$

Given the matrix $\boldsymbol{A}$ is $n \times p$, one can attack the projection by minimizing the function

$$q(\boldsymbol{x}) = \frac{1}{2}\|\boldsymbol{x}-\boldsymbol{u}\|^2 + \frac{1}{2}\|\boldsymbol{A}\boldsymbol{x}-\boldsymbol{v}\|^2.$$

This leads to the solution

$$\boldsymbol{x} = (\boldsymbol{I}_p + \boldsymbol{A}^t\boldsymbol{A})^{-1}(\boldsymbol{A}^t\boldsymbol{v} + \boldsymbol{u}) \quad \text{and} \quad \boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}.$$

If $n < p$, then the Woodbury formula

$$(\boldsymbol{I}_p + \boldsymbol{A}^t\boldsymbol{A})^{-1} = \boldsymbol{I}_p - \boldsymbol{A}^t(\boldsymbol{I}_n + \boldsymbol{A}\boldsymbol{A}^t)^{-1}\boldsymbol{A}$$

reduces the expense of matrix inversion.

Traditionally, convex constraints have been posed as inequalities $C = \{\boldsymbol{x} : a(\boldsymbol{x}) \leq t\}$. Parikh and Boyd (2013) point out how to project onto such sets. The relevant Lagrangian for projecting an external point $\boldsymbol{y}$ amounts to

$$\mathcal{L}(\boldsymbol{x}, \lambda) = \frac{1}{2}\|\boldsymbol{y}-\boldsymbol{x}\|^2 + \lambda[a(\boldsymbol{x}) - t]$$

with $\lambda \geq 0$. The corresponding stationarity condition

$$\boldsymbol{0} = \boldsymbol{x} - \boldsymbol{y} + \lambda\nabla a(\boldsymbol{x}), \tag{7}$$

can be interpreted as $a[\text{prox}_{\lambda a}(\boldsymbol{y})] = t$. One can solve this one-dimensional equation for λ by bisection. Once λ is available, $\boldsymbol{x} = \text{prox}_{\lambda a}(\boldsymbol{y})$ is available as well. Parikh and Boyd (2013) note that the value $a[\text{prox}_{\lambda a}(\boldsymbol{y})]$ is decreasing in λ. One can verify their claim by implicit differentiation of equation (7). This gives

$$\frac{d}{d\lambda}\boldsymbol{x} \;=\; -[\boldsymbol{I} + \lambda d^2 a(\boldsymbol{x})]^{-1}\nabla a(\boldsymbol{x})$$

and consequently the chain rule inequality

$$\frac{d}{d\lambda}a[\text{prox}_{\lambda a}(\boldsymbol{y})] \;=\; -da(\boldsymbol{x})[\boldsymbol{I} + \lambda d^2 a(\boldsymbol{x})]^{-1}\nabla a(\boldsymbol{x}) \;\le\; 0.$$

3. Convergence: Convex Case

In the presence of convexity, the proximal distance algorithm reduces to a proximal gradient algorithm. This follows from the representation

$$\boldsymbol{y} \;=\; \sum_{i=1}^m \alpha_i P_{C_i}(\boldsymbol{x}) \;=\; \boldsymbol{x} - \sum_{i=1}^m \alpha_i \Big[\boldsymbol{x} - P_{C_i}(\boldsymbol{x})\Big] \;=\; \boldsymbol{x} - \nabla q(\boldsymbol{x})$$

involving the penalty $q(\boldsymbol{x})$. Thus, the proximal distance algorithm can be expressed as

$$\boldsymbol{x}_{k+1} \;=\; \text{prox}_{\rho^{-1}f}[\boldsymbol{x}_k - \nabla q(\boldsymbol{x}_k)].$$

In this regard, there is the implicit assumption that $q(\boldsymbol{x})$ is 1-smooth. This is indeed the case. According to the Moreau decomposition (Bauschke and Combettes, 2011), for a single closed convex set C

$$\nabla q(\boldsymbol{x}) \;=\; \boldsymbol{x} - P_C(\boldsymbol{x}) \;=\; \text{prox}_{\delta_C^\star}(\boldsymbol{x}),$$

where $\delta_C^\star(\boldsymbol{x})$ is the Fenchel conjugate of the indicator function

$$\delta_C(\boldsymbol{x}) \;=\; \begin{cases} 0 & \boldsymbol{x} \in C \\ \infty & \boldsymbol{x} \notin C. \end{cases}$$

Because proximal operators of closed convex functions are nonexpansive (Bauschke and Combettes, 2011), the result follows for a single set. For the general penalty $q(\boldsymbol{x})$ with m sets, the Lipschitz constants are scaled by the convex coefficients α_i and added to produce an overall Lipschitz constant of 1.

It is enlightening to view the proximal distance algorithm through the lens of concave-convex programming. Recall that the function

$$s(\boldsymbol{x}) \;=\; \sup_{\boldsymbol{y}\in C}\left[\boldsymbol{y}^t\boldsymbol{x} - \frac{1}{2}\|\boldsymbol{y}\|^2\right] \;=\; \frac{1}{2}\|\boldsymbol{x}\|^2 - \frac{1}{2}\,\text{dist}(\boldsymbol{x}, C)^2 \tag{8}$$

is closed and convex for any nonempty closed set C. Danskin's theorem (Lange, 2016) justifies the directional derivative expression

$$d_{\boldsymbol{v}}s(\boldsymbol{x}) \;=\; \sup_{\boldsymbol{y}\in P_C(\boldsymbol{x})} \boldsymbol{y}^t\boldsymbol{v} \;=\; \sup_{\boldsymbol{y}\in \text{conv}\, P_C(\boldsymbol{x})} \boldsymbol{y}^t\boldsymbol{v}.$$

This equality allows us to identify the subdifferential $\partial s(\boldsymbol{x})$ as the convex hull $\text{conv}\, P_C(\boldsymbol{x})$. For any $\boldsymbol{y} \in \partial s(\boldsymbol{x}_k)$, the supporting hyperplane inequality entails

$$\begin{aligned} \frac{1}{2}\,\text{dist}(\boldsymbol{x}, C)^2 &= \frac{1}{2}\|\boldsymbol{x}\|^2 - s(\boldsymbol{x}) \\ &\le \frac{1}{2}\|\boldsymbol{x}\|^2 - s(\boldsymbol{x}_k) - \boldsymbol{y}^t(\boldsymbol{x} - \boldsymbol{x}_k) \\ &= \frac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|^2 + d, \end{aligned}$$

where d is a constant not depending on $\boldsymbol{x}$. The same majorization can be generated by rearranging the majorization

$$\frac{1}{2}\,\text{dist}(\boldsymbol{x}, C)^2 \;\le\; \frac{1}{2}\sum_i \beta_i\|\boldsymbol{x} - \boldsymbol{p}_i\|^2$$

when $\boldsymbol{y}$ is the convex combination $\sum_i \beta_i\boldsymbol{p}_i$ of vectors $\boldsymbol{p}_i$ from $P_C(\boldsymbol{x}_k)$. These facts demonstrate that the proximal distance algorithm minimizing

$$f(\boldsymbol{x}) + \frac{\rho}{2}\,\text{dist}(\boldsymbol{x}, C)^2 \;=\; f(\boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{x}\|^2 - \rho s(\boldsymbol{x})$$

is a special case of concave-convex programming when $f(\boldsymbol{x})$ is convex. It is worth emphasizing that $f(\boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{x}\|^2$ is often strongly convex regardless of whether $f(\boldsymbol{x})$ itself is convex. If we replace the penalty $\text{dist}(\boldsymbol{x}, C)^2$ by the penalty $\text{dist}(\boldsymbol{D}\boldsymbol{x}, C)^2$ for a matrix $\boldsymbol{D}$, then the function $s(\boldsymbol{D}\boldsymbol{x})$ is still closed and convex, and minimization of $f(\boldsymbol{x}) + \frac{\rho}{2}\,\text{dist}(\boldsymbol{D}\boldsymbol{x}, C)^2$ can also be viewed as an exercise in concave-convex programming.

In the presence of convexity, the proximal distance algorithm is guaranteed to converge. Our exposition relies on well-known operator results (Bauschke and Combettes, 2011). Proximal operators in general and projection operators in particular are nonexpansive and averaged. By definition an averaged operator

$$M(\boldsymbol{x}) \;=\; \alpha\boldsymbol{x} + (1-\alpha)N(\boldsymbol{x})$$

is a convex combination of a nonexpansive operator $N(\boldsymbol{x})$ and the identity operator $\boldsymbol{I}$. The averaged operators on $\mathbb{R}^p$ with $\alpha \in (0, 1)$ form a convex set closed under functional composition. Furthermore, $M(\boldsymbol{x})$ and the base operator $N(\boldsymbol{x})$ share their fixed points. The celebrated theorem of Krasnosel'skii (1955) and Mann (1953) says that if an averaged operator $M(\boldsymbol{x}) = \alpha\boldsymbol{x} + (1-\alpha)N(\boldsymbol{x})$ possesses one or more fixed points, then the iteration scheme $\boldsymbol{x}_{k+1} = M(\boldsymbol{x}_k)$ converges to a fixed point.

These results immediately apply to minimization of the penalized loss

$$h_\rho(\boldsymbol{x}) \;=\; f(\boldsymbol{x}) + \frac{\rho}{2}\sum_{i=1}^m \alpha_i\,\text{dist}(\boldsymbol{x}, C_i)^2. \tag{9}$$

Given the choice $\boldsymbol{y}_k = \sum_{i=1}^m \alpha_i P_{C_i}(\boldsymbol{x}_k)$, the algorithm map $\boldsymbol{x}_{k+1} = \text{prox}_{\rho^{-1}f}(\boldsymbol{y}_k)$ is an averaged operator, being the composition of two averaged operators. Hence, the Krasnosel'skii-Mann theorem guarantees convergence to a fixed point if one or more exist. Now $\boldsymbol{z}$ is a fixed point if and only if

$$h_\rho(\boldsymbol{z}) \;\le\; f(\boldsymbol{x}) + \frac{\rho}{2}\sum_{i=1}^m \alpha_i\|\boldsymbol{x} - P_{C_i}(\boldsymbol{z})\|^2$$

for all $\boldsymbol{x}$. In the presence of convexity, this is equivalent to the directional derivative inequality

$$0 \;\leq\; d_{\boldsymbol{v}} f(\boldsymbol{z}) + \rho \sum_{i=1}^{m} \alpha_i [\boldsymbol{z} - P_{C_i}(\boldsymbol{z})]^t \boldsymbol{v} \;=\; d_{\boldsymbol{v}} h_\rho(\boldsymbol{z})$$

for all $\boldsymbol{v}$, which is in turn equivalent to $\boldsymbol{z}$ minimizing $h_\rho(\boldsymbol{x})$. Hence, if $h_\rho(\boldsymbol{x})$ attains its minimum value, then the proximal distance iterates converge to a minimum point.

Convergence of the overall proximal distance algorithm is tied to the convergence of the classical penalty method (Beltrami, 1970). In our setting, the loss is $f(\boldsymbol{x})$, and the penalty is $q(\boldsymbol{x}) = \frac{1}{2}\sum_{i=1}^m \alpha_i \operatorname{dist}(\boldsymbol{x}, C_i)^2$. Assuming the objective $f(\boldsymbol{x}) + \rho q(\boldsymbol{x})$ is coercive for all $\rho \geq 0$, the theory mandates that the solution path $\boldsymbol{x}_\rho$ is bounded and any limit point of the path attains the minimum value of $f(\boldsymbol{x})$ subject to the constraints. Furthermore, if $f(\boldsymbol{x})$ is coercive and possesses a unique minimum point in the constraint set C, then the path $\boldsymbol{x}_\rho$ converges to that point.

Proximal distance algorithms often converge at a painfully slow rate. Following Mairal (2013), one can readily exhibit a precise bound.

Proposition 1 *Suppose C is closed and convex and $f(\boldsymbol{x})$ is convex. If the point $\boldsymbol{z}$ minimizes $h_\rho(\boldsymbol{x}) = f(\boldsymbol{x}) + \frac{\rho}{2}\operatorname{dist}(\boldsymbol{x}, C)^2$, then the proximal distance iterates satisfy*

$$0 \;\leq\; h_\rho(\boldsymbol{x}_{k+1}) - h_\rho(\boldsymbol{z}) \;\leq\; \frac{\rho}{2(k+1)}\|\boldsymbol{z} - \boldsymbol{x}_0\|^2.$$

The $O(\rho k^{-1})$ convergence rate of the proximal distance algorithm suggests that one should slowly send ρ to ∞ and refuse to wait until convergence occurs for any given ρ. It also suggests that Nesterov acceleration may vastly improve the chances for convergence. Nesterov acceleration for the general proximal gradient algorithm with loss $\ell(\boldsymbol{x})$ and penalty $p(\boldsymbol{x})$ takes the form

$$\begin{aligned} \boldsymbol{z}_k &= \boldsymbol{x}_k + \frac{k-1}{k+d-1}(\boldsymbol{x}_k - \boldsymbol{x}_{k-1}) \\ \boldsymbol{x}_{k+1} &= \operatorname{prox}_{L^{-1}\ell}[\boldsymbol{z}_k - L^{-1}\nabla p(\boldsymbol{z}_k)], \end{aligned} \tag{10}$$

where L is the Lipschitz constant for $\nabla p(\boldsymbol{x})$ and d is typically chosen to be 3. Nesterov acceleration achieves an $O(k^{-2})$ convergence rate (Su et al., 2014), which is vastly superior to the $O(k^{-1})$ rate achieved by proximal gradient descent. The Nesterov update possesses the further desirable property of preserving affine constraints. In other words, if $\boldsymbol{A}\boldsymbol{x}_{k-1} = \boldsymbol{b}$ and $\boldsymbol{A}\boldsymbol{x}_k = \boldsymbol{b}$, then $\boldsymbol{A}\boldsymbol{z}_k = \boldsymbol{b}$ as well. In subsequent examples, we will accelerate our proximal distance algorithms by applying the algorithm map $M(\boldsymbol{x})$ given by equation (2) to the shifted point $\boldsymbol{z}_k$ of equation (10), yielding the accelerated update $\boldsymbol{x}_{k+1} = M(\boldsymbol{z}_k)$. Algorithm 1 provides a schematic of a proximal distance algorithm with Nesterov acceleration. The recent paper of Ghadimi and Lan (2015) extends Nestorov acceleration to nonconvex settings.

In ideal circumstances, one can prove linear convergence of function values in the framework of Karimi et al. (2016).

Proposition 2 *Suppose C is closed and convex and $f(\boldsymbol{x})$ is L-smooth and μ-strongly convex. Then $h_\rho(\boldsymbol{x}) = f(\boldsymbol{x}) + \frac{\rho}{2}\operatorname{dist}(\boldsymbol{x}, C)^2$ possesses a unique minimum point $\boldsymbol{y}$, and the proximal distance iterates $\boldsymbol{x}_k$ satisfy*

$$h_\rho(\boldsymbol{x}_k) - h_\rho(\boldsymbol{y}) \;\leq\; \Big(1 - \frac{\mu^2}{2(L+\rho)^2}\Big)^k [h_\rho(\boldsymbol{x}_0) - h_\rho(\boldsymbol{y})].$$

We now turn to convergence of the penalty function iterates as the penalty constants ρ_k tends to ∞. To simplify notation, we restrict attention to a single closed constraint set S. Let us start with a proposition requiring no convexity assumptions.

Proposition 3 *If $f(\boldsymbol{x})$ is continuous and coercive and S is compact, then the proximal distance iterates $\boldsymbol{x}_k$ are bounded and the distance to the constraint set satisfies*

$$\operatorname{dist}(\boldsymbol{x}_k, S)^2 \;\leq\; \frac{c}{\rho_k}$$

for some constant c. If in addition $f(\boldsymbol{x})$ is continuously differentiable, then

$$\operatorname{dist}(\boldsymbol{x}_k, S)^2 \;\leq\; \frac{d}{\rho_k^2}$$

for some further constant d. Similar claims hold for the solutions $\boldsymbol{y}_k$ of the penalty problem $\min_{\boldsymbol{x}} f(\boldsymbol{x}) + \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{x}, S)^2$ except that the assumption that S is compact can be dropped.

As a corollary, if the penalty sequence ρ_k tends to ∞, then all limit points of $\boldsymbol{x}_k$ must obey the constraint. Proposition 3 puts us into position to prove the next important result.

Proposition 4 *If $f(\boldsymbol{x})$ is continuously differentiable and coercive and S is convex, then the penalty function iterates defined by $\boldsymbol{y}_k \in \operatorname{argmin}_{\boldsymbol{x}}[f(\boldsymbol{x}) + \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{x}, S)^2]$ satisfy*

$$0 \;\leq f(\boldsymbol{y}) - f(\boldsymbol{y}_k) \;\leq\; \tfrac{d+2\sqrt{d}\|\nabla f(\boldsymbol{y})\|}{2\rho_k},$$

where $\boldsymbol{y}$ attains the constrained minimum and d is the constant identified in Proposition 3.

4. Convergence: General Case

Our strategy for addressing convergence in nonconvex problems fixes ρ and relies on Zangwill's global convergence theorem (Luenberger and Ye, 1984). This result depends in turn on the notion of a closed multi-valued map $\boldsymbol{N}(\boldsymbol{x})$. If $\boldsymbol{x}_k$ converges to $\boldsymbol{x}_\infty$ and $\boldsymbol{y}_k \in N(\boldsymbol{x}_k)$ converges to $\boldsymbol{y}_\infty$, then for $\boldsymbol{N}(\boldsymbol{x})$ to be closed, we must have $\boldsymbol{y}_\infty \in N(\boldsymbol{x}_\infty)$. The next proposition furnishes a prominent example.

Proposition 5 *If S is a closed nonempty set in $\mathbb{R}^p$, then the projection operator $P_S(\boldsymbol{x})$ is closed. Furthermore, if the sequence $\boldsymbol{x}_k$ is bounded, then the set $\cup_k P_S(\boldsymbol{x}_k)$ is bounded as well.*

ALGORITHM 1: A typical proximal distance algorithm

input :

$\rho_{\text{initial}} > 0$ # an initial penalty value
$\rho_{\text{inc}} > 1$ # the penalty increment
$\rho_{\max}$ # a maximum penalty value
$K_{\max}$ # the maximum number of iterations
k_ρ # the increment frequency
f # the function to optimize
P_C # the projection onto the constraint set
$\epsilon_{\text{loss}} > 0$ # convergence tolerance for the loss function
$\epsilon_{\text{dist}} > 0$ # convergence tolerance for constraint feasibility

output: A vector $\boldsymbol{x}^+ \approx \operatorname{argmin}_{\boldsymbol{x}} f(\boldsymbol{x})$ # subject to the constraint $\boldsymbol{x} \in C$

$\rho \leftarrow \rho_{\text{initial}}$ # Set initial penalty value
$q_0 = q_1 = \infty$ # Track convergence of f
$d_0 = d_1 = \infty$ # Track distance to constraint
$\boldsymbol{x}_0 = \boldsymbol{x}_1 = \boldsymbol{0}$ # Set initial iterates to origin

# Main algorithm loop
for $k = 2, \ldots, K_{\max}$ **do**
  $\boldsymbol{z}_k \leftarrow \boldsymbol{x}_{k-1} + \frac{k-1}{k+2}(\boldsymbol{x}_{k-1} - \boldsymbol{x}_{k-2})$ # Apply Nesterov acceleration
  $\boldsymbol{x}_{k-2} \leftarrow \boldsymbol{x}_{k-1}$ # Save penultimate iterate
  $\boldsymbol{z}_{\text{proj},k} \leftarrow P_C(\boldsymbol{z}_k)$ # Project onto constraints
  $\boldsymbol{x}_k \leftarrow \text{prox}_{\rho f}(\boldsymbol{z}_{\text{proj},k})$ # Apply proximal distance update
  $q_k \leftarrow f(\boldsymbol{x}_k)$ # Compute new loss
  $d_k \leftarrow \|\boldsymbol{x}_k - \boldsymbol{z}_{\text{proj},k}\|_2$ # Compute new distance to C
  # Exit if converged
  if $|q_k - q_{k-1}| < \epsilon_{\text{loss}}$ and $|d_k - d_{k-1}| < \epsilon_{\text{dist}}$ **then**
    return $\boldsymbol{x}^+ \leftarrow \boldsymbol{x}_{k+1}$
  else
    $q_{k-1} \leftarrow q_k$ # Save current loss
    $d_{k-1} \leftarrow d_k$ # Save current distance to C
    # Update penalty ρ every k_ρ iterations
    if $k = k_\rho$ **then**
      $\rho \leftarrow \min(\rho_{\max}, \rho \times \rho_{\text{inc}})$
      $\boldsymbol{x}_{k-1} \leftarrow \boldsymbol{x}_k$ # Save previous iterate

Zangwill's global convergence theorem is phrased in terms of an algorithm map $M(\boldsymbol{x})$ and a real-valued objective $h(\boldsymbol{x})$. The theorem requires a critical set Γ outside which $M(\boldsymbol{x})$ is closed. Furthermore, all iterates $\boldsymbol{x}_{k+1} \in M(\boldsymbol{x}_k)$ must fall within a compact set. Finally, the descent condition $h(\boldsymbol{y}) \le h(\boldsymbol{x})$ should hold for all $\boldsymbol{y} \in M(\boldsymbol{x})$, with strict inequality when $\boldsymbol{x} \notin \Gamma$. If these conditions are valid, then every convergent subsequence of $\boldsymbol{x}_k$ tends to a point in Γ. In the proximal distance context, we define the complement of Γ to consist of the points $\boldsymbol{x}$ with

$$f(\boldsymbol{y}) + \frac{\rho}{2}\operatorname{dist}(\boldsymbol{y}, S)^2 \quad < \quad f(\boldsymbol{x}) + \frac{\rho}{2}\operatorname{dist}(\boldsymbol{x}, S)^2$$

for all $\boldsymbol{y} \in M(\boldsymbol{x})$. This definition plus the monotonic nature of the proximal distance algorithm

$$\boldsymbol{x}_{k+1} \quad \in \quad M(\boldsymbol{x}_k) \quad = \quad \bigcup_{\boldsymbol{z}_k \in P_S(\boldsymbol{x}_k)} \operatorname{argmin}_{\boldsymbol{x}} \left[f(\boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{z}_k\|^2 \right]$$

force the satisfaction of Zangwill's final requirement. Note that if $f(\boldsymbol{x})$ is differentiable, then a point $\boldsymbol{x}$ belongs to Γ whenever $\boldsymbol{0} \in \nabla f(\boldsymbol{x}) + \rho\boldsymbol{x} - \rho P_S(\boldsymbol{x})$.

In general, the algorithm map $M(\boldsymbol{x})$ is multi-valued in two senses. First, for a given $\boldsymbol{z}_k \in P_S(\boldsymbol{x}_k)$, the minimum may be achieved at multiple points. This contingency is ruled out if the proximal map of $f(\boldsymbol{x})$ is unique. Second, because S may be nonconvex, the projection may be multi-valued. This sounds distressing, but the points $\boldsymbol{x}_k$ where this occurs are exceptionally rare. Accordingly, it makes no practical difference that we restrict the anchor points $\boldsymbol{z}_k$ to lie in $P_S(\boldsymbol{x}_k)$ rather than in $\operatorname{conv} P_S(\boldsymbol{x}_k)$.

Proposition 6 *If S is a closed nonempty set in $\mathbb{R}^p$, then the projection operator $P_S(\boldsymbol{x})$ is single valued except on a set of Lebesgue measure 0.*

In view of the preceding results, one can easily verify the next proposition.

Proposition 7 *The algorithm map $M(\boldsymbol{x})$ is everywhere closed.*

To apply Zangwill's global convergence theory, we must in addition prove that the iterates $\boldsymbol{x}_{k+1} = M(\boldsymbol{x}_k)$ remain within a compact set. This is true whenever the objective is coercive since the algorithm is a descent algorithm. As noted earlier, the coercivity of $f(\boldsymbol{x})$ is a sufficient condition. One can readily concoct other sufficient conditions. For example, if $f(\boldsymbol{x})$ is bounded below, say nonnegative, and S is compact, then the objective is also coercive. Indeed, if S is contained in the ball of radius r about the origin, then

$$\|\boldsymbol{x}\| \quad \le \quad \|\boldsymbol{x} - P_S(\boldsymbol{x})\| + \|P_S(\boldsymbol{x})\| \quad \le \quad \operatorname{dist}(\boldsymbol{x}, S) + r,$$

which proves that $\operatorname{dist}(\boldsymbol{x}, S)$ is coercive. The next proposition summarizes these findings.

Proposition 8 *If S is closed and nonempty, the objective $f(\boldsymbol{x}) + \frac{1}{2}\operatorname{dist}(\boldsymbol{x}, S)^2$ is coercive, and the proximal operator $\operatorname{prox}_{\rho^{-1}f}(\boldsymbol{x})$ is everywhere nonempty, then all limit points of the iterates $\boldsymbol{x}_{k+1} \in M(\boldsymbol{x}_k)$ of the proximal distance algorithm occur in the critical set Γ.*

This result is slightly disappointing. A limit point $\boldsymbol{x}$ could potentially exist with improvement in the objective for some but not all $\boldsymbol{y} \in \operatorname{conv} P_S(\boldsymbol{x})$. This fault is mitigated by the fact that $P_S(\boldsymbol{x})$ is almost always single valued. In common with other algorithms in nonconvex optimization, we also cannot rule out convergence to a local minimum or a saddlepoint. One can improve on Proposition 8 by assuming that the surrogates $g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k)$ are all μ-strongly convex. This is a small concession to make because ρ is typically large. If $f(\boldsymbol{x})$ is convex, then $g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k)$ is ρ-strongly convex by definition. It is also worth noting that any convex MM surrogate $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$ can be made μ-strongly convex by adding the viscosity penalty $\frac{\mu}{2}\|\boldsymbol{x} - \boldsymbol{x}_k\|^2$ majorizing 0. The addition of a viscosity penalty seldom complicates finding the next iterate $\boldsymbol{x}_{n+1}$ and has little impact on the rate of convergence when $\mu > 0$ is small.

Proposition 9 *Under the μ-strongly convexity assumption on the surrogates $g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k)$, the proximal distance iterates satisfy $\lim_{k\to\infty} \|\boldsymbol{x}_{k+1} - \boldsymbol{x}_k\| = 0$. As a consequence, the set of limit points is connected as well as closed. Furthermore, if each limit point is isolated, then the iterates converge to a critical point.*

Further progress requires even more structure. Fortunately, what we now pursue applies to generic MM algorithms. We start with the concept of a Fréchet subdifferential (Kruger, 2003). If $h(\boldsymbol{x})$ is a function mapping $\mathbb{R}^p$ into $\mathbb{R} \cup \{+\infty\}$, then its Fréchet subdifferential at $\boldsymbol{x} \in \operatorname{dom} f$ is the set

$$\partial^F h(\boldsymbol{x}) \quad = \quad \Big\{\boldsymbol{v} : \liminf_{\boldsymbol{y}\to\boldsymbol{x}} \frac{h(\boldsymbol{y}) - h(\boldsymbol{x}) - \boldsymbol{v}^t(\boldsymbol{y} - \boldsymbol{x})}{\|\boldsymbol{y} - \boldsymbol{x}\|} \geq 0\Big\}.$$

The set $\partial^F h(\boldsymbol{x})$ is closed, convex, and possibly empty. If $h(\boldsymbol{x})$ is convex, then $\partial^F h(\boldsymbol{x})$ reduces to its convex subdifferential. If $h(\boldsymbol{x})$ is differentiable, then $\partial^F h(\boldsymbol{x})$ reduces to its ordinary differential. At a local minimum $\boldsymbol{x}$, Fermat's rule $\boldsymbol{0} \in \partial^F h(\boldsymbol{x})$ holds.

Proposition 10 *In an MM algorithm, suppose that $h(\boldsymbol{x})$ is coercive, that the surrogates $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$ are differentiable, and that the algorithm map $M(\boldsymbol{x})$ is closed. Then every limit point $\boldsymbol{z}$ of the MM sequence $\boldsymbol{x}_k$ is critical in the sense that $\boldsymbol{0} \in \partial^F(-h)(\boldsymbol{z})$.*

We will also need to invoke Łojasiewicz's inequality. This deep result depends on some rather arcane algebraic geometry (Bierstone and Milman, 1988; Bochnak et al., 2013). It applies to semialgebraic functions and their more inclusive cousins semianalytic functions and subanalytic functions. For simplicity we focus on semialgebraic functions. The class of semialgebraic subsets of $\mathbb{R}^p$ is the smallest class that:

a) contains all sets of the form $\{\boldsymbol{x} : q(\boldsymbol{x}) > 0\}$ for a polynomial $q(\boldsymbol{x})$ in p variables,

b) is closed under the formation of finite unions, finite intersections, and set complementation.

A function $a : \mathbb{R}^p \mapsto \mathbb{R}^r$ is said to be semialgebraic if its graph is a semialgebraic set of $\mathbb{R}^{p+r}$. The class of real-valued semialgebraic functions contains all polynomials $p(\boldsymbol{x})$ and all 0/1 indicators of algebraic sets. It is closed under the formation of sums, products, absolute

values, reciprocals when $a(\boldsymbol{x}) \neq 0$, nth roots when $a(\boldsymbol{x}) \geq 0$, and maxima $\max\{a(\boldsymbol{x}), b(\boldsymbol{x})\}$ and minima $\min\{a(\boldsymbol{x}), b(\boldsymbol{x})\}$. For our purposes, it is important to note that $\operatorname{dist}(\boldsymbol{x}, S)$ is a semialgebraic function whenever S is a semialgebraic set.

Łojasiewicz's inequality in its modern form (Bolte et al., 2007) requires a function $h(\boldsymbol{x})$ to be closed (lower semicontinuous) and subanalytic with a closed domain. If $\boldsymbol{z}$ is a critical point of $h(\boldsymbol{x})$, then

$$|h(\boldsymbol{x}) - h(\boldsymbol{z})|^\theta \quad \leq \quad c\|\boldsymbol{v}\|$$

for all $\boldsymbol{x} \in B_r(\boldsymbol{z}) \cap \operatorname{dom} \partial^F h$ satisfying $h(\boldsymbol{x}) > h(\boldsymbol{z})$ and all $\boldsymbol{v}$ in $\partial^F h(\boldsymbol{x})$. Here the exponent $\theta \in [0, 1)$, the radius r, and the constant c depend on $\boldsymbol{z}$. This inequality is valid for semialgebraic functions since they are automatically subanalytic. We will apply Łojasiewicz's inequality to the limit points of an MM algorithm. The next proposition is an elaboration and expansion of known results (Attouch et al., 2010; Bolte et al., 2007; Cui et al., 2018; Kang et al., 2015; Le Thi et al., 2009).

Proposition 11 *In an MM algorithm suppose the objective $h(\boldsymbol{x})$ is coercive, continuous, and subanalytic and all surrogates $g(\boldsymbol{x} \mid \boldsymbol{x}_k)$ are continuous, μ-strongly convex, and satisfy the L-smoothness condition*

$$\|\nabla g(\boldsymbol{a} \mid \boldsymbol{x}_k) - \nabla g(\boldsymbol{b} \mid \boldsymbol{x}_k)\| \quad \leq \quad L\|\boldsymbol{a} - \boldsymbol{b}\|$$

on the compact set $\{\boldsymbol{x} : h(\boldsymbol{x}) \leq h(\boldsymbol{x}_0)\}$. Then the MM iterates $\boldsymbol{x}_{k+1} = \operatorname{argmin}_{\boldsymbol{x}} g(\boldsymbol{x} \mid \boldsymbol{x}_k)$ converge to a critical point.

The last proposition applies to proximal distance algorithms. The loss $f(\boldsymbol{x})$ must be subanalytic and differentiable with a locally Lipschitz gradient. Furthermore, all surrogates $g(\boldsymbol{x} \mid \boldsymbol{x}_k) = f(\boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{y}_k\|^2$ should be coercive and μ-strongly convex. Finally, the constraints sets S_i should be subanalytic. Semialgebraic sets and functions will do. Under these conditions and regardless of how the projected points $P_{S_i}(\boldsymbol{x})$ are chosen, the MM iterates are guaranteed to converge to a critical point.

5. Examples

The following examples highlight the versatility of proximal distance algorithms in a variety of convex and nonconvex settings. Programming details matter in solving these problems. Individual programs are not necessarily long, but care must be exercised in projecting onto constraints, choosing tuning schedules, folding constraints into the domain of the loss, implementing acceleration, and declaring convergence. All of our examples are coded in the Julia programming language. Whenever possible, competing software was run in the Julia environment via the Julia module `MathProgBase` (Dunning et al., 2017; Lubin and Dunning, 2015). The sparse PCA problem relies on the software of Witten et al. (Witten et al., 2009), which is coded in R. Convergence is tested at iteration k by the two criteria

$$|f(\boldsymbol{x}_k) - f(\boldsymbol{x}_{k-1})| \quad \leq \quad \epsilon_1[|f(\boldsymbol{x}_{k-1})| + 1] \quad \text{and} \quad \operatorname{dist}(\boldsymbol{x}_k, C) \quad \leq \quad \epsilon_2,$$

where $\epsilon_1 = 10^{-6}$ and $\epsilon_2 = 10^{-4}$ are typical values. The number of iterations until convergence is about 1000 in most examples. This handicap is offset by the simplicity of each stereotyped update. Our code is available as supplementary material to this paper. Readers are encouraged to try the code and adapt it to their own examples.

5.1. Linear Programming

Two different tactics suggest themselves for constructing a proximal distance algorithm. The first tactic rolls the standard affine constraints $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ into the domain of the loss function $\boldsymbol{v}^t\boldsymbol{x}$. The standard nonnegativity requirement $\boldsymbol{x} \geq \boldsymbol{0}$ is achieved by penalization. Let $\boldsymbol{x}_k$ be the current iterate and $\boldsymbol{y}_k = (\boldsymbol{x}_k)_+$ be its projection onto $\mathbb{R}^n_+$. Derivation of the proximal distance algorithm relies on the Lagrangian

$$\boldsymbol{v}^t\boldsymbol{x} + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{y}_k\|^2 + \boldsymbol{\lambda}^t(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}).$$

One can multiply the corresponding stationarity equation

$$\boldsymbol{0} \;=\; \boldsymbol{v} + \rho(\boldsymbol{x} - \boldsymbol{y}_k) + \boldsymbol{A}^t\boldsymbol{\lambda}$$

by $\boldsymbol{A}$ and solve for the Lagrange multiplier $\boldsymbol{\lambda}$ in the form

$$\boldsymbol{\lambda} \;=\; (\boldsymbol{A}\boldsymbol{A}^t)^{-1}(\rho\boldsymbol{A}\boldsymbol{y}_k - \rho\boldsymbol{b} - \boldsymbol{A}\boldsymbol{v}), \tag{11}$$

assuming $\boldsymbol{A}$ has full row rank. Inserting this value into the stationarity equation gives the MM update

$$\boldsymbol{x}_{k+1} \;=\; \boldsymbol{y}_k - \frac{1}{\rho}\boldsymbol{v} - \boldsymbol{A}^-\left(\boldsymbol{A}\boldsymbol{y}_k - \boldsymbol{b} - \frac{1}{\rho}\boldsymbol{A}\boldsymbol{v}\right), \tag{12}$$

where $\boldsymbol{A}^- = \boldsymbol{A}^t(\boldsymbol{A}\boldsymbol{A}^t)^{-1}$ is the pseudo-inverse of $\boldsymbol{A}$.

The second tactic folds the nonnegativity constraints into the domain of the loss. Let $\boldsymbol{p}_k$ denote the projection of $\boldsymbol{x}_k$ onto the affine constraint set $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$. Fortunately, the surrogate function $\boldsymbol{v}^t\boldsymbol{x} + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{p}_k\|^2$ splits the parameters. Minimizing one component at a time gives the update $\boldsymbol{x}_{k+1}$ with components

$$x_{k+1,j} \;=\; \max\left\{p_{kj} - \frac{v_j}{\rho}, 0\right\}. \tag{13}$$

The projection $\boldsymbol{p}_k$ can be computed via

$$\boldsymbol{p}_k \;=\; \boldsymbol{x}_k - \boldsymbol{A}^-(\boldsymbol{A}\boldsymbol{x}_k - \boldsymbol{b}), \tag{14}$$

where $\boldsymbol{A}^-$ is again the pseudo-inverse of $\boldsymbol{A}$.

Table 1 compares the accelerated versions of these two proximal distance algorithms to two efficient solvers. The first is the open-source Splitting Cone Solver (SCS) (O'Donoghue et al., 2016), which relies on a fast implementation of ADMM. The second is the commercial Gurobi solver, which ships with implementations of both the simplex method and a barrier (interior point) method; in this example, we use its barrier algorithm. The first seven rows of the table summarize linear programs with dense data $\boldsymbol{A}$, $\boldsymbol{b}$, and $\boldsymbol{v}$. The bottom six rows rely on random sparse matrices $\boldsymbol{A}$ with sparsity level 0.01. For dense problems, the proximal distance algorithms start the penalty constant ρ at 1 and double it every 100 iterations. Because we precompute and cache the pseudoinverse $\boldsymbol{A}^-$ of $\boldsymbol{A}$, the updates (12) and (13) reduce to vector additions and matrix-vector multiplications.

Table 1: CPU times and optima for linear programming. Here m is the number of constraints, n is the number of variables, PD1 is the proximal distance algorithm over an affine domain, PD2 is the proximal distance algorithm over a nonnegative domain, SCS is the Splitting Cone Solver, and Gurobi is the Gurobi solver. After $m = 512$ the constraint matrix $\boldsymbol{A}$ is initialized to be sparse with sparsity level $s = 0.01$.

For sparse problems the proximal distance algorithms update ρ by a factor of 1.5 every 50 iterations. To avoid computing large pseudoinverses, we appeal to the LSQR variant of the conjugate gradient method (Paige and Saunders, 1982b,a) to solve the linear systems (11) and (14). The optima of all four methods agree to about 4 digits of accuracy. It is hard to declare an absolute winner in these comparisons. Gurobi and SCS clearly perform better on low-dimensional problems, but the proximal distance algorithms are competitive as dimensions increase. PD1, the proximal distance algorithm over an affine domain, tends to be more accurate than PD2. If high accuracy is not a concern, then the proximal distance algorithms are easily accelerated with a more aggressive update schedule for ρ.

5.2. Constrained Least Squares

Constrained least squares programming subsumes constrained quadratic programming. A typical quadratic program involves minimizing the quadratic $\frac{1}{2}\boldsymbol{x}^t\boldsymbol{Q}\boldsymbol{x} - \boldsymbol{p}^t\boldsymbol{x}$ subject to $\boldsymbol{x} \in C$ for a positive definite matrix $\boldsymbol{Q}$. Quadratic programming can be reformulated as least squares by taking the Cholesky decomposition $\boldsymbol{Q} = \boldsymbol{L}\boldsymbol{L}^t$ of $\boldsymbol{Q}$ and noting that

$$\frac{1}{2}\boldsymbol{x}^t\boldsymbol{Q}\boldsymbol{x} - \boldsymbol{p}^t\boldsymbol{x} \;=\; \frac{1}{2}\|\boldsymbol{L}^{-1}\boldsymbol{p} - \boldsymbol{L}^t\boldsymbol{x}\|^2 - \frac{1}{2}\|\boldsymbol{L}^{-1}\boldsymbol{p}\|^2.$$

The constraint $\boldsymbol{x} \in C$ applies in both settings. It is particularly advantageous to reframe a quadratic program as a least squares problem when $\boldsymbol{Q}$ is already presented in factored

Table 2: CPU times and optima for simplex-constrained least squares. Here $\boldsymbol{A} \in \mathbb{R}^{n \times p}$, PD is the proximal distance algorithm, IPOPT is the Ipopt solver, and Gurobi is the Gurobi solver. After $n = 1024$, the predictor matrix $\boldsymbol{A}$ is sparse.

form or when it is nearly singular (Bemporad, 2018). To simplify subsequent notation, we replace $\boldsymbol{L}^t$ by the rectangular matrix $\boldsymbol{A}$ and $\boldsymbol{L}^{-1}\boldsymbol{p}$ by $\boldsymbol{y}$. The key to solving constrained least squares is to express the proximal distance surrogate as

$$\frac{1}{2}\|\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x}\|^2 + \frac{\rho}{2}\|\boldsymbol{x} - P_C(\boldsymbol{x}_k)\|^2 \;=\; \frac{1}{2}\left\|\begin{pmatrix}\boldsymbol{y}\\ \sqrt{\rho}P_C(\boldsymbol{x}_k)\end{pmatrix} - \begin{pmatrix}\boldsymbol{A}\\ \sqrt{\rho}\boldsymbol{I}\end{pmatrix}\boldsymbol{x}\right\|^2$$

as in equation (6). As noted earlier, in sparse problems the update $\boldsymbol{x}_{k+1}$ can be found by a fast stable conjugate gradient solver.

Table 2 compares the performance of the proximal distance algorithm for least squares estimation with probability-simplex constraints to the open source nonlinear interior point solver Ipopt (Wächter and Biegler, 2005, 2006) and the interior point method of Gurobi. Simplex constrained problems arise in hyperspectral imaging (Heylen et al., 2011; Keshava, 2003), portfolio optimization (Markowitz, 1952), and density estimation (Bunea et al., 2010). Test problems were generated by filling an $n \times p$ matrix $\boldsymbol{A}$ and an n-vector $\boldsymbol{y}$ with standard normal deviates. For sparse problems we set the sparsity level of $\boldsymbol{A}$ to be $10/p$. Our setup ensures that $\boldsymbol{A}$ has full rank and that the quadratic program has a solution. For the proximal distance algorithm, we start ρ at 1 and multiply it by 1.5 every 200 iterations. Table 2 suggests that the proximal distance algorithm and the interior point solvers perform equally well on small dense problems. However, in high-dimensional and low-accuracy environments, the proximal distance algorithm provides much better scalability.

5.3. Closest Kinship Matrix

In genetics studies, kinship is measured by the fraction of genes two individuals share identical by descent. For a given pedigree, the kinship coefficients for all pairs of individuals

appear as entries in a symmetric kinship matrix $\boldsymbol{Y}$. This matrix possesses three crucial properties: a) it is positive semidefinite, b) its entries are nonnegative, and c) its diagonal entries are $\frac{1}{2}$ unless some pedigree members are inbred. Inbreeding is the exception rather than the rule. Kinship matrices can be estimated empirically from single nucleotide polymorphism (SNP) data, but there is no guarantee that the three highlighted properties are satisfied. Hence, it helpful to project $\boldsymbol{Y}$ to the nearest qualifying matrix.

This projection problem is best solved by folding the positive semidefinite constraint into the domain of the Frobenius loss function $\frac{1}{2}\|\boldsymbol{X} - \boldsymbol{Y}\|_F^2$. As we shall see, the alternative of imposing two penalties rather than one is slower and less accurate. Projection onto the constraints implied by conditions b) and c) is trivial. All diagonal entries x_{ii} of $\boldsymbol{X}$ are reset to $\frac{1}{2}$, and all off-diagonal entries x_{ij} are reset to $\max\{x_{ij}, 0\}$. If $P(\boldsymbol{X}_k)$ denotes the current projection, then the proximal distance algorithm minimizes the surrogate

$$\begin{aligned} g(\boldsymbol{X} \mid \boldsymbol{X}_k) &= \frac{1}{2}\|\boldsymbol{X} - \boldsymbol{Y}\|_F^2 + \frac{\rho}{2}\|\boldsymbol{X} - P(\boldsymbol{X}_k)\|_F^2 \\ &= \frac{1+\rho}{2}\left\|\boldsymbol{X} - \frac{1}{1+\rho}\boldsymbol{Y} - \frac{\rho}{1+\rho}P(\boldsymbol{X}_k)\right\|_F^2 + c_k, \end{aligned}$$

where c_k is an irrelevant constant. The minimum is found by extracting the spectral decomposition $\boldsymbol{U}\boldsymbol{D}\boldsymbol{U}^t$ of $\frac{1}{1+\rho}\boldsymbol{Y} + \frac{\rho}{1+\rho}P(\boldsymbol{X}_k)$ and truncating the negative eigenvalues. This gives the update $\boldsymbol{X}_{k+1} = \boldsymbol{U}\boldsymbol{D}_+\boldsymbol{U}^t$ in obvious notation. This proximal distance algorithm and its Nesterov acceleration are simple to implement in a numerically oriented language such as Julia. The most onerous part of the calculation is clearly the repeated eigen-decompositions.

Table 3 compares three versions of the proximal distance algorithm to Dykstra's algorithm (Boyle and Dykstra, 1986). Higham proposed Dykstra's algorithm for the related problem of finding the closest correlation matrix Higham (2002). In Table 3 algorithm PD1 is the unadorned proximal distance algorithm, PD2 is the accelerated proximal distance, and PD3 is the accelerated proximal distance algorithm with the positive semidefinite constraints folded into the domain of the loss. On this demanding problem, these algorithms are comparable to Dykstra's algorithm in speed but slightly less accurate. Acceleration of the proximal distance algorithm is effective in reducing both execution time and error. Folding the positive semidefinite constraint into the domain of the loss function leads to further improvements. The data matrices $\boldsymbol{M}$ in these trials were populated by standard normal deviates and then symmetrized by averaging opposing off-diagonal entries. In algorithm PD1 we set $\rho_k = \max\{1.2^k, 2^{22}\}$. In the accelerated versions PD2 and PD3 we started ρ at 1 and multiplied it by 5 every 100 iterations. At the expense of longer compute times, better accuracy can be achieved by all three proximal distance algorithms with a less aggressive update schedule.

5.4. Projection onto a Second-Order Cone Constraint

Second-order cone programming is one of the unifying themes of convex analysis (Alizadeh and Goldfarb, 2003; Lobo et al., 1998). It revolves around conic constraints of the form $\{\boldsymbol{u} : \|\boldsymbol{A}\boldsymbol{u} + \boldsymbol{b}\| \le \boldsymbol{c}^t\boldsymbol{u} + d\}$. Projection of a vector $\boldsymbol{x}$ onto such a constraint is facilitated by parameter splitting. In this setting parameter splitting introduces a vector $\boldsymbol{w}$, a scalar r, and the two affine constraints $\boldsymbol{w} = \boldsymbol{A}\boldsymbol{u} + \boldsymbol{b}$ and $r = \boldsymbol{c}^t\boldsymbol{u} + d$. The conic constraint then

Table 3: CPU times and optima for the closest kinship matrix problem. Here the kinship matrix is $n \times n$, PD1 is the proximal distance algorithm, PD2 is the accelerated proximal distance, PD3 is the accelerated proximal distance algorithm with the positive semidefinite constraints folded into the domain of the loss, and Dykstra is Dykstra's adaptation of alternating projections. All times are in seconds.

Size	PD1		PD2		PD3		Dykstra	
n	Loss	Time	Loss	Time	Loss	Time	Loss	Time
2	1.64	0.36	1.64	0.01	1.64	0.01	1.64	0.00
4	2.86	0.10	2.86	0.01	2.86	0.01	2.86	0.00
8	18.77	0.21	18.78	0.03	18.78	0.03	18.78	0.00
16	45.10	0.84	45.12	0.18	45.12	0.12	45.12	0.02
32	169.58	4.36	169.70	0.61	169.70	0.52	169.70	0.37
64	837.85	16.77	838.44	2.90	838.43	2.63	838.42	4.32
128	3276.41	91.94	3279.44	18.00	3279.25	14.83	3279.23	19.73
256	14029.07	403.59	14045.30	89.58	14043.59	64.89	14043.46	72.79

reduces to the Lorentz cone constraint $\|\boldsymbol{w}\| \leq r$, for which projection is straightforward (Boyd and Vandenberghe, 2009). If we concatenate the parameters into the single vector

$$\boldsymbol{y} \;=\; \begin{pmatrix} \boldsymbol{u} \\ \boldsymbol{w} \\ r \end{pmatrix}$$

and define $L = \{\boldsymbol{y} : \|\boldsymbol{w}\| \leq r\}$ and $M = \{\boldsymbol{y} : \boldsymbol{w} = \boldsymbol{A}\boldsymbol{u} + \boldsymbol{b} \text{ and } r = \boldsymbol{c}^t\boldsymbol{u} + d\}$, then we can rephrase the problem as minimizing $\frac{1}{2}\|\boldsymbol{x} - \boldsymbol{u}\|^2$ subject to $\boldsymbol{y} \in L \cap M$. This is a fairly typical set projection problem except that the $\boldsymbol{w}$ and r components of $\boldsymbol{y}$ are missing in the loss function.

Taking a cue from Example 5.1, we incorporate the affine constraints in the domain of the objective function. If we represent projection onto L by

$$P\begin{pmatrix} \boldsymbol{w}_k \\ r_k \end{pmatrix} \;=\; \begin{pmatrix} \tilde{\boldsymbol{w}}_k \\ \tilde{r}_k \end{pmatrix},$$

then the Lagrangian generated by the proximal distance algorithm amounts to

$$\mathcal{L} \;=\; \frac{1}{2}\|\boldsymbol{x} - \boldsymbol{u}\|^2 + \frac{\rho}{2}\left\|\begin{pmatrix} \boldsymbol{w} - \tilde{\boldsymbol{w}}_k \\ r - \tilde{r}_k \end{pmatrix}\right\|^2 + \boldsymbol{\lambda}^t(\boldsymbol{A}\boldsymbol{u} + \boldsymbol{b} - \boldsymbol{w}) + \theta(\boldsymbol{c}^t\boldsymbol{u} + d - r).$$

This gives rise to a system of three stationarity equations

$$\begin{aligned} \boldsymbol{0} &= \boldsymbol{u} - \boldsymbol{x} + \boldsymbol{A}^t\boldsymbol{\lambda} + \theta\boldsymbol{c} && (15) \\ \boldsymbol{0} &= \rho(\boldsymbol{w} - \tilde{\boldsymbol{w}}_k) - \boldsymbol{\lambda} && (16) \\ 0 &= \rho(r - \tilde{r}_k) - \theta. && (17) \end{aligned}$$

Solving for the multipliers $\boldsymbol{\lambda}$ and θ in equations (16) and (17) and substituting their values in equation (15) yield

$$\begin{aligned} \boldsymbol{0} &= \boldsymbol{u} - \boldsymbol{x} + \rho\boldsymbol{A}^t(\boldsymbol{w} - \tilde{\boldsymbol{w}}_k) + \rho(r - \tilde{r}_k)\boldsymbol{c} \\ &= \boldsymbol{u} - \boldsymbol{x} + \rho\boldsymbol{A}^t(\boldsymbol{A}\boldsymbol{u} + \boldsymbol{b} - \tilde{\boldsymbol{w}}_k) + \rho(\boldsymbol{c}^t\boldsymbol{u} + d - \tilde{r}_k)\boldsymbol{c}. \end{aligned}$$

This leads to the MM update

$$\boldsymbol{u}_{k+1} \;=\; (\rho^{-1}\boldsymbol{I} + \boldsymbol{A}^t\boldsymbol{A} + \boldsymbol{c}\boldsymbol{c}^t)^{-1}[\rho^{-1}\boldsymbol{x} + \boldsymbol{A}^t(\tilde{\boldsymbol{w}}_k - \boldsymbol{b}) + (\tilde{r}_k - d)\boldsymbol{c}]. \qquad (18)$$

The updates $\boldsymbol{w}_{k+1} = \boldsymbol{A}\boldsymbol{u}_{k+1} + \boldsymbol{b}$ and $r_{k+1} = \boldsymbol{c}^t\boldsymbol{u}_{k+1} + d$ follow from the constraints.

Table 4 compares the proximal distance algorithm to SCS and Gurobi. Echoing previous examples, we tailor the update schedule for ρ differently for dense and sparse problems. Dense problems converge quickly and accurately when we set $\rho_0 = 1$ and double ρ every 100 iterations. Sparse problems require a greater range and faster updates of ρ, so we set $\rho_0 = 0.01$ and then multiply ρ by 2.5 every 10 iterations. For dense problems, it is clearly advantageous to cache the spectral decomposition of $\boldsymbol{A}^t\boldsymbol{A} + \boldsymbol{c}\boldsymbol{c}^t$ as suggested in Example 5.2. In this regime, the proximal distance algorithm is as accurate as Gurobi and nearly as fast. SCS is comparable to Gurobi in speed but notably less accurate.

With a large sparse constraint matrix $\boldsymbol{A}$, extraction of its spectral decomposition becomes prohibitive. If we let $\boldsymbol{E} = (\rho^{-1/2}\boldsymbol{I} \;\; \boldsymbol{A}^t \;\; \boldsymbol{c})$, then we must solve a linear system of equations defined by the Gramian matrix $\boldsymbol{G} = \boldsymbol{E}\boldsymbol{E}^t$. There are three reasonable options for solving this system. The first relies on computing and caching a sparse Cholesky decomposition of $\boldsymbol{G}$. The second computes the QR decomposition of the sparse matrix $\boldsymbol{E}$. The R part of the QR decomposition coincides with the Cholesky factor. Unfortunately, every time ρ changes, the Cholesky or QR decomposition must be redone. The third option is the conjugate gradient algorithm. In our experience the QR decomposition offers superior stability and accuracy. When $\boldsymbol{E}$ is very sparse, the QR decomposition is often much faster than the Cholesky decomposition because it avoids forming the dense matrix $\boldsymbol{A}^t\boldsymbol{A}$. Even when only 5% of the entries of $\boldsymbol{A}$ are nonzero, 90% of the entries of $\boldsymbol{A}^t\boldsymbol{A}$ can be nonzero. If exquisite accuracy is not a concern, then the conjugate gradient method provides the fastest update. Table 4 reflects this choice.

5.5. Copositive Matrices

A symmetric matrix $\boldsymbol{M}$ is copositive if its associated quadratic form $\boldsymbol{x}^t\boldsymbol{M}\boldsymbol{x}$ is nonnegative for all $\boldsymbol{x} \geq \boldsymbol{0}$. Copositive matrices find applications in numerous branches of the mathematical sciences (Berman and Plemmons, 1994). All positive semidefinite matrices and all matrices with nonnegative entries are copositive. The variational index

$$\mu(\boldsymbol{M}) \;=\; \min_{\|\boldsymbol{x}\|=1,\, \boldsymbol{x}\geq\boldsymbol{0}} \boldsymbol{x}^t\boldsymbol{M}\boldsymbol{x}$$

is one key to understanding copositive matrices (Hiriart-Urruty and Seeger, 2010). The constraint set S is the intersection of the unit sphere and the nonnegative cone $\mathbb{R}^n_+$. Projection of an external point $\boldsymbol{y}$ onto S splits into three cases. When all components of $\boldsymbol{y}$ are negative, then $P_S(\boldsymbol{y}) = \boldsymbol{e}_i$, where y_i is the least negative component of $\boldsymbol{y}$, and $\boldsymbol{e}_i$ is the standard unit

Table 4: CPU times and optima for the second-order cone projection. Here m is the number of constraints, n is the number of variables, PD is the accelerated proximal distance algorithm, SCS is the Splitting Cone Solver, and Gurobi is the Gurobi solver. After $m = 512$ the constraint matrix $\boldsymbol{A}$ is initialized with sparsity level 0.01.

vector along coordinate direction i. The origin $\mathbf{0}$ is equidistant from all points of S. If any component of $\boldsymbol{y}$ is positive, then the projection is constructed by setting the negative components of $\boldsymbol{y}$ equal to 0, and standardizing the truncated version of $\boldsymbol{y}$ to have Euclidean norm 1.

As a test case for the proximal distance algorithm, consider the Horn matrix (Hall and Newman, 1963)

$$\boldsymbol{M} = \begin{bmatrix} 1 & -1 & 1 & 1 & -1 \\ -1 & 1 & -1 & 1 & 1 \\ 1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & 1 & -1 \\ -1 & 1 & 1 & -1 & 1 \end{bmatrix}.$$

The value $\mu(\boldsymbol{M}) = 0$ is attained for the vectors $\frac{1}{\sqrt{2}}(1,1,0,0,0)^t$, $\frac{1}{\sqrt{6}}(1,2,1,0,0)^t$, and equivalent vectors with their entries permuted. Matrices in higher dimensions with the same Horn pattern of 1's and -1's are copositive as well (Johnson and Reams, 2008). A Horn matrix of odd dimension cannot be written as a positive semidefinite matrix, a nonnegative matrix, or a sum of two such matrices.

The proximal distance algorithm minimizes the criterion

$$g(\boldsymbol{x} \mid \boldsymbol{x}_k) = \frac{1}{2}\boldsymbol{x}^t\boldsymbol{M}\boldsymbol{x} + \frac{\rho}{2}\|\boldsymbol{x} - P_S(\boldsymbol{x}_k)\|^2$$

Table 5: CPU times (seconds) and optima for approximating the Horn variational index of a Horn matrix. Here n is the size of Horn matrix, PD is the proximal distance algorithm, aPD is the accelerated proximal distance algorithm, and Mosek is the Mosek solver.

and generates the updates

$$\boldsymbol{x}_{k+1} = (\boldsymbol{M} + \rho\boldsymbol{I})^{-1}\rho P_S(\boldsymbol{x}_k).$$

It takes a gentle tuning schedule to get decent results. The choice $\rho_k = 1.2^k$ converges in 600 to 700 iterations from random starting points and reliably yields objective values below 10^{-5} for Horn matrices. The computational burden per iteration is significantly eased by exploiting the cached spectral decomposition of $\boldsymbol{M}$. Table 5 compares the performance of the proximal distance algorithm to the Mosek solver on a range of Horn matrices. Mosek uses semidefinite programming to decide whether $\boldsymbol{M}$ can be decomposed into a sum of a positive semidefinite matrix and a nonnegative matrix. If not, Mosek declares the problem infeasible. Nesterov acceleration improves the final loss for the proximal distance algorithm, but it does not decrease overall computing time.

Testing for copositivity is challenging because neither the loss function nor the constraint set is convex. The proximal distance algorithm offers a fast screening device for checking whether a matrix is copositive. On random 1000×1000 symmetric matrices $\boldsymbol{M}$, the method invariably returns a negative index in less than two seconds of computing time. Because the vast majority of symmetric matrices are not copositive, accurate estimation of the minimum is not required. Table 6 summarizes a few random trials with lower-dimensional symmetric matrices. In higher dimensions, Mosek becomes non-competitive, and Nesterov acceleration is of dubious value.

5.6. Linear Complementarity Problem

The linear complementarity problem (Murty and Yu, 1988) consists of finding vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ with nonnegative components such that $\boldsymbol{x}^t\boldsymbol{y} = 0$ and $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{b}$ for a given square

Table 6: CPU times and optima for testing the copositivity of random symmetric matrices. Here n is the size of matrix, PD is the proximal distance algorithm, aPD is the accelerated proximal distance algorithm, and Mosek is the Mosek solver.

Dimension	Optima			CPU Seconds		
n	PD	aPD	Mosek	PD	aPD	Mosek

matrix $\boldsymbol{A}$ and vector $\boldsymbol{b}$. The natural loss function is $\frac{1}{2}\|\boldsymbol{y}-\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b}\|^2$. To project a vector pair $(\boldsymbol{u},\boldsymbol{v})$ onto the nonconvex constraint set, one considers each component pair (u_i,v_i) in turn. If $u_i \geq \max\{v_i,0\}$, then the nearest pair $(\boldsymbol{x},\boldsymbol{y})$ has components $(x_i,y_i)=(u_i,0)$. If $v_i \geq \max\{u_i,0\}$, then the nearest pair has components $(x_i,y_i)=(0,v_i)$. Otherwise, $(x_i,y_i)=(0,0)$. At each iteration the proximal distance algorithm minimizes the criterion

$$\frac{1}{2}\|\boldsymbol{y}-\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b}\|^2+\frac{\rho}{2}\|\boldsymbol{x}-\tilde{\boldsymbol{x}}_k\|^2+\frac{\rho}{2}\|\boldsymbol{y}-\tilde{\boldsymbol{y}}_k\|^2,$$

where $(\tilde{\boldsymbol{x}}_k,\tilde{\boldsymbol{y}}_k)$ is the projection of $(\boldsymbol{x}_k,\boldsymbol{y}_k)$ onto the constraint set. The stationarity equations become

$$\begin{aligned}\boldsymbol{0} &= -\boldsymbol{A}^t(\boldsymbol{y}-\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})+\rho(\boldsymbol{x}-\tilde{\boldsymbol{x}}_k)\\ \boldsymbol{0} &= \boldsymbol{y}-\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b}+\rho(\boldsymbol{y}-\tilde{\boldsymbol{y}}_k).\end{aligned}$$

Substituting the value of $\boldsymbol{y}$ from the second equation into the first equation leads to the updates

$$\begin{aligned}\boldsymbol{x}_{k+1} &= [(1+\rho)\boldsymbol{I}+\boldsymbol{A}^t\boldsymbol{A}]^{-1}[\boldsymbol{A}^t(\tilde{\boldsymbol{y}}_k-\boldsymbol{b})+(1+\rho)\tilde{\boldsymbol{x}}_k] \qquad (19)\\ \boldsymbol{y}_{k+1} &= \frac{1}{1+\rho}(\boldsymbol{A}\boldsymbol{x}_{k+1}+\boldsymbol{b})+\frac{\rho}{1+\rho}\tilde{\boldsymbol{y}}_k.\end{aligned}$$

The linear system (19) can be solved in low to moderate dimensions by computing and caching the spectral decomposition of $\boldsymbol{A}^t\boldsymbol{A}$ and in high dimensions by the conjugate gradient method. Table 7 compares the performance of the proximal gradient algorithm to the Gurobi solver on some randomly generated problems.

5.7. Sparse Principal Components Analysis

Let $\boldsymbol{X}$ be an $n\times p$ data matrix gathered on n cases and p predictors. Assume the columns of $\boldsymbol{X}$ are centered to have mean 0. Principal component analysis (PCA) (Hotelling, 1933;

Table 7: CPU times (seconds) and optima for the linear complementarity problem with randomly generated data. Here n is the size of matrix, PD is the accelerated proximal distance algorithm, and Gurobi is the Gurobi solver.

Dimension	Optima		CPU Seconds	
n	PD	Mosek	PD	Mosek

64	0.000074	0.000000	2.6846	360.5183

Pearson, 1901) operates on the sample covariance matrix $\boldsymbol{S}=\frac{1}{n}\boldsymbol{X}^t\boldsymbol{X}$. Here we formulate a proximal distance algorithm for sparse PCA (SPCA), which has attracted substantial interest in the machine learning community (Berthet and Rigollet, 2013b,a; D'Aspremont et al., 2007; Johnstone and Lu, 2009; Journée et al., 2010; Witten et al., 2009; Zou et al., 2006). According to a result of Ky Fan (Fan, 1949), the first q principal components (PCs) $\boldsymbol{u}_1,\ldots,\boldsymbol{u}_q$ can be extracted by maximizing the function $\mathrm{tr}(\boldsymbol{U}^t\boldsymbol{S}\boldsymbol{U})$ subject to the matrix constraint $\boldsymbol{U}^t\boldsymbol{U}=\boldsymbol{I}_q$, where $\boldsymbol{u}_i$ is the ith column of the $p\times q$ matrix $\boldsymbol{U}$. This constraint set is called a Stiefel manifold. One can impose sparsity by insisting that any given column $\boldsymbol{u}_i$ have at most r nonzero entries. Alternatively, one can require the entire matrix $\boldsymbol{U}$ to have at most r nonzero entries. The latter choice permits sparsity to be distributed non-uniformly across columns.

Extraction of sparse PCs is difficult for three reasons. First, the Stiefel manifold M_q and both sparsity sets are nonconvex. Second, the objective function is concave rather than convex. Third, there is no simple formula or algorithm for projecting onto the intersection of the two constraint sets. Fortunately, it is straightforward to project onto each separately. Let $P_{M_q}(\boldsymbol{U})$ denote the projection of $\boldsymbol{U}$ onto the Stiefel manifold. It is well known that $P_{M_q}(\boldsymbol{U})$ can be calculated by extracting a partial singular value decomposition $\boldsymbol{U}=\boldsymbol{V}\boldsymbol{\Sigma}\boldsymbol{W}^t$ of $\boldsymbol{U}$ and setting $P_{M_q}(\boldsymbol{U})=\boldsymbol{V}\boldsymbol{W}^t$ (Golub and Van Loan, 2012). Here $\boldsymbol{V}$ and $\boldsymbol{W}$ are orthogonal matrices of dimension $p\times q$ and $q\times q$, respectively, and $\boldsymbol{\Sigma}$ is a diagonal matrix of dimension $q\times q$. Let $P_{S_r}(\boldsymbol{U})$ denote the projection of $\boldsymbol{U}$ onto the sparsity set

$$S_r = \{\boldsymbol{V}: v_{ij}\neq 0 \text{ for at most } r \text{ entries of each column } \boldsymbol{v}_i\}.$$

Because $P_{S_r}(\boldsymbol{U})$ operates column by column, it suffices to project each column vector $\boldsymbol{u}_i$ to sparsity. This entails nothing more than sorting the entries of $\boldsymbol{u}_i$ by magnitude, saving the r largest, and sending the remaining $p-r$ entries to 0. If the entire matrix $\boldsymbol{U}$ must have at most r nonzero entries, then $\boldsymbol{U}$ can be treated as a concatenated vector during projection.

The key to a good algorithm is to incorporate the Stiefel constraints into the domain of the objective function (Kiers, 1990; Kiers and ten Berge, 1992) and the sparsity constraints into the distance penalty. Thus, we propose decreasing the criterion

$$f(\boldsymbol{U}) = -\frac{1}{2}\mathrm{tr}(\boldsymbol{U}^t\boldsymbol{S}\boldsymbol{U})+\frac{\rho}{2}\mathrm{dist}(\boldsymbol{U},S_r)^2.$$

at each iteration subject to the Stiefel constraints. The loss can be majorized via

$$\begin{aligned} -\frac{1}{2}\operatorname{tr}(\boldsymbol{U}^t\boldsymbol{S}\boldsymbol{U}) &= -\frac{1}{2}\operatorname{tr}[(\boldsymbol{U}-\boldsymbol{U}_k)^t\boldsymbol{S}(\boldsymbol{U}-\boldsymbol{U}_k)] - \operatorname{tr}(\boldsymbol{U}^t\boldsymbol{S}\boldsymbol{U}_k) + \frac{1}{2}\operatorname{tr}(\boldsymbol{U}_k^t\boldsymbol{S}\boldsymbol{U}_k) \\ &\le -\operatorname{tr}(\boldsymbol{U}^t\boldsymbol{S}\boldsymbol{U}_k) + \frac{1}{2}\operatorname{tr}(\boldsymbol{U}_k^t\boldsymbol{S}\boldsymbol{U}_k) \end{aligned}$$

because $\boldsymbol{S}$ is positive semidefinite. The penalty is majorized by

$$\frac{\rho}{2}\operatorname{dist}(\boldsymbol{U}, S_r)^2 \le -\rho\operatorname{tr}[\boldsymbol{U}^t P_{S_r}(\boldsymbol{U}_k)] + c_k$$

up to an irrelevant constant c_k since the squared Frobenius norm satisfies the relation $\|\boldsymbol{U}^t\boldsymbol{U}\|_F^2 = q$ on the Stiefel manifold. It now follows that $f(\boldsymbol{U})$ is majorized by

$$\frac{1}{2}\|\boldsymbol{U} - \boldsymbol{S}\boldsymbol{U}_k - \rho P_{S_r}(\boldsymbol{U}_k)\|_F^2$$

up to an irrelevant constant. Accordingly, the Stiefel projection

$$\boldsymbol{U}_{k+1} = P_{M_q}[\boldsymbol{S}\boldsymbol{U}_k + \rho P_{S_r}(\boldsymbol{U}_k)]$$

provides the next MM iterate.

Figures 1 and 2 compare the proximal distance algorithm to the SPC function from the R package `PMA` (Witten et al., 2009). The breast cancer data from `PMA` provide the data matrix $\boldsymbol{X}$. The data consist of $p = 19,672$ RNA measurements on $n = 89$ patients. The two figures show computation times and the proportion of variance explained (PVE) by the $p \times q$ loading matrix $\boldsymbol{U}$. For sparse PCA, PVE is defined as $\operatorname{tr}(\boldsymbol{X}_q^t\boldsymbol{X}_q)/\operatorname{tr}(\boldsymbol{X}^t\boldsymbol{X})$, where $\boldsymbol{X}_q = \boldsymbol{X}\boldsymbol{U}(\boldsymbol{U}^t\boldsymbol{U})^{-1}\boldsymbol{U}^t$ (Shen and Huang, 2008). When the loading vectors of $\boldsymbol{U}$ are orthogonal, this criterion reduces to the familiar definition $\operatorname{tr}(\boldsymbol{U}^t\boldsymbol{X}^t\boldsymbol{X}\boldsymbol{U})/\operatorname{tr}(\boldsymbol{X}^t\boldsymbol{X})$ of PVE for ordinary PCA. The proximal distance algorithm enforces either matrix-wise or column-wise sparsity. In contrast, SPC enforces only column-wise sparsity via the constraint $\|\boldsymbol{u}_i\|_1 \le c$ for each column $\boldsymbol{u}_i$ of $\boldsymbol{U}$. We take $c = 8$. The number of nonzeroes per loading vector output by SPC dictates the sparsity level for the column-wise version of the proximal distance algorithm. Summing these counts across all columns dictates the sparsity level for the matrix version of the proximal distance algorithm.

Figures 1 and 2 demonstrate the superior PVE and computational speed of both proximal distance algorithms versus SPC. The type of projection does not appear to affect the computational performance of the proximal distance algorithm, as both versions scale equally well with q. However, the matrix projection, which permits the algorithm to more freely assign nonzeroes to the loadings, attains better PVE than the more restrictive column-wise projection. For both variants of the proximal distance algorithm, Nesterov acceleration improves both fitting accuracy and computational speed, especially as the number of PCs q increases.

6. Discussion

The proximal distance algorithm applies to a host of problems. In addition to the linear and quadratic programming examples considered here, our previous paper (Lange and Keys,

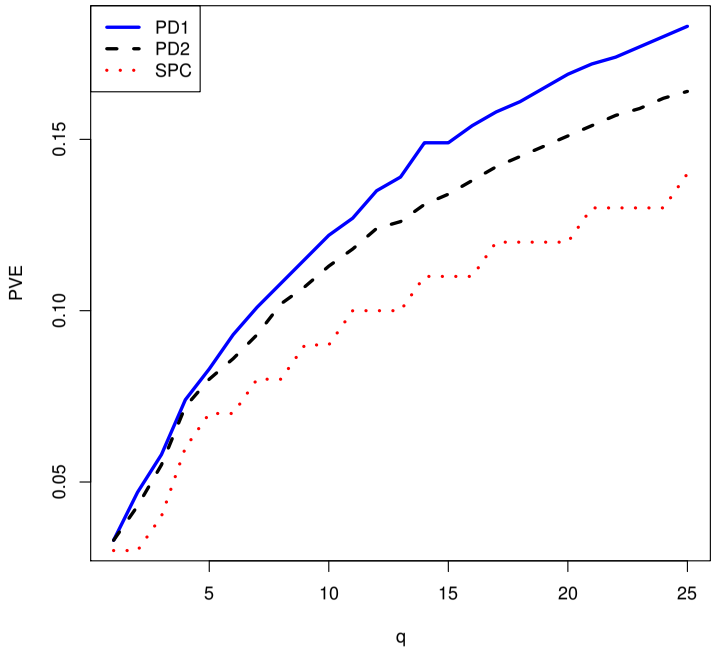

Figure 1: Proportion of variance explained by q PCs for each algorithm. Here PD1 is the accelerated proximal distance algorithm enforcing matrix sparsity, PD2 is the accelerated proximal distance algorithm enforcing column-wise sparsity, and SPC is the orthogonal sparse PCA method from `PMA`.

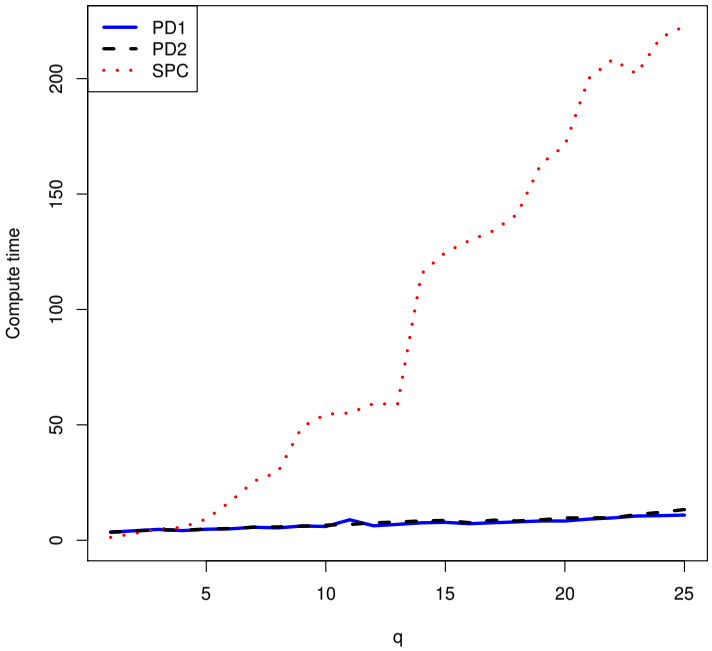

Figure 2: Computation times for q PCs for each algorithm. Here PD1 is the accelerated proximal distance algorithm enforcing matrix sparsity, PD2 is the accelerated proximal distance algorithm enforcing column-wise sparsity, and SPC is the orthogonal sparse PCA method from `PMA`.

2014) derives and tests algorithms for binary piecewise-linear programming, ℓ_0 regression, matrix completion (Cai et al., 2010; Candès and Tao, 2010; Chen et al., 2012; Mazumder et al., 2010), and sparse precision matrix estimation (Friedman et al., 2008). Other potential applications immediately come to mind. An integer linear program in standard form can be expressed as minimizing $\boldsymbol{c}^t\boldsymbol{x}$ subject to $\boldsymbol{A}\boldsymbol{x} + \boldsymbol{s} = \boldsymbol{b}$, $\boldsymbol{s} \geq \boldsymbol{0}$, and $\boldsymbol{x} \in \mathbb{Z}^p$. The latter two constraints can be combined in a single constraint for which projection is trivial. The affine constraints should be folded into the domain of the objective. Integer programming is NP hard, so that the proximal distance algorithm just sketched is merely heuristic. Integer linear programming includes traditional NP hard problems such as the traveling salesman problem, the vertex cover problem, set packing, and Boolean satisfiability. It will be interesting to see if the proximal distance principle is competitive in meeting these challenges. Our experience with the closest lattice point problem (Agrell et al., 2002) and the eight queens problem suggests that the proximal distance algorithm can be too greedy for hard combinatorial problems. The nonconvex problems solved in this paper are in some vague sense easy combinatorial problems.

The behavior of a proximal distance algorithm depends critically on a sensible tuning schedule for increasing ρ. Starting ρ too high puts too much stress on satisfying the constraints. Incrementing ρ too quickly causes the algorithm to veer off the solution path guaranteed by the penalty method. Given the chance of roundoff error even with double precision arithmetic, it is unwise to take ρ all the way to ∞. Trial and error can help in deciding whether a given class of problems will benefit from an aggressive update schedule and strict or loose convergence criteria. In problems with little curvature such as linear programming, more conservative updates are probably prudent. The linear programming, closest kinship matrix, and SPCA problems document the value of folding constraints into the domain of the loss. In the same spirit it is wise to minimize the number of constraints. A single penalty for projecting onto the intersection of two constraint sets is almost always preferable to the sum of two penalties for their separate projections. Exceptions to this rule obviously occur when projection onto the intersection is intractable. The integer linear programming problem mentioned previously illustrates these ideas.

Our earlier proximal distance algorithms ignored acceleration. In many cases the solutions produced had very low accuracy. The realization that convex proximal distance algorithms can be phrased as proximal gradient algorithms convinced us to try Nesterov acceleration. We now do this routinely on the subproblems with ρ fixed. This typically forces tighter path following and a reduction in overall computing times. Our examples generally bear out the contention that Nesterov acceleration is useful in nonconvex problems (Ghadimi and Lan, 2015). It is noteworthy that the value of acceleration often lies in improving the quality of a solution as much as it does in increasing the rate of convergence. Of course, acceleration cannot prevent convergence to an inferior local minimum.

On both convex and nonconvex problems, proximal distance algorithms enjoy global convergence guarantees. On nonconvex problems, one must confine attention to subanalytic sets and subanalytic functions. This minor restriction is not a handicap in practice. Determining local convergence rates is a more vexing issue. For convex problems, we review existing theory for a fixed penalty constant ρ. The classical results buttress an $O(\rho k^{-1})$ sublinear rate for general convex problems. Better results require restrictive smoothness assumptions on both the objective function and the constraint sets. For instance, when $f(\boldsymbol{x})$ is L-smooth

and strongly convex, linear convergence can be demonstrated. When $f(\boldsymbol{x})$ equals a difference of convex functions, proximal distance algorithms reduce to concave-convex programming. Le Thi et al. (2009) attack convergence in this setting.

We hope readers will sense the potential of the proximal distance principle. This simple idea offers insight into many existing algorithms and a straightforward path in devising new ones. Effective proximal and projection operators usually spell the difference between success and failure. The number and variety of such operators is expanding quickly as the field of optimization relinquishes it fixation on convexity. The current paper research leaves many open questions about tuning schedules, rates of convergence, and acceleration in the face of nonconvexity. We welcome the contributions of other mathematical scientists in unraveling these mysteries and in inventing new proximal distance algorithms.

Acknowledgments

We thank Joong-Ho Won for many insightful discussions. In partiular, he pointed out the utility of the least squares criterion (6). Sloan Foundation grant 2013-10-27 to UC Berkeley through the Moore-Sloan Data Sciences Environment initiative at the Berkeley Institute for Data Science (BIDS).

Appendix A. Proofs of the Stated Propositions

A.1. Proposition 1

We first observe that the surrogate function $g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k)$ is ρ-strongly convex. Consequently, the stationarity condition $\mathbf{0} \in \partial g_\rho(\boldsymbol{x}_{k+1} \mid \boldsymbol{x}_k)$ implies

$$g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) \;\geq\; g_\rho(\boldsymbol{x}_{k+1} \mid \boldsymbol{x}_k) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{x}_{k+1}\|^2 \tag{20}$$

for all $\boldsymbol{x}$. In the notation (9), the difference

$$d_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) \;=\; g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) - h_\rho(\boldsymbol{x}) \;=\; \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{y}_k\|^2 - \frac{\rho}{2}\sum_{i=1}^m \alpha_i \operatorname{dist}(\boldsymbol{x}, C_i)^2$$

is ρ-smooth because

$$\nabla d_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) \;=\; \rho(\boldsymbol{x} - \boldsymbol{y}_k) - \rho\sum_{i=1}^m \alpha_i[\boldsymbol{x} - P_{C_i}(\boldsymbol{x})] \;=\; \rho\sum_{i=1}^m \alpha_i P_{C_i}(\boldsymbol{x}) - \rho\boldsymbol{y}_k.$$

The tangency conditions $d_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k) = 0$ and $\nabla d_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k) = \mathbf{0}$ therefore yield

$$d_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) \;\leq\; d_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k) + \nabla d_\rho(\boldsymbol{x}_k)^t(\boldsymbol{x} - \boldsymbol{x}_k) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{x}_k\|^2 \;=\; \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{x}_k\|^2 \tag{21}$$

for all $\boldsymbol{x}$. Combining inequalities (20) and (21) gives

$$\begin{aligned} h_\rho(\boldsymbol{x}_{k+1}) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{x}_{k+1}\|^2 &\leq g_\rho(\boldsymbol{x}_{k+1} \mid \boldsymbol{x}_k) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{x}_{k+1}\|^2 \\ &\leq g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) \\ &= h_\rho(\boldsymbol{x}) + d_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) \\ &\leq h_\rho(\boldsymbol{x}) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{x}_k\|^2. \end{aligned}$$

Adding the result

$$h_\rho(\boldsymbol{x}_{k+1}) - h_\rho(\boldsymbol{x}) \;\leq\; \frac{\rho}{2}\Big(\|\boldsymbol{x} - \boldsymbol{x}_k\|^2 - \|\boldsymbol{x} - \boldsymbol{x}_{k+1}\|^2\Big)$$

over k and invoking the descent property $h_\rho(\boldsymbol{x}_{k+1}) \leq h_\rho(\boldsymbol{x}_k)$ produce the error bound

$$h_\rho(\boldsymbol{x}_{k+1}) - h_\rho(\boldsymbol{x}) \;\leq\; \frac{\rho}{2(k+1)}\Big(\|\boldsymbol{x} - \boldsymbol{x}_0\|^2 - \|\boldsymbol{x} - \boldsymbol{x}_{k+1}\|^2\Big) \;\leq\; \frac{\rho}{2(k+1)}\|\boldsymbol{x} - \boldsymbol{x}_0\|^2.$$

Setting $\boldsymbol{x}$ equal to a minimal point $\boldsymbol{z}$ gives the stated result. ∎

A.2. Proposition 2

The existence and uniqueness of $\boldsymbol{y}$ are obvious. The remainder of the proof hinges on the assumptions that $h_\rho(\boldsymbol{x})$ is μ-strongly convex and the surrogate $g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k)$ is $L + \rho$ smooth. The latter assumption yields

$$\begin{aligned} h_\rho(\boldsymbol{x}) - h_\rho(\boldsymbol{y}) &\leq g_\rho(\boldsymbol{x} \mid \boldsymbol{y}) - g_\rho(\boldsymbol{y} \mid \boldsymbol{y}) \\ &\leq \nabla g_\rho(\boldsymbol{y} \mid \boldsymbol{y})^t(\boldsymbol{x} - \boldsymbol{y}) + \frac{L+\rho}{2}\|\boldsymbol{x} - \boldsymbol{y}\|^2 \\ &= \frac{L+\rho}{2}\|\boldsymbol{x} - \boldsymbol{y}\|^2. \end{aligned} \tag{22}$$

The strong convexity condition $h_\rho(\boldsymbol{y}) - h_\rho(\boldsymbol{x}) \geq \nabla h_\rho(\boldsymbol{x})^t(\boldsymbol{y} - \boldsymbol{x}) + \frac{\mu}{2}\|\boldsymbol{y} - \boldsymbol{x}\|^2$ implies

$$\|\nabla h_\rho(\boldsymbol{x})\| \cdot \|\boldsymbol{y} - \boldsymbol{x}\| \;\geq\; -\nabla h_\rho(\boldsymbol{x})^t(\boldsymbol{y} - \boldsymbol{x}) \;\geq\; \frac{\mu}{2}\|\boldsymbol{y} - \boldsymbol{x}\|^2.$$

It follows that $\|\nabla h_\rho(\boldsymbol{x})\| \geq \frac{\mu}{2}\|\boldsymbol{x} - \boldsymbol{y}\|$. This last inequality and inequality (22) produce the Polyak-Łojasiewicz bound

$$\frac{1}{2}\|\nabla h_\rho(\boldsymbol{x})\|^2 \;\geq\; \frac{\mu^2}{2(L+\rho)}[h_\rho(\boldsymbol{x}) - h_\rho(\boldsymbol{y})].$$

Taking $\boldsymbol{x} = \boldsymbol{x}_k - \frac{1}{L+\rho}\nabla g_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k) = \boldsymbol{x}_k - \frac{1}{L+\rho}\nabla h_\rho(\boldsymbol{x}_k)$, the Polyak-Łojasiewicz bound gives

$$\begin{aligned} h_\rho(\boldsymbol{x}_{k+1}) - h_\rho(\boldsymbol{x}_k) &\leq g_\rho(\boldsymbol{x}_{k+1} \mid \boldsymbol{x}_k) - g_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k) \\ &\leq g_\rho(\boldsymbol{x} \mid \boldsymbol{x}_k) - g_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k) \\ &\leq -\frac{1}{L+\rho}\nabla g_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k)^t\nabla h_\rho(\boldsymbol{x}_k) + \frac{1}{2(L+\rho)}\|\nabla h_\rho(\boldsymbol{x}_k)\|^2 \\ &= -\frac{1}{2(L+\rho)}\|\nabla h_\rho(\boldsymbol{x}_k)\|^2 \\ &\leq -\frac{\mu^2}{2(L+\rho)^2}[h_\rho(\boldsymbol{x}_k) - h_\rho(\boldsymbol{y})]. \end{aligned}$$

Rearranging this inequality yields

$$h_\rho(\boldsymbol{x}_{k+1}) - h_\rho(\boldsymbol{y}) \;\le\; \Big[1 - \frac{\mu^2}{2(L+\rho)^2}\Big][h_\rho(\boldsymbol{x}_k) - h_\rho(\boldsymbol{y})],$$

which can be iterated to give the stated bound. ∎

A.3. Proposition 3

Consider first the proximal distance iterates. The inequality

$$f(\boldsymbol{x}_k) + \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{x}_k, S)^2 \;\le\; f(\boldsymbol{x}_k) + \frac{\rho_k}{2}\|\boldsymbol{x}_k - P_S(\boldsymbol{x}_{k-1})\|^2 \;\le\; f[P_S(\boldsymbol{x}_{k-1})] \;\le\; \sup_{\boldsymbol{x}\in S} f(\boldsymbol{x})$$

plus the coerciveness of $f(\boldsymbol{x})$ imply that $\boldsymbol{x}_k$ is a bounded sequence. The claimed bound now holds for c equal to the finite supremum of the sequence $2[\sup_{\boldsymbol{x}\in S} f(\boldsymbol{x}) - f(\boldsymbol{x}_k)]$. If in addition, $f(\boldsymbol{x})$ is continuously differentiable, then the stationarity equation

$$\boldsymbol{0} \;=\; \nabla f(\boldsymbol{x}_k) + \rho_k[\boldsymbol{x}_k - P_S(\boldsymbol{x}_{k-1})]$$

and the Cauchy-Schwarz inequality give

$$\rho_k\|\boldsymbol{x}_k - P_S(\boldsymbol{x}_{k-1})\|^2 \;=\; -\nabla f(\boldsymbol{x}_k)^t[\boldsymbol{x}_k - P_S(\boldsymbol{x}_{k-1})] \;\le\; \|\nabla f(\boldsymbol{x}_k)\| \cdot \|\boldsymbol{x}_k - P_S(\boldsymbol{x}_{k-1})\|.$$

Dividing this by $\|\boldsymbol{x}_k - P_S(\boldsymbol{x}_{k-1})\|$ and squaring further yield

$$\rho_k^2 \operatorname{dist}(\boldsymbol{x}_k, S)^2 \;\le\; \rho_k^2\|\boldsymbol{x}_k - P_S(\boldsymbol{x}_{k-1})\|^2 \;\le\; \|\nabla f(\boldsymbol{x}_k)\|^2.$$

Taking $d = \sup_k \|\nabla f(\boldsymbol{x}_k)\|^2$ over the bounded sequence $\boldsymbol{x}_k$ completes the proof.

For the penalty method iterates, the bound

$$f(\boldsymbol{y}_k) + \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{y}_k, S)^2 \;\le\; f(\boldsymbol{y})$$

is valid by definition, where $\boldsymbol{y}$ attains the constrained minimum. Thus, coerciveness implies that the sequence $\boldsymbol{y}_k$ is bounded. When $f(\boldsymbol{x})$ is continuously differentiable, the proof of the second claim also applies if we substitute $\boldsymbol{y}_k$ for $\boldsymbol{x}_k$ and $P_S(\boldsymbol{y}_k)$ for $P_S(\boldsymbol{x}_{k-1})$. ∎

A.4. Proposition 4

Because the function $f(\boldsymbol{x}) + \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{x}, S)^2$ is convex and has the value $f(\boldsymbol{y})$ and gradient $\nabla f(\boldsymbol{y})$ at a constrained minimum $\boldsymbol{y}$, the supporting hyperplane principle says

$$\begin{aligned} f(\boldsymbol{y}_k) + \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{y}_k, S)^2 &\ge f(\boldsymbol{y}) + \nabla f(\boldsymbol{y})^t(\boldsymbol{y}_k - \boldsymbol{y}) \\ &= f(\boldsymbol{y}) + \nabla f(\boldsymbol{y})^t[P_S(\boldsymbol{y}_k) - \boldsymbol{y}] + \nabla f(\boldsymbol{y})^t[\boldsymbol{y}_k - P_S(\boldsymbol{y}_k)]. \end{aligned}$$

The first-order optimality condition $\nabla f(\boldsymbol{y})^t[P_S(\boldsymbol{y}_k) - \boldsymbol{y}] \ge 0$ holds given $\boldsymbol{y}$ is a constrained minimum. Hence, the Cauchy-Schwarz inequality and Proposition 3 imply

$$\begin{aligned} f(\boldsymbol{y}) - f(\boldsymbol{y}_k) &\le \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{y}_k, S)^2 - \nabla f(\boldsymbol{y})^t[\boldsymbol{y}_k - P_S(\boldsymbol{y}_k)] \\ &\le \frac{\rho_k}{2}\operatorname{dist}(\boldsymbol{y}_k, S)^2 + \|\nabla f(\boldsymbol{y})\| \cdot \operatorname{dist}(\boldsymbol{y}_k, S) \\ &\le \frac{d + 2\sqrt{d}\|\nabla f(\boldsymbol{y})\|}{2\rho_k}. \end{aligned}$$

∎

A.5. Proposition 5

Let $\boldsymbol{x}_k$ converge to $\boldsymbol{x}_\infty$ and $\boldsymbol{y}_k \in P_S(\boldsymbol{x}_k)$ converge to $\boldsymbol{y}_\infty$. For an arbitrary $\boldsymbol{y} \in S$, taking limits in the inequality $\|\boldsymbol{x}_k - \boldsymbol{y}_k\| \le \|\boldsymbol{x}_k - \boldsymbol{y}\|$ yields $\|\boldsymbol{x}_\infty - \boldsymbol{y}_\infty\| \le \|\boldsymbol{x}_\infty - \boldsymbol{y}\|$; consequently, $\boldsymbol{y}_\infty \in P_S(\boldsymbol{x}_\infty)$. To prove the second assertion, take $\boldsymbol{y}_k \in P_S(\boldsymbol{x}_k)$ and observe that

$$\begin{aligned} \|\boldsymbol{y}_k\| &\le \|\boldsymbol{x}_k - \boldsymbol{y}_k\| + \|\boldsymbol{x}_k\| \\ &\le \|\boldsymbol{x}_k - \boldsymbol{y}_1\| + \|\boldsymbol{x}_k\| \\ &\le \|\boldsymbol{x}_k - \boldsymbol{x}_1\| + \|\boldsymbol{x}_1 - \boldsymbol{y}_1\| + \|\boldsymbol{x}_k\| \\ &\le \|\boldsymbol{x}_k\| + \|\boldsymbol{x}_1\| + \operatorname{dist}(\boldsymbol{x}_1, S) + \|\boldsymbol{x}_k\|, \end{aligned}$$

which is bounded above by the constant $\operatorname{dist}(\boldsymbol{x}_1, S) + 3\sup_{m\ge 1}\|\boldsymbol{x}_m\|$. ∎

A.6. Proposition 6

In fact, a much stronger result holds. Since the function $s(\boldsymbol{x})$ of equation (8) is convex and finite, Alexandrov's theorem (Niculescu and Persson, 2006) implies that it is almost everywhere twice differentiable. In view of the identities $\frac{1}{2}\operatorname{dist}(\boldsymbol{x}, S)^2 = \frac{1}{2}\|\boldsymbol{x}\|^2 - s(\boldsymbol{x})$ and $\boldsymbol{x} - P_S(\boldsymbol{x}) = \nabla\frac{1}{2}\operatorname{dist}(\boldsymbol{x}, S)^2$ where $P_S(\boldsymbol{x})$ is single valued, it follows that $P_S(\boldsymbol{x}) = \nabla s(\boldsymbol{x})$ is almost everywhere differentiable. ∎

A.7. Proposition 8

See the discussion just prior to the statement of the proposition. ∎

A.8. Proposition 9

The strong-convexity inequality

$$g_\rho(\boldsymbol{x}_k \mid \boldsymbol{x}_k) \;\ge\; g_\rho(\boldsymbol{x}_{k+1} \mid \boldsymbol{x}_k) + \frac{\mu}{2}\|\boldsymbol{x}_k - \boldsymbol{x}_{k+1}\|^2$$

and the tangency and domination properties of the algorithm imply

$$h_\rho(\boldsymbol{x}_k) - h_\rho(\boldsymbol{x}_{k+1}) \;\ge\; \frac{\mu}{2}\|\boldsymbol{x}_k - \boldsymbol{x}_{k+1}\|^2. \tag{23}$$

Since the difference in function values tends to 0, this validates the stated limit. The remaining assertions follow from Propositions 7.3.3 and 7.3.5 of (Lange, 2016). ∎

A.9. Proposition 10

Let the subsequence x_{k_m} of the MM sequence $\boldsymbol{x}_{k+1} \in M(\boldsymbol{x}_k)$ converge to $\boldsymbol{z}$. By passing to a subsubsequence if necessary, we may suppose that $\boldsymbol{x}_{k_m+1}$ converges to $\boldsymbol{y}$. Owing to our closedness assumption, $\boldsymbol{y} \in M(\boldsymbol{z})$. Given that $h(\boldsymbol{y}) = h(\boldsymbol{z})$, it is obvious that $\boldsymbol{z}$ also minimizes $g(\boldsymbol{x} \mid \boldsymbol{z})$ and that $\boldsymbol{0} = \nabla g(\boldsymbol{z} \mid \boldsymbol{z})$. Since the difference $\Delta(\boldsymbol{x} \mid \boldsymbol{z}) = g(\boldsymbol{x} \mid \boldsymbol{z}) - h(\boldsymbol{x})$ achieves its minimum at $\boldsymbol{x} = \boldsymbol{z}$, the Fréchet subdifferential $\partial^F\Delta(\boldsymbol{x} \mid \boldsymbol{z})$ satisfies

$$\boldsymbol{0} \;\in\; \partial^F\Delta(\boldsymbol{z} \mid \boldsymbol{z}) \;=\; \nabla g(\boldsymbol{z} \mid \boldsymbol{z}) + \partial^F(-h)(\boldsymbol{z}).$$

It follows that $\boldsymbol{0} \in \partial^F(-h)(\boldsymbol{z})$. ∎

A.10. Proposition 11

Because $\Delta(\boldsymbol{x} \mid \boldsymbol{y}) = g(\boldsymbol{x} \mid \boldsymbol{y}) - h(\boldsymbol{x})$ achieves its minimum at $\boldsymbol{x} = \boldsymbol{y}$, the Fréchet subdifferential $\partial^F \Delta(\boldsymbol{x} \mid \boldsymbol{y})$ satisfies

$$\mathbf{0} \;\in\; \partial^F \Delta(\boldsymbol{y} \mid \boldsymbol{y}) \;=\; \nabla g(\boldsymbol{y} \mid \boldsymbol{y}) + \partial^F(-h)(\boldsymbol{y}).$$

It follows that $-\nabla g(\boldsymbol{y} \mid \boldsymbol{y}) \in \partial^F(-h)(\boldsymbol{y})$. Furthermore, by assumption

$$\|\nabla g(\boldsymbol{a} \mid \boldsymbol{x}_k) - \nabla g(\boldsymbol{b} \mid \boldsymbol{x}_k)\| \;\leq\; L\|\boldsymbol{a} - \boldsymbol{b}\|$$

for all relevant $\boldsymbol{a}$ and $\boldsymbol{b}$ and $\boldsymbol{x}_k$. In particular, because $\nabla g(\boldsymbol{x}_{k+1} \mid \boldsymbol{x}_k) = \mathbf{0}$, we have

$$\|\nabla g(\boldsymbol{x}_k \mid \boldsymbol{x}_k)\| \;\leq\; L\|\boldsymbol{x}_{k+1} - \boldsymbol{x}_k\|. \tag{24}$$

Let W denote the set of limit points. The objective $h(\boldsymbol{x})$ is constant on W with value $\bar{h} = \lim_{k\to\infty} h(\boldsymbol{x}_k)$. According to the Łojasiewicz inequality applied for the subanalytic function $\bar{h} - h(\boldsymbol{x})$, for each $\boldsymbol{z} \in W$ there exists an open ball $B_{r(\boldsymbol{z})}(\boldsymbol{z})$ of radius $r(\boldsymbol{z})$ around $\boldsymbol{z}$ and an exponent $\theta(\boldsymbol{z}) \in [0, 1)$ such that

$$|h(\boldsymbol{u}) - h(\boldsymbol{z})|^{\theta(\boldsymbol{z})} \;=\; |\bar{h} - h(\boldsymbol{u}) - \bar{h} + \bar{h}|^{\theta(\boldsymbol{z})} \;\leq\; c(\boldsymbol{z})\|\boldsymbol{v}\|$$

for all $\boldsymbol{u} \in B_{r(\boldsymbol{z})}(\boldsymbol{z})$ and all $\boldsymbol{v} \in \partial^F(\bar{h} - h)(\boldsymbol{u}) = \partial^F(-h)(\boldsymbol{u})$. We will apply this inequality to $\boldsymbol{u} = \boldsymbol{x}_k$ and $\boldsymbol{v} = -\nabla g(\boldsymbol{x}_k \mid \boldsymbol{x}_k)$. In so doing, we would like to assume that the exponent $\theta(\boldsymbol{z})$ and constant $c(\boldsymbol{z})$ do not depend on $\boldsymbol{z}$. With this end in mind, cover the compact set W by a finite number of balls $B_{r(\boldsymbol{z}_i)}(\boldsymbol{z}_i)$ and take $\theta = \max_i \theta(\boldsymbol{z}_i) < 1$ and $c = \max_i c(\boldsymbol{z}_i)$. For a sufficiently large K, every $\boldsymbol{x}_k$ with $k \geq K$ falls within one of these balls and satisfies $|\bar{h} - h(\boldsymbol{x}_k)| < 1$. Without loss of generality assume $K = 0$. The Łojasiewicz inequality reads

$$|\bar{h} - h(\boldsymbol{x}_k)|^\theta \;\leq\; c\|\nabla g(\boldsymbol{x}_k \mid \boldsymbol{x}_k)\|. \tag{25}$$

In combination with the concavity of the function $t^{1-\theta}$ on $[0, \infty)$, inequalities (23), (24), and (25) imply

$$\begin{aligned}
[h(\boldsymbol{x}_k) - \bar{h}]^{1-\theta} - [h(\boldsymbol{x}_{k+1}) - \bar{h}]^{1-\theta} &\geq \frac{1-\theta}{[h(\boldsymbol{x}_k) - \bar{h}]^\theta}[h(\boldsymbol{x}_k) - h(\boldsymbol{x}_{k+1})] \\
&\geq \frac{1-\theta}{c\|\nabla g(\boldsymbol{x}_k \mid \boldsymbol{x}_k)\|}\frac{\mu}{2}\|\boldsymbol{x}_{k+1} - \boldsymbol{x}_k\|^2 \\
&\geq \frac{(1-\theta)\mu}{2cL}\|\boldsymbol{x}_{k+1} - \boldsymbol{x}_k\|.
\end{aligned}$$

Rearranging this inequality and summing over k yield

$$\sum_{n=0}^{\infty} \|\boldsymbol{x}_{k+1} - \boldsymbol{x}_k\| \;\leq\; \frac{2cL}{(1-\theta)\mu}[h(\boldsymbol{x}_0) - \bar{h}]^{1-\theta}$$

Thus, the sequence $\boldsymbol{x}_k$ is a fast Cauchy sequence and converges to a unique limit in W. ■

Abstract

The problem of learning the solution space of an unknown formula has been studied in multiple embodiments in computational learning theory. In this article, we study a family of such learning problems; this family contains, for each relational structure, the problem of learning the solution space of an unknown conjunctive query evaluated on the structure. A progression of results aimed to classify the learnability of each of the problems in this family, and thus far a culmination thereof was a positive learnability result generalizing all previous ones. This article completes the classification program towards which this progression of results strived, by presenting a negative learnability result that complements the mentioned positive learnability result. In addition, a further negative learnability result is exhibited, which indicates a dichotomy within the problems to which the first negative result applies. In order to obtain our negative results, we make use of universal-algebraic concepts.

Keywords: concept learning, computational learning theory, dichotomy theorems, reductions, universal algebra

1. Introduction

In this section we provide an overview of the question that we address in this paper and describe some related work as well as our contributions to its resolution.

1.1. Overview

The problem of learning the solution space of an unknown formula has long been of interest in computational learning theory. While the general problem of learning the solution space of even a propositional formula is known to be hard (Kearns and Valiant, 1994; Angluin and Kharitonov, 1995), researchers have considered many restricted versions of formula learning over the years, and have obtained a variety of learnability and non-learnability results (see for example Angluin, 1988; Angluin et al., 1992; Arias and Khardon, 2002; Bshouty et al., 2005; Jackson and Servedio, 2006; Bulatov et al., 2007; Idziak et al., 2010; Bshouty, 2013).

Conjunctive queries are formulas which are considered heavily in database theory and in the theory of constraint satisfaction. They can be defined logically as formulas built from predicate applications, equality of variables, conjunction, and existential quantification. For example, if $\mathbf{G} = (V, E)$ is an irreflexive graph (with vertex set V and edge set E, considered as a binary relation on V), then the conjunctive query

$$\exists y \exists z \left(E(x, y) \wedge E(y, z) \wedge E(z, x) \right)$$

is true for a vertex $x \in V$ if and only if x is part of a 3-cycle of the graph.

The problem of deciding, given a conjunctive query and a *relational structure* (which defines the predicates of the query), whether or not the solution space of the query is non-empty, is a formulation of the *constraint satisfaction problem*, a very general NP-complete problem. One obtains a rich framework of problems, by considering, for each relational structure $\mathbf{B}$, the constraint satisfaction problem, denoted $\mathsf{CSP}(\mathbf{B})$, where the relational structure is fixed as $\mathbf{B}$; the computational aspects of this problem framework are of interest and have been explored in numerous contexts (see for example Creignou et al., 2001; Raghavendra, 2008; Allender et al., 2009; Chen, 2012; Bhattacharyya and Yoshida, 2013; Bulatov, 2013; Chen et al., 2016; Chen and Larose, 2017). Schaefer's celebrated dichotomy theorem (Schaefer, 1978) provides that, for each relational structure $\mathbf{B}$ with a two-element universe, $\mathsf{CSP}(\mathbf{B})$ is either polynomial-time decidable or is NP-complete. A line of research strives to obtain a complexity classification of the constraint satisfaction problem over all relational structures with finite universe; results here include sufficient conditions for tractability (Idziak et al., 2010; Barto and Kozik, 2014), a unifying explanation for known intractability proofs (Bulatov et al., 2005), and—as a culmination thus far—the classification of all such structures whose constraint satisfaction problem is polynomial-time tractable (Bulatov, 2017; Zhuk, 2017).

As a means of systematically exploring the boundary between learnability and non-learnability, an analogous framework has been considered in learning theory: for each relational structure $\mathbf{B}$, we may define a problem $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ wherein the aim is to learn the solution space of an unknown conjunctive query evaluated on $\mathbf{B}$ (refer to Section 2 for formal definitions). As three particular examples, consider the following. Other examples can be found in Barto et al. (2017).

Example 1 *Let $\mathbf{B}_{3\mathrm{SAT}}$ be the relational structure with domain $\{0,1\}$ that has, for each triple $(a,b,c) \in \{0,1\}^3$, the ternary relation $R_{(a,b,c)} = \{0,1\}^3 \setminus \{(a,b,c)\}$. Then the set of solution spaces of the conjunctive queries on $\mathbf{B}_{3\mathrm{SAT}}$ is known to be the set of all Boolean relations.*

Example 2 *Let $\mathbf{B}_{\mathrm{HORN-3SAT}}$ be the relational structure with universe $\{0,1\}$ whose relations consists of the four relations $\{0\}$, $\{1\}$, $R_{(1,1,0)}$ and $R_{(1,1,1)}$. It is readily verified that the solution spaces of conjunctive queries on $\mathbf{B}_{\mathrm{HORN-3SAT}}$ are exactly the solution spaces of conjunctions of propositional* Horn clauses*; these solution spaces can be equivalently characterized as those closed under the pointwise application of the Boolean AND ($\wedge$) operation (Creignou et al., 2001, Lemma 4.8).*

Example 3 *For a finite field $\mathbb{F} = (F; +, \cdot, -, 0, 1)$, let $\mathbf{V}_{\mathbb{F}}$ be the relational structure with universe F and whose relations are the singleton unary relations $\{f\}$, for $f \in F$; the graph of the function $x + y$; and, the graph of $\lambda_f(x) = f \cdot x$, for each $f \in F$. Then the solution spaces of conjunctive queries on $\mathbf{V}_{\mathbb{F}}$ are exactly the affine subspaces of the vector spaces $(\langle F, +, -, 0, \lambda_f \rangle_{f \in F})^n$, for $n \geq 1$.*

A primary research goal of this line of inquiry is to completely understand, over all finite structures $\mathbf{B}$, which problems of the form $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ are learnable and which are not.

1.2. Related Previous Work

Let us survey the main known results about the framework of learning problems $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$.[1] Dalmau (1999) presented an analog of Schaefer's theorem, namely, a dichotomy theorem indicating, for each relational structure $\mathbf{B}$, which of the problems $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ are learnable. Precisely, this dichotomy theorem implies that each such problem is either polynomially learnable with equivalence queries, or is not polynomially predictable with membership queries. This dichotomy is sharp in that each problem that is polynomially learnable with equivalence queries is also polynomially predictable with membership queries (Littlestone, 1988, Section 4). The negative result, and all others under discussion, are proved under established cryptographic assumptions which are invoked in the present article (see Section 2.2), and the positive and negative results in the following discussion are proved in the two mentioned models, respectively.

Dalmau and Jeavons (2003) established a link between this framework and universal algebra; gave a general strategy for presenting positive results; and provided dichotomy theorems for two restricted classes of structures. Bulatov et al. (2007) gave a positive learnability result which applies to each relational structure having a so-called *generalized majority-minority polymorphism*. Later, Idziak et al. (2010) gave a positive learnability result generalizing all previous positive results; their result applies to any structure $\mathbf{B}$ for which all solution spaces have *small* (polynomial-size) generating sets, in a precise sense (see the discussion after Definition 9). They point out that all previous positive results were based on small generating sets, and hence that their result is a natural culmination of the progression of positive results.

1.3. Contributions

In this article, we complete the classification program towards which all of these previous works strive, by presenting a negative learnability result that complements the positive learnability result of Idziak et al. and hence that encompasses all previous negative learnability results in the framework at hand. We prove that for any structure $\mathbf{B}$ for which the small generating sets condition of Idziak et al. fails, it holds that $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ is not polynomially predictable with membership queries. We accomplish this by reducing the problem of learning the solution space of an unknown propositional formula, denoted by $\mathcal{C}_{\mathrm{PF}}$, to the problem $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$. We then refine this result by showing that if $\mathbf{B}$ fails to satisfy a weaker condition, that of having a Taylor polymorphism, then the problem $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ is as hard to learn as a prediction problem concerning partial assignments to circuits.

In order to establish our negative results, we make significant use of universal-algebraic notions and results, which we now turn to elaborate on. Each structure $\mathbf{B}$ can be passed to an algebra, its so-called algebra of polymorphisms, and it is known that the complexity of learning $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ is an invariant of this passage (that is, two structures that are passed to the same algebra have the same complexity of learning; see Proposition 4). We consider the variety generated by the algebra of a structure, which we show is justified (Proposition 5). If this variety is *congruence modular*, then we invoke a theorem, due to Barto (2018), which shows that the algebra of $\mathbf{B}$ has a property called *few subpowers*, and thus that the Idziak et al. positive result can be applied. (Barto's theorem resolved in the positive a conjecture known as the *Edinburgh Conjecture*, see Bova et al., 2013).

A main result of this article is the negative learnability result that, if the mentioned variety is *not* congruence modular, then the problem $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ is hard to learn. In order to prove this, we make use of concepts developed in a previous work which also studied non-congruence modularity (Bova et al., 2013). In particular, we make use of a structural result established there (Lemma 21) which essentially shows that, to prove hardness, one can work with a relational structure which can be localized to behave as a set of *pentagons*, which are a certain type of relational structure. Exploiting this structural result in the context of learning, however, is far from obvious, and involves developing significantly more detailed reductions than those used in the previous work (Bova et al., 2013), which dealt with comparing the solution spaces of two given conjunctive queries. The reason the reductions need to be more detailed here is that, when reducing one problem to another, one needs to translate from one concept to a second in a way that closely preserves structure (in our case of studying learning of unknown formulas, reductions need to preserve structure of the solution spaces); this contrasts sharply with the earlier work (Bova et al., 2013), where reductions needed only preserve a single bit, namely, the answer to a decision problem. Indeed, as an intermediate step, we show the hardness of a natural term-learning problem on lattices, which may be of independent interest (Section 5).

To obtain our second negative result, we make use of another part of Bova et al. (2013) that deals with finite structures that fail to have a special type of polymorphism called a Taylor polymorphism. There it is shown that in the absence of a Taylor polymorphism, a finite structure $\mathbf{B}$ interprets, in a certain sense, a structure representing the 3-SAT problem. From this, we prove our hardness result.

2. Preliminaries

When P is a condition (such as a containment $x \in c$), we use $[P]$ to denote the value equal to 1 if P is true, and 0 if P is false. When $f : A \to B$ and $g : B \to C$ are functions, we sometimes use $g(f)$ to denote their composition.

2.1. Concept Learning

Our terminology and notation is based on those employed by Pitt and Warmuth (1990) and by Angluin and Kharitonov (1995).

1. Let us mention that, in the existing literature, (in for example in Bulatov et al., 2007) some positive results are stated for queries where universal quantification is permitted in addition to predicate applications, equality of variables, conjunction, and existential quantification; let us refer to such queries as *quantified conjunctive queries*. Let $\mathbf{B}^*$ be the structure obtained from $\mathbf{B}$ by adding each element of the universe of $\mathbf{B}$ as a relation. These positive results typically apply to the structure $\mathbf{B}^*$ whenever they apply to a structure $\mathbf{B}$. For a structure of the form $\mathbf{B}^*$, it can be readily verified that the solution space of any quantified conjunctive query is also the solution space of a conjunctive query; this can be shown by transforming a quantified conjunctive query into a conjunctive query by using the additional relations to eliminate each instance of universal quantification.

   As the main contribution of the present article is to present a negative result, we focus the present discussion on conjunctive queries.

We assume that objects are encoded over the binary alphabet $\{0,1\}$, and use X to denote $\{0,1\}^*$. When x is a string, we use $|x|$ to denote its length, and for each $n \in \mathbb{N}$, we use $X^{[n]}$ to denote $\{x \in X \ : \ |x| \leq n\}$. A *prediction problem* $\mathcal{C}$ is a subset of $X \times X$; when $(u,x) \in \mathcal{C}$, we refer to u as a *concept name* or *concept representation* (of $\mathcal{C}$). Relative to a prediction problem $\mathcal{C}$, the *concept represented by* u is defined as $\kappa_{\mathcal{C}}(u) = \{x \mid (u,x) \in \mathcal{C}\}$.

A *pwm-algorithm* (short for *prediction with membership queries algorithm*) is an algorithm A with the following properties. The algorithm A takes as input a bound $s \in \mathbb{N}$ on the size of the target concept representation, a bound $n \in \mathbb{N}$ on the length of examples, and an *accuracy bound* ϵ, a positive rational number. It may make three types of oracle calls, the responses to which are determined by an unknown target concept c and an unknown distribution D on $X^{[n]}$: (1) A *membership query* takes a string $x \in X$ as input and returns $[x \in c]$; (2) A request for a random classified example takes no input and returns a pair (x,b), where x is a string chosen independently according to D, and $b = [x \in c]$; (3) A request for an element to predict takes no input and returns a string x chosen independently according to D. The algorithm A may make any number of oracle calls of types 1 and 2; however, in any run, it must make exactly one oracle call of type 3 and then eventually halt with an output of 1 or 0 without making any further oracle calls.

A pwm-algorithm is said to run in polynomial time if its running time is bounded by a polynomial in s, n, and $1/\epsilon$. A pwm-algorithm A is said to *successfully* predict a prediction problem $\mathcal{C}$ if for each input (s,n,ϵ), each concept name $u \in X^{[s]}$ of $\mathcal{C}$, and for each probability distribution D on $X^{[n]}$, when A is run on (s,n,ϵ) and the oracle calls of type 1 and 2 are answered according to $c = \kappa_{\mathcal{C}}(u)$ and D, the probability that the output of A is not equal to $[x \in c]$ is bounded above by ϵ. A prediction problem is *polynomially predictable with membership queries* if there exists a pwm-algorithm that runs in polynomial time and successfully predicts $\mathcal{C}$.

2.2. Problems

We introduce the problems that will be of concern.

A *relational signature* is a finite set of *relation symbols*; each relation symbol has an arity $k \geq 0$ associated with it. Note that we assume that all relational signatures under discussion are finite. A *relational structure* $\mathbf{B}$ over a relational signature σ consists of a finite set B called its *universe* and, for each relation symbol $R \in \sigma$, a relation $R^{\mathbf{B}} \subseteq B^k$, where k is the arity of R. We generally use the letters $\mathbf{A}$, $\mathbf{B}$, ... to denote relational structures, and the corresponding letters A, B, ... to denote their respective universes. Note that we assume that all relational structures under discussion are *finite* in that each has a finite universe; nonetheless, we sometimes state this explicitly for emphasis. A *conjunctive query* on a relational signature σ is a first-order formula built from predicate applications $R(v_1,\ldots,v_k)$ (where $R \in \sigma$ and $v_1,\ldots,v_k$ are variables, with k equal to the arity of R), equality of variables $v = v'$, conjunction, and existential quantification. When $\mathbf{B}$ is a relational structure and $Q \subseteq B^k$ is a relation, we say that Q is *cq-definable* over $\mathbf{B}$ if there exists a conjunctive query $\phi(v_1,\ldots,v_k)$ such that $(b_1,\ldots,b_k)$ satisfies ϕ on $\mathbf{B}$ if and only if $(b_1,\ldots,b_k) \in Q$.

The prediction problems that we study are as follows. There is a problem for each relational structure $\mathbf{B}$. Each conjunctive query $\phi(V)$ over the signature of $\mathbf{B}$ is a concept

representation, and its concept is the set that contains an assignment $f : V \to B$ if it holds that $\mathbf{B}, f \models \phi$, that is, if it satisfies $\phi(V)$ over $\mathbf{B}$. Formally, for each relational structure $\mathbf{B}$, we define $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ to be the prediction problem

$$\{(\phi(V), f) \mid \phi \text{ is a conjunctive query and } f : V \to B \text{ is a mapping such that } \mathbf{B}, f \models \phi\}.$$

Our hardness results for prediction problems are based on the hardness of predicting propositional formulas and of predicting Boolean circuits. By a propositional formula, we understand a formula built from propositional variables and the basis consisting of AND ($\wedge$), OR ($\vee$), and NOT ($\neg$), where the fan-in of AND and OR is assumed to be two. We define $\mathcal{C}_{\mathrm{PF}}$ as the prediction problem containing those pairs (θ, f) where θ is a propositional formula, and f is a propositional assignment to the variables of θ that satisfies θ. (Note that the existence of a pwm-algorithm for $\mathcal{C}_{\mathrm{PF}}$ is readily verified to be insensitive to our assumption of fan-in two for AND and OR gates.) The following cryptographic evidence is known for the hardness of learning $\mathcal{C}_{\mathrm{PF}}$. Let us refer to the following three hypotheses, studied in Kearns and Valiant (1994), as the *Kearns-Valiant hypotheses*: testing quadratic residues is intractable; inverting RSA encryption is intractable; factoring Blum integers is intractable.

Theorem 1 *(Angluin and Kharitonov, 1995, Corollary 3) Under the assumption that one of the Kearns-Valiant hypotheses holds, the prediction problem $\mathcal{C}_{\mathrm{PF}}$ is not polynomially predictable with membership queries.*

By a *Boolean circuit*, we understand a circuit built from input variables and the standard basis consisting of AND ($\wedge$), OR ($\vee$), and NOT ($\neg$). We define $\mathcal{C}_{\mathrm{CIRC}}$ as the prediction problem containing those pairs (T, f) where T is a Boolean circuit, and f is an assignment to the variables of T that satisfies T. We define $\mathcal{C}_{\exists\mathrm{CIRC}}$ as the prediction problem containing those pairs $((T, U), f)$ where T is a Boolean circuit, U is a subset of the variables on which T is defined, and f is an assignment to U that can be extended to an assignment that satisfies T.

3. Reducibility and Hardness

In this section, we describe the notion of reduction that will be used throughout the paper (Section 3.1); we demonstrate how certain standard algebraic constructions are relevant in our learning context, and also present notions of algebra to be used (Section 3.2); and, we provide a certain learning problem on propositional formulas that will be wieldy (Section 3.3).

3.1. Oracular pwm-reducibility

We define an extension of the notion of *pwm-reduction* due to Angluin and Kharitonov (1995); we refer to our notion of reduction as *oracular pwm-reduction*.

An *oracular pwm-reduction* from a prediction problem $\mathcal{C}$ to a second prediction problem $\mathcal{C}'$ is a triple (f, g, H) where f and g are mappings and H is an algorithm with the following properties:

1. There exists a polynomial q such that for each $s, n \in \mathbb{N}$ and for each $u \in X^{[s]}$, it holds that $g(s, n, u)$ is a string with $|g(s, n, u)| \leq q(s, n, |u|)$.

2. For each $s, n \in \mathbb{N}$, for each $u \in X^{[s]}$, and for each $x \in X^{[n]}$, it holds that $x' = f(s, n, x)$ is a string such that $x \in \kappa_{\mathcal{C}}(u)$ if and only if $x' \in \kappa_{\mathcal{C}'}(g(s, n, u))$. Also, there exists a polynomial t such that f is computable in time $t(s, n, |x|)$.

3. For each $s, n \in \mathbb{N}$, for each $u \in X^{[s]}$, and for each $x' \in X^{[n]}$, the algorithm H, on input (s, n, x'), may submit strings $x \in X$ as queries to an oracle, which responds $[x \in \kappa_{\mathcal{C}}(u)]$; the algorithm's output must be $[x' \in \kappa_{\mathcal{C}'}(g(s, n, u))]$. The algorithm H is required to run in polynomial time (in s, n, and $|x'|$).

Let us remark that the existence of a pwm-reduction between two prediction problems immediately implies the existence of an oracular pwm-reduction: pwm-reducibility can be viewed as the special case of oracular pwm-reducibility where the algorithm H can make at most one oracle query and, in the case that this query is made, the result must be the output of H.

Proposition 2 *Let $\mathcal{C}$ and $\mathcal{C}'$ be prediction problems. If there exists an oracular pwm-reduction from $\mathcal{C}$ to C' and it holds that $\mathcal{C}'$ is polynomially predictable with membership queries, then $\mathcal{C}$ is also polynomially predictable with membership queries.*

The proof of Proposition 2 is extremely similar to that of Angluin and Kharitonov (1995, Lemma 2), so we only give the idea of the proof. Let A' be a pwm-algorithm that witnesses that $\mathcal{C}'$ is polynomially predictable with membership queries. We describe a pwm-algorithm A that witnesses that $\mathcal{C}$ is polynomially predictable with membership queries, as follows. When A is run on input (s, n, ϵ), it computes $s' = q(s, n, s)$ and $n' = t(s, n, n)$. It then performs a simulation of A' on input (s', n', ϵ). Oracle calls made by the simulation of A' are answered by A as follows.

1. When A' makes a membership query on string $x' \in X$, the algorithm A runs $H(s, n, x')$ using its own membership queries to respond to the oracle calls of H, and then returns the result to A'.

2. When A' requests a random classified example, the algorithm A makes a request for a random classified example to obtain (x, b), and then returns the pair $(f(s, n, x), b)$ to A'.

3. When A' requests an element to predict, the algorithm A requests an element x, and returns the string $f(s, n, x)$ to A'.

When the simulated algorithm A' halts with an output b, the algorithm A halts with the output b.

For each input (s, n, ϵ), for each concept name $u \in X^{[s]}$ of $\mathcal{C}$, and for each probability distribution D on $X^{[n]}$, set $u' = g(s, n, u)$ and set D' to be the induced distribution $f(s, n, D)$ on $X^{[n']}$. When the algorithm A is invoked on (s, n, ϵ) with u and D, in its simulation of A', membership queries are answered according to the concept $\kappa_{\mathcal{C}'}(u')$ and random classified examples are generated according to D'. The assumption that A' predicts correctly within

an error bound of ϵ can be verified to imply that A will predict within an error bound of ϵ. This concludes our description of the proof of Proposition 2.

The following property, which is straightforward to verify, will be used tacitly.[2]

Proposition 3 *Oracular pwm-reducibility is transitive.*

We leave, to future research, a study of whether and how oracular pwm-reducibility is more general than pwm-reducibility.

3.2. Algebras and Varieties

We make use of basic notions from universal algebra, and suggest Burris and Sankappanavar (1981) and McKenzie et al. (1987) as references. For our purposes in this article, an *algebra* is a pair $(A; F)$ consisting of a nonempty set A, the *universe* of the algebra, and a set F of finitary operations on A, the set of *basic operations* of the algebra. An algebra is *finite* if its universe is finite; we deal here mainly with finite algebras. A *term operation* (or sometimes just term) of an algebra $\mathbb{A}$ is any operation on A that can be obtained from the basic operations of $\mathbb{A}$ and the projection maps on A by composition. The *variety generated by an algebra* $\mathbb{A}$, denoted by $\mathcal{V}(\mathbb{A})$, is the smallest class of algebras containing $\mathbb{A}$ that is closed under taking homomorphic images, subalgebras, and products. An operation $f : B^m \to B$ is a *polymorphism* of a relation $Q \subseteq B^k$ if for any m tuples $(b_1^1, \ldots, b_k^1), \ldots, (b_1^m, \ldots, b_k^m)$ in Q, the tuple $(f(b_1^1, \ldots, b_1^m), \ldots, f(b_k^1, \ldots, b_k^m))$ is in Q. A relational structure $\mathbf{B}$ is *compatible* with an algebra having the same universe B if for each operation $f : B^m \to B$ of the algebra, it holds that f *is a polymorphism of* $\mathbf{B}$, by which is meant, f is a polymorphism of each relation of $\mathbf{B}$. We similarly speak of a single relation or a set of relations being *compatible* with an algebra. For a relational structure $\mathbf{B}$, we define $\mathbb{A}(\mathbf{B})$ to be the algebra with universe B and whose operations are the polymorphisms of $\mathbf{B}$.

We will make use of the following two facts. The first was established in previous work, and shows the relevance of the algebra of a structure to the problem framework at hand. The second shows the relevance of the variety of the algebra of a structure thereto.

Proposition 4 *(follows from Dalmau and Jeavons, 2003, Proof of Lemma 9) Suppose that $\mathbf{B}$ and $\mathbf{B}'$ are relational structures with the same universe and such that $\mathbf{B}$ is compatible with $\mathbb{A}(\mathbf{B}')$. Then there exists an oracular pwm-reduction from $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ to $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B}')$.*

Proposition 5 *Suppose that $\mathbb{B}$ is a finite algebra, and that $\mathbf{A}$ is a finite structure which is compatible with an algebra in $\mathcal{V}(\mathbb{B})$. Then, there exists a relational structure $\mathbf{B}$ which is compatible with $\mathbb{B}$ such that there exists an oracular pwm-reduction from $\mathcal{C}_{\mathrm{CQ}}(\mathbf{A})$ to $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$.*

It is well-known that a finite algebra is in $\mathcal{V}(\mathbb{B})$ if and only if it is a homomorphic image of a subalgebra of a finite power of $\mathbb{B}$. Proposition 5 thus follows immediately from the three following lemmas.

2. We remark that, strictly speaking, transitivity of oracular pwm-reducibility is not needed to derive the main result of the paper. Our main result shows that for certain relational structures $\mathbf{B}$, the prediction problem $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ is not polynomially predictable with membership queries unless $\mathcal{C}_{\mathrm{PF}}$ is as well. To establish this, it suffices to give a sequence of pwm-reductions from $\mathcal{C}_{\mathrm{PF}}$ to $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$ (which is what we do) and then invoke Proposition 2.

Lemma 6 *Suppose that $\mathbb{B}$ is a finite algebra and that $\mathbf{A}$ is a finite structure which is compatible with a finite power $\mathbb{A} = \mathbb{B}^n$ of $\mathbb{B}$. Then there exists a relational structure $\mathbf{B}$ compatible with $\mathbb{B}$ such that there exists an oracular pwm-reduction from $\mathcal{C}_{\mathrm{CQ}}(\mathbf{A})$ to $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$.*

Proof Let $\mathbf{A}$ be a structure on signature $\sigma_{\mathbf{A}}$ which is compatible with $\mathbb{A}$. Define $\sigma_{\mathbf{B}}$ to be the signature having the same symbols as $\sigma_{\mathbf{A}}$, but where the arity of a symbol $R \in \sigma_{\mathbf{B}}$ is nk, where k is the arity of R in $\sigma_{\mathbf{A}}$. Define $\mathbf{B}$ so that a relation $R^{\mathbf{B}}$ contains a tuple $(b_1^1, \ldots, b_1^n, \ldots, b_k^1, \ldots, b_k^n)$ if and only if $R^{\mathbf{A}}$ contains $((b_1^1, \ldots, b_1^n), \ldots, (b_k^1, \ldots, b_k^n))$.

The reduction (f, g, H) is as follows. For a conjunctive query $\phi_{\mathbf{A}}$ on $\sigma_{\mathbf{A}}$, the function g is defined so that $g(s, m, \phi_{\mathbf{A}})$ is equal to $\phi_{\mathbf{B}}$, where $\phi_{\mathbf{B}}$ is derived from $\phi_{\mathbf{A}}$ by replacing each variable v by a tuple $(v^1, \ldots, v^n)$ of variables. The mapping f is defined so that, when h is an assignment from V to $A = B^n$, $f(s, m, h)$ is the map $h' : \{v^1, \ldots, v^n \mid v \in V\} \to B$ such that the following condition holds: for each $v \in V$, it holds that $h(v) = (h'(v^1), \ldots, h'(v^n))$. The algorithm $H(s, m, h' : \{v^1, \ldots, v^n \mid v \in V\} \to B)$ calculates the mapping $h : V \to A$ defined according to the just-stated condition, submits h to its oracle, and outputs the result. This reduction is correct, as for a pair of assignments h, h' satisfying the condition, it holds that h satisfies $\phi_{\mathbf{A}}$ on $\mathbf{A}$ if and only if h' satisfies $\phi_{\mathbf{B}}$ on $\mathbf{B}$. ■

Lemma 7 *Suppose that $\mathbb{B}$ is a finite algebra and that $\mathbf{A}$ is a finite structure which is compatible with a subalgebra $\mathbb{A}$ of $\mathbb{B}$. Then there exists a relational structure $\mathbf{B}$ compatible with $\mathbb{B}$ such that there exists an oracular pwm-reduction from $\mathcal{C}_{\mathrm{CQ}}(\mathbf{A})$ to $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$.*

Proof Suppose that $\mathbf{A}$ is a structure on signature $\sigma_{\mathbf{A}}$ compatible with $\mathbb{A}$. Define $\sigma_{\mathbf{B}}$ to be a signature equal to $\sigma_{\mathbf{A}}$ but expanded by a relation symbol U of arity 1. Let $\mathbf{B}$ be the structure over $\sigma_{\mathbf{B}}$ with universe B where $R^{\mathbf{B}} = R^{\mathbf{A}}$ for each $R \in \sigma_{\mathbf{A}}$ and where $U^{\mathbf{B}} = A$.

The reduction (f, g, H) is as follows. For a conjunctive query $\phi_{\mathbf{A}}$ on $\sigma_{\mathbf{A}}$, define $g(s, n, \phi_{\mathbf{A}})$ to be the formula $\phi_{\mathbf{B}}$ which is obtained from $\phi_{\mathbf{A}}(V)$ by replacing each predicate application $R(v_1, \ldots, v_k)$ by $R(v_1, \ldots, v_k) \wedge U(v_1) \wedge \cdots \wedge U(v_k)$ to obtain $\psi(V)$, and then defining $\phi_{\mathbf{B}} = \psi(V) \wedge \bigwedge_{v \in V} U(v)$. Essentially, $\phi_{\mathbf{B}}$ is obtained from $\phi_{\mathbf{A}}$ by restricting all free and used variables to take on values in $U^{\mathbf{B}} = A$. It is straightforward to verify that $\phi_{\mathbf{A}}$ and $\phi_{\mathbf{B}}$ have the same solutions (with respect to the structures $\mathbf{A}$ and $\mathbf{B}$, respectively). Hence, f may be defined by $f(s, n, h) = h$, and $H(s, n, h')$ may be defined as the algorithm that passes h' to its oracle and outputs the result. ■

A *congruence* of an algebra $\mathbb{A} = (A; F)$ is an equivalence relation on A that is compatible with $\mathbb{A}$. Suppose that θ is a congruence of $\mathbb{A}$. We use a^θ to denote the equivalence class of θ containing $a \in A$. For each operation $f \in F$, the operation f^θ defined by $f^\theta(a_1^\theta, \ldots, a_k^\theta) = (f(a_1, \ldots, a_k))^\theta$ is well-defined. An algebra is a *homomorphic image* of $\mathbb{A}$ if it is isomorphic to an algebra of the form $(A^\theta; F^\theta)$ where $A^\theta = \{a^\theta \mid a \in A\}$ and $F^\theta = \{f^\theta \mid f \in F\}$.

Lemma 8 *Suppose that $\mathbb{B}$ is a finite algebra and that $\mathbf{A}$ is a finite structure which is compatible with a homomorphic image $\mathbb{A}$ of $\mathbb{B}$. Then there exists a relational structure $\mathbf{B}$ compatible with $\mathbb{B}$ such that there exists an oracular pwm-reduction from $\mathcal{C}_{\mathrm{CQ}}(\mathbf{A})$ to $\mathcal{C}_{\mathrm{CQ}}(\mathbf{B})$.*

Proof We assume that $\mathbb{A}$ is equal to (A^θ, F^θ) where θ is a congruence of $\mathbb{B}$. Let $\mathbf{A}$ be a structure over signature $\sigma_{\mathbf{A}}$ which is compatible with $\mathbb{A}$. Define $\mathbf{B}$ to be the structure over signature $\sigma_{\mathbf{A}}$ defined by $R^{\mathbf{B}} = \{(b_1, \ldots, b_k) \mid (b_1^\theta, \ldots, b_k^\theta) \in R^{\mathbf{A}}\}$. For any conjunctive query $\phi(V)$ over $\sigma_{\mathbf{A}}$, it is straightforward to verify that an assignment $h : V \to A$ satisfies ϕ on $\mathbf{A}$ if and only if one (equivalently, every) assignment $h' : V \to B$ with $(h'(v))^\theta = h(v)$ satisfies ϕ on $\mathbf{B}$.

The following is thus a reduction. Define $g(s, n, \phi) = \phi$, define $f(s, n, h)$ to be an assignment h' defined as above, and define $H(s, n, h')$ to be the algorithm that passes the assignment h defined by $h(v) = (h'(v))^\theta$ to its oracle and returns the result. ■

A *lattice* is an algebra $(L; \wedge, \vee)$ where each of the operations $\wedge$ and $\vee$ is binary, idempotent, commutative, and associative; and, the absorption law $a \wedge (a \vee b) = a \vee (a \wedge b) = a$ holds. A lattice naturally induces a partial order $\leq$ defined by $a \leq b$ if and only if $a \wedge b = a$. A lattice is *distributive* if it satisfies the identity $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$. We say that a lattice is *non-trivial* if its universe has size strictly greater than 1. By a *lattice term*, we refer to a term built from variables and the two operation symbols $\wedge$ and $\vee$. The congruences of an algebra naturally form a lattice. An algebra $\mathbb{A}$ is *congruence modular* if its lattice of congruences satisfies the modular law: $x \leq y \to x \vee (y \wedge z) = y \wedge (x \vee z)$. A class of algebras is *congruence modular* if each algebra therein is congruence modular.

Varieties whose members are all congruence modular have special properties and have been extensively studied in the universal algebra literature. For example, there is a useful notion of a commutator for such varieties and it has been used to establish strong structural results (Freese and McKenzie, 1987). Congruence modular varieties can be characterized in terms of the existence of special terms, called *Day terms* or *Gumm terms*, that satisfy particular equations (see Freese and Valeriote, 2009, Section 8). In the special case where the variety is of the form $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ for some finite relational structure $\mathbf{B}$, Barto (2018) has established a deep result that shows that this variety will be congruence modular if and only if $\mathbf{B}$ has a special polymorphism called an *edge term*.

Definition 9 *Let A be a nonempty set and $k > 1$. A* k-edge operation *on A is a $k+1$-ary operation $t(x_1, x_2, \ldots, x_{k+1})$ that satisfies the following equations:*

$$\begin{aligned}
t(y, y, x, x, x, \ldots, x) &= x \\
t(y, x, y, x, x, \ldots, x) &= x \\
t(x, x, x, y, x, \ldots, x) &= x \\
t(x, x, x, x, y, \ldots, x) &= x \\
&\vdots \\
t(x, x, x, x, x, \ldots, y) &= x.
\end{aligned}$$

A structure $\mathbf{B}$ has an edge term polymorphism *if for some $k > 1$ it has a polymorphism that is a k-edge operation.*

Example 4 *1. If $\mathbb{G} = (G, \cdot, {}^{-1}, e)$ is a group then the term operation $t(x_1, x_2, x_3) = x_2 \cdot x_1^{-1} \cdot x_3$ is a 2-edge operation on G.*

2. *If* $\mathbf{L} = (L; \wedge, \vee)$ *is a lattice, then the term operation*

$$m(x_1, x_2, x_3, x_4) = (x_2 \wedge x_3) \vee (x_2 \wedge x_4) \vee (x_3 \wedge x_4)$$

is a 3-edge operation on L.

The notion of an edge term was introduced and investigated in Berman et al. (2010). It is shown in that paper that for a finite algebra $\mathbb{A}$, having a k-edge term for some $k > 1$ is equivalent to the *few subpowers property* for $\mathbb{A}$: there is some polynomial $p(n)$ such that for each $n > 0$, the number of subalgebras of $\mathbb{A}^n$ is less than $2^{p(n)}$. In general, the number of subalgebras of $\mathbb{A}^n$ can grow doubly exponentially in n, so this is a special property of an algebra. It is also shown that having a k-edge term for some $k > 1$ is equivalent to the subalgebras of finite powers of $\mathbb{A}$ having "small generating sets", which means that there is some polynomial $g(n)$ such that for $n > 0$, each subalgebra of $\mathbb{A}^n$ has a generating set of size at most $g(n)$.

In the companion paper (Idziak et al., 2010) it is shown that if a finite relational structure $\mathbf{B}$ has an edge term polymorphism then the prediction problem $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ is polynomially exactly learnable with improper equivalence queries, using a concept representation that is polynomially evaluable. The key property of $\mathbf{B}$ used in the proof of this fact is that the solution space of a conjunctive query over $\mathbf{B}$ is a subalgebra of a power of the algebra $\mathbb{A}(\mathbf{B})$ and so has a small generating set. This allows for a nice compact representation of each concept that is represented by a conjunctive query over $\mathbf{B}$.

A weaker example of a term condition, along the lines of having an edge term, is that of having a *Taylor term* or *Taylor operation*. A *Taylor operation* on a set A is an n-ary function $t : A^n \to A$ that is *idempotent* in that it satisfies the equation $t(x, x, \ldots, x) = x$ and, for each $1 \leq i \leq n$, an equation of the form $t(v_1, v_2, \ldots, v_n) = t(w_1, w_2, \ldots, w_n)$, where the v_j and w_j are variables from the set $\{x, y\}$ and $v_i \neq w_i$. A Taylor term of an algebra $\mathbb{A}$ is a term operation of $\mathbb{A}$ that is a Taylor operation. It can be readily verified that any k-edge operation on a set is also a Taylor operation on it. In Taylor (1977) it is shown that, by some measure, the condition of having a Taylor term is the weakest sort of term condition of this type that an algebra (or variety) can satisfy.

A *Taylor polymorphism* of a structure $\mathbf{B}$ is a polymorphism of $\mathbf{B}$ that is also a Taylor operation. The only polymorphisms of the structure $\mathbf{B}_{\text{3SAT}}$ from Example 1 are the projection maps and so $\mathbf{B}_{\text{3SAT}}$ does not have a Taylor polymorphism (Barto et al., 2017). On the other hand, the structure $\mathbf{B}_{\text{HORN-3SAT}}$ from Example 2 has $x \wedge y$ as a Taylor polymorphism and $\mathbf{V}_{\mathbb{F}}$ from Example 3 has $x - y + z$ (this polymorphism ensures that $\mathcal{V}(\mathbb{A}(\mathbf{V}_{\mathbb{F}}))$ is congruence modular).

Taylor operations have played a central role in the investigation of the constraint satisfaction problem over a finite relational structure or finite algebra. The ultimate resolution of the Feder-Vardi Dichotomy Conjecture (Feder and Vardi, 1999) can be expressed in terms of Taylor polymorphisms, but also in terms of related conditions that are equivalent for finite structures and algebras. In Maróti and McKenzie (2008) it is shown that a finite algebra $\mathbb{A}$ will have a Taylor term if and only if it has a term that is a weak near-unanimity operation. A *weak near-unanimity operation* on a set A is an operation $w(x_1, x_2, \ldots, x_k)$ for some $k > 1$ that satisfies the equations $w(x, x, \ldots, x) = x$ and

$$w(y, x, \ldots, x) = w(x, y, \ldots, x) = \cdots = w(x, x, \ldots, x, y).$$

It is not hard to see that any weak near-unanimity operation is a Taylor operation but quite challenging to show that if a finite algebra has a Taylor term, then it also has a weak near-unanimity term operation. A similar result holds for finite structures: $\mathbf{B}$ will have a Taylor polymorphism if and only if it has a weak near-unanimity polymorphism.

Bulatov (2017) and Zhuk (2017) have shown that for a finite relational structure $\mathbf{B}$ such that for each $b \in B$, the unary relation $\{b\}$ is a relation of $\mathbf{B}$, $\mathsf{CSP}(\mathbf{B})$ is polynomial-time decidable if $\mathbf{B}$ has a Taylor polymorphism (or equivalently, a weak near-unanimity polymorphism). It has been known for some time (Jeavons, 1998) that in the absence of a Taylor polymorphism, this problem is NP-complete and so combining these results (and some other basic facts) leads to the following dichotomy: for a finite relational structure $\mathbf{B}$, $\mathsf{CSP}(\mathbf{B})$ is polynomial-time decidable or is NP-complete.

3.3. Propositional Formulas

By log, we indicate the logarithm base 2. When θ is a formula or a term, we define $\text{depth}(\theta)$ to be the maximum length of a path from the root of θ (viewed as a tree) to a leaf; we define $\text{leafsize}(\theta)$ to be the number of leaves of θ (again, viewed as a tree). Define $\mathcal{C}_{\text{log-MPF}}$ to be the subset of $\mathcal{C}_{\text{PF}}$ that contains a pair $(\theta, h) \in \mathcal{C}_{\text{PF}}$ when θ is *monotone* (that is, does not contain any instance of negation ($\neg$)) and when $\text{depth}(\theta) \leq 6 + 6\log(\text{leafsize}(\theta))$.

The following proposition is readily derivable using Spira's lemma and known techniques for representing a propositional formula as a monotone propositional formula.

Proposition 10 *There exists an oracular pwm-reduction from* $\mathcal{C}_{\text{PF}}$ *to* $\mathcal{C}_{\text{log-MPF}}$.

Let us prove this proposition, in two steps. We first observe a reduction to the following intermediate problem. Define $\mathcal{C}_{\text{log-PF}}$ to be the subset of $\mathcal{C}_{\text{PF}}$ that contains a pair $(\theta, h) \in \mathcal{C}_{\text{PF}}$ when θ has $\text{depth}(\theta) \leq 1 + 4\log(\text{leafsize}(\theta))$.

Lemma 11 *(derivable from Spira's Lemma; see the presentation/discussion in Bonet and Buss, 1994)*[3] *Let* ϕ *be a propositional formula; then there exists an equivalent propositional formula* ϕ' *such that* $\text{depth}(\phi') \leq 1 + 4\log(\text{leafsize}(\phi))$ *and such that* $\text{leafsize}(\phi) \leq \text{leafsize}(\phi') \leq \text{leafsize}(\phi)^3$. *It thus holds that* $\text{depth}(\phi') \leq 1 + 4\log(\text{leafsize}(\phi'))$.

The following proposition is readily derived from Lemma 11.

Proposition 12 *There exists an oracular pwm-reduction from* $\mathcal{C}_{\text{PF}}$ *to* $\mathcal{C}_{\text{log-PF}}$.

It then remains to give a reduction from $\mathcal{C}_{\text{log-PF}}$ to $\mathcal{C}_{\text{log-MPF}}$, which is what we now do.

Proposition 13 *There exists an oracular pwm-reduction from* $\mathcal{C}_{\text{log-PF}}$ *to* $\mathcal{C}_{\text{log-MPF}}$.

3. We remark that to guarantee $\text{leafsize}(\phi) \leq \text{leafsize}(\phi')$, one can repeatedly apply the transformation described in Bonet and Buss (1994) but leaving in the constants (0 and 1) that are introduced. At the end, one can then replace the constants 0 and 1 by $(v \wedge \neg v)$ and $(v \vee \neg v)$, respectively, where v is some variable.

Proof The proof proceeds along the lines of that of Dalmau (1999, Lemma 33). We describe the parts of the reduction. When θ is a propositional formula on variables $v_1, \ldots, v_m$, the mapping g is defined so that $\psi = g(s, n, \theta)$ is logically equivalent to

$$(v_1 \vee v_1') \wedge \cdots \wedge (v_m \vee v_m') \wedge [(v_1 \wedge v_1') \vee \cdots \vee (v_m \wedge v_m') \vee \theta].$$

Note that this expression is written using a conjunction of high fan-in and a disjunction of high fan-in. In each case, each can be rewritten as a formula where conjunction and disjunction have fan-in 2; then, the high fan-in conjunction and high fan-in disjunction are replaced with formulas having depth at most $1 + \log(m + 1)$. By rewriting in this fashion, we obtain ψ. As the depth of each disjunction $(v_i \vee v_i')$ has depth 1, we can naively bound the depth of ψ by $2 * (1 + \log(\text{leafsize}(\psi))) + 1 + \text{depth}(\theta)$ which is upper bounded by $6 + 6\log(\text{leafsize}(\psi))$. The function induced by the formula $g(s, n, \theta)$ evaluates to θ if for each i it holds that $v_i \neq v_i'$; to 0 if there exists an i such that $v_i = v_i'$; and, to 1 otherwise. For each assignment h from a set of variables $\{v_1, \ldots, v_m\}$ to $\{0, 1\}$, the mapping f is defined as $f(s, n, h) = h'$ where h' is the unique extension of h such that $h'(v_i') = \neg v_i$ for each i. The algorithm H, on input $(s, n, h' : \{v_1, v_1', \ldots, v_m, v_m'\} \to \{0, 1\})$, outputs the result of a query call on the restriction of h' to $\{v_1, \ldots, v_m\}$, if for each i it holds that $h'(v_i) \neq h'(v_i')$; 0 if there exists an i such that $h'(v_i) = h'(v_i')$; and, 1 otherwise. ■

4. Main Theorems

We are now in a position to present the main theorems and to explain how they will follow from the results in the following sections.

Theorem 14 *Let* $\mathbf{B}$ *be a finite relational structure.*

- *If the variety* $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ *is congruence modular, then the prediction problem* $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ *is polynomially exactly learnable with improper equivalence queries, using a concept representation that is polynomially evaluable.*
- *Otherwise, there is an oracular pwm-reduction from* $\mathcal{C}_{\text{PF}}$ *to* $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ *and so the prediction problem* $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ *is not polynomially predictable with membership queries unless* $\mathcal{C}_{\text{PF}}$ *is as well, and hence (by Theorem 1) not unless each of the Kearns-Valiant hypotheses fails.*

Let us remark that the following is known: each problem that is polynomially exactly learnable with improper equivalence queries under a polynomially evaluable concept representation is polynomially predictable with membership queries (see for example Angluin, 1988, Section 2.4).

Proof If the variety $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is congruence modular, then by Barto's theorem (Barto, 2018), it holds that this variety has *few subpowers* and that there is a k-edge polymorphism of $\mathbf{B}$; thus, the Idziak et al. result (Idziak et al., 2010, Corollary 5.6) applies. For more details, see the discussion after Definition 9 above. If this variety is not congruence modular, then Proposition 10, Theorem 18, Theorem 20, and Theorem 22 yield a sequence of

oracular pwm-reductions from the prediction problem $\mathcal{C}_{\text{PF}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{A})$, where $\mathbf{A}$ is a structure compatible with an algebra in the variety; an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{A})$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ exists by appeal to Propositions 5 and 4. Hence, $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ is not polynomially predictable with membership queries unless $\mathcal{C}_{\text{PF}}$ is as well, by Proposition 2. ■

The following theorem refines the understanding of the problems that are hard according to Theorem 14.

Theorem 15 *Let* $\mathbf{B}$ *be a finite relational structure.*

- *If* $\mathbf{B}$ *has a Taylor polymorphism, then there is an oracular pwm-reduction from* $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ *to* $\mathcal{C}_{\text{CIRC}}$.
- *Otherwise, there is an oracular pwm-reduction from* $\mathcal{C}_{\exists\text{CIRC}}$ *to* $\mathcal{C}_{\text{CQ}}(\mathbf{B})$.

We note that if $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is congruence modular, then $\mathbf{B}$ will have a Taylor polymorphism and so the positive result of Theorem 15 applies to $\mathcal{C}_{\text{CQ}}(\mathbf{B})$; however, the positive result of Theorem 14 is stronger than that of Theorem 15, since $\mathcal{C}_{\text{CIRC}}$ is not known to be learnable in the sense of the first item of Theorem 14. Hence, Theorem 15 is in essence a theorem concerning the problems that are hard according to Theorem 14.

We believe that it is natural to expect that Theorem 15 gives a true dichotomy in that the problem $\mathcal{C}_{\exists\text{CIRC}}$ is strictly harder than the problem $\mathcal{C}_{\text{CIRC}}$. A heuristic reason for believing this is that the computational decision problem of deciding if a given pair (T, f) belongs to $\mathcal{C}_{\text{CIRC}}$ is polynomial-time computable (instantiate the input variables according to f, and then evaluate the circuit), whereas the computational decision problem of deciding if a given pair $((T, U), f)$ belongs to $\mathcal{C}_{\exists\text{CIRC}}$ is NP-complete (in the case that $U = \emptyset$, this problem amounts to circuit satisfiability).

Before starting the proof of Theorem 15, recall that for a relational structure $\mathbf{B}$, $\mathsf{CSP}(\mathbf{B})$ is the computational problem of deciding, given a conjunctive query, whether or not its solution space over $\mathbf{B}$ is nonempty. Equivalently, $\mathsf{CSP}(\mathbf{B})$ is the problem of deciding, given a conjunctive query ψ whose variables are all existentially quantified, whether or not $\mathbf{B} \models \psi$, that is, whether or not ψ evaluates to true on $\mathbf{B}$. Define $\mathbf{B}^*$ to be the structure derived from $\mathbf{B}$ by adding, for each element $b \in B$, a relation $U_b^{\mathbf{B}^*} = \{b\}$.

Proof If $\mathbf{B}$ has a Taylor polymorphism, we argue as follows. The structure $\mathbf{B}^*$ also has a Taylor polymorphism, since a Taylor operation is idempotent. We obtain from Bulatov (2017) or Zhuk (2017) that $\mathsf{CSP}(\mathbf{B}^*)$ is polynomial-time decidable; hence, there is a polynomial-time computable function that, given a conjunctive query $\phi(V)$, outputs a Boolean circuit T such that for each assignment $f : V \to B$, it holds that $\mathbf{B}, f \models \phi$ if and only if f satisfies T. The existence of the claimed oracular pwm-reduction follows immediately.

If $\mathbf{B}$ does not have a Taylor polymorphism then by Theorem 23 there will be an oracular pwm-reduction from $\mathcal{C}_{\exists\text{CIRC}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B})$. ■

From Theorems 14 and 15, we obtain the following corollary—a trichotomy theorem.

Corollary 16 *Let* $\mathbf{B}$ *be a finite relational structure.*

- *If the variety $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is congruence modular, then the prediction problem $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ is polynomially exactly learnable with improper equivalence queries, using a concept representation that is polynomially evaluable.*
- *If the variety $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is not congruence modular but $\mathbf{B}$ has a Taylor polymorphism, then there is an oracular pwm-reduction from $\mathcal{C}_{\text{PF}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B})$, as well as an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ to $\mathcal{C}_{\text{CIRC}}$.*
- *Otherwise, there is an oracular pwm-reduction from $\mathcal{C}_{\exists\text{CIRC}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B})$.*

We can apply this result to the examples presented in the introduction to determine the complexity of learning the solution spaces of conjunctive queries over them. Since the structure $\mathbf{B}_{\text{3SAT}}$ has no non-trivial polymorphisms, then it has no Taylor polymorphism and so there is an oracular pwm-reduction from $\mathcal{C}_{\exists\text{CIRC}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B}_{\text{3SAT}})$. The structure $\mathbf{B}_{\text{HORN}-\text{3SAT}}$ has a Taylor polymorphism (the operation $x \wedge y$) but $\mathcal{V}(\mathbb{A}(\mathbf{B}_{\text{HORN}-\text{3SAT}}))$ is not congruence modular since this variety is essentially the variety of semilattices. So, there is an oracular pwm-reduction from $\mathcal{C}_{\text{PF}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B}_{\text{HORN}-\text{3SAT}})$, as well as an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{B}_{\text{HORN}-\text{3SAT}})$ to $\mathcal{C}_{\text{CIRC}}$. Since $\mathcal{V}(\mathbb{A}(\mathbf{V}_{\mathbb{F}}))$ is congruence modular for any finite field $\mathbb{F}$, then $\mathcal{C}_{\text{CQ}}(\mathbf{V}_{\mathbb{F}})$ is polynomially exactly learnable with improper equivalence queries, using a concept representation that is polynomially evaluable.

It is worth comparing the above trichotomy theorem with the CSP dichotomy theorem (Bulatov, 2017; Zhuk, 2017). The comparison works well up to a point, namely, if $\mathbf{B}$ falls into either of the first two cases of Corollary 16 then it will have a Taylor polymorphism, and so $\mathsf{CSP}(\mathbf{B})$ will be polynomial-time decidable. On the other hand, for any relational structure $\mathbf{B}$ that has a constant function as a polymorphism, $\mathsf{CSP}(\mathbf{B})$ is trivially polynomial-time decidable, even if $\mathbf{B}$ fails to have a Taylor polymorphism. So there are structures $\mathbf{B}$ such that $\mathsf{CSP}(\mathbf{B})$ is polynomial-time decidable while $\mathcal{C}_{\text{CQ}}(\mathbf{B})$ admits an oracular pwm-reduction from $\mathcal{C}_{\exists\text{CIRC}}$. It is the case that $\mathbf{B}$ will fall into the third case of Corollary 16 if and only if $\mathsf{CSP}(\mathbf{B}^*)$ is NP-complete.

Let us now present a theorem that addresses the effectivity of the dichotomy conditions of Theorems 14 and 15. That is, we address the complexity of deciding, given a relational structure $\mathbf{B}$, whether $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is congruence modular, and whether $\mathbf{B}$ has a Taylor polymorphism.

Theorem 17 *Let $\mathbf{B}$ be a finite relational structure.*

1. *There is an EXPTIME algorithm that decides if the variety $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is congruence modular.*
2. *The problem of deciding if $\mathbf{B}$ has a Taylor polymorphism is in NP.*

Proof Part 1 follows from the characterization of congruence modular varieties given by Day or Gumm (consult Section 8 of Freese and Valeriote, 2009). Using Gumm's characterization, to determine if $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is congruence modular one need only search amongst the ternary functions on B for a finite sequence of polymorphisms of $\mathbf{B}$ that satisfy a specified set of equations. This search can be carried out by an algorithm whose running time is bounded by an exponential function in the size of $\mathbf{B}$. A full discussion of the relevant details can be found in Section 8 of Freese and Valeriote (2009).

For Part 2, the result follows from a result of Siggers (2010) that shows that a finite structure will have a Taylor polymorphism if and only if it has one of arity 6. Thus, to certify that $\mathbf{B}$ has a Taylor polymorphism, we need only be able to quickly check that a given 6-ary operation on B preserves the relations of $\mathbf{B}$ and is a Taylor operation. ■

Kazda (2014) has shown that the decision problem addressed in Part 1 of Theorem 17 actually lies in the class NP. His algorithm is based on a "local" characterization of congruence modularity and a clever encoding of the problem into an instance of the constraint satisfaction problem over the structure. We note that Siggers' result used in the proof of this theorem has been refined in Kearnes et al. (2014) by reducing the arity of the term from 6 to 4.

5. Learning Lattice Terms

In this section, we prove the hardness of a class of prediction problems that deal with lattices, which will serve as a useful intermediate result on the way to our main hardness result; roughly speaking, the problems studied here involve learning the function induced by an unknown term. When $r \geq 1$ and $\mathcal{L}$ is a finite set of finite lattices, define $\mathcal{C}^r_{\text{TERM}}(\mathcal{L})$ to be the prediction problem containing a pair $(t, (\mathbf{L}, h, c))$ when the following conditions hold: t is a lattice term with $\text{depth}(t) \leq r + r\log(\text{leafsize}(t))$; $\mathbf{L} = (L; \wedge, \vee)$ is a lattice in $\mathcal{L}$; h is an assignment mapping each variable of t to an element of L; c is an element of L; and, $\mathbf{L}, h \models (t \geq c)$, that is, under the assignment h, the term t evaluates to a value greater than or equal to c in $\mathbf{L}$.

Theorem 18 *Suppose that $\mathcal{L}$ is a finite set of finite lattices containing a non-trivial lattice. Then, there exists $r > 1$ such that there exists an oracular pwm-reduction from the prediction problem $\mathcal{C}_{\text{log-MPF}}$ to the prediction problem $\mathcal{C}^r_{\text{TERM}}(\mathcal{L})$.*

It is helpful to first establish this theorem in the case of distributive lattices; the proof uses the fact that each finite distributive lattice can be embedded into a finite power of the two-element lattice.

Lemma 19 *Theorem 18 holds in the case that $\mathcal{L}$ contains only distributive lattices.*

Proof Let $\mathbf{L}_{\{0,1\}}$ denote the two-element lattice with bottom element 0 and top element 1. We first show that there exists a reduction from $\mathcal{C} = \mathcal{C}_{\text{log-MPF}}$ to $\mathcal{C}' = \mathcal{C}^6_{\text{TERM}}(\{\mathbf{L}_{\{0,1\}}\})$. The reduction (f, g, H) is defined as follows. The functions g and f are defined by $g(s, n, \theta) = \theta$ and $f(s, n, h) = (\mathbf{L}_{\{0,1\}}, h, 1)$. The algorithm H, on input $(s, n, (\mathbf{L}_{\{0,1\}}, h, b))$, does the following: if $b = 0$, it outputs 1, and if $b = 1$, it submits h as an oracle query and outputs the result. This reduction is correct, as for each monotone propositional formula θ and assignment h to the variables of θ, it always holds that $(\mathbf{L}_{\{0,1\}}, h, 0) \in \kappa_{\mathcal{C}'}(\theta)$; and, it holds that $(\mathbf{L}_{\{0,1\}}, h, 1) \in \kappa_{\mathcal{C}'}(\theta)$ if and only if h satisfies θ.

Now, suppose that $\mathbf{L}$ is a set of distributive lattices containing a non-trivial lattice. We exhibit a reduction from $\mathcal{C} = \mathcal{C}^6_{\text{TERM}}(\{\mathbf{L}_{\{0,1\}}\})$ to $\mathcal{C}' = \mathcal{C}^6_{\text{TERM}}(\mathcal{L})$, which suffices to give the lemma. It is well-known and straightforward to verify that each finite distributive lattice embeds into a finite power of the lattice $\mathbf{L}_{\{0,1\}}$. Let $D \geq 1$ be a sufficiently large

constant so that each $\mathbf{L} \in \mathcal{L}$ has an embedding into $\mathbf{L}_{\{0,1\}}^D$. For each $\mathbf{L} \in \mathcal{L}$, fix $e^{\mathbf{L}}$ to be such an embedding, and let $e_i^{\mathbf{L}}$ be the function that returns the ith coordinate of $e^{\mathbf{L}}$ (for $i = 1, \ldots, D$). Fix $\mathbf{L}^+ \in \mathcal{L}$ to be a non-trivial lattice, and let $\top$ and $\bot$ denote the top and bottom elements of $\mathbf{L}^+$, respectively. Let $e^+ : \{0,1\} \to \{\bot, \top\}$ be the mapping where $e^+(0) = \bot$ and $e^+(1) = \top$. The reduction is (f, g, H), defined as follows. The functions are defined by $g(s, n, t) = t$ and $f(s, n, (\mathbf{L}_{\{0,1\}}, h, c)) = (\mathbf{L}^+, e^+(h), e^+(c))$. The algorithm H, on input $(s, n, (\mathbf{L}, h, c))$, makes D oracle queries: for each $i = 1, \ldots, D$, it submits the query $(\mathbf{L}_{\{0,1\}}, e_i^{\mathbf{L}}(h), e_i^{\mathbf{L}}(c))$ and returns 1 if and only if all oracle calls were answered as 1. The correctness of H follows from the fact that, for any lattice term t, and any triple $(\mathbf{L}, h, c)$, it holds that $\mathbf{L}, h \models t \geq c$ if and only if $\mathbf{L}_{\{0,1\}}^D, e^{\mathbf{L}}(h) \models t \geq e^{\mathbf{L}}(c)$, which in turn is true if and only if for all $i = 1, \ldots, D$, it holds that $\mathbf{L}_{\{0,1\}}, e_i^{\mathbf{L}}(h) \models t \geq e_i^{\mathbf{L}}(c)$. ■

Proof (Theorem 18) By Lemma 19, it suffices to prove the theorem for each such set $\mathbf{L}$ that contains a non-distributive lattice. We prove this by induction on the maximum cardinality of a non-distributive lattice in $\mathbf{L}$. Define $s(x, y, z)$ to be the term $(x \wedge y) \vee (x \wedge z)$, and define $s'(x, y, z)$ to be the term $x \wedge (y \vee z)$. In the scope of this proof, when d and d' are elements of a lattice $\mathbf{L}$ with $d \leq d'$, we use $[d, d']$ to denote the set $\{c \mid d \leq c \leq d'\}$, and we use $\mathbf{L}[d, d']$ to denote the sublattice of $\mathbf{L}$ with universe $[d, d']$. Note that for any elements a, b, c of a lattice $\mathbf{L}$, it always holds that $s(a, b, c) \leq s'(a, b, c)$.

Define $\mathcal{L}^-$ as the set $\{\mathbf{L}[s(a, b, c), s'(a, b, c)] \mid a, b, c \in \mathbf{L} \text{ and } \mathbf{L} \in \mathcal{L}\}$. We will prove that, for any value $r > 1$, it holds that $\mathcal{C}_{\text{TERM}}^r(\mathcal{L}^-)$ has an oracular pwm-reduction to $\mathcal{C}_{\text{TERM}}^{r+4}(\mathcal{L})$. Let us argue that this suffices. Consider a lattice $\mathbf{L} \in \mathcal{L}$. If the lattice $\mathbf{L}$ is distributive, then for any elements $a, b, c \in \mathbf{L}$, it holds that $s(a, b, c) = s'(a, b, c)$ and thus that $\mathbf{L}[s(a, b, c), s'(a, b, c)]$ is a one-element lattice. If the lattice $\mathbf{L}$ is non-distributive, then for any elements $a, b, c \in \mathbf{L}$, if $s'(a, b, c)$ is the top element of $\mathbf{L}$, then a must be equal to the top element of $\mathbf{L}$, which in turn implies that $s(a, b, c) = s'(a, b, c)$. Hence (when $\mathbf{L}$ is non-distributive) each lattice of the form $\mathbf{L}[s(a, b, c), s'(a, b, c)]$ has cardinality strictly smaller than that of $\mathbf{L}$. Now consider two cases. If $\mathcal{L}^-$ contains a non-distributive lattice, then by the argumentation just given and by induction, there exists a value r such that $\mathcal{C}_{\text{TERM}}^r(\mathcal{L}^-)$ admits an oracular pwm-reduction from $\mathcal{C}_{\text{log-MPF}}$, and hence an oracular pwm-reduction from $\mathcal{C}_{\text{TERM}}^r(\mathcal{L}^-)$ to $\mathcal{C}_{\text{TERM}}^{r+4}(\mathcal{L})$ yields the theorem. If $\mathcal{L}^-$ contains only distributive lattices, we claim that $\mathcal{L}^-$ contains a non-trivial lattice, which completes the argument by appeal to Lemma 19. This claim holds because there exists (by assumption) a non-distributive lattice $\mathbf{L} \in \mathcal{L}$; by definition, there exist elements $a, b, c \in \mathbf{L}$ such that $s(a, b, c) \neq s'(a, b, c)$. Hence, the lattice $\mathbf{L}[s(a, b, c), s'(a, b, c)]$ is non-trivial.

It remains to give an oracular pwm-reduction (f, g, H) from $\mathcal{C}_{\text{TERM}}^r(\mathcal{L}^-)$ to $\mathcal{C}_{\text{TERM}}^{r+4}(\mathcal{L})$. First, define $g(r, n, t^-(x_1, \ldots, x_n))$ to be the term $t(z_1, z_2, z_3, x_1, \ldots, x_n)$ defined to be $t^-(x_1^*, \ldots, x_n^*)$, where each x_i^* is defined as the term $(x_i \vee s(z_1, z_2, z_3)) \wedge s'(z_1, z_2, z_3)$. Observe that $\text{depth}(t) \leq \text{depth}(t^-) + 4$. Define $f(r, n, (\mathbf{L}^-, h^-, c^-))$ to be $(\mathbf{L}, h, c^-)$ where $\mathbf{L}$ is a lattice in $\mathbf{L}$ such that there exist $a, b, c \in \mathbf{L}$ with $\mathbf{L}^- = \mathbf{L}[s(a, b, c), s'(a, b, c)]$, and where h is the extension of h^- defined on $\{z_1, z_2, z_3, x_1, \ldots, x_n\}$ where $h(z_1) = a$, $h(z_2) = b$, and $h(z_3) = c$. This f satisfies the needed property, as $\mathbf{L}^-, h^- \models t^- \geq c^-$ holds if and only if $\mathbf{L}, h^- \models t^- \geq c^-$ holds; this latter condition is equivalent to $\mathbf{L}, h \models t \geq c^-$, as $h(x_i^*)$ is equal to $h^-(x_i)$ for each i. Define the algorithm H on $(r, n, (\mathbf{L}, h, d))$ to perform

the following. Let $\mathbf{L}^-$ be the lattice $\mathbf{L}[s(h(z_1), h(z_2), h(z_3)), s'(h(z_1), h(z_2), h(z_3))]$. Define h^- on $\{x_1, \ldots, x_n\}$ by $h^-(x_i) = (h(x_i) \vee s(h(z_1), h(z_2), h(z_3))) \wedge s'(h(z_1), h(z_2), h(z_3))$. Set D^- to be the set $\{d^- \in \mathbf{L}^- \mid d^- \geq d\}$. The algorithm H makes, for each $d^- \in D^-$, the oracle query $(\mathbf{L}^-, h^-, d^-)$, and returns 1 if and only if at least one of the oracle responses was 1. Let us discuss why this algorithm satisfies the desired property. It is readily verified that, when t and t^- are terms with $g(s, n, t^-(x_1, \ldots, x_n)) = t(z_1, z_2, z_3, x_1, \ldots, x_n)$ and $(\mathbf{L}, h, d)$ is a triple, that $\mathbf{L}, h \models t \geq d$ if and only if $\mathbf{L}, h \models t^-(x_1^*, \ldots, x_n^*) \geq d$ if and only if $\mathbf{L}, h^- \models t^-(x_1, \ldots, x_n) \geq d$. Since all values in the image of h^- are in $\mathbf{L}^-$, the last condition $\mathbf{L}, h^- \models t^-(x_1, \ldots, x_n) \geq d$ holds if and only if there exists $d^- \in D^-$ such that $\mathbf{L}^-, h^- \models t^-(x_1, \ldots, x_n) \geq d^-$. ■

6. Hardness From Non-Congruence Modularity

In this section, we make use of 2-sorted relational structures. We thus first give an introduction to these. A 2-*sorted signature* is a finite set of relation symbols, where each symbol has an associated arity which is a string over $\{1, 2\}$. Below, the only 2-sorted signature to be used is $\{R\}$, where the symbol R has arity 122. A 2-*sorted relational structure* over a 2-sorted signature σ consists of two finite sets B_1, B_2 called the *first* and *second* universe, respectively, and, for each relation symbol $S \in \sigma$, a relation $S^{\mathbf{B}}$ that is a subset of $B_{w_1} \times \cdots \times B_{w_k}$, where $w_1 \ldots w_k$ is the arity of S. A conjunctive query on a 2-sorted signature is defined similarly to a conjunctive query on a usual relational signature, but with the differences that each variable has an associated sort (1 or 2), equality of variables may only be written between variables of the same sort, and when $S(v_1, \ldots, v_k)$ is a predicate application, letting $s(v_i)$ denote the sort of v_i, it must be that $s(v_1) \ldots s(v_k)$ is equal to the arity of S.

We now turn to the proper content of this section. Let A be a set. When θ and θ' are binary relations on A, we use $\theta \circ \theta'$ to denote their relational product. We use $\text{Eq}(A)$ to denote the lattice of equivalence relations on A, and we use $0_A = \{(a, a) \mid a \in A\}$ and $1_A = A^2$ to denote the bottom and top elements of $\text{Eq}(A)$, respectively. We define a *pentagon* to be a finite relational structure $\mathbf{P}$ over the signature $\{\alpha, \beta, \gamma\}$ containing three binary relation symbols such that $\alpha^{\mathbf{P}}$, $\beta^{\mathbf{P}}$, and $\gamma^{\mathbf{P}}$ are equivalence relations on P, and the following conditions hold in $\text{Eq}(P)$: $\alpha^{\mathbf{P}} \leq \beta^{\mathbf{P}}$, $\beta^{\mathbf{P}} \wedge \gamma^{\mathbf{P}} = 0_P$, $\beta^{\mathbf{P}} \circ \gamma^{\mathbf{P}} = 1_P$, and $\alpha^{\mathbf{P}} \vee \gamma^{\mathbf{P}} = 1_P$. The universe P of a pentagon $\mathbf{P}$ can be naturally decomposed as a direct product $P = B \times C$ in such a way that $\beta^{\mathbf{P}}$ and $\gamma^{\mathbf{P}}$ are the kernels of the projections of P onto B and C, respectively. Then, via the equivalence relation $\alpha^{\mathbf{P}}$, each element $b \in B$ induces an equivalence relation $\alpha_b^{\mathbf{P}} = \{(c, c') \in C \times C \mid ((b, c), (b, c')) \in \alpha^{\mathbf{P}}\}$ on C. For each pentagon $\mathbf{P}$, we define $\mathbf{L}(\mathbf{P})$ to be the lattice which is the sublattice of $\text{Eq}(C)$ generated by the equivalence relations $\alpha_b^{\mathbf{P}}$ (over $b \in B$); we extend this operator $\mathbf{L}(\cdot)$ to sets of pentagons in the natural fashion.

To each pentagon $\mathbf{P}$, we associate a 2-sorted relational structure, denoted by $\mathbf{P}_2$, which has $B_{\mathbf{P}}$ and $C_{\mathbf{P}}$ as first and second universe, respectively; here, $B_{\mathbf{P}}$ and $C_{\mathbf{P}}$ denote the sets in the decomposition of the universe P as described above. The structure $\mathbf{P}_2$ is defined on signature $\{R\}$ and has $R^{\mathbf{P}_2} = \{(b, c, c') \in B_{\mathbf{P}} \times C_{\mathbf{P}} \times C_{\mathbf{P}} \mid (c, c') \in \alpha_b^{\mathbf{P}}\}$. The definition of $\mathbf{P}_2$ comes from (Bova et al., 2013). In forming conjunctive queries over this signature $\{R\}$

each variable has a sort (first or second) associated with each variable; an atom $R(x, y, y')$ may be formed if x is of the first sort and y and y' are of the second sort. When $\mathcal{P}$ is a set of pentagons, we define the prediction problem $\mathcal{C}_{\text{CQ-2-PENT}}(\mathcal{P})$ to be the set

$$\{(\phi(V_1, V_2), (\mathbf{P}, (h_1, h_2))) \mid \mathbf{P} \in \mathcal{P} \text{ and } h_1 : V_1 \to B_{\mathbf{P}},\ h_2 : V_2 \to C_{\mathbf{P}} \\ \text{such that } \mathbf{P}_2, h_1, h_2 \models \phi\ \}.$$

Here, $\phi(V_1, V_2)$ denotes a conjunctive query over the signature $\{R\}$ with V_1 a set of variables of the first sort and V_2 a set of the second sort.

Theorem 20 *For $\mathcal{P}$ a finite set of pentagons, there exists an oracular pwm-reduction from the prediction problem $\mathcal{C}^r_{\text{TERM}}(\mathbf{L}(\mathcal{P}))$ for any $r > 1$ to the prediction problem $\mathcal{C}_{\text{CQ-2-PENT}}(\mathcal{P})$.*

Proof We make use of a version of a construction presented in the proof of Theorem 10 from Bova et al. (2013), which produces a 2-sorted conjunctive query $\phi_t(x_1, \ldots, x_m, y, y')$ over the signature $\{R\}$ from a lattice term $t(x_1, \ldots, x_m)$, where in ϕ_t the variables x_i are of sort 1 and the variables y and y' are of sort 2. The construction has the property that if $\mathbf{P} \in \mathcal{P}$, then for all $b_1, \ldots, b_m \in B_{\mathbf{P}}$ and for all c, $c' \in C_{\mathbf{P}}$, $\phi_t(b_1, \ldots, b_m, c, c')$ holds in $\mathbf{P}_2$ if and only if the pair (c, c') is in the equivalence relation given by $t^{\mathbf{L}(\mathbf{P})}(\alpha^{\mathbf{P}}_{b_1}, \ldots, \alpha^{\mathbf{P}}_{b_m})$. Let us specify the version of the construction used here.

- If $t = x_i$, then $\phi_t(x_1, \ldots, x_m, y, y') = R(x_i, y, y')$.
- If $t = t_1 \wedge t_2$, then $\phi_t(x_1, \ldots, x_m, y, y') = \phi_{t_1}(x_1, \ldots, x_m, y, y') \wedge \phi_{t_2} t(x_1, \ldots, x_m, y, y')$.
- If $t = t_1 \vee t_2$, then set M to be the maximum size of a second universe $C_{\mathbf{P}}$ over all pentagons $\mathbf{P} \in \mathcal{P}$. Let $z_{0,2}$ and $z_{i,j}$, where $i = 1, \ldots, M$ and $j = 1, 2$, be variables of the second sort, and identify $y = z_{0,2}$ and $y' = z_{M,2}$. Then $\phi_t(x_1, \ldots, x_m, y, y')$ is defined as the formula obtained by existentially quantifying the variables $z_{i,j}$ (other than y and y') before the conjunction

$$\bigwedge_{i=1}^{M} (\phi_{t_1}(x_1, \ldots, x_m, z_{i-1,2}, z_{i,1}) \wedge \phi_{t_2}(x_1, \ldots, x_m, z_{i,1}, z_{i,2})).$$

Note that in each of the latter two cases, the size $|\phi_t|$ of the created formula ϕ_t has size bounded above by a constant times $|\phi_{t_1}| + |\phi_{t_2}|$. Hence, the size of ϕ_t will be polynomial in that of t—when t has logarithmic depth, which will be the case in our application here.

To define the g component of the reduction, the construction just given is not applied directly to a lattice term t. Instead, we first start with a fixed lattice term $s(x_1, \ldots, x_q)$ with the property that for all $\mathbf{P} \in \mathcal{P}$ and all $\delta \in \mathbf{L}(\mathbf{P})$ there are $b_i \in B_{\mathbf{P}}$, for $1 \leq i \leq q$, so that $\delta = s^{\mathbf{L}(\mathbf{P})}(\alpha^{\mathbf{P}}_{b_1}, \ldots, \alpha^{\mathbf{P}}_{b_q})$. We let $\omega(\delta)$ be some sequence $(b_1, \ldots, b_q)$ for which this equality holds. The existence of such a term follows from the fact that $\mathcal{P}$ is a finite set of finite pentagons and that in each pentagon $\mathbf{P}$, the equivalence relations $\alpha^{\mathbf{P}}_b$ generate the lattice $\mathbf{L}(\mathbf{P})$. For future reference, let u be an integer such that $|\mathbf{P}| \leq u$ for all $\mathbf{P} \in \mathcal{P}$. For any lattice term $t(x_1, \ldots, x_m)$, we define $t \star s$ to be the mq-ary lattice term

$$t(s(x_{11}, \ldots, x_{1q}), \ldots, s(x_{m1}, \ldots, x_{mq})).$$

Let us now begin to describe the reduction; the parameters s and n (as described in the definition of oracular pwm-reduction) do not play a role, and we omit their mention. For each lattice term $t(x_1, \ldots, x_m)$, define $g(t)$ to be the following conjunctive query over the signature $\{R\}$:

$$\bigwedge_{1 \leq i \leq u^2} \phi_{t \star s}(x_{11}, x_{12}, \ldots, x_{mq}, y_i, y'_i).$$

For $\mathbf{P} \in \mathcal{P}$, an m-tuple $h = (\delta_1, \ldots, \delta_m)$ over $\mathbf{L}(\mathbf{P})$, and $\theta \in \mathbf{L}(\mathbf{P})$, define the function $f((\mathbf{L}(\mathbf{P}), h, \theta))$ to be $\mathbf{P}$ along with the assignment of the variables $(x_{11}, \ldots, x_{mq})$ to the concatenation of the q-tuples $\omega(\delta_i)$, for $1 \leq i \leq m$. The pairs of variables (y_i, y'_i), for $1 \leq i \leq u^2$, are assigned to pairs $(c, c') \in \theta$ so that each pair in θ is in the range of this assignment. By the choice of u, this is always possible to arrange. Note that $f((\mathbf{L}(\mathbf{P}), h, \theta))$ can be computed in time bounded by some polynomial in m.

It follows from the claim made about the construction ϕ_t in the first paragraph of this proof, and from the properties of the lattice term s that for all lattice terms $t(x_1, \ldots, x_m)$, if $\mathbf{P} \in \mathcal{P}$, $h = (\delta_1, \ldots, \delta_m) \in \mathbf{L}(\mathbf{P})^m$, and $\theta \in \mathbf{L}(\mathbf{P})$ then $t^{\mathbf{L}(\mathbf{P})}(\delta_1, \ldots, \delta_m) \geq \theta$ if and only if $\mathbf{P}_2$ satisfies the conjunctive query $g(t)$ under the assignments given by $f((\mathbf{L}(\mathbf{P}), h, \theta))$.

To complete the definition of our reduction from $\mathcal{C}^r_{\text{TERM}}(\mathbf{L}(\mathcal{P}))$ to $\mathcal{C}_{\text{CQ-2-PENT}}(\mathcal{P})$, define H to be the algorithm that when given $\mathbf{P} \in \mathcal{P}$ and h_1 and h_2 tuples over $B_{\mathbf{P}}$ and $C_{\mathbf{P}}$ respectively, will reject the input if h_1 is not an mq-tuple for some integer m or if h_2 is a tuple which is not of length $2u^2$. Otherwise, with $h_1 = (b_{11}, \ldots, b_{mq})$ and $h_2 = (c_1, c'_1, \ldots, c_{u^2}, c'_{u^2})$, construct in $\mathbf{L}(\mathbf{P})$ the elements $\delta_i = s^{\mathbf{L}(\mathbf{P})}(\alpha^{\mathbf{P}}_{b_{i1}}, \ldots, \alpha^{\mathbf{P}}_{b_{iq}})$ and find the smallest element $\theta \in \mathbf{L}(\mathbf{P})$ such that $(c_i, c'_i) \in \theta$ for all $1 \leq i \leq u^2$. For any lattice term t, the algorithm will return the result of testing if in $\mathbf{P}$, $t \geq \theta$ under the assignment $(\delta_1, \ldots, \delta_m)$. From the properties of g noted earlier, it follows that in $\mathbf{P}$, $t \geq \theta$ under this assignment if and only if $g(t)$ is true in $\mathbf{P}_2$ under the assignment (h_1, h_2). The run time of H can be bounded by a polynomial in the lengths of h_1 and h_2. ■

Lemma 21 *(Bova et al., 2013) Let $\mathbf{B}$ be a finite relational structure such that $\mathcal{V}(\mathbb{A}(\mathbf{B}))$ is not congruence modular. There exists a finite relational structure $\mathbf{A}$ defined on a signature including three binary relation symbols α, β, and γ which is compatible with an algebra in $\mathcal{V}(\mathbb{A}(\mathbf{B}))$, such that the following hold:*

- *There exists a finite set $\mathcal{P}$ of pentagons where for each $\mathbf{P} \in \mathcal{P}$, the universe P of $\mathbf{P}$ is a subset of A, and it holds that $\alpha^{\mathbf{P}} = \alpha^{\mathbf{A}} \cap P^2$, $\beta^{\mathbf{P}} = \beta^{\mathbf{A}} \cap P^2$, and $\gamma^{\mathbf{P}} = \gamma^{\mathbf{A}} \cap P^2$. Moreover, the set $\mathbf{L}(\mathcal{P})$ contains a non-trivial lattice.*
- *For each $k \geq 1$, there exists a relation $D_k \subseteq A^k$ which is cq-definable over $\mathbf{A}$ such that for any elements $a_1, \ldots, a_k \in A$, the tuple $(a_1, \ldots, a_k)$ is in D_k if and only if there exists a $\mathbf{P} \in \mathcal{P}$ such that all of the elements $a_1, \ldots, a_k$ are contained in the universe P of $\mathbf{P}$. In addition, there exists an algorithm that computes a cq-definition of D_k (over $\mathbf{A}$) in polynomial time, when given k as input.*

In the definition of the set $\mathcal{P}$ we may assume that if $\mathbf{P}$, $\mathbf{P}'$ are members, then $P \not\subseteq P'$. This additional property can be arranged by only including in $\mathcal{P}$ those pentagons

whose universes are maximal with respect to inclusion. Doing so will not change the other properties listed in the previous lemma.

Theorem 22 *Let* $\mathbf{A}$ *be a finite relational structure satisfying the conditions described in Lemma 21, and let* $\mathcal{P}$ *be the set of pentagons described there. There exists an oracular pwm-algorithm from* $\mathcal{C}_{\text{CQ-2-PENT}}(\mathcal{P})$ *to* $\mathcal{C}_{\text{CQ}}(\mathbf{A})$.

Essentially, Theorem 22 is proved in the following way. In order to translate a 2-sorted conjunctive query ϕ over pentagons to a conjunctive query ϕ' over $\mathbf{A}$, the relations β and γ are used to simulate the two sorts, and the relation α is used to simulate the behavior of the relation R. Also, in the resulting conjunctive query ϕ', all of the variables are related by the relation D_U (where U is the total number of variables), effectively localizing ϕ' to the pentagons found in the set $\mathcal{P}$.

Proof Let M be a natural number such that $|P| \leq M$ for all $\mathbf{P} \in \mathcal{P}$. For ϕ a 2-sorted conjunctive query over the signature $\{R\}$, let $\{x_1, \ldots, x_n\}$ and $\{y_1, \ldots, y_m\}$ be the variables of the first and second sort, respectively, that appear in ϕ. Assume that the free variables of ϕ are $\{x_1, \ldots, x_{n'}\}$ and $\{y_1, \ldots, y_{m'}\}$ where $n' \leq n$ and $m' \leq m$. We construct a conjunctive query ϕ' from ϕ over the signature $\{\alpha, \beta, \gamma\}$ along the lines of the construction found in the proof of Theorem 7 in Bova et al. (2013); but, instead of adding the conjunct

$$\Delta_{n+m+k}(x'_1, \ldots, x'_n, y'_1, \ldots, y'_m, w'_1, \ldots, w'_k),$$

in the construction of ϕ' we add the conjunct

$$D_{n+m+k+M}(x'_1, \ldots, x'_n, y'_1, \ldots, y'_m, w'_1, \ldots, w'_k, v'_1, \ldots, v'_M),$$

where the v'_i's are fresh variables and the relation D is provided by the previous lemma. The resulting formula ϕ' will have as free variables

$$\{x'_1, \ldots, x'_{n'}\} \cup \{y'_1, \ldots, y'_{m'}\} \cup \{v'_1, \ldots, v'_M\}.$$

In giving the oracular pwm-reduction, the parameters s and n (as described in the definition of oracular pwm-reduction) do not play a role, and we omit their mention. To construct an oracular pwm-reduction (f, g, H) from $\mathcal{C}_{\text{CQ-2-PENT}}(\mathcal{P})$ to $\mathcal{C}_{\text{CQ}}(\mathbf{A})$ we define g to be the function that maps the 2-sorted conjunctive query ϕ to the conjunctive query ϕ'. As in the original construction from Bova et al. (2013) it follows that the size of $g(\phi)$ can be bounded by a polynomial in the size of ϕ. A key point, as appears in the statement of Lemma 21, is that a cq-definition of the relation D_k can be constructed in time bounded by some polynomial in k.

Given $\mathbf{P} \in \mathcal{P}$, let b^* be some fixed member of $B_{\mathbf{P}}$ and c^* some fixed member of $C_{\mathbf{P}}$ and let $(p_1, \ldots, p_M)$ be some listing of the elements of P. For the purposes of this discussion we regard P as being equal to the set $B_{\mathbf{P}} \times C_{\mathbf{P}}$, though strictly speaking, P is a subset of A. For assignments $h_1 = (b_1, \ldots, b_n) \in B_{\mathbf{P}}^n$ and $h_2 = (c_1, \ldots, c_m) \in C_{\mathbf{P}}^m$, define $f((\mathbf{P}, (h_1, h_2)))$ to be the tuple

$$((b_1, c^*), \ldots, (b_n, c^*), (b^*, c_1), \ldots, (b^*, c_m), p_1, \ldots, p_M).$$

Clearly $f((\mathbf{P}, (h_1, h_2)))$ can be computed in time bounded by a polynomial in the sizes of h_1 and h_2.

For ϕ a 2-sorted conjunctive query over the signature $\{R\}$, $\mathbf{P} \in \mathcal{P}$, and (h_1, h_2) a sorted assignment of the free variables of ϕ to $\mathbf{P}_2$, it follows from Claim 4 in the proof of Theorem 7 from Bova et al. (2013) (and referred to as just Claim 4 in the remainder of this proof) that if ϕ is true in $\mathbf{P}_2$ under the sorted assignment (h_1, h_2) then in $\mathbf{A}$, the formula $g(\phi) = \phi'$ is true under the assignment $f((\mathbf{P}, (h_1, h_2)))$. Claim 4 applies in this situation, since, using terminology from it, the assignments (h_1, h_2) and $f((\mathbf{P}, (h_1, h_2)))$, when restricted to its first $n + m$ components, *match*. The addition of the last M components to $f((\mathbf{P}, (h_1, h_2)))$ do not affect the satisfaction of ϕ', since they only appear in the D-relation conjunct of ϕ' and all of the elements lie in the set P and so, together will satisfy the D-relation that appears in ϕ'.

Conversely, if ϕ' is satisfied in $\mathbf{A}$ under the assignment $f((\mathbf{P}, (h_1, h_2)))$ then by Claim 4, there is some $\mathbf{P}' \in \mathcal{P}$ such that in $\mathbf{P}'_2$, the formula ϕ is satisfied under the assignment (h_1, h_2). By Lemma 21, all of the elements of A that appear in $f((\mathbf{P}, (h_1, h_2)))$ must all lie in $\mathbf{P}'$ since they jointly satisfy a D-relation. But by our modification of the set $\mathcal{P}$ and the fact that $(p_1, \ldots, p_M)$ is a listing of the elements of P, it follows that $\mathbf{P} = \mathbf{P}'$. Thus we have established that $\mathbf{P}$ satisfies ϕ under the assignment (h_1, h_2) if and only if $\mathbf{A}$ satisfies $g(\phi)$ under the assignment $f((\mathbf{P}, (h_1, h_2)))$.

To complete the construction of the oracular pwm-reduction, if we are given an assignment

$$h = (b_1, \ldots, b_n, c_1, \ldots, c_m, p_1, \ldots, p_M)$$

of elements from A, the algorithm H will reject h if there is no $\mathbf{P} \in \mathcal{P}$ that contains all of the elements that appear in h. Otherwise, let $\mathcal{P}_h$ be the set of pentagons in $\mathcal{P}$ that contains this set of elements. If $\phi(x_1, \ldots, x_n, y_1, \ldots, y_m)$ is a 2-sorted conjunctive query over the signature $\{R\}$, then by Claim 4, $g(\phi) = \phi'$ will be satisfied in $\mathbf{A}$ under the assignment h if and only if there is at least one $\mathbf{P} \in \mathcal{P}_h$ such that ϕ will be satisfied in $\mathbf{P}$ under the sorted assignment (h_1, h_2) that matches the assignment $(b_1, \ldots, b_n, c_1, \ldots, c_m)$ in P. By this we mean that $h_1 = (b'_1, \ldots, b'_n)$ and $h_2 = (c'_1, \ldots, c'_m)$, where, regarding the b_i and c_j as elements of $P = B_{\mathbf{P}} \times C_{\mathbf{P}}$, we have $b_i = (b'_i, v_i)$ and $c_j = (u_j, c'_j)$ for some elements v_i and u_j.

So, given the assignment h, and a conjunctive query ϕ, the algorithm H will, for each $\mathbf{P} \in \mathcal{P}_h$ compute the matching assignment (h_1, h_2) and query whether ϕ is satisfied in $\mathbf{P}$ under this assignment. If any of the queries are true, then H will return true to the query testing for the satisfaction of ϕ' in $\mathbf{A}$ under the assignment h. Otherwise, H will return false. Since the number of oracle calls that H will make is bounded by the fixed size of $\mathcal{P}$ and since each matching assignment can be quickly computed, the run time of H can be bounded by a polynomial in the size of h. ■

7. Hardness From the Absence of Taylor Polymorphisms

In this section we prove the following theorem.

Theorem 23 *If $\mathbf{B}$ is a finite relational structure that does not have a Taylor polymorphism then there is an oracular pwm-reduction from $\mathcal{C}_{\exists\text{CIRC}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B})$.*

Our proof is based on the proof of Theorem 4 from Bova et al. (2013) and makes use of the fact that a finite relational structure $\mathbf{B}$ fails to have a Taylor polymorphism if and only if the variety generated by $\mathbb{A}(\mathbf{B})$ admits a certain kind of "bad" local behaviour. The theory developed by Hobby and McKenzie (Hobby and McKenzie, 1988), known as tame congruence theory, provides a way to analyze the local structure of finite algebras and identifies fives different types of local behaviour that a finite algebra can exhibit. These five types are: (1) the unary type, (2) the affine type, (3) the boolean type, (4) the lattice type, and (5) the semilattice type. A surprisingly useful invariant of a finite algebra $\mathbb{A}$, called the typeset of $\mathbb{A}$, is the set of types of local behaviour that $\mathbb{A}$ exhibits. The notion of a typeset can be extended to a variety $\mathcal{V}$ (or to any collection of algebras) by taking it to be the union of the typesets of its finite members.

Tame congruence theory establishes, for varieties $\mathcal{V}$ generated by a finite algebra, strong connections between the local behaviour of the finite members of $\mathcal{V}$ and global properties of $\mathcal{V}$. Chapter 9 of Hobby and McKenzie (1988) presents several theorems of this sort, including the following:

Theorem 24 *(Hobby and McKenzie, 1988, see Theorem 9.6) Let $\mathbb{A}$ be a finite algebra. The following are equivalent:*

- *$\mathbb{A}$ has a Taylor term,*
- *The typeset of $\mathcal{V}(\mathbb{A})$ omits the unary type.*

In the proof of Theorem 23 we will use this result to conclude that in the absence of a Taylor polymorphism, some finite member of the variety generated by $\mathbb{A}(\mathbf{B})$ will locally behave as a unary algebra, i.e., an algebra whose basic operations depend on at most one variable. As detailed in the proof, this will provide a way to produce an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{B}_{3\text{SAT}})$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B})$.

Recall the structure $\mathbf{B}_{3\text{SAT}}$ from Example 1. We will make use of the following fact, which follows immediately from the standard assignment-preserving conversion from a Boolean circuit to a 3-SAT formula where existential quantification may be used.

Proposition 25 *There exists an oracular pwm-reduction from $\mathcal{C}_{\exists\text{CIRC}}$ to $\mathcal{C}_{\text{CQ}}(\mathbf{B}_{3\text{SAT}})$.*

We also need the following fact.

Proposition 26 *There is a finite relational structure $\mathbf{C}$ with domain $\{0,1\}$ such that each relation $R \subseteq \{0,1\}^n$ of $\mathbf{C}$ contains the constant tuples $(0,0,\ldots,0)$ and $(1,1,\ldots,1)$ and such that there is an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{B}_{3\text{SAT}})$ to $\mathcal{C}_{\text{CQ}}(\mathbf{C})$.*

Proof We apply the construction from Lemma 4 from Bova et al. (2012) to the structure $\mathbf{B}_{3\text{SAT}}$ to obtain the desired structure $\mathbf{C}$. For each ternary relation R of $\mathbf{B}_{3\text{SAT}}$, $\mathbf{C}$ will have a 5-ary relation R' such that

$$R' = \{(0,1,a,b,c) \mid (a,b,c) \in R\} \cup \{(0,0,0,0,0),(1,1,1,1,1)\}.$$

For any conjunctive query $\phi(x_1,\ldots,x_n)$ of $\mathbf{B}_{3\text{SAT}}$ we construct a corresponding conjunctive query $\phi'(w_0,w_1,x_1,\ldots,x_n)$ of $\mathbf{C}$ by replacing each occurrence of a relation $R(x,y,z)$ in ϕ with $R'(w_0,w_1,x,y,z)$. It is elementary to show that for any n-tuple $\bar{b} = (b_1,\ldots,b_n) \in \{0,1\}^n$, $\phi(\bar{b})$ holds in $\mathbf{B}_{3\text{SAT}}$ if and only if $\phi'(0,1,\bar{b})$ holds in $\mathbf{C}$. Furthermore if each variable x_i appears in at least one conjunct of ϕ, then the only other $(n+2)$-tuples that satisfy ϕ' are the constant tuples $(0,0,\ldots,0)$ and $(1,1,\ldots,1)$. From this it follows that there is an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{B}_{3\text{SAT}})$ to $\mathcal{C}_{\text{CQ}}(\mathbf{C})$. ■

Proof [Proof of Theorem 23] Suppose that $\mathbf{B}$ is a finite relational structure that does not have a Taylor polymorphism. Then by Lemma 9.4 and Theorem 9.6 from Hobby and McKenzie (1988), the variety $\mathcal{V}$ generated by $\mathbb{A}(\mathbf{B})$ admits the unary type. Let $\mathbf{C}$ be a structure as described in Lemma 26. We argue that there is an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{C})$ to $\mathcal{C}_{\text{CQ}}(\mathbf{A})$, where $\mathbf{A}$ is the finite structure from Lemma 1 from Bova et al. (2013). Since $\mathbf{A}$ is compatible with a finite algebra $\mathbb{A} \in \mathcal{V}$ then the Theorem follows from Propositions 3 and 5.

In addition to providing the structure $\mathbf{A}$ and the algebra $\mathbb{A}$, Lemma 1 also gives a polynomial-time construction that on input a conjunctive query ϕ over $\mathbf{C}$, produces a conjunctive query ϕ' over $\mathbf{A}$ that has the same sets of free and bound variables that ϕ has. If $X = \{x_1,\ldots,x_m\}$ are the free variables of ϕ (and of ϕ') then Proposition 2 from Bova et al. (2013) proves that for any assignment $g : X \to \{0,1\}$, $\mathbf{C}, g \models \phi$ if and only if $\mathbf{A}, g \models \phi'$. Conversely, for any $g : X \to A$, the equivalence of the following two statements is established in the proof of Proposition 2:

- $\mathbf{A}, g \models \phi'$ and
- $\mathbf{A}, g \models E_m$ and for every unary polynomial $p(x)$ of $\mathbb{A}$, if $p(g(x)) \in \{0,1\}$ for all $x \in X$, then $\mathbf{C}, p \circ g \models \phi$.

We use the above to produce an oracular pwm-reduction from $\mathcal{C}_{\text{CQ}}(\mathbf{C})$ to $\mathcal{C}_{\text{CQ}}(\mathbf{A})$ as follows. We need to design an algorithm H such that on input a conjunctive query $\phi(x_1,\ldots,x_m)$ over $\mathbf{C}$ and an assignment $g : \{x_1\ldots,x_m\} \to A$, decides if $\mathbb{A}, g \models \phi'$. Using the equivalence, it suffices to have H decide if $\mathbf{A}, g \models E_m$ and, for each unary polynomial $p(x)$ of $\mathbb{A}$ with $p(g(x_i)) \in \{0,1\}$ for all $1 \le i \le m$, if $\mathbf{C}, p \circ g \models \phi$. From Lemma 1 from Bova et al. (2013) it follows that determining if $\mathbf{A}, g \models E_m$ can be checked in time bounded by a polynomial in m, since for $m > k = |A|$, E_m is equal to the conjunction of $\binom{m}{k}$ instances of E_k, one for each k-element subset of variables from $\{x_1,\ldots,x_m\}$.

Since $\mathbb{A}$ is a finite algebra, then the set of unary polynomials $p(x)$ of $\mathbb{A}$ is also finite (of size bounded by k^k). For each such polynomial $p(x)$, H checks to see if $p(g(x_i)) \in \{0,1\}$ for all $1 \le i \le m$. For such a polynomial, H queries whether $\mathbf{C}, p \circ g \models \phi$. If any of these queries are false, then H returns false, otherwise, H returns true. Then $\mathbf{A}, g \models \phi'$ if and only if H returns true on input ϕ and g. The number of queries that H makes is bounded by the constant k^k and the run-time of H is bounded by m and the size of ϕ. ■

8. Open Issues

Let us conclude by highlighting two open issues. First, we ask if one can provide evidence, even of the conditional sort, that the dichotomy of Theorem 15 is a true dichotomy. Second, it would be desirable to pin down the exact complexity of the meta-problems of deciding whether or not an input relational structure satisfies each of the dichotomy conditions; we exhibited upper bounds on these meta-problems in Theorem 17 and the surrounding discussion.

Acknowledgments

Abstract

We develop an approach to risk minimization and stochastic optimization that provides a convex surrogate for variance, allowing near-optimal and computationally efficient trading between approximation and estimation error. Our approach builds off of techniques for distributionally robust optimization and Owen's empirical likelihood, and we provide a number of finite-sample and asymptotic results characterizing the theoretical performance of the estimator. In particular, we show that our procedure comes with certificates of optimality, achieving (in some scenarios) faster rates of convergence than empirical risk minimization by virtue of automatically balancing bias and variance. We give corroborating empirical evidence showing that in practice, the estimator indeed trades between variance and absolute performance on a training sample, improving out-of-sample (test) performance over standard empirical risk minimization for a number of classification problems.

Keywords: variance regularization, robust optimization, empirical likelihood

1. Introduction

We propose and study a new approach to risk minimization that automatically trades between bias—or approximation error—and variance—or estimation error. Let $\mathcal{X}$ be a sample space, P_0 a distribution on $\mathcal{X}$, and Θ a parameter space. For a loss function $\ell : \Theta \times \mathcal{X} \to \mathbb{R}$, consider the problem of finding $\theta \in \Theta$ minimizing the risk

$$R(\theta) := \mathbb{E}[\ell(\theta, X)] = \int \ell(\theta, x) dP(x) \tag{1}$$

given a sample $\{X_1, \ldots, X_n\}$ drawn i.i.d. according to the distribution P. Under appropriate conditions on the loss ℓ, parameter space Θ, and random variables X, a number of researchers (Bartlett et al., 2005, 2006; Boucheron et al., 2005; Koltchinskii, 2006) have shown results of the form that with high probability,

$$R(\theta) \le \frac{1}{n} \sum_{i=1}^n \ell(\theta, X_i) + C_1 \sqrt{\frac{\mathrm{Var}(\ell(\theta, X))}{n}} + \frac{C_2}{n} \quad \text{for all } \theta \in \Theta \tag{2}$$

where C_1 and C_2 depend on the parameters of problem (1) and the desired confidence guarantee. Such bounds justify empirical risk minimization (ERM), which chooses $\widehat{\theta}_n$ to minimize $\frac{1}{n}\sum_{i=1}^n \ell(\theta, X_i)$ over $\theta \in \Theta$. Further, these bounds showcase a tradeoff between bias and variance, where we identify the bias (or approximation error) with the empirical risk $\frac{1}{n}\sum_{i=1}^n \ell(\theta, X_i)$, while the variance arises from the second term in the bound.

Given bounds of the form above and heuristically considering the classical "bias-variance" tradeoff in estimation and statistical learning, it is natural to instead choose θ to directly minimize a quantity trading between approximation and estimation error, say of the form

$$\frac{1}{n} \sum_{i=1}^n \ell(\theta, X_i) + C \sqrt{\frac{\mathrm{Var}_{\widehat{P}_n}(\ell(\theta, X))}{n}}, \tag{3}$$

where $\mathrm{Var}_{\widehat{P}_n}$ denotes the empirical variance of its argument. Maurer and Pontil (2009) considered precisely this idea, giving a number of guarantees on the convergence and good performance of such a procedure. Unfortunately, even when the loss ℓ is convex in θ, the formulation (3) is in general non-convex, yielding computationally intractable problems, which has limited the applicability of procedures that minimize the variance-corrected empirical risk (3). In this paper, we develop an approach that provides a tractable *convex* formulation whenever the loss ℓ is convex and very closely approximates the penalized risk (3). Our approach is based on Owen's empirical likelihood (Owen, 2001) and ideas from distributionally robust optimization (Ben-Tal et al., 2009; Bertsimas et al., 2014; Ben-Tal et al., 2015). Below, we give a number of theoretical guarantees and empirical evidence for its performance.

Before summarizing our contributions, we first describe our approach. Let $\phi : \mathbb{R}_+ \to \mathbb{R}$ be a convex function with $\phi(1) = 0$. Then the *ϕ-divergence* between distributions P and Q defined on a space $\mathcal{X}$ is

$$D_\phi(P \| Q) = \int \phi\left(\frac{dP}{dQ}\right) dQ = \int_{\mathcal{X}} \phi\left(\frac{p(x)}{q(x)}\right) q(x) d\mu(x),$$

where μ is any measure for which $P, Q \ll \mu$, and $p = \frac{dP}{d\mu}$, $q = \frac{dQ}{d\mu}$. Throughout this paper, we use $\phi(t) = \frac{1}{2}(t-1)^2$, which gives the χ^2-divergence (Tsybakov, 2009). Given ϕ and a sample $X_1, \ldots, X_n$, we define the *local neighborhood of the empirical distribution with radius* ρ by

$$\mathcal{P}_n := \left\{ \text{distributions } P \text{ such that } D_\phi\left(P \| \widehat{P}_n\right) \le \frac{\rho}{n} \right\},$$

where $\widehat{P}_n$ denotes the empirical distribution of the sample, and our choice of $\phi(t) = \frac{1}{2}(t-1)^2$ means that $\mathcal{P}_n$ consists of discrete distributions supported on the sample $\{X_i\}_{i=1}^n$. We then define the *robustly regularized risk*

$$R_n(\theta, \mathcal{P}_n) := \sup_{P \in \mathcal{P}_n} \mathbb{E}_P[\ell(\theta, X)] = \sup_P \left\{ \mathbb{E}_P[\ell(\theta, X)] : D_\phi(P \| \widehat{P}_n) \le \frac{\rho}{n} \right\}. \tag{4}$$

As it is the supremum of a family of convex functions, the robust risk $\theta \mapsto R_n(\theta, \mathcal{P}_n)$ is convex in θ whenever ℓ is convex, no matter the value of $\rho \ge 0$. Given the robust empirical risk (4), our proposed estimation procedure is to choose a parameter $\widehat{\theta}_n^{\mathrm{rob}}$ by minimizing $R_n(\theta, \mathcal{P}_n)$.

Let us now discuss a few of the properties of procedures minimizing the robust empirical risk (4). Our first main technical result, which we show in Section 2, is that for bounded loss functions, the robust risk $R_n(\theta, \mathcal{P}_n)$ is a good approximation to the variance-regularized quantity (3). That is,

$$R_n(\theta, \mathcal{P}_n) = \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] + \sqrt{\frac{2\rho \mathrm{Var}_{\widehat{P}_n}(\ell(\theta, X))}{n}} + \varepsilon_n(\theta), \tag{5}$$

where $\varepsilon_n(\theta) \leq 0$ and is $O_P(1/n)$ uniformly in θ. We show specifically that whenever $\ell(\theta, X)$ has suitably large variance, with high probability we have $\varepsilon_n = 0$. From variance expansions of the form (5) and empirical Bernstein inequality (2), we see that $R_n(\theta, \mathcal{P}_n)$ is a $O(1/n)$-approximation to the population risk $R(\theta)$, in contrast to the cruder $O(1/\sqrt{n})$-approximation that the empirical risk $\mathbb{E}_{\widehat{P}_n}[\ell(\theta; X)]$ provides. Based on this intuition that the robustly regularized risk $R_n(\theta; \mathcal{P}_n)$ is a tighter approximation to the population risk $R(\theta)$, we show a number of finite-sample convergence guarantees for the estimator

$$\widehat{\theta}_n^{\mathrm{rob}} \in \operatorname*{argmin}_{\theta \in \Theta} \left\{ \sup_P \left\{ \mathbb{E}_P[\ell(\theta, X)] : D_\phi\left(P \| \widehat{P}_n\right) \leq \frac{\rho}{n} \right\} \right\} \tag{6}$$

that are often tighter than those available for ERM (see Section 3). The above problem is a *convex* optimization problem when the original loss $\ell(\cdot; X)$ is convex and Θ is a convex set.

Based on the expansion (5), solutions $\widehat{\theta}_n^{\mathrm{rob}}$ of problem (6) enjoy automatic finite sample optimality certificates: for $\rho \geq 0$, with probability at least $1 - C_1 \exp(-\rho)$ we have

$$R(\widehat{\theta}_n^{\mathrm{rob}}) = E[\ell(\widehat{\theta}_n^{\mathrm{rob}}; X)] \leq R_n(\widehat{\theta}_n^{\mathrm{rob}}; \mathcal{P}_n) + \frac{C_2\rho}{n} = \inf_{\theta \in \Theta} R_n(\theta, \mathcal{P}_n) + \frac{C_2\rho}{n}$$

where C_1, C_2 are constants (which we specify) that depend on the loss ℓ and domain Θ. That is, with high probability the robust solution has risk no worse than the optimal finite sample robust objective up to an $O(\rho/n)$ error term. To guarantee a desired level of risk performance with probability $1 - \delta$, we may specify the robustness penalty $\rho = O(\log \frac{1}{\delta})$.

Secondly, we show that the procedure (6) allows us to automatically and near-optimally trade between approximation and estimation error (bias and variance), so that

$$R(\widehat{\theta}_n^{\mathrm{rob}}) = E[\ell(\widehat{\theta}_n^{\mathrm{rob}}; X)] \leq \inf_{\theta \in \Theta} \left\{ \mathbb{E}[\ell(\theta; X)] + 2\sqrt{\frac{2\rho}{n} \mathrm{Var}(\ell(\theta; X))} \right\} + \frac{C\rho}{n} \tag{7}$$

with high probability. When there are parameters θ with small risk $R(\theta)$ and small variance $\mathrm{Var}(\ell(\theta, X))$, this guarantees that the excess risk $R(\widehat{\theta}_n^{\mathrm{rob}}) - \inf_{\theta \in \Theta} R(\theta)$ is essentially of order $O(\rho/n)$, where ρ governs our desired confidence level. Our bounds do not require the Bernstein-type condition $\mathrm{Var}(\ell(\theta; X)) \leq MR(\theta)$ often required for ERM. Since it is often the case that M depends on global information (e.g. size of parameter space Θ), we have $\mathrm{Var}(\ell(\theta; X)) \ll MR(\theta)$, in which case the bound (7) offers a tighter guarantee than that available for the ERM solution $\widehat{\theta}_n^{\mathrm{erm}}$. In particular, we give an explicit example in Section 3.3 where our robustly regularized procedure (6) converges at rate $O(\log n/n)$ compared to $O(1/\sqrt{n})$ of empirical risk minimization.

Bounds that trade between risk and variance are known in a number of cases in the empirical risk minimization literature (Mammen and Tsybakov, 1999; Tsybakov, 2004; Bartlett et al., 2005; Boucheron et al., 2005; Bartlett et al., 2006; Boucheron et al., 2013; Koltchinskii, 2006), which is relevant when one wishes to achieve "fast rates" of convergence for statistical learning algorithms (that is, faster than the $O(1/\sqrt{n})$ guaranteed by a number of uniform convergence results (Bartlett and Mendelson, 2002; Boucheron et al., 2005, 2013)). In many cases, however, such tradeoffs require either conditions such as the Mammen and Tsybakov's noise condition (Mammen and Tsybakov, 1999; Boucheron et al., 2005) or localization results made possible by curvature conditions that relate the loss/risk and variance (Bartlett et al., 2006, 2005; Mendelson, 2014). The robust solutions (6) enjoy a different tradeoff between variance and risk than that in this literature, but essentially without conditions except compactness of Θ.

In proposing any new estimator, it is essential to understand the limits of the proposed procedure and identify situations in which its performance may be worse than existing estimators. There are indeed situations in which minimizing the robust-regularized risk (4) yields some inefficiency (for example, in classical statistical estimation problems with correctly specified model). To understand limits of the inefficiency induced by using the distributionally-robustified estimator (6), in Section 4 we study explicit finite sample properties of the robust estimator for general stochastic optimization problems, and we also provide asymptotic normality results in classical problems. There are a number of situations, based on growth conditions on the population risk R, when convergence rates faster than $1/\sqrt{n}$ (or even $1/n$) are attainable (see Shapiro et al. (2009, Chapter 5)). We show that under these conditions, the robust procedure (6) still enjoys (near-optimal) fast rates of convergence, similar to empirical risk minimization (also known as sample average approximation in the stochastic programming literature). Our study of asymptotics makes precise the asymptotic efficiency loss of the robust procedure over minimizing the standard (asymptotically optimal) empirical expectation: there is a bias term that scales as $\sqrt{\rho/n}$ in the limiting distribution of $\widehat{\theta}_n^{\mathrm{rob}}$, though its variance is optimal. o

We complement our theoretical results in Section 5, where we conclude by providing three experiments comparing empirical risk minimization strategies to robustly-regularized risk minimization (6). These results validate our theoretical predictions, showing that the robust solutions are a practical alternative to empirical risk minimization. In particular, we observe that the robust solutions outperform their ERM counterparts on "harder" instances with higher variance. In classification problems, for example, the robustly regularized estimators exhibit an interesting tradeoff, where they improve performance on rare classes (where ERM usually sacrifices performance to improve the common cases—increasing variance slightly) at minor cost in performance on common classes.

Related Work

The theoretical foundations of empirical risk minimization are solid (Vapnik, 1998; Bartlett and Mendelson, 2002; Boucheron et al., 2005, 2013). When the expectation of the excess loss bounds its variance, it is possible to achieve faster rates than the $O(1/\sqrt{n})$ offered by standard uniform convergence arguments (Vapnik and Chervonenkis, 1971, 1974; Bartlett et al., 2006; Koltchinskii, 2006; Boucheron et al., 2013) (see Boucheron et al. (2005, Section

5) for an overview in the case of classification, and Shapiro et al. (2009, Chapter 5.3) for more general stochastic optimization problems). Vapnik and Chervonenkis (1971, 1974) first provided such results in the context of $\{0,1\}$-valued losses for classification (see also (Anthony and Shawe-Taylor, 1993)), where the expectation of the loss always upper bounds its variance, so that if there exists a perfect classifier the convergence rates of empirical risk minimization procedures are $O(1/n)$. Mammen and Tsybakov (Mammen and Tsybakov, 1999; Tsybakov, 2004) give low noise conditions for binary classification substantially generalizing these results, which yield a spectrum of fast rates. Under related conditions, Bartlett, Jordan, and McAuliffe (2006) show similar fast rates of convergence for convex risk minimization under appropriate curvature conditions on the loss. The robust procedure (6), on the other hand, is guaranteed to provide an at most $O(1/n)$ over-estimate of the population risk and a small increase of its variance regularized population counterpart. It may be the case that the variance-regularized risk $\inf_\theta\{R(\theta) + \sqrt{\mathrm{Var}(\ell(\theta, X))/n}\}$ decreases to $R(\theta^\star)$ more slowly than $1/n$. As we note above and detail in Section 4, however, in stochastic optimization problems the variance-regularized approach (6) suffers limited degradation with respect to empirical risk minimization strategies, even under convexity and curvature properties that allow faster rates of convergence than those achievable in classical regimes, as detailed by (Shapiro et al., 2009, Chapter 5.3).

Most related to our work is that of Maurer and Pontil (2009), who propose directly regularizing empirical risk minimization by variance, providing guarantees similar to ours and giving a natural foundation off of which many of our results build. In their setting, however—as they carefully note—it is unclear how to actually solve the variance-regularized problem, as it is generally non-convex. Shivaswamy and Jebara (2010, 2011) build on this and develop an elegant approach for boosting binary classifiers based on a variance penalty applied to the exponential loss; as it is a boosting approach, their approach provides a coordinate-wise strategy for decreasing the loss, but it is not guaranteed to converge to a global minimizer and applies to classification-like problems. Our approach, handling general stochastic optimization problems, removes these obstructions.

The robust procedure (6) is based on distributionally robust optimization ideas that many researchers have developed (Ben-Tal et al., 2013; Bertsimas et al., 2014; Lam and Zhou, 2015), where the goal (as in robust optimization more broadly (Ben-Tal et al., 2009)) is to protect against all deviations from a nominal data model. In the optimization literature, there is substantial work on tractability of the problem (6), including that of Ben-Tal et al. (2013), who show that the dual of (4) often admits a standard form (such as a second-order cone problem) to which standard polynomial-time interior point methods can be applied. Namkoong and Duchi (2016) develop stochastic-gradient-like procedures for solving the problem (6), which efficiently provide low accuracy solutions (which are still sufficient for statistical tasks). Work on the statistical analysis of such procedures is nascent; Bertsimas, Gupta, and Kallus (2014) and Lam and Zhou (2015) provide confidence intervals for solution quality under various conditions, and Duchi et al. (2016) give asymptotics showing that the optimal robust risk $R_n(\widehat{\theta}_n^{\mathrm{rob}}; \mathcal{P}_n)$ is a calibrated upper confidence bound for $\inf_{\theta\in\Theta} \mathbb{E}[\ell(\theta; X)]$. They and Gotoh et al. (2015) also provide a number of asymptotic results showing relationships between the robust risk $R_n(\theta; \mathcal{P}_n)$ and variance regularization, but they do not leverage these results for guarantees on the solutions $\widehat{\theta}_n^{\mathrm{rob}}$.

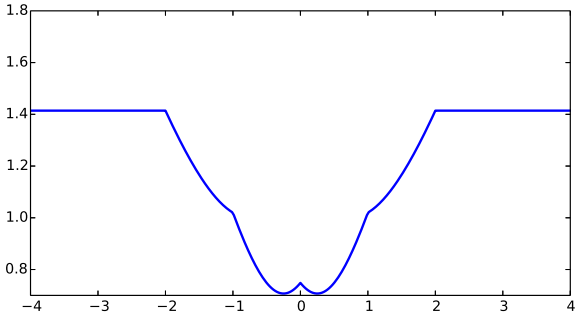

Figure 1. Plot of $\theta \mapsto \sqrt{\mathrm{Var}(\ell(\theta, X))}$ for $\ell(\theta; X) = |\theta - X|$ where $X \sim \mathsf{Uni}(\{-2, -1, 0, 1, 2\})$. The function is non-convex, with multiple local minima, inflection points, and does not grow as $\theta \to \pm\infty$.

Notation We collect our notation here. We let $\mathbb{B}$ denote a unit norm ball in $\mathbb{R}^d$, $\mathbb{B} = \{\theta \in \mathbb{R}^d : \|\theta\| \le 1\}$, where d and $\|\cdot\|$ are generally clear from context. Given sets $A \subset \mathbb{R}^d$ and $B \subset \mathbb{R}^d$, we let $A + B = \{a + b : a \in A, b \in B\}$ denote Minkowski addition. For a convex function f, the subgradient set $\partial f(x)$ of f at x is $\partial f(x) = \{g : f(y) \ge f(x) + g^\top(y - x) \text{ for all } y\}$. For a function $h : \mathbb{R}^d \to \mathbb{R}$, we let h^* denote its Fenchel (convex) conjugate, $h^*(y) = \sup_x\{y^\top x - h(x)\}$. For sequences a_n, b_n, we let $a_n \lesssim b_n$ denote that there is a numerical constant $C < \infty$ such that $a_n \le C b_n$ for all n. For a sequence of random vectors $X_1, X_2, \ldots$, we let $X_n \xrightarrow{d} X_\infty$ denote that X_n converges in distribution to X_∞. For a nonegative sequence $a_1, a_2, \ldots$, we say $X_n = O_P(a_n)$ if $\lim_{c\to\infty} \sup_n \mathbb{P}(\|X_n\| \ge c a_n) = 0$, and we say $X_n = o_P(a_n)$ if $\lim_{c\to 0} \limsup_n \mathbb{P}(\|X_n\| \ge c a_n) = 0$.

2. Variance Expansion

We begin our study of the robust regularized empirical risk $R_n(\theta, \mathcal{P}_n)$ by showing that it is a good approximation to the empirical risk plus a variance term, that is, studying the variance expansion (5). Although the variance of the loss is in general non-convex (see Figure 1 for a simple example), the robust formulation (6) is a convex optimization problem for variance regularization whenever the loss function is convex (the supremum of convex functions is convex (Hiriart-Urruty and Lemaréchal, 1993, Prop. 2.1.2.)).

2.1. Variance expansion for a single variable

To gain intuition for the variance expansion that follows, we begin with a slightly simpler problem, which is to study the quadratically constrained linear maximization problem

$$\underset{p}{\text{maximize}} \ \sum_{i=1}^n p_i z_i \ \ \text{subject to} \ \ p \in \mathcal{P}_n = \left\{p \in \mathbb{R}_+^n : \frac{1}{2}\left\|np - \mathbf{1}\right\|_2^2 \le \rho, \langle \mathbf{1}, p\rangle = 1\right\}, \quad (8)$$

where $z \in \mathbb{R}^n$ is a vector. For simplicity, let $s_n^2 = \frac{1}{n}\|z\|_2^2 - (\overline{z})^2 = \frac{1}{n}\|z - \overline{z}\|_2^2$ denote the empirical "variance" of the vector z, where $\overline{z} = \frac{1}{n}\langle \mathbf{1}, z\rangle$ is the mean value of z. Then by introducing the variable $u = p - \frac{1}{n}\mathbf{1}$, the objective in problem (8) satisfies $\langle p, z\rangle = \overline{z} + \langle u, z\rangle = \overline{z} + \langle u, z - \overline{z}\rangle$ because $\langle u, \mathbf{1}\rangle = 0$. Thus problem (8) is equivalent to solving

$$\operatorname*{maximize}_{u \in \mathbb{R}^n} \ \overline{z} + \langle u, z - \overline{z}\rangle \quad \text{subject to} \ \ \|u\|_2^2 \le \frac{2\rho}{n^2}, \ \ \langle \mathbf{1}, u\rangle = 0, \ u \ge -\frac{1}{n}.$$

Notably, by the Cauchy-Schwarz inequality, we have $\langle u, z - \overline{z}\rangle \le \sqrt{2\rho}\,\|z - \overline{z}\|_2 / n = \sqrt{2\rho s_n^2/n}$, and equality is attained if and only if

$$u_i = \frac{\sqrt{2\rho}(z_i - \overline{z})}{n\,\|z - \overline{z}\|_2} = \frac{\sqrt{2\rho}(z_i - \overline{z})}{n\sqrt{n s_n^2}}.$$

It is possible to choose such u_i while satisfying the constraint $u_i \ge -1/n$ if and only if

$$\min_{i \in [n]} \frac{\sqrt{2\rho}(z_i - \overline{z})}{\sqrt{n s_n^2}} \ge -1. \tag{9}$$

Thus, if inequality (9) holds for the vector z—that is, there is enough variance in z—we have

$$\sup_{p \in \mathcal{P}_n} \langle p, z\rangle = \overline{z} + \sqrt{\frac{2\rho s_n^2}{n}}.$$

For losses $\ell(\theta, X)$ with enough variance relative to $\ell(\theta, X_i) - \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X_i)]$, that is, those satisfying inequality (9), then, we have

$$R_n(\theta, \mathcal{P}_n) = \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] + \sqrt{\frac{2\rho \mathrm{Var}_{\widehat{P}_n}(\ell(\theta, X))}{n}}.$$

A slight elaboration of this argument, coupled with the application of a few concentration inequalities, yields the next theorem. The theorem as stated applies only to bounded random variables, but in subsequent sections we relax this assumption by applying the characterization (9) of the exact expansion. As usual, we assume that $\phi(t) = \frac{1}{2}(t-1)^2$ in our definition of the ϕ-divergence.

Theorem 1 *Let Z be a random variable taking values in $[0, M]$. Let $\sigma^2 = \mathrm{Var}(Z)$ and $s_n^2 = \mathbb{E}_{\widehat{P}_n}[Z^2] - \mathbb{E}_{\widehat{P}_n}[Z]^2$ denote the population and sample variance of Z, respectively. Fix $\rho \ge 0$. Then*

$$\left(\sqrt{\frac{2\rho}{n}s_n^2} - \frac{2M\rho}{n}\right)_+ \le \sup_P \left\{\mathbb{E}_P[Z] : D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}\right\} - \mathbb{E}_{\widehat{P}_n}[Z] \le \sqrt{\frac{2\rho}{n}s_n^2}. \tag{10}$$

Moreover, for $n \ge \max\left\{2, \frac{M^2}{\sigma^2}\max\{8\sigma, 44\}\right\}$, with probability at least $1 - \exp\left(-\frac{3n\sigma^2}{5M^2}\right)$

$$\sup_{P : D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[Z] = \mathbb{E}_{\widehat{P}_n}[Z] + \sqrt{\frac{2\rho}{n}s_n^2}. \tag{11}$$

See Section A for the proof of Theorem 1.

Inequality (10) and the exact expansion (11) show that, at least for bounded loss functions ℓ, the robustly regularized risk (4) is a natural (and convex) surrogate for empirical risk plus standard deviation of the loss, and the robust formulation approximates exact variance regularization with a convex penalty. In the sequel, we leverage this result to provide sharp guarantees for a number of stochastic risk minimization problems.

2.2. Uniform variance expansions

We now turn to a more uniform variant of Theorem 1, which depends on familiar notions of function complexity based on Rademacher averages. For a sample $x_1, \ldots, x_n$ and i.i.d. random signs $\varepsilon_i \in \{-1, 1\}$, independent of the x_i, the empirical Rademacher complexity of the class $\mathcal{F}$ is

$$\mathfrak{R}_n(\mathcal{F}) := \mathbb{E}\left[\sup_{f \in \mathcal{F}} \frac{1}{n}\sum_{i=1}^n \varepsilon_i f(x_i)\right].$$

The *worst-case* Rademacher complexity (Srebro et al., 2010) is

$$\mathfrak{R}_n^{\sup}(\mathcal{F}) := \sup_{x_1, \ldots, x_n \in \mathcal{X}} \mathbb{E}\left[\sup_{f \in \mathcal{F}} \left|\frac{1}{n}\sum_{i=1}^n \varepsilon_i f(x_i)\right|\right].$$

For example, when $\mathcal{F}$ is a class of functions bounded by M with VC-subgraph dimension d, we have the inequalities $\mathbb{E}[\mathfrak{R}_n(\mathcal{F})] \le \mathfrak{R}_n^{\sup}(\mathcal{F}) \lesssim M\sqrt{\frac{d}{n}}$. See van der Vaart and Wellner (1996, Chapter 2) and Bartlett and Mendelson (2002) for other bounds.

With this definition, we provide a result showing that the variance expansion (5) holds uniformly for all functions with *enough* variance.

Theorem 2 *Let $\mathcal{F}$ be a collection of bounded functions $f : \mathcal{X} \to [0, M]$, and $M \le n$. There exists a universal constant C such that if $\tau^2 > 0$ satisfies*

$$\tau^2 \ge \frac{4\rho M^2}{n} + C\left[\mathfrak{R}_n^{\sup}(\mathcal{F})^2 \log^3 n + \frac{M^2}{n}(t + \log\log n)\right].$$

Then with probability at least $1 - 3e^{-t}$

$$\sup_{P : D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[f(X)] = \mathbb{E}_{\widehat{P}_n}[f(X)] + \sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(f(X))} \tag{12}$$

for all $f \in \mathcal{F}$ such that $\mathrm{Var}(f) \ge \tau^2$.

We prove the theorem in Section B. Theorem 2 shows that the variance expansion of Theorem 1 holds uniformly for all functions f with sufficient variance. An asymptotic analogue of the equality (12) for heavier tailed random variables is also possible (Duchi et al., 2016). In the remainder of the section, we provide examples and applications of the theorem.

2.2.1. Linear and margin-based losses

Consider a standard margin-based classification problem (Bartlett and Mendelson, 2002), where we have data pairs $(x, y) \in \mathcal{X} \times \{-1, 1\}$, and $\mathcal{X} \subset \mathbb{R}^d$. Let $\Theta \subset \mathbb{R}^d$ be a norm ball of radius $r(\Theta)$, $\Theta = \{\theta \in \mathbb{R}^d \mid \|\theta\| \le r\}$, and let $\|\cdot\|_*$ be the associated dual norm, assuming also that $\mathcal{X} \subset \{x \in \mathbb{R}^d \mid \|x\|_* \le r(\mathcal{X})\}$. We may then consider the standard loss minimization setting, where for some non-increasing and 1-Lipschitz loss $\ell : \mathbb{R} \to \mathbb{R}_+$, we have the risk

$$R(\theta) := \mathbb{E}\left[\ell(Y \left\langle \theta, X \right\rangle)\right],$$

so that $\ell(y \left\langle x, \theta \right\rangle)$ is the loss suffered by making prediction $\langle \theta, x \rangle$ when the label is y. By taking the function class $\mathcal{F} = \{(x, y) \mapsto \ell(y \left\langle x, \theta \right\rangle) - \ell(0) \mid \theta \in \Theta\}$, in this case, an application of the Ledoux-Talagrand contraction inequality (Ledoux and Talagrand, 1991) implies for any $y_1, x_1, \ldots, y_n, x_n$ that

$$\mathbb{E}\left[\sup_{\theta \in \Theta} \left|\sum_{i=1}^n \varepsilon_i \left[\ell(y_i \left\langle \theta, x_i \right\rangle) - \ell(0)\right]\right|\right] \le \mathbb{E}\left[\sup_{\theta \in \Theta} \left|\sum_{i=1}^n \varepsilon_i \left\langle \theta, x_i \right\rangle\right|\right] \le r(\Theta)\mathbb{E}\left[\left\|\sum_{i=1}^n \varepsilon_i x_i\right\|_*\right]. \quad (13)$$

Example 1 (Euclidean norms) *In the above context, suppose that norm $\|\cdot\|$ is the standard ℓ_2 Euclidean norm so that Θ is contained in an ℓ_2-ball of radius $r(\Theta)$, and $\mathcal{X} \subset \mathbb{R}^d$ in an ℓ_2 ball of radius $r(\mathcal{X})$. Then Jensen's inequality and independence of ε_i's give the bound*

$$\mathbb{E}[\|\sum_{i=1}^n \varepsilon_i x_i\|] \le \sqrt{\mathbb{E}\sum_{j=1}^d \left(\sum_{i=1}^n \varepsilon_i x_{ij}\right)^2} \le r(\mathcal{X})\sqrt{n}.$$

Then, inequality (13) *and Theorem 1 imply that*

$$\sup_{P : D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[\ell(Y \left\langle \theta, X \right\rangle)] = \mathbb{E}_{\widehat{P}_n}[\ell(Y \left\langle \theta, X \right\rangle)] + \sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(\ell(Y \left\langle \theta, X \right\rangle))}$$

for all θ satisfying

$$\mathrm{Var}(\ell(Y \left\langle \theta, X \right\rangle)) \ge \frac{r(\mathcal{X})^2 r(\Theta)^2}{n}\left[4\rho + C\log^3 n + Ct\right],$$

with probability at least $1 - e^{-t}$.

Example 2 (High-dimensional problems) *In high dimensional problems, the Euclidean scaling of Example 1 may be problematic, so that using ℓ_1-constraints is preferred (Bühlmann and van de Geer, 2011). Thus, taking the norm $\|\cdot\|$ in the preceding to be the ℓ_1 norm, so that $\Theta \subset \{\theta \in \mathbb{R}^d \mid \|\theta\|_1 \le r_1(\Theta)\}$ and $\|\cdot\|_* = \|\cdot\|_\infty$, then $\mathbb{E}[\|\sum_{i=1}^n \varepsilon_i x_i\|_\infty] \le r(\mathcal{X})\sqrt{n\log(2d)}$, where $r_\infty(\mathcal{X})$ denotes the ℓ_∞-radius of $\mathcal{X} \subset \mathbb{R}^d$. Thus, if we take the loss class $\mathcal{F} = \{\ell(\langle \theta, \cdot \rangle) - \ell(0) \mid \theta \in \Theta\}$, we obtain*

$$\mathfrak{R}_n^{\sup}(\mathcal{F}) \lesssim \sup_{x_1, \ldots, x_n \in \mathcal{X}} \frac{r_1(\Theta)}{n}\mathbb{E}\left[\left\|\sum_{i=1}^n \varepsilon_i x_i\right\|_\infty\right] \le r_1(\Theta) r_\infty(\mathcal{X})\sqrt{\frac{\log(2d)}{n}}.$$

Then the exact variance expansion (12) *holds with probability at least $1 - e^{-t}$ uniformly over θ satisfying $\mathrm{Var}(\ell(Y \left\langle \theta, X \right\rangle)) \ge \frac{r_1(\Theta)^2 r_\infty(\mathcal{X})^2}{n}[4\rho + C\log d \cdot \log^3 n + Ct]$.*

2.2.2. Covering number guarantees

It is also possible to provide guarantees on the exact variance expansion using standard covering numbers, though careful arguments based on Rademacher complexity can be tighter. We begin by recalling the appropriate notions from approximation theory. Let $\mathcal{V}$ be a vector space and $V \subset \mathcal{V}$ be any collection of vectors in $\mathcal{V}$. Let $\|\cdot\|$ be a (semi)norm on $\mathcal{V}$. We say a collection $v_1, \ldots, v_N \subset \mathcal{V}$ is an *ϵ-cover* of $\mathcal{V}$ if for each $v \in \mathcal{V}$, there exists v_i such that $\|v - v_i\| \le \epsilon$. The *covering number* of V with respect to $\|\cdot\|$ is then

$$N(V, \epsilon, \|\cdot\|) := \inf\left\{N \in \mathbb{N} : \text{ there is an } \epsilon\text{-cover of } V \text{ with respect to } \|\cdot\|\right\}.$$

Now, let $\mathcal{F}$ be a collection of functions $f : \mathcal{X} \to \mathbb{R}$, and define the $L^\infty(\mathcal{X})$ norm on f by

$$\|f - g\|_{L^\infty(\mathcal{X})} := \sup_{x \in \mathcal{X}} |f(x) - g(x)|.$$

We also relax our covering number requirements to empirical ℓ_∞-covering numbers as follows. Define $\mathcal{F}(x) = \{(f(x_1), \ldots, f(x_n)) : f \in \mathcal{F}\}$ for $x \in \mathcal{X}^n$, and define the empirical ℓ_∞-covering numbers

$$N_\infty(\mathcal{F}, \epsilon, n) = \sup_{x \in \mathcal{X}^n} N\left(\mathcal{F}(x), \epsilon, \|\cdot\|_\infty\right),$$

which bound the number of ℓ_∞-balls of radius ϵ required to cover $\mathcal{F}(x)$. Note that we always have $N_\infty(\mathcal{F}, \epsilon, n) \le N(\mathcal{F}, \epsilon, \|\cdot\|_{L^\infty(\mathcal{X})})$ by definition. The classical Dudley entropy integral (Dudley, 1999; van der Vaart and Wellner, 1996) shows that, if P_n denotes the point masses on $x_1, \ldots, x_n$ and $\|\cdot\|_{L^2(P_n)}$ the empirical L^2-norm on functions $f : \mathcal{X} \to [-M, M]$, then

$$\begin{aligned}\mathbb{E}\left[\frac{1}{n}\sup_{f \in \mathcal{F}}\left|\sum_{i=1}^n \varepsilon_i f(x_i)\right|\right] &\lesssim \inf_{\delta \ge 0}\left\{\delta + \frac{1}{\sqrt{n}}\int_\delta^M \sqrt{\log N(\mathcal{F}, \epsilon, \|\cdot\|_{L^2(P_n)})}d\epsilon\right\} \\ &\le \inf_{\delta \ge 0}\left\{\delta + \frac{1}{\sqrt{n}}\int_\delta^M \sqrt{\log N_\infty(\mathcal{F}, \epsilon, n)}d\epsilon\right\}. \quad (14)\end{aligned}$$

Our main (essentially standard (van der Vaart and Wellner, 1996)) motivating example is that of Lipschitz loss functions for a parametric set Θ, as follows.

Example 3 *Let $\Theta \subset \mathbb{R}^d$ and assume that $\ell : \Theta \times \mathcal{X} \to [0, M]$ is L-Lipschitz in θ with respect to the ℓ_2-norm for all $x \in \mathcal{X}$, meaning that $|\ell(\theta, x) - \ell(\theta', x)| \le L\|\theta - \theta'\|_2$. Then taking $\mathcal{F} = \{\ell(\theta, \cdot) : \theta \in \Theta\}$, any ϵ-covering $\{\theta_1, \ldots, \theta_N\}$ of Θ in ℓ_2-norm guarantees that $\min_i |\ell(\theta, x) - \ell(\theta_i, x)| \le L\epsilon$ for all θ, x. That is,*

$$N(\mathcal{F}, \epsilon, \|\cdot\|_{L^\infty(\mathcal{X})}) \le N(\Theta, \epsilon/L, \|\cdot\|_2) \le \left(1 + \frac{\mathrm{diam}(\Theta)L}{\epsilon}\right)^d,$$

where $\mathrm{diam}(\Theta) = \sup_{\theta, \theta' \in \Theta}\|\theta - \theta'\|_2$. Thus ℓ_2-covering numbers of Θ control L^∞-covering numbers of the family $\mathcal{F}$, and we have by the entropy integral (14) *that*

$$\mathfrak{R}_n^{\sup}(\mathcal{F}) \lesssim \sqrt{\frac{d}{n}}\int_0^{\mathrm{diam}(\Theta)L}\sqrt{\log\frac{\mathrm{diam}(\Theta)L}{\epsilon}}d\epsilon \lesssim \mathrm{diam}(\Theta)L\sqrt{\frac{d}{n}}.$$

That is, with high probability, for all θ such that $\mathrm{Var}(\ell(\theta, X)) \ge \frac{4M^2\rho}{n} + \frac{Cd\,\mathrm{diam}(\Theta)^2L^2\log^3 n}{n}$, we have the exact variance expansion (12).

3. Optimization by Minimizing the Robust Loss

Based on the precise variance expansions in the preceding section, it is natural to expect that the robust solution (6) automatically trades between approximation and estimation error. This intuition is accurate, and we show that the robustly regularized objective $R_n(\theta; \mathcal{P}_n)$ overestimates the population risk $R(\theta)$ by at most $O(1/n)$. By virtue of optimizing this tighter approximation—as opposed to the usual $O(1/\sqrt{n})$-approximation given by the empirical risk $\mathbb{E}_{\widehat{P}_n}[\ell(\theta; X)]$—the robustly regularized solution (6) enjoys a number of favorable finite-sample properties, which are not always comparable to those for empirical risk minimization (ERM).

In Section 3.1, we present two versions of our main result that depend on covering numbers and discuss their consequences, and we provide an example where the robustly regularized solution $\widehat{\theta}_n^{\rm rob}$ achieves a tighter excess risk bound compared to those that a straightforward application of localized Rademacher complexities (Bartlett et al., 2005) show that the ERM solution $\widehat{\theta}_n^{\rm erm}$ achieves. As evidenced by the substantial work on Rademacher- and Gaussian-complexity and symmetrization, in some instances covering-number-based arguments do not provide the sharpest scaling (Bartlett and Mendelson, 2002; Bartlett et al., 2005; Srebro et al., 2010); thus, in Section 3.2 we present a version of our main result that depends on localized Rademacher complexities, which can allow more refined uniform concentration bounds than covering numbers. We also provide a concrete (but admittedly somewhat contrived) example where our robustly regularized procedure (6) achieves $R(\widehat{\theta}_n^{\rm rob}) - \inf_{\theta\in\Theta} R(\theta) \lesssim \frac{\log n}{n}$, while empirical risk minimization suffers $R(\widehat{\theta}_n^{\rm erm}) - \inf_{\theta\in\Theta} R(\theta) \gtrsim \frac{1}{\sqrt{n}}$, in Section 3.3. The robust "regularizer" has invariance properties other regularization procedures do not, and we mention these briefly in Section 3.4.

3.1. Covering arguments

Our first guarantee depends on the covering numbers of the function class $\mathcal{F}$ as we describe in Section 2.2.2. While we state our results abstractly, in the loss minimization setting we typically consider the function class $\mathcal{F} := \{\ell(\theta, \cdot) : \theta \in \Theta\}$ parameterized by θ. We have the following theorem, where as usual, we let $\mathcal{F}$ be a collection of functions $f : \mathcal{X} \to [M_0, M_1]$ with $M = M_1 - M_0$.

Theorem 3 *Let $n \geq 8M^2/t$, $t \geq \log 12$, $\epsilon > 0$, and $\rho \geq 9t$. Then with probability at least $1 - 2(3N_\infty(\mathcal{F}, \epsilon, 2n) + 1)e^{-t}$,*

$$\mathbb{E}[f(X)] \leq \sup_{P: D_\phi(P\|\widehat{P}_n) \leq \frac{\rho}{n}} \mathbb{E}_P[f(X)] + \frac{11}{3}\frac{M\rho}{n} + \left(2 + 4\sqrt{\frac{2t}{n}}\right)\epsilon \tag{15}$$

for all $f \in \mathcal{F}$. Defining the empirical minimizer

$$\widehat{f} \in \operatorname*{argmin}_{f\in\mathcal{F}} \left\{ \sup_P \left\{ \mathbb{E}_P[f(X)] : D_\phi(P\|\widehat{P}_n) \leq \frac{\rho}{n} \right\} \right\}$$

we have with the same probability that

$$\mathbb{E}[\widehat{f}(X)] \leq \inf_{f\in\mathcal{F}} \left\{ \mathbb{E}[f] + 2\sqrt{\frac{2\rho}{n}\mathrm{Var}(f)} \right\} + \frac{19M\rho}{3n} + \left(2 + 4\sqrt{\frac{2t}{n}}\right)\epsilon. \tag{16}$$

See Section C for a proof of the theorem. Because uniform L^∞-covering numbers upper bound empirical L^∞-covering numbers, it is immediate that covering $\mathcal{F}$ in $\|\cdot\|_{L^\infty(\mathcal{X})}$ provides an identical result.

3.1.1. Covering bounds: corollaries

We turn to a number of corollaries that expand on Theorem 3 to investigate its consequences. Our first corollary shows that Theorem 3 applies to standard Vapnik-Chervonenkis (VC) classes. As VC dimension is preserved through composition, this result also extends to the procedure (6) in typical empirical risk minimization scenarios.

Corollary 4 *In addition to the conditions of Theorem 3, let $\mathcal{F}$ have finite VC-dimension $\mathsf{VC}(\mathcal{F})$. Then for a numerical constant $c < \infty$, the bounds* (15) *and* (16) *hold with probability at least*

$$1 - \left(c\mathsf{VC}(\mathcal{F})\left(\frac{16Mne}{\epsilon}\right)^{\mathsf{VC}(\mathcal{F})-1} + 2\right)e^{-t}.$$

Proof Let $\|f\|_{L^1(Q)} := \int |f(x)| dQ(x)$ denote the L^1-norm on $\mathcal{F}$ for the probability distribution Q. Then by Theorem 2.6.7 of van der Vaart and Wellner (1996), we have

$$\sup_Q N(\mathcal{F}, \epsilon, \|\cdot\|_{L^1(Q)}) \leq c\mathsf{VC}(\mathcal{F})\left(\frac{8Me}{\epsilon}\right)^{\mathsf{VC}(\mathcal{F})-1}$$

for a numerical constant c. Because $\|x\|_\infty \leq \|x\|_1$, taking Q to be uniform on $x \in \mathcal{X}^{2n}$ yields $N(\mathcal{F}(x), \epsilon, \|\cdot\|_\infty) \leq N(\mathcal{F}, \frac{\epsilon}{2n}, \|\cdot\|_{L^1(Q)})$. The result is immediate. ■

Next, we focus more explicitly on the estimator $\widehat{\theta}_n^{\rm rob}$ defined by minimizing the robust regularized risk (6). Let us assume that $\Theta \subset \mathbb{R}^d$, and that we have a typical linear modeling situation, where a loss h is applied to an inner product, that is, $\ell(\theta, x) = h(\theta^\top x)$. In this case, by making the substitution that the class $\mathcal{F} = \{\ell(\theta, \cdot) : \theta \in \Theta\}$ in Corollary 4, we have $\mathsf{VC}(\mathcal{F}) \leq d$, and we obtain the following corollary. In the corollary, recall the definition (1) of the population risk $R(\theta) = \mathbb{E}[\ell(\theta, X)]$, and the uncertainty set $\mathcal{P}_n = \{P : D_\phi(P\|\widehat{P}_n) \leq \frac{\rho}{n}\}$, and that $R_n(\theta, \mathcal{P}_n) = \sup_{P\in\mathcal{P}_n} \mathbb{E}_P[\ell(\theta, X)]$. By setting $\epsilon = M/n$ in Corollary 4, we obtain the following result.

Corollary 5 *Let the conditions of the previous paragraph hold and let $\widehat{\theta}_n^{\rm rob} \in \operatorname{argmin}_{\theta\in\Theta} R_n(\theta, \mathcal{P}_n)$. Assume also that $\ell(\theta, x) \in [0, M]$ for all $\theta \in \Theta, x \in \mathcal{X}$. Then if $n \geq \rho \geq 9\log 12$,*

$$R(\widehat{\theta}_n^{\rm rob}) \leq R_n(\widehat{\theta}_n^{\rm rob}, \mathcal{P}_n) + \frac{11M\rho}{3n} + \frac{2M}{n}\left(1 + \sqrt{\frac{\rho}{n}}\right) \leq \inf_{\theta\in\Theta}\left\{ R(\theta) + 2\sqrt{\frac{2\rho}{n}\mathrm{Var}(\ell(\theta; X))} \right\} + \frac{11M\rho}{n}$$

with probability at least $1 - 2\exp(c_1 d\log n - c_2\rho)$, where c_i are universal constants with $c_2 \geq 1/9$.

To give an alternate concrete variant of Corollary 5 and Theorem 3, let $\Theta \subset \mathbb{R}^d$ and recall Example 3. We assume that for each $x \in \mathcal{X}$, $\inf_{\theta\in\Theta} \ell(\theta, x) = 0$ and that ℓ is L-Lipschitz in θ. If $D := \mathrm{diam}(\Theta) = \sup_{\theta,\theta'\in\Theta} \|\theta - \theta'\|_2 < \infty$, then $\ell(\theta, x) \leq L\,\mathrm{diam}(\Theta)$, and

for $\delta > 0$, we define

$$\rho = \log \frac{2}{\delta} + d \log(2nDL). \tag{17}$$

Setting $t = \rho$ and $\epsilon = \frac{1}{n}$ in Theorem 3 and assuming that $\delta \lesssim 1/n$, $D \lesssim n^k$ and $L \lesssim n^k$ for a numerical constant k, choosing $\delta = \frac{1}{n}$ we obtain that with probability at least $1-\delta = 1-1/n$,

$$\mathbb{E}[\ell(\widehat{\theta}_n^{\rm rob}; X)] = R(\widehat{\theta}_n^{\rm rob}) \le \inf_{\theta \in \Theta} \left\{ R(\theta) + C \sqrt{\frac{d \operatorname{Var}(\ell(\theta, X))}{n} \log n} \right\} + C \frac{dLD \log n}{n} \tag{18}$$

where C is a numerical constant.

3.1.2. Examples and heuristic discussion

Unpacking Theorem 3, the first result (15) (and its Corollary 5) provides a high-probability guarantee that the true expectation $\mathbb{E}[\widehat{f}]$ cannot be more than $O(1/n)$ worse than its robustly-regularized empirical counterpart. The second result (16) (and inequality (18)) guarantees convergence of the empirical minimizer to a parameter with risk at most $O(\log n/n)$ larger than the best possible variance-corrected risk.

To illustriate how variance regularization can yield tighter guarantees than empirical risk minimization by optimizing a $O(1/n)$ upper bound on the risk, we now compare the second bound (16) with an analogous result for empirical risk minimization (ERM). We first give a heuristic version, making it more precise in a coming example. For the ERM solution $\widehat{\theta}_n^{\rm erm} \in \operatorname{argmin}_{\theta \in \Theta} \mathbb{E}_{\widehat{P}_n}[\ell(\theta; X)]$, one common assumption is an upper bound of the variance by the risk; for example, when the losses take values in $[0, M]$, one has $\operatorname{Var}(\ell(\theta, X)) \le MR(\theta)$. In such cases, there is typically some complexity measure $\mathfrak{Comp}_n$ associated with the class of functions being learned, and it is possible to achieve bounds of the form

$$R(\widehat{\theta}_n^{\rm erm}) \le R(\theta^\star) + C \sqrt{\frac{\mathfrak{Comp}_n M R(\theta^\star)}{n}} + C \frac{\mathfrak{Comp}_n M}{n} \tag{19}$$

where $\theta^\star \in \operatorname{argmin}_{\theta \in \Theta} R(\theta)$, a type of result common for bounded nonnegative losses (Boucheron et al., 2005; Vapnik and Chervonenkis, 1971; Vapnik, 1998). For example, for classes of functions of VC-dimension d, we typically have $\mathfrak{Comp}_n \lesssim d \log \frac{n}{d}$. In this caricature, when $\operatorname{Var}(\ell(\theta^\star, X)) \ll MR(\theta^\star)$ and $\rho \gtrsim \mathfrak{Comp}_n$, the optimality guarantee (16) for variance regularization can be tighter than its ERM counterpart (19). This bound is certainly not always sharp, but yields minimax optimal rates in some cases.

Example 4 (Well-specified least-absolute-deviation regression) *For the least-absolute-deviation (LAD) regression, we compare rates of convergence for the ERM solution given by the localized Rademacher complexity against those for the robust solution. Let $Z = (X, Y) \in \mathbb{R}^d \times \mathbb{R}$, where $X \in \{x \in \mathbb{R}^d \mid \|x\|_2 \le L\}$, and let $D := \operatorname{diam}(\Theta)$ be the ℓ_2-diameter of Θ. The LAD loss is $\ell(\theta; (x, y)) := |y - \langle \theta, x \rangle|$, where we assume that $Y = \langle \theta^\star, X \rangle + \epsilon$ for some $\theta^\star \in \Theta$, and random noise $\epsilon \in [-B, B]$ independent of X. We then have the global bound $\ell(\theta; (X, Y)) \le DL + B =: M$. Suppose for simplicity that ϵ is uniform on $[-B, B]$; then $\theta^\star = \operatorname{argmin}_{\theta \in \Theta} R(\theta)$ and $R(\theta^\star) = \mathbb{E}[\ell(\theta^\star; Z)] = \frac{1}{2}B$. In this case,*

$$\operatorname{Var}\left(\ell(\theta^\star; Z)\right) = \frac{B^2}{12} \le \frac{1}{2}(DL + B)B = M \mathbb{E}[\ell(\theta^\star; Z)] = MR(\theta^\star).$$

Using that the loss is 1-Lipschitz, the L^∞ covering numbers for the set of functions $\mathcal{F} := \{f_\theta(x, y) = |\langle \theta, x \rangle - y| \mid \theta \in \Theta\}$ satisfy $\log N(\mathcal{F}, \epsilon, \|\cdot\|_{L^\infty(\mathcal{X})}) \lesssim d \log \frac{DL}{\epsilon}$, and so applying the bound (18) for the robustly regularized solution $\widehat{\theta}_n^{\rm rob}$ with $\epsilon = DL/n$, we obtain

$$R(\widehat{\theta}_n^{\rm rob}) \le R(\theta^\star) + C \sqrt{\frac{d \log n}{n} B^2} + C \frac{d(LD + B) \log n}{n}$$

with probability at least $1 - 1/n$. On the other hand, even an "optimistic" (but naive) ERM bound, achieved by taking $\mathfrak{Comp}_n \lesssim 1$ in the bound (19), yields

$$R(\widehat{\theta}_n^{\rm erm}) \le R(\theta^\star) + C \sqrt{\frac{\log n}{n}(BDL + B^2)} + C \frac{(LD + B) \log n}{n}$$

with probability at least $1-1/n$. We see that leading term for the robustly regularized solution $\widehat{\theta}_n^{\rm rob}$ only depends on the noise-level B^2 while the corresponding term for the ERM solution $\widehat{\theta}_n^{\rm erm}$ depends on global information like the size of the parameter space D, and a uniform bound over covariates L. For typical VC and other d-dimensional classes, the bound $\mathfrak{Comp}_n$ scales linearly in d (cf. (Bartlett et al., 2005, Corollary 3.7), in which case the bound (19) scales as $R(\theta^\star) + C\sqrt{d(BDL + B^2) \log n/n} + O(\log n/n)$, which is worse.

Example 5 (A hard median estimation problem) *To give a bit more insight into the behavior of the robust estimator, consider the simple 1-dimensional median problem, where $\ell(\theta; x) = |\theta - x|$, and assume that $x \in \{-B, B\}$ with $\mathbb{P}(X = B) = \frac{1+\delta}{2}$ for some $\delta > 0$, so that $\theta^\star = \operatorname{argmin} R(\theta) = B$ and $R(\theta^\star) = (1 - \delta)B$. In this case, taking $\theta_0 = 0$ yields $\operatorname{Var}(\ell(\theta; X)) = 0$ and $R(\theta_0) - R(\theta^\star) = \delta B$. For δ small (on the order of $1/\sqrt{n}$), with constant probability the empirical risk minimizer is $\widehat{\theta}_n^{\rm erm} = -B$, yielding risk $R(\widehat{\theta}_n^{\rm erm}) - R(\theta^\star) = 2\delta B$. On the other hand, with high probability $\widehat{\theta}_n^{\rm rob} \ge 0$ (because $\operatorname{Var}(\ell(\theta_0; X)) = 0$ as $\ell(0; X) \equiv B$), and so $R(\widehat{\theta}_n^{\rm rob}) - R(\theta^\star) \le \delta B$. This gap is of course small, but it shows that the robust solution is more conservative: it chooses $\widehat{\theta}_n^{\rm rob}$ so that large losses (of scale $2B$) are less frequent.*

When the population problem is "easy", it is often possible to achieve faster rates of convergence than the usual $O(1/\sqrt{n})$ rate. The simplest scenario where this occurs is if the problem is realizable $R(\theta^\star) = 0$, in which case $\widehat{\theta}_n^{\rm erm}$ has excess risk of the order $O(\log n/n)$; see the bound (19). The robustly regularized solution $\widehat{\theta}_n^{\rm rob}$ enjoys the same faster rates of convergence under the more general condition that $\operatorname{Var}(\ell(\theta^\star; X))$ is small. As a concrete instance of this, let $\ell(\theta; X) \in [0, M]$ and assume that $\ell(\theta; X)$ satisfies the conditions of the first part of Example 3, and let the problem be realizable $R(\theta^\star) = 0$. Since $\operatorname{Var}(\ell(\theta; X)) \le MR(\theta)$, we have from the bounds (18) and (19) that

$$R(\widehat{\theta}_n^{\rm erm}) \le \frac{CdDL \log n}{n} \quad \text{and} \quad R(\widehat{\theta}_n^{\rm rob}) \le \frac{CdDL \log n}{n}.$$

For example, $\operatorname{Var}(\ell(\theta; X)) = 0$ allows for the existence of some $\theta_0 \in \Theta$ such that $\ell(\theta_0; X) < \ell(\theta^\star; X)$ with positive probability.

3.2. Localized Rademacher Complexity

A somewhat more sophisticated approach to concentration inequalities and generalization bounds is based on localization ideas, motivated by the fact that near the optimum of an empirical risk, the complexity of the function class may be smaller than over the entire (global) class (van der Vaart and Wellner, 1996; Bartlett et al., 2005). With this in mind, we now present a refined version of Theorem 3 that depends on localized Rademacher averages.

The starting point for this approach is a notion of localized Rademacher complexity (we give a slightly less general notion than Bartlett et al. (2005), as it is sufficient for our derivations). For a function class $\mathcal{F}$ of functions $f : \mathcal{X} \to \mathbb{R}$, the localized Rademacher complexity at level r is

$$\mathbb{E}\left[\mathfrak{R}_n\left(\left\{cf \mid f \in \mathcal{F}, c \in [0,1], \mathbb{E}[c^2 f^2 \le r]\right\}\right)\right].$$

In addition, we require a few analytic notions, beginning with *sub-root* functions, where we recall (Bartlett et al., 2005) that a function $\psi : \mathbb{R}_+ \to \mathbb{R}_+$ is *sub-root* if it is nonnegative, nondecreasing, and $r \mapsto \psi(r)/\sqrt{r}$ is nonincreasing for all $r > 0$. Any non-constant sub-root function ψ is continuous and has a unique positive fixed point $r^\star = \psi(r^\star)$, where $r \ge \psi(r)$ for all $r \ge r^\star$. Lastly, we consider upper bounds $\psi_n : \mathbb{R}_+ \to \mathbb{R}_+$ on the localized Rademacher complexity satisfying

$$\psi_n(r) \ge \mathbb{E}[\mathfrak{R}_n(\{cf : f \in \mathcal{F}, c \in [0,1], \mathbb{E}[c^2 f^2] \le r\})], \tag{20}$$

where ψ_n is sub-root. (The localized Rademacher complexity itself is sub-root.) Roots of ψ_n play a fundamental role in providing uniform convergence guarantees, and Bartlett et al. (2005) and Koltchinskii (2006) provide careful analyses of localized Rademacher complexities, with typical results as follows. For a class of functions f with range bounded by 1, for any root $r_n^\star$ of ψ_n, with probability at least $1 - e^{-t}$ we have

$$\mathbb{E}[f] \le \mathbb{E}_{\widehat{P}_n}[f] + \frac{1}{\eta}\mathbb{E}_{\widehat{P}_n}[f] + C(1+\eta)\left(r_n^\star + \frac{1}{n}\right) + \frac{t}{n} \quad \text{for all } f \in \mathcal{F} \text{ and } \eta \ge 0.$$

As an example, when $\mathcal{F}$ is a bounded VC-class, we have $r_n^\star \asymp \frac{\mathsf{VC}(\mathcal{F})\log(n/\mathsf{VC}(\mathcal{F}))}{n}$ (Bartlett et al., 2005, Corollary 3.7).

With this motivation, we have the following theorem.

Theorem 6 *For $M \ge 1$, let $\mathcal{F}$ be a collection of functions $f : \mathcal{X} \to [0, M]$, let ψ_n be a sub-root function bounding the localized complexity* (20)*, and let $r_n^\star \ge \psi_n(r_n^\star)$. Let $t > 0$ be arbitrary and assume that ρ satisfies*

$$\frac{\rho}{n} \ge 8\left(\frac{45M}{n}\left(t + \log\left\lceil \log\frac{n}{t}\right\rceil\right) + 18 r_n^\star\right). \tag{21}$$

Then with probability at least $1 - e^{-t}$,

$$\mathbb{E}[f] \le \left(1 + 2\sqrt{\frac{2\rho}{n}}\right) \sup_{P : D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[f] + \left(13 + 4\sqrt{\frac{2\rho}{n}}\right)\frac{M\rho}{n} \quad \textit{for all } f \in \mathcal{F}. \tag{22}$$

Additionally, if $\widehat{f}$ minimizes $\sup_{P : D_\phi(P\|\widehat{P}_n) \le \rho/n} \mathbb{E}_P[f]$, then with probability at least $1 - 3e^{-t}$,

$$\mathbb{E}[\widehat{f}] \le \left(1 + 2\sqrt{\frac{2\rho}{n}}\right) \inf_{f \in \mathcal{F}} \left(\mathbb{E}[f] + \sqrt{\frac{91\rho}{45n}\mathrm{Var}(f)}\right) + \left(14 + 6\sqrt{\frac{2\rho}{n}}\right)\frac{M(3\rho + t)}{n}. \tag{23}$$

We provide the proof of Theorem 6 in Appendix D. It builds off of and parallels many of the techniques developed by Bartlett, Bousquet, and Mendelson (2005), but we require a bit of care to develop the precise variance bounds we provide.

Let us consider the additional $\sqrt{\frac{\rho}{n}}$ factors in Theorem 6 (as compared to Theorem 3). In general, these terms are negligible to the extent that the variance of f dominates the first moment of the function f—heuristically, in situations in which we expect penalizing the variance to improve performance. Let us make this more precise in a regime where n is large. Letting $f \in \mathcal{F}$, we see that we have the inequality

$$(1 + \sqrt{\rho/n})\left(\mathbb{E}[f] + \sqrt{\frac{\rho}{n}\mathrm{Var}(f)}\right) \le \mathbb{E}[f] + C\sqrt{\frac{\rho}{n}\mathrm{Var}(f)}$$

(for a constant $C > 1 + \sqrt{\rho/n}$) if and only if $(C - 1 - \sqrt{\rho/n})^2\mathrm{Var}(f) \ge \mathbb{E}[f]^2$. Equivalently, as n gets large, this occurs roughly when $\mathbb{E}[f^2] \ge \frac{C^2 - 2C + 2}{C^2 - 2C + 1}\mathbb{E}[f]^2$, which holds for large enough C whenever $\mathrm{Var}(f) > 0$.

In some scenarios, we can obtain substantially tighter bounds by using localized Rademacher averages instead of the covering number arguments considered in Section 3.1. (Recall also the discussion following Theorem 2.) To illustriate this point, we consider the case where $\mathcal{F}$ is a bounded subset of a reproducing kernel Hilbert space generated by some sufficiently nice kernel K; even for the Gaussian kernel $K(x, z) = \exp(-\frac{1}{2}\|x - z\|^2)$, log covering numbers for such function spaces grow at least exponentially in the dimension (Zhou, 2003; Kühn, 2011).

Example 6 (Reproducing kernels and least-absolute-deviation regression) *We now give an example using a non-parametric class of functionals in which covering number arguments do not apply, as the covering numbers of the associated classes are too large. Let $\mathcal{H}$ be a reproducing kernel Hilbert space (RKHS) with norm $\|\cdot\|_{\mathcal{H}}$ and associated kernel (representer of evaluation) $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. Letting P be a distribution on $\mathcal{X}$, Mercer's theorem (e.g. Cristianini and Shawe-Taylor, 2004) implies that the integral operator $T_K : L^2(\mathcal{X}, P) \to L^2(\mathcal{X}, P)$ defined by $T_K(f)(x) = \int K(x, z)dP(z)$ is compact, and $K(x, x') = \sum_{j=1}^\infty \lambda_j \phi_j(x)\phi_j(z)$ where λ_j are the eigenvalues of T in decreasing order and ϕ_j form an orthonormal decomposition of $L^2(\mathcal{X}, P)$.*

Consider now the least absolute deviation (LAD) loss function $\ell(h; x, y) = |h(x) - y|$, defined for $h \in \mathcal{H}$, and let $\mathbb{B}_{\mathcal{H}}$ be the unit $\|\cdot\|_{\mathcal{H}}$-ball of $\mathcal{H}$. Assume additionally that the model is well-specified, and that $y = h^\star(x) + \xi$ for some random variable ξ with $\mathbb{E}[\xi \mid X] = 0$, $\mathbb{E}[\xi^2] \le \sigma^2$, and $h^\star \in \mathbb{B}_{\mathcal{H}}$. Let the function class

$$\{\ell \circ \mathcal{H}\}_{\le r} := \left\{(x, y) \mapsto c\ell(h(x), y) \mid c \in [0,1], c^2\mathbb{E}[\ell(h(X), Y)^2] \le r\right\}.$$

Based on inequality (20)*, we consider the localized complexity*

$$\mathfrak{R}_n(\{\ell \circ \mathcal{H}\}_{\le r}) = \mathbb{E}\left[\frac{1}{n}\sup_{h \in \mathbb{B}_{\mathcal{H}}, c \in [0,1]} \sum \varepsilon_i c\ell(h(x_i), y_i) \mid \mathbb{E}[\ell(h(X), Y)^2] \le r/c^2\right].$$

We claim that

$$\mathfrak{R}_n(\{\ell \circ \mathcal{H}\}_{\le r}) \lesssim \sqrt{r/n} + \left(\frac{1}{n}\sum_{j=1}^{\infty} \min\{\lambda_j, r\}\right)^{\frac{1}{2}}. \tag{24}$$

As this claim is not central to our development—but does show a slightly different localization result based on Gaussian comparison inequalities than available, for example, in Mendelson (2003)—we provide its proof in Appendix G.1.

Let us use inequality (24)*. To apply Theorem 3, we must find a bound on the fixed point of the localized complexity. To give this bound, we require some knowledge on the eigenvalues λ_j, for which there exists a body of work. For example (Mendelson, 2003), the Gaussian kernel $K(x, x') = \exp(-\frac{1}{2}\|x - x'\|_2^2)$ generates a class of smooth functions for which the eigenvalues λ_j decay exponentially, as $\lambda_j \lesssim e^{-j^2}$. Kernel operators underlying Sobolev spaces with different smoothness orders (Birman and Solomjak, 1967; Gu, 2002) typically have eigenvalues scaling as $\lambda_j \lesssim j^{-2\alpha}$ for some $\alpha > \frac{1}{2}$. As a concrete example, the first-order Sobolev (min) kernel $K(x, x') = 1 + \min\{x, x'\}$ generates an RKHS of Lipschitz functions with $\alpha = 1$. In the former case of $\lambda_j \lesssim e^{-j^2}$, $r_n^\star = \frac{\sqrt{\log n}}{n}$*

$$\left(\frac{1}{n}\sum_{j=1}^{\infty} \min\left\{e^{-j^2}, \frac{\log n}{n}\right\}\right)^{\frac{1}{2}} \approx \left(\frac{1}{n}\sum_{j=1}^{\sqrt{\log n}} \frac{\sqrt{\log n}}{n} + \frac{1}{n}\int_{\sqrt{\log n}}^{\infty} e^{-t^2} dt\right)^{\frac{1}{2}} \lesssim \frac{\sqrt{\log n}}{n} = r_n^\star.$$

In the latter case of polynomially decaying eigenvalues $\lambda_j \lesssim j^{-2\alpha}$, we have $j^{-2\alpha} = r$ when $r^{-\frac{1}{2\alpha}} = j$, so

$$\sum_{j=1}^{\infty} \min\{j^{-2\alpha}, r\} \approx r^{\frac{2\alpha-1}{2\alpha}} + \int_{r^{-1/2\alpha}}^{\infty} t^{-2\alpha} dt \asymp r^{\frac{2\alpha-1}{2\alpha}}.$$

Solving for $nr = r^{\frac{2\alpha-1}{2\alpha}}$, we find the fixed point $(r_n^\star)^{\frac{2\alpha-1}{4\alpha}} = r_n^\star\sqrt{n}$ yields $r_n^\star = n^{-\frac{2\alpha}{2\alpha+1}}$.

Ignoring constants, the above analysis shows that in the case that the kernel eigenvalues scale as $\lambda_j \lesssim e^{-j^2}$, as soon as $\rho \gtrsim \sqrt{\log n}$ we have

$$\mathbb{E}[\ell(h(X), Y)] \le (1+2\sqrt{2\rho/n})\left(\mathbb{E}_{\widehat{P}_n}[\ell(h(X), Y)] + \sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(\ell(h(X), Y))}\right) + \frac{C\rho}{n} \quad \text{for all } h \in \mathbb{B}_{\mathcal{H}}$$

with high probability. In the case of polynomial eigenvalues, if $\widehat{h}$ minimizes the robust empirical loss $\sup_{P: D_\phi(P\|\widehat{P}_n) \le \rho/n} \mathbb{E}_P[\ell(h(X), Y)]$ and $\rho \asymp n^{1-\frac{2\alpha}{2\alpha+1}}$, then

$$\mathbb{E}\left[\ell(\widehat{h}(X), Y)\right] \le \left(1 + Cn^{-\frac{\alpha}{2\alpha+1}}\right) \inf_{h \in \mathbb{B}_{\mathcal{H}}} \left(\mathbb{E}[\ell(h(X), Y)] + Cn^{-\frac{\alpha}{2\alpha+1}}\sqrt{\mathrm{Var}(\ell(h(X), Y))}\right) + Cn^{-\frac{2\alpha}{2\alpha+1}}.$$

This rate of convergence holds without any assumptions on the smoothness of the distribution of the noise ξ.

3.3. Beating empirical risk minimization

We now provide a concrete example where the robustly regularized estimator $\widehat{\theta}_n^{\mathrm{rob}}$ exhibits a substantial performance gap over empirical risk minimization. In the sequel, we bound the

performance degradation to show that the formulation (6) in general loses little over empirical risk minimization. For intuition in this section, consider the (admittedly contrived) setting in which we replace the loss $\ell(\theta, X)$ with $\ell(\theta, X) - \ell(\theta^\star, X)$, where $\theta^\star \in \mathrm{argmin}_{\theta\in\Theta} R(\theta)$. Then in this case, by taking $\theta = \theta^\star$ in Corollary 5, we have $R(\widehat{\theta}_n^{\mathrm{rob}}) \le R(\theta^\star) + O(1/n)$ with high probability. More broadly, we expect the robustly regularized approach to offer performance benefits in situations in which the empirical risk minimizer is highly sensitive to noise, say, because the losses are piecewise linear, and slight under- or over-estimates of slope may significantly degrade solution quality.

With this in mind, we construct a concrete 1-dimensional example—estimating the median of a discrete distribution supported on $\mathcal{X} = \{-1, 0, 1\}$—in which the robustly regularized estimator has convergence rate $\log n/n$, while empirical risk minimization is at best $1/\sqrt{n}$. Define the loss $\ell(\theta; x) = |\theta - x| - |x|$, and for $\delta \in (0, 1)$ let the distribution P be defined by

$$P(X = 1) = \frac{1-\delta}{2}, \quad P(X = -1) = \frac{1-\delta}{2}, \quad P(X = 0) = \delta. \tag{25}$$

Then for $\theta \in \mathbb{R}$, the risk of the loss is

$$R(\theta) = \delta|\theta| + \frac{1-\delta}{2}|\theta - 1| + \frac{1-\delta}{2}|\theta + 1| - (1 - \delta).$$

By symmetry, it is clear that $\theta^\star := \mathrm{argmin}_\theta R(\theta) = 0$, which satisfies $R(\theta^\star) = 0$. (Note also that $\ell(\theta, x) = \ell(\theta, x) - \ell(\theta^\star, x)$.) Without loss of generality, we assume that $\Theta = [-1, 1]$ in this problem.

Now, consider a sample $X_1, \ldots, X_n$ drawn i.i.d. from the distribution P, let $\widehat{P}_n$ denote its empirical distribution, and define the empirical risk minimizer

$$\widehat{\theta}_n^{\mathrm{erm}} := \operatorname*{argmin}_{\theta\in\mathbb{R}} \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] = \operatorname*{argmin}_{\theta\in[-1,1]} \mathbb{E}_{\widehat{P}_n}[|\theta - X|].$$

If too many of the observations satisfy $X_i = 1$ or too many satisfy $X_i = -1$, then $\widehat{\theta}_n^{\mathrm{erm}}$ will be either 1 or -1; for small δ, such events become reasonably probable, as the following lemma makes precise. In the lemma, $\Phi(x) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x} e^{-\frac{1}{2}t^2} dt$ denotes the standard Gaussian CDF. (See Section G.2 for a proof.)

Lemma 7 *Let the loss $\ell(\theta; x) = |\theta - x| - |x|$, $\delta \in [0, 1]$, and X follow the distribution* (25)*. Then $R(\widehat{\theta}_n^{\mathrm{erm}}) - R(\theta^\star) \ge \delta$ with probability at least*

$$2\Phi\left(-\sqrt{\frac{n\delta^2}{1-\delta^2}}\right) - (1-\delta^2)^{\frac{n}{2}}\sqrt{\frac{8}{\pi n}}.$$

On the other hand, we certainly have $\ell(\theta^\star; x) = 0$ for all $x \in \mathcal{X}$, so that $\mathrm{Var}(\ell(\theta^\star; X)) = 0$. Now, consider the bound in Theorem 3. We see that $\log N(\{\ell(\theta, \cdot) : \theta \in \Theta\}, \epsilon, \|\cdot\|_{L^\infty(\mathcal{X})}) \le 2\log\frac{1}{\epsilon}$, and taking $\epsilon = \frac{1}{n}$, we have that if $\widehat{\theta}_n^{\mathrm{rob}} \in \mathrm{argmin}_{\theta\in\Theta} R_n(\theta, \mathcal{P}_n)$, then

$$R(\widehat{\theta}_n^{\mathrm{rob}}) \le R(\theta^\star) + \frac{15\rho}{n} \quad \text{with probability } \ge 1 - 4\exp\left(2\log n - \rho\right).$$

In particular, taking $\rho = 3\log n$, we see that

$$R(\widehat{\theta}_n^{\rm rob}) \le R(\theta^\star) + \frac{45\log n}{n} \quad \text{with probability at least } 1 - \frac{4}{n}.$$

The risk for the empirical risk minimizer, as Lemma 7 shows, may be substantially higher; taking $\delta = 1/\sqrt{n}$ we see that with probability at least $2\Phi(-\sqrt{\frac{n}{n-1}}) - 2\sqrt{2}/\sqrt{\pi e n} \ge 2\Phi(-\sqrt{\frac{n}{n-1}}) - n^{-\frac{1}{2}}$,

$$R(\widehat{\theta}_n^{\rm erm}) \ge R(\theta^\star) + n^{-\frac{1}{2}}.$$

(For $n \ge 20$, the probability of this event is $\ge .088$.) For this (specially constructed) example, there is a gap of nearly $n^{\frac{1}{2}}$ in order of convergence.

3.4. Invariance properties

The robust regularization (4) technique enjoys a number of invariance properties. Standard regularization techniques (such as ℓ_1- and ℓ_2-regularization), which generally regularize a parameter toward a particular point in the parameter space, do not. While we leave deeper discussion of these issues to future work, we make two observations, which apply when $\Theta = \mathbb{R}^d$ is unconstrained. Throughout, we let $\widehat{\theta}_n^{\rm rob} \in \operatorname{argmin}_\theta R_n(\theta, \mathcal{P}_n)$ denote the robustly regularized empirical solution.

First, consider a location estimation problem in which we wish to estimate the minimizer of the expectation of a loss of the form $\ell(\theta, X) = h(\theta - X)$, where $h : \mathbb{R}^d \to \mathbb{R}$ is convex and symmetric about zero. Then the robust solution is by inspection shift invariant, as $\ell(\theta + c, X + c) = \ell(\theta, X)$ for any vector $c \in \mathbb{R}^d$. Concretely, in the example of the previous section, ℓ_1- or ℓ_2-regularization achieve better convergence guarantees than ERM does, but if we shift all data $x \mapsto x + c$, then non-invariant regularization techniques lose efficiency (while the robust regularization technique does not). Second, we may consider a generalized linear modeling problem, in which data comes in pairs $(x, y) \in \mathcal{X} \times \mathcal{Y}$ and $\ell(\theta, (x, y)) = h(y, \theta^\top x)$ for a function $h : \mathcal{Y} \times \mathbb{R} \to \mathbb{R}$ that is convex in its second argument. Then $\widehat{\theta}_n^{\rm rob}$ is invariant to invertible linear transformations, in the sense that for any invertible $A \in \mathbb{R}^{d\times d}$,

$$\operatorname*{argmin}_\theta \left\{ \sup_{P: D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[\ell(\theta, (X, Y))] \right\} = \operatorname*{argmin}_\theta \left\{ \sup_{P: D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[\ell(A^{-1}\theta, (AX, Y))] \right\} = \widehat{\theta}_n^{\rm rob}.$$

Our results in this section do not precisely apply as we require unbounded θ, however, the next section shows that localization approaches can address this.

4. Robust regularization cannot be too bad

The previous two sections provide guarantees on the performance of the robust regularized estimator (6), it does not—cannot—dominate classical approaches based on empirical risk minimization (also known as sample average approximation in the stochastic optimization literature), though it can improve on them in some cases. For example, with a correctly specified linear regression model with gaussian noise, least-squares—empirical risk minimization with the loss $\ell(\theta, (x, y)) = \frac{1}{2}(\theta^\top x - y)^2$—is essentially optimal. Our goal in this section is thus to provide more understanding of potential poor behavior of the procedure (6) with

respect to ERM, considering two scenarios. The first is in stochastic (convex) optimization problems, where we investigate the finite-sample convergence rates of the robust solution to the population optimal risk. We show that the robust solution $\widehat{\theta}_n^{\rm rob}$ enjoys fast rates of convergence in cases in which the risk has substantial curvature—precisely as with empirical risk minimization. The second is to consider the asymptotics of the robust solution $\widehat{\theta}_n^{\rm rob}$, where we show that in classical statistical scenarios the robust solution is nearly efficient, though there is an asymptotic bias of order $1/\sqrt{n}$ that scales with the confidence ρ.

4.1. Fast Rates

In cases in which the risk R has curvature, empirical risk minimization often enjoys faster rates of convergence (Boucheron et al., 2005; Shapiro et al., 2009). The robust solution $\widehat{\theta}_n^{\rm rob}$ similarly attains faster rates of convergence in such cases, even with approximate minimizers of $R_n(\theta, \mathcal{P}_n)$. For the risk R and $\epsilon \ge 0$, let

$$S_\star^\epsilon := \left\{ \theta \in \Theta : R(\theta) \le \inf_{\theta^\star \in \Theta} R(\theta^\star) + \epsilon \right\}$$

denote the ϵ-sub-optimal (solution) set, and similarly let

$$\widehat{S}_\star^\epsilon := \left\{ \theta \in \Theta : R_n(\theta, \mathcal{P}_n) \le \inf_{\theta' \in \Theta} R_n(\theta', \mathcal{P}_n) + \epsilon \right\}.$$

For a vector $\theta \in \Theta$, let $\pi_{S_\star}(\theta) = \operatorname{argmin}_{\theta^\star \in S_\star} \|\theta^\star - \theta\|_2$ denote the Euclidean projection of θ onto the set $S_\star$; this projection operator is very useful for showing faster rates of convergence in stochastic optimization (see Shapiro et al. (2009), whose techniques we closely follow). In the statement of the result, for $A \subset \Theta$, we let $\mathfrak{R}_n(A)$ denote the Rademacher complexity of the localized process $\{x \mapsto \ell(\theta; x) - \ell(\pi_{S_\star}(\theta); x) : \theta \in A\}$. We then have the following result, whose proof we provide in Section E.

Theorem 8 *Let Θ be convex and let $\ell(\cdot; x)$ be convex and L-Lipshitz in its first argument for all $x \in \mathcal{X}$. For constants $\lambda > 0$, $\gamma > 1$, and $r > 0$, assume the risk R satisfies*

$$R(\theta) - \inf_{\theta \in \Theta} R(\theta) \ge \lambda \operatorname{dist}(\theta, S_\star)^\gamma \quad \text{for all } \theta \text{ such that } \operatorname{dist}(\theta, S_\star) \le r. \tag{26}$$

Let $t > 0$. If $0 \le \epsilon \le \frac{1}{2}\lambda r^\gamma$ satisfies

$$\epsilon \ge \left(2\frac{8^\gamma L^\gamma}{\lambda}\right)^{\frac{1}{\gamma-1}} \left(\frac{\rho}{n}\right)^{\frac{\gamma}{2(\gamma-1)}} \quad \text{and} \quad \frac{\epsilon}{2} \ge 2\mathbb{E}[\mathfrak{R}_n(S_\star^{2\epsilon})] + L\left(\frac{2\epsilon}{\lambda}\right)^{\frac{1}{\gamma}} \sqrt{\frac{2t}{n}}, \tag{27}$$

then $\mathbb{P}(\widehat{S}_\star^\epsilon \subset S_\star^{2\epsilon}) \ge 1 - e^{-t}$,

We provide a brief discussion of this result as well as a corollary that gives more explicit rates of convergence. First, we note that (by an inspection of the proof) the L-Lipschitz assumption need only hold in the neighborhood $S_\star^{2\epsilon}$ for the result to hold. We also have the following

Corollary 9 *In addition to the conditions of Theorem 8, assume that $S_\star = \{\theta^\star\}$ is a single point and $\Theta \subset \mathbb{R}^d$. Then for any $\epsilon \le \frac{1}{2}\lambda r^\gamma$, we have $\mathbb{P}(\widehat{S}_\star^\epsilon \subset S_\star^{2\epsilon}) \ge 1 - e^{-t}$ for*

$$\epsilon \gtrsim \left(\frac{L^\gamma}{\lambda}\right)^{\frac{1}{\gamma-1}} \left(\frac{d}{n}\log\frac{n}{d} + \frac{t}{n} + \frac{\rho}{n}\right)^{\frac{\gamma}{2(\gamma-1)}}.$$

So long as $\rho \lesssim d \log \frac{n}{d}$, this rate of convergence is as good as that enjoyed by standard empirical risk minimization approaches (Shapiro et al., 2009, Ch. 5) under these types of growth conditions. The case that $\gamma = 2$ corresponds (roughly) to strong convexity, and in this case we get the approximate rate of convergence of $\frac{L^2}{\lambda}\frac{d\log\frac{n}{d}}{n}$, the familiar rate of convergence under these conditions. Of course, if there is too much variance penalization (i.e. ρ is too large), then the rates of convergence may be slower.

Proof That $S_\star$ is a singleton implies that $S_\star^{2\epsilon} \subset \{\theta \mid \|\theta - \theta^\star\| \le (2\epsilon/\lambda)^{\frac{1}{\gamma}}\}$. Moreover, in this case we also have that

$$\left|\mathbb{E}_{\widehat{P}_n}[\ell(\theta; X) - \ell(\theta^\star; X)] - \mathbb{E}_{\widehat{P}_n}[\ell(\theta'; X) - \ell(\theta^\star; X)]\right| \le L\left\|\theta - \theta'\right\|,$$

so that an ϵ/L-cover of $\{\theta \mid \|\theta - \theta^\star\| \le (2\epsilon/\lambda)^{\frac{1}{\gamma}}\}$ is an ϵ-cover of the function class $\mathcal{F} = \{f(x) = \ell(\theta; x) - \ell(\theta^\star; x) \mid \theta \in S_\star^{2\epsilon}\}$ in $\|\cdot\|_{L^2(P_n)}$ norm. Thus, the standard Dudley entropy integral (Dudley, 1999; van der Vaart and Wellner, 1996) yields

$$\begin{aligned}\mathbb{E}[\mathfrak{R}_n(S_\star^{2\epsilon})] &\lesssim \frac{1}{\sqrt{n}}\int_0^\infty \sqrt{\log N(\mathcal{F}, \delta, \|\cdot\|_{L^2(P_n)})}d\delta \\ &\lesssim \frac{1}{\sqrt{n}}\int_0^{L(2\epsilon/\lambda)^{\frac{1}{\gamma}}} \sqrt{d\log\frac{L}{\delta}}d\delta \le L\sqrt{\frac{d}{n}}\left(\frac{2\epsilon}{\lambda}\right)^{\frac{1}{\gamma}}\sqrt{1 + \frac{1}{\gamma}\log\frac{\lambda}{2L^\gamma\epsilon}}\end{aligned}$$

where we have used that $\int_0^\varepsilon \sqrt{\log\frac{L}{\delta}}d\delta \le \varepsilon\sqrt{1 + \log\frac{L}{\varepsilon}}$. Solving for ϵ in the localization inequality (27) then yields the corollary, showing that the specified choice of ϵ is sufficient for all the conditions (27) to hold. ∎

4.2. Asymptotics

It is important to understand the precise limiting behavior of the robust estimator in addition to its finite sample properties—this allows us to more precisely characterize when there may be *degradation* relative to classical risk minimization strategies. With that in mind, in this section we provide asymptotic results for the robust solution (6) to better understand the consequences of penalizing the variance of the loss itself. In particular, we would like to understand efficiency losses relative to (say) maximum likelihood in situations in which maximum likelihood is efficient. Before stating the results, we make a few standard assumptions on the risk $R(\theta)$, the loss ℓ, and the moments of ℓ and its derivatives. Concretely, we assume that

$$\theta^\star := \operatorname*{argmin}_\theta R(\theta) \quad \text{and} \quad \nabla^2 R(\theta^\star) \succ 0,$$

that is, the risk functional has strictly positive definite Hessian at $\theta^\star$, which is thus unique. Additionally, we have the following smoothness assumptions on the loss function, which are satisfied by common loss functions, including the negative log-likelihood for any exponential family or generalized linear model (Lehmann and Casella, 1998). In the assumption, we let $\mathbb{B}$ denote the ℓ_2-ball of radius 1 in $\mathbb{R}^d$.

Assumption A *For some $\epsilon > 0$, there exists a function $L : \mathcal{X} \to \mathbb{R}_+$ satisfying*

$$|\ell(\theta, x) - \ell(\theta', x)| \le L(x)\left\|\theta - \theta'\right\|_2 \quad \text{for } \theta, \theta' \in \theta^\star + \epsilon\mathbb{B}$$

and $\mathbb{E}[L(X)^2] \le L(P) < \infty$. Additionally, there is a function H such that the function $\theta \mapsto \ell(\theta, x)$ has $H(x)$-Lipschitz continuous Hessian (with respect to the Frobenius norm) on $\theta^\star + \epsilon\mathbb{B}$, where $\mathbb{E}[H(X)^2] < \infty$.

Then, recalling the robust estimator (6) as the minimizer of $R_n(\theta, \mathcal{P}_n)$, we have the following theorem, which we prove in Section F.

Theorem 10 *Let Assumption A hold, and let the sequence $\widehat{\theta}_n^{\rm rob}$ be defined by $\widehat{\theta}_n^{\rm rob} \in \operatorname{argmin}_\theta R_n(\theta, \mathcal{P}_n)$. Define*

$$b(\theta^\star) := \frac{\operatorname{Cov}(\nabla_\theta \ell(\theta^\star, X), \ell(\theta^\star, X))}{\sqrt{\operatorname{Var}(\ell(\theta^\star, X))}} \quad \text{and} \quad \Sigma(\theta^\star) = \left(\nabla^2 R(\theta^\star)\right)^{-1}\operatorname{Cov}(\nabla\ell(\theta^\star, X))\left(\nabla^2 R(\theta^\star)\right)^{-1}.$$

Then $\widehat{\theta}_n^{\rm rob} \stackrel{a.s.}{\to} \theta^\star$ and

$$\sqrt{n}(\widehat{\theta}_n^{\rm rob} - \theta^\star) \stackrel{d}{\to} \mathsf{N}\left(-\sqrt{2\rho}\, b(\theta^\star), \Sigma(\theta^\star)\right)$$

The asymptotic variance $\Sigma(\theta^\star)$ in Theorem 10 is generally unimprovable, as made apparent by Le Cam's local asymptotic normality theory and the Hájek-Le Cam local minimax theorems (van der Vaart and Wellner, 1996). Thus, Theorem 10 shows that the robust regularized estimator (6) has some efficiency loss, but it is only in the bias term. We explore this a bit more in the context of the risk of $\widehat{\theta}_n^{\rm rob}$. Letting $W \sim \mathsf{N}(0, \Sigma(\theta^\star))$, as an immediate corollary to this theorem, the delta-method implies that

$$n\left[R(\widehat{\theta}_n^{\rm rob}) - R(\theta^\star)\right] \stackrel{d}{\to} \frac{1}{2}\left\|\sqrt{2\rho}\, b(\theta^\star) + W\right\|^2_{\nabla^2 R(\theta^\star)}, \tag{28}$$

where we recall that $\|x\|_A^2 = x^\top A x$. This follows from a Taylor expansion, because $\nabla R(\theta^\star) = 0$ and so $R(\theta) - R(\theta^\star) = \frac{1}{2}(\theta - \theta^\star)^\top\nabla^2 R(\theta^\star)(\theta - \theta^\star) + o(\|\theta - \theta^\star\|^2)$, or

$$\begin{aligned}n(R(\widehat{\theta}_n^{\rm rob}) - R(\theta^\star)) &= n\left(\frac{1}{2}(\widehat{\theta}_n^{\rm rob} - \theta^\star)^\top\nabla^2 R(\theta^\star)(\widehat{\theta}_n^{\rm rob} - \theta^\star) + o(\|\widehat{\theta}_n^{\rm rob} - \theta^\star\|^2)\right) \\ &= \frac{1}{2}\left(\sqrt{n}(\widehat{\theta}_n^{\rm rob} - \theta^\star)\right)^\top\nabla^2 R(\theta^\star)\left(\sqrt{n}(\widehat{\theta}_n^{\rm rob} - \theta^\star)\right) + o_P(1) \\ &\stackrel{d}{\to} \frac{1}{2}(\sqrt{2\rho}\, b(\theta^\star) + W)^\top\nabla^2 R(\theta^\star)(\sqrt{2\rho}\, b(\theta^\star) + W)\end{aligned}$$

by Theorem 10.

The limiting random variable in expression (28) has expectation

$$\frac{1}{2}\mathbb{E}[\|\sqrt{2\rho}b(\theta^\star) + W\|^2_{\nabla^2 R(\theta^\star)}] = \rho b(\theta^\star)^\top \nabla^2 R(\theta^\star) b(\theta^\star) + \frac{1}{2}\operatorname{tr}(\nabla^2 R(\theta^\star)^{-1}\operatorname{Cov}(\ell(\theta^\star, X)),$$

while the classical empirical risk minimization procedure (standard M-estimation) (Lehmann and Casella, 1998; van der Vaart and Wellner, 1996) has limiting mean-squared error $\frac{1}{2}\operatorname{tr}(\nabla^2 R(\theta^\star)^{-1}\operatorname{Cov}(\ell(\theta^\star, X)))$. Thus there is an additional $\rho\,\|b(\theta^\star)\|^2_{\nabla^2 R(\theta^\star)}$ penalty in the asymptotic risk (at a rate of $1/n$) for the robustly-regularized estimator. An inspection of the proof of Theorem 10 reveals that $b(\theta^\star) = \nabla_\theta \sqrt{\operatorname{Var}(\ell(\theta^\star, X))}$; if the variance of the loss is stable near $\theta^\star$, so that moving to a parameter $\theta = \theta^\star + \Delta$ for some small Δ has little effect on the variance, then the standard loss terms dominate, and robust regularization has asymptotically little effect. On the other hand, highly unstable loss functions for which $\nabla_\theta \sqrt{\operatorname{Var}(\ell(\theta^\star, X))}$ is large yield substantial bias.

We conclude our study of the asymptotics with a (to us) somewhat surprising example. Consider the classical linear regression setting in which $y = x^\top\theta^\star + \varepsilon$, where $\varepsilon \sim \mathsf{N}(0, \sigma^2)$. Using the standard squared error loss $\ell(\theta, (x, y)) = \frac{1}{2}(\theta^\top x - y)^2$, we obtain that

$$\nabla\ell(\theta^\star, (x, y)) = (x^\top\theta^\star - y)x = (x^\top\theta^\star - x^\top\theta^\star - \varepsilon)x = -\varepsilon x,$$

while $\ell(\theta^\star, (x, y)) = \frac{1}{2}\varepsilon^2$. The covariance $\operatorname{Cov}(\varepsilon X, \varepsilon^2) = \mathbb{E}[\varepsilon X(\varepsilon^2 - \sigma^2)] = 0$ by symmetry of the error distribution, and so—in the special classical case of correctly specified linear regression—the bias term $b(\theta^\star) = 0$ for linear regression in Theorem 10. That is, the robustly regularized estimator (6) is asymptotically efficient.

5. Experiments

We present three experiments in this section. The first is a small simulation example, which serves as a proof of concept allowing careful comparison of standard empirical risk minimization (ERM) strategies to our variance-regularized approach. The latter two are classification problems on real datasets; for both of these we compare performance of robust solution (6) to its ERM counterpart.

5.1. Minimizing the robust objective

As a first step, we give a brief description of our (essentially standard) method for solving the robust risk problem. Our work in this paper focuses mainly on the properties of the robust objective (4) and its minimizers (6), so we only briefly describe the algorithm we use; we leave developing faster and more accurate specialized methods to further work. To solve the robust problem, we use a gradient descent-based procedure, and we focus on the case in which the empirical sampled losses $\{\ell(\theta, X_i)\}_{i=1}^n$ have non-zero variance for all parameters $\theta \in \Theta$, which is the case for all of our experiments.

Recall the definition of the subdifferential $\partial f(\theta) = \{g \in \mathbb{R}^d : f(\theta') \geq f(\theta) + \langle g, \theta' - \theta\rangle \text{ for all } \theta'\}$, which is simply the gradient for differentiable functions f. A standard result in convex analysis (Hiriart-Urruty and Lemaréchal, 1993, Theorem VI.4.4.2) is that if the vector $p^* \in \mathbb{R}^n_+$ achieving the supremum in the definition (4) of the robust risk is unique, then

$$\partial_\theta R_n(\theta, \mathcal{P}_n) = \partial_\theta \sup_{P \in \mathcal{P}_n} \mathbb{E}_P[\ell(\theta; X)] = \sum_{i=1}^n p_i^* \partial_\theta \ell(\theta; X_i),$$

where the final summation is the standard Minkowski sum of sets. As this maximizing vector p is indeed unique whenever $\operatorname{Var}_{\widehat{P}_n}(\ell(\theta; X)) \neq 0$, we see that for all our problems, so long as ℓ is differentiable, so too is $R_n(\theta, \mathcal{P}_n)$ and

$$\nabla_\theta R_n(\theta, \mathcal{P}_n) = \sum_{i=1}^n p_i^* \nabla_\theta \ell(\theta; X_i) \;\text{ where }\; p^* = \operatorname*{argmax}_{p \in \mathcal{P}_n} \left\{ \sum_{i=1}^n p_i \ell(\theta; X_i) \right\}. \tag{29}$$

In order to perform gradient descent on the risk $R_n(\theta, \mathcal{P}_n)$, then, by equation (29) we require only the computation of the worst-case distribution p^*. By taking the dual of the maximization (29), this is an efficiently solvable convex problem; for completeness, we provide a procedure for this computation in Section H that requires time $O(n \log n + \log\frac{1}{\epsilon}\log n)$ to compute an ϵ-accurate solution to the maximization (29). As all our examples have smooth objectives, we perform gradient descent on the robust risk $R_n(\cdot, \mathcal{P}_n)$, with stepsizes chosen by a backtracking (Armijo) line search (Boyd and Vandenberghe, 2004, Chapter 9.2).

5.2. Simulation experiment

For our simulation experiment, we use a quadratic loss with linear perturbation. For $v, x \in \mathbb{R}^d$, define the loss $\ell(\theta; x) = \frac{1}{2}\|\theta - v\|_2^2 + x^\top(\theta - v)$. We set $d = 50$ and take $X \sim \mathsf{Uni}(\{-B, B\}^d)$, varying B in the experiment. For concreteness, we let the domain $\Theta = \{\theta \in \mathbb{R}^d : \|\theta\|_2 \leq r\}$ and set $v = \frac{r}{2\sqrt{d}}\mathbf{1}$, so that $v \in \operatorname{int}\Theta$; we take $r = 10$. Notably, standard regularization strategies, such as ℓ_1 or ℓ_2-regularization, pull θ toward 0, while the variance of $\ell(\theta; X)$ is minimized by $\theta = v$ (thus naturally advantaging the variance-based regularization we consider, as $R(v) = \inf_\theta R(\theta) = 0$). Moreover, as X is pure noise, this is an example where we expect variance regularization to be particularly useful. We choose $\delta = .05$ and set ρ as in Eq. (17) (using that ℓ is $(3r + \sqrt{d}B)$-Lipschitz) to obtain robust coverage with probability at least $1 - \delta$. In our experiments, we obtained 100% coverage in the sense of (15), as the high probability bound is conservative.

Figure 2 summarizes the results. The robust solution $\widehat{\theta}_n^{\text{rob}} = \operatorname{argmin}_{\theta\in\Theta} R_n(\theta, \mathcal{P}_n)$ always outperforms the empirical risk minimizer $\widehat{\theta}_n^{\text{erm}} = \operatorname{argmin}_{\theta\in\Theta} \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)]$ in terms of the true risk $\mathbb{E}[\ell(\theta, X)] = \frac{1}{2}\|\theta - v\|_2^2$. Each experiment consists of 1,200 independent replications for each sample size n and value B. In Tables 1 and 2, we display the risks of $\widehat{\theta}_n^{\text{erm}}$ and $\widehat{\theta}_n^{\text{rob}}$ and variances, respectively, computed for the 1,200 independent trials. The gap between the risk of $\widehat{\theta}_n^{\text{erm}}$ and $\widehat{\theta}_n^{\text{rob}}$ is siginificant at level $p < .01$ for all sample sizes and values of B we considered according to a one-sided T-test. Notice also in Table 2 that the variance of the robust solutions is substantially smaller than that of the empirical risk minimizer—often several orders of magnitude smaller for large sample sizes n. This simulation shows that—in a simple setting favorable to it—our procedure outperforms standard alternatives.

. Code is available at `https://github.com/hsnamkoong/robustopt`.

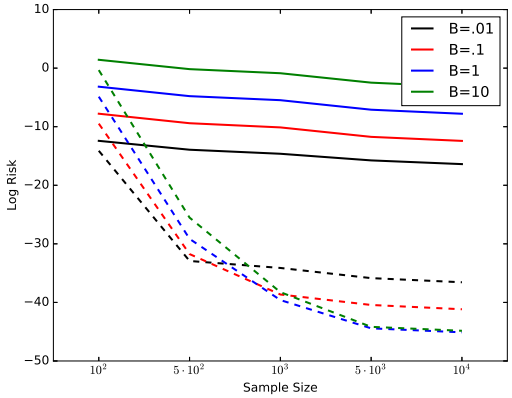

Figure 2. Simulation experiment. $\log \mathbb{E}[R(\widehat{\theta}_n^{\rm erm})]$ is the solid lines, in decreasing order from $B = 10$ (top) to $B = .01$ (bottom). $\log \mathbb{E}[R(\widehat{\theta}_n^{\rm rob})]$ is the dashed line, in the same vertical ordering at sample size $n = 10^2$.

5.3. Protease cleavage experiments

For our second experiment, we compare our robust regularization procedure to other regularizers using the HIV-1 protease cleavage dataset from the UCI ML-repository (Lichman, 2013). In this binary classification task, one is given a string of amino acids (a protein) and a featurized representation of the string of dimension $d = 50960$, and the goal is to predict whether the HIV-1 virus will cleave the amino acid sequence in its central position. We have a sample of $n = 6590$ observations of this process, where the class labels are somewhat skewed: there are 1360 examples with label $Y = +1$ (HIV-1 cleaves) and 5230 examples with $Y = -1$ (does not cleave).

We use the logistic loss $\ell(\theta; (x, y)) = \log(1+\exp(-y\theta^\top x))$. We compare the performance of different constraint sets Θ by taking

$$\Theta = \left\{\theta \in \mathbb{R}^d : a_1 \left\|\theta\right\|_1 + a_2 \left\|\theta\right\|_2 \le r\right\},$$

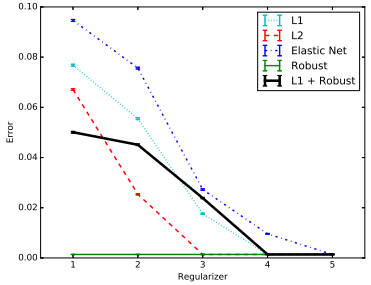

Table 2: Simulation experiment: Variances of $R(\widehat{\theta})$ over 1,200 simulations

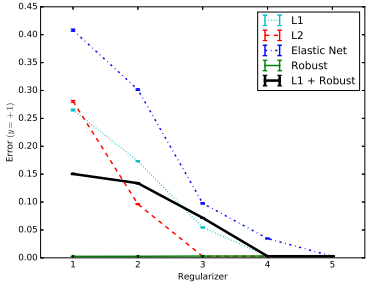
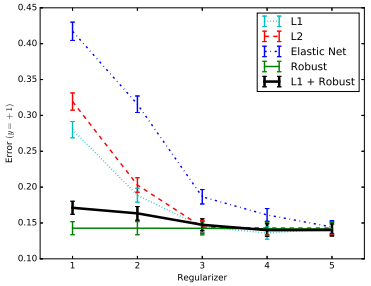
which is equivalent to elastic net regularization (Zou and Hastie, 2005), while varying a_1, a_2, and r. We experiment with ℓ_1-constraints ($a_1 = 1, a_2 = 0$) with $r \in \{50, 100, 500, 1000, 5000\}$, ℓ_2-constraints ($a_1 = 0, a_2 = 1$) with $r \in \{5, 10, 50, 100, 500\}$, elastic net ($a_1 = 1, a_2 = 10$) with $r \in \{100, 200, 1000, 2000, 10000\}$, our robust regularizer with $\rho \in \{100, 1000, 10000, 50000, 100000\}$ and our robust regularizer coupled with the ℓ_1-constraint ($a_1 = 1, a_2 = 0$) with $r = 100$. Though we use a convex surrogate (logistic loss), we measure performance of the classifiers using the 0-1 (misclassification) loss $1\{\text{sign}(\theta^T x)y \le 0\}$. For validation, we perform 50 experiments, where in each experiment we randomly select 9/10 of the data to train the model, evaluating its performance on the held out fraction (test).

We plot results summarizing these experiments in Figure 3. The horizontal axis in each figure indexes our choice of regularization value (so "`Regularizer = 1`" for the ℓ_1-constrained problem corresponds to $r = 50$). The figures show that the robustly regularized risk provides a different type of protection against overfitting than standard regularization or constraint techniques do: while other regularizers underperform in heavily constrained settings, the robustly regularized estimator $\widehat{\theta}_n^{\rm rob}$ achieves low classification error for all values of ρ (Figure 3(b)). Notably, even when coupled with a fairly stringent ℓ_1-constraint ($r = 100$), robust regularization has perofrmance better than ℓ_1 except for large values r, especially on the rare label $Y = +1$ (Figure 3 (d) and (f)).



We investigate the effects of the robust regularizer with a slightly different perspective in Figure 4, where we use $\Theta = \{\theta : \|\theta\|_1 \le r\}$ with $r = 100$ for the constraint set for each experiment. The horizontal axis indicates the tolerance ρ we use in construction of the robust estimator $\widehat{\theta}_n^{\rm rob}$, where `ERM` means $\rho = 0$. In Fig. 4(a), we plot the logistic risk $R(\widehat{\theta}) = \mathbb{E}[\ell(\widehat{\theta}, (X, Y))]$ for the train and test distribution. We also plot the upper confidence bound $R_n(\theta, \mathcal{P}_n)$ in this plot, which certainly over-estimates the test risk—we hope to tighten this overestimate in future work. In Figure 4(b), we plot the misclassification error on train and test for different values of ρ, along with 2-standard-error intervals for the 50 runs. Figures 4(c) and (d) show the error rates restricted to examples from the uncommon (c) and common (d) classes. In Table 3 we give explicit error rates and logistic risk values for the different procedures. Due to the small size of the test dataset ($n_{\rm test} = 659$), the deviation across folds is somewhat large.



(a) Train error

(a) Logistic risk and confidence bound

(b) Misclassification error rate

(c) Error on rare class ($Y_i = +1$)

(d) Error on common class ($Y_i = -1$)

Figure 4. HIV-1 Protease Cleavage plots (2-standard error confidence bars). Plot (a) shows the logistic risk $R(\theta) = \mathbb{E}[\log(1+e^{-Y\theta^\top X})]$ and confidence bounds computed from the robust risk (4). Plots (b)–(d) show misclassification error rates plotted against robustness parameter ρ.

In this experiment, we see (roughly) that the ERM solutions achieve good performance on the common class ($Y = -1$) but sacrifice performance on the uncommon class. As we increase ρ, performance of the robust solution $\widehat{\theta}_n^{\rm rob}$ on the rarer label $Y = +1$ improves (Fig. 4(c)), while the misclassification rate on the common class degrades a small (insignificant) amount (Fig. 4(d)); see also Table 3. This behavior is roughly what we might expect for the robust estimator: the poor performance of the ERM estimator $\widehat{\theta}_n^{\rm erm}$ on the rare class induces (relatively) more variance, which the robust solution reduces by via improved classification performance on the rare ($Y = +1$) class. This occurs at little expense over the more common label $Y = -1$ so that overall performance improves by a small amount. We remark—but are unable to explain—that this improvement on classification error for the rare labels comes despite increases in logistic risk; while the average logistic loss increases, misclassification errors decrease.

Table 3: HIV-1 Cleavage Error

	risk		error (%)		error ($Y=+1$)		error ($Y=-1$)

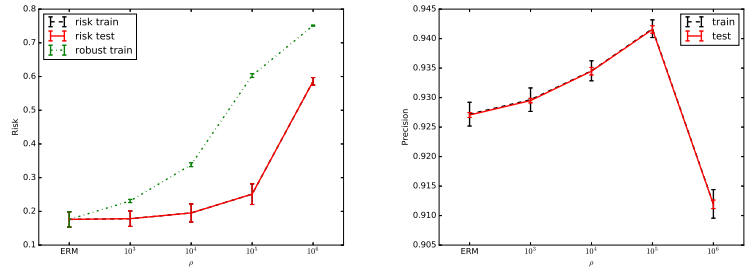
10000	0.283	0.3031	2.39	5.67	7.18	14.65	1.15	3.32

5.4. Document classification in the Reuters corpus

For our final experiment, we consider a multi-label classification problem with a reasonably large dataset. The Reuters RCV1 Corpus (Lewis et al., 2004) has 804,414 examples with $d = 47{,}236$ features, where feature j is an indicator variable for whether word j appears in a given document. The goal is to classify documents as a subset of the 4 categories Corporate, Economics, Goverment, and Markets, and each document in the data is labeled with a subset of those. As each document can belong to multiple categories, we fit binary classifiers on each of the four categories. There are different numbers of documents labeled as each category, with the Economics category having the fewest number of positive examples. Table 4 gives the number of times a document is labeled as each of the four categories (so each document has about 1.18 associated classes). In this experiment, we expect the robust solution to outperform ERM on the rarer category (Economics), as the robustification (6) naturally upweights rarer (harder) instances, which disproportionally affect variance—as in the experiment on HIV-1 cleavage.

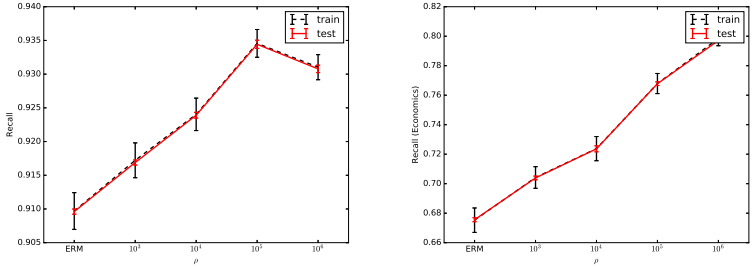
Table 4: Reuters Number of Examples

Corporate	Economics	Government	Markets
381,327	119,920	239,267	204,820



For each category $k \in \{1, 2, 3, 4\}$, we use the logistic loss $\ell(\theta_k; (x, y)) = \log(1+\exp(-y\theta_k^\top x))$. For each binary classifier, we use the ℓ_1 constraint set $\Theta = \left\{\theta \in \mathbb{R}^d : \|\theta\|_1 \le 1000\right\}$. To evaluate performance on this multi-label problem, we use precision (ratio of the number of correct positive labels to the number classified as positive) and recall (ratio of the number of correct positive labels to the number of actual positive labels):

$$\text{precision} = \frac{1}{n}\sum_{i=1}^n \frac{\sum_{k=1}^4 1\{\theta_k^\top x_i \ge 0, y_i = 1\}}{\sum_{k=1}^4 1\{\theta_k^\top x_i > 0\}},$$



$$\text{recall} = \frac{1}{n}\sum_{i=1}^n \frac{\sum_{k=1}^4 1\{\theta_k^\top x_i \ge 0, y_i = 1\}}{\sum_{k=1}^4 1\{y_i = 1\}}.$$

We partition the data into ten equally-sized sub-samples and perform ten validation experiments, where in each experiment we use one of the ten subsets for fitting the logistic models and the remaining nine partitions as a test set to evaluate performance.

In Figure 5, we summarize the results of our experiment averaged over the 10 runs, with 2-standard error bars (computed across the folds). To facilitate comparison across the document categories, we give exact values of these averages in Tables 5 and 6. Both

(a) Logistic risk and confidence bound (b) Precision

(c) Recall (d) Recall on rare category (Economics)

Figure 5: Reuters Corpus (2-standard error deviations)

$\widehat{\theta}_n^{\text{rob}}$ and $\widehat{\theta}_n^{\text{erm}}$ have reasonably high precision across all categories, with increasing ρ giving a mild improvement in precision (from $.93 \pm .005$ to $.94 \pm .005$); see also Figure 5(a). On the other hand, we observe in Figure 5(d) that ERM has low recall (.69 on test) for the Economics category, which contains about 15% of documents. As we increase ρ from 0 (ERM) to 10^5, we see a smooth and substantial improvement in recall for this rarer category (without significant degradation in precision). This improvement in recall amounts to reducing variance in predictions on the rare class. We also note that while the robust solutions outperform ERM in classification performance for $\rho \le 10^5$, for very large $\rho = 10^6 \ge 10n$, the regularizing effects of robustness degrade the solution $\widehat{\theta}_n^{\text{rob}}$. This precision and recall improvement comes in spite of the increase in the average binary logistic risk for each of the 4 classes, which we show in Figure 5a, which plots the average binary logistic loss (on train and test sets) averaged over the 4 categories as well as the upper confidence bound $R_n(\theta, \mathcal{P}_n)$ as we vary ρ. The robust regularization effects reducing variance appear to improve the performance of the binary logistic loss as a surrogate for true misclassification error.

Summary

We have seen through multiple examples that robustification—our convex surrogate for variance regularization—is an effective tool in a number of applications. As we heuristically expect, variance-based regularization (robust regularization) yields predictors with better performance on "hard" instances, or subsets of the problem that induce higher variance, such as classes with relatively few training examples in classification problems. The robust regularization ρ gives a principled knob for tuning performance to trade between variance (uniform or across-the-board performance) and—sometimes—absolute performance.

6. Discussion

In this paper, we have developed theoretical results for robust regularization (6) that apply to general stochastic optimization and learning problems problems. The examples we describe in Section 3 illustrate our expectation that the robust solution $\widehat{\theta}_n^{\rm rob}$ should have good performance in cases in which $\mathrm{Var}(\ell(\theta^\star; X))$ is small (recall also Theorems 3 and 6). Identifying the separation between the performance empirical risk minimization and related estimators and that of the robustly-regularized estimators—as well as variance-regularized estimates—we consider more generally remains a challenge. We hope that this paper inspires work in this direction in machine learning and statistics, and more broadly, torward considering distributionally robust problems. Part of this is likely to come from making rigorous our empirical observations (Section 5) that robust regularization improves performance on "hard" instances without sacrificing performance on easier cases.

Our understanding of so-called "fast rates" for stochastic optimization problems, while considering robustness, is also limited. For empirical risk minimization, fast rates of convergence hold under conditions in which the the gap $R(\theta) - R(\theta^\star)$ controls the variance of the excess loss $\ell(\theta, X) - \ell(\theta^\star, X)$ (cf. Mammen and Tsybakov, 1999; Bartlett et al., 2005;

Boucheron et al., 2005; Bartlett et al., 2006), which usually requires some type of uniform convexity assumption. These bounds typically follow from localization guarantees (Bartlett et al., 2005, Section 5) on the function class

$$\{x \mapsto \ell(\theta, x) - \ell(\theta^\star, x) \mid \theta \in \Theta\}.$$

While in Section 4.1, we show that the robust estimate $\widehat{\theta}_n^{\rm rob}$ enjoys faster rates of convergence under growth conditions analogous to uniform convexity of the risk, as $\mathrm{Var}(\ell(\theta; X) - \ell(\theta^\star; X)) \neq \mathrm{Var}(\ell(\theta; X))$, it is not clear how to directly connect these guarantees to results of the form in Theorems 3 and 6. We leave investigation of these topics to future work.

The last point of our discussion is to revisit Theorem 6, which provides a guarantee for robustly regularized estimators based on localized Rademacher complexities. An investigation of our proof shows that our derivation proceeds by considering the complexity of self-normalized classes of functions of the form

$$\mathcal{G}_r = \left\{ \sqrt{\frac{r}{\mathbb{E}[f^2] \vee r}} f \mid f \in \mathcal{F} \right\}.$$

In contrast, the analogous result of Bartlett et al. (2005, Thereom 3.3) for empirical risk minimization considers the complexity of classes of functions of the form

$$\mathcal{G}_r = \left\{ \frac{r}{\mathbb{E}[f^2] \vee r} f \mid f \in \mathcal{F} \right\}.$$

The latter class normalizes functions f by $\sqrt{\mathbb{E}[f^2]}$—a type of self-normalization that arises in the computation of pivotal (asymptotically independent of the underlying distribution) statistics. While this choice *prima facie* is just a step in our proof, the robust objective $R_n(\theta, \mathcal{P}_n)$ defined in Eq. (4) is an empirical likelihood upper confidence bound on the optimal population risk (see also Duchi et al., 2016). One of the important characteristics of empirical likelihood confidence bounds is that they are self-normalizing and yield pivotal statistics (Owen, 2001). Investigating such self-normalization in complexity guarantees seems likely to yield fruitful insights.

Acknowledgments

We thank Feng Ruan for pointing out a much simpler proof of Theorem 1 than in our original paper. JCD was also partially supported by the National Science Foundation award NSF-CAREER-1553086 and the Sloan Fellowship.

Appendix A. Proof of Theorem 1

The theorem is immediate if $s_n = 0$ or $\sigma^2 = 0$, as in this case $\sup_{P:D_\phi(P\|\widehat{P}_n)\le\rho/n} \mathbb{E}_P[Z] = \mathbb{E}_{\widehat{P}_n}[Z] = \mathbb{E}[Z]$. In what follows, we will thus assume that $\sigma^2, s_n^2 > 0$. We recall the maximization problem (8), which is

$$\operatorname*{maximize}_p \sum_{i=1}^n p_i z_i \quad \text{subject to } p \in \mathcal{P}_n = \left\{ p \in \mathbb{R}_+^n : \frac{1}{2}\left\|np - \mathbf{1}\right\|_2^2 \le \rho, \langle \mathbf{1}, p\rangle = 1 \right\},$$

and the solution criterion (9), which guarantees that the maximizing value of problem (8) is $\overline{z} + \sqrt{2\rho s_n^2/n}$ whenever

$$\sqrt{2\rho}\frac{z_i - \overline{z}}{\sqrt{n s_n^2}} \ge -1.$$

Letting $z = Z$, then under the conditions of the theorem, we have $|z_i - \overline{z}| \le M$, and to satisfy inequality (9) it is certainly sufficient that

$$2\rho\frac{M^2}{n s_n^2} \le 1, \quad \text{or} \quad n \ge \frac{2\rho M^2}{s_n^2}, \quad \text{or} \quad s_n^2 \ge \frac{2\rho M^2}{n}. \tag{30}$$

Conversely, suppose that $s_n^2 < \frac{2\rho M^2}{n}$. Then we have $\frac{2\rho s_n^2}{n} < \frac{4\rho^2 M^2}{n^2}$, which in turn implies that

$$\sup_{p\in\mathcal{P}_n} \langle p, z\rangle \ge \frac{1}{n}\langle \mathbf{1}, z\rangle + \left(\sqrt{\frac{2\rho s_n^2}{n}} - \frac{2M\rho}{n}\right)_+.$$

Combining this inequality with the condition (30) for the exact expansion to hold yields the two-sided variance bounds (10).

We now turn to showing the high-probability exact expansion (11), which occurs whenever the sample variance is large enough by expression (30). To that end, we show that s_n^2 is bounded from below with high probability. Define the event

$$\mathcal{E}_n := \left\{ s_n^2 \ge \frac{3}{64}\sigma^2 \right\},$$

and let $n \ge \frac{4M^2}{\sigma^2}\max\{2\sigma, 11\}$. Then, on event $\mathcal{E}_n$ we have $n \ge \frac{44\rho M^2}{\sigma^2} \ge \frac{2\rho M^2}{s_n^2}$, so that the sufficient condition (30) holds and expression (11) follows. We now argue that the event $\mathcal{E}_n$ has high probability via the following lemma due to Maurer and Pontil.

Lemma 11 (Maurer and Pontil (2009, Theorem 10)) *Let Z_i be i.i.d. random variables taking values in $[0, M]$, and let $s_n^2 = \frac{1}{n}\sum_{i=1}^n Z_i^2 - \left(\frac{1}{n}\sum_{i=1}^n Z_i\right)^2$. Then, for $n \ge 2$*

$$\mathbb{P}\left(s_n \le \sigma - t\right) \vee \mathbb{P}\left(s_n \ge \sigma + t\right) \le \exp\left(-\frac{nt^2}{2M^2}\right).$$

Setting $t = \left(1 - \frac{\sqrt{3}}{8}\right)\sigma$, the final result follows from noting that $\mathbb{P}(\mathcal{E}_n) \ge 1 - \exp\left(-\frac{nt^2}{2M^2}\right)$ from the lemma.

Appendix B. Proof of Theorem 2

Our starting point is to recall from inequality (30) in the proof of Theorem 1 that for each $f \in \mathcal{F}$, the empirical variance equality (12) holds if $n \ge \frac{4\rho M^2}{\mathrm{Var}_{\widehat{P}_n}(f)}$. As a consequence, Theorem 2 will follow if we can provide a uniform lower bound on the sample variances $\mathrm{Var}_{\widehat{P}_n}(f)$ that holds with high enough probability. We use C to denote a universal constant whose value may change from line to line. Noting that $\mathrm{Var}_{\widehat{P}_n}(f) = \mathbb{E}_{\widehat{P}_n}(f - \mathbb{E}[f])^2 - (\mathbb{E}_{\widehat{P}_n}(f - \mathbb{E}[f]))^2$, we proceed in two parts. First, we give a lower bound for $\mathbb{E}_{\widehat{P}_n}(f - \mathbb{E}[f])^2$.

Lemma 12 *Let $\mathcal{F}$ be a collection of bounded functions $f : \mathcal{X} \to [M_0, M_1]$ with $M := M_1 - M_0$. Then, with probability at least $1 - e^{-t}$, for every $f \in \mathcal{F}$*

$$\mathrm{Var}(f) \le 2\mathbb{E}_{\widehat{P}_n}(f - \mathbb{E}[f])^2 + C\left[\mathfrak{R}_n^{\sup}(\mathcal{F})^2 \log^3(nM) + \frac{M^2}{n}\left(t + \log\log n\right)\right].$$

Proof We follow the arguments of Srebro et al. (2010) and Bousquet (2002b, Thm. 6.1). For $x_1, \ldots, x_n \in \mathcal{X}$, let

$$\mathcal{F}_{n,r} := \left\{ f - \mathbb{E}[f] \mid f \in \mathcal{F}, \quad \mathbb{E}_{\widehat{P}_n}[(f - \mathbb{E}[f])^2] \le r \right\},$$

where $\widehat{P}_n$ is the empirical measure on $x_1, \ldots, x_n$. Let $\psi_n^{\sup}$ be a sub-root upper bound on the worst-case Rademacher complexity

$$\psi_n^{\sup}(r) \ge \mathfrak{R}_n^{\sup}(\mathcal{F}_{n,r}),$$

where implicitly in the right hand side we take the supremum over $x_1, \ldots, x_n$ definining $\mathcal{F}_{n,r}$ as well.

Lemma 13 (Srebro et al. (2010, Lemma 2.2)) *Let $\mathcal{H}$ be a class of bounded functions $\mathcal{X} \to [-M, M]$, and let $\kappa : [-M, M] \to \mathbb{R}_+$ be a bounded function with L-Lipschitz derivatives. Then,*

$$\mathfrak{R}_n^{\sup}\left(\left\{\kappa \circ h : h \in \mathcal{H}, \mathbb{E}_{\widehat{P}_n}[\kappa \circ h] \le r\right\}\right) \le C\sqrt{r}\mathfrak{R}_n^{\sup}(\mathcal{H})\log^{\frac{3}{2}}(Mn).$$

Since $\kappa(t) = t^2$ has Lipschitz derivatives, above lemma with $\mathcal{H} = \{f - \mathbb{E}[f] : f \in \mathcal{F}\}$ yields

$$\mathfrak{R}_n^{\sup}(\mathcal{F}_{n,r}^2) \le C\sqrt{r}\mathfrak{R}_n^{\sup}(\mathcal{F})\log^{\frac{3}{2}}(nM) \tag{31}$$

where we recall the notation that $\mathcal{G}^2 = \{g^2 \mid g \in \mathcal{G}\}$ for any function class $\mathcal{G}$. Thus we may take $\psi_n^{\sup}(r) = C\sqrt{r}\mathfrak{R}_n^{\sup}(\mathcal{F})\log^{\frac{3}{2}} n$, which has fixed point $r_n^{\sup} = C^2\mathfrak{R}_n^{\sup}(\mathcal{F})^2\log^3 n$. The following classical result then shows that the fixed point $r_n^{\sup}$ controls generalization of class of functions $\mathcal{F}_{n,r}^2$. Since $f^2 \ge 0$, Theorem 6.1 of Bousquet (2002b) yields that for all $f \in \mathcal{F}$,

$$\mathbb{E}(f - \mathbb{E}[f])^2 \le 2\mathbb{E}_{\widehat{P}_n}(f - \mathbb{E}[f])^2 + C\left[\mathfrak{R}_n^{\sup}(\mathcal{F})^2\log^3 nM + \frac{M^2}{n}\left(t + \log\log n\right)\right]$$

with probability at least $1 - e^{-t}$. ∎

Next, we give an upper bound for $(\mathbb{E}_{\widehat{P}_n}(f - \mathbb{E}[f]))^2$. We use the following version of Talagrand's inequality due to Bousquet (2002a, 2003). (See also Bartlett et al. (2005, Thm 2.1).)

Lemma 14 *Let $r > 0$ and $\mathcal{F}$ be a class of functions that map $\mathcal{X}$ into $[a, b]$ such that for every $f \in \mathcal{F}$, $\mathrm{Var}(f(X)) \le r$. Then, with probability at least $1 - e^{-t}$*

$$\sup_{f\in\mathcal{F}}\{\mathbb{E}[f] - \mathbb{E}_{\widehat{P}_n}[f]\} \le \inf_{\alpha>0}\left\{2(1+\alpha)\mathbb{E}[\mathfrak{R}_n(\mathcal{F})] + \sqrt{\frac{2rt}{n}} + \frac{t}{n}(b-a)\left(\frac{1}{3}+\frac{1}{\alpha}\right)\right\}.$$

The same statement holds with $\sup_{f\in\mathcal{F}}(\mathbb{E}_{\widehat{P}_n}[f] - \mathbb{E}[f])$ replacing the left-hand side of the inequalities.

Applying Lemma 14 and letting $\alpha = \frac{1}{2}$, with probability at least $1 - 2e^{-t}$

$$|\mathbb{E}_{\widehat{P}_n}[f] - \mathbb{E}[f]| \le 3\mathbb{E}[\mathfrak{R}_n(\mathcal{F})] + 2M\sqrt{\frac{2t}{n}}$$

holds for all $f \in \mathcal{F}$. Combining the above display with Lemma 12, we obtain the desired result.

Appendix C. Proof of Theorem 3

Before proving the theorem proper, we state a technical lemma that provides uniform Bernstein-like bounds for the class $\mathcal{F}$ using empirical ℓ_∞-covering numbers.

Lemma 15 (Maurer and Pontil (2009, Theorem 6)) *Let $n \ge \frac{8M^2}{t}$ and $t \ge \log 12$. Then with probability at least $1 - 6N_\infty(\mathcal{F}, \epsilon, 2n)e^{-t}$, we have*

$$\mathbb{E}[f] \le \mathbb{E}_{\widehat{P}_n}[f] + 3\sqrt{\frac{2\mathrm{Var}_{\widehat{P}_n}(f)t}{n}} + \frac{15Mt}{n} + 2\left(1 + 2\sqrt{\frac{2t}{n}}\right)\epsilon \tag{32}$$

for all $f \in \mathcal{F}$.

We return to the proof of Theorem 3. Let $\mathcal{E}_1$ denote that the event that the inequalities (32) hold. Then on $\mathcal{E}_1$ hold, uniformly over $f \in \mathcal{F}$ we have

$$\begin{aligned}
\mathbb{E}[f] &\le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{\frac{18\mathrm{Var}_{\widehat{P}_n}(f(X))t}{n}} + \frac{15Mt}{n} + 2\left(1 + 2\sqrt{\frac{2t}{n}}\right)\epsilon \\
&\overset{(i)}{\le} \sup_{P:D_\phi(P\|\widehat{P}_n)\le\frac{\rho}{n}} \mathbb{E}_P[f(X)] + \sqrt{\frac{2\rho\mathrm{Var}_{\widehat{P}_n}(f(X))}{n}} \\
&\quad - \left(\sqrt{\frac{2\rho\mathrm{Var}_{\widehat{P}_n}(f(X))}{n}} - \frac{2M\rho}{n}\right)_+ + \frac{5M\rho}{3n} + 2\left(1 + 2\sqrt{\frac{2t}{n}}\right)\epsilon \\
&\le \sup_{P:D_\phi(P\|\widehat{P}_n)\le\frac{\rho}{n}} \mathbb{E}_P[f(X)] + \frac{11}{3}\frac{M\rho}{n} + 2\left(1 + 2\sqrt{\frac{2t}{n}}\right)\epsilon \text{ for all } f \in \mathcal{F},
\end{aligned} \tag{33}$$

where inequality (i) follows from the bounds (10) in Theorem 1 and the fact that $\rho \ge 9t$ by assumption. This gives the first result (15).

For the second result (16), we recall that $\widehat{f} \in \mathrm{argmin}_{f\in\mathcal{F}} \sup_P\{\mathbb{E}_P[f(X)] : D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}\}$, and we bound the supremum term in expression (33). First, we note that because $\widehat{f}$ minimizes the supremum term in expression (33), we have

$$\mathbb{E}[\widehat{f}] \le \sup_{P:D_\phi(P|\widehat{P}_n)\le\frac{\rho}{n}} \mathbb{E}_P[f(X)] + \frac{11M\rho}{3n} + 2\left(1 + 2\sqrt{\frac{2t}{n}}\right)\epsilon \text{ for all } f \in \mathcal{F}.$$

Now fix $f \in \mathcal{F}$. As the function f is fixed, by Bernstein's inequality, we have

$$\mathbb{E}_{\widehat{P}_n}[f] \le \mathbb{E}[f] + \sqrt{\frac{2\mathrm{Var}(f)t}{n}} + \frac{2Mt}{3n}$$

with probability at least $1 - e^{-t}$. Similarly, we have by Lemma 11 that

$$\sqrt{\mathrm{Var}_{\widehat{P}_n}(f)} \le \sqrt{\mathrm{Var}(f)} + \sqrt{\frac{2tM^2}{n}}$$

with probability at least $1 - e^{-t}$. That is, for any fixed $f \in \mathcal{F}$, we have with probability at least $1 - 2e^{-t}$ that

$$\begin{aligned}
\sup_{P:D_\phi(P|\widehat{P}_n)\le\frac{\rho}{n}} \mathbb{E}_P[f(X)] &\overset{(i)}{\le} \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{\frac{2\rho\mathrm{Var}_{\widehat{P}_n}(f)}{n}} \\
&\le \mathbb{E}[f] + \sqrt{\frac{2\mathrm{Var}(f)t}{n}} + \frac{2M}{3n}t + \sqrt{\frac{2\rho\mathrm{Var}(f)}{n}} + \frac{2\sqrt{M^2\rho t}}{n} \\
&\overset{(ii)}{\le} \mathbb{E}[f] + 2\sqrt{\frac{2\mathrm{Var}(f)\rho}{n}} + \frac{8}{3}\frac{M\rho}{n},
\end{aligned}$$

where inequality (i) follows from the uniform upper bound (10) of Theorem 1 and inequality (ii) from our assumption that $\rho \ge t$. Substituting this expression into our earlier bound (33) yields that for any $f \in \mathcal{F}$, with probability at least

$$1 - 2(3N_\infty(\mathcal{F}, \epsilon, 2n) + 1)e^{-t},$$

we have

$$\mathbb{E}[\widehat{f}(X)] \le \mathbb{E}[f(X)] + 2\sqrt{\frac{2\rho\mathrm{Var}(f(X))}{n}} + \frac{19}{3}\frac{M\rho}{n} + 2\left(1 + 2\sqrt{\frac{2t}{n}}\right)\epsilon.$$

This gives the theorem.

Appendix D. Proof of Theorem 6

We first show the following version of uniform Bernstein's inequality with Rademacher complexities. The proof uses a peeling technique (Bartlett et al., 2005; van de Geer, 2000), in conjuction with Talagrand's concentration inequality (Lemma 14).

Lemma 16 *Let $r > 0$ and $\mathcal{F}$ be a collection of bounded functions $f : \mathcal{X} \to [0, M]$ with $\mathrm{Var}(f(X)) \le r$. Then, with probability at least $1 - e^{-t}$, for every $f \in \mathcal{F}$*

$$\mathbb{E}[f] \le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{\frac{2e\mathrm{Var}(f)}{n}\left(t + \log\left\lceil \log \frac{nr}{M^2 t}\right\rceil\right)} + 6\mathbb{E}[\mathfrak{R}_n(\mathcal{F})] + \frac{7M}{n}\left(t + \log\left\lceil \log \frac{nr}{M^2 t}\right\rceil\right).$$

The same statements hold with the roles of $\mathbb{E}[f]$ and $\mathbb{E}_{\widehat{P}_n}[f]$ reversed.

We defer the proof to section D at the end of this section. Because $\mathrm{Var}(f) \le M^2$ for all $f \in \mathcal{F}$, Lemma 16 also holds if we replace the terms $\left\lceil \log \frac{nr}{M^2 t}\right\rceil$ with $\left\lceil \log \frac{n}{t}\right\rceil \le 1 + \log \frac{n}{t}$.

Next, we show an important extension of Lemma 16 that replaces the Rademacher complexity term $\mathbb{E}[\mathfrak{R}_n(\mathcal{F})]$ by a local quantity $r_n^\star$, the fixed point of $\psi_n(r)$. To this end, we use another peeling argument and apply Lemma 16 to the self-normalized class

$$\mathcal{G}_r := \left\{ \sqrt{\frac{r}{\mathbb{E}[f^2] \vee r}} f : f \in \mathcal{F} \right\} \subseteq \left\{ cf : f \in \mathcal{F}, \mathbb{E}[c^2 f^2] \le r, c \in [0,1] \right\}.$$

This idea follows the techniques of Bartlett et al. (2005, Thm. 3.3), though we use a type of self-normalizing scale, that is, $f/\sqrt{\mathbb{E}[f^2]}$, whereas they use a variance-normalizing scaling by studying classes of functions of the form $f/\mathbb{E}[f^2]$. Our use of this alternative normalization is important in the next lemma, which allows us to obtain bounds that apply to the robustly regularized risk.

Lemma 17 *Let $\mathcal{F}$ be a collection of bounded functions $f : \mathcal{X} \to [0, M]$ satisfying the localization inequality (20) for some sub-root function $\psi_n(\cdot)$ with root $r_n^\star$. Let $B_n = \frac{1}{n}\left(t + \log\left\lceil \log \frac{n}{t}\right\rceil\right)$. Then with probability at least $1 - e^{-t}$, for every $f \in \mathcal{F}$*

$$\mathbb{E}[f] \le \mathbb{E}_{\widehat{P}_n}[f] + \left(\sqrt{2eB_n} + 6\sqrt{r_n^\star + 7MB_n/3}\right)\sqrt{\mathbb{E}[f^2]} + 6r_n^\star + 14MB_n.$$

The same statement holds with the roles of $\mathbb{E}[f]$ and $\mathbb{E}_{\widehat{P}_n}[f]$ reversed.

See Section D.1 for the proof.

Next, we give an analogous result for f^2.

Lemma 18 *Let $\mathcal{F}$ be a collection of bounded functions $f : \mathcal{X} \to [0, M]$ satisfying the localization inequality (20) for some sub-root function $\psi_n(\cdot)$ with root $r_n^\star$. Let $\eta > 0$. Then, with probability at least $1 - e^{-t}$, for every $f \in \mathcal{F}$*

$$\mathbb{E}[f^2] \le \mathbb{E}_{\widehat{P}_n}[f^2] + \frac{1}{\eta}\mathbb{E}_{\widehat{P}_n}[f^2] + 72M^2(1+\eta)r_n^\star + \frac{Mt}{n}\left(4 + \frac{7}{3}M\right).$$

Also, with probability at least $1 - e^{-t}$, for every $f \in \mathcal{F}$

$$\mathbb{E}_{\widehat{P}_n}[f^2] \le \mathbb{E}[f^2] + \frac{\eta}{1+\eta}\mathbb{E}[f^2] + 72M^2(1+\eta)r_n^\star + \frac{Mt}{n}\left(4 + \frac{7}{3}M\right).$$

See Section D.2 for the proof.

Now, we make two additional pieces of shorthand notation. Let

$$V_n = 4((2e + 84M)B_n + 36r_n^\star).$$

Then, Lemma 17 implies that

$$\mathbb{E}[f] \le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{V_n\mathbb{E}[f^2]} + 6r_n^\star + 14MB_n$$

with probability at least $1 - e^{-t}$. Applying Lemma 18 to this bound with the choice $\eta = 1$ immediately yields that

$$\begin{aligned}\mathbb{E}[f] &\le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{2V_n\mathbb{E}_{\widehat{P}_n}[f^2] + 144M^2V_nr_n^\star + 7V_nM\max\{M,1\}t/n} + 6r_n^\star + 14MB_n \\ &\le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{2V_n\mathbb{E}_{\widehat{P}_n}[f^2]} + 12M\sqrt{V_n\left(r_n^\star + \frac{7\max\{M,1\}}{M}\frac{t}{n}\right)} + 6r_n^\star + 14MB_n\end{aligned}$$

for all $f \in \mathcal{F}$ with probability at least $1 - 2e^{-t}$. Subtracting and adding $(\mathbb{E}_{\widehat{P}_n}[f])^2$ to the second term, we have

$$\sqrt{2V_n\mathbb{E}_{\widehat{P}_n}[f^2]} = \sqrt{2V_n\mathrm{Var}_{\widehat{P}_n}(f) + 2V_n\mathbb{E}_{\widehat{P}_n}[f]^2} \le \sqrt{2V_n\mathrm{Var}_{\widehat{P}_n}(f)} + \sqrt{2V_n}\mathbb{E}_{\widehat{P}_n}[f],$$

where we have used that $f \ge 0$. We thus obtain

$$\begin{aligned}\mathbb{E}[f] &\le \left(1 + \sqrt{2V_n}\right)\mathbb{E}_{\widehat{P}_n}[f] + \sqrt{2V_n\mathrm{Var}_{\widehat{P}_n}(f)} + 12M\sqrt{V_n\left(r_n^\star + \frac{7\max\{M,1\}}{M}\frac{t}{n}\right)} + 6r_n^\star + 14MB_n \\ &\le \left(1 + \sqrt{2V_n}\right)\mathbb{E}_{\widehat{P}_n}[f] + \sqrt{2V_n\mathrm{Var}_{\widehat{P}_n}(f)} + 6MV_n + 6M\left(r_n^\star + \frac{7\max\{M,1\}t}{Mn}\right) + 6r_n^\star + 14MB_n,\end{aligned}$$

where the second inequality follows because $\sqrt{ab} \le \frac{1}{2}a + \frac{1}{2}b$ for $a, b \ge 0$. Recalling the bound (21), which implies $\rho \ge nV_n$, $\rho \ge n(r_n^\star + \frac{7\max\{M,1\}t}{Mn})$, and $\rho/n \ge 6r_n^\star + 14MB_n$, we obtain that

$$\mathbb{E}[f] \le \left(1 + \sqrt{\frac{2\rho}{n}}\right)\mathbb{E}_{\widehat{P}_n}[f] + \sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(f)} + \frac{13M\rho}{n}.$$

Theorem 1 implies $\mathbb{E}_{\widehat{P}_n}[f] + \sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(f)} \le \sup_{P: D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[f(X)] + \frac{2M\rho}{n}$, so we immediately we arrive at

$$\mathbb{E}[f] \le \left(1 + 2\sqrt{\frac{2\rho}{n}}\right)\sup_{P: D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[f(X)] + \left(13 + 4\sqrt{\frac{2\rho}{n}}\right)\frac{M\rho}{n}$$

for all $f \in \mathcal{F}$ with probability at least $1 - 2e^{-t}$. This is the first result (22).

To show the second result, we simply apply Bernstein's inequality and the concentration inequalities for the standard deviation in Lemma 11. For any fixed $f \in \mathcal{F}$, by Bernstein's inequality, we have

$$\mathbb{E}_{\widehat{P}_n}[f] \le \mathbb{E}[f] + \sqrt{\frac{2t\mathrm{Var}(f)}{n}} + \frac{2Mt}{3n}$$

with probability at least $1 - e^{-t}$. From Lemma 11, we have

$$\sqrt{\mathrm{Var}_{\widehat{P}_n}(f)} \le \sqrt{\mathrm{Var}(f)} + \sqrt{\frac{2tM^2}{n}}$$

with probability at least $1 - e^{-t}$.

We thus obtain that for any fixed f,

$$\sup_{P: D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[f] \le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(f)} \le \mathbb{E}[f] + \sqrt{\frac{2t}{n}\mathrm{Var}(f)} + \sqrt{\frac{2\rho}{n}\mathrm{Var}(f)} + \frac{2M\sqrt{\rho t}}{n} + \frac{2Mt}{3n}$$

with probability at least $1 - 2e^{-t}$. Noting that $\rho \ge 45Mt$ by assumption (21), so $\sqrt{\rho} + \sqrt{t} \le \sqrt{46\rho/45 + 45t} \le \sqrt{91\rho/45}$ and that always $2\sqrt{\rho t} \le 3\rho + \frac{1}{3}t$, we have that with probability at least $1 - 2e^{-t}$ that

$$\sup_{P: D_\phi(P\|\widehat{P}_n) \le \frac{\rho}{n}} \mathbb{E}_P[f] \le \mathbb{E}[f] + \sqrt{\frac{91\rho}{45n}\mathrm{Var}(f)} + \frac{3M\rho}{n} + \frac{Mt}{n}.$$

Noting that we could take f to minimize the right hand side of the preceding expression and that $\widehat{f}$ minimizes $\sup_{P: D_\phi(P\|\widehat{P}_n) \le \rho/n} \mathbb{E}_P[f]$, we have the result (23).

We first show the claim for $g \in \mathcal{F}_{\text{centered}} = \{f - \mathbb{E}[f] : f \in \mathcal{F}\}$. To see the claim for $g \in \mathcal{F}_{\text{centered}}$, let us fix $L \in \mathbb{N}$ to be chosen later, and for $l = 1, \ldots, L-1$ define the classes

$$\mathcal{F}_l := \left\{g \in \mathcal{F}_{\text{centered}} : e^{-l} r < \mathbb{E}[g^2] \le e^{-(l-1)} r\right\}, \quad \mathcal{F}_L := \left\{g \in \mathcal{F}_{\text{centered}} : \mathbb{E}[g^2] \le e^{-L} r\right\}$$

so that $\mathcal{F}_{\text{centered}} = \cup_{l=1}^L \mathcal{F}_l$. Let $z > 0$ be such that $t \le z$. Applying Lemma 14 (with the choice $\alpha = \frac{1}{2}$) to $\mathcal{F}_l$ for each $l = 1, \ldots, L-1$, we have with probability at least $1 - e^{-t}$, for every $g \in \mathcal{F}_l$

$$\begin{aligned}\mathbb{E}[g] &\le \mathbb{E}_{\widehat{P}_n}[g] + \sqrt{\frac{2te^{-(l-1)}r}{n}} + 3\mathbb{E}[\mathfrak{R}_n(\mathcal{F}_l)] + 5M\frac{t}{n} \\ &\le \mathbb{E}_{\widehat{P}_n}[g] + \sqrt{\frac{2et}{n}\mathbb{E}[g^2]} + 3\mathbb{E}[\mathfrak{R}_n(\mathcal{F}_l)] + 5M\frac{t}{n}\end{aligned}$$

where in the last line we have used $e^{-l} r \le \mathbb{E}[g^2]$ for $g \in \mathcal{F}_l$. Similarly, applying Lemma 14 to $\mathcal{F}_L$, then with probability at least $1 - e^{-t}$, for every $g \in \mathcal{F}_L$

$$\begin{aligned}\mathbb{E}[g] &\le \mathbb{E}_{\widehat{P}_n}[g] + \sqrt{\frac{2te^{-L}r}{n}} + 3\mathbb{E}[\mathfrak{R}_n(\mathcal{F}_L)] + 5M\frac{t}{n} \\ &\le \mathbb{E}_{\widehat{P}_n}[g] + \sqrt{\frac{2et}{n}\mathbb{E}[g^2]} + \sqrt{\frac{2te^{-L}r}{n}} + 3\mathbb{E}[\mathfrak{R}_n(\mathcal{F}_L)] + 5M\frac{t}{n}.\end{aligned}$$

Taking a union bound, we have with probability at least $1 - Le^{-t}$, for every $g \in \mathcal{F}_{\text{centered}}$

$$\mathbb{E}[g] \le \mathbb{E}_{\widehat{P}_n}[g] + \sqrt{\frac{2et}{n}\mathbb{E}[g^2]} + 3\mathbb{E}[\mathfrak{R}_n(\mathcal{F}_{\text{centered}})] + 5M\frac{t}{n} + \sqrt{\frac{2te^{-L}r}{n}}.$$

Noting that $\mathbb{E}[\mathfrak{R}_n(\mathcal{F}_{\text{centered}})] \le 2\mathbb{E}[\mathfrak{R}_n(\mathcal{F})]$ by Jensen's inequality, we take $L = \lceil \log \frac{rn}{M^2 t} \rceil$ and map t to $t + \log L$ to obtain the lemma. The case when the roles of $\mathbb{E}[f]$ and $\mathbb{E}_{\widehat{P}_n}[f]$ are reversed follows similarly.

D.1. Proof of Lemma 17

Let $r \ge r_n^\star$ be an arbitrary but fixed value to be choosen later. Using this r, define the self-normalized class of functions

$$\mathcal{G}_r := \left\{\sqrt{\frac{r}{\mathbb{E}[f^2] \vee r}} f : f \in \mathcal{F}\right\} \subseteq \left\{cf : f \in \mathcal{F}, \mathbb{E}[c^2 f^2] \le r, c \in [0,1]\right\}.$$

From the truncation by r, we have $\mathbb{E}[g^2] \le r$ for all $g \in \mathcal{G}_r$. Lemma 16 implies that with probability at least $1 - e^{-t}$, uniformly over $g \in \mathcal{G}_r$

$$\mathbb{E}[g] \le \mathbb{E}_{\widehat{P}_n}[g] + \sqrt{\frac{2e}{n}\mathbb{E}[g^2]\left(t + \log\left\lceil \log \frac{n}{t}\right\rceil\right)} + 6\mathbb{E}[\mathfrak{R}_n(\mathcal{G}_r)] + \frac{7M}{n}\left(t + \log\left\lceil \log \frac{n}{t}\right\rceil\right). \quad (34)$$

Using the sub-root property of ψ_n and that $\psi_n(r_n^\star) = r_n^\star$, we have the inequality

$$\psi_n(r) = \sqrt{r}\psi_n(r)/\sqrt{r} \le \sqrt{r}\psi_n(r_n^\star)/\sqrt{r_n^\star} = \sqrt{r r_n^\star}$$

for any $r \ge r_n^\star$, so

$$\mathbb{E}[\mathfrak{R}_n \mathcal{G}_r] \le \mathbb{E}[\mathfrak{R}_n\left\{cf : f \in \mathcal{F}, \mathbb{E}[c^2 f^2] \le r, c \in [0,1]\right\}] \le \psi_n(r) \le \sqrt{r r_n^\star}$$

Using this upper bound in Eq. (34) and recalling the notation $B_n = \frac{1}{n}\left(t + \log\lceil \log \frac{n}{t}\rceil\right)$, we get

$$\mathbb{E}[g] \le \mathbb{E}_{\widehat{P}_n}[g] + \sqrt{2eB_n\mathbb{E}[g^2]} + 6\sqrt{r_n^\star r} + 7MB_n. \quad (35)$$

Now, we return to choose the value r to optimize the bound (35). let r be the largest solution to $6\sqrt{r_n^\star r} + 7MB_n = 6r$. The following elementary lemma provides a bound on r.

Lemma 19 *Let x be the largest solution to $ax + b = \frac{x^2}{d}$ where $a, b, d > 0$. Then $a^2d^2 \le x^2 \le a^2d^2 + 2bd$.*

Proof From the quadratic formula, we have $x = \frac{1}{2}\left(ad + \sqrt{a^2d^2 + 4b}\right)$ from which the lower bound follows. From convexity of $z \mapsto z^2$ and $\sqrt{z_1 + z_2} \le \sqrt{z_1} + \sqrt{z_2}$ for $z_1, z_2 > 0$, we obtain the upper bound. ■

Lemma 19 immediately yields

$$r_n^\star \le r \le r_n^\star + \frac{7MB_n}{3}.$$

For each $g \in \mathcal{G}_r$, there exists $f \in \mathcal{F}$ such that $g = \sqrt{\frac{r}{\mathbb{E}[f^2] \vee r}} f$. If $\mathbb{E}[f^2] \le r$, we have $g = f$ and the bound (35) yields

$$\mathbb{E}[f] \le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{2eB_n\mathbb{E}[f^2]} + 6r_n^\star + 14MB_n.$$

If $\mathbb{E}[f^2] > r$, rescaling g in the bound (35) and using the choice $6r = 6\sqrt{r_n^\star r} + 7MB_n$ yields

$$\begin{aligned}\mathbb{E}[f] &\le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{2eB_n\mathbb{E}[f^2]} + 6\sqrt{r\mathbb{E}[f^2]} \\ &\le \mathbb{E}_{\widehat{P}_n}[f] + \sqrt{2eB_n\mathbb{E}[f^2]} + 6\sqrt{(r_n^\star + 7MB_n/3)\mathbb{E}[f^2]}\end{aligned}$$

instead. Combining the cases $\mathbb{E}[f^2] \lesseqgtr r$, we conclude that for all $f \in \mathcal{F}$,

$$\mathbb{E}[f] \le \mathbb{E}_{\widehat{P}_n}[f] + \left(\sqrt{2eB_n} + 6\sqrt{r_n^\star + 7MB_n/3}\right)\sqrt{\mathbb{E}[f^2]} + 6r_n^\star + 14MB_n$$

with probability at least $1 - e^{-t}$. Similarly, we can reverse the roles of $\mathbb{E}[f]$ and $\mathbb{E}_{\widehat{P}_n}[f]$ to get the second result.

D.2. Proof of Lemma 18

We frequently use the Rademacher contraction principle (Ledoux and Talagrand, 1991, Thm. 4.12) in what follows.

Lemma 20 *Let $\phi : \mathbb{R} \to \mathbb{R}$ be L-Lipschitz. Then, for every class $\mathcal{G}$*

$$\mathbb{E}_\epsilon[\mathfrak{R}_n(\phi \circ \mathcal{G})] \le L\mathbb{E}_\epsilon[\mathfrak{R}_n(\mathcal{G})]$$

where $\phi \circ \mathcal{G} = \{\phi \circ f : f \in \mathcal{G}\}$.

As in Section D.1, define the self-normalized functions in $\mathcal{F}$

$$\mathcal{G}_r := \left\{\sqrt{\frac{r}{\mathbb{E}[f^2] \vee r}} f : f \in \mathcal{F}\right\} \subseteq \left\{cf : f \in \mathcal{F}, \mathbb{E}[c^2 f^2] \le r, c \in [0,1]\right\}$$

where $r \ge r_n^\star$ will be choosen later. Let $\mathcal{G}_r^2 = \{g^2 : g \in \mathcal{G}_r\}$. From the truncation by r, we have that for all $g^2 \in \mathcal{G}_r^2$, $\mathrm{Var}(g^2) \le \mathbb{E}[g^4] \le M^2\mathbb{E}[g^2] \le M^2 r$. Let $c_1 = 3$ and $c_2 = \frac{7}{3}$. Then by Lemma 14 applied to $\mathcal{G}_r^2$, with probability at least $1 - e^{-t}$, for every $g \in \mathcal{G}_r$

$$\begin{aligned}
\mathbb{E}[g^2] &\le \mathbb{E}_{\widehat{P}_n}[g^2] + c_1\mathbb{E}[\mathfrak{R}_n(\mathcal{G}_r^2)] + M\sqrt{\frac{2rt}{n}} + c_2\frac{M^2 t}{n} \\
&\overset{(a)}{\le} \mathbb{E}_{\widehat{P}_n}[g^2] + 2c_1 M\mathbb{E}[\mathfrak{R}_n(\mathcal{G}_r)] + M\sqrt{\frac{2rt}{n}} + \frac{c_2 M^2 t}{n} \\
&\overset{(b)}{\le} \mathbb{E}_{\widehat{P}_n}[g^2] + 2c_1 M\sqrt{r r_n^\star} + M\sqrt{\frac{2rt}{n}} + \frac{c_2 M^2 t}{n} \qquad (36)
\end{aligned}$$

where in step (a) we used the contraction principle (Lemma 20) and that $x \mapsto x^2$ is $2M$-Lipschitz on $[-M, M]$, and in step (b), we used that $\psi_n(r) \le \sqrt{r r_n^\star}$ as in the proof of Lemma 17 in Section D.1.

Let $A = 2c_1 M\sqrt{r_n^\star} + M\sqrt{\frac{2t}{n}}$ and $D = \frac{c_2 M^2 t}{n}$. For any fixed $K > 1$, choose r to be the largest solution to $A\sqrt{r} + D = \frac{r}{K}$ so that the bound (36) becomes

$$\mathbb{E}[g^2] \le \mathbb{E}_{\widehat{P}_n}[g^2] + \frac{r}{D}.$$

From Lemma 19, we have

$$K^2A^2 \le r \le K^2A^2 + 2KD$$

and in particular, $r \ge K^2A^2 \ge r_n^\star$. For each $g \in \mathcal{G}_r$, there exists $f \in \mathcal{F}$ such that $g = \sqrt{\frac{r}{\mathbb{E}[f^2] \vee r}} f$. If $\mathbb{E}[f^2] \le r$, rescaling the inequality (36) and using the upper bound on r, we obtain

$$\mathbb{E}[f^2] \le \mathbb{E}_{\widehat{P}_n}[f^2] + \frac{r}{K} \le \mathbb{E}_{\widehat{P}_n}[f^2] + KA^2 + 2D.$$

If $\mathbb{E}[f^2] > r$, rescaling instead yields

$$\mathbb{E}[f^2] \le \mathbb{E}_{\widehat{P}_n}[f^2] + \frac{\mathbb{E}[f^2]}{K}.$$

Combining the two cases, we obtain

$$\mathbb{E}[f^2] \le \frac{K}{K-1}\mathbb{E}_{\widehat{P}_n}[f^2] + KA^2 + 2D.$$

Noting that $A \le 2\left(4c_1^2 M^2 r_\eta^\star + 2\frac{M^2 t}{n}\right)$ by convexity, we have the first result once we replace K with $\eta = K - 1 > 0$. The second result similarly follows by reversing the roles of $\mathbb{E}[f]$ and $\mathbb{E}_{\widehat{P}_n}[f]$ in the above argument.

Appendix E. Proof of Theorem 8

Recall our shorthand notation that $\pi(\theta) = \mathrm{argmin}_{\theta^* \in S_\star}\{\|\theta - \theta^*\|_2\}$ denotes the Euclidean projection of θ onto $S_\star$, which is a closed convex set. Define also the localized empirical deviation function

$$\Delta_n(\theta) := \mathbb{E}\left[\ell(\theta; X) - \ell(\pi(\theta); X)\right] - \mathbb{E}_{\widehat{P}_n}\left[\ell(\theta; X) - \ell(\pi(\theta); X)\right]. \qquad (37)$$

We begin with the following

Claim 21 *If $\widehat{S}_\star^\epsilon \not\subset S_\star^{2\epsilon}$, then*

$$\sup_{\theta \in S_\star^{2\epsilon}}\left\{\Delta_n(\theta) + \sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(\ell(\theta; X) - \ell(\pi(\theta); X))}\right\} \ge \epsilon. \qquad (38)$$

Deferring the proof of the claim, let us prove the theorem. First, the growth condition (26) shows that

$$S_\star^{2\epsilon} \subset \left\{\theta \in \Theta : \|\theta - \pi(\theta)\|_2 \le \left(\frac{2\epsilon}{\lambda}\right)^{\frac{1}{\gamma}}\right\} = \left\{\theta \in \Theta : \mathrm{dist}(\theta, S_\star) \le \left(\frac{2\epsilon}{\lambda}\right)^{\frac{1}{\gamma}}\right\}.$$

Therefore, we have for all $\theta \in S_\star^{2\epsilon}$ that

$$\mathrm{Var}_{\widehat{P}_n}(\ell(\theta; X) - \ell(\pi(\theta); X)) \le L^2\,\mathrm{dist}(\theta, S_\star)^2 \le L^2\left(\frac{2\epsilon}{\lambda}\right)^{\frac{2}{\gamma}},$$

and so by the assumption (27) that $\epsilon \ge (\frac{8L^2\rho}{n})^{\frac{\gamma}{2(\gamma-1)}}(\frac{2}{\lambda})^{\frac{1}{\gamma-1}}$, we have

$$\sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(\ell(\theta; X) - \ell(\pi(\theta); X))} \le L\sqrt{\frac{2\rho}{n}}\left(\frac{2\epsilon}{\lambda}\right)^{\frac{1}{\gamma}} \le \frac{\epsilon}{2}.$$

In particular, if the event (38) holds then

$$\sup_{\theta \in S_\star^{2\epsilon}} \Delta_n(\theta) \ge \frac{\epsilon}{2},$$

and recalling the definition (37) of Δ_n, it then follows that

$$\mathbb{P}\left(\widehat{S}_\star^\epsilon \not\subset S_\star^{2\epsilon}\right) \le \mathbb{P}\left(\sup_{\theta \in S_\star^{2\epsilon}} \Delta_n(\theta) \ge \frac{\epsilon}{2}\right). \tag{39}$$

To bound the probability (39), we use standard bounded difference and symmetrization arguments (e.g. Boucheron et al., 2013, Theorem 6.5). Letting $f(X_1, \ldots, X_n) := \sup_{\theta \in S_\star^{2\epsilon}} \Delta_n(\theta)$, the function f satisfies bounded differences:

$$\begin{aligned}
&\sup_{x, x' \in \mathcal{X}} |f(X_1, \cdots, X_{j-1}, x, X_{j+1}, \cdots, X_n) - f(X_1, \cdots, X_{j-1}, x', X_{j+1}, \cdots, X_n)| \\
&\le \sup_{x, x' \in \mathcal{X}} \sup_{\theta \in S_\star^{2\epsilon}} \left| \frac{1}{n}(\ell(\theta; x) - \ell(\pi(\theta); x)) - \frac{1}{n}(\ell(\theta; x') - \ell(\pi(\theta); x')) \right| \\
&\le \frac{2L}{n} \sup_{\theta \in S_\star^{2\epsilon}} \operatorname{dist}(\theta, S_\star) \le \frac{2L}{n} \left(\frac{2\epsilon}{\lambda}\right)^{\frac{1}{\gamma}}
\end{aligned}$$

for $j = 1, \ldots, n$. Using the standard symmetrization inequality $\mathbb{E}[\sup_{\theta \in S_\star^{2\epsilon}} \Delta_n(\theta)] \le 2\mathbb{E}[\mathfrak{R}_n(S_\star^{2\epsilon})]$ and the bounded differences inequality (Boucheron et al., 2013, Theorem 6.5), we have

$$\mathbb{P}\left(\sup_{\theta \in S_\star^{2\epsilon}} \Delta_n(\theta) \ge 2\mathbb{E}[\mathfrak{R}_n(S_\star^{2\epsilon})] + t\right) \le \exp\left(-\frac{nt^2}{2L^2}\left(\frac{\lambda}{2\epsilon}\right)^{\frac{2}{\gamma}}\right)$$

for all $t \ge 0$. Letting $u = \frac{nt^2}{2L^2}\left(\frac{\lambda}{2\epsilon}\right)^{\frac{2}{\gamma}}$ above and recalling the assumption (27) upper bounding $\mathbb{E}[\mathfrak{R}_n(S_\star^{2\epsilon})]$, we have $\mathbb{P}(\sup_{\theta \in S_\star^{2\epsilon}} \Delta_n(\theta) \ge \frac{\epsilon}{2}) \le e^{-u}$. The theorem follows from the bound (39).

Proof of Claim 21 If $\widehat{S}_\star^\epsilon \not\subset S_\star^{2\epsilon}$, then certainly it is the case that there is some $\theta \in \Theta \setminus S_\star^{2\epsilon}$ such that

$$R_n(\theta, \mathcal{P}_n) \le \inf_{\theta \in \Theta} R_n(\theta, \mathcal{P}_n) + \epsilon \le R_n(\pi(\theta), \mathcal{P}_n) + \epsilon.$$

Using the convexity of R_n, we have for all $t \in [0, 1]$ that

$$R_n(t\theta + (1-t)\pi(\theta), \mathcal{P}_n) \le tR_n(\theta, \mathcal{P}_n) + (1-t)R_n(\pi(\theta), \mathcal{P}_n) \le R_n(\pi(\theta), \mathcal{P}_n) + t\epsilon.$$

For all $t \in [0, 1]$, we have by definition of orthogonal projection (because the vector $\theta - \pi(\theta)$ belongs to the normal cone to $S_\star$ at $\pi(\theta)$; cf. (Hiriart-Urruty and Lemaréchal, 1993, Prop. III.5.3.3)) that $\pi(t\theta + (1-t)\pi(\theta)) = \pi(\theta)$. Thus, choosing t appropriately, there exists $\theta' \in \operatorname{bd} S_\star^{2\epsilon}$ with $\theta' = t\theta + (1-t)\pi(\theta)$, $\pi(\theta') = \pi(\theta)$, and $R_n(\theta', \mathcal{P}_n) \le R_n(\pi(\theta'), \mathcal{P}_n) + \epsilon$.

Adding and subtracting the risk $R(\theta)$ and $R(\pi(\theta))$, we have that for some $\theta \in \operatorname{bd} S_\star^{2\epsilon}$ that

$$R_n(\theta, \mathcal{P}_n) - R(\theta) + R(\pi(\theta)) - R_n(\pi(\theta), \mathcal{P}_n) \le R(\pi(\theta)) - R(\theta) + \epsilon \le -\epsilon,$$

where we have used that $R(\theta) = R(\pi(\theta)) + 2\epsilon$ by construction. Multiplying by -1 on each side of the preceding display and taking suprema, we find that

$$\begin{aligned}
\epsilon &\le \sup_{\theta \in S_\star^{2\epsilon}} \left\{R(\theta) - R_n(\theta, \mathcal{P}_n) - (R(\pi(\theta)) - R_n(\pi(\theta), \mathcal{P}_n))\right\} \\
&\le \sup_{\theta \in S_\star^{2\epsilon}} \sup_{P : D_\phi(P \| \widehat{P}_n) \le \rho/n} \left\{R(\theta) - R(\pi) + \mathbb{E}_P\left[\ell(\pi(\theta); X) - \ell(\theta; X)\right]\right\}.
\end{aligned}$$

Applying the upper bound in inequality (10) of Theorem 1 gives the claim.

Appendix F. Proof of Theorem 10

We begin by establishing a few technical lemmas, after which the proof of the theorem follows essentially standard arguments in asymptotics. To prove Theorem 10, we first show that (eventually) we have the exact expansion

$$R_n(\theta, \mathcal{P}_n) = \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] + \sqrt{\frac{2\rho \operatorname{Var}_{\widehat{P}_n}(\ell(\theta, X))}{n}}$$

for all θ in a neighborhood of $\theta^\star$. As in the proof of Theorem 1, this exact equality holds once there is suitable variability in the values $\ell(\theta, X_i)$ over $i = 1, \ldots, n$, however, we require a bit more care as the values $\ell(\theta, X_i)$ may be unbounded below and above. Heuristically, however, assuming that we have this exact expansion and that $\widehat{\theta}_n^{\rm rob} - \theta^\star = O_P(n^{-\frac{1}{2}})$, then we can write the expansions

$$\begin{aligned}
0 &= \nabla_\theta R_n(\widehat{\theta}_n^{\rm rob}, \mathcal{P}_n) \\
&= \nabla \frac{1}{n}\sum_{i=1}^n \ell(\theta^\star, X_i) + \nabla^2\left(\frac{1}{n}\sum_{i=1}^n \ell(\theta^\star, X_i)\right)(\widehat{\theta}_n^{\rm rob} - \theta^\star) + \nabla\sqrt{\frac{2\rho \operatorname{Var}_{\widehat{P}_n}(\ell(\widehat{\theta}_n^{\rm rob}, X))}{n}} + o_P(n^{-\frac{1}{2}}) \\
&= \frac{1}{n}\sum_{i=1}^n \nabla\ell(\theta^\star, X_i) + \nabla^2 R(\theta^\star)(\widehat{\theta}_n^{\rm rob} - \theta^\star) + \nabla\sqrt{\frac{2\rho \operatorname{Var}(\ell(\theta^\star, X))}{n}} + o_P(n^{-\frac{1}{2}}).
\end{aligned}$$

Multiplying by $\sqrt{n}$ and solving for $\widehat{\theta}_n^{\rm rob}$ in the preceding expression, computing $\nabla\sqrt{\operatorname{Var}(\ell(\theta^\star, X))}$ then yields the theorem.

The remainder of the proof makes this heuristic rigorous, and the outline is as follows:

1. We show that there is a uniform expansion of the form (12) in a neighborhood of $\theta^\star$. (See Section F.1.)

2. Using the uniform expansion, we can then leverage standard techniques for asymptotic analysis of finite-dimensional estimators (see, e.g. van der Vaart and Wellner (1996) or Lehmann and Casella (1998)), which proceed by performing a Taylor expansion of the objective in a neighborhood of the optimum and using local asymptotic normality arguments. (See Section F.2.)

F.1. The uniform variance expansion

To lighten notation, we define a few quantities similar to those used in the proof of Theorem 1. Let

$$Z(\theta) := \ell(\theta, X) - \mathbb{E}[\ell(\theta, X)]$$

be the deviation of $\ell(\theta, X)$ around its mean (the risk), and similarly let $Z_i(\theta)$ be the version of this quantity for observation X_i. In addition, let $s_n^2(\theta) = \operatorname{Var}_{\widehat{P}_n}(Z(\theta))$ be the empirical variance of $Z(\theta)$, which is identical to the empirical variance of $\ell(\theta, X)$.

Now, recall the problem

$$\operatorname*{maximize}_P \ \mathbb{E}_P[Z(\theta)] \ \text{ subject to } D_\phi(P \| \widehat{P}_n) \le \frac{\rho}{n},$$

and for each $\theta \in \Theta$, let $p(\theta) = \operatorname{argmax}_{p \in \mathcal{P}_n} \sum_{i=1}^n p_i Z_i(\theta)$ be the solution (probability) vectors. Following expression (9) we see for any $\epsilon \geq 0$ that

$$\min_{i \in [n]} \frac{\sqrt{2\rho}(Z_i(\theta) - \overline{Z}(\theta))}{\sqrt{n} s_n(\theta)} \geq -1 \quad \text{for all } \theta \in \theta^\star + \epsilon\mathbb{B}$$

is sufficient for the exact variance expansion to hold. We now show that this is indeed likely. Let $\epsilon > 0$ be small enough that Assumption A holds, that is, the random Lipschitz function $L(X)$ satisfies $|\ell(\theta, x) - \ell(\theta', x)| \leq L(x)\|\theta - \theta'\|$ for $\theta, \theta' \in \theta^\star + \epsilon\mathbb{B}$. Then because

$$\begin{aligned}\left|\sqrt{n} s_n(\theta) - \sqrt{n} s_n(\theta')\right| &\leq \sup_{u : \|u\|_2 \leq 1} \sum_{i=1}^n u_i \left(\ell(\theta, X_i) - \ell(\theta', X_i)\right) \\ &\leq \sup_{u : \|u\|_2 \leq 1} \sum_{i=1}^n u_i L(X_i) \left\|\theta - \theta'\right\| \leq \sqrt{\sum_{i=1}^n L^2(X_i)} \left\|\theta - \theta'\right\|\end{aligned}$$

so $\theta \mapsto s_n(\theta)$ is $\sqrt{\frac{1}{n}\sum_{i=1}^n L(X_i)^2}$-Lipschitz for $\theta \in \theta^\star + \epsilon\mathbb{B}$, we have

$$\inf_{\theta \in \theta^\star + \epsilon\mathbb{B}} \min_{i \in [n]} \left\{ \frac{\sqrt{2\rho}(Z_i(\theta) - \overline{Z}(\theta))}{\sqrt{n} s_n(\theta)} \right\} \geq \min_{i \in [n]} \frac{\sqrt{2\rho}(Z_i(\theta^\star) - \overline{Z}(\theta^\star) - 2\epsilon L(X_i))}{\sqrt{n\left(s_n(\theta^\star) - \epsilon\sqrt{\frac{1}{n}\sum_{j=1}^n L(X_j)^2}\right)}}.$$

Summarizing our development thus far, we have the following lemma.

Lemma 22 *Let the conditions of the previous paragraph hold. Then*

$$\min_{i \in [n]} \left\{ \sqrt{2\rho}(Z_i(\theta^\star) - \overline{Z}(\theta^\star) - 2\epsilon L(X_i)) \right\} \geq \sqrt{n} \sqrt{s_n(\theta^\star) - \epsilon\left(\frac{1}{n}\sum_{i=1}^n L(X_i)^2\right)^{\frac{1}{2}}}$$

implies that

$$R_n(\theta, \mathcal{P}_n) = \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] + \sqrt{\frac{2\rho}{n}\operatorname{Var}_{\widehat{P}_n}(\ell(\theta, X))} \quad \textit{for all } \theta \in \theta^\star + \epsilon\mathbb{B}.$$

Now, we use the following standard result to show that the conditions of Lemma 22 eventually hold with probability one.

Lemma 23 (Owen (Owen, 1990), Lemma 3) *Let Y_i be independent random variables with $\sup_i \mathbb{E}[Y_i^2] < \infty$. Then $n^{-\frac{1}{2}} \max_{1 \leq i \leq n} |Y_i| \stackrel{a.s.}{\to} 0$.*

Based on Lemma 23 and the strong law of large numbers, we see immediately that

$$\frac{1}{\sqrt{n}} \max_{1 \leq i \leq n} |Z_i(\theta^\star)| \stackrel{a.s.}{\to} 0, \quad \text{and} \quad \frac{1}{\sqrt{n}} \max_{1 \leq i \leq n} L(X_i) \stackrel{a.s.}{\to} 0,$$

because $\mathbb{E}[Z(\theta^\star)^2] < \infty$ and $\mathbb{E}[L(X_i)^2] < \infty$. Applying the strong law of large numbers to obtain

$$s_n(\theta^\star) \stackrel{a.s.}{\to} \sqrt{\operatorname{Var}(\ell(\theta^\star, X))} \quad \text{and} \quad \sqrt{\frac{1}{n}\sum_{i=1}^n L(X_i)^2} \stackrel{a.s.}{\to} \sqrt{\mathbb{E}[L(X)^2]},$$

we see immediately that for small enough $\epsilon > 0$, the condition of Lemma 22 holds eventually with probability 1. That is, the following uniform expansion holds.

Lemma 24 *There exists $\epsilon > 0$ such that, with probability 1, there exists an N (which may be random) such that $n \geq N$ implies*

$$R_n(\theta, \mathcal{P}_n) = \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] + \sqrt{\frac{2\rho \operatorname{Var}_{\widehat{P}_n}(\ell(\theta, X))}{n}} \quad \textit{for all } \theta \in \theta^\star + \epsilon\mathbb{B}.$$

F.2. Asymptotics and Taylor expansions

Let $\mathcal{E}_{n,\text{exact}}$ be the event that the exact variance expansion of Lemma 24 occurs for $\theta \in \theta^\star + \epsilon\mathbb{B}$. Now that we know that $\mathbb{P}(\mathcal{E}_{n,\text{exact}} \text{ eventually}) = 1$, we may perform a few asymptotic expansions of the variance-regularized objective to provide the convergence guarantees specified by the theorem. We use the following lemma.

Lemma 25 *Let the conditions of the theorem hold. If*

$$\widehat{\theta}_n^{\text{rob}} \in \operatorname*{argmin}_\theta R_n(\theta, \mathcal{P}_n) \quad \textit{then} \quad \widehat{\theta}_n^{\text{rob}} \stackrel{a.s.}{\to} \theta^\star. \tag{40}$$

The proof is standard, but for completeness we include it in Section G.3.

By combining Lemmas 24 and 25, we see that with probability 1, for any $\epsilon > 0$, we eventually have both

$$\|\widehat{\theta}_n^{\text{rob}} - \theta^\star\|_2 < \epsilon \quad \text{and} \quad R_n(\widehat{\theta}_n^{\text{rob}}, \mathcal{P}_n) = \mathbb{E}_{\widehat{P}_n}[\ell(\widehat{\theta}_n^{\text{rob}}, X)] + \sqrt{\frac{2\rho}{n}\operatorname{Var}_{\widehat{P}_n}(\ell(\widehat{\theta}_n^{\text{rob}}, X))}.$$

Assume for the remainder of the argument that both of these conditions hold. Standard results on subdifferentiability of maxima of collections of convex functions (Hiriart-Urruty and Lemaréchal, 1993, Chapter X) give that $R_n(\theta, \mathcal{P}_n)$ is differentiable near $\theta^\star$, and thus

$$\begin{aligned}0 &= \nabla R_n(\widehat{\theta}_n^{\text{rob}}, \mathcal{P}_n) = \mathbb{E}_{\widehat{P}_n}[\nabla\ell(\widehat{\theta}_n^{\text{rob}}, X)] + \nabla\sqrt{\frac{2\rho}{n}\operatorname{Var}_{\widehat{P}_n}(\ell(\widehat{\theta}_n^{\text{rob}}, X))} \\ &= \frac{1}{n}\sum_{i=1}^n \nabla\ell(\widehat{\theta}_n^{\text{rob}}, X_i) + \sqrt{\frac{2\rho}{n}} \frac{\mathbb{E}_{\widehat{P}_n}\left[(\nabla\ell(\widehat{\theta}_n^{\text{rob}}, X) - \mathbb{E}_{\widehat{P}_n}[\nabla\ell(\widehat{\theta}_n^{\text{rob}}, X)])(\ell(\widehat{\theta}_n^{\text{rob}}, X) - \mathbb{E}_{\widehat{P}_n}[\ell(\widehat{\theta}_n^{\text{rob}}, X)])\right]}{\sqrt{\operatorname{Var}_{\widehat{P}_n}(\ell(\widehat{\theta}_n^{\text{rob}}, X))}}.\end{aligned} \tag{41}$$

Because $\widehat{\theta}_n^{\text{rob}} \stackrel{a.s.}{\to} \theta^\star$, by the continuous mapping theorem and local uniform convergence of the empirical expectations $\mathbb{E}_{\widehat{P}_n}[\cdot]$ to $\mathbb{E}[\cdot]$, the second term of expression (41) satisfies

$$\frac{\mathbb{E}_{\widehat{P}_n}\left[(\nabla\ell(\widehat{\theta}_n^{\text{rob}}, X) - \mathbb{E}_{\widehat{P}_n}[\nabla\ell(\widehat{\theta}_n^{\text{rob}}, X)])(\ell(\widehat{\theta}_n^{\text{rob}}, X) - \mathbb{E}_{\widehat{P}_n}[\ell(\widehat{\theta}_n^{\text{rob}}, X)])\right]}{\sqrt{\operatorname{Var}_{\widehat{P}_n}(\ell(\widehat{\theta}_n^{\text{rob}}, X))}} = \underbrace{\frac{\operatorname{Cov}(\nabla\ell(\theta^\star, X), \ell(\theta^\star, X))}{\sqrt{\operatorname{Var}(\ell(\theta^\star, X))}}}_{=: b(\theta^\star)} + o_P(1).$$

For simplicity, we let $b(\theta^\star)$ denote the final term, which we shall see becomes an asymptotic bias. Thus, performing a Taylor expansion of the terms $\nabla\ell(\widehat{\theta}_n^{\text{rob}}, X_i)$ around $\theta^\star$ in equality (41), there exist (random) error matrices $E_n(X_i)$, where $\|E_n(X_i)\| \leq H(X_i)\|\widehat{\theta}_n^{\text{rob}} - \theta^\star\|$

by Assumption A, such that

$$0 = \mathbb{E}_{\widehat{P}_n}[\nabla \ell(\theta^\star, X)] + \frac{1}{n}\sum_{i=1}^n \left(\nabla^2 \ell(\theta^\star, X_i) + E_n(X_i)\right)(\widehat{\theta}_n^{\rm rob} - \theta^\star) + \sqrt{\frac{2\rho}{n}}(b(\theta^\star) + o_P(1))$$
$$= \mathbb{E}_{\widehat{P}_n}[\nabla \ell(\theta^\star, X)] + \left(\nabla^2 R(\theta^\star) + o_P(1)\right)(\widehat{\theta}_n^{\rm rob} - \theta^\star) + \sqrt{\frac{2\rho}{n}}(b(\theta^\star) + o_P(1)).$$

Multiplying both sides by $\sqrt{n}$, using that $\nabla^2 R(\theta^\star) + o_P(1)$ is eventually invertible, and applying the continuous mapping theorem, we have

$$\sqrt{n}(\widehat{\theta}_n^{\rm rob} - \theta^\star) = -(\nabla^2 R(\theta^\star) + o_P(1))^{-1}\frac{1}{\sqrt{n}}\sum_{i=1}^n \nabla \ell(\theta^\star, X_i) - \sqrt{2\rho} b(\theta^\star) + o_P(1).$$

The first term on the right side of the above display converges in distribution to a $\mathsf{N}(0, \Sigma)$ distribution, where

$$\Sigma = (\nabla^2 R(\theta^\star))^{-1}\operatorname{Cov}(\nabla \ell(\theta^\star, X))(\nabla^2 R(\theta^\star))^{-1},$$

so that

$$\sqrt{n}(\widehat{\theta}_n^{\rm rob} - \theta^\star) \stackrel{d}{\to} \mathsf{N}\left(-\sqrt{2\rho}\, b(\theta^\star), \Sigma\right)$$

as claimed in the theorem statement.

Appendix G. Proofs of Technical Lemmas

G.1. Proof of Inequality (24)

Define the Gaussian complexity

$$\mathfrak{G}_n(\{\ell \circ \mathcal{H}\}_{\le r}) := \mathbb{E}\left[\sup_{h \in \mathbb{B}_{\mathcal{H}}, c \in [0,1]} \sum g_i c \ell(h(x_i), y_i) \mid \mathbb{E}[\ell(h(X), Y)^2] \le r/c^2\right], \tag{42}$$

where $g_i \stackrel{\rm iid}{\sim} \mathsf{N}(0,1)$ (here we recall the standard result (Bartlett and Mendelson, 2002) that Gaussian complexity upper bounds Rademacher complexities up to a constant). Now, the set $h - h^\star$ such that $h \in \mathbb{B}_{\mathcal{H}}$ is contained in $2\mathbb{B}_{\mathcal{H}}$, which is convex. Moreover, we have $\mathbb{E}[\ell(h(X), Y)^2] = \mathbb{E}[(h(X) - h^\star(X))^2] + \sigma^2$, and so we have for any c that

$$\{h \in \mathbb{B}_{\mathcal{H}} \mid c^2 \mathbb{E}[\ell(h(X), Y)^2] \le r\} \subset \{h \in \mathbb{B}_{\mathcal{H}} \mid \mathbb{E}[(h(X) - h^\star(X))^2] \le r/c^2\},$$

and $\mathbb{E}[\ell(h(X), Y)^2] \le r/c^2$ also implies $\sigma^2 \le r/c^2$. Returning to expression (42) and enlarging the sets over which we take suprema, we thus obtain

$$\mathfrak{G}_n(\ell \circ \mathcal{H}) \le \mathbb{E}\left[\sup_{h \in \mathbb{B}_{\mathcal{H}}, c_1, c_2 \in [0,1]} \sum_{i=1}^n g_i |c_1(h(x_i) - h^\star(x_i)) - c_2 \xi_i| \mid \mathbb{E}[(h(X) - h^\star(X))^2] \le \frac{r}{c_1^2}, \sigma^2 \le \frac{r}{c_2^2}\right]$$
$$\le \mathbb{E}\left[\sup_{f \in 2\mathbb{B}_{\mathcal{H}}, c \in [0,1]} \sum_{i=1}^n g_i |f(x_i) - c\xi_i| \mid \mathbb{E}[f(X)^2] \le r, \sigma^2 \le r/c^2\right],$$

where we have used that $h - h^\star \in 2\mathbb{B}_{\mathcal{H}}$ and that the set $\mathbb{B}_{\mathcal{H}}$ is convex to obtain the second inequality. We now upper bound the final display using the classical Sudakov-Fernique comparison theorem (e.g. Chatterjee, 2005). Indeed, define the two Gaussian processes indexed by $f \in \mathcal{H}$ and $c \in [0,1]$ by $Y_{f,c} = \sum_{i=1}^n g_i |f(x_i) - c\xi_i|$ and $Z_{f,c} = \sum_{i=1}^n g_i f(x_i) + c\sum_{i=1}^n w_i \xi_i$, where $g_i \stackrel{\rm iid}{\sim} \mathsf{N}(0,1)$ and $w_i \stackrel{\rm iid}{\sim} \mathsf{N}(0,1)$. Then we have for any $f_1, f_2 \in \mathcal{H}$ and $c_1, c_2 \in [0,1]$ that

$$\mathbb{E}[(Y_{f_1,c_1} - Y_{f_2,c_2})^2] = \sum_{i=1}^n \left(|f_1(x_i) - c_1\xi_i| - |f_2(x_i) - c_2\xi_i|\right)^2$$
$$\le \sum_{i=1}^n \left(f_1(x_i) - f_2(x_i) + (c_2 - c_1)\xi_i\right)^2$$
$$\le 2\sum_{i=1}^n (f_1(x_i) - f_2(x_i))^2 + 2(c_2 - c_1)^2 \sum_{i=1}^n \xi_i^2.$$

Moreover, $\mathbb{E}[(Z_{f_1,c_1} - Z_{f_2,c_2})^2] = \sum_{i=1}^n (f_1(x_i) - f_2(x_i))^2 + (c_1 - c_2)^2 \sum_{i=1}^n \xi_i^2$. Thus, the Sudakov-Fernique inequality guarantees that $\mathbb{E}[\sup_{f,c} Y_{f,c}] \le \sqrt{2}\mathbb{E}[\sup_{f,c} Z_{f,c}]$, and

$$\mathfrak{G}_n(\ell \circ \mathcal{H}) \lesssim \mathbb{E}\left[\sup_{f \in 2\mathbb{B}_{\mathcal{H}}} \sum_{i=1}^n g_i f(x_i) \mid \mathbb{E}[f(X)^2] \le r\right] + \mathbb{E}\left[\sup_{c \in [0,1]} c\sum_{i=1}^n w_i \xi_i \mid c^2\sigma^2 \le r\right].$$

The last term in the expression has bound $\sqrt{nr}$ by Jensen's inequality and the relaxation that $c \in [-1,1]$. For the first term, Mendelson (2003, Thm. 2.1) shows that for RKHS with kernel eigenvalues $\lambda_1, \lambda_2, \ldots$, we have

$$\mathbb{E}\left[\sup_{f \in 2\mathbb{B}_{\mathcal{H}}} \sum_{i=1}^n g_i f(X_i) \mid \mathbb{E}[f(X)^2] \le r\right] \lesssim \sqrt{n}\left(\sum_{j=1}^\infty \min\{\lambda_j, r\}\right)^{\frac{1}{2}},$$

which yields our desired claim (24).

G.2. Proof of Lemma 7

Defining $N_y := \operatorname{card}\{i \in [n] : X_i = y\}$ for $y \in \{-1, 0, 1\}$, we immediately obtain

$$\mathbb{E}_{\widehat{P}_n}[\ell(\theta; X)] = \frac{1}{n}\left[N_{-1}|\theta + 1| + N_1|\theta - 1| + N_0|\theta| - (n - N_0)\right],$$

because $N_1 + N_{-1} + N_0 = n$. In particular, we find that the empirical risk minimizer θ satisfies

$$\widehat{\theta}_n^{\rm erm} := \operatorname*{argmin}_{\theta \in \mathbb{R}} \mathbb{E}_{\widehat{P}_n}[\ell(\theta; X)] = \begin{cases} 1 & \text{if } N_1 > N_0 + N_{-1} \\ -1 & \text{if } N_{-1} > N_0 + N_1 \\ \in [-1,1] & \text{otherwise.} \end{cases}$$

On the events $N_1 > N_{-1} + N_0$ or $N_{-1} > N_0 + N_1$, which are disjoint, then, we have

$$R(\widehat{\theta}_n^{\rm erm}) = \delta = R(\theta^\star) + \delta.$$

Let us give a lower bound on the probability of this event. Noting that marginally $N_1 \sim \mathsf{Bin}(n, \frac{1-\delta}{2})$ and using $N_0 + N_{-1} = n - N_1$, we have $N_1 > N_0 + N_{-1}$ if and only if $N_1 > \frac{n}{2}$, and we would like to lower bound

$$\mathbb{P}\left(N_1 > \frac{n}{2}\right) = \mathbb{P}\left(\mathsf{Bin}\left(n, \frac{1-\delta}{2}\right) > \frac{n}{2}\right) = \mathbb{P}\left(\mathsf{Bin}\left(n, \frac{1+\delta}{2}\right) < \frac{n}{2}\right).$$

Letting $\Phi(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{t} e^{-u^2/2} du$ denote the standard Gaussian CDF, then Zubkov and Serov (2013) show that

$$\mathbb{P}\left(N_1 \geq \frac{n}{2}\right) \geq \Phi\left(-\sqrt{2n D_{\rm kl}\left(\frac{1}{2} \| \frac{1+\delta}{2}\right)}\right)$$

where $D_{\rm kl}\left(p\|q\right) = p \log \frac{p}{q} + (1-p) \log \frac{1-p}{1-q}$ denotes the binary KL-divergence. We have by standard bounds on the KL-divergence (Tsybakov, 2009, Lemma 2.7) that $D_{\rm kl}(\frac{1}{2} \| \frac{1+\delta}{2}) \leq \frac{\delta^2}{2(1-\delta^2)}$, so that

$$\mathbb{P}\left(N_1 > \frac{n}{2} \text{ or } N_{-1} > \frac{n}{2}\right) \geq 2\Phi\left(-\sqrt{\frac{n\delta^2}{1-\delta^2}}\right) - 2\mathbb{P}\left(N_1 = \frac{n}{2}\right).$$

For n odd, the final probability is 0, while for n even, we have

$$\mathbb{P}\left(N_1 = \frac{n}{2}\right) = 2^{-n} \binom{n}{n/2} (1-\delta^2)^{n/2} \leq (1-\delta^2)^{n/2} \sqrt{\frac{2}{\pi n}},$$

where the inequality uses that $\binom{2n}{n} \leq \frac{4^n}{\sqrt{\pi n}}$ by Stirling's approximation. Summarizing, we find that

$$\mathbb{P}\left(N_1 > \frac{n}{2} \text{ or } N_{-1} > \frac{n}{2}\right) \geq 2\Phi\left(-\sqrt{\frac{n\delta^2}{1-\delta^2}}\right) - (1-\delta^2)^{n/2} \sqrt{\frac{8}{\pi n}}.$$

G.3. Proof of Lemma 25

Under the conditions of the theorem, the compactness of $\theta^\star + \epsilon\mathbb{B}$ guarantees that

$$\sup_{\theta \in \theta^\star + \epsilon\mathbb{B}} |\mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] - R(\theta)| \stackrel{a.s.}{\to} 0,$$

as the functions $\theta \mapsto \ell(\theta, x)$ are Lipschitz in a neighborhood of $\theta^\star$ by Assumption A. Similarly,

$$\sup_{\theta \in \theta^\star + \epsilon\mathbb{B}} \left|\mathrm{Var}_{\widehat{P}_n}(\ell(\theta, X)) - \mathrm{Var}(\ell(\theta, X))\right| \stackrel{a.s.}{\to} 0,$$

using the local Lipschitzness of $\nabla^2 \ell$. (See, for example, the Glivenko-Cantelli results in Chapters 2.4–2.5 of van der Vaart and Wellner (1996).) Thus, using the two-sided bounds (10) of Theorem 1, we have that

$$\begin{aligned}
&\sup_{\theta \in \theta^\star + \epsilon\mathbb{B}} |R_n(\theta, \mathcal{P}_n) - R(\theta)| \\
&\leq \sup_{\theta \in \theta^\star + \epsilon\mathbb{B}} \left|\mathbb{E}_{\widehat{P}_n}[\ell(\theta, \mathcal{P}_n)] - R(\theta)\right| + \sqrt{\frac{2\rho}{n}} \sup_{\theta \in \theta^\star + \epsilon\mathbb{B}} \sqrt{\mathrm{Var}_{\widehat{P}_n}(\ell(\theta, X))} \stackrel{a.s.}{\to} 0.
\end{aligned}$$

Now, we use the fact that $\nabla^2 R(\theta^\star) \succ 0$, and that $\theta \mapsto \nabla^2 R(\theta)$ is continuous in a neighborhood of $\theta^\star$. Fix $\epsilon > 0$ small enough that the preceding uniform convergence guarantees hold over $\theta^\star + 2\epsilon\mathbb{B}$ and $\nabla^2 R(\theta) \succeq \lambda I$ for some $\lambda > 0$ and all $\theta \in \theta^\star + 2\epsilon\mathbb{B}$. Let $\theta \notin \theta^\star + \epsilon\mathbb{B}$, but $\theta \in \theta^\star + 2\epsilon\mathbb{B}$. Then for sufficently large n, we have that

$$\begin{aligned}
R_n(\theta, \mathcal{P}_n) \geq \mathbb{E}_{\widehat{P}_n}[\ell(\theta, X)] &\stackrel{(i)}{\geq} R(\theta) - \frac{\lambda}{4}\epsilon^2 \\
&\stackrel{(ii)}{\geq} R(\theta^\star) + \frac{\lambda}{2}\left\|\theta - \theta^\star\right\|_2^2 - \frac{\lambda}{4}\epsilon^2 \stackrel{(iii)}{\geq} R(\theta^\star) + \frac{\lambda}{4}\epsilon^2 \\
&\stackrel{(iv)}{\geq} \mathbb{E}_{\widehat{P}_n}[\ell(\theta^\star, X)] + \frac{\lambda}{4}\epsilon^2 - \frac{\lambda}{8}\epsilon^2 = \mathbb{E}_{\widehat{P}_n}[\ell(\theta^\star, X)] + \frac{\lambda}{8}\epsilon^2,
\end{aligned}$$

where inequalities (i) and (iv) follow from the uniform convergence guarantee, inequality (ii) from the strong convexity of R near $\theta^\star$, and (iii) because $\|\theta - \theta^\star\|_2 \geq \epsilon$. Finally, we have that

$$\mathbb{E}_{\widehat{P}_n}[\ell(\theta^\star, X)] \geq R_n(\theta^\star, \mathcal{P}_n) - \underbrace{\sqrt{\frac{2\rho}{n}\mathrm{Var}_{\widehat{P}_n}(\ell(\theta^\star, X))}}_{\stackrel{a.s.}{\to} 0},$$

so that eventually $R_n(\theta, \mathcal{P}_n) > R_n(\theta^\star, \mathcal{P}_n)$ for all $\theta \in \theta^\star + 2\epsilon\mathbb{B} \setminus \epsilon\mathbb{B}$. By convexity, then this inequality holds for all $\theta \notin \theta^\star + \epsilon\mathbb{B}$. Thus if $\widehat{\theta}_n^{\rm rob} \in \operatorname{argmin}_\theta R_n(\theta, \mathcal{P}_n)$, then for any $\epsilon > 0$ we must eventually have $\|\widehat{\theta}_n^{\rm rob} - \theta^\star\|_2 < \epsilon$.

Appendix H. Efficient solutions to computing the robust expectation

In this appendix, we give a detailed description of the procedure we use to compute the supremum problem (8). In particular, our procedure requires time $O(n \log n + \log \frac{1}{\epsilon} \log n)$, where ϵ is the desired solution accuracy. Let us reformulate this as a minimization problem in a variable $p \in \mathbb{R}^n$ for simplicity. Then we wish to solve

$$\text{minimize } p^\top z \quad \text{subject to } \frac{1}{2n}\left\|np - \mathbf{1}\right\|_2^2 \leq \rho,\ p \geq 0,\ p^\top \mathbf{1} = 1.$$

We take a partial dual of this minimization problem, then maximize this dual to find the optimizing p. Introducing the dual variable $\lambda \geq 0$ for the constraint that $\frac{1}{2}\|p - \frac{1}{n}\mathbf{1}\|_2^2 \leq \frac{\rho}{n}$ and performing the standard min-max swap (Boyd and Vandenberghe, 2004) (strong duality obtains for this problem because the Slater condition is satisfied by $p = \frac{1}{n}\mathbf{1}$) yields the maximization problem

$$\underset{\lambda \geq 0}{\text{maximize}}\ f(\lambda) := \inf_p \left\{\frac{\lambda}{2}\left\|p - \frac{1}{n}\mathbf{1}\right\|_2^2 - \frac{\lambda\rho}{n} + p^\top z \mid p \geq 0,\ \mathbf{1}^\top p = 1\right\}. \tag{43}$$

If we can efficiently compute the infimum (43), then it is possible to binary search over λ. Recall the standard fact (Hiriart-Urruty and Lemaréchal, 1993, Chapter VI.4.4) that for a collection $\{f_p\}_{p \in \mathcal{P}}$ of concave functions, if the infimum $f(x) = \inf_{p \in \mathcal{P}} f_p(x)$ is attained at some p_0 then any vector $\nabla f_{p_0}(x)$ is a supergradient of $f(x)$. Thus, letting $p(\lambda)$ be the (unique) minimizing value of p for any $\lambda > 0$, the objective (43) becomes $f(\lambda) = \frac{\lambda}{2}\|p(\lambda) - \frac{1}{n}\mathbf{1}\|_2^2 - \frac{\lambda\rho}{n} + p(\lambda)^\top z$, whose derivative with respect to λ (holding p fixed) is $f'(\lambda) = \frac{1}{2}\|p(\lambda) - \frac{1}{n}\mathbf{1}\|_2^2 - \frac{\rho}{n}$.

Now we use well-known results on the Euclidean projection of a vector to the probability simplex (Duchi et al., 2008) to provide an efficient computation of the infimum (43). First, we assume with no loss of generality that $z_1 \le z_2 \le \cdots \le z_n$ and that $\mathbf{1}^\top z = 0$, because neither of these changes the original optimization problem (as $\mathbf{1}^\top p = 0$ and the objective is symmetric). Then we define the two vectors $s, \sigma^2 \in \mathbb{R}^n$, which we use for book-keeping in the algorithm, by

$$s_i = \sum_{j \le i} z_j, \quad \sigma_i^2 = \sum_{j \le i} z_j^2,$$

and we let z^2 be the vector whose entries are z_i^2. The infimum problem (43) is equivalent to projecting the vector $v(\lambda) \in \mathbb{R}^n$ defined by

$$v_i = \frac{1}{n} - \frac{1}{\lambda} z_i$$

onto the probability simplex. Notably (Duchi et al., 2008), the projection $p(\lambda)$ has the form $p_i(\lambda) = (v_i - \eta)_+$ for some $\eta \in \mathbb{R}$, where η is chosen such that $\sum_{i=1}^n p_i(\lambda) = 1$. Finding such a value η is equivalent (Duchi et al., 2008, Figure 1) to finding the unique index i such that

$$\sum_{j=1}^{i} (v_j - v_i) < 1 \quad \text{and} \quad \sum_{j=1}^{i+1} (v_j - v_{i+1}) \ge 1,$$

taking $i = n$ if no such index exists (the sum $\sum_{j=1}^i (v_j - v_i)$ is increasing in i and $v_1 - v_1 = 0$). Given the index i, algebraic manipulations show that $\eta = \frac{1}{n} - \frac{1}{i} - \frac{1}{i} \sum_{j=1}^i z_j/\lambda = \frac{1}{n} - \frac{1}{i} - \frac{1}{i} s_i/\lambda$ satisfies the equality $\sum_{i=1}^n (v_i - \eta)_+ = 1$ and that $v_j - \eta \ge 0$ for all $j \le i$ while $v_j - \eta \le 0$ for $j > i$. Of course, given the index i and η, we may calculate the derivative $\frac{\partial}{\partial \lambda} f(\lambda)$ efficiently as well:

$$\begin{aligned} f'(\lambda) &= \frac{\partial}{\partial \lambda} \left\{ \frac{\lambda}{2} \left\| p(\lambda) - n^{-1}\mathbf{1} \right\|_2^2 - \frac{\lambda \rho}{n} + p(\lambda)^\top z \right\} \\ &= \frac{1}{2} \left\| p(\lambda) - n^{-1}\mathbf{1} \right\|_2^2 - \frac{\rho}{n} = \frac{1}{2} \sum_{j=1}^{i} (v_j - \eta - n^{-1})^2 + \frac{1}{2} \sum_{j=i+1}^{n} \frac{1}{n^2} - \frac{\rho}{n} \\ &= \frac{1}{2} \sum_{j=1}^{i} \left(\frac{1}{\lambda} z_j + \eta \right)^2 + \frac{n-i}{2n^2} - \frac{\rho}{n} = \frac{\sigma_i^2}{2\lambda^2} + \frac{i\eta^2}{2} + \frac{s_i \eta}{\lambda} + \frac{n-i}{2n^2} - \frac{\rho}{n}. \end{aligned}$$

Finding the index optimal i can be done by a binary search, which requires $O(\log n)$ time, and $f'(\lambda)$ is then computable in $O(1)$ time using the vectors s and σ^2. It is then possible to perform a binary search over λ using $f'(\lambda)$, which which requires $\log \frac{1}{\epsilon}$ iterations to find λ within accuracy ϵ, from which it is easy to compute $p(\lambda)$ via $p_i(\lambda) = (v_i - \eta)_+ = \left(n^{-1} - \lambda^{-1} z_i - \eta\right)_+$.

We summarize this discussion with pseudo-code in Figures 6 and 7, which provide a main routine and sub-routine for finding the optimal vector p. These routines show that, once provided the sorted vector z with $z_1 \le z_2 \le \cdots \le z_n$ (which requires $n \log n$ time to compute), we require only $O(\log \frac{1}{\epsilon} \cdot \log n)$ computations.

Inputs: Sorted vector $z \in \mathbb{R}^n$ with $\mathbf{1}^\top z = 0$, parameter $\rho > 0$, solution accuracy ϵ

Set $\lambda_{\min} = 0$ and $\lambda_{\max} = \lambda_\infty = \max\{n \|z\|_\infty, \sqrt{n/2\rho}\, \|z\|_2\}$
Set $s_i = \sum_{j \le i} z_j$ and $\sigma_i^2 = \sum_{j \le i} z_j^2$
While $|\lambda_{\max} - \lambda_{\min}| > \epsilon \lambda_\infty$
  Set $\lambda = \frac{\lambda_{\max} + \lambda_{\min}}{2}$
  Set $(\eta, i) = \textsc{FindShift}(z, \lambda, s)$ // (Figure 7)
  Set $f'(\lambda) = \frac{1}{2\lambda^2}\sigma_i^2 + \frac{\eta^2}{2} i^2 + \frac{\eta}{\lambda} s_i + \frac{n-i}{2n^2} - \frac{\rho}{n}$
  If $f'(\lambda) > 0$
    Set $\lambda_{\min} = \lambda$
  Else
    Set $\lambda_{\max} = \lambda$
Set $\lambda = \frac{1}{2}(\lambda_{\max} + \lambda_{\min})$, $(\eta, i) = \textsc{FindShift}(z, \lambda, s)$
Set $p_i = \left(\frac{1}{n} - \frac{1}{\lambda} z_i - \eta\right)_+$ and return p

Figure 6. Procedure FindP to find the vector p minimizing $\sum_{i=1}^n p_i z_i$ subject to the constraint $\frac{1}{2n} \|np - \mathbf{1}\|_2^2 \le \rho$. Method takes $\log \frac{1}{\epsilon}$ iterations of the loop.

Inputs: Sorted vector z with $\mathbf{1}^\top z = 0$, $\lambda > 0$, vector s with $s_i = \sum_{j \le i} z_j$

Set $i_{\text{low}} = 1, i_{\text{high}} = n$
If $\frac{1}{n} - \frac{z_n}{\lambda} \ge 0$
  Return $(\eta = 0, i = n)$
While $i_{\text{low}} \ne i_{\text{high}}$
  $i = \frac{1}{2}(i_{\text{low}} + i_{\text{high}})$
  $s_{\text{left}} = \frac{1}{\lambda}(iz_i - s_i)$ // (this is $s_{\text{left}} = \sum_{j=1}^i (v_j - v_i)$)
  $s_{\text{right}} = \frac{1}{\lambda}((i+1)z_{i+1} - s_{i+1})$ // (this is $s_{\text{right}} = \sum_{j=1}^{i+1} (v_j - v_{i+1})$)
  If $s_{\text{right}} \ge 1$ and $s_{\text{left}} < 1$
    Set $\eta = \frac{1}{n} - \frac{1}{i} - \frac{1}{\lambda i} s_i$ and return (η, i)
  Else if $s_{\text{left}} \ge 1$
    Set $i_{\text{high}} = i - 1$
  Else
    Set $i_{\text{low}} = i + 1$
Set $i = i_{\text{low}}$ and $\eta = \frac{1}{n} - \frac{1}{i} - \frac{1}{\lambda i} s_i$ and return (η, i)

Figure 7. Procedure FindShift to find index i and parameter η such that, for the definition $v_i = \frac{1}{n} - \frac{1}{\lambda} z_i$, we have $v_j - \eta \ge 0$ for $j \le i$, $v_j - \eta \le 0$ for $j > i$, and $\sum_{j=1}^n (v_j - \eta)_+ = 1$. Method requires time $O(\log n)$.

Abstract

Given a vertex of interest in a network G_1, the vertex nomination problem seeks to find the corresponding vertex of interest (if it exists) in a second network G_2. A vertex nomination scheme produces a list of the vertices in G_2, ranked according to how likely they are judged to be the corresponding vertex of interest in G_2. The vertex nomination problem and related information retrieval tasks have attracted much attention in the machine learning literature, with numerous applications to social and biological networks. However, the current framework has often been confined to a comparatively small class of network models, and the concept of statistically consistent vertex nomination schemes has been only shallowly explored. In this paper, we extend the vertex nomination problem to a very general statistical model of graphs. Further, drawing inspiration from the long-established classification framework in the pattern recognition literature, we provide definitions for the key notions of Bayes optimality and consistency in our extended vertex nomination framework, including a derivation of the Bayes optimal vertex nomination scheme. In addition, we prove that no universally consistent vertex nomination schemes exist. Illustrative examples are provided throughout.

Keywords: Vertex nomination, graph inference, recommender systems

1. Introduction

Statistical inference on graphs is an important branch of modern statistics and machine learning. In recent years, there have been numerous papers in the literature developing graph analogues of statistical inference tasks such as hypothesis testing (Asta and Shalizi, 2015; Tang et al., 2017b), classification (Tang et al., 2013; Chen et al., 2016a), and clustering (Luxburg, 2007; Rohe et al., 2011; Sussman et al., 2012; Newman and Clauset, 2016). Moreover, growth in the size and complexity of network data sets have necessitated techniques for network-specific data mining tasks such as link prediction (Liben-Nowell and Kleinberg, 2007; Lü and Zhou, 2011); entity resolution and network alignment (Conte et al., 2004; Lyzinski, 2018); and vertex nomination (Coppersmith and Priebe, 2012; Coppersmith, 2014; Suwan et al., 2015; Fishkind et al., 2015; Lyzinski et al., 2016). Akin to the development of classical statistics, algorithmic advancement has, in many ways, outpaced theoretical developments in these emerging graph-driven domains. This development has been necessitated by the dizzying pace of data generation, but there is nevertheless the need for a firm theoretical context in which to frame algorithmic progress. In this paper, drawing inspiration from the long-established classification framework in the pattern recognition literature (Devroye et al., 1997), we provide a rigorous theoretical framework for understanding statistical consistency in the vertex nomination inference task.

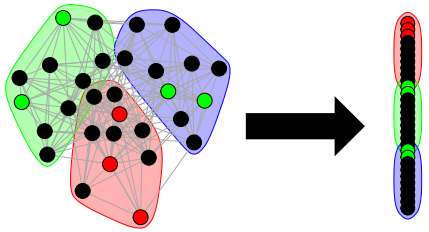

Figure 1: A visual representation of the classical Vertex Nomination framework: Given a community of interest in a network (here the red community) and some examples of vertices that are/are not part of the community of interest (colored red and green, respectively), rank the remaining vertices in the network into a nomination list, with those vertices from the community of interest concentrating at the top of the nomination list.

The vertex nomination (VN) task, which can be viewed as the graph analogue of the more classical recommender system task (Ricci et al., 2011), has traditionally been stated as follows: given a community of interest in a network and some examples of vertices that are or are not part of a community of interest, vertex nomination seeks to rank the remaining vertices in the network into a nomination list, with those vertices from the community of interest (ideally) concentrating at the top of the nomination list. See Figure 1 for a visual representation of this classical Vertex Nomination framework. In limited-resource settings, vertex nomination tools have proven to be effective in efficiently searching and querying large networks, with applications including detecting fraudsters in the Enron email network (Coppersmith and Priebe, 2012; Marchette et al., 2011; Suwan et al., 2015), uncovering web advertisements that have association with human trafficking (Fishkind et al., 2015), and identifying latent structure in connectome data (Fishkind et al., 2015; Yoder et al., 2018).

While related to the community detection problem (Newman, 2006; Luxburg, 2007; Bickel and Chen, 2009; Newman and Clauset, 2016), this traditional formulation of the VN problem is a semi-supervised inference task whose output is not an assignment of vertices to communities, but rather a ranked estimate of which vertices belong to a particular community of interest. That is, in contrast to community detection, the VN problem does

not aim to recover the community memberships of any vertices not in the community of interest. Clearly, any method that can recover the community memberships of all vertices in a graph can recover the interesting community, and hence any community detection algorithm can be repurposed for the VN problem just described with minor adaptation (e.g., by ranking vertices according to their probability of membership in the community of interest); see, for example, the spectral vertex nomination scheme of Fishkind et al. (2015). The specific performance of such an adaptation is highly dependent on the fidelity of the base clustering procedure, and the performance is often below that of the semi-supervised VN specific analogues (see Yoder et al., 2018).

The above formulation of the VN task assumes the presence of strong community structure among the vertices of interest in the graph. In practice, this is often a reasonable assumption, particularly if it is expected that interesting vertices will behave similarly to one another in the network. However, the particular features that mark a vertex as interesting are entirely task-dependent. To paraphrase the common proverb, interestingness is in the eye of the practitioner. Interesting vertices may be, for example, those with large network centrality (Jeong et al., 2001; Newman, 2005), those with a particular role in the network (Lusseau and Newman, 2004), or those corresponding to a given user across social networks (Patsolic et al., 2017). In these applications, interesting vertices need not correspond precisely to the community structure captured by a generative network model, and hence such cases are ill-described by the community-based VN problem described above. To accommodate this task-dependency and broader notion of interesting vertices, we consider the following generalization and extension of the previously-presented VN problem: Given a vertex of interest v^* in a graph $G_1 = (V_1, E_1)$, find the corresponding vertex of interest u^* (if it exists) in a second graph $G_2 = (V_2, E_2)$ by ranking the vertices of G_2 according to our confidence that they correspond to v^* in graph G_1; see Figure 2 for a visual representation of this VN framework. In this formulation, which is an (potentially) unsupervised inference task, what defines v^* as interesting is entirely model-dependent, and different network models can highlight different characteristics of interest in the graph. Potential application domains for this VN generalization abound, including identifying users of interest across social network platforms (see, for example, Patsolic et al., 2017), identifying structural signal across connectomes (see, for example, Sussman et al., 2018), and identifying topics of interest across graphical knowledge bases (see, for example, Sun and Priebe, 2013).

In Fishkind et al. (2015) and Lyzinski et al. (2016), the notion of a consistent vertex nomination scheme (i.e., an asymptotically optimal solution to the VN problem) was proposed for the original formulation of the VN problem, in which community membership entirely determines whether or not a given vertex is interesting. This definition of consistency was based on the *mean average precision* (MAP) of a nomination scheme operating on a graph model with explicit community structure encoded by the the Stochastic Block Model (SBM) of Holland et al. (1983). Under this restricted notion of consistency, Fishkind et al. (2015) derived the analogue of universal Bayes optimality in the VN setting, namely a scheme that achieves the optimal mean average precision for all parameterizations of the underlying SBM. While this derivation of the Bayes optimal scheme somewhat parallels the derivation of the Bayes optimal classifier in the classical pattern recognition literature, the SBM model assumption and MAP formulation greatly narrow the set of models and sets of interesting vertices we can consider. In this paper, we revamp and generalize the concept

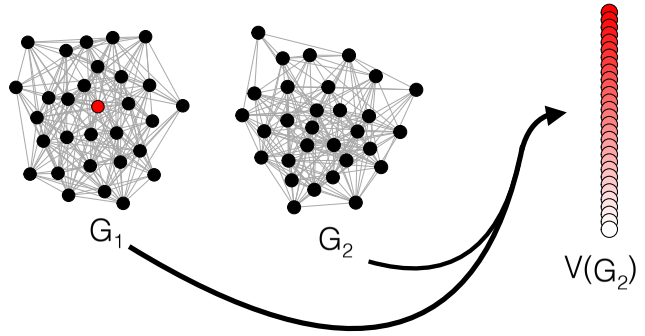

Figure 2: A visual representation of the generalized Vertex Nomination framework: Given a vertex of interest v^* (colored red) in a graph $G_1 = (V_1, E_1)$, find the corresponding vertex of interest u^* (if it exists) in a second graph $G_2 = (V_2, E_2)$, ranking the vertices of G_2 into a nomination list so that u^* ideally appears at the top of the nomination list.

of VN consistency—and of VN Bayes optimality—in the two-graph VN framework. This framework is quite general, and further allows us to highlight the similarities and differences between our new VN consistency formulation and its analogue in the classification literature defined in, for example, Devroye et al. (1997).

The paper is laid out as follows. In the remainder of this section, we provide brief overviews of information retrieval as it relates to vertex nomination (Section 1.1) and the Bayes optimal classifier in the classical setting (Section 1.2), and conclude the introduction by establishing notation for the remainder of the paper (Section 1.3). In Section 2, we define the VN problem framework that is the focus of this paper, and in Section 3 we derive the VN analogue of a Bayes optimal scheme. In Section 4, we define a new notion of VN consistency, and we prove that no universally consistent VN scheme exists, providing an interesting contrast to the standard classification setting. We conclude in Section 5 with a short summary comparing and contrasting VN with classical classification and a discussion of implications and future directions.

1.1. Connections to Information Retrieval

The vertex nomination task is, in some ways, similar to the task faced by recommender systems (Resnick and Varian, 1997; Ricci et al., 2011), in which the aim is to retrieve objects (e.g., documents or images) likely to be of interest to a user based on his or her previous behavior. For example, the celebrated PageRank algorithm (Brin and Page, 1998) recommends webpages based on random walks on the world wide web graph, in which websites are nodes and (directed) edges reflect hyperlinks between pages. The information retrieval (IR) literature includes many such graph-based approaches. We refer the reader to

Ricci et al. (2011) and Mihalcea and Radev (2011) for the state of the art circa 2010, and concentrate here on recapping more recent graph-based information retrieval techniques.

Many graph-based IR techniques rely on the assumption that similar objects (i.e., documents, webpages, etc.) will lie near one another in a suitably-constructed graph. Indeed, this intuition underlies many graph-based approaches throughout machine learning and related disciplines (see, for example, Belkin and Niyogi, 2003; Zhou et al., 2004). Techniques along these lines have been applied toward many tasks in natural language processing, typically inspired by PageRank (Rothe and Schütze, 2014). Along similar lines, Ma et al. (2012) applied a diffusion-based method (Coifman and Lafon, 2006) to the world wide web graph to yield an approach to ranking for query completion and recommendation. These information retrieval techniques can be naturally adapted to the vertex nomination problem by treating the vertex or vertices of interest as the object or objects to be retrieved.

The vertex nomination problem also bears similarities to the task of *learning to rank* (Duh, 2009; Liu, 2009; Li, 2011), in which the goal is to learn an ordering on a set of objects (e.g., documents, images, videos, etc.) according to (estimated) similarity or relevance to a given query object. In the learning to rank literature, graphs usually appear as training instances, with nodes corresponding to objects and edges encoding preferences or similarities among them elicited from users (e.g., an undirected weighted edge may join two documents judged to be similar). The work in Agarwal et al. (2006) is among the earliest to consider the problem of ranking objects in a network. The authors modified the PageRank algorithm to take preference information into account, rather than working solely with the hyperlink graph. In Agarwal (2010), the authors used a *data graph* encoding object similarities to obtain a regularizer similar to Belkin et al. (2006) on the empirical ranking error, with the target ranking encoded in a *preference graph*. More recent efforts along these lines have focused on the problem of incorporating network structure present between entities of different types, for example, between users and events in a social network (Luo et al., 2014; Pham et al., 2016). Here again, any learning to rank algorithm has a natural adaptation to the VN problem by using the first graph, in which some vertices are labeled, as training data to learn a ranking on the vertices of the second graph.

1.2. Bayes Error in Classical Pattern Recognition

In this section, we review the concepts of consistency and Bayes error from the statistical classification literature. We do not aim to give an exhaustive overview of the subject, but only to provide a rough outline as to the structures that we would like to replicate in the context of vertex nomination. For a more thorough treatment, we refer the interested reader to Devroye et al. (1997), whose presentation we follow below.

We begin by recalling the classical definition of Bayes error. Note that we will restrict our attention to the two-class problem to maximally bring forth the similarities (and differences) between statistical classification and VN, as in VN vertices are either of interest or not.

Definition 1 *Consider a set of potential observations $\mathcal{X}$ and a set of unknown class labels $\{0,1\}$ for objects in $\mathcal{X}$. A classifier is a function $h : \mathcal{X} \to \{0,1\}$, which aims to predict the class label of a given observation in $\mathcal{X}$. Given a distribution F supported on $\mathcal{X} \times \{0,1\}$, the error for the classifier h is given by $L(h) = \mathbb{P}(h(X) \neq Y)$ where $(X,Y) \sim F$.*

Any classifier that achieves the lowest possible error is said to be a *Bayes optimal* classifier. We write h^* for any such optimal classifier, which by definition satisfies $h^* \in \arg\min_{h:\mathcal{X}\to\{0,1\}} L(h)$. It is easily seen in this two-class framework that the Bayes optimal classifier is given by

$$h^*(x) = \begin{cases} 1 & \text{if } \mathbb{E}(Y|X=x) = \mathbb{P}(Y=1|X=x) > 1/2; \\ 0 & \text{else.} \end{cases} \tag{1}$$

Practically speaking, the Bayes optimal scheme chooses the label which maximizes the class-conditional probability of the observed data. The corresponding error, $L^* = L(h^*)$, is called the *Bayes error*. Of course, h^* depends on the distribution F of (X,Y), and, when appropriate, we will make this dependence explicit by writing L^*_F.

In practice, a classifier is often constructed based on training data $(X_1,Y_1),(X_2,Y_2),\ldots,(X_n,Y_n)$, where the data (X_i,Y_i) are drawn i.i.d. according to F. This supervised classification framework is defined as follows.

Definition 2 *Consider a set of potential observations $\mathcal{X}$ and a set of unknown class labels $\{0,1\}$ for objects in $\mathcal{X}$. A (supervised) classifier is a function*

$$h_n : \mathcal{X} \times \{\mathcal{X} \times \{0,1\}\}^n \to \{0,1\},$$

which aims to predict the class label of a given observation in $\mathcal{X}$ based on n training observations $(x_1,y_1),(x_2,y_2),\ldots,(x_n,y_n) \in \mathcal{X} \times \{0,1\}$. Given a distribution F supported on $\mathcal{X} \times \{0,1\}$, the error for the classifier h_n is given by

$$L_F(h_n) = \mathbb{P}\big[h_n(X,(X_i,Y_i)_{i=1}^n) \neq Y \mid (X_i,Y_i)_{i=1}^n\big]$$

where $(X,Y),(X_1,Y_1),(X_2,Y_2),\ldots,(X_n,Y_n) \overset{i.i.d.}{\sim} F$.

Note that $L_F(h_n)$ is a random variable in which $\{(X_i,Y_i)\}_{i=1}^n$ are drawn i.i.d. from F, but then held fixed as we average over $(X,Y) \sim F$.

A sequence of classifiers $\mathbf{h} = (h_n)_{n=1}^\infty$ is called a *classification rule*. Informally, a good classification rule is one for which the probability of error becomes arbitrarily close to Bayes optimal as $n \to \infty$. The precise nature of what we mean by close is codified in the concept of statistical consistency.

Definition 3 *A classification rule $\mathbf{h} = (h_n)_{n=1}^\infty$ is* consistent *with respect to F if*

$$\mathbb{E}_F(L(h_n)) \to L^*_F.$$

The rule $\mathbf{h}$ is strongly consistent *if*

$$L_F(h_n) \overset{a.s.}{\to} L^*_F.$$

A rule that is (strongly) consistent for all distributions F on $\mathcal{X} \times \{0,1\}$ is called (strongly) universally consistent.

Perhaps surprisingly, given that F can have arbitrary structure on $\mathcal{X} \times \{0,1\}$, universally consistent classification rules exist; see Stone (1977) for the first proof of this phenomenon.

In Fishkind et al. (2015), a notion of consistency for vertex nomination was presented, roughly analogous to Definition 3. In contrast to the classification task presented above, vertex nomination requires a ranking of the vertices, rather than merely the classification of a single vertex. As such, a vertex nomination scheme is evaluated in Fishkind et al. (2015) based on *average precision* (Manning et al., 2008), rather than simply a fraction of correctly-classified vertices. In Fishkind et al. (2015), VN consistency is defined in the context of stochastic block model (SBM) random graphs with respect to a provably optimal *canonical* nomination scheme. This canonical scheme plays an analogous role of Bayes optimal classifiers in this restricted model framework (see Section 3 below). The goal of this paper is to explore and further develop a broader notion of VN consistency that encompasses a more expressive class of models than the SBM.

1.3. Notation and Background

We conclude this section by establishing notation and reviewing a few of the more popular statistical network models that we will make use of as examples in the sequel.

1.3.1. Notation

For a set S, we let $|S|$ denote its cardinality and $\binom{S}{2}$ denote the set of all unordered pairs of distinct elements from S. Throughout, we will denote graphs via the ordered pair $G = (V, E)$, with vertices V and edges $E \subseteq \binom{V}{2}$. All graphs considered herein will be labeled, hollow (i.e., containing no self-edges), and undirected. We let $\mathcal{G}_n$ denote the set of all labeled, hollow, undirected graphs on n vertices. Given a graph G, we will let $V(G)$ denote the vertices of G and $E(G)$ denote its edges. We note that when G is random, this latter set is a random subset of $\binom{V}{2}$. For a set of vertices $S \subseteq V(G)$, we let $G[S]$ denote the subgraph of G induced by S, i.e., the graph $G' = (S, E)$ with $\{u, v\} \in E$ if and only if $\{u, v\} \in E(G)$. In a few places, we will require the notion of an *asymmetric* graph. A graph $G \in \mathcal{G}_n$ is *asymmetric* if it has no nontrivial automorphisms (Erdős and Rényi, 1963). For a positive integer $n \in \mathbb{Z}$, we will define $[n] = \{1, 2, \ldots, n\}$, and $\mathcal{G}_n$ to be the be the set of labeled graphs on n vertices. Throughout this paper, we will often, in order to simplify notation, suppress dependence of parameters on n. Throughout, the reader should assume that, unless specified otherwise, all parameters depend on the number of vertices n.

1.3.2. Stochastic block models

The stochastic block model (SBM) is a widely studied model for edge-independent random graphs with latent community structure (Holland et al., 1983; Hoff et al., 2002; Karrer and Newman, 2011).

Definition 4 *We say that a random graph $G = (V, E) \in \mathcal{G}_n$ is an instantiation of a stochastic block model with parameters (K, B, b), written $G \sim \mathrm{SBM}(K, B, b)$, if*

i. V is partitioned into K classes (called communities or blocks), $V = V_1 \cup V_2 \cup \cdots \cup V_K$.

ii. The block membership vector $b \in [K]^{|V|}$ is such that for all $k \in [K]$, $b_v = k$ if and only if $v \in V_k$.

iii. The symmetric matrix $B \in [0,1]^{K \times K}$ denotes the edge probabilities between and within blocks, with

$$\mathbb{1}_{\{\{u,v\} \in E(G)\}} \overset{ind.}{\sim} Bernoulli(B_{b_u, b_v}).$$

We note that when $K = 1$, we recover the Erdős-Rényi random graph (Erdős and Rényi, 1959), in which the edges of G are present or absent independently with probability p. In this special case, we write $G \sim \mathrm{ER}(n, p)$. By a slight abuse of notation, for a symmetric matrix $P \in [0,1]^{n \times n}$, we will write $G \sim \mathrm{ER}(P)$ if, identifying the vertices of G with $[n]$, we have $\{i, j\} \in E(G)$ with probability $P_{i,j}$ independent of the other edges. With no restrictions on P, $\mathrm{ER}(P)$ random graphs can be viewed as n-block SBMs and are the most general edge-independent random graph model.

The latent community structure inherent to SBMs makes them a natural model for use in the traditional vertex nomination framework. Recall the traditional VN task: given a community of interest in a network and some examples of vertices that are or are not part of the community of interest, vertex nomination seeks to rank the remaining vertices in the network into a nomination list, with those vertices from the community of interest (ideally) concentrating at the top of the nomination list. As a result, previous work on VN consistency (Fishkind et al., 2015) has been posed within the SBM framework, with the optimal scheme only obtaining its optimality for SBMs. We note that we consider herein the SBM setting where communities are disjoint and each vertex can only belong to a single community. However, the results contained herein translate immediately to the mixed membership SBM setting (Airoldi et al., 2008); details are omitted for brevity.

1.3.3. Random dot product graphs

In stochastic block models, the block assignment vector can be viewed as a latent feature vector for the vertices in the network, with these features (i.e., block memberships) defining the connectivity structure in the network. The random dot product graph (RDPG) model (Young and Scheinerman, 2007) allows for more nuanced vertex features to be incorporated into the model and has been used as the setting for a VN formulation similar to the one proposed here; see Patsolic et al. (2017) for details.

Definition 5 *We say that a random graph $G = (V, E) \in \mathcal{G}_n$ is an instantiation of a d-dimensional random dot product graph with parameters X, written $G \sim \mathrm{RDPG}(X)$, if*

i. The matrix $X \in \mathbb{R}^{n \times d}$ is such that $0 \leq (XX^T)_{i,j} \leq 1$ for all $i, j \in [n]$. The rows of X provide the latent features for the vertices in V.

ii. The edges of G are present or absent independently, with $\{i, j\} \in E(G)$ with probability $(XX^T)_{i,j}$. Written succinctly, $G \sim \mathrm{ER}(XX^T)$.

We can view the RDPG model as a example of the more general *latent position* random graph model (Hoff et al., 2002), in which edge probabilities are determined by hidden vertex-level geometry.

Estimating the latent position structure in RDPGs is particularly amenable to spectral methods, and this model has played a prominent role in recent theoretical developments of spectral graph methods (see, for example, Rohe et al., 2011; Sussman et al., 2012; Tang

et al., 2017a). Note that the RDPG can be extended to a broader class of models, in which edge probabilities are given by evaluating a positive definite link function at vertices' latent positions as in, for example, Tang et al. (2013). While incorporating this more general family of latent position graphs into the present VN framework would be straightforward, we restrict our focus to the RDPG model of Definition 5 for ease of exposition.

1.3.4. Correlation across networks

The vertex nomination problem we consider in this paper presupposes the existence of a vertex of interest in a network G_1 and, ideally, a corresponding vertex of interest in a second network G_2. Often, such correspondences across networks are encoded into random graph models via edge-wise graph correlation (see, for example, Fishkind et al., 2019). Arguably the simplest such structure is seen in the ρ-correlated Erdős-Rényi model (see, for example, Lyzinski et al., 2015).

Definition 6 *We say that bivariate random graphs $(G_1, G_2) \in \mathcal{G}_n \times \mathcal{G}_n$ are an instantiation of a ρ-correlated $\mathrm{ER}(P)$ model, written $(G_1, G_2) \sim \rho\text{-}\mathrm{ER}(P)$, if*

i. Marginally, $G_1 \sim \mathrm{ER}(P)$ and $G_2 \sim \mathrm{ER}(P)$.

ii. Edges are independent across G_1 and G_2 except that the indicators of the events $\{u, v\} \in E(G_1)$ and $\{u, v\} \in E(G_2)$ are jointly distributed as a pair of Bernoulli random variables with success probability $P_{u,v}$ and correlation ρ. If the correlation is allowed to vary across edges, so that these two events have correlation $\rho_{u,v}$, then collecting these correlations in a symmetric matrix $R = [\rho_{i,j}]_{i,j=1}^{n}$, we write $(G_1, G_2) \sim R\text{-}\mathrm{ER}(P)$ (see Lyzinski and Sussman, 2018).

Ranging the values in R from 0 to 1 allows for the consideration of graphs that range from independent ($R = 0$) to isomorphic ($R = 1$). Intermediate values of R allow for the encoding of a correspondence across networks between these two extremes. We will also consider $R < 0$, in which case edges across networks are anti-correlated. This is particularly useful for modeling situations in which corresponding vertices stochastically behave differently across networks.

2. Vertex Nomination

Loosely stated, the vertex nomination problem we consider in this paper can be summarized as follows: Given a vertex of interest v^* in a graph $G_1 = (V_1, E_1)$, find the corresponding vertex of interest u^* (if it exists) in a second graph $G_2 = (V_2, E_2)$ by ranking the vertices of G_2 according to our confidence that they correspond to v^* in graph G_1. To formally define this version of vertex nomination, we will need to consider distributions on graphs with partially-overlapping node sets that have a built-in notion of vertex correspondence across graphs. To this end, we will consider distributions on $\mathcal{G}_n \times \mathcal{G}_m$, where $\mathcal{G}_n$ is the set of labeled graphs on n vertices, with vertex labels given by $\{v_1, v_2, \ldots, v_n\}$, and $\mathcal{G}_m$ is the set of labeled graphs on m vertices, with vertex labels given by $\{u_1, u_2, \ldots, u_m\}$. Note that for $i \in [n] \cap [m]$, v_i and u_i are merely vertex labels, and it is not necessarily the case that $v_i = u_i$. We follow this labeling convention in order to emphasize the reality that the vertex sets of G_1 and G_2 may only partially overlap.

Definition 7 (Nominatable Distributions) *For a given $n, m \in \mathbb{Z} > 0$, the set of* Nominatable Distributions of order (n, m), *denoted $\mathcal{N}_{n,m}$, is the collection of all families of distributions of the following form*

$$\mathbf{F}_{\Theta}^{(n,m)} = \{F_{c,\theta}^{(n,m)} \quad s.t.\ 0 \leq c \leq \min(n, m) \in \mathbb{Z}, \theta \in \Theta \subset \mathbb{R}^{d(n,m)}\}$$

where $F_{c,\theta}^{(n,m)}$ is a distribution on $\mathcal{G}_n \times \mathcal{G}_m$ parameterized by $\theta \in \Theta$ satisfying:

i. The vertex sets $V_1 = \{v_1, v_2, \ldots, v_n\}$ and $V_2 = \{u_1, u_2, \ldots, u_m\}$ satisfy $v_i = u_i$ for $0 < i \leq c$. We refer to $C = \{v_1, v_2, \ldots, v_c\} = \{u_1, u_2, \ldots, u_c\}$ as the core vertices. *These are the vertices that are shared across the two graphs and imbue the model with a natural notion of corresponding vertices.*

ii. Vertices in $J_1 = V_1 \setminus C$ and $J_2 = V_2 \setminus C$, satisfy $J_1 \cap J_2 = \emptyset$. We refer to J_1 and J_2 as junk *vertices. These are the vertices in each graph that have no corresponding vertex in the other graph.*

iv. The induced subgraphs $G_1[J_1]$ and $G_2[J_2]$ are conditionally independent given θ.

A few examples will serve to illustrate this definition. We will return to the three example settings below several times throughout the rest of the paper in order to highlight and illustrate phenomena of interest.

Example 1 (R-ER(P)) Let $(G_1, G_2) \sim R\text{-}\mathrm{ER}(P)$ with $P, R \in \mathbb{R}^{n \times n}$ and $R > 0$ entrywise, so that G_1 and G_2 have correlated edges as described in Section 1.3.4. In this example, the model parameter is $\theta = (P, R)$, and the vertex sets of the two graphs can be thought of as fully overlapping, i.e., $V_1 = V_2 = C = [n]$ and $J_1 = J_2 = \emptyset$, since the correlation structure conveyed in the entries of R encodes an explicit correspondence between the edges of G_1 and the edges of G_2 (and hence also a correspondence between V_1 and V_2). Note that if we consider $C = [k]$ with $k < n$, then we would require (after suitably ordering the vertices) $R_{u,v} = 0$ for $u, v > k$. This highlights the way in which θ (and hence the distribution $F_{c,\theta}^{(n,m)}$) can vary with c, and vice-versa.

Example 2 (RDPG) Let $m > n$ and suppose that $Y \in \mathbb{R}^{m \times d}$ has distinct rows and satisfies $(YY^T)_{i,j} \in [0, 1]$ for all $i, j \in [m]$. Let $X \in \mathbb{R}^{n \times d}$ be a submatrix of Y, and consider $G_1 \sim \mathrm{RDPG}(X)$ and $G_2 \sim \mathrm{RDPG}(Y)$, where G_1 and G_2 are conditionally independent given Y. In this example, we can consider $\theta = Y$, $V_1 = [n] = C$, $J_1 = \emptyset$, $V_2 = [n] \cup J_2$, and $J_2 = \{u_{n+1}, u_{n+2}, \ldots, u_m\}$. Note that as G_1 and G_2 are conditionally independent given θ, we could also consider $0 < c < n$ here as well. This illustrates that θ need not necessarily vary with c, and hence $F_{c,\theta}^{(n,m)}$ need not vary with c, either.

Example 3 (Independent Erdős-Rényi graphs) Let (G_1, G_2) be independent $\mathrm{ER}(n, p)$ random graphs. In this example, we can consider any $c \in [n]$. Note that if $c = 0$ here, then there is no corresponding vertex of interest in G_2, and this example serves as a natural boundary case between models in which nomination is possible and those in which it is not. As we will see below in Theorem 23, $c > 0$ may still yield chance performance for any nomination scheme, and the existence of a vertex correspondence does not necessarily imply any performance guarantees.

Remark 8 In addition to the edge-independent and conditionally edge-independent network models considered above, the class of nominatable distributions contains a host of other popular random graph models, including the Exponential Random Graph Model (Frank and Strauss, 1986; Snijders et al., 2006; Robins et al., 2007), the preferential attachment model (Albert and Barabási, 2002), and the Watts-Strogatz small world model (Watts and Strogatz, 1998), among others. Indeed, if we consider the case where $c = n = m$, then any parametric distribution on $\mathcal{G}_n \times \mathcal{G}_n$ is a nominatable distribution.

Remark 9 The core vertices C in a nominatable distribution correspond to the vertices that can be sensibly identified across graphs. Note that this set does not require any further structure, aside from the conditional independence of $G_1[J_1]$ and $G_2[J_2]$ given the parameter θ. Thus, we are largely free to specify any notion of correspondence we please. Depending on the application, this correspondence may be that of vertices playing similar structural roles, belonging to the same community, or some more complicated application-specific notion of correspondence. That is, the notion of cross-graph correspondence, and hence the notion of vertex similarity, is largely left to the practitioner to specify when she or he specifies an appropriate random graph model.

Given a pair of graphs $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$, if the vertices in C are known across graphs then identifying the corresponding vertex to $v^* \in C$ is immediate from the vertex labels. In practice, this information is unknown and the correspondences across graphs are only partially observed or even unobserved entirely. To model this added uncertainty, we consider passing the vertex labels of G_2 through an obfuscating function.

Definition 10 *Let $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$. An* obfuscating function $\mathfrak{o} : V_2 \to W$ *is a bijection from V_2 to W with $W \cap V_i = \emptyset$ for $i = 1, 2$. We call a set W satisfying $W \cap V_i = \emptyset$ for $i = 1, 2$ an obfuscating set, and for a given obfuscating set W, we let $\mathfrak{O}_W$ be the set of all obfuscating functions $\mathfrak{o} : V_2 \to W$.*

Here, $\mathfrak{o}$ models the practical reality that the correspondence of labels across graph is unknown a priori. Note that to ease notation, we shall write $\mathfrak{o}(G_2)$ (resp., $\mathfrak{o}(g_2)$ and $\mathfrak{o}(\mathcal{G}_m)$) to denote the graph G_2 (respectively, g_2 and $\mathcal{G}_m$) whose labels have been obfuscated via $\mathfrak{o}$.

Before defining a VN scheme, we must make one additional definition: for a graph $g \in \mathcal{G}_m$ and $u \in V(g)$, define

$$\mathcal{I}(u; g) = \{w \in V(g) \text{ s.t. } \exists \text{ an automorphism } \sigma \text{ of } g, \text{ s.t. } \sigma(u) = w\}.$$

Note that by taking σ to be the identity, we have $u \in \mathcal{I}(u; g)$. The vertices in $\mathcal{I}(u; g)$ are those that are, in a sense, topologically equivalent to the vertex u in g, and hence, in the absence of labels, indistinguishable from one another. As such, any sensibly-defined vertex nomination scheme should view all vertices in $\mathcal{I}(u; g)$ as being equally good matches to a vertex of interest v^*. Thus, a well-defined VN scheme should be "label-independent" in the following sense: The set of ranks of each set of equivalent vertices (i.e., each $\mathcal{I}(u; g_2)$) needs to be invariant to the particular choice of obfuscating function; see Figure 3 for an illustration of this consistency criterion. Formally, we have the following.

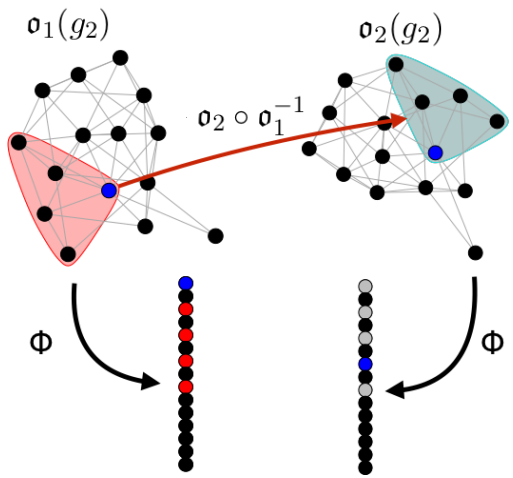

Figure 3: An illustration of the "label-independence" property of VN schemes. If the blue vertex in $\mathfrak{o}_1(g_2)$ (resp., $\mathfrak{o}_2(g_2)$) is $\mathfrak{o}_1(u)$ (resp., $\mathfrak{o}_2(u)$) for $u \in V_2$, then we require the ranks of $\mathcal{I}(\mathfrak{o}_1(u); \mathfrak{o}_1(g_2))$ (outlined in red in the network $\mathfrak{o}_1(g_2)$ and colored red/blue in the ordering provided by Φ) to be equal to the ranks of $\mathcal{I}(\mathfrak{o}_2(u); \mathfrak{o}_2(g_2))$ (outlined in grey in the network $\mathfrak{o}_2(g_2)$ and colored grey/blue in the ordering provided by Φ). Indeed, the set of ranks of $\mathfrak{o}(\mathcal{I}(u; g_2))$ via Φ is independent of the choice of obfuscation function $\mathfrak{o}$.

Definition 11 (Vertex Nomination (VN) Scheme) *For a set A, let $\mathcal{T}_A$ denote the set of all total orderings of the elements of A. For $n, m > 0$ fixed, obfuscating set W, and obfuscating function $\mathfrak{o} \in \mathfrak{O}_W$, a* vertex nomination scheme *is a function $\Phi : \mathcal{G}_n \times \mathfrak{o}(\mathcal{G}_m) \times V_1 \to \mathcal{T}_W$ satisfying the following consistency property: If for each $u \in V_2$, we define $rank_{\Phi(g_1, \mathfrak{o}(g_2), v^*)}\big(\mathfrak{o}(u)\big)$ to be the position of $\mathfrak{o}(u)$ in the total ordering provided by $\Phi(g_1, \mathfrak{o}(g_2), v^*)$, and we define $\mathfrak{r}_\Phi : \mathcal{G}_n \times \mathcal{G}_m \times \mathfrak{O}_W \times V_1 \times 2^{V_2} \mapsto 2^{[m]}$ via*

$$\mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}, v^*, S) = \{rank_{\Phi(g_1, \mathfrak{o}(g_2), v^*)}\big(\mathfrak{o}(u)\big) \text{ s.t. } u \in S\},$$

then we require that for any $g_1 \in \mathcal{G}_n$, $g_2 \in \mathcal{G}_m$, $v^* \in V_1$, obfuscating functions $\mathfrak{o}_1, \mathfrak{o}_2 \in \mathfrak{O}_W$ and any $u \in V(g_2)$,

$$\mathfrak{r}_\Phi\big(g_1, g_2, \mathfrak{o}_1, v^*, \mathcal{I}(u; g_2)\big) = \mathfrak{r}_\Phi\big(g_1, g_2, \mathfrak{o}_2, v^*, \mathcal{I}(u; g_2)\big) \tag{2}$$
$$\Leftrightarrow \mathfrak{o}_2 \circ \mathfrak{o}_1^{-1}\Big[\mathcal{I}\Big(\Phi(g_1, \mathfrak{o}_1(g_2), v^*)[k]\big); \mathfrak{o}_1(g_2)\Big)\Big] = \mathcal{I}\Big(\Phi(g_1, \mathfrak{o}_2(g_2), v^*)[k]; \mathfrak{o}_2(g_2)\Big), \text{ for all } k \in [m],$$

where $\Phi(g_1, \mathfrak{o}(g_2), v^*)[k]$ denotes the k-th element (i.e., the rank-k vertex) in the ordering $\Phi(g_1, \mathfrak{o}(g_2), v^*)$. We let $\mathcal{V}_{n,m}$ denote the set of all such VN schemes.

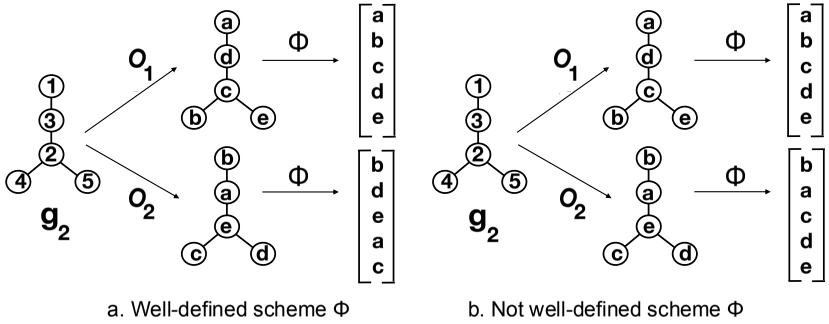

Figure 4: An example of the consistency criterion, Equation (2), in action. The left panel (a) shows a well-defined nomination scheme while the right panel (b) shows an ill-defined scheme. The key in this example is that any scheme satisfying Equation (2) must have $\mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_1, v^*, \{1\}) = \mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_2, v^*, \{1\})$; $\mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_1, v^*, \{3\}) = \mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_2, v^*, \{3\})$; $\mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_1, v^*, \{2\}) = \mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_2, v^*, \{2\})$; and $\mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_1, v^*, \{4, 5\}) = \mathfrak{r}_\Phi(g_1, g_2, \mathfrak{o}_2, v^*, \{4, 5\})$.

Given $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$ realized as $G_1 = g_1$ and $G_2 = g_2$ with $v^* \in V_1$ the vertex of interest in G_1, a VN scheme $\Phi(\cdot, \cdot, \cdot)$ produces a ranked list $\Phi(g_1, \mathfrak{o}(g_2), v^*)$ of the vertices of $\mathfrak{o}(g_2)$ (i.e., the set W), ordered according to how likely each vertex in $V(\mathfrak{o}(g_2))$ is judged to correspond to v^*, with optimal performance corresponding to

$$\Phi(g_1, \mathfrak{o}(g_2), v^*)[1] = \begin{cases} \mathfrak{o}(v^*) & \text{if } v^* \in C \\ \text{arbitrary } v \in W & \text{if } v^* \notin C. \end{cases}$$

Less formally, one can think of a VN scheme as ranking the vertices of G_2 according to how well they resemble the vertex of interest v^* under some task-dependent measure.

Remark 12 Note that if $u \in V_2$ is such that $\mathcal{I}(u; g_2) = \{u\}$ (i.e., u is topologically distinct within g_2), then Equation (2) implies that

$$\text{rank}_{\Phi(g_1, \mathfrak{o}_1(g_2), v^*)}\big(\mathfrak{o}_1(u)\big) = \text{rank}_{\Phi(g_1, \mathfrak{o}_2(g_2), v^*)}\big(\mathfrak{o}_2(u)\big)$$

for any $\mathfrak{o}_1$, $\mathfrak{o}_2$ in $\mathfrak{S}_W$. If $\mathcal{I}(u; g_2)$ contains vertices in addition to u, then Equation (2) implies that the set of vertices topologically equivalent to u (namely, those in $\mathcal{I}(u; g_2)$) must achieve the same ranks via Φ under any two obfuscating functions; see Figure 4 for a simple example of this consistency criterion in action.

Remark 13 (Relation to Fishkind et al. (2015); Lyzinski et al. (2016)) Recall the one-graph vertex nomination task considered in earlier works (Coppersmith, 2014; Fishkind et al., 2015; Lyzinski et al., 2016) and described in Section 1, in which vertices are

considered interesting precisely when they belong to one of K communities in a stochastic block model. While the two-graph VN formulation we consider in the present work (modulo symmetries) involves a single vertex of interest across graphs, the framework is easily extended to the setting where one may have multiple vertices of interest (and not of interest), and in particular it can encode instances of the one-graph version VN problem. To see this, consider an instance of the single-graph VN problem on graph $G = (V, E)$ where V is partitioned into K communities as $V = V_1 \cup V_2 \cup \cdots \cup V_K$ and each of the communities is comprised of labeled (i.e., seed vertices, whose community memberships are observed) and unlabeled (i.e., nonseed, whose community memberships are unobserved) vertices, $V_k = S_k \cup U_k$, where $S_k \subseteq V_k$ is the set of seeds from the k-th block and $U_k \subseteq V_k$ is the set of nonseed vertices. We can encode this one-graph VN instance as an instance of the two-graph problem by encoding additional information in the graph G_1. Construct a vertex set $V' = V \cup \{\ell_1, \ell_2, \ldots, \ell_K\}$. The K new vertices $\{\ell_k\}_{k=1}^K$ will encode the label information present in the graph G. Let $E' = E \cup L$, where $L = \{\{\ell_k, s\} : s \in S_k, k \in [K]\}$, so that edges connect from seed vertices in $S = S_1 \cup S_2 \cup \cdots \cup S_K$ to their corresponding label vertices. Take $G_1 = (V', E')$, and let the interesting vertices (and possible uninteresting vertices) be given by the elements of $S \subseteq V'$. The second graph G_2 is then the subgraph of G induced by the unlabeled vertices $U \subseteq V$ passed through an appropriate obfuscating function. This pair (G_1, G_2), with any $s \in S_1$ chosen to be the interesting vertex, encodes the label information present in the one-graph VN problem as well as the graph structure of G, as required.

3. Bayes Error and Bayes Optimality in Vertex Nomination

Viewing a VN scheme as an information retrieval system suggests that a scheme that puts $\mathfrak{o}(v^*)$ close to the top of the nomination list is potentially of great practical value, even if it fails to obtain perfect performance. Motivated by this, we adapt the recall-at-k metric from classical information retrieval as a measure of performance. To wit, we define the level-k loss function and error for VN as follows.

Definition 14 (VN loss function, level-k error) *Let $\Phi \in \mathcal{V}_{n,m}$ be a vertex nomination scheme and $\mathfrak{o}$ an obfuscating function. For (g_1, g_2) realized from $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$ with vertex of interest $v^* \in C$, and for $k \in [m-1]$, we define the* level-k nomination loss *via*

$$\begin{aligned} \ell_k(\Phi, g_1, g_2, \mathfrak{o}, v^*) &= \mathbb{1}\{rank_{\Phi(g_1, \mathfrak{o}(g_2), v^*)}(\mathfrak{o}(v^*)) \geq k+1\} \\ &= 1 - \mathbb{1}\{rank_{\Phi(g_1, \mathfrak{o}(g_2), v^*)}(\mathfrak{o}(v^*)) \leq k\}. \end{aligned} \tag{3}$$

The level-k error *of Φ at v^* is then defined to be*

$$\begin{aligned} L_k(\Phi, v^*) &= \mathbb{E}_{(G_1, G_2) \sim F_{c,\theta}^{(n,m)}} \left[\ell_k(\Phi, G_1, G_2, \mathfrak{o}, v^*)\right] \\ &= \mathbb{P}_{(G_1, G_2) \sim F_{c,\theta}^{(n,m)}} \left[rank_{\Phi(G_1, \mathfrak{o}(G_2), v^*)}(\mathfrak{o}(v^*)) \geq k+1\right]. \end{aligned} \tag{4}$$

From the definition of the level-k error in Eq. (4), it is immediate that

$$\begin{aligned} L_1(\Phi, v^*) &= 1 - \mathbb{P}_{(G_1,G_2)\sim F_{c,\theta}^{(n,m)}}\left[\text{rank}_{\Phi(G_1,\mathfrak{o}(G_2),v^*)}(\mathfrak{o}(v^*)) = 1\right] \\ &\geq L_2(\Phi, v^*) = 1 - \mathbb{P}_{(G_1,G_2)\sim F_{c,\theta}^{(n,m)}}\left[\text{rank}_{\Phi(G_1,\mathfrak{o}(G_2),v^*)}(\mathfrak{o}(v^*)) \in \{1,2\}\right] \\ &\geq L_3(\Phi, v^*) = 1 - \mathbb{P}_{(G_1,G_2)\sim F_{c,\theta}^{(n,m)}}\left[\text{rank}_{\Phi(G_1,\mathfrak{o}(G_2),v^*)}(\mathfrak{o}(v^*)) \in \{1,2,3\}\right] \\ &\quad\vdots \\ &\geq L_{m-1}(\Phi, v^*) = 1 - \mathbb{P}_{(G_1,G_2)\sim F_{c,\theta}^{(n,m)}}\left[\text{rank}_{\Phi(G_1,\mathfrak{o}(G_2),v^*)}(\mathfrak{o}(v^*)) \in [m-1]\right], \end{aligned} \tag{5}$$

The level-1 loss function is analogous to the classical 0/1 loss function in classification, as $L_1(\Phi, v^*)$ is simply the probability that Φ fails to "classify" $\mathfrak{o}(v^*)$ as the vertex corresponding to v^* in $\mathfrak{o}(G_2)$ (i.e., fails to rank it first). Considering $1 < k \ll m$ enables us to model the practical loss associated with using a VN scheme to search for $\mathfrak{o}(v^*)$ in $\mathfrak{o}(V_2)$ given limited resources.

Remark 15 Unlike in the classification setting described in Section 1.2, where $L_F(h_n)$ is a random variable indexed by n, the nomination errors defined in Definition 14 are sequences indexed by m and n and are not random. In the classical setting, $L_F(h_n)$ denotes the error rate of a classifier that classifies a single observation X based on n training instances $\{(X_i, Y_i)\}_{i=1}^n$. In the case of VN, the notion of labeled training instances is, at best, more hazy. Indeed, in the present setting, the training data and test data are inseparable. The graphs (or, more specifically, their edges) *are* the training data, and in the present work, the graph orders n, m are better thought of as measuring problem dimension rather than training set size.

Analogous to the classification literature, we are now able to define the concept of Bayes optimality in the VN framework.

Definition 16 (Bayes error of a VN scheme) *Let $(G_1, G_2) \sim F_{c,\theta}^{(n,m)}$ with vertex of interest $v^* \in C$ (where we recall that C is the set of core vertices; see Definition 7), and let $\mathfrak{o} \in \mathfrak{O}_W$ be an obfuscating function. For $k \in [m-1]$, we define the* level-k Bayes optimal *VN scheme to be any element $\Psi \in \arg\min_{\Phi\in\mathcal{V}_{n,m}} L_k(\Phi, v^*)$, and define the* level-$k$ Bayes error *to be $L_k^*(v^*) = L_k(\Psi, v^*)$ for level-k Bayes optimal Ψ.*

Now that we have a notion of Bayes error for VN, it is natural to ask whether an optimal VN scheme exists analogous to the Bayes optimal classifier of Equation (1). Toward this end, let (g_1, g_2) be realized from $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$, and consider a vertex of interest $v^* \in C$ and obfuscating function $\mathfrak{o} : V_2 \to W$. In order to avoid the technical complexities associated with graph automorphisms, in what follows we will assume that $F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$ is supported on $\mathcal{G}_n^a \times \mathcal{G}_m^a$, where $\mathcal{G}_n^a$ (resp., $\mathcal{G}_m^a$) is the set of asymmetric graphs in $\mathcal{G}_n$ (resp., $\mathcal{G}_m$). For analogous results in networks with symmetries, see Remark 18.

Letting $\simeq$ denote graph isomorphism, for $(g_1, g_2) \in \mathcal{G}_n \times \mathcal{G}_m$ define the set

$$\begin{aligned} (g_1, [\mathfrak{o}(g_2)]) &= \left\{\left(g_1, \tilde{g}_2\right) \text{ s.t. } \mathfrak{o}(\tilde{g}_2) \simeq \mathfrak{o}(g_2)\right\} \\ &= \left\{\left(g_1, \tilde{g}_2\right) \text{ s.t. } \tilde{g}_2 \simeq g_2\right\}. \end{aligned} \tag{6}$$

In order to define the Bayes optimal scheme, we will also need the following restriction of $(g_1, [\mathfrak{o}(g_2)])$: for each $w \in W$, we define

$$(g_1,[\mathfrak{o}(g_2)])_{w=\mathfrak{o}(v^*)} = \left\{\left(g_1, \tilde{g}_2\right) \text{ s.t. } \exists \text{ isomorphism } \sigma \text{ s.t. } \mathfrak{o}(\tilde{g}_2) = \sigma(\mathfrak{o}(g_2)), \sigma(w) = \mathfrak{o}(v^*)\right\}. \tag{7}$$

We are now ready to define a Bayes optimal VN scheme.

For ease of notation, in the sequel we will write $\mathbb{P}_{F_{c,\theta}^{(n,m)}}$ or even simply $\mathbb{P}$ in place of $\mathbb{P}_{(G_1,G_2)\sim F_{c,\theta}^{(n,m)}}$ where there is no risk of ambiguity. Let

$$\mathbf{g} = \left\{\left(g_1^{(i)}, g_2^{(i)}\right)\right\}_{i=1}^h \tag{8}$$

be such that the sets

$$\left\{\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right\}_{i=1}^h$$

partition $\mathcal{G}_n^a \times \mathcal{G}_m^a$. We will call this partition $\mathcal{P}_{n,m}$, where we suppress dependence on $\mathbf{g}$ and $\mathfrak{o}$ for ease of notation. We will define a Bayes optimal scheme Φ^* (independent of the choice of $\mathbf{g}$) piecewise on each element of this partition, and we will prove in Theorem 17 that Φ^* is level-k Bayes optimal for all $k \in [m-1]$:

$$\begin{aligned} \Phi^*\left(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\right)[1] &\in \underset{u\in W}{\text{argmax}}\, \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)_{u=\mathfrak{o}(v^*)} \;\middle|\; \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right] \\ \Phi^*\left(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\right)[2] &\in \underset{u\in W\setminus\{\Phi^*[1]\}}{\text{argmax}}\, \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)_{u=\mathfrak{o}(v^*)} \;\middle|\; \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right] \\ &\quad\vdots \\ \Phi^*\left(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\right)[m] &\in \underset{u\in W\setminus\{\cup_{j\in[m-1]}\Phi^*[j]\}}{\text{argmax}}\, \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)_{u=\mathfrak{o}(v^*)} \;\middle|\; \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right], \end{aligned} \tag{9}$$

with ties broken arbitrarily but deterministically. We refer the interested reader to Appendix B.1 for discussion of the case where ties are allowed in the ranking function. For each element

$$(g_1, g_2) \in \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right) \setminus \left\{\left(g_1^{(i)}, g_2^{(i)}\right)\right\},$$

choose the permutation σ such that $\mathfrak{o}(g_2) = \sigma(\mathfrak{o}(g_2^{(i)}))$, and define

$$\Phi^*(g_1^{(i)}, \mathfrak{o}(g_2), v^*) = \sigma(\Phi^*(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)).$$

Lastly, the following theorem shows that this scheme (uniquely defined up to tie-breaking) is indeed Bayes optimal. A proof can be found in Appendix A.1.

Theorem 17 *Let $\mathfrak{o} \in \mathfrak{O}_W$ be an obfuscating function, and let*

$$\mathbf{g} = \left\{\left(g_1^{(i)}, g_2^{(i)}\right)\right\}_{i=1}^h$$

be such that the sets

$$\left\{\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right\}_{i=1}^h$$

partition $\mathcal{G}_n^a \times \mathcal{G}_m^a$. *Let* $\Phi^* = \Phi^*_{\mathbf{g}}$ *be as defined in Equation* (9). *Suppose that* $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$ *with* $F_{c,\theta}^{(n,m)}$ *supported on* $\mathcal{G}_n^a \times \mathcal{G}_m^a$, *and consider a vertex of interest* $v^* \in C$. *We have that* $L_k(\Phi^*, v^*) = L_k^*(v^*)$ *for all* $k \in [m-1]$, *partitions* $\mathbf{g}$, *and all obfuscating functions* $\mathfrak{o}$.

Remark 18 The effect of symmetries on Theorem 23 is both subtle and cumbersome, as the specific tie-breaking procedures used in the analogue of Eq. (9) are of great import. To this end, consider $\mathbf{g}$ to be defined as above, and let $T \in \mathcal{T}_W$ be the ordering that specifies the (fixed but otherwise arbitrary) scheme by which elements within each $\mathcal{I}(v; \mathfrak{o}(g_2))$ are ordered. Informally, we will first rank the sets $\mathcal{I}(v; \mathfrak{o}(g_2))$ (rather than the individual vertices), and then use T to rank within and across each of the $\mathcal{I}(v; \mathfrak{o}(g_2))$. Full detail is provided below.

For each $w \in W$ and $v \in V(g_2)$, define

$$(g_1, [\mathfrak{o}(g_2)])_{\mathcal{I}(w;\mathfrak{o}(g_2))=\mathfrak{o}(v)} = \Big\{ \big(g_1, \tilde{g}_2\big) \text{ s.t. } \exists \text{ iso. } \sigma \text{ with } \mathfrak{o}(\tilde{g}_2) = \sigma(\mathfrak{o}(g_2)), \\ \text{and } \sigma(u) = \mathfrak{o}(v) \text{ for some } u \in \mathcal{I}(w; \mathfrak{o}(g_2)) \Big\}. \tag{10}$$

As above, we will define the Bayes' optimal VN scheme on each element of the partition provided via $\mathbf{g}$. We first define a ranking Ψ of the sets

$$\left\{ \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))=\mathfrak{o}(v^*)} \right\}$$

indexed by u, and then will use T to give the total ordering from Ψ. To wit, for each $i \in [k]$, iteratively define (where ties in the argmax are broken in an arbitrary but nonrandom manner)

$$\begin{aligned}
\Psi\Big(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\Big)[1] &\in \underset{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))\subset W}{\operatorname{argmax}} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))=\mathfrak{o}(v^*)} \,\middle|\, \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \\
\Psi\Big(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\Big)[2] &\in \underset{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))\subset W\setminus\{\Psi[1]\}}{\operatorname{argmax}} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))=\mathfrak{o}(v^*)} \,\middle|\, \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \\
&\vdots \\
\Psi\Big(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\Big)[\ell] &\in \underset{\mathcal{I}_{\mathfrak{o}(g_2)}(u)\subset W\setminus\{\cup_{j=1}^{\ell-1}\Psi[j]\}}{\operatorname{argmax}} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))=\mathfrak{o}(v^*)} \,\middle|\, \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right].
\end{aligned} \tag{11}$$

For each element

$$(g_1, g_2) \in (g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]) \setminus \{(g_1^{(i)}, g_2^{(i)})\},$$

choose an isomorphism σ such that $\mathfrak{o}(g_2) = \sigma(\mathfrak{o}(g_2^{(i)}))$, and define

$$\Psi(g_1, \mathfrak{o}(g_2), v^*) = \sigma(\Psi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)).$$

Note that the choice of isomorphism σ does not impact the definition of Ψ.

For each $(g_1, g_2) \in \mathcal{G}_n \times \mathcal{G}_m$, we define a VN scheme Φ_T^* from Ψ as follows:
1. Initialize $\Phi_T^*(g_1, \mathfrak{o}(g_2), v^*)$ as an empty list; initialize $j = 1$;
2. If $\Psi(g_1, \mathfrak{o}(g_2), v^*)[j]$ is nonempty, add the top ranked (according to T) element from $\Psi(g_1, \mathfrak{o}(g_2), v^*)[j]$ to the end of $\Phi_T^*(g_1, \mathfrak{o}(g_2), v^*)$, else do nothing; set $j = j + 1 \pmod{|\Psi(g_1, \mathfrak{o}(g_2), v^*)|}$
3. Repeat Step 2 until there are no more vertices to add to $\Phi_T^*(g_1, \mathfrak{o}(g_2), v^*)$.
If $T[1] = \mathfrak{o}(v^*)$, then $\Phi_T^*(g_1, \mathfrak{o}(g_2), v^*)$ is Bayes optimal (as in Theorem 17) in the sense of Definition 16. See Appendix A.1 for details.

Example 1, continued. Let $(G_1, G_2) \sim R\text{-ER}(P)$ for $P, R \in \mathbb{R}^{n\times n}$. Under mild model assumptions, we have that $\lim_{n\to\infty} L_k^*(v^*) = 0$ for any fixed k. This is due to the fact that the optimal graph matching of G_1 to $\mathfrak{o}(G_2)$ will almost surely recover the true vertex labels of $\mathfrak{o}(G_2)$ for n suitably large; i.e.,

$$\operatorname{argmin}_{Q\in\Pi_n} \|AQ - QB\|_F = \{I_n\} \text{ with probability} \to 1,$$

where Π_n is the set of $n \times n$ permutation matrices, A is the adjacency matrix for G_1 and B the adjacency matrix for G_2. More concretely, we have the following theorem adapted to our present setting from Lyzinski and Sussman (2018). A proof sketch can be found in Appendix B.

Theorem 19 *Let* $(A, B) \sim R\text{-ER}(P)$, *and for any fixed permutation matrix* Q *define the random variable* $\delta(Q) := \|AQ - QB\|_F$. *Define* $0 < \epsilon := \min_{i,j;i\neq j} 2R_{i,j}P_{i,j}(1 - P_{i,j})$. *There exist positive constants* c_1, c_2 *such that if* $\epsilon^2 > c_1 \log(n)/n$, *then for sufficiently large* n,

$$\mathbb{P}\left(\exists\ Q \in \Pi_n \setminus \{I_n\} \text{ s.t. } \delta(Q) \le \delta(I_n)\right) \le 2\exp\left\{-c_2\epsilon^2 n\right\}.$$

Similarly to the Bayes optimal scheme, we define the graph matching VN scheme, denoted Φ_M, separately on each element of $\mathcal{P}_{n,n}$. For a given $(\tilde{g}_1, [\mathfrak{o}(\tilde{g}_2)]) \in \mathcal{P}_{n,n}$, let (g_1, g_2) be an fixed element in $(\tilde{g}_1, [\mathfrak{o}(\tilde{g}_2)])$. Define $\Phi_M(g_1, \mathfrak{o}(g_2), v^*)[1]$ to be a fixed but arbitrary element from

$$\left\{\mathfrak{r}^{-1}(v^*) \text{ s.t. } Q_{\mathfrak{r}} \in \operatorname{argmin}_{Q\in\Pi_n} \|AQ - QB\|_F\right\}, \tag{12}$$

where each $\mathfrak{r} : W \to V_2$ appearing above is a bijection and $Q_{\mathfrak{r}}$ its associated permutation matrix (having identified both W and V_2 with the set $[n]$). Define

$$\mathfrak{R}_1 = \Big\{\mathfrak{r} : W \to V_2 \text{ s.t. } \mathfrak{r} \text{ is a bijection with } \mathfrak{r}^{-1}(v^*) = \Phi_M(g_1, \mathfrak{o}(g_2), v^*)[1]\Big\}.$$

If $j > 1$, define $\Phi_M(g_1, \mathfrak{o}(g_2), v^*)[j]$ to be any element of

$$\left\{\mathfrak{r}^{-1}(v^*) \text{ s.t. } Q_{\mathfrak{r}} \in \underset{Q\in\Pi(n)\setminus\{Q_{\mathfrak{r}}:\mathfrak{r}\in\bigcup_{\ell=1}^{j-1}\mathfrak{R}_\ell\}}{\operatorname{argmin}} \|AQ - QB\|_F\right\},$$

where $\mathfrak{R}_j$ is defined analogously to $\mathfrak{R}_1$. For each element $(g_1', g_2') \in (\tilde{g}_1, [\mathfrak{o}(\tilde{g}_2)]) \setminus \{(g_1, g_2)\}$, choose a permutation σ such that $\mathfrak{o}(g_2') = \sigma(\mathfrak{o}(g_2))$, and we then define $\Phi_M(g_1, \mathfrak{o}(g_2'), v^*) = \sigma(\Phi_M(g_1, \mathfrak{o}(g_2), v^*))$. Theorem 19 states that under mild model assumptions, we have that $\Phi_M(G_1, \mathfrak{o}(G_2), v^*)[1] = \mathfrak{o}(v^*)$ asymptotically almost surely, and thus $\lim_{n\to\infty} L_1(\Phi_M, v^*) = 0$. Indeed, in this setting, for any fixed $k \ge 1$, $\lim_{n\to\infty} L_k(\Phi_M, v^*) = 0$. It is then immediate

that $\lim_{n\to\infty} L_k^*(v^*) = 0$ in this model for any fixed k.

The next two examples serve to illustrate how the level-k Bayes error behaves in the presence of stochastically indistinguishable vertices. In essence, we cannot hope to perform better than randomly ordering stochastically equivalent vertices.

Example 3, continued. Let G_1 and G_2 be independent ER(n,p) graphs. Since the vertices are stochastically indistinguishable within each of the two graphs, no nomination scheme can do better than random chance in this model. Thus, with $c = n$, we have that $L_k^*(v^*) = (1 - k/n)(1 + o(1))$ for all $k \in [n-1]$ and all $v^* \in [n]$.

Example 4 Let $p_1, p_2, q \in [0,1]$ with $1 \geq p_1 > p_2 \geq 0$ and $q \neq p_1, p_2$. Define the matrix

$$B = \begin{pmatrix} p_1 & q \\ q & p_2 \end{pmatrix},$$

and let G_1, G_2 be independent SBM$\,(2, B, b_n)$ graphs where $b_n(i) = 1$ if $i \leq n/2$ (n even) and $b_n(i) = 2$ if $i > n/2$. With $c = n$ and the correspondence equal to the identity function, let $(k_n)_{n=2}^{\infty}$ be a nondecreasing divergent sequence satisfying $k_n \leq n/2$ for all $n > 1$, then $\lim_n L_{k_n}^*(v^*) = \lim_n [(1 - 2k_n/n) \vee 0]$ for all v^*. Indeed, $L_{k_n}^*$ is asymptotically equivalent to randomly ordering the $n/2$ vertices in G_2 that are stochastically equivalent to v^*.

4. VN Consistency

With the definition of Bayes optimality and the Bayes optimal scheme in hand, it is now possible to define a notion of consistent vertex nomination analogous to consistent classification in the pattern recognition literature. Before defining a consistent VN rule (i.e., a sequence of VN schemes), we must first define the notion of sequences of nominatable distributions with *nested cores*. Such sequences of distributions are necessary in order to speak sensibly of a sequence of vertex nomination problem instances.

Definition 20 *Let* $\mathbf{F} = \left(F_{c_n,\theta_n}^{(n,m_n)}\right)_{n=n_0}^{\infty}$ *be a sequence of distributions such that* $F_{c_n,\theta_n}^{(n,m_n)} \in \mathcal{N}_{n,m_n}$ *for all* n. *We say that* $\mathbf{F}$ *has* nested cores *if for all* $n_0 \leq n_1 < n_2$, *if*

$$(G_1, G_2) \sim F_{n_1} = F_{c_{n_1},\theta_{n_1}}^{(n_1,m_{n_1})} \text{ and } (\widetilde{G}_1, \widetilde{G}_2) \sim F_{n_2} = F_{c_{n_2},\theta_{n_2}}^{(n_2,m_{n_2})},$$

we have, letting C_1 *and* C_2 *be the core vertices associated with* F_{n_1} *and* F_{n_2} *respectively, and denoting the junk vertices* $J_{1,1}, J_{2,1}, J_{1,2}, \widetilde{J}_{2,2}$ *analogously,*
[i.] $V(G_1) = C_1 \cup J_{1,1} \subset V(\widetilde{G}_1) = C_2 \cup J_{2,1}$;
[ii.] $V(G_2) = C_2 \cup J_{1,2} \subset V(\widetilde{G}_2) = C_2 \cup J_{2,2}$;
[iii.] $C_1 \subset C_2$.

We are now ready to define a consistent VN rule.

Definition 21 *Let*

$$\mathbf{F} = \left(F_n = F_{c_n,\theta_n}^{(n,m_n)}\right)_{n=n_0}^{\infty}$$

be a sequence of distributions such that $F_n \in \mathcal{N}_{n,m(n)}$ *with nested cores satisfying* $\lim_{n\to\infty} m_n = \infty$. *For a given non-decreasing sequence* (k_n), *we say that a VN rule* $\mathbf{\Phi} = (\Phi_{n,m_n})_{n=n_0}^{\infty}$ *is* level-(k_n) consistent *at* v^* *with respect to* $\mathbf{F}$ *if*

$$\lim_{n\to\infty} L_{k_n}(\Phi_{n,m_n}, v^*) - L_{k_n}^*(v^*) = 0,$$

for any sequence of obfuscating functions of V_2 *with* $|V_2| = m_n$. *If a rule* $\mathbf{\Phi}$ *is level-*(k_n) *consistent at* v^* *for a constant sequence* $k_n = k$, $n = 1, 2, \ldots$, *then we say simply that* $\mathbf{\Phi}$ *is* level-k consistent.

Remark 22 Equation (5) has an interesting implication for VN consistency in the setting where $L_{k_n}^*(v^*) \to 0$. In this case, level-(k_n) consistency of a VN rule $\mathbf{\Phi}$ implies that $\mathbf{\Phi}$ is (k'_n)-consistent for all (k'_n) such that $\liminf \frac{k'_n}{k_n} \geq 1$. We conjecture that this implication holds true for the case where $L_{k_n}^*(v^*) \to c > 0$, but this problem remains open at present.

Example 1, continued. Let $\mathbf{F} = (F_{n,\theta_n=(P_n,R_n)}^{(n,n)})$ be a sequence of R_n-ER(P_n) random graph models in $\mathcal{N}_{n,n}$ for some sequence of probability matrices $(P_n)_{n=n_0}^{\infty}$ and correlation matrices $(R_n)_{n=n_0}^{\infty}$. Under mild model assumptions (see Theorem 19), the graph matching vertex nomination rule $\mathbf{\Phi}_M$ defined in Equation (12) above is level-1 consistent, and hence level-(k_n) consistent for all (k_n) sequences.

Example 3, continued. Let $\mathbf{F} = (F_{n,\theta_n=p}^{(n,n)})$ be a sequence of independent ER(n,p) random graph models in $\mathcal{N}$. All vertex nomination rules are level-(k_n) consistent for all (k_n) sequences. This holds for all possible values of $c \in [n]$ in the nested sequence of ER(n,p) distributions, as all VN rules have effectively chance performance, regardless of core size under this model.

We define the consistency of a VN rule with respect to a broad class of graph sequences, and it is perhaps no surprise that there cannot be any level-(k_n) universally consistent VN rules. Indeed, even for constant sequences $k_n := k$ (i.e., those that are level-(k_n) consistent for all sequences of nominatable distributions $\mathbf{F}$ with nested cores) there cannot be any level-k universally consistent VN rules. To prove this result, we will first establish an analogue to the "arbitrary poor performance" theorems for classifiers (see, e.g., Devroye et al., 1997, Theorem 7.1), which state that for a fixed n and m, any VN scheme can be shown to have arbitrarily poor performance with respect to a well-chosen adversarial distribution $F_{c,\theta}^{(n,m)}$. Our theorem mirrors the classical classification literature, as for a given classification rule, there exists "a sufficiently complex distribution for which the sample size n is hopelessly small" (Devroye et al., 1997, pg. 111), so that a classification rule can be made to perform arbitrarily poorly by selecting a suitably complex data distribution. Nonetheless, in the case of classification, this model complexity and the implicit dependence on n can be overcome asymptotically by a classification rule. That is, universally consistent classifiers exist (see, for example, Stone, 1977; Steinwart, 2002; Tang et al., 2013). In contrast, in the VN problem, the complexity of the model generating the data can also grow in n, which effectively thwarts the ability of a VN rule to asymptotically overcome a sequence of adversarial graph models. Formalizing the above, we arrive at the following theorem, a proof of which can be found in Appendix A.2.

Theorem 23 *Let n and m be large enough to guarantee the existence of asymmetric graphs $g_1 \in \mathcal{G}_n$ and $g_2 \in \mathcal{G}_m$. Consider a VN scheme $\Phi \in \mathcal{V}_{n,m}$, obfuscating function $\mathfrak{o}$, and strictly increasing sequence $(\epsilon_i)_{i=1}^m$ satisfying $\epsilon_i \in (0, \frac{i}{m})$. Then there exists a distribution $F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$ over $\mathcal{G}_n \times \mathcal{G}_m$ and $v^* \in C$ such that for each $k \in [c-1]$,*

$$L_k^*(v^*) \leq \epsilon_{m-k} < 1 - \frac{k}{m} < 1 - \epsilon_k < L_k(\Phi, v^*),$$

where $1 - \frac{k}{m}$ represents the error probability of chance performance, i.e., the error probability of a VN scheme in the independent Erdős-Rényi setting.

In the remainder of the section, we will suppress the dependence of $m = m_n$ on n. If we consider sequences $(\epsilon_{m,i})_{i=1}^m$ satisfying the assumptions of Theorem 23 and $\lim_n \epsilon_{m,m-k_n} = \epsilon \in (0,1)$ for a given (k_n) satisfying $k_n = o(m)$, we arrive at the following Corollary, namely that level-(k_n) universally consistent VN schemes do not exist for any sequence $(k_n)_{n=n_0}^\infty$ that does not grow as fast as $m = |V(G_2)|$.

Corollary 24 *Let $\epsilon \in (0,1)$ be arbitrary, and consider a VN rule $\mathbf{\Phi} = (\Phi_{n,m})$. For any nondecreasing sequence $(k_n)_{n=n_0}^\infty$ satisfying $k_n = o(m)$, there exists a sequence of distributions $(F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m})_{n=n_0}^\infty$ with nested cores such that*

$$\limsup_{n\to\infty} L_{k_n}^*(v^*) = \epsilon < 1 = \lim_{n\to\infty} L_{k_n}(\Phi_{n,m}, v^*).$$

Corollary 24 has a number of practical implications. Below, we will briefly outline two such implications. Unlike in the classification setting, where universally consistent rules (e.g., k-nearest neighbors) are theoretically guaranteed to perform well in big-data settings, the VN practitioner enjoys no such certainty. Indeed, in VN, the practitioner first needs to identify the consistency class of a VN rule (i.e., the set of models for which the VN rule is consistent) before applying it in real settings. Unfortunately, identifying and enumerating these consistency classes is theoretically and practically nontrivial, and we are investigating theory and heuristics for this at present. In a streaming data setting, the performance of a universally consistent classifier will approach Bayes optimality for the distribution governing the data, and the classifier will be guaranteed to successfully adapt itself to any changes in the underlying data distribution. The lack of universal consistency in the VN setting implies that his is not the case for graph data, as the performance, as the performance of a consistent VN scheme in the streaming setting could precipitously decline in the presence of distributional shifts in the data. Recognizing these shifts and their potential impact on VN performance is paramount and is the subject of current research.

4.1. Global Consistency

We have just seen that no universally consistent VN schemes exist. This is a consequence of the complexity of the models available when choosing a sequence of nominatable distributions. Indeed, nested-core nominatable sequences $\mathbf{F}$ allow for (nearly) arbitrary dependence structure and model complexity as n increases: corresponding vertex behavior may be correlated (see Example 1), independent (see Example 4), or negatively correlated (see Example 5) across networks. This model flexibility is in service of modeling the complexity of real

world networks, but, as we will demonstrate below, restricting our model class to simpler dependency structures still does not necessarily guarantee the existence of universally consistent schemes.

It is thus natural to explore a weaker notion of consistency, namely consistency for a sufficiently large family of nominatable sequences rather than for all nominatable sequences.

Definition 25 *Let*

$$\mathfrak{F} = \left\{ \mathbf{F}_\alpha = \left(F_{c_n,\theta_n}^{(n,m_n),\alpha} \right)_{n=n_0}^\infty : \alpha \in \mathcal{A} \right\}$$

be a family of nominatable sequences, indexed by some set $\mathcal{A}$. We say that VN scheme Φ is level-(k_n) $\mathfrak{F}$-globally consistent *if Φ is level-(k_n) consistent for every $\mathbf{F} \in \mathfrak{F}$. We call such a family* level-(k_n) globally consistent.

The question of the maximal family $\mathfrak{F}$ for which a level-(k_n) $\mathfrak{F}$-globally consistent rule exists is of prime interest. While we cannot offer a satisfactory complete answer to that question in the present work, we do offer some examples of globally consistent families.

Example 1 continued: In settings where corresponding vertices have correlated neighborhood structures across networks, there is hope for finding globally consistent rules. In the ongoing Example 1, we have seen a simple example of this in the R-ER(P) model, in which the matrix of correlations R encodes a correspondence across the two graphs. As mentioned previously, Theorem 19 asserts that under some mild model assumptions on R and P in the R-ER(P) model, level-1 globally consistent VN rules exist (namely the graph matching VN scheme). If $\mathfrak{F}$ denotes the set of distributions obeying these model assumptions, then we have that level-(k_n) $\mathfrak{F}$-globally consistent rules exist for all sequences (k_n). While we do not expect the conditions of Theorem 19 to produce a maximal level-(k_n) globally consistent family for any given (k_n), this example nonetheless provides an important intuition for the properties such maximal families might possess.

Example 4 continued: The SBM provides a prime example of global consistency. Working in the one-graph framework of Remark 13, under appropriate growth conditions on the parameters of every sequence in family $\mathfrak{F}$, Theorem 6 in Lyzinski et al. (2016) implies the existence of a likelihood-based nomination scheme that is level-$(|U_1|)$ globally consistent for this family of models. Under similar growth conditions, Theorem 6 in Lyzinski et al. (2014) implies the existence of a level-$(|U_1|)$ globally consistent scheme based on spectral clustering, in which vertices are nominated based on their proximity to the vertex or vertices of interest.

Remark 26 An attempt at systematically constructing a maximal globally consistent family might begin by putting model restrictions onto elements of $\mathcal{N}_{n,m}$. A natural restriction to consider would be to demand that the models in $\mathfrak{F}$ be nested in the following sense: For $\mathbf{F} \in \mathfrak{F}$, if $(G_1, G_2) \sim F_{c_{n_2},\theta_{n_2}}^{(n_2,m_{n_2})}$ with $n_1 < n_2$, then $(G_1[[n_1]], G_2[[m_{n_1}]]) \stackrel{\mathcal{L}}{=} (G_1', G_2')$ where $(G_1', G_2') \sim F_{c_{n_1},\theta_{n_1}}^{(n_1,m_{n_1})}$. This property would allow us to consider "streaming" network models $\mathbf{F}$, where for $n_1 < n_2$, if (g_1, g_2) is realized from $(G_1, G_2) \sim F_{c_{n_2},\theta_{n_2}}^{(n_2,m_{n_2})}$, and (g_1', g_2') is realized from $(G_1', G_2') \sim F_{c_{n_1},\theta_{n_1}}^{(n_1,m_{n_1})}$ then (g_1, g_2) can be constructed by appropriately adding

$n_2 - n_1$ vertices to (g_1', g_2'). Additionally, this would serve to mimic the nested nature of the data in the classification consistency literature. However, as we will see in Example 5, global consistency depends both on the dependency structure within each graph (as seen in Theorem 23) *and* the vertex correspondence (i.e., the potential dependency structure across graphs) encoded in the model.

4.2. Behavioral (In)consistency and Global (In)consistency

We suspect that if the vertices of interest have a common distinguishing probabilistic and/or topological characteristic (e.g., correlated neighborhoods, common SBM block structure, high network centrality, etc.) then a globally consistent rule may exist. Indeed, under mild model assumptions, this is the case in the R-ER(P) of Example 1; in the i.i.d. SBM of Example 4 where the correspondence is the identity function (Lyzinski et al., 2014); and in the i.i.d. ER of Example 3, to name a few. In each of these examples, there is a stochastic/topological similarity (or in the ER case, uniformity) between corresponding vertices across networks. In each, corresponding vertices behave similarly across networks. While we suspect that this behavioral similarity is not sufficient for global consistency, Example 5 demonstrates that behavioral inconsistencies within a family of nominatable distributions can preclude the existence of globally consistent nomination rules.

Example 5 For each n, consider n-vertex random graphs $G_1 \sim$ asym-SBM$(2, B_1, b_n^{(1)})$ independent of $G_2 \sim$ asym-SBM$(2, B_2, b_n^{(2)})$, where asym-SBM denotes the stochastic blockmodel distribution restricted to have support on asymmetric graphs. This restriction is made to avoid the unpleasantries of symmetries, and is asymptotically negligible as the SBMs considered in this example are asymptotically almost surely asymmetric.

Case 1. In this case, corresponding vertices behave similarly across networks. To wit, let $\mathbf{F} = (F_n)_{n=n_0}^{\infty}$ be the sequence of models where

$$B_1 = B_2 = \begin{pmatrix} p_1 & q \\ q & p_2 \end{pmatrix}, \; b_n^{(1)}(i) = b_n^{(2)}(i) = \begin{cases} 1 & \text{if } i \leq n/2; \\ 2 & \text{if } i > n/2, \end{cases}$$

$p_1 \neq p_2$, $c = n$, and the correspondence is the identity function. As stated before, in this model $L^*_{n/2}(v^*) \to 0$ for all $v^* \in C$. Without loss of generality, consider $v^* = v_1 = u_1 = 1$. If $\mathbf{\Phi}$ is consistent with respect to $\mathbf{F}$ then

$$\mathbb{P}_{F_n}(\text{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v_1)}(\mathfrak{o}(u_1)) \geq n/2 + 1) \to 0.$$

By the distributional equivalence of vertices within the same block, and the consistency property in the definition of a VN scheme, for any $u, v \in b_n^{-1}(1)$, $k \in [n]$ we have that

$$\mathbb{P}_{F_n}(\text{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v_1)}(\mathfrak{o}(u)) = k) = \mathbb{P}_{F_n}(\text{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v_1)}(\mathfrak{o}(v)) = k).$$

Letting this common value be set to $\alpha_{k,n}$ (with $\beta_{k,n}$ defined similarly as the common value of $\mathbb{P}_{F_n}(\text{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v_1)}(\mathfrak{o}(u)) = k)$ for u in block 2), we have that

$$\sum_{i=1}^{n} \mathbb{P}_{F_n}(\text{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v_1)}(\mathfrak{o}(u_i)) = k) = 1 = \frac{n(\alpha_{k,n} + \beta_{k,n})}{2}$$

giving us that $\alpha_{k,n} = 2/n - \beta_{k,n}$. Consistency implies that

$$\sum_{k=1}^{n/2} \alpha_{k,n} \to 1,$$

which implies that

$$\sum_{k=1}^{n/2} \alpha_{k,n} = \sum_{k=1}^{n/2} (2/n - \beta_{k,n}) = 1 - \sum_{k=1}^{n/2} \beta_{k,n} \to 1,$$

implying $\sum_{k=1}^{n/2} \beta_{k,n} \to 0$. Therefore, for any u in block 2,

$$\mathbb{P}_{F_n}(\text{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v_1)}(\mathfrak{o}(u)) \geq n/2 + 1) \to 1.$$

Case 2. In this case, corresponding vertices behave differently across networks. To wit, let $\tilde{\mathbf{F}} = (\tilde{F}_n)_{n=n_0}^{\infty}$ be the sequence of models where

$$B_1 = \begin{pmatrix} p_1 & q \\ q & p_2 \end{pmatrix}, \quad B_2 = \begin{pmatrix} p_2 & q \\ q & p_1 \end{pmatrix}, \; b_n^{(1)}(i) = b_n^{(2)}(i) = \begin{cases} 1 \text{ if } i \leq n/2; \\ 2 \text{ if } i > n/2, \end{cases}$$

$c = n$, and the correspondence is the identity function. As in Case 1 considered above, in this model $L^*_{n/2}(v^*) \to 0$ for all $v^* \in C$, and, as above, consider $v^* = v_1 = u_1$. If $\mathbf{\Phi}$ is consistent with respect to $\tilde{\mathbf{F}}$ then

$$\mathbb{P}_{\tilde{F}_n}(\text{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v_1)}(\mathfrak{o}(u_1)) \geq n/2 + 1) \to 0.$$

Note that if σ is the permutation such that

$$\sigma(i) = \begin{cases} i + n/2 & \text{if } i \leq n/2; \\ i - n/2 & \text{if } i > n/2, \end{cases},$$

then $\mathbb{P}_{F_n}(g_1, g_2) = \mathbb{P}_{\tilde{F}_n}(g_1, \sigma(g_2))$. Define

$$E_n = \{(g_1, g_2) \text{ s.t. } \text{rank}_{\Phi(g_1, \mathfrak{o}(g_2), v_1)}(\mathfrak{o}(u_1)) \geq n/2 + 1\}\}$$

i.e., and $\tilde{E}_n = \{(g_1, g_2) \text{ s.t. } (g_1, \sigma(g_2)) \in E_n\}$, i.e.,

$$\tilde{E}_n = \{(g_1, g_2) \text{ s.t. } \text{rank}_{\Phi(g_1, \mathfrak{o}(g_2), v_1)}(\mathfrak{o}(u_{n/2+1})) \geq n/2 + 1\}.$$

If $\mathbf{\Phi}$ is consistent with respect to $\mathbf{F}$ we have that $\mathbb{P}_{F_n}(E_n) \to 0$ which implies (as $(g_1, g_2) \in E_n \Leftrightarrow (g_1, \sigma(g_2)) \in \tilde{E}_n$) $\mathbb{P}_{\tilde{F}_n}(\tilde{E}_n) \to 0$. If $\mathbf{\Phi}$ is consistent with respect to $\tilde{\mathbf{F}}$ then $\mathbb{P}_{\tilde{F}_n}(E_n) \to 0$ and $\mathbb{P}_{\tilde{F}_n}(\tilde{E}_n) \to 1$. We arrive at a contradiction, and $\mathbf{\Phi}$ cannot be $(n/2)$-consistent with respect to both $\mathbf{F}$ and $\tilde{\mathbf{F}}$.

Although Example 5 may seem artificial, it is a simple representation of a common phenomenon observed in network data. Often the same entity can behave quite differently across networks; see Patsolic et al. (2017) for an example of this in social networks and Chen et al. (2016b) for an example of this in connectomics. In such a setting, intuition says that a universal scheme that works in both behavioral settings should not exist. Indeed, at least in the simple block model setting considered above, we see that no such scheme exists. Example 5 also highlights an important difference between the VN setting and the more standard classification framework. We already noted that classification's universal consistency relies on the distribution not changing in n, whereas in VN the distributions must vary with n (indeed, the graph sizes grow in n). Further, Example 5 shows that the nonexistence of a universally consistent scheme is not simply a consequence of changing the underlying distributional parameters with n, as these two SBM distributions are (essentially) fixed, in that the matrix B does not change with n. In this example the "training data" provided by G_1 cannot be uniformly beneficial for a single VN scheme across the two differing model settings we consider. Contrast this with the classification setting of Devroye et al. (1997), where the training data uniformly provides progressively better estimates of the class-conditional distributions. Indeed, the training data helps delineate potentially interesting vertices from non-interesting ones in G_2 in Case (1) for one VN scheme, and in Case (2) for another VN scheme, but there does not exist a VN scheme that achieves this desired class separation across both cases.

Remark 27 In the cases considered in Example 5, if we introduce positive edge-wise correlation of

$$\rho \leq \sqrt{\min\left(\frac{p_1(1-p_2)}{p_2(1-p_1)}, \frac{p_2(1-p_1)}{p_1(1-p_2)}\right)}$$

into both Case 1 and Case 2, then under mild assumptions on the growth of p_1 and p_2, joint consistency can be recovered via a USVT centered graph matching nomination scheme (see Lyzinski and Sussman, 2018, for details). This example demonstrates that it is sometimes possible to toggle a family of models to allow for global consistency. A note of caution is needed, however, as in this particular example the correlation ρ is introducing a behavioral consistency across networks that addresses the precise issue brought forth by the behavioral inconsistency in Example 5. In other, more nuanced model families, we do not expect the global-consistency modification (if it indeed exists) to be as straightforward as adding additional edge-correlation into the model.

4.3. Vertex Nomination on Networks with Node Covariates

It is natural to ask if incorporating vertex features into the VN framework can resolve the lack of universally consistent VN schemes. While straightforward to implement, the ameliorating effect of features is significantly more nuanced. Before defining the VN scheme with features, we need the following extension of $\mathcal{I}(v;g)$ for $g \in \mathcal{G}_n$ and $v \in V(g)$. Letting $\mathcal{X}$ be the space of vertex features for graphs in $\mathcal{G}_n$, for $g \in \mathcal{G}_n$, $v \in V(g)$, and $X \in \mathcal{X}^n$ we define

$$\widetilde{\mathcal{I}}(v;g,X) = \{u \in V(g) : \exists \text{ automorphism } \tau \text{ of } g \text{ s.t. } \tau(v) = u \text{ and } X_u = X_v\},$$

where X_v is the feature associated to v via X.

Definition 28 (Vertex Nomination (VN) Scheme with features) *Let $\mathcal{X}$ (resp., $\mathcal{Y}$) be the space of vertex features of graphs in $\mathcal{G}_n$ (resp., $\mathcal{G}_m$). For $n, m > 0$ fixed, obfuscating set W and obfuscating function $\mathfrak{o} \in \mathfrak{O}_W$, a* vertex nomination scheme with features *is a function*

$$\Phi : \mathcal{G}_n \times \mathcal{X}^n \times \mathfrak{o}(\mathcal{G}_m) \times \mathcal{Y}^m \times V_1 \to \mathcal{T}_W$$

satisfying the following consistency property: If for each $u \in V_2$, we define

$$rank_{\Phi(g_1,X,\mathfrak{o}(g_2),\mathfrak{o}(Y),v^*)}\big(\mathfrak{o}(u)\big)$$

to be the position of $\mathfrak{o}(u)$ in the total ordering provided by $\Phi(g_1, X, \mathfrak{o}(g_2), \mathfrak{o}(Y), v^*)$, and we define $\mathfrak{r}_\Phi : \mathcal{G}_n \times \mathcal{X}^n \times \mathcal{G}_m \times \mathcal{Y}^m \times \mathfrak{O}_W \times V_1 \times 2^{V_2} \mapsto 2^{[m]}$ via

$$\mathfrak{r}_\Phi(g_1, X, \mathfrak{o}(g_2), \mathfrak{o}(Y), v^*, S) = \{rank_{\Phi(g_1,X,\mathfrak{o}(g_2),\mathfrak{o}(Y),v^*)}\big(\mathfrak{o}(u)\big) \text{ s.t. } u \in S\},$$

then we require that for any $g_1 \in \mathcal{G}_n$, $g_2 \in \mathcal{G}_m$, $v^* \in V_1$, $X \in \mathcal{X}^n$, $Y \in \mathcal{Y}^m$, obfuscating functions $\mathfrak{o}_1, \mathfrak{o}_2 \in \mathfrak{O}_W$ and any $u \in V(g_2)$,

$$\mathfrak{r}_\Phi\big(g_1, X, \mathfrak{o}_1(g_2), \mathfrak{o}_1(Y), v^*, \widetilde{\mathcal{I}}(u; g_2, Y)\big) = \mathfrak{r}_\Phi\big(g_1, X, \mathfrak{o}_2(g_2), \mathfrak{o}_2(Y), v^*, \widetilde{\mathcal{I}}(u; g_2, Y)\big). \quad (13)$$

We let $\widetilde{\mathcal{V}}_{n,m}$ denote the set of all such VN schemes.

It is immediate that if the features are sufficiently informative, consistency can be established with features where it could not be without. Indeed, consider in Example 5 features that encode the community memberships of a few vertices (e.g., a few vertices whose correspondences across the two graphs are known a priori). Combined with spectral methods, these would be sufficient for consistent VN under either behavior regime. It is also immediate that the fundamental idea presented in Example 5 has an analogue when vertex features are available, as illustrated by the following example.

Example 6 For each n, consider n-vertex random graphs $G_1 \sim$ asym-SBM$(3, B_1, b_n^{(1)})$ independent of $G_2 \sim$ asym-SBM$(3, B_2, b_n^{(2)})$, where asym-SBM again indicates the stochastic block model with support restricted to the asymmetric graphs.
Case 1. In this case, corresponding vertices behave similarly across networks. To wit, let $\mathbf{F} = (F_n)_{n=n_0}^{\infty}$ be the sequence of models where $3|n$ and

$$B_1 = B_2 = \begin{pmatrix} p_1 & q & q \\ q & p_2 & q \\ q & q & p_2 \end{pmatrix}, \; b_n^{(1)}(i) = b_n^{(2)}(i) = \begin{cases} 1 & \text{if } i \leq n/3; \\ 2 & \text{if } i \in (n/3, 2n/3] \\ 3 & \text{if } i > n/3, \end{cases}$$

$p_1 \neq p_2$, $c = n$, the correspondence is the identity function, and $v^* = 1$ is in block 1.
Case 2. In this case, corresponding vertices behave differently across networks. To wit, let $\mathbf{F} = (F_n)_{n=n_0}^{\infty}$ be the sequence of models where $3|n$ and

$$B_1 = \begin{pmatrix} p_1 & q & q \\ q & p_2 & q \\ q & q & p_2 \end{pmatrix}, \; B_2 = \begin{pmatrix} p_2 & q & q \\ q & p_1 & q \\ q & q & p_2 \end{pmatrix}, \; b_n^{(1)}(i) = b_n^{(2)}(i) = \begin{cases} 1 & \text{if } i \leq n/3; \\ 2 & \text{if } i \in (n/3, 2n/3] \\ 3 & \text{if } i > n/3, \end{cases}$$

$p_1 \neq p_2$, $c = n$, the correspondence is the identity function, and $v^* = 1$ is in block 1. Similar to Example 5, without features no VN scheme can be $(n/3)$-consistent for both Cases 1 and 2 simultaneously. In a similar fashion, if we consider features X and Y defined via

$$X_v = Y_v = \begin{cases} 1 & \text{if } b^{(1)}(v) = 1 \\ -1 & \text{if } b^{(1)}(v) = 2, 3, \end{cases}$$

then joint consistency is achievable for both Cases 1 and 2, for example by relying on features and ignoring graph structure. However, if we consider features X and Y defined via

$$X_v = Y_v = \begin{cases} 1 & \text{if } b^{(1)}(v) = 1, 2 \\ -1 & \text{if } b^{(1)}(v) = 3, \end{cases}$$

then joint consistency is again not achievable for both Cases 1 and 2 simultaneously.

This example demonstrates that features, in general, are not enough to ensure universal consistency. Nevertheless, insofar as features supply additional information, they have the potential to improve VN performance. A more thorough examination of the effect and effectiveness of vertex features in VN is beyond the scope of this work, and is the subject of current research.

5. Discussion

In this work, we have introduced a notion of consistency for the vertex nomination task that better reflects the broad range of models under which VN may be deployed. Rather than being restricted to the stochastic block model structure required in previous formulations of the problem, our framework allows for arbitrary dependence structure both within and between graph pairs, while encompassing the original SBM formulation of the problem. Additionally, we have demonstrated how this framework relates to the well-studied notion of Bayes optimal classifiers in the pattern recognition literature. Unlike in the classification setting, we have seen that while Bayes optimal VN schemes always exist, no universally consistent scheme exists. This fact is due essentially to the additional leeway provided by the graph model, in which observing more vertices does not necessarily correspond to receiving more information about the underlying distribution. This is in contrast to the classification setting studied in Stone (1977) and others (Devroye et al., 1997), in which observing more samples allows more accurate estimation of the underlying distribution and class boundary. For this reason, one especially interesting line of investigation concerns the nominatable distributions for which larger n does indeed correspond to more information about the underlying graph distribution. A simple example of this is the initial formulation of the vertex nomination problem, in which observing more vertices allows one to better estimate the model parameters, including the block memberships, and thus more accurately identify the vertices from the interesting block. We suspect that the essential property at play here is that under models of this sort, each vertex is analogous to a sample from a single distribution, though this may not be in and of itself a sufficient condition for consistency. For example, in the case of (G_1, G_2) being i.i.d. or ρ-correlated marginally identical draws from a random dot product graph model with the identity correspondence, each vertex (along with its incident edges) is, in a sense, a noisy sample from the underlying latent

position distribution. Hence, for large n, one can estimate the latent positions or their distribution to arbitrary accuracy, and provided that the latent positions of the interesting vertices are suitably separated from those of the rest of the graph, one should have VN consistency for the collection of these latent position models.

More broadly, it would be good to better understand whether there exist families of nominatable distributions $\mathfrak{F}$ for which certain VN schemes are consistent, and precisely how large these families can be made to be. In a similar vein, it would be of interest to explore how the dependence structure allowed both within and between graphs influences vertex nomination. In particular, if one rules out certain pathologically hard dependence structures as considered in Example 5, can one obtain global consistency with respect to this restricted set of distributions? We hope to explore these questions in future work.

We are also exploring alternative formulations of the VN problem and alternate formulations of the VN loss function. While the extension to multiple vertices of interest in each network G_1 and G_2 is straightforward, we are considering several generalizations of the VN problem considered here. One formulation of prime interest in applications (especially in connectomics and social networks) is as follows: given a collection of vertices of interest in one graph, find those that play a similar structural (based on the topology of the underlying network) or functional (based on vertex or edge covariates) role in the other graph. In addition, as seen in Section 4.3 the impact on VN consistency (and the potential existence of universally consistent schemes) when incorporating edge and vertex covariates into the VN framework is of prime interest, and a deeper analysis of the VN inference task in this framework is the subject of our current and future work.

The loss function considered in the present work is an analogue of the 0/1 recall-at-k loss function in the information retrieval literature. Under this loss function, we have shown that no universally consistent VN rule exists. It is natural to ask whether alternative loss functions can be considered under which universal consistency is achievable. While we conjecture that Example 5 will nearly always provide a counterexample to universal consistency, this question remains open and is the subject of current research.

Appendix A. Proofs of Main Results

Here we collect the proofs of the two main theorems in this work, Theorems 17 and 23.

A.1. Theorem 17 and Remark 18

In this section, we present proofs of Theorem 17 and the claim in Remark 18.

Proof [Proof of Theorem 17]

Let Φ be an arbitrary VN scheme and Φ^* the scheme defined at Eq. (9). Recall the definition

$$(g_1, [\mathfrak{o}(g_2)])_{w=\mathfrak{o}(v)} = \Big\{ \big(g_1, \tilde{g}_2\big) \text{ s.t. } \exists \text{ iso. } \sigma \text{ with } \mathfrak{o}(\tilde{g}_2) = \sigma(\mathfrak{o}(g_2)), \text{ and } \sigma(w) = \mathfrak{o}(v^*) \Big\}.$$

With $\mathbf{g}$ defined as in the theorem, note that for each $i \in [h]$,

$$\begin{aligned}
U^j_{i,\mathbf{g}} :&= \Big\{ (g_1, g_2) \in \Big(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \Big) \text{ s.t. } \operatorname{rank}_{\Phi(g_1, \mathfrak{o}(g_2), v^*)}(\mathfrak{o}(v^*)) = j \Big\} \\
&= \Big\{ (g_1, g_2) \in \Big(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \Big) \text{ s.t. } \Phi(g_1, \mathfrak{o}(g_2), v^*)[j] = \mathfrak{o}(v^*) \Big\} \\
&= \Big\{ (g_1, g_2) \in \Big(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \Big) \text{ s.t. } \exists \text{ iso. } \sigma \text{ s.t. } \sigma(\mathfrak{o}(g_2^{(i)})) = \mathfrak{o}(g_2) \text{ and} \\
&\qquad\qquad \sigma(\Phi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j]) = \mathfrak{o}(v^*) \Big\} \\
&= \Big(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \Big)_{\Phi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j] = \mathfrak{o}(v^*)}.
\end{aligned}$$

For each $i \in [h]$ define $p_{i,\Phi} \in [0,1]^m$ via

$$p_{i,\Phi}[j] := \mathbb{P}_{F^{(n,m)}_{c,\theta}} \left(U^j_{i,\mathbf{g}} \,\middle|\, (g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]) \right).$$

Observe that for each $i \in [h]$, it is immediate that p_{i,Φ^*} majorizes $p_{i,\Phi}$. To see this, note that for any fixed $\xi \in [m]$, letting $q^{\xi}_{i,\Phi}$ be $(p_{i,\Phi}[j])_{j=1}^{\xi}$ with entries sorted in descending order, we have $p_{i,\Phi^*}[j] \geq q^{\xi}_{i,\Phi}[j]$ for all $j \in [\xi]$, and majorization follows immediately. With $\mathcal{P}_{\mathbf{g}}$ denoting the partition induced by $\mathbf{g}$, this majorization property implies

$$\begin{aligned}
L_\xi(\Phi, v^*) &= 1 - \sum_{j=1}^{\xi} \mathbb{P}\left(\operatorname{rank}_{\Phi(G_1, \mathfrak{o}(G_2), v^*)}(\mathfrak{o}(v^*)) = j \right) \\
&= 1 - \sum_{\mathcal{P}_{\mathbf{g}}} \sum_{j=1}^{\xi} \mathbb{P}\left[U^j_{i,\mathbf{g}} \,\middle|\, (g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]) \right] \mathbb{P}\left[(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]) \right] \\
&= \sum_{\mathcal{P}_{\mathbf{g}}} \left(1 - \sum_{j=1}^{\xi} p_{i,\Phi}[j] \right) \mathbb{P}\left[(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]) \right] \\
&\geq \sum_{\mathcal{P}_{\mathbf{g}}} \left(1 - \sum_{j=1}^{\xi} p_{i,\Phi^*}[j] \right) \mathbb{P}\left[(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]) \right] \\
&= L_\xi(\Phi^*, v^*).
\end{aligned}$$

As Φ, $\mathbf{g}$, and $\mathfrak{o}$ were arbitrary, the proof follows. ■

Proof [Proof of Remark 18] Fix i, and let $\xi_i = |\Psi(g_1^{(i)}, g_2^{(i)}, v^*)|$. Note that for each $j \leq \xi_i$, the set of graphs $(g_1, g_2) \in \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)$ for which $\Psi(g_1, g_2, v^*)[j] = \mathcal{I}(\mathfrak{o}(v^*); \mathfrak{o}(g_2))$ is precisely

$$\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\Psi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j] = \mathfrak{o}(v^*)}.$$

If the tie breaking scheme T satisfies $T[1] = \mathfrak{o}(v^*)$, then the set set of graphs $(g_1, g_2) \in \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)$ for which $\Phi^*_T(g_1, g_2, v^*)[j] = \mathfrak{o}(v^*)$ is then also

$$\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\Psi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j] = \mathfrak{o}(v^*)}.$$

The proof proceeds as follows. For an arbitrary VN scheme Φ, and for each $i \in [h]$,

$$\begin{aligned}
U^j_{i,\mathbf{g}} :&= \Big\{ (g_1, g_2) \in \Big(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \Big) \text{ s.t. } \operatorname{rank}_{\Phi(g_1, \mathfrak{o}(g_2), v^*)}(\mathfrak{o}(v^*)) = j \Big\} \\
&\subset \Big\{ (g_1, g_2) \in \Big(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \Big) \text{ s.t. } \exists \text{ iso. } \sigma \text{ s.t. } \sigma(\mathfrak{o}(g_2^{(i)})) = \mathfrak{o}(g_2) \text{ and} \\
&\qquad\qquad \sigma\left(\mathcal{I}\left(\Phi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j]; \mathfrak{o}(g_2^{(i)}) \right) \right) \ni \mathfrak{o}(v^*) \Big\} \\
&= \Big(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \Big)_{\mathcal{I}\left(\Phi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j]; \mathfrak{o}(g_2^{(i)}) \right) = \mathfrak{o}(v^*)}
\end{aligned}$$

We then have that $T[1] = \mathfrak{o}(v^*)$ implies that

$$\begin{aligned}
1 - L_\ell(\Phi, v^*) &= \sum_{\mathcal{P}_{\mathbf{g}}} \mathbb{P}\left[\left(\bigcup_{j=1}^{\ell} U^j_{i,\mathbf{g}} \right) \mid \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \\
&\leq \sum_{\mathcal{P}_{\mathbf{g}}} \mathbb{P}\left[\bigcup_{j=1}^{\ell} \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\mathcal{I}\left(\Phi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j]; \mathfrak{o}(g_2^{(i)}) \right) = o(v^*)} \mid \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \\
&= \sum_{\mathcal{P}_{\mathbf{g}}} \sum_{j \in \mathcal{J}_i} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\mathcal{I}\left(\Phi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j]; \mathfrak{o}(g_2^{(i)}) \right) = o(v^*)} \mid \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \\
&\leq \sum_{\mathcal{P}_{\mathbf{g}}} \sum_{j \in \mathcal{J}_i} \underbrace{\mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right)_{\Psi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j] = \mathfrak{o}(v^*)} \mid \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right]}_{= \mathbb{P}\left[(g_1, g_2) \in \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \text{ s.t. } \Phi^*_T(g_1, \mathfrak{o}(g_2), v^*)[j] = \mathfrak{o}(v^*) \,\middle|\, \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right]} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})] \right) \right] \\
&\leq 1 - L_\ell(\Phi^*_T, v^*),
\end{aligned}$$

where $\mathcal{J}_i \subset [\ell]$ is the lexicographically smallest set of indices for which

$$\left\{ \left(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}) \right)_{\mathcal{I}\left(\Phi(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[j]; \mathfrak{o}(g_2^{(i)}) \right) = o(v^*)} \right\}_{j \in \mathcal{J}_i}$$

are distinct. ■

A.2. Proof of Theorem 23

Proof Define a probability vector $\xi \in \mathbb{R}^m$ by $\xi_i = \epsilon_i - \epsilon_{i-1}$ for $i \in [m-1]$ (where we take $\epsilon_0 := 0$), and let $\xi_m = 1 - \epsilon_{m-1}$. Consider asymmetric graphs $(g_1, g_2) \in \mathcal{G}_n \times \mathcal{G}_m$ and construct a distribution $F_{c,\theta}^{(n,m)} \in \mathcal{N}$ as follows.

i. $c = n \wedge m$;

ii. The support of $F_{c,\theta}^{(n,m)}$ is $(g_1, [\mathfrak{o}(g_2)])$;

iii. For each $k \in [m]$ define

$$R_{\Phi,k} = \left\{(g_1, \tilde{g}_2) \in (g_1, [\mathfrak{o}(g_2)]) \text{ s.t. } \Phi(g_1, \mathfrak{o}(\tilde{g}_2), v^*)[k] = \mathfrak{o}(v^*)\right\}.$$

Then we define $\mathbb{P}_{F_{c,\theta}^{(n,m)}}(R_{\Phi,k}) := \xi[k]$ with all elements of $R_{\Phi,k}$ being assigned equal mass under $F_{c,\theta}^{(n,m)}$.

It is clear then that $L_k(\Phi, v^*) = 1 - \epsilon_k > 1 - \frac{k}{m}$. It is also clear that $L_k^*(v^*) \leq \epsilon_{m-k}$. Indeed, consider Φ' which is defined by reversing the order provided by Φ; then $L_k(\Phi', v^*) = \epsilon_{m-k}$; which completes the proof. ■

Appendix B. Proof of Theorem 19

Herein we will provide a sketch of the proof of Theorem 19 for completeness. Let Q be a permutation matrix in Π_n (with associated permutation σ_Q) that permutes precisely k labels (i.e., $\sum_i Q_{i,i} = n - k$), and let T denote the number of transpositions induced by σ_Q, and note $|T| \leq k/2$. By exploiting the cyclic structure of Q acting on $\text{vec}(B)$, we have that

$$\mathbb{E}\delta(Q) - \mathbb{E}\delta(I_n) = \mathbb{E}\|AQ - QB\|_F^2 - \mathbb{E}\|A - B\|_F^2 \geq \epsilon\left((n-k)k + \binom{k}{2} - T\right).$$

Combining this expectation bound with the following McDiarmid-like concentration result will yield the proof of Theorem 19.

Proposition 29 (Proposition 3.2 from Kim et al. (2002)) *Let $X_1, \ldots, X_n$ be a sequence of independent Bernoulli random variables where $\mathbb{E}[X_i] = p_i$. Let $f : \{0,1\}^n \mapsto \Re$ be such that changing any X_i to $1 - X_i$ changes f by at most*

$$M = \sup_i \sup_{X_1,\ldots,X_n} |f(X_1, \ldots, X_i, \ldots, X_n) - f(X_1, \ldots, 1 - X_i, \ldots, X_n)|.$$

Let $\sigma^2 = M^2 \sum_i p_i(1 - p_i)$ and let $Y = f(X_1, \ldots, X_n)$.
Then

$$\Pr[|Y - \mathbb{E}[Y]| \geq t\sigma] \leq 2e^{-t^2/4}$$

for all $0 < t < 2\sigma/M$.

Indeed, we see that $X_Q := \delta(Q) - \delta(I_n)$ is a function of N_Q independent Bernoulli random variables, where $N_Q = 3\left(\binom{k}{2} + k(n-k) - |T|\right) \leq 3kn$. Let S_Q be the sum of these N_Q Bernoulli random variables, and it follows that $\text{Var}(S_Q) \leq N_Q/4$. By setting $t = C\frac{\epsilon kn}{\sigma}$ for an appropriate constant $C > 0$ in Proposition 29, we have for n sufficiently large

$$\Pr(X_Q \leq 0) \leq \Pr(|X_Q - \mathbb{E}(X_Q)| \geq \mathbb{E}(X_Q)) \leq 2\exp\left\{-\Theta(\epsilon^2 kn)\right\}.$$

A union bound over all such Q (of which there are $\leq n^k$) and over k yields

$$\mathbb{P}(\exists\, Q \in \Pi_n \setminus \{I_n\} \text{ s.t. } \delta(Q) \leq \delta(I_n)) \leq \sum_{k=2}^{n} 2\exp\left\{k\log(n) - \Theta(\epsilon^2 kn)\right\} = 2\exp\left\{-\Theta(\epsilon^2 n)\right\},$$

as desired.

B.1. VN Schemes with Ties

We can incorporate ties into the VN framework as follows. With ties allowed, any sensibly-defined vertex nomination scheme should view all vertices in $\mathcal{I}(u; g)$ as being equally good matches to a vertex of interest v^*. To this end, we will view VN schemes as providing *weak orderings* of the elements of W:

Definition 30 *For a set A, let $\mathfrak{W}_A$ denote the set of all weak orderings of the elements of A (i.e., the set of all total orderings where ties are allowed). For $x \in \mathfrak{W}_A$, let t_x be any maximum-length total ordering induced by x. For each $a \in A$, we define*

$$rank_x(a) = rank_{t_x}(a'),$$

where $a = a'$ according to the ordering x.

Example 7 *If $A = \{a, b, c, d, e\}$ and $x : a > c > d = e > b$, then $t(x) : a > c > d > b$, or $t(x) : a > c > e > b$; in either case, $rank_x(a) = 1$, $rank_x(c) = 2$, $rank_x(d) = 3$, $rank_x(e) = 3$, and $rank_x(b) = 4$.*

A well-defined VN scheme should be "label-independent" in the following sense: Each element of each $\mathcal{I}(\mathfrak{o}(u); \mathfrak{o}(g_2))$ should be ranked identically by Φ, and these ranks should be independent of the obfuscation function $\mathfrak{o}$. Formally, we have the following.

Definition 31 (Vertex Nomination (VN) Scheme) *For $n, m > 0$ fixed, obfuscating set W, and $\mathfrak{o} \in \mathfrak{O}_W$, a* vertex nomination scheme *is a function $\Phi : \mathcal{G}_n \times \mathfrak{o}(\mathcal{G}_m) \times V_1 \to \mathfrak{W}_W$ satisfying the following properties: For all $(g_1, g_2) \in \mathcal{G}_n \times \mathcal{G}_m$,*

i. If $u_1 \notin \mathcal{I}(u_2; g_2)$ then either $\mathfrak{o}(u_1) > \mathfrak{o}(u_2)$ or $\mathfrak{o}(u_1) < \mathfrak{o}(u_2)$ in the ordering provided by $\Phi(g_1, \mathfrak{o}(g_2), v^*)$;

ii. If $u_1 \in \mathcal{I}(u_2; g_2)$ then $\mathfrak{o}(u_1) = \mathfrak{o}(u_2)$ in the ordering provided by $\Phi(g_1, \mathfrak{o}(g_2), v^*)$;

iii. (consistency criterion) If $\mathfrak{o}_1, \mathfrak{o}_2 \in \mathfrak{O}_W$, then for each $v \in V(g_2)$

$$rank_{\Phi(g_1, \mathfrak{o}_1(g_2), v^*)}(\mathfrak{o}_1(v)) = rank_{\Phi(g_1, \mathfrak{o}_2(g_2), v^*)}(\mathfrak{o}_2(v)). \tag{14}$$

We let $\mathcal{V}_{n,m}$ denote the set of all such VN schemes.

The VN loss functions and level-k errors are defined as in the totally ordered setting. To define the Bayes optimal scheme, let (g_1, g_2) be realized from $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$, and consider a vertex of interest $v^* \in C$ and obfuscating function $\mathfrak{o} : V_2 \to W$. Letting $\simeq$ denote graph isomorphism, for $(g_1, g_2) \in \mathcal{G}_n \times \mathcal{G}_m$ define the set

$$\begin{aligned}(g_1, [\mathfrak{o}(g_2)]) &= \big\{\big(g_1, \tilde{g}_2\big) \text{ s.t. } \mathfrak{o}(\tilde{g}_2) \simeq \mathfrak{o}(g_2)\big\} \\ &= \big\{\big(g_1, \tilde{g}_2\big) \text{ s.t. } \tilde{g}_2 \simeq g_2\big\}\end{aligned} \tag{15}$$

In order to define the Bayes optimal scheme, we will also need the following restrictions of $(g_1, [\mathfrak{o}(g_2)])$: for each $w \in W$, and $v \in V_2$ we define

$$\begin{aligned}(g_1, [\mathfrak{o}(g_2)])_{\mathcal{I}(w;\mathfrak{o}(g_2))=\mathfrak{o}(v)} = \Big\{\big(g_1, \tilde{g}_2\big) \text{ s.t. } \exists \text{ iso. } \sigma \text{ with } \mathfrak{o}(\tilde{g}_2) = \sigma(\mathfrak{o}(g_2)), \\ \text{and } \sigma(u) = \mathfrak{o}(v) \text{ for some } u \in \mathcal{I}(w; \mathfrak{o}(g_2))\Big\}.\end{aligned} \tag{16}$$

Note that for a fixed v, if $\{\mathcal{I}(w; \mathfrak{o}(g_2))\}_{w \in W'}$ partitions W (for some suitable $W' \subseteq W$), then

$$\big\{(g_1, [\mathfrak{o}(g_2)])_{\mathcal{I}(w;\mathfrak{o}(g_2))=\mathfrak{o}(v)}\big\}_{w \in W'}$$

partitions $(g_1, [\mathfrak{o}(g_2)])$. We are now ready to define a Bayes optimal VN scheme.

For ease of notation, in the sequel we will write $\mathbb{P}_{F_{c,\theta}^{(n,m)}}$ or even simply $\mathbb{P}$ in place of $\mathbb{P}_{(G_1,G_2)\sim F_{c,\theta}^{(n,m)}}$ where there is no risk of ambiguity. Let

$$\mathbf{g} = \left\{\left(g_1^{(i)}, g_2^{(i)}\right)\right\}_{i=1}^{h} \tag{17}$$

be such that the sets

$$\left\{\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right\}_{i=1}^{h}$$

partition $\mathcal{G}_n \times \mathcal{G}_m$. We will call this partition $\mathcal{P}_{n,m}$, where we suppress dependence on $\mathbf{g}$ and $\mathfrak{o}$ for ease of notation. We will define a Bayes optimal scheme $\Phi^* = \Phi_{\mathbf{g}}^*$ piecewise on each element of this partition. For each $i \in [h]$, define (where ties in the argmax's are broken in an arbitrary but nonrandom manner)

$$\begin{aligned}\Phi^*\Big(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\Big)[1] &\in \operatorname*{argmax}_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))\subset W} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))=\mathfrak{o}(v^*)} \,\middle|\, \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right] \\ \Phi^*\Big(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\Big)[2] &\in \operatorname*{argmax}_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))\subset W\setminus\{\Phi^*[1]\}} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))=\mathfrak{o}(v^*)} \,\middle|\, \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right] \\ &\vdots \\ \Phi^*\Big(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*\Big)[\ell] &\in \operatorname*{argmax}_{\mathcal{I}_{\mathfrak{o}(g_2)}(u)\subset W\setminus\{\cup_{j=1}^{\ell-1}\Phi^*[j]\}} \mathbb{P}\left[\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)_{\mathcal{I}(u;\mathfrak{o}(g_2^{(i)}))=\mathfrak{o}(v^*)} \,\middle|\, \left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right]\end{aligned} \tag{18}$$

so that the ranking provided by Φ^* is (where $\Phi^*(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)[i] = \{u_1^{(i)}, \ldots, u_{n_i}^{(i)}\}$)

$$\underbrace{u_1^{(1)} = u_2^{(1)} = \cdots = u_{n_1}^{(1)}}_{n_1} > \underbrace{u_1^{(2)} = u_2^{(2)} = \cdots = u_{n_2}^{(2)}}_{n_2} > \cdots > \underbrace{u_1^{(\ell)} = u_2^{(\ell)} = \cdots = u_{n_\ell}^{(\ell)}}_{n_\ell}.$$

For each element

$$(g_1', g_2') \in (g_1^{(i)}, [\mathfrak{o}(\tilde{g}_2^{(i)})]) \setminus \{(g_1^{(i)}, g_2^{(i)})\},$$

choose any isomorphism σ such that $\mathfrak{o}(g_2') = \sigma(\mathfrak{o}(g_2^{(i)}))$, and define

$$\Phi^*(g_1, \mathfrak{o}(g_2'), v^*) = \sigma(\Phi^*(g_1^{(i)}, \mathfrak{o}(g_2^{(i)}), v^*)),$$

noting that $\Phi^*(g_1, \mathfrak{o}(g_2'), v^*)$ is independent of the choice of isomorphism σ. The next proposition states that, modulo ties, the definition of $\Phi_{\mathbf{g}}^*$ is independent of the choice of $\mathbf{g}$.

Proposition 32 *Let $\mathfrak{o} \in \mathfrak{O}_W$ be an obfuscating function, and let*

$$\mathbf{g} = \left\{\left(g_1^{(i)}, g_2^{(i)}\right)\right\}_{i=1}^{h} \neq \tilde{\mathbf{g}} = \left\{\left(g_1^{(i)}, \tilde{g}_2^{(i)}\right)\right\}_{i=1}^{h}$$

be such that the sets

$$\left\{\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right\}_{i=1}^{h}, \left\{\left(g_1^{(i)}, [\mathfrak{o}(\tilde{g}_2^{(i)})]\right)\right\}_{i=1}^{h}$$

partition $\mathcal{G}_n \times \mathcal{G}_m$. Suppose that $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$, and consider a vertex of interest $v^* \in C$. Then there exists a fixed strategy for breaking ties in the argmax's for $\Phi_{\mathbf{g}}^*$ and $\Phi_{\tilde{\mathbf{g}}}^*$ that yields $\Phi_{\mathbf{g}}^* = \Phi_{\tilde{\mathbf{g}}}^*$. In particular, under any such tie-breaking strategy, we have that $L_k(\Phi_{\mathbf{g}}^*, v^*) = L_k(\Phi_{\tilde{\mathbf{g}}}^*, v^*)$ for all $k \in [m-1]$.

Lastly, the following theorem shows that this scheme (or schemes) is indeed Bayes optimal. The proof is analogous to the totally ordered setting and is thus omitted.

Theorem 33 *Let $\mathfrak{o} \in \mathfrak{O}_W$ be an obfuscating function, and let*

$$\mathbf{g} = \left\{\left(g_1^{(i)}, g_2^{(i)}\right)\right\}_{i=1}^{h}$$

be such that the sets

$$\left\{\left(g_1^{(i)}, [\mathfrak{o}(g_2^{(i)})]\right)\right\}_{i=1}^{h}$$

partition $\mathcal{G}_n \times \mathcal{G}_m$. Let $\Phi^* = \Phi_{\mathbf{g}}^*$ be as defined in Equation (9). Suppose that $(G_1, G_2) \sim F_{c,\theta}^{(n,m)} \in \mathcal{N}_{n,m}$, and consider a vertex of interest $v^* \in C$. We have that $L_k(\Phi^*, v^*) = L_k^*(v^*)$ for all $k \in [m-1]$ and all obfuscating functions $\mathfrak{o}$.

Abstract

An approximate method for conducting resampling in Lasso, the ℓ_1 penalized linear regression, in a semi-analytic manner is developed, whereby the average over the resampled datasets is directly computed without repeated numerical sampling, thus enabling an inference free of the statistical fluctuations due to sampling finiteness, as well as a significant reduction of computational time. The proposed method is based on a message passing type algorithm, and its fast convergence is guaranteed by the state evolution analysis, when covariates are provided as zero-mean independently and identically distributed Gaussian random variables. It is employed to implement bootstrapped Lasso (Bolasso) and stability selection, both of which are variable selection methods using resampling in conjunction with Lasso, and resolves their disadvantage regarding computational cost. To examine approximation accuracy and efficiency, numerical experiments were carried out using simulated datasets. Moreover, an application to a real-world dataset, the wine quality dataset, is presented. To process such real-world datasets, an objective criterion for determining the relevance of selected variables is also introduced by the addition of noise variables and resampling. MATLAB codes implementing the proposed method are distributed in (Obuchi, 2018).

Keywords: bootstrap method, Lasso, variable selection, message passing algorithm, replica method

1. Introduction

Variable selection is an important problem in statistics, signal processing, and machine learning. A desire for useful techniques of variable selection has recently been growing, as cumulated advances in measurement and information technologies have started to steadily produce a large amount of high-dimensional data in science and engineering. A naive method for selecting relevant variables requires solving discrete optimization problems. This involves a serious computational difficulty as the dimensionality of the variables increases, even in the simplest case of linear models (Natarajan, 1995). Hence, certain relaxations or approximations are required for handling such large high-dimensional datasets.

A great deal of progress has been made with regard to relaxation techniques by introducing an ℓ_1 penalty (Tibshirani, 1996; Meinshausen and Bühlmann, 2004; Banerjee et al., 2006; Friedman et al., 2008). Its model consistency, that is, whether the estimated model converges to the true model in the large size limit of data, has been extensively studied, particularly in the case of linear models (Knight and Fu, 2000; Zhao and Yu, 2006; Yuan and Lin, 2007; Wainwright, 2009; Meinshausen and Yu, 2009). These studies show that a naive usage of the ℓ_1 penalty affects model consistency in realistic settings: The resultant estimator cannot completely reject variables not present in the true model if there exist non-trivial correlations between covariates, although the normal consistency in the ℓ_2 sense is retained. This fact motivated the development of further techniques for recovering model consistency in the variable selection context, particularly in the last decade, including traditional approaches using confidence interval and hypothesis testing (Zou, 2006; Bach, 2008; Meinshausen and Bühlmann, 2010; Javanmard and Montanari, 2014a,b, 2015; Lockhart et al., 2014; G'Sell et al., 2013; Takahashi and Kabashima, 2018). If the distribution of the estimator is accurately figured out and the corresponding P-value is efficiently computed, those traditional approaches are quite efficient and powerful enough to correctly perform variable selection. However in many practical situations, the functional form of the distribution is not clear. In such cases, certain numerical approaches are employed to approximately estimate the distribution. Resampling is one of the representative methods and is focused on in the present paper.

Resampling is a versatile idea applicable to a wide range of problems in statistical modeling and is broadly used in machine learning algorithms; some examples can be found in boosting and bagging (Trevor et al., 2009). In statistics, Efron's bootstrap method is a pioneering example in which resampling is efficiently and systematically used (Efron and Tibshirani, 1994). In the case of the ℓ_1-penalized linear regression or Lasso (Tibshirani, 1996), through a fine evaluation of each variable's probability to be selected (positive probability) in a fairly general setting, Bach showed that it is possible to perform statistically consistent variable selection by utilizing the bootstrap method (Bach, 2008); the associated algorithm is called *bootstrapped Lasso* (Bolasso). Another algorithm based on a similar idea, called *stability selection* (SS), was also implemented by randomizing the penalty coefficient in Lasso (Meinshausen and Bühlmann, 2010). All these examples demonstrate that resampling is powerful and versatile.

A common disadvantage of such resampling approaches is their computational cost. For example, in the Bolasso case, the ℓ_1-penalized linear regression should be recursively solved according to the number of resampled datasets, which should be sufficiently large so that the positive probability of variables may be estimated. This multiple computational cost precludes the application of such resampling techniques to large datasets. The aim of this study is to avoid this problem by developing an approximation whereby the resampling is conducted in a semi-analytic manner, and to implement it in Lasso.

Such an approximation was already obtained by Malzahn and Opper (2003), where a general framework of semi-analytic resampling was developed using the replica method from statistical mechanics, and was demonstrated in Gaussian process regression. We follow their idea and pursue how it works in Lasso with certain resampling manners.

The remaining of the paper is organized as follows. In the next section, the general framework for semi-analytic resampling using the replica method is reviewed. Concrete formulas in the Lasso case are also provided. After taking the average with respect to the resampling, there remains an intractable statistical model. Handling this model is another key issue, and certain approximations (expected to be exact under certain conditions) should

be adopted. In this study, Gaussian approximation is used in conjunction with the so-called cavity method, providing a message passing type algorithm. Its dynamical behavior is analyzed by the so-called state evolution, which guarantees that the algorithm convergence is free from the model dimensionality and the dataset size when covariates are provided as zero-mean independently and identically distributed (i.i.d.) Gaussian random variables. They are explained in Section 3. In Section 4, numerical experiments are carried out on both simulated and real-world datasets to examine the accuracy and efficiency of the proposed semi-analytic method. For processing real-world datasets, an objective criterion for determining the relevance of selected variables is also proposed, based on the addition of noise variables and resampling. The last section concludes the paper.

2. Formulation for semi-analytic resampling

Let us start from preparing notations and definitions. We denote by D a given dataset, which usually consists of a set of inputs $\boldsymbol{x}_\mu$ and outputs y_μ as $D = \{(\boldsymbol{x}_\mu, y_\mu)\}_{\mu=1}^M$, and denote our basic statistics by $\hat{\boldsymbol{\beta}}(D) = (\hat{\beta}_1(D), \cdots, \hat{\beta}_N(D))^\top$. They are interpreted as an estimator of true parameters in the true model that is inferred. Based on the Bayesian inference framework, it is assumed that the basic estimator can be expressed as an average over a certain posterior distribution $P(\boldsymbol{\beta}|\boldsymbol{\lambda}, D)$, that is,

$$\hat{\boldsymbol{\beta}}(\boldsymbol{\lambda}, D) = \int d\boldsymbol{\beta}\, \boldsymbol{\beta} P(\boldsymbol{\beta}|\boldsymbol{\lambda}, D) \equiv \langle \boldsymbol{\beta} \rangle \,, \tag{1}$$

where $\langle \cdot \rangle$ represents the average over the posterior distribution which is supposed to be constructed as follows:

$$P(\boldsymbol{\beta}|\boldsymbol{\lambda}, D) = \frac{1}{Z(\boldsymbol{\lambda}, D)} P_0(\boldsymbol{\beta}|\boldsymbol{\lambda}) P(D|\boldsymbol{\beta}). \tag{2}$$

Here, $P_0(\boldsymbol{\beta}|\boldsymbol{\lambda})$ is the prior distribution characterized by the parameters $\boldsymbol{\lambda}$, and $P(D|\boldsymbol{\beta})$ represents the likelihood. The normalization constant or the partition function can be explicitly expressed by

$$Z(\boldsymbol{\lambda}, D) = \int d\boldsymbol{\beta}\, P_0(\boldsymbol{\beta}|\boldsymbol{\lambda}) P(D|\boldsymbol{\beta}). \tag{3}$$

Considering the construction of a subsample by resampling from the full data D of size M with replacement, let an indicator vector $\boldsymbol{c} = (c_1, \cdots, c_M)^\top$ specify any such subsample; each c_μ is a non-negative integer counting the number of occurrences of the μ-th datapoint of D in the subsample. A subsample identified by $\boldsymbol{c}$ is denoted by $D_{\boldsymbol{c}}$. Specifying a resampling defines the distribution $P(\boldsymbol{c})$ of $\boldsymbol{c}$, and the question is the behavior of the basic estimators and their functions with respect to the average over $P(\boldsymbol{c})$. In some resampling techniques, additional randomization is introduced in the prior distribution (Meinshausen and Bühlmann, 2010). Hence, an average over the parameters $\boldsymbol{\lambda}$ is further considered, and the distribution $P(\boldsymbol{\lambda})$ of $\boldsymbol{\lambda}$ is introduced. For notational simplicity, the average over these distributions is denoted by square brackets with appropriate subscripts as follows:

$$[(\cdots)]_{\boldsymbol{c},\boldsymbol{\lambda}} \equiv \sum_{\boldsymbol{c}} \int d\boldsymbol{\lambda} (\cdots) P(\boldsymbol{c}) P(\boldsymbol{\lambda}).$$

The average of this type is called *configurational average* throughout this paper.

2.1. General theory of semi-analytic resampling

The purpose of resampling is to obtain the distribution of the basic estimator

$$P(\beta_i) = \left[\delta\left(\beta_i - \hat{\beta}_i(\boldsymbol{\lambda}, D_c) \right) \right]_{\boldsymbol{c},\boldsymbol{\lambda}}, \tag{4}$$

which is reduced to computing the moments $\left[\hat{\beta}_i^r(\boldsymbol{\lambda}, D_{\boldsymbol{c}}) \right]_{\boldsymbol{c},\boldsymbol{\lambda}}$ of arbitrary degree $\forall r \in \mathbb{N}$. We thus show that these moments can be evaluated in the following manner.

By definition, the moment $\left[\hat{\beta}_i^r(\boldsymbol{\lambda}, D_{\boldsymbol{c}}) \right]_{\boldsymbol{c},\boldsymbol{\lambda}}$ with $r \in \mathbb{N}$ can be written as

$$\left[\hat{\beta}_i^r(\boldsymbol{\lambda}, D_{\boldsymbol{c}}) \right]_{\boldsymbol{c},\boldsymbol{\lambda}} = \left[\frac{1}{Z^r(\boldsymbol{\lambda}, D_{\boldsymbol{c}})} \int \left\{ \prod_{a=1}^r d\boldsymbol{\beta}^a\, \beta_i^a P_0(\boldsymbol{\beta}^a|\boldsymbol{\lambda}) P(D_{\boldsymbol{c}}|\boldsymbol{\beta}^a) \right\} \right]_{\boldsymbol{c},\boldsymbol{\lambda}} \tag{5}$$

$$= \lim_{n\to 0} \left[Z^{n-r}(\boldsymbol{\lambda}, D_{\boldsymbol{c}}) \int \left\{ \prod_{a=1}^r d\boldsymbol{\beta}^a\, \beta_i^a P_0(\boldsymbol{\beta}^a|\boldsymbol{\lambda}) P(D_{\boldsymbol{c}}|\boldsymbol{\beta}^a) \right\} \right]_{\boldsymbol{c},\boldsymbol{\lambda}} \tag{6}$$

$$\doteq \lim_{n\to 0} \left[\int \left\{ \prod_{b=1}^n d\boldsymbol{\beta}^b \right\} \left\{ \prod_{a=1}^r \beta_i^a \right\} \left\{ \prod_{b=1}^n P_0(\boldsymbol{\beta}^b|\boldsymbol{\lambda}) P(D_{\boldsymbol{c}}|\boldsymbol{\beta}^b) \right\} \right]_{\boldsymbol{c},\boldsymbol{\lambda}}. \tag{7}$$

The evaluation of (5) is technically difficult owing to the existence of $Z^r(\boldsymbol{\lambda}, D_{\boldsymbol{c}})$ in the denominator: The negative power of the partition function does not allow the analytical evaluation of the average over $\boldsymbol{c}$ and $\boldsymbol{\lambda}$, even if $P(\boldsymbol{c})$ and $P(\boldsymbol{\lambda})$ take reasonable forms. To overcome this difficulty, an auxiliary parameter n is introduced in (6). The exponent n is assumed to be a positive integer larger than r in (7); thus, the power of the partition function can be expanded in the integral form (3). Integral variables $\{\boldsymbol{\beta}^1, \boldsymbol{\beta}^2, \ldots, \boldsymbol{\beta}^n\}$ are termed *replicas* since they are regarded as constituting n copies of the original system. In (7), the configurational average can be analytically computed under appropriate approximations. This yields an expression as a function of n that is analytically continuable from $\mathbb{N}$ to $\mathbb{R}$. The $n \to 0$ limit is taken by employing the analytically continued expression after all computations. The evaluation technique based on these procedures is often called the *replica method* (Mézard et al., 1987; Nishimori, 2001; Dotsenko, 2005). Evidently, this technique is not justified in a strict sense, but it is known that the replica method gives correct results for many problems. Justification of the replica method is known to be difficult (Talagrand, 2003), and here we leave it as a future work and just employ the method for our purpose. In the present problem, it is far from trivial to obtain an analytically continuable expression, and below we concentrate on its derivation.

Accordingly, the configurational average of any power of the basic estimator can be evaluated from the following quantities:

$$\Xi\left(\{\boldsymbol{\beta}^a\}_{a=1}^n \mid D \right) \equiv \int \left\{ \prod_{a=1}^n d\boldsymbol{\beta}^a \right\} \left[\prod_{a=1}^n P_0(\boldsymbol{\beta}^a|\boldsymbol{\lambda}) P(D_{\boldsymbol{c}}|\boldsymbol{\beta}^a) \right]_{\boldsymbol{c},\boldsymbol{\lambda}},$$

$$P\left(\{\boldsymbol{\beta}^a\}_{a=1}^n \mid D \right) \equiv \frac{1}{\Xi\left(\{\boldsymbol{\beta}^a\}_{a=1}^n \mid D \right)} \left[\prod_{a=1}^n P_0(\boldsymbol{\beta}^a|\boldsymbol{\lambda}) P(D_{\boldsymbol{c}}|\boldsymbol{\beta}^a) \right]_{\boldsymbol{c},\boldsymbol{\lambda}},$$

where the former is called replicated partition function and the latter is called replicated Boltzmann distribution. The average over the replicated Boltzmann distribution is denoted by

$$\overline{\langle\cdots\rangle} \equiv \int \left\{\prod_{a=1}^{n} d\boldsymbol{\beta}^a\right\} (\cdots)\, P\left(\{\boldsymbol{\beta}^a\}_{a=1}^n \,|\, D\right). \tag{8}$$

It follows from (5)–(7) that this average converges to the desired total average over the posterior and the configurational variables $\boldsymbol{c}$ and $\boldsymbol{\lambda}$ as $n \to 0$. The next step is to compute this average. The nontrivial technical difficulties are in the integrations with respect to replicas $\{\boldsymbol{\beta}^a\}_{a=1}^n$ and in deriving a functional form that is analytically continuable with respect to n. These will be handled after considering the specific case of Lasso.

2.2. Specifics to Lasso with independent sampling

The above general theory is now rephrased in the context of Lasso. Given a set of covariates $\boldsymbol{x}_\mu \in \mathbb{R}^N$ and responses $y_\mu \in \mathbb{R}$, $D = \{(\boldsymbol{x}_\mu, y_\mu)\}_{\mu=1}^M$, the usual estimator by Lasso is

$$\hat{\boldsymbol{\beta}}(\lambda, D) = \arg\min_{\boldsymbol{\beta}} \left\{ \frac{1}{2} \sum_{\mu=1}^{M} \left(y_\mu - \sum_i x_{\mu i} \beta_i \right)^2 + \lambda ||\boldsymbol{\beta}||_1 \right\}.$$

In contrast to this, considering Bolasso and SS, given the resampled data $D_{\boldsymbol{c}}$ and the randomized penalty coefficients $\boldsymbol{\lambda} = (\lambda_1, \cdots, \lambda_N)^\top$, the following estimator is introduced:

$$\hat{\boldsymbol{\beta}}(\boldsymbol{\lambda}, D_{\boldsymbol{c}}) = \arg\min_{\boldsymbol{\beta}} \left\{ \frac{1}{2} \sum_{\mu=1}^{M} c_\mu \left(y_\mu - \sum_i x_{\mu i} \beta_i \right)^2 + \sum_{i=1}^{N} \lambda_i |\beta_i| \right\}. \tag{9}$$

For representing this in terms of the posterior average, the following quantities are introduced:

$$\begin{aligned}
\mathcal{H}(\boldsymbol{\beta}|\boldsymbol{\lambda}, D_{\boldsymbol{c}}) &= \frac{1}{2} \sum_{\mu=1}^{M} c_\mu \left(y_\mu - \sum_i x_{\mu i} \beta_i \right)^2 + \sum_{i=1}^{N} \lambda_i |\beta_i|, \\
Z_\gamma(\boldsymbol{\lambda}, D_{\boldsymbol{c}}) &= \int d\boldsymbol{\beta}\, e^{-\gamma \mathcal{H}(\boldsymbol{\beta}|\boldsymbol{\lambda}, D_{\boldsymbol{c}})}, \\
P_\gamma(\boldsymbol{\beta}|\boldsymbol{\lambda}, D_{\boldsymbol{c}}) &= \frac{1}{Z_\gamma} e^{-\gamma \mathcal{H}(\boldsymbol{\beta}|\boldsymbol{\lambda}, D_{\boldsymbol{c}})},
\end{aligned}$$

where these quantities are called (in the order they appear) Hamiltonian, partition function, and Boltzmann distribution, in accordance with physics terminology. As $\gamma \to \infty$, the Boltzmann distribution converges to a pointwise measure at $\hat{\boldsymbol{\beta}}(\boldsymbol{\lambda}, D_{\boldsymbol{c}})$ and thereby becomes the desired posterior distribution, allowing the identification of the Boltzmann distribution with the posterior distribution; thus, the average over the Boltzmann distribution is thereafter denoted by $\langle\cdots\rangle$ introduced in (1)[1]. The prior distribution $P_0(\boldsymbol{\beta}|\boldsymbol{\lambda})$ and the likelihood

1. It is assumed that the order of the integration and the $\gamma \to \infty$ limit may be changed.

$P(D|\boldsymbol{\beta})$ in (2) correspond to the factors $e^{-\gamma \sum_i \lambda_i |\beta_i|}$ and $e^{-\frac{\gamma}{2} \sum_{\mu=1}^M c_\mu \left(y_\mu - \sum_i x_{\mu i} \beta_i\right)^2}$ in the Boltzmann distribution, respectively.

Considering Bolasso and SS, we draw the subsample $\boldsymbol{c}$ of a fixed size m in an unbiased manner. Each sample comes out with a probability of $M^{-m} m!/(c_1! \cdots c_M!)$, which has a weak dependency among $\{c_\mu\}_\mu$. However, this dependency is not essential for large M and m; thus, it is ignored. Using Stirling's formula $m! \approx (\frac{m}{e})^m$ in conjunction with the relation $m = \sum_{\mu=1}^M c_\mu$, c_μ is approximately regarded as an i.i.d. variable from a Poisson distribution of mean $\tau = m/M$, namely,

$$P(\boldsymbol{c}) = \prod_{\mu=1}^{M} \frac{\tau^{c_\mu}}{c_\mu!} e^{-\tau} = \prod_{\mu=1}^{M} P(c_\mu).$$

It is also natural to require that $P(\boldsymbol{\lambda})$ is factorized into a batch of identical distributions as follows:

$$P(\boldsymbol{\lambda}) = \prod_{i=1}^{N} P(\lambda_i).$$

At this point, the explicit form of $P(\lambda_i)$ is not specified. These factorized natures allow us to express the replicated Boltzmann distribution as

$$P_\gamma(\{\boldsymbol{\beta}^a\}_{a=1}^n | D) \propto \left[e^{-\gamma \sum_{a=1}^n \mathcal{H}(\boldsymbol{\beta}^a|\boldsymbol{\lambda}, D_{\boldsymbol{c}})} \right]_{\boldsymbol{c},\boldsymbol{\lambda}} = \prod_{\mu=1}^{M} \Phi_\mu\left(\{\boldsymbol{\beta}_i\}_{i=1}^N\right) \prod_{i=1}^{N} \Psi\left(\boldsymbol{\beta}_i\right), \tag{10}$$

where

$$\begin{aligned}
\Phi_\mu\left(\{\boldsymbol{\beta}_i\}_{i=1}^N\right) &= \left[e^{-\frac{1}{2}\gamma c \sum_a (y_\mu - \sum_i x_{\mu i} \beta_i^a)^2} \right]_c, \\
\Psi\left(\boldsymbol{\beta}_i\right) &= \left[e^{-\gamma \lambda \sum_{a=1}^n |\beta_i^a|} \right]_\lambda,
\end{aligned}$$

and the vector notation $\boldsymbol{\beta}_i = (\beta_i^a)_a$ was introduced for later convenience. Φ_μ is hereafter called μ-th potential function.

To proceed further, an approximation should be introduced to make the right-hand side of (10) tractable. Although there are several ways for that, we here make an approximation based on the cavity method from statistical physics. The details are in the next section.

3. Handling the replicated system

We below work with the cavity method, or the belief propagation (BP) in computer science, and use a Gaussian approximation. This treatment is essentially identical to that used in deriving the known approximate message passing (AMP) (Kabashima, 2003; Donoho et al., 2009), and can be justified if each covariate is i.i.d. from Gaussian distributions (Bayati and Montanari, 2011; Barbier et al., 2017). For treating nontrivial correlations between covariates, more sophisticated approximations (Opper and Winther, 2001a,b, 2005; Kabashima and Vehkapera, 2014; Çakmak et al., 2014; Cespedes et al., 2014; Rangan et al., 2016; Ma and Ping, 2017; Takeuchi, 2017) are required. Such extensions are left as future work.

(10) implies that the replicated Boltzmann distribution naturally has a factor graph structure. Hence, by the cavity method, (10) can be "approximately" decomposed into two messages as follows:

$$\widetilde{\phi}_{\mu\to i}(\boldsymbol{\beta}_i) = \frac{1}{Z_{\mu\to i}} \int \prod_{j(\neq i)} d\boldsymbol{\beta}_j \; \Phi_\mu\left(\{\boldsymbol{\beta}_i\}_{i=1}^N\right) \prod_{j(\neq i)} \phi_{j\to\mu}(\boldsymbol{\beta}_j), \tag{11}$$

$$\phi_{i\to\mu}(\boldsymbol{\beta}_i) = \frac{1}{Z_{i\to\mu}} \Psi\left(\boldsymbol{\beta}_i\right) \prod_{\nu(\neq\mu)} \widetilde{\phi}_{\nu\to i}(\boldsymbol{\beta}_i), \tag{12}$$

where $Z_{\mu\to i}, Z_{i\to\mu}$ are normalization factors that are not relevant and will be discarded below. The average of (8) can be computed by employing this set of equations.

3.1. Gaussian approximation on cavity method

A crucial observation for assessing (11),(12) is that the residual $R_\mu^a = y_\mu - \sum_j x_{\mu j}\beta_j^a$ appearing in Φ_μ has a sum of a large number of random variables; thus, the central limit theorem justifies treating it as a Gaussian variable with the appropriate mean and variance. This consideration leads to the following decomposition in (11)

$$R_\mu^a + x_{\mu i}\beta_i^a \equiv y_\mu - \sum_{j(\neq i)} x_{\mu j}\beta_j^a \approx y_\mu - \sum_{j(\neq i)} x_{\mu j}\overline{\beta}_j^{\backslash\mu} + Z_{\mu i}^a \equiv r_{\mu i} + Z_{\mu i}^a,$$

where $Z_{\mu i}^a$ is a zero-mean Gaussian variable whose covariance is equivalent to that of $\sum_{j(\neq i)} x_{\mu j}\beta_j^a$, and $\overline{(\cdots)}^{\backslash\mu}$ is the average over $\prod_j \phi_{j\to\mu}(\boldsymbol{\beta}_j)$ or the replicated Boltzmann distribution without μ-th potential function. This shows that it is difficult to consider the correlation between β_i and β_j with different i, j in the present framework. This could be overcome even in the cavity method framework (Opper and Winther, 2001a,b); however, it is beyond the scope of this study.

The so-called replica symmetry is now assumed in the messages. This symmetry implies that any permutation of the replicas $\{\beta_i^1, \cdots, \beta_i^n\}$ yields an identical message, which in turn implies, by De Finetti's theorem (Hewitt and Savage, 1955), that the messages can be expressed as

$$\phi_{i\to\mu}(\boldsymbol{\beta}_i) = \int d\mathcal{F}\rho_{i\to\mu}(\mathcal{F}) \prod_{a=1}^n \mathcal{F}(\beta_i^a),$$
$$\widetilde{\phi}_{\mu\to i}(\boldsymbol{\beta}_i) = \int d\mathcal{G}\rho_{\mu\to i}(\mathcal{G}) \prod_{a=1}^n \mathcal{G}(\beta_i^a),$$

where $d\mathcal{F}\rho_{i\to\mu}(\mathcal{F})$ and $d\mathcal{G}\rho_{i\to\mu}(\mathcal{G})$ are probability measures over the probability distribution functions $\mathcal{F}$ and $\mathcal{G}$, respectively. From this form, two different variances naturally emerge:

$$V_i^{\backslash\mu} \equiv \overline{(\beta_i^a)^2 - \beta_i^a\beta_i^b}^{\backslash\mu} = \int d\boldsymbol{\beta}_i \left((\beta_i^a)^2 - \beta_i^a\beta_i^b\right) \int d\mathcal{F}\rho_{i\to\mu}(\mathcal{F}) \prod_{c=1}^n \mathcal{F}(\beta_i^c)$$
$$= \int d\mathcal{F}\rho_{i\to\mu}(\mathcal{F}) \left\{ \int \mathcal{F}(\beta)\beta^2 d\beta - \left(\int \mathcal{F}(\beta)\beta d\beta\right)^2 \right\},$$
$$W_i^{\backslash\mu} \equiv \overline{\beta_i^a\beta_i^b}^{\backslash\mu} - \overline{\beta_i^a}^{\backslash\mu}\overline{\beta_i^b}^{\backslash\mu}$$
$$= \int d\mathcal{F}\rho_{i\to\mu}(\mathcal{F}) \left(\int \mathcal{F}(\beta)\beta d\beta\right)^2 - \left(\int d\mathcal{F}\rho_{i\to\mu}(\mathcal{F}) \int \mathcal{F}(\beta)\beta d\beta\right)^2,$$

where it was assumed that $a \neq b$. Below, the μ-dependence of $V_i^{\backslash\mu}$ and $W_i^{\backslash\mu}$ is ignored, as it is small, and let

$$V_i^{\backslash\mu} \approx V_i = \overline{(\beta_i^a)^2 - \beta_i^a\beta_i^b},$$
$$W_i^{\backslash\mu} \approx W_i = \overline{\beta_i^a\beta_i^b} - \overline{\beta_i^a}\,\overline{\beta_i^b}.$$

It can be implied that V_i describes the average of the variance inside a fixed resampled dataset, whereas W_i represents the inter-sample variance. Using V_i and W_i, the covariance of $\boldsymbol{\beta}_i$ is generally written as

$$\mathrm{Cov}^{\backslash\mu}\left(\beta_i^a, \beta_i^b\right) \equiv \overline{\beta_i^a\beta_i^b}^{\backslash\mu} - \overline{\beta_i^a}^{\backslash\mu}\overline{\beta_i^b}^{\backslash\mu} = W_i^{\backslash\mu} + V_i^{\backslash\mu}\delta_{ab} \approx W_i + V_i\delta_{ab}.$$

Using this relation, the covariance of $\{Z_{\mu i}^a\}_a$ can be expressed as

$$\mathrm{Cov}^{\backslash\mu}\left(Z_{\mu i}^a, Z_{\mu i}^b\right) = \sum_{j,k(\neq i)} x_{\mu i}x_{\mu j}\mathrm{Cov}^{\backslash\mu}\left(\beta_j^a, \beta_k^b\right) \approx \sum_j x_{\mu j}^2 \mathrm{Cov}^{\backslash\mu}\left(\beta_j^a, \beta_j^b\right)$$
$$\approx \sum_j x_{\mu j}^2 (W_j + V_j\delta_{ab}) \equiv W_\mu + V_\mu\delta_{ab}.$$

The correlation between β_j and β_k for $j \neq k$ is neglected in the second sum because it is not taken into account in the present framework, as explained above. Moreover, the addition of the i-th term in the same sum does not affect the following discussion because it is sufficiently small in the summation. Based on these observations, $Z_{\mu i}^a$ is decomposed as follows:

$$Z_{\mu i}^a = D_{\mu i} + \Delta_{\mu i}^a,$$

where $D_{\mu i}$ and $\Delta_{\mu i}^a$ are zero-mean Gaussian variables whose covariances are $\mathrm{Cov}^{\backslash\mu}(D_{\mu i}, D_{\mu i}) = W_\mu$, $\mathrm{Cov}^{\backslash\mu}\left(D_{\mu i}, \Delta_{\mu i}^a\right) = 0$, $\mathrm{Cov}^{\backslash\mu}\left(\Delta_{\mu i}^a, \Delta_{\mu i}^b\right) = V_\mu\delta_{ab}$.

$\widetilde{\phi}_{\mu\to i}$ can now be computed. The integration with respect to $\{\boldsymbol{\beta}_j\}_{j(\neq i)}$ in (11) is replaced by that over D_i and Δ_i^a. The result is

$$\widetilde{\phi}_{\mu\to i}(\boldsymbol{\beta}_i) \approx \int dD_{\mu i}P(D_{\mu i}) \int \prod_a d\Delta_{\mu i}^a P(\Delta_{\mu i}^a) \left[e^{-\frac{1}{2}\gamma c\sum_a (r_{\mu i} - x_{\mu i}\beta_i^a + D_{\mu i} + \Delta_{\mu i}^a)^2}\right]_c$$
$$= \left[U(c)^{-\frac{1}{2}}\left(1 + c\gamma V_\mu\right)^{-\frac{n}{2}} e^{-\frac{1}{2}S(c)\sum_a\left(r_{\mu i} - x_{\mu i}\beta_i^a\right)^2 + \frac{1}{2}T(c)\left(\sum_a (r_{\mu i} - x_{\mu i}\beta_i^a)\right)^2}\right]_c,$$

where

$$S(c) = \frac{c\gamma}{1+c\gamma V_\mu},$$
$$T(c) = \frac{c^2\gamma^2 W_\mu}{(1+c\gamma V_\mu)(1+c\gamma(V_\mu+nW_\mu))},$$
$$U(c) = \frac{1+c\gamma(V_\mu+nW_\mu)}{1+c\gamma V_\mu}.$$

$\ln\widetilde{\phi}_{\mu\to i}(\boldsymbol{\beta}_i)$ can be expanded with respect to $x_{\mu i}\beta_i^a$, and the expansion up to the second order leads to an effective Gaussian approximation of the message, yielding

$$\widetilde{\phi}_{\mu\to i}(\boldsymbol{\beta}_i) \approx e^{-\frac{1}{2}\gamma\tilde{A}_{\mu\to i}\sum_a\left(\beta_i^a\right)^2+\frac{1}{2}\gamma^2\tilde{C}_{\mu\to i}\left(\sum_a\beta_i^a\right)^2+\gamma\tilde{B}_{\mu\to i}\sum_a\beta_i^a},$$

where

$$\tilde{A}_{\mu\to i} = \left[\frac{c}{1+c\gamma V_\mu}\right]_c x_{\mu i}^2, \tag{16a}$$
$$\tilde{B}_{\mu\to i} = \left[\frac{c}{1+c\gamma V_\mu}\right]_c r_{\mu i}x_{\mu i}, \tag{16b}$$
$$\tilde{C}_{\mu\to i} = \left\{\left[\left(\frac{c}{1+c\gamma V_\mu}\right)^2\right]_c W_\mu + \left(\left[\left(\frac{c}{1+c\gamma V_\mu}\right)^2\right]_c - \left[\frac{c}{1+c\gamma V_\mu}\right]_c^2\right)(r_{\mu i})^2\right\} x_{\mu i}^2. \tag{16c}$$

It should be noted that the $n\to 0$ limit was already taken in these coefficients.

Owing to the Gaussian approximation of $\widetilde{\phi}_{\mu\to i}(\boldsymbol{\beta}_i)$, the marginal distribution of the replicated Boltzmann distribution can be simply written as

$$P_i(\boldsymbol{\beta}_i|D) \equiv \int\prod_{j(\neq i)} d\boldsymbol{\beta}_j P(\{\boldsymbol{\beta}_i\}_i|D) \propto \Psi(\boldsymbol{\beta}_i)\prod_\mu \widetilde{\phi}_{\mu\to i}(\boldsymbol{\beta}_i)$$
$$\approx \left[\int Dz\; e^{\gamma\left(-\frac{1}{2}A_i\sum_a\left(\beta_i^a\right)^2+(B_i+\sqrt{C_i}z)\sum_a\beta_i^a-\lambda\sum_a|\beta_i^a|\right)}\right]_\lambda, \tag{17}$$

where $Dz = dze^{-\frac{1}{2}z^2}/\sqrt{2\pi}$, and the following identity was used:

$$e^{\frac{1}{2}Cx^2} = \int Dz\; e^{\sqrt{C}zx}.$$

Moreover, $A_i = \sum_\mu \tilde{A}_{\mu\to i}$, $B_i = \sum_\mu \tilde{B}_{\mu\to i}$, and $C_i = \sum_\mu \tilde{C}_{\mu\to i}$. All replicas are now factorized, and the average can be taken for each replica independently, allowing passing to the $n\to 0$ limit by analytic continuation from $\mathbb{N}$ to $\mathbb{R}$ with respect to n. For example, the mean of β_i^a is computed as

$$\overline{\beta_i^a} = \left[\int Dz\left(\int d\beta\, e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}\right)^n\right]_\lambda^{-1}$$
$$\times\left[\int Dz\int d\beta\;\beta e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}\left(\int d\beta\, e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}\right)^{n-1}\right]_\lambda$$
$$\xrightarrow{n\to 0}\left[\int Dz\frac{\int d\beta\;\beta e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}}{\int d\beta\, e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}}\right]_\lambda \xrightarrow{\gamma\to\infty}\left[\int DzS_\lambda(B_i+\sqrt{C_i}z;A_i)\right]_\lambda,$$

where S_λ is the so-called soft thresholding function

$$S_\lambda(x;A) = \frac{1}{A}(x-\lambda\mathrm{sgn}\,(x))\theta(|x|-\lambda),$$

and $\theta(x)$ is the step function that is equal to 1 if $x>0$ and 0 otherwise. Thus, the mean of the basic estimator takes a reasonable form.

In the above average, it is assumed that the coefficients A_i, B_i, C_i remain finite as $\gamma\to\infty$. This is the case if the following holds:

$$\chi_\mu \equiv \gamma V_\mu = \sum_i x_{\mu i}^2\gamma V_i \to O(1),\ (\gamma\to\infty).$$

This scaling is consistent, which can be shown by

$$\chi_i \equiv \gamma V_i = \gamma\left\{\overline{\left(\beta_i^a\right)^2-\beta_i^a\beta_i^b}\right\}$$
$$\xrightarrow{n\to 0}\left[\int Dz\,\gamma\left\{\frac{\int d\beta\,\beta^2 e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}}{\int d\beta\, e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}}-\left(\frac{\int d\beta\,\beta e^{\gamma\left(-\frac{1}{2}A_i\beta+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}}{\int d\beta\, e^{\gamma\left(-\frac{1}{2}A_i\beta^2+(B_i+\sqrt{C_i}z)\beta_i-\lambda|\beta|\right)}}\right)^2\right\}\right]_\lambda$$
$$\xrightarrow{\gamma\to\infty}\frac{1}{A_i}\left[\int Dz\theta\left(|B_i+\sqrt{C_i}z|-\lambda\right)\right]_\lambda = \frac{\partial\overline{\beta_i}}{\partial B_i}.$$

In contrast to V_i, the inter-sample fluctuation W_i takes a finite value even as $\gamma\to\infty$. Its explicit form is

$$W_i = \overline{\beta_i^a\beta_i^b}-\overline{\beta_i^a}\,\overline{\beta_i^b}$$
$$\xrightarrow{n\to 0,\ \gamma\to\infty}\left[\int DzS_\lambda^2\left(B_i+\sqrt{C_i}z;A_i\right)\right]_\lambda-\left(\left[\int DzS_\lambda\left(B_i+\sqrt{C_i}z;A_i\right)\right]_\lambda\right)^2.$$

It follows that any moment of the basic estimator can be computed from (17), once the coefficients $\{A_i,B_i,C_i\}_{i=1}^N$ are correctly estimated. Hence, the next task is to derive a set of self-consistent equations for the coefficients and to construct an algorithm for solving it.

3.2. Self-consistent equations and a message passing algorithm

Using (12), we obtain

$$\phi_{i\to\mu}(\boldsymbol{\beta}_i) \propto \Psi\left(\boldsymbol{\beta}_i\right)\prod_{\nu(\neq\mu)}\widetilde{\phi}_{\nu\to i}(\boldsymbol{\beta}_i)$$
$$\approx\left[\int Dz\; e^{\gamma\left(-\frac{1}{2}A_{i\to\mu}\sum_a\left(\beta_i^a\right)^2+(B_{i\to\mu}+\sqrt{C_{i\to\mu}}z)\sum_a\beta_i^a-\lambda\sum_a|\beta_i^a|\right)}\right]_\lambda,$$

where $A_{i\to\mu}=\sum_{\nu(\neq\mu)}\tilde{A}_{\nu\to i}$, $B_{i\to\mu}=\sum_{\nu(\neq\mu)}\tilde{B}_{\nu\to i}$, and $C_{i\to\mu}=\sum_{\nu(\neq\mu)}\tilde{C}_{\nu\to i}$. Inserting this into (11), we can derive a set of self-consistent equations determining all the cavity coefficients $\{A_{i\to\mu},B_{i\to\mu},C_{i\to\mu},\tilde{A}_{\mu\to i},\tilde{B}_{\mu\to i},\tilde{C}_{\mu\to i}\}_{i,\mu}$. This procedure suggests an iterative

algorithm, conventionally called BP algorithm, which is schematically described as follows:

$$\{\tilde{A}_{\mu\to i}, \tilde{B}_{\mu\to i}, \tilde{C}_{\mu\to i}\}^{(t)} \leftarrow \{\overline{\beta_i}^{\setminus\mu}, V_i, W_i\}^{(t)}, \tag{18a}$$
$$\{A_{i\to\mu}, B_{i\to\mu}, C_{i\to\mu}\}^{(t+1)} \leftarrow \{\tilde{A}_{\mu\to i}, \tilde{B}_{\mu\to i}, \tilde{C}_{\mu\to i}\}^{(t)}, \tag{18b}$$
$$\{\overline{\beta_i}^{\setminus\mu}, V_i, W_i\}^{(t+1)} \leftarrow \{A_{i\to\mu}, B_{i\to\mu}, C_{i\to\mu}\}^{(t+1)}, \tag{18c}$$

where $t = 0, 1, \cdots$, denotes the algorithm time step. If the BP algorithm converges, the full coefficients $\{A_i, B_i, C_i\}_{i=1}^N$ are given from the converged values of $\{\tilde{A}_{\mu\to i}, \tilde{B}_{\mu\to i}, \tilde{C}_{\mu\to i}\}_{i,\mu}$. However, this algorithm is not particularly efficient because its computational cost is $O(NM^2)$.

A more efficient algorithm is derived by approximately rewriting the cavity coefficients and the cavity mean $\overline{\boldsymbol{\beta}}^{\setminus\mu}$ using the full coefficients $\{A_i, B_i, C_i\}_i$. To this end, $\phi_{i\to\mu}(\boldsymbol{\beta}_i)$ is connected with $P_i(\boldsymbol{\beta}_i|D)$ in a perturbative manner. Comparing the coefficients, it follows that the difference between A_i and $A_{i\to\mu}$ is negligibly small, as it is proportional to $x_{\mu i}^2 = O(1/N)$. The same is true between C_i and $C_{i\to\mu}$. Hence, the relevant difference is only $\Delta B_i^{(t)} = B_i^{(t)} - B_{i\to\mu}^{(t)}$ and is expressed as

$$\begin{aligned}\Delta B_i^{(t)} &= \left[\frac{c}{1+c\chi_\mu^{(t-1)}}\right]_c r_{\mu i}^{(t-1)} x_{\mu i} = a_\mu^{(t-1)} x_{\mu i} + \left[\frac{c}{1+c\chi_\mu^{(t-1)}}\right]_c \left(\overline{\beta_i}^{\setminus\mu}\right)^{(t-1)} x_{\mu i}^2 \\ &\approx a_\mu^{(t-1)} x_{\mu i},\end{aligned}$$

where

$$a_\mu^{(t)} \equiv \left[\frac{c}{1+c\chi_\mu^{(t)}}\right]_c \left(y_\mu - \sum_j x_{\mu j}\left(\overline{\beta_j}^{\setminus\mu}\right)^{(t)}\right) = \left[\frac{c}{1+c\chi_\mu^{(t)}}\right]_c \left(r_{\mu i}^{(t)} - x_{\mu i}\left(\overline{\beta_i}^{\setminus\mu}\right)^{(t)}\right). \tag{19}$$

Accordingly, the difference between $\overline{\beta_i}^{\setminus\mu}$ and $\overline{\beta_i}$ is computed as

$$\left(\overline{\beta_i}^{\setminus\mu}\right)^{(t)} \approx \overline{\beta_i}^{(t)} - \frac{\partial\overline{\beta_i}^{(t)}}{\partial B_i^{(t)}}\Delta B_i^{(t)} = \overline{\beta_i}^{(t)} - \chi_i^{(t)} a_\mu^{(t-1)} x_{\mu i}, \tag{20}$$

Inserting (20) into (19) yields

$$a_\mu^{(t)} = \left[\frac{c}{1+c\chi_\mu^{(t)}}\right]_c \left(y_\mu - \sum_j x_{\mu j}\overline{\beta_j}^{(t)} + \chi_\mu^{(t)} a_\mu^{(t-1)}\right),$$

where the last term is interpreted as the Onsager reaction term in physics. Rewriting $r_{\mu i}$ using a_μ in the right-hand sides of (16) and collecting several factors, a simplified message

passing algorithm corresponding to (18) is obtained as follows:

$$\chi_\mu^{(t)} = \sum_i x_{\mu i}^2 \chi_i^{(t)}, \tag{21a}$$
$$W_\mu^{(t)} = \sum_i x_{\mu i}^2 W_i^{(t)}, \tag{21b}$$
$$\left(f_{1\mu}^{(t)}, f_{2\mu}^{(t)}\right) = \left(\left[\frac{c}{1+c\chi_\mu^{(t)}}\right]_c, \left[\left(\frac{c}{1+c\chi_\mu^{(t)}}\right)^2\right]_c\right), \tag{21c}$$
$$a_\mu^{(t)} = f_{1\mu}^{(t)}\left(y_\mu - \sum_j x_{\mu j}\overline{\beta_j}^{(t)} + \chi_\mu^{(t)} a_\mu^{(t-1)}\right), \tag{21d}$$
$$A_i^{(t+1)} = \sum_\mu x_{\mu i}^2 f_{1\mu}^{(t)}, \tag{21e}$$
$$B_i^{(t+1)} = \sum_\mu x_{\mu i} a_\mu^{(t)} + \left(\sum_\mu x_{\mu i}^2 f_{1\mu}^{(t)}\right)\overline{\beta_i}^{(t)}, \tag{21f}$$
$$C_i^{(t+1)} = \sum_\mu x_{\mu i}^2 \left\{f_{2\mu}^{(t)} W_\mu^{(t)} + \left(f_{2\mu}^{(t)} - \left(f_{1\mu}^{(t)}\right)^2\right)\left(\frac{a_\mu^{(t)}}{f_{1\mu}^{(t)}}\right)^2\right\}, \tag{21g}$$
$$\overline{\beta_i}^{(t+1)} = \left[\int Dz S_\lambda\left(B_i^{(t+1)} + \sqrt{C_i^{(t+1)}}z; A_i^{(t+1)}\right)\right]_\lambda, \tag{21h}$$
$$\chi_i^{(t+1)} = \frac{1}{A_i^{(t+1)}}\left[\int Dz\ \theta\left(\left|B_i^{(t+1)} + \sqrt{C_i^{(t+1)}}z\right| - \lambda\right)\right]_\lambda, \tag{21i}$$
$$W_i^{(t+1)} = \left[\int Dz S_\lambda^2\left(B_i^{(t+1)} + \sqrt{C_i^{(t+1)}}z; A_i^{(t+1)}\right)\right]_\lambda - \left(\overline{\beta_i}^{(t+1)}\right)^2. \tag{21j}$$

We call the algorithm (21) AMPR (Approximate Message Passing with Resampling) because it can be regarded as an extension of the AMP in the usual Lasso to the resampling case. The computational cost is $O(NM)$ per iteration and is significantly reduced compared with the BP algorithm. This yields the main result of this study.

There is an ambiguity in the initial condition for AMPR. Here we assume that we are given an initial estimate $\{\overline{\beta_i}^{(0)}, \chi_i^{(0)}, W_i^{(0)}\}_i$ and conduct the iteration based on (21) until convergence. Still, there is an ambiguity in computing $a_\mu^{(0)}$, due to the presence of $a_\mu^{(-1)}$ in (21d). To resolve this, we assume $a_\mu^{(-1)} = 0$, yielding

$$a_\mu^{(0)} = \left[\frac{c}{1+c\chi_\mu^{(0)}}\right]_c \left(y_\mu - \sum_j x_{\mu j}\overline{\beta_j}^{(0)}\right). \tag{22}$$

These completely determine the initial condition.

As explained at the end of Section 3.1, the convergent solution of AMPR, $\{A_i^*, B_i^*, C_i^*\}_i$, enables the computation of any moment of the basic estimator as follows:

$$[\langle\beta_i\rangle^r]_{\mathbf{c},\boldsymbol{\lambda}} = \lim_{n\to 0}\overline{\prod_{a=1}^r \beta_i^a} = \left[\int Dz S_\lambda^r\left(B_i^* + \sqrt{C_i^*}z; A_i^*\right)\right]_\lambda,$$

which indicates that the marginal distribution of the basic estimator is obtained as

$$P(\beta_i) = \left[\int Dz \ \delta \left(\beta_i - S_\lambda \left(B_i^* + \sqrt{C_i^*} z; A_i^* \right) \right) \right]_\lambda .$$

This yields the positive probability, which is important for variable selection techniques, as follows:

$$\Pi_i \equiv \text{Prob}\left(|\hat{\beta}_i| \neq 0 \right) = \left[\int Dz \ \theta \left(\left| B_i^* + \sqrt{C_i^*} z \right| - \lambda \right) \right]_\lambda . \tag{23}$$

Applications using these relations are provided in Section 4.

3.3. State evolution for AMPR

A benefit of the AMP type algorithms is that it is possible to track the macroscopic dynamical behavior of the algorithm. This can be done by using the so-called state evolution (SE) equations. Here we derive the SE equations associated with AMPR. The derivation relies on the i.i.d. assumption of the covariates, and hence we assume each $x_{\mu i}$ is i.i.d. from the zero-mean Gaussian as

$$x_{\mu i} \sim \mathcal{N}(0, \sigma_x^2). \tag{24}$$

The variance value is arbitrary in general, but for notational simplicity it is chosen as $\sigma_x^2 = 1/N$ in this section. Furthermore, we assume the data is generated from the following linear process:

$$\boldsymbol{y} = X\boldsymbol{\beta}_0 + \boldsymbol{\xi},$$

where $\boldsymbol{\xi}$ is the noise vector whose component is i.i.d. from $\mathcal{N}(0, \sigma_\xi^2)$ and $\boldsymbol{\beta}_0$ is the true parameters whose component is also i.i.d. from a certain distribution $P_{\beta_0}(\cdot)$.

Under the assumption (24) with $\sigma_x^2 = 1/N$, the intra- and inter-sample variances can be simplified as

$$\chi_\mu = \sum_i x_{\mu i}^2 \chi_i \approx \sum_i \mathrm{E}\left[x_{\mu i}^2 \chi_i \right] \approx \frac{1}{N} \sum_i \chi_i \equiv \tilde{\chi}, \tag{25}$$

$$W_\mu = \sum_i x_{\mu i}^2 W_i \approx \sum_i \mathrm{E}\left[x_{\mu i}^2 W_i \right] \approx \frac{1}{N} \sum_i W_i \equiv \tilde{W}, \tag{26}$$

where we have neglected the correlations between $x_{\mu i}$ and the variances[2]. Accordingly, many quantities appearing in (21) become independent of the subscripts μ and i. Terms retaining the dependence are only the linear terms with respect to $x_{\mu i}$ such as $\overline{\beta}_i, B_i$ and a_μ. To derive the SE equations, we need to handle those terms.

2. Remembering the discussion in Section 3.2, these variances are actually the ones computed in the absence of the μ-th potential function, $\chi_i^{\setminus \mu}$ and $W_i^{\setminus \mu}$, and hence this neglect can be justified. The same discussion can be applied to the following.

We start from the following form of $B_i^{(t+1)}$:

$$B_i^{(t+1)} = \sum_\nu \left[\frac{c}{1 + c\chi_\nu} \right]_c r_{\nu i}^{(t)} x_{\nu i} \approx f_1^{(t)} \sum_\nu x_{\nu i} \left(y_\nu - \sum_{j(\neq i)} x_{\nu j} \left(\overline{\beta}_j^{\setminus \nu} \right)^{(t)} \right). \tag{27}$$

The righthand side is the sum of a large number of random variables, and hence we can treat it as a Gaussian variable with appropriate mean and variance. The mean is

$$\begin{aligned} &\mathrm{E}\left[f_1^t \sum_\nu x_{\nu i} \left(y_\nu - \sum_{j(\neq i)} x_{\nu j} \left(\overline{\beta}_j^{\setminus \nu} \right)^{(t)} \right) \right] \\ &= f_1^t \sum_\nu \left(\mathrm{E}\left[x_{\nu i}^2 \right] \beta_{0i} + \sum_{j(\neq i)} \mathrm{E}\left[x_{\nu i} x_{\nu j} \right] \left(\beta_{0j} - \left(\overline{\beta}_j^{\setminus \mu} \right)^{(t)} \right) + \mathrm{E}\left[x_{\nu i} \xi_\nu \right] \right) \\ &= f_1^t \sum_\nu \frac{1}{N} \beta_{0i} = \alpha f_1^t \beta_{0i}, \end{aligned} \tag{28}$$

where $\alpha = M/N$ is the ratio of the dataset size to the dimensionality. In the same way, the variance becomes

$$\mathrm{V}\left[f_1^t \sum_\nu x_{\nu i} \left(y_\nu - \sum_{j(\neq i)} x_{\nu i} \left(\overline{\beta}_j^{\setminus \nu} \right)^{(t)} \right) \right] \approx \alpha \left(f_1^t \right)^2 \left(\mathrm{MSE}^{(t)} + \sigma_\xi^2 \right) \equiv v_0^{(t+1)}, \tag{29}$$

where $\mathrm{MSE}^{(t)}$ denotes the mean-squared error (MSE) between the true and averaged parameters:

$$\mathrm{MSE}^{(t)} \equiv \frac{1}{N} \sum_{i=1}^N \left(\beta_{0i} - \overline{\beta}_i^{(t)} \right)^2 \approx \frac{1}{N} \sum_{i=1}^N \left(\beta_{0i} - \left(\overline{\beta}_i^{\setminus \mu} \right)^{(t)} \right)^2 . \tag{30}$$

Hence, we may write

$$B_i^{(t+1)} = \alpha f_1^t \beta_{0i} + \sqrt{v_0^{(t+1)}} u_i, \tag{31}$$

where $u_i \sim \mathcal{N}(0, 1)$. Besides, in the computation of $C_i^{(t+1)}$, we have

$$\sum_\nu x_{\nu i}^2 f_{2\nu}^{(t)} W_\nu^{(t)} \approx \alpha f_2^{(t)} \tilde{W}^{(t)}, \tag{32}$$

$$\sum_\nu x_{\nu i}^2 \left(r_{\nu i}^{(t)} \right)^2 \approx \alpha \left(\mathrm{MSE}^{(t)} + \sigma_\xi^2 \right). \tag{33}$$

This yields

$$C_i^{(t+1)} \approx C^{(t+1)} = \alpha f_2^{(t)} \tilde{W}^{(t)} + \alpha \left(f_2^{(t)} - \left(f_1^{(t)} \right)^2 \right) \left(\mathrm{MSE}^{(t)} + \sigma_\xi^2 \right). \tag{34}$$

In the same level of approximation, we get $A_i^{(t+1)} \approx A^{(t+1)} = \alpha f_1^{(t)}$.

To derive a closed set of equations, we have to compute $\tilde{\chi}^{(t+1)}, \tilde{W}^{(t+1)}$ and $\mathrm{MSE}^{(t+1)}$ from $\{A^{(t+1)}, \{B_i^{(t+1)}\}_i, C^{(t+1)}\}$. As an example, we show the derivation of $\tilde{\chi}^{(t+1)}$ from (21i) in the following:

$$\tilde{\chi}^{(t+1)} = \frac{1}{N}\sum_{i=1}^{N}\chi_i^{(t+1)} \approx \frac{1}{N}\sum_{i=1}^{N}\frac{1}{A^{(t+1)}}\left[\int Dz\ \theta\left(\left|B_i^{(t+1)} + \sqrt{C^{(t+1)}}z\right| - \lambda\right)\right]_\lambda$$
$$\approx \frac{1}{A^{(t+1)}}\int d\beta P_{\beta_0}(\beta)\int Du\left[\int Dz\ \theta\left(\left|\alpha f_1^{(t)}\beta + \sqrt{v_0^{(t+1)}}u + \sqrt{C^{(t+1)}}z\right| - \lambda\right)\right]_\lambda, \quad (35)$$

where we have applied the law of large numbers. The other quantities $\tilde{W}, \mathrm{MSE}$ are computed in the same manner. Overall, we reach the following set of equations:

$$\left(f_1^{(t)}, f_2^{(t)}\right) = \left(\left[\frac{c}{1+c\tilde{\chi}^{(t)}}\right]_c, \left[\left(\frac{c}{1+c\tilde{\chi}^{(t)}}\right)^2\right]_c\right), \quad (36a)$$

$$A^{(t+1)} = \alpha f_1^{(t)}, \quad (36b)$$

$$C^{(t+1)} = \alpha f_2^{(t)}\tilde{W}^{(t)} + \alpha\left(f_2^{(t)} - \left(f_1^{(t)}\right)^2\right)\left(\mathrm{MSE}^{(t)} + \sigma_\xi^2\right), \quad (36c)$$

$$v_0^{(t+1)} = \alpha\left(f_1^{(t)}\right)^2\left(\mathrm{MSE}^{(t)} + \sigma_\xi^2\right), \quad (36d)$$

$$\tilde{\chi}^{(t+1)} = \frac{1}{A^{(t+1)}}\int d\beta P_{\beta_0}(\beta)\int Du$$
$$\times\left[\int Dz\ \theta\left(\left|A^{(t+1)}\beta + \sqrt{v_0^{(t+1)}}u + \sqrt{C^{(t+1)}}z\right| - \lambda\right)\right]_\lambda, \quad (36e)$$

$$\tilde{W}^{(t+1)} = \int d\beta P_{\beta_0}(\beta)\int Du\left\{\left[\int DzS_\lambda^2\left(A^{(t+1)}\beta + \sqrt{v_0^{(t+1)}}u + \sqrt{C^{(t+1)}}z; A^{(t+1)}\right)\right]_\lambda\right.$$
$$\left. - \left[\int DzS_\lambda\left(A^{(t+1)}\beta + \sqrt{v_0^{(t+1)}}u + \sqrt{C^{(t+1)}}z; A^{(t+1)}\right)\right]_\lambda^2\right\}, \quad (36f)$$

$$\mathrm{MSE}^{(t+1)} = \int d\beta P_{\beta_0}(\beta)\int Du$$
$$\times\left\{\beta - \left[\int DzS_\lambda\left(A^{(t+1)}\beta + \sqrt{v_0^{(t+1)}}u + \sqrt{C^{(t+1)}}z; A^{(t+1)}\right)\right]_\lambda\right\}^2. \quad (36g)$$

Given an initial condition $\{\tilde{\chi}^{(0)}, \tilde{W}^{(0)}, \mathrm{MSE}^{(0)}\}$, we can track the dynamical evolution of those quantities according to (36). This is the SE equations for AMPR.

A direct consequence of the SE equations is the convergence property of AMPR: Its convergence depends on neither the dataset size M nor the model dimensionality N. Hence, we can assume the iteration steps required for convergence is $O(1)$ and the total computational cost of AMPR is thus guaranteed to be $O(NM)$. This reinforces the superiority of the present approach.

We, however, warn that the discussion based on the SE equations strongly relies on the i.i.d. assumption among covariates, which is not necessarily satisfied in real-world datasets. For covariates with non-trivial correlations and heterogeneity, it is known that

AMP type algorithms tend to show slow convergence, or even not to converge in particular cases (Caltagirone et al., 2014). A common prescription to overcome this difficulty is to introduce a damping factor in the update of the messages (Rangan et al., 2014), which is also employed in our implementation (Obuchi, 2018). In Sections 4.1.5 and 4.2, we see how this prescription works for datasets with nontrivial covariates in numerical simulations.

4. Numerical experiments

In this section, the accuracy and the computational time of the proposed semi-analytic method based on AMPR is examined by a comparison with direct numerical resampling. We also check how nontrivial correlations among covariates affect the performance of AMPR. Both simulated and real-world datasets (from UCI machine learning repository, Lichman, 2013) are used.

For all experiments involving numerical resampling, *Glmnet* (Friedman et al., 2010), implemented as an *MEX* subroutine in MATLAB®, was employed for solving (9), given a sample $\{\boldsymbol{\lambda}, D_c\}$. Moreover, the proposed AMPR algorithm was implemented as raw code in MATLAB. This is not the most optimized approach because AMPR uses a number of *for* and *while* loops which are slow in MATLAB; hence, the comparison of computational time is not necessarily fair. However, even in this comparison, there is a significant difference in the computational time between the proposed semi-analytic method and the numerical resampling approach. For reference, it should be noted that all experiments below were conducted in a single thread on a single CPU of Intel(R) Xeon(R) E5-2630 v3 2.4GHz.

For actual computations, the distribution $P(\boldsymbol{\lambda})$ should be specified. In SS, the following distribution is used (Meinshausen and Bühlmann, 2010):

$$P(\boldsymbol{\lambda}) = \prod_{i=1}^{N}\left\{p_w\delta\left(\lambda_i - \lambda/w\right) + (1-p_w)\delta\left(\lambda_i - \lambda\right)\right\},$$

with $0 < w \leq 1$ and $0 < p_w < 1$. The case of the non-random penalty coefficient, in which Bolasso is included (Bach, 2008), is recovered at $w = 1$, irrespective of the value of p_w. This distribution is adopted below.

4.1. Simulated dataset

Here, simulated datasets are treated. The data is supposed to be generated from the following linear model:

$$\boldsymbol{y} = X\boldsymbol{\beta}_0 + \boldsymbol{\xi},$$

where each component of the design matrix $X = (\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_N)$ is i.i.d. from $\mathcal{N}\left(0, N^{-1}\right)$, and $\boldsymbol{\xi}$ is the noise vector, whose component is i.i.d. from $\mathcal{N}(0, \sigma_\xi^2)$. The ratio of the dataset size M to the model dimensionality N is denoted as $\alpha \equiv M/N$ hereafter. These settings are identical to the ones assumed in Section 3.3. The true signal $\boldsymbol{\beta}_0 \in \mathbb{R}^N$ is assumed to be $K_0(= N\rho_0)$-sparse vector, and the non-zero components are i.i.d. from $\mathcal{N}(0, 1/\rho_0)$, setting the power of the signal unity. The index set of non-zero components is denoted by $S_0 = \{i | |\beta_{0i}| \neq 0\}$ and is called true support. Any estimator of the true support is simply called support and is hereafter denoted by S.

For simplicity, the number of resampling times is fixed at $N_{\mathrm{res}} = 1000$ in the experiments with numerical resampling.

4.1.1. Accuracy of the semi-analytic method

Let us first check the consistency between the results of our semi-analytic method and of the direct numerical resampling.

Figure 1 shows the plots of the experimental values of the quantities $\{\overline{\beta_i}, W_i, \Pi_i\}_i$ against their semi-analytic counterparts for the non-random penalty case $w = 1$ with the bootstrap resampling $\tau = 1$, which is the situation considered in Bolasso. The same plots in the SS situation, $w = 0.5(< 1)$, $p_w = 0.5$, and $\tau = 0.5$, are shown in Figure 2. Other detailed parameters are provided in the captions. These results show that the proposed semi-analytic

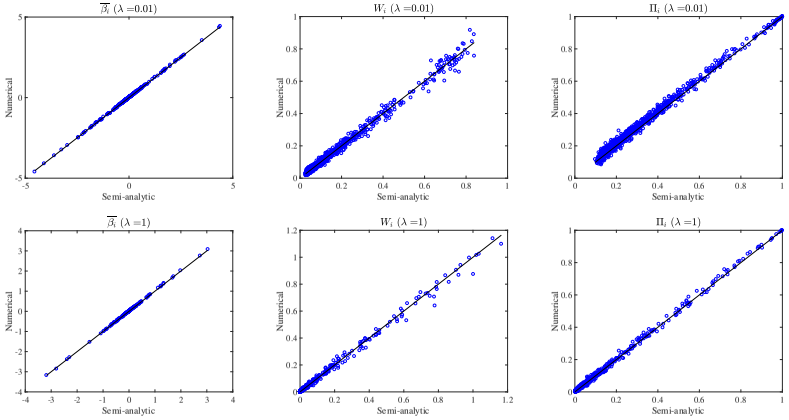

Figure 1: Experimental values of $\overline{\beta_i}$ (left), W_i (middle), and Π_i (right) are plotted against those computed by the semi-analytic method in the non-random penalty $w = 1$ and $\tau = 1$ case. The upper panels are for $\lambda = 0.01$ and the lower are for $\lambda = 1$. The other parameters are set to be $(N, \alpha, \rho_0, \sigma_\xi^2) = (1000, 0.5, 0.2, 0.01)$.

method reproduces the numerical results fairly accurately. As far as it was examined, results of similar accuracy were obtained for a very wide range of parameters. These validate the proposed semi-analytic method.

In the above experiments using Glmnet, we set a threshold ϵ to judge the algorithm convergence as $\epsilon = 10^{-10}$, which is rather tighter than the default value. This is necessary for examining consistency with the proposed semi-analytic method. For example, for $\lambda = 0.01$ (the upper panels in Figures 1 and 2), a systematic deviation from the proposed semi-analytic method ($\overline{\beta}_i$ tends to be underestimated) emerges at the default value $\epsilon = 10^{-7}$.

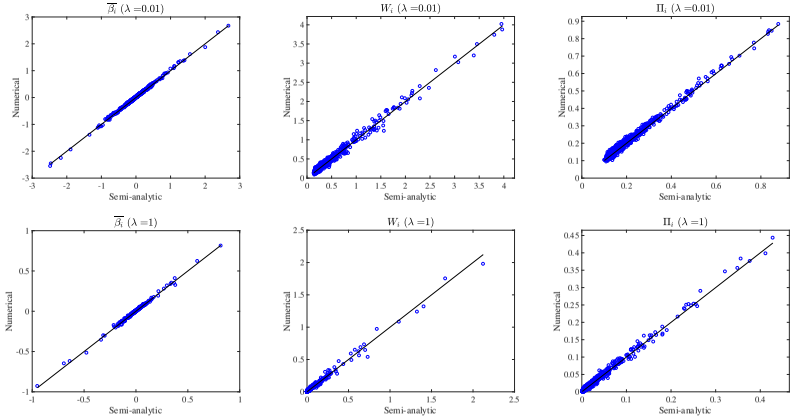

Figure 2: Same plots as in Figure 1 in the random penalty case with $w = 0.5$, $p_w = 0.5$, and $\tau = 0.5$. The parameters of each panel are identical to the corresponding parameters in Figure 1. In comparison to Figure 1, $|\overline{\beta}_i|$ and Π_i tend to be smaller, whereas W_i tends to be larger. This is probably due to the additional stochastic variation coming from the randomization on the penalty coefficient and the difference between $\tau = 1$ and $1/2$.

This implies that a rather tight threshold is required for microscopic quantities such as $\overline{\beta_i}$ and W_i. Unless explicitly mentioned, this value $\epsilon = 10^{-10}$ is used below.

4.1.2. Comparison with state evolution

To examine the convergence properties of AMPR, we next see the dynamical behavior of the macroscopic quantities $(\tilde{\chi}^{(t)}, \tilde{W}^{(t)}, \mathrm{MSE}^{(t)})$ as the algorithm step t proceeds, in comparison with the SE equations (36). Figure 3 shows the plots of them against t for different parameters. In all the cases, these macroscopic quantities rapidly take stable values and

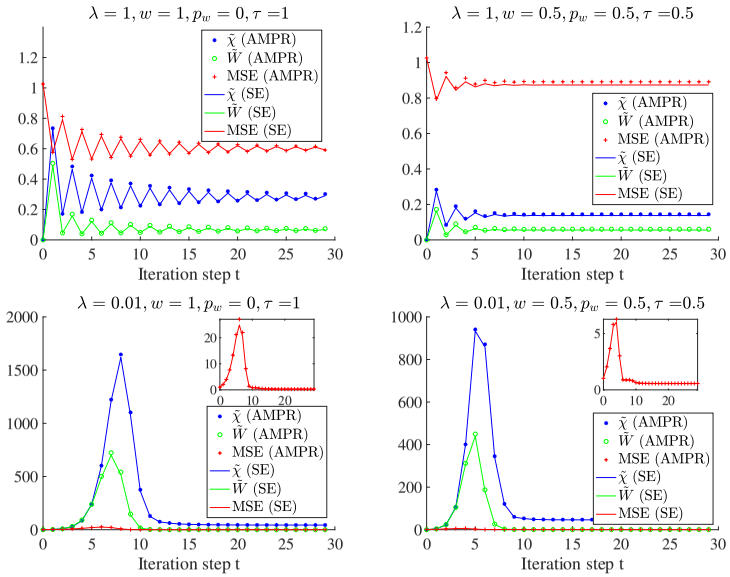

Figure 3: Dynamical behavior of macroscopic parameters $(\tilde{\chi}^{(t)}, \tilde{W}^{(t)}, \mathrm{MSE}^{(t)})$ initialized at $(\tilde{\chi}^{(0)}, \tilde{W}^{(0)}) = (0, 0)$ and $\mathrm{MSE}^{(0)} \approx 1$. The result computed by SE is denoted by lines while the one by AMPR is represented by markers, and the agreement is fairly good. (Left) The non-randomized penalty case ($w = 1, p_w = 0, \tau = 1$). (Right) The randomized penalty case ($w = p_w = \tau = 1/2$). The upper panels are for $\lambda = 1$, while the lower ones are of $\lambda = 0.01$ for which insets are given to show the MSE values in visible scales. The AMPR result is obtained at $N = 20000$. The other parameters are fixed at $(\alpha, \rho_0, \sigma_\xi^2) = (0.5, 0.2, 0.01)$.

the agreement between the AMPR and SE results is excellent. This demonstrates the fast convergence of AMPR, which does not depend on both N and M. To see a good agreement

with the SE result by just one sample of $\{\boldsymbol{\beta}_0, X, \boldsymbol{\xi}\}$, the model dimensionality N is chosen as a rather large value of $N = 20000$ in the AMPR experiment. Although in Figure 3 the initial condition is fixed at $\boldsymbol{\chi}^{(0)} = \boldsymbol{W}^{(0)} = \overline{\boldsymbol{\beta}}^{(0)} = \boldsymbol{0}$ corresponding to $(\tilde{\chi}^{(0)}, \tilde{W}^{(0)}) = (0, 0)$ and $\mathrm{MSE}^{(0)} \approx 1$, we also examined several other initial conditions and confirmed the good agreement between the AMPR and SE results in all the cases.

4.1.3. Application to Bolasso

Bolasso is a variable selection method utilizing the positive probability (23) evaluated by the bootstrap resampling $\tau = 1$ with no penalty randomization $w = 1$. Its soft version, abbreviated as Bolasso-S (Bach, 2008), selects variables with $\Pi_i \geq 0.9$ as active variables and other variables are rejected from the support. We here adopt this manner and see the performance of AMPR used for implementing this.

The left panel of Figure 4 shows the plot of the true positive ratio (TP) against the false positive ratio (FP) as the values of α change. Bolasso requires scaling the regularization parameter as $\lambda \propto \sqrt{\alpha}$, and here, it is set to $\lambda = (1/2)\sqrt{\alpha}$. The other parameters are fixed at $(N, \rho_0, \sigma_\xi^2) = (1000, 0.2, 0.01)$. As was theoretically shown (Bach, 2008), TP converges to unity, whereas FP tends to zero in this setup. This demonstrates that the

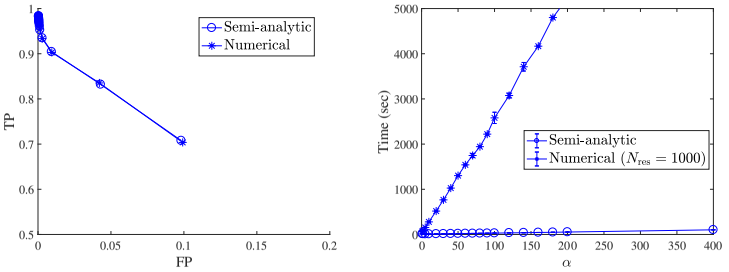

Figure 4: Bolasso experiment at $(N, \rho_0, \sigma_\xi^2) = (1000, 0.2, 0.01)$. The semi-analytic result (circle) is plotted with the numerical resampling result (asterisk). (Left) TP is plotted against FP as α increases: TP approaches unity, whereas FP tends to zero. The semi-analytic result completely overlaps that of the numerical resampling. Error bars are omitted for clarity. (Right) Computational time plotted against α. The observed large difference is attributed to the numerical resampling cost.

model consistency in the variable selection context is recovered. The contribution of this study is a significant reduction of the computational time: In the right panel, the actual computational time is compared between the semi-analytic method using AMPR and the direct numerical resampling, by plotting it against α. The computational costs of AMPR and Glmnet are both scaled as $O(NM)$ and thus should be scaled linearly with respect to α for fixed N. Figure 4 clearly shows this linearity. The significant difference in compu-

tational time is fully attributed to the numerical resampling cost. This demonstrates the efficiency of AMPR. It should be noted that the average over 10 different samples of D is taken in Figure 4 to obtain smooth curves and error bars.

4.1.4. Application to stability selection

SS is another variable selection method utilizing positive probability. The difference from Bolasso is the presence of the penalty coefficient randomization ($w < 1$) and that τ is set to 0.5. These introduce a further stochastic variation in the method, and consequently they tend to show a clearer discrimination in the positive probabilities between the variables in and outside the true support. AMPR can easily implement this, and here, it is compared with numerical resampling.

Figure 5 shows the plots of the positive probability values against λ, the so-called stability path (Meinshausen and Bühlmann, 2010), and the computational time for obtaining the stability path against the covariate dimensionality N. The other parameters are fixed at $(\alpha, \rho_0, \sigma_\xi^2, w, p_w) = (2, 0.2, 0.01, 0.5, 0.5)$. Drawing all stability paths $\{\Pi_i\}_i$ leads to an

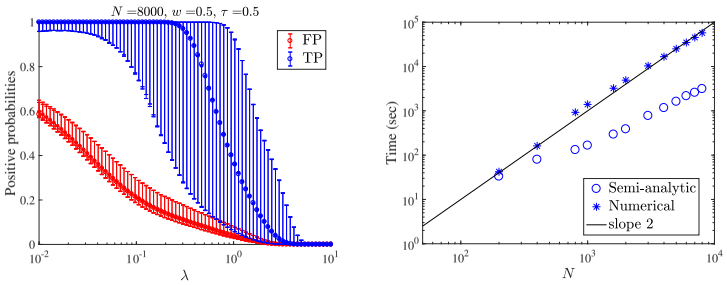

Figure 5: SS experiment at $(\alpha, \rho_0, \sigma_\xi^2, w, p_w) = (2, 0.2, 0.01, 0.5, 0.5)$. The semi-analytic result (circle) is plotted with the numerical resampling result (asterisk). (Left) Plots of the medians (points) and q-percentiles (bars) of $\{\Pi_i\}_{i\in S_0}$ (TP) and $\{\Pi_i\}_{i\notin S_0}$ (FP) with $q = 16$ and 84 against λ for $N = 8000$. The semi-analytic result well overlaps that of the numerical resampling. There is a clear gap between TP and FP, suggesting that an accurate variable selection is possible. (Right) Computational time plotted against N on double-logarithmic scale. The dominant reason for the difference is again the numerical resampling cost.

unclear plot; thus, only the median and q-percentiles of $\{\Pi_i\}_{i\in S_0}$ and those of $\{\Pi_i\}_{i\notin S_0}$ are plotted, which are denoted by TP and FP in the left panel of Figure 5, respectively. The medians are represented by points, and the percentiles of $q = 16$ and 84, approximately corresponding to one-sigma points in normal distributions, are represented by bars. There is a clear gap between TP and FP, suggesting that an accurate variable selection is possible by setting an appropriate threshold of probability value, as discussed by Meinshausen and

Bühlmann (2010). The right panel shows a plot of the computational time by AMPR and by the numerical resampling. Both are supposed to be scaled as $O(NM = N^2)$. Although such a scaling is not observed in the AMPR result, it is expected to appear for larger N. Again, a significant difference in computational time is present between the semi-analytic and the numerical resampling methods, demonstrating the effectiveness of the proposed method.

4.1.5. Correlated covariates

In the derivation of AMPR and the associated SE equations, the weakness of correlations between covariates is assumed, but this assumption does not necessarily hold in realistic situations. Hence, it is important to check the accuracy of results obtained by AMPR for datasets with correlated covariates. Here we numerically examine this point.

To introduce correlations into the simulated dataset described above in a systematic way, we generate our covariates $\{\boldsymbol{x}_i\}_{i=1}^N$ in the following manner: As a common component we first generate a vector $\boldsymbol{x}^{\rm com} \in \mathbb{R}^M$ each component of which is i.i.d. from $\mathcal{N}(0, 1/N)$; choose a number $0 \le r^{\rm com} < 1$ controlling the ratio of the common component and generate a binary vector $\boldsymbol{m}_i$ each component of which independently takes 1 with probability $r^{\rm com}$; take another vector $\tilde{\boldsymbol{x}}_i \in \mathbb{R}^M$ each component of which is i.i.d. from $\mathcal{N}(0, 1/N)$, and generate a covariate vector $\boldsymbol{x}_i$ as a linear combination between $\boldsymbol{x}^{\rm com}$ and $\tilde{\boldsymbol{x}}_i$ with using $\boldsymbol{m}_i$ as a mask. These operations can be summarized in the following equation:

$$\boldsymbol{x}_i = \boldsymbol{x}^{\rm com} \circ \boldsymbol{m}_i(r^{\rm com}) + \tilde{\boldsymbol{x}}_i \circ (1 - \boldsymbol{m}_i(r^{\rm com})), \tag{37}$$

where $\circ$ denotes Hadamard (component-wise) product. The covariates' correlations monotonically increase as $r^{\rm com}$ grows. To quantify this, we compute an overlap between the covariates, $\mathrm{overlap}_{ij} = \boldsymbol{x}_i^\top \boldsymbol{x}_j / \left(\sqrt{\boldsymbol{x}_i^\top \boldsymbol{x}_i}\sqrt{\boldsymbol{x}_j^\top \boldsymbol{x}_j}\right)$, and plot its mean value over i and j ($\neq i$) in Figure 6. Keeping in mind this quantitative information, we check the accuracy of AMPR below.

To directly see the accuracy of AMPR for correlated covariates, we plot the experimental values of the quantities $\{\overline{\beta}_i, W_i, \Pi_i\}_i$ against those of AMPR in Figure 7 for two different values of the common component ratio, $r^{\rm com} = 0.4$ and $r^{\rm com} = 0.8$. For $r^{\rm com} = 0.8$, the AMPR result shows a clear deviation from the experimental one, while for $r^{\rm com} = 0.4$ it still exhibits a good agreement with the experiment. Although Figure 7 is the specific result to the non-random penalty case ($w = 1, \tau = 1$) with parameters $(N, \alpha, \rho_0, \sigma_\xi^2, \lambda) = (1000, 0.5, 0.2, 0.01, 1)$, we have tested several different cases and observed similar tendency. To capture more global and quantitative information, we introduce a normalized MSE of $\overline{\beta}$ between the experimental $\overline{\beta}^{\rm exp}$ and AMPR $\overline{\beta}^{\rm AMPR}$ values as

$$\frac{\sum_{i=1}^N \left(\overline{\beta}_i^{\rm exp} - \overline{\beta}_i^{\rm AMPR}\right)^2}{\sum_{i=1}^N \left(\overline{\beta}_i^{\rm AMPR}\right)^2}. \tag{38}$$

The counterparts for W and Π are defined in the same way. Plots of the normalized MSEs for these quantities against $r^{\rm com}$ are given in Figure 8. Here the results for both the randomized ($w = p_w = \tau = 0.5$) and non-randomized ($w = \tau = 1, p_w = 0$) penalty

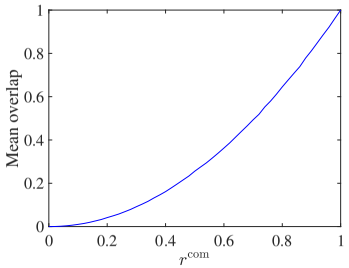

Figure 6: Plot of mean overlap of covariates against the common component ratio r^{com}. This is a result of a single numerical simulation at $(N, \alpha) = (1000, 0.5)$, but the invariability of the result against changing the parameters has been also checked.

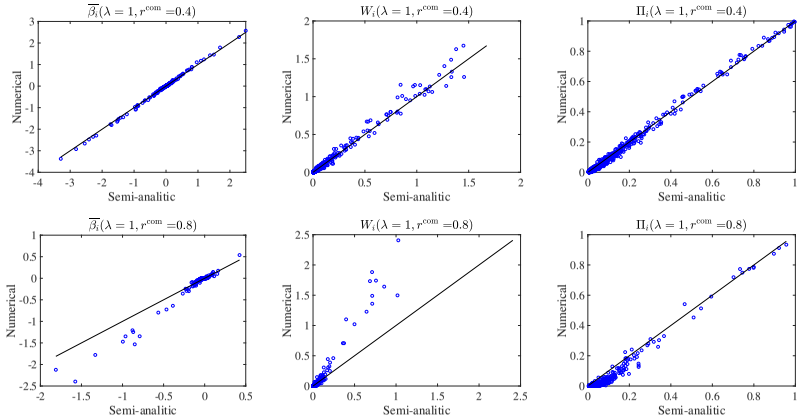

Figure 7: Experimental values of $\overline{\beta_i}$ (left), W_i (middle), and Π_i (right) are plotted against those computed by AMPR for correlated covariates with $r^{\mathrm{com}} = 0.4$ (upper) and $r^{\mathrm{com}} = 0.8$ (lower). For the lower panels, there exists a systematic deviation in the AMPR result. Here the non-random penalty case $(w = 1, \tau = 1)$ is treated and the other parameters are $(N, \alpha, \rho_0, \sigma_\xi^2, \lambda) = (1000, 0.5, 0.2, 0.01, 1)$.

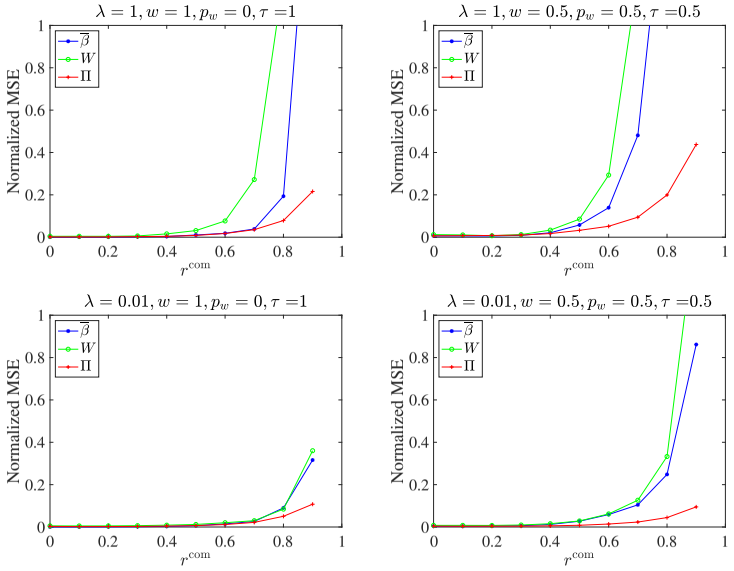

Figure 8: Plots of normalized MSEs of $\overline{\beta}, W, \Pi$ against r^{com} of the non-randomized (left, $w = 1, p_w = 0, \tau = 1$) and randomized (right, $w = p_w = \tau = 1/2$) penalty cases. The upper panels are for $\lambda = 1$ while the lower ones are of $\lambda = 0.01$. The other parameters are $(N, \alpha, \rho_0, \sigma_\xi^2) = (1000, 0.5, 0.2, 0.01)$.

cases are presented, with two different values of λ. This suggests that AMPR is practically reliable up to a certain level of correlations: For example if $r^{\mathrm{com}} \leq 0.6$, the normalized MSE of $\overline{\beta}$ is well suppressed and is commonly less than 0.2. According to Figure 6, $r^{\mathrm{com}} = 0.6$ corresponds to the mean overlap value of about 0.36 which is not small. This speaks for the effectiveness of AMPR even for real-world datasets, as long as the correlations are not too large.

The above discussion clarifies the accuracy of AMPR for correlated covariates, but a more crucial issue is in its convergent property. For the non-correlated case of $r^{\mathrm{com}} = 0$, AMPR converges very rapidly as shown in Figure 3, but for correlated cases it tends to badly converge and can even diverge. A common way to overcome this is to introduce a damping factor γ in the update (Caltagirone et al., 2014; Rangan et al., 2014), and we adopted this in the above experiments. The update with the damping factor can be symbolized as

$$\boldsymbol{\theta}^{(t+1)} = (1-\gamma)\boldsymbol{\theta}^{(t)} + \gamma G(\boldsymbol{\theta}^{(t)}), \tag{39}$$

where $\boldsymbol{\theta}$ is a variable summarizing $(\overline{\boldsymbol{\beta}}, \boldsymbol{\chi}, \boldsymbol{W})$ and G represents the AMPR operations. The original message passing update corresponds to $\gamma = 1$. Smaller values of γ are better for the stability of the algorithm but takes a longer time until the convergence. Our experiments on the simulated dataset seemingly show that a smaller value of γ is needed for larger r^{com} and smaller λ. For example for obtaining Figure 7, we needed to set $\gamma < 0.1$ for avoiding divergence. This value is found experimentally, and it is desired to find a more principled way to choose an appropriate value of γ or a more effective way to better control the convergence of AMP type algorithms. Some earlier studies tackled this problem (Caltagirone et al., 2014; Rangan et al., 2014), but the complete understanding of the convergent property is still missing. Investigation along this direction is an important topic but is beyond the purpose of the present paper.

4.2. Real-world dataset

In this subsection, AMPR is applied to a real-world dataset, and the stability path is computed for examining the relevant covariates or variables. The dataset treated here is the wine quality dataset (Lichman, 2013): The data size is $M = 4898$ (only white wine is treated), and the number of covariates, which represent physicochemical aspects of wine, is $N_0 = 11$. The basic aim of this dataset is to model wine quality in terms of the physicochemical aspects only, and the response is an integer-valued quality score from zero to ten obtained by human expert evaluation. This dataset can be used in both classification and regression, and the linear model was also tested in earlier studies (Cortez et al., 2009; Melkumova and Shatskikh, 2017). Lasso and SS are applied to this dataset.

As preprocessing, N_{noise} noise variables are added into the dataset. Each component of the noise variables is i.i.d. from $\mathcal{N}(0, 1/N)$. The usual standardization, zeroing the mean of all variables and responses and normalizing the variables to be of unit norm, is also conducted.

The reason of the introduction of the noise variables is to make an objective criterion for judging relevant stability paths. The noise variables are by definition irrelevant for describing the responses and hence if some stability paths of original variables behave similarly to the ones of the noise variables then those variables can be regarded as irrelevant. A distribution of stability paths of the noise variables thus defines a kind of "rejection region",

resolving the arbitrariness of judging criterion of the positive probability both in Bolasso and SS. As far as we have searched, this kind of active construction of rejection regions has never been observed in literatures, and hence this proposition itself can be regarded as a part of new results of this paper.

This sort of manipulation to dataset is usually unfavored because it increases the computational cost and tends to contaminate the dataset. However thanks to AMPR, the first computational issue becomes less serious since the computational time of AMPR increases just linearly with respect to the number of added noise variables N_{noise}. The second issue does not seem to be serious either for the wine quality dataset, because the dataset size $M = 4898$ is very large compared to the number of original variables $N_0 = 11$. Below, we experimentally check if this strategy works well or not.

Let us start from checking how the noise variables influence on the dataset. To this end, we plot the solution paths and the generalization errors estimated by 10-fold cross validation (CV) in Figure 9 in the cases with and without the noise variables. This figure

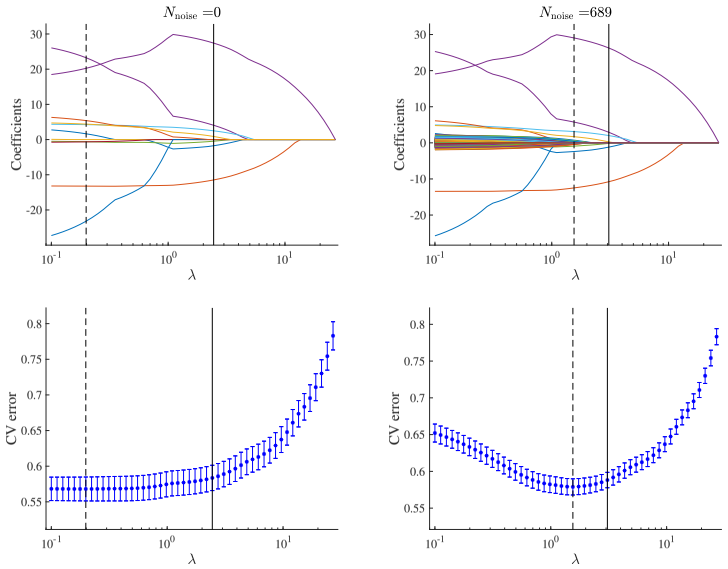

Figure 9: Solution paths (top) and CV errors plotted against λ (bottom), for Nnoise $= 0$ (left) and Nnoise $= 689$ (right). The vertical dotted line denotes the location of the CV error minimum, λ_{min}, whereas the vertical straight line represents the location selected by the one-standard-error rule that "defines" the optimal λ value, λ_{opt}. The effect of the noise variables addition is weak around λ_{opt}.

Table 1: Overlap of the 3rd covariate (citric acid) and the others

index i	1	2	3	4	5	6	7	8	9	10	11
overlap $\boldsymbol{x}_i^\top \boldsymbol{x}_3$	0.29	-0.15	1.00	0.09	0.11	0.09	0.12	0.15	-0.16	0.06	-0.07

indicates that the solution paths of the original variables and the CV error value are stable against the introduction of noise variables, particularly in the relevant range of λ. At the optimal λ ($\lambda_{\rm opt}$), chosen by the one-standard-error rule (Trevor et al., 2009), the variables in the support are common in both cases: They are indexed as $1, 2, 4, 5, 6, 10$, and 11, which represent fixed acidity, volatile acidity, residual sugar, chlorides, free sulfur dioxide, sulphates, and alcohol, respectively. Hence, we can conclude that the introduction of the noise variables hardly affects the estimates of the original variables, and we can effectively use the noise variables to judge the significance of each original variable.

Subsequently, the result of applying SS with $(\tau, w, p_w) = (0.5, 0.5, 0.5)$ to this dataset is examined. Figure 10 shows the plots of the stability paths according to the three categories of variables: The "important" variables are defined as being in the support, at $\lambda_{\rm opt}$ in the Lasso analysis, and thus their indices are $1, 2, 4, 5, 6, 10, 11$; the "neutral" variables are the other variables in the original dataset, and the corresponding indices are $3, 7, 8, 9$; the remaining are the noise variables. Both the results of AMPR (circle) and the direct numerical resampling (asterisk) are shown (the same variable is depicted in the same color).

Consequences of Figure 10 are three-fold. The first one is consistent agreement between the results of AMPR and the direct numerical resampling. For all categories, the two curves of each stability path $\Pi_i(\lambda)$ by AMPR and the direct numerical resampling are very close to each other. This is an additional evidence supporting the accuracy of the proposed semi-analytic method in real-world datasets with correlated covariates. The computational time for obtaining these results in an experiment is 1077 s by AMPR and 2859 s by the numerical resampling, demonstrating the efficiency of AMPR. It should be stressed that this efficiency can be enhanced by optimizing the implementation of AMPR. The second consequence is the different behaviors of stability paths in different categories. The positive probabilities of the important variables (upper left) are growing largely even for $\lambda > \lambda_{\rm min}$, while those of the noise variables (lower left) do not grow well unless λ drops below $\lambda_{\rm min}$. The behavior of the neutral variables (upper right) is somewhat elusive, and a better interpretation is provided by utilizing the noise variables, which is the third consequence: As discussed above, we can define a rejection region from the distribution of stability paths of the noise variables; an actual definition here is the q-percentiles with $q = 16$ and 84 of the distribution, which is in the lower right panel depicted by red bars with the median (red markers) of the distribution, the legend of which is given as FP, in the same manner as Figure 5. This analysis shows that citric acid and total sulfur dioxide of the neutral variables tend to be in the rejection region, implying that they are irrelevant for modeling wine quality. Moreover, density and pH are well beyond the interval of the rejection region, and they can be regarded as relevant, even though the behavior of density's path is rather tricky.

The above conclusion of citric acid's irrelevance contradicts that in Cortez et al. (2009), where citric acid was concluded to be the fourth most important variable. This may be explained by the collinearity of the covariates. In Table 1, the covariates' overlap between citric acid and the others is summarized. This shows a strong collinearity of the 3rd variable

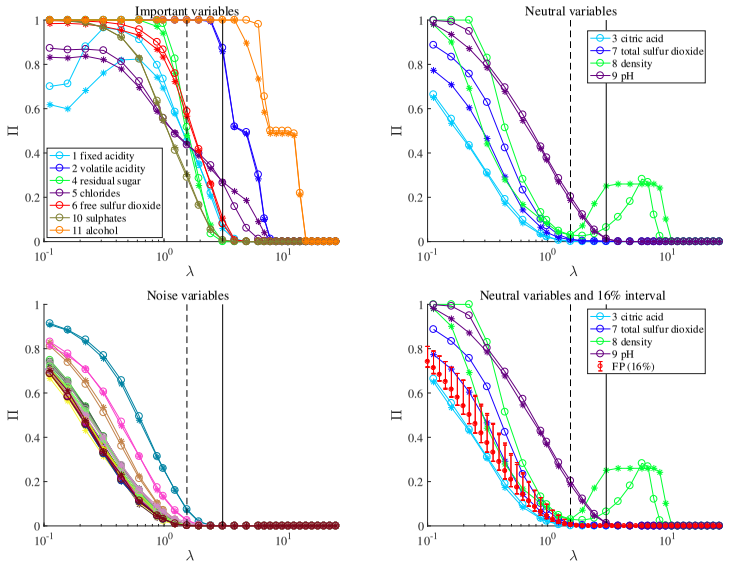

Figure 10: Stability paths for the wine quality data with $N_{\rm noise} = 689$. The paths of the important variables are in the upper left, those of the neutral variables are in the upper right, and those of the noise variables are in the lower left panels. For the lower left panel, the paths of only a part of the noise variables are shown. The vertical dotted and straight lines denote $\lambda_{\rm min}$ and $\lambda_{\rm opt}$, respectively, as in Figure 9. Circles denote the result by AMPR and asterisks represent that by the direct numerical resampling, and the same variable is depicted in the same color; the semi-analytic and numerical results show a consistent agreement for all cases. The lower right panel is the simultaneous plot of the stability paths of the neutral variables and the FP interval computed from paths of the noise variables.

with several others, particularly with the 1st variable. This implies that citric acid can be replaced by the 1st variable or fixed acidity. This is a plausible explanation because the proposed model puts considerably more weight on fixed acidity than on citric acid, whereas the opposite is the case in Cortez et al. (2009). Further thorough comparison will be required to determine which model is better.

Table 1 also implies why AMPR works well for the wine quality dataset: The maximum value of the covariates's overlap is about 0.29 which corresponds $r^{\rm com} \approx 0.5$ in Figure 6; Figure 8 shows that the accuracy of AMPR is commonly good around that value of $r^{\rm com}$, explaining the accuracy of AMPR. This consideration indicates that given a new dataset we can judge whether AMPR will give an accurate result or not for the dataset from the covariates' overlap and Figures 6 and 8.

Overall, the analysis using stability paths provides richer information that cannot be obtained by solely using Lasso. A new objective criterion could be proposed for determining the relevance of variables by utilizing the distribution of stability paths of the added noise variables. These facts highlight the effectiveness of the resampling strategy in variable selection, and the proposed semi-analytic method can implement this strategy in a computationally efficient manner.

5. Conclusion

An approximate method was developed for performing resampling in Lasso in a semi-analytic manner. The replica method enables us to analytically take the resampling average over the given data and the average over the penalty coefficient randomness, and the resultant replicated model is approximately handled by a Gaussian approximation using the cavity method. A message passing algorithm named AMPR is thus derived, the computational cost of which is $O(NM)$ per iteration and is sufficiently reasonable. Its convergence in $O(1)$ iterations is guaranteed by a state evolution analysis when covariates are given as zero-mean i.i.d. Gaussian random variables. We demonstrated how it actually works through numerical experiments using simulated and real-world datasets. Comparison with direct numerical resampling has evidenced its approximation accuracy and efficiency in terms of computational cost, even for covariates with correlations of a moderate level. AMPR was also employed to approximately perform Bolasso and SS, and it was applied to the wine quality dataset (Lichman, 2013; Cortez et al., 2009). To provide a finer quantitative analysis of the dataset, an objective criterion was proposed for determining the relevance of the stability paths by processing the added noise variables, yielding reasonable results in satisfactory computational time.

An advantage of the present framework is its generality. For example, its extension to a generalized linear model is straightforward. This is an immediate future research direction. Extensions to other resampling techniques, such as the multiscale bootstrap method (Shimodaira et al., 2004), would also be interesting.

An unsatisfactory aspect of the present AMPR is that the correlations between covariates are neglected by the approximation. This is a clear drawback, and certain issues arise when the present AMPR is applied to problems involving significantly correlated covariates, although numerical experiments showed that the accuracy of AMPR is still good in the presence of correlations of a moderate level. This drawback may be overcome using more

sophisticated approximations, such as the expectation propagation or the adaptive TAP method (Opper and Winther, 2001a,b, 2005; Kabashima and Vehkapera, 2014; Çakmak et al., 2014; Cespedes et al., 2014; Rangan et al., 2016; Ma and Ping, 2017; Takeuchi, 2017). Applying those approximations with retaining the benefit of message passing algorithms, the low computational cost, is still a nontrivial challenge and promising future work.

Resampling is a very versatile framework applicable to various contexts and models in statistics and machine learning. Reducing its computational cost by extending the present method will thus be beneficial in various fields, and can even be imperative, as available data in society will continue to increase rapidly.

Abstract

Conditional gradient algorithms (also often called Frank–Wolfe algorithms) are popular due to their simplicity of only requiring a linear optimization oracle and more recently they also gained significant traction for online learning. While simple in principle, in many cases the actual implementation of the linear optimization oracle is costly. We show a general method to *lazify* various conditional gradient algorithms, which in actual computations leads to several orders of magnitude of speedup in wall-clock time. This is achieved by using a faster separation oracle instead of a linear optimization oracle, relying only on *few* linear optimization oracle calls.

Keywords: Frank–Wolfe algorithm, conditional gradient, caching, linear optimization oracle, convex optimization

1. Introduction

Convex optimization is an important technique both from a theoretical and an applications perspective. Gradient descent based methods are widely used due to their simplicity and easy applicability to many real-world problems. We are interested in solving constraint convex optimization problems of the form

$$\min_{x \in P} f(x), \tag{1}$$

where f is a smooth convex function and P is a polytope, with access to f being limited to first-order information, i.e., we can obtain $\nabla f(x)$ and $f(x)$ for a given $x \in P$ and access to P via a linear minimization oracle, which returns $\mathrm{LP}_P(c) = \operatorname{argmin}_{x \in P} cx$ for a given linear objective c.

When solving Problem (1) using gradient descent approaches in order to maintain feasibility, typically a projection step is required. This projection back into the feasible region P is potentially computationally expensive, especially for complex feasible regions in very large dimensions. As such, projection-free methods gained a lot of attention recently, in particular the Frank–Wolfe algorithm Frank and Wolfe (1956) (also known as conditional gradient descent Levitin and Polyak (1966); see also Jaggi (2013) for an overview) and its online version Hazan and Kale (2012) due to their simplicity. We recall the basic Frank–Wolfe algorithm in Algorithm 1. These methods eschew the projection step and rather use a

Algorithm 1 Frank–Wolfe Algorithm Frank and Wolfe (1956)
Input: smooth convex function f with curvature C, start vertex $x_1 \in P$, linear minimization oracle LP_P
Output: points x_t in P
1: **for** $t = 1$ **to** $T - 1$ **do**
2: $v_t \leftarrow \mathrm{LP}_P(\nabla f(x_t))$
3: $x_{t+1} \leftarrow (1 - \gamma_t)x_t + \gamma_t v_t$ with $\gamma_t \coloneqq \frac{2}{t+2}$
4: **end for**

linear optimization oracle to stay within the feasible region. While convergence rates and regret bounds are often suboptimal, in many cases the gain due to only having to solve a *single* linear optimization problem over the feasible region in every iteration still leads to significant computational advantages (see e.g., (Hazan and Kale, 2012, Section 5)). This led to conditional gradient algorithms being used for e.g., online optimization and more generally machine learning. Also the property that these algorithms naturally generate sparse distributions over the extreme points of the feasible region is often helpful. Further increasing the relevance of these methods, it was shown recently that conditional gradient methods can also achieve linear convergence (see e.g., Garber and Hazan (2013); Lacoste-Julien and Jaggi (2015); Garber and Meshi (2016)) as well as that the number of total gradient evaluations can be reduced while maintaining the optimal number of oracle calls as shown in Lan and Zhou (2014).

Unfortunately, for complex feasible regions even solving the linear optimization problem might be time-consuming and as such the cost of solving the LP might be non-negligible. This could be the case, e.g., when linear optimization over the feasible region is a hard problem or when solving large-scale optimization or learning problems. As such it is natural to ask the following questions:

(i) Does the linear optimization oracle have to be called in every iteration?

(ii) Does one need approximately optimal solutions for convergence?

(iii) Can one reuse information across iterations?

We will answer these questions in this work, showing that (i) the LP oracle is not required to be called in every iteration, (ii) much weaker guarantees are sufficient, and (iii) we can reuse information. To significantly reduce the cost of oracle calls *while* maintaining identical convergence rates up to small constant factors, we replace the linear optimization oracle by a *(weak) separation oracle* (Oracle 1) which approximately solves a *separation problem*

Oracle 1 Weak Separation Oracle $\mathrm{LPsep}_P(c, x, \Phi, K)$
Input: linear objective $c \in \mathbb{R}^n$, point $x \in P$, accuracy $K \geq 1$, objective value $\Phi > 0$;
Output: Either (1) vertex $y \in P$ with $c(x - y) > \Phi/K$, or (2) **false**: $c(x - z) \leq \Phi$ for all $z \in P$.

within a multiplicative factor and returns improving vertices. We stress that the weak separation oracle is significantly weaker than approximate minimization, which has been

already considered in Jaggi (2013). In fact, there is no guarantee that the improving vertices returned by the oracle are near to the optimal solution to the linear minimization problem. It is this relaxation of dual bounds and approximate optimality that will provide a significant speedup as we will see later. However, if the oracle does not return an improving vertex (returns **false**), then this fact can be used to derive a reasonably small dual bound of the form: $f(x_t) - f(x^*) \leq \nabla f(x_t)(x_t - x^*) \leq \Phi_t$ for some $\Phi_t > 0$. While the accuracy K is presented here as a formal argument of the oracle, an oracle implementation might restrict to a fixed value $K > 1$, which often makes implementation easier. We point out that the cases (1) and (2) potentially overlap if $K > 1$. This is intentional and in this case it is unspecified which of the cases the oracle should choose (and it does not matter for the algorithms).

This new oracle encapsulates the smart use of the *original* linear optimization oracle, even though for some problems it could potentially be implemented directly without relying on a linear programming oracle. Concretely, a weak separation oracle can be realized by a single call to a linear optimization oracle and as such is no more complex than the original oracle. However it has two important advantages: it allows for *caching* and *early termination*. Caching refers to storing previous solutions, and first searching among them to satisfy the oracle's separation condition. The underlying linear optimization oracle is called only, when none of the cached solutions satisfy the condition. Algorithm 2 formalizes this process. Early termination is the technique to stop the linear optimization algorithm before it finishes at an appropriate stage, when from its internal data a suitable oracle answer can be easily recovered; this is clearly an implementation dependent technique. The two techniques can be combined, e.g., Algorithm 2 could use an early terminating linear oracle or other implementation of the weak separation oracle in line 4.

Algorithm 2 $\mathrm{LPsep}_P(c, x, \Phi, K)$ via LP oracle

Input: linear objective $c \in \mathbb{R}^n$, point $x \in P$, accuracy $K \geq 1$, objective value $\Phi > 0$;
Output: Either (1) vertex $y \in P$ with $c(x - y) > \Phi/K$, or (2) **false**: $c(x - z) \leq \Phi$ for all $z \in P$.

1: **if** $y \in P$ cached with $c(x - y) > \Phi/K$ exists **then**
2: **return** y {Cache call}
3: **else**
4: $y \leftarrow \operatorname{argmax}_{x \in P} cx$ {LP call}
5: **if** $c(x - y) > \Phi/K$ **then**
6: add y to cache
7: **return** y
8: **else**
9: **return false**
10: **end if**
11: **end if**

We call *lazification* the technique of replacing a linear programming oracle with a much weaker one, and we will demonstrate significant speedups in wall-clock performance (see e.g., Figure 12), while maintaining identical theoretical convergence rates.

To exemplify our approach we provide conditional gradient algorithms employing the weak separation oracle for the standard Frank–Wolfe algorithm as well as the variants in

Hazan and Kale (2012); Garber and Meshi (2016); Garber and Hazan (2013), which have been chosen due to requiring modified convergence arguments that go beyond those required for the vanilla Frank–Wolfe algorithm. Complementing the theoretical analysis we report computational results demonstrating effectiveness of our approach via a significant reduction in wall-clock time compared to their linear optimization counterparts.

Related Work

There has been extensive work on Frank–Wolfe algorithms and conditional gradient algorithms, so we will restrict to review work most closely related to ours. The Frank–Wolfe algorithm was originally introduced in Frank and Wolfe (1956) (also known as conditional gradient descent Levitin and Polyak (1966) and has been intensely studied in particular in terms of achieving stronger convergence guarantees as well as affine-invariant versions. We demonstrate our approach for the vanilla Frank–Wolfe algorithm Frank and Wolfe (1956) (see also Jaggi (2013)) as an introductory example. We then consider more complicated variants that require non-trivial changes to the respective convergence proofs to demonstrate the versatility of our approach. This includes the linearly convergent variant via local linear optimization Garber and Hazan (2013) as well as the pairwise conditional gradient variant of Garber and Meshi (2016), which is especially efficient in terms of implementation. However, our technique also applies to the *Away-Step Frank–Wolfe* algorithm, the *Fully-Corrective Frank–Wolfe* algorithm, the *Pairwise Conditional Gradient* algorithm, as well as the *Block-Coordinate Frank–Wolfe* algorithm. Recently, in Freund and Grigas (2016) guarantees for arbitrary step-size rules were provided and an analogous analysis can be also performed for our approach. On the other hand, the analysis of the inexact variants, e.g., with approximate linear minimization does not apply to our case as our oracle is significantly weaker than approximate minimization as pointed out earlier. For more information, we refer the interested reader to the excellent overview in Jaggi (2013) for Frank–Wolfe methods in general as well as Lacoste-Julien and Jaggi (2015) for an overview with respect to global linear convergence.

It was also recently shown in Hazan and Kale (2012) that the Frank–Wolfe algorithm can be adjusted to the online learning setting and in this work we provide a lazy version of this algorithm. Combinatorial convex online optimization has been investigated in a long line of work (see e.g., Kalai and Vempala (2005); Audibert et al. (2013); Neu and Bartók (2013)). It is important to note that our regret bounds hold in the *structured online learning* setting, i.e., our bounds depend on the ℓ_1-diameter or sparsity of the polytope, rather than its ambient dimension for arbitrary convex functions (see e.g., Cohen and Hazan (2015); Gupta et al. (2016)). We refer the interested reader to Hazan (2016) for an extensive overview.

A key component of the new oracle is the ability to cache and reuse old solutions, which accounts for the majority of the observed speed up. The idea of caching of oracle calls was already explored in various other contexts such as cutting plane methods (see e.g., Joachims et al. (2009)) as well as the *Block-Coordinate Frank–Wolfe* algorithm in Shah et al. (2015); Osokin et al. (2016). Our lazification approach (which uses caching) is however much more lazy, requiring no multiplicative approximation guarantee; see (Osokin et al., 2016, Proof of Theorem 3. Appendix F) and Lacoste-Julien et al. (2013) for comparison to our setup.

Contribution

The main technical contribution of this paper is a new approach, whereby instead of finding the optimal solution, the oracle is used only to find a *good enough solution* or a *certificate* that such a solution does not exist, both ensuring the desired convergence rate of the conditional gradient algorithms.

Our contribution can be summarized as follows:

(i) *Lazifying approach.* We provide a general method to lazify conditional gradient algorithms. For this we replace the linear optimization oracle with a weak separation oracle, which allows us to reuse feasible solutions from previous oracle calls, so that in many cases the oracle call can be skipped. In fact, once a simple representation of the underlying feasible region is learned no further oracle calls are needed. We also demonstrate how parameter-free variants can be obtained.

(ii) *Lazified conditional gradient algorithms.* We exemplify our approach by providing lazy versions of the vanilla Frank–Wolfe algorithm as well as of the conditional gradient methods in Hazan and Kale (2012); Garber and Hazan (2013); Garber and Meshi (2016).

(iii) *Weak separation through augmentation.* We show in the case of 0/1 polytopes how to implement a weak separation oracle with at most k calls to an augmentation oracle that on input $c \in \mathbb{R}^n$ and $x \in P$ provides either an improving solution $\overline{x} \in P$ with $c\overline{x} < cx$ or ensures optimality, where k denotes the ℓ_1-diameter of P. This is useful when the solution space is sparse.

(iv) *Computational experiments.* We demonstrate computational superiority by extensive comparisons of the weak separation based versions with their original versions. In all cases we report significant speedups in wall-clock time often of several orders of magnitude.

It is important to note that in all cases, we inherit the same requirements, assumptions, and properties of the baseline algorithm that we lazify. This includes applicable function classes, norm requirements, as well as smoothness and (strong) convexity requirements. We also maintain identical convergence rates up to (small) constant factors.

A previous version of this work appeared as extended abstract in Braun et al. (2017); this version has been significantly revised over the conference version including a representative subset of more extensive computational results, full proofs for all described variants, as well as a variant that uses an augmentation oracle instead of linear optimization oracle (see Section 7).

Outline

We briefly recall notation and notions in Section 2 and consider conditional gradient algorithms in Section 3. In Section 4 we consider parameter-free variants of the proposed algorithms, and in Section 5 we examine online versions. Finally, in Section 7 we show a realization of a weak separation oracle with an even weaker oracle in the case of combinatorial problem and we provide extensive computational results in Section 8.

2. Preliminaries

Let $\|\cdot\|$ be an arbitrary norm on $\mathbb{R}^n$, and let $\|\cdot\|^*$ denote the dual norm of $\|\cdot\|$. A function f is *L-Lipschitz* if $|f(y) - f(x)| \leq L\|y - x\|$ for all $x, y \in \operatorname{dom} f$. A convex function f is *smooth* with *curvature* at most C if

$$f(\gamma y + (1-\gamma)x) \leq f(x) + \gamma \nabla f(x)(y - x) + C\gamma^2/2$$

for all $x, y \in \operatorname{dom} f$ and $0 \leq \gamma \leq 1$. A function f is *S-strongly convex* if

$$f(y) - f(x) \geq \nabla f(x)(y - x) + \frac{S}{2}\|y - x\|^2$$

for all $x, y \in \operatorname{dom} f$. Unless stated otherwise Lipschitz continuity and strong convexity will be measured in the norm $\|\cdot\|$. Moreover, let $\mathbb{B}_r(x) \coloneqq \{y \mid \|x - y\| \leq r\}$ be the ball around x with radius r with respect to $\|.\|$. In the following, P will denote the feasible region, a polytope and the vertices of P will be denoted by $v_1, \ldots, v_N$.

3. Lazy Conditional Gradient

We start with the most basic Frank–Wolfe algorithm as a simple example for lazifying by means of a *weak separation oracle*. We then lazify more complex Frank–Wolfe algorithms in Garber and Hazan (2013) and Garber and Meshi (2016). Throughout this section $\|\cdot\|$ denotes the ℓ_2-norm.

3.1. Lazy Conditional Gradient: a basic example

We start with lazifying the original Frank–Wolfe algorithm (arguably the simplest Conditional Gradient algorithm), adapting the baseline argument from (Jaggi, 2013, Theorem 1). While the vanilla version has suboptimal convergence rate $O(1/T)$, its simplicity makes it an illustrative example of the main idea of lazification. The lazy algorithm (Algorithm 3) maintains an upper bound Φ_t on the convergence rate, guiding its eagerness for progress when searching for an improving vertex v_t. If the weak separation oracle provides an improving vertex v_t we refer to this as a *positive call* and if the oracle claims there are no improving vertices we call it a *negative call*.

The step size γ_t is chosen to (approximately) minimize Φ_t in Line 2; roughly Φ_{t-1}/KC.

Theorem 1 *Assume f is convex and smooth with curvature C. Then Algorithm 3 with $\gamma_t = \frac{2(K^2+1)}{K(t+K^2+2)}$ and $f(x_1) - f(x^*) \leq \Phi_0$ has convergence rate*

$$f(x_t) - f(x^*) \leq \frac{2\max\{C, \Phi_0\}(K^2+1)}{t + K^2 + 2},$$

where x^* is a minimum point of f over P.

Proof *We prove by induction that*

$$f(x_t) - f(x^*) \leq \Phi_{t-1}.$$

Algorithm 3 Lazy Conditional Gradient

Input: smooth convex function f with curvature C, start vertex $x_1 \in P$, weak linear separation oracle LPsep_P, accuracy $K \geq 1$, step sizes γ_t, initial upper bound Φ_0
Output: points x_t in P

1: **for** $t = 1$ **to** $T - 1$ **do**
2: $\quad \Phi_t \leftarrow \frac{\Phi_{t-1} + \frac{C\gamma_t^2}{2}}{1 + \frac{\gamma_t}{K}}$
3: $\quad v_t \leftarrow \text{LPsep}_P(\nabla f(x_t), x_t, \Phi_t, K)$
4: $\quad$ **if** $v_t =$ **false then**
5: $\quad\quad x_{t+1} \leftarrow x_t$
6: $\quad$ **else**
7: $\quad\quad x_{t+1} \leftarrow (1 - \gamma_t)x_t + \gamma_t v_t$
8: $\quad$ **end if**
9: **end for**

The claim is clear for $t = 1$ by the choice of Φ_0. Assuming the claim is true for t, we prove it for $t + 1$. We distinguish two cases depending on the return value of the weak separation oracle in Line 3.

In case of a positive call, i.e., when the oracle returns an improving solution v_t, then $\nabla f(x_t)(x_t - v_t) \geq \Phi_t/K$, which is used in the second inequality below. The first inequality follows by smoothness of f, and the second inequality by the induction hypothesis and the fact that v_t is an improving solution:

$$\begin{aligned} f(x_{t+1}) - f(x^*) &\leq \underbrace{f(x_t) - f(x^*)}_{\leq \Phi_{t-1}} + \gamma_t \underbrace{\nabla f(x_t)(v_t - x_t)}_{\leq -\Phi_t/K} + \frac{C\gamma_t^2}{2} \\ &\leq \Phi_{t-1} - \gamma_t \frac{\Phi_t}{K} + \frac{C\gamma_t^2}{2} \\ &= \Phi_t, \end{aligned}$$

In case of a negative call, i.e., when the oracle returns no improving solution, then in particular $\nabla f(x_t)(x_t - x^*) \leq \Phi_t$, hence by Line 5

$$f(x_{t+1}) - f(x^*) = f(x_t) - f(x^*) \leq \nabla f(x_t)(x_t - x^*) \leq \Phi_t.$$

Finally, using the specific values of γ_t we prove the upper bound

$$\Phi_{t-1} \leq \frac{2\max\{C, \Phi_0\}(K^2 + 1)}{t + K^2 + 2}$$

by induction on t. The claim is obvious for $t = 1$. The induction step is an easy computation relying on the definition of Φ_t on Line 2:

$$\Phi_t = \frac{\Phi_{t-1} + \frac{C\gamma_t^2}{2}}{1 + \frac{\gamma_t}{K}} \leq \frac{\frac{2\max\{C,\Phi_0\}(K^2+1)}{t+K^2+2} + \frac{\max\{C,\Phi_0\}\gamma_t^2}{2}}{1 + \frac{\gamma_t}{K}} \leq \frac{2\max\{C, \Phi_0\}(K^2 + 1)}{t + K^2 + 3}.$$

Here the last inequality follows from the concrete value of γ_t. ■

Note that by design, the algorithm converges at the worst-case rate that we postulate due to the negative calls when it does not move. Clearly, this is highly undesirable, therefore the algorithm should be understood as the *textbook variant* of lazy conditional gradient. We will present an improved, parameter-free variant of Algorithm 3 in Section 4 that converges at the best possible rate that the non-lazy variant would achieve (up to a small constant factor).

3.2. Lazy Pairwise Conditional Gradient

In this section we provide a lazy variant (Algorithm 4) of the Pairwise Conditional Gradient algorithm from Garber and Meshi (2016), using separation instead of linear optimization. We make identical assumptions: the feasible region is a 0/1 polytope, i.e., all vertices of P have only 0/1 entries, and moreover it is given in the form $P = \{x \in \mathbb{R}^n \mid 0 \leq x \leq \mathbb{1}, Ax = b\}$, where $\mathbb{1}$ denotes the all-one vector.

Algorithm 4 Lazy Pairwise Conditional Gradient (LPCG)

Input: polytope P, smooth and S-strongly convex function f with curvature C, accuracy $K \geq 1$, non-increasing step-sizes η_t, eagerness Δ_t
Output: points x_t

1: $x_1 \in P$ arbitrary and $\Phi_0 \geq f(x_1) - f(x^*)$
2: **for** $t = 1, \ldots, T$ **do**
3: $\quad \widetilde{\nabla} f(x_t)_i \coloneqq \begin{cases} \nabla f(x_t)_i & \text{if } x_{t,i} > 0 \\ -\infty & \text{if } x_{t,i} = 0 \end{cases}$
4: $\quad \Phi_t \leftarrow \frac{2\Phi_{t-1} + \eta_t^2 C}{2 + \frac{\eta_t}{K\Delta_t}}$
5: $\quad c_t \leftarrow \left(\nabla f(x_t), -\widetilde{\nabla} f(x_t)\right)$
6: $\quad (v_t^+, v_t^-) \leftarrow \text{LPsep}_{P\times P}\left(c_t,\, (x_t, x_t),\, \frac{\Phi_t}{\Delta_t},\, K\right)$
7: $\quad$ **if** $(v_t^+, v_t^-) =$ **false then**
8: $\quad\quad x_{t+1} \leftarrow x_t$
9: $\quad$ **else**
10: $\quad\quad \tilde{\eta}_t \leftarrow \max\{2^{-\delta} \mid \delta \in \mathbb{Z}_{\geq 0},\ 2^{-\delta} \leq \eta_t\}$
11: $\quad\quad x_{t+1} \leftarrow x_t + \tilde{\eta}_t(v_t^+ - v_t^-)$
12: $\quad$ **end if**
13: **end for**

Observe that Algorithm 4 calls the linear separation oracle LPsep on the cartesian product of P with itself. Choosing the objective function as in Line 5 allows us to simultaneously find an improving direction and an away-step direction.

Let $\operatorname{card} x$ denote the number of non-zero entries of the vector x.

Theorem 2 *Let x^* be a minimum point of f in P, and Φ_0 an upper bound of $f(x_1) - f(x^*)$. Furthermore, let $\operatorname{card}(x^*) \leq \alpha$, $M_1 \coloneqq \sqrt{\frac{S}{8\alpha}}$, $\kappa \coloneqq \min\left\{\frac{M_1}{KC}, 1/\sqrt{\Phi_0}\right\}$, $\eta_t \coloneqq \kappa\sqrt{\Phi_{t-1}}$ and*

$\Delta_t \coloneqq \sqrt{\frac{2\alpha\Phi_{t-1}}{S}}$, *then Algorithm 4 has convergence rate*

$$f(x_{t+1}) - f(x^*) \leq \Phi_t \leq \Phi_0 \left(\frac{1+B}{1+2B}\right)^t,$$

where $B \coloneqq \kappa \cdot \frac{M_1}{2K}$.

We recall a technical lemma for the proof.

Lemma 3 ((Garber and Meshi, 2016, Lemma 2)) *Let $x, y \in P$. Then x is a liner combination $x = \sum_{i=1}^k \lambda_i v_i$ of some vertices v_i of P (in particular, $\sum_{i=1}^k \lambda_i = 1$) with $x - y = \sum_{i=1}^k \gamma_i (v_i - z)$ for some $0 \leq \gamma_i \leq \lambda_i$ and $z \in P$ such that $\sum_{i=1}^k \gamma_i \leq \sqrt{\operatorname{card}(y)}\|x-y\|$.*

Proof [Proof of Theorem 2] The feasibility of the iterates x_t is ensured by Line 10 and the monotonicity of the sequence $\{\eta_t\}_{t\geq 1}$ with the same argument as in (Garber and Meshi, 2016, Lemma 1 and Observation 2).

We first show by induction that

$$f(x_{t+1}) - f(x^*) \leq \Phi_t.$$

For $t = 0$ we have $\Phi_0 \geq f(x_1) - f(x^*)$. Now assume the statement for some $t \geq 0$. In case of a negative call (Line 8), we use the guarantee of Oracle 1 to get

$$c_t[(x_t, x_t) - (z_1, z_2)] \leq \frac{\Phi_t}{\Delta_t}$$

for all $z_1, z_2 \in P$, which is equivalent to (as $c_t(x_t, x_t) = 0$)

$$\widetilde{\nabla} f(x_t) z_2 - \nabla f(x_t) z_1 \leq \frac{\Phi_t}{\Delta_t}$$

and therefore

$$\nabla f(x_t)(\tilde{z}_2 - z_1) \leq \frac{\Phi_t}{\Delta_t}, \tag{2}$$

for all $\tilde{z}_2, z_1 \in P$ with $\operatorname{supp}(\tilde{z}_2) \subseteq \operatorname{supp}(x_t)$, where $\operatorname{supp}(x)$ denotes the set of non-zero coordinates of x. We use Lemma 3 for the decompositions $x_t = \sum_{i=1}^k \lambda_i v_i$ and $x_t - x^* = \sum_{i=1}^k \gamma_i (v_i - z)$ with $0 \leq \gamma_i \leq \lambda_i$, $z \in P$ and

$$\sum_{i=1}^k \gamma_i \leq \sqrt{\operatorname{card}(x^*)}\|x_t - x^*\| \leq \sqrt{\frac{2\operatorname{card}(x^*)\Phi_{t-1}}{S}} \leq \Delta_t,$$

using the induction hypothesis and strong convexity in the second inequality. Then

$$f(x_{t+1}) - f(x^*) = f(x_t) - f(x^*) \leq \nabla f(x_t)(x_t - x^*) = \sum_{i=1}^k \gamma_i \cdot \underbrace{\nabla f(x_t)(v_i - z)}_{\leq \Phi_t/\Delta_t} \leq \Phi_t,$$

where we used Equation (2) for the last inequality.

In case of a positive call (Lines 10 and 11) we get, using first smoothness of f, then $\eta_t/2 < \tilde{\eta}_t \leq \eta_t$ and $\nabla f(x_t)(v_t^+ - v_t^-) \leq -\Phi_t/(K\Delta_t)$, and finally the definition of Φ_t:

$$\begin{aligned} f(x_{t+1}) - f(x^*) &= f(x_t) - f(x^*) + f(x_t + \tilde{\eta}_t(v_t^+ - v_t^-)) - f(x_t) \\ &\leq \Phi_{t-1} + \tilde{\eta}_t \nabla f(x_t)(v_t^+ - v_t^-) + \frac{\tilde{\eta}_t^2 C}{2} \\ &\leq \Phi_{t-1} - \frac{\eta_t}{2} \cdot \frac{\Phi_t}{K\Delta_t} + \frac{\eta_t^2 C}{2} = \Phi_t. \end{aligned}$$

Plugging in the values of η_t and Δ_t to the definition of Φ_t gives the desired bound.

$$\Phi_t = \frac{2\Phi_{t-1} + \eta_t^2 C}{2 + \frac{\eta_t}{K\Delta_t}} = \Phi_{t-1}\frac{1 + \kappa^2 C/2}{1 + \kappa M_1/K} \leq \Phi_{t-1}\frac{1+B}{1+2B} \leq \Phi_0 \left(\frac{1+B}{1+2B}\right)^t.$$

■

3.3. Lazy Local Conditional Gradient

In this section we provide a lazy version (Algorithm 5) of the conditional gradient algorithm from Garber and Hazan (2013). Let $P \subseteq \mathbb{R}^n$ be any polytope, D denote an upper bound on the ℓ_2-diameter of P, and $\mu \geq 1$ be an affine invariant parameter of P satisfying Lemma 4 below, see (Garber and Hazan, 2013, Section 2) for a possible definition. As the algorithm is not affine invariant by nature, we need a non-invariant version of smoothness: Recall that a convex function f is *β-smooth* if

$$f(y) - f(x) \leq \nabla f(x)(y - x) + \beta\|y - x\|^2/2.$$

Algorithm 5 Lazy Local Conditional Gradient (LLCG)

Input: feasible polytope P, β-smooth and S-strongly convex function f, parameters K, S, β, μ; diameter D
Output: points x_t

1: $x_1 \in P$ arbitrary and $\Phi_0 \geq f(x_1) - f(x^*)$
2: $\alpha \leftarrow \frac{S}{2K\beta n\mu^2}$
3: **for** $t = 1, \ldots, T$ **do**
4: $\quad r_t \leftarrow \sqrt{\frac{2\Phi_{t-1}}{S}}$
5: $\quad \Phi_t \leftarrow \frac{\Phi_{t-1} + \frac{\beta}{2}\alpha^2 \min\{n\mu^2 r_t^2, D^2\}}{1+\alpha/K}$
6: $\quad p_t \leftarrow \mathrm{LLPsep}_P\left(\nabla f(x_t), x_t, r_t, \Phi_t, K\right)$
7: $\quad$ **if** $p_t =$ **false then**
8: $\quad\quad x_{t+1} \leftarrow x_t$
9: $\quad$ **else**
10: $\quad\quad x_{t+1} \leftarrow x_t + \alpha(p_t - x_t)$
11: $\quad$ **end if**
12: **end for**

Algorithm 6 Weak Local Separation $\mathrm{LLPsep}_P(c, x, r, \Phi, K)$

Input: polytope P together with invariant μ, linear objective $c \in \mathbb{R}^n$, point $x \in P$, radius $r > 0$, objective value $\Phi > 0$, accuracy $K \geq 1$

Output: Either (1) $y \in P$ with $\|x - y\| \leq \sqrt{n}\mu r$ and $c(x - y) > \Phi/K$, or (2) **false**: $c(x - z) \leq \Phi$ for all $z \in P \cap \mathbb{B}_r(x)$.

1: $\Delta \leftarrow \min\left\{\frac{\sqrt{n}\mu}{D} r, 1\right\}$
2: Decompose x: $x = \sum_{j=1}^{M} \lambda_j v_j$, $\lambda_j > 0$, $\sum_j \lambda_j = 1$.
3: Sort vertices: $i_1, \ldots, i_M$ $\quad cv_{i_1} \geq \cdots \geq cv_{i_M}$.
4: $k \leftarrow \min\{k : \sum_{j=1}^{k} \lambda_{i_j} \geq \Delta\}$
5: $p_- \leftarrow \sum_{j=1}^{k-1} \lambda_{i_j} v_{i_j} + \left(\Delta - \sum_{j=1}^{k-1} \lambda_{i_j}\right) v_{i_k}$
6: $v^* \leftarrow \mathrm{LPsep}_P\left(c, \frac{p_-}{\Delta}, \frac{\Phi}{\Delta}\right)$
7: **if** $v^* =$ **false then**
8: **return false**
9: **else**
10: **return** $y \leftarrow x - p_- + \Delta v^*$
11: **end if**

As an intermediary step, we first implement a *local weak separation oracle* in Algorithm 6, a *local* version of Oracle 1, which finds improving points only in a small neighborhood of the original point, analogously to the local linear optimization oracle in Garber and Hazan (2013). To this end, we recall a technical lemma from Garber and Hazan (2013).

Lemma 4 *(Garber and Hazan, 2013, Lemma 7) Let $P \subseteq \mathbb{R}^n$ be a polytope and $v_1, \ldots, v_N$ be its vertices. Let $x, y \in P$ and $x = \sum_{i=1}^{N} \lambda_i v_i$ a convex combination of the vertices of P. Then there are numbers $0 \leq \gamma_i \leq \lambda_i$ and $z \in P$ satisfying*

$$x - y = \sum_{i \in [N]} \gamma_i (z - v_i)$$

$$\sum_{i \in [N]} \gamma_i \leq \frac{\sqrt{n}\mu}{D} \|x - y\|.$$

Now we prove the correctness of the weak local separation algorithm.

Lemma 5 *Algorithm 6 is correct. In particular* $\mathrm{LLPsep}_P(c, x, r, \Phi, K)$

(i) returns either an $y \in P$ with $\|x - y\| \leq \sqrt{n}\mu r$ and $c(x - y) \geq \Phi/K$,

(ii) or returns ***false****, and then $c(x - z) \leq \Phi$ for all $z \in P \cap \mathbb{B}_r(x)$.*

Proof *We first consider the case when the algorithm exits in Line 10. Observe that $y \in P$ since y is a convex combination of vertices of by construction: $y = \sum_{j=1}^{M} (\lambda_{i_j} - \gamma_j) v_{i_j} + \Delta v^*$ with $\Delta = \sum_{j=1}^{M} \gamma_j \leq \frac{\sqrt{n}\mu}{D} r$, where $\gamma_j = \lambda_{i_j}$ for $j < k$, and $\gamma_k = \Delta - \sum_{j=1}^{k-1} \lambda_{i_j}$, and $\gamma_j = 0$ for $j > k$. Therefore*

$$\|x - y\| = \left\| \sum_{j=1}^{M} \gamma_j (v_{i_j} - v^*) \right\| \leq \sum_{j=1}^{M} \gamma_j \|v_{i_j} - v^*\| \leq \sqrt{n}\mu r.$$

Finally using the guarantee of LPsep_P *we get*

$$c(x - y) = \Delta c\left(\frac{p_-}{\Delta} - v^*\right) \geq \frac{\Phi}{K}.$$

If the algorithm exits in Line 8, we use Lemma 4 to decompose any $y \in P \cap \mathbb{B}_r(x)$:

$$x - y = \sum_{i=1}^{M} \gamma_i (v_i - z),$$

with $z \in P$ and $\sum_{i=1}^{M} \gamma_i \leq \frac{\sqrt{n}\mu}{D} \|x - y\| \leq \Delta$. Since $\sum_{i=1}^{M} \lambda_i = 1 \geq \Delta$, there are numbers $\gamma_i \leq \eta_i^- \leq \lambda_i$ with $\sum_{i=1}^{M} \eta_i^- = \Delta$. Let

$$\tilde{p}_- \coloneqq \sum_{i=1}^{M} \eta_i^- v_i,$$

$$\tilde{p}_+ \coloneqq y - x + \tilde{p}_- = \sum_{i=1}^{M} (\eta_i^- - \gamma_i) v_i + \sum_{i=1}^{M} \gamma_i z,$$

so that $\tilde{p}_+/\Delta \in P$. To bound the function value we first observe that the choice of p_- in the algorithm assures that $cu \leq cp_-$ for all $u = \sum_{i=1}^{M} \eta_i v_i$ with $\sum_{i=1}^{M} \eta_i = \Delta$ and all $0 \leq \eta_i \leq \lambda_i$. In particular, $c\tilde{p}_- \leq cp_-$. The function value of the positive part $\tilde{p}_+$ can be bounded with the guarantee of LPsep_P*:*

$$c\left(\frac{p_-}{\Delta} - \frac{\tilde{p}_+}{\Delta}\right) \leq \frac{\Phi}{\Delta},$$

i.e., $c(p_- - \tilde{p}_+) \leq \Phi$. Finally combining these bounds gives

$$c(x - y) = c(\tilde{p}_- - \tilde{p}_+) \leq c(p_- - \tilde{p}_+) \leq \Phi$$

as desired. ■

We are ready to examine the Conditional Gradient Algorithm based on LLPsep_P:

Theorem 6 *Algorithm 5 converges with the following rate:*

$$f(x_{t+1}) - f(x^*) \leq \Phi_t \leq \Phi_0 \left(\frac{1 + \alpha/(2K)}{1 + \alpha/K}\right)^t.$$

Proof *The proof is similar to the proof of Theorem 2. We prove this rate by induction. For $t = 0$ the choice of Φ_0 guarantees that $f(x_1) - f(x^*) \leq \Phi_0$. Now assume the theorem holds for $t \geq 0$. With strong convexity and the induction hypothesis we get*

$$\|x_t - x^*\|^2 \leq \frac{2}{S}(f(x_t) - f(x^*)) \leq \frac{2}{S}\Phi_{t-1} = r_t^2,$$

i.e., $x^* \in P \cap \mathbb{B}_{r_t}(x_t)$. In case of a negative call, i.e., when $p_t =$ **false***, then case (ii) of Lemma 5 applies:*

$$f(x_{t+1}) - f(x^*) = f(x_t) - f(x^*) \leq \nabla f(x_t)(x_t - x^*) \leq \Phi_t.$$

In case of a positive call, i.e., when Line 10 is executed, we get the same inequality via:

$$\begin{aligned} f(x_{t+1}) - f(x^*) &\leq \Phi_{t-1} + \alpha \nabla f(x_t)(p_t - x_t) + \frac{\beta}{2}\alpha^2 \|x_t - p_t\|^2 \\ &\leq \Phi_{t-1} - \alpha \frac{\Phi_t}{K} + \frac{\beta}{2}\alpha^2 \min\{n\mu^2 r_t^2, D^2\} \\ &= \Phi_t. \end{aligned}$$

Therefore using the definition of α and r_t we get the desired bound:

$$\Phi_t \leq \frac{\Phi_{t-1} + \frac{\beta}{2}\alpha^2 r_t^2 n\mu^2}{1 + \alpha/K} = \Phi_{t-1}\left(\frac{1 + \alpha/(2K)}{1 + \alpha/K}\right) \leq \Phi_0 \left(\frac{1 + \alpha/(2K)}{1 + \alpha/K}\right)^t.$$

■

4. Parameter-free Conditional Gradient via Weak Separation

In this section we provide a parameter-free variant of the Lazy Frank–Wolfe Algorithm, which is inspired by Pokutta (2017) and which exhibits a very favorable behavior in computations; the same technique applies to all other variants from Section 3 as well. The idea is that instead of using predetermined values for progress parameters, like Φ_t and γ_t in Algorithm 3, to optimize worst-case progress, the parameters are adjusted adaptively, using data encountered by the algorithm, and avoiding hard-to-estimate parameters, like the curvature C. In practice, this leads to faster convergence, as usual for adaptive methods, while the theoretical convergence rate is worse only by a small constant factor. See Figure 14 for a comparison and Section 8.1.1 for more experimental results.

The occasional halving of the Φ_t is reminiscent of an adaptive restart strategy, considering successive iterates with the same Φ_t as an epoch. It ensures that Φ_t is always at least half of the primal gap, while quickly reducing it if it is too large for the algorithm to make progress, and as such it represents a reasonable amount of expected progress throughout the whole run of the algorithm, not just at the initial iterates.

Remark 7 (Additional LP call for initial bound) *Note that Algorithm 7 finds a tight initial bound Φ_0 with a single extra LP call. If this is undesired, this can be also done approximately as long as Φ_0 is a valid upper bound, for example by means of binary search via the weak separation oracle.*

Theorem 8 *Let f be a smooth convex function with curvature C. Algorithm 7 converges at a rate proportional to $1/t$. In particular to achieve a bound $f(x_t) - f(x^*) \leq \varepsilon$, given an initial upper bound $f(x_1) - f(x^*) \leq 2\Phi_0$, the number of required steps is upper bounded by*

$$t \leq \left\lceil \log \frac{\Phi_0}{\varepsilon} \right\rceil + 1 + 4K \left\lceil \log \frac{\Phi_0}{KC} \right\rceil + \frac{16K^2 C}{\varepsilon}.$$

Proof *The main idea of the proof is to maintain an approximate upper bound on the optimality gap. We then show that negative calls halve the upper bound $2\Phi_t$ and positive oracle calls make significant objective function improvement.*

Algorithm 7 Parameter-free Lazy Conditional Gradient (LCG)

Input: smooth convex function f, start vertex $x_1 \in P$, weak linear separation oracle LPsep_P, accuracy $K \geq 1$
Output: points x_t in P

1: $\Phi_0 \leftarrow \max_{x \in P} \nabla f(x_1)(x_1 - x)/2$ {Initial bound}
2: **for** $t = 1$ **to** $T - 1$ **do**
3: $\quad v_t \leftarrow \text{LPsep}_P(\nabla f(x_t), x_t, \Phi_{t-1}, K)$
4: $\quad$ **if** $v_t =$ **false then**
5: $\quad\quad x_{t+1} \leftarrow x_t$
6: $\quad\quad \Phi_t \leftarrow \frac{\Phi_{t-1}}{2}$ {Update Φ}
7: $\quad$ **else**
8: $\quad\quad \gamma_t \leftarrow \text{argmin}_{0 \leq \gamma \leq 1} f((1-\gamma)x_t + \gamma v_t)$ {Line search}
9: $\quad\quad x_{t+1} \leftarrow (1 - \gamma_t)x_t + \gamma_t v_t$ {Update iterate}
10: $\quad\quad \Phi_t \leftarrow \Phi_{t-1}$
11: $\quad$ **end if**
12: **end for**

*We analyze iteration t of the algorithm. If Oracle 1 in Line 3 returns a negative answer (i.e., **false**, case (2)), then this guarantees $\nabla f(x_t)(x_t - x) \leq \Phi_{t-1}$ for all $x \in P$, in particular, using convexity, $f(x_{t+1}) - f(x^*) = f(x_t) - f(x^*) \leq \nabla f(x_t)(x_t - x^*) \leq \Phi_{t-1} = 2\Phi_t$.*

If Oracle 1 returns a positive answer (case (1)), then we have $f(x_t) - f(x_{t+1}) \geq \gamma_t \Phi_{t-1}/K - (C/2)\gamma_t^2$ by smoothness of f. By minimality of γ_t, therefore $f(x_t) - f(x_{t+1}) \geq \min_{0 \leq \gamma \leq 1}(\gamma \Phi_{t-1}/K - (C/2)\gamma^2)$, which is $\Phi_{t-1}^2/(2CK^2)$ if $\Phi_{t-1} < KC$, and $\Phi_{t-1}/K - C/2 \geq \frac{C}{2}$ if $\Phi_{t-1} \geq KC$.

Now we bound the number t' of consecutive positive oracle calls immediately following an iteration t with a negative oracle call. Note that the same argument bounds the number of initial consecutive positive oracle calls with the choice $t = 0$, as we only use $f(x_{t+1}) - f(x^*) \leq 2\Phi_t$ below.

Note that $\Phi_t = \Phi_{t+1} = \cdots = \Phi_{t+t'}$. Therefore

$$2\Phi_t \geq f(x_{t+1}) - f(x^*) \geq \sum_{\tau=t+1}^{t+t'} (f(x_\tau) - f(x_{\tau+1})) \geq \begin{cases} t' \frac{\Phi_t^2}{2CK^2} & \text{if } \Phi_t < KC \\ t' \left(\frac{\Phi_t}{K} - \frac{C}{2}\right) & \text{if } \Phi_t \geq KC \end{cases},$$

which gives in the case $\Phi_t < KC$ that $t' \leq 4CK^2/\Phi_t$, and in the case $\Phi_t \geq KC$ that

$$t' \leq \frac{2\Phi_t}{\frac{\Phi_t}{K} - \frac{C}{2}} = \frac{4K\Phi_t}{2\Phi_t - KC} \leq \frac{4K\Phi_t}{2\Phi_t - \Phi_t} = 4K.$$

Thus iteration t is followed by at most $4K$ consecutive positive oracle calls as long as $\Phi_t \geq KC$, and $4CK^2/\Phi_t < 2^{\ell+1} \cdot 4K$ ones for $2^{-\ell-1}KC < \Phi_t \leq 2^{-\ell}KC$ with $\ell \geq 0$.

Adding up the number of oracle calls gives the desired rate: in addition to the positive oracle calls we also have at most $\lceil \log(\Phi_0/\varepsilon) \rceil + 1$ negative oracle calls, where $\log(\cdot)$ is the binary logarithm and ε is the (additive) accuracy. Thus after a total of

$$\left\lceil \log \frac{\Phi_0}{\varepsilon} \right\rceil + 1 + 4K \left\lceil \log \frac{\Phi_0}{KC} \right\rceil + \sum_{\ell=0}^{\lceil \log(KC/\varepsilon) \rceil} 2^{\ell+1} \cdot 4K \leq \left\lceil \log \frac{\Phi_0}{\varepsilon} \right\rceil + 1 + 4K \left\lceil \log \frac{\Phi_0}{KC} \right\rceil + \frac{16K^2 C}{\varepsilon}$$

iterations (or equivalently oracle calls) we have $f(x_t) - f(x^*) \leq \varepsilon$. ■

As seen from the proof, the algorithm receives few negative oracle calls by design; these are usually more expensive than positive ones as the oracle has to compute a certificate by, e.g., executing a full linear optimization oracle call.

Corollary 9 *Algorithm 7 receives at most* $\lceil \log \Phi_0/\varepsilon \rceil + 1$ *negative oracle answers.*

Remark 10 (Improved use of Linear Optimization oracle) *A possible improvement to Line 6 is* $\Phi_t \leftarrow \max_{x \in P} \nabla f(x_t)(x_t - x)/2$*, assuming that at a negative call the oracle also provides the dual gap* $\max_{x \in P} \nabla f(x_t)(x_t - x)$ *as well as the minimizer* $\bar{x} \in P$ *of the oracle call. This is the case e.g., when the weak separation oracle is implemented as in Algorithm 2. Clearly, the minimizer* $\bar{x}$ *can be also used to perform a progress step; albeit without guarantee w.r.t. to* Φ_t*.*

Remark 11 (Line Search) *If line search is too expensive we can choose* $\gamma_t = \min\{1, \Phi_t/KC\}$ *in Algorithm 7. In this case an estimate of the curvature* C *is required.*

5. Lazy Online Conditional Gradient

In this section we lazify the online conditional gradient algorithm of Hazan and Kale (2012) over arbitrary polytopes $P = \{x \in \mathbb{R}^n \mid Ax \leq b\}$, resulting in Algorithm 8. We slightly improve constant factors by replacing (Hazan and Kale, 2012, Lemma 3.1) with a better estimation via solving a quadratic inequality arising from strong convexity. In this section the norm $\|\cdot\|$ can be arbitrary.

Theorem 12 *Let* $0 \leq b, s < 1$*. Let* $K \geq 1$ *be an accuracy parameter. Assume* f_t *is L-Lipschitz, and smooth with curvature at most* Ct^{-b}*. Let* $D \coloneqq \max_{y_1, y_2 \in P} \|y_1 - y_2\|$ *denote the diameter of* P *in norm* $\|\cdot\|$*. Then the following hold for the points* x_t *computed by Algorithm 8 where* x_T^* *is the minimizer of* $\sum_{t=1}^T f_t$*:*

(i) With the choice

$$\gamma_t = t^{-(1-b)/2},$$

the x_t *satisfy*

$$\frac{1}{T}\sum_{t=1}^{T}(f_t(x_T) - f_t(x_T^*)) \leq AT^{-(1-b)/2},$$

where

$$A \coloneqq \frac{CK}{2(1-b)} + L(K+1)D.$$

(ii) Moreover, if all the f_t *are* St^{-s}*-strongly convex, then with the choice*

$$\gamma_t = t^{(b+s-2)/3},$$

Algorithm 8 Lazy Online Conditional Gradient (LOCG)

14: $\quad\quad \Phi_t \leftarrow h_t - \sum_{i=1}^t f_i(x_t) + \sum_{i=1}^t f_i(x_{t+1})$
15: $\quad$ **end if**
16: **end for**

the x_t *satisfy*

$$\frac{1}{T}\sum_{t=1}^{T}(f_t(x_T) - f_t(x_T^*)) \leq AT^{-(2(1+b)-s)/3}, \tag{3}$$

where

$$A \coloneqq 2\left((K+1)(K+2)\frac{L^2}{S} + \frac{CK}{2(1-b)}\right).$$

Proof *We prove only Claim (ii), as the proof of Claim (i) is similar and simpler. Let* $F_T \coloneqq \sum_{t=1}^T f_t$*. Furthermore, let* $\overline{h}_T \coloneqq AT^{1-(2(1+b)-s)/3}$ *be* T *times the right-hand side of Equation* (3)*. In particular,* F_T *is* S_T*-strongly convex, and smooth with curvature at most* C_{F_T} *where*

$$C_{F_T} \coloneqq \frac{CT^{1-b}}{1-b} \geq C\sum_{t=1}^{T} t^{-b}, \qquad S_T \coloneqq ST^{1-s} \leq S\sum_{t=1}^{T} t^{-s}.$$

We prove $F_t(x_t) - F_t(x_t^*) \leq h_t \leq \overline{h}_t$ *by induction on* t*. The case* $t = 1$ *is clear. Let* $\overline{\Phi}_t$ *denote the value of* Φ_t *in Line 8, while we reserve* Φ_t *to denote its value as used in Line 6. We start by showing* $F_t(x_{t+1}) - F_t(x_t^*) \leq \Phi_t \leq \overline{\Phi}_t$*. We distinguish two cases depending on the oracle answer* v_t *from Line 9. For a negative oracle answer (*$v_t =$ ***false****), we have* $\Phi_t = \overline{\Phi}_t$ *and the weak separation oracle asserts* $\max_{y \in P} \nabla F_t(x_t)(x_t - y) \leq \Phi_t$*, which combined with the convexity of* F_t *provides*

$$F_t(x_{t+1}) - F_t(x_t^*) = F_t(x_t) - F_t(x_t^*) \leq \nabla F_t(x_t)(x_t - x_{t^*}) \leq \Phi_t = \overline{\Phi}_t.$$

Otherwise, for a positive oracle answer, Line 14 and the induction hypothesis provides $F_t(x_{t+1}) - F_t(x_t^*) \leq h_t + F_t(x_{t+1}) - F_t(x_t) = \Phi_t$. *To prove* $\Phi_t \leq \overline{\Phi}_t$, *we apply the smoothness of* F_t *followed by the inequality provided by the choice of* v_t:

$$F_t(x_{t+1}) - F_t(x_t) - \frac{C_{F_t}\gamma_t^2}{2} \leq \nabla F_t(x_t)(x_{t+1} - x_t) = \gamma_t \nabla F_t(x_t)(v_t - x_t) \leq -\frac{\gamma_t \overline{\Phi}_t}{K}.$$

Rearranging provides the inequality:

$$\Phi_t = h_t + F_t(x_{t+1}) - F_t(x_t) \leq h_t - \frac{\gamma_t \overline{\Phi}_t}{K} + \frac{C_{F_t}\gamma_t^2}{2} = \overline{\Phi}_t.$$

For later use, we bound the difference between $\overline{h}_t$ *and* $\overline{\Phi}_t$ *using the value of parameters,* $h_t \leq \overline{h}_t$, *and* $\gamma_t \leq 1$:

$$\overline{h}_t - \overline{\Phi}_t \geq \overline{h}_t - \frac{\overline{h}_t + \frac{C_{F_t}\gamma_t^2}{2}}{1 + \frac{\gamma_t}{K}} = \frac{\overline{h}_t \gamma_t}{K} - \frac{\frac{C_{F_t}\gamma_t^2}{2}}{1 + \frac{\gamma_t}{K}} \geq \frac{\frac{\overline{h}_t \gamma_t}{K} - \frac{C_{F_t}\gamma_t^2}{2}}{1 + \frac{1}{K}} = \frac{A - \frac{CK}{2(1-b)}}{K+1} t^{[2s-(1+b)]/3}.$$

We now apply $F_t(x_{t+1}) - F_t(x_t^*) \leq \Phi_t$, *together with convexity of* f_{t+1}, *and the minimality* $F_t(x_t^*) \leq F_t(x_{t+1}^*)$ *of* x_t^*, *followed by strong convexity of* F_{t+1}:

$$\begin{aligned} F_{t+1}(x_{t+1}) - F_{t+1}(x_{t+1}^*) &\leq (F_t(x_{t+1}) - F_t(x_t^*)) + (f_{t+1}(x_{t+1}) - f_{t+1}(x_{t+1}^*)) \\ &\leq \Phi_t + \|\nabla_{t+1}\|^* \cdot \|x_{t+1} - x_{t+1}^*\| \\ &\leq \Phi_t + \|\nabla_{t+1}\|^* \sqrt{\frac{2}{S_{t+1}}(F_{t+1}(x_{t+1}) - F_{t+1}(x_{t+1}^*))}. \end{aligned} \tag{4}$$

Solving the quadratic inequality provides

$$F_{t+1}(x_{t+1}) - F_{t+1}(x_{t+1}^*) \leq \Phi_t + \frac{\|\nabla_{t+1}\|^{*2}}{S_{t+1}} + 2\sqrt{\frac{\|\nabla_{t+1}\|^{*2}}{2S_{t+1}}\left(\frac{\|\nabla_{t+1}\|^{*2}}{2S_{t+1}} + \Phi_t\right)}. \tag{5}$$

From Equation (4), *ignoring the last line, we also obtain* $F_{t+1}(x_{t+1}) - F_{t+1}(x_{t+1}^*) \leq \Phi_t + \|\nabla_{t+1}\|^* D$ *via the estimate* $\|x_{t+1} - x_{t+1}^*\| \leq D$. *Thus* $F_{t+1}(x_{t+1}) - F_{t+1}(x_{t+1}^*) \leq h_{t+1}$, *by Line 6, as claimed.*

Now we estimate the right-hand side of Equation (5) *by using the actual value of the parameters, the estimate* $\|\nabla_{t+1}\|^* \leq L$, *and the inequality* $s + b \leq 2$. *In fact, we estimate a proxy for the right-hand side. Note that* A *was chosen to satisfy the second inequality:*

$$\begin{aligned} \frac{L^2}{S_{t+1}} + 2\sqrt{\frac{L^2}{2S_{t+1}}\overline{h}_t} &\leq \frac{L^2}{St^{1-s}} + 2\sqrt{\frac{L^2}{2St^{1-s}}\overline{h}_t} \leq \frac{L^2}{S} t^{[2s-(1+b)]/3} + 2\sqrt{\frac{L^2}{2St^{1-s}}\overline{h}_t} \\ &= \left(\frac{L^2}{S} + \sqrt{2\frac{L^2}{S}A}\right) t^{[2s-(1+b)]/3} \leq \frac{A - \frac{CK}{2(1-b)}}{K+1} t^{[2s-(1+b)]/3} \\ &\leq \overline{h}_t - \overline{\Phi}_t \leq \overline{h}_t - \Phi_t. \end{aligned}$$

In particular, $\frac{L^2}{2S_{t+1}} + \Phi_t \leq \overline{h}_t$ *hence combining with Equation* (5) *we obtain*

$$\begin{aligned} h_{t+1} &\leq \Phi_t + \frac{L^2}{S_{t+1}} + 2\sqrt{\frac{L^2}{2S_{t+1}}\left(\frac{L^2}{2S_{t+1}} + \Phi_t\right)} \\ &\leq \Phi_t + \frac{L^2}{S_{t+1}} + 2\sqrt{\frac{L^2}{2S_{t+1}}\overline{h}_t} \\ &\leq \overline{h}_t \leq \overline{h}_{t+1}. \end{aligned}$$

■

5.1. Stochastic and Adversarial Versions

Complementing the offline algorithms from Section 3, we will now derive various online versions. The presented cases here are similar to those in Hazan and Kale (2012) and thus we state them without proof.

For stochastic cost functions f_t, we obtain bounds from Theorem 12 (i) similar to (Hazan and Kale, 2012, Theorems 4.1 and 4.3) (with δ replaced by δ/T in the bound to correct an inaccuracy in the original argument). The proof is analogous and hence omitted, but note that $\|y_1 - y_2\|_2 \leq \sqrt{\|y_1 - y_2\|_1 \|y_1 - y_2\|_\infty} \leq \sqrt{k}$ for all $y_1, y_2 \in P$.

Corollary 13 *Let* f_t *be convex functions sampled i.i.d. with expectation* $\mathbb{E}[f_t] = f^*$, *and* $\delta > 0$. *Assume that the* f_t *are* L*-Lipschitz in the* 2*-norm.*

(i) If all the f_t *are smooth with curvature at most* C, *then Algorithm 8 applied to the* f_t *(with* $b = 0$*) yields with probability* $1 - \delta$

$$\sum_{t=1}^{T} f^*(x_t) - \min_{x \in P} \sum_{t=1}^{T} f^*(x) \leq O\left(C\sqrt{T} + Lk\sqrt{nT\log(nT^2/\delta)\log T}\right).$$

(ii) Without any smoothness assumption, Algorithm 8 (applied to smoothenings of the f_t*) provides with probability* $1 - \delta$

$$\sum_{t=1}^{T} f^*(x_t) - \min_{x \in P} \sum_{t=1}^{T} f^*(x) \leq O\left(\sqrt{n}LkT^{2/3} + Lk\sqrt{nT\log(nT^2/\delta)\log T}\right).$$

Similar to (Hazan and Kale, 2012, Theorem 4.4), from Theorem 12 (ii) we obtain the following regret bound for adversarial cost functions with an analogous proof.

Corollary 14 *For any* L*-Lipschitz convex cost functions* f_t, *Algorithm 8 applied to the functions* $\tilde{f}_t(x) := \nabla f_t(x_t)x + \frac{2L}{\sqrt{k}} t^{-1/4} \|x - x_1\|_2^2$ *(with* $b = s = 1/4$, $C = L\sqrt{k}$, $S = L/\sqrt{k}$, *and Lipschitz constant* $3L$*) achieving regret*

$$\sum_{t=1}^{T} f_t(x_t) - \min_{x \in P} \sum_{t=1}^{T} f_t(x) \leq O(L\sqrt{k}T^{3/4})$$

with at most T *calls to the weak separation oracle.*

Note that the gradient of the $\tilde{f}_t$ are easily computed via the formula $\nabla \tilde{f}_t(x) = \nabla f_t(x_t) + 4Lt^{-1/4}(x - x_1)/\sqrt{k}$, particularly because the gradient of the f_t need not be recomputed, so that we obtain a weak separation-based stochastic gradient descent algorithm, where we only have access to the f_t through a stochastic gradient oracle, while retaining all the favorable properties of the Frank–Wolfe algorithm with a convergence rate $O(T^{-1/4})$ (c.f., Garber and Hazan (2013)).

6. Non-polytopal domains

So far we have formulated our results for the polytopal case as most of the base methods that we lazify are usually formulated for polytopal domains. However, whenever a base method extends to general compact convex sets as domains then so does our lazification of the base method. In fact it is not even required to use vertices or extremal points as answers to either the LP oracle or weak-separation oracle calls; this is usually only required to obtain iterates as convex combinations of *extremal points* but it is not necessary for convergence.

Base methods that extend to general compact convex sets in particular include the vanilla Frank–Wolfe algorithm, the Away-Step Frank–Wolfe algorithm, and the Pairwise Frank–Wolfe algorithm. Note, however that for the Away-Step Frank–Wolfe algorithm and the Pairwise Frank–Wolfe algorithm (irrespective of lazification) it is not known whether a linear rate of convergence can be achieved for strongly convex functions over general compact convex sets. Base variants that do not readily apply to the non-polyhedral case are the variants in Garber and Meshi (2016) (see Section 3.2) and Garber and Hazan (2013) (see Section 3.3).

We further would like to mention, that often (but not always) for non-polyhedral domains the linear optimization oracle might be more expensive, so that lazification might offer attractive benefits in this case as the effect of caching and early termination might be even more pronounced. We present computational tests for non-polyedral domains for matrix completion, where the feasible domain is given via $\|X\|_* \leq R$, where $\|\cdot\|_*$ is the (non-polyhedral) nuclear norm (see Section 8.1).

7. Weak Separation through Augmentation

So far we realized the weak separation oracle via lazy optimization. We will now create a (weak) separation oracle for integral polytopes, employing an even weaker, so-called augmentation oracle, which only provides an improving solution but provides no guarantee with respect to optimality. We call this approach *lazy augmentation*. This is especially useful when a fast augmentation oracle is available or the vertices of the underlying polytope P are particularly sparse, i.e., $\|y_1 - y_2\|_1 \leq k \ll n$ for all $y_1, y_2 \in P$, where n is the ambient dimension of P. As before theoretical convergence rates are maintained.

For simplicity of exposition we restrict to 0/1 polytopes P here. For general integral polytopes, one considers a so-called *directed augmentation oracle*, which can be similarly linearized after splitting variables in positive and negative parts; we refer the interested reader to see Schulz and Weismantel (2002); Bodic et al. (2015) for an in-depth discussion.

Let k denote the ℓ_1-diameter of P. Upon presentation with a 0/1 solution x and a linear objective $c \in \mathbb{R}^n$, an augmentation oracle either provides an improving 0/1 solution $\bar{x}$ with $c\bar{x} < cx$ or asserts optimality for c:

Oracle 2 Linear Augmentation Oracle AUG_P(c, x)
Input: linear objective $c \in \mathbb{R}^n$, vertex $x \in P$
Output: vertex $\bar{x} \in P$ with $c\bar{x} < cx$ when exists, otherwise $\bar{x} = x$

Such an oracle is significantly weaker than a linear optimization oracle but also significantly easier to implement and much faster; we refer the interested reader to Grötschel and Lovász (1993); Schulz et al. (1995); Schulz and Weismantel (2002) for an extensive list of examples. While augmentation and optimization are polynomially equivalent (even for convex integer programming Oertel et al. (2014)) the current best linear optimization algorithms based on an augmentation oracle are slow for general objectives. While optimizing an *integral* objective $c \in \mathbb{R}^n$ needs $O(k \log\|c\|_\infty)$ calls to an augmentation oracle (see Schulz et al. (1995); Schulz and Weismantel (2002); Bodic et al. (2015)), a general objective function, such as the gradient in Frank–Wolfe algorithms has only an $O(kn^3)$ guarantee in terms of required oracle calls (e.g., via simultaneous diophantine approximations Frank and Tardos (1987)), which is not desirable for large n. In contrast, here we use an augmentation oracle to perform separation, without finding the optimal solution. Allowing a multiplicative error $K > 1$, we realize an augmentation-based weak separation oracle (see Algorithm 9), which decides given a linear objective function $c \in \mathbb{R}^n$, an objective value $\Phi > 0$, and a starting point $x \in P$, whether there is a $y \in P$ with $c(x - y) > \Phi/K$ or $c(x - y) \leq \Phi$ for all $y \in P$. In the former case, it actually provides a certifying $y \in P$, i.e., with $c(x - y) > \Phi/K$. Note that a constant accuracy K requires a linear number of oracle calls in the diameter k, e.g., $K = (1 - 1/e)^{-1} \approx 1.582$ needs at most $N \leq k$ oracle calls, which can be much smaller than the ambient dimension of the polytope.

At the beginning, in Line 2, the algorithm has to replace the input point x with an integral point x_0. If the point x is given as a convex combination of integral points, then a possible solution is to evaluate the objective c on these integral points, and choose x_0 the first one with $cx_0 \leq cx$. This can be easily arranged for Frank–Wolfe algorithms as they maintain convex combinations.

Proposition 15 *Assume $\|y_1 - y_2\|_1 \leq k$ for all $y_1, y_2 \in P$. Then Algorithm 9 is correct, i.e., it outputs either (1) $y \in P$ with $c(x - y) > \Phi/K$, or (2)* **false**. *In the latter case $c(x - y) \leq \Phi$ for all $y \in P$ holds. The algorithm calls AUG_P at most $N \leq \lceil \log(1 - 1/K)/\log(1 - 1/k) \rceil$ many times.*

Proof *First note that $(\mathbb{1} - 2x)v + \|x\|_1 = \|v - x\|_1$ for $x, v \in \{0,1\}^n$, hence Line 7 is equivalent to $x_i \leftarrow \text{AUG}_P(c + \frac{\Phi - c(x - x_{i-1})}{k}\|\cdot - x_{i-1}\|_1, x_{i-1})$.*

The algorithm obviously calls the oracle at most N times by design, and always returns a value, so we need to verify only the correctness of the returned value. We distinguish cases according to the output.

Algorithm 9 Augmenting Weak Separation $\mathrm{LPsep}_P(c, x, \Phi, K)$

Input: linear objective $c \in \mathbb{R}^n$, point $x \in P$, objective value $\Phi > 0$; accuracy $K > 1$
Output: Either (1) $y \in P$ vertex with $c(x-y) > \Phi/K$, or (2) **false**: $c(x-z) \leq \Phi$ for all $z \in P$.

1: $N \leftarrow \lceil \log(1-1/K)/\log(1-1/k) \rceil$
2: Choose $x_0 \in P$ vertex with $cx_0 \leq cx$.
3: **for** $i = 1$ **to** N **do**
4: **if** $c(x - x_{i-1}) \geq \Phi$ **then**
5: **return** x_{i-1}
6: **end if**
7: $x_i \leftarrow \mathrm{AUG}_P(c + \frac{\Phi - c(x-x_{i-1})}{k}(\mathbb{1} - 2x_{i-1}), x_{i-1})$
8: **if** $x_i = x_{i-1}$ **then**
9: **return false**
10: **end if**
11: **end for**
12: **return** x_N

Clearly, Line 5 always returns an x_{i-1} with $c(x - x_{i-1}) \geq \Phi > [1-(1-1/k)^N]\Phi$. When Line 9 is executed, the augmentation oracle just returned $x_i = x_{i-1}$, i.e., for all $y \in P$

$$cx_{i-1} \leq cy + \frac{\Phi - c(x-x_{i-1})}{k}\|y - x_{i-1}\|_1 \leq cy + \frac{\Phi - c(x-x_{i-1})}{k}k = c(y-x) + cx_{i-1} + \Phi,$$

so that $c(x-y) \leq \Phi$, as claimed.

Finally, when Line 12 is executed, the augmentation oracle has found an improving vertex x_i at every iteration, i.e.,

$$cx_{i-1} > cx_i + \frac{\Phi - c(x-x_{i-1})}{k}\|x_i - x_{i-1}\|_1 \geq cx_i + \frac{\Phi - c(x-x_{i-1})}{k},$$

using $\|x_i - x_{i-1}\|_1 \geq 1$ by integrality. Rearranging provides the convenient form

$$\Phi - c(x - x_i) < \left(1 - \frac{1}{k}\right)[\Phi - c(x - x_{i-1})],$$

which by an easy induction provides

$$\Phi - c(x - x_N) < \left(1 - \frac{1}{k}\right)^N [\Phi - c(x - x_0)] \leq \left(1 - \frac{1}{K}\right)\Phi,$$

i.e., $c(x - x_N) \geq \frac{\Phi}{K}$, finishing the proof. ■

8. Experiments

We implemented and compared the parameter-free variant of LCG (Algorithm 7) to the standard Frank–Wolfe algorithm (CG), then Algorithm 4 (LPCG) to the Pairwise Conditional Gradient algorithm (PCG) of Garber and Meshi (2016), as well as Algorithm 8 (LOCG) to the Online Frank–Wolfe algorithm (OCG) of Hazan and Kale (2012). While we did implement the Local Conditional Gradient algorithm of Garber and Hazan (2013) as well, the very large constants in the original algorithms made it impractical to run. Unless stated otherwise the weak separation oracle is implemented as sketched in Algorithm 2 through caching and early termination of the original LP oracle.

We have used $K = 1.1$ and $K = 1$ as multiplicative factors for the weak separation oracle; for the impact of the choice of K see Section 8.2.2. For the baseline algorithms we use inexact variants, i.e., we solve linear optimization problems only approximately. This is a significant speedup in favor of non-lazy algorithms at the (potential) cost of accuracy, while neutral to lazy optimization as it solves an even more relaxed problem anyways. To put things in perspective, the non-lazy baselines could not complete even a single iteration for a significant fraction of the considered problems in the given time frame if we were to exactly solve the linear optimization problems. In terms of using line search, for all tests we treated all algorithms equally: either *all* or *none* used line search. If not stated otherwise, we used (simple backtracking) line search.

The linear optimization oracle over $P \times P$ for LPCG was implemented by calling the respective oracle over P twice: once for either component. Contrary to the non-lazy version, the lazy algorithms depend on the initial upper bound Φ_0. For the instances that need a very long time to solve the (approximate) linear optimization even once, we used a binary search for Φ_0 for the lazy algorithms: starting from a conservative initial value, using the update rule $\Phi_0 \leftarrow \Phi_0/2$ until the separation oracle returns an improvement for the first time and then we start the algorithm with $2\Phi_0$, which is an upper bound on the Wolfe gap and hence also on the primal gap. This initial phase is also included in the reported wall-clock time. Alternatively, if the linear optimization was less time consuming we used a single (approximate) linear optimization at the start to obtain an initial bound on Φ_0 (see e.g., Section 4).

In some cases, especially when the underlying feasible region has a high dimension and the (approximate) linear optimization can be solved relatively fast compared to the cost of computing an inner product, we observed that the costs of maintaining the cache was very high. In these cases we reduced the cache size every 100 steps by keeping only the 100 points that were used the most so far. Both the number of steps and the approximate size of the cache were chosen arbitrarily, however 100 for both worked very well for all our examples. Of course there are many different strategies for maintaining the cache, which could be used here and which could lead to further improvements in performance.

The stopping criteria for each of the experiments was a given wall clock time limit in seconds. The time limit was enforced separately for the main code and the oracle code, so in some cases the actual time used can be larger, when the last oracle call started before the time limit was reached and took longer than the time left.

We implemented all algorithms in Python 2.7 with critical functions *cythonized* for performance employing Numpy. We used these packages from the Anaconda 4.2.0 distribution as well as Gurobi 7.0 Gurobi Optimization (2016) as a black box solver for the linear optimization oracle. The weak separation oracle was implemented via a callback function to stop linear optimization as soon as a good enough feasible solution has been found in a schema as outlined in Algorithm 2. The parameters for Gurobi were kept at their

default settings except for enforcing the time limit of the tests and setting the acceptable duality gap to 10%, allowing Gurobi to terminate the linear optimization early avoiding the expensive *proof* of optimality. This is used to realize the inexact versions of the baseline algorithms. All experiments were performed on a 16-core machine with Intel Xeon E5-2630 v3 @ 2.40GHz CPUs and 128GB of main memory. While our code does not explicitly use multiple threads, both Gurobi and the numerical libraries use multiple threads internally.

8.1. Computational results

We performed computational tests on a large variety of different problems that are instances of the three machine learning tasks *video colocalization*, *matrix completion*, and *structured regression*.

Video colocalization. Video colocalization is the problem of identifying objects in a sequence of multiple frames in a video. In Joulin et al. (2014) it is shown that video colocalization can be reduced to optimizing a quadratic objective function over a flow or a path polytope, which is the problem we are going to solve. The resulting linear program is an instance of the minimum-cost network flow problem, see (Joulin et al., 2014, Eq. (3)) for the concrete linear program and more details. The quadratic functions are of the form $\|Ax - b\|^2$ where we choose the non-zero entries in A according to a density parameter at random and then each of these entries to be $[0, 1]$-uniformly distributed, while b is chosen as a linear combination of the columns of A with random multipliers from $[0, 1]$. For some of the instances we also use $\|x - b\|^2$ as the objective function with $b_i \in [0, 1]$ uniformly at random.

Matrix completion. The formulation of the matrix completion problem we are going to use is the following:

$$\min_X \sum_{(i,j)\in\Omega} |X_{i,j} - A_{i,j}|^2 \qquad \text{s.t.} \quad \|X\|_* \leq R, \tag{6}$$

where $\|\cdot\|_*$ denotes the nuclear norm, i.e., $\|A\|_* = \operatorname{Tr}(\sqrt{A^t A})$. The set Ω, the matrix A and R are given parameters. Similarly to Lan and Zhou (2014) we generate the $m \times n$ matrix A as the product of A_L of size $m \times r$ and A_R of size $r \times n$. The entries in A_L and A_R are chosen from a standard Gaussian distribution. The set Ω is chosen uniformly of size $s = \min\{5r(m+n-r), \lceil 0.99mn \rceil\}$. The linear optimization oracle is implemented in this case by a singular value decomposition of the linear objective function and we essentially solve the LP to (approximate) optimality. The matrix completion tests will only demonstrate the impact of caching solutions. Note that this test is also informative as due to the 'roundness' of the feasible region the solution of the actual LP oracle will induce a direction that is equal to the true gradient and as such it provides insight into how much per-iteration progress is lost due to working with gradient approximations from the weak separation oracle.

Structured regression. The structured regression problem consists of solving a quadratic function of the form $\|Ax - b\|^2$ over some structured feasible set or a polytope P, i.e., we solve $\min_{x\in P} \|Ax - b\|^2$. We construct the objective functions in the same way as for the video colocalization problem.

Tests. In the following two sections we will present our results for various problems grouped by the versions of the considered algorithms. Every figure contains two columns, each containing one experiment. We use different measures to report performance: we report progress of loss or function value in wall-clock time in the first row (including time spent by the oracle), in the number of iterations in the second row, and in the number of linear optimization calls in the last row. Obviously, the latter only makes sense for the lazy algorithms. In some other cases we report in another row the dual bound or Wolfe gap in wall-clock time. The red line denotes the non-lazy algorithm and the green line denotes the lazy variants. For each experiment we also report the cache hit rate, which is the number of oracle calls answered with a point from the cache over all oracle calls given in percent.

While we found convergence rates in the number of iterations quite similar (as expected!), we consistently observe a significant speedup in wall-clock time. In particular for many large-scale or hard combinatorial problems, lazy algorithms performed several thousand iterations whereas the non-lazy versions completed only a handful of iterations due to the large time spent approximately solving the linear optimization problem. The observed cache hit rate was at least 90% in most cases, and often even above 99%.

Compared to the non-lazy variants, the lazy variants might use weaker descent directions (due to employing the weak-separation oracle instead of the LP oracle), and hence one expects that the lazy algorithms in general require more iterations despite being faster in wall-clock time. However, the lazy and non-lazy algorithms usually generate different sequences of iterates, and hence the lazy algorithms may converge faster even in the number of iterations by chance; this is even expected in a small number of cases by the law of large numbers. This happens for example in Figures 3 and 14.

8.1.1. Offline Results

We describe the considered instances in the offline case separately for the vanilla Frank–Wolfe method and the Pairwise Conditional Gradient method.

Vanilla Frank–Wolfe Method We tested the vanilla Frank–Wolfe algorithm on the six video colocalization instances with underlying path polytopes from `http://lime.cs.elte.hu/~kpeter/data/mcf/netgen/` (Figure 1). In these instances we additionally report the dual bound or Wolfe gap in wall clock time. We further tested the vanilla Frank–Wolfe algorithm on eight instances of the matrix completion problem generated as described above, for which we did not use line search; the parameter-free lazy variant is run with approximate minimization as described in Remark 11, the others use their respective standard step sizes. We provide the used parameters for each example in the figures below (Figures 2 and 3). The last tests for this version were performed on three instances of the structured regression problem, two with the feasible region containing flow-based formulations of Hamiltonian cycles in graphs (Figure 4), and further tests on two spanning tree instances of different size (Figure 5).

We observed a significant speedup of LCG compared to CG, due to the faster iteration of the lazy algorithm.

Pairwise Conditional Gradient Algorithm As we inherit structural restrictions of PCG on the feasible region, the problem repertoire is limited in this case. We tested the

Pairwise Conditional Gradient algorithm on the structured regression problem with feasible regions from the MIPLIB instances `eil33-2`, `air04` (Figure 6).

Again similarly to the vanilla Frank–Wolfe algorithm, we observed a significant improvement in wall-clock time of LPCG compared to CG, due to the faster iteration of the lazy algorithm.

8.1.2. Online Results

Additionally to the quadratic objective functions above we tested the online version on random linear functions $cx + b$ with $c \in [-1, +1]^n$ and $b \in [0, 1]$. For online algorithms, each experiment used a random sequence of 100 different random loss functions. In every figure the left column uses linear loss functions, while the right one uses quadratic loss functions over the same polytope. As customary, we did not use line search here but used the respective prescribed step sizes.

As an instance of the structured regression problem we used the standard formulation of the cut polytope for graphs with 28 nodes as the feasible region (Figure 7). We also tested our algorithm on the quadratic unconstrained boolean optimization (QUBO) instances defined on Chimera graphs Dash (2013), which are available at `http://researcher.watson.ibm.com/researcher/files/us-sanjeebd/chimera-data.zip`. The instances are relatively hard albeit their rather small size and in general the problem is NP-hard. (Figure 8).

One instance of the video colocalization problem uses a path polytope from `http://lime.cs.elte.hu/~kpeter/data/mcf/netgen/` that was generated with the `netgen` graph generator (Figure 9). Most of these instances are very large-scale minimum cost flow instances with several tens of thousands nodes in the underlying graphs, therefore solving still takes considerable time despite the problem being in P. Finally, for the spanning tree problem, we used the well-known extended formulation with $O(n^3)$ inequalities for an n-node graph. We considered graphs with 25 nodes (Figures 10).

We observed that similarly to the offline case while OCG and LOCG converge comparably in the number of iterations, the lazy LOCG performed significantly more iterations; for hard problems, where linear optimization is costly and convergence requires a large number of iterations, this led LOCG converging much faster in wall-clock time. In extreme cases OCG could not complete even a single iteration. This is due to LOCG only requiring *some* good enough solution, whereas OCG requires a stronger guarantee. This is reflected in faster oracle calls for LOCG.

Weak-Separation via Augmentation As discussed in Section 7 in some cases it can be very beneficial to realize the weak-separation oracle by means of augmentation instead of linear optimization. To verify this we implemented a weak-separation oracle via an augmentation oracle for quadratic unconstrained boolean optimization (QUBO) instances (see above for details). For those instances, the primal heuristics of Gurobi (or CPLEX) can find improving solutions very fast due to the structure of the instances. We obtain the augmentation oracle then by exiting the Gurobi call as soon as the first improving solution is found. For comparability, apart from using the augmentation oracle we used the same configuration as above. The results can be found in Figure 11, where we can observe a significant speedup of the lazified variant of OCG using augmentation over the base OCG algorithm. Also observe that this is in contrast to Figure 8, where the advantage of LOCG

(without augmentation) over OCG was not that pronounced. To provide further insight in this case we also report *oracle time*, which denotes actual time spent in the augmentation oracle, which is minimal in both cases as can be seen.

8.2. Performance improvements, parameter sensitivity, and tuning

8.2.1. Effect of caching

As mentioned before, lazy algorithms have two improvements: caching and early termination. Here we depict the effect of caching in Figure 12, comparing OCG (no caching, no early termination), LOCG (caching and early termination) and LOCG (only early termination) (see Algorithm 8). We did not include a caching-only OCG variant, because caching without early termination does not make much sense: in each iteration a new linear optimization problem has to be solved; previous solutions can hardly be reused as they are unlikely to be optimal for the new linear optimization problem.

8.2.2. Effect of K

If the parameter K of the oracle can be chosen, which depends on the actual oracle implementation, then we can increase K to bias the algorithm towards performing more positive calls. At the same time the steps get shorter. As such there is a natural trade-off between the cost of many positive calls vs. a negative call. We depict the impact of the parameter choice for K in Figure 13.

8.2.3. Parameter-free vs. textbook variant

For illustrative purposes, we compare the textbook variant of the lazy conditional gradient (Algorithm 3) with its parameter-free counterpart (Algorithm 7) in Figure 14. The parameter-free variant outperforms the textbook variant due to the active management of Φ combined with line search.

Similar parameter-free variants can be derived for the other algorithms; see discussion in Section 4.

9. Final Remarks

As discussed above in Section 6, if a given baseline algorithm works over general compact convex sets P, then so does the lazified version. In fact, as the lazified algorithm runs, it produces a polyhedral approximation of the set P with very few vertices (subject to optimality vs. sparsity tradeoffs; see (Jaggi, 2013, Appendix C)).

Moreover, the weak separation oracle does not need to return extreme points. All algorithms also work with maximal solutions that are not necessarily extremal (e.g., lying in a higher-dimensional face). However, in that case we lose the desirable property that the final solution is a sparse convex combination of extreme points (typically vertices in the polyhedral setup).

We would also like to briefly address potential downsides of our approach. In fact, we believe the right perspective is the following: when using the lazy oracle over the LP oracle, we obtain potentially *weaker* approximations $v_t - x_t$ of the true gradient $\nabla f(x_t)$ compared

to solving the actual LP, but the computation might be much faster. This is the tradeoff that one has to consider: working with weaker approximations (which implies potentially less progress per iteration) vs. potentially significantly faster computation of the approximations. If solving the LP is expensive, then lazification will be usually very beneficial, if the LP is very cheap as in the case of $P = [0, 1]^n$ or $P = \Delta_n$ being the probability simplex, then lazification might be slower.

A related remark in this context is that once the lazified algorithm has obtained vertices $x_1, \ldots, x_m$ of P, so that the minimizer x^* of f satisfies $x^* \in \operatorname{conv}\{x_1, \ldots, x_m\}$, then from that point onwards no actual calls to the true LP oracle have to be performed anymore for primal progress and the algorithm will only use cache calls; the only remaining true LP calls are at most a logarithmic number for dual progress updates of the Φ_t.

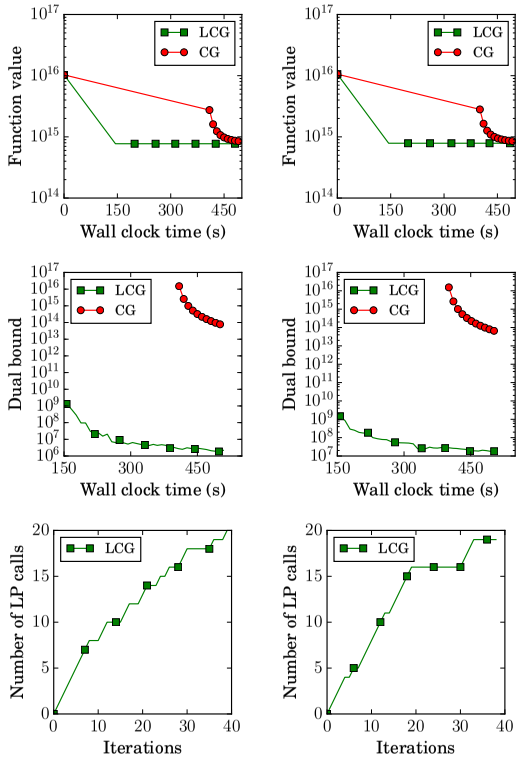

Figure 1: LCG vs. CG on large netgen instances `netgen 16a` (left) and `netgen 16b` (right) with quadratic objective functions. In both cases the difference in function value between the two versions of the algorithm is large. In the dual bound the performance of the lazy version is multiple orders of magnitude better than the performance of the non-lazy counterpart. The cache hit rates for these two instances are lower due to the high dimension of the polytope.

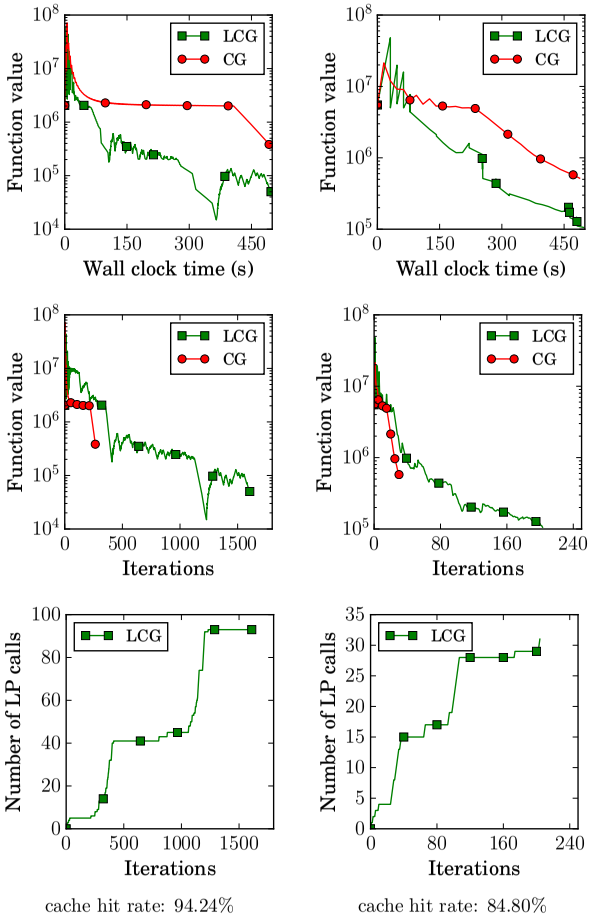

Figure 2: LCG vs. CG on two matrix completion instances. We solve the problem as given in Equation (6) with the parameters $n = 3000$, $m = 1000$, $r = 10$ and $R = 30000$ for the left instance and $n = 10000$, $m = 100$, $r = 10$ and $R = 10000$ for the right instance. In both cases the lazy version is slower in iterations, however significantly faster in wall clock time. Note that we used the short-step rule for step sizes for both algorithms as line search for matrix completion is very expensive.

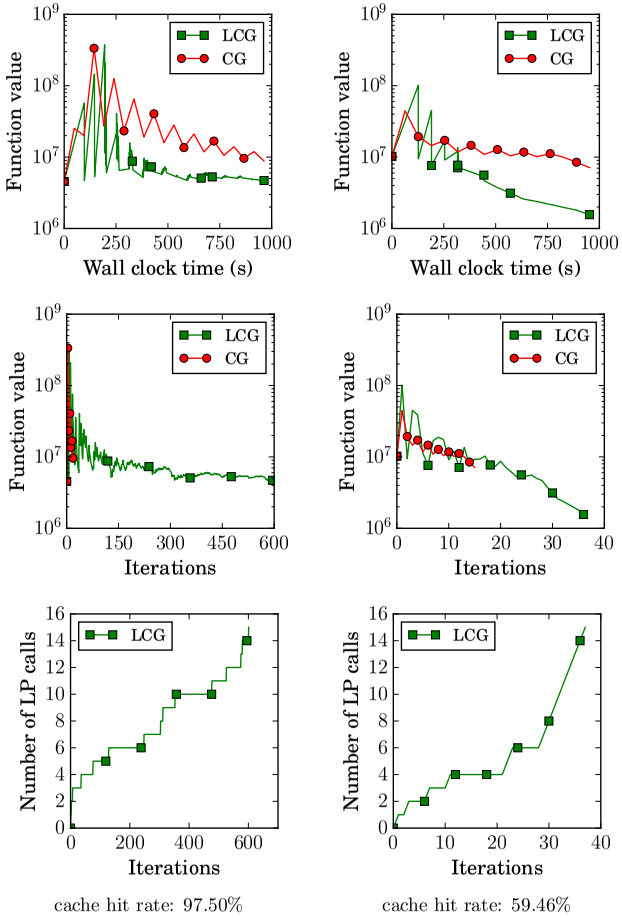

Figure 3: LCG vs. CG on two matrix completion instances. The parameters for Equation (6) are given by $n = 5000$, $m = 4000$, $r = 10$ and $R = 50000$ for the left instance and $n = 100$, $m = 20000$, $r = 10$ and $R = 15000$ for the right instance. In both of these cases the performance of the lazy and the non-lazy version are comparable in iterations, however in wall clock time the lazy version reaches lower function values faster. Note that we used the short-step rule for step sizes for both algorithms as line search for matrix completion is very expensive.

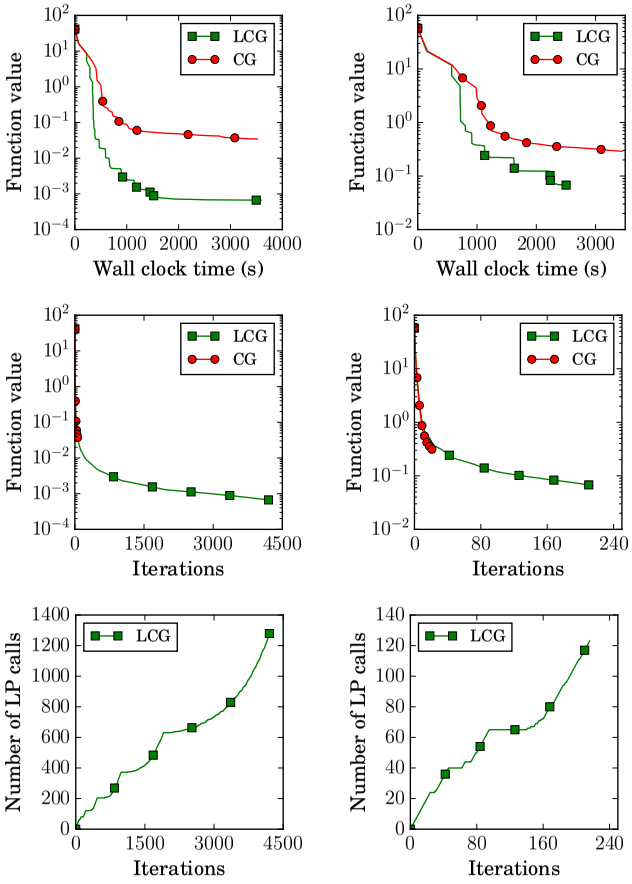

Figure 4: LCG vs. CG on structured regression problems with feasible regions being a TSP polytope over 11 nodes (left) and 12 nodes (right). In both cases LCG is significantly faster in wall-clock time.

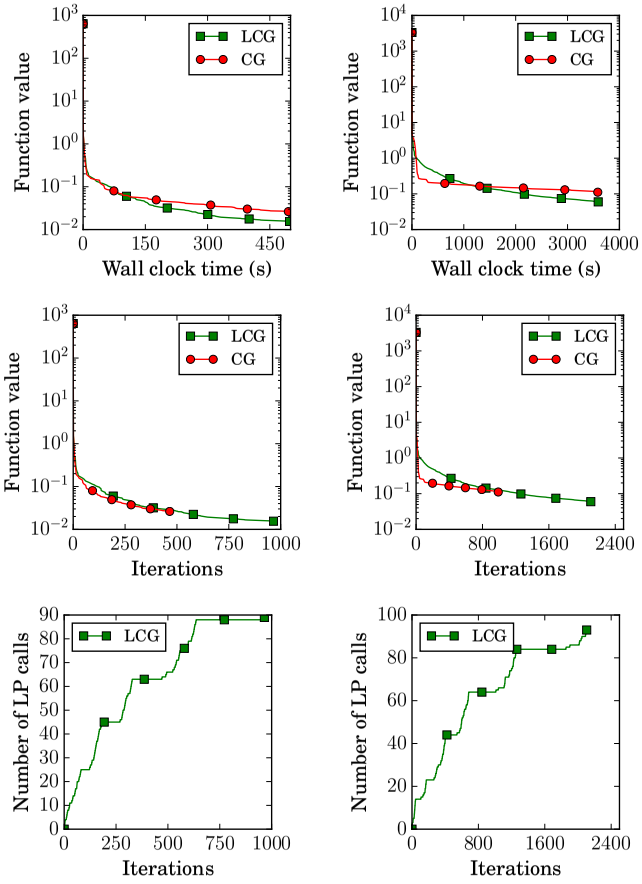

Figure 5: LCG vs. CG on structured regression instances with extended formulation of the spanning tree problem on a 10 node graph on the left and a 15 node graph on the right.

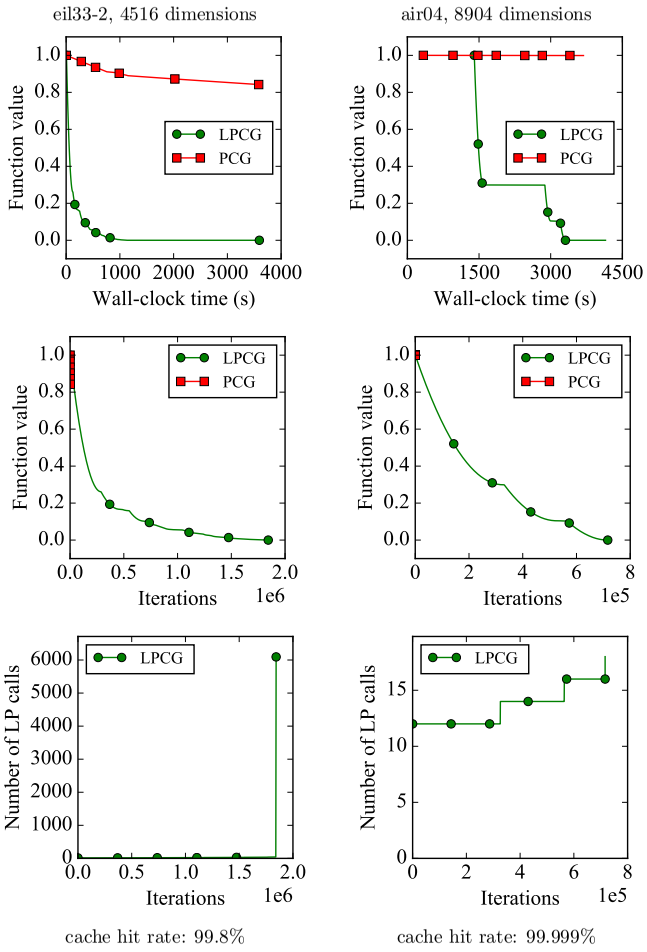

Figure 6: LPCG vs. PCG on two MIPLIB instances `eil33-2` and `air04`. LPCG converges very fast, making millions of iterations with a relatively few oracle calls, while PCG completed only comparably few iterations due to the time-consuming oracle calls. This clearly illustrates the advantage of lazy methods when the cost of linear optimization is non-negligible. On the left, when reaching ε-optimality, LPCG performs many (negative) oracle calls to (re-)prove optimality; at that point one might opt for stopping the algorithm. On the right LPCG needed a rather long time for the initial bound tightening of Φ_0, before converging significantly faster than PCG.

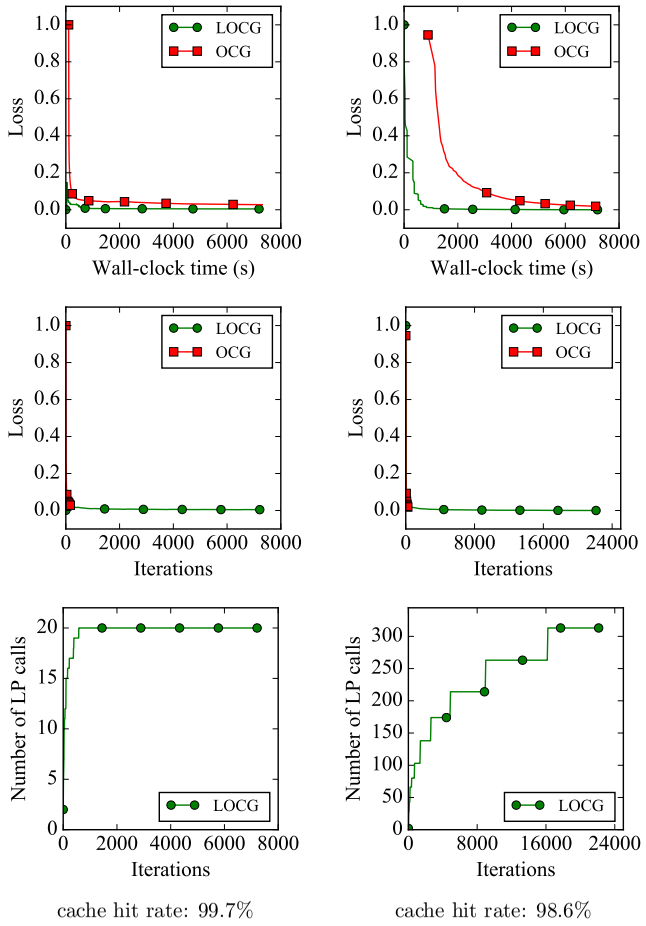

Figure 7: LOCG vs. OCG over cut polytope for a 28-node graph. As for the smaller problem, this also illustrates the advantage of lazy algorithms when linear optimization is expensive. Again, LOCG needed no oracle calls after a small initial amount of time.

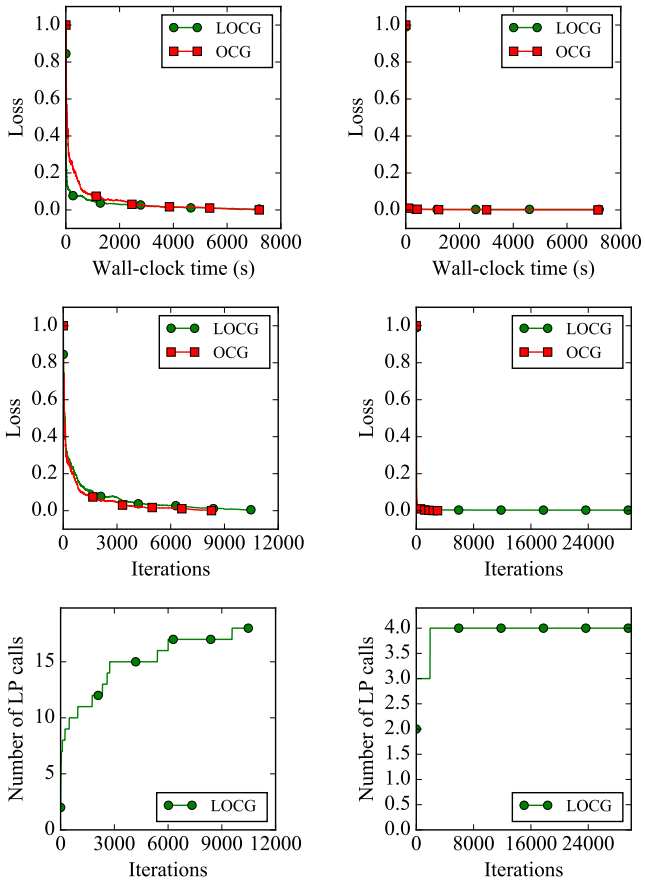

Figure 8: LOCG vs. OCG on a large QUBO instance. Both algorithms converge fast to the optimum. Interestingly, LOCG only performs 4 LP calls.

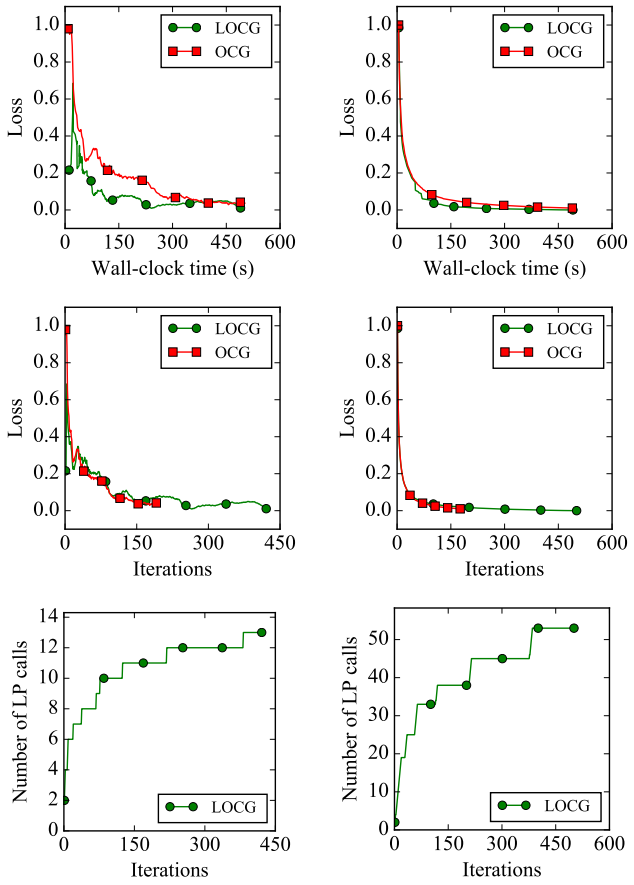

Figure 9: LOCG vs. OCG over a path polytope. Similar convergence rate in the number of iterations, but significant difference in terms of wall-clock time.

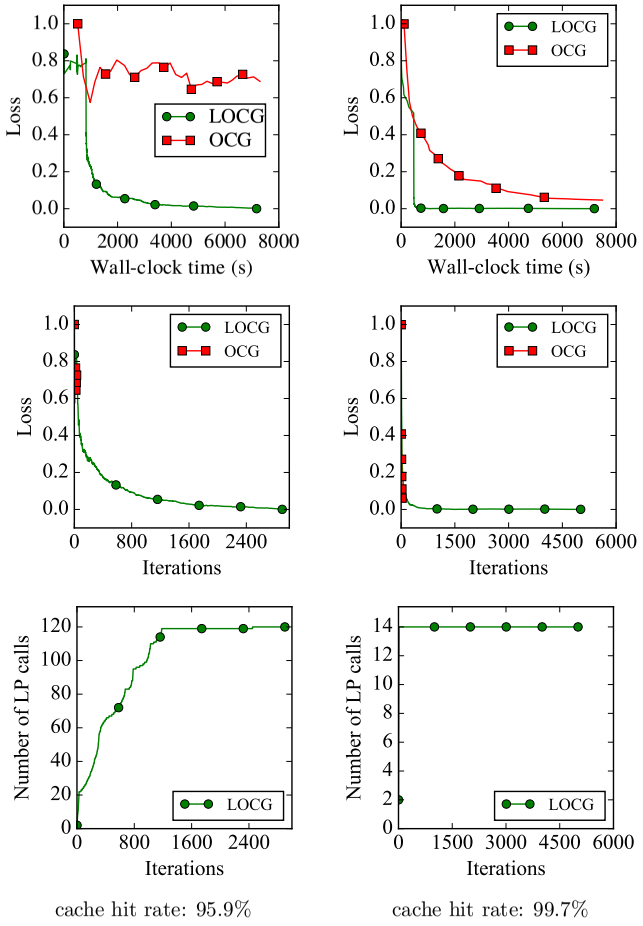

Figure 10: LOCG vs. OCG over a spanning tree instance for a 25-node graph. On the left, early fluctuation can be observed, bearing no consequence for later convergence rate. OCG did not get past this early stage. In both cases LOCG converges significantly faster.

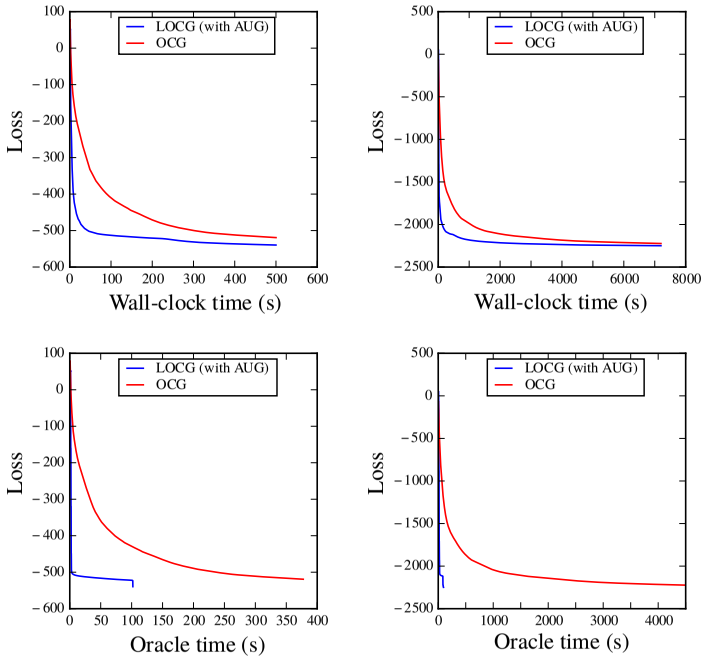

Figure 11: Lazy OCG (with augmentation) vs. OCG on two QUBO instances. In both cases the lazy variant together with augmentation significantly outperforms OCG.

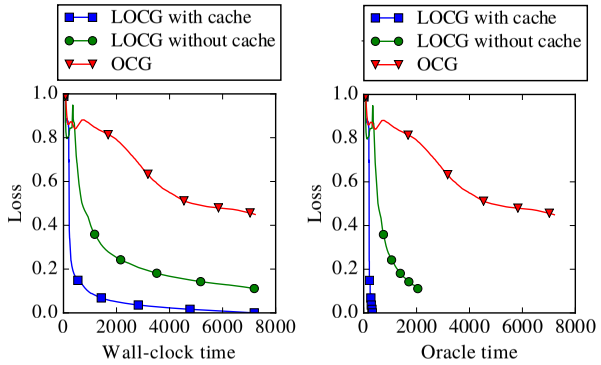

Figure 12: Performance gain due to caching and early termination for online optimization over a maximum cut problem with linear losses. The red line is the OCG baseline, the green one is the lazy variant using only early termination, and the blue one uses caching and early termination. Left: loss vs. wall-clock time. Right: loss vs. total time spent in oracle calls. Time limit was 7200 seconds. Caching allows for a significant improvement in loss reduction in wall-clock time. The effect is even more obvious in oracle time as caching cuts out a large number of oracle calls.

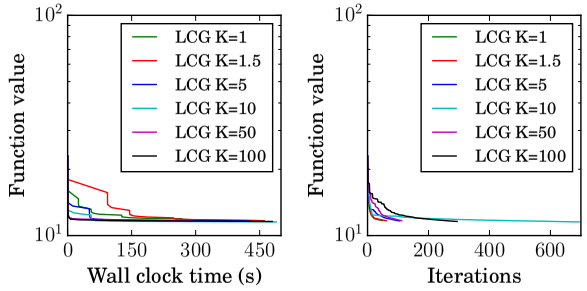

Figure 13: Impact of the oracle approximation parameter K depicted for the Lazy CG algorithm. We can see that increasing K leads to a deterioration of progress in iterations but improves performance in wall-clock time. The behavior is similar for other algorithms.

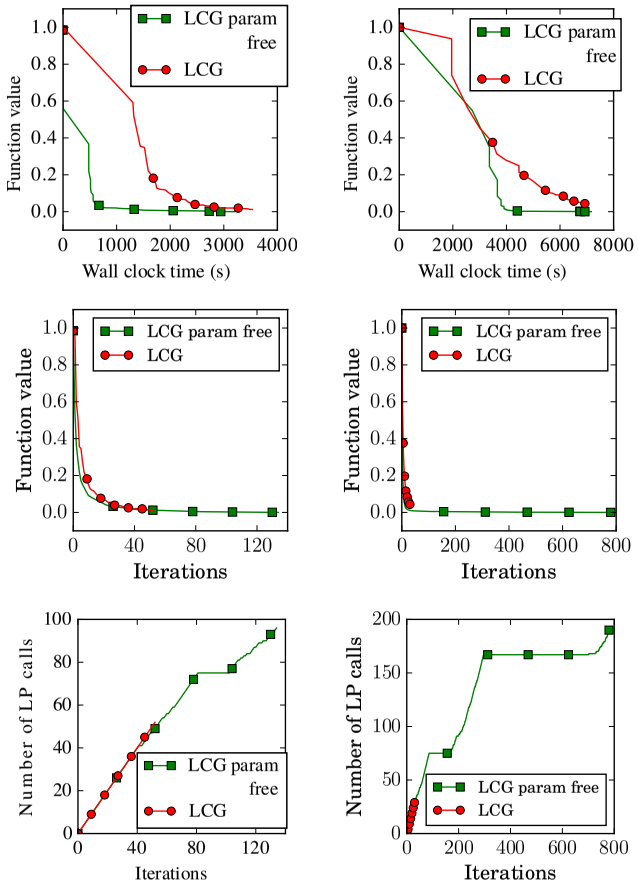

Figure 14: Comparison of the 'textbook' variant of the Lazy CG algorithm (Algorithm 3) vs. the Parameter-free Lazy CG (Algorithm 7) depicted for two sample instances to demonstrate behavior. The parameter-free variant usually has a slightly improved behavior in terms of iterations and a significantly improved behavior in terms of wall-clock performance. In particular, the parameter-free variant can execute significantly more oracle calls, due to the Φ-halving strategy and the associated bounded number of negative calls (see Theorem 9).

Abstract

Performance of distributed optimization and learning systems is bottlenecked by "straggler" nodes and slow communication links, which significantly delay computation. We propose a distributed optimization framework where the dataset is "encoded" to have an overcomplete representation with built-in redundancy, and the straggling nodes in the system are dynamically treated as missing, or as "erasures" at every iteration, whose loss is compensated by the embedded redundancy. For quadratic loss functions, we show that under a simple encoding scheme, many optimization algorithms (gradient descent, L-BFGS, and proximal gradient) operating under data parallelism converge to an approximate solution even when stragglers are ignored. Furthermore, we show a similar result for a wider class of convex loss functions when operating under model parallelism. The applicable classes of objectives covers several popular learning problems such as linear regression, LASSO, support vector machine, collaborative filtering, and generalized linear models including logistic regression. These convergence results are deterministic, *i.e.*, they establish sample path convergence for arbitrary sequences of delay patterns or distributions on the nodes, and are independent of the tail behavior of the delay distribution. We demonstrate that equiangular tight frames have desirable properties as encoding matrices, and propose efficient mechanisms for encoding large-scale data. We implement the proposed technique on Amazon EC2 clusters, and demonstrate its performance over several learning problems, including matrix factorization, LASSO, ridge regression and logistic regression, and compare the proposed method with uncoded, asynchronous, and data replication strategies.

Keywords: Distributed optimization, straggler mitigation, proximal gradient, coordinate descent, restricted isometry property

1. Introduction

Solving learning and optimization problems at present scale often requires parallel and distributed implementations to deal with otherwise infeasible computational and memory requirements. However, such distributed implementations often suffer from system-level issues such as slow communication and unbalanced computational nodes. The runtime of many distributed implementations are therefore throttled by that of a few slow nodes, called stragglers, or a few slow communication links, whose delays significantly encumber the overall learning task Dean and Barroso (2013). In this paper, we propose a distributed optimization framework based on proceeding with each iteration without waiting for the stragglers, and encoding the dataset across nodes to add redundancy in the system in order to mitigate the resulting potential performance degradation due to lost updates.

We consider the master-worker architecture, where the dataset is distributed across a set of worker nodes which directly communicate to a master node to optimize a global objective. The encoding framework consists of an efficient linear transformation (coding) of the dataset that results in an overcomplete representation, which is then partitioned and distributed across the worker nodes. The distributed optimization algorithm is then performed directly on the encoded data, with all worker nodes oblivious to the encoding scheme, *i.e.*, no explicit decoding of the data is performed, and nodes simply solve the effective optimization problem on the encoded data. In order to mitigate the effect of stragglers, in each iteration, the master node only waits for the first k updates to arrive from the m worker nodes (where $k \leq m$ is a design parameter) before moving on; the remaining $m - k$ node results are treated as missing (erasures), whose loss is compensated by the data encoding.

The framework is applicable to both the data parallelism and model parallelism paradigms of distributed learning, and can be applied to distributed implementations of several popular optimization algorithms, including gradient descent, limited-memory-BFGS, proximal gradient, and block coordinate descent. Under data parallelism, we focus on quadratic loss functions with arbitrary convex regularization terms or arbitrary convex constraint sets, whereas for model parallelism, we consider general convex objectives where the vector of parameters act linearly on input data, such as logistic regression. We show that if the linear transformation is designed to satisfy a spectral condition resembling the restricted isometry property, the iterates resulting from the encoded version of these algorithms deterministically converge to an exact solution for the case of model paralellism, and an approximate one under data parallelism, where the approximation quality only depends on the properties of encoding and the parameter k. These convergence guarantees are deterministic in the sense that they hold for any pattern of node delays, *i.e.*, even if an adversary chooses which nodes to delay at every iteration. In addition, the convergence behavior is independent of the tail behavior of the node delay distribution, and can tolerate unbounded delay. Such a worst-case guarantee is not possible for the asynchronous versions of these algorithms, whose convergence rates deteriorate with increasing node delays. We point out that our approach is particularly suited to computing networks with a high degree of variability and

unpredictability, where a large number of nodes can delay their computations for arbitrarily long periods of time.

Our contributions are as follows: (i) we propose the encoded distributed optimization framework, and prove deterministic convergence guarantees under this framework for gradient descent, L-BFGS, proximal gradient and block coordinate descent algorithms; (ii) we provide three classes of encoding matrices, and discuss their properties, and describe how to efficiently encode with such matrices on large-scale data; (iii) we implement the proposed technique on Amazon EC2 clusters and compare their performance to uncoded, replication, and asynchronous strategies for problems such as ridge regression, collaborative filtering, logistic regression, and LASSO. In these tasks we show that in the presence of stragglers, the technique can result in significant speed-ups (specific amounts depend on the underlying system, and examples are provided in Section 5) compared to the uncoded case when we wait for all workers in each iteration, to achieve the same test error.

Related work. The approaches to mitigating the effect of stragglers can be broadly classified into three categories: replication-based techniques, asynchronous optimization, and coding-based techniques.

Replication-based techniques consist of either re-launching a certain task if it is delayed, or pre-emptively assigning each task to multiple nodes and moving on with the copy that completes first. Such techniques have been proposed and analyzed in Gardner et al. (2015); Ananthanarayanan et al. (2013); Shah et al. (2016); Wang et al. (2015); Yadwadkar et al. (2016), among others. Our framework does not preclude the use of such system-level strategies, which can still be built on top of our encoded framework to add another layer of robustness against stragglers. However, it is not possible to achieve the worst-case guarantees provided by encoding with such schemes, since it is still possible for both replicas to be delayed.

Perhaps the most popular approach in distributed learning to address the straggler problem is asynchronous optimization, where each worker node asynchronously pushes updates to and fetches iterates from a parameter server independently of other workers, hence the stragglers do not hold up the entire computation. This approach was studied in Recht et al. (2011); Agarwal and Duchi (2011); Dean et al. (2012); Li et al. (2014) (among many others) for the case of data parallelism, and Liu et al. (2015); You et al. (2016); Peng et al. (2016); Sun et al. (2017) for coordinate descent methods (model parallelism). Although this approach has been largely successful, all asynchronous convergence results depend on either a hard bound on the allowable delays on the updates, or a bound on the moments of the delay distribution, and the resulting convergence rates explicitly depend on such bounds. In contrast, our framework allows for completely unbounded delays. Further, as in the case of replication, one can still consider asynchronous strategies on top of the encoding, although we do not focus on such techniques within the scope of this paper.

A more recent line of work that address the straggler problem is based on coding-theory-inspired techniques Tandon et al. (2017); Lee et al. (2018); Dutta et al. (2016); Karakus et al. (2017a,b); Yang et al. (2017); Halbawi et al. (2017); Reisizadeh et al. (2017). Some of these works focus exclusively on coding for distributed linear operations, which are considerably simpler to handle. The works in Tandon et al. (2017); Halbawi et al. (2017) propose coding techniques for distributed gradient descent that can be applied more generally. However,

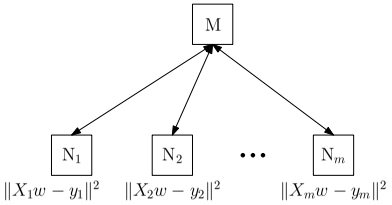

Figure 1: Uncoded distributed optimization with data parallelism, where X and y are partitioned as $X = [X_i]_{i\in[m]}$ and $y = [y_i]_{i\in[m]}$.

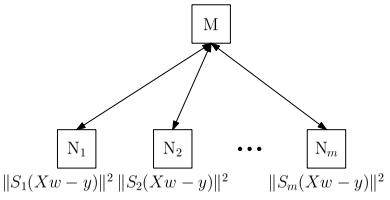

Figure 2: Encoded setup with data parallelism, where node i stores (S_iX, S_iy), instead of (X_i, y_i). The uncoded case corresponds to $S = I$.

the approach proposed in these works require a redundancy factor of $r + 1$ in the code, to mitigate r stragglers. Our approach relaxes the exact gradient recovery requirement of these works, consequently reducing the amount of redundancy required by the code.

The proposed technique, especially under data parallelism, is also closely related to randomized linear algebra and sketching techniques in Mahoney et al. (2011); Drineas et al. (2011); Pilanci and Wainwright (2015), used for dimensionality reduction of large convex optimization problems. The main difference between this literature and the proposed coding technique is that the former focuses on reducing the problem dimensions to lighten the computational load, whereas encoding *increases* the dimensionality of the problem to provide robustness. As a result of the increased dimensions, coding can provide a much closer approximation to the original solution compared to sketching techniques. In addition, unlike these works, our model allows for an arbitrary convex regularizer in addition to the encoded loss term.

2. Encoded Distributed Optimization

We will use the notation $[j] = \{i \in \mathbb{Z} : 1 \leq i \leq j\}$. All vector norms refer to 2-norm, and all matrix norms refer to spectral norm, unless otherwise noted. The superscript ^{c} will refer to complement of a subset, *i.e.*, for $A \subseteq [m]$, $A^c = [m]\backslash A$. For a sequence of matrices $\{M_i\}$ and a set A of indices, we will denote $[M_i]_{i\in A}$ to mean the matrix formed by stacking the matrices M_i vertically. The main notation used throughout the paper is provided in Table 1.

We consider a distributed computing network where the dataset $\{(x_i, y_i)\}_{i=1}^n$ is stored across a set of m worker nodes, which directly communicate with a single master node. In practice the master node can be implemented using a fully-connected set of nodes, but this can still be abstracted as a single master node.

It is useful to distinguish between two paradigms of distributed learning and optimization; namely, data parallelism, where the dataset is partitioned across data samples, and model parallelism, where it is partitioned across features (see Figures 1 and 3). We will describe these two models in detail next.

Notation	Explanation
$[j]$	The set $\{i \in \mathbb{Z} : 1 \leq i \leq j\}$
m	Number of worker nodes
n, p	The dimensions of the data matrix $X \in \mathbb{R}^{n\times p}$, vector $y \in \mathbb{R}^{n\times 1}$
k_t	Number of updates the master node waits for in iteration t, before moving on
η_t	Fraction of nodes waited for in iteration, *i.e.*, $\eta_t = \frac{k_t}{m}$
A_t	The subset of nodes $[m]$ which send the fastest k_t updates at iteration t
$f(w), \widetilde{f}(w)$	The original and encoded objectives, respectively, under data parallelism
$g(w) = \phi(Xw)$	The original objective under model parallelism
$\widetilde{g}(v) = \phi(XS^\top v)$	The encoded objective under model parallelism
$h(w)$	Regularization function (potentially non-smooth)
ν	Strong convexity parameter
L	Smoothness parameter for $h(w)$ (if smooth), and $g(w)$
λ	Regularization parameter
Ψ_t	Mapping from gradient updates to step $\{\nabla f_i(t)\}_{i\in A_t} \mapsto d_t$
d_t	Descent direction chosen by the algorithm
α_t, α	Step size
M, μ	Largest and smallest eigenvalues of $X^\top X$, respectively
β	Redundancy factor ($\beta \geq 1$)
S	Encoding matrix with dimensions $\beta n \times n$
S_i	ith row-block of S, corresponding to worker i
S_A	Submatrix of S formed by $\{S_i\}_{i\in A\subseteq[m]}$ stacked vertically

Table 1: Notation used in the paper.

2.1. Data parallelism

We focus on objectives of the form

$$f(w) = \frac{1}{2n}\|Xw - y\|^2 + \lambda h(w), \tag{1}$$

where $X \in \mathbb{R}^{n\times p}$ and $y \in \mathbb{R}^n$ are the data matrix and data vector, respectively. We assume each row of X corresponds to a data sample, and the data samples and response variables can be horizontally partitioned as $X = \begin{bmatrix} X_1^\top & X_2^\top & \cdots & X_m^\top \end{bmatrix}^\top$ and $y = \begin{bmatrix} y_1^\top & y_2^\top & \cdots & y_m^\top \end{bmatrix}^\top$. In the uncoded setting, machine i stores the row-block X_i (Figure 1). We denote the largest and smallest eigenvalues of $X^\top X$ with $M > 0$, and $\mu \geq 0$, respectively. We assume $\lambda \geq 0$, and $h(w) \geq 0$ is a convex, extended real-valued function of w that does not depend on data. Since $h(w)$ can take the value $h(w) = \infty$, this model covers arbitrary convex constraints on the optimization. Several important learning problems, such as ridge regression, LASSO, collaborative filtering (solved via alternating minimization), and support vector machine[1] fall within this formulaton.

The encoding consists of solving the proxy problem

$$\widetilde{f}(w) = \frac{1}{2n}\|S\left(Xw - y\right)\|^2 + \lambda h(w) = \frac{1}{2n}\sum_{i=1}^{m} \underbrace{\|S_i\left(Xw - y\right)\|^2}_{f_i(w)} + \lambda h(w), \tag{2}$$

1. The dual formulation of SVM with squared hinge loss can be solved as a quadratic minimization over the simplex (Jaggi (2013); Li et al. (2009))

instead, where $S \in \mathbb{R}^{\beta n\times n}$ is a designed encoding matrix with redundancy factor $\beta \geq 1$, partitioned as $S = \begin{bmatrix} S_1^\top & S_2^\top & \cdots & S_m^\top \end{bmatrix}^\top$ across m machines. Based on this partition, worker node i stores (S_iX, S_iy), and operates to solve the problem (2) in place of (1) (Figure 2). We will denote $\hat{w} \in \arg\min \widetilde{f}(w)$, and $w^* \in \arg\min f(w)$.

In general, the regularizer $h(w)$ can be non-smooth. We will say that $h(w)$ is L-smooth if $\nabla h(w)$ exists everywhere and satisfies

$$h(w') \leq h(w) + \langle \nabla h(w), w' - w\rangle + \frac{L}{2}\|w' - w\|^2$$

for some $L > 0$, for all w, w'. The objective f is ν-strongly convex if, for all x, y,

$$f(y) \geq f(x) + \langle \nabla f(x), y - x\rangle + \frac{\nu}{2}\|x - y\|^2.$$

Once the encoding is done and appropriate data is stored in the nodes, the optimization process works in iterations. At iteration t, the master node broadcasts the current iterate w_t to the worker nodes, and wait for k_t gradient updates $\nabla f_i(w)$ to arrive, corresponding to that iteration, and then chooses a step direction d_t and a step size α_t (based on algorithm Ψ_t that maps the set of gradients updates to a step) to update the parameters. We will denote $\eta_t = \frac{k_t}{m}$. We will also drop the time dependence of k and η whenever it is kept constant.

The set of fastest k_t nodes to send gradients for iteration t will be denoted as A_t. Once k_t updates have been collected, the remaining nodes, denoted A_t^c, are interrupted by the master node[2]. Algorithms 1 and 2 describe the generic mechanism of the proposed distributed optimization scheme at the master node and a generic worker node, respectively.

The intuition behind the encoding idea is that waiting for only $k_t < m$ workers prevents the stragglers from holding up the computation, while the redundancy provided by using a tall matrix S compensates for the information lost by proceeding without the updates from stragglers (the nodes in the subset A_t^c).

We next describe the three specific algorithms that we consider under data parallelism, to compute d_t.

Gradient descent. In this case, we assume that $h(w)$ is L-smooth. Then we simply set the descent direction

$$d_t = -\left(\frac{1}{2n\eta}\sum_{i\in A_t} \nabla f_i(w_t) + \lambda \nabla h(w_t)\right).$$

We keep $k_t = k$ constant, chosen based on the number of stragglers in the network, or based on the desired operating regime.

2. If the communication is already in progress at the time when k_t faster gradient updates arrive, the communication can be finished without interruption, and the late update can be dropped upon arrival. Otherwise, such interruption can be implemented by having the master node send an interrupt signal, and having one thread at each worker node keep listening for such a signal.

Limited-memory-BFGS. We assume that $h(w) = \|w\|^2$, and assume $\mu + \lambda > 0$. Although L-BFGS is traditionally a batch method, requiring updates from all nodes, its stochastic variants have also been proposed by Mokhtari and Ribeiro (2015); Berahas et al. (2016). The key modification to ensure convergence in this case is that the Hessian estimate must be computed via gradient components that are common in two consecutive iterations, *i.e.*, from the nodes in $A_t \cap A_{t-1}$. We adapt this technique to our scenario. For $t > 0$, define $u_t := w_t - w_{t-1}$, and[3]

$$r_t := \frac{m}{2n\left|A_t \cap A_{t-1}\right|} \sum_{i \in A_t \cap A_{t-1}} \left(\nabla f_i(w_t) - \nabla f_i(w_{t-1})\right).$$

Then once the gradient terms $\{\nabla f_i(w_t)\}_{i \in A_t}$ are collected, the descent direction is computed by $d_t = -B_t \widetilde{g}_t$, where $\widetilde{g}_t = \frac{1}{2\eta n} \sum_{i \in A_t} \nabla f_i(w_t)$, and B_t is the inverse Hessian estimate for iteration t, which is computed by

$$B_t^{(\ell+1)} = V_{j_{\ell,t}}^\top B_t^{(\ell)} V_{j_{\ell,t}} + \rho_{j_{\ell,t}} u_{j_{\ell,t}} u_{j_{\ell,t}}^\top, \quad \rho_j = \frac{1}{r_j^\top u_j}, \quad V_j = I - \rho_j r_j u_j^\top$$

with $j_{\ell,t} = t - \widetilde{\sigma} + \ell$, $B_t^{(0)} = \frac{r_t^\top r_t}{r_t^\top u_t} I$, and $B_t := B_t^{(\widetilde{\sigma})}$ with $\widetilde{\sigma} := \min\{t, \sigma\}$, where σ is the L-BFGS memory length. Once the descent direction d_t is computed, the step size is determined through exact line search[4]. To do this, each worker node computes $S_i X d_t$, and sends it to the master node. Once again, the master node only waits for the fastest k_t nodes, denoted by $D_t \subseteq [m]$ (where in general $D_t \neq A_t$), to compute the step size that minimizes the function along d_t, given by

$$\alpha_t = -\rho \frac{d_t^\top \widetilde{g}_t}{d_t^\top \widetilde{X}_D^\top \widetilde{X}_D d_t}, \tag{3}$$

where $\widetilde{X}_D = [S_i X]_{i \in D_t}$, and $0 < \rho < 1$ is a back-off factor of choice.

Proximal gradient. Here, we consider the general case of non-smooth $h(w) \geq 0, \lambda \geq 0$. The descent direction d_t is given by

$$d_t = \arg\min_w \widetilde{F}_t(w) - w_t,$$

where

$$\widetilde{F}_t(w) := \frac{1}{2\eta n} \sum_{i \in A_t} f_i(w_t) + \left\langle \frac{1}{2\eta n} \sum_{i \in A_t} \nabla f_i(w_t), w - w_t \right\rangle + \lambda h(w) + \frac{1}{2\alpha} \|w - w_t\|^2.$$

We keep the step size $\alpha_t = \alpha$ and $k_t = k$ constant.

3. Note that we assume here that the intersection $A_t \cap A_{t-1}$ is non-empty. This can be ensured by adaptively choosing k_t (waiting for sufficiently many workers) so that $A_t \cap A_{t-1} \neq \varnothing$. This is further discussed in Section 3. However, our experiments indicate that convergence is still possible even when this condition does not hold.
4. Note that exact line search is not more expensive than backtracking line search for a quadratic loss, since it only requires a single matrix-vector multiplication.

Algorithm 1 Generic encoded distributed optimization procedure under data parallelism, at the master node.

Given: Ψ_t, a sequence of functions that map gradients $\{\nabla f_i(w_t)\}_{i \in A_t}$ to a descent direction d_t
Initialize w_0, α_0
for $t = 1, \ldots, T$ **do**
  broadcast w_t to all worker nodes
  wait to receive k_t gradient updates $\{\nabla f_i(w_t)\}_{i \in A_t}$
  send interrupt signal to the nodes in A_t^c
  compute the descent direction $d_t = \Psi_t\left(\{\nabla f_i(w_t)\}_{i \in A_t}\right)$
  determine step size α_t
  take the step $w_{t+1} = w_t + \alpha_t d_t$
end for

Algorithm 2 Generic encoded distributed optimization procedure under data parallelism, at worker node i.

Given: $f_i(w) = \|S_i(Xw - y)\|^2$
for $t = 1, \ldots, T$ **do**
  wait to receive w_t
  while not interrupted by master **do**
    compute $\nabla f_i(w_t)$
  end while
  if computation was interrupted **then**
    continue
  else
    send $\nabla f_i(w_t)$
  end if
end for

2.2. Model parallelism

Under the model parallelism paradigm, we focus on objectives of the form

$$\min g(w) := \min_w \phi(Xw) = \min_w \phi\left(\sum_{i=1}^m X_i w_i\right), \tag{4}$$

where the data matrix is partitioned as $X = [X_1\, X_2\, \cdots\, X_m]$, the parameter vector is partitioned as $w = \left[w_1^\top\, w_2^\top\, \cdots\, w_m^\top\right]^\top$, ϕ is convex, and $g(w)$ is L-smooth. Note that the data matrix X is partitioned horizontally, meaning that the dataset is split across features, instead of data samples (see Figure 3). This class of objectives is applicable to any classification or regression problem with generalized linear models, such as logistic regression, softmax regression, and multinomial regression.

We encode the problem (4) by setting $w = S^\top v$, and solving the problem

$$\min_v \widetilde{g}(v) := \phi\left(XS^\top v\right) = \min_v \phi\left(\sum_{i=1}^m X S_i^\top v_i\right), \tag{5}$$

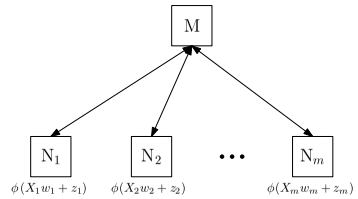

Figure 3: Uncoded distributed optimization with model parallelism, where ith node stores the ith partition of the model w_i. For $i = 1, \ldots, m$, $z_i = \sum_{j \neq i} X_j w_j$.

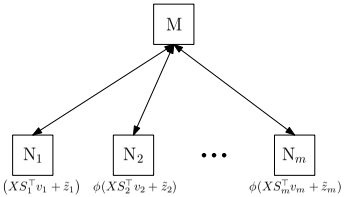

Figure 4: Encoded setup with model parallelism, where ith node stores the partition v_i of the model in the "lifted" space. For $i = 1, \ldots, m$, $\widetilde{z}_i = \sum_{j \neq i} u_j = \sum_{j \neq i} X S_j^\top v_j$.

where $w \in \mathbb{R}^p$ and $S^\top = \begin{bmatrix} S_1^\top & S_2^\top & \cdots & S_m^\top \end{bmatrix} \in \mathbb{R}^{p \times \beta p}$ (see Figure 4). As a result, worker i stores the column-block $XS_i^\top$, as well as the iterate partition v_i. Note that we increase the dimensions of the parameter vector by multiplying the dataset X with a wide encoding matrix $S^\top$ from the right, and as a result we have redundant coordinates in the system. As in the case of data parallelism, such redundant coordinates provide robustness against erasures arising due to stragglers. Such increase in coordinates means that the problem is simply lifted onto a larger dimensional space, while preserving the original geometry of the problem. We will denote $u_{i,t} = XS_i^\top v_{i,t}$, where $v_{i,t}$ is the parameter iterates of worker i at iteration t. In order to compute updates to its parameters v_i, worker i needs the up-to-date value of $\widetilde{z}_i := \sum_{j \neq i} u_j$, which is provided by the master node at every iteration.

Let $\mathcal{S} = \arg\min_w g(w)$, and given w, let w^* be the projection of w onto $\mathcal{S}$. We will say that $g(w)$ satisfies ν-restricted-strong convexity (Lai and Yin (2013)) if

$$\langle \nabla g(w), w - w^* \rangle \geq \nu \|w - w^*\|^2$$

for all w. Note that this is weaker than (implied by) strong convexity since w^* is restricted to be the projection of w, but unlike strong convexity, it is satisfied under the case where ϕ is strongly convex, but X has a non-trivial null space, *e.g.*, when it has more columns than rows.

For a given $w \in \mathbb{R}^p$, we define the level set of g at w as $D_g(w) := \{w' : g(w') \leq g(w)\}$. We will say that the level set at w_0 has diameter R if

$$\sup \left\{ \|w - w'\| : w, w' \in D_g(w_0) \right\} \leq R.$$

As in the case of data parallelism, we assume that the master node waits for k updates at every iteration, and then moves onto the next iteration (see Algorithms 3 and 4). We similarly define A_t as the set of k fastest nodes in iteration t, and also define

$$I_{i,t} = \begin{cases} 1 & i \in A_t \\ 0 & i \notin A_t. \end{cases}$$

Algorithm 3 Encoded block coordinate descent at worker node i.

1: Given: X_i, v_i.
2: **for** $t = 1, \ldots, T$ **do**
3: wait to receive $(I_{i,t-1}, \widetilde{z}_{i,t})$
4: **if** $I_{i,t} == 1$ **then**
5: take step $v_{i,t} = v_{i,t-1} + d_{i,t-1}$
6: **else**
7: set $v_{i,t} = v_{i,t-1}$
8: **end if**
9: **while** not interrupted by master **do**
10: compute next step $d_{i,t} = \alpha S_i X^\top \nabla \phi \left(X S_i^\top v_{i,t} + \widetilde{z}_{i,t} \right)$
11: compute $u_{i,t} = X S_i^\top v_{i,t}$
12: **end while**
13: **if** computation was interrupted **then**
14: continue
15: **else**
16: send $u_{i,t}$ to master node
17: **end if**
18: **end for**

Algorithm 4 Encoded block coordinate descent at the master node.

1: **for** $t = 1, \ldots, T$ **do**
2: **for** $i = 1, \ldots, m$ **do**
3: send $(I_{i,t-1}, \widetilde{z}_{i,t})$ to worker i
4: **end for**
5: wait to receive k updated parameters $\{u_{i,t}\}_{i \in A_t}$
6: send interrupt signal to the nodes in A_t^c
7: set $u_{i,t} = u_{i,t-1}$ for $i \in A_t^c$
8: compute $\widetilde{z}_{i,t} = \sum_{j \neq i} u_{j,t}$ for all i
9: **end for**

Under model parallelism, we consider block coordinate descent, described in Algorithm 3, where worker i stores the current values of the partition v_i, and performs updates on it, given the latest values of the rest of the parameters. The parameter estimate at time t is denoted by $v_{i,t}$, and we also define $\widetilde{z}_{i,t} = \sum_{j \neq i} u_{i,t} = \sum_{j \neq i} X S_j^\top v_j$. The iterates are updated by

$$v_{i,t} - v_{i,t-1} = \Delta_{i,t} := \begin{cases} -\alpha \nabla_i \widetilde{g}(v_{t-1}), & \text{if } i \in A_t \\ 0, & \text{otherwise,} \end{cases}$$

for a step size parameter $\alpha > 0$, where ∇_i refers to gradient only with respect to the variables v_i, *i.e.*, $\nabla \widetilde{g} = [\nabla_i \widetilde{g}]_{i \in [m]}$. Note that if $i \notin A_t$ then v_i does not get updated in worker i, which ensures the consistency of parameter values across machines. This is achieved by lines 4–8 in Algorithm 3. Worker i learns about this in the next iteration, when $I_{i,t-1}$ is sent by the master node.

3. Main Theoretical Results: Convergence Analysis

In this section, we prove convergence results for the algorithms described in Section 2. Note that since we modify the original optimization problem and solve it obliviously to this change, it is not obvious that the solution has any optimality guarantees with respect to the original problem. We show that, it is indeed possible to provide convergence guarantees in terms of the *original* objective under the encoded setup.

3.1. A spectral condition

In order to show convergence under the proposed framework, we require the encoding matrix S to satisfy a certain spectral criterion on S. Let S_A denote the submatrix of S associated with the subset of machines A, *i.e.*, $S_A = [S_i]_{i\in A}$. Then the criterion in essence requires that for any sufficiently large subset A, S_A behaves approximately like a matrix with orthogonal columns. We make this precise in the following statement.

Definition 1 *Let $\beta \geq 1$, and $\frac{1}{\beta} \leq \eta \leq 1$ be given. A matrix $S \in \mathbb{R}^{\beta n\times n}$ is said to satisfy the (m,η,ϵ)-block-restricted isometry property ((m,η,ϵ)-BRIP) if for any $A \subseteq [m]$ with $|A| \geq \eta m$,*

$$(1-\epsilon)I_n \preceq \frac{1}{\eta}S_A^\top S_A \preceq (1+\epsilon)I_n. \tag{6}$$

Note that this is similar to the restricted isometry property used in compressed sensing (Candes and Tao (2005)), except that we do not require (6) to hold for every submatrix of S of size $\mathbb{R}^{\eta n\times n}$. Instead, (6) needs to hold only for the submatrices of the form $S_A = [S_i]_{i\in A}$, which is a less restrictive condition. In general, it is known to be difficult to analytically prove that a structured, deterministic matrix satisfies the general RIP condition. Such difficulty extends to the BRIP condition as well. However, it is known that i.i.d. sub-Gaussian ensembles and randomized Fourier ensembles satisfy this property (Candes and Tao (2006)). In addition, numerical evidence suggests that there are several families of constructions for S whose submatrices have eigenvalues that mostly tend to concentrate around 1. We point out that although the strict BRIP condition is required for the theoretical analysis, in practice the algorithms perform well as long as the bulk of the eigenvalues of S_A lie within a small interval $(1-\epsilon, 1+\epsilon)$, even though the extreme eigenvalues may lie outside of it (in the non-adversarial setting). In Section 4, we explore several classes of matrices and discuss their relation to this condition.

3.2. Convergence of encoded gradient descent

We first consider the algorithms described under data parallelism architecture. The following theorem summarizes our results on the convergence of gradient descent for the encoded problem.

Theorem 2 *Let w_t be computed using encoded gradient descent with an encoding matrix that satisfies (m,η,ϵ)-BRIP, with step size $\alpha_t = \frac{2\zeta}{M(1+\epsilon)+\lambda L}$ for some $0 < \zeta \leq 1$, for all t. Let $\{A_t\}$ be an arbitrary sequence of subsets of $[m]$ with cardinality $|A_t| \geq \eta m$ for all t. Then, for f as given in (1),*

1.

$$\frac{1}{t}\sum_{\tau=1}^{t} f(w_\tau) - \kappa_1 f(w^*) \leq \frac{4\epsilon f(w_0) + \frac{1}{2\alpha}\|w_0 - w^*\|^2}{(1-7\epsilon)\,t}$$

2. If f is in addition ν-strongly convex, then

$$f(w_t) - \frac{\kappa_2^2(\kappa_2-\gamma)}{1-\kappa_2\gamma} f(w^*) \leq (\kappa_2\gamma)^t f(w_0), \quad t = 1, 2, \ldots,$$

where $\kappa_1 = \frac{1+3\epsilon}{1-7\epsilon}$, $\kappa_2 = \frac{1+\epsilon}{1-\epsilon}$, and $\gamma = \left(1 - \frac{4\nu\zeta(1-\zeta)}{M(1+\epsilon)+\lambda L}\right)$, where ϵ is assumed to be small enough so that $\kappa_2\gamma < 1$.

The proof is provided in Appendix A, which relies on the fact that the solution to the effective "instantaneous" problem corresponding to the subset A_t lies in a bounded set $\{w : f(w) \leq \kappa f(w^*)\}$ (where κ depends on the encoding matrix and strong convexity assumption on f), and therefore each gradient descent step attracts the iterate towards a point in this set, which must eventually converge to this set. Theorem 2 shows that encoded gradient descent can achieve the standard $O\left(\frac{1}{t}\right)$ convergence rate for the general case[5], and linear convergence rate for the strongly convex case, up to an approximate minimum. For the convex case, the convergence is shown on the running mean of past function values, whereas for the strongly convex case we can bound the function value at every step. Note that although the nodes actually minimize the encoded objective $\widetilde{f}(w)$, the convergence guarantees are given in terms of the original objective $f(w)$. Note that under the strongly convex case, linear convergence requires condition $\kappa_2\gamma < 1$. Since γ, which is slightly smaller than 1, is a decreasing function of the fraction of the strong convexity parameter to the smoothness parameter, the practical implication of this is that the less the curvature of the function (the smaller the strong convexity parameter ν), the more workers we need to wait in each iteration, so that κ_2 is small enough to satisfy $\kappa_2\gamma < 1$, which ensures the linear convergence guarantee of the theorem. Note that even if this condition is not satisfied, the algorithm can still converge, but not necessarily at the linear rate promised by the theorem.

Theorem 2 provides deterministic, sample path convergence guarantees under any (adversarial) sequence of active nodes $\{A_t\}$, which is in contrast to the stochastic methods, which show convergence typically in expectation. Further, the convergence rate is not affected by the tail behavior of the delay distribution, since the delayed updates of stragglers are not applied to the iterates.

Note that since we do not seek exact solutions under data parallelism, we can keep the redundancy factor β fixed regardless of the number of stragglers. Increasing number of stragglers in the network simply results in a looser approximation of the solution, allowing for a graceful degradation. This is in contrast to existing work Tandon et al. (2017) seeking exact convergence under coding, which shows that the redundancy factor must grow linearly with the number of stragglers.

5. Since the convergence result is deterministic, the variance reduction factor $\frac{1}{m}$ present in stochastic algorithms does not appear in our convergence rate.

3.3. Convergence of encoded L-BFGS

We consider the variant of L-BFGS described in Section 2. For our convergence result for L-BFGS, we need another assumption on the matrix S, in addition to (6). Defining $\breve{S}_t = [S_i]_{i\in A_t\cap A_{t-1}}$ for $t > 0$, we assume that for some $\delta > 0$,

$$\delta I \preceq \breve{S}_t^\top \breve{S}_t \tag{7}$$

for all $t > 0$. Note that this requires that one should wait for sufficiently many nodes to send updates so that the overlap set $A_t \cap A_{t-1}$ has more than $\frac{1}{\beta}$ nodes, and thus the matrix $\breve{S}_t$ can be full rank. When the columns of X are linearly independent, this is satisfied if $\eta \geq \frac{1}{2} + \frac{1}{2\beta}$ in the worst-case, and in the case where node delays are i.i.d. across machines, it is satisfied in expectation if $\eta \geq \frac{1}{\sqrt{\beta}}$. One can also choose k_t adaptively so that $k_t = \min\left\{k : |A_t(k) \cap A_{t-1}| > \frac{1}{\beta}\right\}$. We note that although this condition is required for the theoretical analysis, the algorithm may perform well in practice even when this condition is not satisfied.

We first show that this algorithm results in stable inverse Hessian estimates under the proposed model, under arbitrary realizations of $\{A_t\}$ (of sufficiently large cardinality), which is done in the following lemma.

Lemma 3 *Let $\mu + \lambda > 0$. Then there exist constants $c_1, c_2 > 0$ such that for all t, the inverse Hessian estimate B_t satisfies $c_1 I \preceq B_t \preceq c_2 I$.*

The proof, provided in Appendix A, is based on the well-known trace-determinant method. Using Lemma 3, we can show the following convergence result.

Theorem 4 *Let $\mu + \lambda > 0$, and let w_t be computed using the L-BFGS method described in Section 2, with an encoding matrix that satisfies (m, η, ϵ)-BRIP. Let $\{A_t\}, \{D_t\}$ be arbitrary sequences of subsets of $[m]$ with cardinality $|A_t|, |D_t| \geq \eta m$ for all t. Then, for f as described in Section 2,*

$$f(w_t) - \frac{\kappa^2(\kappa-\gamma)}{1-\kappa\gamma} f(w^*) \leq (\kappa\gamma)^t f(w_0),$$

where $\kappa = \frac{1+\epsilon}{1-\epsilon}$, and $\gamma = \left(1 - \frac{4(\mu+\lambda)c_1c_2}{(M+\lambda)(1+\epsilon)(c_1+c_2)^2}\right)$, where c_1 and c_2 are the constants in Lemma 3.

Similar to Theorem 2, the proof is based on the observation that the solution of the effective problem at time t lies in a bounded set around the true solution w^*. As in gradient descent, coding enables linear convergence deterministically, unlike the stochastic and multi-batch variants of L-BFGS, *e.g.*, Mokhtari and Ribeiro (2015); Berahas et al. (2016).

3.4. Convergence of encoded proximal gradient

Next we consider the encoded proximal gradient algorithm, described in Section 2, for objectives with potentially non-smooth regularizers $h(w)$. The following theorem characterizes our convergence results under this setup.

Theorem 5 *Let w_t be computed using encoded proximal gradient with an encoding matrix that satisfies (m, η, ϵ)-BRIP, with step size $\alpha_t = \alpha < \frac{1}{M}$, and where $\epsilon < \frac{1}{7}$. Let $\{A_t\}$ be an arbitrary sequence of subsets of $[m]$ with cardinality $|A_t| \geq \eta m$ for all t. Then, for f as described in Section 2,*

1. *For all t,*

$$\frac{1}{t}\sum_{\tau=1}^{t} f(w_\tau) - \kappa f(w^*) \leq \frac{4\epsilon f(w_0) + \frac{1}{2\alpha}\|w_0 - w^*\|^2}{(1-7\epsilon)\,t},$$

2. *For all t,*

$$f(w_{t+1}) \leq \kappa f(w_t),$$

where $\kappa = \frac{1+7\epsilon}{1-3\epsilon}$.

As in the previous algorithms, the convergence guarantees hold for arbitrary sequences of active nodes $\{A_t\}$. Note that as in the gradient descent case, the convergence is shown on the mean of past function values. Since this does not prevent the iterates from having a sudden jump at a given iterate, we include the second part of the theorem to complement the main convergence result, which implies that the function value cannot increase by more than a small factor of its current value.

3.5. Convergence of encoded block coordinate descent

Finally, we consider the convergence of encoded block coordinate descent algorithm. The following theorem characterizes our main convergence result for this case.

Theorem 6 *Let $w_t = S^\top v_t$, where v_t is computed using encoded block coordinate descent as described in Section 2. Let S satisfy (m, η, ϵ)-BRIP, and the step size satisfy $\alpha < \frac{1}{L(1+\epsilon)}$. Let $\{A_t\}$ be an arbitrary sequence of subsets of $[m]$ with cardinality $|A_t| \geq \eta m$ for all t. Let the level set of g at the first iterate $D_g(w_0)$ have diameter R. Then, for $g(w) = \phi(Xw)$ as described in Section 2, the following hold.*

1. *If ϕ is convex, then*

$$g(w_t) - g(w^*) \leq \frac{1}{\frac{1}{\pi_0} + Ct},$$

where $\pi_0 = g(w_0) - g(w^*)$, and $C = \frac{(1-\epsilon)\alpha}{R^2}\left(1 - \frac{\alpha L'}{2}\right)$.

2. *If g is ν-restricted-strongly convex, then*

$$g(w_t) - g(w^*) \leq \left(1 - \frac{1}{\xi}\right)^t (g(w_0) - g(w^*)),$$

where $\xi = \frac{2}{\nu(1-\epsilon)\alpha}\left(1 - \frac{L(1+\epsilon)\alpha}{2}\right)^{-1}$.

Theorem 6 demonstrates that the standard $O\left(\frac{1}{t}\right)$ rate for the general convex, and linear rate for the strongly convex case can be obtained under the encoded setup. Similar to the previous cases, encoding allows for deterministic convergence guarantees under adversarial failure patterns.

Note that unlike the data parallelism setup, we can achieve exact minimum under model parallelism, since the underlying geometry of the problem does not change under encoding; the same objective is simply mapped onto a higher-dimensional space, which has redundant coordinates. In every iteration, such redundancy serves as a "soft" error correction mechanism, by allowing each worker to receive sufficient information about the up-to-date values of the rest of the parameters hosted in the other nodes, even though a subset of them are not able to send their updates sufficiently fast. The smaller the ϵ is in the BRIP condition, the more representative the redundant coordinates are for the missing ones, which is reflected in the convergence rate, as a non-zero ϵ slightly weakens the constants in the convergence expressions. Still, note that this penalty in convergence rate only depends on the encoding matrix and not on the delay profile in the system. This is in contrast to the asynchronous coordinate descent methods; for instance, in Liu et al. (2015), the step size is required to shrink *exponentially* in the maximum allowable delay, and thus the guaranteed convergence rate can exponentially degrade with increasing worst-case delay in the system. The same is true for the linear convergence guarantee in Peng et al. (2016).

4. Code Design

4.1. Block RIP condition and code design

We first discuss two classes of encoding matrices with regard to the BRIP condition; namely equiangular tight frames, and random matrices.

Tight frames. A unit-norm *frame* for $\mathbb{R}^n$ is a set of vectors $F = \{a_i\}_{i=1}^{n\beta}$ with $\|a_i\| = 1$, where $\beta \geq 1$, such that there exist constants $\xi_2 \geq \xi_1 > 0$ such that, for any $u \in \mathbb{R}^n$,

$$\xi_1 \|u\|^2 \leq \sum_{i=1}^{n\beta} |\langle u, a_i \rangle|^2 \leq \xi_2 \|u\|^2.$$

The frame is *tight* if the above is satisfied with $\xi_1 = \xi_2$. In this case, it can be shown that the constants are equal to the redundancy factor of the frame, *i.e.*, $\xi_1 = \xi_2 = \beta$. If we form $S \in \mathbb{R}^{(\beta n)\times n}$ by rows that form a *tight frame*, then we have $S^\top S = \beta I$, which ensures $\|Xw - y\|^2 = \frac{1}{\beta}\|SXw - Sy\|^2$. Then for any solution $\hat{w}$ to the encoded problem (with $k = m$),

$$\nabla \widetilde{f}(\hat{w}) = X^\top S^\top S(X\hat{w} - y) = \beta X^\top (X\hat{w} - y) = \beta \nabla f(\hat{w}).$$

Therefore, the solution to the encoded problem satisfies the optimality condition for the original problem as well:

$$-\nabla \widetilde{f}(\hat{w}) \in \partial h(\hat{w}), \quad \Leftrightarrow \quad -\nabla f(\hat{w}) \in \partial h(\hat{w}),$$

and if f is also strongly convex, then $\hat{w} = w^*$ is the unique solution. This means that for $k = m$, obliviously solving the encoded problem results in the same objective value as in the original problem.

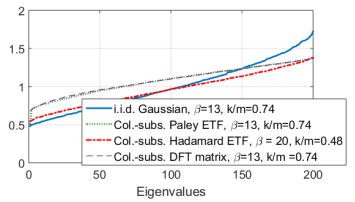

Figure 5: Sample spectrum of $S_A^\top S_A$ for various constructions with high redundancy, and small k (normalized).

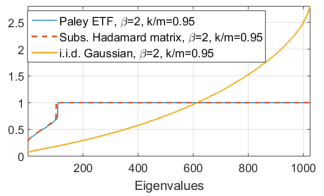

Figure 6: Sample spectrum of $S_A^\top S_A$ for various constructions with moderate redundancy, and large k (normalized).

Define the maximal inner product of a unit-norm tight frame $F = \{a_i\}_{i=1}^{n\beta}$, where $a_i \in \mathbb{R}^n, \forall i$, by

$$\omega(F) := \max_{\substack{a_i, a_j \in F \\ i \neq j}} |\langle a_i, a_j \rangle|.$$

Definition 7 (Equiangular tight frame (ETF)) *A tight frame is called an* equiangular tight frame *(ETF) if* $|\langle a_i, a_j \rangle| = \omega(F)$ *for every* $i \neq j$.

Proposition 8 (Welch (1974)) *Let* $F = \{a_i\}_{i=1}^{n\beta}$ *be a tight frame, where* $a_i \in \mathbb{R}^n$ *for* $i = 1, \ldots, n\beta$. *Then* $\omega(F) \geq \sqrt{\frac{\beta - 1}{n\beta - 1}}$. *Moreover, equality is satisfied if and only if* F *is an equiangular tight frame.*

Therefore, an ETF minimizes the correlation between its individual elements, making each submatrix $S_A^\top S_A$ as close to orthogonal as possible. This, combined with the property that tight frames preserve the optimality condition when all nodes are waited for ($k = m$), make ETFs good candidates for encoding, in light of the required property (6). We specifically evaluate the Paley ETF from Paley (1933) and Goethals and Seidel (1967); Hadamard ETF from Szöllősi (2013) (not to be confused with Hadamard matrix); and Steiner ETF from Fickus et al. (2012) in our experiments.

Although the derivation of tight eigenvalue bounds for subsampled ETFs is a long-standing problem, numerical evidence (see Figures 5, 6) suggests that they tend to have their eigenvalues more tightly concentrated around 1 than random matrices (also supported by the fact that they satisfy Welch bound, Proposition 8 with equality).

Random matrices. Another natural choice of encoding could be to use i.i.d. random matrices. Although encoding with such random matrices can be computationally expensive and may not have the desirable properties of encoding with tight frames, their eigenvalue behavior can be characterized analytically. In particular, using the existing results on the eigenvalue scaling of large i.i.d. Gaussian matrices from Geman (1980); Silverstein (1985) and union bound, it can be shown that

$$\mathbb{P}\left(\max_{A:|A|=k} \lambda_{\max}\left(\frac{1}{\beta\eta m} S_A^\top S_A\right) > \left(1 + \sqrt{\frac{1}{\beta\eta}}\right)^2\right) \to 0 \tag{8}$$

$$\mathbb{P}\left(\min_{A:|A|=k} \lambda_{\min}\left(\frac{1}{\beta\eta n} S_A^\top S_A\right) < \left(1-\sqrt{\frac{1}{\beta\eta}}\right)^2\right) \to 0, \tag{9}$$

as $n \to \infty$, if the elements of S_A are drawn i.i.d. from $N(0,1)$. Hence, for sufficiently large redundancy and problem dimension, i.i.d. random matrices are good candidates for encoding as well. However, for finite β, even if $k = m$, in general the optimum of the original problem is not recovered exactly, for such matrices.

4.2. Discussion on required redundancy

A common problem with worst-case bounds is that they are often pessimistic when compared against actual performance on real instances. In our case, directly computing the redundancy for small enough $\epsilon < 1$ (as required by Theorem 5, for instance) suggests a required redundancy β of more than 200. However, as we also show in Section 5, in practice much lower values values of redundancy (such as $\beta = 2$) results in good performance. The reason for this apparent discrepancy is that in the proofs of the theorems, we take a conservative approach and bound quadratic terms of the form

$$\xi(w) = \frac{\left|(Xw-y)^\top (S_A^\top S_A - I)(Xw-y)\right|}{\|Xw-y\|^2},$$

which is at worst

$$\xi(w) \leq \epsilon = \max\left\{\lambda_{\max}\left(S_A^\top S_A - I\right), -\lambda_{\min}\left(S_A^\top S_A - I\right)\right\}.$$

Note that the inequality is tight if $Xw - y$ is an extremal eigenvector of $S_A^T S_A - I$, which, although possible, is highly unlikely. We illustrate this point through an example experiment shown in Figure 7, which plots $\xi(w_t)$ for a run of gradient descent on linear regression with random data, where w_t is the t^{th} iterate. In the entire optimization process, it is clear that ϵ is a very pessimistic upper bound on $\xi(w_t)$.

In particular, most of the energy of the vector $Xw_t - y$ lies in the eigenspace associated with the bulk of the eigenvalues of $S_A^\top S_A$. From another perspective, if we were to use the "empirical" maximum of the value ϵ for this particular run (instead of the worst-case bound, the largest eigenvalue), we would achieve $\epsilon = 0.074$ at redundancy $\beta = 2$, a dramatic improvement compared to the above requirement of $\beta > 200$ for $\epsilon = \frac{1}{7}$.

This observation implies that for good practical performance, what is more important is to ensure that most eigenvalues lie close to, or is exactly 1. The following proposition shows that for ETFs, the bulk of the eigenvalues can be identically 1.

Proposition 9 *If the rows of S are chosen to form an ETF with redundancy β, then for $\eta \geq 1 - \frac{1}{\beta}$, $\frac{1}{\beta} S_A^\top S_A$ has $n(1-\beta(1-\eta))$ eigenvalues equal to 1.*

This follows immediately from Cauchy interlacing theorem, using the fact that $S_A S_A^\top$ and $S_A^\top S_A$ have the same spectra except zeros. Therefore for sufficiently large η, ETFs have a mostly flat spectrum even for low redundancy, and thus in practice one would expect ETFs to perform well even for small amounts of redundancy. This is also confirmed by Figure 6, as well as our numerical results.

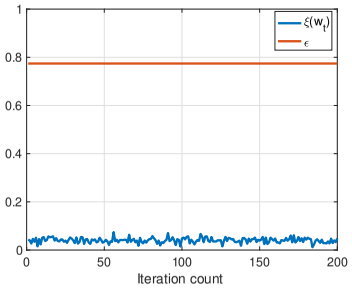

Figure 7: The evolution of $\xi(w_t)$ and ϵ against iteration count. The parameters are $(n, d, \beta) = (2001, 1400, 2)$, where we encode the data variables with a Paley ETF. We initialize the elements of w_0 with a standard normal distribution. We set $\eta = 0.9$, *i.e.*, we wait for 90% of the machines at every step.

4.3. Efficient encoding

In this section we discuss some of the possible practical approaches to encoding. Some of the practical issues involving encoding include the computational complexity of encoding, as well as the loss of sparsity in the data due to the multiplication with S, and the resulting increase in time and space complexity. We address these issues in this section.

4.3.1. Efficient distributed encoding with sparse matrices

Let the dataset (X, y) lie in a database, accessible to each worker node, where each node is responsible for computing their own encoded partitions $S_i X$ and $S_i y$. We assume that S has a sparse structure. Given S, define $B_i(S) = \{j : S_{ij} \neq 0\}$ as the set of indices of the non-zero elements of the ith row of S. For a set $\mathcal{I}$ of rows, we define $B_{\mathcal{I}}(S) = \cup_{i\in\mathcal{I}} B_i(S)$.

Let us partition the set of rows of S, $[\beta n]$, into m machines, and denote the partition of machine k as $\mathcal{I}_k$, *i.e.*, $\bigsqcup_{k=1}^m \mathcal{I}_k = [\beta n]$, where $\sqcup$ denotes disjoint union. Then the set of non-zero columns of S_k is given by $B_{\mathcal{I}_k}(S)$. Note that in order to compute $S_k X$, machine k only requires the rows of X in the set $B_{\mathcal{I}_k}(S)$. In what follows, we will denote this submatrix of X by $\widetilde{X}_k$, *i.e.*, if $x_i^\top$ is the ith row of X, $\widetilde{X}_k := \left[x_i^\top\right]_{i\in B_{\mathcal{I}_k}(S)}$. Similarly $\widetilde{y}_k = [y_i]_{i\in B_{\mathcal{I}_k}(S)}$, where y_i is the ith element of y.

Consider the specific computation that needs to be done by worker k during the iterations, for each algorithm. Under the data parallelism setting, worker k computes the following gradient:

$$\nabla f_k(w) = X^\top S_k^\top S_k (Xw - y) \overset{(a)}{=} \widetilde{X}_k^\top S_k^\top S_k (\widetilde{X}_k w - \widetilde{y}_k) \tag{10}$$

where (a) follows since the rows of X that are not in $B_{\mathcal{I}_k}$ get multiplied by zero vector. Note that the last expression can be computed without any matrix-matrix multiplication. This gives a natural storage and computation scheme for the workers. Instead of computing $S_k X$ offline and storing it, which can result in a loss of sparsity in the data, worker k

can store $\widetilde{X}_k$ in uncoded form, and compute the gradient through (10) whenever needed, using only matrix-vector multiplications. Since S_k is sparse, the overhead associated with multiplications of the form $S_k v$ and $S_k^\top v$ is small.

Similarly, under model parallelism, the computation required by worker k is

$$\nabla_k \widetilde{g}(v) = S_k X^\top \nabla_k \phi\left(X S_k^\top v_k + \widetilde{z}_k\right) = S_k \widetilde{X}_k^\top \nabla_k \phi\left(\widetilde{X}_k S_k^\top v_k + \widetilde{z}_k\right), \tag{11}$$

and as in the data parallelism case, the worker can store $\widetilde{X}_k$ uncoded, and compute (11) online through matrix-vector multiplications.

Example: Steiner ETF. We illustrate the described technique through Steiner ETF, based on the construction proposed in Fickus et al. (2012), using $(2, 2, v)$-Steiner systems. Let v be a power of 2, let $H \in \mathbb{R}^{v\times v}$ be a real Hadamard matrix, and let h_i be the ith column of H, for $i = 1, \ldots, v$. Consider the matrix $V \in \{0, 1\}^{v\times v(v-1)/2}$, where each column is the incidence vector of a distinct two-element subset of $\{1, \ldots, v\}$. For instance, for $v = 4$,

$$V = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 \end{bmatrix}.$$

Note that each of the v rows have exactly $v - 1$ non-zero elements. We construct Steiner ETF S as a $v^2 \times \frac{v(v-1)}{2}$ matrix by replacing each 1 in a row with a distinct column of H, and normalizing by $\sqrt{v-1}$. For instance, for the above example, we have

$$S = \frac{1}{\sqrt{3}} \begin{bmatrix} h_2 & h_3 & h_4 & 0 & 0 & 0 \\ h_2 & 0 & 0 & h_3 & h_4 & 0 \\ 0 & h_2 & 0 & h_3 & 0 & h_4 \\ 0 & 0 & h_2 & 0 & h_3 & h_4 \end{bmatrix}.$$

We will call a set of rows of S that arises from the same row of V a block. In general, this procedure results in a matrix S with redundancy factor $\beta = \frac{2v}{v-1}$. In full generality, Steiner ETFs can be constructed for larger redundancy levels; we refer the reader to Fickus et al. (2012) for a full discussion of these constructions.

We partition the rows of the V matrix into m machines, so that each machine gets assigned $\frac{v}{m}$ rows of V, and thus the corresponding $\frac{v}{m}$ blocks of S.

This construction and partitioning scheme is particularly attractive for our purposes for two reasons. First, it is easy to see that for any node k, $|B_{\mathcal{I}_k}|$ is upper bounded by $\frac{v(v-1)}{m} = \frac{2n}{m}$, which means the memory overhead compared to the uncoded case is limited to a factor[6] of β. Second, each block of S_k consists of (almost) a Hadamard matrix, so the multiplication $S_k v$ can be efficiently implemented through Fast Walsh-Hadamard Transform.

6. In practice, we have observed that the convergence performance improves when the blocks are broken into multiple machines, so one can, for instance, assign half-blocks to each machine.

Example: Haar matrix. Another possible choice of sparse matrix is column-subsampled Haar matrix, which is defined recursively by

$$H_{2n} = \frac{1}{\sqrt{2}} \begin{bmatrix} H_n \otimes [1\ 1] \\ I_n \otimes [1\ -1] \end{bmatrix}, \quad H_1 = 1,$$

where $\otimes$ denotes Kronecker product. Given a redundancy level β, one can obtain S by randomly sampling $\frac{n}{\beta}$ columns of H_n. It can be shown that in this case, we have $|B_{\mathcal{I}_k}| \leq \frac{\beta n \log(n)}{m}$, and hence encoding with Haar matrix incurs a memory cost by logarithmic factor.

4.3.2. Fast transforms

Another computationally efficient method for encoding is to use fast transforms: Fast Fourier Transform (FFT), if S is chosen as a subsampled DFT matrix, and the Fast Walsh-Hadamard Transform (FWHT), if S is chosen as a subsampled real Hadamard matrix. In particular, one can insert rows of zeroes at random locations into the data pair (X, y), and then take the FFT or FWHT of each column of the augmented matrix. This is equivalent to a randomized Fourier or Hadamard ensemble, which is known to satisfy the RIP with high probability by Candes and Tao (2006). However, such transforms do not have the memory advantages of the sparse matrices, and thus they are more useful for the setting where the dataset is dense, and the encoding is done offline.

4.4. Cost of encoding

Since encoding increases the problem dimensions, it clearly comes with the cost of increased space complexity. The memory and storage requirement of the optimization still increases by a factor of 2, if the encoding is done offline (for dense datasets), or if the techniques described in the previous subsection are applied (for sparse datasets)[7]. Note that the added redundancy can come by increasing the amount of effective data points per machine, by increasing the number of machines while keeping the load per machine constant, or a combination of the two. In the first case, the computational load per machine increases by a factor of β. Although this can make a difference if the system is bottlenecked by the computation time, distributed computing systems are typically communication-limited, and thus we do not expect this additional cost to dominate the speed-up from the mitigation of stragglers.

5. Numerical Results

We implement the proposed technique on four problems: ridge regression, matrix factorization, logistic regression, and LASSO.

7. Note that the increase in space complexity is not higher for sparse matrices, since the sparsity loss can be avoided using the technique described in Section 4.3.1

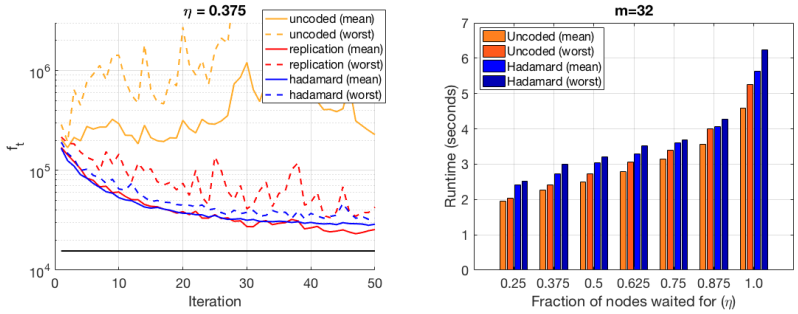

Figure 8: **Left:** Sample evolution of uncoded, replication, and Hadamard (FWHT)-coded cases, for $k = 12$, $m = 32$. **Right:** Runtimes of the schemes for different values of η, for the same number of iterations for each scheme. Note that this essentially captures the delay profile of the network, and does not reflect the relative convergence rates of different methods.

5.1. Data parallelism

5.1.1. Ridge regression

We generate the elements of matrix X i.i.d. $\sim N(0,1)$, and the elements of y are generated from X and an i.i.d. $N(0,1)$ parameter vector w^*, through a linear model with Gaussian noise, for dimensions $(n,p) = (4096, 6000)$. We solve the problem $\min_w \frac{1}{2n}\|S(Xw-y)\|^2 + \frac{\lambda}{2}\|w\|^2$, for regularization parameter $\lambda = 0.05$. We evaluate column-subsampled Hadamard matrix with redundancy $\beta = 2$ (encoded using FWHT), replication and uncoded schemes. We implement distributed L-BFGS as described in Section 3 on an Amazon EC2 cluster using `mpi4py` Python package, over $m = 32$ `m1.small` instances as worker nodes, and a single `c3.8xlarge` instance as the central server.

Figure 8 shows the result of our experiments, which are aggregated from 20 trials. In addition to uncoded scheme, we consider data replication, where each uncoded partition is replicated $\beta = 2$ times across nodes, and the server discards the duplicate copies of a partition, if received in an iteration. It can be seen that for low η, uncoded L-BFGS may not converge when a fixed number of nodes are waited for, whereas the Hadamard-coded case stably converges. We also observe that the data replication scheme converges on average, but its performance may deteriorate if both copies of a partition are delayed. Figure 8 suggests that this performance can be achieved with an approximately 40% reduction in the runtime, compared to waiting for all the nodes.

Note that in the left plot of Figure 8, iteration count does not equal time. The combined message of the two plots is that although encoding incurs a computational overhead due to increased dimensions (as can be seen by the fact that for the same η, Hadamard-encoded case takes longer than the uncoded case), the time savings due to waiting for fewer nodes per iteration (reduced η) dominates this overhead, especially for communication-limited scenarios. However, when η is reduced, uncoded optimization can destabilize or lead to

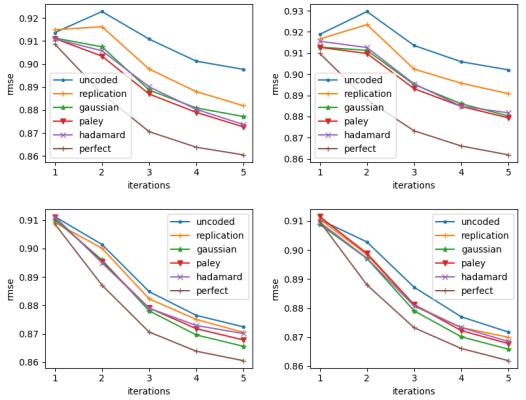

Figure 9: Test RMSE for $m = 8$ (left) and $m = 24$ (right) nodes, where the server waits for $k = m/8$ (top) and $k = m/2$ (bottom) responses. "Perfect" refers to the case where $k = m$.

Figure 10: Total runtime with $m = 8$ and $m = 24$ nodes for different values of k, under fixed 100 iterations for each scheme.

less accurate solutions, as can be seen from the aggregated sample evolution on the left. The left plot shows that, encoding effectively counteracts this effect, maintaining smooth convergence due to the redundant data in the nodes.

5.1.2. Matrix factorization

We next apply matrix factorization on the MovieLens-1M dataset (Riedl and Konstan (1998)) for the movie recommendation task. We are given R, a sparse matrix of movie ratings 1–5, of dimension $\#users \times \#movies$, where R_{ij} is specified if user i has rated movie j. We withhold randomly 20% of these ratings to form an 80/20 train/test split. The goal is to recover user vectors $x_i \in \mathbb{R}^p$ and movie vectors $y_i \in \mathbb{R}^p$ (where p is the embedding dimension) such that $R_{ij} \approx x_i^T y_j + u_i + v_j + b$, where u_i, v_j, and b are user, movie, and global biases, respectively. The optimization problem is given by

$$\min_{x_i,y_j,u_i,v_j} \sum_{i,j:\ \text{observed}} (R_{ij} - u_i - v_j - x_i^T y_j - b)^2 + \lambda \left(\sum_i \|x_i\|_2^2 + \|u\|_2^2 + \sum_j \|y_j\|_2^2 + \|v\|_2^2 \right). \tag{12}$$

We choose $b = 3$, $p = 15$, and $\lambda = 10$, which achieves test RMSE 0.861, close to the current best test RMSE on this dataset using matrix factorization[8].

Problem (12) is often solved using alternating minimization, minimizing first over all (x_i, u_i), and then all (y_j, v_j), in repetition. Each such step further decomposes by row and column, made smaller by the sparsity of R. To solve for (x_i, u_i), we first extract

8. `http://www.mymedialite.net/examples/datasets.html`

$I_i = \{j \mid r_{ij} \text{ is observed}\}$, and minimize

$$\left([y_{I_i}^T, \mathbf{1}] \begin{bmatrix} x_i \\ u_i \end{bmatrix} - (R_{i,I_i}^T - v_{I_i} - b\mathbf{1}) \right)^2 + \lambda \left(\sum_i \|x_i\|_2^2 + \|u\|_2^2 \right) \tag{13}$$

for each i, which gives a sequence of regularized least squares problems with variable $w = [x_i^T, u_i]^T$, which we solve distributedly using coded L-BFGS; and repeat for $w = [y_j^T, v_j]^T$, for all j.

The Movielens experiment is run on a single 32-core machine with Linux 4.4. In order to simulate network latency, an artificial delay of $\Delta \sim \exp(10 \text{ ms})$ is imposed each time the worker completes a task. Small problem instances ($n < 500$) are solved locally at the central server, using the built-in function `numpy.linalg.solve`. To reduce overhead, we create a bank of encoding matrices $\{S_n\}$ for Paley ETF and Hadamard ETF, for $n = 100, 200, \ldots, 3500$, and then given a problem instance, subsample the columns of the appropriate matrix S_n to match the dimensions. Overall, we observe that encoding overhead is amortized by the speed-up of the distributed optimization.

Figure 9 gives the final performance of our distributed L-BFGS for various encoding schemes, for each of the 5 epochs, which shows that coded schemes are most robust for small k. A full table of results is given in Appendix D.

5.1.3. LASSO

We solve the LASSO problem, with the objective

$$\min_w \frac{1}{2n} \|Xw - y\|^2 + \lambda \|w\|_1,$$

where $X \in \mathbb{R}^{130{,}000 \times 100{,}000}$ is a matrix with i.i.d. $N(0,1)$ entries, and y is generated from X and a parameter vector w^* through a linear model with Gaussian noise:

$$y = Xw^* + \sigma z,$$

where $\sigma = 40$, $z \sim N(0,1)$. The parameter vector w^* has 7695 non-zero entries out of 100,000, where the non-zero entries are generated i.i.d. from $N(0,4)$. We choose $\lambda = 0.6$ and consider the sparsity recovery performance of the corresponding LASSO problem, solved using proximal gradient (iterative shrinkage/thresholding algorithm).

We implement the algorithm over 128 `t2.medium` worker nodes which collectively store the matrix X, and a `c3.4xlarge` master node. We measure the sparsity recovery performance of the solution using the F1 score, defined as the harmonic mean

$$F1 = \frac{2PR}{P+R},$$

where P and R are precision recall of the solution vector $\hat{w}$ respectively, defined as

$$P = \frac{|\{i : w_i^* \neq 0, \hat{w}_i \neq 0\}|}{|i : \hat{w}_i \neq 0|}, \quad R = \frac{|\{i : w_i^* \neq 0, \hat{w}_i \neq 0\}|}{|i : w_i^* \neq 0|}$$

.

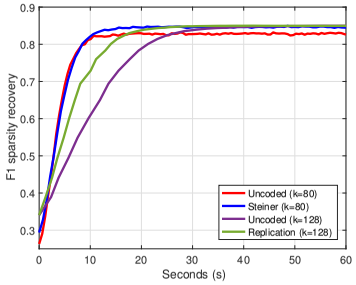

Figure 11: Evolution of F1 sparsity recovery performance for each scheme.

Figure 11 shows the sample evolution of the F1 score of the model under uncoded, replication, and Steiner encoded scenarios, with artificial multi-modal communication delay distribution $q_1\mathcal{N}(\mu_1, \sigma_1^2) + q_2\mathcal{N}(\mu_s, \sigma_2^2) + q_3\mathcal{N}(\mu_3, \sigma_3^2)$, where $q_1 = 0.8$, $q_2 = 0.1$, $q_3 = 0.1$; $\mu_1 = 0.2$s, $\mu_s = 0.6$s, $\mu_3 = 1$s; and $\sigma_1 = 0.1$s, $\sigma = 0.2$s, $\sigma_3 = 0.4$s, independently at each node. We observe that the uncoded case $k = 80$ results in a performance loss in sparsity recovery due to data dropped from delayed noes, and uncoded and replication with $k = 128$ converges slow due to stragglers, while Steiner coding with $k = 80$ is not delayed by stragglers, while maintaining almost the same sparsity recovery performance as the solution of the uncoded $k = 128$ case.

5.2. Model parallelism

5.2.1. Logistic regression

In our next experiment, we apply logistic regression for document classification for Reuters Corpus Volume 1 (`rcv1.binary`) dataset from Lewis et al. (2004), where we consider the binary task of classifying the documents into corporate/industrial/economics vs. government/social/markets topics. The dataset has 697,641 documents, and 47,250 term frequency-inverse document frequency (tf-idf) features. We randomly select 32,500 features for the experiment, and reserve 100,000 documents for the test set. We use logistic regression with ℓ_2-regularization for the classification task, with the objective

$$\min_{w,b} \frac{1}{n} \sum_{i=1}^{n} \log\left(1 + \exp\left\{-z_i^\top w + b\right\}\right) + \lambda \|w\|^2,$$

where $z_i = y_i x_i$ is the data sample x_i multiplied by the label $y_i \in \{-1, 1\}$, and b is the bias variable. We solve this optimization using encoded distributed block coordinate descent as described in Section 2, and implement Steiner and Haar encoding as described in Section 4, with redundancy $\beta = 2$. In addition we implement the asynchronous coordinate descent, as well as replication, which represents the case where each partition Z_i is replicated across two nodes, and the faster copy is used in each iteration. We use $m = 128$ `t2.medium` instances as worker nodes, and a single `c3.4xlarge` instance as the master node, which

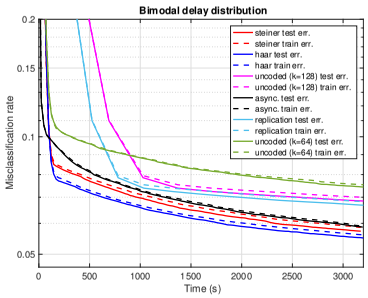

Figure 12: Test and train errors over time (in seconds) for each scheme, for the bimodal delay distribution. Steiner and Haar encoding is done with $k = 64$, $\beta = 2$.

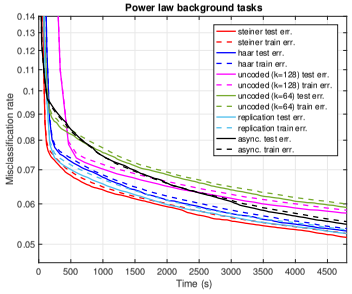

Figure 13: Test and train errors over time (in seconds) for each scheme. Number of background tasks follow a power law. Steiner and Haar encoding is done with $k = 80$, $\beta = 2$.

# Nodes (m)	Dimensions ($n \times d$)
8	8000×3000
32	32000×12000
128	128000×48000

Table 2: Problem dimensions for each experiment.

communicate using the `mpi4py` package. We consider two models for stragglers. In the first model, at each node, we add a random delay drawn from a Gaussian mixture distribution $q\mathcal{N}(\mu_1, \sigma_1^2) + (1-q)\mathcal{N}(\mu_s, \sigma_2^2)$, where $q = 0.5$, $\mu_1 = 0.5$s, $\mu_s = 20$s, $\sigma_1 = 0.2$s, $\sigma_2 = 5$s. In the second model, we do not directly add any delay, but at each machine we launch a number of dummy background tasks (matrix multiplication) that are executed throughout the computation. The number of background tasks across the nodes is distributed according to a power law with exponent $\alpha = 1.5$. The number of background tasks launched is capped at 50.

Figures 12 and 13 shows the evolution of training and test errors as a function of wall clock time. We observe that for each straggler model, either Steiner or Haar encoded optimization dominates all schemes. Figures 14 and 15 show the statistics of how frequent each node participates in an update, for the case with background tasks, for encoded and asynchronous cases, respectively. We observe that the stark difference in the relative speeds of different machines result in vastly different update frequencies for the asynchronous case, which results in updates with large delays, and a corresponding performance loss.

5.3. Speed tests

In order to quantify the speed-up achieved by the encoding scheme, we design a set of controlled distributed optimization experiments which compares it against other commonly

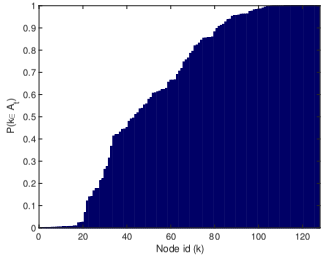

Figure 14: The fraction of iterations each worker node participates in (the empirical probability of the event $\{k \in A_t\}$), plotted for Steiner encoding with $k = 80$, $m = 128$. The number of background tasks are distributed by a power law with $\alpha = 1.5$ (capped at 50).

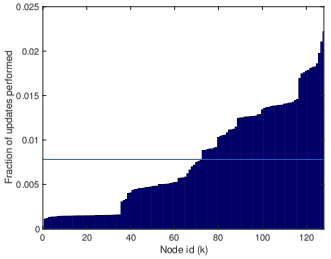

Figure 15: The fraction of updates performed by each node, for asynchronous block coordinate descent. The horizontal line represents the uniformly distributed case. The number of background tasks are distributed by a power law with $\alpha = 1.5$ (capped at 50).

Scheme	Runtime (s) $\mu_s = 0$	Runtime (s) $\mu_s = \gamma$	Runtime (s) $\mu_s = 2\gamma$

Table 5: The average wall-clock time taken to achieve $1.05 \times$ MMSE for each scheme, for $m = 128$ workers.

straggler mitigation schemes, namely replication and asynchronous optimization, as well as the uncoded synchronous case. To do this, we focus on ridge regression, and use the mean-squared error (MSE) in predicting the test-set response variable y as our metric. We compare the methods against each other by measuring the wall-clock time of optimization required to achieve a fixed mean-squared error.

Note that since the speed-up is due to the mitigation of stragglers, the performance of the proposed technique depends strongly on many cluster- and problem-specific factors, such as computational power of nodes, number of nodes, background processes running at nodes, networking configurations, latency and bandwidth available in the network, compute-to-communication ratio required by the problem, availability of nodes[9]. Since these experiments are intended purely as speed measurements, we make several design decisions to build a highly-controlled computing environment, in order to isolate the effects of the straggler mitigation technique and side-step problem- or network-specific artifacts that might affect the results.

First, to have direct control over the delays induced by the workers and measure the exact effect of the delay distribution on the runtime, we use compute-optimized, high-performance, high-bandwidth `c4.4xlarge` and `c4.large` instances available through Amazon EC2, set a node to be a straggler with probability $q = 0.25$, and for stragglers in each step we add an artificial delay drawn from Gaussian distribution $\mathcal{N}\left(\mu_s, \sigma_s^2\right)$, to simulate more unreliable clusters. In our tests, we vary μ_s to measure the effect of the amount of straggler delay (keeping $\sigma_s = 0.4\mu_s$). We sweep μ_s over the values $\{0, \gamma, 2\gamma\}$, where γ is chosen as the amount of time it takes for a non-straggler node to perform 5-6 iterations for the given problem dimensions. Note that such delays can be observed in practice in unreliable/burstable clusters (see, for instance, the EC2 experiments in Tandon et al. (2016) conducted on `t2.micro` instances, where the stragglers are $8\times$ slower, or Ananthanarayanan et al. (2013) which similarly reports $8\times$ straggler delay for latency-limited tasks).

Second, as we scale the number of workers, we scale the problem proportionally as well, in order to maintain the same computation-communication ratio. To be able to control exact problem dimensions, we use synthetic data, where the data matrix $X \in \mathbb{R}^{n\times d}$ is generated i.i.d. $\mathcal{N}(0,1)$, and $y = X\bar{w} + \eta$ for some ground truth $\bar{w}$ and noise $\eta \in \mathcal{N}\left(0, \sigma_\eta^2\right)$, with σ_η^2 proportional to n.

Third, since under data-parallelism the proposed method does not converge to the exact minimum, we first find the minimum MSE (MMSE) achieved for the given problem through a preliminary experiment using fully synchronous optimization with all nodes, as well as hyper-parameter optimization to determine a good value for the regularization parameter λ, which we determine to be $\lambda = 0.025$. Then, we set the MSE bar as $1.05 \times \mathsf{MMSE}$. Note that if the exact minimum is desired for encoded scenarios in a real application, one can always increase k_t to m (*i.e.*, start using all nodes) towards the end of the optimization, after this approximate target is reached.

Under this setup, we perform three experiments, sweeping the number of workers in the set $m \in \{8, 32, 128\}$. The problem dimensions for each case is given in Table 2. For encoding we use Steiner ETFs described in Section 4 with redundancy $\beta = 2$, and $k_t = 0.75m$. In

9. For instance, in Amazon EC2 clusters, burstable `t2` and `t3`-type instances can provide high performance for a limited period of time, before slowing down to a baseline level of performance; or low-cost spot instances, which can instantly become available or unavailable based on supply and demand.

all cases, we use gradient descent with step size $\alpha_t = 0.2$, which is run for 120 steps. γ is determined to be 0.2s, 0.3s, and 1.2s for the three problem sizes, respectively.

The results are provided in Tables 3–5, where four methods are compared: Steiner encoding, uncoded synchronous optimization, uncoded asynchronous optimization, and replication, where each data shard is replicated across two nodes, and the faster copy is used in optimization. Note that Steiner encoding and replication schemes have double the data per worker. The results are averaged over 5 trials.

We observe that when there is no delay ($\mu_s = 0$), the additional computation overhead of encoding (as well as the perturbation of data) results in relatively high runtime to achieve the desired MSE. We see a similar overhead for replication, although replication enjoys the advantage of having access to raw, uncoded data. However, in the regime where the system is bottlenecked by stragglers ($\mu_s = \gamma$ and $\mu_s = 2\gamma$), the scheme results in significant speed up, ranging from approximately $3\times$ to $7\times$ against the uncoded synchronous; and up to $2\times$ against the replication baseline. Note that replication still gets impacted by straggler nodes if both copies of a shard happen to be delayed. When there are no stragglers, and for modest cluster sizes, asynchronous optimization achieves the best performance. However, since the gradient staleness scales linearly with the cluster size, asynchronous performance falls behind Steiner for $m = 128$ workers even in the absence of stragglers. We also observe that when stragglers are introduced, outdated gradients significantly degrade the asynchronous performance, as the desired MSE bar is not reached at the end of 120 steps. We have run the same experiment for the uncoded case with erasures as well; however, the method failed to achieve the MSE target in all the experiments, including the case with $\mu_s = 0$. This is because the straggler nodes tend to persist their slow computation throughout optimization. In other words, it is usually approximately the same subset of nodes that provide the updates, effectively removing the data stored in straggler nodes from the optimization. Finally, we note that the runtime for the encoded case also increases in the presence of stragglers (though less severely than the other schemes), due to various implementation overheads such as the interruption of the stragglers for the next iteration. However, we believe that part of this overhead could be mitigated in a more efficient implementation.

We conclude from these experiments that encoding can result in large speed-ups in highly unreliable, low-cost clusters which can induce large delays (such as EC2 `t2` instances), or clusters with intermittent node availability (such as EC2 spot instances). It is less suited to reliable clusters with high-capacity, high-bandwidth nodes due to the computational overhead associated with it.

Appendix A. Proofs of Theorems 2 and 4

In the proofs, we will ignore the normalization constants on the objective functions for brevity. We will assume the normalization $\frac{1}{\sqrt{\eta}}$ is absorbed into the encoding matrix S_A. Let $f(w) = \|Xw - y\|^2 + \lambda h(w)$. Let $\widetilde{f}_t^A := \|S_{A_t}(Xw_t - y)\|^2 + \lambda h(w_t)$, and $\widetilde{f}^A(w) := \|S_{A_t}(Xw - y)\|^2 + \lambda h(w)$, where we set $A \equiv A_t$. Let $\widetilde{w}_t^*$ denote the solution to the effective "instantaneous" problem at iteration t, *i.e.*, $\widetilde{w}_t^* = \arg\min_w \widetilde{f}^A(w)$.

Unless otherwise stated, throughout this appendix, we will also denote

$$w^* = \arg\min_w \|Xw - y\|^2 + \lambda h(w)$$
$$\hat{w} = \arg\min_w \|S_A(Xw - y)\|^2 + \lambda h(w)$$

unless otherwise noted, where A is a fixed subset of $[m]$.

A.1. Lemmas

Lemma 10 (Approximation error) *If S satisfies (6) (BRIP) for any $A \subseteq [m]$ with $|A| \geq k$, for any convex set C,*

$$\|X\hat{w} - y\|^2 \leq \kappa^2 \|Xw^* - y\|^2,$$

where $\kappa = \frac{1+\epsilon}{1-\epsilon}$, $\hat{w} = \arg\min_{w\in C} \|S_A(Xw - y)\|^2$, and $w^* = \arg\min_{w\in C} \|Xw - y\|^2$.

Proof Define $e = \hat{w} - w^*$ and note that

$$\|X\hat{w} - y\| = \|Xw^* - y + Xe\| \leq \|Xw^* - y\| + \|Xe\|$$

by triangle inequality, which implies

$$\|X\hat{w} - y\|^2 \leq \left(1 + \frac{\|Xe\|}{\|Xw^* - y\|}\right)^2 \|Xw^* - y\|^2. \tag{14}$$

Note that we have

$$\|S_A(X\hat{w} - y)\|^2 \leq \|S_A(Xw^* - y)\|^2$$

by the definition of $\hat{w}$. Expanding the quadratic terms and canceling the common term $y^\top S_A^\top S_A y$ from both sides, we get

$$\hat{w}^\top X^\top S_A^\top S_A X\hat{w} - 2y^\top S_A^\top S_A X\hat{w} \leq w^{*\top} X^\top S_A^\top S_A Xw^* - 2y^\top S_A^\top S_A Xw^*.$$

Adding $-2w^{*\top} X^\top S_A^\top S_A X\hat{w} + w^{*\top} X^\top S_A^\top S_A Xw^*$ to both sides,

$$\begin{aligned}\hat{w}^\top X^\top S_A^\top S_A X\hat{w} - 2w^{*\top} X^\top S_A^\top S_A X\hat{w} + w^{*\top} X^\top S_A^\top S_A Xw^* - 2y^\top S_A^\top S_A X\hat{w} \\ \leq 2w^{*\top} X^\top S_A^\top S_A Xw^* - 2y^\top S_A^\top S_A Xw^* - 2w^{*\top} X^\top S_A^\top S_A X\hat{w},\end{aligned}$$

which can be re-arranged into

$$\|S_A X(\hat{w} - w^*)\|^2 \leq 2y^\top S_A^\top S_A X(\hat{w} - w^*) - 2w^{*\top} X^\top S_A^\top S_A X(\hat{w} - w^*),$$

which, using the definition $e = \hat{w} - w^*$, is equivalent to

$$\|S_A Xe\|^2 \leq -2(Xw^* - y)^\top S_A^\top S_A Xe = -2e^\top X^\top S_A^\top S_A(Xw^* - y). \tag{15}$$

Now, for any $c > 0$, consider

$$\begin{aligned}\|Xe\|^2 &\overset{(a)}{\leq} \frac{\|S_A Xe\|^2}{1-\epsilon} \overset{(b)}{\leq} -2\frac{e^\top X^\top S_A^\top S_A(Xw^* - y)}{1-\epsilon} \\ &= -2\frac{e^\top X^\top \left(S_A^\top S_A - cI\right)(Xw^* - y)}{1-\epsilon} - \frac{2c}{1-\epsilon} e^\top X^\top (Xw^* - y) \\ &\overset{(c)}{\leq} -2\frac{e^\top X^\top \left(S_A^\top S_A - cI\right)(Xw^* - y)}{1-\epsilon} \\ &\overset{(d)}{\leq} 2\frac{\left\|e^\top X^\top \left(cI - S_A^\top S_A\right)\right\|}{1-\epsilon} \|Xw^* - y\| \\ &\overset{(e)}{\leq} 2\frac{\left\|cI - S_A^\top S_A\right\|}{1-\epsilon} \|Xw^* - y\| \|Xe\|,\end{aligned}$$

where (a) follows from the BRIP property for S_A; (b) follows by (15); (c) follows by the fact that since $\hat{w} \in C$, e represents a feasible direction of the constrained optimization, and thus the convex optimality condition implies $\langle \nabla p(w^*), \hat{w} - w^* \rangle = 2e^\top X^\top (Xw^* - y) \geq 0$, where $p(w) := \|Xw - y\|^2$; (d) follows by Cauchy-Schwarz inequality; and (e) follows by the definition of matrix norm.

The above chain of inequalities then imply that

$$\frac{\|Xe\|}{\|Xw^* - y\|} \leq \frac{2\left\|cI - S_A^\top S_A\right\|}{1-\epsilon}.$$

Since this is true for any $c > 0$, we make the minimizing choice $c = \frac{\lambda_{\max} + \lambda_{\min}}{2}$ (where $\lambda_{\max}$ and $\lambda_{\min}$ represent the largest and smallest eigenvalues of $S_A^\top S_A$, respectively), which gives

$$\frac{\|Xe\|}{\|Xw^* - y\|} \leq \frac{\lambda_{\max} - \lambda_{\min}}{1-\epsilon} \leq \frac{2\epsilon}{1-\epsilon}.$$

Plugging this back in (14), we get the desired result. ∎

Lemma 11 (Approximation error with regularization) *If S satisfies (6) (BRIP) for any $A \subseteq [m]$ with $|A| \geq k$,*

$$f(\hat{w}) \leq \kappa^2 f(w^*),$$

where $\kappa = \frac{1+\epsilon}{1-\epsilon}$, $\hat{w} = \arg\min_w \|S_A(Xw - y)\|^2 + \lambda h(w)$, and $w^* = \arg\min_w \|Xw - y\|^2 + \lambda h(w)$.

Proof Consider a fixed $A_t = A$, and a corresponding

$$\hat{w} = \widetilde{w}_t^* \in \arg\min_w \|S_A(Xw - y)\|^2 + \lambda h(w)$$

Define

$$\hat{w}(r) = \underset{w:\lambda h(w)\le r}{\arg\min} \|S_A(Xw-y)\|^2$$
$$w^*(r) = \underset{w:\lambda h(w)\le r}{\arg\min} \|Xw-y\|^2.$$

Finally, define

$$r^* = \arg\min_r \|Xw^*(r)-y\|^2 + r.$$

Now, consider

$$\begin{aligned} f(\hat{w}) &= \|X\hat{w}-y\|^2 + \lambda h(\hat{w}) = \min_r \left(\|X\hat{w}(r)-y\|^2 + r\right) \\ &\le \|X\hat{w}(r^*)-y\|^2 + r^* \overset{(a)}{\le} \kappa^2 \|Xw^*(r^*)-y\|^2 + r^* \\ &\le \kappa^2 \left(\|Xw^*(r^*)-y\|^2 + r^*\right) = \kappa^2 f(w^*), \end{aligned}$$

which shows the desired result, where (a) follows by Lemma 10, and by the fact that the set $\{w : \lambda h(w) \le r\}$ is a convex set. ■

Lemma 12 (Error evolution) *Let $\kappa = \frac{1+\epsilon}{1-\epsilon}$. If*

$$\widetilde{f}^A_{t+1} - \widetilde{f}^A(\widetilde{w}^*_t) \le \gamma\left(\widetilde{f}^A_t - \widetilde{f}^A(\widetilde{w}^*_t)\right)$$

for all $t > 0$, and for some $0 < \gamma < 1$ with $\kappa\gamma < 1$, where $\widetilde{w}^*_t \in \arg\min_w \widetilde{f}^A_t$, then

$$f(w_t) \le (\kappa\gamma)^t f(w_0) + \frac{\kappa^2(\kappa-\gamma)}{1-\kappa\gamma} f(w^*).$$

Proof Since for any w,

$$(1-\epsilon)\|Xw-y\|^2 \le (Xw-y)^\top S_A^\top S_A (Xw-y),$$

we have

$$(1-\epsilon) f(w) \le \widetilde{f}^A(w).$$

Similarly $\widetilde{f}^A(w) \le (1+\epsilon) f(w)$, and therefore, using the assumption of the lemma

$$(1-\epsilon) f(w_{t+1}) - (1+\epsilon) f(\widetilde{w}^*_t) \le \gamma\left((1+\epsilon) f(w_t) - (1-\epsilon) f(\widetilde{w}^*_t)\right),$$

which can be re-arranged into the linear recursive inequality

$$f(w_{t+1}) \le \kappa\gamma f(w_t) + (\kappa-\gamma) f(\widetilde{w}^*_t) \overset{(a)}{\le} \kappa\gamma f(w_t) + \kappa^2(\kappa-\gamma) f(w^*),$$

where $\kappa = \frac{1+\epsilon}{1-\epsilon}$ and (a) follows by Lemma 11. By considering such inequalities for $0 \le \tau \le t$, multiplying each by $(\kappa\gamma)^{t-\tau}$ and summing, we get

$$\begin{aligned} f(w_t) &\le (\kappa\gamma)^t f(w_0) + \kappa^2(\kappa-\gamma) f(w^*) \sum_{\tau=0}^{t-1} (\kappa\gamma)^\tau \\ &\le (\kappa\gamma)^t f(w_0) + \frac{\kappa^2(\kappa-\gamma)}{1-\kappa\gamma} f(w^*). \end{aligned}$$

■

Lemma 13 (Strong convexity parameter) *Under the assumptions of Theorem 4, $\widetilde{f}^A(w)$ is $(1-\epsilon)(\mu+\lambda)$-strongly convex.*

Proof It is sufficient to show that the minimum eigenvalue of $\widetilde{X}_A^\top \widetilde{X}_A$ is bounded away from zero. This can easily be shown by the fact that

$$u^\top \widetilde{X}_A^\top \widetilde{X}_A u = u^\top \hat{X}^\top S_A^\top S_A \hat{X} u \ge (1-\epsilon)\|\hat{X}u\|^2 \ge (1-\epsilon)(\mu+\lambda)\|u\|^2,$$

for any unit vector u. ■

Lemma 14 (Rotation bound) *Let $M \in \mathbb{R}^{p\times p}$ be a symmetric positive definite matrix, with the condition number (ratio of maximum eigenvalue to the minimum eigenvalue) given by κ. Then, for any unit vector u,*

$$\frac{u^\top M u}{\|Mu\|} \ge \frac{2\sqrt{\kappa}}{\kappa+1}.$$

Proof We point out that this is a special case of Kantorovich inequality, but provide a dedicated proof here for completeness.

Let M have the eigen-decomposition $M = Q^\top D Q$, where Q has orthonormal columns, and D is a diagonal matrix with positive, decreasing entries $d_1 \ge d_2 \ge \cdots \ge d_n$, with $\frac{d_1}{d_n} = \kappa$. Let $y = (Qu)^{\circ 2}$, where $^{\circ 2}$ denotes entry-wise square. Then the quantity we are interested in can be represented as

$$\hat{y} = \arg\inf_{y\in\Delta} \frac{\sum_{i=1}^n d_i y_i}{\sqrt{\sum_{i=1}^n d_i^2 y_i}},$$

and $\frac{u^\top M u}{\|Mu\|}$ is lower bounded by the optimal objective value of the above optimization problem. The set $\Delta = \{y \ge 0 : \mathbf{1}^\top y = 1\}$ is the simplex. Note that $\hat{y}$ is invariant to any positive scaling on the entire vector d, so we can consider a convexification, where the minimum is attained since y is confined to a compact set, and where $\hat{y}$ is the solution to:

$$\begin{array}{ll} \textbf{min.} & \hat{d}^T y \\ \textbf{subj.to} & \sum_{i=1}^n \hat{d}_i^2 y_i = 1 \\ & y \ge 0,\ y^T \mathbf{1} = 1 \end{array}$$

and $\hat{d}$ is the scaled version of d such that $\sum_{i=1}^n \hat{d}_i^2 y_i = 1$. The Lagrange dual is

$$\begin{array}{ll} \textbf{max.} & \alpha + \beta \\ \textbf{subj.to} & \hat{d} - \beta \hat{d}^{\circ 2} - \alpha \mathbf{1} \geq \mathbf{0} \end{array}$$

where by complementary slackness, the gap in the inequality corresponds to the nonzero pattern of y, e.g.

$$y_i(\hat{d}_i - \beta \hat{d}_i^2 - \alpha) = 0, \ \forall i \in [n].$$

Now we consider the quadratic function $d - \beta d^2 - \alpha$ in terms of a scalar d, with fixed α and β. It is clear that this concave function can have at most 2 zeros. In other words, there can be at most two indices i, j where

$$\hat{d}_k - \beta \hat{d}_k^2 - \alpha = 0, \ k \in \{i, j\}, \quad y_k = 0 \ k \notin \{i, j\}$$

and it is possible that $i = j$. (At least one solution must exist, since $y^T \mathbf{1} = 1$, so y cannot be all 0.) This reduces our primal optimization problem significantly, to two variables y_i and y_j, where the two linear constraints can be inverted directly

$$y_i = \frac{1 - \hat{d}_j^2}{\hat{d}_i^2 - \hat{d}_j^2}, \ y_j = \frac{\hat{d}_i^2 - 1}{\hat{d}_i^2 - \hat{d}_j^2}$$

Plugging back into the primal objective,

$$y_i \hat{d}_i + y_j \hat{d}_j = \frac{\hat{d}_i - \hat{d}_i \hat{d}_j^2 + \hat{d}_j \hat{d}_i^2 - \hat{d}_j}{\hat{d}_i^2 - \hat{d}_j^2} = \frac{1 + (\hat{d}_i \hat{d}_j)}{\hat{d}_i + \hat{d}_j}$$

which is minimized when $\hat{d}_i$ and $\hat{d}_j$ are as far apart as possible; e.g., $i = 1$ and $j = n$.

We can equivalently reparametrize y_1 and y_n in terms of d_1 and d_n as

$$y_1(c) = \frac{c^2 - d_n^2}{d_1^2 - d_n^2}, \ y_n(c) = \frac{d_1^2 - c^2}{d_1^2 - d_n^2}$$

where $c^2 = d_1^2 y_1 + d_n^2 y_n$. Now we consider our original optimization problem, significantly simplified

$$\inf_{y \in \Delta} \frac{\sum_{i=1}^n d_i y_i}{\sqrt{\sum_{i=1}^n d_i^2 y_i}} = \inf_{c \geq 0} \frac{d_1 y_1(c) + d_n y_n(c)}{c} = \inf_{c \geq 0} \frac{c^2 + d_1 d_n}{c(d_1 + d_n)}.$$

This is now a scalar nonconvex optimization problem, with minimum at either the boundaries ($c = 0$ or $c \to +\infty$) or the one stationary point ($c = d_1 d_n$). The stationary point is the only one in which this quantity is not positive infinity, and is thus the solution. Therefore, simplifying with $\kappa = d_1/d_n$, we arrive at

$$\hat{y}_1 = \frac{1}{\kappa + 1}, \ \hat{y}_n = \frac{\kappa}{\kappa + 1}.$$

and for any unit-normed u,

$$\frac{u^\top M u}{\|Mu\|} \geq \frac{c^2 + d_1 d_n}{c(d_1 + d_n)} = \frac{(1 + d_1 d_n)}{(d_1 + d_n)} = \frac{(1/d_n + d_1)}{(\kappa + 1)} \geq \frac{2\sqrt{d_1/d_n)}}{(\kappa + 1)} = \frac{2\sqrt{\kappa})}{(\kappa + 1)}.$$

where the inequality comes from the arithmetic-geometric mean inequality. ■

A.2. Proof of Theorem 2

The proof of the first part of the theorem is a special case of the proof of Theorem 5 (with $\lambda = 0$, and the smooth regularizer incorporated into $p(w)$) and thus we omit this proof and refer the reader to Appendix B. We prove the second part here.

Note that because of the condition in (6) (BRIP), we have

$$(1 - \epsilon) I \preceq S_A^\top S_A \preceq (1 + \epsilon) I.$$

Using smoothness of the objective, and the choices $d_t = -\nabla \widetilde{f}^A(w_t)$ and $\alpha_t = \alpha$, we have

$$\begin{aligned} &\widetilde{f}^A(w_{t+1}) - \widetilde{f}^A(w_t) \leq \alpha \nabla \widetilde{f}^A(w_t)(w_t)^\top d_t + \frac{1}{2}\alpha^2 d_t^\top X^\top S_A^\top S_A X d_t + \lambda \frac{L}{2}\alpha^2 \|d_t\|^2 \\ &\leq -\alpha \left(1 - \frac{(1+\epsilon)M + \lambda L}{2}\alpha\right) \left\|\nabla \widetilde{f}^A(w_t)\right\|^2 = -\frac{2\zeta(1-\zeta)}{(1+\epsilon)M + \lambda L} \|\nabla \widetilde{f}^A(w_t)\|^2 \\ &\overset{(a)}{\leq} -\frac{4\nu\zeta(1-\zeta)}{M(1+\epsilon) + \lambda L} \left(\widetilde{f}^A(w_t) - \widetilde{f}^A(\widetilde{w}_t^*)\right), \end{aligned}$$

where (a) follows by strong convexity. Re-arranging this inequality, and using the definition of γ, we get

$$\widetilde{f}_{t+1}^A - \widetilde{f}^A(\widetilde{w}_t^*) \leq \gamma \left(\widetilde{f}_t^A - \widetilde{f}^A(\widetilde{w}_t^*)\right),$$

which, using Lemma 12, implies the result.

A.3. Proof of Theorem 4

We first present the proof of Lemma 3, then move on to the main proof.

Proof [Proof of Lemma 3] The reader is referred to Section 2.1 for notation. Define $\breve{S}_t := S_{A_t \cap A_{t-1}}$. First note that

$$\begin{aligned} r_t^\top u_t &= \left(X^\top \breve{S}_t^\top \breve{S}_t \left[(Xw_t - y) - (Xw_{t-1} - y)\right]\right)^\top (w_t - w_{t-1}) \\ &= (w_t - w_{t-1})^\top X^\top \breve{S}_t^\top \breve{S}_t X (w - w_{t-1}) \\ &\geq \delta \mu \|u_t\|^2, \end{aligned} \tag{16}$$

by (7), where recall $\delta \geq 0$ is the smallest eigenvalue of $\breve{S}_t^\top \breve{S}_t$. Also consider

$$\frac{\|r_t\|^2}{r_t^\top u_t} = \frac{(w_t - w_{t-1})^\top \left(X^\top \breve{S}_t^\top \breve{S}_t X\right) \left(X^\top \breve{S}_t^\top \breve{S}_t X\right) (w_t - w_{t-1})}{(w_t - w_{t-1})^\top X^\top \breve{S}_t^\top \breve{S}_t X (w_t - w_{t-1})},$$

which implies

$$\delta \mu \leq \frac{\|r_t\|^2}{r_t^\top u_t} \leq (1 + \epsilon) M,$$

again by (6). Now, setting $j_\ell = t - \tilde{\sigma} + \ell$, consider the trace

$$\mathbf{tr}\left(B_t^{(\ell+1)}\right) = \mathbf{tr}\left(B_t^{(\ell)}\right) - \mathbf{tr}\left(\frac{B_t^{(\ell)} u_{j_\ell} u_{j_\ell}^\top B_t^{(\ell)}}{u_{j_\ell}^\top B_t^{(\ell)} u_{j_\ell}}\right) + \mathbf{tr}\left(\frac{r_{j_\ell} r_{j_\ell}^\top}{r_{j_\ell}^\top u_{j_\ell}}\right)$$

$$\begin{aligned}
&\overset{(a)}{\leq} \mathbf{tr}\left(B_t^{(\ell)}\right) + \mathbf{tr}\left(\frac{r_{j_\ell} r_{j_\ell}^\top}{r_{j_\ell}^\top u_{j_\ell}}\right) \\
&= \mathbf{tr}\left(B_t^{(\ell)}\right) + \frac{\|r_{j_\ell}\|^2}{r_{j_\ell}^\top u_{j_\ell}} \\
&\leq \mathbf{tr}\left(B_t^{(\ell)}\right) + (1+\epsilon)M,
\end{aligned}$$

where (a) follows since the trace of a positive semidefinite matrix is always non-negative. This implies $\mathbf{tr}\left(B_t\right) \leq (1+\epsilon)M\left(\widetilde{\sigma}+d\right)$. We now do a similar exercise for the determinant. Note first that for two arbitrary vectors a and b,

$$\begin{aligned}
\det(I - aa^T + bb^T) &= \det\left(I + \begin{bmatrix}-a & b\end{bmatrix}\begin{bmatrix}a^T \\ b^T\end{bmatrix}\right) \overset{(a)}{=} \det\left(I + \begin{bmatrix}a^T \\ b^T\end{bmatrix}\begin{bmatrix}-a & b\end{bmatrix}\right) \\
&= (1 - a^T a)(1 + b^T b) + (a^T b)^2
\end{aligned}$$

where (a) is by Sylvester's identity. Since $B_t^{(\ell)} \succ 0$, we can take the Cholesky factorization $B_t^{(\ell)} = LL^T$ and write the recursion for $B_t^{(\ell)}$ as a product:

$$B_t^{(\ell+1)} \quad = \quad L\left(I - L^T \frac{u_{j_\ell} u_{j_\ell}^T}{u_{j_\ell}^T B_t^{(\ell)} u_{j_\ell}} L + L^{-1} \frac{r_{j_\ell} r_{j_\ell}^T}{r_{j_\ell}^T u_{j_\ell}} L^{-T}\right) L^T.$$

Using the above identity for

$$a = \frac{1}{u_{j_\ell}^T B_t^{(\ell)} u_{j_\ell}} L^T u_{j_\ell}, \qquad b = \frac{1}{\sqrt{r_{j_\ell}}^T u_{j_\ell}} L^T r_{j_\ell}$$

we can see that $a^T a = 1$, and $(a^T b)^2 = \frac{r_{j_\ell}^T u_{j_\ell}}{u_{j_\ell}^T B_t^{(\ell)} u_{j_\ell}}$. Therefore

$$\begin{aligned}
\det\left(B_t^{(\ell+1)}\right) &= \det\left(B_t^{(\ell)}\right) \cdot \frac{r_{j_\ell}^\top u_{j_\ell}}{u_{j_\ell}^\top B_t^{(\ell)} u_{j_\ell}} \\
&= \det\left(B_t^{(\ell)}\right) \cdot \frac{r_{j_\ell}^\top u_{j_\ell}}{\|u_{j_\ell}\|^2} \cdot \frac{\|u_{j_\ell}\|^2}{u_{j_\ell}^\top B_t^{(\ell)} u_{j_\ell}} \\
&\geq \det\left(B_t^{(\ell)}\right) \cdot \delta\mu \cdot \frac{\|u_{j_\ell}\|^2}{u_{j_\ell}^\top B_t^{(\ell)} u_{j_\ell}} \\
&\geq \det\left(B_t^{(\ell)}\right) \cdot \delta\mu \cdot \frac{1}{\lambda_{\min}(B_t^{(\ell)})} \\
&\geq \det\left(B_t^{(\ell)}\right) \cdot \delta\mu \cdot \frac{1}{\mathbf{tr}\left(B_t^{(\ell)}\right)} \\
&\geq \det\left(B_t^{(\ell)}\right) \frac{\delta\mu}{(1+\epsilon)M\left(\widetilde{\sigma}+d\right)},
\end{aligned}$$

which implies $\det\left(B_t\right) \geq \det\left(B_t^{(0)}\right)\left(\frac{\delta\mu}{(1+\epsilon)M(\widetilde{\sigma}+d)}\right)^{\widetilde{\sigma}}$. By construction, $\mathbf{tr}\left(B_t^{(0)}\right)$ is bounded above and $\det(B_t^{(0)})$ is bounded below, which means $\mathbf{tr}\left(B_t\right)$ is bounded above and $\det(B_t)$ is bounded below. Therefore there must exist $0 < c_1 \leq c_2$ such that

$$c_1 I \preceq B_t \preceq c_2 I.$$

■

Proof [Proof of Theorem 4]

Since $h(w)$ is constrained to be quadratic, we can absorb this term into the error term to get

$$\min_w \left\| \begin{bmatrix} S & 0 \\ 0 & I \end{bmatrix} \left(\begin{bmatrix} X \\ \sqrt{\lambda} I \end{bmatrix} w - \begin{bmatrix} y \\ 0 \end{bmatrix} \right) \right\|.$$

Note that as long as S satisfies (6), the effective encoding matrix $\mathrm{diag}\left([S, I]\right)$ also satisfies the same. Therefore, without loss of generality we can ignore $h(w)$, and consider minimizing the unregularized quadratic problem

$$\min_w \|\hat{X}w - y\|, \qquad \hat{X} = \begin{bmatrix} X \\ \sqrt{\lambda} I \end{bmatrix}.$$

Here,

$$(\mu + \lambda) I \preceq \hat{X}^\top \hat{X} \preceq (M + \lambda) I.$$

We also define the extreme eigenvalues of the encoding matrices as $\lambda_{\min} = 1 - \epsilon$ and $\lambda_{\max} = 1 + \epsilon$ for convenience. Using convexity and the closed-form expression for the step size, we have

$$\begin{aligned}
&\widetilde{f}^A\left(w_{t+1}\right) - \widetilde{f}^A(w_t) \leq \alpha_t \nabla \widetilde{f}^A(w_t)^\top d_t + \frac{1}{2}\alpha_t^2 d_t^\top \hat{X}^\top S_A^\top S_A \hat{X} d_t \\
&= -\frac{\rho\left(\nabla \widetilde{f}^A(w_t)^\top d_t\right)^2}{d_t^\top \hat{X}^\top S_D^\top S_D \hat{X} d_t} + \frac{1}{2}\frac{\rho^2\left(\nabla \widetilde{f}^A(w_t)^\top d_t\right)^2}{d_t^\top \hat{X}^\top S_D^\top S_D \hat{X} d_t} \cdot \frac{d_t^\top \hat{X}^\top S_A^\top S_A \hat{X} d_t}{d_t^\top \hat{X}^\top S_D^\top S_D \hat{X} d_t} \\
&= \left(\frac{d_t^\top \hat{X}^\top \left(\rho^2 S_A^\top S_A - 2\rho S_D^\top S_D\right) \hat{X} d_t}{2\left(d_t^\top \hat{X}^\top S_D^\top S_D \hat{X} d_t\right)^2}\right)\left(d_t^\top \nabla \widetilde{f}^A(w_t)\right)^2 \\
&\overset{(a)}{=} -\rho\left(\frac{z^\top\left(S_D^\top S_D - \frac{\rho}{2} S_A^\top S_A\right) z}{\left(z^\top S_D^\top S_D z\right)^2}\right)\frac{\left(d_t^\top \nabla \widetilde{f}^A(w_t)\right)^2}{\|\hat{X} d_t\|^2} \\
&\overset{(b)}{\leq} -\rho\left(\frac{\lambda_{\min} - \frac{\rho}{2}\lambda_{\max}}{\lambda_{\min}^2}\right)\frac{\left(d_t^\top \nabla \widetilde{f}^A(w_t)\right)^2}{\|\hat{X} d_t\|^2} \overset{(c)}{\leq} -\frac{\rho}{M+\lambda}\left(\frac{\lambda_{\min} - \frac{\rho}{2}\lambda_{\max}}{\lambda_{\min}^2}\right)\frac{\left(d_t^\top \nabla \widetilde{f}^A(w_t)\right)^2}{\|d_t\|^2} \\
&\overset{(d)}{=} -\frac{\rho}{M+\lambda}\left(\frac{\lambda_{\min} - \frac{\rho}{2}\lambda_{\max}}{\lambda_{\min}^2}\right)\frac{\left(\nabla \widetilde{f}^A(w_t)^\top B_t \nabla \widetilde{f}^A(w_t)\right)^2}{\|B_t \nabla \widetilde{f}^A(w_t)\|^2}
\end{aligned}$$

$$\overset{(e)}{\leq} -\frac{4\rho}{M+\lambda}\left(\frac{\lambda_{\min}-\frac{\rho}{2}\lambda_{\max}}{\lambda_{\min}^2}\right)\frac{c_1c_2}{(c_1+c_2)^2}\|\nabla\widetilde{f}^A(w_t)\|^2$$
$$\overset{(f)}{\leq} -\frac{8(\mu+\lambda)\rho}{M+\lambda}\left(\frac{\lambda_{\min}-\frac{\rho}{2}\lambda_{\max}}{\lambda_{\min}^2}\right)\frac{c_1c_2}{(c_1+c_2)^2}\left(\widetilde{f}\left(w_t\right)-\widetilde{f}\left(\widetilde{w}_t^*\right)\right)$$
$$\overset{(g)}{=} -\frac{4(\mu+\lambda)c_1c_2}{(M+\lambda)(1+\epsilon)\left(c_1+c_2\right)^2}\left(\widetilde{f}\left(w_t\right)-\widetilde{f}\left(\widetilde{w}_t^*\right)\right)\overset{(h)}{=}-\left(1-\gamma\right)\left(\widetilde{f}^A\left(w_t\right)-\widetilde{f}^A\left(\widetilde{w}_t^*\right)\right).$$

where (a) follows by defining $z=\frac{\hat{X}d_t}{\|\hat{X}d_t\|}$; (b) follows by (6); (c) follows by the assumption that $\hat{X}^\top\hat{X}\preceq(M+\lambda)I$; (d) follows by the definition of d_t; (e) follows by Lemmas 14 and 3; (f) follows by strong convexity of $\widetilde{f}$ (by Lemma 13), which implies $\|\nabla\widetilde{f}^A(w_t)\|^2\geq 2(\mu+\lambda)\left(\widetilde{f}\left(\theta_t\right)-\widetilde{f}\left(\widetilde{w}_t^*\right)\right)$; (g) follows by choosing $\rho=\frac{\lambda_{\min}}{\lambda_{\max}}$; and (h) follows using the definition of γ.

Re-arranging the inequality, we obtain

$$\widetilde{f}_{t+1}^A-\widetilde{f}^A\left(\widetilde{w}_t^*\right)\leq\gamma\left(\widetilde{f}_t^A-\widetilde{f}^A\left(\widetilde{w}_t^*\right)\right),$$

and hence applying Lemma 12, we get the desired result. ■

Appendix B. Proof of Theorem 5

Throughout this appendix, we will define $p(w)=\frac{1}{2}\|Xw-y\|^2$ and $\widetilde{p}_t(w)=\frac{1}{2}\|S_{A_t}\left(Xw-y\right)\|^2$ for convenience, where the normalization by $\sqrt{\eta}$ is absorbed into S_A. We will omit the normalization by n for brevity. Let us also define

$$w^*=\arg\min_w p(w)+\lambda h(w)$$

to be the true solution of the optimization problem.

By M-smoothness of $p(w)$,

$$\begin{aligned}p(w_{t+1})&\leq p(w_t)+\langle\nabla p(w_t),w_{t+1}-w_t\rangle+\frac{M}{2}\|w_{t+1}-w_t\|^2\\&\leq p(w^*)-\langle\nabla p(w_t),w^*-w_t\rangle+\langle\nabla p(w_t),w_{t+1}-w_t\rangle+\frac{M}{2}\|w_{t+1}-w_t\|^2\\&\leq p(w^*)-\langle\nabla p(w_t),w^*-w_t\rangle+\langle\nabla p(w_t),w_{t+1}-w_t\rangle+\frac{1}{2\alpha}\|w_{t+1}-w_t\|^2\\&\leq p(w^*)+\langle\nabla p(w_t),w_{t+1}-w^*\rangle+\frac{1}{2\alpha}\|w_{t+1}-w_t\|^2\end{aligned}\tag{17}$$

where the second line follows by convexity of p, and the third line follows since $\alpha<\frac{1}{M}$. Since $w_{t+1}=\arg\min_w\widetilde{F}_t(w)$, by optimality conditions

$$0\in\lambda\cdot\partial h(w_{t+1})+\nabla\widetilde{p}_t(w_t)+\frac{1}{\alpha}\left(w_{t+1}-w_t\right).\tag{18}$$

Since h is convex, any subgradient $g\in\partial h$ at $w=w_{t+1}$ satisfies

$$h(w^*)\geq h(w_{t+1})+\langle g,w^*-w_{t+1}\rangle,$$

and therefore (18) implies

$$\lambda h(w^*)\geq\lambda h(w_{t+1})-\langle\nabla\widetilde{p}_t(w_t),w^*-w_{t+1}\rangle-\frac{1}{\alpha}\langle w_{t+1}-w_t,w^*-w_{t+1}\rangle.\tag{19}$$

Combining (17) and (19),we have

$$f(w_{t+1})=p(w_{t+1})+\lambda h(w_{t+1})\tag{20}$$
$$\begin{aligned}&=p(w^*)+\langle\nabla p(w_t),w_{t+1}-w^*\rangle+\frac{1}{2\alpha}\|w_{t+1}-w_t\|^2\\&\leq f(w^*)+\langle\nabla p(w_t)-\nabla\widetilde{p}_t(w_t),w_{t+1}-w^*\rangle\\&\quad-\frac{1}{\alpha}\langle w_t-w_{t+1},w^*-w_{t+1}\rangle+\frac{1}{2\alpha}\|w_t-w_{t+1}\|^2\\&=f(w^*)+\langle\nabla p(w_t)-\nabla\widetilde{p}_t(w_t),w_{t+1}-w^*\rangle\\&\quad+\frac{1}{2\alpha}\left(\|w_t\|^2-2w_t^\top w^*+\|w^*\|^2+2w_{t+1}^\top w^*-\|w^*\|^2-\|w_{t+1}\|^2\right)\\&=f(w^*)+\langle\nabla p(w_t)-\nabla\widetilde{p}_t(w_t),w_{t+1}-w^*\rangle\\&\quad+\frac{1}{2\alpha}\left(\|w_t-w^*\|^2-\|w_{t+1}-w^*\|^2\right)\end{aligned}\tag{21}$$
$$\tag{22}$$

Define $\Delta=I-S_A^\top S_A$, and consider the second term on the right-hand side of (22).

$$\begin{aligned}&\langle\nabla p(w_t)-\nabla\widetilde{p}_t(w_t),w_{t+1}-w^*\rangle=\left\langle X^\top\Delta(Xw_t-y),w_{t+1}-w^*\right\rangle\\&=\langle\Delta(Xw_t-y),Xw_{t+1}-y\rangle-\langle\Delta(Xw_t-y),Xw^*-y\rangle\\&=\frac{1}{2}\Big[\left(X\left(w_t+w_{t+1}\right)-2y\right)^\top\Delta\left(X\left(w_t+w_{t+1}\right)-2y\right)\\&\quad-\left(Xw_{t+1}-y\right)^\top\Delta\left(Xw_{t+1}-y\right)+\left(Xw^*-y\right)^\top\Delta\left(Xw^*-y\right)\\&\quad-\left(X\left(w_t+w^*\right)-2y\right)^\top\Delta\left(X\left(w_t+w^*\right)-2y\right)\Big]\\&=2\left(X\left(\frac{w_t+w_{t+1}}{2}\right)-y\right)^\top\Delta\left(X\left(\frac{w_t+w_{t+1}}{2}\right)-y\right)\\&\quad-2\left(X\left(\frac{w_t+w^*}{2}\right)-y\right)^\top\Delta\left(X\left(\frac{w_t+w^*}{2}\right)-y\right)\\&\quad-\frac{1}{2}\left(Xw_{t+1}-y\right)^\top\Delta\left(Xw_{t+1}-y\right)+\frac{1}{2}\left(Xw^*-y\right)^\top\Delta\left(Xw^*-y\right)\\&\leq 4\epsilon p\left(\frac{w_t+w_{t+1}}{2}\right)+4\epsilon p\left(\frac{w_t+w^*}{2}\right)+\epsilon p(w_{t+1})+\epsilon p(w^*)\\&\overset{(a)}{\leq}2\epsilon p(w_t)+2\epsilon p(w_{t+1})+2\epsilon p(w_t)+2\epsilon p(w^*)+\epsilon p(w_{t+1})+\epsilon p(w^*)\\&=\epsilon\left[4p(w_t)+3p(w_{t+1})+3p(w^*)\right]\\&\overset{(b)}{\leq}\epsilon\left[4f(w_t)+3f(w_{t+1})+3f(w^*)\right],\end{aligned}$$

where (a) is by convexity of $p(w)$ and Jensen's inequality, and (b) follows by non-negativity of h. Plugging this back in (22),

$$(1-3\epsilon)\, f(w_{t+1}) - 4\epsilon f(w_t) \leq (1+3\epsilon)\, f(w^*) + \frac{1}{2\alpha}\left(\|w_t - w^*\|^2 - \|w_{t+1} - w^*\|^2\right).$$

Adding this for $t = 0, \ldots, (T-1)$,

$$(1-7\epsilon)\sum_{t=1}^{T-1} f(w_t) + (1-3\epsilon) f(w_T) \leq T\,(1+3\epsilon)\, f(w^*) + 4\epsilon f(w_0) + \frac{1}{2\alpha}\left(\|w_0 - w^*\|^2 - \|w_T - w^*\|^2\right)$$

$$\Rightarrow (1-7\epsilon)\sum_{t=1}^{T} f(w_t) \leq T\,(1+3\epsilon)\, f(w^*) + 4\epsilon f(w_0) + \frac{1}{2\alpha}\left(\|w_0 - w^*\|^2 - \|w_T - w^*\|^2\right)$$

$$\leq T\,(1+3\epsilon)\, f(w^*) + 4\epsilon f(w_0) + \frac{1}{2\alpha}\|w_0 - w^*\|^2.$$

Defining $\bar{f}_t = \frac{1}{T}\sum_{t=1}^{T} f(w_t)$, and $\kappa = \frac{1+3\epsilon}{1-7\epsilon}$, we get

$$\bar{f}_T - \kappa f(w^*) \leq \frac{4\epsilon f(w_0) + \frac{1}{2\alpha}\|w_0 - w^*\|^2}{(1-7\epsilon)\, T},$$

which proves the first part of the theorem. To establish the second part of the theorem, note that the convexity of h implies

$$h(w_t) \geq h(w_{t+1}) + \langle g, w_t - w_{t+1}\rangle,$$

where $g \in \partial h(w_{t+1})$. By the optimality condition (18), this implies

$$\lambda h(w_t) \geq \lambda h(w_{t+1}) - \langle \nabla \widetilde{p}_t(w_t), w_t - w_{t+1}\rangle + \frac{1}{\alpha}\|w_{t+1} - w_t\|^2.$$

Combining this with the smoothness condition of $p(w)$,

$$p(w_{t+1}) \leq p(w_t) + \langle \nabla p(w_t), w_{t+1} - w_t\rangle + \frac{M}{2}\|w_{t+1} - w_t\|^2$$

and using the fact that $\alpha < \frac{1}{M}$, we have

$$f(w_{t+1}) \leq f(w_t) + \langle \nabla p(w_t) - \nabla \widetilde{p}_t(w_t), w_{t+1} - w_t\rangle - \frac{1}{2\alpha}\|w_t - w_{t+1}\|^2.$$

As in the previous analysis, we can show that

$$\langle \nabla p(w_t) - \nabla \widetilde{p}_t(w_t), w_{t+1} - w_t\rangle \leq \epsilon\left[7 f(w_t) + 3 f(w_{t+1})\right],$$

and therefore

$$f(w_{t+1}) \leq \frac{1+7\epsilon}{1-3\epsilon} f(w_t) - \frac{1}{2\alpha(1-3\epsilon)}\|w_t - w_{t+1}\|^2$$

$$\leq \frac{1+7\epsilon}{1-3\epsilon} f(w_t).$$

Appendix C. Proof of Theorem 6

For an iterate v_t, let $w_t := S v_t$. Define the solution set $\mathcal{S} = \arg\min_w g(w)$, and $w_t^* = \mathcal{P}_{\mathcal{S}}(w_t)$, where $\mathcal{P}_{\mathcal{S}}(\cdot)$ is the projection operator onto the set $\mathcal{S}$. Let v_t^* be such that $w_t^* = S^\top v_t^*$, which always exists since S has full column rank.

We also define $L' := L(1+\epsilon)$, and $g^* = \min_w g(w) = g(w_t^*)$ for any t.

C.1. Lemmas

Lemma 15 *$\widetilde{g}(v)$ is L'-smooth.*

Proof For any u, v,

$$\widetilde{g}(u) = g(S^\top u) \leq g(S^\top v) + \langle \nabla g(S^\top v), S^\top(u-v)\rangle + \frac{L}{2}\|S^\top(u-v)\|^2,$$

$$\overset{(a)}{\leq} g(S^\top v) + \langle S\nabla g(S^\top v), u - v\rangle + \frac{L(1+\epsilon)}{2}\|u-v\|^2,$$

$$\overset{(b)}{=} \widetilde{g}(v) + \langle \nabla \widetilde{g}(v), u - v\rangle + \frac{L(1+\epsilon)}{2}\|u-v\|^2,$$

where (a) follows from smoothness of g, and from (m, η, ϵ)-BRIP property, and (b) is by the chain rule of derivatives and the definition of $\widetilde{g}(v)$. Therefore $\widetilde{g}$ is $L(1+\epsilon)$-smooth. ■

Lemma 16 *For any t,*

$$\widetilde{g}^* := \min_v \widetilde{g}(v) = \min_w g(w) =: g^*.$$

Proof It is clear that

$$\min_v \tilde{g}(v) = \min_v g(S^\top v) \geq \min_w g(w).$$

To show the other direction, set $v^* = S(S^\top S)^{-1} w^*$, where $S^\top S$ is invertible since S has full column rank. Then $g(w^*) = \tilde{g}(v^*) \geq \min_v \tilde{g}(v)$. ■

Lemma 17 *If g is ν-restricted-strongly convex, then*

$$g(w) - g^* \geq \frac{\nu}{2}\|w - w^*\|^2,$$

where $w^* = \mathcal{P}_{\mathcal{S}}(w)$.

Proof We follow the proof technique in Zhang and Yin (2013). We have

$$g(w) = g^* + \int_0^1 \langle \nabla g(w^* + \tau(w - w^*)), w - w^*\rangle d\tau$$

$$= g^* + \int_0^1 \frac{1}{\tau}\langle \nabla g(w^* + \tau(w - w^*)), \tau(w - w^*)\rangle d\tau$$

$$\overset{(a)}{\geq} g^* + \int_0^1 \frac{1}{\tau}\nu\tau^2\|w - w^*\|^2 d\tau$$
$$= g^* + \nu\|w - w^*\|^2 \int_0^1 \tau d\tau$$
$$= g^* + \frac{1}{2}\nu\|w - w^*\|^2,$$

which is the desired result, where in (a) we used ν-restricted strong convexity, and the fact that

$$\mathcal{P}_{\mathcal{S}}(w^* + \tau(w - w^*)) = w^*,$$

for all $\tau \in [0, 1]$, since $w^* = \mathcal{P}_{\mathcal{S}}(w)$ is the orthogonal projection. ■

C.2. Proof of Theorem 6

Recall that the step for block i at time t, $\Delta_{i,t}$, is defined by

$$\Delta_{i,t} := \begin{cases} -\alpha\nabla_i \widetilde{g}(v_{t-1}), & \text{if } i \in A_t \\ 0, & \text{otherwise.} \end{cases}$$

By smoothness and definition of Δ_t,

$$\begin{aligned}\widetilde{g}(v_{t+1}) - \widetilde{g}(v_t) &\leq \langle \nabla\widetilde{g}(v_t), \Delta_t\rangle + \frac{L'}{2}\|\Delta_t\|^2 \\ &= \sum_{i\in A_t}\left(\langle \nabla_i\widetilde{g}(v_t), \Delta_{i,t}\rangle + \frac{L'}{2}\|\Delta_{i,t}\|^2\right) \\ &= \sum_{i\in A_t}\left(-\frac{1}{\alpha}\langle \Delta_{i,t}, \Delta_{i,t}\rangle + \frac{L'}{2}\|\Delta_{i,t}\|^2\right) \\ &= -\left(\frac{1}{\alpha} - \frac{L'}{2}\right)\|\Delta_t\|^2. \end{aligned} \tag{23}$$

Now, for any t,

$$\begin{aligned}\widetilde{g}(v_t) - \widetilde{g}^* &\leq \langle \nabla\widetilde{g}(v_t), v_t^* - v_t\rangle = \left\langle S\nabla g(S^\top v_t), v_t^* - v_t\right\rangle \\ &\overset{(a)}{\leq} \left\|\nabla g(S^\top v_t)\right\| \cdot \left\|S^\top(v_t^* - v_t)\right\| = \left\|\nabla g(S^\top v_t)\right\| \cdot \|w_t^* - w_t\|, \end{aligned} \tag{24}$$

where (a) is due to Cauchy-Schwartz inequality. Using

$$\Delta_t = -\alpha P_t \begin{bmatrix} S_{A_t}\nabla g(S^\top v_t) \\ 0 \end{bmatrix},$$

where P_t is a block permutation matrix mapping $\{1, \ldots, k\}$ to the node indices in A_t, we have

$$\|\Delta_t\|^2 = \alpha^2 \nabla g(S^\top v_t)^\top S_{A_t}^\top P_t^\top P_t S_{A_t}\nabla g(S^\top v_t) \geq (1-\epsilon)\alpha^2\left\|\nabla g(S^\top v_t)\right\|^2. \tag{25}$$

Because of (23), we have

$$\widetilde{g}(v_{t+1}) - \widetilde{g}(v_t) = g(w_{t+1}) - g(w_t) \leq 0$$

when $\alpha < 2/L'$, and hence w_t is contained in the level set defined by the initial iterate for all t, *i.e.*,

$$w_t \in \{w : g(w) \leq g(w_0)\}.$$

By the diameter assumption on this set, we have $\|w_t - w_t^*\| \leq R$ for all t. Using this and (25) in (24), we get

$$\widetilde{g}(v_t) - \widetilde{g}^* \leq \frac{R}{\alpha}\sqrt{\frac{1}{1-\epsilon}}\|\Delta_t\|.$$

Note that the fact that $\epsilon > 0$ weakens the per-step bound here, since we do not take the steepest descent direction. Another penalty from non-zero $\epsilon > 0$ comes due to the increase in the smoothness parameter of the objective $L' = (1+\epsilon)L$, which slightly limits the maximum step size.

Combining the above with (23),

$$\widetilde{g}(v_{t+1}) - \widetilde{g}(v_t) \leq -\frac{(1-\epsilon)\alpha}{R^2}\left(1 - \frac{\alpha L'}{2}\right)\left(\widetilde{g}(v_t) - \widetilde{g}^*\right)^2.$$

Defining $\pi_t := \widetilde{g}(v_t) - \widetilde{g}^*$, and $C := \frac{(1-\epsilon)\alpha}{R^2}\left(1 - \frac{\alpha L'}{2}\right)$, this implies

$$\pi_{t+1} \leq \pi_t - C\pi_t^2.$$

Dividing both sides by $\pi_t\pi_{t+1}$, and noting that $\pi_{t+1} \leq \pi_t$ due to (23),

$$\frac{1}{\pi_t} \leq \frac{1}{\pi_{t+1}} - C\frac{\pi_t}{\pi_{t+1}} \leq \frac{1}{\pi_{t+1}} - C$$

Therefore

$$\frac{1}{\pi_t} \geq \frac{1}{\pi_0} + Ct,$$

which implies

$$\pi_t \leq \frac{1}{\frac{1}{\pi_0} + Ct}.$$

Since $g(w_t) = g(S^\top v_t) = \widetilde{g}(v_t)$ by definition, and $g^* = \widetilde{g}^*$ by Lemma 16, $\pi_t = g(w_t) - g^*$, and therefore we have established the first part of the theorem.

To prove the second part, we make the additional assumption that g satisfies ν-restricted-strong convexity, which, through Lemma 17, implies $g(w) - g^* \geq \frac{\nu}{2}\|w - w^*\|^2$, for $w^* = \mathcal{P}_{\mathcal{S}}(w)$. Plugging in $w = w_t$ then gives the bound

$$\|w_t - w_t^*\|^2 \leq \frac{2}{\nu}\pi_t.$$

Using this bound as well as (25) in (24), we have

$$\pi_t^2 \leq \frac{2\|\Delta_t\|^2}{\nu(1-\epsilon)\alpha^2}\pi_t.$$

Using (23), this gives

$$\pi_t \leq \frac{2}{\nu(1-\epsilon)\alpha^2}\left(\frac{1}{\alpha}-\frac{L'}{2}\right)^{-1}(\pi_t - \pi_{t+1}),$$

which, defining $\xi = \frac{2}{\nu(1-\epsilon)\alpha}\left(1-\frac{L'\alpha}{2}\right)^{-1}$, results in

$$\pi_t \leq \left(1-\frac{1}{\xi}\right)^t \pi_0,$$

which shows the desired result.

Appendix D. Full results of the Matrix factorization experiment

Abstract

In this paper, we provide new insights on the Unadjusted Langevin Algorithm. We show that this method can be formulated as the first order optimization algorithm for an objective functional defined on the Wasserstein space of order 2. Using this interpretation and techniques borrowed from convex optimization, we give a non-asymptotic analysis of this method to sample from log-concave smooth target distribution on $\mathbb{R}^d$. Based on this interpretation, we propose two new methods for sampling from a non-smooth target distribution. These new algorithms are natural extensions of the Stochastic Gradient Langevin Dynamics (SGLD) algorithm, which is a popular extension of the Unadjusted Langevin Algorithm for largescale Bayesian inference. Using the optimization perspective, we provide non-asymptotic convergence analysis for the newly proposed methods.

Keywords: Unadjasted Langevin Algorithm, convex optimization, Bayesian inference, gradient flow, Wasserstein metric

1. Introduction

This paper deals with the problem of sampling from a probability measure π on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ which admits a density, also denoted by π, with respect to the Lebesgue measure given for all $x \in \mathbb{R}^d$ by

$$\pi(x) = \mathrm{e}^{-U(x)} \Big/ \int_{\mathbb{R}^d} \mathrm{e}^{-U(y)} \mathrm{d}y \ ,$$

where $U : \mathbb{R}^d \to \mathbb{R}$. This problem arises in various fields such that Bayesian statistical inference (Gelman et al., 2014), machine learning (Andrieu et al., 2003), ill-posed inverse problems (Stuart, 2010), and computational physics (Krauth, 2006). Common and current methods to tackle this problem are Markov Chain Monte Carlo methods (Brooks et al., 2011), for example the Hastings-Metropolis algorithm (Metropolis et al., 1953; Hastings, 1970) or Gibbs sampling (Geman and Geman, 1984). All these methods boil down to building a Markov kernel on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ whose invariant probability distribution is π. Yet, choosing an appropriate proposal distribution for the Hastings-Metropolis algorithm is a tricky subject. For this reason, it has been proposed to consider continuous dynamics which naturally leave the target distribution π invariant. Perhaps, one of the most famous examples is the over-damped Langevin diffusion (Rossky et al., 1978; Parisi, 1981) associated with U, which is assumed to be continuously differentiable:

$$\mathrm{d}\mathbf{Y}_t = -\nabla U(\mathbf{Y}_t)\mathrm{d}t + \sqrt{2}\mathrm{d}B_t \ , \tag{1}$$

where $(B_t)_{t\geq 0}$ is a d-dimensional Brownian motion. With appropriate conditions on U, this SDE admits a unique strong solution $(\mathbf{Y}_t)_{t\geq 0}$ and defines a strong Markov semi-group $(P_t)_{t\geq 0}$ which converges to π in total variation (Roberts and Tweedie, 1996, Theorem 2.1) or Wasserstein distance (Bolley et al., 2012). However, simulating exact solutions of such stochastic differential equations is not possible in most cases, and discretizations of these equations are used instead. In addition, numerical solutions associated with these schemes define Markov kernels for which π is not invariant anymore. Therefore quantifying the error introduced by these approximations is crucial to justify their use to sample from the target π. We consider in this paper the Euler-Maruyama discretization of (1) which defines the (possibly inhomogeneous) Markov chain $(X_k)_{k\geq 0}$ given for all $k \geq 0$ by

$$X_{k+1} = X_k - \gamma_{k+1}\nabla U(X_k) + \sqrt{2\gamma_{k+1}}G_{k+1} \ , \tag{2}$$

where $(\gamma_k)_{k\geq 1}$ is a sequence of stepsizes which can be held constant or converges to 0, and $(G_k)_{k\geq 1}$ is a sequence of i.i.d. standard d-dimensional Gaussian random variables. The use of the Euler-Maruyama discretization (2) to approximatively sample from π is referred to as the Unadjusted Langevin Algorithm (ULA) (or the Langevin Monte Carlo algorithm (LMC)), and has already been the matter of many works. For example, weak error estimates have been obtained in Talay and Tubaro (1990); Mattingly et al. (2002) for the constant stepsize setting and in Lamberton and Pagès (2003); Lemaire (2005) when $(\gamma_k)_{k\geq 1}$ is non-increasing and goes to 0. Explicit and non-asymptotic bounds on the total variation (Dalalyan, 2016; Durmus and Moulines, 2017) or the Wasserstein distance (Durmus and Moulines, 2016) between the distribution of X_k and π have been obtained. Roughly, all these results are based on the comparison between the discretization and the diffusion process and the quantification of error accumulation throughout the algorithm. In this paper, we propose another point of view on ULA, which shares nevertheless some relations with the Langevin diffusion (1). Indeed, it has been shown in Jordan et al. (1998) that the family of distributions $(\mu_0 P_t)_{t\geq 0}$, is the solution of a gradient flow equation in the Wasserstein space of order 2 associated with the Kullback-Leibler (KL) divergence, $\mathscr{F}$, where $(P_t)_{t\geq 0}$ is the semi-group associated with (1) and μ_0 is a probability measure on $\mathcal{B}(\mathbb{R}^d)$ admitting a second moment (see Section 2). If π is invariant for $(P_t)_{t\geq 0}$, then it is a stationary solution of this equation, and is the unique minimizer of $\mathscr{F}$ if U is convex. Starting from this observation, we interpret ULA as the first order optimization algorithm on the Wasserstein space of order 2 with objective functional $\mathscr{F}$. Namely, we adapt some proofs of convergence for the gradient descent algorithm from the convex optimization literature to obtain non-asymptotic and explicit bounds between the Kullback-Leibler (KL) divergence from π to distributions of averaged distributions associated with ULA for the constant and non-increasing stepsize setting. Then, these bounds easily imply computable bounds in total variation norm and Wasserstein distance. Note that these two metrics are different in nature since convergence

in one of them does not imply convergence in the other. Convergence in one of these metrics implies a control on the bias of MCMC based estimators of the form $\hat{f}_n = n^{-1}\sum_{k=1}^{n} f(Y_k)$, where $(Y_k)_{k\in\mathbb{N}}$ is Markov chain ergodic with respect to the target density π, for f belonging to a certain class of functions. In the case of the total variation distance, this class is the set of measurable and bounded functions, in the case of the Wasserstein distance, it is the set of Lipschitz functions. If the potential U is strongly convex and gradient Lipschitz, we get back the results of Durmus and Moulines (2017, 2016); Cheng and Bartlett (2017), when the stepsize is held constant in (2). In the case where U is only convex and from a warm start, we get a bound on the complexity for ULA of order $d\bar{\mathcal{O}}(\varepsilon^{-2})$ and $d\bar{\mathcal{O}}(\varepsilon^{-4})$ to get one sample distributed close from π with accuracy $\varepsilon > 0$, in KL divergence and total variation distance respectively. Overview of bounds on computational complexity of ULA is presented in Table 1.

	Strongly convex U		Convex U

Table 1: Overview of bounds on computational complexity of ULA, with constant stepsize. We present complexity to get one sample distributed close from π with accuracy $\varepsilon > 0$ in Wasserstein distance (Wasserstein), total variation distance (TV), and Kullback Leibler divergence (KL). We compare the best results (Best) from literature with ours (Ours) in the strongly convex and convex cases. In the convex case we consider two possible initial measures: a warm start, *i.e.* $W_2^2(\mu_0, \pi) \leq C$, for some absolute constant $C \geq 0$ (Warm start) and starting from Dirac delta at a minimizer of U, $x^\star$.

In addition, we propose two new algorithms to sample from a class of non-smooth log-concave distributions for which we derive computable non-asymptotic bounds as well. The first one can be applied to Lipschitz convex potential for which unbiased estimates of subgradients are available. Remarkably, the bounds we obtain for this algorithm depend on the dimension only through the initial condition and the variance of the stochastic subgradient estimates. Precisely, we get a bound on the complexity to get a sample with distribution close from π with accuracy $\varepsilon > 0$, of order $(M^2 + D^2)\bar{\mathcal{O}}(\varepsilon^{-2})$ in the case of the KL divergence and $(M^2 + D^2)\bar{\mathcal{O}}(\varepsilon^{-4})$ in the case of the total variation distance, where M is Lipschitz constant of the potential U and D^2 is a bound on the variance of the considered stochastic subgradient.

The second method we propose is a generalization of the Stochastic Gradient Langevin Dynamics algorithm (Welling and Teh, 2011), which extends ULA by replacing the gradient

with a sequence of i.i.d. unbiased estimators. In this new scheme, we assume that U can be decomposed as the sum of two functions U_1 and U_2, where U_1 is at least continuously differentiable and U_2 is only convex, and use stochastic gradient estimates for U_1 and the proximal operator associated with U_2. This new method is close to the one proposed in Durmus et al. (2018) but contrary on this work we do not need to approximate U_2 by its Moreau envelope. To get computable bounds from the target distribution π, we interpret this algorithm as a first order optimization algorithm and provide explicit bounds between the KL divergence from π to distributions associated with SGLD. In the case where U is strongly convex and gradient Lipschitz (*i.e.* $U_2 = 0$), we get back the same complexity as Dalalyan and Karagulyan (2017) which is of order $d\bar{\mathcal{O}}(\varepsilon^{-2})$ for the Wasserstein distance. We obtain the same complexity for the total variation distance and a complexity of order $d\bar{\mathcal{O}}(\varepsilon^{-1})$ for the KL divergence . In the case where U is only convex, not necessarily smooth (*i.e.* U_2 could be non-smooth), and from a warm start, we get a complexity of order $d\bar{\mathcal{O}}(\varepsilon^{-2})$ and $d\bar{\mathcal{O}}(\varepsilon^{-4})$ to get one sample distributed close from π with accuracy $\varepsilon > 0$ in KL divergence and total variation distance respectively. Overview of bounds for SGLD is presented in Table 2.

Extensive studies have also analyzed SGLD in a general setting, *i.e.* the potential U is not necessarily convex. In Vollmer et al. (2016) and Nagapetyan et al. (2017), a study of this scheme is done by weak error estimates. Finally, Raginsky et al. (2017) and Xu et al. (2017) gives some results regarding the potential use of SGLD as an optimization algorithm to minimize the potential U by targeting a target density proportional to $x \mapsto \mathrm{e}^{-\beta U(x)}$ for some $\beta > 0$.

Table 2: Overview of bounds on computational complexity of SGLD, with constant stepsize. We present complexity to get one sample distributed close from π with accuracy $\varepsilon > 0$ in Wasserstein distance (Wasserstein), total variation distance (TV), and Kullback Leibler divergence (KL). We compare the best results (Best) from literature with ours (Ours) in the strongly convex and convex cases. In the convex case we consider two possible initial measures: warm start, *i.e.* $W_2^2(\mu_0, \pi) \leq C$, for some absolute constant $C \geq 0$ (Warm start) and starting from Dirac delta at a minimizer of U, $x^\star$.

In summary, our contributions are the following:

- We give a new interpretation of ULA and use it to get bounds on the KL divergence from π to the iterates of ULA. We recover the dependence on the dimension of Cheng and Bartlett (2017, Theorem 3) in the strongly convex case and get tighter bounds. Note that this result implies previously known bounds between π and ULA in Wasserstein distance and the total variation distance but with a completely different technique. We also give computable bounds when U is only convex which improves the results of Durmus and Moulines (2017); Dalalyan (2016); Cheng and Bartlett (2017).
- We give two new methodologies to sample from a non-smooth potential U and make a non-asymptotic analysis of them. These two new algorithms are generalizations of SGLD.

The paper is organized as follows. In Section 2, we give some intuition on the strategy we take to analyze ULA and its variants. These ideas come from gradient flow theory in Wasserstein space. In Section 3, we give the main results we obtain on ULA and their proof. In Section 4, two variants of ULA are presented and analyzed. Finally, numerical experiments on logistic regression models are presented in Section 5 to support our theoretical findings regarding our new methodologies.

1.1. Notations and Conventions

Denote by $\mathcal{B}(\mathbb{R}^d)$ the Borel σ-field of $\mathbb{R}^d$, Leb the Lebesgue measure on $\mathcal{B}(\mathbb{R}^d)$, $\mathbb{F}(\mathbb{R}^d)$ the set of all Borel measurable functions on $\mathbb{R}^d$ and for $f \in \mathbb{F}(\mathbb{R}^d)$, $\|f\|_\infty = \sup_{x\in\mathbb{R}^d} |f(x)|$. For μ a probability measure on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ and $f \in \mathbb{F}(\mathbb{R}^d)$ a μ-integrable function, denote by $\mu(f)$ the integral of f w.r.t. μ. Let μ and ν be two sigma-finite measures on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$. Denote by $\mu \ll \nu$ if μ is absolutely continuous w.r.t. ν and $\mathrm{d}\mu/\mathrm{d}\nu$ the associated density. Let μ, ν be two probability measures on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$. Define the Kullback-Leibler (KL) divergence of μ from ν by

$$\mathrm{KL}\left(\mu|\nu\right) = \begin{cases} \int_{\mathbb{R}^d} \frac{\mathrm{d}\mu}{\mathrm{d}\nu}(x) \log\left(\frac{\mathrm{d}\mu}{\mathrm{d}\nu}(x)\right) \mathrm{d}\nu(x) \;, & \text{if } \mu \ll \nu \\ +\infty & \text{otherwise .} \end{cases}$$

We say that ζ is a transference plan of μ and ν if it is a probability measure on $(\mathbb{R}^d \times \mathbb{R}^d, \mathcal{B}(\mathbb{R}^d \times \mathbb{R}^d))$ such that for all measurable set A of $\mathbb{R}^d$, $\zeta(\mathsf{A} \times \mathbb{R}^d) = \mu(\mathsf{A})$ and $\zeta(\mathbb{R}^d \times \mathsf{A}) = \nu(\mathsf{A})$. We denote by $\Pi(\mu, \nu)$ the set of transference plans of μ and ν. Furthermore, we say that a couple of $\mathbb{R}^d$-random variables (X, Y) is a coupling of μ and ν if there exists $\zeta \in \Pi(\mu, \nu)$ such that (X, Y) are distributed according to ζ. For two probability measures μ and ν, we define the Wasserstein distance of order 2 as

$$W_2(\mu, \nu) = \left(\inf_{\zeta \in \Pi(\mu,\nu)} \int_{\mathbb{R}^d \times \mathbb{R}^d} \|x - y\|^2 \, \mathrm{d}\zeta(x, y) \right)^{1/2} . \tag{3}$$

By (Villani, 2009, Theorem 4.1), for all μ, ν probability measures on $\mathbb{R}^d$, there exists a transference plan $\zeta^\star \in \Pi(\mu, \nu)$ such that for any coupling (X, Y) distributed according to $\zeta^\star$, $W_2(\mu, \nu) = \mathbb{E}[\|X - Y\|^2]^{1/2}$. This kind of transference plan (respectively coupling) will be called an optimal transference plan (respectively optimal coupling) associated with W_2. We denote by $\mathcal{P}_2(\mathbb{R}^d)$ the set of probability measures with finite second moment: for all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$, $\int_{\mathbb{R}^d} \|x\|^2 \, \mathrm{d}\mu(x) < +\infty$. By (Villani, 2009, Theorem 6.16), $\mathcal{P}_2(\mathbb{R}^d)$ equipped with the Wasserstein distance W_2 of order 2 is a complete separable metric space. Denote by $\mathcal{P}^{\mathrm{a}}(\mathbb{R}^d) = \{\mu \in \mathcal{P}_2(\mathbb{R}^d) \,:\, \mu \ll \mathrm{Leb}\}$. For two probability measures μ and ν on $\mathbb{R}^d$, the total variation distance distance between μ and ν is defined by $\|\mu - \nu\|_{\mathrm{TV}} = \sup_{\mathsf{A}\in\mathcal{B}(\mathbb{R}^d)} |\mu(\mathsf{A}) - \nu(\mathsf{A})|$.

Let $n \in \mathbb{N} \cup \{\infty\}$ and $\mathsf{U} \subset \mathbb{R}^d$ be an open set of $\mathbb{R}^d$. Denote by $C^n(\mathsf{U})$ the set of n-th continuously differentiable function from U to $\mathbb{R}$. Denote by $C^n_c(\mathsf{U})$ the set of n-th continuously differentiable function from U to $\mathbb{R}$ with compact support. Let $I \subset \mathbb{R}$ be an interval and $f : I \to \mathbb{R}$. f is absolutely continuous on I if for all $\varepsilon > 0$, there exists $\delta > 0$ such that for all $n \in \mathbb{N}^*$ and $t_1, \ldots, t_{2n} \in I$, $t_1 \le \cdots \le t_{2n}$,

$$\text{if } \sum_{k=1}^{n} \{t_{2k} - t_{2k-1}\} \le \delta \;\text{ then }\; \sum_{k=1}^{n} |f(t_{2k}) - f(t_{2k-1})| \le \varepsilon \;.$$

In the sequel, we take the convention that $\sum_p^n = 0$ and $\prod_p^n = 1$ for $n, p \in \mathbb{N}$, $n < p$.

2. Interpretation of ULA as an Optimization Algorithm

Throughout this paper, we assume that U satisfies the following condition for $m \ge 0$.

A 1 (m) $U : \mathbb{R}^d \to \mathbb{R}$ is m-convex, *i.e.* for all $x, y \in \mathbb{R}^d$,

$$U(tx + (1-t)y) \le tU(x) + (1-t)U(y) - t(1-t)(m/2)\|x - y\|^2$$

Note that $\mathbf{A}\,1(m)$ includes the case where U is only convex when $m = 0$. We consider in this Section the following additional condition on U which will be relaxed in Section 4.

A 2 U is continuously differentiable and L-gradient Lipschitz, *i.e.* there exists $L \ge 0$ such that for all $x, y \in \mathbb{R}^d$, $\|\nabla U(x) - \nabla U(y)\| \le L\|x - y\|$

Under $\mathbf{A}\,1$ and $\mathbf{A}\,2$, the Langevin diffusion (1) has a unique strong solution $(\mathbf{Y}^x_t)_{t\ge0}$ starting at $x \in \mathbb{R}^d$. The Markovian semi-group $(P_t)_{t\ge0}$, given for all $t \ge 0$, $x \in \mathbb{R}^d$ and $\mathsf{A} \in \mathcal{B}(\mathbb{R}^d)$ by $P_t(x, \mathsf{A}) = \mathbb{P}(\mathbf{Y}^x_t \in \mathsf{A})$, is reversible with respect to π and π is its unique invariant probability measure, see (Ambrosio et al., 2009, Theorem 1.2 and Theorem 1.6). Using this probabilistic framework, (Roberts and Tweedie, 1996, Theorem 1.2) shows that $(P_t)_{t\ge0}$ is irreducible with respect to the Lebesgue measure, strong Feller and $\lim_{t\to+\infty} \|P_t(x, \cdot) - \pi\|_{\mathrm{TV}} = 0$ for all $x \in \mathbb{R}^d$. But to study the properties of the semi-group $(P_t)_{t\ge0}$, an other complementary and significant approach can be used. This dual point of view is based on the adjoint of the infinitesimal generator associated with $(P_t)_{t\ge0}$. The *strong* generator of (1) $(\mathcal{A}, \mathrm{D}(\mathcal{A}))$ is defined for all $f \in \mathrm{D}(\mathcal{A})$ and $x \in \mathbb{R}^d$ by

$$\mathcal{A}f(x) = \lim_{t\to0} t^{-1}(P_t f(x) - f(x)) \;,$$

where $\mathrm{D}(\mathcal{A})$ is the subset of $C_0(\mathbb{R}^d)$ such that for all $f \in \mathrm{D}(\mathcal{A})$, there exists $g \in C_0(\mathbb{R}^d)$ such that $\lim_{t\to0} \left\|t^{-1}(P_t f - f) - g\right\|_\infty = 0$. In particular for $f \in C^2_c(\mathbb{R}^d)$, we get by Itô's formula

$$\mathcal{A}f = \langle \nabla f, \nabla U \rangle + \Delta f \;.$$

In addition, by (Ethier and Kurtz, 1986, Proposition 1.5), for all $f \in C_c^2(\mathbb{R}^d)$, $P_t f(x) \in \mathrm{D}(\mathcal{A})$ and for $x \in \mathbb{R}^d$, $t \mapsto P_t f(x)$ is continuously differentiable,

$$\frac{\mathrm{d}P_t f(x)}{\mathrm{d}t} = \mathcal{A}P_t f(x) = P_t \mathcal{A} f(x) \; . \tag{4}$$

For all $\mu_0 \in \mathcal{P}_2^{\mathrm{a}}(\mathbb{R}^d)$ and $t > 0$, by Girsanov's Theorem (Karatzas and Shreve, 1991, Theorem 5.1, Corollary 5.16, Chapter 3), $\mu_0 P_t(\cdot)$ admits a density with respect to the Lebesgue measure denoted by ρ_t. This density is solution by (4) of the Fokker-Planck equation (in the weak sense):

$$\frac{\partial \rho_t}{\partial t} = \mathrm{div}(\nabla \rho_t + \rho_t \nabla U(x)) \; ,$$

meaning that for all $\phi \in C_c^\infty(\mathbb{R}^d)$ and $t > 0$,

$$\frac{\partial}{\partial t} \int_{\mathbb{R}^d} \phi(y) \rho_t(\mathrm{d}y) = \int_{\mathbb{R}^d} \mathcal{A}\phi(y) \, \rho_t(\mathrm{d}y) \; . \tag{5}$$

In the landmark paper Jordan et al. (1998), the authors shows that if U is infinitely continuously differentiable, $(\rho_t)_{t>0}$ is the limit of the minimization scheme which defines a sequence of probability measures $(\tilde{\rho}_{k,\gamma})_{k \in \mathbb{N}}$ as follows. For $\gamma > 0$ set $\rho_{0,\gamma} = \mathrm{d}\mu_0/\mathrm{d}\,\mathrm{Leb}$ and

$$\tilde{\rho}_{k+1,\gamma} = \frac{\mathrm{d}\tilde{\mu}_{k+1,\gamma}}{\mathrm{d}\,\mathrm{Leb}} \; , \qquad \tilde{\mu}_{k+1,\gamma} = \operatorname*{argmin}_{\mu \in \mathcal{P}_2^{\mathrm{a}}(\mathbb{R}^d)} \; W_2^2(\tilde{\mu}_{k,\gamma}, \mu)/2 + \gamma \mathscr{F}(\mu) \; , \; k \in \mathbb{N} \; , \tag{6}$$

where $\mathscr{F} : \mathcal{P}_2(\mathbb{R}^d) \to (-\infty, +\infty]$ is the free energy functional,

$$\mathscr{F} = \mathscr{H} + \mathscr{E} \; , \tag{7}$$

$\mathscr{H}, \mathscr{E} : \mathcal{P}_2(\mathbb{R}^d) \to (-\infty, +\infty]$ are the Boltzmann H-functional and the potential energy functional, given for all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ by

$$\mathscr{H}(\mu) = \begin{cases} \int_{\mathbb{R}^d} \frac{\mathrm{d}\mu}{\mathrm{d}\,\mathrm{Leb}}(x) \log\left(\frac{\mathrm{d}\mu}{\mathrm{d}\,\mathrm{Leb}}(x)\right) \mathrm{d}x & \text{if } \mu \ll \mathrm{Leb} \\ +\infty \text{ otherwise} \; , \end{cases} \tag{8}$$

$$\mathscr{E}(\mu) = \int_{\mathbb{R}^d} U(x) \mathrm{d}\mu(x) \; . \tag{9}$$

More precisely, setting $\bar{\rho}_{0,\gamma} = \mathrm{d}\mu_0/\mathrm{d}\,\mathrm{Leb}$ and $\bar{\rho}_{t,\gamma} = \tilde{\rho}_{k,\gamma}$ for $t \in [k\gamma, (k+1)\gamma)$, (Jordan et al., 1998, Theorem 5.1) shows that for all $t > 0$, $\bar{\rho}_{t,\gamma}$ converges to ρ_t weakly in $\mathrm{L}^1(\mathbb{R}^d)$ as γ goes to 0. Note that the minimization scheme in (6) can be seen as a proximal type algorithm (see Martinet (1970) and Rockafeller (1976)) on the Wasserstein space $(\mathcal{P}_2(\mathbb{R}^d), W_2)$ used to minimize the functional $\mathscr{F}$. On $\mathbb{R}^d$, for continuous convex function f the proximal update with step size γ corresponds to one step of backward Euler discretization of the gradient flow ordinary differential equation (ODE) $\mathrm{d}x(t)/\mathrm{d}t = -\nabla f(x(t))$ with parameter γ. Therefore piecewise constant functions $(\bar{\rho}_{t,\gamma})_{\gamma>0}$ can be interpreted as backward Euler discretizations of an informal ODE $\partial \mu_t / \partial t = -\nabla \mathscr{F}(\mu_t)$ and their limit as $\gamma \to 0$, can be interpreted as a solution to this equation. This idea has been formalized and extended

to construct the framework of gradient flows in the Wasserstein space $(\mathcal{P}_2(\mathbb{R}^d), W_2)$, see Ambrosio et al. (2008). We provide a short introduction to this topic in Section A and present useful concepts and results for our proofs.

The following lemma shows that π is the unique minimizer of $\mathscr{F}$. As a result, the distribution of the Langevin diffusion is the steepest descent flow of $\mathscr{F}$ and we get back intuitively that this process converges to the target distribution π.

Lemma 1 *Assume* ***A*** *1(0). The following holds:*

a) $\pi \in \mathcal{P}_2(\mathbb{R}^d)$, $\mathscr{E}(\pi) < +\infty$ *and* $\mathscr{H}(\pi) < +\infty$.

b) For all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ *satisfying* $\mathscr{E}(\mu) < \infty$

$$\mathscr{F}(\mu) - \mathscr{F}(\pi) = \mathrm{KL}\,(\mu|\pi) \; . \tag{10}$$

Proof The proof is postponed to Section 7.1. ■

Based on this interpretation, we could think about minimizing $\mathscr{F}$ on the Wasserstein space to get close to π using the minimization scheme (6). However, while this scheme is shown in Jordan et al. (1998) to be well-defined, finding explicit recursions $(\tilde{\rho}_{k,\gamma})_{k \in \mathbb{N}}$ is as difficult as minimizing $\mathscr{F}$ and can not be used in practice. In addition, to the authors knowledge, there is no efficient and practical schemes to optimize this functional. On the other hand, discretization schemes have been used to approximate the Langevin diffusion $(\mathbf{Y}_t)_{t \geq 0}$ (1) and its long-time behavior. One of the most popular method is the Euler-Maruyama discretization $(X_k)_{k \in \mathbb{N}}$ given in (2). While most work study the theoretical properties of this discretization to ensure to get samples close to the target distribution π, by comparing the distributions of $(X_k)_{k \in \mathbb{N}}$ and $(\mathbf{Y}_t)_{t \geq 0}$ through couplings or weak error expansions, we interpret this scheme as the first order optimization algorithm for the objective functional $\mathscr{F}$.A similar approach has been recently applied in Wibisono (2018) and in Bernton (2018). We postpone the comparison of our contributions and the results of this two papers in Section 4.2 where it is the most relevant.

3. Main Results for the Unadjusted Langevin Algorithm

Let $f : \mathbb{R}^d \to \mathbb{R}$ be a convex continuously differentiable objective function with $x_f \in \arg\min_{\mathbb{R}^d} f \neq \emptyset$. The *inexact* or *stochastic* gradient descent algorithm used to estimate $f(x_f)$ defines the sequence $(x_k)_{k \in \mathbb{N}}$ starting from $x_0 \in \mathbb{R}^d$ by the following recursion for $k \in \mathbb{N}$:

$$x_{k+1} = x_k - \gamma_{k+1} \nabla f(x_k) + \gamma_{k+1} \Xi(x_k) \; ,$$

where $(\gamma_k)_{k \in \mathbb{N}^*}$ is a non-increasing sequence of stepsizes and $\Xi : \mathbb{R}^d \to \mathbb{R}^d$ is a deterministic or/and stochastic perturbation of ∇f. To get explicit bound on the convergence (in expectation) of the sequence $(f(x_k))_{k \in \mathbb{N}}$ to $f(x_f)$, one possibility (see e.g. Beck and Teboulle (2009)) is to show that the following inequality holds: for all $k \in \mathbb{N}$,

$$2\gamma_{k+1}(f(x_{k+1}) - f(x_f)) \leq \|x_k - x_f\|^2 - \|x_{k+1} - x_f\|_2^2 + C\gamma_{k+1}^2 \; , \tag{11}$$

for some constant $C \geq 0$. In a similar manner as for inexact gradient algorithms, in this section we will establish that ULA satisfies an inequality of the form (11) with the objective function $\mathscr{F}$ defined by (7) on $\mathcal{P}_2(\mathbb{R}^d)$, but instead of the Euclidean norm, the Wasserstein distance of order 2 will be used.

Consider the family of Markov kernels $(R_{\gamma_k})_{k\in\mathbb{N}^*}$ associated with the Euler-Maruyama discretization $(X_k)_{k\in\mathbb{N}}$, (2), for a sequence of stepsizes $(\gamma_k)_{k\in\mathbb{N}^*}$, given for all $\gamma > 0, x \in \mathbb{R}^d$ and $\mathsf{A} \in \mathcal{B}(\mathbb{R}^d)$ by

$$R_\gamma(x, \mathsf{A}) = (4\pi\gamma)^{-d/2} \int_{\mathsf{A}} \exp\left(-\left\|y - x - \gamma\nabla U(x)\right\|^2/(4\gamma)\right) \mathrm{d}y \ . \tag{12}$$

Proposition 2 *Assume* $\boldsymbol{A}\,1(m)$ *for* $m \geq 0$ *and* $\boldsymbol{A}\,2$. *For all* $\gamma \in (0, L^{-1}]$ *and* $\mu \in \mathcal{P}_2(\mathbb{R}^d)$, *we have*

$$2\gamma\left\{\mathscr{F}(\mu R_\gamma) - \mathscr{F}(\pi)\right\} \leq (1 - m\gamma)W_2^2(\mu, \pi) - W_2^2(\mu R_\gamma, \pi) + 2\gamma^2 L d \ , \tag{13}$$

where $\mathscr{F}$ *is defined in* (7).

The main difficulty in establishing Proposition 2 is to deal with the entropy function $\mathscr{H}$ defined by (8) in $\mathscr{F}$. To obtain the desired result, we decompose R_γ for all $\gamma > 0$ in the product of two elementary kernels S_γ and T_γ given for all $x \in \mathbb{R}^d$ and $\mathsf{A} \in \mathcal{B}(\mathbb{R}^d)$ by

$$S_\gamma(x, \mathsf{A}) = \delta_{x-\gamma\nabla U(x)}(\mathsf{A}) \ , \ T_\gamma(x, \mathsf{A}) = (4\pi\gamma)^{-d/2} \int_{\mathsf{A}} \exp\left(-\left\|y - x\right\|^2/(4\gamma)\right) \mathrm{d}y \ . \tag{14}$$

We take the convention that $S_0 = T_0 = \mathrm{Id}$ is the identity kernel given for all $x \in \mathbb{R}^d$ by $\mathrm{Id}(x, \{x\}) = 1$. S_γ is the deterministic part of the Euler-Maruyama discretization, which corresponds to gradient descent step relative to U for the $\mathscr{E}$ functional, whereas T_γ is the random part, that corresponds to going along the gradient flow of $\mathscr{H}$. Note then $R_\gamma = S_\gamma T_\gamma$ and consider the following decomposition

$$\mathscr{F}(\mu R_\gamma) - \mathscr{F}(\pi) = \mathscr{E}(\mu R_\gamma) - \mathscr{E}(\mu S_\gamma) + \mathscr{E}(\mu S_\gamma) - \mathscr{E}(\pi) + \mathscr{H}(\mu R_\gamma) - \mathscr{H}(\pi) \ . \tag{15}$$

The proof of Proposition 2 then consists in bounding each difference in the decomposition above. This is the matter of the following Lemmas. While the proofs of the bounds for the first two terms are quite elementary, the one for the final term uses results from gradient flow theory which are summarized in Section A. It is worthwhile to observe that we do not apply this theory to the Langevin semi-group but only to the heat semi-group.

Lemma 3 *Assume* $\boldsymbol{A}\,2$. *For all* $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ *and* $\gamma > 0$,

$$\mathscr{E}(\mu T_\gamma) - \mathscr{E}(\mu) \leq L d \gamma \ .$$

Proof First note that by (Nesterov, 2004, Lemma 1.2.3), for all $x, \tilde{x} \in \mathbb{R}^d$, we have

$$\left|U(\tilde{x}) - U(x) - \langle\nabla U(x), \tilde{x} - x\rangle\right| \leq (L/2)\left\|\tilde{x} - x\right\|^2 \ . \tag{16}$$

Therefore, for all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma > 0$, we get

$$\begin{aligned}\mathscr{E}(\mu T_\gamma) - \mathscr{E}(\mu) &= (4\pi\gamma)^{-d/2} \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \left\{U(x + y) - U(x)\right\} \mathrm{e}^{-\|y\|^2/(4\gamma)} \mathrm{d}y\mathrm{d}\mu(x) \\ &\leq (4\pi\gamma)^{-d/2} \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \left\{\langle\nabla U(x), y\rangle + (L/2)\left\|y\right\|^2\right\} \mathrm{e}^{-\|y\|^2/(4\gamma)} \mathrm{d}y\mathrm{d}\mu(x) \ ,\end{aligned}$$

which concludes the proof. ∎

Lemma 4 *Assume* $\boldsymbol{A}\,1(m)$ *for* $m \geq 0$ *and* $\boldsymbol{A}\,2$. *For all* $\gamma \in (0, L^{-1}]$ *and* $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$,

$$2\gamma\left\{\mathscr{E}(\mu S_\gamma) - \mathscr{E}(\nu)\right\} \leq (1 - m\gamma)W_2^2(\mu, \nu) - W_2^2(\mu S_\gamma, \nu) - \gamma^2(1 - \gamma L)\int_{\mathbb{R}^d} \left\|\nabla U(x)\right\|^2 \mathrm{d}\mu(x) \ ,$$

where $\mathscr{E}$ *and* T_γ *are defined in* (9) *and* (14) *respectively.*

Proof Using (16) and $\mathbf{A}\,1(m)$, for all $x, y \in \mathbb{R}^d$, we get

$$\begin{aligned}U(x - \gamma\nabla U(x)) - U(y) &= U(x - \gamma\nabla U(x)) - U(x) + U(x) - U(y) \\ &\leq -\gamma(1 - \gamma L/2)\left\|\nabla U(x)\right\|^2 + \langle\nabla U(x), x - y\rangle - (m/2)\left\|y - x\right\|^2 \ .\end{aligned}$$

Multiplying both sides by 2γ we obtain:

$$\begin{aligned}2\gamma\left\{U(x - \gamma\nabla U(x)) - U(y)\right\} \leq (1 - m\gamma)\left\|x - y\right\|^2 - \left\|x - \gamma\nabla U(x) - y\right\|^2 \\ - \gamma^2(1 - \gamma L)\left\|\nabla U(x)\right\|^2 \ .\end{aligned} \tag{17}$$

Let now (X, Y) be an optimal coupling between μ and ν. Then by definition and (17), we get

$$\begin{aligned}2\gamma\left\{\mathscr{E}(\mu S_\gamma) - \mathscr{E}(\nu)\right\} \leq (1 - m\gamma)W_2^2(\mu, \nu) - \mathbb{E}\left[\left\|X - \gamma\nabla U(X) - Y\right\|^2\right] \\ - \gamma^2(1 - \gamma L)\mathbb{E}\left[\left\|\nabla U(X)\right\|^2\right] \ .\end{aligned}$$

Using that $W_2^2(\mu S_\gamma, \nu) \leq \mathbb{E}[\left\|X - \gamma\nabla U(X) - Y\right\|^2]$ concludes the proof. ∎

Lemma 5 *Let* $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$, $\mathscr{H}(\nu) < \infty$. *Then for all* $\gamma > 0$,

$$2\gamma\left\{\mathscr{H}(\mu T_\gamma) - \mathscr{H}(\nu)\right\} \leq W_2^2(\mu, \nu) - W_2^2(\mu T_\gamma, \nu) \ ,$$

where T_γ *is given in* (14).

Proof Denote for all $t \geq 0$ by $\mu_t = \mu T_t$. Since $(T_t)_{t\geq 0}$ is the Markov semi-group associated with the Brownian motion, then $(\mu_t)_{t\geq 0}$ is the solution (in the sense of distribution) of the Fokker-Plank equation:

$$\frac{\partial\mu_t}{\partial t} = \Delta\mu_t \ ,$$

and μ_t goes to μ as t goes to 0 in $(\mathcal{P}_2(\mathbb{R}^d), W_2)$. Let $\nu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma > 0$. Then by Theorem 31, for all $\epsilon \in (0, \gamma)$, there exists $(\delta_t) \in \mathrm{L}^1((\epsilon, \gamma))$ such that

$$W_2^2(\mu_\gamma, \nu) - W_2^2(\mu_\epsilon, \nu) = \int_\epsilon^\gamma \delta_s \mathrm{d}s \tag{18}$$

$$\delta_s/2 \leq \mathscr{H}(\nu) - \mathscr{H}(\mu_s) \ , \ \text{for almost all } s \in (\epsilon, \gamma) \ . \tag{19}$$

In addition by (Villani, 2009, Particular case 24.3), $s \mapsto \mathscr{H}(\mu_s)$ is non-increasing on $\mathbb{R}_+^*$ and therefore (19) becomes

$$\delta_s/2 \leq \mathscr{H}(\nu) - \mathscr{H}(\mu_\gamma) \ , \ \text{for almost all } s \in (\epsilon, \gamma) \ .$$

Plugging this bound in (18) yields that for all $\epsilon \in \mathbb{R}_+^*$,

$$W_2^2(\mu_t, \nu) - W_2^2(\mu_\epsilon, \nu) \leq 2(\gamma - \epsilon) \left\{ \mathscr{H}(\nu) - \mathscr{H}(\mu_\gamma) \right\} \ .$$

Taking $\epsilon \to 0$ concludes the proof. ■

We now have all the tools to prove Proposition 2.

Proof [Proof of Proposition 2] Let $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma \in \mathbb{R}_+^*$. By Lemma 3, we get

$$\mathscr{E}(\mu R_\gamma) - \mathscr{E}(\mu S_\gamma) = \mathscr{E}(\mu S_\gamma T_\gamma) - \mathscr{E}(\mu S_\gamma) \leq Ld\gamma \ .$$

By Lemma 4 since $\pi \in \mathcal{P}_2(\mathbb{R}^d)$ (see Lemma 1-a)),

$$2\gamma \left\{ \mathscr{E}(\mu S_\gamma) - \mathscr{E}(\pi) \right\} \leq (1 - m\gamma) W_2^2(\mu, \nu) - W_2^2(\mu S_\gamma, \nu) \ .$$

By Lemma 5 and Lemma 1-a),

$$\begin{aligned} 2\gamma \left\{ \mathscr{H}(\mu R_\gamma) - \mathscr{H}(\pi) \right\} &= 2\gamma \left\{ \mathscr{H}((\mu S_\gamma) T_\gamma) - \mathscr{H}(\pi) \right\} \\ &\leq W_2^2(\mu S_\gamma, \pi) - W_2^2(\mu R_\gamma, \pi) \ . \end{aligned}$$

Plugging these bounds in (15) concludes the proof. ■

Based on inequalities of the form (11) and using the convexity of f, for all $n \in \mathbb{N}$, non-asymptotic bounds (in expectation) between $f(\bar{x}_n)$ and $f(x_f)$ can be derived, where $(\bar{x}_k)_{k \in \mathbb{N}}$ is the sequence of averages of $(x_k)_{k \in \mathbb{N}}$ given for all $n \in \mathbb{N}$ by $\bar{x}_n = n^{-1} \sum_{k=1}^n x_k$. Besides, if f is assumed to be strongly convex, a bound on $\mathbb{E}[\|x_n - x_f\|^2]$ can be established. We will adapt this methodology to get some bounds on the convergence of sequences of averaged measures defined as follows. Let $(\gamma_k)_{k \in \mathbb{N}^*}$ and $(\lambda_k)_{k \in \mathbb{N}^*}$ be two non-increasing sequences of reals numbers referred to as the sequence of stepsizes and weights respectively. Define for all $n, N \in \mathbb{N}$, $n \geq 1$,

$$\Gamma_{N,N+n} = \sum_{k=N+1}^{N+n} \gamma_k \ , \qquad \Lambda_{N,N+n} = \sum_{k=N+1}^{N+n} \lambda_k \ . \tag{20}$$

Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ be an initial distribution. The sequence of probability measures $(\nu_n^N)_{n \in \mathbb{N}^*}$ is defined for all $n, N \in \mathbb{N}$, $n \geq 1$, by

$$\nu_n^N = \Lambda_{N,N+n}^{-1} \sum_{k=N+1}^{N+n} \lambda_k \, \mu_0 Q_\gamma^k \ , \qquad Q_\gamma^k = R_{\gamma_1} \cdots R_{\gamma_k} \ , \ \text{for } k \in \mathbb{N}^* \ , \tag{21}$$

where R_γ is defined by (12) and N is a burn-in time. We take in the following, the convention that Q_γ^0 is the identity operator.

Contrary to most works on ULA, we state our next results in terms of average measures ν_n^N, defined by (21) for $N \in \mathbb{N}$ and $n \in \mathbb{N}^*$ instead of the final iterates $\mu_0 Q_\gamma^n$. Indeed, in the case where $m = 0$, Proposition 2 does not imply very informative bounds for Q_γ^n. However using that $\mathrm{KL}(\cdot|\pi)$ is convex and applying Proposition 2 allow to use averaging trick from optimization to obtain useful bounds on $\mathrm{KL}(\nu_n^N|\pi)$.

Theorem 6 *Assume* ***A*** *1(m) for $m \geq 0$ and* ***A*** *2. Let $(\gamma_k)_{k \in \mathbb{N}^*}$ and $(\lambda_k)_{k \in \mathbb{N}^*}$ be two non-increasing sequences of positive real numbers satisfying $\gamma_1 \leq L^{-1}$, and for all $k \in \mathbb{N}^*$, $\lambda_{k+1}(1 - m\gamma_{k+1})/\gamma_{k+1} \leq \lambda_k/\gamma_k$. Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ and $N \in \mathbb{N}$. Then for all $n \in \mathbb{N}^*$, it holds:*

$$\begin{aligned} &\mathrm{KL}\left(\nu_n^N|\pi\right) + \lambda_{N+n} W_2^2\left(\mu_0 Q_\gamma^{N+n}, \pi\right) / (2\gamma_{N+n} \Lambda_{N,N+n}) \\ &\quad \leq \lambda_{N+1}(1 - m\gamma_{N+1}) W_2^2\left(\mu_0 Q_\gamma^N, \pi\right) / (2\gamma_{N+1} \Lambda_{N,N+n}) + (Ld/\Lambda_{N,N+n}) \sum_{k=N+1}^{N+n} \gamma_k \lambda_k \ , \end{aligned}$$

where ν_n^N and Q_γ^N are defined in (21).

Proof Using the convexity of KL divergence (see (Cover and Thomas, 2006, Theorem 2.7.2) or (van Erven and Harremos, 2014, Theorem 11)) and Proposition 2, we obtain

$$\begin{aligned} \mathrm{KL}\left(\nu_n^N|\pi\right) &\leq \Lambda_{N,N+n}^{-1} \sum_{k=N+1}^{N+n} \lambda_k \, \mathrm{KL}\left(\mu_0 Q_\gamma^k \middle| \pi\right) \\ &\leq (2\Lambda_{N,N+n})^{-1} \left[\frac{(1 - m\gamma_{N+1})\lambda_{N+1}}{\gamma_{N+1}} W_2^2\left(\mu_0 Q_\gamma^N, \pi\right) - \frac{\lambda_{N+n}}{\gamma_{N+n}} W_2^2\left(\mu_0 Q_\gamma^{N+n}, \pi\right) \right. \\ &\quad \left. + \sum_{k=N+1}^{N+n-1} \left\{ \frac{(1 - m\gamma_{k+1})\lambda_{k+1}}{\gamma_{k+1}} - \frac{\lambda_k}{\gamma_k} \right\} W_2^2\left(\mu_0 Q_\gamma^k, \pi\right) + \sum_{k=N+1}^{N+n} Ld\lambda_k\gamma_k \right] \ . \end{aligned}$$

We get the thesis using that $\lambda_{k+1}(1 - m\gamma_{k+1})/\gamma_{k+1} \leq \lambda_k/\gamma_k$ for all $k \in \mathbb{N}^*$. ■

Corollary 7 *Assume* ***A*** *1(0) and* ***A*** *2. Let $\varepsilon > 0$ and $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Let*

$$\gamma_\varepsilon \leq \min\left\{\varepsilon/(2Ld), L^{-1}\right\} \ , \qquad n_\varepsilon \geq \lceil W_2^2(\mu_0, \pi) \gamma_\varepsilon^{-1} \varepsilon^{-1} \rceil \ .$$

Then it holds $\mathrm{KL}\left(\nu_{n_\varepsilon}|\pi\right) \leq \varepsilon$ where $\nu_{n_\varepsilon} = n_\varepsilon^{-1} \sum_{k=1}^{n_\varepsilon} \mu_0 R_{\gamma_\varepsilon}^k$.

Proof We apply Theorem 6 with $\gamma_k = \gamma_\varepsilon$ and $\lambda_k = 1$ for all $k \geq 1$. We obtain

$$\mathrm{KL}\left(\nu_{n_\varepsilon}|\pi\right) + W_2^2\left(\mu_0 Q_\gamma^{n_\varepsilon}, \pi\right)/(2\gamma_\varepsilon n_\varepsilon) \leq W_2^2\left(\mu_0, \pi\right)/(2\gamma_\varepsilon n_\varepsilon) + (Ld/n_\varepsilon)\sum_{k=1}^{n_\varepsilon} \gamma_\varepsilon \ ,$$

and the proof is concluded by a straightforward calculation using the definition of γ_ε and n_ε. ■

Corollary 8 *Assume* ***A*** *1(m) for $m \geq 0$ and* ***A*** *2. Let $\alpha \in (0,1)$. Define $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ for all $k \in \mathbb{N}^*$ by $\gamma_k = \gamma_1/k^\alpha$, $\lambda_k = \gamma_1/(k+1)^\alpha$, $\gamma_1 \in \left(0, L^{-1}\right)$. Then, there exists $C \geq 0$ such that for all $n \in \mathbb{N}^*$ we have $\mathrm{KL}\left(\nu_n^0|\pi\right) \leq C\max(n^{\alpha-1}, n^{-\alpha})$, if $\alpha \neq 1/2$, and for $\alpha = 1/2$, we have $\mathrm{KL}\left(\nu_n^0|\pi\right) \leq C(\ln(n)+1)n^{-1/2}$, where ν_n^0 is defined by* (21).

Proof The proof is postponed to Section 7.2. ■

In the case where a warm start is available for the Wasserstein distance, *i.e.* $W_2^2(\mu_0, \pi) \leq C$, for some absolute constant $C \geq 0$, then Corollary 7 implies that the complexity of ULA to obtain a sample close from π in KL with a precision $\varepsilon > 0$ is of order $d\bar{\mathcal{O}}(\varepsilon^{-2})$. In addition, by Pinsker inequality, we have for all probability measure μ on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$, $\|\mu - \pi\|_{\mathrm{TV}} \leq \{2\,\mathrm{KL}(\mu|\pi)\}^{1/2}$, which implies that the complexity of ULA for the total variation distance is of order $d\bar{\mathcal{O}}(\varepsilon^{-4})$.

In addition if we have access to $\eta > 0$ and $M_\eta \geq 0$, independent of the dimension, such that for all $x \in \mathbb{R}^d$, $x \notin \mathrm{B}(x^\star, M_\eta)$, $U(x) - U(x^\star) \geq \eta\|x - x^\star\|$, $x^\star \in \arg\min_{\mathbb{R}^d} U$, Proposition 32 in Appendix B shows that for all $\int_{\mathbb{R}^d}\|x - x^\star\|^2 \,\mathrm{d}\pi(x) \leq 2\eta^{-2}d(1+d) + M_\eta^2$. Therefore, starting at $\delta_{x^\star}$, the overall complexity for the KL is in this case $d^3\bar{\mathcal{O}}(\varepsilon^{-2})$ and $d^3\bar{\mathcal{O}}(\varepsilon^{-4})$ for the total variation distance. This discussion justifies the bound we state in Table 1.

In the case where $m > 0$, based on Proposition 2, we can directly get a bound on the Wasserstein distance between the final iterate of ULA and π.

Theorem 9 *Assume* ***A*** *1(m) for $m > 0$ and* ***A*** *2. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ be a non-increasing sequence of positive real numbers, $\gamma_1 \in \left(0, L^{-1}\right]$, and $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Then for all $n \in \mathbb{N}^*$, it holds*

$$W_2^2\left(\mu_0 Q_\gamma^n, \pi\right) \leq \left\{\prod_{k=1}^n (1 - m\gamma_k)\right\} W_2^2\left(\mu_0, \pi\right) + 2Ld\sum_{k=1}^n \gamma_k^2 \prod_{i=k+1}^n (1 - m\gamma_i) \ ,$$

where Q_γ^n is defined in (21).

Proof Using Proposition 2 and since the KL divergence is non-negative, we get for all $k \in \{1, \ldots, n\}$,

$$W_2^2\left(\mu_0 Q_\gamma^k, \pi\right) \leq (1 - m\gamma_k) W_2^2\left(\mu_0 Q_\gamma^{k-1}, \pi\right) + 2Ld\gamma_k^2 \ .$$

The proof then follows from a direct induction. ■

Corollary 10 *Assume* ***A*** *1(m) for $m > 0$ and* ***A*** *2. Let $\varepsilon > 0$ and $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Define:*

$$\gamma_\varepsilon \leq \min\left\{m\varepsilon/(4Ld), L^{-1}\right\} \ , \qquad n_\varepsilon \geq \lceil \ln(2W_2^2(\mu_0, \pi)/\varepsilon)\gamma_\varepsilon^{-1}m^{-1}\rceil \ .$$

Then we have $W_2^2\left(\mu_0 R_{\gamma_\varepsilon}^{n_\varepsilon}, \pi\right) \leq \varepsilon$, where R_{γ_ε} is defined by (12).

Proof By Theorem 9, we have

$$W_2^2\left(\mu_0 Q_\gamma^{n_\varepsilon}, \pi\right) \leq (1 - m\gamma_\varepsilon)^{n_\varepsilon} W_2^2\left(\mu_0, \pi\right) + 2Ld\sum_{k=1}^{n_\varepsilon} \gamma_\varepsilon^2 (1 - m\gamma_\varepsilon)^{n_\varepsilon - k} \ .$$

On one hand, by definition of γ_ε, we get $2Ld\sum_{k=1}^{n_\varepsilon}\gamma_\varepsilon^2(1-m\gamma_\varepsilon)^{n_\varepsilon-k} \leq 2Ld\gamma_\varepsilon/m \leq \varepsilon/2$. On the other hand, using that for all $t \in \mathbb{R}_+$, $1 - t \leq \exp(-t)$ and the definition of n_ε, we obtain $(1-m\gamma_\varepsilon)^{n_\varepsilon} W_2^2\left(\mu_0, \pi\right) \leq \exp(-m\gamma_\varepsilon n_\varepsilon) W_2^2\left(\mu_0, \pi\right) \leq \varepsilon/2$. Then the thesis of the corollary follows directly from the above inequalities. ■

Note that the bound in the right hand side of Theorem 9 is tighter than the previous bound given in Dalalyan and Karagulyan (2017, Theorem 1) (for constant stepsize) and in Durmus and Moulines (2016, Theorem 5) (for both constant and non-increasing stepsizes). Indeed Dalalyan and Karagulyan (2017, Theorem 1) shows that, in the constant stepsize setting $\gamma_k = \gamma$, for all $k \in \mathbb{N}$,

$$W_2(\mu_0 Q_\gamma^k, \pi) \leq (1 - m\gamma)^k W_2(\mu_0, \pi) + 1.65(L/m)(\gamma d)^{1/2} \ .$$

On the other hand, the inequality $(t+s)^{1/2} \leq t^{1/2} + s^{1/2}$ for $t, s \geq 0$ and Theorem 9 imply that for all $k \in \mathbb{N}$,

$$W_2(\mu_0 Q_\gamma^k, \pi) \leq (1 - m\gamma)^{k/2} W_2(\mu_0, \pi) + \{2\gamma dL/m\}^{1/2} \ . \tag{22}$$

Thus, the dependency on the condition number L/m is improved. This bound is in agreement for the case where π is the zero-mean d-dimensional Gaussian distribution with covariance matrix Σ. In that case, all the iterates $(X_k)_{k\in\mathbb{N}^*}$ defined by (2) for $\gamma > 0$, starting from $x \in \mathbb{R}^d$, follows the Gaussian distribution with mean $(\mathrm{Id} - \gamma\Sigma)^k x$ and covariance matrix $2\gamma\sum_{i=0}^{k-1}(1-\gamma\Sigma)^{2i}$. Since the Wasserstein distance between d-dimensional Gaussian distributions can be explicitly computed, see Givens and Shortt (1984), denoting by L and m the largest and smallest eigenvalues of Σ respectively, we have by an explicit calculation for $\gamma \in \left(0, L^{-1}\right]$,

$$W_2(\mu_0 Q_\gamma^k, \pi) \leq (1 - m\gamma)^k W_2(\mu_0, \pi) + (d/m)^{1/2}\left\{(1 - \gamma L/2)^{-1/2} - 1\right\} \ .$$

Since for $t \in [0, 1/2]$, $(1-t)^{-1/2} - 1 - t \leq 0$, we get

$$W_2(\mu_0 Q_\gamma^k, \pi) \leq (1 - m\gamma)^k W_2(\mu_0, \pi) + 2^{-1}\gamma(d/m)^{1/2}\left\{(1 - \gamma L)^{-1/2} - 1\right\} \ .$$

Using that $\gamma \leq L^{-1}$, we get that the second term in the right hand side is bounded by $(dL\gamma/m)^{1/2}$, which is precisely the order we get from (22).

Finally, if $(\gamma_k)_{k\in\mathbb{N}^*}$ is given for all $k \in \mathbb{N}^*$, by $\gamma_k = \gamma_1/k^\alpha$, for $\alpha \in (0,1)$, then using (Durmus and Moulines, 2016, Lemma 7) and the same calculation of (Durmus and Moulines, 2015, Section 6.1), we get that there exists $C \geq 0$ such that for all $n \in \mathbb{N}^*$, $W_2(\mu_0 Q_\gamma^n, \pi) \leq Cn^{-\alpha/2}$.

Based on Theorem 9, we can improve Corollary 7 in the case where U is strongly convex using an appropriate burn-in time.

Corollary 11 *Assume* **A** *1(m) for $m > 0$ and* **A** *2. Let $\varepsilon > 0$, $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ and*

$$\gamma_\varepsilon \leq \min\left\{m\varepsilon/(4Ld), L^{-1}\right\} , \qquad \tilde{\gamma}_\varepsilon \leq \min\left\{\varepsilon/2Ld, L^{-1}\right\} ,$$
$$N_\varepsilon \geq \lceil \ln(2W_2^2(\mu_0,\pi)/\varepsilon)(\gamma_\varepsilon m)^{-1}\rceil , \qquad n_\varepsilon \geq \lceil \tilde{\gamma}_\varepsilon^{-1}\rceil .$$

Let $(\gamma_k)_{k\in\mathbb{N}}$ defined by $\gamma_k = \gamma_\varepsilon$ for $k \in \{1,\dots,N_\varepsilon\}$ and $\gamma_k = \tilde{\gamma}_\varepsilon$ for $k > N_\varepsilon$. Then we have $\mathrm{KL}\left(\nu_{n_\varepsilon}^{N_\varepsilon}|\pi\right) \leq \varepsilon$ where $\nu_{n_\varepsilon}^{N_\varepsilon} = n_\varepsilon^{-1}\sum_{k=1}^{n_\varepsilon}\mu_0 R_{\gamma_\varepsilon}^{N_\varepsilon} R_{\tilde{\gamma}_\varepsilon}^k$.

Proof Using Corollary 10, we have $W_2^2\left(\mu_0 Q_\gamma^{N_\varepsilon}, \pi\right) \leq \varepsilon$. Now applying Theorem 6 we get:

$$\mathrm{KL}\left(\nu_{n_\varepsilon}^{N_\varepsilon}|\pi\right) \leq W_2^2\left(\mu_{N_\varepsilon},\pi\right)/(2\tilde{\gamma}_\varepsilon n_\varepsilon) + (Ld/n_\varepsilon\tilde{\gamma}_\varepsilon)\sum_{k=N_\varepsilon+1}^{N_\varepsilon+n_\varepsilon}(\tilde{\gamma}_\varepsilon)^2 \leq \varepsilon/(2\tilde{\gamma}_\varepsilon n_\varepsilon) + Ld\tilde{\gamma}_\varepsilon \leq \varepsilon$$

■

By (Durmus and Moulines, 2016, Proposition 1), we have $\int_{\mathbb{R}^d}\|x - x^\star\|^2 \mathrm{d}\pi(x) \leq d/m$, where $x^\star = \arg\min_{\mathbb{R}^d} U$. Therefore we have that in the constant stepsize setting, $\gamma_k = \gamma \in (0, L^{-1}]$ for all $k \in \mathbb{N}^*$, Corollary 10 implies that the sufficient number of iterations to have $W_2(\delta_{x^\star}Q_\gamma^n, \pi) \leq \varepsilon$ is of order $d\bar{\mathcal{O}}(\varepsilon^{-2})$. Then Corollary 11 implies that the sufficient number of iterations to get $\mathrm{KL}\left(\nu_n^N|\pi\right) \leq \varepsilon$, for $\varepsilon > 0$, is of order $d\bar{\mathcal{O}}(\varepsilon^{-1})$. By Pinsker inequality, we obtain that a sufficient number of iterations to get $\|\nu_n^N - \pi\|_{\mathrm{TV}} \leq \varepsilon$, for $\varepsilon > 0$, is of order $d\bar{\mathcal{O}}(\varepsilon^{-2})$.

For a sufficiently small constant stepsize γ, ULA produces a Markov Chain with a stationary measure π_γ. In general this measure is different from the measure of interest π. Based on our previous results, we establish computable bounds on the distance between π and π_γ.

Theorem 12 *Assume* **A** *1(m) for $m \geq 0$ and* **A** *2. Let $\gamma \in \left(0, L^{-1}\right]$. Then there exists a measure π_γ, such that $\pi_\gamma R_\gamma = \pi_\gamma$ where R_γ is defined by* (12)*. In addition, we have*

$$\mathrm{KL}\left(\pi_\gamma|\pi\right) \leq Ld\gamma, \qquad \|\pi_\gamma - \pi\|_{\mathrm{TV}} \leq \sqrt{2Ld\gamma}$$

Furthermore, if $m > 0$ we also have $W_2^2\left(\pi_\gamma,\pi\right) \leq 2Ld\gamma/m$.

Proof Under **A** 1 and **A** 2, (Durmus and Moulines, 2017, Proposition 13) shows that R_γ satisfies a geometric Foster-Lyapunov drift condition for $\gamma \leq L^{-1}$. In addition, it is easy to see that R_γ is Leb-irreducible and weak Feller and therefore by (Meyn and Tweedie, 2009, Theorem 6.0.1 together with Theorem 5.5.7), all compact sets are small. Then, by (Meyn and Tweedie, 2009, Theorem 16.0.1), R_γ has a unique invariant distribution π_γ.

Second, taking $\mu = \pi_\gamma$ in Proposition 2 we obtain:

$$2\gamma\,\mathrm{KL}\left(\pi_\gamma R_\gamma|\pi\right) \leq (1-m\gamma)W_2^2(\pi_\gamma,\pi) - W_2^2(\pi_\gamma R_\gamma,\pi) + 2\gamma^2 Ld\,, \tag{23}$$

and because $\pi_\gamma R_\gamma = \pi_\gamma$, the above implies $2\,\mathrm{KL}\left(\pi_\gamma|\pi\right) + mW_2^2(\pi_\gamma,\pi) \leq 2Ld\gamma$. Since both the KL divergence and Wasserstein distance are positive, the desired bounds in KL and W_2^2 follow. The bound in total variation follows from the bound in KL-divergence and Pinsker inequality. ■

4. Extensions of ULA

In this section, two extensions of ULA are presented and analyzed. These two algorithms can be applied to non-continuously differentiable convex potential $U : \mathbb{R}^d \to \mathbb{R}$ and therefore **A** 2 is not assumed anymore. In addition, for the two new algorithms we present, only i.i.d. unbiased estimates of (sub)gradients of U are necessary as in Stochastic Gradient Langevin Dynamics (SGLD) (Welling and Teh, 2011). The main difference in these two approaches is that one relies on the subgradient of U while the other is based on proximal operators which are tools commonly used in non-smooth optimization. However, the theoretical results that we can show for these two algorithms, hold for different sets of conditions.

4.1. Stochastic SubGradient Langevin Dynamics

Note that if U is convex and l.s.c then for any point $x \in \mathbb{R}^d$, its subdifferential $\partial U(x)$ defined by

$$\partial U(x) = \left\{v \in \mathbb{R}^d \,:\, U(y) \geq U(x) + \langle v, y - x\rangle \text{ for all } y \in \mathbb{R}^d\right\} , \tag{24}$$

is non empty, see (Rockafellar and Wets, 1998, Proposition 8.12, Theorem 8.13). For all $x \in \mathbb{R}^d$, any elements of $\partial U(x)$ is referred to as a subgradient of U at x. Consider the following condition on U which assumes that we have access to unbiased estimates of subgradients of U at any point $x \in \mathbb{R}^d$.

A 3 (i) The potential U is M-Lipschitz, *i.e.* for all $x, y \in \mathbb{R}^d$, $|U(x) - U(y)| \leq M\|x - y\|$.

(ii) There exists a measurable space $(\mathsf{Z}, \mathcal{Z})$, a probability measure η on $(\mathsf{Z}, \mathcal{Z})$ and a measurable function $\Theta : \mathbb{R}^d \times \mathsf{Z} \to \mathbb{R}^d$ for all $x \in \mathbb{R}^d$,

$$\int_{\mathsf{Z}} \Theta(x,z)\mathrm{d}\eta(z) \in \partial U(x) .$$

Note that under **A** 3-(i), for all $x \in \mathbb{R}^d$ and $v \in \partial U(x)$,

$$\|v\| \leq M . \tag{25}$$

Assumption **A**3 is satisfied for example in the case where $U = U_1 + U_2$, U_1 is L-gradient Lipschitz and Lipschitz and U_2 is non-smooth but Lipschitz, if there exists a measurable $\tilde{\Theta} : \mathbb{R}^d \times \mathsf{Z} \to \mathbb{R}^d$ such that $\int_{\mathsf{Z}} \tilde{\Theta}(x,z)\mathrm{d}\eta(z) = \nabla U_1(x)$ for any $x \in \mathbb{R}^d$. Then by (Bauschke

and Combettes, 2011, Corollary 16.38), unbiased and i.i.d. estimates of ∇f can be computed setting $\Theta = \partial g + \tilde{\Theta}$.

Let $(Z_k)_{k\in\mathbb{N}^*}$ be a sequence of i.i.d. random variables distributed according to η, $(\gamma_k)_{k\in\mathbb{N}^*}$ be a sequence of non-increasing stepsizes and $\bar{X}_0$ distributed according to $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Stochastic SubGradient Langevin Dynamics (SSGLD) defines the sequence of random variables $(\bar{X}_k)_{k\in\mathbb{N}}$ starting at $\bar{X}_0$ for $n \geq 0$ by

$$\bar{X}_{n+1} = \bar{X}_n - \gamma_{n+1}\Theta(\bar{X}_n, Z_{n+1}) + \sqrt{2\gamma_{n+2}}G_{n+1} \;, \tag{26}$$

where $(G_k)_{k\in\mathbb{N}^*}$ is a sequence of i.i.d. d-dimensional standard Gaussian random variables, independent of $(Z_k)_{k\in\mathbb{N}^*}$, see Algorithm 1. Consequently this method defines a new sequence of Markov kernels $(\bar{R}_{\gamma_k,\gamma_{k+1}})_{k\in\mathbb{N}^*}$ given for all $\gamma, \tilde{\gamma} > 0$, $x \in \mathbb{R}^d$ and $\mathsf{A} \in \mathcal{B}(\mathbb{R}^d)$ by

$$\bar{R}_{\gamma,\tilde{\gamma}}(x, \mathsf{A}) = (4\pi\tilde{\gamma})^{-d/2} \int_{\mathsf{A}\times\mathsf{Z}} \exp\left(-\left\|y - x + \gamma\Theta(x,z)\right\|^2/(4\tilde{\gamma})\right) \mathrm{d}\eta(z)\mathrm{d}y \;. \tag{27}$$

Algorithm 1: SSGLD

Data: initial distribution $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$, non-increasing sequence $(\gamma_k)_{k\geq 1}$, U, Θ, η satisfying **A**3
Result: $(\bar{X}_k)_{k\in\mathbb{N}}$
begin
  Draw $\bar{X}_0 \sim \mu_0$;
  for $k \geq 0$ **do**
    Draw $G_{k+1} \sim \mathcal{N}(0, \mathrm{Id})$ and $Z_{k+1} \sim \eta$;
    Set $\bar{X}_{k+1} = \bar{X}_k - \gamma_{k+1}\Theta(\bar{X}_k, Z_{k+1}) + \sqrt{2\gamma_{k+2}}G_{k+1}$

Let $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ be two non-increasing sequences of reals numbers and $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ be an initial distribution. The weighted averaged distribution associated with (26) $(\bar{\nu}_n^N)_{n\in\mathbb{N}}$ is defined for all $N, n \in \mathbb{N}$, $n \geq 1$ by

$$\bar{\nu}_n^N = \Lambda_{N,N+n}^{-1} \sum_{k=N+1}^{N+n} \lambda_k \, \mu_0 \bar{Q}_\gamma^k \;, \qquad \bar{Q}_\gamma^k = \bar{R}_{\gamma_1,\gamma_2} \cdots \bar{R}_{\gamma_k,\gamma_{k+1}} \;, \text{ for } k \in \mathbb{N}^* \;, \tag{28}$$

where N is a burn-in time and $\Lambda_{N,N+n}$ is defined in (20). We take in the following the convention that $\bar{Q}_\gamma^0$ is the identity operator.

Under **A**3, define for all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\upsilon_\Theta(\mu) = \int_{\mathbb{R}^d\times\mathsf{Z}} \left\| \Theta(x,z) - \int_{\mathsf{Z}} \Theta(x,\tilde{z})\mathrm{d}\eta(\tilde{z}) \right\|^2 \mathrm{d}\eta(z)\mathrm{d}\mu(x) = \mathbb{E}\left[\left\| \Theta(\bar{X}_0, Z_1) - v \right\|^2 \right] \;, \tag{29}$$

where $\bar{X}_0, Z_1$ are independent random variables with distribution μ and η respectively and $v \in \partial U(X_0)$ almost surely. In addition, consider $\bar{S}_\gamma$, the Markov kernel on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ defined for all $x \in \mathbb{R}^d$ and $\mathsf{A} \in \mathcal{B}(\mathbb{R}^d)$ by

$$\bar{S}_\gamma(x, \mathsf{A}) = \int_{\mathsf{Z}} \mathbb{1}_{\mathsf{A}}\left(x - \gamma\Theta(x,z)\right) \mathrm{d}\eta(z) \;. \tag{30}$$

Theorem 13 *Assume* ***A*** *1(0) and* ***A*** *3. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ be two non-increasing sequences of positive real numbers satisfying for all $k \in \mathbb{N}^*$, $\lambda_{k+1}/\gamma_{k+2} \leq \lambda_k/\gamma_{k+1}$. Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ and $N \in \mathbb{N}$. Then for all $n \in \mathbb{N}^*$, it holds*

$$\mathrm{KL}\left(\bar{\nu}_n^N \middle| \pi\right) \leq \lambda_{N+1} W_2^2\left(\mu_0 \bar{Q}_\gamma^N \bar{S}_{\gamma_{N+1}}, \pi\right)/(2\gamma_{N+2}\Lambda_{N,N+n}) + (2\Lambda_{N,N+n})^{-1} \sum_{k=N+1}^{N+n} \left\{ \gamma_{k+1}\lambda_k \left(M^2 + \upsilon_\Theta(\mu_0 \bar{Q}_\gamma^k) \right) \right\} \;,$$

where $\bar{\nu}_n^N$ and $\bar{Q}_\gamma^N$ are defined in (28).

Proof The proof is postponed to Section 7.3.1.. ■

Note that in the bound given by Theorem 13, we need to control the ergodic average of the variance of the stochastic gradient estimates. When **A** 3 is satisfied, a possible assumption is that $x \mapsto \upsilon(\delta_x)$ is uniformly bounded. This assumption will be satisfied for example when the potential U is a sum of Lipschitz continuous functions.

Corollary 14 *Assume* ***A*** *1(0) and* ***A*** *3. Assume that $\sup_{x\in\mathbb{R}^d} \upsilon_\Theta(\delta_x) \leq D^2 < \infty$. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ given for all $k \in \mathbb{N}^*$ by $\lambda_k = \gamma_k = \gamma > 0$. Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Then for any $N \in \mathbb{N}, n \in \mathbb{N}^*$ we have*

$$\mathrm{KL}\left(\bar{\nu}_n^N \middle| \pi\right) \leq W_2^2\left(\mu_0 \bar{Q}_\gamma^N \bar{S}_\gamma, \pi\right)/(2n\gamma) + (\gamma/2)\left(M^2 + D^2\right) \;.$$

Furthermore, let $\varepsilon > 0$ and

$$\gamma_\varepsilon \leq \varepsilon/(M^2 + D^2) \;, \qquad n_\varepsilon \geq \lceil W_2^2(\mu_0 \bar{S}_\gamma, \pi)(\gamma_\varepsilon \varepsilon)^{-1} \rceil \;.$$

Then for $\gamma = \gamma_\varepsilon$ we have $\mathrm{KL}\left(\bar{\nu}_{n_\varepsilon}^0 \middle| \pi\right) \leq \varepsilon$.

Proof The first inequality is a direct consequence of Theorem 13. The bound for $\mathrm{KL}\left(\bar{\nu}_{n_\varepsilon}^0 \middle| \pi\right)$ follows directly from this inequality and definitions of γ_ε and n_ε. ■

In the case where a warm start is available for the Wasserstein distance, *i.e.* $W_2^2(\mu_0, \pi) \leq C$, for some absolute constant $C \geq 0$, then Corollary 14 implies that the complexity of SSGLD to obtain a sample close from π in KL with a precision target $\varepsilon > 0$ is of order $(M^2 + D^2)\bar{\mathcal{O}}(\varepsilon^{-2})$. Therefore, this complexity bound depends on the dimension only trough M and D^2 contrary to ULA. In addition, Pinsker inequality implies that the complexity of SSGLD for the total variation distance is of order $(M^2 + D^2)\bar{\mathcal{O}}(\varepsilon^{-4})$.

In addition if we have access to $\eta > 0$ and $M_\eta \geq 0$, independent of the dimension, such that for all $x \in \mathbb{R}^d$, $x \notin \mathrm{B}(x^\star, M_\eta)$, $U(x) - U(x^\star) \geq \eta \left\| x - x^\star \right\|$, where $x^\star \in \arg\min_{\mathbb{R}^d} U$, Proposition 32 and **A**3-(i) imply that starting at $\delta_{x^\star}$, the overall complexity of SSGLD for the KL is in this case $(\eta^{-2}d^2 + M_\eta^2)(M^2 + D^2)\bar{\mathcal{O}}(\varepsilon^{-2})$ and $(\eta^{-2}d^2 + M_\eta^2)(M^2 + D^2)\bar{\mathcal{O}}(\varepsilon^{-4})$ for the total variation distance.

If $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ are given for all $k \in \mathbb{N}^*$ by $\gamma_k = \lambda_k = \gamma_1/k^{-\alpha}$, with $\alpha \in (0,1)$, then by the same reasoning as in the proof of Corollary 8, we obtain that there exists $C \geq 0$

such that for all $n \in \mathbb{N}^*$, we have $\mathrm{KL}\left(\bar{\nu}_n^0 | \pi\right) \leq C \max(n^{\alpha-1}, n^{-\alpha})$, if $\alpha \neq 1/2$, and for $\alpha = 1/2$, we have $\mathrm{KL}\left(\bar{\nu}_n^0 | \pi\right) \leq C(\ln(n)+1)n^{-1/2}$.

We can have a better control on the variance terms using the following conditions on Θ.

A4 There exists $\tilde{L} \geq 0$ such that for η-almost every $z \in \mathsf{Z}$, $x \mapsto \Theta(x,z)$ is $1/\tilde{L}$-cocoercive, *i.e.* for all $x \in \mathbb{R}^d$,

$$\langle \Theta(x,z) - \Theta(y,z), x-y \rangle \geq (1/\tilde{L}) \left\| \Theta(x,z) - \Theta(y,z) \right\|^2 .$$

This assumption is for example satisfied if η-almost every z, $x \mapsto \Theta(x,z)$ is the gradient of a continuously differentiable convex function with Lipschitz gradient, see Nesterov (2004, Thereom 2.1.5) and Zhu and Marcotte (1995). Note that in general **A**4 is not implied by **A**1(0) and **A**2. Indeed, **A**4 is a regularity condition on the stochastic (sub)gradient of U, Θ, while **A**1 and **A**2 depend only on U. However, if U is continuously differentiable, Jensen inequality and **A**4 imply that **A**2 is satisfied with L equals $\tilde{L}$.

Proposition 15 *Assume **A**3 and **A**4. Then we have for all $x \in \mathbb{R}^d$ and $\gamma, \tilde{\gamma} > 0$, $\gamma \leq \tilde{L}^{-1}$*

$$2\gamma(\tilde{L}^{-1} - \gamma) \upsilon_\Theta(\delta_x) \leq \|x - x^\star\|^2 - \int_{\mathbb{R}^d} \|y - x^\star\|^2 \bar{R}_{\gamma,\tilde{\gamma}}(x, \mathrm{d}y) + 2\gamma^2 \upsilon_\Theta(\delta_{x^\star}) + 2\tilde{\gamma} d ,$$

where υ_Θ is defined by (29).

Proof Consider $\bar{X}_1 = x - \gamma\Theta(x, Z_1) + \sqrt{2\tilde{\gamma}} G_1$, where Z_1 and G_1 are two independent random variables, Z_1 has distribution η and G_1 is the standard Gaussian random variables. Then using **A**4, we have

$$\begin{aligned}
\mathbb{E}\left[\left\|\bar{X}_1 - x^\star\right\|^2\right] &= \mathbb{E}\left[\|x - \gamma\Theta(x,Z_1) - x^\star\|\right] + 2\tilde{\gamma} d \\
&= \|x - x^\star\|^2 + \mathbb{E}\left[\gamma^2 \|\Theta(x,Z_1)\|^2 - 2\gamma \langle \Theta(x,Z_1), x - x^\star \rangle\right] + 2\tilde{\gamma} d \\
&\leq \|x - x^\star\|^2 - 2\gamma(\tilde{L}^{-1} - \gamma)\mathbb{E}\left[\|\Theta(x,Z_1) - \Theta(x^\star, Z_1)\|^2\right] \\
&\qquad + 2\gamma^2 \mathbb{E}\left[\|\Theta(x^\star, Z_1)\|^2\right] + 2\tilde{\gamma} d .
\end{aligned}$$

The proof is completed upon noting that $\upsilon_\Theta(\delta_x) \leq \mathbb{E}[\|\Theta(x,Z_1) - \Theta(x^\star, Z_1)\|^2]$ and $\upsilon_\Theta(\delta_{x^\star}) = \mathbb{E}\left[\|\Theta(x^\star, Z_1)\|^2\right]$ ■

Combining Theorem 13 and Proposition 15, we get the following result.

Corollary 16 *Assume **A**1(0)-**A**3 and **A**4. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ defined for all $k \in \mathbb{N}^*$ by $\gamma_k = \lambda_k = \gamma \in (0, \tilde{L}^{-1})$. Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Then for all $N \in \mathbb{N}$ and $n \in \mathbb{N}^*$, we have*

$$\begin{aligned}
&\mathrm{KL}\left(\bar{\nu}_n^N | \pi\right) \leq W_2^2\left(\mu_0 \bar{R}^N_{\gamma,\gamma} \bar{S}_\gamma, \pi\right) \Big/ (2\gamma n) \\
&\quad + \gamma M^2/2 + (2(\tilde{L}^{-1} - \gamma))^{-1} \left\{ (2n)^{-1} \int_{\mathbb{R}^d} \|x - x^\star\|^2 \, \mathrm{d}\mu_0 \bar{R}^{N+1}_{\gamma,\gamma}(x) + \gamma^2 \upsilon_\Theta(\delta_{x^\star}) + \gamma d \right\} .
\end{aligned}$$

Furthermore, let $\varepsilon > 0$ and

$$\gamma_\varepsilon \leq \min\left[\varepsilon \Big/ \left\{2M^2 + 4\tilde{L}d\right\}, \sqrt{\varepsilon\left(4\tilde{L}\upsilon_\Theta(\delta_{x^\star})\right)^{-1}}, (2\tilde{L})^{-1} \right] ,$$

$$n_\varepsilon \geq 2\max\left\{ \left\lceil W_2^2(\mu_0 \bar{S}_{\gamma_\varepsilon}, \pi)(\gamma_\varepsilon \varepsilon)^{-1} \right\rceil, \left\lceil \tilde{L}\varepsilon^{-1} \int_{\mathbb{R}^d} \|x - x^\star\|^2 \, \mathrm{d}\mu_0 \bar{R}_{\gamma_\varepsilon,\gamma_\varepsilon}(x) \right\rceil \right\} .$$

Then for $\gamma = \gamma_\varepsilon$, then we have $\mathrm{KL}\left(\bar{\nu}^0_{n_\varepsilon} | \pi\right) \leq \varepsilon$.

Proof The proof is postponed to Section 7.3.2. ■

Note that compared to Corollary 14, the dependence on the variance of the stochastic subgradients in the bound on n_ε, given in Corollary 16, is less significant since n_ε scales as $(\upsilon_\Theta(\delta_{x^\star}))^{1/2}$ and not as $\sup_{x\in\mathbb{R}^d} \upsilon_\Theta(\delta_x)$. However, the dependency on the dimension deteriorates a little.

4.2. Stochastic Proximal Gradient Langevin Dynamics

In this section, we propose and analyze an other algorithm to handle non-smooth target distribution using stochastic gradient estimates and proximal operators. For $m \geq 0$, consider the following assumptions on the gradient.

A5 (m) There exists $U_1 : \mathbb{R}^d \to \mathbb{R}$ and $U_2 : \mathbb{R}^d \to \mathbb{R}$ such that $U = U_1 + U_2$ and satisfying the following assumptions:

(i) U_1 satisfies **A**1(m) and **A**2. In addition, there exists a measurable space $(\tilde{\mathsf{Z}}, \tilde{\mathcal{Z}})$, a probability measure $\tilde{\eta}_1$ on $(\tilde{\mathsf{Z}}, \tilde{\mathcal{Z}})$ and a measurable function $\tilde{\Theta}_1 : \mathbb{R}^d \times \tilde{\mathsf{Z}} \to \mathbb{R}^d$ such that for all $x \in \mathbb{R}^d$,

$$\int_{\tilde{\mathsf{Z}}} \tilde{\Theta}_1(x, \tilde{z}) \mathrm{d}\tilde{\eta}_1(\tilde{z}) = \nabla U_1(x) .$$

(ii) U_2 satisfies **A**1(0) and is M_2-Lipschitz.

Under **A**5, consider the proximal operator associated with U_2 with parameter $\gamma > 0$ (see Rockafellar and Wets (1998, Chapter 1 Section G)), defined for all $x \in \mathbb{R}^d$ by

$$\mathrm{prox}^\gamma_{U_2}(x) = \operatorname*{arg\,min}_{y\in\mathbb{R}^d} \left\{ U_2(y) + (2\gamma)^{-1} \|x - y\|^2 \right\} .$$

Note that taking the derivative in the right hand side of this equation, we get that for any $x \in \mathbb{R}^d$ and $\gamma > 0$,

$$\mathrm{prox}^\gamma_{U_2}(x) \in x - \gamma \partial U_2(\mathrm{prox}^\gamma_{U_2}(x)) . \tag{31}$$

Let $(\tilde{Z}_k)_{k\in\mathbb{N}^*}$ be a sequence of i.i.d. random variables distributed according to $\tilde{\eta}_1$, $(\gamma_k)_{k\in\mathbb{N}^*}$ be a sequence of non-increasing stepsizes and $\tilde{X}_0$ distributed according to $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Stochastic Proximal Gradient Langevin Dynamics (SPGLD) defines the sequence of random variables $(\tilde{X}_n)_{n\in\mathbb{N}}$ starting at $\tilde{X}_0$ for $n \geq 0$ by

$$\tilde{X}_{n+1} = \mathrm{prox}^{\gamma_{n+1}}_{U_2}(\tilde{X}_n) - \gamma_{n+2} \tilde{\Theta}_1\{\mathrm{prox}^{\gamma_{n+1}}_{U_2}(\tilde{X}_n), \tilde{Z}_{n+1}\} + \sqrt{2\gamma_{n+2}} G_{n+1} , \tag{32}$$

where $(G_k)_{k\in\mathbb{N}^*}$ is a sequence of i.i.d. d-dimensional standard Gaussian random variables, independent of $(\tilde{Z}_k)_{k\in\mathbb{N}^*}$. The recursion (32) is associated with the family of Markov kernels $(\tilde{R}_{\gamma_k,\gamma_{k+1}})_{k\in\mathbb{N}^*}$ given for all $\gamma,\tilde{\gamma}>0$, $x\in\mathbb{R}^d$ and $\mathsf{A}\in\mathcal{B}(\mathbb{R}^d)$ by

$$\begin{aligned}&\tilde{R}_{\gamma,\tilde{\gamma}}(x,\mathsf{A})\\&=(4\pi\tilde{\gamma})^{-d/2}\int_{\mathsf{A}\times\tilde{\mathsf{Z}}}\exp\left(-\left\|y-\mathrm{prox}^{\gamma}_{U_2}(x)+\tilde{\gamma}\tilde{\Theta}_1\{\mathrm{prox}^{\gamma}_{U_2}(x),z\}\right\|^2\Big/(4\tilde{\gamma})\right)\mathrm{d}\tilde{\eta}_1(z)\mathrm{d}y\ .\end{aligned}\tag{33}$$

Note that for all $\gamma,\tilde{\gamma}>0$, $\tilde{R}_{\gamma,\tilde{\gamma}}$ can be decomposed as the product $\tilde{S}^2_{\gamma}\tilde{S}^1_{\tilde{\gamma}}T_{\tilde{\gamma}}$ where $T_{\tilde{\gamma}}$ is defined by (14) and for all $x\in\mathbb{R}^d$ and $\mathsf{A}\in\mathcal{B}(\mathbb{R}^d)$

$$\tilde{S}^1_{\tilde{\gamma}}(x,\mathsf{A})=\int_{\tilde{\mathsf{Z}}}\mathbb{1}_{\mathsf{A}}(x-\tilde{\gamma}\tilde{\Theta}_1(x,z))\mathrm{d}\tilde{\eta}_1(z)\ ,\qquad \tilde{S}^2_{\gamma}(x,\mathsf{A})=\delta_{\mathrm{prox}^{\gamma}_{U_2}(x)}(\mathsf{A})\ .\tag{34}$$

Algorithm 2: SPGLD

Data: initial distribution $\mu_0\in\mathcal{P}_2(\mathbb{R}^d)$, non-increasing sequence $(\gamma_k)_{k\geq1}$, $U=U_1+U_2,\tilde{\Theta}_1,\tilde{\eta}_1$ satisfying **A**5
Result: $(\tilde{X}_k)_{k\in\mathbb{N}}$
begin
  Draw $\tilde{X}_0\sim\mu_0$;
  for $k\geq1$ **do**
    Draw $G_{k+1}\sim\mathcal{N}(0,\mathrm{Id})$ and $\tilde{Z}_{k+1}\sim\tilde{\eta}_1$;
    Set $\tilde{X}_{k+1}=\mathrm{prox}^{\gamma_{k+1}}_{U_2}(\tilde{X}_k)-\gamma_{k+2}\tilde{\Theta}_1(\mathrm{prox}^{\gamma_{k+1}}_{U_2}(\tilde{X}_k),\tilde{Z}_{k+1})+\sqrt{2\gamma_{k+2}}G_k$

Let$(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ be two non-increasing sequences of reals numbers and $\mu_0\in\mathcal{P}_2(\mathbb{R}^d)$ be an initial distribution. The weighted averaged distribution associated with (32) $(\tilde{\nu}^N_n)_{n\in\mathbb{N}}$ is defined for all $N,n\in\mathbb{N}$, $n\geq1$ by

$$\tilde{\nu}^N_n=\Lambda^{-1}_{N,N+n}\sum_{k=N+1}^{N+n}\lambda_k\,\mu_0\tilde{Q}^k_{\gamma}\ ,\qquad \tilde{Q}^k_{\gamma}=\tilde{R}_{\gamma_1,\gamma_2}\cdots\tilde{R}_{\gamma_k,\gamma_{k+1}}\ ,\ \text{for } k\in\mathbb{N}^*\ ,\tag{35}$$

where N is a burn-in time and $\Lambda_{N,N+n}$ is defined in (20). We take in the following the convention that $\tilde{Q}^0_{\gamma}$ is the identity operator.

Under **A**3, define for all $\mu\in\mathcal{P}_2(\mathbb{R}^d)$,

$$\begin{aligned}\upsilon_1(\mu)&=\int_{\mathbb{R}^d\times\tilde{\mathsf{Z}}}\left\|\tilde{\Theta}_1(x,z)-\int_{\tilde{\mathsf{Z}}}\tilde{\Theta}_1(x,\tilde{z})\mathrm{d}\tilde{\eta}_1(\tilde{z})\right\|^2\mathrm{d}\eta(z)\mathrm{d}\mu(x)\\&=\mathbb{E}\left[\left\|\tilde{\Theta}_1(\tilde{X}_0,\tilde{Z}_1)-\nabla U_1(\tilde{X}_0)\right\|^2\right]\ ,\end{aligned}\tag{36}$$

where $\tilde{X}_0,\tilde{Z}_1$ are independent random variables with distribution μ and $\tilde{\eta}_1$ respectively.

Theorem 17 *Assume* ***A****5(m), for $m\geq0$. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ be two non-increasing sequences of positive real numbers satisfying $\gamma_1\in\left(0,L^{-1}\right]$, and for all $k\in\mathbb{N}^*$, $\lambda_{k+1}/\gamma_{k+2}\leq\lambda_k/\gamma_{k+1}$. Let $\mu_0\in\mathcal{P}_2(\mathbb{R}^d)$ and $N\in\mathbb{N}$. Then for all $n\in\mathbb{N}^*$, we have*

$$\begin{aligned}\mathrm{KL}\left(\tilde{\nu}^N_n|\pi\right)\leq\ &\lambda_{N+1}W_2^2\left(\mu_0\tilde{Q}^N_{\gamma}\tilde{S}^2_{\gamma_{N+1}},\pi\right)\Big/(2\gamma_{N+2}\Lambda_{N,N+n})\\&+(2\Lambda_{N,N+n})^{-1}\sum_{k=N+1}^{N+n}\lambda_k\gamma_{k+1}\{2Ld+(1+\gamma_{k+1}L)\upsilon_1(\mu_0Q^{k-1}_{\gamma}\tilde{S}^2_{\gamma_k})+2M_2^2\}\ .\end{aligned}$$

Proof The proof is postponed to Section 7.4.1. ■

Corollary 18 *Assume* ***A*** *5(m), for $m\geq0$. Assume that $\sup_{x\in\mathbb{R}^d}\upsilon_1(\delta_x)\leq D^2<\infty$. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ given for all $k\in\mathbb{N}^*$ by $\lambda_k=\gamma_k=\gamma\in\left(0,L^{-1}\right]$. Let $\mu_0\in\mathcal{P}_2(\mathbb{R}^d)$. Then for any $N\in\mathbb{N},n\in\mathbb{N}^*$ we have*

$$\mathrm{KL}\left(\tilde{\nu}^N_n|\pi\right)\leq W_2^2\left(\mu_0\bar{Q}^N_{\gamma}\bar{S}_{\gamma},\pi\right)/(2n\gamma)+\gamma\left(Ld+M_2^2+D^2\right)\ ,$$

Furthermore, let $\varepsilon>0$ and

$$\gamma_{\varepsilon}\leq\min\left\{\varepsilon/(2(Ld+M_2^2+D^2)),L^{-1}\right\}\ ,\qquad n_{\varepsilon}\geq\left\lceil W_2^2(\mu_0\tilde{S}^2_{\gamma_1},\pi)(\gamma_{\varepsilon}\varepsilon)^{-1}\right\rceil.$$

Then we have $\mathrm{KL}\left(\tilde{\nu}^0_{n_{\varepsilon}}|\pi\right)\leq\varepsilon$.

In the case where a warm start is available for the Wasserstein distance, *i.e.* $W_2^2(\mu_0,\pi)\leq C$, for some absolute constant $C\geq0$, then Corollary 18 implies that the complexity of SPGLD to obtain a sample close from π in KL with a precision target $\varepsilon>0$ is of order $(d+M_2^2+D^2)\bar{\mathcal{O}}(\varepsilon^{-2})$. In addition, Pinsker inequality implies that the complexity of SPGLD for the total variation distance is of order $(d+M_2^2+D^2)\bar{\mathcal{O}}(\varepsilon^{-4})$.

In addition if we have access to $\eta>0$ and $M_{\eta}\geq0$, independent of the dimension, such that for all $x\in\mathbb{R}^d$, $x\notin\mathrm{B}(x^\star,M_{\eta})$, $U(x)-U(x^\star)\geq\eta\left\|x-x^\star\right\|$, Proposition 32, **A**5-(ii), (31) and (25) imply that starting at $\delta_{x^\star}$, the overall complexity of SPGLD for the KL is in this case $(\eta^{-2}d^2+M_{\eta}^2)(d+M_2^2+D^2)\bar{\mathcal{O}}(\varepsilon^{-2})$ and $(\eta^{-2}d^2+M_{\eta}^2)(d+M_2^2+D^2)\bar{\mathcal{O}}(\varepsilon^{-4})$ for the total variation distance If $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ are given for all $k\in\mathbb{N}^*$ by $\gamma_k=\lambda_k=\gamma_1/k^{-\alpha}$, $\gamma_1\in\left(0,L^{-1}\right]$. Then by the same reasoning as in the proof of Corollary 8, we obtain that there exists $C\geq0$ such that for all $n\in\mathbb{N}^*$, we have $\mathrm{KL}\left(\bar{\nu}^0_n|\pi\right)\leq C\max(n^{\alpha-1},n^{-\alpha})$, if $\alpha\neq1/2$, and for $\alpha=1/2$, we have $\mathrm{KL}\left(\bar{\nu}^0_n|\pi\right)\leq C(\ln(n)+1)n^{-1/2}$.

If $\sup_{x\in\mathbb{R}^d}\upsilon_1(\delta_x)<+\infty$ does not hold, we can control the variance of stochastic gradient estimates using **A**4 again based on this following result.

Proposition 19 *Assume* ***A*** *5 and $\tilde{\Theta}_1$ satisfies* ***A*** *4. Then we have for all $x\in\mathbb{R}^d$ and $\gamma\in(0,\tilde{L}^{-1}]$*

$$2\gamma(\tilde{L}^{-1}-\gamma)\upsilon_1(\delta_x)\leq\|x-x^\star\|^2-\int_{\mathbb{R}^d}\|y-x^\star\|^2(\tilde{S}^1_{\gamma}T_{\gamma}\tilde{S}^2_{\gamma})(x,\mathrm{d}y)+2\gamma^2\upsilon_1(\delta_{x^\star})+2\gamma d\ ,$$

where $\tilde{S}^1_{\gamma},\tilde{S}^2_{\gamma}$ and υ_1 are defined by (34)-(36) *respectively.*

Proof Let $\gamma > 0$, $x \in \mathbb{R}^d$ and consider $\tilde{X}_1 = \mathrm{prox}_{U_2}^{\gamma}\left\{x - \gamma\tilde{\Theta}_1(x, \tilde{Z}_1) + \sqrt{2\gamma}G_1\right\}$, where $\tilde{Z}_1$ and G_1 are two independent random variables, $\tilde{Z}_1$ has distribution $\tilde{\eta}_1$ and G_1 is the standard Gaussian random variable, so that $\tilde{X}_1$ has distribution $\tilde{S}_\gamma^1 T_\gamma \tilde{S}_\gamma^2(x, \cdot)$. First by (Bauschke and Combettes, 2011, Theorem 26.2(vii)), we have that $x^\star = \mathrm{prox}_{U_2}^{\gamma}(x^\star - \gamma\nabla U_1(x^\star))$ and by (Bauschke and Combettes, 2011, Proposition 12.27), the proximal is non-expansive, for all $x, y \in \mathbb{R}^d$, $\|\mathrm{prox}_{U_2}^{\gamma}(x) - \mathrm{prox}_{U_2}^{\gamma}(y)\| \leq \|x - y\|$. Using these two results and the fact that $\tilde{\Theta}_1$ satisfies **A** 4, we have

$$
\begin{aligned}
\mathbb{E}\left[\left\|\tilde{X}_1 - x^\star\right\|^2\right] &= \mathbb{E}\left[\left\|\mathrm{prox}_{U_2}^{\gamma}\left\{x - \gamma\tilde{\Theta}_1(x, \tilde{Z}_1) + \sqrt{2\gamma}G_1\right\} - \mathrm{prox}_{U_2}^{\gamma}\{x^\star - \gamma\nabla U_1(x^\star)\}\right\|^2\right] \\
&\leq \mathbb{E}\left[\left\|\left(x - \gamma\tilde{\Theta}_1(x, \tilde{Z}_1) + \sqrt{2\gamma}G_1\right) - (x^\star - \gamma\nabla U_1(x^\star))\right\|^2\right] \\
&\leq \|x - x^\star\|^2 \\
&\quad + \mathbb{E}\left[2\gamma\left\langle x - x^\star, \nabla U_1(x^\star) - \tilde{\Theta}_1(x, \tilde{Z}_1)\right\rangle + \gamma^2\left\|\nabla U_1(x^\star) - \tilde{\Theta}_1(x, \tilde{Z}_1)\right\|^2\right] + 2\gamma d \\
&\leq \|x - x^\star\|^2 - 2\gamma(\tilde{L}^{-1} - \gamma)\mathbb{E}\left[\left\|\tilde{\Theta}_1(x, \tilde{Z}_1) - \tilde{\Theta}_1(x^\star, \tilde{Z}_1)\right\|^2\right] \\
&\qquad + 2\gamma^2\mathbb{E}\left[\left\|\tilde{\Theta}_1(x^\star, \tilde{Z}_1) - \nabla U_1(x^\star)\right\|^2\right] + 2\gamma d\,.
\end{aligned}
$$

The proof is completed upon noting that $\upsilon_1(\delta_x) \leq \mathbb{E}[\left\|\tilde{\Theta}_1(x, \tilde{Z}_1) - \tilde{\Theta}_1(x^\star, \tilde{Z}_1)\right\|^2]$. ■

Combining Theorem 17 and Proposition 19, we get the following result.

Corollary 20 *Assume* ***A*** *5(m) for $m \geq 0$ and that $\tilde{\Theta}_1$ satisfies* ***A*** *4. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ and $(\lambda_k)_{k\in\mathbb{N}^*}$ be two non-increasing sequences of positive real numbers given for all $k \in \mathbb{N}^*$ by $\gamma_k = \lambda_k = \gamma \in (0, L^{-1}]$, $\gamma < \tilde{L}^{-1}$. Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ and $N \in \mathbb{N}$. Then for all $n \in \mathbb{N}^*$, it holds*

$$
\begin{aligned}
\mathrm{KL}\left(\tilde{\nu}_n^N \middle| \pi\right) &\leq W_2^2\left(\mu_0\tilde{Q}_\gamma^N\tilde{S}_{\gamma_{N+1}}^2, \pi\right)\Big/(2\gamma n) + \gamma(Ld + M_2^2) \\
&\quad + (1 + \gamma L)(2(\tilde{L}^{-1} - \gamma))^{-1}\left\{(2n)^{-1}\int_{\mathbb{R}^d}\|x - x^\star\|^2\,\mathrm{d}\mu_0\tilde{Q}_\gamma^N\tilde{S}_\gamma^2(y) + \gamma^2\upsilon_1(\delta_{x^\star}) + \gamma d\right\}\,.
\end{aligned}
$$

Furthermore, for $\varepsilon > 0$, consider stepsize and a number of iterations satisfying:

$$
\begin{aligned}
\gamma_\varepsilon &\leq \min\left[\varepsilon\Big/\left\{4M_2^2 + 4Ld + 8\tilde{L}d\right\}, \sqrt{\varepsilon/\left(8\tilde{L}\upsilon_1(\delta_{x^\star})\right)}, L^{-1}, (2\tilde{L})^{-1}\right]\,, \\
n_\varepsilon &\geq 2\max\left\{\left\lceil W_2^2(\mu_0\tilde{S}_{\gamma_\varepsilon}^2, \pi)(\gamma_\varepsilon\varepsilon)^{-1}\right\rceil, \left\lceil 2\tilde{L}\varepsilon^{-1}\int_{\mathbb{R}^d}\|x - x^\star\|^2\,\mathrm{d}\mu_0\tilde{S}_\gamma^2(y)\right\rceil\right\}\,.
\end{aligned}
$$

Then, we have $\mathrm{KL}\left(\tilde{\nu}_{n_\varepsilon}^0 \middle| \pi\right) \leq \varepsilon$.

Proof The proof of the corollary is a direct consequence of Theorem 17 and Proposition 19, and is postponed to Section 7.4.2. ■

Note that the dependency on the variance of the stochastic gradients is improved compared to the bound given by Corollary 18. We specify once again the result of Theorem 17 for strongly convex potential.

Theorem 21 *Assume* ***A*** *5(m), for $m > 0$. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ be a non-increasing sequences of positive real numbers satisfying for all $k \in \mathbb{N}^*$, $\gamma_k \in \left(0, L^{-1}\right]$. Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Then for all $n \in \mathbb{N}^*$, it holds*

$$
\begin{aligned}
W_2^2(\mu_0\tilde{Q}_\gamma^n\tilde{S}_{\gamma_{n+1}}^2, \pi) &\leq \left\{\prod_{k=1}^n(1 - m\gamma_{k+1})\right\}W_2^2(\mu_0\tilde{S}_{\gamma_1}^2, \pi) \\
&\quad + \sum_{k=1}^n\gamma_{k+1}^2\left\{\prod_{i=k+2}^{n+1}(1 - m\gamma_i)\right\}\left\{2Ld + (1 + \gamma_{k+1}L)\upsilon_1(\mu_0\tilde{Q}_\gamma^{k-1}\tilde{S}_{\gamma_k}^2) + 2M_2^2\right\}\,.
\end{aligned}
$$

Proof The proof is postponed to Section 7.4.3. ■

Corollary 22 *Assume* ***A*** *5(m), for $m > 0$. Assume that $\sup_{x\in\mathbb{R}^d}\upsilon_1(\delta_x) \leq D^2 < \infty$. Let $\varepsilon > 0$, $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$, and*

$$
\gamma_\varepsilon \leq \min\left\{m\varepsilon/(4(Ld + D^2 + M_2^2)), L^{-1}\right\}\,, \qquad n_\varepsilon \geq \left\lceil \ln(2W_2^2(\mu_0\tilde{S}_{\gamma_\varepsilon}^2, \pi)/(\varepsilon\gamma_\varepsilon m)^{-1}\right\rceil\,.
$$

Then $W_2^2(\mu_0\tilde{R}_{\gamma_\varepsilon,\gamma_\varepsilon}^{n_\varepsilon}\tilde{S}_{\gamma_\varepsilon}^2, \pi) \leq \varepsilon$, where $\tilde{R}_{\gamma,\gamma}$ and $\tilde{S}_\gamma^2$ are defined by (33) and (34) respectively.

Proof Since $\gamma_\varepsilon \leq L^{-1}$, we have $(1 + \gamma_\varepsilon L)\upsilon_1(\mu_0\tilde{R}_{\gamma_\varepsilon}^k\tilde{S}_\gamma^2) \leq 2D^2$ for all $k \geq 1$. Using Theorem 21 then concludes the proof. ■

Note that the bounds given by Theorem 21 are tighter the one given by Dalalyan and Karagulyan (2017, Theorem 3) which shows under **A**5 with $U_2 = 0$ and $\sup_{x\in\mathbb{R}^d}\upsilon_1(\delta_x) \leq D^2$ that

$$
W_2(\mu_0\tilde{R}_{\gamma,\gamma}, \pi) \leq (1 - mh)W_2(\mu_0, \pi) + 1.65(L/m)(\gamma d)^{1/2} + D^2(\gamma d)^{1/2}/(1.65L + Dm)\,.
$$

Indeed, for constant stepsize $\gamma_k = \gamma \in (0, L^{-1}]$ for all $k \in \mathbb{N}^*$, Theorem 21 implies with the same assumptions that

$$
W_2(\mu_0\tilde{R}_{\gamma,\gamma}, \pi) \leq (1 - mh)^{1/2}W_2(\mu_0, \pi) + (2Ld\gamma/m)^{1/2} + ((1 + \gamma)\gamma/m)^{1/2}D\,.
$$

As for ULA, the dependency on the condition number L/m is improved.

In the strongly convex case, we can improve the dependency on the variance of the stochastic gradient under the following condition.

A 6 There exist $\tilde{L}_1, \tilde{m}_1 > 0$ such that for all for $\tilde{\eta}_1$-almost every $z \in \tilde{\mathsf{Z}}$, for all $x, y \in \mathbb{R}^d$, we have

$$
\left\langle\tilde{\Theta}_1(x, z) - \tilde{\Theta}_1(y, z), x - y\right\rangle \geq \tilde{m}_1\|x - y\|^2 + (1/\tilde{L}_1)\left\|\tilde{\Theta}_1(x, z) - \tilde{\Theta}_1(y, z)\right\|^2\,.
$$

The condition **A**6 is for example satisfied if η-almost surely, $x \mapsto \tilde{\Theta}_1(x,z)$ is strongly convex, see (Nesterov, 2004, Theorem 2.1.12).

Proposition 23 *Assume* ***A*** *5(m) for $m>0$ and* ***A*** *6. Then for all $\gamma>0$ we have*

$$2\gamma(\tilde{L}_1^{-1}-\gamma)\upsilon_1(\delta_x) \le (1-\tilde{m}_1\gamma)\left\|x-x^\star\right\|^2 - \int_{\mathbb{R}^d} \|y-x^\star\|^2 \, (\tilde{S}_\gamma^1 T_\gamma \tilde{S}_\gamma^2)(x,\mathrm{d}y) + 2\gamma^2\upsilon_1(\delta_{x^\star}) + 2\gamma d \;,$$

where $\tilde{S}_\gamma^1, \tilde{S}_\gamma^2$ and υ_1 are defined by (34)-(36) *respectively.*

Proof The proof is similar to the proof of Proposition 19 and is postponed to Section 7.4.4. ■

Corollary 24 *Assume* ***A*** *5(m), for $m>0$ and that $\tilde{\Theta}_1$ satisfies* ***A*** *6. Let $(\gamma_k)_{k\in\mathbb{N}^*}$ defined for all $k\in\mathbb{N}^*$ by $\gamma_k=\gamma\in(0, L^{-1}\wedge(2\tilde{L}_1)^{-1}]$. Let $\mu_0\in\mathcal{P}_2(\mathbb{R}^d)$. Define $\tilde{m}=\min(m,\tilde{m}_1)$ and*

$$\begin{aligned}\Delta_1 &= 2(Ld+M_2)/m + \{2\tilde{L}_1(1+\gamma L)/\tilde{m}\}d \\ \Delta_2 &= \{2\tilde{L}_1(1+\gamma L)/\tilde{m}\}\upsilon_1(\delta_{x^\star}) \\ \Delta_3 &= \gamma\tilde{L}_1(1+\gamma L)\left\{\int_{\mathbb{R}^d}\|x-x^\star\|^2\,\mathrm{d}\mu_0\tilde{S}^2_{\gamma_\varepsilon}(x)\right\}\;.\end{aligned} \tag{37}$$

Then for all $n\in\mathbb{N}^*$, it holds

$$W_2^2(\mu_0\tilde{R}^n_{\gamma,\gamma}\tilde{S}^2_\gamma,\pi) \;\le\; (1-m\gamma)^n W_2^2(\mu_0\tilde{S}^2_\gamma,\pi) + (1-\tilde{m}\gamma)^n\Delta_3 + \gamma\Delta_1 + \gamma^2\Delta_2 \;, \tag{38}$$

where $\tilde{R}_{\gamma,\gamma}$ and $\tilde{S}^2_\gamma$ are defined by (33) *and* (34).

Therefore, for $\varepsilon>0$ and

$$\begin{aligned}\gamma_\varepsilon &\le \min\left\{\varepsilon/(4\Delta_1), [\varepsilon/(4\Delta_2)]^{1/2}, L^{-1}, (2\tilde{L}_1)^{-1}\right\} \\ n_\varepsilon &\ge \max\left\{\lceil\ln(4W_2^2(\mu_0\tilde{S}^2_{\gamma_\varepsilon},\pi)/\varepsilon)(\gamma_\varepsilon m)^{-1}\rceil, \lceil\ln(4\Delta_3/\varepsilon)(\gamma_\varepsilon\tilde{m})^{-1}\rceil\right\}\;,\end{aligned}$$

it holds $W_2^2(\mu_0\tilde{R}^{n_\varepsilon}_{\gamma_\varepsilon,\gamma_\varepsilon}\tilde{S}^2_{\gamma_\varepsilon},\pi)\le\varepsilon$.

Proof The proof of the corollary is postponed to Section 7.4.5. ■

Corollary 25 *Assume* ***A*** *5(m), for $m>0$ and that $\tilde{\Theta}_1$ satisfies* ***A*** *6. Define $\tilde{m}=\min(m,\tilde{m}_1)$. Let $\varepsilon>0$, $\mu_0\in\mathcal{P}_2(\mathbb{R}^d)$ and*

$$\begin{aligned}\gamma_\varepsilon &\le \min\left\{\varepsilon/(4\Delta_1), [\varepsilon/(4\Delta_2)]^{1/2}, L^{-1}, (2\tilde{L}_1)^{-1}\right\}\;, \\ N_\varepsilon &\ge \max\left\{\lceil\ln(4W_2^2(\mu_0\tilde{S}^2_{\gamma_\varepsilon},\pi)/\varepsilon)(\gamma_\varepsilon m)^{-1}\rceil, \lceil\ln(4\Delta_3/\varepsilon)(\gamma_\varepsilon\tilde{m})^{-1}\rceil\right\} \\ \tilde{\gamma}_\varepsilon &\le \min\left[\varepsilon\Big/\left\{4M_2^2+4Ld+8\tilde{L}d\right\}, \sqrt{\varepsilon/\left(8\tilde{L}\upsilon_1(\delta_{x^\star})\right)}, L^{-1}, (2\tilde{L})^{-1}\right]\;, \\ n_\varepsilon &\ge 2\max\left\{\lceil\gamma_\varepsilon^{-1}\rceil, \left\lceil 2\tilde{L}\varepsilon^{-1}\int_{\mathbb{R}^d}\|x-x^\star\|^2\,\mathrm{d}\mu_0\tilde{R}^{N_\varepsilon}_{\gamma_\varepsilon,\gamma_\varepsilon}\tilde{S}^2_\gamma(y)\right\rceil\right\}\;,\end{aligned}$$

where $\Delta_1,\Delta_2,\Delta_3$ are defined in (37) *and $\tilde{R}_{\gamma,\gamma}$ and $\tilde{S}^2_\gamma$ are defined by* (33) *and* (34). *Let $(\gamma_k)_{k\in\mathbb{N}}$ defined by $\gamma_k=\gamma_\varepsilon$ for $k\in\{1,\dots,N_\varepsilon\}$ and $\gamma_k=\tilde{\gamma}_\varepsilon$ for $k>N_\varepsilon$. Then we have $\mathrm{KL}\left(\tilde{\nu}^{N_\varepsilon}_{n_\varepsilon}|\pi\right)\le\varepsilon$ where $\tilde{\nu}^{N_\varepsilon}_{n_\varepsilon}=n_\varepsilon^{-1}\sum_{k=1}^{n_\varepsilon}\mu_0\tilde{R}^{N_\varepsilon}_{\gamma_\varepsilon,\gamma_\varepsilon}\tilde{R}^k_{\tilde{\gamma}_\varepsilon,\tilde{\gamma}_\varepsilon}$.*

Proof Corollary 24 implies that after the burn in phase of N_ε steps with stepsize γ_ε, we have $W_2^2(\mu_0\tilde{Q}^{N_\varepsilon}_\gamma\tilde{S}^2_{\gamma_\varepsilon},\pi)\le\varepsilon$. Then, since we can treat $\mu_0\tilde{Q}^{N_\varepsilon}_\gamma$ as a new starting measure, Corollary 20 concludes the proof. ■

4.2.1. Discussion on Related Works

Note that the SPGLD is different from the algorithm MYULA proposed by Durmus et al. (2018) which approximates U_2 by its Moreau envelope, and under **A**5 defines the Markov chain $(X^{\mathrm{M}}_k)_{k\in\mathbb{N}}$ by the recursion:

$$X^{\mathrm{M}}_{k+1} = (1-\gamma/\lambda^{\mathrm{M}}) + (\gamma/\lambda^{\mathrm{M}})\,\mathrm{prox}^{\lambda^{\mathrm{M}}}_{U_2}(X^{\mathrm{M}}_k) - \gamma\nabla U_1(X^{\mathrm{M}}_k) + \sqrt{2\gamma}G_{k+1}\;,$$

for a stepsize $\gamma>0$, $(G_k)_{k\in\mathbb{N}^*}$ a sequence of i.i.d. d-dimensional standard Gaussian random variables and $\lambda^{\mathrm{M}}>0$ a regularization parameter. So taking $\lambda^{\mathrm{M}}=\gamma$, we get that the recursion boils down to

$$X^{\mathrm{M}}_{k+1} = \mathrm{prox}^{\gamma}_{U_2}(X^{\mathrm{M}}_k) - \gamma\nabla U_1(X^{\mathrm{M}}_k) + \sqrt{2\gamma}G_{k+1}\;.$$

Then the main difference with (32) setting $\gamma_k=\gamma$ for all $k\in\mathbb{N}^*$ and $\tilde{\Theta}_1=\nabla U_1$ is that $\nabla U_1(X^{\mathrm{M}}_k)$ is replaced in (32) by $\nabla U_1(\mathrm{prox}^{\gamma}_{U_2}(X^{\mathrm{M}}_k))$.

Recently, two papers have independently interpreted ULA as an algorithm that optimizes $\mathscr{F}$ on the Wasserstein space. They both relies on this interpretation to derive and analyze different algorithms for sampling log-concave target measures, that use the proximal operator associated with U.

First, Wibisono (2018) proposed and analyzed the symmetrized Langevin algorithm (SLA) in order to reduce the discretization bias. SLA combines backward and forward steps, *i.e.* it defines the Markov chain $(X^{\mathrm{SLA}}_k)_{k\in\mathbb{N}}$ by the recursion

$$X^{\mathrm{SLA}}_{k+1} = \mathrm{prox}^{\gamma}_{U}\left\{X^{\mathrm{SLA}}_k - \gamma\nabla U(X^{\mathrm{SLA}}_k) + \sqrt{4\gamma}G_{k+1}\right\}\;, \tag{39}$$

for a stepsize $\gamma>0$ and $(G_k)_{k\in\mathbb{N}^*}$ a sequence of i.i.d. d-dimensional standard Gaussian random variables. Wibisono (2018) shows that in the Gaussian case, *i.e.* for any $x\in\mathbb{R}^d$, $U(x)=\langle(x-\bar{x})\Sigma^{-1},(x-\bar{x})\rangle/2$ for some mean $\bar{x}\in\mathbb{R}^d$ and covariance matrix $\Sigma\in\mathbb{R}^{d\times d}$, SLA is unbiased and converges with an exponential rate to π. For general strongly convex potentials U, exponential convergence in Wasserstein distance of the sequence of distributions associated with $(X^{\mathrm{SLA}}_k)_{k\in\mathbb{N}}$ to a biased limit $\pi^{\mathrm{SLA}}_\gamma$ is established as $k\to+\infty$. However, no explicit bound on $W_2(\pi_\gamma,\pi^{\mathrm{SLA}})$ or nonasymptotic convergence rates are given.

In a parallel work, Bernton (2018) considers the proximal Langevin algorithm (PLA). This algorithm defines the Markov chain $(X^{\mathrm{PLA}}_k)_{k\in\mathbb{N}}$ by the recursion

$$X^{\mathrm{PLA}}_{k+1} = \mathrm{prox}^{\gamma_{k+1}}_{U}(X^{\mathrm{PLA}}_k) - \gamma\sqrt{2\gamma_{k+1}}G_{k+1}\;.$$

Applying techniques from Ambrosio et al. (2008), quantitative results on the Wasserstein distance between the above discretization and gradient flow of KL divergence are obtained. From those results, bounds on the Wasserstein distance between iterates and target distributions are given, in the case where U is strongly convex. The complexity bounds for PLA obtained in Bernton (2018) are of order $d\bar{\mathcal{O}}(\varepsilon^{-2})$ when U is smooth and strongly convex, and are equivalent to our results up to dependence on the starting measure. In the case of $U = U_1 + U_2$ where U_1 is strongly convex and U_2 is Lipschitz, bounds in Bernton (2018) are of order $d^2\bar{\mathcal{O}}(\varepsilon^{-4})$ while our bounds are still of the same order as in the smooth case.

5. Numerical Experiments

In this section, we experiment SPGLD and SSGLD on a Bayesian logistic regression problem, see e.g. (Holmes and Held, 2006; Gramacy and Polson, 2012; Park and Hastie, 2007). Consider i.i.d. observations $(X_i, Y_i)_{i\in\{1,\dots,N\}}$, where $(Y_i)_{i\in\{1,\dots,N\}}$ are binary response variables and $(X_i)_{i\in\{1,\dots,N\}}$ are d-dimensional covariance variables. For all $i \in \{1,\dots,N\}$, Y_i is assumed to be a Bernoulli random variable with parameter $\Phi(\beta^{\mathrm{T}} X_i)$ where β is the parameter of interest and for all $u \in \mathbb{R}$, $\Phi(u) = \mathrm{e}^u/(1+\mathrm{e}^u)$. We choose as prior distributions (see Genkin et al. (2007) and Li and Lin (2010)) a d-dimensional Laplace distribution and a combination of the Laplace distribution and the Gaussian distribution, with density with respect to the Lebesgue measure given respectively for all $\beta \in \mathbb{R}^d$ by

$$\mathrm{p}_1(\beta) \propto \exp\left(-a_1 \sum_{i=1}^{d} |\beta_i|\right) , \qquad \mathrm{p}_{1,2}(\beta) \propto \exp\left(-a_1 \sum_{i=1}^{d} |\beta_i| - a_2 \sum_{i=1}^{d} \beta_i^2\right) ,$$

where a_1 is set to 1 in the case of p_1 and $a_1 = 0.9$, $a_2 = 0.1$ in the case of $\mathrm{p}_{1,2}$. The chosen priors on the one hand reduce impact of the irrelevant features by shrinking them close to zero. On the other hand this choice of priors leads to the log-concave posteriors. Both these property are highly desirable in the high dimensional setting. We obtain then the two different a posteriori distributions $\mathrm{p}_1(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$ and $\mathrm{p}_{1,2}(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$ with potentials given, respectively, by

$$\beta \mapsto \sum_{n=1}^{N} \ell_n(\beta) + a_1 \sum_{i=1}^{d} |\beta_i| , \qquad \beta \mapsto \sum_{n=1}^{N} \ell_n(\beta) + a_2 \sum_{i=1}^{d} \beta_i^2 + a_1 \sum_{i=1}^{d} |\beta_i| .$$

where

$$\ell_n(\beta) = -Y_n \beta^{\mathrm{T}} X_n + \log[1 + \exp(\beta^{\mathrm{T}} X_n)] .$$

We consider the three data sets from UCI repository (Dua and Efi, 2017) Heart disease dataset ($N = 270$, $d = 14$), Australian Credit Approval dataset ($N = 690$, $d = 34$) and Musk dataset ($N = 476$, $d = 166$). We approximate $\mathrm{p}_1(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$ using SPGLD and SSGLD, since the associated potential is Lipschitz, whereas regarding $\mathrm{p}_{1,2}(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$ we only apply SPGLD.

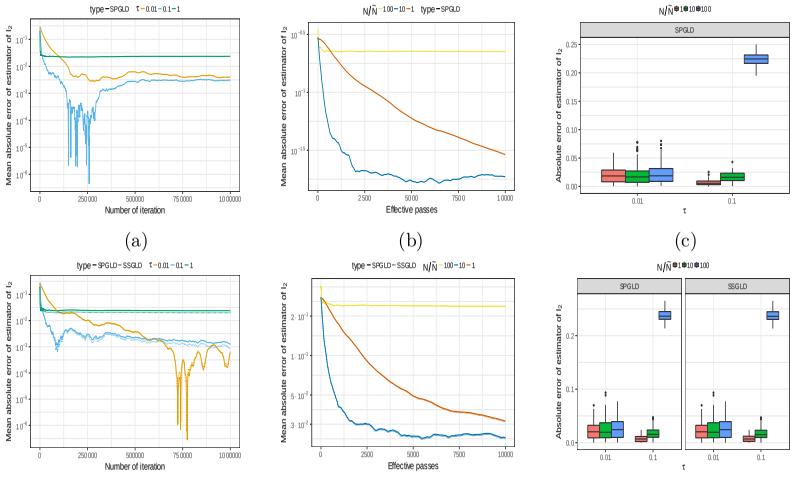

Figure 1: Mean absolute error of estimator of I_2 for Australian Credit Approval dataset: (top row) results for $\mathrm{p}_{1,2}(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$; (a) convergence of SPGLD for $\tilde{N} = N$, (b) convergence of SPGLD in terms of effective passes for $\tau = 0.1$, (c) boxplot of SPGLD for full runs; (bottom row) results for $\mathrm{p}_1(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$; (d) convergence of SPGLD and SSGLD for $\tilde{N} = N$, (e) convergence of SPGLD and SSGLD in terms of effective passes for $\tau = 0.1$, (f) boxplot of SPGLD and SSGLD for full run.

SPGLD is performed using the following stochastic gradient

$$\tilde{\Theta}_1(\beta, Z) = (N/\tilde{N}) \sum_{n\in Z} \nabla \ell_n(\beta) + a_2 \beta ,$$

where a_2 is set to 0 in the case of $\mathrm{p}_1(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$ and Z is a uniformly distributed random subset of $\{1,\dots,N\}$ with cardinal $\tilde{N} \in \{1,\dots,N\}$. In addition, the proximal operator associated with $\beta \mapsto a_1 \sum_{i=1}^{d} |\beta_i|$ is given for all $\beta \in \mathbb{R}^d$ and $\gamma > 0$ by (see e.g. Parikh and Boyd (2013))

$$(\mathrm{prox}^{\gamma}_{a_1,\ell_1}(\beta))_i = \mathrm{sign}(\beta_i) \max(|\beta_i| - a_1\gamma, 0) , \quad \text{for } i \in \{1,\dots,d\} .$$

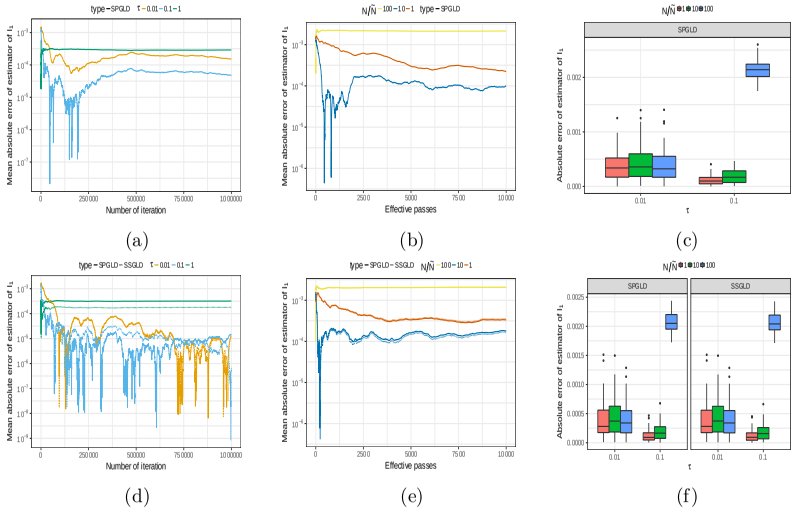

Figure 2: Mean absolute error of estimator of I_1 for Australian Credit Approval dataset: (top row) results for $\mathrm{p}_{1,2}(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$; (a) convergence of SPGLD for $\tilde{N} = N$, (b) convergence of SPGLD in terms of effective passes for $\tau = 0.1$, (c) boxplot of SPGLD for full runs; (bottom row) results for $\mathrm{p}_1(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$; (d) convergence of SPGLD and SSGLD for $\tilde{N} = N$, (e) convergence of SPGLD and SSGLD in terms of effective passes for $\tau = 0.1$, (f) boxplot of SPGLD and SSGLD for full run.

SSGLD is performed using the following stochastic subgradient

$$\Theta(\beta, Z) = (N/\tilde{N}) \sum_{n\in Z} \nabla \ell_n(\beta) + a_1 \sum_{i=1}^{d} \mathrm{sign}(\beta_i)\mathbf{e}_i \ ,$$

where $(\mathbf{e}_i)_{i\in\{1,\dots,d\}}$ denotes the canonical basis and Z is a uniformly distributed random subset of $\{1,\dots,N\}$ with cardinal $\tilde{N} \in \{1,\dots,N\}$.

Based on the results of SPGLD and SSGLD, we estimate the posterior mean I_1 and I_2 of the test functions $\beta \mapsto \beta_1$ and $\beta \mapsto (1/d)\sum_{i=1}^{d} \beta_i^2$. For our experiments, we use constant stepsizes γ of the form $\tau(L+m)^{-1}$ with $\tau = 0.01, 0.1, 1$ and for stochastic (sub) gradient we use $\tilde{N} = N, \lfloor N/10 \rfloor, \lfloor N/100 \rfloor$. For all datasets and all settings of τ, $\tilde{N}$ we run 100 independent runs of SPGLD (SSGLD), where each run was of length 10^6. For each set of parameters we estimate I_1, I_2 and we compute the absolute errors, where the true value were obtained by prox-MALA (see Pereyra (2015)) with 10^7 iterations and stepsize corresponding to optimal acceptance ratio ≈ 0.5, see (Roberts and Rosenthal, 1998). The results for I_2 are presented on Figure 1, Figure 3 and Figure 5 for Australian Credit Approval dataset,

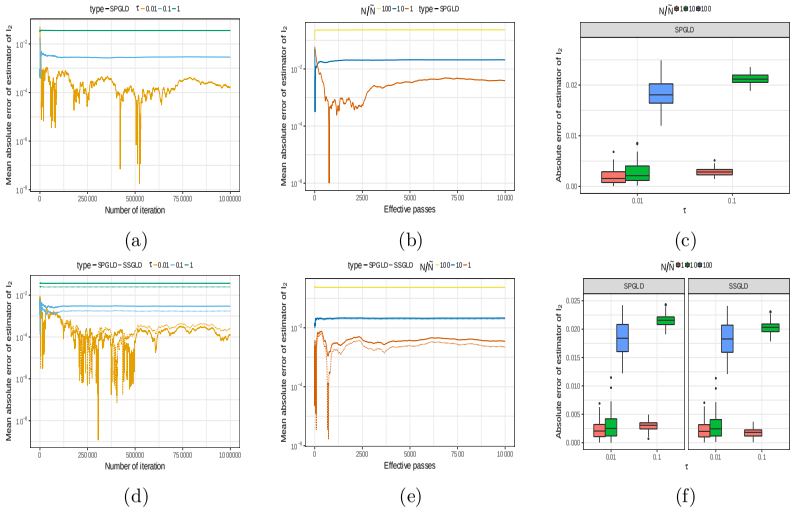

Figure 3: Mean absolute error of estimator of I_2 for Heart disease dataset: (top row) results for $\mathrm{p}_{1,2}(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$; (a) convergence of SPGLD for $\tilde{N} = N$, (b) convergence of SPGLD in terms of effective passes for $\tau = 0.1$, (c) boxplot of SPGLD for full run; (bottom row) results for $\mathrm{p}_1(\cdot|(X,Y)_{i\in\{1,\dots,N\}})$; (d) convergence of SPGLD and SSGLD for $\tilde{N} = N$, (e) convergence of SPGLD and SSGLD in terms of effective passes for $\tau = 0.1$, (f) boxplot of SPGLD and SSGLD for full run.

Heart disease dataset and Musk data respectively. The results for I_1 are presented on Figure 2, Figure 4 and Figure 6 for Australian Credit Approval dataset, Heart disease dataset and Musk data respectively. We note that in the all cases, bias decreases but convergence becomes slower with decreasing γ. When we look for stochastic (sub)gradient then the bias of estimators and also their variance increase when we decrease $\tilde{N}$. However if we look for the effective passes, i.e. the number of iteration is scaled with the cost of computing gradients, we observe that convergence is faster with reasonably small $\tilde{N}$. If we compare SSGLD with SPGLD we see that in the almost all cases, except Musk dataset, SSGLD leads to slightly smaller bias. For the Musk dataset differences between SSGLD and SPGLD are negligible and we do not present the results for SPGLD. In the presented experiments, all results agrees with our theoretical findings and suggest that SPGLD or SSGLD could be an alternative for other MCMC methods.

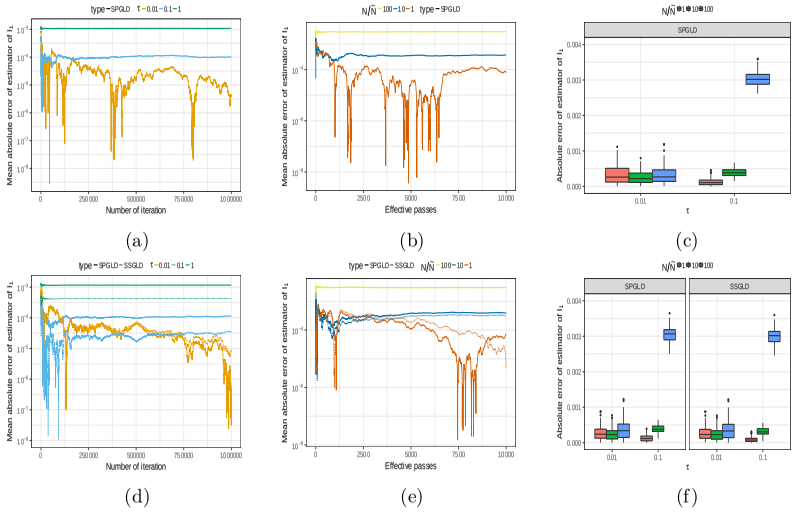

Figure 4: Mean absolute error of estimator of I_1 for Heart disease dataset: (top row) results for $\mathrm{p}_{1,2}(\cdot|(X,Y)_{i\in\{1,\ldots,N\}})$; (a) convergence of SPGLD for $\tilde{N} = N$, (b) convergence of SPGLD in terms of effective passes for $\tau = 0.1$, (c) boxplot of SPGLD for full run; (bottom row) results for $\mathrm{p}_1(\cdot|(X,Y)_{i\in\{1,\ldots,N\}})$; (d) convergence of SPGLD and SSGLD for $\tilde{N} = N$, (e) convergence of SPGLD and SSGLD in terms of effective passes for $\tau = 0.1$, (f) boxplot of SPGLD and SSGLD for full run.

6. Discussion

In this paper, we presented a novel interpretation of the Unadjusted Langevin Algorithm as the first order optimization algorithm, and a new technique of proving non-asymptotic bounds for ULA, based on the proof techniques known from convex optimization. Our proof technique gives simpler proofs of some of the previously known non-asymptotic results for ULA. It can be also used to prove non-asymptotic bound that were previously unknown. Specifically, to the best of the authors knowledge, we provide the first non-asymptotic results for Stochastic Gradient ULA in the non-strongly convex case, as well as the first non-asymptotic results in the non-smooth non-strongly convex case. Furthermore, our technique extends effortlessly to the stochastic non-smooth case, and to the best of the authors knowledge we provide the first non-asymptotic analysis of that case.

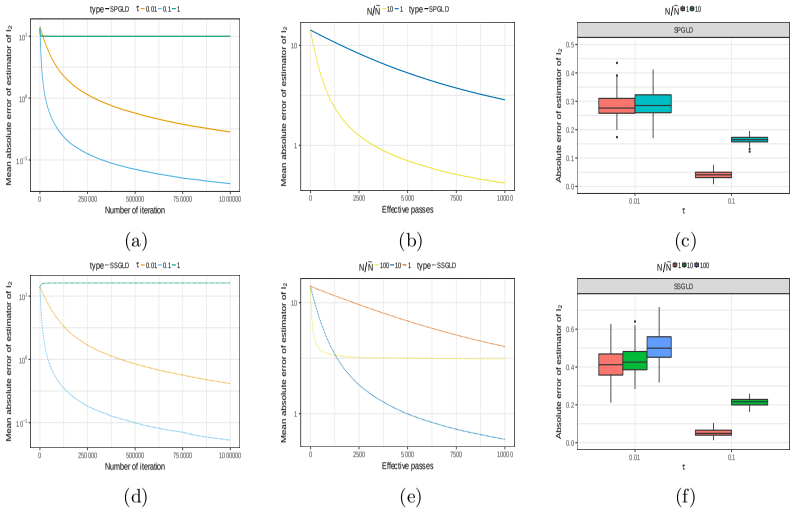

Figure 5: Mean absolute error of estimator of I_2 for Musk dataset: (top row) results for p_{1-2} prior; (a) convergence of SPGLD for $\tilde{N} = N$, (b) convergence of SPGLD in terms of effective passes for $\tau = 0.1$, (c) boxplot of SPGLD for full run; (bottom row) results for p_1 prior; (d) convergence of SSGLD for $\tilde{N} = N$, (e) convergence of SSGLD in terms of effective passes for $\tau = 0.1$, (f) boxplot of SSGLD for full run.

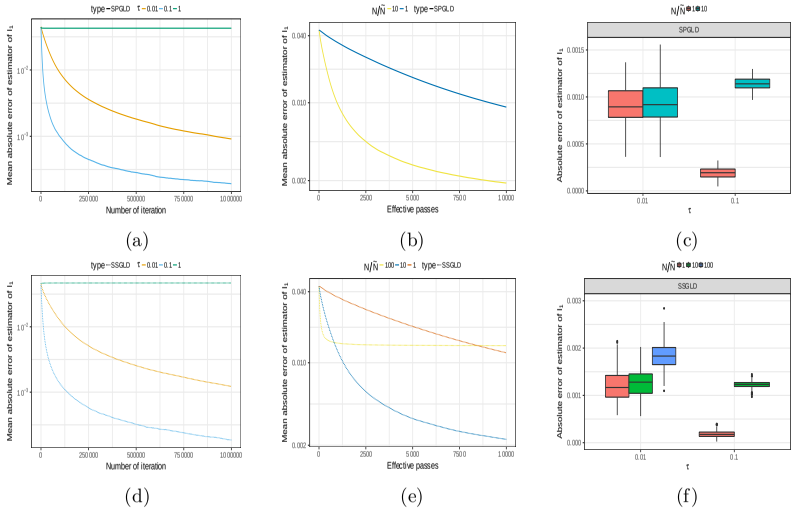

Furthermore our new perspective on the Unadjusted Langevin Algorithm, provides a starting point for the further research into connections between Langevin Monte Carlo and Optimization. In particular, we believe that a very promising direction for future research is to try to modify well-known effective optimization algorithms to minimize the KL divergence with respect to some target density π in Wasserstein space.

7. Postponed Proofs

7.1. Proof of Lemma 1

a) Since e^{-U} is integrable with respect to the Lebesgue measure, under $\mathbf{A}1(m)$ for $m \geq 0$, by (Brazitikos et al., 2014, Lemma 2.2.1), there exists $C_1, C_2 > 0$ such that for all $x \in \mathbb{R}^d$, $U(x) \geq C_1 \|x\| - C_2$. This inequality and $\mathbf{A}2$ implies that $\pi \in \mathcal{P}_2(\mathbb{R}^d)$. In addition, since the function $x \mapsto U(x)\mathrm{e}^{-U(x)/2}$ is bounded on $[-C_2, +\infty)$, we have for all $x \in \mathbb{R}^d$,

$$\left| \left(U(x)\mathrm{e}^{-U(x)/2} \right) \mathrm{e}^{-U(x)/2} \right| \leq C_3 \mathrm{e}^{-U(x)/2}$$

(a) (b) (c)

(d) (e) (f)

Figure 6: Mean absolute error of estimator of I_1 for Musk dataset: (top row) results for p_{1-2} prior; (a) convergence of SPGLD for $\tilde{N} = N$, (b) convergence of SPGLD in terms of effective passes for $\tau = 0.1$, (c) boxplot of SPGLD for full run; (bottom row) results for p_1 prior; (d) convergence of SSGLD for $\tilde{N} = N$, (e) convergence of SSGLD in terms of effective passes for $\tau = 0.1$, (f) boxplot of SSGLD for full run.

for some constant C_3. From this, and $U(x) \geq C_1 \|x\| - C_2$ we conclude that $\mathscr{E}(\pi) < +\infty$. Using the same reasoning, we have $\mathscr{H}(\pi) < +\infty$ which finishes the proof of the first part.
b) First, if μ does not admit a density with respect to Lebesgue measure, then both sides of (10) are $+\infty$. Second, if μ admits a density still denoted by μ with respect to the Lebesgue measure, we have by (7):

$$\mathscr{F}(\mu) - \mathscr{F}(\pi) = \mathrm{KL}\left(\mu|\pi\right) + \int_{\mathbb{R}^d} \{\mu(x) - \pi(x)\} \{U(x) + \log(\pi(x))\} \, \mathrm{d}x = \mathrm{KL}\left(\mu|\pi\right) \ .$$

7.2. Proof of Corollary 8

Using Theorem 6 we first get

$$\mathrm{KL}\left(\nu_n|\pi\right) \leq W_2^2\left(\mu_0, \pi\right)/(2\Gamma_{0,n}) + (Ld/\Gamma_{0,n}) \sum_{k=1}^{n} \gamma_k^2 \ . \tag{40}$$

Note that using a simple integral test, we have $\Gamma_{0,n} \geq C_1 n^{1-\alpha}$ for some constant $C_1 \geq 0$. On the other hand, for some constant $C_2 \geq 0$ we have $\sum_{k=1}^{n} \gamma_k^2 \leq C_2(1 + n^{1-2\alpha})$ if $\alpha \neq 1/2$, and $\sum_{k=1}^{n} \gamma_k^2 \leq C_2(1+\log(n))$ if $\alpha = 1/2$. Combining all these inequalities in (40) concludes the proof.

7.3. Proofs of Section 4.1

Note that for all $\gamma, \tilde{\gamma} > 0$, $\bar{R}_{\gamma,\tilde{\gamma}}$ can be decomposed as $\bar{S}_\gamma T_{\tilde{\gamma}}$ where $T_{\tilde{\gamma}}$ is defined in (14) and $\bar{S}_\gamma$ is given by (30). Then similarly to the proof of Theorem 6, we first give a preliminary bound on $\mathscr{F}(\mu\bar{R}_{\gamma,\tilde{\gamma}}) - \mathscr{F}(\pi)$ for $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma, \tilde{\gamma} > 0$ as in Proposition 2.

Lemma 26 *Assume* ***A****1(0) and* ***A****3. For all $\gamma > 0$ and $\mu \in \mathcal{P}_2(\mathbb{R}^d)$,*

$$2\gamma \left\{\mathscr{E}(\mu) - \mathscr{E}(\pi)\right\} \leq W_2^2(\mu, \pi) - W_2^2(\mu\bar{S}_\gamma, \pi) + \gamma^2 \left\{M^2 + v_\Theta(\mu)\right\} \ ,$$

where $\mathscr{E}$ and T_γ are defined in (9) *and* (14) *respectively, $v_\Theta(\mu)$ in* (29) *and $\bar{S}_\gamma$ in* (30)*.*

Proof Let Z be a random variable with distribution η, $\gamma > 0$ and $\mu \in \mathcal{P}_2(\mathbb{R}^d)$. For all $x, y \in \mathbb{R}^d$, we have using the definition of $\partial U(x)$ (24) and **A**3-(ii)

$$\begin{aligned}
\|y - x + \gamma\Theta(x, Z)\|^2 &= \|y - x\|^2 + 2\gamma \left\langle \Theta(x, Z), y - x \right\rangle + \gamma^2 \|\Theta(x, Z)\|^2 \\
&\leq \|y - x\|^2 - 2\gamma \left\{U(x) - U(y)\right\} + 2\gamma \left\langle \Theta(x, Z) - \mathbb{E}\left[\Theta(x, Z)\right], y - x \right\rangle + \gamma^2 \|\Theta(x, Z)\|^2 \ .
\end{aligned}$$

Let (X, Y) be an optimal coupling between μ and π independent of Z. Then by **A**3-(ii) and rearranging the terms in the previous inequality, we obtain

$$2\gamma \left\{\mathscr{E}(\mu) - \mathscr{E}(\nu)\right\} \leq W_2^2(\mu, \pi) - \mathbb{E}\left[\|Y - X + \gamma\Theta(X, Z)\|^2\right] + \gamma^2 \mathbb{E}\left[\|\Theta(X, Z)\|^2\right] \ .$$

The proof is concluded upon noting that $W_2^2(\mu\bar{S}_\gamma, \pi) \leq \mathbb{E}[\|Y - X + \gamma\Theta(X, Z)\|^2]$ and $\mathbb{E}[\|\Theta(X, Z)\|^2] \leq M^2 + v_\Theta(\mu)$. ■

Proposition 27 *Assume* ***A****1(0) and* ***A****3. For all $\gamma, \tilde{\gamma} > 0$ and $\mu \in \mathcal{P}_2(\mathbb{R}^d)$,*

$$2\tilde{\gamma} \left\{\mathscr{F}(\mu\bar{R}_{\gamma,\tilde{\gamma}}) - \mathscr{F}(\pi)\right\} \leq \left\{W_2^2\left(\mu\bar{S}_\gamma, \pi\right) - W_2^2\left(\mu\bar{R}_{\gamma,\tilde{\gamma}}\bar{S}_{\tilde{\gamma}}, \pi\right)\right\} + \tilde{\gamma}^2 \left\{M^2 + v_\Theta(\mu\bar{R}_{\gamma,\tilde{\gamma}})\right\} \ .$$

where $\mathscr{F}$ is defined in (9)*, $v_\Theta(\mu)$ in* (29)*, $\bar{R}_{\gamma,\tilde{\gamma}}$ and $\bar{S}_\gamma$ in* (27) *in* (30) *respectively.*

Proof Note that by Lemma 26, we have

$$2\tilde{\gamma} \left\{\mathscr{E}(\mu\bar{R}_{\gamma,\tilde{\gamma}}) - \mathscr{E}(\pi)\right\} \leq W_2^2\left(\mu\bar{R}_{\gamma,\tilde{\gamma}}, \pi\right) - W_2^2\left(\mu\bar{R}_{\gamma,\tilde{\gamma}}\bar{S}_{\tilde{\gamma}}, \pi\right) + \tilde{\gamma}^2 \left\{M^2 + v_\Theta(\mu\bar{R}_{\gamma,\tilde{\gamma}})\right\} \ . \tag{41}$$

In addition by Lemma 5, it holds

$$2\tilde{\gamma} \left\{\mathscr{H}(\mu\bar{R}_{\gamma,\tilde{\gamma}}) - \mathscr{H}(\pi)\right\} \leq W_2^2\left(\mu\bar{S}_\gamma, \pi\right) - W_2^2\left(\mu\bar{R}_{\gamma,\tilde{\gamma}}, \pi\right) \ .$$

The proof then follows from combining this inequality with (41). ■

7.3.1. Proof of Theorem 13

By Proposition 27, for all $k \in \mathbb{N}^*$, we have

$$\mathscr{F}(\mu\bar{Q}_\gamma^k) - \mathscr{F}(\pi) \leq (2\gamma_{k+1})^{-1} \left\{ W_2^2 \left(\mu\bar{Q}_\gamma^{k-1} \bar{S}_{\gamma_k}, \pi \right) - W_2^2 \left(\mu\bar{Q}_\gamma^k \bar{S}_{\gamma_{k+1}}, \pi \right) \right\} + (\gamma_{k+1}/2) \left\{ M^2 + \upsilon_\Theta(\mu\bar{Q}_\gamma^k) \right\} .$$

Similarly to the proof of Theorem 6 using the convexity of KL divergence and the condition that $(\lambda_k/\gamma_{k+1})_{k\in\mathbb{N}^*}$ is non-increasing concludes the proof.

7.3.2. Proof of Corollary 16

On the one hand, using Theorem 13, we get:

$$\mathrm{KL}\left(\tilde{\nu}_n^N \middle| \pi\right) \leq (2\gamma n)^{-1} W_2^2 \left(\mu_0 \bar{Q}_\gamma^N \bar{S}_\gamma, \pi\right) + \gamma M^2/2 + (\gamma/(2n)) \sum_{k=N+1}^{N+n} \upsilon_\Theta(\mu_0 \bar{Q}_\gamma^k) \ .$$

On the other hand, using Proposition 15, we obtain:

$$2\gamma(\tilde{L}^{-1} - \gamma) \left(\sum_{k=N+1}^{N+n} \upsilon_\Theta(\mu_0 \bar{Q}_\gamma^k) \right) \leq \int_{\mathbb{R}^d} \|x - x^\star\|^2 \, \mathrm{d}\mu_0 \bar{Q}_\gamma^{N+1}(x) - \int_{\mathbb{R}^d} \|x - x^\star\|^2 \, \mathrm{d}\mu_0 \bar{Q}_\gamma^{N+n+1} + 2n\gamma^2 \upsilon_\Theta(\delta_{x^\star}) + 2n\gamma d \ .$$

Combining the two inequalities above finishes the proof of the first part of Corollary 16. For the second part, first observe that since $\gamma_\varepsilon \leq (2\tilde{L})^{-1}$ we have $(2(\tilde{L}^{-1} - \gamma))^{-1} \leq \tilde{L}$. Furthermore, from the definition of γ_ε we have $\gamma_\varepsilon(\frac{M^2}{2} + \tilde{L}d) \leq \varepsilon/4$, as well as $\gamma_\varepsilon^2 \tilde{L} \upsilon_\Theta(\delta_{x^\star}) \leq \varepsilon/4$. On the other hand, from the definition of n_ε we have $W_2^2(\mu_0 \bar{S}_{\gamma_\varepsilon}, \pi)/(2\gamma\varepsilon n_\varepsilon) \leq \varepsilon/4$ as well as $\tilde{L}(2n_\varepsilon)^{-1} \int_{\mathbb{R}^d} \|x - x^\star\|^2 \, \mathrm{d}\mu_0 \bar{R}_{\gamma_\varepsilon, \gamma_\varepsilon}(x) \leq \varepsilon/4$. Combining those four bounds together finishes the proof.

7.4. Proof of Section 4.2

We proceed for the proof of Theorem 17 similarly to the one of Theorem 6, by decomposing $\mathscr{F}(\mu\tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{F}(\pi) = \mathscr{E}(\mu\tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{E}(\pi) + \mathscr{H}(\mu\tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{H}(\pi)$, for $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma, \tilde{\gamma} > 0$. The main difference is that we now need to handle carefully the proximal step in the first term of the decomposition. To this end, we decompose the potential energy functional according to the decomposition of U, $\mathscr{E} = \mathscr{E}_1 + \mathscr{E}_2$ where for all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\mathscr{E}_1(\mu) = \int_{\mathbb{R}^d} U_1 \mathrm{d}\mu(x) \ , \qquad \mathscr{E}_2(\mu) = \int_{\mathbb{R}^d} U_2 \mathrm{d}\mu(x) \ , \tag{42}$$

and consider

$$\mathscr{F}(\mu\tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{F}(\pi) = \mathscr{E}_1(\mu\tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{E}_1(\mu\tilde{S}_\gamma^2\tilde{S}_{\tilde{\gamma}}^1) + \mathscr{E}_1(\mu\tilde{S}_\gamma^2\tilde{S}_{\tilde{\gamma}}^1) - \mathscr{E}_1(\pi) + \mathscr{E}_2(\mu\tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{E}_2(\pi) + \mathscr{H}(\mu\tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{H}(\pi) \ . \tag{43}$$

The first and last terms in the right hand side will be controlled using Lemma 3 and Lemma 5. In the next lemmas, we bound the other terms separately.

Lemma 28 *Assume* $\boldsymbol{A}5(m)$*, for* $m \geq 0$*. For all* $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$ *and* $\gamma \in (0, L^{-1}]$*,*

$$2\gamma\{\mathscr{E}_1(\mu\tilde{S}_\gamma^1) - \mathscr{E}_1(\nu)\} \leq (1 - m\gamma)W_2^2(\mu,\nu) - W_2^2(\mu\tilde{S}_\gamma^1, \nu) - \gamma^2(1 - \gamma L) \int_{\mathbb{R}^d} \|\nabla U_1(x)\|^2 \, \mathrm{d}\mu(x) + \gamma^2(1 + \gamma L)\upsilon_1(\mu) \ ,$$

where $\mathscr{E}_1, \tilde{S}_\gamma^1$ *is defined by* (42)-(34) *and* $\upsilon_1(\mu)$ *by* (36)*.*

Proof Let $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma > 0$. Since U_1 satisfies $\mathbf{A}2$ by (Nesterov, 2004, Lemma 1.2.3), for all $x, \tilde{x} \in \mathbb{R}^d$, we have $|U_1(\tilde{x}) - U_1(x) - \langle \nabla U_1(x), \tilde{x} - x \rangle| \leq (L/2) \|\tilde{x} - x\|^2$. Using that U_1 is m-strongly convex by $\mathbf{A}5(m)$, for all $x, y \in \mathbb{R}^d$, $z \in \mathsf{Z}$, we get

$$\begin{aligned} U_1(x - \gamma\tilde{\Theta}_1(x,z)) - U_1(y) &= U_1(x - \gamma\tilde{\Theta}_1(x,z)) - U_1(x) + U_1(x) - U_1(y) \\ &\leq -\gamma \left\langle \nabla U_1(x), \tilde{\Theta}_1(x,z) \right\rangle + (L\gamma^2/2) \left\| \tilde{\Theta}_1(x,z) \right\|^2 + \langle \nabla U_1(x), x - y \rangle - (m/2) \|y - x\|^2 \ . \end{aligned}$$

Then multiplying both sides by γ, we obtain

$$\begin{aligned} 2\gamma \left\{ U_1(x - \gamma\tilde{\Theta}_1(x,z)) - U_1(y) \right\} &\leq (1 - m\gamma) \|x - y\|^2 - \left\| x - \gamma\tilde{\Theta}_1(x,z) - y \right\|^2 \\ &- 2\gamma^2 \left\langle \nabla U_1(x), \tilde{\Theta}_1(x,z) \right\rangle + \gamma^2(1 + \gamma L) \left\| \tilde{\Theta}_1(x,z) \right\|^2 + 2\gamma \left\langle \nabla U_1(x) - \tilde{\Theta}_1(x,z), x - y \right\rangle \ . \end{aligned} \tag{44}$$

Let now (X, Y) be an optimal coupling between μ and ν and Z with distribution η independent of (X, Y). Note that $\mathbf{A}5$ implies that $\mathbb{E}[\tilde{\Theta}_1(X, Z)|(X, Y)] = \nabla U_1(X)$. Then by definition and (44), we get

$$\begin{aligned} 2\gamma \left\{ \mathscr{E}(\mu\tilde{S}_\gamma^1) - \mathscr{E}(\nu) \right\} &\leq (1 - m\gamma)W_2^2(\mu,\nu) - \mathbb{E}\left[\left\| X - \gamma\tilde{\Theta}_1(X) - Y \right\|^2 \right] \\ &\quad - 2\gamma^2 \mathbb{E}\left[\|\nabla U_1(X)\|^2 \right] + \gamma^2(1 + \gamma L)\mathbb{E}\left[\left\| \tilde{\Theta}_1(X) \right\|^2 \right] \\ &\leq (1 - m\gamma)W_2^2(\mu,\nu) - \mathbb{E}\left[\left\| X - \gamma\tilde{\Theta}_1(X) - Y \right\|^2 \right] \\ &\quad - \gamma^2(1 - \gamma L)\mathbb{E}\left[\|\nabla U_1(X)\|^2 \right] + \gamma^2(1 + \gamma L)\upsilon_1(\mu) \ . \end{aligned}$$

Using that $W_2^2(\mu\tilde{S}_\gamma^1, \nu) \leq \mathbb{E}[\|X - \gamma\tilde{\Theta}_1(X) - Y\|^2]$ concludes the proof. ∎

Lemma 29 *Assume* $\boldsymbol{A}5(m)$ *for* $m \geq 0$*. For all* $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$ *and* $\gamma > 0$*, we have*

$$2\gamma \{\mathscr{E}_2(\mu) - \mathscr{E}_2(\nu)\} \leq W_2^2(\mu,\nu) - W_2^2(\mu\tilde{S}_\gamma^2, \nu) + 2\gamma^2 M_2^2 \ ,$$

where $\mathscr{E}_2, \tilde{S}_\gamma^2$ *are defined by* (42) *and* (34) *respectively.*

Proof Let $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma > 0$. First we bound for any $x, y \in \mathbb{R}^d$, $U_2(x) - U_2(y)$ using the decomposition $U_2(x) - U_2(\mathrm{prox}^\gamma_{U_2}(x)) + U_2(\mathrm{prox}^\gamma_{U_2}(x)) - U_2(y)$. For any $x, y \in \mathbb{R}^d$, we have using that $\gamma^{-1}(x - \mathrm{prox}^\gamma_{U_2}(x)) \in \partial U_2(\mathrm{prox}^\gamma_{U_2}(x))$ (see Rockafellar and Wets (1998, Chapter 1 Section G)), where ∂U_2 is the subdifferential of U_2 defined by (24),

$$U_2(\mathrm{prox}^\gamma_{U_2}(x)) - U_2(y) \leq \gamma^{-1} \left\langle x - \mathrm{prox}^\gamma_{U_2}(x), \mathrm{prox}^\gamma_{U_2}(x) - y \right\rangle .$$

Since $\|x - y\|^2 = \|x - \mathrm{prox}^\gamma_{U_2}(x)\|^2 + \|\mathrm{prox}^\gamma_{U_2}(x) - y\|^2 + 2\langle x - \mathrm{prox}^\gamma_{U_2}(x), \mathrm{prox}^\gamma_{U_2}(x) - y\rangle$, we get for all $x, y \in \mathbb{R}^d$,

$$U_2(\mathrm{prox}^\gamma_{U_2}(x)) - U_2(y) \leq (2\gamma)^{-1}(\|x - y\|^2 - \|\mathrm{prox}^\gamma_{U_2}(x) - y\|^2) . \tag{45}$$

Second, since U_2 is M_2-Lipschitz, we get for any $x \in \mathbb{R}^d$, $|U_2(x) - U_2(\mathrm{prox}^\gamma_{U_2}(x))| \leq M_2\|x - \mathrm{prox}^\gamma_{U_2}(x)\|$. Then using that $\gamma^{-1}(x - \mathrm{prox}^\gamma_{U_2}(x)) \in \partial U_2(\mathrm{prox}^\gamma_{U_2}(x))$, and for any $v \in \partial U_2(\mathrm{prox}^\gamma_{U_2}(x))$, since U_2 is M_2-Lipschitz, $\|v\| \leq M_2$, we obtain $|U_2(x) - U_2(\mathrm{prox}^\gamma_{U_2}(x))| \leq \gamma M_2^2$. Combining this result and (45) yields for any $x, y \in \mathbb{R}^d$

$$2\gamma \{U_2(x) - U_2(y)\} \leq \|x - y\|^2 - \|\mathrm{prox}^\gamma_{U_2}(x) - y\|^2 + 2\gamma^2 M_2^2 .$$

Let (X, Y) be an optimal coupling for μ and ν. The proof then follows from using the inequality above for (X, Y), taking the expectation and because $W_2^2(\mu \tilde{S}^1_\gamma, \nu) \leq \|\mathrm{prox}^\gamma_{U_2}(X) - Y\|^2$. ∎

Lemma 30 *Assume* ***A*** *5(m), for $m \geq 0$. For all $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma, \tilde{\gamma} \in \left(0, L^{-1}\right]$,*

$$2\tilde{\gamma}\{\mathscr{F}(\mu_0 \tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{F}(\pi)\} \leq (1 - m\tilde{\gamma}) W_2^2(\mu_0 \tilde{S}^2_\gamma, \pi) - W_2^2(\mu_0 \tilde{R}_{\gamma,\tilde{\gamma}} \tilde{S}^2_{\tilde{\gamma}}, \pi) + \tilde{\gamma}^2 \{2Ld + (1 + \tilde{\gamma}L) \upsilon_1(\mu_0 \tilde{S}^2_\gamma) + 2M_2^2\} ,$$

where $\mathscr{F}$, $\tilde{R}_{\gamma,\tilde{\gamma}}$ and $\tilde{S}^2_\gamma$ are defined by (7)-(33)-(34) *respectively.*

Proof Let $\mu_0 \in \mathcal{P}_2(\mathbb{R}^d)$ and $\gamma, \tilde{\gamma} \in \left(0, L^{-1}\right]$. By Lemma 3 and since $\tilde{R}_{\gamma,\tilde{\gamma}} = \tilde{S}^2_\gamma \tilde{S}^1_{\tilde{\gamma}} T_{\tilde{\gamma}}$, we have

$$\mathscr{E}_1(\mu_0 \tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{E}_1(\mu_0 \tilde{S}^2_\gamma \tilde{S}^1_{\tilde{\gamma}}) \leq 2Ld\tilde{\gamma} . \tag{46}$$

By Lemma 28 since $\tilde{\gamma} \leq 1/L$,

$$2\tilde{\gamma}\{\mathscr{E}_1(\mu_0 \tilde{S}^2_\gamma \tilde{S}^1_{\tilde{\gamma}}) - \mathscr{E}_1(\pi)\} \leq (1 - \tilde{\gamma}m) W_2^2(\mu_0 \tilde{S}^2_\gamma, \pi) - W_2^2(\mu_0 \tilde{S}^2_\gamma \tilde{S}^1_{\tilde{\gamma}}, \pi) + \tilde{\gamma}^2(1 + \tilde{\gamma}L) \upsilon_1(\mu_0 \tilde{S}^2_\gamma) . \tag{47}$$

By Lemma 29, we have

$$2\tilde{\gamma}\{\mathscr{E}_2(\mu_0 \tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{E}_2(\pi)\} \leq W_2^2(\mu_0 \tilde{R}_\gamma, \pi) - W_2^2(\mu_0 \tilde{R}_{\gamma,\tilde{\gamma}} \tilde{S}^2_{\tilde{\gamma}}, \pi) + 2\tilde{\gamma}^2 M_2^2 . \tag{48}$$

Finally by Lemma 5, we have

$$2\tilde{\gamma}\{\mathscr{H}(\mu_0 \tilde{R}_{\gamma,\tilde{\gamma}}) - \mathscr{H}(\pi)\} \leq W_2^2(\mu_0 \tilde{S}^2_\gamma \tilde{S}^1_{\tilde{\gamma}}, \pi) - W_2^2(\mu_0 \tilde{R}_{\gamma,\tilde{\gamma}}, \pi) . \tag{49}$$

Combining (46)-(47)-(48)-(49) in (43) concludes the proof. ∎

7.4.1. Proof of Theorem 17

Using the convexity of KL divergence and Lemma 30, we obtain

$$\begin{aligned}
\mathrm{KL}\left(\tilde{\nu}_n^N \middle| \pi\right) &\leq \Lambda_{N,N+n}^{-1} \sum_{k=N+1}^{N+n} \lambda_k \,\mathrm{KL}\left(\mu_0 \tilde{Q}^k_\gamma \middle| \pi\right) \\
&\leq (2\Lambda_{N,N+n})^{-1} \left[\frac{(1 - m\gamma_{N+2})\lambda_{N+1}}{\gamma_{N+2}} W_2^2\left(\mu_0 \tilde{Q}^N_\gamma \tilde{S}^2_{\gamma_{N+1}}, \pi\right) \right. \\
&\quad - \frac{\lambda_{N+n}}{\gamma_{N+n+1}} W_2^2\left(\mu_0 \tilde{Q}^{N+n}_\gamma \tilde{S}^2_{\gamma_{N+n+1}}, \pi\right) \\
&\quad + \sum_{k=N+1}^{N+n-1} \left\{ \frac{(1 - m\gamma_{k+2})\lambda_{k+1}}{\gamma_{k+2}} - \frac{\lambda_k}{\gamma_{k+1}} \right\} W_2^2\left(\mu_0 Q^{k-1}_\gamma \tilde{S}^2_{\gamma_{k+1}}, \pi\right) \\
&\quad \left. + \sum_{k=N+1}^{N+n} \lambda_k \gamma_{k+1} \{2Ld + (1 + \gamma_{k+1}L) \upsilon_1(\mu_0 Q^k_\gamma \tilde{S}^2_{\gamma_k}) + 2M_2^2\} \right] .
\end{aligned}$$

We get the thesis using that $\lambda_{k+1}(1 - m\gamma_{k+2})/\gamma_{k+2} \leq \lambda_k/\gamma_{k+1}$ for all $k \in \mathbb{N}$.

7.4.2. Proof of Corollary 20

Using Theorem 17 we get:

$$\mathrm{KL}\left(\tilde{\nu}_n^N \middle| \pi\right) \leq W_2^2\left(\mu_0 \tilde{Q}^N_\gamma \tilde{S}^2_\gamma, \pi\right) \Big/ (2\gamma n) + \gamma(Ld + M_2^2) + \frac{\gamma}{2n} \sum_{k=N+1}^{N+n} (1 + \gamma L) \upsilon_1(\mu_0 Q^k_\gamma \tilde{S}^2_\gamma)$$

and using Proposition 19 we obtain:

$$\begin{aligned}
2\gamma(\tilde{L}^{-1} - \gamma) \left(\sum_{k=N+1}^{N+n} \upsilon_1(\mu_0 Q^k_\gamma \tilde{S}^2_\gamma) \right) &\leq \int_{\mathbb{R}^d} \|y - x^\star\|^2 \,\mathrm{d}\mu_0 Q^{N+1}_\gamma \tilde{S}^2_\gamma(y) \\
&\quad - \int_{\mathbb{R}^d} \|y - x^\star\|^2 \,\mathrm{d}\mu_0 Q^{N+n+1}_\gamma \tilde{S}^2_\gamma(y) + 2n\gamma^2 \upsilon_1(\delta_{x^\star}) + 2n\gamma d ,
\end{aligned}$$

Combining the two inequalities above finishes the proof of the first part of Corollary 20. For the second part, observe that since $\gamma_\varepsilon \leq L^{-1}$ and $\gamma_\varepsilon \leq (2\tilde{L})^{-1}$ we have $(1 + \gamma L)(2(\tilde{L}^{-1} - \gamma))^{-1} \leq 2\tilde{L}$. Therefore from definition of γ_ε we have $\gamma_\varepsilon(Ld + M_2^2 + 2\tilde{L}d) \leq \varepsilon/4$, as well as $\gamma_\varepsilon^2 2\tilde{L} \upsilon_1(\delta_{x^\star}) \leq \varepsilon/4$. On the other hand, from definition of n_ε we have $W_2^2(\mu_0 \tilde{S}^2_{\gamma_\varepsilon}, \pi)/(2n_\varepsilon\gamma_\varepsilon) \leq \varepsilon/4$ as well as $2\tilde{L}(2n_\varepsilon)^{-1} \int_{\mathbb{R}^d} \|x - x^\star\|^2 \,\mathrm{d}\mu_0 \tilde{S}^2_\gamma(y) \leq \varepsilon/4$. Combining this four bounds we get the thesis.

7.4.3. Proof of Theorem 21

Using Lemma 30 and since the KL divergence is non-negative, we get for all $k \in \{1, \ldots, n\}$,

$$W_2^2\left(\mu_0 \tilde{Q}^k_\gamma \tilde{S}^2_{\gamma_{k+1}}, \pi\right) \leq (1 - m\gamma_{k+1}) W_2^2\left(\mu_0 Q^{k-1}_\gamma \tilde{S}^2_{\gamma_k}, \pi\right) + \gamma^2_{k+1} \{2Ld + (1 + \gamma_{k+1}L) \upsilon_1(\mu_0 Q^{k-1}_\gamma \tilde{S}^2_{\gamma_k}) + 2M_2^2\} .$$

The proof then follows from a direct induction.

7.4.4. Proof of Proposition 23

Let $\gamma > 0$, $x \in \mathbb{R}^d$ and consider $\tilde{X}_1 = \mathrm{prox}^{\gamma}_{U_2}\left\{x - \gamma\tilde{\Theta}_1(x, Z_1) + \sqrt{2\gamma}G_1\right\}$, where Z_1 and G_1 are two independent random variables, Z_1 has distribution $\tilde{\eta}_1$ and G_1 is a standard Gaussian random variable, so that $\tilde{X}_1$ has distribution $\tilde{S}^1_\gamma T_\gamma \tilde{S}^2_\gamma(x, \cdot)$. First by (Bauschke and Combettes, 2011, Theorem 26.2(vii)), we have that $x^\star = \mathrm{prox}^{\gamma}_{U_2}(x^\star - \gamma\nabla U_1(x^\star))$ and by (Bauschke and Combettes, 2011, Proposition 12.27), the proximal is non-expansive, for all $x, y \in \mathbb{R}^d$, $\|\mathrm{prox}^{\gamma}_{U_2}(x) - \mathrm{prox}^{\gamma}_{U_2}(y)\| \le \|x - y\|$. Using these two results and the fact that $\tilde{\Theta}_1$ satisfies **A**4, we have

$$
\begin{aligned}
\mathbb{E}\left[\left\|\tilde{X}_1 - x^\star\right\|^2\right] &= \mathbb{E}\left[\left\|\mathrm{prox}^{\gamma}_{U_2}\left\{x - \gamma\tilde{\Theta}_1(x, Z_1) + \sqrt{2\gamma}G_1\right\} - \mathrm{prox}^{\gamma}_{U_2}\{x^\star - \gamma\nabla U_1(x^\star)\}\right\|^2\right] \\
&\le \mathbb{E}\left[\left\|\left(x - \gamma\tilde{\Theta}_1(x, Z_1) + \sqrt{2\gamma}G_1\right) - (x^\star - \gamma\nabla U_1(x^\star))\right\|^2\right] \\
&\le \|x - x^\star\|^2 \\
&\quad + \mathbb{E}\left[2\gamma\left\langle x - x^\star, \nabla U_1(x^\star) - \tilde{\Theta}_1(x, Z_1)\right\rangle + \gamma^2\left\|\nabla U_1(x^\star) - \tilde{\Theta}_1(x, Z_1)\right\|^2\right] + 2\gamma d \\
&\le (1 - \tilde{m}_1\gamma)\|x - x^\star\|^2 - 2\gamma(\tilde{L}_1^{-1} - \gamma)\mathbb{E}\left[\left\|\tilde{\Theta}_1(x, Z_1) - \tilde{\Theta}_1(x^\star, Z_1)\right\|^2\right] \\
&\qquad + 2\gamma^2\mathbb{E}\left[\left\|\tilde{\Theta}_1(x^\star, Z_1) - \nabla U_1(x^\star)\right\|^2\right] + 2\gamma d\,.
\end{aligned}
$$

The proof is completed upon noting that $\upsilon_1(\delta_x) \le \mathbb{E}[\|\Theta(x, Z_1) - \Theta(x^\star, Z_1)\|^2]$.

7.4.5. Proof of Corollary 24

Using Theorem 21 we get:

$$
\begin{aligned}
W_2^2(\mu_0\tilde{R}^n_{\gamma,\gamma}\tilde{S}^2_\gamma, \pi) &\le (1 - m\gamma)^n W_2^2(\mu_0\tilde{S}^2_\gamma, \pi) \\
&\quad + \gamma^2\sum_{k=1}^{n}(1 - m\gamma)^{n-k}\left(2Ld + (1 + \gamma L)\upsilon_1(\mu_0\tilde{R}^k_{\gamma,\gamma}\tilde{S}^2_\gamma) + 2M_2^2\right) \\
&\le (1 - m\gamma)^n W_2^2(\mu_0\tilde{S}^2_\gamma, \pi) + 2(Ld + M_2)\gamma/m \\
&\quad + \gamma^2\sum_{k=1}^{n}(1 - \tilde{m}\gamma)^{n-k}(1 + \gamma L)\upsilon_1(\mu_0\tilde{R}^k_{\gamma,\gamma}\tilde{S}^2_\gamma)\,. \qquad (50)
\end{aligned}
$$

In addition, using Proposition 23 and $\gamma \le (2\tilde{L}_1)^{-1}$, we have

$$
\begin{aligned}
\gamma\tilde{L}_1^{-1}\sum_{k=1}^{n}(1 - \tilde{m}\gamma)^{n-k}\upsilon_1(\mu_0\tilde{R}^k_{\gamma,\gamma}\tilde{S}^2_\gamma) &\le 2\gamma\sum_{k=1}^{n}(1 - \tilde{m}\gamma)^{n-k}(\gamma\upsilon_1(\delta_{x^\star}) + d) \\
&\quad + \sum_{k=1}^{n}(1 - \tilde{m}\gamma)^{n-k+1}\int_{\mathbb{R}^d}\|x - x^\star\|^2\,\mathrm{d}\mu_0 R^k_{\gamma,\gamma}\tilde{S}^2_\gamma(x) \\
&\quad - \sum_{k=1}^{n}(1 - \tilde{m}\gamma)^{n-k}\int_{\mathbb{R}^d}\|x - x^\star\|^2\,\mathrm{d}\mu_0 R^{k+1}_{\gamma,\gamma}\tilde{S}^2_\gamma(x)\,.
\end{aligned}
$$

Combining this result and (50) concludes the proof of (38).

Now, for $\gamma_\varepsilon, n_\varepsilon$ as defined in the thesis of the corollary we have $\gamma_\varepsilon\Delta_1 \le \varepsilon/4$ and $\Delta_2\gamma_\varepsilon^2 \le \varepsilon/4$. Furthermore, $(1 - m\gamma_\varepsilon)^{n_\varepsilon}W_2^2(\mu_0\tilde{S}^2_{\gamma_\varepsilon}, \pi) \le \exp(-n_\varepsilon m\gamma_\varepsilon)W_2^2(\mu_0\tilde{S}^2_{\gamma_\varepsilon}, \pi) \le \varepsilon/4$, and $(1 - \gamma_\varepsilon\tilde{m})\Delta_3 \le \varepsilon/4$ similarly. Together, the above inequalities conclude the proof.

Appendix A. Definitions and Useful Results from Theory of Gradient Flows

For a continously differentiable function $f : \mathbb{R}^d \to \mathbb{R}$, the gradient flow associated with f starting at x_0 is the solution $(x(t))_{t\in\mathbb{R}_+}$ of the ordinary differential equation: $\mathrm{d}x(t)/\mathrm{d}t = -\nabla f(x(t))$, with $x(0) = x_0$. Classical theory of gradient flows was developed for functions defined on $\mathbb{R}^d$, and later extended to functionals on Banach spaces. Main motivation for this development were connections between gradient flows in Banach spaces and some partial differential equation - for example the heat equation can be formulated as the gradient flow of $u \mapsto \int_{\mathbb{R}^d}\|\nabla u\|^2\,\mathrm{d}x$ (which is called the Dirichlet energy) on $\mathrm{L}^2(\mathbb{R}^d) = \{u : \mathbb{R}^d \to \mathbb{R} : u \text{ is measurable and } \int_{\mathbb{R}^d}\|u\|^2\,\mathrm{d}x < +\infty\}$. Similarly, widespread interest in the theory of gradient flows in metric spaces started with the work of Jordan et al. (1998), which showed that gradient flow of the free energy functional defined in (7) in the space $(\mathcal{P}_2(\mathbb{R}^d), W_2)$ is a measure valued solution of the Fokker-Planck equation.

For a brief overview of the theory of gradient flows in Euclidean and metric spaces, with a focus on Wasserstein spaces, we refer to (Santambrogio, 2017). For a detailed introduction to the theory of gradient flows in metric spaces we refer the reader to (Ambrosio et al., 2008). Below, we only introduce definitions and results from the theory of gradient flows in the space of probability measures, which are relevant to our work.

Let $I \subset \mathbb{R}$ be an open interval of $\mathbb{R}$ and $(\mu_t)_{t\in I}$ be a curve on $\mathcal{P}_2(\mathbb{R}^d)$, *i.e.* a family of probability measures belonging to $\mathcal{P}_2(\mathbb{R}^d)$. $(\mu_t)_{t\in I}$ is said to be absolutely continuous if there exists $\ell \in \mathrm{L}^1(I)$ such that for all $s, t \in I$, $s \le t$, $W_2(\mu_s, \mu_t) \le \int_s^t |\ell|\,(u)\mathrm{d}u$. Denote by $\mathrm{AC}(I)$ the set of absolutely continuous curves on I and

$$
\mathrm{AC}_{\mathrm{loc}}(\mathbb{R}^*_+) = \left\{(\mu_t)_{t\ge 0} \;:\; (\mu_t)_{t\in I} \in \mathrm{AC}(I) \text{ for any open interval } I \subset \mathbb{R}^*_+\right\}\,.
$$

Note that if $(\mu_t)_{t\in I} \in \mathrm{AC}(I)$, then for any $\nu \in \mathcal{P}_2(\mathbb{R}^d)$, $t \mapsto W_2(\nu, \mu_t)$ is absolutely continuous on I (as a curve from I to $\mathbb{R}_+$). Therefore by (Nielsen, 1997, Theorem 20.8) and (Mitrovic and Zubrinic, 1997, Exercise 4, p.45), $t \mapsto W_2(\nu, \mu_t)$ has derivative for the almost all $t \in I$ and there exists $\delta : I \to \mathbb{R}$ satisfying

$$
\int_I |\delta|\,(u)\mathrm{d}u < +\infty \text{ and } W_2^2(\nu, \mu_t) - W_2^2(\nu, \mu_s) = \int_s^t \delta(u)\mathrm{d}u\,, \text{ for all } s, t \in I \qquad (51)
$$

Let $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$. A constant speed geodesic $(\lambda_t)_{t\in[0,1]}$ between μ and ν is a curve in $\mathcal{P}_2(\mathbb{R}^d)$ such that $\lambda_0 = \mu$, $\lambda_1 = \nu$ and for all for all $s, t \in [0, 1]$, $W_2(\lambda_s, \lambda_t) = |t - s|\,W_2(\mu, \nu)$.

Note that by the triangle inequality, this definition is equivalent to the following: for all $s,t \in [0,1]$, $W_2(\lambda_s,\lambda_t) \le |t-s|\, W_2(\mu,\nu)$. Indeed by the triangle inequality and the assumption $W_2(\lambda_s,\lambda_t) \le |t-s|\, W_2(\mu,\nu)$, we have for all $s,t \in [0,1]$, $s<t$,

$$W_2(\mu,\nu) \le W_2(\mu,\lambda_t) + W_2(\lambda_t,\lambda_s) + W_2(\lambda_s,\nu) \le W_2(\mu,\nu) \; .$$

Therefore the first inequality is in fact an equality, and therefore using again the assumption for $W_2(\mu,\lambda_t)$ and $W_2(\lambda_s,\nu)$ concludes the proof. By definition of the Wasserstein distance of order 2, a constant speed geodesic $(\lambda_t)_{t\in[0,1]}$ between μ and ν is given for all $t \in [0,1]$ by $\lambda_t = (t\,\mathrm{proj}_1 + (1-t)\,\mathrm{proj}_2)_\sharp \zeta$ where ζ is an optimal transport plan between μ and ν and $\mathrm{proj}_1, \mathrm{proj}_2 : \mathbb{R}^{2d} \to \mathbb{R}^d$ are the projections on the first and the last d components respectively.

Let $\mathscr{S} : \mathcal{P}_2(\mathbb{R}^d) \to (-\infty, +\infty]$. The functional $\mathscr{S}$ is said to be lower semi-continuous if for all $M \in \mathbb{R}$, $\{\mathscr{S} \le M\}$ is a closed set of $\mathcal{P}_2(\mathbb{R}^d)$ and m-geodesically convex for $m \ge 0$ if for any $\mu,\nu \in \mathcal{P}_2(\mathbb{R}^d)$ there exists a constant speed geodesic $(\lambda_t)_{t\in[0,1]}$ between μ and ν such that for all $t \in [0,1]$

$$\mathscr{S}(\lambda_t) \le t\mathscr{S}(\mu) + (1-t)\mathscr{S}(\nu) - t(1-t)(m/2)W_2^2(\mu,\nu) \; .$$

If $m = 0$, $\mathscr{S}$ will be simply said geodesically convex.

A curve $(\mu_t)_{t>0} \in \mathrm{AC}_{\mathrm{loc}}(\mathbb{R}_+^*)$ is said to be a gradient flow for the lower semi-continuous and m-geodesically convex function $\mathscr{S} : \mathcal{P}_2(\mathbb{R}^d) \to (-\infty, +\infty]$ if for all $\nu \in \mathcal{P}_2(\mathbb{R}^d)$, $\mathscr{S}(\nu) < +\infty$, and for almost all $t \in \mathbb{R}_+^*$,

$$(1/2)\delta_t + (m/2)W_2^2(\mu_t,\nu) \le \mathscr{S}(\nu) - \mathscr{S}(\mu_t) \; ,$$

where $\delta : \mathbb{R}_+^* \to \mathbb{R}$ satisfies (51) for all open interval of $\mathbb{R}_+^*$. We say that $(\mu_t)_{t\in\mathbb{R}_+^*}$ starts at μ if $\lim_{t\to 0} W_2(\mu_t,\mu) = 0$ and then set $\mu_0 = \mu$. By (Ambrosio et al., 2008, Theorem 11.1.4), there exists at most one gradient flow associated with $\mathscr{S}$.

Consider the functional $\tilde{\mathscr{F}} : \mathcal{P}_2(\mathbb{R}^d) \to (-\infty, +\infty]$ given by $\tilde{\mathscr{F}} = \mathscr{H} + \tilde{\mathscr{E}}$ where $\mathscr{H}$ is defined by (8) and $\tilde{\mathscr{E}}$ for all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ by

$$\tilde{\mathscr{E}}(\mu) = \int_{\mathbb{R}^d} V(x)\mathrm{d}\mu(x) \; ,$$

where $V : \mathbb{R}^d \to (-\infty, +\infty]$ is a convex lower-semicontinuous function (for all $M \ge 0$, $\{V \le M\}$ is closed subset of $\mathbb{R}^d$) with $\{V < +\infty\} \neq \emptyset$ and the interior of this set is non empty as well. By (Ambrosio et al., 2008, Proposition 9.3.2, Theorem 9.4.12), $\tilde{\mathscr{F}}$ is geodesically convex and (Ambrosio et al., 2008, Theorem 11.2.8,Theorem 11.1.4) shows that there exists the unique gradient flow $(\mu_t)_{t\ge 0}$ starting at $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ and this curve is the unique solution of the Fokker-Plank equation (in the sense of distributions) :

$$\frac{\partial \mu_t}{\partial t} = \mathrm{div}(\nabla \mu_t^x + \mu_t^x \nabla V(x)) \; ,$$

i.e. for all $\phi \in C_c^\infty(\mathbb{R}^d)$ and $t > 0$,

$$\frac{\partial}{\partial t}\int_{\mathbb{R}^d} \phi(y)\mu_t(\mathrm{d}y) = \int_{\mathbb{R}^d} \mathcal{A}\phi(y)\,\mu_t(\mathrm{d}y) \; .$$

In addition for all $t > 0$, μ_t is absolutely continuous with respect to the Lebesgue measure. In particular for $V = 0$, we get the following result.

Theorem 31 *For all $\mu \in \mathcal{P}_2(\mathbb{R}^d)$, there exists a unique solution of the Fokker-Plank equation (in the sense of distributions) :*

$$\frac{\partial \mu_t}{\partial t} = \Delta \mu_t \; .$$

In addition $(\mu_t)_{t\ge 0} \in \mathrm{AC}(\mathbb{R}_+^*)$ and satisfies for almost all $t \in \mathbb{R}_+^*$,

$$\delta_t/2 \le \mathscr{H}(\nu) - \mathscr{H}(\mu_t) \; ,$$

where δ_t is given in (51).

Appendix B. On the Second Order Moment of Log-Concave Measures

A7 *There exist $\eta > 0$, $M_\eta \ge 0$ such that for all $x \in \mathbb{R}^d$, $x \notin \mathrm{B}(0, M_\eta)$,*

$$U(x) - U(x^\star) \ge \eta \left\| x - x^\star \right\| \; .$$

In this section, we give some bounds on to deal with the distance of the initial condition of the algorithms from π in W_2.

Proposition 32 *Assume **A**1(0) and **A**7. Then, we have*

$$\int_{\mathbb{R}^d} \left\| x - x^\star \right\|^2 \mathrm{d}\pi(x) \le 2\eta^{-2} d(1+d) + M_\eta^2 \; .$$

Proof Note that under **A**7, we have

$$\begin{aligned} &\int_{\mathbb{R}^d} \left\| x - x^\star \right\|^2 \mathrm{d}\pi(x) \le \eta^{-2} \int_{\mathbb{R}^d} |U(x) - U(x^\star)|^2 \,\mathrm{d}\pi(x) + M_\eta^2 \\ &\le 2\eta^{-2} \int_{\mathbb{R}^d} |U(x) + \log(\mathrm{Z}) + \mathscr{H}(\pi)|^2 \,\mathrm{d}\pi(x) + 2\eta^{-2} \left| -\mathscr{H}(\pi) - \log(\mathrm{Z}) - U(x^\star) \right|^2 + M_\eta^2 \; . \end{aligned} \tag{52}$$

where $\mathscr{H}$ is defined by (8) and $\mathrm{Z} = \int_{\mathbb{R}^d} \mathrm{e}^{-U(y)}\mathrm{d}y$. Then, by (Bobkov and Madiman, 2011, Proposition I.2), $|-\mathscr{H}(\pi) - \log(\mathrm{Z}) - U(x^\star)| \le d$ and by (Fradelizi et al., 2016, Theorem 2.3), (see also Nguyen (2013) and Wang (2014)), $\int_{\mathbb{R}^d} |U(x) + \log(\mathrm{Z}) + \mathscr{H}(\pi)|^2 \,\mathrm{d}\pi(x) \le d$. Combining these two results in (52) concludes the proof. ■

Abstract

In this paper we develop a deep learning method for optimal stopping problems which directly learns the optimal stopping rule from Monte Carlo samples. As such, it is broadly applicable in situations where the underlying randomness can efficiently be simulated. We test the approach on three problems: the pricing of a Bermudan max-call option, the pricing of a callable multi barrier reverse convertible and the problem of optimally stopping a fractional Brownian motion. In all three cases it produces very accurate results in high-dimensional situations with short computing times.

Keywords: optimal stopping, deep learning, Bermudan option, callable multi barrier reverse convertible, fractional Brownian motion

1. Introduction

We consider optimal stopping problems of the form $\sup_\tau \mathbb{E}\, g(\tau, X_\tau)$, where $X = (X_n)_{n=0}^N$ is an $\mathbb{R}^d$-valued discrete-time Markov process and the supremum is over all stopping times τ based on observations of X. Formally, this just covers situations where the stopping decision can only be made at finitely many times. But practically all relevant continuous-time stopping problems can be approximated with time-discretized versions. The Markov assumption means no loss of generality. We make it because it simplifies the presentation and many important problems already are in Markovian form. But every optimal stopping problem can be made Markov by including all relevant information from the past in the current state of X (albeit at the cost of increasing the dimension of the problem).

In theory, optimal stopping problems with finitely many stopping opportunities can be solved exactly. The optimal value is given by the smallest supermartingale that dominates the reward process – the so-called Snell envelope – and the smallest (largest) optimal stopping time is the first time the immediate reward dominates (exceeds) the continuation value; see, e.g., Peskir and Shiryaev (2006) or Lamberton and Lapeyre (2008). However, traditional numerical methods suffer from the curse of dimensionality. For instance, the complexity of standard tree- or lattice-based methods increases exponentially in the dimension. For typical problems they yield good results for up to three dimensions. To treat higher-dimensional problems, various Monte Carlo based have been developed over the last years. A common approach consists in estimating continuation values to either derive stopping rules or recursively approximate the Snell envelope; see, e.g., Tilley (1993), Barraquand and Martineau (1995), Carriere (1996), Longstaff and Schwartz (2001), Tsitsiklis and Van Roy (2001), Boyle et al. (2003), Broadie and Glasserman (2004), Bally et al. (2005), Kolodko and Schoenmakers (2006), Egloff et al. (2007), Berridge and Schumacher (2008), Jain and Oosterlee (2015), Belomestny et al. (2018) or Haugh and Kogan (2004) and Kohler et al. (2010), which use neural networks with one hidden layer to do this. A different strand of the literature has focused on approximating optimal exercise boundaries; see, e.g., Andersen (2000), García (2003) and Belomestny (2011). Based on an idea of Davis and Karatzas (1994), a dual approach was developed by Rogers (2002) and Haugh and Kogan (2004); see Jamshidian (2007) and Chen and Glasserman (2007) for a multiplicative version and Andersen and Broadie (2004), Broadie and Cao (2008), Belomestny et al. (2009), Rogers (2010), Desai et al. (2012), Belomestny (2013), Belomestny et al. (2013) and Lelong (2016) for extensions and primal-dual methods. In Sirignano and Spiliopoulos (2018) optimal stopping problems in continuous time are treated by approximating the solutions of the corresponding free boundary PDEs with deep neural networks.

In this paper we use deep learning to approximate an optimal stopping time. Our approach is related to policy optimization methods used in reinforcement learning (Sutton and Barto, 1998), deep reinforcement learning (Schulman et al., 2015; Mnih et al., 2015; Silver et al., 2016; Lillicrap et al., 2016) and the deep learning method for stochastic control problems proposed by Han and E (2016). However, optimal stopping differs from the typical control problems studied in this literature. The challenge of our approach lies in the implementation of a deep learning method that can efficiently learn optimal stopping times. We do this by decomposing an optimal stopping time into a sequence of 0-1 stopping decisions and approximating them recursively with a sequence of multilayer feedforward neural networks. We show that our neural network policies can approximate optimal stopping times to any degree of desired accuracy. A candidate optimal stopping time $\hat{\tau}$ can be obtained by running a stochastic gradient ascent. The corresponding expectation $\mathbb{E}\, g(\hat{\tau}, X_{\hat{\tau}})$ provides a lower bound for the optimal value $\sup_\tau \mathbb{E}\, g(\tau, X_\tau)$. Using a version of the dual method of Rogers (2002) and Haugh and Kogan (2004), we also derive an upper bound. In all our examples, both bounds can be computed with short run times and lie close together.

The rest of the paper is organized as follows: In Section 2 we introduce the setup and explain our method of approximating optimal stopping times with neural networks. In Section 3 we construct lower bounds, upper bounds, point estimates and confidence intervals for the optimal value. In Section 4 we test the approach on three examples: the pricing of a Bermudan max-call option on different underlying assets, the pricing of a callable multi barrier reverse convertible and the problem of optimally stopping a fractional Brownian motion. In the first two examples, we use a multi-dimensional Black–Scholes model to describe the dynamics of the underlying assets. Then the pricing of a Bermudan max-call option amounts to solving a d-dimensional optimal stopping problem, where d is the number of assets. We provide numerical results for $d = 2, 3, 5, 10, 20, 30, 50, 100, 200$ and 500. In the case of a callable MBRC, it becomes a $d+1$-dimensional stopping problem since one also needs to keep track of the barrier event. We present results for $d = 2, 3, 5, 10, 15$ and 30. In the third example we only consider a one-dimensional fractional Brownian

motion. But fractional Brownian motion is not Markov. In fact, all of its increments are correlated. So, to optimally stop it, one has to keep track of all past movements. To make it tractable, we approximate the continuous-time problem with a time-discretized version, which if formulated as a Markovian problem, has as many dimensions as there are time-steps. We compute a solution for 100 time-steps.

2. Deep Learning Optimal Stopping Rules

Let $X = (X_n)_{n=0}^N$ be an $\mathbb{R}^d$-valued discrete-time Markov process on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, where N and d are positive integers. We denote by $\mathcal{F}_n$ the σ-algebra generated by $X_0, X_1, \ldots, X_n$ and call a random variable $\tau\colon \Omega \to \{0, 1, \ldots, N\}$ an X-stopping time if the event $\{\tau = n\}$ belongs to $\mathcal{F}_n$ for all $n \in \{0, 1, \ldots, N\}$.

Our aim is to develop a deep learning method that can efficiently learn an optimal policy for stopping problems of the form

$$\sup_{\tau \in \mathcal{T}} \mathbb{E}\, g(\tau, X_\tau), \tag{1}$$

where $g\colon \{0, 1, \ldots, N\} \times \mathbb{R}^d \to \mathbb{R}$ is a measurable function and $\mathcal{T}$ denotes the set of all X-stopping times. To make sure that problem (1) is well-defined and admits an optimal solution, we assume that g satisfies the integrability condition

$$\mathbb{E}\,|g(n, X_n)| < \infty \quad \text{for all } n \in \{0, 1, \ldots, N\}; \tag{2}$$

see, e.g., Peskir and Shiryaev (2006) or Lamberton and Lapeyre (2008). To be able to derive confidence intervals for the optimal value (1), we will have to make the slightly stronger assumption

$$\mathbb{E}\big[g(n, X_n)^2\big] < \infty \quad \text{for all } n \in \{0, 1, \ldots, N\} \tag{3}$$

in Subsection 3.3 below. This is satisfied in all our examples in Section 4.

2.1. Expressing Stopping Times in Terms of Stopping Decisions

Any X-stopping time can be decomposed into a sequence of 0-1 stopping decisions. In principle, the decision whether to stop the process at time n if it has not been stopped before, can be made based on the whole evolution of X from time 0 until n. But to optimally stop the Markov process X, it is enough to make stopping decisions according to $f_n(X_n)$ for measurable functions $f_n\colon \mathbb{R}^d \to \{0, 1\}$, $n = 0, 1, \ldots, N$. Theorem 1 below extends this well-known fact and serves as the theoretical basis of our method.

Consider the auxiliary stopping problems

$$V_n = \sup_{\tau \in \mathcal{T}_n} \mathbb{E}\, g(\tau, X_\tau) \tag{4}$$

for $n = 0, 1, \ldots, N$, where $\mathcal{T}_n$ is the set of all X-stopping times satisfying $n \le \tau \le N$. Obviously, $\mathcal{T}_N$ consists of the unique element $\tau_N \equiv N$, and one can write $\tau_N = N f_N(X_N)$ for the constant function $f_N \equiv 1$. Moreover, for given $n \in \{0, 1, \ldots, N\}$ and a sequence of measurable functions $f_n, f_{n+1}, \ldots, f_N\colon \mathbb{R}^d \to \{0, 1\}$ with $f_N \equiv 1$,

$$\tau_n = \sum_{m=n}^{N} m f_m(X_m) \prod_{j=n}^{m-1} (1 - f_j(X_j)) \tag{5}$$

defines[1] a stopping time in $\mathcal{T}_n$. The following result shows that, for our method of recursively computing an approximate solution to the optimal stopping problem (1), it will be sufficient to consider stopping times of the form (5).

Theorem 1 *For a given $n \in \{0, 1, \ldots, N-1\}$, let τ_{n+1} be a stopping time in $\mathcal{T}_{n+1}$ of the form*

$$\tau_{n+1} = \sum_{m=n+1}^{N} m f_m(X_m) \prod_{j=n+1}^{m-1} (1 - f_j(X_j)) \tag{6}$$

for measurable functions $f_{n+1}, \ldots, f_N\colon \mathbb{R}^d \to \{0, 1\}$ with $f_N \equiv 1$. Then there exists a measurable function $f_n\colon \mathbb{R}^d \to \{0, 1\}$ such that the stopping time $\tau_n \in \mathcal{T}_n$ given by (5) satisfies

$$\mathbb{E}\, g(\tau_n, X_{\tau_n}) \ge V_n - \big(V_{n+1} - \mathbb{E}\, g(\tau_{n+1}, X_{\tau_{n+1}})\big)\,,$$

where V_n and V_{n+1} are the optimal values defined in (4).

Proof Denote $\varepsilon = V_{n+1} - \mathbb{E}\, g(\tau_{n+1}, X_{\tau_{n+1}})$, and consider a stopping time $\tau \in \mathcal{T}_n$. By the Doob–Dynkin lemma (see, e.g., Aliprantis and Border, 2006, Theorem 4.41), there exists a measurable function $h_n\colon \mathbb{R}^d \to \mathbb{R}$ such that $h_n(X_n)$ is a version of the conditional expectation $\mathbb{E}\big[g(\tau_{n+1}, X_{\tau_{n+1}}) \mid X_n\big]$. Moreover, due to the special form (6) of τ_{n+1},

$$g(\tau_{n+1}, X_{\tau_{n+1}}) = \sum_{m=n+1}^{N} g(m, X_m) 1_{\{\tau_{n+1} = m\}} = \sum_{m=n+1}^{N} g(m, X_m) 1_{\{f_m(X_m) \prod_{j=n+1}^{m-1} (1 - f_j(X_j)) = 1\}}$$

is a measurable function of $X_{n+1}, \ldots, X_N$. So it follows from the Markov property of X that $h_n(X_n)$ is also a version of the conditional expectation $\mathbb{E}\big[g(\tau_{n+1}, X_{\tau_{n+1}}) \mid \mathcal{F}_n\big]$. Since the events

$$D = \{g(n, X_n) \ge h_n(X_n)\} \quad \text{and} \quad E = \{\tau = n\}$$

are in $\mathcal{F}_n$, $\tau_n = n 1_D + \tau_{n+1} 1_{D^c}$ belongs to $\mathcal{T}_n$ and $\tilde{\tau} = \tau_{n+1} 1_E + \tau 1_{E^c}$ to $\mathcal{T}_{n+1}$. It follows from the definitions of V_{n+1} and ε that $\mathbb{E}\, g(\tau_{n+1}, X_{\tau_{n+1}}) = V_{n+1} - \varepsilon \ge \mathbb{E}\, g(\tilde{\tau}, X_{\tilde{\tau}}) - \varepsilon$. Hence,

$$\mathbb{E}\big[g(\tau_{n+1}, X_{\tau_{n+1}}) 1_{E^c}\big] \ge \mathbb{E}[g(\tilde{\tau}, X_{\tilde{\tau}}) 1_{E^c}] - \varepsilon = \mathbb{E}[g(\tau, X_\tau) 1_{E^c}] - \varepsilon,$$

from which one obtains

$$\begin{aligned}
&\mathbb{E}\, g(\tau_n, X_{\tau_n}) = \mathbb{E}\big[g(n, X_n) I_D + g(\tau_{n+1}, X_{\tau_{n+1}}) I_{D^c}\big] = \mathbb{E}[g(n, X_n) I_D + h_n(X_n) I_{D^c}] \\
&\ge \mathbb{E}[g(n, X_n) I_E + h_n(X_n) I_{E^c}] = \mathbb{E}\big[g(n, X_n) I_E + g(\tau_{n+1}, X_{\tau_{n+1}}) I_{E^c}\big] \\
&\ge \mathbb{E}[g(n, X_n) I_E + g(\tau, X_\tau) I_{E^c}] - \varepsilon = \mathbb{E}\, g(\tau, X_\tau) - \varepsilon.
\end{aligned}$$

Since $\tau \in \mathcal{T}_n$ was arbitrary, this shows that $\mathbb{E}\, g(\tau_n, X_{\tau_n}) \ge V_n - \varepsilon$. Moreover, one has $1_D = f_n(X_n)$ for the function $f_n\colon \mathbb{R}^d \to \{0, 1\}$ given by

$$f_n(x) = \begin{cases} 1 & \text{if } g(n, x) \ge h_n(x) \\ 0 & \text{if } g(n, x) < h_n(x) \end{cases}.$$

1. In expressions of the form (5), we understand the empty product $\prod_{j=n}^{n-1} (1 - f_j(X_j))$ as 1.

Therefore,

$$\tau_n = n f_n(X_n) + \tau_{n+1}(1 - f_n(X_n)) = \sum_{m=n}^{N} m f_m(X_m) \prod_{j=n}^{m-1} (1 - f_j(X_j)),$$

which concludes the proof. ∎

Remark 2 *Since for $f_N \equiv 1$, the stopping time $\tau_N = f_N(X_N)$ is optimal in $\mathcal{T}_N$, Theorem 1 inductively yields measurable functions $f_n \colon \mathbb{R}^d \to \{0,1\}$ such that for all $n \in \{0,1,\dots,N-1\}$, the stopping time τ_n given by (5) is optimal among $\mathcal{T}_n$. In particular,*

$$\tau = \sum_{n=1}^{N} n f_n(X_n) \prod_{j=0}^{n-1} (1 - f_j(X_j)) \tag{7}$$

is an optimal stopping time for problem (1).

Remark 3 *In many applications, the Markov process X starts from a deterministic initial value $x_0 \in \mathbb{R}^d$. Then the function f_0 enters the representation (7) only through the value $f_0(x_0) \in \{0,1\}$; that is, at time 0, only a constant and not a whole function has to be learned.*

2.2. Neural Network Approximation

Our numerical method for problem (1) consists in iteratively approximating optimal stopping decisions $f_n \colon \mathbb{R}^d \to \{0,1\}$, $n = 0,1,\dots,N-1$, by a neural network $f^\theta \colon \mathbb{R}^d \to \{0,1\}$ with parameter $\theta \in \mathbb{R}^q$. We do this by starting with the terminal stopping decision $f_N \equiv 1$ and proceeding by backward induction. More precisely, let $n \in \{0,1,\dots,N-1\}$, and assume parameter values $\theta_{n+1}, \theta_{n+2}, \dots, \theta_N \in \mathbb{R}^q$ have been found such that $f^{\theta_N} \equiv 1$ and the stopping time

$$\tau_{n+1} = \sum_{m=n+1}^{N} m f^{\theta_m}(X_m) \prod_{j=n+1}^{m-1} (1 - f^{\theta_j}(X_j))$$

produces an expected value $\mathbb{E}\, g(\tau_{n+1}, X_{\tau_{n+1}})$ close to the optimum V_{n+1}. Since f^θ takes values in $\{0,1\}$, it does not directly lend itself to a gradient-based optimization method. So, as an intermediate step, we introduce a feedforward neural network $F^\theta \colon \mathbb{R}^d \to (0,1)$ of the form

$$F^\theta = \psi \circ a_I^\theta \circ \varphi_{q_{I-1}} \circ a_{I-1}^\theta \circ \cdots \circ \varphi_{q_1} \circ a_1^\theta,$$

where

- $I, q_1, q_2, \dots, q_{I-1}$ are positive integers specifying the depth of the network and the number of nodes in the hidden layers (if there are any),
- $a_1^\theta \colon \mathbb{R}^d \to \mathbb{R}^{q_1}, \dots, a_{I-1}^\theta \colon \mathbb{R}^{q_{I-2}} \to \mathbb{R}^{q_{I-1}}$ and $a_I^\theta \colon \mathbb{R}^{q_{I-1}} \to \mathbb{R}$ are affine functions,
- for $j \in \mathbb{N}$, $\varphi_j \colon \mathbb{R}^j \to \mathbb{R}^j$ is the component-wise ReLU activation function given by $\varphi_j(x_1,\dots,x_j) = (x_1^+,\dots,x_j^+)$

- $\psi \colon \mathbb{R} \to (0,1)$ is the standard logistic function $\psi(x) = e^x/(1+e^x) = 1/(1+e^{-x})$.

The components of the parameter $\theta \in \mathbb{R}^q$ of F^θ consist of the entries of the matrices $A_1 \in \mathbb{R}^{q_1 \times d}, \dots, A_{I-1} \in \mathbb{R}^{q_{I-1} \times q_{I-2}}, A_I \in \mathbb{R}^{1 \times q_{I-1}}$ and the vectors $b_1 \in \mathbb{R}^{q_1}, \dots, b_{I-1} \in \mathbb{R}^{q_{I-1}}, b_I \in \mathbb{R}$ given by the representation of the affine functions

$$a_i^\theta(x) = A_i x + b_i, \quad i = 1,\dots,I.$$

So the dimension of the parameter space is

$$q = \begin{cases} d+1 & \text{if } I = 1 \\ 1 + q_1 + \cdots + q_{I-1} + d q_1 + \cdots + q_{I-2} q_{I-1} + q_{I-1} & \text{if } I \geq 2, \end{cases}$$

and for given $x \in \mathbb{R}^d$, $F^\theta(x)$ is continuous as well as almost everywhere smooth in θ. Our aim is to determine $\theta_n \in \mathbb{R}^q$ so that

$$\mathbb{E}\Big[g(n, X_n) F^{\theta_n}(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - F^{\theta_n}(X_n)) \Big]$$

is close to the supremum $\sup_{\theta \in \mathbb{R}^q} \mathbb{E}\big[g(n, X_n) F^\theta(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - F^\theta(X_n)) \big]$. Once this has been achieved, we define the function $f^{\theta_n} \colon \mathbb{R}^d \to \{0,1\}$ by

$$f^{\theta_n} = 1_{[0,\infty)} \circ a_I^{\theta_n} \circ \varphi_{q_{I-1}} \circ a_{I-1}^{\theta_n} \circ \cdots \circ \varphi_{q_1} \circ a_1^{\theta_n}, \tag{8}$$

where $1_{[0,\infty)} \colon \mathbb{R} \to \{0,1\}$ is the indicator function of $[0,\infty)$. The only difference between F^{θ_n} and f^{θ_n} is the final nonlinearity. While F^{θ_n} produces a stopping probability in $(0,1)$, the output of f^{θ_n} is a hard stopping decision given by 0 or 1, depending on whether F^{θ_n} takes a value below or above $1/2$.

The following result shows that for any depth $I \geq 2$, a neural network of the form (8) is flexible enough to make almost optimal stopping decisions provided it has sufficiently many nodes.

Proposition 4 *Let $n \in \{0,1,\dots,N-1\}$ and fix a stopping time $\tau_{n+1} \in \mathcal{T}_{n+1}$. Then, for every depth $I \geq 2$ and constant $\varepsilon > 0$, there exist positive integers $q_1, \dots, q_{I-1}$ such that*

$$\begin{aligned} &\sup_{\theta \in \mathbb{R}^q} \mathbb{E}\Big[g(n, X_n) f^\theta(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - f^\theta(X_n)) \Big] \\ &\geq \sup_{f \in \mathcal{D}} \mathbb{E}\big[g(n, X_n) f(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - f(X_n)) \big] - \varepsilon, \end{aligned}$$

where $\mathcal{D}$ is the set of all measurable functions $f \colon \mathbb{R}^d \to \{0,1\}$.

Proof Fix $\varepsilon > 0$. It follows from the integrability condition (2) that there exists a measurable function $\tilde{f} \colon \mathbb{R}^d \to \{0,1\}$ such that

$$\begin{aligned} &\mathbb{E}\Big[g(n, X_n) \tilde{f}(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - \tilde{f}(X_n)) \Big] \\ &\geq \sup_{f \in \mathcal{D}} \mathbb{E}\big[g(n, X_n) f(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - f(X_n)) \big] - \varepsilon/4. \end{aligned} \tag{9}$$

$\tilde{f}$ can be written as $\tilde{f} = 1_A$ for the Borel set $A = \{x \in \mathbb{R}^d : \tilde{f}(x) = 1\}$. Moreover, by (2),

$$B \mapsto \mathbb{E}[|g(n, X_n)|1_B(X_n)] \quad \text{and} \quad B \mapsto \mathbb{E}\big[|g(\tau_{n+1}, X_{\tau_{n+1}})|1_B(X_n)\big]$$

define finite Borel measures on $\mathbb{R}^d$. Since every finite Borel measure on $\mathbb{R}^d$ is tight (see, e.g., Aliprantis and Border, 2006), there exists a compact (possibly empty) subset $K \subseteq A$ such that

$$\begin{aligned} &\mathbb{E}\big[g(n, X_n)1_K(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - 1_K(X_n))\big] \\ &\geq \mathbb{E}\Big[g(n, X_n)\tilde{f}(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - \tilde{f}(X_n))\Big] - \varepsilon/4. \end{aligned} \tag{10}$$

Let $\rho_K \colon \mathbb{R}^d \to [0, \infty]$ be the distance function given by $\rho_K(x) = \inf_{y \in K} \|x - y\|_2$. Then

$$k_j(x) = \max\{1 - j\rho_K(x), -1\}, \quad j \in \mathbb{N},$$

defines a sequence of continuous functions $k_j \colon \mathbb{R}^d \to [-1, 1]$ that converge pointwise to $1_K - 1_{K^c}$. So it follows from Lebesgue's dominated convergence theorem that there exists a $j \in \mathbb{N}$ such that

$$\begin{aligned} &\mathbb{E}\Big[g(n, X_n)\, 1_{\{k_j(X_n) \geq 0\}} + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - 1_{\{k_j(X_n) \geq 0\}})\Big] \\ &\geq \mathbb{E}\big[g(n, X_n)1_K(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - 1_K(X_n))\big] - \varepsilon/4. \end{aligned} \tag{11}$$

By Theorem 1 of Leshno et al. (1993), k_j can be approximated uniformly on compacts by functions of the form

$$\sum_{i=1}^{r} (v_i^T x + c_i)^+ - \sum_{i=1}^{s} (w_i^T x + d_i)^+ \tag{12}$$

for $r, s \in \mathbb{N}$, $v_1, \ldots, v_r, w_1, \ldots, w_s \in \mathbb{R}^d$ and $c_1, \ldots, c_r, d_1, \ldots, d_s \in \mathbb{R}$. So there exists a function $h \colon \mathbb{R}^d \to \mathbb{R}$ expressible as in (12) such that

$$\begin{aligned} &\mathbb{E}\big[g(n, X_n)\, 1_{\{h(X_n) \geq 0\}} + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - 1_{\{h(X_n) \geq 0\}})\big] \\ &\geq \mathbb{E}\Big[g(n, X_n)\, 1_{\{k_j(X_n) \geq 0\}} + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - 1_{\{k_j(X_n) \geq 0\}})\Big] - \varepsilon/4. \end{aligned} \tag{13}$$

Now note that for any integer $I \geq 2$, the composite mapping $1_{[0,\infty)} \circ h$ can be written as a neural net f^θ of the form (8) with depth I for suitable integers $q_1, \ldots, q_{I-1}$ and parameter value $\theta \in \mathbb{R}^q$. Hence, one obtains from (9), (10), (11) and (13) that

$$\begin{aligned} &\mathbb{E}\Big[g(n, X_n)\, f^\theta(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - f^\theta(X_n))\Big] \\ &\geq \sup_{f \in \mathcal{D}} \mathbb{E}\big[g(n, X_n)f(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - f(X_n))\big] - \varepsilon, \end{aligned}$$

and the proof is complete. ■

We always choose $\theta_N \in \mathbb{R}^q$ such that[2] $f^{\theta_N} \equiv 1$. Then our candidate optimal stopping time

$$\tau^\Theta = \sum_{n=1}^{N} n f^{\theta_n}(X_n) \prod_{j=0}^{n-1} (1 - f^{\theta_j}(X_j)) \tag{14}$$

2. It is easy to see that this is possible.

is specified by the vector $\Theta = (\theta_0, \theta_1, \ldots, \theta_{N-1}) \in \mathbb{R}^{Nq}$. The following is an immediate consequence of Theorem 1 and Proposition 4:

Corollary 5 *For a given optimal stopping problem of the form* (1)*, a depth $I \geq 2$ and a constant $\varepsilon > 0$, there exist positive integers $q_1, \ldots, q_{I-1}$ and a vector $\Theta \in \mathbb{R}^{Nq}$ such that the corresponding stopping time* (14) *satisfies $\mathbb{E}\, g(\tau^\Theta, X_{\tau^\Theta}) \geq \sup_{\tau \in \mathcal{T}} \mathbb{E}\, g(\tau, X_\tau) - \varepsilon$.*

2.3. Parameter Optimization

We train neural networks of the form (8) with fixed depth $I \geq 2$ and given numbers $q_1, \ldots, q_{I-1}$ of nodes in the hidden layers[3]. To numerically find parameters $\theta_n \in \mathbb{R}^q$ yielding good stopping decisions f^{θ_n} for all times $n \in \{0, 1, \ldots, N-1\}$, we approximate expected values with averages of Monte Carlo samples calculated from simulated paths of the process $(X_n)_{n=0}^N$.

Let $(x_n^k)_{n=0}^N$, $k = 1, 2, \ldots$ be independent realizations of such paths. We choose $\theta_N \in \mathbb{R}^q$ such that $f^{\theta_N} \equiv 1$ and determine determine $\theta_n \in \mathbb{R}^q$ for $n \leq N-1$ recursively. So, suppose that for a given $n \in \{0, 1, \ldots, N-1\}$, parameters $\theta_{n+1}, \ldots, \theta_N \in \mathbb{R}^q$, have been found so that the stopping decisions $f^{\theta_{n+1}}, \ldots, f^{\theta_N}$ generate a stopping time

$$\tau_{n+1} = \sum_{m=n+1}^{N} m f^{\theta_m}(X_m) \prod_{j=n+1}^{m-1} (1 - f^{\theta_j}(X_j))$$

with corresponding expectation $\mathbb{E}\, g(\tau_{n+1}, X_{\tau_{n+1}})$ close to the optimal value V_{n+1}. If $n = N-1$, one has $\tau_{n+1} \equiv N$, and if $n \leq N-2$, τ_{n+1} can be written as

$$\tau_{n+1} = l_{n+1}(X_{n+1}, \ldots, X_{N-1})$$

for a measurable function $l_{n+1} \colon \mathbb{R}^{d(N-n-1)} \to \{n+1, n+2, \ldots, N\}$. Accordingly, denote

$$l_{n+1}^k = \begin{cases} N & \text{if } n = N-1 \\ l_{n+1}(x_{n+1}^k, \ldots, x_{N-1}^k) & \text{if } n \leq N-2 \end{cases}.$$

If at time n, one applies the soft stopping decision F^θ and afterward behaves according to $f^{\theta_{n+1}}, \ldots, f^{\theta_N}$, the realized reward along the k-th simulated path of X is

$$r_n^k(\theta) = g(n, x_n^k)F^\theta(x_n^k) + g(l_{n+1}^k, x_{l_{n+1}^k}^k)(1 - F^\theta(x_n^k)).$$

For large $K \in \mathbb{N}$,

$$\frac{1}{K} \sum_{k=1}^{K} r_n^k(\theta) \tag{15}$$

approximates the expected value

$$\mathbb{E}\Big[g(n, X_n)F^\theta(X_n) + g(\tau_{n+1}, X_{\tau_{n+1}})(1 - F^\theta(X_n))\Big].$$

3. For a given application, one can try out different choices of I and $q_1, \ldots, q_{I-1}$ to find a suitable trade-off between accuracy and efficiency. Alternatively, the determination of I and $q_1, \ldots, q_{I-1}$ could be built into the training algorithm.

Since $r_n^k(\theta)$ is almost everywhere differentiable in θ, a stochastic gradient ascent method can be applied to find an approximate optimizer $\theta_n \in \mathbb{R}^q$ of (15). The same simulations $(x_n^k)_{n=0}^N$, $k = 1, 2, \ldots$ can be used to train the stopping decisions f^{θ_n} at all times $n \in \{0, 1, \ldots, N-1\}$. In the numerical examples in Section 4 below, we employed mini-batch gradient ascent with Xavier initialization (Glorot and Bengio, 2010), batch normalization (Ioffe and Szegedy, 2015) and Adam updating (Kingma and Ba, 2015).

Remark 6 *If the Markov process X starts from a deterministic initial value $x_0 \in \mathbb{R}^d$, the initial stopping decision is given by a constant $f_0 \in \{0, 1\}$. To learn f_0 from simulated paths of X, it is enough to compare the initial reward $g(0, x_0)$ to a Monte Carlo estimate $\hat{C}$ of $\mathbb{E}\, g(\tau_1, X_{\tau_1})$, where $\tau_1 \in \mathcal{T}_1$ is of the form*

$$\tau_1 = \sum_{n=1}^{N} n f^{\theta_n}(X_n) \prod_{j=1}^{n-1} (1 - f^{\theta_j}(X_j))$$

for $f^{\theta_N} \equiv 1$ and trained parameters $\theta_1, \ldots, \theta_{N-1} \in \mathbb{R}^q$. Then one sets $f_0 = 1$ (that is, stop immediately) if $g(0, x_0) \geq \hat{C}$ and $f_0 = 0$ (continue) otherwise. The resulting stopping time is of the form

$$\tau^\Theta = \begin{cases} 0 & \text{if } f_0 = 1 \\ \tau_1 & \text{if } f_0 = 0. \end{cases}$$

3. Bounds, Point Estimates and Confidence Intervals

In this section we derive lower and upper bounds as well as point estimates and confidence intervals for the optimal value $V_0 = \sup_{\tau \in \mathcal{T}} \mathbb{E}\, g(\tau, X_\tau)$.

3.1. Lower Bound

Once the stopping decisions f^{θ_n} have been trained, the stopping time τ^Θ given by (14) yields a lower bound $L = \mathbb{E}\, g(\tau^\Theta, X_{\tau^\Theta})$ for the optimal value $V_0 = \sup_{\tau \in \mathcal{T}} \mathbb{E}\, g(\tau, X_\tau)$. To estimate it, we simulate a new set[4] of independent realizations $(y_n^k)_{n=0}^N$, $k = 1, 2, \ldots, K_L$, of $(X_n)_{n=0}^N$. τ^Θ is of the form $\tau^\Theta = l(X_0, \ldots, X_{N-1})$ for a measurable function $l \colon \mathbb{R}^{dN} \to \{0, 1, \ldots, N\}$. Denote $l^k = l(y_0^k, \ldots, y_{N-1}^k)$. The Monte Carlo approximation

$$\hat{L} = \frac{1}{K_L} \sum_{k=1}^{K_L} g(l^k, y_{l^k}^k)$$

gives an unbiased estimate of the lower bound L, and by the law of large numbers, $\hat{L}$ converges to L for $K_L \to \infty$.

4. In particular, we assume that the samples $(y_n^k)_{n=0}^N$, $k = 1, \ldots, K_L$, are drawn independently from the realizations $(x_n^k)_{n=0}^N$, $k = 1, \ldots, K$, used in the training of the stopping decisions.

3.2. Upper Bound

The Snell envelope of the reward process $(g(n, X_n))_{n=0}^N$ is the smallest[5] supermartingale with respect to $(\mathcal{F}_n)_{n=0}^N$ that dominates $(g(n, X_n))_{n=0}^N$. It is given[6] by

$$H_n = \operatorname{ess\,sup}_{\tau \in \mathcal{T}_n} \mathbb{E}[g(\tau) \mid \mathcal{F}_n], \quad n = 0, 1, \ldots, N;$$

see, e.g., Peskir and Shiryaev (2006) or Lamberton and Lapeyre (2008). Its Doob–Meyer decomposition is

$$H_n = H_0 + M_n^H - A_n^H,$$

where M^H is the $(\mathcal{F}_n)$-martingale given[6] by

$$M_0^H = 0 \quad \text{and} \quad M_n^H - M_{n-1}^H = H_n - \mathbb{E}[H_n \mid \mathcal{F}_{n-1}], \quad n = 1, \ldots, N,$$

and A^H is the nondecreasing $(\mathcal{F}_n)$-predictable process given[6] by

$$A_0^H = 0 \quad \text{and} \quad A_n^H - A_{n-1}^H = H_{n-1} - \mathbb{E}[H_n \mid \mathcal{F}_{n-1}], \quad n = 1, \ldots, N.$$

Our estimate of an upper bound for the optimal value V_0 is based on the following variant[7] of the dual formulation of optimal stopping problems introduced by Rogers (2002) and Haugh and Kogan (2004).

Proposition 7 *Let $(\varepsilon_n)_{n=0}^N$ be a sequence of integrable random variables on $(\Omega, \mathcal{F}, \mathbb{P})$. Then*

$$V_0 \geq \mathbb{E}\left[\max_{0 \leq n \leq N} \left(g(n, X_n) - M_n^H - \varepsilon_n\right)\right] + \mathbb{E}\left[\min_{0 \leq n \leq N} \left(A_n^H + \varepsilon_n\right)\right]. \tag{16}$$

Moreover, if $\mathbb{E}[\varepsilon_n \mid \mathcal{F}_n] = 0$ for all $n \in \{0, 1, \ldots, N\}$, one has

$$V_0 \leq \mathbb{E}\left[\max_{0 \leq n \leq N} \left(g(n, X_n) - M_n - \varepsilon_n\right)\right] \tag{17}$$

for every $(\mathcal{F}_n)$-martingale $(M_n)_{n=0}^N$ starting from 0.

Proof First, note that

$$\begin{aligned} &\mathbb{E}\left[\max_{0 \leq n \leq N} \left(g(n, X_n) - M_n^H - \varepsilon_n\right)\right] \leq \mathbb{E}\left[\max_{0 \leq n \leq N} \left(H_n - M_n^H - \varepsilon_n\right)\right] \\ &= \mathbb{E}\left[\max_{0 \leq n \leq N} \left(H_0 - A_n^H - \varepsilon_n\right)\right] = V_0 - \mathbb{E}\left[\min_{0 \leq n \leq N} \left(A_n^H + \varepsilon_n\right)\right], \end{aligned}$$

which shows (16).

Now, assume that $\mathbb{E}[\varepsilon_n \mid \mathcal{F}_n] = 0$ for all $n \in \{0, 1, \ldots, N\}$, and let τ be an X-stopping time. Then

$$\mathbb{E}\, \varepsilon_\tau = \mathbb{E}\left[\sum_{n=0}^{N} 1_{\{\tau = n\}} \varepsilon_n\right] = \mathbb{E}\left[\sum_{n=0}^{N} 1_{\{\tau = n\}} \mathbb{E}[\varepsilon_n \mid \mathcal{F}_n]\right] = 0.$$

5. in the $\mathbb{P}$-almost sure order
6. up to $\mathbb{P}$-almost sure equality
7. See also the discussion on noisy estimates in Andersen and Broadie (2004).

So one obtains from the optional stopping theorem (see, e.g., Grimmett and Stirzaker, 2001),

$$\mathbb{E}\, g(\tau, X_\tau) = \mathbb{E}[g(\tau, X_\tau) - M_\tau - \varepsilon_\tau] \le \mathbb{E}\left[\max_{0\le n\le N} (g(n, X_n) - M_n - \varepsilon_n)\right]$$

for every $(\mathcal{F}_n)$-martingale $(M_n)_{n=0}^N$ starting from 0. Since $V_0 = \sup_{\tau\in\mathcal{T}} \mathbb{E}\, g(\tau, X_\tau)$, this implies (17). ■

For every $(\mathcal{F}_n)$-martingale $(M_n)_{n=0}^N$ starting from 0 and each sequence of integrable error terms $(\varepsilon_n)_{n=0}^N$ satisfying $\mathbb{E}[\varepsilon_n \mid \mathcal{F}_n] = 0$ for all n, the right side of (17) provides an upper bound[8] for V_0, and by (16), this upper bound is tight if $M = M^H$ and $\varepsilon \equiv 0$. So we try to use our candidate optimal stopping time τ^Θ to construct a martingale close to M^H. The closer τ^Θ is to an optimal stopping time, the better the value process[9]

$$H_n^\Theta = \mathbb{E}\Big[g(\tau_n^\Theta, X_{\tau_n^\Theta}) \mid \mathcal{F}_n\Big], \quad n = 0, 1, \dots, N,$$

corresponding to

$$\tau_n^\Theta = \sum_{m=n}^{N} m f^{\theta_m}(X_m) \prod_{j=n}^{m-1} (1 - f^{\theta_j}(X_j)), \quad n = 0, 1, \dots, N,$$

approximates the Snell envelope $(H_n)_{n=0}^N$. The martingale part of $(H_n^\Theta)_{n=0}^N$ is given by $M_0^\Theta = 0$ and

$$M_n^\Theta - M_{n-1}^\Theta = H_n^\Theta - \mathbb{E}\big[H_n^\Theta \mid \mathcal{F}_{n-1}\big] = f^{\theta_n}(X_n) g(n, X_n) + (1 - f^{\theta_n}(X_n)) C_n^\Theta - C_{n-1}^\Theta, \; n \ge 1, \tag{18}$$

for the continuation values[10]

$$C_n^\Theta = \mathbb{E}[g(\tau_{n+1}^\Theta, X_{\tau_{n+1}^\Theta}) \mid \mathcal{F}_n] = \mathbb{E}[g(\tau_{n+1}^\Theta, X_{\tau_{n+1}^\Theta}) \mid X_n], \quad n = 0, 1, \dots, N-1.$$

Note that C_N^Θ does not have to be specified. It formally appears in (18) for $n = N$. But $(1 - f^{\theta_N}(X_N))$ is always 0. To estimate M^Θ, we generate a third set[11] of independent realizations $(z_n^k)_{n=0}^N$, $k = 1, 2, \dots, K_U$, of $(X_n)_{n=0}^N$. In addition, for every z_n^k, we simulate J continuation paths $\tilde{z}_{n+1}^{k,j}, \dots, \tilde{z}_N^{k,j}$, $j = 1, \dots, J$, that are conditionally independent[12] of each other and of $z_{n+1}^k, \dots, z_N^k$. Let us denote by $\tau_{n+1}^{k,j}$ the value of τ_{n+1}^Θ along $\tilde{z}_{n+1}^{k,j}, \dots, \tilde{z}_N^{k,j}$. Estimating the continuation values as

$$C_n^k = \frac{1}{J} \sum_{j=1}^{J} g\left(\tau_{n+1}^{k,j}, \tilde{z}_{\tau_{n+1}^{k,j}}^{k,j}\right), \quad n = 0, 1, \dots, N-1,$$

yields the noisy estimates

$$\Delta M_n^k = f^{\theta_n}(z_n^k) g(n, z_n^k) + (1 - f^{\theta_n}(z_n^k)) C_n^k - C_{n-1}^k$$

of the increments $M_n^\Theta - M_{n-1}^\Theta$ along the k-th simulated path $z_0^k, \dots, z_N^k$. So

$$M_n^k = \begin{cases} 0 & \text{if } n = 0 \\ \sum_{m=1}^n \Delta M_m^k & \text{if } n \ge 1 \end{cases}$$

can be viewed as realizations of $M_n^\Theta + \varepsilon_n$ for estimation errors ε_n with standard deviations proportional to $1/\sqrt{J}$ such that $\mathbb{E}[\varepsilon_n \mid \mathcal{F}_n] = 0$ for all n. Accordingly,

$$\hat{U} = \frac{1}{K_U} \sum_{k=1}^{K_U} \max_{0\le n\le N} \left(g\left(n, z_n^k\right) - M_n^k\right),$$

is an unbiased estimate of the upper bound

$$U = \mathbb{E}\left[\max_{0\le n\le N} \left(g(n, X_n) - M_n^\Theta - \varepsilon_n\right)\right],$$

which, by the law of large numbers, converges to U for $K_U \to \infty$.

3.3. Point Estimate and Confidence Intervals

Our point estimate of V_0 is the average

$$\frac{\hat{L} + \hat{U}}{2}.$$

To derive confidence intervals, we assume that $g(n, X_n)$ is square-integrable[13] for all n. Then

$$g(\tau^\theta, X_{\tau^\Theta}) \quad \text{and} \quad \max_{0\le n\le N} \left(g(n, X_n) - M_n^\Theta - \varepsilon_n\right)$$

are square-integrable too. Hence, one obtains from the central limit theorem that for large K_L, $\hat{L}$ is approximately normally distributed with mean L and variance $\hat{\sigma}_L^2/K_L$ for

$$\hat{\sigma}_L^2 = \frac{1}{K_L - 1} \sum_{k=1}^{K_L} \left(g(l^k, y_{l^k}^k) - \hat{L}\right)^2.$$

8. Note that for the right side of (17) to be a valid upper bound, it is sufficient that $\mathbb{E}[\varepsilon_n \mid \mathcal{F}_n] = 0$ for all n. In particular, $\varepsilon_0, \varepsilon_1, \dots, \varepsilon_N$ can have any arbitrary dependence structure.
9. Again, since H_n^Θ, M_n^Θ and C_n^Θ are given by conditional expectations, they are only specified up to $\mathbb{P}$-almost sure equality.
10. The two conditional expectations are equal since $(X_n)_{n=0}^N$ is Markov and τ_{n+1}^Θ only depends on $(X_{n+1}, \dots, X_{N-1})$.
11. The realizations $(z_n^k)_{n=0}^N$, $k = 1, \dots, K_U$, must be drawn independently of $(x_n^k)_{n=0}^N$, $k = 1, \dots, K$, so that our estimate of the upper bound does not depend on the samples used to train the stopping decisions. But theoretically, they can depend on $(y_n^k)_{n=0}^N$, $k = 1, \dots, K_L$, without affecting the unbiasedness of the estimate $\hat{U}$ or the validity of the confidence interval derived in Subsection 3.3 below.
12. More precisely, the tuples $(\tilde{z}_{n+1}^{k,j}, \dots, \tilde{z}_N^{k,j})$, $j = 1, \dots, J$, are simulated according to $p_n(z_n^k, \cdot)$, where p_n is a transition kernel from $\mathbb{R}^d$ to $\mathbb{R}^{(N-n)d}$ such that $p_n(X_n, B) = \mathbb{P}[(X_{n+1}, \dots, X_N) \in B \mid X_n]$ $\mathbb{P}$-almost surely for all Borel sets $B \subseteq \mathbb{R}^{(N-n)d}$. We generate them independently of each other across j and k. On the other hand, the continuation paths starting from z_n^k do not have to be drawn independently of those starting from $z_{n'}^k$ for $n \ne n'$.
13. See condition (3).

So, for every $\alpha \in (0,1]$,

$$\left[\hat{L} - z_{\alpha/2}\frac{\hat{\sigma}_L}{\sqrt{K_L}}\,,\,\infty\right)$$

is an asymptotically valid $1-\alpha/2$ confidence interval for L, where $z_{\alpha/2}$ is the $1-\alpha/2$ quantile of the standard normal distribution. Similarly,

$$\left(-\infty\,,\,\hat{U} + z_{\alpha/2}\frac{\hat{\sigma}_U}{\sqrt{K_U}}\right] \quad \text{with} \quad \hat{\sigma}_U^2 = \frac{1}{K_U - 1}\sum_{k=1}^{K_U}\left(\max_{0\le n\le N}\left(g\left(n, z_n^k\right) - M_n^k\right) - \hat{U}\right)^2,$$

is an asymptotically valid $1-\alpha/2$ confidence interval for U. It follows that for every constant $\varepsilon > 0$, one has

$$\begin{aligned}&\mathbb{P}\left[V_0 < \hat{L} - z_{\alpha/2}\frac{\hat{\sigma}_L}{\sqrt{K_L}} \quad \text{or} \quad V_0 > \hat{U} + z_{\alpha/2}\frac{\hat{\sigma}_U}{\sqrt{K_U}}\right]\\ &\le \mathbb{P}\left[L < \hat{L} - z_{\alpha/2}\frac{\hat{\sigma}_L}{\sqrt{K_L}}\right] + \mathbb{P}\left[U > \hat{U} + z_{\alpha/2}\frac{\hat{\sigma}_U}{\sqrt{K_U}}\right] \le \alpha + \varepsilon\end{aligned}$$

as soon as K_L and K_U are large enough. In particular,

$$\left[\hat{L} - z_{\alpha/2}\frac{\hat{\sigma}_L}{\sqrt{K_L}}\,,\,\hat{U} + z_{\alpha/2}\frac{\hat{\sigma}_U}{\sqrt{K_U}}\right] \tag{19}$$

is an asymptotically valid $1-\alpha$ confidence interval for V_0.

4. Examples

In this section we test[14] our method on three examples: the pricing of a Bermudan max-call option, the pricing of a callable multi barrier reverse convertible and the problem of optimally stopping a fractional Brownian motion.

4.1. Bermudan Max-Call Options

Bermudan max-call options are one of the most studied examples in the numerics literature on optimal stopping problems (see, e.g., Longstaff and Schwartz, 2001; Rogers, 2002; García, 2003; Boyle et al., 2003; Haugh and Kogan, 2004; Broadie and Glasserman, 2004; Andersen and Broadie, 2004; Broadie and Cao, 2008; Berridge and Schumacher, 2008; Belomestny, 2011, 2013; Jain and Oosterlee, 2015; Lelong, 2016). Their payoff depends on the maximum of d underlying assets.

Assume the risk-neutral dynamics of the assets are given by a multi-dimensional Black–Scholes model[15]

$$S_t^i = s_0^i \exp\left(\left[r - \delta_i - \sigma_i^2/2\right]t + \sigma_i W_t^i\right), \quad i = 1, 2, \ldots, d, \tag{20}$$

14. All computations were performed in single precision (float32) on a NVIDIA GeForce GTX 1080 GPU with 1974 MHz core clock and 8 GB GDDR5X memory with 1809.5 MHz clock rate. The underlying system consisted of an Intel Core i7-6800K 3.4 GHz CPU with 64 GB DDR4-2133 memory running Tensorflow 1.11 on Ubuntu 16.04.

15. We make this assumption so that we can compare our results to those obtained with different methods in the literature. But our approach works for any asset dynamics as long as it can efficiently be simulated.

for initial values $s_0^i \in (0,\infty)$, a risk-free interest rate $r \in \mathbb{R}$, dividend yields $\delta_i \in [0,\infty)$, volatilities $\sigma_i \in (0,\infty)$ and a d-dimensional Brownian motion W with constant instantaneous correlations[16] $\rho_{ij} \in \mathbb{R}$ between different components W^i and W^j. A Bermudan max-call option on $S^1, S^2, \ldots, S^d$ has payoff $\left(\max_{1\le i\le d} S_t^i - K\right)^+$ and can be exercised at any point of a time grid $0 = t_0 < t_1 < \cdots < t_N$. Its price is given by

$$\sup_\tau \mathbb{E}\left[e^{-r\tau}\left(\max_{1\le i\le d} S_\tau^i - K\right)^+\right],$$

where the supremum is over all S-stopping times taking values in $\{t_0, t_1, \ldots, t_N\}$ (see, e.g., Schweizer, 2002). Denote $X_n^i = S_{t_n}^i$, $n = 0, 1, \ldots, N$, and let $\mathcal{T}$ be the set of X-stopping times. Then the price can be written as $\sup_{\tau\in\mathcal{T}} \mathbb{E}\, g(\tau, X_\tau)$ for

$$g(n,x) = e^{-rt_n}\left(\max_{1\le i\le d} x^i - K\right)^+,$$

and it is straight-forward to simulate $(X_n)_{n=0}^N$.

In the following we assume the time grid to be of the form $t_n = nT/N$, $n = 0, 1, \ldots, N$, for a maturity $T > 0$ and $N+1$ equidistant exercise dates. Even though $g(n, X_n)$ does not carry any information that is not already contained in X_n, our method worked more efficiently when we trained the optimal stopping decisions on Monte Carlo simulations of the $d+1$-dimensional Markov process $(Y_n)_{n=0}^N = (X_n, g(n, X_n))_{n=0}^N$ instead of $(X_n)_{n=0}^N$. Since Y_0 is deterministic, we first trained stopping times $\tau_1 \in \mathcal{T}_1$ of the form

$$\tau_1 = \sum_{n=1}^N n f^{\theta_n}(Y_n)\prod_{j=1}^{n-1}(1 - f^{\theta_j}(Y_k))$$

for $f^{\theta_N} \equiv 1$ and $f^{\theta_1}, \ldots, f^{\theta_{N-1}} \colon \mathbb{R}^{d+1} \to \{0,1\}$ given by (8) with $I = 2$ and $q_1 = q_2 = d+40$. Then we determined our candidate optimal stopping times as

$$\tau^\Theta = \begin{cases} 0 & \text{if } f_0 = 1\\ \tau_1 & \text{if } f_0 = 0\end{cases}$$

for a constant $f_0 \in \{0,1\}$ depending[17] on whether it was optimal to stop immediately at time 0 or not (see Remark 6 above).

It is straight-forward to simulate from model (20). We conducted 3,000$+d$ training steps, in each of which we generated a batch of 8,192 paths of $(X_n)_{n=0}^N$. To estimate the lower bound L we simulated $K_L = 4{,}096{,}000$ trial paths. For our estimate of the upper bound U, we produced $K_U = 1{,}024$ paths $(z_n^k)_{n=0}^N$, $k = 1, \ldots, K_U$, of $(X_n)_{n=0}^N$ and $K_U \times J$ realizations $(v_n^{k,j})_{n=1}^N$, $k = 1, \ldots, K_U$, $j = 1, \ldots, J$, of $(W_{t_n} - W_{t_{n-1}})_{n=1}^N$ with $J = 16{,}384$. Then for all n and k, we generated the i-th component of the j-th continuation path departing from z_n^k according to

$$z_m^{i,k,j} = z_n^{i,k}\exp\left(\left[r - \delta_i - \sigma_i^2/2\right](m-n)\Delta t + \sigma_i[v_{n+1}^{i,k,j} + \cdots + v_m^{i,k,j}]\right), \quad m = n+1, \ldots, N.$$

16. That is, $\mathbb{E}[(W_t^i - W_s^i)(W_t^j - W_s^i)] = \rho_{ij}(t-s)$ for all $i \ne j$ and $s < t$.

17. In fact, in none of the examples in this paper it is optimal to stop at time 0. So $\tau^\Theta = \tau_1$ in all these cases.

Symmetric case
We first considered the special case, where $s_0^i = s_0$, $\delta_i = \delta$, $\sigma_i = \sigma$ for all $i = 1, \dots, d$, and $\rho_{ij} = \rho$ for all $i \neq j$. Our results are reported in Table 1.

Asymmetric case
As a second example, we studied model (20) with $s_0^i = s_0$, $\delta_i = \delta$ for all $i = 1, 2, \dots, d$, and $\rho_{ij} = \rho$ for all $i \neq j$, but different volatilities $\sigma_1 < \sigma_2 < \cdots < \sigma_d$. For $d \leq 5$, we chose the specification $\sigma_i = 0.08 + 0.32 \times (i-1)/(d-1)$, $i = 1, 2, \dots, d$. For $d > 5$, we set $\sigma_i = 0.1 + i/(2d)$, $i = 1, 2, \dots, d$. The results are given in Table 2.

4.2. Callable Multi Barrier Reverse Convertibles

A MBRC is a coupon paying security that converts into shares of the worst-performing of d underlying assets if a prespecified trigger event occurs. Let us assume that the price of the i-th underlying asset in percent of its starting value follows the risk-neutral dynamics

$$S_t^i = \begin{cases} 100 \exp\big([r - \sigma_i^2/2]t + \sigma_i W_t^i\big) & \text{for } t \in [0, T_i) \\ 100(1-\delta_i) \exp\big([r - \sigma_i^2/2]t + \sigma_i W_t^i\big) & \text{for } t \in [T_i, T] \end{cases} \tag{21}$$

for a risk-free interest rate $r \in \mathbb{R}$, volatility $\sigma_i \in (0, \infty)$, maturity $T \in (0, \infty)$, dividend payment time $T_i \in (0, T)$, dividend rate $\delta_i \in [0, \infty)$ and a d-dimensional Brownian motion W with constant instantaneous correlations $\rho_{ij} \in \mathbb{R}$ between different components W^i and W^j.

Let us consider a MBRC that pays a coupon c at each of N time points $t_n = nT/N$, $n = 1, 2, \dots, N$, and makes a time-T payment of

$$G = \begin{cases} F & \text{if } \min_{1 \leq i \leq d} \min_{1 \leq m \leq M} S_{u_m}^i > B \text{ or } \min_{1 \leq i \leq d} S_T^i > K \\ \min_{1 \leq i \leq d} S_T^i & \text{if } \min_{1 \leq i \leq d} \min_{1 \leq m \leq M} S_{u_m}^i \leq B \text{ and } \min_{1 \leq i \leq d} S_T^i \leq K, \end{cases}$$

where $F \in [0, \infty)$ is the nominal amount, $B \in [0, \infty)$ a barrier, $K \in [0, \infty)$ a strike price and u_m the end of the m-th trading day. Its value is

$$\sum_{n=1}^{N} e^{-rt_n} c + e^{-rT} \mathbb{E}\, G \tag{22}$$

and can easily be estimated with a standard Monte Carlo approximation.

A callable MBRC can be redeemed by the issuer at any of the times $t_1, t_2, \dots, t_{N-1}$ by paying back the notional. To minimize costs, the issuer will try to find a $\{t_1, t_2, \dots, T\}$-valued stopping time such that

$$\mathbb{E}\left[\sum_{n=1}^{\tau} e^{-rt_n} c + 1_{\{\tau < T\}} e^{-r\tau} F + 1_{\{\tau = T\}} e^{-rT} G\right]$$

is minimal.

Let $(X_n)_{n=1}^N$ be the $d+1$-dimensional Markov process given by $X_n^i = S_{t_n}^i$ for $i = 1, \dots, d$, and

$$X_n^{d+1} := \begin{cases} 1 & \text{if the barrier has been breached before or at time } t_n \\ 0 & \text{else.} \end{cases}$$

500	110	601.261	504.9	603.243	760.8	602.252	[600.988, 603.707]	

Table 2: Summary results for max-call options on d asymmetric assets for parameter values of $r = 5\%$, $\delta = 10\%$, $\rho = 0$, $K = 100$, $T = 3$, $N = 9$. t_L is the number of seconds it took to train τ^Θ and compute $\hat{L}$. t_U is the computation time for $\hat{U}$ in seconds. 95% CI is the 95% confidence interval (19). The last column reports the 95% confidence intervals of Broadie and Cao (2008).

Then the issuer's minimization problem can be written as

$$\inf_{\tau \in \mathcal{T}} \mathbb{E}\, g(\tau, X_\tau), \tag{23}$$

where $\mathcal{T}$ is the set of all X-stopping times and

$$g(n,x) = \begin{cases} \sum_{m=1}^{n} e^{-rt_m} c + e^{-rt_n} F & \text{if } 1 \leq n \leq N-1 \text{ or } x^{d+1} = 0 \\ \sum_{m=1}^{N} e^{-rt_m} c + e^{-rt_N} h(x) & \text{if } n = N \text{ and } x^{d+1} = 1, \end{cases}$$

where

$$h(x) = \begin{cases} F & \text{if } \min_{1 \leq i \leq d} x^i > K \\ \min_{1 \leq i \leq d} x^i & \text{if } \min_{1 \leq i \leq d} x^i \leq K. \end{cases}$$

Since the issuer cannot redeem at time 0, we trained stopping times of the form

$$\tau^\Theta = \sum_{n=1}^{N} n f^{\theta_n}(Y_n) \prod_{j=1}^{n-1} (1 - f^{\theta_j}(Y_k)) \in \mathcal{T}_1$$

for $f^{\theta_N} \equiv 1$ and $f^{\theta_1}, \ldots, f^{\theta_{N-1}} \colon \mathbb{R}^{d+1} \to \{0,1\}$ given by (8) with $I = 2$ and $q_1 = q_2 = d+40$. Since (23) is a minimization problem, τ^Θ yields an upper bound and the dual method a lower bound.

We simulated the model (21) like (20) in Subsection 4.1 with the same number of trials except that here we used the lower number $J = 1{,}024$ to estimate the dual bound. Numerical results are reported in Table 3.

4.3. Optimally Stopping a Fractional Brownian Motion

A fractional Brownian motion with Hurst parameter $H \in (0,1]$ is a continuous centered Gaussian process $(W_t^H)_{t \geq 0}$ with covariance structure

$$\mathbb{E}[W_t^H W_s^H] = \frac{1}{2}\left(t^{2H} + s^{2H} - |t-s|^{2H}\right);$$

see, e.g., Mandelbrot and Van Ness (1968) or Samoradnitsky and Taqqu (1994). For $H = 1/2$, W^H is a standard Brownian motion. So, by the optional stopping theorem, one has $\mathbb{E}\, W_\tau^{1/2} = 0$ for every $W^{1/2}$-stopping time τ bounded above by a constant; see, e.g., Grimmett and Stirzaker (2001). However, for $H \neq 1/2$, the increments of W^H are correlated – positively for $H \in (1/2, 1]$ and negatively for $H \in (0, 1/2)$. In both cases, W^H is neither a martingale nor a Markov process, and there exist bounded W^H-stopping times τ such that $\mathbb{E}\, W_\tau^H > 0$; see, e.g., Kulikov and Gusyatnikov (2016) for two classes of simple stopping rules $0 \leq \tau \leq 1$ and estimates of the corresponding expected values $\mathbb{E}\, W_\tau^H$.

To approximate the supremum

$$\sup_{0 \leq \tau \leq 1} \mathbb{E}\, W_\tau^H \tag{24}$$

Table 3: Summary results for callable MBRCs with d underlying assets for $F = K = 100$, $B = 70$, $T = 1$ year (= 252 trading days), $N = 12$, $c = 7/12$, $\delta_i = 5\%$, $T_i = 1/2$, $r = 0$, $\sigma_i = 0.2$ and $\rho_{ij} = \rho$ for $i \neq j$. t_U is the number of seconds it took to train τ^Θ and compute $\hat{U}$. t_L is the number of seconds it took to compute $\hat{L}$. The last column lists fair values of the same MBRCs without the callable feature. We estimated them by averaging 4,096,000 Monte Carlo samples of the payoff. This took between 5 (for $d = 2$) and 44 (for $d = 30$) seconds.

over all W^H-stopping times $0 \leq \tau \leq 1$, we denote $t_n = n/100$, $n = 0, 1, 2, \ldots, 100$, and introduce the 100-dimensional Markov process $(X_n)_{n=0}^{100}$ given by

$$\begin{aligned} X_0 &= (0, 0, \ldots, 0) \\ X_1 &= (W^H_{t_1}, 0, \ldots, 0) \\ X_2 &= (W^H_{t_2}, W^H_{t_1}, 0, \ldots, 0) \\ &\vdots \\ X_{100} &= (W^H_{t_{100}}, W^H_{t_{99}}, \ldots, W^H_{t_1}). \end{aligned}$$

The discretized stopping problem

$$\sup_{\tau \in \mathcal{T}} \mathbb{E}\, g(X_\tau), \tag{25}$$

where $\mathcal{T}$ is the set of all X-stopping times and $g\colon \mathbb{R}^{100} \to \mathbb{R}$ the projection $(x^1, \ldots, x^{100}) \mapsto x^1$, approximates (24) from below.

We computed estimates of (25) for $H \in \{0.01, 0.05, 0.1, 0.15, \ldots, 1\}$ by training networks of the form (8) with depth $I = 2$, $d = 100$ and $q_1 = q_2 = 140$. To simulate the vector $Y = (W^H_{t_n})_{n=0}^{100}$, we used the representation $Y = BZ$, where BB^T is the Cholesky decomposition of the covariance matrix of Y and Z a 100-dimensional random vector with independent standard normal components. We carried out 6,000 training steps with a batch size of 2,048. To estimate the lower bound L we generated $K_L = 4{,}096{,}000$ simulations of Z. For our estimate of the upper bound U, we first simulated $K_U = 1{,}024$ realizations v^k,

$k = 1, \ldots, K_U$ of Z and set $w^k = Bv^k$. Then we produced another $K_U \times J$ simulations $\tilde{v}^{k,j}$, $k = 1, \ldots, K_U$, $j = 1, \ldots, J$, of Z, and generated for all n and k, continuation paths starting from

$$z^k_n = (w^k_n, \ldots, w^k_1, 0, \ldots, 0)$$

according to

$$\tilde{z}^{k,j}_m = (\tilde{w}^{k,j}_m, \ldots, \tilde{w}^{k,j}_{n+1}, w^k_n, \ldots, w^k_1, 0 \ldots, 0), \quad m = n+1, \ldots, 100,$$

with

$$\tilde{w}^{k,j}_l = \sum_{i=1}^{n} B_{li} v^k_i + \sum_{i=n+1}^{l} B_{li} \tilde{v}^{k,j}_i, \quad l = n+1, \ldots, m.$$

For $H \in \{0.01, ..., 0.4\} \cup \{0.6, ..., 1.0\}$, we chose $J = 16{,}384$, and for $H \in \{0.45, 0.5, 0.55\}$, $J = 32{,}768$. The results are listed in Table 4 and depicted in graphical form in Figure 1. Note that for $H = 1/2$ and $H = 1$, our 95% confidence intervals contain the true values, which in these two cases, can be calculated exactly. As mentioned above, $W^{1/2}$ is a Brownian motion, and therefore, $\mathbb{E}\, W^{1/2}_\tau = 0$ for every $(W^{1/2}_{t_n})_{n=0}^{100}$-stopping time τ. On the other hand, one has[18] $W^1_t = tW^1_1$, $t \geq 0$. So, in this case, the optimal stopping time is given[18] by

$$\tau = \begin{cases} 1 & \text{if } W^1_{t_1} > 0 \\ t_1 & \text{if } W^1_{t_1} \leq 0, \end{cases}$$

and the corresponding expectation by

$$\mathbb{E}\, W^1_\tau = \mathbb{E}\Big[W^1_1 1_{\{W^1_{t_1} > 0\}} - W^1_{t_1} 1_{\{W^1_{t_1} \leq 0\}}\Big] = 0.99\, \mathbb{E}\Big[W^1_1 1_{\{W^1_1 > 0\}}\Big] = 0.99/\sqrt{2\pi} = 0.39495...$$

Moreover, it can be seen that for $H \in (1/2, 1)$, our estimates are up to three times higher than the expected payoffs generated by the heuristic stopping rules of Kulikov and Gusyatnikov (2016). For $H \in (0, 1/2)$, they are up to five times higher.

Abstract

Algorithmic decision making is employed in an increasing number of real-world applications to aid human decision making. While it has shown considerable promise in terms of improved decision accuracy, in some scenarios, its outcomes have been also shown to impose an unfair (dis)advantage on people from certain social groups (*e.g.*, women, blacks). In this context, there is a need for computational techniques to limit unfairness in algorithmic decision making. In this work, we take a step forward to fulfill that need and introduce a flexible constraint-based framework to enable the design of fair margin-based classifiers. The main technical innovation of our framework is a general and intuitive measure of decision boundary unfairness, which serves as a tractable proxy to several of the most popular computational definitions of unfairness from the literature. Leveraging our measure, we can reduce the design of fair margin-based classifiers to adding tractable constraints on their decision boundaries. Experiments on multiple synthetic and real-world datasets show that our framework is able to successfully limit unfairness, often at a small cost in terms of accuracy.

Keywords: Supervised learning, margin-based classifiers, fairness, discrimination, disparate impact.

1. Introduction

Algorithmic decision making systems are assisting, or in some cases even replacing, human decision making in an increasing number of application domains. Examples of such domains include credit approval (FICO, 2017), criminal risk assessment (Perry, 2013), hiring (Posse, 2016; Taylor, 2016) and education (Romero and Ventura, 2011). By leveraging vast amounts of (training) data and modern machine learning methods, algorithmic decision systems are able to provide highly accurate predictions, often surpassing even human accuracy (Kleinberg et al., 2017a; Liu et al., 2017). However, recent studies by civil organizations (Bhandari, 2016), governments (Podesta et al., 2014; Muñoz et al., 2016), and researchers (Sweeney, 2013) alike have raised concerns about the unfairness of these algorithmic decision systems towards people from certain social groups (*e.g.*, women, blacks). Importantly, in various countries, these concerns are often grounded on anti-discrimination laws which prohibit unfair treatment of people based on one or more *sensitive features*, such as gender and race (Civil Rights Act, 1964; Barocas and Selbst, 2016).

To overcome the above concerns, a number of recent studies in the emerging field of ethical machine learning have proposed mechanisms to ensure that algorithmic decision systems do not lead to unfair outcomes (Kamiran and Calders, 2009; Corbett-Davies et al., 2017; Hardt et al., 2016; Feldman et al., 2015; Zafar et al., 2017b,a; Zemel et al., 2013; Dwork et al., 2012). In doing so, they have have measured the (un)fairness of a decision making process through the distribution of its outcomes among people from different sensitive feature groups (*e.g.*, men, women). More specifically, they have typically adopted one of the following three notions of (un)fairness: [1]

— ***Disparate treatment***: a decision making process suffers from disparate treatment if its outcomes change based on a change in the sensitive feature value with all other features being the same.

— ***Disparate impact***: a decision making process suffers from disparate impact if it grants disproportionately large fraction of beneficial (or positive classification) outcomes to certain sensitive feature groups (*e.g.*, men, women).

— ***Disparate mistreatment***: a decision making process suffers from disparate mistreatment if its accuracy (or error rate) is different for different sensitive feature groups.

However, the mechanisms proposed in prior studies typically lack flexibility with respect to one or more of the following aspects:

(i) They are specifically designed for only one of the above notions. As a consequence, they cannot accommodate more than one of them *simultaneously* (*e.g.*, disparate treatment and disparate impact).

(ii) They cannot ensure fairness with respect to multiple sensitive features *simultaneously* (*e.g.*, gender and race).

(iii) They are only limited to a narrow range of classification models (*e.g.*, logistic regression).

In this work, we propose a flexible framework to design a variety of fair classifiers that do not suffer from the above limitations. More specifically, for any convex boundary-based classifier, our framework defines an intuitive measure of decision boundary unfairness: the covariance between the sensitive features and the signed distance between the (non sensitive) feature vectors and the decision boundary of the classifier for a subset the subjects which depends on the fairness notion of interest. This measure can be readily incorporated into the classifier formulation in the form of convex of convex-concave constraints, one per sensitive feature or fairness notion, which can be efficiently solved using well-known meth-

. A preliminary version of this work appeared in Zafar et al. (2017a,b).

. Open-source code implementation is available at: http://fate-computing.mpi-sws.org/.

1. As we later discuss in Section 2, the same notions are often referred to by different names by different studies.

ods (Boyd and Vandenberghe, 2004; Shen et al., 2016). Interestingly, our framework also allows for a dual formulation which maximizes fairness under accuracy constraints and, as a consequence, it ensures compliance with the business necessity clause of anti-discrimination doctrines (Barocas and Selbst, 2016), an aspect not considered by prior studies. Experiments on multiple synthetic and real-world datasets show that our framework is able to successfully limit disparate treatment, disparate impact and disparate mistreatment, often at a small cost in terms of accuracy, and it provides more flexibility than state-of-the-art methods (see Table 3).

The rest of the paper is organized as follows. First, we first revisit several well-known fairness notions from the literature and discuss the type of scenarios each notion is most suitable for (Section 2). Then, we formally state the problem of fairness-aware classification (Section 3) and describe our framework (Section 4). Later, we experiment with several datasets, including comparisons with related methodologies to highlight the effectiveness of our mechanism in controlling unfairness (Section 5). Finally, we conclude with a review of the related work on unfairness in algorithmic decision making and strategies proposed to mitigate unfairness (Section 6) as well as a discussion of future work (Section 7).

2. Background on different notions of (un)fairness

In this section, we revisit three of the most popular notions of fairness used in the machine learning literature: disparate treatment, disparate impact, and disparate mistreatment. More specifically, we first elaborate on each of these notions separately in the context of automated decision making systems and then highlight the differences between them.

— **Disparate treatment.** A decision making system suffers from disparate treatment if it provides different outputs for groups of people with the same (or similar) values of non-sensitive features but different values of sensitive features (Barocas and Selbst, 2016). In other words, (partly) basing the decision outcomes on the sensitive feature value amounts to disparate treatment. [2] This notion has been also referred to as *direct discrimination* (Pedreschi et al., 2008).

Figure 1 provides examples of binary classifiers with and without disparate treatment in a *stop-and-frisk* (Gelman et al., 2007) application. In all cases, the classifiers need to decide whether to stop a pedestrian on the suspicion of possessing an illegal weapon based on a set of features such as bulge in clothing and proximity to a crime scene. The "ground truth" on whether a pedestrian actually possesses an illegal weapon is also shown. We deem classifiers $\mathbf{C_2}$ and $\mathbf{C_3}$ to be unfair due to disparate treatment since $\mathbf{C_2}$'s ($\mathbf{C_3}$'s) decisions for *Male* 1 and *Female* 1 (*Male* 2 and *Female* 2) are different even though they have the

2. Technically, the disparate treatment doctrine tries to counter *explicit* as well as *intentional* discrimination (Barocas and Selbst, 2016). It follows from the specification of disparate treatment that a decision maker with an intent to discriminate could try to disadvantage a group with a certain sensitive feature value (*e.g.*, a specific race group) not by *explicitly using the sensitive feature* itself, but by *intentionally basing decisions on a correlated feature* (*e.g.*, the non-sensitive feature location might be correlated with the sensitive feature race). This practice is often referred to as *redlining* in the US anti-discrimination law and also qualifies as disparate treatment (Gano, 2017). However, such hidden intentional disparate treatment maybe be hard to detect, and some authors argue that disparate impact might be a more suitable framework for detecting such covert discrimination (Siegel, 2014). Hence, in this paper, when discussing disparate treatment, we will focus only on *explicit* disparate treatment.

User Attributes			Ground Truth (Has Weapon)	Classifier's Decision to Stop		
Sensitive	Non-sensitive					
Gender	Clothing Bulge	Prox. Crime		C_1	C_2	C_3
Male 1	1	1	✓	1	1	1
Male 2	1	0	✓	1	1	0
Male 3	0	1	✗	1	0	1
Female 1	1	1	✓	1	0	1
Female 2	1	0	✗	1	1	1
Female 3	0	0	✓	0	1	0

	Disp. Treat.	Disp. Imp.	Disp. Mist.
$\mathbf{C_1}$	✗	✓	✓
$\mathbf{C_2}$	✓	✗	✓
$\mathbf{C_3}$	✓	✗	✗

Figure 1: Decisions of three fictitious classifiers ($\mathbf{C_1}$, $\mathbf{C_2}$ and $\mathbf{C_3}$) on whether (1) or not (0) to stop a pedestrian on the suspicion of possessing an illegal weapon. Gender is a sensitive attribute, whereas the other two attributes (suspicious bulge in clothing and proximity to a crime scene) are non-sensitive. Ground truth on whether the person is actually in possession of an illegal weapon is also shown. $\mathbf{C_1}$ has no disparate treatment. It has disparate impact because it stops disproportional fractions of males and females (1.0 and 0.66, respectively). It has disparate mistreatment because it has different false negative rates (0.0 and 0.5, respectively) for males and females. $\mathbf{C_2}$ has disparate treatment since, of a male and a female having same non-sensitive attributes (Male 1 and Female 1), it stops only one of them. It has no disparate impact, since it stops equal fractions (0.66) of males and females. It has disparate mistreatment because of different false positive (0.0 and 1.0, respectively) and false negative rates (0.0 and 0.5, respectively) for males and females. $\mathbf{C_3}$ has disparate treatment and no disparate impact. It has no disparate mistreatment because both false positive rates (1.0) and false negative rates (0.5) for males and females are equal.

same values of non-sensitive features. On the other hand, classifier $\mathbf{C_1}$ does not suffer from disparate treatment since, with all feature values except gender being equal, its decisions are identical.

— **Disparate impact.** A decision making system suffers from disparate impact if it provides outputs that benefit (hurt) a group of people sharing a value of a sensitive feature more frequently than other groups of people (Barocas and Selbst, 2016). This notion has been also referred to as *statistical parity* (Corbett-Davies et al., 2017) or *demographic parity* (Dwork et al., 2012).

Similarly as with disparate treatment, Figure 1 provides examples of binary classifiers with and without disparate impact in a stop-and-frisk application. Under the assumption that a pedestrian benefits from a decision of not being stopped, we deem classifier $\mathbf{C_1}$ to be unfair due to disparate impact because the fraction of males and females that were stopped are different (1.0 and 0.66, respectively), where the latter benefit from a decision of not being stopped. On the other hand, classifiers $\mathbf{C_2}$ and $\mathbf{C_3}$ do not suffer from disparate impact because the fractions of males and females that were stopped are the same (0.66).

— **Disparate mistreatment.** A decision making system suffers from disparate mistreatment if it achieves different classification accuracy (or conversely, error rate) for groups of people sharing different values of a sensitive feature (Zafar et al., 2017a). This notion has been also referred to as *equality of opportunity* (Hardt et al., 2016) and *predictive equality* (Corbett-Davies et al., 2017). In addition to overall classification accuracy, this notion has been also particularized to *different types of misclassifications*, *i.e.*, false positives and

false negatives. In that context, a decision making system suffers from disparate mistreatment if individual misclassification rates (*e.g.*, false positive rate, false negative rate) are different for groups of people sharing different values of a sensitive feature.

In Figure 1, we deem classifiers $\mathbf{C_1}$ and $\mathbf{C_2}$ to be unfair due to disparate mistreatment since their rate of erroneous decisions for males and females are different: $\mathbf{C_1}$ has different false negative rates for males and females (0.0 and 0.5, respectively), whereas $\mathbf{C_2}$ has different false positive rates (0.0 and 1.0) as well as different false negative rates (0.0 and 0.5) for males and females. Finally, classifier $\mathbf{C_3}$ does not suffer from disparate mistreatment because it has the same false negative and false positive rates for males and females.

Differences among (un)fairness notions. The above (un)fairness notions account for either *direct* (or *intentional*) and *indirect* (or *unintentional*) unfairness (Altman, 2016). More specifically, *disparate treatment accounts for direct unfairness*, *i.e.*, a situation where a decision making process directly (or intentionally) uses the sensitive feature information to put a group of people sharing a value of a sensitive feature on relative disadvantage. In this way, removing disparate treatment corresponds to a very intuitive notion of fairness: two otherwise similar persons should not be treated differently solely because of the difference in gender. On the other hand, *disparate impact and disparate mistreatment account for indirect unfairness*, *i.e.*, a situation where the decision making process can indirectly or unintentionally leverage the correlation between sensitive features and class labels to put a sensitive feature group at relative disadvantage (through low beneficial outcome rate under disparate impact and through high misclassification rate under disparate mistreatment).

Moreover, while disparate impact and disparate mistreatment both account for indirect unfairness, their application scenarios strongly differ. Unlike in the case of disparate mistreatment, the notion of disparate impact is independent of the "ground truth" information about the decisions, *i.e.*, whether or not the decisions are correct or valid. Thus, the notion of disparate impact is particularly appealing in application scenarios where ground truth information for decisions does not exist and the historical decisions used during training are not reliable and thus cannot be trusted (Barocas and Selbst, 2016). Unreliability of historical decisions for automated decision making systems is particularly concerning in scenarios like recruiting or loan approvals, where biased judgments by humans in the past may be used when training classifiers for the future. In such application scenarios, it is hard to distinguish correct and incorrect decisions, making it hard to assess or use disparate mistreatment as a notion of fairness.

However, in scenarios where ground truth information for decisions can be obtained, disparate impact can be quite misleading as a notion of fairness. That is, in scenarios where the validity of decisions can be reliably ascertained, it would be possible to distinguish disproportionality in decision outcomes for sensitive groups that arises from justifiable reasons (*e.g.*, qualification of the candidates) and disproportionality that arises for non-justifiable reasons (*i.e.*, discrimination against certain groups). By requiring decision outcomes to be proportional, disparate impact risks introducing reverse-discrimination against qualified candidates. Such practices have previously been deemed unlawful (*e.g.*, *Ricci vs. DeStefano, 2009*). In contrast, when the correctness of decisions can be determined, disparate mistreatment can not only be accurately assessed, but also avoids reverse-discrimination, making it a more appealing notion of fairness (Hardt et al., 2016; Zafar et al., 2017a).

3. Fairness in classification

In a binary classification task, [3] one aims to find a mapping function $f(\boldsymbol{x})$ between user feature vectors $\boldsymbol{x} \in \mathbb{R}^d$ and class labels $y \in \{-1, 1\}$. This task is achieved by utilizing a training set, $\mathcal{D} = \{(\boldsymbol{x}_i, y_i)\}_{i=1}^N$, to construct a mapping that works *well* on an *unseen* test set. For decision boundary-based classifiers, finding this mapping usually reduces to building a decision boundary in feature space that separates users in the training set according to their class labels. One typically looks for a decision boundary, defined by a set of parameters $\boldsymbol{\theta}^*$, that achieves the greatest classification accuracy in a test set, by minimizing a loss function over a training set $L(\boldsymbol{\theta})$, *i.e.*, $\boldsymbol{\theta}^* = \text{argmin}_{\boldsymbol{\theta}} L(\boldsymbol{\theta})$. Then, given an *unseen* feature vector $\boldsymbol{x}_i$ from the test set, the classifier predicts the label $\hat{y}_i = f_{\boldsymbol{\theta}}(\boldsymbol{x}_i) = 1$ if $d_{\boldsymbol{\theta}^*}(\boldsymbol{x}_i) \geq 0$ and $\hat{y}_i = -1$ otherwise, where $d_{\boldsymbol{\theta}^*}(\boldsymbol{x})$ denotes the signed distance from the feature vector $\boldsymbol{x}$ to the decision boundary.

In the context of fairness in binary classification, each user also has an associated sensitive feature $z \in \{0, 1\}$[4] and the goal is finding a mapping (or decision boundary) that provides both accurate predictions and fairness guarantees. More formally, we can express the absence of disparate treatment, disparate impact and disparate mistreatment in a binary classifier as follows:

1. No disparate treatment. A binary classifier does not suffer from disparate treatment if the probability that the classifier outputs a specific value of $\hat{y}$ given a feature vector $\boldsymbol{x}$ does not change after observing the sensitive feature z, *i.e.*,

$$P(\hat{y}|\boldsymbol{x}, z) = P(\hat{y}|\boldsymbol{x}). \tag{3.1}$$

2. No disparate impact. A binary classifier does not suffer from disparate impact if the probability that a classifier assigns a user to the positive class, $\hat{y} = 1$, is the same for both values of the sensitive feature z, *i.e.*,

$$P(\hat{y} = 1|z = 0) = P(\hat{y} = 1|z = 1). \tag{3.2}$$

Notice that neither disparate treatment nor disparate impact depend on the subjects' ground truth label (y).

3. No disparate mistreatment. A binary classifier does not suffer from disparate mistreatment if the misclassification rates for different groups of people having different values of the sensitive feature z are the same. Table 1 describes various ways of measuring misclassification rates. Specifically, misclassification rates can be measured as fractions over the *class distribution in the ground truth labels*, *i.e.*, as false positive and false negative rates, or over the *class distribution in the predicted labels*, *i.e.*, as false omission and false discovery rates. [5] Consequently, the absence of disparate mistreatment in a binary classification task

3. For simplicity, we consider binary classification tasks in this work. However, our ideas can be easily extended to m-ary classification.
4. For ease of exposition, we assume z to be unidimensional and binary, however, our setup can be easily generalized to categorical as well as multiple sensitive features.
5. In prediction tasks where a positive prediction entails a large cost (*e.g.*, cost involved in the treatment of a disease), one might be more interested in measuring error rates as fractions over the class distribution

		Predicted Label		
		$\hat{y}=1$	$\hat{y}=-1$	
True Label	$y=1$	True positive	False negative	$P(\hat{y}\neq y \vert y=1)$ False Negative Rate
	$y=-1$	False positive	True negative	$P(\hat{y}\neq y \vert y=-1)$ False Positive Rate
		$P(\hat{y}\neq y \vert \hat{y}=1)$ False Discovery Rate	$P(\hat{y}\neq y \vert \hat{y}=-1)$ False Omission Rate	$P(\hat{y}\neq y)$ Overall Misclass. Rate

Table 1: In addition to the overall misclassification rate, error rates can be measured in two different ways: false negative rate and false positive rate are defined as fractions over the *class distribution in the ground truth labels*, or true labels. On the other hand, false discovery rate and false omission rate are defined as fractions over the *class distribution in the predicted labels*.

can be specified with respect to the different misclassification measures as follows:

— ***Overall misclassification rate (OMR)***:

$$P(\hat{y}\neq y|z=0) = P(\hat{y}\neq y|z=1), \tag{3.3}$$

— ***False positive rate (FPR)***:

$$P(\hat{y}\neq y|y=-1,z=0) = P(\hat{y}\neq y|y=-1,z=1), \tag{3.4}$$

— ***False negative rate (FNR)***:

$$P(\hat{y}\neq y|y=1,z=0) = P(\hat{y}\neq y|y=1,z=1), \tag{3.5}$$

— ***False omission rate (FOR)***:

$$P(\hat{y}\neq y|\hat{y}=-1,z=0) = P(\hat{y}\neq y|\hat{y}=-1,z=1), \tag{3.6}$$

— ***False discovery rates (FDR)***:

$$P(\hat{y}\neq y|\hat{y}=1,z=0) = P(\hat{y}\neq y|\hat{y}=1,z=1). \tag{3.7}$$

Remarks. We would like to note that the formal criteria to avoid disparate impact and disparate mistreatment, as given by Eqs.(3.2–3.7), represent equality in certain *group-conditional probabilities* for the two sensitive feature groups, *i.e.*, $P(\cdot|z=0)$ and $P(\cdot|z=1)$. For example, the disparate impact criterion in Eq. (3.2) requires the group-conditional probabilities of positive class outcomes to be the same for users with $z=0$ and $z=1$, whereas the disparate mistreatment criterion in Eq. (3.3) requires the group-conditional probabilities of users being misclassified to be the same. In Section 4, we will show that these group-conditional equalities can be relaxed by various decision boundary covariances to facilitate efficient training of fair classifiers.
