Finally, we would also like to highlight that some recent works have explored the cost of achieving fairness in a decision making process and pointed out some inherent tensions between fairness and accuracy (Chouldechova, 2016; Corbett-Davies et al., 2017; Kleinberg et al., 2017b; Menon and Williamson, 2017). In fact, this cost can become prohibitively high if one aims to achieve multiple fairness criteria *simultaneously*. For example, Chouldechova (2016) and Kleinberg et al. (2017b) have recently shown that, when the fraction of users with positive class labels differ between members of different sensitive attribute value groups, it is impossible to construct classifiers that are equally *well-calibrated* (where well-calibration essentially measures the false discovery and false omission rates of a classifier) and also satisfy the equal false positive and false negative rate criterion (except for a "dumb", or null, classifier that assign all examples to a single class). Pleiss et al. (2017) further expand on this impossibility result. These results suggest that satisfying all five criteria of disparate mistreatment (Table 1) simultaneously is impossible when the underlying distribution of data is different for different groups. Similarly, Kleinberg et al. (2017b) show that when the fraction of users with positive class labels differ between members of different sensitive attribute value groups, it is impossible to satisfy disparate impact and disparate mistreatment simultaneously—where disparate mistreatment is defined in terms of false positive and false negative rates, in terms of false discovery and false omission rates, or both. However, in practice, it may still be interesting to explore the best, even if imperfect, extent of fairness a classifier can achieve.

4. Our fair classification framework

In this section, we present our framework to design boundary-based classifiers which are free of disparate treatment, disparate impact and disparate mistreatment, as defined in Section 3.

4.1. Fairness criteria as constraints during training

To design a *fair* convex boundary-based classifier, one can think of including fairness constraints during training. More specifically, minimizing the corresponding loss function under fairness constraints, *i.e.*,

$$\begin{aligned} &\text{minimize} && L(\boldsymbol{\theta}) && \} \text{ Classifier loss function} \\ &\text{subject to} && P(.|z=0) = P(.|z=1) && \} \text{ Fairness constraints,} \end{aligned} \tag{4.1}$$

where the probabilities in the constraint(s) can be replaced with the respective disparate impact and disparate mistreatment criteria in Eqs. (3.2–3.7). Here, note that, if $z \notin \boldsymbol{x}$ (*i.e.*, $\boldsymbol{x}$ and z consist of disjoint feature sets), the resulting classifier does not suffer from disparate treatment since z is not used during test (*i.e.*, at decision time).

Due to its flexibility, the above formulation exhibits several advantages:

(i) it can satisfy both disparate impact and (any version of) disparate mistreatment by including the corresponding constraints. Disparate treatment can be achieved by excluding the sensitive features z from $\boldsymbol{x}$ so that they are not used during test.

in the *predicted labels*, rather than over the class distribution in the *ground truth labels*, *e.g.*, to ensure that the false discovery rates, instead of false positive rates, for all groups are the same.

(ii) it can accommodate any convex decision boundary based classifier.
(iii) it can ensure fairness with respect to multiple sensitive features (*e.g.*, gender, race) by including constraints for each sensitive feature separately.

Unfortunately, solving the formulation given by Eq. (4.1) is very challenging. First, for many such classifiers (*e.g.*, SVM), the probabilities in Eqs. (3.2–3.7) are a non-convex function of the classifier parameters $\boldsymbol{\theta}$, therefore leading to non-convex formulations, which are difficult to solve efficiently. Second, as long as the user feature vectors lie on the same side of the decision boundary, the probabilities are invariant to changes in the decision boundary. In other words, the probabilities are functions having saddle points. The presence of saddle points furthers complicate the procedure for solving non-convex optimization problems (Dauphin et al., 2014).

To overcome these challenges, we next introduce a relaxation of the group-conditional probability constraints given by Eqs. (3.2–3.7) using a novel covariance measure of decision boundary unfairness.

4.2. Designing fair classifiers using decision boundary covariances

In this section, we first introduce our covariance measure of decision boundary unfairness in the context of disparate impact, use this measure to design classifiers free of disparate impact, and then generalize our measure to disparate mistreatment.

4.2.1. Disparate impact

We measure the decision boundary (un)fairness due to disparate impact by means of the covariance between the users' sensitive attribute z and the signed distance from the users' feature vectors to the decision boundary $d_{\boldsymbol{\theta}}(\boldsymbol{x})$, *i.e.*,

$$\text{Cov}_{DI}(z, d_{\boldsymbol{\theta}}(\boldsymbol{x})) = \mathbb{E}[(z-\bar{z})d_{\boldsymbol{\theta}}(\boldsymbol{x})] - \mathbb{E}[(z-\bar{z})]\bar{d}_{\boldsymbol{\theta}}(\boldsymbol{x}) \approx \frac{1}{N}\sum_{(\boldsymbol{x},z)\in\mathcal{D}} (z-\bar{z})\, d_{\boldsymbol{\theta}}(\boldsymbol{x}), \quad (4.2)$$

where $\mathbb{E}[(z-\bar{z})]\bar{d}_{\boldsymbol{\theta}}(\boldsymbol{x})$ cancels out since $\mathbb{E}[(z-\bar{z})] = 0$. Note that, if a decision boundary satisfies Eq. (3.2), *i.e.*, $P(d_{\boldsymbol{\theta}}(\boldsymbol{x}) \geq 0|z=0) = P(d_{\boldsymbol{\theta}}(\boldsymbol{x}) \geq 0|z=1)$, then the (empirical) covariance defined above will be (approximately) zero (for a sufficiently large training set)[6]. Moreover, in contrast to the group-conditional probabilities given by Eq. (3.2) the decision boundary covariance in Eq. (4.2) is a convex function with respect to the decision boundary parameters $\boldsymbol{\theta}$ because $d_{\boldsymbol{\theta}}(\boldsymbol{x})$ is convex with respect to $\boldsymbol{\theta}$ for all linear, convex boundary-based classifiers. [7] Hence, it can be easily included in the formulation of these classifiers without increasing the complexity of their training.

6. Note that the converse is not true, that is why we call our covariance measure a proxy.
7. For non-linear convex boundary-based classifiers like non-linear SVM, the equivalent of $d_{\boldsymbol{\theta}}(\boldsymbol{x})$ (via Representer Theorem) is still convex in the corresponding reproducing kernel Hilbert space as we will discuss shortly.

More specifically, to train a classifier free of disparate impact, one can replace the (intractable) constraint in Eq. (4.1) by an alternative constraint including the decision boundary covariance constraint as follows:

$$\begin{aligned} &\text{minimize} && L(\boldsymbol{\theta}) \\ &\text{subject to} && \tfrac{1}{N}\textstyle\sum_{(\boldsymbol{x},z)\in\mathcal{D}} (z-\bar{z})\, d_{\boldsymbol{\theta}}(\boldsymbol{x}) \leq c, \\ &&& \tfrac{1}{N}\textstyle\sum_{(\boldsymbol{x},z)\in\mathcal{D}} (z-\bar{z})\, d_{\boldsymbol{\theta}}(\boldsymbol{x}) \geq -c, \end{aligned} \quad (4.3)$$

where $c \in \mathbb{R}^+$ is a given threshold, which trades off accuracy and unfairness due to disparate impact. Furthermore, note that since the above optimization problem is convex, our scheme ensures that the trade-off between the classifier loss function and decision boundary covariance is Pareto optimal.

When considering *multiple sensitive features* (*e.g.*, gender, race), one can include constraints for each sensitive feature separately. For *polyvalent sensitive features* having $k \geq 2$ values, one can first convert the sensitive feature into k binary sensitive features using one hot encoding, and then add constraints for each of the k sensitive features. To avoid "fairness-gerrymandering" (Kearns et al., 2018) when considering multiple sensitive features, one could construct all possible combinations of the sensitive feature values (*e.g.*, white man, black women) and add constraints for each combination separately.

4.2.2. Disparate Mistreatment

We can naturally extend our covariance measure to (un)fairness due to disparate mistreatment. More specifically, for the case disparate mistreatment with respect to the overall misclassification rate, we compute the covariance between the users' sensitive attributes and the signed distance between the feature vectors of *misclassified* users and the classifier decision boundary, *i.e.*,

$$\text{Cov}_{OMR}(z, g_{\boldsymbol{\theta}}(y,\boldsymbol{x})) = \mathbb{E}[(z-\bar{z})(g_{\boldsymbol{\theta}}(y,\boldsymbol{x}) - \bar{g}_{\boldsymbol{\theta}}(y,\boldsymbol{x}))] \approx \frac{1}{N}\sum_{(\boldsymbol{x},y,z)\in\mathcal{D}} (z-\bar{z})\, g_{\boldsymbol{\theta}}(y,\boldsymbol{x}), \quad (4.4)$$

where $g_{\boldsymbol{\theta}}(y,\boldsymbol{x}) = \min(0, y d_{\boldsymbol{\theta}}(\boldsymbol{x}))$ and the term $\mathbb{E}[(z-\bar{z})]\bar{g}_{\boldsymbol{\theta}}(\boldsymbol{x})$ cancels out since $\mathbb{E}[(z-\bar{z})] = 0$. As in the case of disparate impact, if a decision boundary satisfies Eq. (3.3), then the (empirical) covariance defined above will be (approximately) zero (for a sufficiently large training set) and we can train a classifier free of disparate mistreatment with respect to overall misclassification rate by replacing the (intractable) constraint in Eq. (4.1) by an alternative constraint as follows:

$$\begin{aligned} &\text{minimize} && L(\boldsymbol{\theta}) \\ &\text{subject to} && \tfrac{1}{N}\textstyle\sum_{(\boldsymbol{x},y,z)\in\mathcal{D}} (z-\bar{z})\, g_{\boldsymbol{\theta}}(y,\boldsymbol{x}) \leq c, \\ &&& \tfrac{1}{N}\textstyle\sum_{(\boldsymbol{x},y,z)\in\mathcal{D}} (z-\bar{z})\, g_{\boldsymbol{\theta}}(y,\boldsymbol{x}) \geq -c, \end{aligned} \quad (4.5)$$

where $c \in \mathbb{R}^+$ is a given threshold, which trades off accuracy and unfairness due to disparate mistreatment. Similarly, we can define the above covariance measure for disparate mistreatment with respect to false positive rates, false negative rates, false omission rates

or false discovery rates. For example, for false positive rates, one needs to consider the set of *misclassified* users with (ground-truth) negative labels ($\mathcal{D}^-$), *i.e.*,

$$\text{Cov}_{FPR}(z, g_{\boldsymbol{\theta}}(y, \boldsymbol{x})) \approx \frac{1}{N^-} \sum_{(\boldsymbol{x},y,z)\in\mathcal{D}^-} (z - \bar{z})\, g_{\boldsymbol{\theta}}(y, \boldsymbol{x}), \tag{4.6}$$

where N^- represents the size of $\mathcal{D}^-$.

In contrast with the covariance measure in the case of disparate impact, defined by Eq. (4.2), the above covariance measures are not convex. Fortunately, the covariance constraints for disparate mistreatment with respect to overall misclassification rates, false positive rates and false negative rates can be easily converted into convex-concave constraints, which can be handled efficiently (Shen et al., 2016), as follows. Consider the constraints in Eq. (4.5), *i.e.*,

$$\sum_{(\boldsymbol{x},y,z)\in\mathcal{D}} (z - \bar{z})\, g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) \sim c,$$

where $\sim$ denotes '$\geq$' and '$\leq$' and, without loss of generality, we just left out the constant term $\frac{1}{N}$. Then, we can split the sum in the above expression into two terms:

$$\sum_{(\boldsymbol{x},y)\in\mathcal{D}_0} (0 - \bar{z})\, g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) + \sum_{(\boldsymbol{x},y)\in\mathcal{D}_1} (1 - \bar{z})\, g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) \sim c, \tag{4.7}$$

where $\mathcal{D}_0$ and $\mathcal{D}_1$ are the subsets of the training dataset $\mathcal{D}$ taking values $z = 0$ and $z = 1$, respectively. Define $N_0 = |\mathcal{D}_0|$ and $N_1 = |\mathcal{D}_1|$, then one can write $\bar{z} = \frac{(0\times N_0)+(1\times N_1)}{N} = \frac{N_1}{N}$ and rewrite Eq. (4.7) as:

$$\frac{-N_1}{N} \sum_{(\boldsymbol{x},y)\in\mathcal{D}_0} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) + \frac{N_0}{N} \sum_{(\boldsymbol{x},y)\in\mathcal{D}_1} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) \sim c,$$

which, given that $g_{\boldsymbol{\theta}}(y, \boldsymbol{x})$ is convex in $\boldsymbol{\theta}$, results into a convex-concave (or, difference of convex) function. Finally, we can rewrite the problem defined by (4.5) as:

$$\begin{aligned} &\text{minimize} && L(\boldsymbol{\theta}) \\ &\text{subject to} && \tfrac{-N_1}{N} \textstyle\sum_{(\boldsymbol{x},y)\in\mathcal{D}_0} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) + \tfrac{N_0}{N} \sum_{(\boldsymbol{x},y)\in\mathcal{D}_1} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) \leq c \\ &&& \tfrac{-N_1}{N} \textstyle\sum_{(\boldsymbol{x},y)\in\mathcal{D}_0} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) + \tfrac{N_0}{N} \sum_{(\boldsymbol{x},y)\in\mathcal{D}_1} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) \geq -c, \end{aligned} \tag{4.8}$$

which is a Disciplined Convex-Concave Program (DCCP) for any convex loss $L(\boldsymbol{\theta})$, and can be efficiently solved using well-known heuristics (Shen et al., 2016). Note that the non-convexity of the formulation in Eq. (4.8) implies that the resulting tradeoff between the classifier loss function and decision boundary covariance is not guarenteed to be Pareto optimal. This is in contrast with the convex formulation in Eq. (4.3). However, as we show via comparisons with related methods in Section 5.2.2, Eq. (4.8) can still lead to competitive results in comparison with the state-of-the-art.

Proceeding similarly, we can convert the covariance constraints for disparate mistreatment with respect to false positive rates and false negative rates to convex-concave constraints. For example, Eq. (4.1) can be rewritten to impose equality in false positive rates

as:

$$\begin{aligned} &\text{minimize} && L(\boldsymbol{\theta}) \\ &\text{subject to} && \tfrac{-N_1^-}{N^-} \textstyle\sum_{(\boldsymbol{x},y)\in\mathcal{D}_0^-} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) + \tfrac{N_0^-}{N^-} \sum_{(\boldsymbol{x},y)\in\mathcal{D}_1^-} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) \leq c \\ &&& \tfrac{-N_1^-}{N^-} \textstyle\sum_{(\boldsymbol{x},y)\in\mathcal{D}_0^-} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) + \tfrac{N_0^-}{N^-} \sum_{(\boldsymbol{x},y)\in\mathcal{D}_1^-} g_{\boldsymbol{\theta}}(y, \boldsymbol{x}) \geq -c, \end{aligned} \tag{4.9}$$

where $\mathcal{D}_i^-$ is the subset of the training data with $z = i$ and $y = -1$, and $N_i^- = |\mathcal{D}_i^-|$. Note that unlike in Zafar et al. (2017a), we define the false positive rate covariance (Eq. (4.6)) only over the ground truth negative dataset instead of the whole dataset. In cases where $\frac{N_0^-}{N_0} \neq \frac{N_1^-}{N_1}$ (or in other words, the base-rates are different for the two sensitive feature groups), the false positive rate covariance as defined by Zafar et al. (2017a) would not fully remove disparate mistreatment.

Finally, while the covariance constraints for disparate mistreatment with respect to false omission and false discovery rates can be readily defined, the corresponding constraints cannot be easily converted into convex-concave constraints. Handling such constraints efficiently is left as an interesting venue for future work.

4.3. Accounting for the business necessity clause

In the previous section, we have used covariance constraints to design classifiers that maximize accuracy under fairness constraints. However, if the underlying correlation between the class labels and the sensitive attributes in the training set is very high, enforcing these constraints may results in underwhelming performance (accuracy) and thus be unacceptable in terms of business objectives. This is particularly concerning in the case of disparate impact, where a "business necessity" clause has been argued for—an employer would need to ensure that the decision making causes *least possible* disparate impact under the given performance (accuracy) constraints (Barocas and Selbst, 2016).

Fortunately we can account for the above mentioned "business necessity" clause in disparate impact using an alternative formulation that maximizes fairness (minimizes disparate impact) subject to accuracy constraints. More specifically, we can find the decision boundary parameters $\boldsymbol{\theta}$ by minimizing the corresponding (absolute) decision boundary covariance over the training set under constraints on the classifier loss function, *i.e.*:

$$\begin{aligned} &\text{minimize} && |\tfrac{1}{N} \textstyle\sum_{i=1}^{N} (z_i - \bar{z})\, d_{\boldsymbol{\theta}}(\boldsymbol{x}_i)| \\ &\text{subject to} && L(\boldsymbol{\theta}) \leq (1+\gamma) L(\boldsymbol{\theta}^*), \end{aligned} \tag{4.10}$$

where $L(\boldsymbol{\theta}^*)$ denotes the optimal loss over the training set provided by the unconstrained classifier and $\gamma \geq 0$ specifies the maximum additional loss with respect to the loss provided by the unconstrained classifier. Here, we can ensure maximum fairness with no loss in accuracy by setting $\gamma = 0$.

Remarkably, in many classifiers, including logistic regression and SVMs, the loss function (or the dual of the loss function) is additive over the points in the training set, *i.e.*, $L(\boldsymbol{\theta}) = \sum_{i=1}^{N} L_i(\boldsymbol{\theta})$, where $L_i(\boldsymbol{\theta})$ is the individual loss associated with the i-th point in the training set. Moreover, the individual loss $L_i(\boldsymbol{\theta})$ typically tells us how *close* the predicted label $f(\boldsymbol{x}_i)$ is to the true label y_i, by means of the signed distance to the decision boundary. Therefore, one may think of incorporating loss constraints for a certain set of users, and consequently, prevent individual users originally classified as positive (by the unconstrained

classifier) from being classified as negative by the constrained classifier. To do so, we find the decision boundary parameters $\boldsymbol{\theta}$ as:

$$\begin{array}{ll} \text{minimize} & |\frac{1}{N}\sum_{i=1}^{N}(z_i - \bar{z})\, d_{\boldsymbol{\theta}}(\boldsymbol{x}_i)| \\ \text{subject to} & L_i(\boldsymbol{\theta}) \leq (1+\gamma_i) L_i(\boldsymbol{\theta}^*) \quad \forall i \in \{1,\ldots,N\}, \end{array} \tag{4.11}$$

where $L_i(\boldsymbol{\theta}^*)$ is the individual loss associated to the i-th user in the training set provided by the unconstrained classifier and $\gamma_i \geq 0$ is her allowed additional loss.

The problem formulation in Eq. (4.11) could be used to ensure that certain set of users who are correctly classified by the unconstrained classifier are not misclassified by the fairness-constrained classifier (*e.g.*, to make sure that applying fairness constraints does not lead to egregious misclassification of certain users). However, note that, in comparison with Eq. (4.10), Eq. (4.11) involves a tighter set of constraints—it aims to bound *individual* users' losses as opposed to the *aggregate* loss over all the users. As a result, Eq. (4.11) could lead to larger drops in accuracy for the same level of fairness (refer to Figure 10 for an example).

One could also think of extending the formulation of disparate mistreatment-free classification given by Eq. (4.8) to include a similar business necessity clause. However, such a formulation would result in an optimization problem—with a convex-concave objective and convex constraints—that is currently not supported by the standard convex-concave solvers (Shen et al., 2016). Extending these solvers to cater to such problems, or reformulating the optimization problem and solving it with alternative optimizers (*e.g.*, using evolutionary multi-objective optimization as in Quadrianto and Sharmanska (2017)) would be an interesting direction for future work.

4.4. Examples

In this section, we illustrate how to design fair logistic regression classifiers and linear and nonlinear SVMs using our covariance measures.

Logistic regression free of disparate impact. In logistic regression classifiers, one maps the feature vectors $\boldsymbol{x}_i$ to the class labels y_i by means of a probability distribution:

$$p(y=1|\boldsymbol{x},\boldsymbol{\theta}) = \frac{1}{1+e^{-\boldsymbol{\theta}^T\boldsymbol{x}}}, \tag{4.12}$$

where $\boldsymbol{\theta}$ is obtained by solving a maximum likelihood problem over the training set, *i.e.*, $\boldsymbol{\theta}^* = \text{argmin}_{\boldsymbol{\theta}} -\sum_{(\boldsymbol{x},y)\in\mathcal{D}} \log p(y|\boldsymbol{x},\boldsymbol{\theta})$. Thus, the corresponding loss function is given by $-\sum_{(\boldsymbol{x},y)\in\mathcal{D}} \log p(y|\boldsymbol{x},\boldsymbol{\theta})$, and the problem defined by Eq. (4.3) adopts the following form:

$$\left.\begin{array}{ll} \text{minimize} & -\sum_{(\boldsymbol{x},y)\in\mathcal{D}} \log p(y|\boldsymbol{x},\boldsymbol{\theta}) \end{array}\right\} \text{Logistic regression formulation}$$
$$\left.\begin{array}{ll} \text{subject to} & \frac{1}{N}\sum_{(\boldsymbol{x},z)\in\mathcal{D}}(z-\bar{z})\,\boldsymbol{\theta}^T\boldsymbol{x} \leq c, \\ & \frac{1}{N}\sum_{(\boldsymbol{x},z)\in\mathcal{D}}(z-\bar{z})\,\boldsymbol{\theta}^T\boldsymbol{x} \geq -c. \end{array}\right\} \text{Disparate impact constraints} \tag{4.13}$$

Linear SVM free of disparate mistreatment. A linear SVM distinguishes among classes using a linear hyperplane $\boldsymbol{\theta}^T\boldsymbol{x} = 0$. In this case, the parameter vector $\boldsymbol{\theta}$ of the *fair* linear SVM can be found by solving the problem defined by Eq. (4.8), which becomes the following quadratic program with convex-concave constraints:

$$\left.\begin{array}{ll} \text{minimize} & \|\boldsymbol{\theta}\|^2 + C\sum_{i=1}^{N}\xi_i \\ \text{subject to} & y_i\boldsymbol{\theta}^T\boldsymbol{x}_i \geq 1-\xi_i, \forall i \in \{1,\ldots,N\} \\ & \xi_i \geq 0, \forall i \in \{1,\ldots,N\}, \end{array}\right\} \text{SVM formulation}$$
$$\left.\begin{array}{l} \frac{-N_1}{N}\sum_{(\boldsymbol{x},y)\in\mathcal{D}_0}\min(0, y\boldsymbol{\theta}^T\boldsymbol{x}) + \frac{N_0}{N}\sum_{(\boldsymbol{x},y)\in\mathcal{D}_1}\min(0, y\boldsymbol{\theta}^T\boldsymbol{x}) \leq c, \\ \frac{-N_1}{N}\sum_{(\boldsymbol{x},y)\in\mathcal{D}_0}\min(0, y\boldsymbol{\theta}^T\boldsymbol{x}) + \frac{N_0}{N}\sum_{(\boldsymbol{x},y)\in\mathcal{D}_1}\min(0, y\boldsymbol{\theta}^T\boldsymbol{x}) \geq -c, \end{array}\right\} \begin{array}{c}\text{Disparate} \\ \text{mistreatment} \\ \text{constraints}\end{array} \tag{4.14}$$

where $\boldsymbol{\theta}$ and ξ are the variables, $\|\boldsymbol{\theta}\|^2$ corresponds to the boundary between the *support vectors* assigned to different classes, and $C\sum_{i=1}^{n}\xi_i$ penalizes the number of data points falling inside the boundary.

Nonlinear SVM free of disparate impact. In a nonlinear SVM, the decision boundary takes the form $\boldsymbol{\theta}^T\Phi(\boldsymbol{x}) = 0$, where $\Phi(\cdot)$ is a nonlinear transformation that maps every feature vector $\boldsymbol{x}$ into a higher dimensional transformed feature space. Similarly as in the case of a linear SVM, one may think of finding the parameter vector $\boldsymbol{\theta}$ by solving a constrained quadratic program, similar to the one defined by Eq. (4.14). However, the dimensionality of the transformed feature space can be large, or even infinite, making the corresponding optimization problem difficult to solve. Fortunately, we can leverage the *kernel trick* (Schölkopf and Smola, 2002) both in the original optimization problem and the fairness inequalities, and resort instead to the dual form of the problem, which can be solved efficiently. In particular, the dual form is given by (for conciseness, we use the dual form notation of Gentle et al. (2012)):

$$\left.\begin{array}{ll} \text{minimize} & \frac{1}{2}\boldsymbol{\alpha}^T\mathbf{G}\boldsymbol{\alpha} - \mathbf{1}^T\boldsymbol{\alpha} \\ \text{subject to} & 0 \leq \boldsymbol{\alpha} \leq C, \\ & \boldsymbol{y}^T\boldsymbol{\alpha} = 0, \end{array}\right\} \text{SVM formulation}$$
$$\left.\begin{array}{l} \frac{1}{N}\sum_{(\boldsymbol{x},z)\in\mathcal{D}}(z-\bar{z})\, d_{\boldsymbol{\alpha}}(\boldsymbol{x}) \leq c, \\ \frac{1}{N}\sum_{(\boldsymbol{x},z)\in\mathcal{D}}(z-\bar{z})\, d_{\boldsymbol{\alpha}}(\boldsymbol{x}) \geq -c, \end{array}\right\} \begin{array}{c}\text{Disparate impact} \\ \text{constraints}\end{array} \tag{4.15}$$

where $\boldsymbol{\alpha} = [\alpha_1, \alpha_2, \ldots, \alpha_N]^T$ are the dual variables, $\boldsymbol{y} = [y_1, y_2, \ldots, y_N]^T$ are the class labels, $\boldsymbol{G}$ is the $N \times N$ Gram matrix with $\boldsymbol{G}_{i,j} = y_i y_j k(\boldsymbol{x}_i, \boldsymbol{x}_j)$, and the kernel function $k(\boldsymbol{x}_i, \boldsymbol{x}_j) = \langle\phi(\boldsymbol{x}_i), \phi(\boldsymbol{x}_j)\rangle$ denotes the inner product between a pair of transformed feature vectors. Here, $d_{\boldsymbol{\alpha}}(\boldsymbol{x}_i) = \sum_{j=1}^{N}\alpha_j y_j k(\boldsymbol{x}_i, \boldsymbol{x}_j)$ can still be interpreted as a signed distance to the decision boundary in the transformed feature space.

5. Evaluation

In this section, we first experiment with synthetic datasets in which we simulate various kind of unfairness and analyze both quantitatively and qualitatively the effectiveness of our framework at designing fair classifiers. We then evaluate the performance of our framework on several real-world datasets in comparison with multiple baselines.

Across this section, we quantify disparate impact (Eq. 3.2) as the absolute difference between the positive class probability for the sensitive feature groups with $z = 0$ and $z = 1$, as various prior studies (Corbett-Davies et al., 2017; Calders and Verwer, 2010; Menon and Williamson, 2017), *i.e.*,

$$DI = \Big|P(\hat{y} = 1|z = 0) - P(\hat{y} = 1|z = 1)\Big|, \tag{5.1}$$

where a value of DI closer to zero denotes a smaller degree of disparate impact. Similarly, we quantify disparate mistreatment with respect to false positive rates and false negative rates (Eqs. (3.4-3.5)) as the difference between false positive (negative) rate probabilities, *i.e.*,

$$DM_{FPR} = P(\hat{y} \neq y|z = 0, y = -1) - P(\hat{y} \neq y|z = 1, y = -1), \tag{5.2}$$
$$DM_{FNR} = P(\hat{y} \neq y|z = 0, y = 1) - P(\hat{y} \neq y|z = 1, y = 1), \tag{5.3}$$

where the closer the values of DM_{FPR} and DM_{FNR} to 0, the lower the degree of disparate mistreatment. Note that unlike in the case of disparate impact in Eq. (5.1), we do not use the absolute difference while quantifying disparate mistreatment. As we later show in Section 5.1.2, the (in)equality in the signs of DM_{FPR} and DM_{FNR} carries significant consequences when considering disparate mistreatment w.r.t. false positive rate and false negative rate simultaneously. In such cases, the sign of the differences should also be taken into account.

5.1. Experiments on synthetic data

In this section, we first generate synthetic data where a classifier optimizing for accuracy would lead to disparate impact and then generate data where the accuracy-optimizing classifier would lead to disparate mistreatment. In both the cases, we *simultaneously* control for disparate treatment as well, that is, the classifiers do not leverage sensitive feature during decision time in either of the cases.

5.1.1. Mitigating disparate impact

To simulate different degrees of disparate impact in classification outcomes, we generate two synthetic datasets with different levels of correlation between a single, binary sensitive attribute and class labels. Specifically, we generate 4,000 binary class labels uniformly at random and assign a 2-dimensional user feature vector per label by drawing samples from two different Gaussian distributions:

$$p(\boldsymbol{x}|y = 1) = \mathcal{N}([2; 2], [5,\ 1; 1,\ 5])$$
$$p(\boldsymbol{x}|y = -1) = \mathcal{N}([-2; -2], [10,\ 1; 1,\ 3]).$$

Then, we draw each user's sensitive attribute z from a Bernoulli distribution: $p(z = 1) = p(\boldsymbol{x}'|y = 1)/(p(\boldsymbol{x}'|y = 1) + p(\boldsymbol{x}'|y = -1))$, where $\boldsymbol{x}' = [\cos(\phi),\ -\sin(\phi); \sin(\phi),\ \cos(\phi)]\boldsymbol{x}$ is simply a rotated version of the feature vector, $\boldsymbol{x}$. We generate two datasets with different values for the parameter ϕ ($\pi/4$ and $\pi/8$), which controls the correlation between the sensitive attribute, z, and the class labels, y (and hence, the resulting degree of disparate impact). Here, the closer ϕ is to zero, the higher the correlation between z and y.

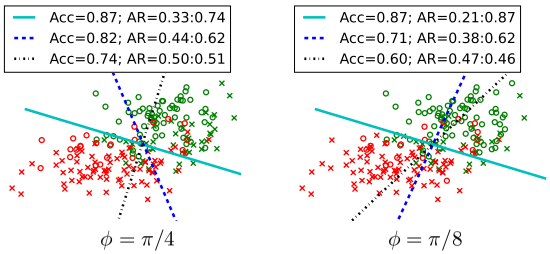

Figure 2: [Disparate impact constraints] Performance of different (unconstrained and constrained) classifiers along with their accuracy (Acc) and positive class acceptance rates (AR) for groups $z = 0$ (crosses) and $z = 1$ (circles). Green points represent examples with $y = 1$ and red points represent example with $y = -1$. The solid lines show the decision boundaries for logistic regression classifiers without fairness constraints. The dashed lines show the decision boundaries for logistic regression classifiers trained to maximize accuracy under fairness constraints (Eq. (4.13)). Each column corresponds to a dataset with different correlation value between sensitive attribute values and class labels.

Next, we train logistic regression classifiers optimizing for accuracy on both the datasets. The accuracy of the classifiers in both cases is 0.87 (note that the datasets only differ in terms of the correlation between z and y). However, the classifiers lead to $DI = |0.33 - 0.74| = 0.41$ and $DI = |0.21 - 0.87| = 0.66$ on datasets with $\phi = \pi/4$ and $\phi = \pi/8$, respectively. To overcome the unfairness, we train logistic regression classifiers with disparate impact constraints (Eq. 4.13) on both datasets.

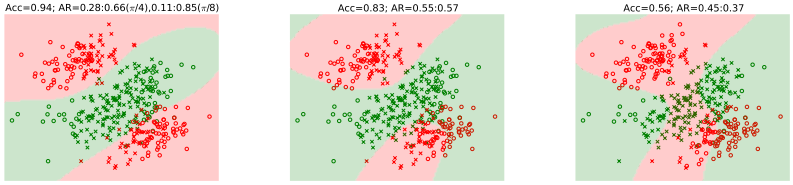

Figure 2 shows the decision boundaries provided by the classifiers for two (successively decreasing) covariance thresholds, c. We compare these boundaries against the unconstrained decision boundary (solid line). As expected, given the data generation process, fairness constraints map into a rotation of the decision boundary (dashed lines), which is greater as we decrease threshold value c or increase the correlation in the original data (from $\phi = \pi/4$ to $\phi = \pi/8$). This movement of the decision boundaries shows that our fairness constraints are successfully undoing (albeit in a highly controlled setting) the rotations we used to induce disparate impact in the dataset. Moreover, a smaller covariance threshold (a larger rotation) leads to a more fair solution, although, it comes at a larger cost in accuracy.

Next, we illustrate how the decision boundary of an non-linear classifier, a SVM with radial basis function (RBF) kernel, changes under disparate impact constraints (Eq. (4.15)). To this end, we generate 4,000 user binary class labels uniformly at random and assign a 2-dimensional user feature vector per label by drawing samples from

$$p(\boldsymbol{x}|y = 1, \beta) = \beta\mathcal{N}([2; 2], [5\ 1; 1\ 5]) + (1 - \beta)\mathcal{N}([-2; -2], [10\ 1; 1\ 3])$$
$$p(\boldsymbol{x}|y = -1, \beta) = \beta\mathcal{N}([4; -4], [4\ 4; 2\ 5]) + (1 - \beta)\mathcal{N}([-4; 6], [6\ 2; 2\ 3])$$

where $\beta \in \{0, 1\}$ is sampled from Bernoulli(0.5). Then, we generate each user's sensitive attribute z by applying the same rotation as described earlier.

Figure 3 shows the decision boundaries provided by the SVM that maximizes accuracy under fairness constraints with $c = 0$ for two different correlation values: $\phi = \pi/4$ and

(a) Unconstrained (b) $\phi = \pi/4$ (c) $\phi = \pi/8$

Figure 3: [Disparate impact constraints] Decision boundaries for SVM classifier with RBF Kernel trained without fairness constraints (left) and with fairness constraints (middle and right) on two synthetic datasets. Also shown are the classification accuracy (Acc) and acceptance rate (AR) for each group.

$\phi = \pi/8$, in comparison with the unconstrained SVM. We observe that, in this case, the decision boundaries provided by the constrained SVMs are very different to the decision boundary provided by the unconstrained SVM, and are not just simple shifts or rotations of the latter.

5.1.2. Mitigating disparate mistreatment

In a manner similar to the previous section, we now experiment with synthetic datasets where training classifiers optimizing for accuracy would lead to disparate mistreatment. However, disparate mistreatment can arise in multiple different ways, as detailed below. To study these different situations, we first start with a simple scenario in which the classifier is unfair in terms of *only* false positive rate *or* false negative rate. Then, we focus on a more complex scenario in which the classifier is unfair in terms of *both*.

Disparate mistreatment on *only* false positive rate *or* false negative rate. The first scenario considers a case where a classifier maximizing accuracy leads to disparate mistreatment in terms of only the false positive rate (false negative rate), while being fair with respect to false negative rate (false positive rate), *i.e.*, $DM_{FPR} \neq 0$ and $DM_{FNR} = 0$ (or, alternatively, $DM_{FPR} = 0$ and $DM_{FNR} \neq 0$).

To simulate this scenario, we generate 10,000 binary class labels ($y \in \{-1, 1\}$) and corresponding sensitive attribute values ($z \in \{0, 1\}$), both uniformly at random, and assign a two-dimensional user feature vector ($\boldsymbol{x}$) to each of the points. To ensure different distributions for negative classes of the two sensitive attribute value groups (so that the two groups have different false positive rates), the user feature vectors are sampled from the following distributions (we sample 2500 points from each distribution):

$$
\begin{aligned}
p(\boldsymbol{x}|z=0, y=1) &= \mathcal{N}([2,2],[3,1;1,3]) \\
p(\boldsymbol{x}|z=1, y=1) &= \mathcal{N}([2,2],[3,1;1,3]) \\
p(\boldsymbol{x}|z=0, y=-1) &= \mathcal{N}([1,1],[3,3;1,3]) \\
p(\boldsymbol{x}|z=1, y=-1) &= \mathcal{N}([-2,-2],[3,1;1,3]).
\end{aligned}
$$

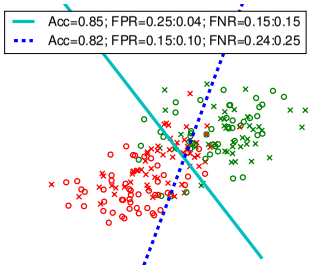

Figure 4: [Disparate mistreatment constraints] The figure shows the original decision boundary (solid line) and fair decision boundary (dashed line), along with corresponding accuracy and false positive rates for groups $z = 0$ (crosses) and $z = 1$ (circles). Fairness constraints cause the original decision boundary to rotate such that previously misclassified subjects with $z = 0$ are moved into the negative class (decreasing false positives), while well-classified subjects with $z = 1$ are moved into the positive class (increasing false positives), leading to equal false positive rates for both groups.

Next, we train a logistic regression classifier optimizing for accuracy on this data. The classifier is able to achieve an accuracy of 0.85. However, due to difference in feature distributions for the two sensitive attribute groups, it achieves $DM_{FNR} = 0.15 - 0.15 = 0$ and $DM_{FPR} = 0.25 - 0.04 = 0.21$, which constitutes a clear case of disparate mistreatment in terms of false positive rate. We then train a logistic regression classifier subject to fairness constraints on false positive rate, with a covariance threshold $c = 0$.

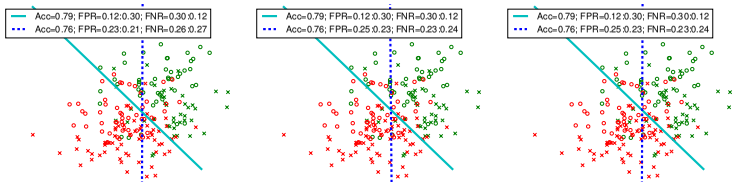

Figure 4 shows the decision boundaries for both the unconstrained classifier (solid) and the fairness-constrained classifier (dashed). We observe that applying the fairness constraint successfully causes the false positive rates for both groups ($z = 0$ and $z = 1$) to converge, and hence, the outcomes of the classifier become more fair, *i.e.*, $DM_{FPR} \to 0$, while DM_{FNR} remains close to zero. We note that the invariance of DM_{FNR} may however change depending on the underlying distribution of the data.

Disparate mistreatment on *both* false positive rate and false negative rate. In this part, we consider a more complex scenario, where the outcomes of the classifier suffer from disparate mistreatment with respect to *both* false positive rate and false negative rate, *i.e.*, both DM_{FPR} and DM_{FNR} are non-zero. This scenario can in turn be split into two cases:

I. DM_{FPR} and DM_{FNR} have *opposite signs*, *i.e.*, the decision boundary disproportionately *favors* subjects from a certain sensitive attribute value group to be in the positive class (even when such assignments are misclassifications) while disproportionately assigning the subjects from the other group to the negative class. As a result, false positive rate for one group is higher than the other, while the false negative rate for the same group is lower.

II. DM_{FPR} and DM_{FNR} have the *same sign*, *i.e.*, both false positive as well as false negative rate are higher for a certain sensitive attribute value group. These cases might arise in scenarios when a certain group is harder to classify than the other.

Next, we experiment with each of the above cases separately.

(a) FPR constraints (b) FNR constraints (c) Both constraints

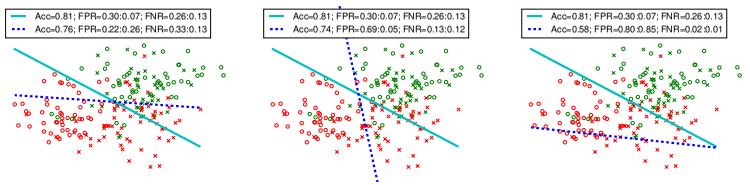

Figure 5: [Disparate mistreatment constraints] DM_{FPR} and DM_{FNR} have opposite signs. Removing disparate mistreatment on FPR can potentially help remove disparate mistreatment on FNR. Removing disparate mistreatment on both at the same time leads to very similar results.

— **Case I:** To simulate this scenario, we first generate 2,500 samples from each of the following distributions:

$$\begin{aligned} p(\boldsymbol{x}|z=0,y=1) &= \mathcal{N}([2,0],[5,1;1,5]) \\ p(\boldsymbol{x}|z=1,y=1) &= \mathcal{N}([2,3],[5,1;1,5]) \\ p(\boldsymbol{x}|z=0,y=-1) &= \mathcal{N}([-1,-3],[5,1;1,5]) \\ p(\boldsymbol{x}|z=1,y=-1) &= \mathcal{N}([-1,0],[5,1;1,5]) \end{aligned}$$

An accuracy-maximizing logistic regression classifier on this dataset attains an overall accuracy of 0.79 but leads to a false positive rate of 0.12 and 0.30 (*i.e.*, $DM_{FPR} = 0.12 - 0.30 = -0.18$) for the sensitive attribute groups $z = 0$ and $z = 1$, respectively; and false negative rates of 0.30 and 0.12 (*i.e.*, $DM_{FNR} = 0.30 - 0.12 = 0.18$). To remove this disparate mistreatment, we train three different classifiers, with fairness constraints on (i) false positive rates (ii) false negative rates and (iii) on both false positive and false negative rates.

Figure 5 summarizes the results for this scenario by showing the decision boundaries for the unconstrained classifier (solid) and the constrained fair classifiers. Here, we can observe several interesting patterns. First, removing disparate mistreatment on only false positive rate causes a rotation in the decision boundary to move previously *misclassified* subjects with $z = 1$ into the negative class, *decreasing* their false positive rate. However, in the process, it also moves previously *well-classified* subjects with $z = 1$ into the negative class, *increasing* their false negative rate. As a consequence, controlling disparate mistreatment on false positive rate (Figure 5(a)), also removes disparate mistreatment on false negative rate. A similar effect occurs when we control disparate mistreatment only with respect to the false negative rate (Figure 5(b)), and therefore, provides similar results as the constrained classifier for both false positive and false negative rates (Figure 5(c)). This effect is explained by the distribution of the data, where the centroids of the clusters for the group with $z = 0$ are shifted with respect to the ones for the group $z = 1$.

(a) FPR constraints (b) FNR constraints (c) Both constraints

Figure 6: [Disparate mistreatment constraints] DM_{FPR} and DM_{FNR} have the same sign. Removing disparate mistreatment on FPR can potentially increase disparate mistreatment on FNR. Removing disparate mistreatment on both at the same time causes a larger drop in accuracy.

— **Case II:** To simulate the scenario where both DM_{FPR} and DM_{FNR} have the same sign, we generate 2,500 samples from each of the following distributions:

$$\begin{aligned} p(\boldsymbol{x}|z=0,y=1) &= \mathcal{N}([1,2],[5,2;2,5]) \\ p(\boldsymbol{x}|z=1,y=1) &= \mathcal{N}([2,3],[10,1;1,4]) \\ p(\boldsymbol{x}|z=0,y=-1) &= \mathcal{N}([0,-1],[7,1;1,7]) \\ p(\boldsymbol{x}|z=1,y=-1) &= \mathcal{N}([-5,0],[5,1;1,5]) \end{aligned}$$

We then train a accuracy-optimizing logistic regression classifier on this dataset. It attains an accuracy of 0.81 but leads to $DM_{FPR} = 0.30 - 0.07 = 0.23$ and $DM_{FNR} = 0.26 - 0.13 = 0.13$, resulting in disparate mistreatment in terms of both false positive and negative rates. Then, similarly to the previous scenario, we train three different kind of constrained classifiers to remove disparate mistreatment on (i) false positive rate, (ii) false negatives rate, and (iii) both.

Figure 6 summarizes the results by showing the decision boundaries for both the unconstrained classifiers (solid) and the fair constrained classifier (dashed) when controlling for disparate mistreatment with respect to false positive rate, false negative rate and both, respectively. We observe following noticeable patterns. First, controlling disparate mistreatment for only false positive rate (false negative rate), leads to a minor drop in accuracy, but in contrast to Case I, can exacerbate the disparate mistreatment on false negative rate (false positive rate). For example, while the decision boundary is moved to control for disparate mistreatment on false negative rate, that is, to ensure that more subjects with $z = 0$ are well-classified in the positive class (reducing false negative rate), it also moves previously well-classified negative subjects into the positive class, hence increasing the false positive rate. A similar phenomenon occur when controlling disparate mistreatment with respect to only false positive rate. As a consequence, controlling for both types of disparate mistreatment simultaneously brings DM_{FPR} and DM_{FNR} close to zero, but causes a large drop in accuracy.

5.2. Real-world datasets

We now evaluate the effectiveness of our covariance framework in removing disparate impact and disparate mistreatment on several real-world datasets. In doing so, we also compare the performance of our framework to several methods from the fair machine learning literature.

In all the experiments, to obtain more reliable estimates of accuracy and fairness, we repeatedly split each dataset into a train (70%) and test (30%) set 5 times and report the average statistics for accuracy and fairness.

5.2.1. Mitigating disparate impact

Datasets and experimental setup. Here, we experiment with two real-world datasets: The Adult income dataset (Adult, 1996) and the Bank marketing dataset (Bank, 2014).

The Adult dataset contains a total of 45,222 subjects, each with 14 features (*e.g.*, age, educational level) and a binary label, which indicates whether a subject's incomes is above (positive class) or below (negative class) 50K USD. With the aim of experimenting with binary as well as non-binary (polyvalent) sensitive attributes, we consider the features gender and race to be sensitive. Here, gender (with feature values: men and women) serves as an example of binary sensitive attribute and race (with feature values: American-Indian, Asian, Black, White and Other) serves as an example of a non-binary sensitive attribute.

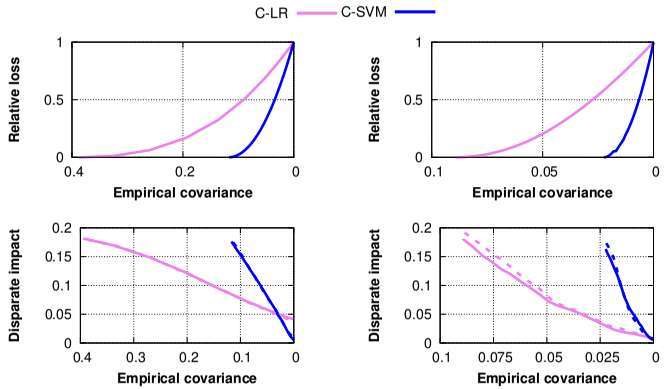
The Bank dataset contains a total of 41,188 subjects, each with 20 attributes (*e.g.*, marital status) and a binary label, which indicates whether the client has subscribed (positive class) or not (negative class) to a term deposit. In this case, we consider age as (binary) sensitive attribute, which is discretized to indicate whether the client's age is between 25 and 60 years. For detailed statistics about the distribution of different sensitive attributes in positive class in these datasets, we refer the reader to Appendix A.

For the sake of conciseness, while presenting the results for binary sensitive attributes, we refer to women and men, respectively, as protected and non-protected groups in Adult data. Similarly, in Bank data, we refer to users between age 25 and 60 as protected and rest of the users as non-protected group.

Methods. In our experiments, we also compare our approach to well-known competing method from fairness-aware machine learning literature (detailed in Section 6). More specifically, we consider the following methods:

- ***Our method (C-LR and C-SVM)*:** Implements our covariance constraints-based methods for controlling disparate impact with a logistic regression classifier (Eq. (4.13)) and a dual-form SVM classifier with a linear kernel (Eq. (4.15)). [8] On the datasets considered here, different choices of kernel (linear vs. RBF) lead to a very similar performance in terms of accuracy and disparate impact. This method does not use the sensitive feature information at decision time.
- ***Preferential sampling (PS-LR and PS-SVM)*:** Implements the data pre-processing technique of Kamiran and Calders (2010) on a logistic regression and a SVM classifier. Specifically, this method operates as follows: (i) We first train a standard (potentially unfair) classifier on the given dataset. (ii) Next, we move / replicate the protected group data points to / on the positive side of the decision boundary (and vice versa for the non-protected group) until the decision boundary leads to zero disparate impact, *i.e.*, until it satisfies Eq. (3.2). (iii) We then train the final (fair) classifier on the perturbed dataset. This method does not use the sensitive feature information at decision time.
- ***Fairness-regularized logistic regression (FR-LR)*:** The in-processing technique of Kamishima et al. (2011). This technique is only limited to the logistic regression classification model. This technique works by adding a fairness regularization term in the objective function that penalizes the mutual information between the sensitive feature and the classifier decisions. In this way, this method treats the mutual information as the unfairness proxy, as opposed to covariance in our case. This technique needs the sensitive feature information at decision time, hence cannot remove disparate treatment.
- ***Post-Processing (PP-LR and PP-SVM)*:** The post-processing technique discussed in Corbett-Davies et al. (2017). This method works by first training a standard logistic regression or SVM classifier on the given dataset and then finding a pair of positive class acceptance thresholds [9] such that the decisions based on those thresholds lead to maximum accuracy while having no disparate impact. This technique also requires the sensitive feature information at decision time so it cannot avoid disparate treatment.

Results. First, we experiment with two standard (unconstrained) logistic regression and SVM classifiers. In the Adult dataset, the logistic regression classifier leads to an accuracy of 0.846. However, the classifier results in highly disparate positive class acceptance rates for protected and non-protected groups: 0.08 and 0.26. The SVM classifier leads to a similar accuracy (0.847) and disparity in positive class acceptance rates (0.08 vs 0.25). In the Bank dataset, the two classifiers lead to accuracies of 0.911 and 0.910, respectively, and acceptance rates of 0.06 vs. 0.25, and 0.05 vs. 0.23 respectively. The high disparity in acceptance rates over the two datasets clearly constitutes a case of disparate impact.



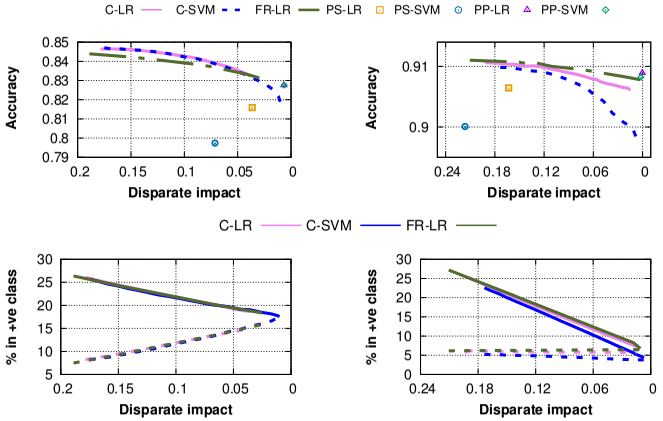
We then apply our framework to limit disparate impact with respect to a single binary sensitive attribute, gender and age, for respectively, the Adult and Bank datasets. For each dataset, we train several logistic regression and SVM classifiers (denoted by 'C-LR' and 'C-SVM', respectively), each subject to fairness constraints with different values of covariance threshold, c (Eqs.(4.13, 4.15)). Next, we study the effect of covariance constraints on the loss function value, level of disparate impact and accuracy of the classifier.

Figure 7 (top row) shows the empirical decision boundary covariance against the relative loss incurred by the classifier. The 'relative loss' is normalized between the loss incurred by an unconstrained classifier and by the classifier with a covariance threshold of 0. We notice that as expected, a decreasing value of empirical covariance results in an increasing loss. However, each pair of (covariance, loss) values is guaranteed to be Pareto optimal, since our problem formulation is convex.

The bottom row in Figure 7 investigates the correspondence between decision boundary covariance and disparate impact, as defined in Eq. (5.1), computed on the training set (solid

8. For the SVM classifier, the hyperparameter C (in Eq. (4.15)) is only cross-validated for the unconstrained classifier, and the same hyperparameter is used for the fairness-constrained classifiers. One could further optimize the classifier performance by cross-validating the value of C for each value of the covariance threshold separately.

9. The acceptance threshold is zero for a standard logistic regression or SVM classifier.

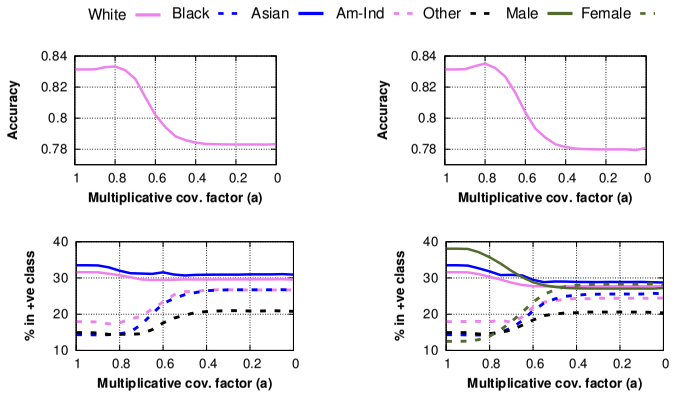


Adult data Bank data

Figure 7: [Disparate impact constraints: Single, binary sensitive attribute] Panels in the top row show the trade-off between the empirical covariance in Eq. (4.2) and the relative loss with respect to the unconstrained classifier, for the Adult and Bank (training) datasets. Here each pair of (covariance, loss) values is guaranteed to be Pareto optimal by construction. Panels in the bottom row show the correspondence between the empirical covariance and disparate impact in Eq. (5.1) for classifiers trained under fairness constraints. Solid lines correspond to the training data whereas dashed lines correspond to the test data. The figure shows that a decreasing empirical covariance leads to higher loss but lower disparate impact. Moreover, the classifiers do not lead to "fairness overfitting"—in fact, the dashed lines for the Adult data are barely visible due to strong correspondance between the performance on the training and test sets.

lines) as well as the test set (dashed lines). The figure shows that, as desired: (i) the lower the covariance, the lower the disparate impact of the classifier; (ii) zero disparate impact maps to roughly zero covariance; and, (iii) there is a strong correspondence between the covariance-fairness relationship across the training and the test set, that is, a fair classifier on the training data also leads to fair outcomes on the test data.

We next compare the performance of our constrained classifiers in terms of disparate impact–accuracy tradeoffs with the baselines methods mentioned above. The results presented in Figure 8, top row, show that: (i) the performance of our classifiers (C-LR, C-SVM) and fairness-regularized logistic regression (FR-LR) is comparable, ours are slightly better for Adult data (left column) while slightly worse for Bank data (right column); (ii) the preferential sampling presents the worst performance and results in high disparate impact; and, (iii) the post-processing technique leads to the best performance among all methods. However, we note that both FR-LR and PP-LR / PP-SVM use the sensitive feature information at decision time while the other two techniques do not use it.



Adult data Bank data

Figure 8: [Disparate impact constraints: Single, binary sensitive attribute] The figure shows the accuracy against disparate impact in Eq. 5.1 (top) and the percentage of protected (dashed) and non-protected (solid) users in the positive class against the disparate impact value (bottom). For all methods, a decreasing degree of disparate impact also leads to a decreasing accuracy. The post-processing technique (PP-LR and PP-SVM) achieves the best disparate impact-accuracy tradeoff. However, this technique as well as FR-LR use the sensitive feature information at decision time (as opposed to C-LR, C-SVM, PS-LR and PS-SVM), and would hence result in disparate treatment.

For a more fair comparison, we also train our method with access to sensitive features at decision time. Specifically, we train constrained logistic regression classifiers (C-LR) under the same setup as above, with the exception that the non-sensitive ($\boldsymbol{x}$) and sensitive features (z) are not disjoint feature sets—that is, the classifier learns a non-zero weight for the sensitive feature z.

Under this setup, on the Adult dataset, our constrained logistic regression classifier (C-LR) achieves an accuracy of 0.839 and DI of 0.09, as compared to 0.828 accuracy and 0.01 DI achieved by the PP-LR classifier. In this case C-LR achieves a better accuracy than PP-LR, but does not remove DI as well as PP-LR. Next, we adjust the thresholds of PP-LR in a way that the resulting classifier has DI ≤ 0.9 (*i.e.*, it tries to match the DI of C-LR) while maximizing accuracy. Under these thresholds, PP-LR achieves an accuracy of 0.840 and DI of 0.07. On the Bank dataset, C-LR achieves an accuracy of 0.908 (0.909 for PP-LR) and DI of 0.01 (0.0 for PP-LR). On both Bank and Adult datasets, both methods achieve similar accuracy for a similar level of DI (with PP-LR performing marginally better).

The bottom row of Figure 8 shows the percentage of users from protected and non-protected groups in the positive class along with the degree of disparate impact. We note

(a) Non-binary (polyvalent) sensitive attribute (b) Multiple sensitive attributes

Figure 9: [Disparate impact constraints: Non-binary and several sensitive attributes] The figure shows accuracy (top) and percentage of users in positive class (bottom) against a multiplicative factor $a \in [0, 1]$ such that $c = ac^*$, where c^* denotes the unconstrained classifier covariance.

that in the Adult data, all classifiers move non-protected users (men) to the negative class and protected users (women) to the positive class to remove disparate impact. In contrast, in the Bank data, they only move non-protected (young and old) users originally labeled as positive to the negative class since it provides a smaller accuracy loss. However, the latter can be problematic: from a business perspective, a bank may be interested in finding potential subscribers rather than losing existing customers. This observation could motivate the business necessity clause of the disparate impact doctrine. To counter such situations, one can use our alternative formulation in Section 4.3. We experiment with this formulation later in this section.

Finally, we apply our framework to control disparate impact with respect to non-binary (race) and several (gender and race) sensitive attributes in the Adult dataset. We do not compare with competing methods since they cannot handle non-binary or several sensitive attributes. Figure 9 summarizes the results by showing the accuracy and the percentage of subjects sharing each sensitive attribute value classified as positive against a multiplicative covariance factor $a \in [0, 1]$ such that $c = ac^*$, where c^* is the unconstrained classifier covariance[10] (note that disparate impact in Eq. (5.1) is only defined for a binary sensitive feature). As expected, as the value of c decreases, the percentage of subjects in the positive

10. For several sensitive features, we compute the initial covariance c_k^* for each of the sensitive feature k, and then compute the covariance threshold separately for each sensitive feature as ac_k^*.

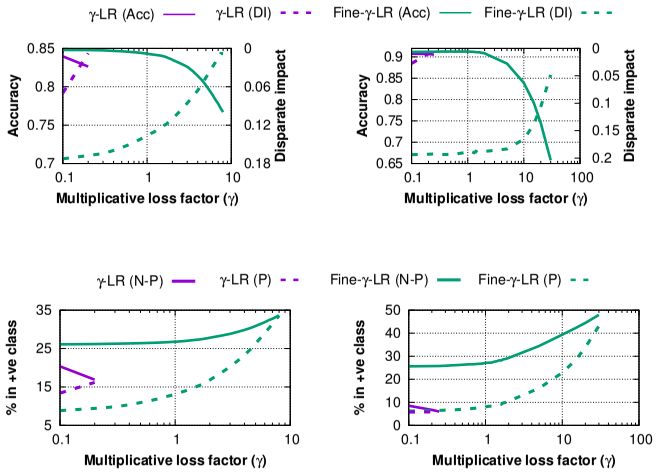


Figure 10: [Business necessity clause] Panels in top row show the accuracy (solid) and disparate impact (dashed) against γ. Panels in the bottom row show the percentage of protected (P, dashed) and non-protected (N-P, solid) users in the positive class against γ.

class from sensitive attribute value groups become nearly equal [11] while the loss in accuracy is modest.

Disparate impact's business necessity clause. We now experiment with our formulation for handling the business necessity clause (Section 4.3) to avoid scenarios where removing disparate impact leads to almost all the users being assigned the negative class label (Figure 8). Specifically, we demonstrate that our formulation in Section 4.3 can minimize disparate impact while precisely controlling loss in accuracy. We also demonstrate that our formulation can additionally provide guarantees for classifying certain users in the positive class while minimizing disparate impact.

To this end, we first train several logistic regression classifiers (denoted by 'γ-LR'), which minimize the decision boundary covariance subject to accuracy constraints over the entire dataset by solving problem (4.10) with increasing values of γ. Then, we train logistic regression classifiers (denoted by 'Fine-γ-LR') that minimize the decision boundary covariance subject to *fine-grained* accuracy constraints by solving problem (4.11). Here, we prevent the non-protected users that were classified as positive by the unconstrained logistic regression

11. The scarce representation of the race value 'Other' (only 0.8% of the data) hinders an accurate estimation of the decision boundary covariance and, as a result, the classifier does not reach perfect fairness with respect to this sensitive attribute value.

classifier from being classified as negative by constraining that their distance from decision boundary stays positive while learning the fair boundary. We then increase $\gamma_i = \gamma$ for the remaining users. In both cases, we increased the value of γ until we reach 0 disparate impact during training. Figure 10 summarizes the results for both datasets, by showing (a) the average accuracy (solid curves) and disparate impact (dashed curves) against γ, and (b) the percentage of non-protected (N-P, solid curves) and protected (P, dashed curves) users in the positive class against γ. We observe that, as we increase γ, the classifiers that constrain the overall training loss (γ-LR) remove non-protected users from the positive class and add protected users to the positive class, in contrast, the classifiers that prevent the non-protected users that were classified as positive in the unconstrained classifier from being classified as negative (Fine-γ-LR) add both protected and non-protected users to the positive class. As a consequence, the latter achieves lower accuracy for the same value of disparate impact.

5.2.2. Mitigating disparate mistreatment

Datasets and experimental setup. In this section, we experiment with two real-world datasets: COMPAS risk assessment dataset (Larson et al., 2016a) and the NYPD stop-question-and-frisk (SQF) dataset (Stop, Question and Frisk Data, 2017).

The ProPublica COMPAS dataset consists of data about $7,215$ pretrial criminal defendants, and contains a number of features such as age of the criminal defendant, number of prior criminal offenses *etc.*, and a class label indicating whether a person would recidivate within two years (positive class) or not (negative class). For more information about the data collection, we point the reader to a detailed description (Larson et al., 2016b) and some of the follow-up discussion on this dataset (Angwin and Larson; Flores et al., 2016). We designate race as the sensitive feature. Following ProPublica's analysis (Larson et al., 2016b), we only consider a subset of offenders whose race (the sensitive feature) is either black or white. Recidivism rates for the two groups are shown in Table 6 in Appendix A. For modeling the classification task, we use the same set of features as used by ProPublica (Larson et al., 2016b). [12] After performing the filtering described above, we obtain $5,287$ subjects and 5 features.

The NYPD SQF dataset consists of $84,868$ pedestrians who were stopped in the year 2012 on the suspicion of having a weapon. The dataset also contains over 100 features (*e.g.*, gender, height, reason for stop) and a binary label which indicates whether (negative class) or not (positive class) a weapon was discovered. For our analysis, we consider the race to be the sensitive feature with values blacks and whites. The classes in this dataset are highly imbalanced (97% of subjects in positive class), and as a result, a logistic regression classifier classifies almost all data points into the positive class. To counter this imbalance, we subsample the dataset to have equal number of subjects from each class. Information about weapon discovery rate for both races in included in Tables 7 and 8 in Appendix A.

12. Notice that goal of this section is not to analyze the best set of features for recidivism prediction, rather, we focus on showing that our method can effectively remove disparate mistreatment in a given dataset. Hence, we chose to use the same set of features as used by ProPublica for their analysis. Moreover, since race is one of the features in the learnable set, we additionally assume that *all* the methods have access to the sensitive attributes while making decisions.

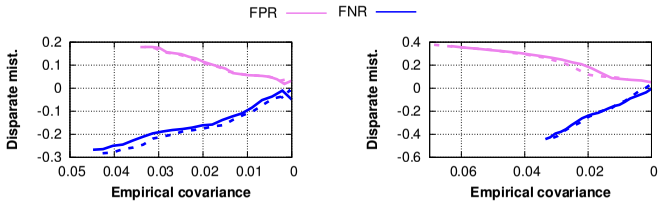
Algorithm 1: Baseline method for removing disparate mistreatment w.r.t. FPR.

Input: Training set $\mathcal{D} = \{(\boldsymbol{x}_i, y_i, z_i)\}_{i=1}^N$, $\Delta > 0$ $\epsilon > 0$
Output: Fair baseline decision boundary $\boldsymbol{\theta}$
Initialize: Penalty $C = 1$
Train (unfair) classifier $\boldsymbol{\theta} = \text{argmin}_{\boldsymbol{\theta}} \sum_{\mathbf{d} \in \mathcal{D}} L(\boldsymbol{\theta}, \mathbf{d})$
Compute $\hat{y}_i = \text{sign}(d_{\boldsymbol{\theta}}(\boldsymbol{x}_i))$ and D_{FP} on $\mathcal{D}$.
if $D_{FP} > 0$ **then** $s = 0$
else $s = 1$
$\mathcal{P} = \{\boldsymbol{x}_i, y_i, z_i | \hat{y} \neq y_i, z_i = s\}$, $\bar{\mathcal{P}} = \mathcal{D} \setminus \mathcal{P}$.
while $D_{FP} > \epsilon$ **do**
  Increase penalty: $C = C + \Delta$.
  $\boldsymbol{\theta} = \text{argmin}_{\boldsymbol{\theta}} \quad C \sum_{\mathbf{d} \in \mathcal{P}} L(\boldsymbol{\theta}, \mathbf{d}) + \sum_{\mathbf{d} \in \bar{\mathcal{P}}} L(\boldsymbol{\theta}, \mathbf{d})$
end

Furthermore, for training the classifiers, we consider a similar set of features as Goel et al. (2015). After performing these two filtering steps, we obtain $5,832$ subjects and 19 features.

Methods. In our experiments, we compare our approach to two baseline methods. More specifically, we consider the following methods:

- ***Our method***: Implements our scheme to avoid disparate treatment and disparate mistreatment *simultaneously*. Disparate mistreatment is avoided by using fairness constraints on false positive and / or false negative rates. Disparate treatment is avoided by ensuring that sensitive attribute information is not used while making decisions, *i.e.*, by keeping user feature vectors ($\boldsymbol{x}$) and the sensitive features (z) disjoint.
- ***Our method$_{sen}$***: Implements our scheme to avoid disparate mistreatment only. The user feature vectors ($\boldsymbol{x}$) and the sensitive features (z) are not disjoint, that is, the classifier learns a non-zero weight for z. Therefore, the sensitive feature information is used for decision making, resulting in disparate treatment.
- ***Hardt et al.*** (Hardt et al., 2016): Operates by post-processing the outcomes of a possibly discriminatory classifier (logistic regression in this case) and using different decision thresholds for different sensitive feature value groups to remove disparate mistreatment. By construction, it needs the sensitive feature information while making decisions, and hence cannot avoid disparate treatment. This method is similar to the post-processing scheme discussed in Corbett-Davies et al. (2017).
- ***Donini et al.*** (Donini et al., 2018): This pre- / in-processing method aims to remove the discrepancy in the false negative rate of the two groups by adding constraints to a SVM classifier. We use the implementation provided by the authors[13] and train the method such that it has access to the sensitive feature information at decision time.
- ***Baseline***: Baseline introduced by us to facilitate a third comparison method. Tries to remove disparate mistreatment by introducing different penalties for misclassified



13. https://github.com/jmikko/fair_ERM

data points with different sensitive attribute values during training phase. Specifically, it proceeds in two steps. First, it trains an (unfair) classifier minimizing a loss function (*e.g.*, logistic loss) over the training data. Next, it selects the set of misclassified data points from the sensitive attribute value group that presents the higher error rate. For example, if one wants to remove disparate mistreatment with respect to false positive rate and $DM_{FPR} > 0$ (which means the false positive rate for points with $z = 0$ is higher than that of $z = 1$), it selects the set of misclassified data points in the training set having $z = 0$ and $y = -1$. Next, it iteratively re-trains the classifier with increasingly higher penalties on this set of data points until a certain fairness level is achieved in the training set (until $DM_{FPR} \leq \epsilon$). The algorithm is summarized in Figure 1, particularized to ensure fairness in terms of false positive rate. This process can be intuitively extended to account for fairness in terms of false negative rate or for *both* false positive rate and false negative rate. This method can be trained with or without using sensitive feature information while making decisions. We opt for the latter option.

Results. First, we experiment with a standard logistic regression classifier optimizing for accuracy on both datasets. For the COMPAS dataset, the (unconstrained) logistic regression classifier leads to an accuracy of 0.664. However, the classifier yields false positive rates of 0.35 and 0.17, respectively, for blacks and whites (*i.e.*, $DM_{FPR} = 0.18$), and false negative rates of 0.32 and 0.61 (*i.e.*, $DM_{FNR} = -0.29$). These results constitute a clear case of disparate mistreatment in terms of both false positive rate and false negative rate. The classifier puts one group (blacks) at relative disadvantage by disproportionately misclassifying negative (did not recidivate) subjects from this group into positive (did recidivate) class. This disproportional assignment results in a significantly higher false positive rate for blacks as compared to whites. On the other hand, the classifier puts the other group (whites) on a relative advantage by disproportionately misclassifying positive (did recidivate) subjects from this group into negative (did not recidivate) class (resulting in a higher false negative rate). Note that this scenario resembles our synthetic example Case I in Section 5.1.2.

For the SQF data, the (unconstrained) logistic regression classifier leads to an accuracy of 0.751. However, the classifier yields false positive rates of 0.38 and 0.11, respectively, for blacks and whites (*i.e.*, $DM_{FPR} = 0.27$), and false negative rates of 0.19 and 0.31 (*i.e.*, $DM_{FNR} = -0.12$). Notice that unlike the COMPAS dataset, being classified positive in here is an advantageous outcome—positive class in this case is not being stopped whereas the positive class in the COMPAS dataset is being classified as being a recidivist. This scenario also resembles our synthetic example Case I in Section 5.1.2.

Next, we apply our framework on a logistic regression classifier to mitigate disparate mistreatment with respect to false positive rate, false negative rate, and on both. Figure 11 shows the link between the empirical decision boundary covariance when imposing the constraints to remove disparate mistreatment based on false positive rate or false negative rate on the ProPublica COMPAS and NYPD SQF datasets. The figure shows that: (i) a lower value of false positive or false negative rate covariance corresponds to a lower degree of disparate mistreatment with respect to the corresponding error rate, *i.e.*, Eqs. (5.2) and (5.3) respectively; and, (ii) a zero disparate mistreatment roughly corresponds to zero

ProPublica COMPAS data NYPD SQF data

Figure 11: [Disparate mistreatment constraints] The figure shows the effect of applying Our method$_{\text{sen}}$ to limit disparate mistreatment with respect to false positive rate and false negative rate, as defined by Eqs. (5.2) and (5.3)), respectively. Each type of constraint is applied separately. The plots show the correspondence between the empirical covariance (for each constraint type) and disparate mistreatment caused by the classifiers trained under fairness constraints on ProPublica COMPAS (left) and NYPD SQF (right) datasets. Solid lines correspond to the training data whereas dashed lines correspond to the test data. The figure shows that a decreasing empirical covariance leads to lower disparate mistreatment. Moreover, the statistics for training and test sets show a close correspondence, meaning that the constraints do not seem to be overfitting on the training data.

		FPR constraints			FNR constraints			Both constraints		
		Acc	D_{FPR}	D_{FNR}	Acc	D_{FPR}	D_{FNR}	Acc	D_{FPR}	D_{FNR}
ProPuclica COMPAS	**Our method$_{\text{sen}}$**	0.653	0.03	−0.10	0.656	−0.05	−0.01	0.654	−0.02	−0.03
	Baseline	0.631	0.01	−0.18	0.656	−0.03	−0.03	0.615	−0.19	0.13
	Hardt et al.	0.661	0.01	−0.08	0.654	−0.06	0.01	0.632	0.02	0.01
	Donini et al.	–	–	–	0.649	0.03	−0.09	–	–	–
NYPD SQF	**Our method**	0.633	0.06	−0.01	0.705	0.22	−0.07	0.642	0.05	0.04
	Our method$_{\text{sen}}$	0.727	0.08	0.07	0.743	0.18	0.00	0.726	0.07	0.07
	Baseline	0.527	0.02	−0.08	0.734	0.14	0.01	0.435	−0.71	0.95
	Hardt et al.	0.725	0.03	0.12	0.734	0.14	0.04	0.722	0.02	0.06
	Donini et al.	–	–	–	0.737	0.21	−0.04	–	–	–

Table 2: Performance of different methods while removing disparate mistreatment with respect to false positive rate, false negative rate and both.

covariance (though the correspondence is not completely strict on the ProPublica COMPAS data).

Next, we compare the performance of our scheme with the three alternative methods. While controlling for disparate mistreatment with respect to FPR and FNR simultaneously, the method of Hardt et al. can be interpreted as finding the optimal point that minimizes the loss on the average of the two group-conditional ROC curves (one curve for each sensitive feature group), or the one that minimizes the loss on the point-wise minimum of the two

curves. The optimal point in both cases lies on the point-wise minimum of the two curves. Both variants lead to similar performance, hence we report the results for the former.

Table 2 summarizes the results by showing the trade-off between fairness and accuracy achieved by our method, the methods by Hardt et al. and Donini et al., and the baseline. Similarly to the results in Section 5.1.2, we observe that for all four methods, controlling for disparate mistreatment on false positive rate (false negative rate) also helps decrease disparate mistreatment on false negative rate (false positive rate), at least to a limited extent. Moreover, our method and the methods by Hardt et al. and Donini et al. achieve similar accuracy for a given level of fairness when provided with the same amount of information (sensitive attribute information). The baseline on the other hand leads to the worst performance (especially on the NYPD SQF data.) We also note that the baseline tends to be somewhat unstable and fails to converge to a fair solution in some cases (*e.g.*, both FPR and FNR constraints on COMPAS and SQF datasets).

6. Related Work

6.1. Algorithmic decision making and evidence of unfairness

Algorithmic (or, automated) decision making has been used in applications involving human subjects since several decades. For example, previous works have studied the factors determining whether a criminal defendant would recidivate if granted bail (Burgess, 1928), or whether a loan applicant is likely to return their loan or not (Furletti, 2002). However, with the advent of complex learning methods, and convenient accessibility of 'big data' in several domains, automated decision making has permeated into a large number of human-centric applications, *e.g.*, job screening (Posse, 2016; Taylor, 2016), community safety (Perry, 2013; Lowenkamp, 2009; Kleinberg et al., 2017a), product personalization (Covington et al., 2016; Gomez-Uribe and Hunt, 2015) and online ad delivery (Google AdSense).

Several recent studies have shown that algorithmic decision making systems can potentially lead to (unintentional) unfairness against certain legally "protected" groups (Civil Rights Act, 1964). For example, Sweeney (2013) showed that Google ad platform is more likely to link typically African-American names with having criminal records as compared to typically white names. A recent study by ProPublica (Larson et al., 2016a) found that a criminal risk assessment tool used in Broward County, Florida was disproportionately marking African-American defendants as high risk (as compared to whites), even when they did not recidivate. Since the fairness of a decision making process is often a legally mandated criterion (Barocas and Selbst, 2016; Civil Rights Act, 1964), in the face of potential unfairness by automated decision making systems, a number of studies by regulatory authorities have called for taking fairness into account while designing algorithmic decision systems. (Podesta et al., 2014; Muñoz et al., 2016; Ramirez et al., 2016).

While automated decision making spans a variety of tasks including classification, ranking and recommendations, in this paper, we only focus on fairness in the context of classification. Next, we discuss the state-of-the-art in the context of the notions of unfairness discussed in Section 1.

6.2. Avoiding unfairness in classification

In this section, we will discuss techniques that aim to remove disparate treatment, disparate impact or disparate mistreatment from classification outcomes.

The first study on fair classification dates back to 2008 when Pedreschi et al. (2008) proposed techniques to avoid unfairness in classification rule mining. In the years that followed, a number of studies proposed techniques to remove unfairness from classification outcomes. Especially, last year or so has seen a flurry of methods proposed to control unfairness in classification. These studies operate by first specifying one or more measures of unfairness that they aim to control, *i.e.*, disparate treatment, disparate impact or disparate mistreatment, and then propose techniques to control for the selected measure(s).

These techniques can be divided into three different categories: *pre-processing*, *in-processing* and *post-processing*. Below, we discuss each of these categories separately.

6.2.1. Pre-processing

This technique consists of pre-processing the training data that would later be fed to a training algorithm Kamiran and Calders (2010); Luong et al. (2011); Feldman et al. (2015); Calmon et al. (2017). The goal is to pre-process the training data such that *any* classification algorithm trained on this data would generate unfairness-free outcomes. This strategy can be roughly divided into two different sub-categories. Below, we briefly discuss these subcategories:

The first sub-category involves changing the values of class labels for certain data points Kamiran and Calders (2010); Luong et al. (2011). For example, Kamiran and Calders (2010) propose a pre-processing technique that operates by first training an unconstrained classifier, and then moving / duplicating the data points from the group with lower acceptance rate (as compared to the other group) until the classification outcomes are free of disparate impact.

The second sub-category involves perturbing the non-sensitive features Feldman et al. (2015), or mapping the data to a transformed space Calmon et al. (2017). For example, building on ideas in the area of privacy-preserving data analysis (specifically t-closeness), Feldman et al. (2015) "repair" the non-sensitive features such that it is impossible to predict the sensitive features from non-sensitive features (which in turn means that the classifier trained on this data will not incur disparate impact), while ensuring that the resulting distribution is close to the original data distribution.

On the plus side, the pre-processing techniques have an advantage that the transformed dataset can be used to train any downstream algorithm.

However, these techniques also suffer from some disadvantages. First, since these techniques are not optimized for any specific classification model, and treat the learning algorithm as a black box, as a consequence, the pre-processing can lead to unpredictable loss in accuracy or may not remove unfairness on the test data (as we saw in Section 5.2.1). Furthermore, transforming the dataset might also affect the explainability of the classifier—*e.g.*, since the feature values were transformed during pre-processing, the feature weights of a linear classifiers might not be interpretable anymore.

Table 3: Capabilities of different methods in mitigating disparate treatment (DT), disparate impact (DI) and disparate mistreatment (DM). We also show the type of each method: pre-processing (pre), in-processing (in) and post-processing (post). None of the prior methods addresses disparate impact's business necessity (BN) clause. Many of the methods do not generalize to multiple (*e.g.*, gender and race) or polyvalent sensitive features (*e.g.*, race, that has more than two values). The strategy by Feldman et al. (2015) is limited to only numerical non-sensitive features.

6.2.2. In-processing

The second strategy consists of modifying the training procedure of the classifier. Examples of this scheme include Calders and Verwer (2010); Kamishima et al. (2011); Goh et al. (2016); Woodworth et al. (2017); Kamiran et al. (2010); Quadrianto and Sharmanska (2017). Our proposed covariance constraints also fall under this category.

For example, the technique by Kamishima et al. (2011)—which is only limited to a logistic regression classifier—works by adding a regularization term in the objective that penalizes the mutual information between the sensitive feature and the classifier decisions. The method of Kamiran et al. (2010), which is limited to a decision tree classifier, operates by changing the splitting or the leaf node labeling criterion of the tree learning phase to remove disparate impact.

Goh et al. (2016), Woodworth et al. (2017) and Quadrianto and Sharmanska (2017) on the other hand suggest adding constraints similar to ours to the classification model. However, their works are only limited to a single specific loss function (Goh et al., 2016; Quadrianto and Sharmanska, 2017) or to a single notion of unfairness (Woodworth et al., 2017).

Zemel et al. (2013), building on Dwork et al. (2012), combined pre-processing and in-processing by jointly learning a 'fair' representation of the data and the classifier parameters. The joint representation is learnt using a multi-objective loss function that ensures that (i) the resulting representations do not lead to disparate impact, (ii) the reconstruction loss from the original data and intermediate representations is small and (iii) the class label can be predicted with high accuracy. This approach has two main limitations: i) it leads to a non-convex optimization problem and does not guarantee optimality, and ii) the accuracy of the classifier depends on the dimension of the fair representation, which needs to be chosen rather arbitrarily. Inspired by Zemel et al. (2013), the methods of Edwards and Storkey (2016) and Madras et al. (2018) also aim at learning fair representations of the data.

6.2.3. Post-processing

The third and final strategy consists of post-processing the classifier scores such that the new outcomes contain no disparate impact or disparate mistreatment (Hardt et al., 2016; Corbett-Davies et al., 2017; Dwork et al., 2018; Menon and Williamson, 2018).

This approach usually involves learning different decision thresholds for a given score function to remove unfairness (specifically, disparate impact or disparate mistreatment). However, since these strategies require the sensitive feature information at the decision time, they cannot be used in cases where sensitive feature information is unavailable (*e.g.*, due to privacy reasons) or prohibited from being used due to disparate treatment laws (Barocas and Selbst, 2016).

Dwork et al. (2018) combine the in-processing and post-processing scheme by first training a number of classifiers for each group (with each classifier having different acceptance rate for the given group), and then selecting the group-conditional classifiers that minimize a certain loss function. The loss function is formulated as a combination of the loss in accuracy and a penalty term penalizing the deviation from the fairness criterion. Like Hardt et al. (2016) and Corbett-Davies et al. (2017), this method too requires access to the sensitive feature information at the decision time.

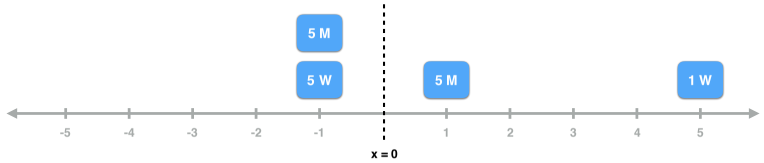

Figure 12: Covariance constraints may perform unfavorably in the presence of outliers. The figure shows a hypothetical dataset with just one feature (x) with values ranging from -5 to 5. Data points belong to two groups: men (M) or women (W). Each box shows the number of subjects of from a certain group (M or W) with that feature value. The decision boundary is at $x = 0$. The decision boundary covariance in this case is 0, yet the disparity in positive class outcome rates between men and women (0.5 for men and 0.17 for women) is very high. This situation is caused by one woman with feature value 5—this outlier point cancels out the effect of five normal examples (W with feature value -1) while computing the covariance.

In addition to the issues discussed above, most prior studies suffer from one or more of the following limitations: (i) they only accommodate a single, binary sensitive feature, (ii) they are restricted to a narrow range of classifiers, and, (iii) they cannot accommodate multiple unfairness notions *simultaneously*. Table 3 compares the capabilities of different methods in meeting different fairness criteria.

Finally, some recent studies (Kusner et al., 2017; Kilbertus et al., 2017) focus on detecting and removing unfairness by leveraging causal inference techniques. However, these studies often require access to causal graphs specifying causal relationships between different features, which can be quite challenging to obtain in practice.

7. Discussion, limitations and future work

In this work, we introduced a constraint-based framework to design fair margin-based classifiers that do not suffer from disparate treatment, disparate impact and disparate mistreatment. The key technical innovation of our framework is a general and intuitive measure of decision boundary unfairness, which serves as a tractable proxy for the above mentioned unfairness notions. Evaluation on various real-world datasets shows that our constrained-based framework is effective in limiting various forms of unfairness from classification outcomes, often at a small cost in terms of accuracy.

However, we also note that covariance mechanism only serves as a *proxy* for the unfairness measure under consideration (*i.e.*, disparate impact or disparate mistreatment). As a result, one may encounter cases where a zero value of the covariance proxy still results in a non-zero value of the unfairness measure. Such situations can arise due to various reasons. Below, we (non-exhaustively) list some of the reasons and leave a detailed formal analysis of such reasons for future work.

First, since our mechanism relies on empirically estimating the decision boundary covariance, very small presence of a certain group in the dataset can lead to poor estimate of the covariance and might not fully remove unfairness. Moreover, while the post-processing

schemes to remove unfairness (Hardt et al., 2016; Corbett-Davies et al., 2017) operate on the data of dimensionality 1 (that is, the scalar score assigned to each item by the classifier), our method operates by using all the features used in classification in order to compute the decision boundary covariance. As a result, our method is expected to suffer more from the data sparsity problem.

Second, we also notice that our method might not perform well in the presence of outliers. Consider for instance the example shown in Figure 12, where an outlier point causes the decision boundary covariance with respect to disparate impact (Eq. (4.2)) to be zero, even when the disparity in positive class outcomes caused by the corresponding decision boundary is very high. However, such outliers can in fact deteriorate the performance of any learning task (Bishop, 2006), even when no other constraints are applied, and one might wish to remove such outliers before training any classification model.

Third, while we observed that a decreasing covariance threshold corresponds to a more fair classifier (with respect to disparate impact or disparate mistreatment), the relation between the two is only empirically observed. A precise mapping between covariance and the precise value of the fairness notion under consideration is quite challenging to derive analytically, since it depends on the specific classifier and the dataset being used. Such a theoretical analysis would be an interesting future direction.

Our framework also opens many avenues for future work. For example, one could include fairness constraints in other supervised (*e.g.*, regression, recommendation) as well as unsupervised (*e.g.*, set selection, ranking) learning tasks. Our fairness constraints can be solved using standard convex or convex-concave optimizers (*e.g.*, SLSQP and DCCP, respectively) and we faced no scalability issues during the experiments conducted in this paper. However, extending these solvers to scale to cases when datasets or resulting optimization problems are too large to fit into memory would be an interesting future direction.

Appendix A. Additional dataset details

In this section, we show the distribution of sensitive features and class labels in the real-world datasets used in the evaluation (Section 5).

Gender	Low income (-ve)	High income (+ve)	Total
Males	20,988(69%)	9,539(21%)	30,527(100%)

Editor: Aapo Hyvarinen

Abstract

A common challenge in estimating parameters of probability density functions is the intractability of the normalizing constant. While in such cases maximum likelihood estimation may be implemented using numerical integration, the approach becomes computationally intensive. The score matching method of Hyvärinen (2005) avoids direct calculation of the normalizing constant and yields closed-form estimates for exponential families of continuous distributions over $\mathbb{R}^m$. Hyvärinen (2007) extended the approach to distributions supported on the non-negative orthant, $\mathbb{R}^m_+$. In this paper, we give a generalized form of score matching for non-negative data that improves estimation efficiency. As an example, we consider a general class of pairwise interaction models. Addressing an overlooked inexistence problem, we generalize the regularized score matching method of Lin et al. (2016) and improve its theoretical guarantees for non-negative Gaussian graphical models.

Keywords: exponential family, graphical model, positive data, score matching, sparsity

1. Introduction

Score matching was first developed in Hyvärinen (2005) for continuous distributions supported on all of $\mathbb{R}^m$. Consider such a distribution P_0, with density p_0 and support equal to $\mathbb{R}^m$. Let $\mathcal{P}$ be a family of distributions with twice continuously differentiable densities. The score matching estimator of p_0 using $\mathcal{P}$ as a model is the minimizer of the expected squared ℓ_2 distance between the gradients of $\log p_0$ and a log-density from $\mathcal{P}$. So we minimize the loss $\int_{\mathbb{R}^m} p_0(\boldsymbol{x}) \|\nabla \log p(\boldsymbol{x}) - \nabla \log p_0(\boldsymbol{x})\|_2^2 \, \mathrm{d}\boldsymbol{x}$ with respect to densities p from $\mathcal{P}$. The loss depends on p_0, but integration by parts can be used to rewrite it in a form that can be approximated by averaging over the sample without knowing p_0. A key feature of score matching is that normalizing constants cancel in gradients of log-densities, allowing for simple treatment of models with intractable normalizing constants. For exponential families, the loss is quadratic in the canonical parameter, making optimization straightforward.

If the considered distributions are supported on a proper subset of $\mathbb{R}^m$, then the integration by parts arguments underlying the score matching estimator may fail due to discontinuities at the boundary of the support. For data supported on the non-negative orthant $\mathbb{R}^m_+$, Hyvärinen (2007) addresses this problem by modifying the loss to $\int_{\mathbb{R}^m} p_0(\boldsymbol{x}) \|\nabla \log p(\boldsymbol{x}) \circ \boldsymbol{x} - \nabla \log p_0(\boldsymbol{x}) \circ \boldsymbol{x}\|_2^2 \, \mathrm{d}\boldsymbol{x}$, where $\circ$ denotes entrywise multiplication. In this loss, boundary effects are dampened by multiplying gradients elementwise with the identity functions x_j.

In this paper, we propose *generalized score matching* methods that are based on elementwise multiplication with functions other than x_j. As we show, this can lead to drastically improved estimation accuracy, both theoretically and empirically. To demonstrate these advantages, we consider a family of graphical models on $\mathbb{R}^m_+$, which does not have tractable normalizing constants and hence serves as a practical example.

Graphical models specify conditional independence relations for a random vector $\boldsymbol{X} = (X_i)_{i \in V}$ indexed by the nodes of a graph (Lauritzen, 1996). For undirected graphs, variables X_i and X_j are required to be conditionally independent given $(X_k)_{k \neq i,j}$ if there is no edge between i and j. The smallest undirected graph with this property is the *conditional independence graph* of $\boldsymbol{X}$. Estimation of this graph and associated interaction parameters has been a topic of continued research as reviewed by Drton and Maathuis (2017).

Largely due to their tractability, Gaussian graphical models (GGMs) have gained great popularity. The conditional independence graph of a multivariate normal vector $\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ is determined by the *inverse covariance matrix* $\mathbf{K} \equiv \boldsymbol{\Sigma}^{-1}$, also termed *concentration* or *precision matrix*. Specifically, X_i and X_j are conditionally independent given all other variables if and only if the (i,j)-th and the (j,i)-th entries of $\mathbf{K}$ are both zero. This simple relation underlies a rich literature including Drton and Perlman (2004), Meinshausen and Bühlmann (2006), Yuan and Lin (2007) and Friedman et al. (2008), among others.

More recent work has provided tractable procedures also for non-Gaussian graphical models. This includes Gaussian copula models (Liu et al., 2009; Dobra and Lenkoski, 2011; Liu et al., 2012), Ising models (Ravikumar et al., 2010), other exponential family models (Chen et al., 2015; Yang et al., 2015), as well as semi- or non-parametric estimation techniques (Fellinghauer et al., 2013; Voorman et al., 2014). In this paper, we apply our method to a class of pairwise interaction models that generalizes non-negative Gaussian random variables, as recently considered by Lin et al. (2016) and Yu et al. (2016), as well as square root graphical models proposed by Inouye et al. (2016) when the sufficient statistic function is a pure power. However, our main ideas can also be applied for other classes of exponential families whose support is restricted to a rectangular set.

Our focus will be on *pairwise interaction power models* with probability distributions having (Lebesgue) densities proportional to

$$\exp\left\{-\frac{1}{2a}\boldsymbol{x}^{a\top}\mathbf{K}\boldsymbol{x}^a + \boldsymbol{\eta}^\top \frac{\boldsymbol{x}^b - \mathbf{1}_m}{b}\right\} \tag{1}$$

on $\mathbb{R}^m_+ \equiv [0,\infty)^m$. Here $a > 0$ and $b \geq 0$ are known constants, and $\mathbf{K} \in \mathbb{R}^{m \times m}$ and $\boldsymbol{\eta} \in \mathbb{R}^m$ are unknown parameters of interest. When $b = 0$ we define $(x^b - 1)/b \equiv \log x$ and $\mathbb{R}^m_+ \equiv (0,\infty)^m$. This class of models is motivated by the form of important univariate distributions for non-negative data, including gamma and truncated normal distributions. It provides a framework for pairwise interaction that is concrete yet rich enough to capture key differences in how densities may behave at the boundary of the non-negative orthant,

$\mathbb{R}^m_+$. Moreover, the conditional independence graph of a random vector $\boldsymbol{X}$ with distribution as in (1) is determined just as in the Gaussian case: X_i and X_j are conditionally independent given all other variables if and only if $\kappa_{ij} = \kappa_{ji} = 0$ in the interaction matrix $\mathbf{K}$. Section 5.1 gives further details on these models. We will develop estimators of $(\boldsymbol{\eta}, \mathbf{K})$ in (1) and the associated conditional independence graph using the proposed *generalized score matching*.

A special case of (1) are truncated Gaussian graphical models, with $a = b = 1$. Let $\boldsymbol{\mu} \in \mathbb{R}^m$, and let $\mathbf{K}$ be a positive definite matrix. Then a non-negative random vector $\boldsymbol{X}$ follows a truncated normal distribution for mean parameter $\boldsymbol{\mu}$ and inverse covariance parameter $\mathbf{K}$, in symbols $\boldsymbol{X} \sim \mathrm{TN}(\boldsymbol{\mu}, \mathbf{K})$, if it has density proportional to

$$\exp\left\{-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^\top \mathbf{K}(\boldsymbol{x}-\boldsymbol{\mu})\right\} \tag{2}$$

on $\mathbb{R}^m_+$. We refer to $\boldsymbol{\Sigma} = \mathbf{K}^{-1}$ as the covariance parameter of the distribution, and note that the $\boldsymbol{\eta}$ parameter in (1) is $\mathbf{K}\boldsymbol{\mu}$. Another special case of (1) is the exponential square root graphical models in Inouye et al. (2016), where $a = b = 1/2$.

Lin et al. (2016) estimate truncated GGMs based on Hyvärinen's modification, with an ℓ_1 penalty on the entries of $\mathbf{K}$ added to the loss. However, the paper overlooks the fact that the loss can be unbounded from below in the high-dimensional setting even with an ℓ_1 penalty, such that no minimizer may exist. Since the unpenalized loss is quadratic in the parameter to be estimated, we propose modifying it by adding small positive values to the diagonals of the positive semi-definite matrix that defines the quadratic part, in order to ensure that the loss is bounded and strongly convex and admits a unique minimizer. We apply this to the estimator for GGMs considered in Lin et al. (2016), which uses score-matching on $\mathbb{R}^m$, and to the *generalized score matching* estimator for pairwise interaction power models on $\mathbb{R}^m_+$ proposed in this paper. In these cases, we show, both empirically and theoretically, that the consistency results still hold (or even improve) if the positive values added are smaller than a threshold that is readily computable.

The rest of the paper is organized as follows. Section 2 introduces score matching and our proposed *generalized score matching*. In Section 3, we apply generalized score matching to exponential families, with univariate truncated normal distributions as an example. *Regularized generalized score matching* for graphical models is formulated in Section 4. The estimators for pairwise interaction power models are shown in Section 5, while theoretical consistency results are presented in Section 6, where we treat the probabilistically most tractable case of truncated GGMs. Simulation results and applications to RNAseq data are given in Section 7. Proofs for theorems in Sections 2–6 are presented in Appendices A and B. Additional experimental results are presented in Appendix C.

1.1. Notation

Constant scalars, vectors, and functions are written in lower-case (e.g., a, $\boldsymbol{a}$), random scalars and vectors in upper-case (e.g., X, $\boldsymbol{X}$). Regular font is used for scalars (e.g. a, X), and boldface for vectors (e.g. $\boldsymbol{a}$, $\boldsymbol{X}$). Matrices are in upright bold, with constant matrices in upper-case ($\mathbf{K}$, $\mathbf{M}$) and random matrices holding observations in lower-case ($\mathbf{x}$, $\mathbf{y}$). Subscripts refer to entries in vectors and columns in matrices. Superscripts refer to rows in matrices. So X_j is the j-th component of a random vector $\boldsymbol{X}$. For a data matrix

$\mathbf{x} \in \mathbb{R}^{n\times m}$, each row comprising one observation of m variables/features, $X_j^{(i)}$ is the j-th feature for the i-th observation. Stacking the columns of a matrix $\mathbf{K} = [\kappa_{ij}]_{i,j} \in \mathbb{R}^{q\times r}$ gives its vectorization $\mathrm{vec}(\mathbf{K}) = (\kappa_{11}, \ldots, \kappa_{q1}, \kappa_{12}, \ldots, \kappa_{q2}, \ldots, \kappa_{1r}, \ldots, \kappa_{qr})^\top$. For a matrix $\mathbf{K} \in \mathbb{R}^{q\times q}$, $\mathrm{diag}(\mathbf{K}) \in \mathbb{R}^q$ denotes its diagonal, and for a vector $\boldsymbol{v} \in \mathbb{R}^q$, $\mathrm{diag}(\boldsymbol{v})$ is the $q \times q$ diagonal matrix with diagonals $v_1, \ldots, v_q$.

For $a \geq 1$, the ℓ_a-norm of a vector $\boldsymbol{v} \in \mathbb{R}^q$ is denoted

$$\|\boldsymbol{v}\|_a = \left(\sum_{j=1}^q |v_j|^a\right)^{1/a},$$

with $\|\boldsymbol{v}\|_\infty = \max_{j=1,\ldots,q} |v_j|$. A matrix $\mathbf{K} = [\kappa_{ij}]_{i,j} \in \mathbb{R}^{q\times r}$ has Frobenius norm

$$|||\mathbf{K}|||_F \equiv \|\mathrm{vec}(\mathbf{K})\|_2 \equiv \sqrt{\sum_{i=1}^q \sum_{j=1}^r \kappa_{ij}^2},$$

and max norm $\|\mathbf{K}\|_\infty \equiv \|\mathrm{vec}(\mathbf{K})\|_\infty \equiv \max_{i,j} |\kappa_{ij}|$. Its ℓ_a-ℓ_b operator norm is

$$|||\mathbf{K}|||_{a,b} \equiv \max_{\boldsymbol{x}\neq\mathbf{0}} \frac{\|\mathbf{K}\boldsymbol{x}\|_b}{\|\boldsymbol{x}\|_a}$$

with shorthand notation $|||\mathbf{K}|||_a \equiv |||\mathbf{K}|||_{a,a}$; for instance, $|||\mathbf{K}|||_\infty \equiv \max_{i=1\ldots,q} \sum_{j=1}^r |\kappa_{ij}|$.

For a function $f : \mathbb{R}^m \to \mathbb{R}$, we define $\partial_j f(\boldsymbol{x})$ as the partial derivative with respect to x_j, and $\partial_{jj} f(\boldsymbol{x}) = \partial_j \partial_j f(\boldsymbol{x})$. For $\boldsymbol{f} : \mathbb{R} \to \mathbb{R}^m$, $\boldsymbol{f}(x) = (f_1(x), \ldots, f_m(x))^\top$, we let $\boldsymbol{f}'(x) = (f_1'(x), \ldots, f_m'(x))^\top$ be the vector of derivatives. Likewise $\boldsymbol{f}''(x)$ is used for second derivatives. The symbol $\mathbb{1}_A(\cdot)$ denotes the indicator function of the set A, while $\mathbf{1}_n \in \mathbb{R}^n$ is the vector of all 1's. For $\boldsymbol{a}, \boldsymbol{b} \in \mathbb{R}^m$, $\boldsymbol{a} \circ \boldsymbol{b} \equiv (a_1 b_1, \ldots, a_m b_m)^\top$. A density of a distribution is always a probability density function with respect to Lebesgue measure. When it is clear from the context, $\mathbb{E}_0$ denotes the expectation under a true distribution P_0.

2. Score Matching

In this section, we review the original score matching and develop our generalized score matching estimators.

2.1. Original Score Matching

Let $\boldsymbol{X}$ be a random vector taking values in $\mathbb{R}^m$ with distribution P_0 and density p_0. Let $\mathcal{P}$ be a family of distributions of interest with twice continuously differentiable densities supported on $\mathbb{R}^m$. Suppose $P_0 \in \mathcal{P}$. The *score matching loss* for $P \in \mathcal{P}$, with density p, is given by

$$J(P) = \int_{\mathbb{R}^m} p_0(\boldsymbol{x}) \|\nabla \log p(\boldsymbol{x}) - \nabla \log p_0(\boldsymbol{x})\|_2^2 \, \mathrm{d}\boldsymbol{x}. \tag{3}$$

The gradients in (3) can be thought of as gradients with respect to a hypothetical location parameter, evaluated at the origin (Hyvärinen, 2005). The loss $J(P)$ is minimized if and only

if $P = P_0$, which forms the basis for estimation of P_0. Importantly, since the loss depends on p only through its log-gradient, it suffices to know p up to a normalizing constant. Under mild conditions, (3) can be rewritten as

$$J(P) = \int_{\mathbb{R}^m} p_0(\boldsymbol{x}) \sum_{j=1}^{m} \left[\partial_{jj} \log p(\boldsymbol{x}) + \frac{(\partial_j \log p(\boldsymbol{x}))^2}{2} \right] \mathrm{d}\boldsymbol{x}, \tag{4}$$

plus a constant independent of p. The integral in (4) can be approximated by a sample average; this alleviates the need for knowing the true density p_0, and provides a way to estimate p_0.

2.2. Generalized Score Matching for Non-Negative Data

When the true density p_0 is supported on a proper subset of $\mathbb{R}^m$, the integration by parts underlying the equivalence of (3) and (4) may fail due to discontinuity at the boundary. For distributions supported on the non-negative orthant, $\mathbb{R}^m_+$, Hyvärinen (2007) addressed this issue by instead minimizing the *non-negative score matching loss*

$$J_+(P) = \int_{\mathbb{R}^m_+} p_0(\boldsymbol{x}) \|\nabla \log p(\boldsymbol{x}) \circ \boldsymbol{x} - \nabla \log p_0(\boldsymbol{x}) \circ \boldsymbol{x}\|_2^2 \, \mathrm{d}\boldsymbol{x}. \tag{5}$$

This loss can be motivated via gradients with respect to a hypothetical scale parameter (Hyvärinen, 2007). Under mild conditions, $J_+(P)$ can again be rewritten in terms of an expectation of a function independent of p_0, thus allowing one to form a sample loss.

In this work, we consider generalizing the non-negative score matching loss as follows.

Definition 1 *Let $\mathcal{P}_+$ be the family of distributions of interest, and assume every $P \in \mathcal{P}_+$ has a twice continuously differentiable density supported on $\mathbb{R}^m_+$. Suppose the m-variate random vector $\boldsymbol{X}$ has true distribution $P_0 \in \mathcal{P}_+$, and let p_0 be its twice continuously differentiable density. Let $h_1, \ldots, h_m : \mathbb{R}_+ \to \mathbb{R}_+$ be a.s. positive functions that are absolutely continuous in every bounded sub-interval of $\mathbb{R}_+$, and set $\boldsymbol{h}(\boldsymbol{x}) = (h_1(x_1), \ldots, h_m(x_m))^\top$. For $P \in \mathcal{P}_+$ with density p, the* generalized $\boldsymbol{h}$-score matching loss *is*

$$J_{\boldsymbol{h}}(P) = \int_{\mathbb{R}^m_+} \frac{1}{2} p_0(\boldsymbol{x}) \|\nabla \log p(\boldsymbol{x}) \circ \boldsymbol{h}(\boldsymbol{x})^{1/2} - \nabla \log p_0(\boldsymbol{x}) \circ \boldsymbol{h}(\boldsymbol{x})^{1/2}\|_2^2 \, \mathrm{d}\boldsymbol{x}, \tag{6}$$

where $\boldsymbol{h}^{1/2}(\boldsymbol{x}) \equiv (h_1^{1/2}(x_1), \ldots, h_m^{1/2}(x_m))^\top$.

Proposition 2 *The distribution P_0 is the unique minimizer of $J_{\boldsymbol{h}}(P)$ for $P \in \mathcal{P}_+$.*

Proof First, observe that $J_{\boldsymbol{h}}(P) \geq 0$ and $J_{\boldsymbol{h}}(P_0) = 0$. For uniqueness, suppose $J_{\boldsymbol{h}}(P_1) = 0$ for some $P_1 \in \mathcal{P}_+$. Let p_0 and p_1 be the respective densities. By assumption $p_0(\boldsymbol{x}) > 0$ a.s. and $h_j^{1/2}(\boldsymbol{x}) > 0$ a.s. for all $j = 1, \ldots, m$. Therefore, we must have $\nabla \log p_1(\boldsymbol{x}) = \nabla \log p_0(\boldsymbol{x})$ a.s., or equivalently, $p_1(\boldsymbol{x}) = \text{const} \times p_0(\boldsymbol{x})$ almost surely in $\mathbb{R}^m_+$. Since p_1 and p_0 are continuous densities supported on $\mathbb{R}^m_+$, it follows that $p_1(\boldsymbol{x}) = p_0(\boldsymbol{x})$ for all $\boldsymbol{x} \in \mathbb{R}^m_+$. ■

Choosing all $h_j(x) = x^2$ recovers the loss from (5). In our generalization, we will focus on using functions h_j that are increasing but are bounded or grow rather slowly. This will alleviate the need to estimate higher moments, leading to better practical performance and improved theoretical guarantees.

We will consider the following assumptions:

(A1) $p_0(\boldsymbol{x}) h_j(x_j) \partial_j \log p(\boldsymbol{x}) \Big|_{x_j \searrow 0^+}^{x_j \nearrow +\infty} = 0$, $\quad \forall \boldsymbol{x}_{-j} \in \mathbb{R}_+^{m-1}, \quad \forall p \in \mathcal{P}_+$;

(A2) $\mathbb{E}_{p_0} \|\nabla \log p(\boldsymbol{X}) \circ \boldsymbol{h}^{1/2}(\boldsymbol{X})\|_2^2 < +\infty$, $\mathbb{E}_{p_0} \|(\nabla \log p(\boldsymbol{X}) \circ \boldsymbol{h}(\boldsymbol{X}))'\|_1 < +\infty$, $\forall p \in \mathcal{P}_+$,

where $\partial_j \log p(\boldsymbol{x}) \equiv \frac{\partial \log p(\boldsymbol{y})}{\partial y_j}\Big|_{\boldsymbol{y}=\boldsymbol{x}}$, $f(\boldsymbol{x}) \Big|_{x_j \searrow 0^+}^{x_j \nearrow +\infty} \equiv \lim_{x_j \nearrow +\infty} f(\boldsymbol{x}) - \lim_{x_j \searrow 0} f(\boldsymbol{x})$, "$\forall p \in \mathcal{P}_+$" is a shorthand for "for all p being the density of some $P \in \mathcal{P}_+$", and the prime symbol denotes component-wise differentiation. While the second half of (A2) was not made explicit in Hyvärinen (2005, 2007), (A1)-(A2) were both required for integration by parts and Fubini-Tonelli to apply.

Once the forms of p_0 and p are given, sufficient conditions for $\boldsymbol{h}$ for Assumptions (A1)-(A2) to hold are easy to find. In particular, (A1) and (A2) are easily satisfied and verified for exponential families.

Integration by parts yields the following theorem which shows that $J_{\boldsymbol{h}}$ from (6) is an expectation (under P_0) of a function that does not depend on p_0, similar to (4). The proof is given in Appendix A.1.

Theorem 3 *Under (A1) and (A2), the loss from (6) equals*

$$J_{\boldsymbol{h}}(P) = \int_{\mathbb{R}^m_+} p_0(\boldsymbol{x}) \sum_{j=1}^{m} \Big[h_j'(x_j) \partial_j (\log p(\boldsymbol{x})) + h_j(x_j) \partial_{jj} (\log p(\boldsymbol{x})) + \frac{1}{2} h_j(x_j) \left(\partial_j (\log p(\boldsymbol{x}))\right)^2 \Big] \mathrm{d}\boldsymbol{x} \tag{7}$$

plus a constant independent of p.

Given a data matrix $\mathbf{x} \in \mathbb{R}^{n \times m}$ with rows $\boldsymbol{X}^{(i)}$, we define the sample version of (7) as

$$\hat{J}_{\boldsymbol{h}}(P) = \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1}^{m} \left\{ h_j'(X_j^{(i)}) \partial_j (\log p(\boldsymbol{X}^{(i)})) + h_j(X_j^{(i)}) \left[\partial_{jj} (\log p(\boldsymbol{X}^{(i)})) + \frac{1}{2} \left(\partial_j (\log p(\boldsymbol{X}^{(i)})) \right)^2 \right] \right\}. \tag{8}$$

Subsequently, for a distribution P with density p, we let $J_{\boldsymbol{h}}(p) \equiv J_{\boldsymbol{h}}(P)$. Similarly, when a distribution $P_{\boldsymbol{\theta}}$ with density $p_{\boldsymbol{\theta}}$ is associated to a parameter vector $\boldsymbol{\theta}$, we write $J_{\boldsymbol{h}}(\boldsymbol{\theta}) \equiv J_{\boldsymbol{h}}(p_{\boldsymbol{\theta}}) \equiv J_{\boldsymbol{h}}(P_{\boldsymbol{\theta}})$. We apply similar conventions to the sample version $\hat{J}_{\boldsymbol{h}}(P)$. We note that this type of loss is also treated in slightly different settings in Parry (2016) and Almeida and Gidas (1993).

Remark 4 In the one-dimensional case, using the notation in Parry et al. (2012), $J_{\boldsymbol{h}}(P)$ and $\hat{J}_{\boldsymbol{h}}(P)$ correspond to $d(P_0, P)$ and $S(x, P)$, respectively, and can be generated by $\phi(x, p, p_1) \equiv -h(x)p_1^2/(2p)$ (c.f. Equations (39), (51), (53) and Section 10.1 therein). Thus Theorem 3 follows from this correspondence. While (A1) is equivalent to the condition implied by the boundary divergence $d_b = 0$ in that paper, (A2), which we assume for invoking Fubini-Tonelli due to multi-dimensionality, is not present. On the other hand, while Parry (2016) treats the multivariate case, it does not cover the connection between our $J_{\boldsymbol{h}}$ and $\hat{J}_{\boldsymbol{h}}$. Since ϕ is concave but not strictly concave in (p, p_1), the results in Parry (2016) only imply that P_0 is *a* minimizer, a weaker conclusion than Proposition 2.

3. Exponential Families

In this section, we study the case where $\mathcal{P}_+ \equiv \{p_{\boldsymbol{\theta}} : \boldsymbol{\theta} \in \boldsymbol{\Theta}\}$ is an exponential family comprising continuous distributions with support $\mathbb{R}_+^m$. More specifically, we consider densities that are indexed by the canonical parameter $\boldsymbol{\theta} \in \mathbb{R}^r$ and have the form

$$\log p_{\boldsymbol{\theta}}(\boldsymbol{x}) = \boldsymbol{\theta}^\top \boldsymbol{t}(\boldsymbol{x}) - \psi(\boldsymbol{\theta}) + b(\boldsymbol{x}), \quad \boldsymbol{x} \in \mathbb{R}_+^m, \tag{9}$$

where $\boldsymbol{t}(\boldsymbol{x}) \in \mathbb{R}_+^r$ comprises the sufficient statistics, $\psi(\boldsymbol{\theta})$ is a normalizing constant depending on $\boldsymbol{\theta}$ only, and $b(\boldsymbol{x})$ is the base measure, with $\boldsymbol{t}$ and b a.s. differentiable with respect to each component. Define $\boldsymbol{t}_{\boldsymbol{j}}'(\boldsymbol{x}) \equiv (\partial_j t_1(\boldsymbol{x}), \ldots, \partial_j t_r(\boldsymbol{x}))^\top$ and $b_j'(\boldsymbol{x}) \equiv \partial_j b(\boldsymbol{x})$.

Theorem 5 *Under Assumptions (A1)-(A2) from Section 2.2, the empirical generalized $\boldsymbol{h}$-score matching loss (8) can be rewritten as a quadratic function in $\boldsymbol{\theta} \in \mathbb{R}^r$:*

$$\hat{J}_{\boldsymbol{h}}(p_{\boldsymbol{\theta}}) = \frac{1}{2}\boldsymbol{\theta}^\top \boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta} - \boldsymbol{g}(\mathbf{x})^\top \boldsymbol{\theta} + \text{const}, \quad \textit{where} \tag{10}$$

$$\boldsymbol{\Gamma}(\mathbf{x}) = \frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m h_j(X_j^{(i)}) \boldsymbol{t}_j'(\boldsymbol{X}^{(i)}) \boldsymbol{t}_j'(\boldsymbol{X}^{(i)})^\top \quad \textit{and} \tag{11}$$

$$\boldsymbol{g}(\mathbf{x}) = -\frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m \left[h_j(X_j^{(i)}) b_j'(\boldsymbol{X}^{(i)}) \boldsymbol{t}_j'(\boldsymbol{X}^{(i)}) + h_j(X_j^{(i)}) \boldsymbol{t}_j''(\boldsymbol{X}^{(i)}) + h_j'(X_j^{(i)}) \boldsymbol{t}_j'(\boldsymbol{X}_i) \right] \tag{12}$$

are sample averages of functions of the data matrix $\mathbf{x}$ only.

Define $\boldsymbol{\Gamma}_0 \equiv \mathbb{E}_{p_0}\boldsymbol{\Gamma}(\mathbf{x})$, $\boldsymbol{g}_0 \equiv \mathbb{E}_{p_0}\boldsymbol{g}(\mathbf{x})$, and $\boldsymbol{\Sigma}_0 \equiv \mathbb{E}_{p_0}[(\boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta}_0 - g(\mathbf{x}))(\boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta}_0 - g(\mathbf{x}))^\top]$.

Theorem 6 *Suppose that*

(C1) $\boldsymbol{\Gamma}$ is a.s. invertible, and

(C2) $\boldsymbol{\Gamma}_0$, $\boldsymbol{\Gamma}_0^{-1}$, $\boldsymbol{g}_0$ and $\boldsymbol{\Sigma}_0$ exist and are entry-wise finite.

Then the minimizer of (10) is a.s. unique with closed-form solution $\hat{\boldsymbol{\theta}} \equiv \boldsymbol{\Gamma}(\mathbf{x})^{-1}\boldsymbol{g}(\mathbf{x})$. Moreover,

$$\hat{\boldsymbol{\theta}} \to_{a.s.} \boldsymbol{\theta}_0 \quad \textit{and} \quad \sqrt{n}(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \to_d \mathcal{N}_r\left(\mathbf{0}, \boldsymbol{\Gamma}_0^{-1}\boldsymbol{\Sigma}_0\boldsymbol{\Gamma}_0^{-1}\right) \quad \textit{as } n \to \infty.$$

Theorems 5 and 6 are proved in Appendix A.2. Theorem 5 clarifies the quadratic nature of the loss, and Theorem 6 provides a basis for asymptotically valid tests and confidence intervals for the parameter $\boldsymbol{\theta}$. Note that Condition (C1) holds if and only if $h_j(X_j) > 0$ a.s. and $[\boldsymbol{t}_j'(\boldsymbol{X}^{(1)}), \ldots, \boldsymbol{t}_j'(\boldsymbol{X}^{(n)})] \in \mathbb{R}^{r\times n}$ has rank r a.s. for some $j = 1, \ldots, m$.

The conclusion in Theorem 6 indicates that, similar to the estimator in Hyvärinen (2007) with $h_j(x) = x^2$, the closed-form solution for our generalized $\hat{\boldsymbol{\theta}}$ allows one to consistently estimate the canonical parameter in an exponential family distribution without needing to calculate the often complicated normalizing constant $\psi(\boldsymbol{\theta})$ or resort to numerical methods. Computational details are explicated in Section 5.3.

Below we illustrate the estimator $\hat{\boldsymbol{\theta}}$ in the case of univariate truncated normal distributions. We assume (A1)-(A2) and (C1)-(C2) throughout.

Example 3.1 *Univariate ($m = r = 1$) truncated normal distributions for mean parameter μ and variance parameter σ^2 have density*

$$p_{\mu,\sigma^2}(x) \propto \exp\left\{-\frac{(x-\mu)^2}{2\sigma^2}\right\}, \quad x \in \mathbb{R}_+. \tag{13}$$

If σ^2 is known but μ unknown, then writing the density in canonical form as in (9) yields

$$p_\theta(x) \propto \exp\{\theta t(x) + b(x)\}, \quad \theta \equiv \frac{\mu}{\sigma^2}, \quad t(x) \equiv x, \quad b(x) = -\frac{x^2}{2\sigma^2}.$$

Given an i.i.d. sample $X_1, \ldots, X_n \sim p_{\mu_0,\sigma^2}$, the generalized h-score matching estimator of μ is

$$\hat{\mu}_h \equiv \frac{\sum_{i=1}^n h(X_i)X_i - \sigma^2 h'(X_i)}{\sum_{i=1}^n h(X_i)}.$$

If $\lim_{x\searrow 0^+} h(x) = 0$, $\lim_{x\nearrow+\infty} h^2(x)(x-\mu_0)p_{\mu_0,\sigma^2}(x) = 0$ and the expectations are finite (for example, when $h(x) = o(\exp(Mx^2))$ for $M < \frac{1}{4\sigma^2}$), then

$$\sqrt{n}(\hat{\mu}_h - \mu_0) \to_d \mathcal{N}\left(0, \frac{\mathbb{E}_0[\sigma^2 h^2(X) + \sigma^4 h'^2(X)]}{\mathbb{E}_0^2[h(X)]}\right).$$

We recall that the Cramér-Rao lower bound *(i.e. the lower bound on the variance of any unbiased estimator) for estimating μ is*

$$\frac{\sigma^4}{\text{var}(X - \mu_0)}.$$

Example 3.2 *Consider the univariate truncated normal distributions from (13) in the setting where the mean parameter μ is known but the variance parameter $\sigma^2 > 0$ is unknown. In canonical form as in (9), we write*

$$p_\theta(x) \propto \exp\{\theta t(x) + b(x)\}, \quad \theta \equiv \frac{1}{\sigma^2}, \quad t(x) \equiv -(x-\mu)^2/2, \quad b(x) = 0.$$

Given an i.i.d. sample $X_1, \ldots, X_n \sim p_{\mu,\sigma_0^2}$, the generalized h-score matching estimator of σ^2 is

$$\hat{\sigma}_h^2 \equiv \frac{\sum_{i=1}^n h(X_i)(X_i-\mu)^2}{\sum_{i=1}^n h(X_i) + h'(X_i)(X_i-\mu)}.$$

If, in addition to the assumptions in Example 3.1, $\lim_{x\nearrow+\infty} h^2(x)(x-\mu)^3 p_{\mu,\sigma_0^2}(x) = 0$, *then*

$$\sqrt{n}(\hat{\sigma}_h^2 - \sigma_0^2) \to_d \mathcal{N}\left(0, \frac{2\sigma_0^6 \mathbb{E}_0[h^2(X)(X-\mu)^2] + \sigma_0^8 \mathbb{E}_0[h'^2(X)(X-\mu)^2]}{\mathbb{E}_0^2[h(X)(X-\mu)^2]}\right).$$

Moreover, the Cramér-Rao lower bound *for estimating* σ^2 *is*

$$\frac{4\sigma_0^8}{\mathrm{var}(X-\mu)^2}.$$

Remark 7 In Example 3.2, if $\mu_0 = 0$, then $h(x) \equiv 1$ also satisfies (A1)-(A2) and (C1)-(C2) and one recovers the sample variance $\frac{1}{n}\sum_i X_i^2$, which obtains the Cramér-Rao lower bound.

In these examples, there is a benefit in using a bounded function h, which can be explained as follows. When $\mu \gg \sigma$, there is effectively no truncation to the Gaussian distribution, and our method adapts to using low moments in (6), since a bounded and increasing $h(x)$ becomes almost constant as it reaches its asymptote for x large. Hence, we effectively revert to the original score matching (recall Section 2.1). In the other cases, the truncation effect is significant and our estimator uses higher moments accordingly.

Figure 1 plots the asymptotic variance of $\hat{\mu}_h$ from Example 3.1, with $\sigma = 1$ known. Efficiency as measured by the Cramér-Rao lower bound divided by the asymptotic variance is also shown. We see that two truncated versions of $\log(1+x)$ have asymptotic variance close to the Cramér-Rao bound. This asymptotic variance is also reflective of the variance for smaller finite samples.

Figure 2 is the analog of Figure 1 for $\hat{\sigma}_h^2$ from Example 3.2 with $\mu = 0.5$ known. While the specifics are a bit different the benefits of using bounded or slowly growing h are again clear. We note that when σ is small, the effect of truncation to the positive part of the real line is small.

In both plots we order/color the curves based on their overall efficiency, so they have different colors in one from the other, although the same functions are presented. For all functions presented here (A1)–(A2) and (C1)–(C2) are satisfied.

4. Regularized Generalized Score Matching

In high-dimensional settings, when the number r of parameters to estimate may be larger than the sample size n, it is hard, if not impossible, to estimate the parameters consistently without turning to some form of regularization. More specifically, for exponential families, condition (C1) in Section 3 fails when $r > n$. A popular approach is then the use of ℓ_1 regularization to exploit possible sparsity.

Let the data matrix $\mathbf{x} \in \mathbb{R}^{n\times m}$ comprise n i.i.d. samples from distribution P_0. Assume P_0 has density p_0 belonging to an exponential family $\mathcal{P}_+ \equiv \{p_{\boldsymbol{\theta}} : \boldsymbol{\theta} \in \boldsymbol{\Theta}\}$, where $\boldsymbol{\Theta} \subseteq \mathbb{R}^r$. Adding an ℓ_1 penalty to (10), we obtain the regularized generalized score matching loss

$$\frac{1}{2}\boldsymbol{\theta}^\top \boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta} - \boldsymbol{g}(\mathbf{x})^\top \boldsymbol{\theta} + \lambda\|\boldsymbol{\theta}\|_1 \tag{14}$$

as in Lin et al. (2016). The loss in (14) involves a quadratic smooth part as in the familiar lasso loss for linear regression. However, although the matrix $\boldsymbol{\Gamma}$ is positive semidefinite,

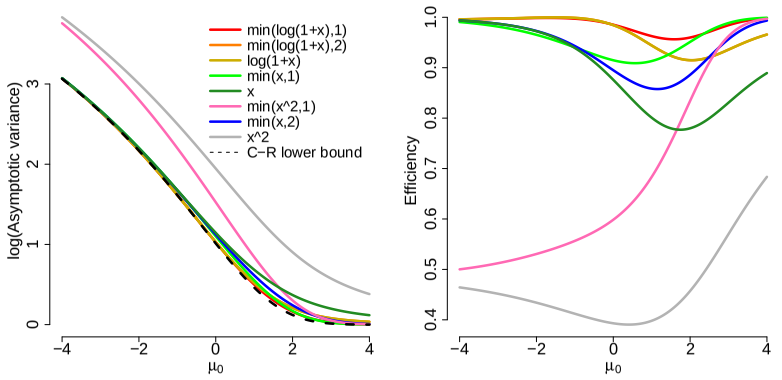

Figure 1: Log of asymptotic variance and efficiency with respect to the Cramér-Rao bound for $\hat{\mu}_h$ ($\sigma^2 = 1$ known).

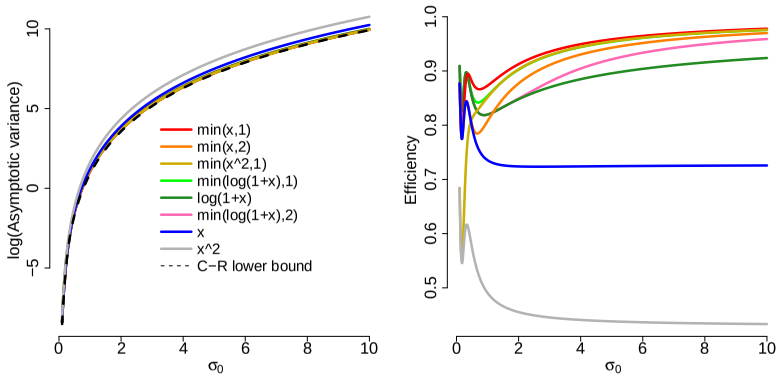

Figure 2: Log of asymptotic variance and efficiency with respect to the Cramér-Rao bound for $\hat{\sigma}_h^2$ ($\mu = 0.5$ known).

the regularized loss in (14) is not guaranteed to be bounded unless the tuning parameter λ is sufficiently large—a problem that does not occur in lasso. We note that here, and throughout, we suppress the dependence on the data $\mathbf{x}$ for $\boldsymbol{\Gamma}(\mathbf{x})$, $\boldsymbol{g}(\mathbf{x})$ and derived quantities.

For a more detailed explanation, note that that by (11), $\boldsymbol{\Gamma} = \mathbf{H}^\top\mathbf{H}$ for some $\mathbf{H} \in \mathbb{R}^{nm\times r}$. In the high-dimensional case, the rank of $\boldsymbol{\Gamma}$, or equivalently $\mathbf{H}$, is at most $nm < r$. Hence, $\boldsymbol{\Gamma}$ is not invertible and $\boldsymbol{g}$ does not necessarily lie in the column span of $\boldsymbol{\Gamma}$. Let $\mathrm{Ker}(\boldsymbol{\Gamma})$ be the kernel of $\boldsymbol{\Gamma}$. Then there may exist $\boldsymbol{\nu} \in \mathrm{Ker}(\boldsymbol{\Gamma})$ with $\boldsymbol{g}^\top\boldsymbol{\nu} \neq 0$. In this case, if

$$0 \leq \lambda < \sup_{\boldsymbol{\nu}\in\mathrm{Ker}(\boldsymbol{\Gamma})} |\boldsymbol{g}^\top\boldsymbol{\nu}|/\|\boldsymbol{\nu}\|_1,$$

there exists $\boldsymbol{\nu} \in \mathrm{Ker}(\boldsymbol{\Gamma})$ with $\frac{1}{2}\boldsymbol{\nu}^\top\boldsymbol{\Gamma}\boldsymbol{\nu} = 0$ and $-\boldsymbol{g}^\top\boldsymbol{\nu} + \lambda\|\boldsymbol{\nu}\|_1 < 0$. Evaluating at $\boldsymbol{\theta}(a) = a\cdot\boldsymbol{\nu}$ for scalar $a > 0$, the loss becomes $a\left(-\boldsymbol{g}^\top\boldsymbol{\nu} + \lambda\|\boldsymbol{\nu}\|_1\right)$, which is negative and linear in a, and thus unbounded below. In this case no minimizer of (14) exists for small values of λ. This issue also exists for the estimators from Zhang and Zou (2014) and Liu and Luo (2015), which correspond to score matching for GGMs. We note that in the context of estimating the interaction matrix in pairwise models, $r = m^2$; thus, the condition $nm < r$ reduces to $n < m$, or $n < m + 1$ when both $\mathbf{K}$ and $\boldsymbol{\eta}$ are estimated.

To circumvent the unboundedness problem, we add small values $\gamma_\ell > 0$ to the diagonal entries of $\boldsymbol{\Gamma}$, which become $\boldsymbol{\Gamma}_{\ell,\ell} + \gamma_\ell$, $\ell = 1,\ldots,r$. This is in the spirit of work such as Ledoit and Wolf (2004) and corresponds to an elastic net-type penalty (Zou and Hastie, 2005) with weighted ℓ_2 penalty $\sum_{\ell=1}^r \gamma_\ell\theta_\ell^2$. After this modification, $\boldsymbol{\Gamma}$ is positive definite, our regularized loss is strongly convex in $\boldsymbol{\theta}$, and a unique minimizer exists for all $\lambda \geq 0$. For the special case of truncated GGMs, we will show that a result on consistent estimation holds if we choose $\gamma_\ell = \delta_0\boldsymbol{\Gamma}_{\ell,\ell}$ for a suitably small constant $\delta_0 > 0$, for which we propose a particular choice to avoid tuning. This choice of γ_ℓ depends on the data through $\boldsymbol{\Gamma}_{\ell,\ell}$.

Definition 8 *For $\boldsymbol{\gamma} \in \mathbb{R}_+^r\backslash\{\mathbf{0}\}$, let $\boldsymbol{\Gamma}_{\boldsymbol{\gamma}} \equiv \boldsymbol{\Gamma} + \mathrm{diag}(\boldsymbol{\gamma})$. The* regularized generalized $\boldsymbol{h}$-score matching estimator *with tuning parameter $\lambda \geq 0$ and* amplifier $\boldsymbol{\gamma}$ *is the estimator*

$$\hat{\boldsymbol{\theta}} \in \operatorname*{argmin}_{\boldsymbol{\theta}\in\boldsymbol{\Theta}} \hat{J}_{\boldsymbol{h},\lambda,\boldsymbol{\gamma}}(\boldsymbol{\theta}) \equiv \operatorname*{argmin}_{\boldsymbol{\theta}\in\boldsymbol{\Theta}} \frac{1}{2}\boldsymbol{\theta}^\top\boldsymbol{\Gamma}_{\boldsymbol{\gamma}}(\mathbf{x})\boldsymbol{\theta} - \boldsymbol{g}(\mathbf{x})^\top\boldsymbol{\theta} + \lambda\|\boldsymbol{\theta}\|_1. \tag{15}$$

In the case where $\boldsymbol{\gamma} = (\delta - 1)\mathrm{diag}(\boldsymbol{\Gamma})$ for some $\delta > 1$, we also call δ the *multiplier*. We note that $\hat{\boldsymbol{\theta}}$ from (15) is a *piecewise linear* function of λ (Lin et al., 2016).

5. Score Matching for Graphical Models for Non-negative Data

In this section we apply our generalized score matching estimator to a general class of graphical models for non-negative data.

5.1. A General Framework of Pairwise Interaction Models

We consider the class of pairwise interaction power models with density introduced in (1). We recall the form of the density:

$$p_{\boldsymbol{\eta},\mathbf{K}}(\boldsymbol{x}) \propto \exp\left(-\frac{1}{2a}\boldsymbol{x}^{a\top}\mathbf{K}\boldsymbol{x}^a + \boldsymbol{\eta}^\top\frac{\boldsymbol{x}^b - \mathbf{1}_m}{b}\right)\mathbb{1}_{\mathbb{R}_+^m}(\boldsymbol{x}), \tag{16}$$

where a and b are known constants, and the interaction matrix $\mathbf{K}$ and the vector $\boldsymbol{\eta}$ are parameters. When $b = 0$, we use the convention that $\frac{x^0-1}{0} \equiv \log x$ and apply the logarithm element-wise. Our focus will be on the interaction matrix $\mathbf{K}$ that determines the conditional independence graph through its support $S(\mathbf{K}) \equiv \{(i,j) : \kappa_{ij} \neq 0\}$. However, unless $\boldsymbol{\eta}$ is known or assumed to be zero, we also need to estimate $\boldsymbol{\eta}$ as a nuisance parameter. In the case where we assume $\boldsymbol{\eta} \equiv \mathbf{0}$ is known (i.e. the linear part $(\boldsymbol{x}^b - \mathbf{1}_m)/b$ is not present), we call the distribution (and the corresponding estimator) a *centered* distribution (estimator), in contrast to the general case termed *non-centered* when we assume $\boldsymbol{\eta} \neq \mathbf{0}$ or unknown.

We first give a set of sufficient conditions for the density to be valid, i.e., the right-hand side of (16) to be integrable. The proof is given in Appendix A.3.

Theorem 9 *Define conditions*

(CC1) $\mathbf{K}$ *is* strictly co-positive, *i.e.,* $\boldsymbol{v}^\top\mathbf{K}\boldsymbol{v} > 0$ *for all* $\boldsymbol{v} \in \mathbb{R}_+^m\backslash\{\mathbf{0}\}$*;*

(CC2) $2a > b > 0$*;*

(CC3) $a > 0$, $b = 0$, *and* $\eta_j > -1$ *for* $j = 1,\ldots,m$ *($\boldsymbol{\eta} \succ -\mathbf{1}_m$).*

In the non-centered case, if (CC1) and one of (CC2) and (CC3) holds, then the function on the right-hand side of (16) is integrable over $\mathbb{R}_+^m$. In the centered case, (CC1) and $a > 0$ are sufficient.

We emphasize that (CC1) is a weaker condition than positive definiteness. Criteria for strict co-positivity are discussed in Väliaho (1986).

5.2. Implementation for Different Models

In this section we give some implementation details for the regularized generalized $\boldsymbol{h}$-score matching estimator defined in (15) applied to the pairwise interaction models from (16). We again let $\boldsymbol{\Psi} \equiv \left(\mathbf{K}^\top, \boldsymbol{\eta}\right)^\top \in \mathbb{R}^{(m+1)\times m}$. The unregularized loss is then

$$\hat{J}_{\boldsymbol{h}}(P) = \frac{1}{2}\mathrm{vec}(\boldsymbol{\Psi})^\top\boldsymbol{\Gamma}(\boldsymbol{x})\mathrm{vec}(\boldsymbol{\Psi}) - \boldsymbol{g}(\boldsymbol{x})^\top\mathrm{vec}(\boldsymbol{\Psi}).$$

The general form of the matrix $\boldsymbol{\Gamma}$ and the vector $\boldsymbol{g}$ in the loss were given in equations (10)–(12). Here $\boldsymbol{\Gamma} \in \mathbb{R}^{(m+1)m\times(m+1)m}$ is block-diagonal, with the j-th $\mathbb{R}^{(m+1)\times(m+1)}$ block

$$\begin{aligned}\boldsymbol{\Gamma}_j(\mathbf{x}) &\equiv \begin{bmatrix}\boldsymbol{\Gamma}_{11,j} & \boldsymbol{\Gamma}_{12,j}\\ \boldsymbol{\Gamma}_{12,j}^\top & \Gamma_{22,j}\end{bmatrix} \qquad (17)\\ &\equiv \frac{1}{n}\sum_{i=1}^n \begin{bmatrix} h_j\left(X_j^{(i)}\right){X_j^{(i)}}^{2a-2}\boldsymbol{X}^{(i)^a}\boldsymbol{X}^{(i)^{a\top}} & -h_j\left(X_j^{(i)}\right){X_j^{(i)}}^{a+b-2}\boldsymbol{X}^{(i)^a}\\ -h_j\left(X_j^{(i)}\right){X_j^{(i)}}^{a+b-2}\boldsymbol{X}^{(i)^{a\top}} & h_j\left(X_j^{(i)}\right){X_j^{(i)}}^{2b-2}\end{bmatrix}\\ &= \frac{1}{n}\mathbf{y}^\top\mathbf{y}, \quad \mathbf{y} \equiv \left[-(\sqrt{\boldsymbol{h}_j(\boldsymbol{X}_j)}\circ\boldsymbol{X}_j^{a-1})\circ\mathbf{x}^a \quad \sqrt{\boldsymbol{h}_j(\boldsymbol{X}_j)}\circ\boldsymbol{X}_j^{b-1}\right] \in \mathbb{R}^{n,m+1}, \qquad (18)\end{aligned}$$

where the $\circ$ product between a vector and a matrix means an elementwise multiplication of the vector with each *column* of the matrix, and $\boldsymbol{h}_j(\boldsymbol{X}_j) \equiv [h_j(X_j^{(1)}),\ldots,h_j(X_j^{(n)})^\top] \in \mathbb{R}^m$.

Furthermore, $\boldsymbol{g} \equiv \begin{bmatrix} \mathrm{vec}(\mathbf{g}_1) \\ \boldsymbol{g}_2 \end{bmatrix} \in \mathbb{R}^{(m+1)m}$, where $\mathbf{g}_1$ and $\boldsymbol{g}_2$ correspond to each entry of $\mathbf{K}$ and $\boldsymbol{\eta}$, respectively. The j-th column of $\mathbf{g}_1 \in \mathbb{R}^{m\times m}$, written as $\boldsymbol{g}_{1,j}(\mathbf{x})$, is

$$\frac{1}{n}\sum_{i=1}^{n}\left(h_j'\left(X_j^{(i)}\right){X_j^{(i)}}^{a-1} + (a-1)h_j\left(X_j^{(i)}\right){X_j^{(i)}}^{a-2}\right)\boldsymbol{X}^{(i)a} + a h_j\left(X_j^{(i)}\right){X_j^{(i)}}^{2a-2}\boldsymbol{e}_{j,m},$$

where $\boldsymbol{e}_{j,m}$ is the m-vector with 1 at the j-th position and 0 elsewhere, and the j-th entry of $\boldsymbol{g}_2 \in \mathbb{R}^m$ is

$$g_{2,j} = \frac{1}{n}\sum_{i=1}^{n} -h_j'\left(X_j^{(i)}\right){X_j^{(i)}}^{b-1} - (b-1)h_j\left(X_j^{(i)}\right){X_j^{(i)}}^{b-2}.$$

These formulae also hold for $b = 0$ since $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ only depend on the gradient of the log density, and $\frac{\mathrm{d}(x^b-1)/b}{\mathrm{d}x} = x^{b-1}$ also holds for $b = 0$. In the centered case where we know $\boldsymbol{\eta}_0 \equiv \mathbf{0}$, we only estimate $\mathbf{K} \in \mathbb{R}^{m\times m}$, and $\boldsymbol{\Gamma} \in \mathbb{R}^{m^2\times m^2}$ is still block-diagonal, with the j-th block being the $\boldsymbol{\Gamma}_{11,j}$ submatrix in (17), while $\boldsymbol{g}$ is just $\mathrm{vec}(\mathbf{g}_1)$. Since b only appears in the $\boldsymbol{\eta}$ part of the density, the formulae only depend on a in the centered case.

We emphasize that it is indeed necessary to introduce amplifiers $\boldsymbol{\gamma} \succ \mathbf{0}$ or a multiplier $\delta > 1$ in addition to the ℓ_1 penalty. It is clear from (18) that $\mathrm{rank}(\boldsymbol{\Gamma}_j) \le \min\{n, m+1\}$ (or $\min\{n, m\}$ if centered). Thus, $\boldsymbol{\Gamma}$ is non-invertible when $n \le m$ (or $n < m$ if centered) and $\boldsymbol{g}$ need not lie in its column span.

We claim that including amplifiers/multipliers for the submatrices $\boldsymbol{\Gamma}_{11,j}$ only is sufficient for unique existence of a solution for all penalty parameters $\lambda \ge 0$. To see this, consider any nonzero vector $\boldsymbol{\nu} \in \mathbb{R}^{m+1}$. Partition it as $\boldsymbol{\nu} \equiv (\boldsymbol{\nu}_1, \boldsymbol{\nu}_2)$ with $\boldsymbol{\nu}_1 \in \mathbb{R}^m$. Let $\boldsymbol{\Gamma}_{j,\boldsymbol{\gamma}}$ be our amplified version of the matrix $\boldsymbol{\Gamma}_j$ from (21), so

$$\boldsymbol{\Gamma}_{j,\boldsymbol{\gamma}} \;=\; \begin{pmatrix} \boldsymbol{\Gamma}_{11,j} + \mathrm{diag}(\gamma_1, \ldots, \gamma_m) & \boldsymbol{\Gamma}_{12,j} \\ \boldsymbol{\Gamma}_{12,j}^\top & \Gamma_{22,j} \end{pmatrix}.$$

As $\boldsymbol{\Gamma}_j$ itself is positive semidefinite, we find that if at least one of the first m entries of $\boldsymbol{\nu}$ is nonzero then

$$\boldsymbol{\nu}^\top\boldsymbol{\Gamma}_{j,\boldsymbol{\gamma}}\boldsymbol{\nu} \;\ge\; \boldsymbol{\nu}^\top\boldsymbol{\Gamma}_j\boldsymbol{\nu} + \sum_{k=1}^{m}\nu_k^2\boldsymbol{\gamma}_k \;\ge\; \sum_{k=1}^{m}\nu_k^2\boldsymbol{\gamma}_k \;>\; 0.$$

If only the last entry of $\boldsymbol{\nu}$ is nonzero then

$$\boldsymbol{\nu}^\top\Gamma_{j,\boldsymbol{\gamma}}\boldsymbol{\nu} \;=\; \nu_{m+1}^2\Gamma_{22,j} \;>\; 0$$

almost surely; recall that $\Gamma_{22,j} = \frac{1}{n}\sum_{i=1}^{n} h_j\left(X_j^{(i)}\right)X_j^{2b-2}$. We conclude that $\boldsymbol{\Gamma}_{j,\boldsymbol{\gamma}}$ (and thus the entire amplified $\boldsymbol{\Gamma}$) is a.s. positive definite, which ensures unique existence of the loss minimizer.

Given the formulae for $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$, one adds the ℓ_1 penalty on $\boldsymbol{\Psi}$ to get the regularized loss (24). Our methodology readily accommodates two different choices of the penalty parameter λ for $\mathbf{K}$ and $\boldsymbol{\eta}$. This is also theoretically supported for truncated GGMs, since if the ratio of the respective values $\lambda_{\mathbf{K}}$ and $\lambda_{\boldsymbol{\eta}}$ is fixed, the proof of the theorems in Section 6 can be

easily modified by replacing $\boldsymbol{\eta}$ by $(\lambda_{\boldsymbol{\eta}}/\lambda_{\mathbf{K}})\boldsymbol{\eta}$. To avoid picking two tuning parameters, one may also choose to remove the penalty on $\boldsymbol{\eta}$ altogether by profiling out $\boldsymbol{\eta}$ and solve for $\hat{\boldsymbol{\eta}} \equiv \boldsymbol{\Gamma}_{22}^{-1}\left(\boldsymbol{g}_2 - \boldsymbol{\Gamma}_{12}^\top\mathrm{vec}(\hat{\mathbf{K}})\right)$, with $\hat{\mathbf{K}}$ the minimizer of the profiled loss

$$\hat{J}_{\boldsymbol{h},\lambda,\boldsymbol{\gamma},\mathrm{profile}}(\mathbf{K}) \equiv \frac{1}{2}\mathrm{vec}(\mathbf{K})^\top\boldsymbol{\Gamma}_{\boldsymbol{\gamma},11.2}\mathrm{vec}(\mathbf{K}) - (\boldsymbol{g}_1 - \boldsymbol{\Gamma}_{12}\boldsymbol{\Gamma}_{22}^{-1}\boldsymbol{g}_2)^\top\mathrm{vec}(\mathbf{K}) + \lambda\|\mathbf{K}\|_1, \qquad (19)$$

where the Schur complement $\boldsymbol{\Gamma}_{\boldsymbol{\gamma},11.2} \equiv \boldsymbol{\Gamma}_{\boldsymbol{\gamma},11} - \boldsymbol{\Gamma}_{12}\boldsymbol{\Gamma}_{22}^{-1}\boldsymbol{\Gamma}_{12}^\top$ is a.s. positive definite such that the profiled estimator exists a.s. for all $\lambda \ge 0$. This profiled approach corresponds to choosing $\lambda_{\boldsymbol{\eta}}/\lambda_{\mathbf{K}} = 0$. A detailed theoretical analysis of the profiled estimator is beyond the scope of this paper, however. We note that in the other extreme, with $\lambda_{\boldsymbol{\eta}}/\lambda_{\mathbf{K}} = +\infty$, the non-centered estimator reduces to the estimator from the centered case.

Example 5.3 *The truncated normal model comprises the density*

$$p_{\boldsymbol{\mu},\mathbf{K}}(\boldsymbol{x}) \;\propto\; \exp\left\{-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^\top\mathbf{K}(\boldsymbol{x}-\boldsymbol{\mu})\right\}\mathbb{1}_{[0,\infty)^m}(\boldsymbol{x}). \qquad (20)$$

This corresponds to (16) with $a = b = 1$, and $\boldsymbol{\eta} = \mathbf{K}\boldsymbol{\mu}$. The j-th $(m+1)\times(m+1)$ block of $\boldsymbol{\Gamma}(\mathbf{x})$ is

$$\frac{1}{n}\begin{bmatrix} \mathbf{x}^\top\mathrm{diag}(\boldsymbol{h}_j(\boldsymbol{X}_j))\mathbf{x} & -\mathbf{x}^\top\boldsymbol{h}_j(\boldsymbol{X}_j) \\ -\boldsymbol{h}_j(\boldsymbol{X}_j)^\top\mathbf{x} & \boldsymbol{h}_j(\boldsymbol{X}_j)^\top\mathbf{1}_n \end{bmatrix}. \qquad (21)$$

Partitioning the vector $\boldsymbol{g}(\mathbf{x})$ into m subvectors $\boldsymbol{g}_j(\mathbf{x}) \in \mathbb{R}^{m+1}$, where the entries of $\boldsymbol{g}_j(\mathbf{x})$ correspond to column $\boldsymbol{\Psi}_j$, the k-th entry of $\boldsymbol{g}_j(\mathbf{x})$ is

$$g_{jk}(\mathbf{x}) \equiv \begin{cases} \frac{1}{n}\sum_{i=1}^{n} h_j'\left(X_j^{(i)}\right)X_k^{(i)} & \text{if } k \le m,\ k \ne j, \\ \frac{1}{n}\sum_{i=1}^{n} h_j'\left(X_j^{(i)}\right)X_k^{(i)} + h_j\left(X_j^{(i)}\right) & \text{if } k = j, \\ -\frac{1}{n}\sum_{i=1}^{n} h_j'\left(X_j^{(i)}\right) & \text{if } k = m+1. \end{cases} \qquad (22)$$

Example 5.4 *The exponential square-root graphical model in Inouye et al. (2016) has*

$$p_{\boldsymbol{\eta},\mathbf{K}}(\boldsymbol{x}) \propto \exp\left(-\sqrt{\boldsymbol{x}}^\top\mathbf{K}\sqrt{\boldsymbol{x}} + 2\boldsymbol{\eta}^\top\sqrt{\boldsymbol{x}}\right)\mathbb{1}_{[0,\infty)^m}(\boldsymbol{x}),$$

which corresponds to (16) with $a = b = 1/2$. We refer to this as the exponential *model. In this case, the j-th $\mathbb{R}^{(m+1)\times(m+1)}$ block of $\boldsymbol{\Gamma}$ is*

$$\boldsymbol{\Gamma}_j(\mathbf{x}) \equiv \frac{1}{n}\sum_{i=1}^{n}\frac{h_j\left(X_j^{(i)}\right)}{X_j^{(i)}}\begin{pmatrix} -\sqrt{\boldsymbol{X}^{(i)}} \\ 1 \end{pmatrix}\left(-\sqrt{\boldsymbol{X}^{(i)}}^\top, 1\right)$$

and $\boldsymbol{g} = \mathrm{vec}(\mathbf{g}_0)$, where the j-th column of $\mathbf{g}_0 \in \mathbb{R}^{(m+1)\times m}$ is

$$\boldsymbol{g}_j(\mathbf{x}) \equiv \frac{1}{n}\sum_{i=1}^{n}\frac{2h_j'\left(X_j^{(i)}\right)X_j^{(i)} - h_j\left(X_j^{(i)}\right)}{2{X_j^{(i)}}^{3/2}}\begin{pmatrix} \sqrt{\boldsymbol{X}^{(i)}} \\ -1 \end{pmatrix} + \frac{h_j\left(X_j^{(i)}\right)}{2X_j^{(i)}}\boldsymbol{e}_{j,m+1}.$$

Example 5.5 *If $a = 1/2$ and $b = 0$, then (16) becomes*

$$p_{\boldsymbol{\eta},\mathbf{K}}(\boldsymbol{x}) \propto \exp\left(-\sqrt{\boldsymbol{x}}^\top \mathbf{K}\sqrt{\boldsymbol{x}} + \boldsymbol{\eta}^\top \log(\boldsymbol{x})\right) \mathbb{1}_{(0,\infty)^m}(\boldsymbol{x}). \tag{23}$$

If $\mathbf{K}$ is diagonal in this case, then $\boldsymbol{X} \sim p_{\boldsymbol{\eta},\mathbf{K}}$ has independent entries with X_j following the gamma distribution with rate κ_{jj} and shape $\eta_j + 1$, which gives an intuition for condition (CC3) $\eta_j > -1$ in Theorem 9. We can thus view (23) as a multivariate gamma distribution with pairwise interactions among the covariates, and call this the gamma *model. For this model, the j-th block of $\boldsymbol{\Gamma}$ is*

$$\boldsymbol{\Gamma}_j(\mathbf{x}) \equiv \frac{1}{n}\sum_{i=1}^n \frac{h_j\left(X_j^{(i)}\right)}{{X_j^{(i)}}^2} \begin{pmatrix} -\sqrt{X_j^{(i)}\boldsymbol{X}^{(i)}} \\ 1 \end{pmatrix} \left(-\sqrt{X_j^{(i)}\boldsymbol{X}^{(i)}}^\top, 1\right)$$

and the part of $\boldsymbol{g}$ corresponding to $\mathbf{K}_j$ is

$$\boldsymbol{g}_{1,j}(\mathbf{x}) \equiv \frac{1}{n}\sum_{i=1}^n \frac{2h_j'\left(X_j^{(i)}\right)X_j^{(i)} - h_j\left(X_j^{(i)}\right)}{2{X_j^{(i)}}^{3/2}}\sqrt{\boldsymbol{X}^{(i)}} + \frac{h_j\left(X_j^{(i)}\right)}{2X_j^{(i)}}\boldsymbol{e}_{j,m},$$

while the part for η_j is

$$g_{2,j}(\mathbf{x}) = \frac{1}{n}\sum_{i=1}^n \frac{h_j\left(X_j^{(i)}\right)}{{X_j^{(i)}}^2} - \frac{h_j'\left(X_j^{(i)}\right)}{X_j^{(i)}}.$$

We note that the $\boldsymbol{\Gamma}_{11,j}$ sub-matrix of $\boldsymbol{\Gamma}_j$ and the $\boldsymbol{g}_{1,j}$ sub-vector of $\boldsymbol{g}_j$ for the gamma model are the same as those for the exponential model, since $a = 1/2$ in both cases and the parts involving $\mathbf{K}$ in the densities are the same.

5.3. Computational Details

In the most general exponential family setting, as in Eq. (10)–(12) in Theorem 5, the time complexity for forming $\boldsymbol{\Gamma} \in \mathbb{R}^{r\times r}$ and $\boldsymbol{g} \in \mathbb{R}^r$ is $\mathcal{O}\left(nm(f_{b'}(m) + r^2 + r(f_{t'}(m) + f_{t''}(m)))\right)$. Here $f_{b'}(m)$ is the average time complexity for calculating $\partial_j b(\boldsymbol{x})$ over $j = 1,\dots,m$, and similarly $f_{t'}(m)$ for $\partial_j t_\ell(\boldsymbol{x})$ and $f_{t''}(m)$ for $\partial_{jj} t_\ell(\boldsymbol{x})$ over $j = 1,\dots,m$ and $\ell = 1\dots,r$. In many applications, however, these three functions would be constant in m, thus giving an $\mathcal{O}(nmr^2)$ computational complexity, with the dominating term coming from the operations for $\boldsymbol{t}_j'\boldsymbol{t}_j'^\top$ in $\boldsymbol{\Gamma}$ since $\boldsymbol{\Gamma}$ is of dimension $r \times r$.

For pairwise interaction power models, $r = m^2$ and the formula above becomes $\mathcal{O}(nm^5)$. However, since $\boldsymbol{\Gamma}$ is block-diagonal with only m^3 nonzero entries and by the special form of $\boldsymbol{t}(\boldsymbol{x}) = \boldsymbol{x}^a\boldsymbol{x}^{a\top}$, the true complexity is in fact $\mathcal{O}(nm^3)$.

While the introduction of the ℓ_1 penalty inevitably precludes the estimator from having a closed-form solution and introduces non-differentiability, state-of-art numerical optimization algorithms, such as coordinate-descent (Friedman et al., 2007), can be applied for fast estimation. To speed up estimation, one can usually use warm starts using the solution from the previous λ's, as well as lasso-type strong screening rules (Tibshirani et al., 2012) to eliminate components of $\hat{\boldsymbol{\theta}}$ that are known a priori to have zero estimates.

In our implementation for pairwise interaction models of Section 5.1 (that will become available in an R package), we optimize our loss functions with respect to a symmetric matrix $\hat{\mathbf{K}}$; in the non-centered case the vector $\hat{\boldsymbol{\eta}}$ is also included. We use a coordinate-descent method analogous to Algorithm 2 in Lin et al. (2016), where in each step we update each element of $\hat{\mathbf{K}}$ and $\hat{\boldsymbol{\eta}}$ based on the other entries from the previous steps, while maintaining symmetry. In our simulations in Section 7 we always scale the data matrix by column ℓ_2 norms before proceeding to estimation. Note that estimation of $\hat{\mathbf{K}}$ without symmetry can be parallelized as the loss can be decomposed into a sum over the columns.

5.4. Choice of the Function $\boldsymbol{h}$

In this subsection we discuss the requirements on the function $\boldsymbol{h}$ as well as some reasonable choices of $\boldsymbol{h}$.

5.4.1. Requirements on $\boldsymbol{h}$

In Section 2.2, we presented two assumptions (A1) and (A2) under which the generalized score-matching loss is valid, i.e., the integration by parts is justified and Theorem 3 holds. In this section, we present some sufficient (and nearly necessary) requirements on $\boldsymbol{h}$ such that (A1) and (A2) are satisfied.

Definition 10 *Suppose $\boldsymbol{h} : \mathbb{R}_+^m \to \mathbb{R}_+^m$ with $\boldsymbol{h}(\boldsymbol{x}) = (h_1(x_1),\dots,h_m(x_m))^\top$. We write that $\boldsymbol{h} \in \mathcal{H}_{a,b}$ (for simplicity we omit the dependency on m) if for all $j = 1,\dots,m$:*

i) h_j is absolutely continuous in every bounded sub-interval of $\mathbb{R}_+$, and thus has derivative h_j' a.s.;

ii) $h_j(x) > 0$ a.s. on $\mathbb{R}_+$;

iii) h_j and h_j' are both bounded by some piecewise powers of x a.s. on $\mathbb{R}_+$;

iv) $\lim_{x\searrow 0+} h_j(x)/x_j^q = 0$, where $q \equiv \begin{cases} \max\{1-a, 1-b\} & \text{if } b > 0, \\ 1 - \eta_{0,j} & \text{if } b = 0. \end{cases}$

Theorem 11 *Assume every P in the family of distribution $\mathcal{P}_+$ satisfies (CC1)–(CC3) and thus has finite normalizing constants. If $\boldsymbol{h} \in \mathcal{H}_{a,b}$, then (A1) and (A2) are satisfied.*

In centered models, where $\boldsymbol{\eta} \equiv \mathbf{0}$, we can assume $b = 2a$ and iv) in the definition of $\mathcal{H}_{a,2a}$ has $q = 1 - a$. For truncated GGMs, $a = b = 1$, so iv) in Definition 10 is simply $\lim_{x_j\searrow 0^+} h_j(x_j) = 0$.

In the case of $b = 0$, $\boldsymbol{\eta}$ is an unknown parameter, and (CC3) requires each of its component to be greater than -1. If one has prior information on $\boldsymbol{\eta}$ or restricts the parameter space for $\boldsymbol{\eta}$, the requirement reduces to $h_j(x_j) = o(x_j^{1-\eta_{0,j}})$ as $x_j \searrow 0^+$. Otherwise, it suffices to require $h_j(x_j) = o(x_j^2)$. Note that this is only a condition for $x_j \searrow 0^+$, and the globally quadratic behavior of $h_j(x_j) = x_j^2$ from the original score matching is not needed on the entire $\mathbb{R}_+$, leaving opportunities for improvements.

5.4.2. Reasonable Choices of $\boldsymbol{h}$

Assume a common univariate h for all components in $\boldsymbol{h}$. Inspired by Theorem 11, we consider h that behaves like a power of x both as $x \nearrow +\infty$ and as $x \searrow 0^+$. Since the requirements on the two tails are separate, we can choose h to be a piecewise defined function that joins two powers with possibly different degrees. In other words, $h(x) = \min(x^{p_1}, cx^{p_2})$ for some powers $p_1 \geq p_2 \geq 0$ and constant $c > 0$. Only one constant c is required since generalized score matching is invariant to scaling of h. In determining the exact power of p_1 we have the following considerations:

a) In the centered case:

   (i) (A1) and (A2): Theorem 11 requires that $p_1 \geq 1 - a$.

   (ii) "Controlled $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ for $\boldsymbol{x}^{a}$": We propose avoiding poles at the origin for the entries of $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$. The formula for $\boldsymbol{\Gamma}_{11}$ in (18) shows that to this end $\sqrt{h(x)}x^{a-1}$ needs to have a non-negative degree . This requires $p_1 \geq 2 - 2a$. The formula for $\boldsymbol{g}_1$ similarly shows that $h'(x)x^{a-1}$, $h(x)x^{a-2}$ and $h(x)x^{2a-2}$ all need to have a non-negative degree for small x. This requires $p_1 \geq 2 - a$.

b) In the non-centered case, in addition to (i) and (ii),

   (iii) (A1) and (A2): Theorem 11 requires $p_1 \geq \max\{1 - a, 1 - b\}$ for $b > 0$, or $1 - \min_j \eta_{0,j}$ for $b = 0$.

   (iv) "Controlled $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ for $\boldsymbol{x}^{b}$": From the definition of $\boldsymbol{\Gamma}_{22}$ and $\boldsymbol{g}_2$ and by the same reasoning as above, $\sqrt{h(x)}x^{b-1}$, $h'(x)x^{b-1}$ and $h(x)x^{b-2}$ need to be non-negative powers of x, thus requiring $p_1 \geq \max\{2 - b, 2 - 2b\} = 2 - b$.

The choice of p_2, is only relevant for large data points. Our main consideration is then merely how well $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ concentrate on their true population values (Theorem 13). From this perspective, our intuition is that p_2 should be chosen small so that the tails of the distributions of the entries of $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ are well-behaved. Thus, we can choose $p_2 = 0$, in which case $h(x) = \min(x^{p_1}, c)$ is a truncated power.

5.5. Tuning Parameter Selection

By treating the unpenalized loss (i.e., $\lambda = 0$, $\boldsymbol{\gamma} = 0$) as a negative log-likelihood, we may use the extended Bayesian Information Criterion (eBIC) to choose the tuning parameter (Chen and Chen, 2008; Foygel and Drton, 2010). Consider the centered case as an example. Let $\hat{S}^\lambda \equiv \{(i,j) : \hat{\kappa}_{ij}^\lambda \neq 0, i < j\}$, where $\hat{\mathbf{K}}^\lambda$ be the estimate associated with tuning parameter λ. The eBIC is then

$$\text{eBIC}(\lambda) = -n\text{vec}(\hat{\mathbf{K}})^\top \boldsymbol{\Gamma}(\mathbf{x})\text{vec}(\hat{\mathbf{K}}) + 2n\boldsymbol{g}(\mathbf{x})^\top \text{vec}(\hat{\mathbf{K}}) + |\hat{S}^\lambda| \log n + 2\log \binom{p(p-1)/2}{|\hat{S}^\lambda|},$$

where $\hat{\mathbf{K}}$ can be either the original estimate associated with λ, or a refitted solution obtained by restricting the support to $\hat{S}^\lambda$.

We use the eBIC instead of the ordinary BIC (Bayesian Information Criterion) since the BIC tends to choose an overly complex model when the model space is large, as encountered in the high-dimensional setting. The extension in eBIC comes from the last term in the above display which can be motivated by a prior distribution under which the number of edges in the conditional independence graph is uniformly distributed; see also Żak-Szatkowska and Bogdan (2011) and Barber and Drton (2015).

6. Theory for Graphical Models

In our regularized generalized score matching framework, we introduced the amplifiers/ multipliers to address the inexistence problem. We also proposed using a general function $\boldsymbol{h}$ in place of $\boldsymbol{x}^2$ as a means to improve estimation accuracy. This section provides a theoretical analysis of these two aspects.

In Section 6.1, we present the theory for our regularized generalized score matching estimators for general pairwise interaction models before going into the details for the special cases of (truncated) GGMs. Next, we show that a specific choice of amplifiers/multipliers yields consistent estimation without the need for tuning. This point is important even in the case of Gaussian models on all of $\mathbb{R}^m$. Therefore, in Section 6.2 we digress from non-negative data and consider the original score matching of Hyvärinen (2005) for centered Gaussian distributions. Finally, in Section 6.3, we derive probabilistic results for $\hat{\boldsymbol{\Psi}}$ based on Theorem 13, justifying the benefits of using a general bounded $\boldsymbol{h}$ over $\boldsymbol{x}^2$ in the non-negative setting. As the most important models from the class of pairwise interaction power models over $\mathbb{R}_+^m$, we only treat truncated GGMs since they have the most tractable concentration bounds; this case also provides a comparison to Corollary 2 in Lin et al. (2016), which uses $\boldsymbol{x}^2$.

6.1. Theory for Pairwise Interaction Models

The graphical models we treat are parametrized by the interaction matrix $\mathbf{K}$ and the coefficients $\boldsymbol{\eta}$ on $(\boldsymbol{x}^b - \mathbf{1}_m)/b$. It is convenient to accommodate this setting with a matrix-valued parameter $\boldsymbol{\Psi} \in \mathbb{R}^{r_1 \times r_2}$ (in place of $\boldsymbol{\theta}$) and specify our regularized $\boldsymbol{h}$-score matching loss as

$$\hat{J}_{\boldsymbol{h},\lambda,\boldsymbol{\gamma}}(\boldsymbol{\Psi}) \equiv \operatorname*{argmin}_{\boldsymbol{\Psi} \in \mathbb{R}^{r_1 \times r_2}} \frac{1}{2}\text{vec}(\boldsymbol{\Psi})^\top \boldsymbol{\Gamma}_{\boldsymbol{\gamma}}(\mathbf{x})\text{vec}(\boldsymbol{\Psi}) - \boldsymbol{g}(\mathbf{x})^\top \text{vec}(\boldsymbol{\Psi}) + \lambda\|\boldsymbol{\Psi}\|_1. \tag{24}$$

In the non-centered case we thus take $\boldsymbol{\Psi} = [\mathbf{K}, \boldsymbol{\eta}]^\top \in \mathbb{R}^{m(m+1)\times m}$. In the centered case, $\boldsymbol{\Psi}$ is simply the $m \times m$ interaction matrix $\mathbf{K}$. Following related prior work such as Lin et al. (2016), for ease of proof we allow the matrix $\mathbf{K}$ to be nonsymmetric, which allows us to decouple optimization over the different columns of $\mathbf{K}$ or $\boldsymbol{\Psi}$, while in our implementations we ensure that $\mathbf{K}$ is symmetric.

Definition 12 *Let $\boldsymbol{\Gamma}_0 \equiv \mathbb{E}_0\boldsymbol{\Gamma}(\mathbf{x})$ and $\boldsymbol{g}_0 \equiv \mathbb{E}_0\boldsymbol{g}(\mathbf{x})$ be the population versions of $\boldsymbol{\Gamma}(\mathbf{x})$ and $\boldsymbol{g}(\mathbf{x})$ under the distribution given by a true parameter matrix $\boldsymbol{\Psi}_0$. The support of a matrix $\boldsymbol{\Psi}$ is $S(\boldsymbol{\Psi}) \equiv \{(i,j) : \psi_{ij} \neq 0\}$, and we let $S_0 = S(\boldsymbol{\Psi}_0)$. For a matrix $\boldsymbol{\Psi}_0$, we define $d_{\boldsymbol{\Psi}_0}$ to be the maximum number of non-zero entries in any column, and $c_{\boldsymbol{\Psi}_0} \equiv |||\boldsymbol{\Psi}_0|||_{\infty,\infty}$. Writing $\boldsymbol{\Gamma}_{0,AB}$ for the $A \times B$ submatrix of $\boldsymbol{\Gamma}_0$, we define*

$$c_{\boldsymbol{\Gamma}_0} \equiv |||(\boldsymbol{\Gamma}_{0,S_0S_0})^{-1}|||_{\infty,\infty}. \tag{25}$$

Finally, $\boldsymbol{\Gamma}_0$ satisfies the irrepresentability condition with incoherence parameter $\alpha \in (0,1]$ and edge set S_0 *if*

$$|||\boldsymbol{\Gamma}_{0,S_0^cS_0}(\boldsymbol{\Gamma}_{0,S_0S_0})^{-1}|||_{\infty,\infty} \leq (1 - \alpha). \tag{26}$$

Our analysis of the regularized generalized $\boldsymbol{h}$-score matching estimator builds on the following theorem taken from Lin et al. (2016, Theorem 1).

Theorem 13 *Suppose $\boldsymbol{\Gamma}_0$ has $\boldsymbol{\Gamma}_{0,S_0S_0}$ invertible and satisfies the irrepresentability condition (26) with incoherence parameter $\alpha \in (0,1]$. Assume that*

$$\|\boldsymbol{\Gamma}_{\boldsymbol{\gamma}}(\mathbf{x}) - \boldsymbol{\Gamma}_0\|_\infty < \epsilon_1, \qquad \|\boldsymbol{g}(\mathbf{x}) - \boldsymbol{g}_0\|_\infty < \epsilon_2, \tag{27}$$

with $d_{\boldsymbol{\Psi}_0}\epsilon_1 \le \alpha/(6c_{\boldsymbol{\Gamma}_0})$. If

$$\lambda > \frac{3(2-\alpha)}{\alpha}\max\{c_{\boldsymbol{\Psi}_0}\epsilon_1, \epsilon_2\},$$

then the following holds:

(a) The regularized generalized $\boldsymbol{h}$-score matching estimator $\hat{\boldsymbol{\Psi}}$ minimizing (24) is unique, with support $\hat{S} \equiv S(\hat{\boldsymbol{\Psi}}) \subseteq S_0$, and satisfies

$$\|\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0\|_\infty \le \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda.$$

(b) If

$$\min_{1\le j<k\le m} |\boldsymbol{\Psi}_{0,jk}| > \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda,$$

then $\hat{S} = S_0$ and $\operatorname{sign}(\hat{\boldsymbol{\Psi}}_{jk}) = \operatorname{sign}(\boldsymbol{\Psi}_{0,jk})$ for all $(j,k) \in S_0$.

This result is deterministic, and the improvement of our generalized estimator over the one in Lin et al. (2016) is in its probabilistic guarantees, as shown for truncated GGMs in Theorems 16 and 17 in Section 6.3. Before going into these examples, we state a general corollary.

Corollary 14 *Under the assumptions of Theorem 13, the matrix $\hat{\boldsymbol{\Psi}}$ minimizing (24) satisfies*

$$\begin{aligned}\|\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0\|_F &\le \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda\sqrt{|S_0|} \le \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda\sqrt{d_{\boldsymbol{\Psi}_0}m},\\ \|\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0\|_2 &\le \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda\min(\sqrt{|S_0|}, d_{\boldsymbol{\Psi}_0}).\end{aligned}$$

6.2. Revisiting Gaussian Score Matching

In this section we consider estimating the inverse covariance matrix $\mathbf{K}$ of a centered Gaussian distribution $\mathrm{N}(\mathbf{0},\mathbf{K})$, which of course has density proportional to (2) on all of $\mathbb{R}^m$. As shown, e.g., in Example 1 of Lin et al. (2016), the ℓ_1-regularized score matching loss then takes the form

$$\frac{1}{2}\operatorname{tr}(\mathbf{K}\mathbf{K}\mathbf{x}\mathbf{x}^\top) - \operatorname{tr}(\mathbf{K}) + \lambda\|\mathbf{K}\|_1, \tag{28}$$

which can be written as (14) with $\boldsymbol{\theta} = \operatorname{vec}(\mathbf{K})$, $\boldsymbol{\Gamma} = \operatorname{diag}(\mathbf{x}\mathbf{x}^\top,\dots,\mathbf{x}\mathbf{x}^\top)$ and $\boldsymbol{g} = \operatorname{vec}(\mathbf{I}_m)$. Thus, in general, the kernel of $\boldsymbol{\Gamma}$ need not be orthogonal to $\boldsymbol{g}$, and for λ small the loss can be unbounded below as discussed above. Hence, an amplifier/multiplier on the diagonals of $\boldsymbol{\Gamma}$ is needed. We have the following theorem on the estimator using the amplification.

Theorem 15 *Suppose the data matrix $\mathbf{x}$ holds n i.i.d. copies of $\boldsymbol{X} \sim \mathrm{N}(\mathbf{0},\mathbf{K}_0)$. Adopt the amplifying in Section 4 and redefine the loss in (28) as*

$$\frac{1}{2}\operatorname{tr}(\mathbf{K}\mathbf{K}\mathbf{G}) - \operatorname{tr}(\mathbf{K}) + \lambda\|\mathbf{K}\|_1, \quad \mathbf{G}_{jk} = (\mathbf{x}\mathbf{x}^\top)_{jk}\left(\mathbb{1}_{\{j\neq k\}} + (\delta-1)\mathbb{1}_{\{j=k\}}\right), \tag{29}$$

where $1 < \delta < 2 - \left(1 + 80\sqrt{\log m/n}\right)^{-1}$. Let $\hat{\mathbf{K}}$ be the resulting estimator. Let $c^* \equiv 12800\,(\max_j \boldsymbol{\Sigma}_{0,jj})^2$ and $c_1 = 4c_{\boldsymbol{\Gamma}_0}/\alpha$. If for some $\tau > 2$, the regularization parameter and the sample size satisfy

$$\begin{aligned}&\lambda > (2c_{\mathbf{K}_0}(2-\alpha)\sqrt{c^*(\tau\log m + \log 4)/n})/\alpha,\\ &n > \max(c^*c_1^2 d_{\mathbf{K}_0}^2, 2)(\tau\log m + \log 4),\end{aligned}$$

then $\|\hat{\mathbf{K}} - \mathbf{K}_0\|_\infty \le \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda$ with probability $1 - m^{2-\tau}$.

In Corollary 1 of Lin et al. (2016) the same results were shown with $c^* \equiv 3200\,(\max_j \boldsymbol{\Sigma}_{0,jj})^2$ when a unique minimizer exists, but the existence was not guaranteed.

6.3. Generalized Score Matching for Truncated GGMs

Next, we provide theory for the regularized generalized $\boldsymbol{h}$-score matching estimator $\hat{\boldsymbol{\Psi}}$ in the special case of truncated GGMs. Again, assume a common h for all components in $\boldsymbol{h}$.

Theorem 16 *Suppose the data matrix $\mathbf{x}$ holds n i.i.d. copies of $\boldsymbol{X} \sim \mathrm{TN}(\mathbf{0},\mathbf{K}_0)$, where the mean parameter is known to be zero. Assume that $\boldsymbol{h} \in \mathcal{H}_{1,1}$ and that $0 \le h \le M$, $0 \le h' \le M'$ a.s. for constants M, M', and choose $\boldsymbol{\gamma} = (\delta-1)\operatorname{diag}(\boldsymbol{\Gamma})$ with*

$$1 < \delta < C(n,m) \equiv 2 - \left(1 + 4e\max\{6\log m/n, \sqrt{6\log m/n}\}\right)^{-1}.$$

Suppose that the $\boldsymbol{\Gamma}_{0,S_0S_0}$ block of $\boldsymbol{\Gamma}_0$ is invertible and $\boldsymbol{\Gamma}_0$ satisfies the irrepresentability condition (26) with $\alpha \in (0,1]$ and true edge set S_0. Define $c_{\boldsymbol{X}} \equiv 2\max_j\left(2\sqrt{(\mathbf{K}_0^{-1})_{jj}} + \sqrt{e}\,\mathbb{E}_0 X_j\right)$. If for $\tau > 3$ the sample size and the regularization parameter satisfy

$$n > \mathcal{O}\left(\tau\log m\max\left\{\frac{M^2c_{\boldsymbol{\Gamma}_0}^2c_{\boldsymbol{X}}^4d_{\mathbf{K}_0}^2}{\alpha^2}, \frac{Mc_{\boldsymbol{\Gamma}_0}c_{\boldsymbol{X}}^2d_{\mathbf{K}_0}}{\alpha}\right\}\right), \tag{30}$$

$$\lambda > \mathcal{O}\left[(Mc_{\mathbf{K}_0}c_{\boldsymbol{X}}^2 + M'c_{\boldsymbol{X}} + M)\left(\sqrt{\frac{\tau\log m}{n}} + \frac{\tau\log m}{n}\right)\right], \tag{31}$$

then the following statements hold with probability $1 - m^{3-\tau}$:

(a) The regularized generalized $\boldsymbol{h}$-score matching estimator $\hat{\mathbf{K}}$ that minimizes (24) is unique, has its support included in the true support, $\hat{S} \equiv S(\hat{\mathbf{K}}) \subseteq S_0$, and satisfies

$$\|\hat{\mathbf{K}} - \mathbf{K}_0\|_\infty \le \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda,$$

$$|||\hat{\mathbf{K}} - \mathbf{K}_0|||_F \le \frac{c_{\mathbf{\Gamma}_0}}{2-\alpha}\lambda\sqrt{|S_0|},$$
$$|||\hat{\mathbf{K}} - \mathbf{K}_0|||_2 \le \frac{c_{\mathbf{\Gamma}_0}}{2-\alpha}\lambda \min(\sqrt{|S_0|}, d_{\mathbf{K}_0}),$$

where $c_{\mathbf{\Gamma}_0}$ is defined in (25).

(b) Moreover, if

$$\min_{j,k:(j,k)\in S_0} |\kappa_{0,jk}| > \frac{c_{\mathbf{\Gamma}_0}}{2-\alpha}\lambda,$$

then $\hat{S} = S_0$ and $\mathrm{sign}(\hat{\kappa}_{jk}) = \mathrm{sign}(\kappa_{0,jk})$ for all $(j,k) \in S_0$.

The theorem is proved in Appendix A.4, where details on the dependencies on constants are provided. A key ingredient of the proof is a tail bound on $\|\mathbf{\Gamma}_\gamma - \mathbf{\Gamma}_0\|_\infty$, which features products of the $X_j^{(i)}$'s. In Lin et al. (2016), the products are up to fourth order. Using bounded $\boldsymbol{h}$, our products automatically calibrates to a quadratic polynomial when the observed values are large, and resort to higher moments only when they are small. This leads to improved bounds and convergence rates, underscored in the new requirement on the sample size n, which should be compared to $n \ge \mathcal{O}(d^2_{\mathbf{K}_0}(\log m^\tau)^8)$ in Lin et al. (2016).

For the non-centered case, by definition, $c_{\mathbf{\Psi}_0} \equiv |||\mathbf{\Psi_0}^\top|||_{\infty,\infty} \le c_{\mathbf{K}_0} + \|\boldsymbol{\eta}_0\|_\infty$, $d_{\mathbf{\Psi}_0} \le d_{\mathbf{K}_0}+1$. The proof given for Theorem 16 goes through again here, and we have the following consistency results.

Theorem 17 *Suppose the data matrix holds n i.i.d. copies of $\boldsymbol{X} \sim \mathrm{TN}(\boldsymbol{\mu}_0, \mathbf{K}_0)$. Assume that $\boldsymbol{h} \in \mathcal{H}_{1,1}$ and that $0 \le h \le M$, $0 \le h' \le M'$ a.s. for constants M, M'. Let $\boldsymbol{\gamma}$ be a vector of amplifiers that are non-zero only for the diagonal entries of the matrices $\mathbf{\Gamma}_{11,j}$, amplifying those by $(\delta-1)\mathrm{diag}(\mathbf{\Gamma}_{11,j})$ with*

$$1 < \delta < C(n,m) \equiv 2 - \left(1 + 4e\max\{6\log m/n, \sqrt{6\log m/n}\}\right)^{-1}.$$

Suppose further that $\mathbf{\Gamma}_{0,S_0S_0}$ is invertible and satisfies the irrepresentability condition (26) with $\alpha \in (0,1]$. Define $c_{\boldsymbol{X}} \equiv 2\max_j\left(2\sqrt{(\mathbf{K}_0^{-1})_{jj}} + \sqrt{e}\,\mathbb{E}_0 X_j\right)$. Suppose for $\tau > 3$ the sample size and the regularization parameter satisfy

$$n > \mathcal{O}\left(\tau\log m \max\left\{\frac{M^2 c^2_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0} c^4_{\boldsymbol{X}} d^2_{\mathbf{\Psi}_0}}{\alpha^2}, \frac{M c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0} c^2_{\boldsymbol{X}} d_{\mathbf{\Psi}_0}}{\alpha}\right\}\right), \tag{32}$$

$$\lambda > \mathcal{O}\left[(M c_{\mathbf{\Psi}_0} c^2_{\boldsymbol{X}} + M' c_{\boldsymbol{X}} + M)\left(\sqrt{\frac{\tau\log m}{n}} + \frac{\tau\log m}{n}\right)\right], \tag{33}$$

where $c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0}$ is $c_{\mathbf{\Gamma}_0}$ as in (25) but with notation $\mathbf{\Psi}_0$ to differentiate it from the centered case. Then the following statements hold with probability $1 - m^{3-\tau}$:

(a) The regularized generalized $\boldsymbol{h}$-score matching estimator $\hat{\mathbf{\Psi}}$ that minimizes (24) is unique, has its support included in the true support, $\hat{S} \equiv S(\hat{\mathbf{\Psi}}) \subseteq S_0$, and satisfies

$$\|\hat{\mathbf{K}} - \mathbf{K}_0\|_\infty \le \frac{c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0}}{2-\alpha}\lambda, \qquad \|\hat{\boldsymbol{\eta}} - \boldsymbol{\eta}_0\|_\infty \le \frac{c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0}}{2-\alpha}\lambda,$$

$$|||\hat{\mathbf{K}} - \mathbf{K}_0|||_F \le \frac{c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0}}{2-\alpha}\lambda\sqrt{|S_0|}, \qquad \|\hat{\boldsymbol{\eta}} - \boldsymbol{\eta}_0\|_F \le \frac{c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0}}{2-\alpha}\lambda\sqrt{|S_0|},$$
$$|||\hat{\mathbf{K}} - \mathbf{K}_0|||_2 \le \frac{c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0}}{2-\alpha}\lambda \min\left(\sqrt{|S_0|}, d_{\mathbf{\Psi}_0}\right), \quad \|\hat{\boldsymbol{\eta}} - \boldsymbol{\eta}_0\|_2 \le \frac{c_{\mathbf{\Gamma}_0,\mathbf{\Psi}_0}}{2-\alpha}\lambda \min\left(\sqrt{|S_0|}, d_{\mathbf{\Psi}_0}\right).$$

(b) Moreover, if

$$\min_{j,k:(j,k)\in S_0} |\kappa_{0,jk}| > \frac{c_{\mathbf{\Gamma}_0}}{2-\alpha}\lambda \qquad \textit{and} \qquad \min_{j:(m+1,j)\in S_0} |\eta_{0,j}| > \frac{c_{\mathbf{\Gamma}_0}}{2-\alpha}\lambda,$$

then $\hat{S} = S_0$ and $\mathrm{sign}(\hat{\kappa}_{jk}) = \mathrm{sign}(\kappa_{0,jk})$ for all $(j,k) \in S_0$ and $\mathrm{sign}(\hat{\eta}_j) = \mathrm{sign}(\eta_{0j})$ for $(m+1,j) \in S_0$.

Remark 18 The quantity $c_{\boldsymbol{X}}$ in Theorem 17 depends on $\mathbb{E}_0 X_j$, which in turn depends on the structure of both $\boldsymbol{\mu}_0$ and $\mathbf{K}_0$. If $\mu_{0,j}$ is large compared to $(\mathbf{K}_0)^{-1}_{jj}$, then $c_{\boldsymbol{X}}$ seems to scale as $\boldsymbol{\mu}_0$, which negatively impacts the guarantees stated in Theorem 17. However, as in the one-dimensional case for estimation of μ_0 (Example 3.1), our estimator should automatically adapt to the large mean parameter. This suggests that it might be possible to improve our analysis involving $c_{\boldsymbol{X}}$.

7. Numerical Experiments

In this section, we compare the performance of our estimator with different choices of $\boldsymbol{h}$ to the existing approaches for pairwise interaction power models. In our simulation experiments, we consider $m = 100$ variables and $n = 80$ and $n = 1000$ samples, corresponding to high- and low-dimensional settings. We also tried intermediate sample sizes between these two extremes, but found no interesting result worth reporting. For $n = 80$, amplification is necessary. Except in Section 7.2.2, the amplifier is set based on Theorem 16 to $\delta = C(n,m) = 1.8647$ for truncated GGMs. The same amplifier is also used for settings with other a and b. For $n = 1000$, we consider $\delta = 1$, i.e., no amplification, and $\delta = C(n,m) = 1.6438$ (again, based on Theorem 16). Throughout, we assume a common univariate h for all components in $\boldsymbol{h}$.

7.1. Structure of K

The underlying interaction matrices are selected as follows: Proceeding as in Section 4.2 of Lin et al. (2016), the graph is chosen to have 10 disconnected subgraphs, each containing $m/10$ nodes. Thus, $\mathbf{K}_0$ is block-diagonal. In each block, each lower-triangular element is set to 0 with probability $1-\pi$ for some $\pi \in (0,1)$, and is otherwise drawn from Uniform[0.5, 1]. The upper triangular elements are determined by symmetry. The diagonal elements of $\mathbf{K}_0$ are chosen as a common positive value such that the minimum eigenvalue of $\mathbf{K}_0$ is 0.1.

We generate 5 different true precision matrices $\mathbf{K}_0$, and run 10 trials with each of these precision matrices. For $n = 1000$, we choose $\pi = 0.8$, which is in accordance with Lin et al. (2016). For $n = 80$, we set $\pi = 0.2$. This way $n/(d^2_{\mathbf{K}_0}\log m)$ is roughly constant; recall Theorems 16 and 17 for truncated GGMs.

In Appendix C, we report results on *Erdős-Rényi graphs*, which lead to similar conclusions.

7.2. Truncated GGMs

Given our focus on truncated GGMs and their relevance in graphical modeling applications, we start with experiments for these models.

7.2.1. Choice of $\boldsymbol{h}$

Our estimator requires choosing a function $\boldsymbol{h} : \mathbb{R}_+^m \to \mathbb{R}_+^m$. For simplicity, we will always specify $\boldsymbol{h}(\boldsymbol{x}) = (h(x_1), \ldots, h(x_m))$ for a single non-decreasing univariate function $h : \mathbb{R}_+ \to \mathbb{R}_+$, i.e. all coordinates share the same h function.

As previously explained, $\boldsymbol{h} \in \mathcal{H}_{a,b}$ is a sufficient condition for assumptions (A1)-(A2), as well as (C1)-(C2) in the case of unregularized estimators. Only in the proofs of our theoretical guarantees in Section 6 for truncated GGMs, did we require h to be bounded and to have bounded derivatives. As motivated by the discussion in Section 5.4.2, we consider truncated and untruncated powers, $\min(x, c)$ and x (since $2 - a = 2 - b = 1$); we evaluate this choice by contrasting them with powers $x^{1.5}$ and x^2. We also explore functions like $\log(1 + x)$ that seem natural and are linear near 0. In particular, we make a further comparison to functions linear near 0 with a finite asymptote as $x \nearrow +\infty$ but differentiable everywhere: MCP- (Fan and Li, 2001) and SCAD-like (Zhang, 2010) functions defined below. The results we report are based on selections of best performing choices of h.

$$\mathrm{SCAD}(x; \lambda, \gamma) \equiv \begin{cases} \lambda x & \text{if } 0 \le x \le \lambda, \\ \frac{2\gamma\lambda x - x^2 - \lambda^2}{2(\gamma - 1)} & \text{if } \lambda < x < \gamma\lambda, \\ \frac{\lambda^2(\gamma+1)}{2} & \text{if } x \ge \gamma\lambda; \end{cases} \quad \mathrm{MCP}(x; \lambda, \gamma) \equiv \begin{cases} \lambda x - \frac{x^2}{2\gamma} & \text{if } 0 \le x \le \gamma\lambda, \\ \frac{1}{2}\gamma\lambda^2 & \text{if } x > \gamma\lambda. \end{cases}$$

We do not observe any clear relationship between features such as convexity, differentiability or the slope of h at 0, and performance of the estimator. Nonetheless, for many choices of rather simple functions h, our estimator provides a significant improvement over existing methods. In particular, most h functions that behave linearly for small x, namely $\log(1 + x)$ and x and their truncations, and additionally MCP and SCAD, always perform better than $x^{1.5}$ and x^2. This agrees with our discussion in Section 5.4.2, where $2 - a = 1$ is a reasonable choice of the power for small x; also see Section 7.3. However, we conclude that there is no real gain from making the function smoother by using MCP or SCAD.

Truncated Centered GGMs: For data from a truncated centered Gaussian distribution, we compare our generalized score matching estimator with various choices of h, to *SpaCE JAM* (SJ, Voorman et al., 2014), which estimates graphs using additive models for conditional means, a pseudo-likelihood method *SPACE* (Peng et al., 2009) in the reformulation of Khare et al. (2015), *graphical lasso* (GLASSO, Yuan and Lin, 2007; Friedman et al., 2008), the *neighborhood selection* estimator (NS) of Meinshausen and Bühlmann (2006), and *nonparanormal SKEPTIC* (Liu et al., 2012) with Kendall's τ. Recall that the choice of $h(x) = x^2$ corresponds to the estimator from Lin et al. (2016).

The ROC (*receiver operating characteristic*) curves for different estimators are shown in Figure 3 on Page 26. Each plotted curve corresponds to the average of 50 ROC curves, where the averaging is based on the vertical averaging from Algorithm 3 in Fawcett (2006), and is mean AUC-preserving. The x and y axes of each ROC curve represent the false positive and true positive rates at varying levels of penalty parameter λ, defined as

Table 1: Mean and standard deviation of areas under the ROC curves (AUC) using different estimators in the centered setting, with $n = 80$ and multiplier 1.8647, or $n = 1000$ and multiplier 1 and 1.6438. Methods include our estimator with different choices of h, GLASSO, SPACE, neighborhood selection (NS), and Space JAM (SJ).

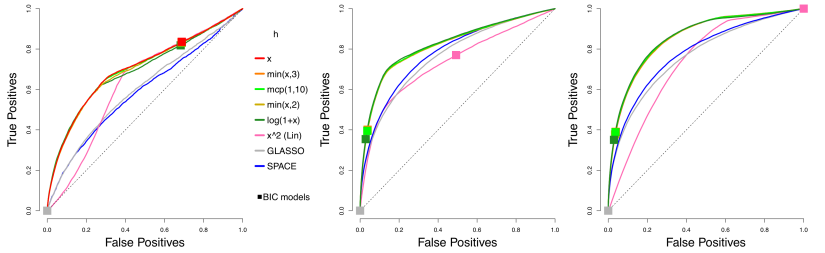
$$\mathrm{FPR} \equiv \frac{|\hat{S}_{\mathrm{off}} \backslash S_{0,\mathrm{off}}|}{m(m-1) - |S_{0,\mathrm{off}}|} \qquad \text{and} \qquad \mathrm{TPR} \equiv \frac{|\hat{S}_{\mathrm{off}} \cap S_{0,\mathrm{off}}|}{|S_{0,\mathrm{off}}|},$$

where $S_{0,\mathrm{off}} \equiv \{(i,j) : i \neq j \wedge \kappa_{0,ij} \neq 0\}$, and $\hat{S}_{\mathrm{off}} \equiv \{(i,j) : i \neq j \wedge \hat{\kappa}_{ij} \neq 0\}$.

To reduce clutter, we only report the results for the top performing competing methods. In particular, results for nonparanormal SKEPTIC are omitted, as the method always performs the worst in our experiments. The corresponding means and standard deviations of AUCs (*areas under the curves*) over 50 curves are given in Table 1.

Looking at the mean AUCs, with the standard deviations in mind, all choices of h considered here perform better than $h(x) = x^2$ from Hyvärinen (2007) and Lin et al. (2016) and the competing methods. The results for $n = 1000$ in Table 1 also show that the multiplier does help improve the AUCs, a matter to be discussed in Section 7.2.2.

Truncated Non-Centered GGMs: We generate data from a truncated non-centered Gaussian distribution with both parameters $\boldsymbol{\mu}$ and $\mathbf{K}$ unknown. In each trial, we form the true $\mathbf{K}_0$ as in Section 7.1, and generate each component of $\boldsymbol{\mu}_0$ independently from the normal distribution with mean 0 and standard deviation 0.5.



We compare the performance of our *profiled* estimator based on (19), with different h functions, but with no penalty on $\boldsymbol{\eta} \equiv \mathbf{K}\boldsymbol{\mu}$, to SPACE, SpaCE JAM (SJ), GLASSO, and neighborhood selection (NS). As before, we consider 50 trials. Representative ROC curves are plotted in Figure 4, and the corresponding AUCs are summarized in Table 2.

Table 2: Mean and standard deviation of AUC using different profiled estimators in the non-centered setting, with $n = 80$ and multiplier 1.8647, or $n = 1000$ and multipliers 1 and 1.6438. Methods include our estimator with different choices of h, GLASSO, SPACE, neighborhood selection (NS), and Space JAM (SJ).

(a) $n = 80$, mult = 1.8647 (b) $n = 1000$, mult = 1 (c) $n = 1000$, mult = 1.6438

Figure 3: Average ROC curves of our centered estimator with various choices of h, compared to SPACE and GLASSO, for the truncated centered GGM case; $m = 100$ variables and $n = 80$ or 1000 samples are considered. Squares indicate average true positive rate (TPR) and false positive rate (FPR) of models picked by eBIC with refitting for the estimator in the same color.

(a) $n = 80$, mult = 1.8647 (b) $n = 1000$, mult = 1 (c) $n = 1000$, mult = 1.6438

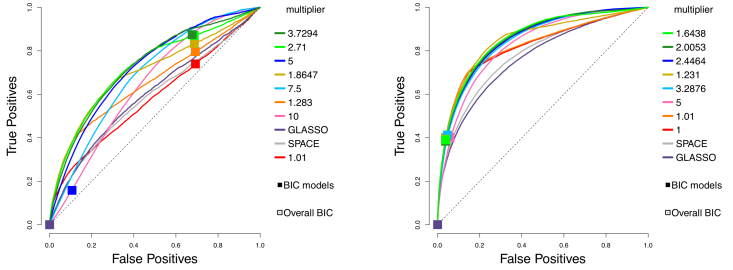

Figure 4: Average ROC curves of our non-centered profiled estimator with various choices of h, compared to SPACE and GLASSO, for the truncated non-centered GGM case; $m = 100$ variables and $n = 80$ or 1000 samples are considered. Squares indicate average true positive rate (TPR) and false positive rate (FPR) of models picked by eBIC with refitting for the estimator in the same color.

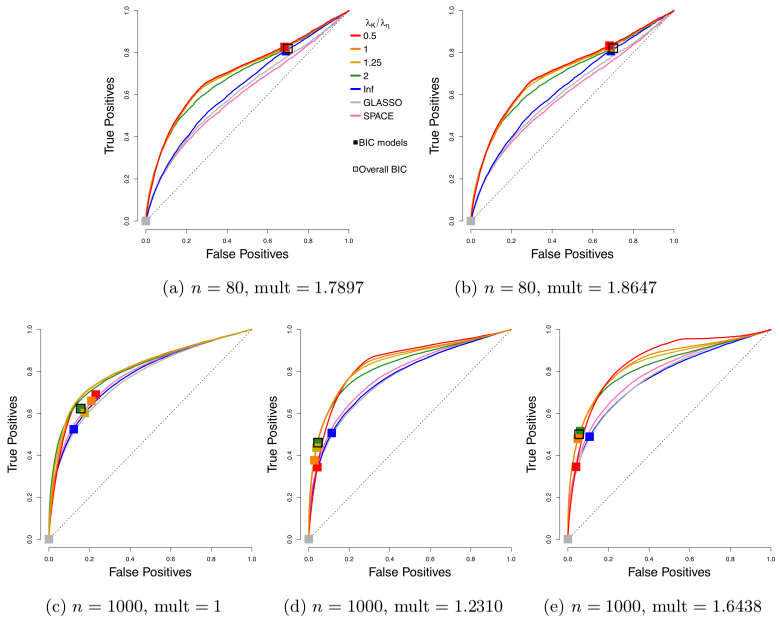
Even without tuning the extra penalty parameter on $\boldsymbol{\eta} \equiv \mathbf{K}\boldsymbol{\mu}$, our profiled estimator beats the competing methods by a large margin when $n = 80$. With multipliers 1 and $n = 1000$, our estimators still do better than Space JAM and GLASSO, and have performance comparable to other competing methods. It might appear that the performance of our estimators deteriorate with a multiplier larger than 1; however, as we will see, there can be significant improvement in AUCs if we tune an additional parameter for the multiplier. As in the centered case, the leading h functions in each category perform similarly, and the exact choice is not crucial. Subsequently, we will simply use $h(x) = \min(x, 3)$.

7.2.2. Choice of multiplier

Truncated Centered GGMs: In Figure 5, the ROC curves for GLASSO, SPACE, and our estimator with $h(x) = \min(x, 3)$, but with different levels of amplification, via different choices of multipliers δ, are compared for the centered case of Section 7.2.1.

While Theorem 16 guarantees consistency only for $\delta < C(n, m)$, we observe that there can be a gain from going beyond the *upper-bound multiplier* $C(n, m)$, which is 1.8647 for $n = 80$ and 1.6438 for $n = 1000$ (when $n = 1000$, $C(n, m)$ turns out to be the best-performing multiplier). However, the effect deteriorates fast as the multiplier grows larger. The figure suggests that while some additional gains are possible by tuning over the choice of multiplier, the *upper-bound multiplier* is a good default.



(a) $n = 80$ (b) $n = 1000$

Figure 5: Performance of $\min(x, 3)$ for truncated centered GGMs using different multipliers, compared to GLASSO and SPACE, in the centered setting, $n = 80$ or 1000.

Truncated Non-Centered GGMs : In Figure 6, we consider the non-centered case of Section 7.2.1, and use the non-profiled estimator; that is, the non-centered estimator with ℓ_1 penalty on both $\mathbf{K}$ and $\boldsymbol{\eta} \equiv \mathbf{K}\boldsymbol{\mu}$. The ROC curves are compared to competing methods GLASSO and SPACE. For the choice of amplification in our estimator, we consider the upper-bound multiplier $C(n, m)$ from Theorem 17 as the default. We refer to this as *high* amplification. We also consider lower amplification, with $\delta = 2 - (1 + 24e \log m/n)^{-1}$, referred to as *medium*. For $n = 1000$, we also consider a *low* multiplier 1, which corresponds to no amplification. We compare these possible defaults to a finer grid of multipliers of which we show some representatives in the plots.

We see that among our defaults, the upper-bound choice $C(n, m)$ performs best. Some additional gains are possible by tuning the multiplier over a grid of values containing this choice. Moreover, we see that it can be beneficial to tune over both $\lambda_{\mathbf{K}}$ and $\lambda_{\mathbf{K}}/\lambda_{\boldsymbol{\eta}}$.

We remark that while for each run, the best model picked by BIC falls on the ROC curve, a few squares are off the curve in Figure 6 (c). This is because these squares correspond to the average of the true and false positive rates of the chosen BIC models over 50 runs, potentially due to multimodality of the distribution of the models. Nonetheless, in all cases, the average of the models picked by BIC tuned over both $\lambda_{\mathbf{K}}$ and $\lambda_{\mathbf{K}}/\lambda_{\boldsymbol{\eta}}$ looks reasonable.

(a) $n = 80$, mult $= 1.7897$ (b) $n = 80$, mult $= 1.8647$

(c) $n = 1000$, mult $= 1$ (d) $n = 1000$, mult $= 1.2310$ (e) $n = 1000$, mult $= 1.6438$

Figure 6: Performance of the non-centered estimator with $h(x) = \min(x, 3)$. Each curve corresponds to a different choice of $\lambda_{\mathbf{K}}/\lambda_{\boldsymbol{\eta}}$. Squares indicate models picked by eBIC with refit. The square with black outline has the highest eBIC among all models (combinations of $\lambda_{\mathbf{K}}$, $\lambda_{\boldsymbol{\eta}}$). Multipliers correspond to medium or high for $n = 80$, and low, medium or high for $n = 1000$, respectively.

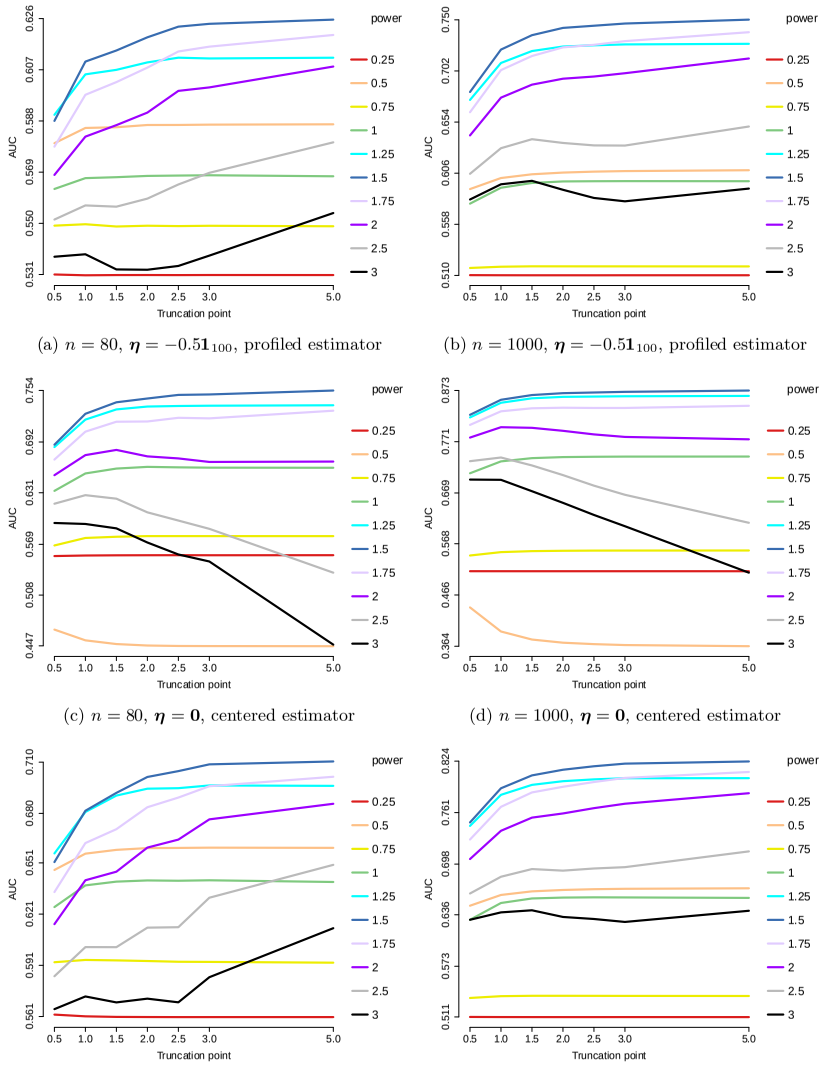
7.3. Other a/b Models

We now turn to the non-Gaussian ($a \neq 1$ or $b \neq 1$) setting. Based on the observations in Section 5.4.2, we focus on functions of type $\min(x^p, c)$ for some power $p > 0$ and truncation point $c > 0$. For simplicity, for the non-centered models we use the profiled estimator (19) (i.e., $\lambda_{\boldsymbol{\eta}} = 0$) and use the multiplier $C(n, m)$ in Theorem 16 for truncated GGMs as a guidance. We note that tuning over the $\lambda_{\boldsymbol{\eta}}$ parameter and the multiplier can potentially give a significant improvement as seen in Section 7.2.

These simulations suggest that among the class of functions of the form $\min(x^p, c)$, x^{2-a} or $\min(x^{2-a}, c)$ with a moderately large c can be used as the default choice of $h(x)$. This agrees with our findings in Section 7.2.1. We note that bounded h functions were only used in the proof for truncated GGMs, and picking a moderately large truncation point can correspond to having an untruncated power.

7.3.1. Exponential Setting

For the exponential models, $a = b = 1/2$. Since $a = b$, for both centered and non-centered settings, based on the principle in Section 5.4.2, choosing $h(x) = \min(x^{3/2}, c)$ satisfies (A1) and (A2) and also ensures that entries in $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ are bounded (for small x), while choosing $h(x) = \min(\sqrt{x}, c)$ only guarantees (A1) and (A2).



In Figure 7, we present the AUCs for the ROC curves of edge recovery with different choices of $h(x) = \min(x^{\text{pow}}, c)$. As before, we set $n = 80$ or 1000 and $m = 100$, but we use an $\boldsymbol{\eta}_0$ with each component uniformly equal to -0.5, 0 or 0.5; for $\boldsymbol{\eta}_0 \equiv \mathbf{0}$, we assume this information is known and use the centered estimator. The results suggest that $\text{pow} = 3/2 = 2 - a$ is the best choice of power. For this optimal choice, the performance improves with larger c, so x^{2-a} gives the best results. For sub-optimal powers, including truncation gives better results.

7.3.2. Gamma Setting

The centered gamma models reduce to the centered exponential models. Thus, in this section, we only consider the non-centered settings, with $a = 1/2$, $b = 0$. From Section 5.4.2, we have the following choices:

- $\min(x^2, c)$ both satisfies (A1)–(A2) and ensures $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ are bounded;
- $\min(x^{\max\{3/2, 1-\min_j \eta_{0,j}\}}, c)$ ensures (A1)–(A2) and bounds $\boldsymbol{\Gamma}_{11}$ and $\boldsymbol{g}_1$; by default without prior information on $\boldsymbol{\eta}_0$ this is $\min(x^2, c)$;
- $\min(x^{3/2}, c)$ satisfies both conditions on the interaction part only ($\boldsymbol{x}^a$), but does not guarantee (A1)–(A2);
- $\min(x^{1/2}, c)$ satisfies the sufficient conditions for (A1)–(A2) on the interaction only.

The results are shown in Figure 8, where we consider $n = 80$, 1000, and $\boldsymbol{\eta} = \pm 0.5\mathbf{1}_{100}$. They suggest that $\text{pow} = 2 - a = 1.5$ works consistently well, although slightly outperformed by 1 and 1.25 in one case. As in the exponential case, with the optimal power it is beneficial to choose a large truncation point, or work with an untruncated power $x^{1.5}$. We conclude that the performance is likely only dependent on the $(2 - a)$ power requirement for the ${\boldsymbol{x}^a}^\top \mathbf{K} \boldsymbol{x}^a$ part or $2 - \min_j \eta_{0,j}$; simulations in the next section rule out the possibility of the latter.

(a) $n = 80$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator

(b) $n = 1000$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator

(c) $n = 80$, $\boldsymbol{\eta} = \mathbf{0}$, centered estimator

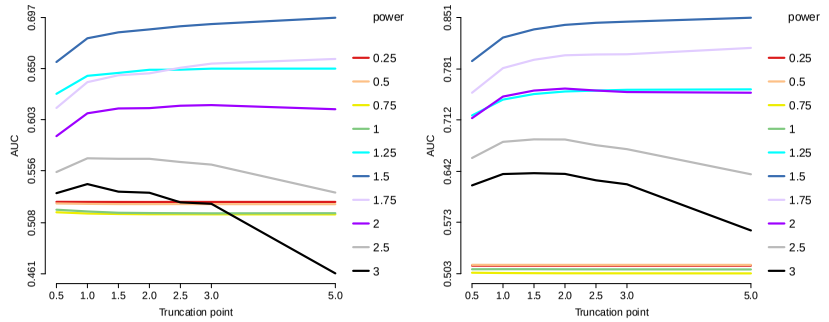
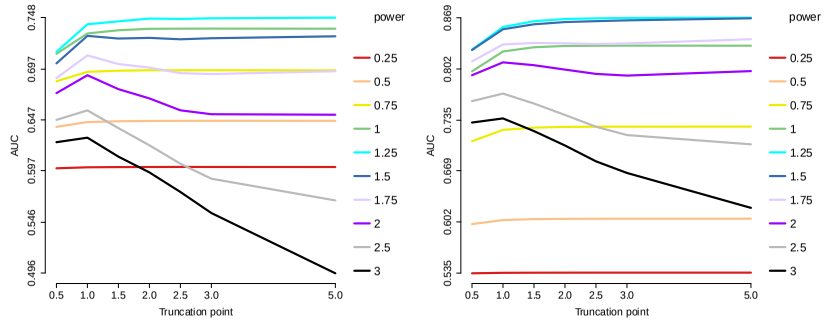
(e) $n = 80$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator



(f) $n = 1000$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator

Figure 7: AUCs for edge recovery using generalized score matching for the exponential models. Each curve represents a different choice of power p in $h(x) = \min(x^p, c)$, and the x axis marks the truncation point c. Colors are sorted by p.

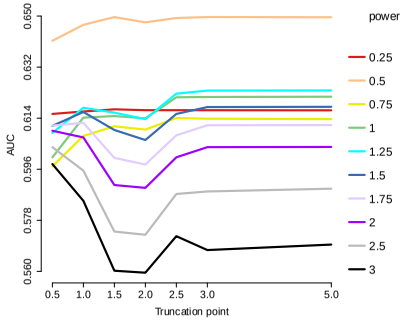
7.3.3. Other Choices of a and b



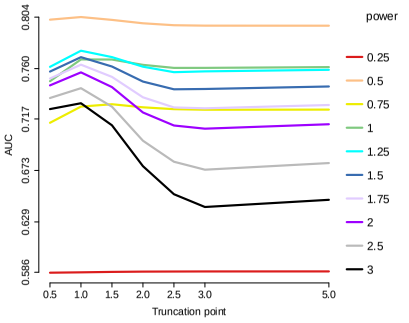
In this section, we consider other choices of a and b. Specifically, $a = 3/2$ and $b = 1/2$ or 0. These combinations are chosen to confirm, in a more extreme setting, that the performance is mainly determined by requirements on the power based on a, which correspond to choosing a power of $1-a$ or $2-a$, but not those on b (or on $\boldsymbol{\eta}$ when $b = 0$) that correspond to $1-b$ and $2-b$. The relationship between these two settings is analogous to that between the exponential and gamma models (same a, b nonzero/zero).

The results are shown in Figures 9 and 10, and indeed confirm that $x^{2-a} = x^{0.5}$ consistently gives the optimal results, even though $\boldsymbol{\eta}^\top \boldsymbol{x}^b$ is in favor of $x^{2-b} = x^{1.5}$ for $b = 0.5$, and $\boldsymbol{\eta}^\top \log(\boldsymbol{x})$ is in favor of x^2 or at least $x^{1-\min_j \eta_{0,j}}$ when $b = 0$. There are two possible explanations for the optimality of $2-a$ over $\max\{2-a, 2-b\}$ or $\max\{2-a, 1-\min_j \eta_{0,j}\}$: (1) The AUC metric is measured only on our interest, edge recovery for the interaction matrix, which only depends on $\boldsymbol{x}^a$; (2) using the profiled estimator weakens the effect of b.

(a) $n = 80$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator



(b) $n = 1000$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator



(c) $n = 80$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator

(d) $n = 1000$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator

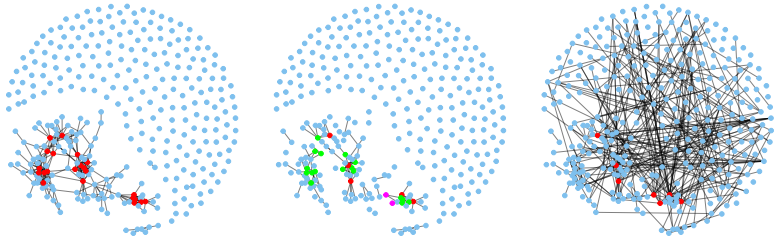
7.4. RNAseq Data

In this section we apply our regularized generalized $\boldsymbol{h}$-score matching estimator for truncated non-centered GGMs to RNAseq data also studied in Lin et al. (2016), since the same model is considered therein. The data consists of $n = 487$ prostate adenocarcinoma samples from The Cancer Genome Atlas (TCGA) data set. Following Lin et al. (2016), we focus on $m = 333$ genes that belong to the known cancer pathways in the Kyoto Encyclopedia of Genes and Genomes (KEGG) and that have no more than 10% missing values. Missing values are set to 0. We choose $h(x) = \min(x, 3)$ and use the upper-bound multiplier (*high*), as discussed in Section 7.2.2. For simplicity, we use the profiled estimator, and choose the regularization parameter λ so that the estimated graph has exactly $m = 333$ edges, all these choices being as in Lin et al. (2016).



We compare our graph to the one in Lin et al. (2016), which corresponds to $h(x) = x^2$ with no multiplier. Shown in Figure 11 are the estimated graphs, with their intersection in the middle. To improve visualization, isolated nodes are removed and the layouts are optimized for each plot. Red-colored points are the "hub nodes", namely nodes with degree at least 10. In Figure 12, we plot the same graphs in a fixed layout optimized for the graph corresponding to $h = \min(x, 3)$, and include the isolated nodes.

Out of 333 edges, the two estimated graphs share 117 edges in common. Assuming that edges are placed at random between nodes and the two graphs are independent, the distribution of the number R of common edges follow a hypergeometric distribution, so $P(R = r) = \frac{\binom{m}{r}\binom{m(m-1)/2-m}{m-r}}{\binom{m(m-1)/2}{m}}$. For $m = 333$ the probability of at least 117 common edges is essentially zero. The large number of shared edges between the two methods can be explained by the fact that they both minimize the same underlying score-matching loss.

(a) $\min(x, 3)$ (b) Common edges (c) Lin et al.

Figure 11: Graphs estimated by regularized generalized score matching estimator with $h(x) = \min(x, 3)$ with upper-bound multiplier (left) and $h(x) = x^2$ with no multiplier (Lin et al., 2016, right), and their intersection graph (middle). Isolated nodes with no edges are removed, and the layout is optimized for each plot. In (a) and (c), red points indicate nodes with degree at least 10 ("hub nodes").

(a) $\min(x, 3)$ (b) Common edges (c) Lin et al.

Figure 12: Graphs estimated by regularized generalized score matching estimator with $h(x) = \min(x, 3)$ with upper-bound multiplier (left) and $h(x) = x^2$ with no multiplier (Lin et al., 2016, right), and their intersection graph (middle). Isolated nodes are included and the layout is fixed across plots and optimized for graph (a). In (b) the red nodes are hub nodes shared by both graphs, the green ones are hub nodes in graph (a) only, and the magenta ones are hub nodes in graph (c) only.

The graph using $h(x) = \min(x, 3)$ has much more isolated nodes (204) than the other (108), and has a slightly smaller max degree (16 versus 19). Table 3 provides another way of comparing between the two graphs by listing the genes with the highest node degrees.

Table 3: List of genes with the highest node degrees in each estimated graph.

In Table 3 we list the top ten genes in terms of node degree for both estimated graphs. Due to ties, 13 genes are listed for $h(x) = \min(x, 3)$ and 11 for Lin et al. (2016). As noted in Lin et al. (2016), genes with high node-degrees are known to be important in biological

networks (Carter et al., 2004; Jeong et al., 2001; Han et al., 2004). Among these top genes, six are common in both graphs, and are discussed in Lin et al. (2016). We next elaborate on the evidence supporting the first four of the newly discovered genes.

- MMP2 (Matrix metalloproteinase 2): According to Trudel et al. (2003), increased MMP-2 expression is an independent predictor of decreased prostate cancer disease-free survival. Morgia et al. (2005) state that activity of MMP-2 can be useful in diagnosis, therapy, and assessment of malignant progression in prostate cancer.

- GLI2 (GLI family zinc finger 2): GLI2 is a primary mediator of the hedgehog signaling pathway, which has been reported in prostate cancer, and plays a critical role in the malignant phenotype of prostate cancer cells (Thiyagarajan et al., 2007). Its increased level of expression is also related to AI prostate cancer, and may be a therapeutic target in castrate-resistant prostate cancer (Narita et al., 2008).

- LAMA4 (Laminin subunit alpha 4): LAMA4 is consistently upregulated in benign prostatic hyperplasia when compared to normal prostate tissues (Luo et al., 2002).

- RASSF5 (RAS association domain family member 5): The combination of RASSF5 along with four other DNA methylation markers can effectively differentiate between benign prostate biopsy cores from non-cancer patients and cancer cores, and can be used to identify patients at risk without repeat biopsies (Brikun et al., 2014).

We note that the two methods indeed use different estimators (different h functions and multipliers), and it is thus not surprising to see that some of the top genes by one method are not among those for the other. In particular, CCNE2, BRCA2, SKP2 and STAT5B, while previously reported as newly discovered in Lin et al. (2016), are dropped by our new analysis. Testing and inference (potentially using bootstrapping) is an important problem but is beyond the scope of this paper.

8. Discussion

In this paper, we proposed a generalization of the score matching estimator of Hyvärinen (2007), based on scaling the log-gradients to be matched with a suitably chosen function $\boldsymbol{h}$. The generalization retains the advantages of Hyvärinen's method: Estimates can be computed without knowledge of normalizing constants, and for canonical parameters of exponential families, the estimation loss is a quadratic function.

For high-dimensional exponential family graphical models, following Lin et al. (2016), we add an ℓ_1 penalty to regularize the generalized score matching loss. One practical issue that is overlooked in Lin et al. (2016) is the fact that the score matching loss can be unbounded below for a small tuning parameter, when the dimension m exceeds the sample size n. We fix this issue by amplifying the diagonal entries in the quadratic matrix in the definition of the generalized score matching loss by a factor/multiplier, and we give an upper bound on that multiplier that guarantees consistency.

As examples we consider *pairwise interaction power models* on the non-negative orthant $\mathbb{R}^m_+$. Specifically, the considered models are exponential families in which the log density is

the sum of pairwise interactions between entries in of powers $\boldsymbol{x}^a$ plus linearly weighted effects $\boldsymbol{x}^b$, or $\log(\boldsymbol{x})$ when $b = 0$. Our main interest is in the matrix of interaction parameters whose support determines the distributions' conditional independence graph. The considered framework covers truncated normal distributions ($a = b = 1$), exponential square root graphical models ($a = b = 1/2$) from Inouye et al. (2016), as well as a class of multivariate gamma distributions ($a = 1/2$, $b = 0$).

In the case of multivariate truncated normal distributions, where the conditional independence graph is given by the underlying Gaussian inverse covariance matrix, the sample size required for the consistency of our method using bounded $\boldsymbol{h}$ is $\Omega(d^2 \log m)$, where d is the degree of the graph. This matches the rates for Gaussian graphical models in Ravikumar et al. (2011) and Lin et al. (2016). In contrast, the sample complexity for truncated Gaussian models given in Lin et al. (2016) is $\Omega(d^2 \log^8 m)$.

For the considered class of pairwise interaction models, we recommend using the function $\boldsymbol{h}$ with coordinates $h_j(x) = \min\left(x^{2-a}, c\right)$ for some moderately large c, or simply $h_j(x) = x^{2-a}$. While this choice is effective, it would be an interesting problem for future work to develop a method that adaptively chooses an optimized function $\boldsymbol{h}$ from data.

Appendix A. Proofs

A.1. Proof of Theorem 3

The following integration by parts lemma is used in the proof of Theorem 3.

Lemma 19 *Let $f, g : \mathbb{R}_+ \to \mathbb{R}$ be functions that are absolutely continuous in every bounded sub-interval of $\mathbb{R}_+$. Then*

$$\lim_{x \nearrow +\infty} f(x)g(x) - \lim_{x \searrow 0^+} f(x)g(x) = \int_0^\infty f(\boldsymbol{x}) \frac{\mathrm{d}g(x)}{\mathrm{d}x}\,\mathrm{d}x + \int_0^\infty g(\boldsymbol{x}) \frac{\mathrm{d}f(x)}{\mathrm{d}x}\,\mathrm{d}x.$$

Proof This is an analog of Lemma 4 from Hyvärinen (2005) that can be proved by integrating the partial derivatives, and follows from the fundamental theorem of calculus for absolutely continuous functions and the product rule. In particular, we work on integrals in bounded $[0, c]$, where the product of two absolutely continuous functions in a bounded interval is again absolutely continuous, and the result is then obtained by letting $c \nearrow +\infty$. ■

Proof [Proof of Theorem 3] Recall the following assumptions from Section 2.2:

(A1) $p_0(\boldsymbol{x}) h_j(x_j) \partial_j \log p(\boldsymbol{x}) \Big|_{x_j \searrow 0^+}^{x_j \nearrow +\infty} = 0\ ,\ \ \forall \boldsymbol{x}_{-j} \in \mathbb{R}_+^{m-1}, \quad \forall p \in \mathcal{P}_+$;

(A2) $\mathbb{E}_{p_0} \|\nabla \log p(\boldsymbol{X}) \circ \boldsymbol{h}^{1/2}(\boldsymbol{X})\|_2^2 < +\infty,\ \ \mathbb{E}_{p_0} \|(\nabla \log p(\boldsymbol{X}) \circ \boldsymbol{h}(\boldsymbol{X}))'\|_1 < +\infty,\ \ \forall p \in \mathcal{P}_+$.

Without explicitly writing the domains $\mathbb{R}_+$ or $\mathbb{R}_+^m$ in all integrals, by (6) we have

$$\begin{aligned} J_{\boldsymbol{h}}(p) &= \frac{1}{2} \int p_0(\boldsymbol{x}) \Big[\|\nabla \log p(\boldsymbol{x}) \circ \boldsymbol{h}^{1/2}(\boldsymbol{x})\|_2^2 \\ &\qquad -2(\nabla \log p(\boldsymbol{x}) \circ \boldsymbol{h}^{1/2}(\boldsymbol{x}))^\top (\nabla \log p_0(\boldsymbol{x}) \circ \boldsymbol{h}^{1/2}(\boldsymbol{x})) + \|\nabla \log p_0(\boldsymbol{x}) \circ \boldsymbol{h}^{1/2}(\boldsymbol{x})\|_2^2 \Big]\,\mathrm{d}\boldsymbol{x} \\ &= \underbrace{\frac{1}{2} \int p_0(\boldsymbol{x}) \sum_{j=1}^m h_j(x_j) \left(\frac{\partial \log p(\boldsymbol{x})}{\partial x_j} \right)^2 \mathrm{d}\boldsymbol{x}}_{\equiv A} + \underbrace{\frac{1}{2} \int p_0(\boldsymbol{x}) \sum_{j=1}^m h_j(x_j) \left(\frac{\partial \log p_0(\boldsymbol{x})}{\partial x_j} \right)^2 \mathrm{d}\boldsymbol{x}}_{\equiv C} \\ &\qquad \underbrace{- \int p_0(\boldsymbol{x}) \sum_{j=1}^m h_j(x_j) \frac{\partial \log p(\boldsymbol{x})}{\partial x_j} \frac{\partial \log p_0(\boldsymbol{x})}{\partial x_j}\,\mathrm{d}\boldsymbol{x}}_{\equiv B}, \end{aligned}$$

where A will simply appear in the final display as is, C is a constant as it only involves the true pdf p_0, and we wish to simplify B by integration by parts. We can split the integral into these three parts since A and C are assumed finite in the first part of (A2), and the integrand in B is integrable since $|2ab| \le a^2 + b^2$. Thus, by linearity and Fubini's theorem, we can write

$$\begin{aligned} B &= -\sum_{j=1}^m \int p_0(\boldsymbol{x}) h_j(x_j) \frac{\partial \log p(\boldsymbol{x})}{\partial x_j} \frac{\partial \log p_0(\boldsymbol{x})}{\partial x_j}\,\mathrm{d}\boldsymbol{x} \\ &= -\sum_{j=1}^m \int \left[\int p_0(\boldsymbol{x}) h_j(x_j) \frac{\partial \log p(\boldsymbol{x})}{\partial x_j} \frac{\partial \log p_0(\boldsymbol{x})}{\partial x_j}\,\mathrm{d}x_j \right] \mathrm{d}\boldsymbol{x}_{-j}. \end{aligned}$$

By the fact that $\frac{\partial \log p_0(\boldsymbol{x})}{\partial x_j} = \frac{1}{p_0(\boldsymbol{x})}\frac{\partial p_0(\boldsymbol{x})}{\partial x_j}$, this can be simplified to

$$B = -\sum_{j=1}^{m}\int\left[\int \frac{\partial p_0(\boldsymbol{x})}{\partial x_j}h_j(x_j)\frac{\partial \log p(\boldsymbol{x})}{\partial x_j}\,\mathrm{d}x_j\right]\mathrm{d}\boldsymbol{x}_{-j}.$$

But, we assume p_0 and p are twice continuously differentiable, for every $j = 1,\dots,m$ and fixed $\boldsymbol{x}_{-j} \in \mathbb{R}_+^{m-1}$. Hence, in every bounded sub-interval of $\mathbb{R}_+$, $p_0(\boldsymbol{x}_{-j}; x_j)$ is an absolutely continuous function of x_j, $\partial_j \log p(\boldsymbol{x}_{-j}, x_j) = \partial_j p(\boldsymbol{x}_{-j}, x_j)/p(\boldsymbol{x}_{-j}, x_j)$ is a continuously differentiable (and hence absolutely continuous) function of x_j by the quotient rule. Thus $h_j(x_j)\partial_j \log p(\boldsymbol{x}_{-j}; x_j)$ is also absolutely continuous by the absolute continuity assumption on h_j. Then, by Lemma 19, where we take $f \equiv p_0(\boldsymbol{x}_{-j}; x_j)$ and $g \equiv h_j(x_j)\partial_j \log p(\boldsymbol{x}_{-j}; x_j)$ as functions of x_j, followed by assumption (A1),

$$\begin{aligned}B =& -\sum_{j=1}^{m}\int\Bigg[\lim_{a\nearrow+\infty, b\searrow 0^+}\left[p_0(\boldsymbol{x}_{-j}; a)h_j(a)\partial_j \log p(\boldsymbol{x}_{-j}, a) - p_0(\boldsymbol{x}_{-j}; b)h_j(b)\partial_j \log p(\boldsymbol{x}_{-j}, b)\right]\\ &- \int p_0(\boldsymbol{x})\frac{\partial\left(h_j(x_j)\partial_j \log p(\boldsymbol{x})\right)}{\partial x_j}\,\mathrm{d}x_j\Bigg]\mathrm{d}\boldsymbol{x}_{-j}\\ =& \sum_{j=1}^{m}\int\left[\int p_0(\boldsymbol{x})\frac{\partial(h_j(x_j)\partial_j \log p(\boldsymbol{x}))}{\partial x_j}\,\mathrm{d}x_j\right]\mathrm{d}\boldsymbol{x}_{-j}.\end{aligned}$$

Justified by the second half of (A2), by Fubini-Tonelli and linearity again

$$\begin{aligned}B &= \sum_{j=1}^{m}\int p_0(\boldsymbol{x})\frac{\partial(h_j(x_j)\partial_j \log p(\boldsymbol{x}))}{\partial x_j}\,\mathrm{d}\boldsymbol{x},\\ &= \sum_{j=1}^{m}\int h_j'(x_j)\frac{\partial \log p(\boldsymbol{x})}{\partial x_j}p_0(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x} + \sum_{j=1}^{m}\int h_j(x_j)\frac{\partial^2 \log p(\boldsymbol{x})}{\partial x_j^2}p_0(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}.\end{aligned}$$

Thus,

$$\begin{aligned}&J_{\boldsymbol{h}}(p)\\ =&B + A + C\\ =&\int_{\mathbb{R}_+^m} p_0(\boldsymbol{x})\sum_{j=1}^{m}\left[h_j'(x_j)\frac{\partial \log p(\boldsymbol{x})}{\partial x_j} + h_j(x_j)\frac{\partial^2 \log p(\boldsymbol{x})}{\partial x_j^2} + \frac{1}{2}h_j(x_j)\left(\frac{\partial \log p(\boldsymbol{x})}{\partial x_j}\right)^2\right]\mathrm{d}\boldsymbol{x} + C,\end{aligned}$$

where C is a constant that does not depend on p. ■

A.2. Proof of Theorems and Examples in Section 3

Proof [Proof of Theorem 5] For exponential families and under the assumptions, the empirical loss $\hat{J}_{\boldsymbol{h}}(p_{\boldsymbol{\theta}})$ in (8) becomes (up to an additive constant)

$$\begin{aligned}&\hat{J}_{\boldsymbol{h}}(p_{\boldsymbol{\theta}})\\ =&\frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{m}\left[h_j'(X_j^{(i)})\frac{\partial \log p_{\boldsymbol{\theta}}(\boldsymbol{X}^{(i)})}{\partial X_j^{(i)}} + h_j(X_j^{(i)})\frac{\partial^2 \log p_{\boldsymbol{\theta}}(\boldsymbol{X}^{(i)})}{\partial (X_j^{(i)})^2}\right.\\ &\left.+\frac{1}{2}h_j(X_j^{(i)})\left(\frac{\partial \log p_{\boldsymbol{\theta}}(\boldsymbol{X}^{(i)})}{\partial X_j^{(i)}}\right)^2\right]\\ =&\frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{m}\left[h_j'(X_j^{(i)})(\boldsymbol{\theta}^\top \boldsymbol{t}_j'(\boldsymbol{X}^{(i)}) + b_j'(\boldsymbol{X}^{(i)})) + h_j(X_j^{(i)})(\boldsymbol{\theta}^\top \boldsymbol{t}_j''(\boldsymbol{X}^{(i)}) + b_j''(\boldsymbol{X}^{(i)}))\right.\\ &\left.+\frac{1}{2}h_j(X_j^{(i)})(\boldsymbol{\theta}^\top \boldsymbol{t}_j'(\boldsymbol{X}^{(i)}) + b_j'(\boldsymbol{X}^{(i)}))^2\right]\\ =&\frac{1}{n}\left\{\frac{1}{2}\boldsymbol{\theta}^\top\left[\sum_{i=1}^{n}\sum_{j=1}^{m}h_j(X_j^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}^{(i)})^\top\right]\boldsymbol{\theta} + \right.\\ &\left.\left[\sum_{i=1}^{n}\sum_{j=1}^{m}h_j(X_j^{(i)})b_j'(\boldsymbol{X}^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}^{(i)}) + h_j(X_j^{(i)})\boldsymbol{t}_j''(\boldsymbol{X}^{(i)}) + h_j'(X_j^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}^{(i)})\right]^\top\boldsymbol{\theta}\right\} + \text{const},\end{aligned}$$

which is quadratic in $\boldsymbol{\theta}$. Let

$$\boldsymbol{\Gamma}(\mathbf{x}) = \frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{m}h_j(X_j^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}^{(i)})^\top, \tag{34}$$

$$\boldsymbol{g}(\mathbf{x}) = -\frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{m}\left[h_j(X_j^{(i)})b_j'(\boldsymbol{X}^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}^{(i)}) + h_j(X_j^{(i)})\boldsymbol{t}_j''(\boldsymbol{X}^{(i)}) + h_j'(X_j^{(i)})\boldsymbol{t}_j'(\boldsymbol{X}_i)\right]. \tag{35}$$

Then we can write $\hat{J}_{\boldsymbol{h}}(p_{\boldsymbol{\theta}}) = \frac{1}{2}\boldsymbol{\theta}^\top\boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta} - \boldsymbol{g}(\mathbf{x})^\top\boldsymbol{\theta} + \text{const}$. ■

Proof [Proof of Theorem 6] By Theorem 5, $\hat{J}_{\boldsymbol{h}}(p_{\boldsymbol{\theta}}) = \frac{1}{2}\boldsymbol{\theta}^\top\boldsymbol{\Gamma}\boldsymbol{\theta} - \boldsymbol{g}^\top\boldsymbol{\theta} + \text{const}$. The minimizer of $\hat{J}_{\boldsymbol{h}}(p_{\boldsymbol{\theta}})$ is thus available in the unique closed form $\hat{\boldsymbol{\theta}} \equiv \boldsymbol{\Gamma}(\mathbf{x})^{-1}\boldsymbol{g}(\mathbf{x})$ as long as $\boldsymbol{\Gamma}$ is invertible (C1). Since $\boldsymbol{\Gamma}$ and $\boldsymbol{g}$ are sample averages, the weak law of large numbers yields that $\boldsymbol{\Gamma} \to_p \mathbb{E}_{p_0}\boldsymbol{\Gamma} \equiv \boldsymbol{\Gamma}_0$ and $\boldsymbol{g} \to_p \mathbb{E}_{p_0}\boldsymbol{g} \equiv \boldsymbol{g}_0$, where existence of $\boldsymbol{\Gamma}_0$ and $\boldsymbol{g}_0$ is assumed in (C2). Since $J_{\boldsymbol{h}}(p_{\boldsymbol{\theta}}) = \mathbb{E}[\hat{J}_{\boldsymbol{h}}(p_{\boldsymbol{\theta}})] = \mathbb{E}[\frac{1}{2}\boldsymbol{\theta}^\top\boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta} - \boldsymbol{g}(\mathbf{x})^\top\boldsymbol{\theta}] = \frac{1}{2}\boldsymbol{\theta}^\top\boldsymbol{\Gamma}_0\boldsymbol{\theta} - \boldsymbol{g}_0\boldsymbol{\theta}$ and we know $\boldsymbol{\theta}_0$ minimizes $J_{\boldsymbol{h}}(p_{\boldsymbol{\theta}})$ by definition, by the first-order condition we must have $\boldsymbol{\Gamma}_0\boldsymbol{\theta}_0 = \boldsymbol{g}_0$. Then by the Lindeberg-Lévy central limit theorem,

$$\sqrt{n}(\boldsymbol{g}(\mathbf{x}) - \boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta}_0) \to_d \mathcal{N}_m(\mathbf{0}, \boldsymbol{\Sigma}_0),$$

where $\boldsymbol{\Sigma}_0 \equiv \mathbb{E}_{p_0}[(\boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta}_0 - \boldsymbol{g}(\mathbf{x}))(\boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta}_0 - \boldsymbol{g}(\mathbf{x}))^\top]$, as long as $\boldsymbol{\Sigma}_0$ exists (C2). Thus, by Slutsky's theorem,

$$\sqrt{n}(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \equiv \sqrt{n}(\boldsymbol{\Gamma}(\mathbf{x})^{-1}(\boldsymbol{g}(\mathbf{x}) - \boldsymbol{\Gamma}(\mathbf{x})\boldsymbol{\theta}_0)) \to_d \mathcal{N}_r(\mathbf{0}, \boldsymbol{\Gamma}_0^{-1}\boldsymbol{\Sigma}\boldsymbol{\Gamma}_0^{-1}),$$

as long as $\mathbf{\Gamma}_0$ is invertible (C2).

For the second half of the theorem, (C2) $\mathbb{E}_{p_0}\mathbf{\Gamma}(\mathbf{x}) < \infty$ and $\mathbb{E}_{p_0}\boldsymbol{g}(\mathbf{x}) < \infty$ implies $\mathbb{E}_{p_0}|\mathbf{\Gamma}(\mathbf{x})| < \infty$ and $\mathbb{E}_{p_0}|\boldsymbol{g}(\mathbf{x})| < \infty$, so by strong law of large numbers (and a union bound on at most k^2 null sets)

$$\mathbf{\Gamma}(\mathbf{x}) \to_{\text{a.s.}} \mathbf{\Gamma}_0, \quad \boldsymbol{g}(\mathbf{x}) \to_{\text{a.s.}} \boldsymbol{g}_0.$$

Then outside a null set,

$$\hat{\boldsymbol{\theta}} \equiv \mathbf{\Gamma}(\mathbf{x})^{-1}\boldsymbol{g}(\mathbf{x}) \to_{\text{a.s.}} \mathbf{\Gamma}_0^{-1}\boldsymbol{g}_0 = \boldsymbol{\theta}_0.$$

■

Proof [Proof for Example 3.1] We choose to estimate $\theta \equiv \mu/\sigma^2$. Then by (11) and (12),

$$\begin{aligned}
\hat{\mu}_h &= \sigma^2\hat{\theta} \equiv \sigma^2\Gamma(\boldsymbol{x})^{-1}g(\boldsymbol{x}) \\
&= -\sigma^2\left[\sum_{i=1}^n h(X_i)t'(X_i)^2\right]^{-1}\left[\sum_{i=1}^n h(X_i)b'(X_i)t'(X_i) + h(X_i)t''(X_i) + h'(X_i)t'(X_i)\right] \\
&= -\sigma^2\left[\sum_{i=1}^n h(X_i)\right]^{-1}\left[\sum_{i=1}^n -h(X_i)\frac{X_i}{\sigma^2} + h'(X_i)\right].
\end{aligned}$$

By Theorem 6,

$$\begin{aligned}
\sqrt{n}(\hat{\mu}_h - \mu_0) &\to_d \mathcal{N}\left(0, \frac{\sigma^4\mathbb{E}_0\left[-h(X)\frac{X-\mu_0}{\sigma^2} + h'(X)\right]^2}{\mathbb{E}_0^2[h(X)]}\right) \\
&\sim \mathcal{N}\left(0, \frac{\mathbb{E}_0\left[-h(X)(X-\mu_0) + \sigma^2 h'(X)\right]^2}{\mathbb{E}_0^2[h(X)]}\right).
\end{aligned}$$

By integration by parts, (suppressing the dependence of p_{μ_0} on μ_0)

$$\begin{aligned}
&\mathbb{E}_0[h(X)h'(X)(X-\mu_0)] \\
&= \int_0^\infty h'(x)h(x)(x-\mu_0)p(x)\,\mathrm{d}x \\
&= \int_0^\infty h(x)(x-\mu_0)p(x)\,\mathrm{d}h(x) \\
&= h^2(x)(x-\mu_0)p(x)|_0^\infty - \int h(x)\,\mathrm{d}h(x)(x-\mu_0)p(x) \\
&= -\int h^2(x)p(x)\,\mathrm{d}x - \int h(x)h'(x)(x-\mu_0)p(x)\,\mathrm{d}x + \int h^2(x)\frac{(x-\mu_0)^2}{\sigma^2}p(x)\,\mathrm{d}x,
\end{aligned}$$

where the last step follows from the assumptions $\lim_{x\searrow 0^+} h(x) = 0$ and $\lim_{x\nearrow+\infty} h^2(x)(x-\mu_0)p_{\mu_0}(x) = 0$. So

$$\mathbb{E}_0[h(X)h'(X)(X-\mu_0)] = \frac{\mathbb{E}[h^2(X)((X-\mu_0)^2/\sigma^2 - 1)]}{2}. \tag{36}$$

The asymptotic variance is thus

$$\begin{aligned}
&\frac{\mathbb{E}_0\left[-h(X)(X-\mu_0) + \sigma^2 h'(X)\right]^2}{\mathbb{E}_0^2[h(X)]} \\
&= \frac{\mathbb{E}_0\left[h^2(X)(X-\mu_0)^2 - 2\sigma^2 h^2(X)\left((X-\mu_0)^2/\sigma^2 - 1\right)/2 + \sigma^4 h'^2(X)\right]}{\mathbb{E}_0^2[h(X)]} \\
&= \frac{\mathbb{E}_0[\sigma^2 h^2(X) + \sigma^4 h'^2(X)]}{\mathbb{E}_0^2[h(X)]}.
\end{aligned}$$

The Cramér-Rao lower bound follows from taking the second derivative of $\log p_{\mu_0}$ with respect to μ_0. ■

Proof [Proof for Example 3.2] We estimate $\theta \equiv 1/\sigma^2$. By (11) and (12),

$$\begin{aligned}
\hat{\theta} &\equiv \Gamma(\boldsymbol{x})^{-1}g(\boldsymbol{x}) \\
&= -\left[\sum_{i=1}^n h(X_i)t'(X_i)^2\right]^{-1}\left[\sum_{i=1}^n h(X_i)b'(X_i)t'(X_i) + h(X_i)t''(X_i) + h'(X_i)t'(X_i)\right] \\
&= \left[\sum_{i=1}^n h(X_i)(X_i-\mu)^2\right]^{-1}\left[\sum_{i=1}^n h(X_i) + h'(X_i)(X_i-\mu)\right].
\end{aligned}$$

By Theorem 6, $\sqrt{n}(\hat{\theta} - \theta) \to_d \mathcal{N}(0, \varsigma^2)$, where

$$\begin{aligned}
\varsigma^2 &\equiv \frac{\mathbb{E}_0\left[h(X)((X-\mu)^2/\sigma_0^2 - 1) - h'(X)(X-\mu)\right]^2}{\mathbb{E}_0^2[h(X)(X-\mu)^2]} \\
&= \frac{1}{\mathbb{E}_0^2[h(X)(X-\mu)^2]}\Big(\mathbb{E}_0[h^2(X)(X-\mu)^4/\sigma_0^4 - 2h^2(X)(X-\mu)^2/\sigma_0^2 + h^2(X) \\
&\qquad + h'^2(X)(X-\mu)^2 - 2h(X)h'(X)(X-\mu)^3/\sigma_0^2 + 2h(X)h'(X)(X-\mu)\Big).
\end{aligned}$$

By integration by parts, (suppressing the dependence of $p_{\sigma_0^2}$ on σ_0^2)

$$\begin{aligned}
&\mathbb{E}_0[h(X)h'(X)(X-\mu)^3] \\
&= \int_0^\infty h'(x)h(x)(x-\mu)^3p(x)\,\mathrm{d}x \\
&= \int_0^\infty h(x)(x-\mu)^3p(x)\,\mathrm{d}h(x) \\
&= h^2(x)(x-\mu)^3p(x)|_0^\infty - \int h(x)\,\mathrm{d}h(x)(x-\mu)^3p(x) \\
&= -\int h(x)h'(x)(x-\mu)^3p(x)\,\mathrm{d}x - 3\int h^2(x)(x-\mu)^2p(x)\,\mathrm{d}x + \int h^2(x)\frac{(x-\mu)^4}{\sigma_0^2}p(x)\,\mathrm{d}x,
\end{aligned}$$

where the last step follows from the assumptions $\lim_{x\searrow 0^+} h(x) = 0$ and $\lim_{x\nearrow+\infty} h^2(x)(x-\mu)^3 p_{\sigma_0^2}(x) = 0$. Combining this with (36) we get

$$\sqrt{n}(\hat{\theta}-\theta) \to_d \mathcal{N}(0,\varsigma^2) \sim \mathcal{N}\left(0, \frac{2\mathbb{E}_0[h^2(X)(X-\mu)^2/\sigma_0^2] + \mathbb{E}_0[h'^2(X-\mu)^2]}{\mathbb{E}_0^2[h(X)(X-\mu)^2]}\right),$$

and so by the delta method, for $\hat{\sigma}_k^2 \equiv \hat{\theta}^{-1}$,

$$\sqrt{n}(\hat{\sigma}_h^2 - \sigma_0^2) \to_d \mathcal{N}\left(0, \frac{2\sigma_0^6\mathbb{E}_0[h^2(X)(X-\mu)^2] + \sigma_0^8\mathbb{E}_0[h'^2(X-\mu)^2]}{\mathbb{E}_0^2[h(X)(X-\mu)^2]}\right).$$

The Cramér-Rao lower bound follows from taking the second derivative of $\log p_{\sigma_0^2}$ with respect to σ_0^2. ■

A.3. Proof of Theorems in Section 5

Proof [Proof of Theorem 9]
Case $b \neq 0$: We use a strategy similar to that of Inouye et al. (2016). Let $\mathcal{V}_1 = \{\boldsymbol{v} : \|\boldsymbol{v}\|_1 = 1, \boldsymbol{v} \in \mathbb{R}_+^m\}$. Then by Fubini-Tonelli the normalizing constant is,

$$\begin{aligned}
&\int_{\mathbb{R}_+^m} \exp\left(\boldsymbol{\eta}^\top \frac{\boldsymbol{x}^b - \mathbf{1}_m}{b} - \frac{1}{2a}\boldsymbol{x}^{a\top}\mathbf{K}\boldsymbol{x}^a\right) \mathrm{d}\boldsymbol{x} \\
&= \int_{\mathcal{V}_1}\int_0^\infty \exp\left(\boldsymbol{\eta}^\top \frac{z^b\boldsymbol{v}^b - \mathbf{1}_m}{b} - \frac{1}{2a}z^{2a}\boldsymbol{v}^{a\top}\mathbf{K}\boldsymbol{v}^a\right) \mathrm{d}z\,\mathrm{d}\boldsymbol{v} \\
&\propto \int_{\mathcal{V}_1}\int_0^\infty \exp\left(z^b(\boldsymbol{\eta}^\top\boldsymbol{v}^b)/b - z^{2a}(\boldsymbol{v}^{a\top}\mathbf{K}\boldsymbol{v}^a)/(2a)\right) \mathrm{d}z\,\mathrm{d}\boldsymbol{v}.
\end{aligned}$$

Here $\mathcal{V}_1$ is compact and the inner integral, if finite, is continuous in $\boldsymbol{v}$. It thus suffices to show that the inner integral is finite at every single $\boldsymbol{v} \in \mathcal{V}_1$.

Fixing $\boldsymbol{v} \in \mathcal{V}_1$, write $A \equiv A(\boldsymbol{v}) \equiv \boldsymbol{v}^{a\top}\mathbf{K}\boldsymbol{v}^a/(2a)$ and $B \equiv B(\boldsymbol{v}) \equiv (\boldsymbol{\eta}^\top\boldsymbol{v}^b)/b$. We need to show that

$$N(A,B,a,b) \equiv \int_0^\infty \exp\left(-Az^{2a} + Bz^b\right) \mathrm{d}z < +\infty.$$

Recall that (CC1) $\boldsymbol{v}^\top\mathbf{K}\boldsymbol{v} > 0$ for all $\boldsymbol{v} \in \mathbb{R}_+^m\backslash\{\mathbf{0}\}$, so $A > 0$.

(i) Suppose $B \leq 0$. Then $N(A,B,a,b) \leq \int_0^\infty \exp(-Az^{2a})\,\mathrm{d}z = A^{-a/2}\Gamma(1+1/(2a))$, a finite constant since $A > 0$ and $a > 0$.

(ii) Suppose $B > 0$. We first want to bound $\exp(-Az^{2a} + Bz^b) \leq N_0\exp(-Az^{2a}/2)$ by some finite constant $N_0 > 0$, so that $N(A,B,a,b) \leq N_0\int_0^\infty \exp(-Az^{2a}/2)\,\mathrm{d}z$, a finite constant for $a > 0$. Thus, it remains to give conditions so that $\exp(-Az^{2a}/2 + Bz^b)$ is bounded by some finite constant N_0, which by continuity only requires a finite limit as $z \searrow 0$ and as $z \nearrow +\infty$. As $z \nearrow +\infty$, $Bz^b \nearrow +\infty$, while $-Az^{2a}/2 \searrow -\infty$. We thus need $b < 2a$ so that the sum of the two does not go to positive infinity. On the other hand, as $z \searrow 0$, $-Az^{2a}/2 \nearrow 0$, so we need $b > 0$, otherwise $z^b \nearrow +\infty$. In conclusion, we require that $2a > b > 0$.

It thus suffices to require (CC1) and (CC2) $2a > b > 0$ to eliminate restrictions on B, and hence on $\boldsymbol{\eta}$. That is, $\boldsymbol{\eta}$ can take value in the entirety of $\mathbb{R}^m$.

Case $b = 0$: Again in (CC1) we assume $\boldsymbol{v}^\top\mathbf{K}\boldsymbol{v} > 0$ for all $\boldsymbol{v} \in \mathbb{R}_+^m\backslash\{\mathbf{0}\}$. Since $\mathcal{V}_2 \equiv \{\boldsymbol{v} : \|\boldsymbol{v}\|_2 = 1, \boldsymbol{v} \in \mathbb{R}_+^m\}$ is compact and $\boldsymbol{v}^\top\mathbf{K}\boldsymbol{v}$ is continuous in $\boldsymbol{v}$ and strictly positive on $\mathcal{V}_2$, the image of $\mathcal{V}_2$ under $\boldsymbol{v}^\top\mathbf{K}\boldsymbol{v}$ is a compact subset of $(0,\infty)$, i.e. $N_{\mathbf{K}} \equiv \min_{\boldsymbol{v}\in\mathbb{R}_+^m\backslash\{\mathbf{0}\}} \boldsymbol{v}^\top\mathbf{K}\boldsymbol{v}/\boldsymbol{v}^\top\boldsymbol{v} \equiv \min_{\boldsymbol{v}\in\mathcal{V}_2} \boldsymbol{v}^\top\mathbf{K}\boldsymbol{v} > 0$. We thus have

$$\begin{aligned}
&\int_{\mathbb{R}_+^m} \exp\left(\boldsymbol{\eta}^\top\log(\boldsymbol{x}) - \frac{1}{2a}\boldsymbol{x}^{a\top}\mathbf{K}\boldsymbol{x}^a\right)\mathrm{d}\boldsymbol{x} \\
&\leq \int_{\mathbb{R}_+^m} \exp\left(\boldsymbol{\eta}^\top\log(\boldsymbol{x}) - \frac{N_{\mathbf{K}}}{2a}\boldsymbol{x}^{a\top}\boldsymbol{x}^a\right)\mathrm{d}\boldsymbol{x} \\
&= \prod_{j=1}^m \int_0^\infty \exp\left(\eta_j\log(x_j) - \frac{N_{\mathbf{K}}}{2a}x_j^{2a}\right)\mathrm{d}x_j \\
&= \prod_{j=1}^m \left[\Gamma\left(\frac{\eta_j+1}{2a}\right)\frac{(N_{\mathbf{K}}/2a)^{-\frac{\eta_j+1}{2a}}}{2a}\right],
\end{aligned}$$

where the integration follows by change of variable and requires $a > 0$. Assuming $a > 0$, the last quantity is finite if and only if $\boldsymbol{\eta} \succ -\mathbf{1}_m$, by definition of the gamma function.

In conclusion, given conditions (CC1) $\min_{\boldsymbol{v}\in\mathbb{R}_+^m\backslash\{\mathbf{0}\}} \boldsymbol{v}^\top\mathbf{K}\boldsymbol{v} > 0$, (CC2) $2a > b > 0$, and (CC3) $a > 0$, $b = 0$ and $\boldsymbol{\eta} \succ -\mathbf{1}_m$, the unnormalized density (16) has a finite normalizing constant when (CC1) and (CC2) both hold, or (CC1) and (CC3) both hold.

The centered settings, where the term involving $\boldsymbol{x}^b$ is excluded, can be considered as a special case of both (1) and (2) with $\boldsymbol{\eta} \equiv \mathbf{0}$, and thus (CC1) and $a > 0$ are sufficient. ■

Proof [Proof of Theorem 11] Recall assumptions (A1) and (A2):

(A1) $p_0(\boldsymbol{x})h_j(x_j)\partial_j\log p(\boldsymbol{x})\Big|_{x_j\searrow 0^+}^{x_j\nearrow+\infty} = 0\,, \quad \forall \boldsymbol{x}_{-j} \in \mathbb{R}_+^{m-1}, \quad \forall p \in \mathcal{P}_+;$

(A2) $\mathbb{E}_{p_0}\|\nabla\log p(\boldsymbol{X})\circ\boldsymbol{h}^{1/2}(\boldsymbol{X})\|_2^2 < +\infty,\ \ \mathbb{E}_{p_0}\|(\nabla\log p(\boldsymbol{X})\circ\boldsymbol{h}(\boldsymbol{X}))'\|_1 < +\infty,\ \ \forall p \in \mathcal{P}_+.$

Let $\mathbf{K}_0$ and $\boldsymbol{\eta}_0$ be the true parameters so that $p_0 \in \mathcal{P}_+$, with $\mathcal{P}_+$ corresponding to a parameter space in which all parameters satisfy the conditions for a finite normalizing constant. We now give sufficient conditions for h to satisfy (A1) and (A2).

Conditions for (A1): Fix $j = 1,\ldots,m$ and $\boldsymbol{x}_{-j} \in \mathbb{R}_+^{m-1}$. We show that the conditions on h_j imply that the limits go to 0 as $x_j \nearrow +\infty$ and as $x_j \searrow 0^+$, which is stronger than (A1); in fact, from (37) below, the limits cannot go to a nonzero finite constant assuming an h with polynomial tail, since $a > 0$ and $B_1 \equiv \kappa_{0,jj} > 0$ for all j. Now,

$$\begin{aligned}
&p_0(\boldsymbol{x})h_j(x_j)\partial_j\log p(\boldsymbol{x}) \\
&\propto h_j(x_j)\exp\left(-\frac{1}{2a}\boldsymbol{x}^{a\top}\mathbf{K}_0\boldsymbol{x}^a + \boldsymbol{\eta}_0^\top\frac{\boldsymbol{x}^b - \mathbf{1}_m}{b}\right)\partial_j\left(-\frac{1}{2a}\boldsymbol{x}^{a\top}\mathbf{K}\boldsymbol{x}^a + \boldsymbol{\eta}^\top\frac{\boldsymbol{x}^b - \mathbf{1}_m}{b}\right)
\end{aligned}$$

$$\propto h_j(x_j)\exp\left(-\frac{1}{a}(\boldsymbol{k}_{0,j,-j}^\top \boldsymbol{x}_{-j}^a)x_j^a - \frac{\kappa_{0,jj}}{2a}x_j^{2a} + \eta_{0,j}\frac{x_j^b-1}{b}\right)\times \left(-\boldsymbol{k}_{j,-j}^\top \boldsymbol{x}_{-j}^a x_j^{a-1} - \kappa_{jj}x_j^{2a-1} + \eta_j x_j^{b-1}\right)$$

$$\equiv h_j(x_j)\exp\left(\frac{A_1 x_j^a}{a} + \frac{B_1 x_j^{2a}}{2a} + C_1\frac{x_j^b-1}{b}\right)\left(A_2 x_j^{a-1} + B_2 x_j^{2a-1} + C_2 x_j^{b-1}\right), \quad (37)$$

where $A_1 \equiv -\boldsymbol{k}_{0,j,-j}^\top \boldsymbol{x}_{-j}^a$, $A_2 \equiv -\boldsymbol{k}_{j,-j}^\top \boldsymbol{x}_{-j}^a$, $B_1 \equiv -\kappa_{0,jj} < 0$ and $B_2 \equiv -\kappa_{jj} < 0$ by condition (CC1). Finally $C_1 \equiv \eta_{0,j}$, $C_2 \equiv \eta_j$.

(1) Let $x_j \nearrow +\infty$. If $b > 0$, since $2a > b > 0$ and $B_1 < 0$, the exponential term in (37) decreases to 0 exponentially and its reciprocal dominates any polynomial functions. Thus, the entire product goes to 0 if $h_j(x_j)$ grows no faster than polynomially as $x_j \nearrow +\infty$. If $b = 0$, the $C_1 \log x_j$ term is again dominated by $B_1 x_j^{2a}/(2a)$, and the same conclusion holds.

(2) Let $x_j \searrow 0$.

(i) Let $b > 0$. Then the exponential term in (37) goes to constant $\exp(-C_1/b)$, and we only need

$$\lim_{x_j \searrow 0^+} h_j(x_j)(A_2 x_j^{a-1} + B_2 x_j^{2a-1} + C_2 x_j^{b-1}) = 0. \quad (38)$$

- If $a > 1$ and $b > 1$, the second term in (38) is a polynomial with three terms having powers $\geq \min\{a-1, b-1\}$. The product goes to zero if and only if $h_j(x_j) = o(x_j^{\max\{1-a,1-b\}})$ as $x_j \searrow 0$. Note that this is satisfied by any h_j that has a finite right limit at 0.
- If $a = 1$ and $b \geq 1$, or $a \geq 1$ and $b = 1$, then the second term in (38) is a polynomial of non-negative power plus a potentially nonzero constant. A sufficient condition for (38) is thus $\lim_{x_j \searrow 0} h_j(x_j) = 0$.
- If $a < 1$ or $b < 1$, then the second part in (38) is a polynomial having terms with negative degree $\geq \min\{a-1, b-1\}$. To counteract this a sufficient condition is $h_j(x_j) = o(x_j^{\max\{1-a,1-b\}})$.

In conclusion, $\lim_{x_j \searrow 0^+} p_0(\boldsymbol{x}) h_j(x_j) \partial_j \log p(\boldsymbol{x}) = 0$ if and only if

$$\lim_{x_j \searrow 0^+} h_j(x_j)/x_j^{\max\{1-a,1-b\}} = 0.$$

(ii) Now assume $b = 0$. Then, (37) now becomes

$$h_j(x_j)\exp\left(A_1 x_j^a/a + B_1 x_j^{2a}/(2a) + C_1 \log x_j\right)\left(A_2 x_j^{a-1} + B_2 x_j^{2a-1} + C_2/x_j\right).$$

With $C_1 \log x_j$ dominating, the exponential part scales as $x_j^{C_1}$. We thus require

$$\lim_{x_j \searrow 0^+} h_j(x_j)(A_2 x_j^{a-1+C_1} + B_2 x_j^{2a-1+C_1} + C_2 x_j^{C_1-1}) = 0,$$

which by the previous discussion on (38) holds if and only if

$$\lim_{x_j \searrow 0^+} h_j(x_j)/x_j^{1-C_1} = 0$$

since $1 - a - C_1 < 1 - C_1$.

In summary, (A1) is satisfied if $h_j(x_j)$ grows at most polynomially as $x_j \nearrow +\infty$, and $\lim_{x_j \searrow 0^+} h_j(x_j)/x_j^{\max\{1-a,1-b\}} = 0$ if $b > 0$, or $\lim_{x_j \searrow 0^+} h_j(x_j)/x_j^{1-\eta_{0,j}} = 0$ if $b = 0$.

Conditions for (A2): For (A2), we consider powers of x as the h functions for simplicity; conclusions for other functions that have the same tail behavior (big-O scaling) as $x \searrow 0$ and $x \nearrow +\infty$ follow similarly. Sufficiency results for piecewise power functions follow by partitioning, and similarly for other functions h whose function values and derivatives can be bounded by those of some piecewise power function (e.g. truncated powers), since (A2) is on integrability of products involving positive powers of h and h'.

Let $\mathbf{K}_0$ and $\boldsymbol{\eta}_0$ be the true parameters from the parameter space that satisfies the conditions for finite normalizing constant. By part (2) of the proof of Theorem 9, the assumption that $\mathbf{K}_0$ satisfies (CC1) implies that $\min_{\boldsymbol{v} \in \mathbb{R}_+^m \setminus \{\mathbf{0}\}} \boldsymbol{v}^\top \mathbf{K}_0 \boldsymbol{v}/\boldsymbol{v}^\top \boldsymbol{v} \equiv N_{\mathbf{K}_0} > 0$. Then we have the following decomposition

$$p_{\mathbf{K}_0,\boldsymbol{\eta}_0}(\boldsymbol{x}) \equiv \exp\left(-\frac{1}{2a}\boldsymbol{x}^{a\top}\mathbf{K}_0\boldsymbol{x}^a + \boldsymbol{\eta}_0^\top \frac{\boldsymbol{x}^b - \mathbf{1}_m}{b}\right) \leq \prod_{j=1}^m \exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_j^{2a} + \eta_{0,j}\frac{x_j^b-1}{b}\right).$$

Then for any other $\mathbf{K}$ and $\boldsymbol{\eta}$ in the parameter space, for the first part of (A2) it suffices to show for any $j = 1, \ldots, m$ that $D < \infty$, where

$$D \equiv \int_{\mathbb{R}_+^m} \prod_{j=1}^m \exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_j^{2a} + \eta_{0,j}\frac{x_j^b-1}{b}\right) h_j(x_j) \times \left(-\kappa_{jj}x_j^{2a-1} - \sum_{i \neq j}\kappa_{ji}x_i^a x_j^{a-1} + \eta_j x_j^{b-1}\right)^2 \mathrm{d}\boldsymbol{x}$$

$$\geq \int_{\mathbb{R}_+^m} p_0(\boldsymbol{x}) h_j(x_j) \left(\partial_j \log p(\boldsymbol{x})\right)^2 \mathrm{d}\boldsymbol{x}.$$

Note that

$$\left(-\kappa_{jj}x_j^{2a-1} - \sum_{i\neq j}\kappa_{ji}x_i^a x_j^{a-1} + \eta_j x_j^{b-1}\right)^2 = \kappa_{jj}^2 x_j^{4a-2} + \sum_{i\neq j,\ell\neq j}\kappa_{ji}\kappa_{j\ell}x_i^a x_\ell^a x_j^{2a-2} + \eta_j^2 x_j^{2b-2} + 2\sum_{i\neq j}\kappa_{jj}\kappa_{ji}x_i^a x_j^{3a-2} - 2\sum_{i\neq j}\kappa_{ji}\eta_j x_i^a x_j^{a+b-2} - 2\kappa_{jj}\eta_j x_j^{2a+b-2}.$$

Thus, plugging this back in the definition of D, we can split D into a sum of six terms D_1 through D_6, each of which is a sum of terms of the form

$$\begin{aligned}&\int_{\mathbb{R}_+^m}\prod_{k=1}^m \exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_k^{2a}+\eta_{0,k}\frac{x_k^b-1}{b}\right)h_j(x_j)x_i^{\mathrm{pow}_i}x_\ell^{\mathrm{pow}_\ell}x_j^{\mathrm{pow}_j}\,\mathrm{d}\boldsymbol{x}\\ =&\prod_{k\neq j}\int_0^\infty \exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_k^{2a}+\eta_{0,k}\frac{x_k^b-1}{b}\right)x_k^{\mathrm{pow}_k}\,\mathrm{d}x_k\\ &\qquad\times\int_0^\infty \exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_j^{2a}+\eta_{0,j}\frac{x_j^b-1}{b}\right)h_j(x_j)x_j^{\mathrm{pow}_j}\,\mathrm{d}x_j\end{aligned}$$

times a constant involving $\mathbf{K}$ and η_j, where $\mathrm{pow}_k \geq 0$ for each $k \neq j$. We have thus decomposed the integral into a product of univariate integrals. Note that

$$\int_0^\infty \exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_i^{2a}+\eta_{0,i}\frac{x_i^b-1}{b}\right)x_i^{\mathrm{pow}_i}\,\mathrm{d}x_i$$

is finite for all $\mathrm{pow}_i \geq 0$ regardless of whether b is nonzero, since we assumed $\mathbf{K}_0$ and $\boldsymbol{\eta}_0$ to lie in the parameter space with a finite normalizing constant. Indeed, if $b > 0$ then the terms in the exponential is a regular polynomial with positive degree and a negative leading term; if $b = 0$ then integrability follows from $\eta_{0,i} + \mathrm{pow}_i \geq \eta_{0,i} > -1$. Thus, we only need to consider the univariate integral that involve the x_j terms, namely

$$\int_0^\infty \exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_j^{2a}+\eta_{0,j}\frac{x_j^b-1}{b}\right)h_j(x_j)x_j^{\mathrm{pow}_j}\,\mathrm{d}x_j,$$

where pow_j takes value in $\{4a-2, 2a-2, 2b-2, 3a-2, a+b-2, 2a+b-2\} \subseteq [2\min\{a,b\}-2, 4a-2]$. We split the integral into two parts over $[0,1]$ and $[1,\infty]$, respectively.

- If $b > 0$, on $[0,1]$ the exponential part is bounded above and below by positive constants, and for (A1) we require $h_j(x) = o(x^{1-\min\{a,b\}})$ as $x \searrow 0^+$, so the integrand is $o(x^{\min\{a,b\}-1}) = o(x^{-1})$ and is thus integrable on $[0,1]$. The integrand on $[1,\infty)$ is integrable as in (A1) we assume h to grow at most polynomially.
- If $b = 0$, $\mathrm{pow}_j \in [-2, 4a-2]$ and the integrand becomes

  $$\exp(-N_{\mathbf{K}_0}x_j^{2a}/(2a))h_j(x_j)x_j^{\mathrm{pow}_j+\eta_{0,j}}.$$

  On $[0,1]$, (A1) requires $h_j(x) = o(x^{1-\min_j \eta_{0,j}})$, so $h_j(x_j)x_j^{\mathrm{pow}_j+\eta_{0,j}} = o(x^{-1})$ and the integrand is again integrable. Integrability on $[1,\infty)$ follows similarly to the case with $b > 0$.

Now consider the second part of (A2). By definition $\mathbb{E}_{p_0}\|(\nabla \log p(\boldsymbol{X}) \circ \boldsymbol{h}(\boldsymbol{X}))'\|_1$ equals

$$\int_{\mathbb{R}_+^m} p_0(\boldsymbol{x})\sum_{j=1}^m \left|h_j'(X_j)\partial_j \log p(\boldsymbol{X}) + h_j(X_j)\partial_j^2 \log p(\boldsymbol{X})\right|\mathrm{d}\boldsymbol{x}$$

$$\begin{aligned}\leq\sum_{j=1}^m\int_{\mathbb{R}_+^m}\exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_j^{2a}+\eta_{0,j}\frac{x_j^b-1}{b}\right)\Bigg|h_j'(x_j)\left(-\kappa_{jj}x_j^{2a-1}-\sum_{i\neq j}\kappa_{ji}x_i^a x_j^{a-1}+\eta_j x_j^{b-1}\right)\\ +h_j(x_j)\left(-\kappa_{jj}(2a-1)x_j^{2a-2}-\sum_{i\neq j}\kappa_{ji}(a-1)x_i^a x_j^{a-2}+(b-1)\eta_j x_j^{b-2}\right)\Bigg|\,\mathrm{d}\boldsymbol{x}.\end{aligned}$$

By the triangle inequality and the fact that $h_j \geq 0$ and $h_j' \geq 0$, similar to the proof for the first part, for each j the integral can be bounded by a sum of six integrals, each of the form

$$\text{const}\times\int_{\mathbb{R}_+^m}\prod_{k=1}^m\exp\left(-\frac{N_{\mathbf{K}_0}}{2a}x_k^{2a}+\eta_{0,k}\frac{x_k^b-1}{b}\right)h_j(x_j)x_i^{\mathrm{pow}_i}x_j^{\mathrm{pow}_j}\,\mathrm{d}\boldsymbol{x},$$

or with h_j replaced by h_j'. Finiteness thus follows from the same type of discussion by noting that $h_j(x) = o\left(x^{1-\min\{a,b\}}\right)$ and $h_j'(x) = o\left(x^{-\min\{a,b\}}\right)$.

We conclude that if the true and the proposed parameters give densities with finite normalizing constants, and if h satisfies assumption (A1), then (A2) is automatically satisfied.

In the centered case where we assume $\boldsymbol{\eta} \equiv \mathbf{0}$, we only need $\lim_{x_j\searrow 0^+} h_j(x_j)/x_j^{1-a} = 0$ as it is a special case with $b = 2a$. ■

A.4. Proof of Theorems in Section 6

Proof [Proof of Corollary 14] By Theorem 13, under assumptions in that theorem, the support of $\hat{\boldsymbol{\Psi}}$ is a subset of the true support of $\boldsymbol{\Psi}_0$, and $\|\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0\|_\infty \leq \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda$. Since $\boldsymbol{\Psi}_0$ has $|S_0|$ nonzero entries,

$$\|\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0\|_F = \left[\sum_{\boldsymbol{\Psi}_{0,jk}\neq 0}(\hat{\boldsymbol{\Psi}}_{jk} - \boldsymbol{\Psi}_{0,jk})^2\right]^{1/2} \leq \sqrt{|S_0|}\|\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0\|_\infty \leq \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda\sqrt{|S_0|}.$$

Similarly, by the definition of matrix ℓ_∞-ℓ_∞ norm,

$$|||\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0|||_2 \leq |||\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0|||_\infty = \max_{j=1,..,m}\sum_{k=1}^m |\hat{\boldsymbol{\Psi}}_{jk} - \boldsymbol{\Psi}_{0,jk}| \leq \frac{c_{\boldsymbol{\Gamma}_0}}{2-\alpha}\lambda d_{\boldsymbol{\Psi}_0}.$$

The result follows by also noting that $|||\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0|||_2 \leq |||\hat{\boldsymbol{\Psi}} - \boldsymbol{\Psi}_0|||_F$. ■

Proof [Proof of Theorem 15] The proof is based on Theorem 13 and a probabilistic bound on $\|\boldsymbol{\Gamma}_{\boldsymbol{\gamma}} - \boldsymbol{\Gamma}_0\|_\infty$, where in the case of centered Gaussian $\boldsymbol{\Gamma} = \mathrm{diag}(\mathbf{x}\mathbf{x}^\top, \ldots, \mathbf{x}\mathbf{x}^\top)$. Denote $\boldsymbol{\Sigma}_0 = \mathbf{K}_0^{-1}$. In particular, given $\tau > 2$ we wish to show that for $\epsilon = 80\sqrt{2}c_0\max_j(\Sigma_{0,jj})$, assuming $c_0 \equiv \sqrt{(\tau\log m + \log 4)/n} < 1/\sqrt{2}$,

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^n X_j^{(i)}X_k^{(i)} + \gamma_{1j}\mathbb{1}_{\{j=k\}} - \mathbb{E}X_jX_k\right| > \epsilon\right) \leq m^{2-\tau},$$

and so the results follow from Theorem 13.

By Lemma 1 of Ravikumar et al. (2011), since $X_j/\sqrt{\Sigma_{0,jj}}$ is Gaussian with mean 0 and standard deviation 1,

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_j^{(i)}X_k^{(i)} - \mathbb{E}X_jX_k\right| > t\right) \le 4\exp\left(-\frac{nt^2}{3200\max_j(\Sigma_{0,jj})^2}\right)$$

for $t \in (0, 40\max_j(\Sigma_{0,jj}))$. Denote the event as $\mathcal{E}_{j,k}(t)$. Note that $\mathbb{E}X_j^2 \le \max_j \Sigma_{0,jj} = \epsilon/(80\sqrt{2}c_0)$. Then letting $t = \epsilon/2$ and conditioning on the complement of $\mathcal{E}_{j,j}(\epsilon/2)$, we have

$$n^{-1}\sum_{i=1}^{n} {X_j^{(i)}}^2 \le \mathbb{E}X_j^2 + \epsilon/2 \le \frac{\epsilon}{2}\left(1 + \frac{1}{40\sqrt{2}c_0}\right).$$

Thus, choosing $\gamma_{\ell j} = (\delta-1)\sum_{i=1}^{n} {X_j^{(i)}}^2/n$ for $\ell = 1, \ldots, m$ ($\mathbf{\Gamma}$ has m identical blocks) with $1 < \delta < 1 + \left(1 + 1/(40\sqrt{2}c_0)\right)^{-1}$, by the triangle inequality and a union bound we have

$$\mathbb{P}\left(\max_{j,k}\left|n^{-1}\sum_{i=1}^{n} X_j^{(i)}X_k^{(i)} + \gamma_{1j}\mathbb{1}_{\{j=k\}} - \mathbb{E}X_jX_k\right| > \epsilon\right) \le \mathbb{P}(\mathcal{E}_{j,k}(\epsilon/2)) = m^{2-\tau}.$$

Since $\tau > 2$, it holds that $1 + \left(1 + 1/(40\sqrt{2}c_0)\right)^{-1} = 2 - (1 + 40\sqrt{2}c_0)^{-1}$ is larger than $2 - (1 + 80\sqrt{\log m/n})^{-1} \equiv C(n,m)$, so it is safe to choose any $\delta \in (1, C(n,m))$. Thus by the requirement on ϵ, the theorem statement holds when $n > \max(c^* c_1^2 d_{\mathbf{K}}^2, 2)(\tau\log m + \log 4)$ with $c^* = 12800\max_j(\Sigma_{0,jj})^2$. ■

Proof [Proof of Theorem 16] The proof of Theorem 13 from Lin et al. (2016) does not rely on the fact that the original $\mathbf{\Gamma}$ is an unbiased estimator for the population $\mathbf{\Gamma}_0$, but instead only requires one to bound $\|\mathbf{\Gamma} - \mathbf{\Gamma}_0\|_\infty$. Thus, for $\mathbf{\Gamma}_{\boldsymbol{\gamma}} = \mathbf{\Gamma} + \mathrm{diag}(\boldsymbol{\gamma})$, by Theorem 13 it suffices to prove that for any $\tau > 3$, we can bound $\|\mathbf{\Gamma}(\mathbf{x}) + \mathrm{diag}(\boldsymbol{\gamma}(\mathbf{x})) - \mathbf{\Gamma}_0\|_\infty$ by some ϵ_1 and $\|\boldsymbol{g}(\mathbf{x}) - \boldsymbol{g}_0\|_\infty$ by some ϵ_2, uniformly with probability $1 - m^{3-\tau}$. Recall from (21) that the j^{th} block of $\mathbf{\Gamma}_{\boldsymbol{\gamma}} \in \mathbb{R}^{m^2\times m^2}$ has (k,ℓ)-th entry

$$n^{-1}\sum_{i=1}^{n} X_k^{(i)}X_\ell^{(i)}h_j\left(X_j^{(i)}\right) + \gamma_{kj}\cdot\mathbb{1}_{\{k=\ell\}}.$$

The entry in $\boldsymbol{g} \in \mathbb{R}^{m^2}$ (obtained by linearizing a $m\times m$ matrix) corresponding to (j,k) is

$$n^{-1}\sum_{i=1}^{n} X_k^{(i)}h_j'\left(X_j^{(i)}\right) + n^{-1}\mathbb{1}_{\{j=k\}}\sum_{i=1}^{n} h_j\left(X_j^{(i)}\right).$$

Denote $M \equiv \max_j \sup_{x>0} h_j(x)$, $M' \equiv \max_j \sup_{x>0} h_j'(x)$, and $c_{\boldsymbol{X}} \equiv 2\max_j(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}_0 X_j)$. Using results for sub-Gaussian random variables from Lemma 22.2 in Appendix B, we have for any $t_1 > 0$,

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_k^{(i)}X_\ell^{(i)}h_j\left(X_j^{(i)}\right) - \mathbb{E}_0X_kX_\ell h_j(X_j)\right| > t_1\right) \le 2\exp\left(-\min\left(\frac{nt_1^2}{2M^2c_{\boldsymbol{X}}^4}, \frac{nt_1}{2Mc_{\boldsymbol{X}}^2}\right)\right).$$

Thus, choosing $\epsilon_1 \equiv 2Mc_{\boldsymbol{X}}^2 c_{n,m}$, where $c_{n,m} \equiv \max\left\{\frac{2(\log m^\tau + \log 6)}{n}, \sqrt{\frac{2(\log m^\tau+\log 6)}{n}}\right\}$, for $\gamma_{kj} \le \epsilon_1/2$, we have

$$\begin{aligned}
&\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_k^{(i)}X_\ell^{(i)}h_j\left(X_j^{(i)}\right) + \gamma_{kj}\mathbb{1}_{\{k=\ell\}} - \mathbb{E}_0X_kX_\ell h_j(X_j)\right| > \epsilon_1\right)\\
&\le \mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_k^{(i)}X_\ell^{(i)}h_j\left(X_j^{(i)}\right) - \mathbb{E}_0X_kX_\ell h_j(X_j)\right| > \epsilon_1/2\right) \qquad (39)\\
&\le 2\exp\left(-\min\left(\frac{n\epsilon_1^2}{8M^2c_{\boldsymbol{X}}^4}, \frac{n\epsilon_1}{4Mc_{\boldsymbol{X}}^2}\right)\right) \le \frac{1}{3m^\tau}. \qquad (40)
\end{aligned}$$

Denote the event inside the probability in (39) as $\mathcal{E}_{k,\ell,j}(\epsilon_1/2)$.
By definition,

$$c_{\boldsymbol{X}}^2 = 4\max_k\left(4\Sigma_{kk} + 4\sqrt{e}\sqrt{\Sigma_{kk}}\,\mathbb{E}_0X_k + e(\mathbb{E}_0X_k)^2\right) \ge 4e\max_k\left(\Sigma_{kk} + (\mathbb{E}_0X_k)^2\right).$$

By Lemmas 21.2 and 22.1 from Appendix B, $\mathrm{var}(X_k) \le \Sigma_{kk}$, so $c_{\boldsymbol{X}}^2 \ge 4e\max_k \mathbb{E}_0X_k^2 \ge 4e\mathbb{E}_0X_k^2h_j(X_j)/M$. Thus, setting $\epsilon_1 = 2Mc_{\boldsymbol{X}}^2c_{n,m}$, on the complement of $\mathcal{E}_{k,k,j}(\epsilon_1/2)$ we have

$$n^{-1}\sum_{i=1}^{n} {X_k^{(i)}}^2h_j\left(X_j^{(i)}\right) \le \mathbb{E}_0X_k^2h_j(X_j) + \epsilon_1/2 \le \frac{\epsilon_1}{2}\left(1 + \frac{1}{4ec_{n,m}}\right).$$

Then

$$\frac{1}{1 + 1/(4ec_{n,m})}\frac{1}{n}\sum_{i=1}^{n} {X_k^{(i)}}^2h_j\left(X_j^{(i)}\right) \le \epsilon_1/2 \qquad (41)$$

on the complement of $\mathcal{E}_{k,k,j}(\epsilon_1/2)$, again with $c_{n,m} \equiv \max\left\{\frac{2(\log m^\tau+\log 6)}{n}, \sqrt{\frac{2(\log m^\tau+\log 6)}{n}}\right\}$.
Note that the multiplier on the left of (41) is increasing in $c_{n,m}$, and that $2(\log m^\tau + \log 6) > 6\log m$ by the assumption that $\tau > 3$. Thus, if we let

$$\gamma_{kj} \equiv \frac{1}{1 + 1/\left(4e\max\left\{6\log m/n, \sqrt{6\log m/n}\right\}\right)}\frac{1}{n}\sum_{i=1}^{n} {X_k^{(i)}}^2h_j\left(X_j^{(i)}\right),$$

which is just a constant multiple of the (k,k)-th entry of $\mathbf{\Gamma}_j$ itself, with the constant explicitly calculable and a function of p and n only, then for $k = \ell$

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_k^{(i)}X_\ell^{(i)}h_j\left(X_j^{(i)}\right) + \gamma_{kj} - \mathbb{E}_0X_kX_\ell h_j(X_j)\right| \ge \epsilon_1\right) \le \mathbb{P}(\mathcal{E}_{k,\ell,j}(\epsilon_1/2)) \le \frac{1}{3m^\tau}.$$

Since this also holds for $k \ne \ell$ without the γ_{kj} term, by a union bound over m^3 events,

$$\mathbb{P}\left(\max_{j,k,\ell}\left|n^{-1}\sum_{i=1}^{n} X_k^{(i)}X_\ell^{(i)}h_j\left(X_j^{(i)}\right) + \gamma_{kj}\mathbb{1}_{\{k=\ell\}} - \mathbb{E}_0X_kX_\ell h_j(X_j)\right| \ge \epsilon_1\right) \le \frac{1}{3m^{\tau-3}}. \qquad (42)$$

Now, on the other hand, Lemma 22.1 and Hoeffding's inequality give for any $t_{2,1}, t_{2,2} > 0$ that

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_k^{(i)} h_j'\left(X_j^{(i)}\right) - \mathbb{E}_0 X_k h_j'(X_j)\right| \geq t_{2,1}\right) \leq 2\exp\left(-\frac{nt_{2,1}^2}{2M'^2 c_{\boldsymbol{X}}^2}\right),$$
$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} h_j\left(X_j^{(i)}\right) - \mathbb{E}_0 h_j(X_j)\right| \geq t_{2,2}\right) \leq 2\exp\left(-2nt_{2,2}^2/M^2\right).$$

Choosing $\epsilon_{2,1} \equiv \sqrt{2}M' c_{\boldsymbol{X}}\sqrt{\frac{\log m^{\tau-1}+\log 6}{n}}$, $\epsilon_{2,2} \equiv M\sqrt{\frac{\log m^{\tau-2}+\log 6}{2n}}$ and taking union bounds over m^2, and m events, respectively, we have

$$\mathbb{P}\left(\max_{j,k}\left|n^{-1}\sum_{i=1}^{n} X_k^{(i)} h_j'\left(X_j^{(i)}\right) - \mathbb{E}_0 X_k h_j'(X_j)\right| \geq \epsilon_{2,1}\right) \leq \frac{1}{3m^{\tau-3}}, \tag{43}$$
$$\mathbb{P}\left(\max_{j}\left|n^{-1}\sum_{i=1}^{n} h_j\left(X_j^{(i)}\right) - \mathbb{E}_0 h_j(X_j)\right| \geq \epsilon_{2,2}\right) \leq \frac{1}{3m^{\tau-3}}. \tag{44}$$

Hence, by (42) (43) (44), with probability at least $1 - m^{3-\tau}$, $\|\boldsymbol{\Gamma}_{\boldsymbol{\gamma}}(\mathbf{x}) - \boldsymbol{\Gamma}_0\|_\infty < \epsilon_1$ and $\|\boldsymbol{g}(\mathbf{x}) - \boldsymbol{g}_0\|_\infty < \epsilon_2 \equiv \epsilon_{2,1} + \epsilon_{2,2}$. Consider any $\tau > 3$, and let

$$\begin{aligned}
c_2 &\equiv \frac{6}{\alpha} c_{\boldsymbol{\Gamma}_0}, \\
n &> \max\{2M^2 c_{\boldsymbol{X}}^4 c_2^2 d_{\mathbf{K}_0}^2(\tau\log m + \log 6), 2Mc_{\boldsymbol{X}}^2 c_2 d_{\mathbf{K}_0}(\tau\log m + \log 6)\}, \\
\lambda &> \frac{3(2-\alpha)}{\alpha}\max\{c_{\mathbf{K}_0}\epsilon_1, \epsilon_2\} \\
&\equiv \frac{3(2-\alpha)}{\alpha}\max\left\{4Mc_{\mathbf{K}_0}c_{\boldsymbol{X}}^2\frac{(\log m^\tau + \log 6)}{n},\right. \\
&\quad \left. 2Mc_{\mathbf{K}_0}c_{\boldsymbol{X}}^2\sqrt{\frac{2(\log m^\tau + \log 6)}{n}}, \sqrt{2}M' c_{\boldsymbol{X}}\sqrt{\frac{\log m^{\tau-1}+\log 6}{n}} + M\sqrt{\frac{\log m^{\tau-2}+\log 6}{2n}}\right\}.
\end{aligned}$$

Then $d_{\mathbf{K}_0}\epsilon_1 \leq \alpha/(6c_{\boldsymbol{\Gamma}_0})$ and the results follow from Theorem 13. ■

Proof [Proof of Theorem 17] Similar to the proof of Theorem 16, by Theorem 13 it suffices to prove that for any $\tau > 3$, we can bound $\|\boldsymbol{\Gamma}_{\boldsymbol{\gamma}}(\mathbf{x}) - \boldsymbol{\Gamma}_0\|_\infty$ by some ϵ_1 and $\|\boldsymbol{g}(\mathbf{x}) - \boldsymbol{g}_0\|_\infty$ by some ϵ_2, uniformly with probability $1 - m^{3-\tau}$. Recall that $\boldsymbol{\Gamma} \in \mathbb{R}^{(m^2+m)\times(m^2+m)}$ is a rearrangement of $\boldsymbol{\Gamma}^{(*)}$, which is in turn formed by $\boldsymbol{\Gamma}_{11} \in \mathbb{R}^{m^2\times m^2}$, $\boldsymbol{\Gamma}_{12} \in \mathbb{R}^{m^2\times m}$, $\boldsymbol{\Gamma}_{12}^\top$ and $\boldsymbol{\Gamma}_{22} \in \mathbb{R}^{m\times m}$, all of which are block-diagonal with m blocks.
The j^{th} block of $\boldsymbol{\Gamma}_{11} \in \mathbb{R}^{m^2\times m^2}$ has (k,ℓ)-th entry

$$n^{-1}\sum_{i=1}^{n} X_k^{(i)} X_\ell^{(i)} h_j\left(X_j^{(i)}\right),$$

the k^{th} entry in the j^{th} block of $\boldsymbol{\Gamma}_{12}$ is

$$-n^{-1}\sum_{i=1}^{n} X_k^{(i)} h_j\left(X_j^{(i)}\right),$$

the j^{th} diagonal entry of $\boldsymbol{\Gamma}_{22}$ is

$$n^{-1}\sum_{i=1}^{n} h_j\left(X_j^{(i)}\right).$$

On the other hand, $\boldsymbol{g} \in \mathbb{R}^{(m^2+m)}$ is a rearrangement of $\boldsymbol{g}^{(*)} \equiv [\boldsymbol{g}_1^\top, \boldsymbol{g}_2^\top]^\top$, where the entry in $\boldsymbol{g}_1 \in \mathbb{R}^{m^2}$ (obtained by linearizing a $m \times m$ matrix) corresponding to (j,k), is

$$n^{-1}\sum_{i=1}^{n} X_k^{(i)} h_j'\left(X_j^{(i)}\right) + n^{-1}\mathbb{1}_{\{j=k\}}\sum_{i=1}^{n} h_j\left(X_j^{(i)}\right),$$

while the j-th component of $\boldsymbol{g}_2 \in \mathbb{R}^m$ is

$$-n^{-1}\sum_{i=1}^{n} h_j'\left(X_j^{(i)}\right).$$

Recalling that the bounds in Lemma 22 also hold when $\boldsymbol{\mu} \neq 0$, we may then use bounds similar to those in the proof of Theorem 16, and use union bounds to arrive at analogous consistency results, modulus different constants. The amplifiers $\boldsymbol{\gamma}$ can be incorporated analogously. ■

Appendix B. Auxiliary Lemmas and Definitions

In this appendix, to simplify notation, when it is clear from the context, the operator $\mathbb{E}$ is defined as the expectation under the true distribution, unless otherwise noted.

Definition 20 (Sub-Gaussian and Sub-Exponential Variables)
The sub-Gaussian ($r = 2$) *and* sub-exponential ($r = 1$) norms *of a random variable are*

$$\|X\|_{\psi_r} \equiv \sup_{q\geq 1} q^{-1/r}(\mathbb{E}|X|^{rq})^{1/(rq)} \equiv \sup_{q\geq 1} q^{-1/r}\|X\|_{rq}.$$

If $\|X\|_{\psi_2} < \infty$ *we say* X *is* sub-Gaussian*; if* $\|X\|_{\psi_1} < \infty$ *we call* X sub-exponential. *For a* zero-mean *sub-Gaussian random variable* X *also define the* sub-Gaussian parameter

$$\tau(X) = \inf\{\tau \geq 0 : \mathbb{E}\exp(tX) \leq \exp(\tau^2 t^2/2),\ \forall t \in \mathbb{R}\}.$$

The definition of sub-Gaussian norm here allows for a non-centered variable and differs from the one in Vershynin (2012), which uses $\|X\|_q$. Instead, it coincides with θ_2 in Buldygin and Kozachenko (2000). The sub-Gaussian parameter is defined as in Buldygin and Kozachenko (2000) and the sub-exponential norm as in Vershynin (2012).

Lemma 21 (Properties of Sub-Gaussian and Sub-Exponential Variables)

1) For any X *and* $r = 1, 2$, $\|X - \mathbb{E}X\|_{\psi_r} \leq 2\|X\|_{\psi_r}$ *and* $\|X\|_{\psi_r} \leq \|X - \mathbb{E}X\|_{\psi_r} + |\mathbb{E}X|$, *as long as the expectation and norms are finite.*

2) (Buldygin and Kozachenko, 2000) $\tau(X)$ is a norm on the space of all zero-mean sub-Gaussian variables; so $\tau(X+Y) \le \tau(X) + \tau(Y)$. If X is zero-mean sub-Gaussian, then $\mathrm{var}(X) \le \tau^2(X)$, $\|X\|_{\psi_2} \le 2\tau(X)/\sqrt{e}$, $\tau(X) \le \sqrt{e}\|X\|_{\psi_2}$. If $X_1, \dots, X_n$ are i.i.d. zero-mean sub-Gaussian, $\tau\left(n^{-1}\sum_{i=1}^n X_i\right) \le n^{-1/2}\tau(X_i)$.

3) If X_1 and X_2 are sub-Gaussian (not necessarily independent) with $\|X_1\|_{\psi_2} \le K_1$ and $\|X_2\|_{\psi_2} \le K_2$, then X_1X_2 is sub-exponential with $\|X_1X_2\|_{\psi_1} \le K_1K_2$.

4) (Buldygin and Kozachenko, 2000) If X is zero-mean sub-Gaussian and $q > 0$, then

$$\mathbb{E}|X|^q \le 2(q/e)^{q/2}\tau^q(X).$$

5) (Buldygin and Kozachenko, 2000) If $X_1, \dots, X_n$ are independent zero-mean, sub-Gaussian variables, then for any $\epsilon > 0$,

$$\mathbb{P}(|X_1| \ge \epsilon) \le 2\exp\left(-\frac{\epsilon^2}{2\tau^2(X_1)}\right),$$
$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^n X_i\right| > \epsilon\right) \le 2\exp\left(-\frac{n\epsilon^2}{2\max_i \tau^2(X_i)}\right).$$

6) (Vershynin, 2012) If $X_1, \dots, X_n$ are independent zero-mean sub-exponential random variables with $K \ge \max_i \|X_i\|_{\psi_1}$, then for any $\epsilon > 0$,

$$\mathbb{P}(|X_1| \ge \epsilon) \le 2\exp\left(-\min\left(\frac{\epsilon^2}{8e^2K^2}, \frac{\epsilon}{4eK}\right)\right),$$
$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^n X_i\right| \ge \epsilon\right) \le 2\exp\left(-\min\left(\frac{n\epsilon^2}{8e^2K^2}, \frac{n\epsilon}{4eK}\right)\right).$$

7) (Boucheron et al., 2013) If for X_i i.i.d. there exists some $B > 0$ such that

$$\sup_{q\ge 2}\left(\frac{\mathbb{E}|X|^q}{q!}\right)^{1/q} \le B/2$$

then for all $\epsilon > 0$,

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^n (X_i - \mathbb{E}X_i)\right| \ge \epsilon\right) \le 2\exp\left(-\min\left(\frac{n\epsilon^2}{2B^2}, \frac{n\epsilon}{2B}\right)\right).$$

Proof

1) For $r = 1, 2$, by the triangle inequality, $\|X - \mathbb{E}X\|_{\psi_r} \le \|X\|_{\psi_r} + \|\mathbb{E}X\|_{\psi_r} = \|X\|_{\psi_r} + |\mathbb{E}X| \le \|X\|_{\psi_r} + \mathbb{E}|X| \le 2\|X\|_{\psi_r}$, where in the last step we used the definition of $\|\cdot\|_{\psi_r}$ with $q = 1$ for $r = 1$ and $\mathbb{E}|X| \le (\mathbb{E}|X|^2)^{1/2}$ with $q = 2$ for $r = 2$. On the other hand, $\|X\|_{\psi_r} \le \|X - \mathbb{E}X\|_{\psi_r} + \|\mathbb{E}X\|_{\psi_r} = \|X - \mathbb{E}X\|_{\psi_r} + |\mathbb{E}X|$.

2) These follow from Theorems 1.2 and 1.3 and Lemmas 1.2 and 1.7 from Buldygin and Kozachenko (2000), and $\sqrt[4]{3.1}e^{9/16}/\sqrt{2} \approx 1.6467 \le 1.6487 \approx \sqrt{e}$.

3) By Hölder's inequality (or Cauchy-Schwarz),

$$\begin{aligned}\|X_1X_2\|_{\psi_1} &= \sup_{q\ge1} q^{-1}(\mathbb{E}|X_1X_2|^q)^{1/q} = \sup_{q\ge1} q^{-1}(\mathbb{E}|X_1^qX_2^q|)^{1/q}\\ &\le \sup_{q\ge1} q^{-1}\left[(\mathbb{E}|X_1|^{2q})^{1/2}(\mathbb{E}|X_2|^{2q})^{1/2}\right]^{1/q}\\ &\le \sup_{q\ge1}\left[q^{-1/2}(\mathbb{E}|X_1|^{2q})^{1/2q}\right]\sup_{q\ge1}\left[q^{-1/2}(\mathbb{E}|X_2|^{2q})^{1/2q}\right]\\ &= \|X_1\|_{\psi_2}\|X_2\|_{\psi_2} \le K_1K_2.\end{aligned}$$

4-6) These are Lemma 1.4 and Theorem 1.5 in Buldygin and Kozachenko (2000), and a consequence of Corollary 5.17 in Vershynin (2012).

7) By Theorem 2.10 of Boucheron et al. (2013) wherein we let $v \equiv nB^2/2$ and $c \equiv B/2$, we have

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^n (X_i - \mathbb{E}X_i)\right| \ge \epsilon\right) \le 2\exp\left(-\frac{n\epsilon^2}{B^2 + B\epsilon}\right)$$

for all $\epsilon > 0$. (Theorem 2.10 gives an one-sided bound; bound for the other side is obtained by taking $X_i = -X_i$). The inequality follows by splitting into cases $\epsilon \le B$ and $\epsilon > B$. ■

Lemma 22 *Suppose $\boldsymbol{X}$ follows a truncated normal distribution on $\mathbb{R}^m_+$ with parameters $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma} = \mathbf{K}^{-1} \succ \mathbf{0}$. Let $\boldsymbol{X}^{(1)}, \dots, \boldsymbol{X}^{(n)}$ be i.i.d. copies of $\boldsymbol{X}$, with j-th component of the i-th copy being $X_j^{(i)}$. Then*

1. *For $j = 1, \dots, p$, $\tau(X_j - \mathbb{E}X_j) \le \sqrt{\Sigma_{jj}}$. That is, the sub-Gaussian parameter of any marginal distribution of $\boldsymbol{X}$, after centering, is bounded by the square root of its corresponding diagonal entry in the covariance parameter $\boldsymbol{\Sigma}$. Then, for any $\epsilon > 0$,*

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^n X_j^{(i)} - \mathbb{E}X_j\right| > \epsilon\right) \le 2\exp\left(-\frac{n\epsilon^2}{2\Sigma_{jj}}\right).$$

In particular, if h_0 is a function bounded by M_0, then for any $\epsilon > 0$,

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^n X_j^{(i)}h_0\left(X_k^{(i)}\right) - \mathbb{E}X_jh_0(X_k)\right| \ge \epsilon\right) \le 2\exp\left(-\frac{n\epsilon^2}{8M_0^2(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}X_j)^2}\right),$$
$$\tau\left(n^{-1}\sum_{i=1}^n X_j^{(i)}h_0\left(X_k^{(i)}\right) - \mathbb{E}X_jh_0(X_k)\right) \le \frac{2M_0}{\sqrt{n}}\left(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}X_j\right),$$
$$\left\|n^{-1}\sum_{i=1}^n X_j^{(i)}h_0\left(X_k^{(i)}\right) - \mathbb{E}X_jh_0(X_k)\right\|_{\psi_2} \le \frac{4M_0}{\sqrt{en}}\left(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}X_j\right).$$

2. *For $j, k, \ell \in \{1, \dots, p\}$, if h_0 is a function bounded by M_0, then*

$$\|X_jX_kh_0(X_\ell) - \mathbb{E}X_jX_kh_0(X_\ell)\|_{\psi_1} \le \frac{M_0}{2e}c_{\boldsymbol{X}}^2, \tag{45}$$

where $c_{\boldsymbol{X}} \equiv 2\max_j(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}X_j)$. *In particular, for any* $\epsilon > 0$,

$$\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_j^{(i)}X_k^{(i)}h_0\left(X_\ell^{(i)}\right) - \mathbb{E}X_jX_kh_0(X_\ell)\right| > \epsilon\right) \leq 2\exp\left(-\min\left(\frac{n\epsilon^2}{2M_0^2c_{\boldsymbol{X}}^4}, \frac{n\epsilon}{2M_0c_{\boldsymbol{X}}^2}\right)\right).$$

Proof [Proof of Lemma 22]
1. Without loss of generality choose $j = 1$. By the definition of sub-Gaussian parameters, we need to show that for all $t \in \mathbb{R}$,

$$\mathbb{E}\exp(tX_1) \leq \exp\left(t^2\Sigma_{11}/2 + t\mathbb{E}X_1\right),$$

which is equivalent to

$$t^2\Sigma_{11}/2 + t\mathbb{E}X_1 - \log\mathbb{E}\exp(tX_1) \geq 0 \quad \forall t \in \mathbb{R}. \tag{46}$$

Since the left-hand side of (46) equals 0 at $t = 0$, it suffices to show that its derivative,

$$t\Sigma_{11} + \mathbb{E}X_1 - \frac{\mathrm{d}\log\mathbb{E}\exp(tX_1)}{\mathrm{d}t} = t\Sigma_{11} + \mathbb{E}X_1 - \frac{\frac{\mathrm{d}\mathbb{E}\exp(tX_1)}{\mathrm{d}t}}{\mathbb{E}\exp(tX_1)}, \tag{47}$$

is non-negative on $(0, \infty)$ and non-positive on $(-\infty, 0)$. By properties of moment-generating functions, $\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}\exp(tX_1)$ evaluated at $t = 0$ equals $\mathbb{E}X_1$, so (47) equals 0 at $t = 0$. It in turn suffices to show the derivative of (47), namely

$$\Sigma_{11} - \frac{\mathrm{d}^2\log\mathbb{E}\exp(tX_1)}{\mathrm{d}t^2} \tag{48}$$

is non-negative in $t \in \mathbb{R}$.

Given any vector $\boldsymbol{v} \in \mathbb{R}^p$, define $\mathbb{R}^p_+ - \boldsymbol{v} \equiv \{\boldsymbol{u} - \boldsymbol{v} : \boldsymbol{u} \in \mathbb{R}^p_+\}$. By Tallis (1961), denoting the first column of $\boldsymbol{\Sigma}$ as $\boldsymbol{\Sigma}_1$, the moment-generating function of the marginal distribution of X_1 is

$$\frac{\int_{\mathbb{R}^p_+ - (\boldsymbol{\mu} + t\boldsymbol{\Sigma}_1)} \exp\left(-\frac{1}{2}\boldsymbol{x}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{x}\right)\mathrm{d}\boldsymbol{x}}{\int_{\mathbb{R}^p_+ - \boldsymbol{\mu}} \exp\left(-\frac{1}{2}\boldsymbol{x}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{x}\right)\mathrm{d}\boldsymbol{x}} \exp\left(t\mu_1 + \frac{1}{2}t^2\Sigma_{11}\right).$$

(48) thus becomes

$$-\frac{\mathrm{d}^2}{\mathrm{d}t^2}\log\int_{\mathbb{R}^p_+ - (\boldsymbol{\mu} + t\boldsymbol{\Sigma}_1)} \exp\left(-\frac{1}{2}\boldsymbol{x}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{x}\right)\mathrm{d}\boldsymbol{x}.$$

Showing this is non-negative in $t \in \mathbb{R}$ is equivalent to showing that the integral itself is log-concave in t. But

$$\int_{\mathbb{R}^p_+ - (\boldsymbol{\mu} + t\boldsymbol{\Sigma}_1)} \exp\left(-\frac{1}{2}\boldsymbol{x}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{x}\right)\mathrm{d}\boldsymbol{x} = \int_{\mathbb{R}^p} \exp\left(-\frac{1}{2}\boldsymbol{x}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{x}\right)\mathbb{1}_{\mathbb{R}^p_+ - \boldsymbol{\mu}}(\boldsymbol{x} + t\boldsymbol{\Sigma}_1)\,\mathrm{d}\boldsymbol{x}$$

with $\exp\left(-\frac{1}{2}\boldsymbol{x}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{x}\right)$ log-concave in $\boldsymbol{x}$ and $\mathbb{1}_{\mathbb{R}^p_+ - \boldsymbol{\mu}}(\boldsymbol{x} + t\boldsymbol{\Sigma}_1)$ log-concave in $(\boldsymbol{x}, t)$ since $\mathbb{R}^p_+ - \boldsymbol{\mu}$ is a convex set. Since log-concavity is closed under multiplication and integration

over $\mathbb{R}^p$, the integral is indeed log-concave, and our proof of the bound on the sub-Gaussian parameter of $X_j - \mathbb{E}X_j$ is complete. The tail bound follows from 5) of Lemma 21.

Now by 1) and 2) of Lemma 21,

$$\|X_j\|_{\psi_2} \leq 2\sqrt{\Sigma_{jj}/e} + \mathbb{E}X_j.$$

If h_0 is a function bounded by M_0, then by definition

$$\|X_jh_0(X_k)\|_{\psi_2} \leq M_0\left(2\sqrt{\Sigma_{jj}/e} + \mathbb{E}X_j\right).$$

By 1) and 2) of Lemma 21 again,

$$\begin{aligned}\tau(X_jh_0(X_k) - \mathbb{E}X_jh_0(X_k)) &\leq \sqrt{e}\|X_jh_0(X_k) - \mathbb{E}X_jh_0(X_k)\|_{\psi_2} \\ &\leq 2\sqrt{e}\|X_jh_0(X_k)\|_{\psi_2} \\ &\leq 2M_0(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}X_j).\end{aligned}$$

The tail bound thus follows from the first inequality using 5) of Lemma 21. By 2) of the Lemma 21,

$$\tau\left(n^{-1}\sum_{i=1}^{n} X_j^{(i)}h_0\left(X_k^{(i)}\right) - \mathbb{E}X_jh_0(X_k)\right) \leq \frac{2M_0}{\sqrt{n}}\left(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}X_j\right),$$
$$\left\|n^{-1}\sum_{i=1}^{n} X_j^{(i)}h_0\left(X_k^{(i)}\right) - \mathbb{E}X_jh_0(X_k)\right\|_{\psi_2} \leq \frac{4M_0}{\sqrt{en}}\left(2\sqrt{\Sigma_{jj}} + \sqrt{e}\,\mathbb{E}X_j\right).$$

2. By the proof of 1) of this lemma, $\|X_j\|_{\psi_2} \leq 2\sqrt{\Sigma_{jj}/e} + \mathbb{E}X_j$, and by 3) of Lemma 21,

$$\|X_jX_k\|_{\psi_1} \leq \left(2\sqrt{\Sigma_{jj}/e} + \mathbb{E}X_j\right)\left(2\sqrt{\Sigma_{kk}/e} + \mathbb{E}X_k\right) \leq \max_j\left(2\sqrt{\Sigma_{jj}/e} + \mathbb{E}X_j\right)^2.$$

Since h_0 is a function bounded by M_0, by definition

$$\|X_jX_kh_0(X_\ell)\|_{\psi_1} \leq M_0\max_j\left(2\sqrt{\Sigma_{jj}/e} + \mathbb{E}X_j\right)^2.$$

Then by 1) of Lemma 21 again,

$$\|X_jX_kh_0(X_\ell) - \mathbb{E}X_jX_kh_0(X_\ell)\|_{\psi_1} \leq 2M_0\max_j\left(2\sqrt{\Sigma_{jj}/e} + \mathbb{E}X_j\right)^2.$$

The tail bound then follows from 6) of Lemma 21. ■

Although not used for our consistency results, in the special case of $h_0 \equiv 1$, we also have the following lemma. The notable difference between bounds (49) below and (45) from Lemma 22.2 is in the constants and dependency on $\mathbb{E}X_j$: The constants in the denominator in the right-hand side of (45) is smaller and thus gives a tighter bound, but (49) is preferred when $\mathbb{E}X_j$ is notably large compared to $\sqrt{\Sigma_{jj}}$, since the constant is only linear in $\mathbb{E}X_j$.

Lemma 23 *Consider the setting in Lemma 22. Then for $j,k \in \{1,\dots,p\}$, for any $\epsilon > 0$,*

$$\mathbb{P}\left(n^{-1}\left|\sum_{i=1}^{n} X_j^{(i)} X_k^{(i)} - \mathbb{E}X_j X_k\right| \geq \epsilon\right) \leq 4\exp\left(-\min\left(\frac{2n\epsilon^2}{C_1^2}, \frac{n\epsilon}{C_1}\right)\right), \tag{49}$$

where $C_1 \equiv 91\max_j \Sigma_{jj} + 72\max_j \mathbb{E}X_j \max_j \sqrt{\Sigma_{jj}}$.

Proof [Proof of Lemma 23] We use a proof similar to Lemma 1 in Ravikumar et al. (2011) (note that $\mathbb{E}X_j$ may be nonzero in our case). Define

$$U_{jk}^{(i)} \equiv X_j^{(i)} + X_k^{(i)}, \quad U_{jk} \equiv X_j + X_k, \quad V_{jk}^{(i)} \equiv X_j^{(i)} - X_k^{(i)}, \quad V_{jk} \equiv X_j - X_k.$$

Since $X_j^{(i)} X_k^{(i)} = \frac{1}{4}\left({U_{jk}^{(i)}}^2 - {V_{jk}^{(i)}}^2\right)$, by union bound we have

$$\begin{aligned}
&\mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} X_j^{(i)} X_k^{(i)} - \mathbb{E}X_j X_k\right| \geq \epsilon\right) \\
&\leq \mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} {U_{jk}^{(i)}}^2 - \mathbb{E}U_{jk}^2\right| \geq 2\epsilon\right) + \mathbb{P}\left(\left|n^{-1}\sum_{i=1}^{n} {V_{jk}^{(i)}}^2 - \mathbb{E}V_{jk}^2\right| \geq 2\epsilon\right).
\end{aligned}$$

We next define

$$\begin{aligned}
&Z_{jk}^{(i)} \equiv {U_{jk}^{(i)}}^2 - \mathbb{E}U_{jk}^2 = {A_{jk}^{(i)}}^2 + B_{jk}^{(i)} + C_{jk}, && \overline{X}_j^{(i)} \equiv X_j^{(i)} - \mathbb{E}X_j, \\
&A_{jk}^{(i)} \equiv \overline{X}_j^{(i)} + \overline{X}_k^{(i)}, \quad B_{jk}^{(i)} \equiv 2(\mathbb{E}X_j + \mathbb{E}X_k)(\overline{X}_j^{(i)} + \overline{X}_k^{(i)}), && C_{jk} \equiv -\mathbb{E}(\overline{X}_j^{(i)} + \overline{X}_k^{(i)})^2.
\end{aligned}$$

Then since τ is a norm by 2) of Lemma 21, A_{jk} is sub-Gaussian with parameter $\leq \sqrt{\Sigma_{jj}} + \sqrt{\Sigma_{kk}}$, and B_{jk} is sub-Gaussian with parameter $\leq 2(\mathbb{E}X_j + \mathbb{E}X_k)\left(\sqrt{\Sigma_{jj}} + \sqrt{\Sigma_{kk}}\right)$. Using 4) of Lemma 21 together with the inequality $(a+b+c)^q \leq (3\max\{a,b,c\})^q \leq 3^q(a^q+b^q+c^q)$ for all $a,b,c \geq 0$ and $q > 0$, we have for any $q \geq 2$

$$\begin{aligned}
(\mathbb{E}|Z_{jk}|^q)^{1/q} &\leq \left(3^q\left(\mathbb{E}|A_{jk}|^{2q} + \mathbb{E}|B_{jk}|^q + |C_{jk}|^q\right)\right)^{1/q} \\
&\leq 3^{1+1/q}\left((\mathbb{E}|A_{jk}|^{2q})^{1/q} + (\mathbb{E}|B_{jk}|^q)^{1/q} + |C_{jk}|\right) \\
&\leq 3^{1+1/q}\left(2^{1/q}(2q/e)\left(\sqrt{\Sigma_{jj}} + \sqrt{\Sigma_{kk}}\right)^2\right. \\
&\qquad \left. + 2^{1/q}\sqrt{q/e}\,2(\mathbb{E}X_j + \mathbb{E}X_k)(\sqrt{\Sigma_{jj}} + \sqrt{\Sigma_{kk}}) + \mathrm{var}(X_j + X_k)\right).
\end{aligned}$$

Using $\mathrm{var}(X+Y) \leq 2(\mathrm{var}(X) + \mathrm{var}(Y))$ and the fact that $\mathrm{var}(X_j) = \mathrm{var}(X_j - \mathbb{E}X_j) \leq \tau^2(X_j - \mathbb{E}X_j) \leq \Sigma_{jj}$ (by 2) of Lemma 21 and 1) of Lemma 22, we then have

$$\begin{aligned}
&\left(\frac{\mathbb{E}|Z_{jk}|^q}{q!}\right)^{1/q} \\
&\quad \leq 3^{1+1/q}\frac{2^{3+1/q}(q/e)\max_j \Sigma_{jj} + 2^{3+1/q}\sqrt{q/e}\max_j \mathbb{E}X_j \cdot \max_j \sqrt{\Sigma_{jj}} + 4\max_j \Sigma_{jj}}{(q!)^{1/q}}.
\end{aligned}$$

Since all three coefficients involving q are decreasing in $q \geq 2$, we have

$$\sup_{q\geq 2}\left(\frac{\mathbb{E}|Z_{jk}|^q}{q!}\right)^{1/q} \leq \left(48\sqrt{3}/e + 6\sqrt{6}\right)\max_j \Sigma_{jj} + 24\sqrt{6/e}\max_j \mathbb{E}X_j \max_j \sqrt{\Sigma_{jj}}.$$

Thus by 7) of Lemma 21, letting $B \equiv \left(91\max_j \Sigma_{jj} + 72\max_j \mathbb{E}X_j \max_j \sqrt{\Sigma_{jj}}\right)$, we have for all $\epsilon > 0$:

$$\mathbb{P}\left(n^{-1}\left|\sum_{i=1}^{n} Z_{jk}^{(i)}\right| \geq 2\epsilon\right) \leq 2\exp\left(-\min\left(\frac{2n\epsilon^2}{B^2}, \frac{n\epsilon}{B}\right)\right).$$

A tail bound for the sample average of V_{jk}^2 can be similarly derived, and the result follows. ■

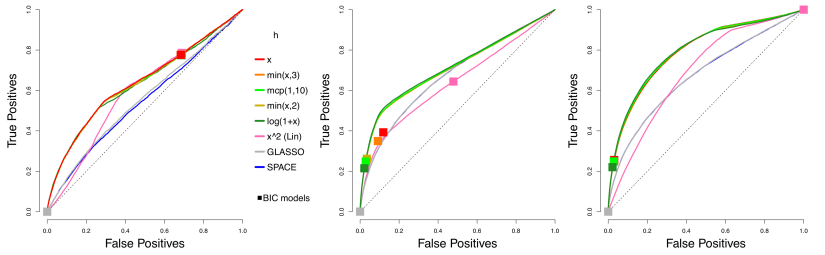
Appendix C. Simulation Results for Erdös-Rényi Graphs

We revisit the simulations from Section 7 but use Erdös-Rényi (ER) graphs in which each possible edge is independently included with probability π. Independent uniform draws from $[0.5, 1]$ are used to fill the non-zero off-diagonal entries of the symmetric matrix $\mathbf{K}_0$. The diagonal elements are set such that $\mathbf{K}_0$ has minimum eigenvalue 0.1. We choose $\pi = 0.08$ for $n = 1000$, and $\pi = 0.02$ for $n = 80$.

C.1. Truncated GGMs

In this section we present the results for truncated GGMs.

C.1.1. Choice of h



The results for truncated centered GGMs are reported in Table 4 and Figure 13. Those for truncated non-centered GGMs using the profiled estimator are in Table 5 and Figure 14.

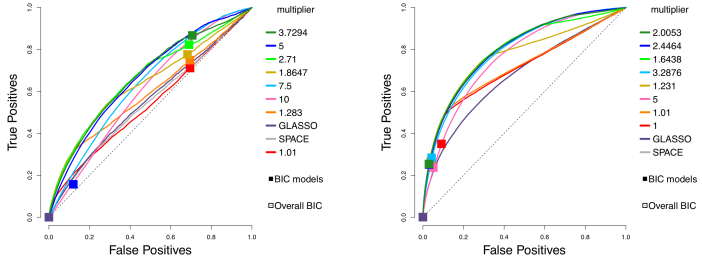
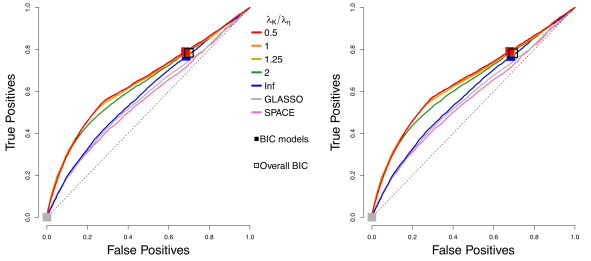
Table 5: Mean and standard deviation of AUC using different profiled estimators in the non-centered setting, with $n = 80$ and multiplier 1.8647, or $n = 1000$ and multipliers 1 and 1.6438. Methods as for Table 4.



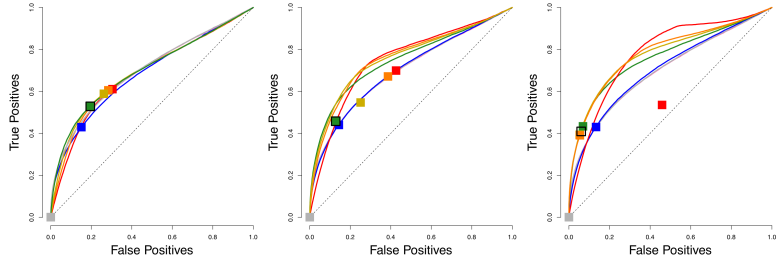
(a) $n = 80$, mult = 1.8647, ER (b) $n = 1000$, mult = 1, ER (c) $n = 1000$, mult = 1.6438, ER

Figure 14: Average for the truncated non-centered GGM case. $n = 80$ or 1000, $m = 100$.



C.1.2. Choice of multiplier

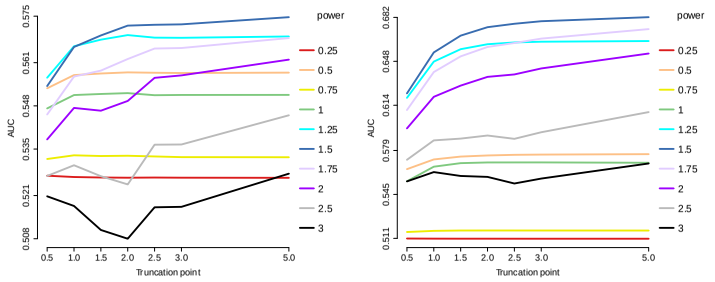
The results for truncated centered GGMs where each curve represents a different multiplier are shown in Figure 15, and those for truncated non-centered GGMs are in Figure 16, where each curve corresponds to a different ratio $\lambda_{\mathbf{K}}/\lambda_{\boldsymbol{\eta}}$.



(a) $n = 80$, ER (b) $n = 1000$, ER

Figure 15: Performance of $\min(x, 3)$ for truncated centered GGMs with different multipliers, compared to GLASSO and SPACE, in the centered setting, $n = 80$ or 1000.

(a) $n = 80$, mult = 1.7897, ER (b) $n = 80$, mult = 1.8647, ER



(c) $n = 1000$, mult = 1, ER (d) $n = 1000$, mult = 1.2310, ER (e) $n = 1000$, mult = 1.6438, ER

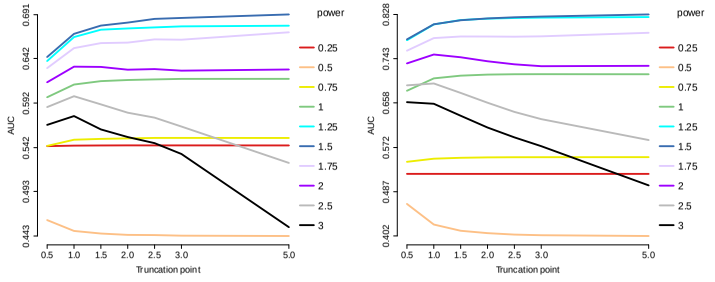


Figure 16: Performance of the non-centered estimator with $h(x) = \min(x, 3)$. Each curve corresponds to a different choice of $\lambda_{\mathbf{K}}/\lambda_{\boldsymbol{\eta}}$. Squares indicate models picked by eBIC with refit. The square with black outline has the highest eBIC among all models (combinations of $\lambda_{\mathbf{K}}$, $\lambda\boldsymbol{\eta}$). The multipliers correspond to medium or high for $n = 80$, and low, medium and high for $n = 1000$, respectively.

C.2. Other a/b Models

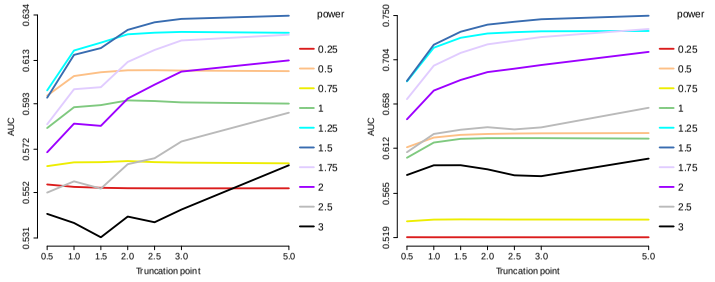

Figure 17 exhibits the results for the exponential models.

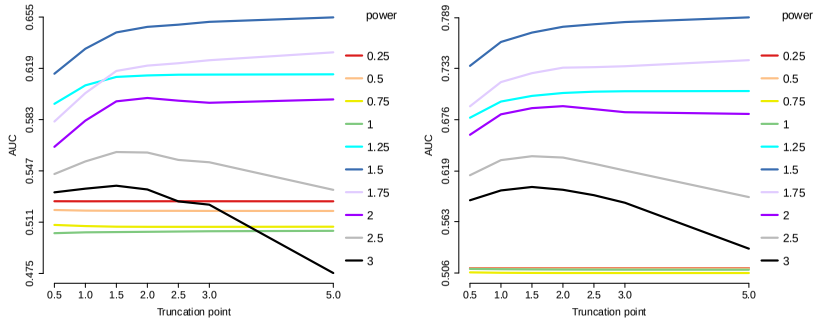
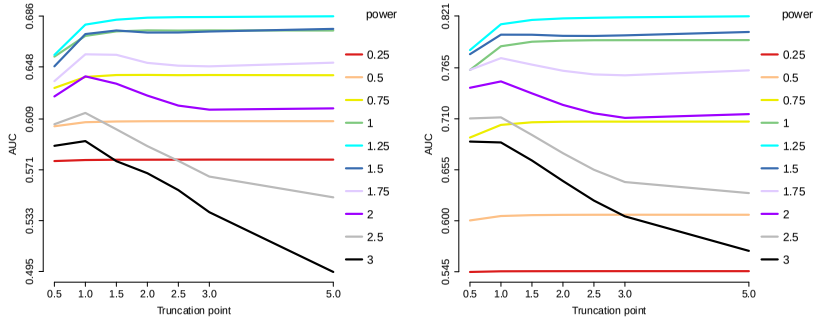
(a) $n = 80$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled est, ER (b) $n = 1000$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled est, ER



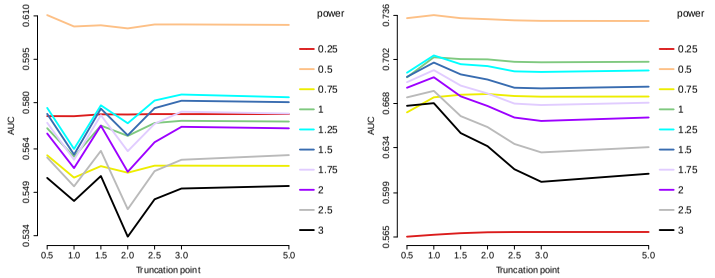
(c) $n = 80$, $\boldsymbol{\eta} = \mathbf{0}$, centered est, ER (d) $n = 1000$, $\boldsymbol{\eta} = \mathbf{0}$, centered est, ER



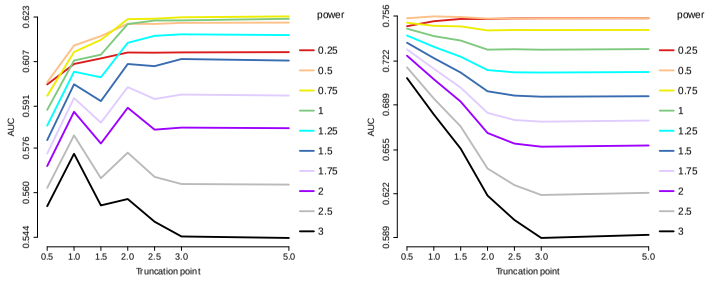
(e) $n = 80$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled est, ER (f) $n = 1000$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled est, ER

Figure 17: AUCs for edge recovery using generalized score matching for the exponential models. Each curve represents a different choice of power p in $h(x) = \min(x^p, c)$, and the x axis marks the truncation point c. Colors are sorted by p.

Figure 18 displays the results for the gamma models.

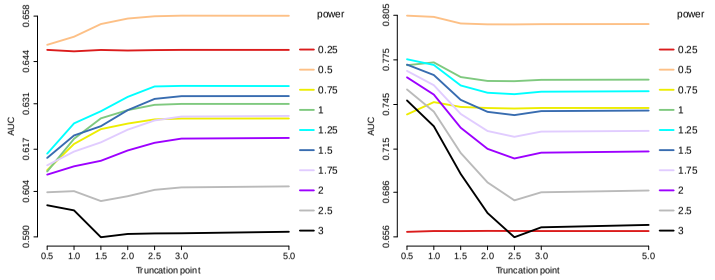


(a) $n = 80$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator, ER (b) $n = 1000$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator, ER



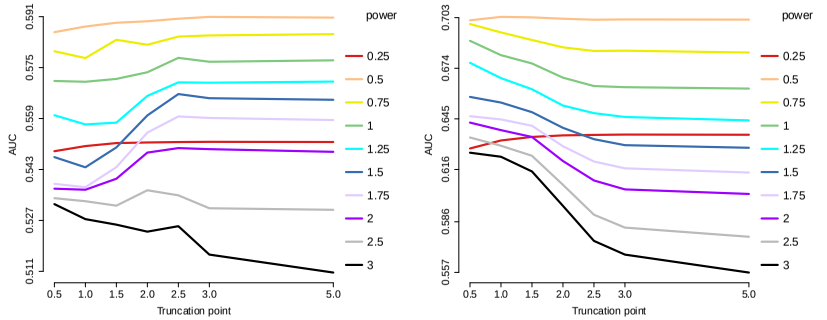
(c) $n = 80$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator, ER (d) $n = 1000$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator, ER

Figure 18: AUCs for edge recovery using generalized score matching for the gamma models. Each curve represents a different choice of power p in $h(x) = \min(x^p, c)$, and the x axis marks the truncation point c. Colors are sorted by p.

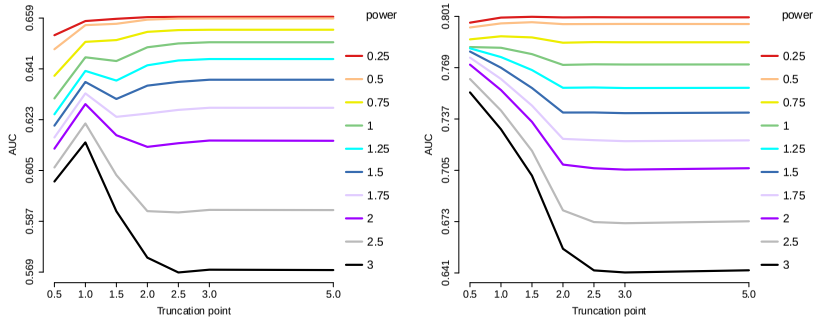


Figures 19 and 20 demonstrate the results for $a = 3/2$ and $b = 1/2$ or $b = 0$, respectively.

(a) $n = 80$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled est, ER (b) $n = 1000$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled est, ER



(c) $n = 80$, $\boldsymbol{\eta} = \mathbf{0}$, centered est, ER (d) $n = 1000$, $\boldsymbol{\eta} = \mathbf{0}$, centered est, ER



(e) $n = 80$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled est, ER (f) $n = 1000$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled est, ER

Figure 19: AUCs for edge recovery using generalized score matching for $a = 3/2$, $b = 1/2$. Each curve represents a different choice of power p in $h(x) = \min(x^p, c)$, and the x axis marks the truncation point c. Colors are sorted by p.

(a) $n = 80$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator, ER (b) $n = 1000$, $\boldsymbol{\eta} = -0.5\mathbf{1}_{100}$, profiled estimator, ER

(c) $n = 80$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator, ER (d) $n = 1000$, $\boldsymbol{\eta} = 0.5\mathbf{1}_{100}$, profiled estimator, ER

Figure 20: AUCs for edge recovery using generalized score matching for $a = 3/2$, $b = 0$. Each curve represents a different choice of power p in $h(x) = \min(x^p, c)$, and the x axis marks the truncation point c. Colors are sorted by p.

Abstract

Evaluating the joint significance of covariates is of fundamental importance in a wide range of applications. To this end, p-values are frequently employed and produced by algorithms that are powered by classical large-sample asymptotic theory. It is well known that the conventional p-values in Gaussian linear model are valid even when the dimensionality is a non-vanishing fraction of the sample size, but can break down when the design matrix becomes singular in higher dimensions or when the error distribution deviates from Gaussianity. A natural question is when the conventional p-values in generalized linear models become invalid in diverging dimensions. We establish that such a breakdown can occur early in nonlinear models. Our theoretical characterizations are confirmed by simulation studies.

Keywords: Nonuniformity, p-value, breakdown point, generalized linear model, high dimensionality, joint significance testing

1. Introduction

In many applications it is often desirable to evaluate the significance of covariates in a predictive model for some response of interest. Identifying a set of significant covariates can facilitate domain experts to further probe their causal relationships with the response. Ruling out insignificant covariates can also help reduce the fraction of false discoveries and narrow down the scope of follow-up experimental studies by scientists. These tasks certainly require an accurate measure of feature significance in finite samples. The tool of p-values has provided a powerful framework for such investigations.

As p-values are routinely produced by algorithms, practitioners should perhaps be aware that those p-values are usually based on classical large-sample asymptotic theory. For example, marginal p-values have been employed frequently in large-scale applications when the number of covariates p greatly exceeds the number of observations n. Those p-values are based on marginal regression models linking each individual covariate to the response separately. In these marginal regression models, the ratio of sample size to model dimensionality is equal to n, which results in justified p-values as sample size increases. Yet due to the correlations among the covariates, we often would like to investigate the joint significance of a covariate in a regression model conditional on all other covariates, which is the main focus of this paper. A natural question is whether conventional joint p-values continue to be valid in the regime of diverging dimensionality p.

It is well known that fitting the linear regression model with $p > n$ using the ordinary least squares can lead to perfect fit giving rise to zero residual vector, which renders the p-values undefined. When $p \leq n$ and the design matrix is nonsingular, the p-values in the linear regression model are well defined and valid thanks to the exact normality of the least-squares estimator when the random error is Gaussian and the design matrix is deterministic. When the error is non-Gaussian, Huber (1973) showed that the least-squares estimator can still be asymptotically normal under the assumption of $p = o(n)$, but is generally no longer normal when $p = o(n)$ fails to hold, making the conventional p-values inaccurate in higher dimensions. For the asymptotic properties of M-estimators for robust regression, see, for example, Huber (1973); Portnoy (1984, 1985) for the case of diverging dimensionality $p = o(n)$ and Karoui et al. (2013); Bean et al. (2013) for the scenario when the dimensionality p grows proportionally to sample size n.

We have seen that the conventional p-values for the least-squares estimator in linear regression model can start behaving wildly and become invalid when the dimensionality p is of the same order as sample size n and the error distribution deviates from Gaussianity. A natural question is whether similar phenomenon holds for the conventional p-values for the maximum likelihood estimator (MLE) in the setting of diverging-dimensional nonlinear models. More specifically, we aim to answer the question of whether $p \sim n$ is still the breakdown point of the conventional p-values when we move away from the regime of linear regression model, where $\sim$ stands for asymptotic order. To simplify the technical presentation, in this paper we adopt the generalized linear model (GLM) as a specific family of nonlinear models (McCullagh and Nelder, 1989). The GLM with a canonical link assumes that the conditional distribution of $\mathbf{y}$ given $\mathbf{X}$ belongs to the canonical exponential family, having the following density function with respect to some fixed measure

$$f_n(\mathbf{y}; \mathbf{X}, \boldsymbol{\beta}) \equiv \prod_{i=1}^{n} f_0(y_i; \theta_i) = \prod_{i=1}^{n} \left\{ c(y_i) \exp\left[\frac{y_i \theta_i - b(\theta_i)}{\phi} \right] \right\}, \tag{1}$$

where $\mathbf{X} = (\mathbf{x}_1, \cdots, \mathbf{x}_p)$ is an $n \times p$ design matrix with $\mathbf{x}_j = (x_{1j}, \cdots, x_{nj})^T$, $j = 1, \cdots, p$, $\mathbf{y} = (y_1, \cdots, y_n)^T$ is an n-dimensional response vector, $\boldsymbol{\beta} = (\beta_1, \cdots, \beta_p)^T$ is a p-dimensional regression coefficient vector, $\{f_0(y; \theta) : \theta \in \mathbb{R}\}$ is a family of distributions in the regular exponential family with dispersion parameter $\phi \in (0, \infty)$, and $\boldsymbol{\theta} = (\theta_1, \cdots, \theta_n)^T = \mathbf{X}\boldsymbol{\beta}$. As is common in GLM, the function $b(\theta)$ in (1) is implicitly assumed to be twice continuously differentiable with $b''(\theta)$ always positive. Popularly used GLMs include the linear regression model, logistic regression model, and Poisson regression model for continuous, binary, and count data of responses, respectively.

The key innovation of our paper is the formal justification that the conventional p-values in nonlinear models of GLMs can become invalid in diverging dimensions and such a breakdown can occur *much earlier* than in linear models, which spells out a fundamental difference between linear models and nonlinear models. To begin investigating p-values in diverging-dimensional GLMs, let us gain some insights into this problem by looking at the specific case of logistic regression. Recently, Candès (2016) established an interesting phase transition phenomenon of perfect hyperplane separation for high-dimensional classification with an elegant probabilistic argument. Suppose we are given a random design matrix $\mathbf{X} \sim N(\mathbf{0}, I_n \otimes I_p)$ and arbitrary binary y_i's that are not all the same. The phase transition of perfect hyperplane separation happens at the point $p/n = 1/2$. With such a separating hyperplane, there exist some $\boldsymbol{\beta}^* \in \mathbb{R}^p$ and $t \in \mathbb{R}$ such that $\mathbf{x}_i^T \boldsymbol{\beta}^* > t$ for all cases $y_i = 1$ and $\mathbf{x}_i^T \boldsymbol{\beta}^* < t$ for all controls $y_i = 0$. Let us fit a logistic regression model with an intercept. It is easy to show that multiplying the vector $(-t, (\boldsymbol{\beta}^*)^T)^T$ by a divergence sequence of positive numbers c, we can obtain a sequence of logistic regression fits with the fitted response vector approaching $\mathbf{y} = (y_1, \cdots, y_n)^T$ as $c \to \infty$. As a consequence, the MLE algorithm can return a pretty wild estimate that is close to infinity in topology when the algorithm is set to stop. Clearly, in such a case the p-value of the MLE is no longer justified and meaningful. The results in Candès (2016) have two important implications. First, such results reveal that unlike in linear models, p-values in nonlinear models can break down and behave wildly when p/n is of order 1/2; see Karoui et al. (2013); Bean et al. (2013) and discussions below. Second, these results motivate us to characterize the breakdown point of p-values in nonlinear GLMs with $p \sim n^{\alpha_0}$ in the regime of $\alpha_0 \in [0, 1/2)$. In fact, our results show that the breakdown point can be even much earlier than $n/2$.

It is worth mentioning that our work is different in goals from the limited but growing literature on p-values for high-dimensional nonlinear models, and makes novel contributions to such a problem. The key distinction is that existing work has focused primarily on identifying the scenarios in which conventional p-values or their modifications continue to be valid with some sparsity assumption limiting the growth of intrinsic dimensions. For example, Fan and Peng (2004) established the oracle property including the asymptotic normality for nonconcave penalized likelihood estimators in the scenario of $p = o(n^{1/5})$, while Fan and Lv (2011) extended their results to the GLM setting of non-polynomial (NP) dimensionality. In the latter work, the p-values were proved to be valid under the assumption that the intrinsic dimensionality $s = o(n^{1/3})$. More recent work on high-dimensional inference in nonlinear model settings includes van de Geer et al. (2014); Athey et al. (2016) under sparsity assumptions. In addition, two tests were introduced in Guo and Chen (2016) for high-dimensional GLMs without or with nuisance regression parameters, but the p-values were obtained for testing the global hypothesis for a given set of covariates, which is different from our goal of testing the significance of individual covariates simultaneously. Portnoy (1988) studied the asymptotic behavior of the MLE for exponential families under the classical i.i.d. non-regression setting, but with diverging dimensionality. In contrast, our work under the GLM assumes the regression setting in which the design matrix $\mathbf{X}$ plays an important role in the asymptotic behavior of the MLE $\widehat{\boldsymbol{\beta}}$. The validity of the asymptotic normality of the MLE was established in Portnoy (1988) under the condition of $p = o(n^{1/2})$, but the precise breakdown point in diverging dimensionality was not investigated therein. Another line of work is focused on generating asymptotically valid p-values when p/n converges to a

fixed positive constant. For instance, Karoui et al. (2013) and Bean et al. (2013) considered M-estimators in the linear model and showed that their variance is greater than classically predicted. Based on this result, it is possible to produce p-values by making adjustments for the inflated variance in high dimensions. Recently, Sur and Candès (2018) showed that similar adjustment is possible for the likelihood ratio test (LRT) for logistic regression. Our work differs from this line of work in two important aspects. First, our focus is on the *classical* p-values and their validity. Second, their results concern dimensionality that is comparable to sample size, while we aim to analyze the problem for a lower range of dimensionality and pinpoint the exact breakdown point of p-values.

The rest of the paper is organized as follows. Section 2 provides characterizations of p-values in low dimensions. We establish the nonuniformity of GLM p-values in diverging dimensions in Section 3. Section 4 presents several simulation examples verifying the theoretical phenomenon. We discuss some implications of our results in Section 5. The proofs of all the results are relegated to the Appendix.

2. Characterizations of P-values in Low Dimensions

To pinpoint the breakdown point of GLM p-values in diverging dimensions, we start with characterizing p-values in low dimensions. In contrast to existing work on the asymptotic distribution of the penalized MLE, our results in this section focus on the asymptotic normality of the unpenalized MLE in diverging-dimensional GLMs, which justifies the validity of conventional p-values. Although Theorems 1 and 4 to be presented in Sections 2.2 and A are in the conventional sense of relatively small p, to the best of our knowledge such results are not available in the literature before in terms of the maximum range of dimensionality p without any sparsity assumption.

2.1. Maximum likelihood estimation

For the GLM (1), the log-likelihood $\log f_n(\mathbf{y}; \mathbf{X}, \boldsymbol{\beta})$ of the sample is given, up to an affine transformation, by

$$\ell_n(\boldsymbol{\beta}) = n^{-1} \left[\mathbf{y}^T \mathbf{X}\boldsymbol{\beta} - \mathbf{1}^T \mathbf{b}(\mathbf{X}\boldsymbol{\beta}) \right], \tag{2}$$

where $\mathbf{b}(\boldsymbol{\theta}) = (b(\theta_1), \cdots, b(\theta_n))^T$ for $\boldsymbol{\theta} = (\theta_1, \cdots, \theta_n)^T \in \mathbb{R}^n$. Denote by $\widehat{\boldsymbol{\beta}} = (\widehat{\beta}_1, \cdots, \widehat{\beta}_p)^T \in \mathbb{R}^p$ the MLE which is the maximizer of (2), and

$$\boldsymbol{\mu}(\boldsymbol{\theta}) = (b'(\theta_1), \cdots, b'(\theta_n))^T \quad \text{and} \quad \boldsymbol{\Sigma}(\boldsymbol{\theta}) = \operatorname{diag}\{b''(\theta_1), \cdots, b''(\theta_n)\}. \tag{3}$$

A well-known fact is that the n-dimensional response vector $\mathbf{y}$ in GLM (1) has mean vector $\boldsymbol{\mu}(\boldsymbol{\theta})$ and covariance matrix $\phi \boldsymbol{\Sigma}(\boldsymbol{\theta})$. Clearly, the MLE $\widehat{\boldsymbol{\beta}}$ is given by the unique solution to the score equation

$$\mathbf{X}^T [\mathbf{y} - \boldsymbol{\mu}(\mathbf{X}\boldsymbol{\beta})] = \mathbf{0} \tag{4}$$

when the design matrix $\mathbf{X}$ is of full column rank p.

It is worth mentioning that for the linear model, the score equation (4) becomes the well-known normal equation $\mathbf{X}^T\mathbf{y} = \mathbf{X}^T\mathbf{X}\boldsymbol{\beta}$ which admits a closed form solution. On the other hand, equation (4) does not admit a closed form solution in general nonlinear models. This fact due to the nonlinearity of the mean function $\boldsymbol{\mu}(\cdot)$ causes the key difference between

the linear and nonlinear models. In future presentations, we will occasionally use the term *nonlinear GLMs* to exclude the linear model from the family of GLMs when necessary.

We will present in the next two sections some sufficient conditions under which the asymptotic normality of MLE holds. In particular, Section 2.2 concerns the case of fixed design and Section A deals with the case of random design. In addition, Section 2.2 allows for general regression coefficient vector $\boldsymbol{\beta}_0$ and the results extend some existing ones in the literature, while Section A assumes the global null $\boldsymbol{\beta}_0 = \mathbf{0}$ and Gaussian random design which enable us to pinpoint the exact breakdown point of the asymptotic normality for the MLE.

2.2. Conventional p-values in low dimensions under fixed design

Recall that we condition on the design matrix $\mathbf{X}$ in this section. We first introduce a deviation probability bound that facilitates our technical analysis. Consider both cases of bounded responses and unbounded responses. In the latter case, assume that there exist some constants $M, v_0 > 0$ such that

$$\max_{1\le i\le n} E\left\{\exp\left[\frac{|y_i - b'(\theta_{0,i})|}{M}\right] - 1 - \frac{|y_i - b'(\theta_{0,i})|}{M}\right\} M^2 \le \frac{v_0}{2} \tag{5}$$

with $(\theta_{0,1}, \cdots, \theta_{0,n})^T = \boldsymbol{\theta}_0 = \mathbf{X}\boldsymbol{\beta}_0$, where $\boldsymbol{\beta}_0 = (\beta_{0,1}, \cdots, \beta_{0,p})^T$ denotes the true regression coefficient vector in model (1). Then by Fan and Lv (2011, 2013), it holds that for any $\mathbf{a} \in \mathbb{R}^n$,

$$P\left(\left|\mathbf{a}^T\mathbf{Y} - \mathbf{a}^T\boldsymbol{\mu}(\boldsymbol{\theta}_0)\right| > \|\mathbf{a}\|_2\, \varepsilon\right) \le \varphi(\varepsilon), \tag{6}$$

where $\varphi(\varepsilon) = 2e^{-c_1\varepsilon^2}$ with $c_1 > 0$ some constant, and $\varepsilon \in (0, \infty)$ if the responses are bounded and $\varepsilon \in (0, \|\mathbf{a}\|_2/\|\mathbf{a}\|_\infty]$ if the responses are unbounded.

For nonlinear GLMs, the MLE $\widehat{\boldsymbol{\beta}}$ solves the nonlinear score equation (4) whose solution generally does not admit an explicit form. To address such a challenge, we construct a solution to equation (4) in an asymptotically shrinking neighborhood of $\boldsymbol{\beta}_0$ that meets the MLE $\widehat{\boldsymbol{\beta}}$ thanks to the uniqueness of the solution. Specifically, define a neighborhood of $\boldsymbol{\beta}_0$ as

$$\mathcal{N}_0 = \{\boldsymbol{\beta} \in \mathbb{R}^p : \|\boldsymbol{\beta} - \boldsymbol{\beta}_0\|_\infty \le n^{-\gamma}\log n\} \tag{7}$$

for some constant $\gamma \in (0, 1/2]$. Assume that $p = O(n^{\alpha_0})$ for some $\alpha_0 \in (0, \gamma)$ and let $b_n = o\{\min(n^{1/2-\gamma}\sqrt{\log n}, s_n^{-1}n^{2\gamma-\alpha_0-1/2}/(\log n)^2\}$ be a diverging sequence of positive numbers, where s_n is a sequence of positive numbers that will be specified in Theorem 1 below. We need some basic regularity conditions to establish the asymptotic normality of the MLE $\widehat{\boldsymbol{\beta}}$.

Condition 1 *The design matrix* $\mathbf{X}$ *satisfies*

$$\left\|\left[\mathbf{X}^T\boldsymbol{\Sigma}(\boldsymbol{\theta}_0)\mathbf{X}\right]^{-1}\right\|_\infty = O(b_n n^{-1}), \tag{8}$$

$$\max_{\boldsymbol{\beta}\in\mathcal{N}_0} \max_{j=1}^p \lambda_{\max}\left[\mathbf{X}^T\mathrm{diag}\left\{|\mathbf{x}_j| \circ \left|\boldsymbol{\mu}''(\mathbf{X}\boldsymbol{\beta})\right|\right\}\mathbf{X}\right] = O(n) \tag{9}$$

with $\circ$ *denoting the Hadamard product and derivatives understood componentwise. Assume that* $\max_{j=1}^p \|\mathbf{x}_j\|_\infty < c_1^{1/2}\{n/(\log n)\}^{1/2}$ *if the responses are unbounded.*

Condition 2 *The eigenvalues of* $n^{-1}\mathbf{A}_n$ *are bounded away from* 0 *and* ∞, $\sum_{i=1}^n (\mathbf{z}_i^T\mathbf{A}_n^{-1}\mathbf{z}_i)^{3/2} = o(1)$, *and* $\max_{i=1}^n E|y_i - b'(\theta_{0,i})|^3 = O(1)$, *where* $\mathbf{A}_n = \mathbf{X}^T\boldsymbol{\Sigma}(\boldsymbol{\theta}_0)\mathbf{X}$ *and* $(\mathbf{z}_1, \cdots, \mathbf{z}_n)^T = \mathbf{X}$.

Conditions 1 and 2 put some basic restrictions on the design matrix $\mathbf{X}$ and a moment condition on the responses. For the case of linear model, bound (8) becomes $\|(\mathbf{X}^T\mathbf{X})^{-1}\|_\infty = O(b_n/n)$ and bound (9) holds automatically since $b'''(\theta) \equiv 0$. Condition 2 is related to the Lyapunov condition.

Theorem 1 (Asymptotic normality) *Assume that Conditions 1–2 and probability bound* (6) *hold. Then*

a) there exists a unique solution $\widehat{\boldsymbol{\beta}}$ *to score equation (4) in* $\mathcal{N}_0$ *with asymptotic probability one;*

b) the MLE $\widehat{\boldsymbol{\beta}}$ *satisfies that for each vector* $\mathbf{u} \in \mathbb{R}^p$ *with* $\|\mathbf{u}\|_2 = 1$ *and* $\|\mathbf{u}\|_1 = O(s_n)$,

$$(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}(\mathbf{u}^T\widehat{\boldsymbol{\beta}} - \mathbf{u}^T\boldsymbol{\beta}_0) \xrightarrow{\mathscr{D}} N(0, \phi) \tag{10}$$

and specifically for each $1 \le j \le p$,

$$(\mathbf{A}_n^{-1})_{jj}^{-1/2}(\widehat{\beta}_j - \beta_{0,j}) \xrightarrow{\mathscr{D}} N(0, \phi), \tag{11}$$

where $\mathbf{A}_n = \mathbf{X}^T\boldsymbol{\Sigma}(\boldsymbol{\theta}_0)\mathbf{X}$ *and* $(\mathbf{A}_n^{-1})_{jj}$ *denotes the* j*th diagonal entry of matrix* $\mathbf{A}_n^{-1}$.

Theorem 1 establishes the asymptotic normality of the MLE and consequently justifies the validity of the conventional p-values in low dimensions. Note that for simplicity, we present here only the marginal asymptotic normality, and the joint asymptotic normality also holds for the projection of the MLE onto any fixed-dimensional subspace. This result can also be extended to the case of misspecified models; see, for example, Lv and Liu (2014).

As mentioned in the Introduction, the asymptotic normality was shown in Fan and Lv (2011) for nonconcave penalized MLE having intrinsic dimensionality $s = o(n^{1/3})$. In contrast, our result in Theorem 1 allows for the scenario of $p = o(n^{1/2})$ with no sparsity assumption in view of our technical conditions. In particular, we see that the conventional p-values in GLMs generally remain valid in the regime of slowly diverging dimensionality $p = o(n^{1/2})$.

3. Nonuniformity of GLM P-values in Diverging Dimensions

So far we have seen that for nonlinear GLMs, the p-values can be valid when $p = o(n^{1/2})$ as shown in Section 2, and can become meaningless when $p \ge n/2$ as discussed in the Introduction. Apparently, there is a big gap between these two regimes of growth of dimensionality p. To provide some guidance on the practical use of p-values in nonlinear GLMs, it is of crucial importance to characterize their breakdown point. To highlight the main message with simplified technical presentation, hereafter we content ourselves with the specific case of logistic regression model for binary response. Moreover, we investigate the distributional property in (11) for the scenario of true regression coefficient vector $\boldsymbol{\beta}_0 = \mathbf{0}$, that is, under the global null. We argue that this specific model is sufficient for our purpose because if the

conventional p-values derived from MLEs fail (i.e., (11) fails) for at least one $\boldsymbol{\beta}_0$ (in particular $\boldsymbol{\beta}_0 = \mathbf{0}$), then conventional p-values are not justified. Therefore, the breakdown point for logistic regression is at least the breakdown point for general nonlinear GLMs. This argument is fundamentally different from that of proving the overall validity of conventional p-values, where one needs to prove the asymptotic normality of MLEs under general GLMs rather than any specific model.

3.1. The wild side of nonlinear regime

For the logistic regression model (1), we have $b(\theta) = \log(1+e^{\theta})$, $\theta \in \mathbb{R}$ and $\phi = 1$. The mean vector $\boldsymbol{\mu}(\boldsymbol{\theta})$ and covariance matrix $\phi\boldsymbol{\Sigma}(\boldsymbol{\theta})$ of the n-dimensional response vector $\mathbf{y}$ given by (3) now take the familiar form of $\boldsymbol{\mu}(\boldsymbol{\theta}) = \left(\frac{e^{\theta_1}}{1+e^{\theta_1}}, \cdots, \frac{e^{\theta_n}}{1+e^{\theta_n}}\right)^T$ and

$$\boldsymbol{\Sigma}(\boldsymbol{\theta}) = \operatorname{diag}\left\{\frac{e^{\theta_1}}{(1+e^{\theta_1})^2}, \cdots, \frac{e^{\theta_n}}{(1+e^{\theta_n})^2}\right\}$$

with $\boldsymbol{\theta} = (\theta_1, \cdots, \theta_n)^T = \mathbf{X}\boldsymbol{\beta}$. In many real applications, one would like to interpret the significance of each individual covariate produced by algorithms based on the conventional asymptotic normality of the MLE as established in Theorem 1. As argued at the beginning of this section, in order to justify the validity of p-values in GLMs, the underlying theory should at least ensure that the distributional property (11) holds for logistic regression under the global null. As we will see empirically in Section 4, as the dimensionality increases, p-values from logistic regression under the global null have a distribution that is skewed more and more toward zero. Consequently, classical hypothesis testing methods which reject the null hypothesis when p-value is less than the pre-specified level α would result in more false discoveries than the desired level of α. As a result, practitioners may simply lose the theoretical backup and the resulting decisions based on the p-values can become ineffective or even misleading. For this reason, it is important and helpful to identify the breakdown point of p-values in diverging-dimensional logistic regression model under the global null.

Characterizing the breakdown point of p-values in nonlinear GLMs is highly nontrivial and challenging. First, the nonlinearity generally causes the MLE to take no analytical form, which makes it difficult to analyze its behavior in diverging dimensions. Second, conventional probabilistic arguments for establishing the central limit theorem of MLE only enable us to see when the distributional property holds, but not exactly at what point it fails. To address these important challenges, we introduce novel geometric and probabilistic arguments presented later in the proofs of Theorems 2–3 that provide a rather delicate analysis of the MLE. In particular, our arguments unveil that the early breakdown point of p-values in nonlinear GLMs is essentially due to the *nonlinearity* of the mean function $\boldsymbol{\mu}(\cdot)$. This shows that p-values can behave wildly much early on in diverging dimensions when we move away from linear regression model to nonlinear regression models such as the widely applied logistic regression; see the Introduction for detailed discussions on the p-values in diverging-dimensional linear models.

Before presenting the main results, let us look at the specific case of logistic regression model under the global null. In such a scenario, it holds that $\boldsymbol{\theta}_0 = \mathbf{X}\boldsymbol{\beta}_0 = \mathbf{0}$ and thus

$\boldsymbol{\Sigma}(\boldsymbol{\theta}_0) = 4^{-1}I_n$, which results in

$$\mathbf{A}_n = \mathbf{X}^T\boldsymbol{\Sigma}(\boldsymbol{\theta}_0)\mathbf{X} = 4^{-1}\mathbf{X}^T\mathbf{X}.$$

In particular, we see that when $n^{-1}\mathbf{X}^T\mathbf{X}$ is close to the identity matrix I_p, the asymptotic standard deviation of the jth component $\widehat{\beta}_j$ of the MLE $\widehat{\boldsymbol{\beta}}$ is close to $2n^{-1/2}$ when the asymptotic theory in (11) holds. As mentioned in the Introduction, when $p \geq n/2$ the MLE can blow up with excessively large variance, a strong evidence against the distributional property in (11). In fact, one can also observe inflated variance of the MLE relative to what is predicted by the asymptotic theory in (11) even when the dimensionality p grows at a slower rate with sample size n. As a consequence, the conventional p-values given by algorithms according to property (11) can be much biased toward zero and thus produce more significant discoveries than the truth. Such a breakdown of conventional p-values is delineated clearly in the simulation examples presented in Section 4.

3.2. Main results

We now present the formal results on the invalidity of GLM p-values in diverging dimensions.

Theorem 2 (Uniform orthonormal design) [1] *Assume that $n^{-1/2}\mathbf{X}$ is uniformly distributed on the Stiefel manifold $V_p(\mathbb{R}^n)$ consisting of all $n \times p$ orthonormal matrices. Then for the logistic regression model under the global null, the asymptotic normality of the MLE established in (11) fails to hold when $p \sim n^{2/3}$, where $\sim$ stands for asymptotic order.*

Theorem 3 (Correlated Gaussian design) *Assume that $\mathbf{X} \sim N(\mathbf{0}, I_n \otimes \boldsymbol{\Sigma})$ with covariance matrix $\boldsymbol{\Sigma}$ nonsingular. Then for the logistic regression model under the global null, the same conclusion as in Theorem 2 holds.*

Theorem 4 in Appendix A states that under the global null in GLM with Gaussian design, the p-value based on the MLE remains valid as long as the dimensionality p diverges with n at a slower rate than $n^{2/3}$. This together with Theorems 2 and 3 shows that under the global null, the exact breakdown point for the uniformity of p-value is $n^{2/3}$. We acknowledge that these results are mainly for theoretical interests because in practice one cannot check precisely whether the global null assumption holds or not. However, these results clearly suggest that in GLM with diverging dimensionality, one needs to be very cautious when using p-values based on the MLE.

The key ingredients of our new geometric and probabilistic arguments are demonstrated in the proof of Theorem 2 in Section B.3. The assumption that the rescaled random design matrix $n^{-1/2}\mathbf{X}$ has the Haar measure on the Stiefel manifold $V_p(\mathbb{R}^n)$ greatly facilitates our technical analysis. The major theoretical finding is that the nonlinearity of the mean function $\boldsymbol{\mu}(\cdot)$ can be negligible in determining the asymptotic distribution of MLE as given in (11) when the dimensionality p grows at a slower rate than $n^{2/3}$, but such nonlinearity can become dominant and deform the conventional asymptotic normality when p grows at rate $n^{2/3}$ or faster. See the last paragraph of Section B.3 for more detailed in-depth discussions

1. For completeness, we present Theorem 4 in Appendix A which provides a random design version of Theorem 1 under global null and a partial converse of Theorems 2 and 3.

on such an interesting phenomenon. Furthermore, the global null assumption is a crucial component of our geometric and probabilistic argument. The global null assumption along with the distributional assumption on the design matrix ensures the symmetry property of the MLE and the useful fact that the MLE can be asymptotically independent of the random design matrix. In the absence of such an assumption, we may suspect that p-values of the noise variables can be affected by the signal variables due to asymmetry. Indeed, our simulation study in Section 4 reveals that as the number of signal variables increases, the breakdown point of the p-values occurs even earlier.

Theorem 3 further establishes that the invalidity of GLM p-values in high dimensions beyond the scenario of orthonormal design matrices considered in Theorem 2. The breakdown of the conventional p-values occurs regardless of the correlation structure of the covariates.

Our theoretical derivations detailed in the Appendix also suggest that the conventional p-values in nonlinear GLMs can generally fail to be valid when $p \sim n^{\alpha_0}$ with α_0 ranging between 1/2 and 2/3, which differs significantly from the phenomenon for linear models as discussed in the Introduction. The special feature of logistic regression model that the variance function $b''(\theta)$ takes the maximum value 1/4 at natural parameter $\theta = 0$ leads to a higher transition point of $p \sim n^{\alpha_0}$ with $\alpha_0 = 2/3$ for the case of global null $\boldsymbol{\beta}_0 = \mathbf{0}$.

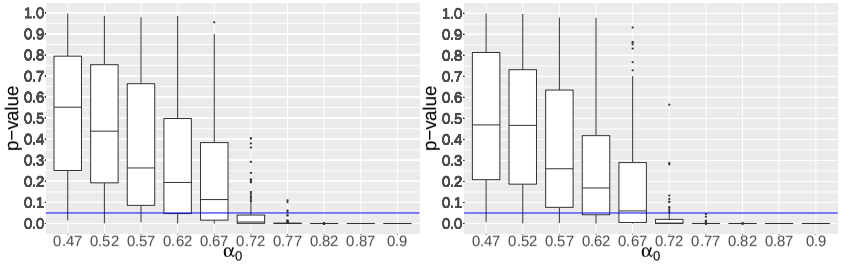
4. Numerical Studies

We now investigate the breakdown point of p-values for nonlinear GLMs in diverging dimensions as predicted by our major theoretical results in Section 3 with several simulation examples. Indeed, these theoretical results are well supported by the numerical studies.

4.1. Simulation examples

Following Theorems 2–3 in Section 3, we consider three examples of the logistic regression model (1). The response vector $\mathbf{y} = (y_1, \cdots, y_n)^T$ has independent components and each y_i has Bernoulli distribution with parameter $e^{\theta_i}/(1+e^{\theta_i})$, where $\boldsymbol{\theta} = (\theta_1, \cdots, \theta_n)^T = \mathbf{X}\boldsymbol{\beta}_0$. In example 1, we generate the $n \times p$ design matrix $\mathbf{X} = (\mathbf{x}_1, \cdots, \mathbf{x}_p)$ such that $n^{-1/2}\mathbf{X}$ is uniformly distributed on the Stiefel manifold $V_p(\mathbb{R}^n)$ as in Theorem 2, while examples 2 and 3 assume that $\mathbf{X} \sim N(\mathbf{0}, I_n \otimes \boldsymbol{\Sigma})$ with covariance matrix $\boldsymbol{\Sigma}$ as in Theorem 3. In particular, we choose $\boldsymbol{\Sigma} = (\rho^{|j-k|})_{1 \le j,k \le p}$ with $\rho = 0, 0.5$, and 0.8 to reflect low, moderate, and high correlation levels among the covariates. Moreover, examples 1 and 2 assume the global null model with $\boldsymbol{\beta}_0 = \mathbf{0}$ following our theoretical results, whereas example 3 allows sparsity $s = \|\boldsymbol{\beta}_0\|_0$ to vary.

To examine the asymptotic results we set the sample size $n = 1000$. In each example, we consider a spectrum of dimensionality p with varying rate of growth with sample size n. As mentioned in the Introduction, the phase transition of perfect hyperplane separation happens at the point $p/n = 1/2$. Recall that Theorems 2–3 establish that the conventional GLM p-values can become invalid when $p \sim n^{2/3}$. We set $p = [n^{\alpha_0}]$ with α_0 in the grid $\{2/3 - 4\delta, \cdots, 2/3 - \delta, 2/3, 2/3 + \delta, \cdots, 2/3 + 4\delta, (\log(n) - \log(2))/\log(n)\}$ for $\delta = 0.05$. For example 3, we pick s signals uniformly at random among all but the first components, where a random half of them are chosen as 3 and the other half are set as -3.



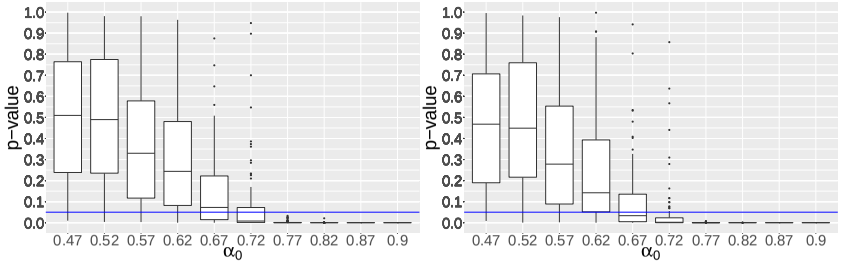
The goal of the simulation examples is to investigate empirically when the conventional GLM p-values could break down in diverging dimensions. When the asymptotic theory for

the MLE in (11) holds, the conventional p-values would be valid and distributed uniformly on the interval $[0, 1]$ under the null hypothesis. Note that the first covariate $\mathbf{x}_1$ is a null variable in each simulation example. Thus in each replication, we calculate the conventional p-value for testing the null hypothesis $H_0 : \beta_{0,1} = 0$. To check the validity of these p-values, we further test their uniformity.

For each simulation example, we first calculate the p-values for a total of $1,000$ replications as described above and then test the uniformity of these $1,000$ p-values using, for example, the Kolmogorov–Smirnov (KS) test (Kolmogorov, 1933; Smirnov, 1948) and the Anderson–Darling (AD) test (Anderson and Darling, 1952, 1954). We repeat this procedure 100 times to obtain a final set of 100 new p-values from each of these two uniformity tests. Specifically, the KS and AD test statistics for testing the uniformity on $[0, 1]$ are defined as

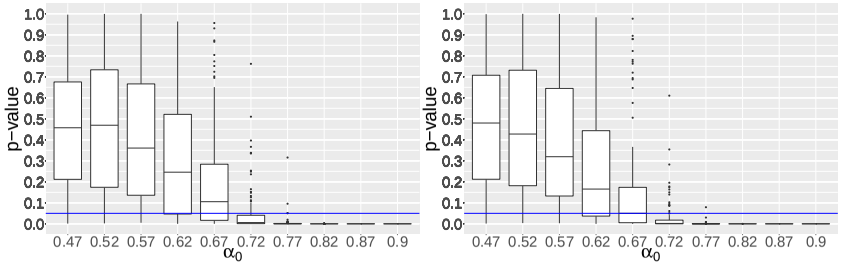
$$\mathrm{KS} = \sup_{x \in [0,1]} |F_m(x) - x| \quad \text{and} \quad \mathrm{AD} = m \int_0^1 \frac{[F_m(x) - x]^2}{x(1-x)}\, dx,$$

respectively, where $F_m(x) = m^{-1} \sum_{i=1}^m I_{(-\infty, x]}(x_i)$ is the empirical distribution function for a given sample $\{x_i\}_{i=1}^m$.



(a) KS test (b) AD test

Figure 1: Results of KS and AD tests for testing the uniformity of GLM p-values in simulation example 1 for diverging-dimensional logistic regression model with uniform orthonormal design under global null. The vertical axis represents the p-value from the KS and AD tests, and the horizontal axis stands for the growth rate α_0 of dimensionality $p = [n^{\alpha_0}]$.



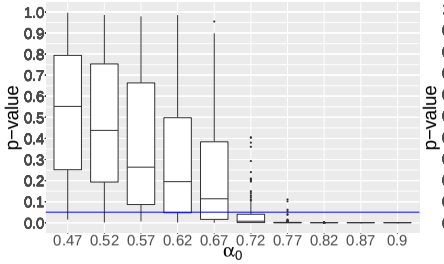
4.2. Testing results

For each simulation example, we apply both KS and AD tests to verify the asymptotic theory for the MLE in (11) by testing the uniformity of conventional p-values at significance level 0.05. As mentioned in Section 4.1, we end up with two sets of 100 new p-values from the KS and AD tests. Figures 1–3 depict the boxplots of the p-values obtained from both KS and AD tests for simulation examples 1–3, respectively. In particular, we observe that the numerical results shown in Figures 1–2 for examples 1–2 are in line with our theoretical results established in Theorems 2–3, respectively, for diverging-dimensional logistic

(a) KS test for $\rho = 0.5$

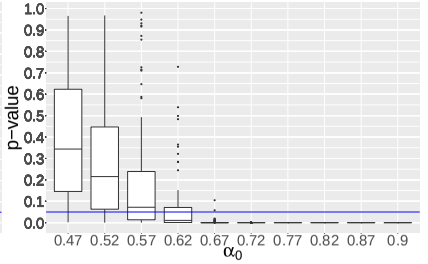
(b) AD test for $\rho = 0.5$

(c) KS test for $\rho = 0.8$



(d) AD test for $\rho = 0.8$

Figure 2: Results of KS and AD tests for testing the uniformity of GLM p-values in simulation example 2 for diverging-dimensional logistic regression model with correlated Gaussian design under global null for varying correlation level ρ. The vertical axis represents the p-value from the KS and AD tests, and the horizontal axis stands for the growth rate α_0 of dimensionality $p = [n^{\alpha_0}]$.



regression model under global null that the conventional p-values break down when $p \sim n^{\alpha_0}$ with $\alpha_0 = 2/3$. Figure 3 for example 3 examines the breakdown point of p-values with varying sparsity s. It is interesting to see that the breakdown point shifts even earlier when s increases as suggested in the discussions in Section 3.2. The results from the AD test are similar so we present only the results from the KS test for simplicity.

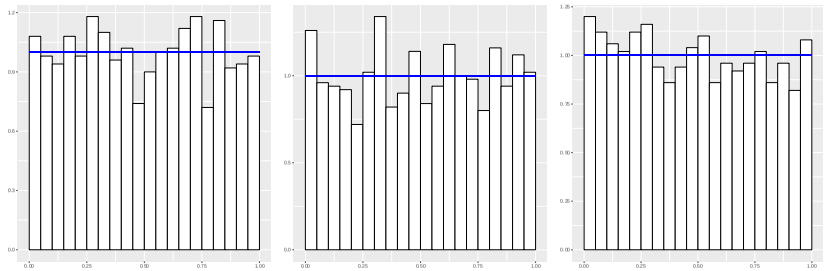
To gain further insights into the nonuniformity of the null p-values, we next provide an additional figure in the setting of simulation example 1. Specifically, in Figure 4 we present the histograms of the 1,000 null p-values from the first simulation repetition (out of 100) for each value of α_0. It is seen that as the dimensionality increases (i.e., α_0 increases), the null p-values have a distribution that is skewed more and more toward zero, which is prone to produce more false discoveries if these p-values are used naively in classical hypothesis testing methods.

To further demonstrate the severity of the problem, we estimate the probability of making type I error at significance level a, as the fraction of p-values below a. The means

(a) KS test for $s = 0$

(b) KS test for $s = 2$

Figure 3: Results of KS test for testing the uniformity of GLM p-values in simulation example 3 for diverging-dimensional logistic regression model with uncorrelated Gaussian design under global null for varying sparsity s. The vertical axis represents the p-value from the KS test, and the horizontal axis stands for the growth rate α_0 of dimensionality $p = [n^{\alpha_0}]$.



and standard deviations of the estimated probabilities are reported in Table 1 for $a = 0.05$ and 0.1. When the null p-values are distributed uniformly, the probabilities of making type I error should all be close to the target level a. However, Table 1 shows that when the growth rate of dimensionality α_0 approaches or exceeds $2/3$, these probabilities can be much larger than a, which again supports our theoretical findings. Also it is seen that when α_0 is close to but still smaller than $2/3$, the averages of estimated probabilities exceed slightly a, which could be the effect of finite sample size.

	α_0	0.10	0.47	0.57	0.67	0.77	0.87

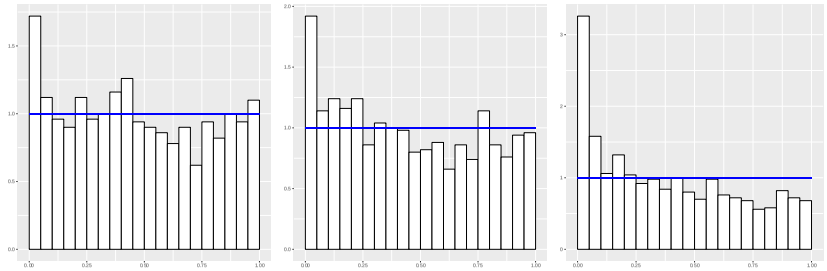
Table 1: Means and standard deviations (SD) for estimated probabilities of making type I error in simulation example 1 with α_0 the growth rate of dimensionality $p = [n^{\alpha_0}]$. Two significance levels $a = 0.05$ and 0.1 are considered.

5. Discussions



In this paper we have provided characterizations of p-values in nonlinear GLMs with diverging dimensionality. The major findings are that the conventional p-values can remain valid when $p = o(n^{1/2})$, but can become invalid much earlier in nonlinear models than in linear models, where the latter case can allow for $p = o(n)$. In particular, our theoretical results

(a) $\alpha_0 = 0.47$ (b) $\alpha_0 = 0.52$ (c) $\alpha_0 = 0.57$

(d) $\alpha_0 = 0.62$ (e) $\alpha_0 = 0.67$ (f) $\alpha_0 = 0.72$

(g) $\alpha_0 = 0.77$ (h) $\alpha_0 = 0.82$ (i) $\alpha_0 = 0.87$

Figure 4: Histograms of null p-values in simulation example 1 from the first simulation repetition for different growth rates α_0 of dimensionality $p = [n^{\alpha_0}]$.

pinpoint the breakdown point of $p \sim n^{2/3}$ for p-values in diverging-dimensional logistic regression model under global null with uniform orthonormal design and correlated Gaussian design, as evidenced in the numerical results. It would be interesting to investigate such a phenomenon for more general class of random design matrices.

The problem of identifying the breakdown point of p-values becomes even more complicated and challenging when we move away from the setting of global null. Our technical analysis suggests that the breakdown point $p \sim n^{\alpha_0}$ can shift even earlier with α_0 ranging between $1/2$ and $2/3$. But the exact breakdown point can depend upon the number of signals s, the signal magnitude, and the correlation structure among the covariates in a rather complicated fashion. Thus more delicate mathematical analysis is needed to obtain the exact relationship. We leave such a problem for future investigation. Moving beyond the GLM setting will further complicate the theoretical analysis.

As we routinely produce p-values using algorithms, the phenomenon of nonuniformity of p-values occurring early in diverging dimensions unveiled in the paper poses useful cautions to researchers and practitioners when making decisions in real applications using results from p-value based methods. For instance, when testing the joint significance of covariates in diverging-dimensional nonlinear models, the effective sample size requirement should be checked before interpreting the testing results. Indeed, statistical inference in general high-dimensional nonlinear models is particularly challenging since obtaining accurate p-values is generally not easy. One possible route is to bypass the use of p-values in certain tasks including the false discovery rate (FDR) control; see, for example, Barber and Candès (2015); Candès et al. (2018); Fan et al. (2018) for some initial efforts made along this line.

Acknowledgments

The first and last authors sincerely thank Emmanuel Candès for helpful discussions on this topic. The authors would like to thank the Associate Editor and referees for their valuable comments that helped improve the article substantially.

Appendix A. Conventional P-values in Low Dimensions under Random Design

Under the specific assumption of Gaussian design and global null $\boldsymbol{\beta}_0 = \mathbf{0}$, we can show that the asymptotic normality of MLE continues to hold without previous Conditions 1–2.

Theorem 4 *Assume that $\boldsymbol{\beta}_0 = \mathbf{0}$, the rows of $\mathbf{X}$ are i.i.d. from $N(\mathbf{0}, \boldsymbol{\Sigma})$, $b^{(5)}(\cdot)$ is uniformly bounded in its domain, and $\mathbf{y} - \boldsymbol{\mu}_0$ has uniformly sub-Gaussian components. Then if $p = O(n^{\alpha})$ with some $\alpha \in [0, 2/3)$, we have the componentwise asymptotic normality*

$$(\mathbf{A}_n^{-1})_{jj}^{-1/2} \widehat{\beta}_j \xrightarrow{\mathscr{D}} N(0, \phi),$$

where all the notation is the same as in (11).

Theorem 4 shows that the conclusions of Theorem 1 continue to hold for the case of random design and global null with the major difference that the dimensionality can be

pushed as far as $p \sim n^{2/3}$. The main reasons for presenting Theorem 4 under Gausssian design are twofold. First, Gaussian design is a widely used assumption in the literature. Second, our results on the nonuniformity of GLM p-values in diverging dimensions use geometric and probabilistic arguments which require random design setting; see Section 3 for more details. To contrast more accurately the two regimes and maintain self-contained theory, we have chosen to present Theorem 4 under Gaussian design. On the other hand, we would like to point out that Theorem 4 is not for practitioners who want to justify the usage of classical p-values. The global null assumption of $\boldsymbol{\beta}_0 = \mathbf{0}$ restricts the validity of Theorem 4 in many practical scenarios.

Appendix B. Proofs of Main Results

We provide the detailed proofs of Theorems 1–3 in this Appendix.

B.1. Proof of Theorem 1

To ease the presentation, we split the proof into two parts, where the first part locates the MLE $\widehat{\boldsymbol{\beta}}$ in an asymptotically shrinking neighborhood $\mathcal{N}_0$ of the true regression coefficient vector $\boldsymbol{\beta}_0$ with significant probability and the second part further establishes its asymptotic normality.

Part 1: Existence of a unique solution to score equation (4) in $\mathcal{N}_0$ under Condition 1 and probability bound (6). For simplicity, assume that the design matrix $\mathbf{X}$ is rescaled columnwise such that $\|\mathbf{x}_j\|_2 = \sqrt{n}$ for each $1 \le j \le p$. Consider an event

$$\mathcal{E} = \left\{ \|\boldsymbol{\xi}\|_\infty \le c_1^{-1/2} \sqrt{n \log n} \right\}, \tag{12}$$

where $\boldsymbol{\xi} = (\xi_1, \cdots, \xi_p)^T = \mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}(\boldsymbol{\theta}_0)]$. Note that for unbounded responses, the assumption of $\max_{j=1}^p \|\mathbf{x}_j\|_\infty < c_1^{1/2}\{n/(\log n)\}^{1/2}$ in Condition 1 entails that $c_1^{-1/2}\sqrt{\log n} < \min_{j=1}^p \{\|\mathbf{x}_j\|_2/\|\mathbf{x}_j\|_\infty\}$. Thus by $\|\mathbf{x}_j\|_2 = \sqrt{n}$, probability bound (6), and Bonferroni's inequality, we deduce

$$\begin{aligned} P(\mathcal{E}) &\ge 1 - \sum_{j=1}^p P\left(|\xi_j| > c_1^{-1/2} \sqrt{n \log n} \right) \\ &\ge 1 - 2pn^{-1} = 1 - O\{n^{-(1-\alpha_0)}\}, \end{aligned} \tag{13}$$

since $p = O(n^{\alpha_0})$ for some $\alpha_0 \in (0, \gamma)$ with $\gamma \in (0, 1/2]$ by assumption. Hereafter we condition on the event $\mathcal{E}$ defined in (12) which holds with significant probability.

We will show that for sufficiently large n, the score equation (4) has a solution in the neighborhood $\mathcal{N}_0$ which is a hypercube. Define two vector-valued functions

$$\boldsymbol{\gamma}(\boldsymbol{\beta}) = (\gamma_1(\boldsymbol{\beta}), \cdots, \gamma_p(\boldsymbol{\beta}))^T = \mathbf{X}^T \boldsymbol{\mu}(\mathbf{X}\boldsymbol{\beta})$$

and

$$\boldsymbol{\Psi}(\boldsymbol{\beta}) = \boldsymbol{\gamma}(\boldsymbol{\beta}) - \boldsymbol{\gamma}(\boldsymbol{\beta}_0) - \boldsymbol{\xi}, \quad \boldsymbol{\beta} \in \mathbb{R}^p.$$

Then equation (4) is equivalent to $\boldsymbol{\Psi}(\boldsymbol{\beta}) = \mathbf{0}$. We need to show that the latter has a solution inside the hypercube $\mathcal{N}_0$. To this end, applying a second order Taylor expansion of $\boldsymbol{\gamma}(\boldsymbol{\beta})$ around $\boldsymbol{\beta}_0$ with the Lagrange remainder term componentwise leads to

$$\boldsymbol{\gamma}(\boldsymbol{\beta}) = \boldsymbol{\gamma}(\boldsymbol{\beta}_0) + \mathbf{X}^T \boldsymbol{\Sigma}(\boldsymbol{\theta}_0) \mathbf{X}(\boldsymbol{\beta} - \boldsymbol{\beta}_0) + \mathbf{r}, \tag{14}$$

where $\mathbf{r} = (r_1, \cdots, r_p)^T$ and for each $1 \le j \le p$,

$$r_j = \frac{1}{2} (\boldsymbol{\beta} - \boldsymbol{\beta}_0)^T \nabla^2 \gamma_j(\boldsymbol{\beta}_j) (\boldsymbol{\beta} - \boldsymbol{\beta}_0)$$

with $\boldsymbol{\beta}_j$ some p-dimensional vector lying on the line segment joining $\boldsymbol{\beta}$ and $\boldsymbol{\beta}_0$. It follows from (9) in Condition 1 that

$$\begin{aligned} \|\mathbf{r}\|_\infty &\le \max_{\boldsymbol{\delta} \in \mathcal{N}_0} \max_{j=1}^p \frac{1}{2} \lambda_{\max} \left[\mathbf{X}^T \operatorname{diag}\left\{ |\mathbf{x}_j| \circ \left| \boldsymbol{\mu}''(\mathbf{X}\boldsymbol{\delta}) \right| \right\} \mathbf{X} \right] \|\boldsymbol{\beta} - \boldsymbol{\beta}_0\|_2^2 \\ &= O\left\{ pn^{1-2\gamma} (\log n)^2 \right\}. \end{aligned} \tag{15}$$

Let us define another vector-valued function

$$\overline{\boldsymbol{\Psi}}(\boldsymbol{\beta}) \equiv \left[\mathbf{X}^T \boldsymbol{\Sigma}(\boldsymbol{\theta}_0) \mathbf{X} \right]^{-1} \boldsymbol{\Psi}(\boldsymbol{\beta}) = \boldsymbol{\beta} - \boldsymbol{\beta}_0 + \mathbf{u}, \tag{16}$$

where $\mathbf{u} = -[\mathbf{X}^T \boldsymbol{\Sigma}(\boldsymbol{\theta}_0) \mathbf{X}]^{-1} (\boldsymbol{\xi} - \mathbf{r})$. It follows from (12), (15), and (8) in Condition 1 that for any $\boldsymbol{\beta} \in \mathcal{N}_0$,

$$\begin{aligned} \|\mathbf{u}\|_\infty &\le \left\| \left[\mathbf{X}^T \boldsymbol{\Sigma}(\boldsymbol{\theta}_0) \mathbf{X} \right]^{-1} \right\|_\infty (\|\boldsymbol{\xi}\|_\infty + \|\mathbf{r}\|_\infty) \\ &= O\left[b_n n^{-1/2} \sqrt{\log n} + b_n p n^{-2\gamma} (\log n)^2 \right]. \end{aligned} \tag{17}$$

By the assumptions of $p = O(n^{\alpha_0})$ with constant $\alpha_0 \in (0, \gamma)$ and $b_n = o\{\min(n^{1/2-\gamma}\sqrt{\log n}, n^{2\gamma - \alpha_0 - 1/2}/(\log n)^2\}$, we have

$$\|\mathbf{u}\|_\infty = o(n^{-\gamma} \log n).$$

Thus in light of (16), it holds for large enough n that when $(\boldsymbol{\beta} - \boldsymbol{\beta}_0)_j = n^{-\gamma}\sqrt{\log n}$,

$$\overline{\Psi}_j(\boldsymbol{\beta}) \ge n^{-\gamma} \sqrt{\log n} - \|\mathbf{u}\|_\infty \ge 0, \tag{18}$$

and when $(\boldsymbol{\beta} - \boldsymbol{\beta}_0)_j = -n^{-\gamma}\sqrt{\log n}$,

$$\overline{\Psi}_j(\boldsymbol{\beta}) \le -n^{-\gamma} \sqrt{\log n} + \|\mathbf{u}\|_\infty \le 0, \tag{19}$$

where $\overline{\boldsymbol{\Psi}}(\boldsymbol{\beta}) = (\overline{\Psi}_1(\boldsymbol{\beta}), \cdots, \overline{\Psi}_p(\boldsymbol{\beta}))^T$.

By the continuity of the vector-valued function $\overline{\boldsymbol{\Psi}}(\boldsymbol{\beta})$, (18), and (19), Miranda's existence theorem Vrahatis (1989) ensures that equation $\overline{\boldsymbol{\Psi}}(\boldsymbol{\beta}) = \mathbf{0}$ has a solution $\widehat{\boldsymbol{\beta}}$ in $\mathcal{N}_0$. Clearly, $\widehat{\boldsymbol{\beta}}$ also solves equation $\boldsymbol{\Psi}(\boldsymbol{\beta}) = \mathbf{0}$ in view of (16). Therefore, we have shown that score equation (4) indeed has a solution $\widehat{\boldsymbol{\beta}}$ in $\mathcal{N}_0$. The strict concavity of the log-likelihood function (2) by assumptions for model (1) entails that $\widehat{\boldsymbol{\beta}}$ is the MLE.

Part 2: Conventional asymptotic normality of the MLE $\widehat{\boldsymbol{\beta}}$. Fix any $1 \le j \le p$. In light of (16), we have $\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0 = \mathbf{A}_n^{-1}(\boldsymbol{\xi} - \mathbf{r})$, which results in

$$(\mathbf{A}_n^{-1})_{jj}^{-1/2}(\widehat{\beta}_j - \beta_{0,j}) = (\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\boldsymbol{\xi} - (\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\mathbf{r} \tag{20}$$

with $\mathbf{e}_j \in \mathbb{R}^p$ having one for the jth component and zero otherwise. Note that since the smallest and largest eigenvalues of $n^{-1}\mathbf{A}_n$ are bounded away from 0 and ∞ by Condition 2, it is easy to show that $(\mathbf{A}_n^{-1})_{jj}^{-1/2}$ is of exact order $n^{1/2}$. In view of (17), it holds on the event $\mathcal{E}$ defined in (12) that

$$\begin{aligned} \left\|\mathbf{A}_n^{-1}\mathbf{r}\right\|_\infty &\le \left\|\left[\mathbf{X}^T\boldsymbol{\Sigma}\left(\boldsymbol{\theta}_0\right)\mathbf{X}\right]^{-1}\right\|_\infty \|\mathbf{r}\|_\infty \\ &= O\left[b_n p n^{-2\gamma}(\log n)^2\right] = o(n^{-1/2}), \end{aligned}$$

since $b_n = o\{n^{2\gamma-\alpha_0-1/2}/(\log n)^2\}$ by assumption. This leads to

$$(\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\mathbf{r} = O(n^{1/2})\cdot o_P(n^{-1/2}) = o_P(1). \tag{21}$$

It remains to consider the term $(\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\boldsymbol{\xi} = \sum_{i=1}^n \eta_i$, where $\eta_i = (\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\mathbf{z}_i[y_i - b'(\theta_{0,i})]$. Clearly, the n random variables η_i's are independent with mean 0 and

$$\sum_{i=1}^n \mathrm{var}(\eta_i) = (\mathbf{A}_n^{-1})_{jj}^{-1}\mathbf{e}_j^T\mathbf{A}_n^{-1}(\phi\mathbf{A}_n)\mathbf{A}_n^{-1}\mathbf{e}_j = \phi.$$

It follows from Condition 2 and the Cauchy–Schwarz inequality that

$$\begin{aligned} \sum_{i=1}^n E\left|\eta_i\right|^3 &= \sum_{i=1}^n \left|(\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\mathbf{z}_i\right|^3 E\left|y_i - b'\left(\theta_{0,i}\right)\right|^3 \\ &= O(1)\sum_{i=1}^n \left|(\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\mathbf{z}_i\right|^3 \\ &\le O(1)\sum_{i=1}^n \left\|(\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1/2}\right\|_2^3 \left\|\mathbf{A}_n^{-1/2}\mathbf{z}_i\right\|_2^3 \\ &= O(1)\sum_{i=1}^n \left(\mathbf{z}_i^T\mathbf{A}_n^{-1}\mathbf{z}_i\right)^{3/2} = o(1). \end{aligned}$$

Thus an application of Lyapunov's theorem yields

$$(\mathbf{A}_n^{-1})_{jj}^{-1/2}\mathbf{e}_j^T\mathbf{A}_n^{-1}\boldsymbol{\xi} = \sum_{i=1}^n \eta_i \xrightarrow{\mathscr{D}} N(0,\phi). \tag{22}$$

By Slutsky's lemma, we see from (20)–(22) that

$$(\mathbf{A}_n^{-1})_{jj}^{-1/2}(\widehat{\beta}_j - \beta_{0,j}) \xrightarrow{\mathscr{D}} N(0,\phi),$$

showing the asymptotic normality of each component $\widehat{\beta}_j$ of the MLE $\widehat{\boldsymbol{\beta}}$.

We further establish the asymptotic normality for the one-dimensional projections of the MLE $\widehat{\boldsymbol{\beta}}$. Fix an arbitrary vector $\mathbf{u} \in \mathbb{R}^p$ with $\|\mathbf{u}\|_2 = 1$ satisfying the L_1 sparsity bound $\|\mathbf{u}\|_1 = O(s_n)$. In light of (16), we have $\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0 = \mathbf{A}_n^{-1}(\boldsymbol{\xi} - \mathbf{r})$, which results in

$$(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}(\mathbf{u}^T\widehat{\boldsymbol{\beta}} - \mathbf{u}^T\boldsymbol{\beta}_0) = (\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\boldsymbol{\xi} - (\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{r}. \tag{23}$$

Note that since the smallest and largest eigenvalues of $n^{-1}\mathbf{A}_n$ are bounded away from 0 and ∞ by Condition 2, it is easy to show that $(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}$ is of exact order $n^{1/2}$. In view of (17), it holds on the event $\mathcal{E}$ defined in (12) that

$$\begin{aligned} \left\|\mathbf{A}_n^{-1}\mathbf{r}\right\|_\infty &\le \left\|\left[\mathbf{X}^T\boldsymbol{\Sigma}\left(\boldsymbol{\theta}_0\right)\mathbf{X}\right]^{-1}\right\|_\infty \|\mathbf{r}\|_\infty \\ &= O\left\{b_n p n^{-2\gamma}(\log n)^2\right\} = o(s_n^{-1}n^{-1/2}) \end{aligned}$$

since $b_n = o\{s_n^{-1}n^{2\gamma-\alpha_0-1/2}/(\log n)^2\}$ by assumption. This leads to

$$(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{r} = O(n^{1/2})\cdot\|\mathbf{u}\|_1\cdot\|\mathbf{A}_n^{-1}\mathbf{r}\|_\infty = o_P(1) \tag{24}$$

since $\|\mathbf{u}\|_1 = O(s_n)$ by assumption.

It remains to consider the term $(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\boldsymbol{\xi} = \sum_{i=1}^n \eta_i$ with $\eta_i = (\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{z}_i[y_i - b'(\theta_{0,i})]$. Clearly, the n random variables η_i's are independent with mean 0 and

$$\sum_{i=1}^n \mathrm{var}(\eta_i) = (\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1}\mathbf{u}^T\mathbf{A}_n^{-1}(\phi\mathbf{A}_n)\mathbf{A}_n^{-1}\mathbf{u} = \phi.$$

It follows from Condition 2 and the Cauchy–Schwarz inequality that

$$\begin{aligned} \sum_{i=1}^n E\left|\eta_i\right|^3 &= \sum_{i=1}^n \left|(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{z}_i\right|^3 E\left|y_i - b'\left(\theta_{0,i}\right)\right|^3 \\ &= O(1)\sum_{i=1}^n \left|(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{z}_i\right|^3 \\ &\le O(1)\sum_{i=1}^n \left\|(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1/2}\right\|_2^3 \left\|\mathbf{A}_n^{-1/2}\mathbf{z}_i\right\|_2^3 \\ &= O(1)\sum_{i=1}^n \left(\mathbf{z}_i^T\mathbf{A}_n^{-1}\mathbf{z}_i\right)^{3/2} = o(1). \end{aligned}$$

Thus an application of Lyapunov's theorem yields

$$(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}\mathbf{u}^T\mathbf{A}_n^{-1}\boldsymbol{\xi} = \sum_{i=1}^n \eta_i \xrightarrow{\mathscr{D}} N(0,\phi). \tag{25}$$

By Slutsky's lemma, we see from (23)–(25) that

$$(\mathbf{u}^T\mathbf{A}_n^{-1}\mathbf{u})^{-1/2}(\mathbf{u}^T\widehat{\beta} - \mathbf{u}^T\boldsymbol{\beta}_0) \xrightarrow{\mathscr{D}} N(0,\phi),$$

showing the asymptotic normality of any L_1-sparse one-dimensional projection $\mathbf{u}^T\widehat{\boldsymbol{\beta}}$ of the MLE $\widehat{\boldsymbol{\beta}}$. This completes the proof of Theorem 1.

B.2. Proof of Theorem 4

The proof is similar to that for Theorem 1. Without loss of generality, we assume that $\mathbf{\Sigma} = I_p$ because under global null, a rotation of $\mathbf{X}$ yields standard normal rows. First let $\boldsymbol{\xi} = (\xi_1, \cdots, \xi_p)^T = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0]$, where $\boldsymbol{\mu}_0 = b'(0)\mathbf{1}$ with $\mathbf{1} = (1, \cdots, 1)^T \in \mathbb{R}^n$ because $\boldsymbol{\beta}_0 = 0$. Then $\mathbf{y} - \boldsymbol{\mu}_0$ has i.i.d. uniform sub-Gaussian components and is independent of $\mathbf{X} = (\mathbf{z}_1, \cdots, \mathbf{z}_p) \in \mathbb{R}^{n\times p}$. Define event

$$\mathcal{E} = \{\|\boldsymbol{\xi}\|_\infty \le c_2\sqrt{n^{-1}\log n}\}.$$

By Lemma 5, it is seen that $P(\mathcal{E}) \ge 1 - o(p^{-a})$. Furthermore, define the neighborhood

$$\mathcal{N}_0 = \{\|\boldsymbol{\beta}\|_\infty \le c_3\sqrt{n^{-1}\log n}\} \tag{26}$$

for some $c_3 > c_2(b''(0))^{-1}$. We next show that the MLE must fall into the region $\mathcal{N}_0$ with probability at least $1 - O(p^{-a})$ following the similar arguments in Theorem 1.

First, we define

$$\boldsymbol{\gamma}(\boldsymbol{\beta}) = (\gamma_1(\boldsymbol{\beta}), \cdots, \gamma_p(\boldsymbol{\beta}))^T \equiv \mathbf{X}^T\boldsymbol{\mu}(\mathbf{X}\boldsymbol{\beta})$$

and

$$\mathbf{\Psi}(\boldsymbol{\beta}) = \boldsymbol{\gamma}(\boldsymbol{\beta}) - \boldsymbol{\gamma}(\boldsymbol{\beta}_0) - \mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0], \quad \boldsymbol{\beta} \in \mathbb{R}^p.$$

Applying a forth order Taylor expansion of $\boldsymbol{\gamma}(\boldsymbol{\beta})$ around $\boldsymbol{\beta}_0 = \mathbf{0}$ with the Lagrange remainder term componentwise leads to

$$\boldsymbol{\gamma}(\boldsymbol{\beta}) = \boldsymbol{\gamma}(\boldsymbol{\beta}_0) + b''(0)\mathbf{X}^T\mathbf{X}(\boldsymbol{\beta} - \boldsymbol{\beta}_0) + \mathbf{r} + \mathbf{s} + \mathbf{t},$$

where $\mathbf{r} = (r_1, \cdots, r_p)^T$, $\mathbf{s} = (s_1, \cdots, s_p)^T$, $\mathbf{t} = (t_1, \cdots, t_p)^T$ and for each $1 \le j \le p$,

$$r_j = \frac{b'''(0)}{2}\sum_{i=1}^n x_{ij}(\mathbf{x}_i^T\boldsymbol{\beta})^2 \tag{27}$$

$$s_j = \frac{b^{(4)}(0)}{6}\sum_{i=1}^n x_{ij}(\mathbf{x}_i^T\boldsymbol{\beta})^3 \tag{28}$$

$$t_j = \frac{1}{24}\sum_{i=1}^n b^{(5)}(\mathbf{x}_i^T\widetilde{\boldsymbol{\beta}^j})x_{ij}(\mathbf{x}_i^T\boldsymbol{\beta})^4. \tag{29}$$

with $\widetilde{\boldsymbol{\beta}^j}$ some p-dimensional vector lying on the line segment joining $\boldsymbol{\beta}$ and $\boldsymbol{\beta}_0$.

Let us define another vector-valued function

$$\overline{\mathbf{\Psi}}(\boldsymbol{\beta}) \equiv \left[b''(0)\mathbf{X}^T\mathbf{X}\right]^{-1}\mathbf{\Psi}(\boldsymbol{\beta}) = \boldsymbol{\beta} - \boldsymbol{\beta}_0 + \mathbf{u}, \tag{30}$$

where $\mathbf{u} = -(b''(0))^{-1}\boldsymbol{\xi} + [b''(0)\mathbf{X}^T\mathbf{X}]^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t})$. It follows from the above derivation that for any $\boldsymbol{\beta} \in \mathcal{N}_0$,

$$\|\mathbf{u}\|_\infty \le \left\|(b''(0))^{-1}\boldsymbol{\xi}\right\|_\infty + \left\|\left[b''(0)\mathbf{X}^T\mathbf{X}\right]^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t})\right\|_\infty.$$

Now, we bound the terms on the right hand side.

First note that on event $\mathcal{E}$,

$$\left\|(b''(0))^{-1}\boldsymbol{\xi}\right\|_\infty \le (b''(0))^{-1}c_2\sqrt{n\log n}. \tag{31}$$

Then, we consider the next term: $\left\|\left[b''(0)\mathbf{X}^T\mathbf{X}\right]^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t})\right\|_\infty$. We observe that

$$\begin{aligned}\left\|\left[b''(0)\mathbf{X}^T\mathbf{X}\right]^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t})\right\|_\infty &\le |b''(0)|^{-1}\left\|\left[n^{-1}\mathbf{X}^T\mathbf{X}\right]^{-1}\right\|_\infty \left\|n^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t})\right\|_\infty \\ &\le |b''(0)|^{-1}\left\|\left[n^{-1}\mathbf{X}^T\mathbf{X}\right]^{-1}\right\|_\infty \\ &\quad \cdot \left(\left\|n^{-1}\mathbf{r}\right\|_\infty + \left\|n^{-1}\mathbf{s}\right\|_\infty + \left\|n^{-1}\mathbf{t}\right\|_\infty\right).\end{aligned}$$

By Lemma 6, we have that $\left\|\left[n^{-1}\mathbf{X}^T\mathbf{X}\right]^{-1}\right\|_\infty \le 1 + O(pn^{-1/2})$. Lemmas 10, 11, 12 assert that

$$\begin{aligned}&\left(\left\|n^{-1}\mathbf{r}\right\|_\infty + \left\|n^{-1}\mathbf{s}\right\|_\infty + \left\|n^{-1}\mathbf{t}\right\|_\infty\right) \\ &= \{n^{\alpha-5/6}\log n + n^{3/2\alpha-5/4}(\log n)^{3/2} + n^{\alpha-1}(\log n)^{1/2} + n^{2\alpha-3/2}(\log n)^{3/2}\}\sqrt{n^{-1}\log n}.\end{aligned}$$

We combine last two bounds so that we have

$$\left\|\left[b''(0)\mathbf{X}^T\mathbf{X}\right]^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t})\right\|_\infty = o(\sqrt{n^{-1}\log n}) \tag{32}$$

with probability at least $1 - o(p^{-c})$ when $p = O(n^\alpha)$ with $\alpha < 2/3$.

Combining equations (31) and (32), we obtain that if $p = O(n^\alpha)$ with $\alpha \in [0, 2/3)$, then

$$\|\mathbf{u}\|_\infty \le c_3\sqrt{n^{-1}\log n}.$$

Thus, the MLE must fall into the region $\mathcal{N}_0$ following the similar arguments in Theorem 1.

Next, we show the componentwise asymptotic normality of the MLE $\widehat{\boldsymbol{\beta}}$. By equation (30), we have $\widehat{\boldsymbol{\beta}} = -\mathbf{u} = (b''(0))^{-1}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0] - [b''(0)\mathbf{X}^T\mathbf{X}]^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t})$. So, we can write

$$\hat{\beta}_j = (b''(0))^{-1}n^{-1}\mathbf{e}_j^T\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0] + (b''(0))^{-1}T - \mathbf{e}_j^T[b''(0)\mathbf{X}^T\mathbf{X}]^{-1}(\mathbf{r} + \mathbf{s} + \mathbf{t}) \tag{33}$$

where $T = \mathbf{e}_j^T(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0] - n^{-1}\mathbf{e}_j^T\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0]$. By Lemma 13 and Equation (32), both $n^{1/2}(b''(0))^{-1}T$ and $n^{1/2}\mathbf{e}_j^T[b''(0)\mathbf{X}^T\mathbf{X}]^{-1}(\mathbf{r}+\mathbf{s}+\mathbf{t})$ converges to zero in probability. So, it is enough to consider the first summand in (33). Now, we show that $n^{-1/2}\mathbf{e}_j^T\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0]$ is asymptotically normal. In fact, we can write $\mathbf{e}_j^T\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0] = \sum_{i=1}^n x_{ij}y_i$ where each summand $x_{ij}y_i$ is independent over i and has variance $\phi b''(0)$. Moreover, $\sum_{i=1}^n E|x_{ij}y_i|^3 = O(n)$ since $|x_{ij}|^3$ and $|y_i|^3$ are independent and finite mean. So, we apply Lyapunov's theorem to obtain $b''(0)^{-1/2}n^{-1/2}\mathbf{e}_j^T\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}_0] \xrightarrow{\mathscr{D}} N(0, \phi)$. Finally, we know that $b''(0)n(\mathbf{A}_n^{-1})_{jj} \to 1$ in probability from the remark in Theorem 1. Thus, Slutsky's lemma yields

$$(\mathbf{A}_n^{-1})_{jj}^{-1/2}\hat{\beta}_j \xrightarrow{\mathscr{D}} N(0, \phi). \tag{34}$$

This completes the proof of the theorem.

Lemma 5 *Assume that the components of* $\mathbf{y}-\boldsymbol{\mu}_0$ *are uniform sub-Gaussians. That is, there exist a positive constant* C *such that* $P(|(\mathbf{y}-\boldsymbol{\mu}_0)_i|>t)\le C\exp\{-Ct^2\}$ *for all* $1\le i\le n$. *Then, it holds that, for some positive constant* c_2,

$$\|(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty \le c_2\sqrt{n^{-1}\log n}.$$

with asymptotic probability $1-o(p^{-a})$.

Proof We prove the result by conditioning on $\mathbf{X}$. Let $\mathbf{E}=n^{-1}\mathbf{X}^T\mathbf{X}-\mathbf{I}_p$. Then by matrix inversion,

$$\begin{aligned}(n^{-1}\mathbf{X}^T\mathbf{X})^{-1} &= (\mathbf{I}_p+\mathbf{E})^{-1} = \mathbf{I}_p-\sum_{k=1}^{\infty}(-1)^{k+1}(\mathbf{E})^k\\ &= \mathbf{I}_p-\mathbf{E}+\sum_{k=2}^{\infty}(-1)^k(\mathbf{E})^k = 2\mathbf{I}_p-n^{-1}\mathbf{X}^T\mathbf{X}+\sum_{k=2}^{\infty}(-1)^k(\mathbf{E})^k.\end{aligned}$$

Thus, it follows that

$$\begin{aligned}&\|(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty\\ &\le \|2n^{-1}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty+\|n^{-2}\mathbf{X}^T\mathbf{X}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty+\left\|n^{-1}\sum_{k=2}^{\infty}(-1)^k(\mathbf{E})^k\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\right\|_\infty\\ &= \eta_1+\eta_2+\eta_3.\end{aligned}$$

In the rest of the proof, we will bound η_1, η_2 and η_3.

Part 1: Bound of η_1.

First, it is easy to see that

$$\begin{aligned}\eta_1 &= \|2n^{-1}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty\\ &= 2\max_{1\le j\le p}\left|n^{-1}\sum_{i=1}^{n}x_{ij}(\mathbf{y}-\boldsymbol{\mu}_0)_i\right|.\end{aligned}$$

We observe that each summand $x_{ij}(\mathbf{y}-\boldsymbol{\mu}_0)_i$ is the product of two subgaussian random variables, and so satisfies $P(|x_{ij}(\mathbf{y}-\boldsymbol{\mu}_0)_i|>t)\le C\exp(-Ct)$ for some constant $C>0$ by Lemma 1 in Fan et al. (2016). Moreover, $E[x_{ij}(\mathbf{y}-\boldsymbol{\mu}_0)_i]=0$ since x_{ij} and $(\mathbf{y}-\boldsymbol{\mu}_0)_i$ are independent and have zero mean. Thus, we can use Lemma 9 by setting $W_{ij}=x_{ij}(\mathbf{y}-\boldsymbol{\mu}_0)_i$ and $\alpha=1$. So, we get

$$\eta_1 = 2\max_{1\le j\le p}\left|n^{-1}\sum_{i=1}^{n}x_{ij}(\mathbf{y}-\boldsymbol{\mu}_0)_i\right| \le c_2\sqrt{n^{-1}\log p} \tag{35}$$

with probability $1-O(p^{-c})$ for some positive constants c and c_2.

Part 2: Bound of η_2.

Now, we study $\eta_2=\|n^{-2}\mathbf{X}^T\mathbf{X}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty$. Let $\mathbf{z}_k$ be the k-th column of X, that is $\mathbf{z}_k=\mathbf{X}\mathbf{e}_k$. Direct calculations yield

$$\mathbf{e}_k^T\mathbf{X}^T\mathbf{X}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)=\sum_{j=1}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))=\|\mathbf{z}_k\|_2^2\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)+\sum_{j\ne k}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0)).$$

Thus, it follows that

$$\left\|(\mathbf{X}^T\mathbf{X}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\right\|_\infty \le \max_k\left|\|\mathbf{z}_k\|_2^2\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right|+\max_k\left|\sum_{j\ne k}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))\right|. \tag{36}$$

First, we consier $\max_k\left|\|\mathbf{z}_k\|_2^2\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right|$. Lemma 14 shows that $\max_k\|\mathbf{z}_k\|_2^2\le O(n)$ with probability $1-O(p^{-c})$. We also have $\max_k\left|\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right|=\frac{n}{2}\eta_1\le O(\sqrt{n\log p})$ by equation (35). It follows that

$$\max_k\left|\|\mathbf{z}_k\|_2^2\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right| \le \max_k\|\mathbf{z}_k\|_2^2\max_k\left|\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right| \le O(n\sqrt{n\log p}). \tag{37}$$

Next, let $a_j=\mathbf{z}_k^T\mathbf{z}_j/\|\mathbf{z}_k\|_2$ and $b_j=\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0)/\|\mathbf{y}-\boldsymbol{\mu}_0\|_2$. Then it is easy to see that conditional on $\mathbf{z}_k$ and $\mathbf{y}$, $a_j\sim N(0,1)$, $b_j\sim N(0,1)$ and $\mathrm{cov}(a_j,b_j|\mathbf{z}_k,\mathbf{y})=\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)/(\|\mathbf{z}_k\|_2\|\mathbf{y}-\boldsymbol{\mu}_0\|_2)$. By (E.6) of Lemma 7 in Fan et al. (2016), it can be shown that

$$\begin{aligned}&P\left(\frac{1}{p-1}\left|\sum_{j\ne k}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))-\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right|\ge c\|\mathbf{z}_k\|_2\|\mathbf{y}-\boldsymbol{\mu}_0\|_2\sqrt{p^{-1}\log p}\Big|\mathbf{z}_k,\mathbf{y}\right)\\ &= P\left(\frac{1}{p-1}\left|\sum_{j\ne k}^{p}a_jb_j-\frac{\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)}{\|\mathbf{z}_k\|_2\|\mathbf{y}-\boldsymbol{\mu}_0\|_2}\right|\ge c\sqrt{p^{-1}\log p}\Big|\mathbf{z}_k,\mathbf{y}\right)\le cp^{-c_1},\end{aligned}$$

where c_1 is some large positive constant independent of $\mathbf{z}_k$ and $\mathbf{y}$. Moreover, we can choose c_1 as large as we want by increasing c. Thus, it follows that

$$P\left(\frac{1}{p-1}\left|\sum_{j\ne k}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))-\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right|\ge c\|\mathbf{z}_k\|_2\|\mathbf{y}-\boldsymbol{\mu}_0\|_2\sqrt{p^{-1}\log p}\right)\le cp^{-c_1}.$$

It follows from probability union bound that

$$P\left(\frac{1}{p-1}\max_k\left|\frac{1}{\|\mathbf{z}_k\|_2\|\mathbf{y}-\boldsymbol{\mu}_0\|_2}\sum_{j\ne k}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))-\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right|\ge c\sqrt{p^{-1}\log p}\right)\le cp^{-c_1+1}.$$

Taking $c_1>1$ yields that with probability at least $1-o(p^{-a})$ for some $a>0$,

$$\max_k\left\{\frac{1}{\|\mathbf{z}_k\|_2\|\mathbf{y}-\boldsymbol{\mu}_0\|_2}\left|\frac{1}{p-1}\sum_{j\ne k}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))-\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right|\right\}\le c\sqrt{p^{-1}\log p}.$$

By Lemma 14, we have $\max_k \|\mathbf{z}_k\|_2 = \sqrt{\max_k \|\mathbf{z}_k\|_2^2} \le O_p(\sqrt{n})$. Therefore, by using the fact that $\|\mathbf{y}-\boldsymbol{\mu}_0\|_2 \le O_p(\sqrt{n})$, we have

$$\begin{aligned}
&\max_k \left|\sum_{j\neq k}^{p}(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))\right| \\
&\le \max_k \left|\sum_{j\neq k}^{p}[(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0))] - (p-1)\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)\right| + (p-1)\max_k |\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)| \\
&\le p\max_k \|\mathbf{z}_k\|_2 \|\mathbf{y}-\boldsymbol{\mu}_0\|_2 \max_k \left\{ \frac{1}{\|\mathbf{z}_k\|_2\|\mathbf{y}-\boldsymbol{\mu}_0\|_2}\left|\frac{1}{p-1}\sum_{j\neq k}^{p}[(\mathbf{z}_k^T\mathbf{z}_j)(\mathbf{z}_j^T(\mathbf{y}-\boldsymbol{\mu}_0)) - \mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)]\right|\right\} \\
&\quad + p\max_k |\mathbf{z}_k^T(\mathbf{y}-\boldsymbol{\mu}_0)| \\
&\le cpn\sqrt{\log p}\sqrt{p^{-1}\log p} + cp\sqrt{n\log p}. \qquad (38)
\end{aligned}$$

Combining (36)–(38) yields

$$\eta_2 = \|n^{-2}\mathbf{X}^T\mathbf{X}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty \le cp^{1/2}n^{-1}\log p = o(\sqrt{n^{-1}\log n}). \qquad (39)$$

Part 3: Bound of η_3.

Finally, we study η_3. We observe that $\eta_3 \le \left\|\sum_{k=2}^{\infty}(-1)^{k+1}(\mathbf{E})^k\right\|_\infty \|n^{-1}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty$. Lemma 7 proves that $\left\|\sum_{k=2}^{\infty}(-1)^{k+1}(\mathbf{E})^k\right\|_\infty \le O(p^{3/2}n^{-1})$ while equation (35) shows that $\|n^{-1}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty = O(\sqrt{n^{-1}\log p})$ with probability $1-O(p^{-c})$. Putting these facts together, we obtain

$$\eta_3 \le O(p^{3/2}n^{-1}\sqrt{n^{-1}\log p}) = o(\sqrt{n^{-1}\log n}) \qquad (40)$$

where we use $p = O(n^{\alpha_0})$ with $\alpha_0 \in [0, 2/3)$.

Combining equations (35), (39), and (40), we obtain that with probability at least $1-o(p^{-a})$,

$$\|(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)\|_\infty \le c\sqrt{n^{-1}\log n}.$$

■

Lemma 6 *Under the assumptions of Theorem 4, $\|(n^{-1}\mathbf{X}^T\mathbf{X})^{-1}\|_\infty \le 1 + O(pn^{-1/2})$ with probability $1-O(p^{-c})$.*

Proof Let $\mathbf{E} = n^{-1}\mathbf{X}^T\mathbf{X} - \mathbf{I}_p$. Then, $\|\mathbf{E}\|_2 \le C(p/n)^{1/2}$ for some constant C with probability $1-O(p^{-c})$ by Theorem 4.6.1 in Vershynin (2016). Furthermore, by matrix inversion, we get

$$(n^{-1}\mathbf{X}^T\mathbf{X})^{-1} = (\mathbf{I}_p+\mathbf{E})^{-1} = \mathbf{I}_p - \sum_{k=1}^{\infty}(-1)^{k+1}(\mathbf{E})^k.$$

Now, we take the norm and use triangle inequalities to get

$$\begin{aligned}
\|(n^{-1}\mathbf{X}^T\mathbf{X})^{-1}\|_\infty &\le \|\mathbf{I}_p\|_\infty + \sum_{k=1}^{\infty}\|\mathbf{E}^k\|_\infty \le 1 + p^{1/2}\sum_{k=1}^{\infty}\|\mathbf{E}^k\|_2 \\
&\le 1 + p^{1/2}\sum_{k=1}^{\infty}\|\mathbf{E}\|_2^k \le 1 + Cp^{1/2}\sum_{k=1}^{\infty}((p/n)^{1/2})^k \\
&\le 1 + Cp^{1/2}(p/n)^{1/2}
\end{aligned}$$

where we use the fact that p/n is bounded by a constant less than 1. ■

Lemma 7 *In the same setting as Lemma 6, if $\mathbf{E} = n^{-1}\mathbf{X}^T\mathbf{X} - \mathbf{I}_p$, then $\left\|\sum_{k=2}^{\infty}(-1)^{k+1}(\mathbf{E})^k\right\|_\infty \le Cp^{3/2}n^{-1}$, with probability $1-O(p^{-c})$.*

Proof Again, we use that $\|\mathbf{E}\|_2 \le C(p/n)^{1/2}$ for some constant C with probability $1-O(p^{-c})$. By similar calculations as in Lemma 6, we deduce

$$\begin{aligned}
\left\|\sum_{k=2}^{\infty}(-1)^{k+1}(\mathbf{E})^k\right\|_\infty &\le \sum_{k=2}^{\infty}\left\|(-1)^{k+1}(\mathbf{E})^k\right\|_\infty \le \sum_{k=2}^{\infty}p^{1/2}\left\|(\mathbf{E})^k\right\|_2 \\
&= \sum_{k=2}^{\infty}p^{1/2}\|\mathbf{E}\|_2^k \le \sum_{k=2}^{\infty}p^{1/2}(p/n)^{k/2} \le Cp^{3/2}n^{-1}.
\end{aligned}$$

■

Lemma 8 *Let $\mathbf{W}_j$ be nonnegative random variables for $1 \le j \le p$ that are not necessarily independent. If $P(W_j > t) \le C_1\exp(-C_2a_nt^2)$ for some constants C_1 and C_2 and for some sequence a_n, then for any $c > 0$, $\max_{1\le j\le p} W_j \le ((c+1)/C_2)^{1/2}a_n^{-1/2}(\log p)^{1/2}$ with probability at least $1-O(p^{-c})$.*

Proof Using union bound, we get

$$P(\max_{1\le j\le p} W_j > t) \le \sum_{1\le j\le p} P(W_j > t) \le pC_1\exp(-C_2a_nt^2).$$

Taking $t = a_n^{-1/2}(\log p)^{1/2}((c+1)/C_2)^{1/2}$ concludes the proof since then

$$P(\max_{1\le j\le p} W_j > a_n^{-1/2}(\log p)^{1/2}((c+1)/C_2)^{1/2}) \le C_1p^{-c}.$$

■

Lemma 9 *Let W_{ij} be random variables which are independent over the index i. Assume that there are constants C_1 and C_2 such that $P(|W_{ij}| > t) \le C_1 \exp(-C_2 t^\alpha)$ with $0 < \alpha \le 1$. Then, with probability $1 - O(p^{-c})$,*

$$\max_{0\le j\le p} \left| n^{-1} \sum_{i=1}^{n} (W_{ij} - EW_{ij}) \right| \le C n^{-(1/2)\alpha} (\log p)^{1/2},$$

for some positive constants c and C.

Proof We have $P(|n^{-1}\sum_{i=1}^n (W_{ij} - EW_{ij})| > t) \le C_3 \exp(-C_4 n^\alpha t^2)$ by Lemma 6 of Fan et al. (2016) where C_3 and C_4 are some positive constants which only depend on C_1 and C_2. This probability bound shows that the assumption of Lemma 8 holds with $a_n = n^\alpha$. Thus, Lemma 8 finishes the proof. ■

Lemma 10 *With probability $1 - O(p^{-c})$, the vector $\mathbf{r}$ defined in (27) satisfies the bound $\|n^{-1}\mathbf{r}\|_\infty = O(n^{\alpha - 5/6} \log n \sqrt{n^{-1}\log n})$.*

Proof We begin by observing that both x_{ij} and $(\mathbf{x}_i^T \boldsymbol{\beta}/\|\boldsymbol{\beta}\|_2)$ are standard normal variables. So, using Lemma 1 of Fan et al. (2016), we have $P(x_{ij}(\mathbf{x}_i^T\boldsymbol{\beta}/\|\boldsymbol{\beta}\|_2)^2 > t) \le C\exp(-Ct^{2/3})$ for some constant C which does not depend $\boldsymbol{\beta}$. It is easy to see that $x_{ij}(\mathbf{x}_i^T\boldsymbol{\beta})^2$ are independent random variables across i's with mean 0. By Lemma 9, $\max_{1\le j\le p} |n^{-1}\sum_{i=1}^n x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^2|$ is of order $O(n^{-1/3}(\log p)^{1/2})$. Moreover, $\|\boldsymbol{\beta}\|_2 \le p^{1/2}\|\boldsymbol{\beta}\|_\infty \le O(p^{1/2}\sqrt{n^{-1}\log n})$ when $\boldsymbol{\beta} \in \mathcal{N}_0$. Therefore,

$$\begin{aligned}
\|n^{-1}\mathbf{r}\|_\infty &= \max_{1\le j\le p} \left| \frac{b^{(3)}(0)}{2} \|\boldsymbol{\beta}\|_2^2 n^{-1} \sum_{i=1}^n x_{ij} (\mathbf{x}_i^T \boldsymbol{\beta}/\|\boldsymbol{\beta}\|_2)^2 \right| \\
&\le Cpn^{-1}(\log n) n^{-1/3} (\log p)^{1/2} = Cn^{\alpha - 4/3} (\log n)^{3/2} \\
&= O(n^{\alpha - 5/6} (\log n) \sqrt{n^{-1}\log n}),
\end{aligned}$$

since $p = O(n^\alpha)$. ■

Lemma 11 *With probability $1 - O(p^{-c})$, the vector $\mathbf{s}$ defined in (28) satisfies the bound $\|n^{-1}\mathbf{s}\|_\infty = O((n^{3/2\alpha - 5/4}(\log n)^{3/2} + (n^{\alpha-1}(\log n)^{1/2})\sqrt{n^{-1}\log n})$.*

Proof First, observe that for some constant C, $|n^{-1}s_j| \le C\|\boldsymbol{\beta}\|_2^3 n^{-1}\sum_{i=1}^n x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3$. Moreover, the summands $x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3$ are independent over i and they satisfy the probability bound $P(|x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3| > t) \le C\exp(-Ct^{1/2})$ by Lemma 1 of Fan et al. (2016). Thus, by Lemma 9, we obtain

$$\max_{1\le j\le p} \left| n^{-1} \sum_{i=1}^n \left(x_{ij} \left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3 - E\left[\left(x_{ij} \frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2} \right)^3 \right] \right) \right| = O(n^{-1/4}(\log p)^{1/2}).$$

Now, we calculate the expected value of the summand $x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3$. We decompose $\mathbf{x}_i^T\boldsymbol{\beta}$ as $x_{ij}\beta_j + \mathbf{x}_{i,-j}^T\boldsymbol{\beta}_{-j}$ where $\mathbf{x}_{i,-j}$ and $\boldsymbol{\beta}_{-j}$ are the vectors $\mathbf{x}_i$ and $\boldsymbol{\beta}$ whose jth entry is removed. We use the independence of $\mathbf{x}_{i,-j}$ and x_{ij} and get

$$\begin{aligned}
E\left[x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3 \right] &= \frac{1}{\|\boldsymbol{\beta}\|_2^3} E\left[x_{ij}\left(x_{ij}\beta_j + \mathbf{x}_{i,-j}^T\boldsymbol{\beta}_{-j}\right)^3 \right] \\
&= \frac{1}{\|\boldsymbol{\beta}\|_2^3} E\left[x_{ij}^4\beta_j^3 + 3x_{ij}^3\beta_j^2\left(\mathbf{x}_{i,-j}^T\boldsymbol{\beta}_{-j}\right) + 3x_{ij}^2\beta_j\left(\mathbf{x}_{i,-j}^T\boldsymbol{\beta}_{-j}\right)^2 + x_{ij}\left(\mathbf{x}_{i,-j}^T\boldsymbol{\beta}_{-j}\right)^3 \right] \\
&= \frac{1}{\|\boldsymbol{\beta}\|_2^3}\left[3\beta_j^3 + 3\beta_j\|\boldsymbol{\beta}_{-j}\|_2^2 \right] \\
&= \frac{3\beta_j}{\|\boldsymbol{\beta}\|_2}.
\end{aligned}$$

Finally, we can combine the result of Lemma 9 and the expected value of $x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3$. We bound $\|n^{-1}\mathbf{s}\|_\infty$ as follows

$$\begin{aligned}
\|n^{-1}\mathbf{s}\|_\infty &\le C\|\boldsymbol{\beta}\|_2^3 \max_{1\le j\le p} \left| n^{-1}\sum_{i=1}^n x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^3 \right| \\
&\le O\left(\|\boldsymbol{\beta}\|_2^3 (n^{-1/4}(\log p)^{1/2} + \frac{\|\boldsymbol{\beta}\|_\infty}{\|\boldsymbol{\beta}\|_2}) \right) \\
&\le O\left(\|\boldsymbol{\beta}\|_2^3 n^{-1/4}(\log p)^{1/2} + \|\boldsymbol{\beta}\|_\infty \|\boldsymbol{\beta}\|_2^2 \right).
\end{aligned}$$

Since $\boldsymbol{\beta} \in \mathcal{N}_0$, we have $\|\boldsymbol{\beta}\|_2 = O(p^{1/2}n^{-1/2}(\log p)^{1/2})$ and $\|\boldsymbol{\beta}\|_\infty = O(n^{-1/2}(\log p)^{1/2})$. Thus, $\|n^{-1}\mathbf{s}\|_\infty = O((n^{3/2\alpha-5/4}(\log n)^{3/2} + (n^{\alpha-1}(\log n)^{1/2})\sqrt{n^{-1}\log n})$ when $p = O(n^\alpha)$. ■

Lemma 12 *With probability $1 - O(p^{-c})$, the vector $\mathbf{t}$ defined in (29) satisfies the bound $\|n^{-1}\mathbf{t}\|_\infty = O(n^{2\alpha - 3/2}(\log n)^{3/2}\sqrt{n^{-1}\log n})$.*

Proof The proof is similar to the proof of Lemma 11. Since $b^{(5)}(\cdot)$ is uniformly bounded, $|n^{-1}t_j| \le C\|\boldsymbol{\beta}\|_2^4 n^{-1}\sum_{i=1}^n \left| x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^4 \right|$ for some constant C. We focus on the summands $\left| x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^4 \right|$ which are independent across i. Moreover, repeated application of Lemma 1 of Fan et al. (2016) yields $P(x_{ij}(\mathbf{x}_i^T\boldsymbol{\beta}/\|\boldsymbol{\beta}\|_2)^2 > t) \le C\exp(-Ct^{2/5})$ for some constant C independent of $\boldsymbol{\beta}$. We can bound the expected value of the summand by Cauchy-Schwartz: $E\left[\left| x_{ij}\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^4 \right| \right] \le \left(Ex_{ij}^2 E\left[\left(\frac{\mathbf{x}_i^T\boldsymbol{\beta}}{\|\boldsymbol{\beta}\|_2}\right)^8 \right] \right)^{1/2} = \sqrt{105}$. So, by Lemma 9, we get

$$\begin{aligned}
\|n^{-1}\mathbf{t}\|_\infty &\le C\|\boldsymbol{\beta}\|_2^4 (\sqrt{105} + n^{-1/5}(\log p)^{1/2}) \\
&= O(\|\boldsymbol{\beta}\|_2^4) = O(p^2 n^{-2}(\log n)^2).
\end{aligned}$$

Finally, we can deduce that $\|n^{-1}\mathbf{t}\|_\infty = O(n^{2\alpha-3/2}(\log n)^{3/2}\sqrt{n^{-1}\log n})$ when $p = O(n^\alpha)$. ■

Lemma 13 *Let* $T = \mathbf{e}_j^T(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T[\mathbf{y}-\boldsymbol{\mu}_0] - n^{-1}\mathbf{e}_j^T\mathbf{X}^T[\mathbf{y}-\boldsymbol{\mu}_0]$. *Under the assumptions of Theorem 4, we have*

$$\mathbf{e}_j^T(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T[\mathbf{y}-\boldsymbol{\mu}_0] - n^{-1}\mathbf{e}_j^T\mathbf{X}^T[\mathbf{y}-\boldsymbol{\mu}_0] = o_p(n^{-1/2}). \tag{41}$$

Proof Since $\mathbf{X}$ and $\mathbf{y}$ are independent, expectation of T is clearly zero. Then, we consider the variance of T. To this end, we condition on X. We can calculate the conditional variance of T as follows

$$\begin{aligned}\mathrm{var}[T|\mathbf{X}] &= \mathrm{var}[\mathbf{e}_j^T((\mathbf{X}^T\mathbf{X})^{-1} - n^{-1}I_p)\mathbf{X}^T(\mathbf{y}-\boldsymbol{\mu}_0)|\mathbf{X}] \\ &= \phi b''(0)\mathbf{e}_j^T((\mathbf{X}^T\mathbf{X})^{-1} - n^{-1}I_p)\mathbf{X}^T\mathbf{X}((\mathbf{X}^T\mathbf{X})^{-1} - n^{-1}I_p)\mathbf{e}_j\end{aligned}$$

where we use $\mathrm{var}[y] = \phi b''(0)I_n$. When we define $\mathbf{E} = n^{-1}\mathbf{X}^T\mathbf{X} - I_p$, simple calculations show that

$$\begin{aligned}\mathrm{Var}[T|\mathbf{X}] &= \phi b''(0)n^{-1}\mathbf{e}_j^T((n^{-1}\mathbf{X}^T\mathbf{X})^{-1} - I_p) + (n^{-1}\mathbf{X}^T\mathbf{X} - I_p))\mathbf{e}_j \\ &= \phi b''(0)n^{-1}\mathbf{e}_j^T\left(\sum_{k=2}^{\infty}(-1)^k\mathbf{E}^k\right)\mathbf{e}_j.\end{aligned}$$

Now, we can obtain the unconditional variance using the law of total variance.

$$\begin{aligned}\mathrm{var}[T] &= E[\mathrm{var}[T|\mathbf{X}]] + \mathrm{var}[E[T|\mathbf{X}]] \\ &= \phi b''(0)n^{-1}\mathbf{e}_j^T E\left(\sum_{k=2}^{\infty}(-1)^k\mathbf{E}^k\right)\mathbf{e}_j.\end{aligned}$$

Thus, using Lemma 7, we can show that $\mathrm{var}[T] = o(n^{-1})$. Finally, we use Chebyshev's inequality $P(|T| > n^{-1/2}) \le n\mathrm{var}[T] = o(1)$. So, we conclude that $T = o_p(n^{-1/2})$ ■

Lemma 14 *Let* x_{ij} *be standard normal random variables for* $1 \le i \le n$ *and* $1 \le j \le p$. *Then,* $\max_{1\le j\le p}\sum_{i=1}^n x_{ij}^2 \le n + O(n^{1/2}(\log p)^{1/2})$ *with probability* $1 - O(p^{-c})$ *for some positive constant* c. *Consequently, when* $\log p = O(n^\alpha)$ *for some* $0 < \alpha \le 1$, *we have* $\max_{1\le j\le p}\sum_{i=1}^n x_{ij}^2 = O(n)$, *for large enough* n *with probability* $1 - O(p^{-c})$.

Proof Since x_{ij} is a standard normal variable, x_{ij}^2 is subexponential random variable whose mean is 1. So, Lemma 9 entails that

$$\max_{1\le j\le p}\left|n^{-1}\sum_{i=1}^n(x_{ij}^2 - 1)\right| = O(n^{-1/2}(\log p)^{1/2})$$

with probability $1 - O(p^{-c})$. Thus, simple calculations yields

$$\max_{1\le j\le p}\sum_{i=1}^n x_{ij}^2 = \max_{1\le j\le p}\left|n + \sum_{i=1}^n(x_{ij}^2 - 1)\right| \le n + O(n^{1/2}(\log p)^{1/2})$$

with probability $1 - O(p^{-c})$. ■

B.3. Proof of Theorem 2

To prove the conclusion in Theorem 2, we use the proof by contradiction. Let us make an assumption (A) that the asymptotic normality (11) in Theorem 1 which has been proved to hold when $p = o(n^{1/2})$ continues to hold when $p \sim n^{\alpha_0}$ for some constant $1/2 < \alpha_0 \le 1$, where $\sim$ stands for asymptotic order. As shown in Section 3.1, in the case of logistic regression under global null (that is, $\boldsymbol{\beta}_0 = \mathbf{0}$) with deterministic rescaled orthonormal design matrix $\mathbf{X}$ (in the sense of $n^{-1}\mathbf{X}^T\mathbf{X} = I_p$) the limiting distribution in (11) by assumption (A) becomes

$$2^{-1}n^{1/2}\widehat{\beta}_j \xrightarrow{\mathscr{D}} N(0,1), \tag{42}$$

where $\widehat{\boldsymbol{\beta}} = (\widehat{\beta}_1, \cdots, \widehat{\beta}_p)^T$ is the MLE.

Let us now assume that the rescaled random design matrix $n^{-1/2}\mathbf{X}$ is uniformly distributed on the Stiefel manifold $V_p(\mathbb{R}^n)$ which can be thought of as the space of all $n \times p$ orthonormal matrices. Then it follows from (42) that

$$2^{-1}n^{1/2}\widehat{\beta}_j \xrightarrow{\mathscr{D}} N(0,1) \ \text{ conditional on } \mathbf{X}. \tag{43}$$

Based on the limiting distribution in (43), we can make two observations. First, it holds that

$$2^{-1}n^{1/2}\widehat{\beta}_j \xrightarrow{\mathscr{D}} N(0,1) \tag{44}$$

unconditional on the design matrix $\mathbf{X}$. Second, $\widehat{\beta}_j$ is asymptotically independent of the design matrix $\mathbf{X}$, and so is the MLE $\widehat{\boldsymbol{\beta}}$.

Since the distribution of $n^{-1/2}\mathbf{X}$ is assumed to be the Haar measure on the Stiefel manifold $V_p(\mathbb{R}^n)$, we have

$$n^{-1/2}\mathbf{X}\mathbf{Q} \overset{d}{=} n^{-1/2}\mathbf{X}, \tag{45}$$

where $\mathbf{Q}$ is any fixed $p \times p$ orthogonal matrix and $\overset{d}{=}$ stands for equal in distribution. Recall that the MLE $\widehat{\boldsymbol{\beta}}$ solves the score equation (4), which is in turn equivalent to equation

$$\mathbf{Q}^T\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}(\mathbf{X}\boldsymbol{\beta})] = \mathbf{0} \tag{46}$$

since $\mathbf{Q}$ is orthogonal. We now use the fact that the model is under global null which entails that the response vector $\mathbf{y}$ is independent of the design matrix $\mathbf{X}$. Combining this fact with (45)–(46) yields

$$\mathbf{Q}^T\widehat{\boldsymbol{\beta}} \overset{d}{=} \widehat{\boldsymbol{\beta}} \tag{47}$$

by noting that $\mathbf{X}\boldsymbol{\beta} = (\mathbf{X}\mathbf{Q})(\mathbf{Q}^T\boldsymbol{\beta})$. Since the distributional identity (47) holds for any fixed $p \times p$ orthogonal matrix $\mathbf{Q}$, we conclude that the MLE $\widehat{\boldsymbol{\beta}}$ has a spherical distribution on $\mathbb{R}^p$. It is a well-known fact that all the marginal characteristic functions of a spherical distribution have the same generator. Such a fact along with (44) entails that

$$2^{-1}n^{1/2}\widehat{\boldsymbol{\beta}} \text{ is asymptotically close to } N(\mathbf{0}, I_p). \tag{48}$$

To simplify the exposition, let us now make the asymptotic limit exact and assume that

$$\widehat{\boldsymbol{\beta}} \sim N(\mathbf{0}, 4n^{-1}I_p) \text{ and is independent of } \mathbf{X}. \tag{49}$$

The remaining analysis focuses on the score equation (4) which is solved exactly by the MLE $\widehat{\boldsymbol{\beta}}$, that is,

$$\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}(\mathbf{X}\widehat{\boldsymbol{\beta}})] = \mathbf{0}, \tag{50}$$

which leads to

$$\boldsymbol{\xi} \equiv n^{-1/2}\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}(\mathbf{0})] = n^{-1/2}\mathbf{X}^T[\boldsymbol{\mu}(\mathbf{X}\widehat{\boldsymbol{\beta}}) - \boldsymbol{\mu}(\mathbf{0})] \equiv \boldsymbol{\eta}. \tag{51}$$

Let us first consider the random variable $\boldsymbol{\xi}$ defined in (51). Note that $2[\mathbf{y} - \boldsymbol{\mu}(\mathbf{0})]$ has independent and identically distributed (i.i.d.) components each taking value 1 or -1 with equal probability $1/2$, and is independent of $\mathbf{X}$. Thus since $n^{-1/2}\mathbf{X}$ is uniformly distributed on the Stiefel manifold $V_p(\mathbb{R}^n)$, it is easy to see that

$$\boldsymbol{\xi} = n^{-1/2}\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}(\mathbf{0})] \stackrel{d}{=} 2^{-1}n^{-1/2}\mathbf{X}^T\mathbf{1}, \tag{52}$$

where $\mathbf{1} \in \mathbb{R}^n$ is a vector with all components being one. Using similar arguments as before, we can show that $\boldsymbol{\xi}$ has a spherical distribution on $\mathbb{R}^p$. Thus the joint distribution of $\boldsymbol{\xi}$ is determined completely by the marginal distribution of $\boldsymbol{\xi}$. For each $1 \le j \le p$, denote by ξ_j the jth component of $\boldsymbol{\xi} = 2^{-1}n^{-1/2}\mathbf{X}^T\mathbf{1}$ using the distributional representation in (52). Let $\mathbf{X} = (\mathbf{x}_1, \cdots, \mathbf{x}_p)$ with each $\mathbf{x}_j \in \mathbb{R}^n$. Then we have

$$\xi_j = 2^{-1}n^{-1/2}\mathbf{x}_j^T\mathbf{1} \stackrel{d}{=} 2^{-1}(n^{1/2}/\|\widetilde{\mathbf{x}}_j\|_2)n^{-1/2}\widetilde{\mathbf{x}}_j^T\mathbf{1}, \tag{53}$$

where $\widetilde{\mathbf{x}}_j \sim N(\mathbf{0}, 4^{-1}I_n)$. It follows from (53) and the concentration phenomenon of Gaussian measures that each ξ_j is asymptotically close to $N(0, 4^{-1})$ and thus consequently $\boldsymbol{\xi}$ is asymptotically close to $N(\mathbf{0}, 4^{-1}I_p)$. *A key fact (i) for the finite-sample distribution of $\boldsymbol{\xi}$ is that the standard deviation of each component ξ_j converges to $1/2$ at rate $O_P(n^{-1/2})$ that does not depend upon the dimensionality p at all.*

We now turn our attention to the second term $\boldsymbol{\eta}$ defined in (51). In view of (49) and the fact that $n^{-1/2}\mathbf{X}$ is uniformly distributed on the Stiefel manifold $V_p(\mathbb{R}^n)$, we can show that with significant probability,

$$\|\mathbf{X}\widehat{\boldsymbol{\beta}}\|_\infty \le o(1) \tag{54}$$

for $p \sim n^{\alpha_0}$ with $\alpha_0 < 1$. The uniform bound in (54) enables us to apply the mean value theorem for the vector-valued function $\boldsymbol{\eta}$ around $\boldsymbol{\beta}_0 = \mathbf{0}$, which results in

$$\begin{aligned}\boldsymbol{\eta} &= n^{-1/2}\mathbf{X}^T[\boldsymbol{\mu}(\mathbf{X}\widehat{\boldsymbol{\beta}}) - \boldsymbol{\mu}(\mathbf{0})] = 4^{-1}n^{-1/2}\mathbf{X}^T\mathbf{X}\widehat{\boldsymbol{\beta}} + \mathbf{r} \\ &= 4^{-1}n^{1/2}\widehat{\boldsymbol{\beta}} + \mathbf{r}\end{aligned} \tag{55}$$

since $n^{-1/2}\mathbf{X}$ is assumed to be orthonormal, where

$$\mathbf{r} = n^{-1/2}\mathbf{X}^T\left\{\int_0^1 \left[\boldsymbol{\Sigma}(t\mathbf{X}\widehat{\boldsymbol{\beta}}) - 4^{-1}I_n\right] dt\right\}\mathbf{X}\widehat{\boldsymbol{\beta}}. \tag{56}$$

Here, the remainder term $\mathbf{r} = (r_1, \cdots, r_p)^T \in \mathbb{R}^p$ is stochastic and each component r_j is generally of order $O_P\{p^{1/2}n^{-1/2}\}$ in light of (49) when the true model may deviate from the global null case of $\boldsymbol{\beta}_0 = \mathbf{0}$.

Since our focus in this theorem is the logistic regression model under the global null, we can in fact claim that each component r_j is generally of order $O_P\{pn^{-1}\}$, which is a better rate of convergence than the one mentioned above thanks to the assumption of $\boldsymbol{\beta}_0 = \mathbf{0}$. To prove this claim, note that the variance function $b''(\theta)$ is symmetric in $\theta \in \mathbb{R}$ and takes the maximum value $1/4$ at $\theta = 0$. Thus in view of (54), we can show that with significant probability,

$$4^{-1}I_n - \boldsymbol{\Sigma}(t\mathbf{X}\widehat{\boldsymbol{\beta}}) \ge c\mathrm{diag}\{(t\mathbf{X}\widehat{\boldsymbol{\beta}}) \circ (t\mathbf{X}\widehat{\boldsymbol{\beta}})\} = ct^2\mathrm{diag}\{(\mathbf{X}\widehat{\boldsymbol{\beta}}) \circ (\mathbf{X}\widehat{\boldsymbol{\beta}})\} \tag{57}$$

for all $t \in [0, 1]$, where $c > 0$ is some constant and $\ge$ stands for the inequality for positive semidefinite matrices. Moreover, it follows from (49) and the fact that $n^{-1/2}\mathbf{X}$ is uniformly distributed on the Stiefel manifold $V_p(\mathbb{R}^n)$ that with significant probability, all the n components of $\mathbf{X}\widehat{\boldsymbol{\beta}}$ are concentrated in the order of $p^{1/2}n^{-1/2}$. This result along with (57) and the fact that $n^{-1}\mathbf{X}^T\mathbf{X} = I_p$ entails that with significant probability,

$$\begin{aligned}&n^{-1/2}\mathbf{X}^T\left\{\int_0^1 \left[4^{-1}I_n - \boldsymbol{\Sigma}(t\mathbf{X}\widehat{\boldsymbol{\beta}})\right] dt\right\}\mathbf{X} \\ &\ge n^{-1/2}\mathbf{X}^T\left\{\int_0^1 c_* t^2 pn^{-1} dt\right\}\mathbf{X} \\ &= 3^{-1}c_* pn^{-3/2}\mathbf{X}^T\mathbf{X} = 3^{-1}c_* pn^{-1/2}I_p,\end{aligned} \tag{58}$$

where $c_* > 0$ is some constant. Thus combining (56), (58), and (49) proves the above claim.

We make two important observations about the remainder term $\mathbf{r}$ in (55). First, $\mathbf{r}$ has a spherical distribution on $\mathbb{R}^p$. This is because by (55) and (51) it holds that

$$\mathbf{r} = \boldsymbol{\eta} - 4^{-1}n^{1/2}\widehat{\boldsymbol{\beta}} = \boldsymbol{\xi} - 4^{-1}n^{1/2}\widehat{\boldsymbol{\beta}},$$

which has a spherical distribution on $\mathbb{R}^p$. Thus the joint distribution of $\mathbf{r}$ is determined completely by the marginal distribution of $\mathbf{r}$. Second, for the nonlinear setting of logistic regression model, the appearance of the remainder term $\mathbf{r}$ in (55) is due solely to *the nonlinearity of the mean function* $\boldsymbol{\mu}(\cdot)$, and we have shown that each component r_j can indeed achieve the worst-case order pn^{-1} in probability. For each $1 \le j \le p$, denote by η_j the jth component of $\boldsymbol{\eta}$. Then in view of (49) and (55), *a key fact (ii) for the finite-sample distribution of $\boldsymbol{\eta}$ is that the standard deviation of each component η_j converges to $1/2$ at rate $O_P\{pn^{-1}\}$ that generally does depend upon the dimensionality p.*

Finally, we are ready to compare the two random variables $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$ on the two sides of equation (51). Since equation (51) is a distributional identity in $\mathbb{R}^p$, naturally the square root of the sum of varξ_j's and the square root of the sum of varη_j's are expected to converge to the common value $2^{-1}p^{1/2}$ at rates that are asymptotically negligible. However, the former has rate $p^{1/2}O_P(n^{-1/2}) = O_P\{p^{1/2}n^{-1/2}\}$, whereas the latter has rate $p^{1/2}O_P\{pn^{-1}\} = O_P\{p^{3/2}n^{-1}\}$. A key consequence is that when $p \sim n^{\alpha_0}$ for some constant $2/3 \le \alpha_0 < 1$, there is a profound difference between the two asymptotic rates in that the former rate is $O_P\{n^{-(1-\alpha_0)/2}\} = o_P(1)$, while the latter rate becomes $O_P\{n^{3\alpha_0/2-1}\}$ which is now asymptotically diverging or nonvanishing. Such an intrinsic asymptotic difference is, however, prohibited by the distributional identity (51) in $\mathbb{R}^p$, which results in a contradiction. Therefore, we have now argued that assumption (A) we started with for

$2/3 \le \alpha_0 < 1$ must be false, that is, the asymptotic normality (11) which has been proved to hold when $p = o(n^{1/2})$ generally would not continue to hold when $p \sim n^{\alpha_0}$ with constant $2/3 \le \alpha_0 \le 1$. In other words, we have proved the invalidity of the conventional GLM p-values in this regime of diverging dimensionality, which concludes the proof of Theorem 2.

B.4. Proof of Theorem 3

By assumption, $\mathbf{X} \sim N(\mathbf{0}, I_n \otimes \mathbf{\Sigma})$ with covariance matrix $\mathbf{\Sigma}$ nonsingular. Let us first make a useful observation. For the general case of nonsingular covariance matrix $\mathbf{\Sigma}$, we can introduce a change of variable by letting $\widetilde{\boldsymbol{\beta}} = \mathbf{\Sigma}^{1/2}\boldsymbol{\beta}$ and correspondingly $\widetilde{\mathbf{X}} = \mathbf{X}\mathbf{\Sigma}^{-1/2}$. Clearly, $\widetilde{\mathbf{X}} \sim N(\mathbf{0}, I_n \otimes I_p)$ and the MLE for the transformed parameter vector $\widetilde{\boldsymbol{\beta}}$ is exactly $\mathbf{\Sigma}^{1/2}\widehat{\boldsymbol{\beta}}$, where $\widehat{\boldsymbol{\beta}}$ denotes the MLE under the original design matrix $\mathbf{X}$. Thus to show the breakdown point of the conventional asymptotic normality of the MLE, it suffices to focus on the specific case of $\mathbf{X} \sim N(\mathbf{0}, I_n \otimes I_p)$.

Hereafter we assume that $\mathbf{X} \sim N(\mathbf{0}, I_n \otimes I_p)$ with $p = o(n)$. The rest of the arguments are similar to those in the proof of Theorem 2 in Section B.3 except for some modifications needed for the case of Gaussian design. Specifically, for the case of logistic regression model under global null (that is, $\boldsymbol{\beta}_0 = \mathbf{0}$), the limiting distribution in (11) becomes

$$2^{-1}n^{1/2}\widehat{\beta}_j \xrightarrow{\mathscr{D}} N(0,1), \tag{59}$$

since $n^{-1}\mathbf{X}^T\mathbf{X} \to I_p$ almost surely in spectrum and thus $4^{-1}n(\mathbf{A}_n^{-1})_{jj} \to 1$ in probability as $n \to \infty$. Here, we have used a claim that both the largest and smallest eigenvalues of $n^{-1}\mathbf{X}^T\mathbf{X}$ converge to 1 almost surely as $n \to \infty$ for the case of $p = o(n)$, which can be shown by using the classical results from random matrix theory (RMT) Geman (1980); Silverstein (1985); Bai (1999).

Note that since $\mathbf{X} \sim N(0, I_n \otimes I_p)$, it holds that

$$n^{-1/2}\mathbf{X}\mathbf{Q} \overset{d}{=} n^{-1/2}\mathbf{X}, \tag{60}$$

where $\mathbf{Q}$ is any fixed $p \times p$ orthogonal matrix and $\overset{d}{=}$ stands for equal in distribution. By $\mathbf{X} \sim N(0, I_n \otimes I_p)$, it is also easy to see that

$$\boldsymbol{\xi} = n^{-1/2}\mathbf{X}^T[\mathbf{y} - \boldsymbol{\mu}(\mathbf{0})] \overset{d}{=} 2^{-1}n^{-1/2}\mathbf{X}^T\mathbf{1}, \tag{61}$$

where $\mathbf{1} \in \mathbb{R}^n$ is a vector with all components being one. In view of (49) and the assumption of $\mathbf{X} \sim N(0, I_n \otimes I_p)$, we can show that with significant probability,

$$\|\mathbf{X}\widehat{\boldsymbol{\beta}}\|_\infty \le o(1) \tag{62}$$

for $p \sim n^{\alpha_0}$ with constant $\alpha_0 < 1$. It holds further that with significant probability, all the n components of $\mathbf{X}\widehat{\boldsymbol{\beta}}$ are concentrated in the order of $p^{1/2}n^{-1/2}$. This result along with (57) and the fact that $n^{-1}\mathbf{X}^T\mathbf{X} \to I_p$ almost surely in spectrum entails that with asymptotic

probability one,

$$\begin{aligned} n^{-1/2}\mathbf{X}^T\left\{\int_0^1 \left[4^{-1}I_n - \mathbf{\Sigma}(t\mathbf{X}\widehat{\boldsymbol{\beta}})\right] dt\right\}\mathbf{X} \\ \ge n^{-1/2}\mathbf{X}^T\left\{\int_0^1 c_* t^2 p n^{-1} dt\right\}\mathbf{X} \\ = 3^{-1}c_* p n^{-3/2}\mathbf{X}^T\mathbf{X} \to 3^{-1}c_* p n^{-1/2} I_p, \end{aligned} \tag{63}$$

where $c_* > 0$ is some constant. This completes the proof of Theorem 3.

Abstract

We show that prediction performance for global-local shrinkage regression can overcome two major difficulties of global shrinkage regression: (i) the amount of relative shrinkage is monotone in the singular values of the design matrix and (ii) the shrinkage is determined by a single tuning parameter. Specifically, we show that the horseshoe regression, with heavy-tailed component-specific local shrinkage parameters, in conjunction with a global parameter providing shrinkage towards zero, alleviates both these difficulties and consequently, results in an improved risk for prediction. Numerical demonstrations of improved prediction over competing approaches in simulations and in a pharmacogenomics data set confirm our theoretical findings.

1. Introduction

We develop theoretical results on prediction risk in the high-dimensional linear regression model

$$y = X\beta + \epsilon, \tag{1}$$

where $y \in \mathbb{R}^n, X \in \mathbb{R}^{n\times p}, \beta \in \mathbb{R}^p$, $\epsilon \sim \mathcal{N}(0, \sigma^2\mathbf{I}_n)$ with $p > n$, and the design matrix X is assumed fixed. Let $\hat{\beta}$ denote the estimate of β based on the observed data y and design X. Let y^* denote a future observation generated from the same model, independent of y. Define the quadratic predictive risk

$$R = \mathbb{E}_{y^*,y|X,\beta}(y^* - X\hat{\beta})^2, \tag{2}$$

where the subscript denotes that the expectation is with respect to the data generating distribution, with X and β held fixed. We focus on comparing estimators $\hat{\beta}$ according to the criterion of Equation (2) in a *non-asymptotic* fixed n, fixed $p > n$ setting. Our approach follows the paradigm of Stein (1956), with risk results that are valid for all p and n, rather than asymptotic oracle properties. Our specific contribution, established by Theorem 5.1 and Corollary 5.1, is to identify the shortcomings of some commonly used global shrinkage estimators in prediction, with shrinkage driven by a single tuning parameter, and to demonstrate that under certain conditions, suitably-chosen component-specific local shrinkage parameters can result in theoretically lower predictive risk.

1.1. Connections with existing global shrinkage regression approaches

We define shrinkage estimators with a single tuning parameter as "global." Examples include ridge regression (Hoerl and Kennard, 1970) and principal components regression or PCR (Jolliffe, 1982), and they remain popular in prediction under the high-dimensional model of Equation (1). Shrinkage methods enjoy a number of advantages over simultaneous shrinkage and selection-based methods such as the lasso (Tibshirani, 1996) and comfortably outperform them in predictive performance in certain situations. Prominent among these is when the predictors are correlated and the resulting lasso estimate is unstable, whereas ridge or PCR estimates are not (see, e.g, the discussion in Chapter 3 of Hastie et al., 2009). On the theoretical side, Polson and Scott (2012a) used a representation devised by Frank and Friedman (1993) to show that many commonly used high-dimensional shrinkage regression estimates, such as the estimates of ridge regression, regression with g-prior (Zellner, 1986) and PCR, can be viewed as posterior means under a unified framework of "global" shrinkage prior on the regression coefficients that are suitably orthogonalized. Polson and Scott (2012a) also demonstrated that purely global shrinkage regression methods suffer from two major difficulties: (i) the amount of relative shrinkage is monotone in the singular values of the design matrix and (ii) the shrinkage is determined by a single tuning parameter. Both of these factors can translate to poor out of sample prediction performance, which they demonstrated numerically.

Polson and Scott (2012a) further provided numerical evidence that the difficulties mentioned above can be resolved by allowing "local," component-specific shrinkage terms, in conjunction with a global shrinkage parameter as used in ridge or PCR, giving rise to the

so-called "global-local" shrinkage regression models. Specifically, Polson and Scott (2012a) demonstrated by simulations that using the horseshoe prior of Carvalho et al. (2010) on the regression coefficients performed well over a variety of competitors in terms of predictive performance, including the lasso, ridge, PCR and sparse partial least squares (Chun and Keles, 2010). While these empirical results are encouraging, a theoretical investigation of the conditions required for the horseshoe regression to outperform a global shrinkage regression method such as ridge or PCR in terms of prediction has been lacking. Our work bridges this theoretical gap by developing formal tools for comparing the finite sample predictive risk for shrinkage methods.

1.2. Regression with non-convex penalties

The ℓ_1 or ℓ_2 penalties that correspond to lasso or ridge regression are convex. While this simplifies the computation, it also results in a number of drawbacks such as bias in estimating large signals (Fan and Li, 2001). This problem can be remedied using non-convex ℓ_q penalties for $0 < q < 1$, but this introduces other problems such as non-uniqueness of solutions and greater computational burden. Prominent examples of non-convex penalties include the smoothly clipped absolute deviation or SCAD (Fan and Li, 2001) and the minimax concave penalty of MCP (Zhang, 2010). In particular, the MCP estimate enjoys a number of asymptotic optimality properties and conditions required for an iterative computational algorithm to reach the global optimum are available (Mazumder et al., 2011). The optimality results, however, are valid only in an asymptotic regime with various assumptions on the design X and do not characterize finite sample risk properties. Nevertheless, the univariate MCP estimator is identical to the firm shrinkage estimator of Gao and Bruce (1997), who provide explicit finite sample expressions for predictive risk, a fact utilized later in Section 6.

1.3. Finite sample estimates of predictive risk

The quadratic risk in Equation (2) involves the future observation y^* and must be estimated. Developing a formal estimate based on the training data (X, y) to compare predictive performance of competing regression methods is important in both frequentist and Bayesian settings. This is because the frequentist tuning parameter or the Bayesian hyper-parameters can then be chosen to minimize the estimated predictive risk, if prediction of future observations is the main modeling goal. A *finite sample unbiased estimate* of R in Equation (2) is given by Stein's unbiased risk estimate or SURE (Stein, 1981).

We will focus on SURE as our estimate of R for the remainder of this article, which is an example of a model-based covariance penalty. Other examples of covariance penalties include Mallows' C_p (Mallows, 1973), Akaike's information criterion (Akaike, 1974) and risk inflation criterion (Foster and George, 1994). Nonparametric penalties include the generalized cross validation of Craven and Wahba (1978), which has the advantage of being model free but usually produces a prediction error estimate with high variance (Efron, 1983). The relationship between the covariance penalties and nonparametric approaches were further explored by Efron (2004), who showed the covariance penalties to be a Rao-Blackwellized version of the nonparametric penalties. Thus, Efron (2004) concluded that model-based penalties such as SURE or Mallows' C_p (the two coincide for models where the fit is linear

in the response variable) offer substantially lower variance in estimating the prediction risk, assuming of course the model is true. From a computational perspective, calculating SURE, when it is explicitly available, is substantially less burdensome than performing cross validation, which usually requires several Monte Carlo replications. Furthermore, SURE, an estimate of quadratic risk in prediction, also has connections with the Kullback–Leiber risk for the predictive density (George et al., 2006).

1.4. Outline of main contributions

Our main contribution is to analyze the finite sample predictive risk of global shrinkage regression methods, examine where these methods fall short, and demonstrate a remedy using local shrinkage parameters. The main results are summarized as follows.

1.4.1. Theoretical findings

The key technique to our innovation is an orthogonalized representation first employed by Frank and Friedman (1993) that allows shrinkage regression estimates to be viewed as posterior means under some suitable priors. This is formulated in Section 2. Using this representation in Sections 3 and 4, we devise general, explicit and numerically stable techniques for computing SURE for regression models that can be employed to compare the performances of global as well as horseshoe regressions. We characterize the finite sample risk properties of all competing methods by computing expectations of SURE. Consequently, all results provided in our article are valid under minimal assumptions on the design matrix, similar to the risk results by Stein (1956), where the only requirement is $n > 2$. This is at a contrast with most existing results in linear regression focusing on asymptotic minimax risk that require various assumptions on the singular values of X (e.g., Raskutti et al., 2011; Castillo et al., 2015; Dobriban and Wager, 2017).

Using the developed tools for SURE, we provide explicit finite sample risk comparisons between the global ridge and global-local horseshoe regressions in Section 5, where for all methods the tuning parameter is chosen to optimize SURE. Specifically, we demonstrate that the horseshoe regression can outperform the optimal ridge regression in prediction when most true signals are zero, but a few are large. We also compare risk of the horseshoe regression with non-convex penalized likelihood approaches such as MCP in Section 6 and show that when most of the true signals are away from zero, the risk of MCP can be quite large, unlike that of the horseshoe regression.

1.4.2. Empirical findings

Extensive numerical results are provided in Section 7 and Supplementary Section S.1. Our simulation results treat three distinct regimes: (i) sparse-robust: where most true signals are zero and a few are large, (ii) null: where all signals are zero and (iii) dense: where all signals are large. Our major finding is that the horseshoe regression outperforms the other methods in (i). Moreover, it is not much worse than ridge in (iii) and adaptive lasso in (ii), which are usually the best performers in these settings. Being a shrinkage estimate, the results for the horseshoe are numerically stable, unlike that of the selection-based estimators in the dense case. We conclude with a demonstration on real data in Section 8 and by outlining some possible extensions of the current work in Section 9.

2. Shrinkage regression estimates as posterior means

Let $X = UDW^T$ be the singular value decomposition of the design matrix. Let $D = \text{diag}(d_1, \ldots, d_n)$ with $d_1 \geq \ldots \geq d_n > 0$ and $\text{Rank}(D) = \min(n, p) = n$. Define $Z = UD$ and $\alpha = W^T\beta$. Then the regression model of Equation (1) can be reformulated as:

$$y = Z\alpha + \epsilon. \tag{3}$$

The ordinary least squared (OLS) estimate of α is $\hat{\alpha} = (Z^TZ)^{-1}Z^Ty = D^{-1}U^Ty$. Following the original results by Frank and Friedman (1993), several authors have used the well-known orthogonalization technique (Polson and Scott, 2012a; Clyde et al., 1996; Denison and George, 2012) to demonstrate that the estimates of many shrinkage regression methods can be expressed in terms of the posterior mean of the "orthogonalized" regression coefficients α under the following hierarchical model:

$$(\hat{\alpha}_i \mid \alpha_i, \sigma^2) \overset{ind}{\sim} \mathcal{N}(\alpha_i, \sigma^2 d_i^{-2}), \tag{4}$$

$$(\alpha_i \mid \sigma^2, \tau^2, \lambda_i^2) \overset{ind}{\sim} \mathcal{N}(0, \sigma^2\tau^2\lambda_i^2), \tag{5}$$

with $\sigma^2, \tau^2 > 0$. The global term τ controls the amount of shrinkage and the fixed λ_i^2 terms depend on the method at hand. Given λ_i and τ, the estimate for β under the global shrinkage prior, denoted by $\tilde{\beta}$, can be expressed in terms of the posterior mean estimate for α as follows:

$$\tilde{\alpha}_i = \frac{\tau^2\lambda_i^2 d_i^2}{1 + \tau^2\lambda_i^2 d_i^2}\hat{\alpha}_i, \quad \text{and} \quad \tilde{\beta} = \sum_{i=1}^{n} \tilde{\alpha}_i w_i, \tag{6}$$

where $\tilde{\alpha}_i = E(\alpha_i \mid \tau, \lambda_i^2, X, y)$; w_i is a $p \times 1$ vector and is the ith column of the $p \times n$ matrix W and the term $\tau^2\lambda_i^2 d_i^2/(1+\tau^2\lambda_i^2 d_i^2) \in (0, 1)$ is the shrinkage factor. The expression from Equation (6) makes it clear that it is the orthogonalized OLS estimates $\hat{\alpha}_i$s that are shrunk. We shall show that this orthogonalized representation is also particularly suitable for calculating the prediction risk estimate. The reason is tied to the independence assumption that is now feasible in Equations (4) and (5). To give a few concrete examples, we note below that several popular shrinkage regression models fall under the framework of Equations (4–5):

1. For ridge regression, $\lambda_i^2 = 1, \forall i$, and we have $\tilde{\alpha}_i = \tau^2 d_i^2 \hat{\alpha}_i/(1 + \tau^2 d_i^2)$.
2. For K component PCR, λ_i^2 is infinite for the first K components and then 0. Thus, $\tilde{\alpha}_i = \hat{\alpha}_i$ for $i = 1, \ldots, K$ and $\tilde{\alpha}_i = 0$ for $i = K+1, \ldots, n$.
3. For regression with g-prior, $\lambda_i^2 = d_i^{-2}$ and we have $\tilde{\alpha}_i = \tau^2\hat{\alpha}_i/(1+\tau^2)$ for $i = 1, \ldots, n$.

This shows the amount of relative shrinkage $\tilde{\alpha}_i/\hat{\alpha}_i$ is constant in d_i for PCR and g-prior and is monotone in d_i for ridge regression. In none of these cases it depends on the OLS estimate $\hat{\alpha}_i$ (consequently, on y). In the next section we quantify the effect of this behavior on the prediction risk estimate.

3. Stein's unbiased risk estimate for global shrinkage regression

Define the fit $\tilde{y} = X\tilde{\beta} = Z\tilde{\alpha}$, where $\tilde{\alpha}$ is the posterior mean of α. As noted by Stein (1981), the fitted risk is an underestimation of the prediction risk, and SURE for prediction is defined as:

$$SURE = ||y - \tilde{y}||^2 + 2\sigma^2 \sum_{i=1}^{n} \frac{\partial \tilde{y}_i}{\partial y_i},$$

where the $\sum_{i=1}^{n}(\partial\tilde{y}_i/\partial y_i)$ term is also known as the "degrees of freedom" (Efron, 2004). By Tweedie's formula (Masreliez, 1975; Pericchi and Smith, 1992) that relates the posterior mean with the marginals; we have for a Gaussian model of Equations (4–5) that: $\tilde{\alpha} = \hat{\alpha} + \sigma^2 D^{-2}\nabla_{\hat{\alpha}} \log m(\hat{\alpha})$, where $m(\hat{\alpha})$ is the marginal for $\hat{\alpha}$. Noting $y = Z\hat{\alpha}$ yields $\tilde{y} = y + \sigma^2 UD^{-1}\nabla_{\hat{\alpha}} \log m(\hat{\alpha})$. Using the independence of α_is, the formula for SURE becomes

$$SURE = \sigma^4 \sum_{i=1}^{n} d_i^{-2} \left\{ \frac{\partial}{\partial \hat{\alpha}_i} \log m(\hat{\alpha}_i) \right\}^2 + 2\sigma^2 \sum_{i=1}^{n} \left\{ 1 + \sigma^2 d_i^{-2} \frac{\partial^2}{\partial \hat{\alpha}_i^2} \log m(\hat{\alpha}_i) \right\}. \tag{7}$$

Thus, the prediction risk estimate for shrinkage regression can be quantified in terms of the first two derivatives of the log marginal for $\hat{\alpha}$. Integrating out α_i from Equations (4–5) yields in all these cases,

$$(\hat{\alpha}_i \mid \sigma^2, \tau^2, \lambda_i^2) \overset{ind}{\sim} \mathcal{N}(0, \sigma^2(d_i^{-2} + \tau^2\lambda_i^2)).$$

The marginal of $\hat{\alpha}$ is given by

$$m(\hat{\alpha}) \propto \prod_{i=1}^{n} \exp\left\{ -\frac{\hat{\alpha}_i^2/2}{\sigma^2(d_i^{-2} + \tau^2\lambda_i^2)} \right\},$$

which yields

$$\frac{\partial \log m(\hat{\alpha}_i)}{\partial \hat{\alpha}_i} = \frac{-\hat{\alpha}_i}{\sigma^2(d_i^{-2} + \tau^2\lambda_i^2)}; \qquad \frac{\partial^2 \log m(\hat{\alpha}_i)}{\partial \hat{\alpha}_i^2} = \frac{-1}{\sigma^2(d_i^{-2} + \tau^2\lambda_i^2)}. \tag{8}$$

Therefore, Equation (7) reduces to the following expression for SURE for global shrinkage regressions: $SURE = \sum_{i=1}^{n} SURE_i$, where,

$$SURE_i = \frac{\hat{\alpha}_i^2 d_i^2}{(1 + \tau^2\lambda_i^2 d_i^2)^2} + 2\sigma^2 \frac{\tau^2\lambda_i^2 d_i^2}{(1 + \tau^2\lambda_i^2 d_i^2)}. \tag{9}$$

From a computational perspective, the expression in Equation (9) is attractive, as it avoids costly matrix inversions. For a given σ one can choose τ to minimize the prediction risk, which amounts to a one-dimensional optimization. Note that in our notation, $d_1 \geq d_2 \ldots \geq d_n > 0$. Clearly, this is the SURE when λ_is are fixed and finite (e.g., ridge regression). For K component PCR, only the first K terms appear in the sum. The d_i terms are features of the design matrix X and one may try to control the prediction risk by varying τ. When $\tau \to \infty$, $SURE \to 2n\sigma^2$, the risk of prediction with ordinary least squares (unbiased). When $\tau \to 0$, we get the mean-only model (zero variance): $SURE \to \sum_{i=1}^{n} \hat{\alpha}_i^2 d_i^2$. Regression models with $\tau \in (0, \infty)$ represent a bias-variance tradeoff. Following are the two major difficulties of global shrinkage regression:

1. The first term of Equation (9) shows that $SURE$ is increased by those components for which $\hat{\alpha}_i^2 d_i^2$ is large. Choosing a large τ alleviates this problem, but at the expense of an $SURE_i$ of $2\sigma^2$ even for components for which $\hat{\alpha}_i^2 d_i^2$ is small (due to the second term in Equation (9)). Thus, it might be beneficial to *differentially minimize* the effect of the components for which $\hat{\alpha}_i^2 d_i^2$ is large, while ensuring those for which $\hat{\alpha}_i^2 d_i^2$ is small make a contribution less than $2\sigma^2$ to $SURE$. Yet, regression models with λ_i fixed, such as ridge, PCR, regression with g-priors, provide no mechanism for achieving this, since the relative shrinkage, defined as the ratio $\tilde{\alpha}_i/\hat{\alpha}_i$, equals $\tau^2\lambda_i^2 d_i^2/(1+\tau^2\lambda_i^2 d_i^2)$, and is solely driven by a single quantity τ.

2. Equation (6) shows that the relative shrinkage for $\hat{\alpha}_i$ is monotone in d_i; that is, those $\hat{\alpha}_i$ corresponding to a smaller d_i are necessarily shrunk more (in a relative amount). This is only sensible in the case where one has reasons to believe the low variance eigen-directions (i.e., principal components) of the design matrix are not important predictors of the response variables, an assumption that can be violated in real data (Polson and Scott, 2012a).

In the light of these two problems, we proceed to demonstrate that putting a heavy-tailed prior on λ_is, in combination with a suitably small value of τ to enable global-local shrinkage can resolve both these issues. The intuition behind this is that a small value of a *global* parameter τ enables shrinkage towards zero for all the components while the heavy tails of the *local* or component-specific λ_i terms ensure the components with large values of $\hat{\alpha}_i d_i$ are not shrunk too much, and allow the λ_i terms to be learned from the data. Simultaneously ensuring both of these factors helps in controlling the prediction risk for both the noise as well as the signal terms.

4. Stein's unbiased risk estimate for the horseshoe regression

The global-local horseshoe shrinkage regression of Polson and Scott (2012a) extends the global shrinkage regression models of the previous section by putting a local (component-specific), heavy-tailed half-Cauchy prior on the λ_i terms that allow these terms to be learned from the data, in addition to a global τ. The model equations become:

$$(\hat{\alpha}_i \mid \alpha_i, \sigma^2) \overset{ind}{\sim} \mathcal{N}(\alpha_i, \sigma^2 d_i^{-2}), \tag{10}$$

$$(\alpha_i \mid \sigma^2, \tau^2, \lambda_i^2) \overset{ind}{\sim} \mathcal{N}(0, \sigma^2\tau^2\lambda_i^2), \tag{11}$$

$$\lambda_i \overset{ind}{\sim} C^+(0,1), \tag{12}$$

with $\sigma^2, \tau^2 > 0$ and $C^+(0,1)$ denotes a standard half-Cauchy random variable with density $p(\lambda_i) = (2/\pi)(1+\lambda_i^2)^{-1}$. The posterior mean $\tilde{\alpha}$ and the regression estimate $\tilde{\beta}$ are then obtained analogously to Equation (6), with the only difference being one uses the posterior mean $\mathbb{E}(\lambda_i \mid \hat{\alpha}_i, \tau)$ instead of a fixed λ_i. The marginal prior on α_is that is obtained as a normal scale mixture by integrating out λ_is from Equations (11) and (12) is called the horseshoe prior (Carvalho et al., 2010). Improved mean square error over competing approaches in regression has been empirically observed by Polson and Scott (2012a) with horseshoe prior on α_is. The intuitive explanation for this improved performance is that a heavy tailed prior of λ_i leaves the large α_i terms of Equation (11) un-shrunk in the posterior, whereas

the global τ term provides shrinkage towards zero for all components (see, for example, the discussion by Polson and Scott, 2012b; Bhadra et al., 2017; Carvalho et al., 2010, and the references therein). However, no explicit formulation of the prediction risk under horseshoe shrinkage is available so far and we demonstrate below the heavy-tailed priors on λ_i terms, in addition to a global τ, can be beneficial in controlling the overall prediction risk.

Under the model of Equations (10–12), after integrating out α_i from the first two equations, we have,

$$(\hat{\alpha}_i \mid \sigma^2, \tau^2, \lambda_i^2) \overset{ind}{\sim} \mathcal{N}(0, \sigma^2(d_i^{-2} + \tau^2\lambda_i^2)).$$

We have, $p(\lambda_i) \propto 1/(1+\lambda_i^2)$. Thus, the marginal of $\hat{\alpha}$, denoted by $m(\hat{\alpha})$, is given up to a constant of proportionality by

$$\begin{aligned} m(\hat{\alpha}) =& \prod_{i=1}^n \int_0^\infty \mathcal{N}(\hat{\alpha}_i \mid 0, \sigma^2(d_i^{-2} + \tau^2\lambda_i^2)) p(\lambda_i) d\lambda_i \\ \propto& (2\pi\sigma^2)^{-n/2} \prod_{i=1}^n \int_0^\infty \exp\left\{ -\frac{\hat{\alpha}_i^2 d_i^2/2}{\sigma^2(1+\tau^2 d_i^2\lambda_i^2)} \right\} \frac{d_i}{(1+\tau^2 d_i^2\lambda_i^2)^{1/2}} \frac{1}{1+\lambda_i^2} d\lambda_i. \end{aligned} \tag{13}$$

This integral involves the normalizing constant of a compound confluent hypergeometric distribution that can be computed using a result of Gordy (1998).

Proposition 4.1 *(Gordy, 1998). The compound confluent hypergeometric (CCH) density is given by*

$$\mathrm{CCH}(x; p, q, r, s, \nu, \theta) = \frac{x^{p-1}(1-\nu x)^{q-1}\{\theta + (1-\theta)\nu x\}^{-r} \exp(-sx)}{B(p,q) H(p,q,r,s,\nu,\theta)},$$

for $0 < x < 1/\nu$, where the parameters satisfy $p > 0$, $q > 0$, $r \in \mathbb{R}$, $s \in \mathbb{R}$, $0 \le \nu \le 1$ and $\theta > 0$. Here $B(p,q)$ is the beta function and the function $H(\cdot)$ is given by

$$H(p,q,r,s,\nu,\theta) = \nu^{-p} \exp(-s/\nu) \Phi_1(q, r, p+q, s/\nu, 1-\theta),$$

where Φ_1 is the confluent hypergeometric function of two variables, given by

$$\Phi_1(\alpha, \beta, \gamma, x_1, x_2) = \sum_{m=0}^\infty \sum_{n=0}^\infty \frac{(\alpha)_m (\beta)_n}{(\gamma)_{m+n} m! n!} x_1^m x_2^n, \tag{14}$$

where $(a)_k$ denotes the rising factorial with $(a)_0 = 1$, $(a)_1 = a$ and $(a)_k = (a+k-1)(a)_{k-1}$.

We present our first result in the following theorem and show that the marginal $m(\hat{\alpha})$ and all its derivatives lend themselves to a series representation in terms of the first and second moments of a random variable that follows a CCH distribution. Consequently, we quantify SURE for the horseshoe regression.

Theorem 4.1 *Denote $m'(\hat{\alpha}_i) = (\partial/\partial\hat{\alpha}_i) m(\hat{\alpha}_i)$ and $m''(\hat{\alpha}_i) = (\partial^2/\partial\hat{\alpha}_i^2) m(\hat{\alpha}_i)$. Then, the following holds.*

A. *SURE for the horseshoe shrinkage regression model defined by Equations (10–12) is given by* $SURE = \sum_{i=1}^{n} SURE_i$, *where the component-wise contribution* $SURE_i$ *is given by*

$$SURE_i \;=\; 2\sigma^2 - \sigma^4 d_i^{-2}\left\{\frac{m'(\hat{\alpha}_i)}{m(\hat{\alpha}_i)}\right\}^2 + 2\sigma^4 d_i^{-2}\frac{m''(\hat{\alpha}_i)}{m(\hat{\alpha}_i)}. \tag{15}$$

B. *Under independent standard half-Cauchy prior on* λ_i*s, for the second and third terms in Equation (15) we have:*

$$\frac{m'(\hat{\alpha}_i)}{m(\hat{\alpha}_i)} = -\frac{\hat{\alpha}_i d_i^2}{\sigma^2}\mathbb{E}(Z_i), \quad \textit{and} \quad \frac{m''(\hat{\alpha}_i)}{m(\hat{\alpha}_i)} = -\frac{d_i^2}{\sigma^2}\mathbb{E}(Z_i) + \frac{\hat{\alpha}_i^2 d_i^4}{\sigma^4}\mathbb{E}(Z_i^2),$$

where $(Z_i \mid \hat{\alpha}_i, \sigma, \tau)$ *follows a* $\mathrm{CCH}(p=1, q=1/2, r=1, s=\hat{\alpha}_i^2 d_i^2/2\sigma^2, v=1, \theta = 1/\tau^2 d_i^2)$ *distribution.*

A proof is given in Appendix A.1. Theorem 4.1 provides a computationally tractable mechanism for calculating SURE for the horseshoe shrinkage regression in terms of the moments of CCH random variables. Gordy (1998) provides a simple formula for all integer moments of CCH random variables. Specifically, he shows if $X \sim \mathrm{CCH}(x; p, q, r, s, \nu, \theta)$ then

$$\mathbb{E}(X^k) = \frac{(p)_k}{(p+q)_k}\frac{H(p+k, q, r, s, \nu, \theta)}{H(p, q, r, s, \nu, \theta)}, \tag{16}$$

for integers $k \geq 1$. Moreover, as demonstrated by Gordy (1998), these moments can be numerically evaluated quite easily over a range of parameter values and calculations remain very stable. A consequence of this explicit formula for SURE is that the global shrinkage parameter τ can now be chosen to minimize SURE by performing a one-dimensional numerical optimization. Another consequence is that an application of Theorem 3 of Carvalho et al. (2010) shows

$$\lim_{|\hat{\alpha}_i|\to\infty}\frac{m'(\hat{\alpha}_i)}{m(\hat{\alpha}_i)} = \lim_{|\hat{\alpha}_i|\to\infty}\frac{\partial \log m(\hat{\alpha}_i)}{\partial \hat{\alpha}_i} = 0,$$

with high probability, where $m(\hat{\alpha}_i)$ is the marginal under the horseshoe prior. Recall that the posterior mean $\tilde{\alpha}_i$ and the OLS estimate $\hat{\alpha}_i$ are related by Tweedie's formula as $\tilde{\alpha}_i = \hat{\alpha}_i + \sigma^2 d_i^{-2}\partial \log m(\hat{\alpha}_i)/\partial\hat{\alpha}_i$. Thus, $\tilde{\alpha}_i \approx \hat{\alpha}_i$, with high probability, as $|\hat{\alpha}_i| \to \infty$, for any fixed d_i and σ for the horseshoe regression. Since $\hat{\alpha}_i$ is unbiased for α_i, the resultant horseshoe posterior mean is also seen to be unbiased when $|\hat{\alpha}_i|$ is large. Compare with the resultant $\tilde{\alpha}_i$ for global shrinkage regression of Equation (6), which is monotone decreasing in d_i, and therefore can be highly biased if a true large $|\alpha_i|$ corresponds to a small d_i. Perhaps more importantly, we can use the expression from Theorem 4.1 to estimate the prediction risk of the horseshoe regression for the signal and the noise terms. First we treat the case when $|\hat{\alpha}_i|$ is large. We have the following result.

Theorem 4.2 *Define* $s_i = \hat{\alpha}_i^2 d_i^2/2\sigma^2$, $\theta_i = (\tau^2 d_i^2)^{-1}$. *For any* $s_i \geq 1, \theta_i \geq 1$, *we have for the horseshoe regression of Equations (10–12) that*

$$\left\{1 - \theta_i(\tilde{C}_1 + \tilde{C}_2)\frac{(1+s_i)}{s_i^2} - \theta_i^2(\tilde{C}_1+\tilde{C}_2)^2\frac{(1+s_i)^2}{s_i^3}\right\} \leq \frac{SURE_i}{2\sigma^2} \leq \left\{1 + 2\theta_i(1+s_i)\left(\frac{C_1}{s_i^2} + \frac{C_2}{s_i^{3/2}}\right)\right\},$$

where $C_1 = \{1 - 5/(2e)\}^{-1/2} \approx 3.53, C_2 = 16/15, \tilde{C}_1 = (1-2/e)^{-1/2} \approx 1.95, \tilde{C}_2 = 4/3$, *are constants.*

A proof is given in Appendix A.2. Our result is non-asymptotic, i.e., it is valid for any $s_i \geq 1$. However, an easy consequence is that $SURE_i \to 2\sigma^2$, almost surely, as $s_i \to \infty$, provided $\tau^2 \leq d_i^{-2}$. An intuitive explanation of this result is that component-specific shrinkage is feasible in the horseshoe regression model due to the heavy-tailed λ_i terms, which prevents the signal terms from getting shrunk too much and consequently, making a large contribution to SURE due to a large bias. With just a global parameter τ, this component-specific shrinkage is not possible. A comparison of $SURE_i$ resulting from Theorem 4.2 with that from Equation (9) demonstrates using global-local horseshoe shrinkage, we can rectify a major shortcoming of global shrinkage regression, in that the terms with large s_i do not make a large contribution to the prediction risk. Moreover, the main consequence of Theorem 4.2, that is $SURE_i \to 2\sigma^2$, almost surely, as $s_i \to \infty$, holds for a larger class of "global-local" priors, of which the horseshoe is a special case.

Theorem 4.3 *Consider the hierarchy of Equations (10–11) and suppose the prior on* λ_i *in Equation (12) satisfies* $p(\lambda_i^2) \sim (\lambda_i^2)^{a-1}L(\lambda_i^2)$ *as* $\lambda_i^2 \to \infty$, *where* $f(x) \sim g(x)$ *means* $\lim_{x\to\infty} f(x)/g(x) = 1$. *Assume* $a \leq 0$ *and* $L(\cdot)$ *is a slowly-varying function, defined as* $\lim_{|x|\to\infty} L(tx)/L(x) = 1$ *for all* $t \in (0, \infty)$. *Then we have* $SURE_i \to 2\sigma^2$, *almost surely, as* $s_i \to \infty$.

A proof is given in Appendix A.3. Densities that satisfy $p(\lambda_i^2) \sim (\lambda_i^2)^{a-1}L(\lambda_i^2)$ as $\lambda_i^2 \to \infty$ are sometimes called regularly varying or heavy-tailed. Clearly, the horseshoe prior is a special case, since for the standard half-Cauchy we have $p(\lambda_i) \propto 1/(1+\lambda_i^2)$, which yields by a change of variables $p(\lambda_i^2) = (\lambda_i^2)^{-3/2}\{\lambda_i^2/(1+\lambda_i^2)\}$, which is of the form $(\lambda_i^2)^{a-1}L(\lambda_i^2)$ with $a = -1/2$ since $L(\lambda_i^2) = \lambda_i^2/(1+\lambda_i^2)$ is seen to be slowly-varying. Other priors that fall in this framework are the horseshoe+ prior of Bhadra et al. (2017), for which $p(\lambda_i) \propto \log(\lambda_i)/(\lambda_i^2 - 1) = \lambda_i^{-2}L(\lambda_i^2)$ with $L(\lambda_i^2) = \log(\lambda_i)\lambda_i^2/(\lambda_i^2-1)$. Ghosh et al. (2016) show that the generalized double Pareto prior (Armagan et al., 2013) and the three parameter beta prior (Armagan et al., 2011) also fall in this framework. Thus, Theorem 4.3 generalizes the main consequence of Theorem 4.2 to a broader class of priors in the asymptotic sense as $s_i \to \infty$.

Next, for the case when $|\hat{\alpha}_i|$ is small, we have the following result for estimating the prediction risk of the horseshoe regression.

Theorem 4.4 *Define* $s_i = \hat{\alpha}_i^2 d_i^2/2\sigma^2$ *and* $\theta_i = (\tau^2 d_i^2)^{-1}$. *Then the following statements are true for the horseshoe regression.*

A. $SURE_i$ *is an increasing function of* s_i *in the interval* $s_i \in [0, 1]$ *for any fixed* τ.

B. *When* $s_i = 0$, *we have that* $SURE_i$ *is a monotone increasing function of* τ, *and is bounded in the interval* $(0, 2\sigma^2/3]$ *when* $\tau^2 d_i^2 \in (0, 1]$.

C. *When* $s_i = 1$, *we have that* $SURE_i$ *is bounded in the interval* $(0, 1.93\sigma^2]$ *when* $\tau^2 d_i^2 \in (0, 1]$.

A proof is given in Appendix A.4. This theorem establishes that: (i) the terms with smaller s_i in the interval $[0, 1]$ contribute less to SURE, with the minimum achieved at $s_i = 0$ (these terms can be thought of as the noise terms) and (ii) if τ is chosen to be sufficiently small, the terms for which $s_i = 0$, has an upper bound on SURE at $2\sigma^2/3$. Note that the OLS estimator has risk $2\sigma^2$ for these terms. At $s_i = 0$, the PCR risk is either 0 or $2\sigma^2$, depending on whether the term is or is not included. A commonly used technique for shrinkage regressions is to choose the global τ to minimize a data-dependent estimate of the risk, such as C_L or SURE (Mallows, 1973). The ridge regression SURE at $s_i = 0$ is an increasing function of τ and thus, it might make sense to choose a small τ if all s_i terms were small. However, in the presence of some s_i terms that are large, ridge regression cannot choose a very small τ, since the large s_i terms will then be heavily shrunk and contribute too much to SURE. This is not the case with global-local shrinkage regression methods such as the horseshoe, which can still choose a small τ to mitigate the contribution from the noise terms and rely on the heavy-tailed λ_i terms to ensure large signals are not shrunk too much. Consequently, the ridge regression risk estimate is usually larger than the global-local regression risk estimate even for very small s_i terms, when some terms with large s_i are present along with mostly noise terms. At this point, the results concern the risk estimate (i.e., SURE) rather than risk itself, the discussion of which is deferred until Section 5.

To summarize the theoretical findings, Theorem 4.2 together with Theorem 4.4 establishes that the horseshoe regression is effective in handling both very large and very small values of $\hat{\alpha}_i^2 d_i^2$. Specifically, Theorem 4.4 asserts that a small enough τ shrinks the noise terms towards zero, minimizing their contribution to SURE. Whereas, according to Theorem 4.2, the heavy tails of the Cauchy priors for the λ_i terms ensure the large signals are not shrunk too much and ensures a SURE of $2\sigma^2$ for these terms, which is an improvement over purely global methods of shrinkage.

5. Prediction risk for the global and horseshoe regressions

In this section we compare the theoretical prediction risks of global and global-local horseshoe shrinkage regressions. While SURE is a data-dependent estimate of the theoretical risk, these two quantities are equal in expectation for all n. We use a concentration argument to derive conditions under which the horseshoe regression will outperform global shrinkage regression, e.g., ridge regression, in terms of predictive risk. While the analysis seems difficult for an arbitrary design matrix X, we are able to treat the case of ridge regression for orthogonal design, i.e., $X^T X = I$. Clearly, if the SVD of X is written as $X = UDV^T$, then we have $D = I$ and for ridge regression $\lambda_i = 1$ for all i. Thus, for orthogonal design, Equations (4) and (5) become

$$\begin{aligned}(\hat{\alpha}_i \mid \alpha_i, \sigma^2) &\overset{ind}{\sim} \mathcal{N}(\alpha_i, \sigma^2),\\ (\alpha_i \mid \sigma^2, \tau^2, \lambda_i^2) &\overset{ind}{\sim} \mathcal{N}(0, \sigma^2\tau^2),\end{aligned}$$

where τ is the global shrinkage parameter. Since the fit in this model is linear in $\hat{\alpha}_i$, SURE is equivalent to Mallows' C_L. Equation (14) of Mallows (1973) shows that if τ is chosen to

minimize C_L, then the optimal ridge estimate is given in closed form by

$$\alpha_i^\star = \left(1 - \frac{n\sigma^2}{\sum_{i=1}^n \hat{\alpha}_i^2}\right)\hat{\alpha}_i.$$

Alternatively, the solution can be directly obtained from Equation (9) by taking $d_i = \lambda_i = 1$ for all i and by setting $\tau^\star = \text{argmin}_\tau \sum_{i=1}^n SURE_i$. It is perhaps interesting to note that this "optimal" ridge estimate, where the tuning parameter is allowed to depend on the data, is no longer linear in $\hat{\alpha}$. In fact, the optimal solution $\alpha^\star$ can be seen to be closely related to the James–Stein estimate of α and its risk can therefore be quantified using the risk bounds on the James–Stein estimate. As expected due to the global nature of ridge regression, the relative shrinkage $\alpha_i^\star/\hat{\alpha}_i$ of the optimal solution only depends on $|\hat{\alpha}|^2 = \sum_{i=1}^n \hat{\alpha}_i^2$ but not on the individual components of $\hat{\alpha}$. Theorem 1 of Casella and Hwang (1982) shows that

$$1 - \frac{n-2}{n+|\alpha|^2} \le \frac{R(\alpha, \alpha^\star)}{R(\alpha, \hat{\alpha})} \le 1 - \frac{(n-2)^2}{n}\left(\frac{1}{n-2+|\alpha|^2}\right).$$

Consequently, if $|\alpha|^2/n \to c$ as $n \to \infty$ then the James–Stein estimate satisfies

$$\lim_{n\to\infty} \frac{R(\alpha, \alpha^\star)}{R(\alpha, \hat{\alpha})} = \frac{c}{c+1}.$$

Thus, $\alpha^\star$ offers large benefits over the least squares estimate $\hat{\alpha}$ for small c but it is practically equivalent to the least squares estimate for large c. The prediction risk of the least squares estimate for $p > n$ is simply $2n\sigma^2$, or an average component-specific risk of $2\sigma^2$. We first show that when true $\alpha_i = 0$, the component-specific risk bound of the horseshoe shrinkage regression with a fixed $\tau = 1$ (i.e., the case of purely local shrinkage) is less than $2\sigma^2$. We have the following result.

Theorem 5.1 *(Prediction risk for the purely local horseshoe regression). Let $D = I$ and let the global shrinkage parameter in the horseshoe regression be $\tau^2 = 1$. When true $\alpha_i = 0$, an upper bound of the component-wise risk of the purely local horseshoe regression is $1.75\sigma^2 < 2\sigma^2$.*

A proof can be found in Appendix A.5. The proof uses the fact that the actual risk can be obtained by computing the expectation of SURE. We split the domains of integration into three distinct regions and use the bounds on SURE from Theorems 4.2 and 4.4, as appropriate.

When true α_i is large enough, a consequence of Theorem 4.2 is that the component-specific risk for global-local shrinkage regression is $2\sigma^2$. This is because SURE in this case is almost surely equal to $2\sigma^2$ and $\hat{\alpha}_i$ is concentrated around true α_i. Therefore, it is established that if only a few components of true α are large and the rest are zero in such a way that $|\alpha|^2/n$ is large, then the horseshoe regression with fixed $\tau = 1$ outperforms ridge regression in terms of predictive risk. The benefit arises from a lower risk for the $\alpha_i = 0$ terms. On the other hand, if all components of true α are zero or all are large, the horseshoe regression need not outperform ridge regression.

Although Theorem 5.1 shows the horseshoe regression with a fixed $\tau = 1$ outperforms the optimal ridge regression in predictive risk when $\alpha = 0$, a useful corollary is that the optimal horseshoe regression still outperforms the optimal ridge regression, where the optimal global tuning parameters for both methods are chosen by minimizing their respective SURE.

Corollary 5.1 *(Prediction risk for the optimal horseshoe regression). Let* $SURE_{HS}(\tau = 1)$ *and* $SURE_{HS}(\tau = \tau^*_{HS})$ *denote the SURE for the horseshoe regression with fixed* $\tau = 1$ *and* $\tau = \tau^*_{HS} = \text{argmin}_\tau\,(SURE_{HS}(\tau))$*. Then, for any* α*,* $R(\alpha, \hat{\alpha}^{HS}(\tau = \tau^*_{HS})) \leq R(\alpha, \hat{\alpha}^{HS}(\tau = 1))$*.*

Proof

$$R(\alpha, \hat{\alpha}^{HS}(\tau = \tau^*_{HS})) = \mathbb{E}_{\hat{\alpha}|\alpha}(SURE_{HS}(\tau = \tau^*_{HS})) \leq \mathbb{E}_{\hat{\alpha}|\alpha}(SURE_{HS}(\tau = 1)) = R(\alpha, \hat{\alpha}^{HS}(\tau = 1)).$$

■

Clearly, τ^*_{HS} is a function of the data and this complicates exact prediction risk calculations for the optimal horseshoe regression as an expectation of SURE as in Theorem 5.1. It is not clear if an explicit minimizer of SURE analogous to Equation (14) of Mallows (1973) for ridge regression can be obtained for the horseshoe regression. Nevertheless, Corollary 5.1 shows the risk for the horseshoe regression can only decrease further if one sets $\tau = \tau^*_{HS}$, similar to the risk result of Stein (1956). This holds because the expectations of SURE are computed with respect to the distribution of $\hat{\alpha}$, which is independent of τ given true α.

6. Risk comparisons with other non-convex regressions

In this section we compare the risk of the proposed horseshoe regression with other approaches that are not shrinkage methods. Specifically, we consider the minimax concave penalty (MCP) of Zhang (2010). Again, for simplicity assume that the design matrix X is orthogonal. As pointed out by Zhang (2010), in this case the solution to the MCP estimator is available in closed form and reduces to the firm shrinkage estimator of Gao and Bruce (1997), which is given by

$$\delta_{\lambda,\gamma}(\hat{\alpha}_i) = \begin{cases} 0, & \text{if } |\hat{\alpha}_i| \leq \lambda, \\ \text{sign}(\hat{\alpha}_i)\frac{\gamma(|\hat{\alpha}_i| - \lambda)}{\gamma - 1}, & \text{if } \lambda \leq |\hat{\alpha}_i| \leq \gamma\lambda, \\ \hat{\alpha}_i, & \text{if } |\hat{\alpha}_i| > \gamma\lambda, \end{cases}$$

for $\lambda > 0$ and $\gamma > 1$. For a fixed λ, soft and hard thresholding estimators are obtained as $\gamma \to \infty$ and $\gamma \to 1+$ respectively. An explicit expression for the risk of this estimator is given in Theorem 1 of Gao and Bruce (1997), from which it can be seen easily that $R(\delta_{\lambda,\gamma}) > \lambda^2\{1/2 - \Phi(-2\lambda)\}$ when $\alpha_i = \lambda$ for any fixed $\lambda > 0$ and $\gamma > 1$, where $\Phi(\cdot)$ is the standard normal distribution function. Thus, for MCP to work well, a small value for λ is essential. However, λ is the threshold below which the estimates are shrunk to zero and a large λ is favored in a "dense" situation, where there are many true parameters several standard deviations away from zero. While this behavior is not necessarily a problem for the MCP, since it is designed with a sparse situation in mind, it is perhaps desirable to avoid a large risk at a given λ. The horseshoe regression achieves exactly that, since its component-specific risk in a dense case is $2\sigma^2$ by Theorem 4.2. In Supplementary Section S.1 we verify that the MCP performs worse than both global and global-local shrinkage methods in a dense situation under a variety of designs X.

Table 1: The true orthogonalized regression coefficients α_{0i}, their ordinary least squared estimates $\hat{\alpha}_i$, and singular values d_i of the design matrix, for $n = 100$ and $p = 500$.

7. Numerical examples

We simulate data where $n = 100$, and consider the cases $p = 100, 200, 300, 400, 500$. Let B be a $p \times k$ factor loading matrix, with all entries equal to 1. Let F_i be $k \times 1$ matrix of factor values, with all entries drawn independently from $\mathcal{N}(0, 1)$. The ith row of the $n \times p$ design matrix X is generated by a factor model, with number of factors $k = 8$, as follows:

$$X_i = BF_i + \xi_i, \quad \xi_i \sim \mathcal{N}(0, 0.1), \quad \text{for} \quad i = 1, \ldots, n.$$

Thus, the columns of X are correlated. Let $X = UDW^T$ denote the singular value decomposition of X. The observations y are generated from Equation (3) with $\sigma^2 = 1$, where for the true orthogonalized regression coefficients α_0, the 6, 30, 57, 67, and 96th components are randomly selected as signals, and the remaining 95 components are noise terms. Coefficients of the signals are generated by a $\mathcal{N}(10, 0.5)$ distribution, and coefficients of the noise terms are generated by a $\mathcal{N}(0, 0.5)$ distribution. For the case $n = 100$ and $p = 500$, some of the true orthogonalized regression coefficients α_0, their ordinary least squared estimates $\hat{\alpha}$, and the corresponding singular values d of the design matrix, are shown in Table 1.

Table 2 lists the SURE for prediction and actual out of sample sum of squared prediction error (SSE) for the ridge, lasso, PCR and horseshoe regressions. Out of sample prediction error of the adaptive lasso is also included in the comparisons, although we are unaware of a formula for computing the SURE for the adaptive lasso. SURE for ridge and PCR can be

Table 2: SURE and average out of sample prediction SSE (standard deviation of SSE) on one training set and 200 testing sets for the competing methods for $n = 100$, for ridge regression (RR), the lasso regression (LASSO), the adaptive lasso (A_LASSO), principal components regression (PCR) and the horseshoe regression (HS). The lowest SURE in each row is in italics and the lowest average prediction SSE is in bold. A formula for SURE is unavailable for the adaptive lasso.

computed by an application of Equation (9) and SURE for the horseshoe regression is given by Theorem 4.1. SURE for the lasso is calculated using the result given by Tibshirani and Taylor (2012). In each case, the model is trained on 100 samples. We report the SSE on 100 testing samples, averaged over 200 testing data sets, and their standard deviations. For ridge, lasso, PCR and horseshoe regression, the global shrinkage parameters were chosen to minimize SURE for prediction. In adaptive lasso, the shrinkage parameters were chosen by cross validation due to SURE being unavailable. It can be seen that SURE in most cases are within one standard deviation of the actual out of sample prediction SSE, suggesting SURE is an accurate method for evaluating actual out of sample prediction performance. When $p = 100, 200, 300, 400$, horseshoe regression has the lowest prediction SSE. When $p = 500$, SSE of the lasso and horseshoe regression are close, and the lasso performs marginally better. The horseshoe regression also has the lowest SURE in all but one cases. Generally, SURE increases with p for all methods. The SURE for ridge regression approaches the OLS risk, which is $2n\sigma^2 = 200$ in these situations. SURE for PCR is larger than the OLS risk and PCR happens to be the poorest performer in most settings. Performance of the adaptive lasso also degrades compared to the lasso and the horseshoe, which remain the two best performers. Finally, the horseshoe regression outperforms the lasso in four out of the five settings we considered.

Figure 1 shows contribution to SURE by each component for $n = 100$ and $p = 500$, for ridge, PCR, lasso and horseshoe regressions. The components are ordered left to right on the x-axis by decreasing magnitude of d_i, and SURE for prediction on each component are shown on the y-axis. Note from Table 1 that the $6, 30, 57, 67$ and 96th components are the signals, meaning these terms correspond to a large α_0. The PCR risk on the 96th component is 203.22, which is out of range for the y-axis in the plot. For this data set, PCR selects

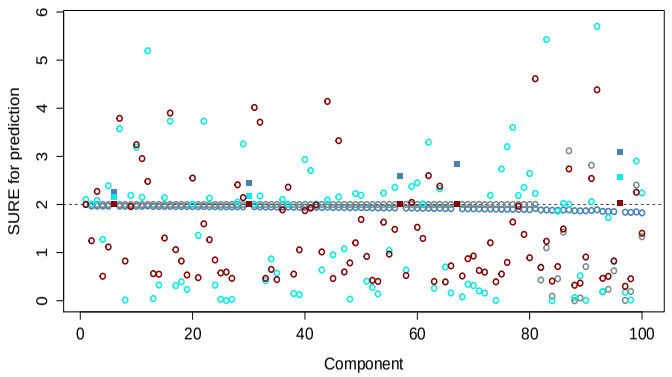

Figure 1: Component-wise SURE for ridge (blue), PCR (gray), lasso (cyan), and horseshoe regression (red), for $n = 100$ and $p = 500$. Signal components are shown in solid squares and noise components shown in blank circles. Dashed horizontal line is at $2\sigma^2 = 2$.

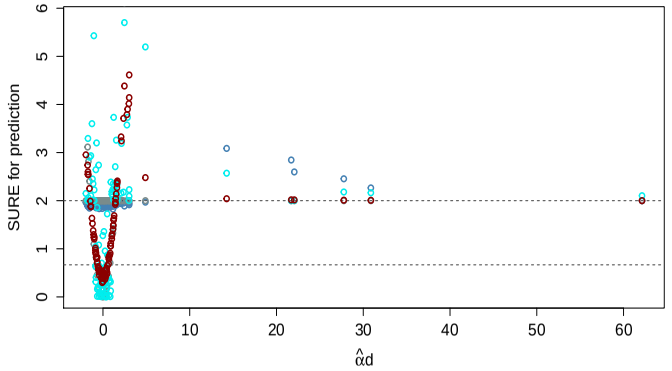

Figure 2: SURE for ridge (blue), PCR (gray), lasso (cyan) and horseshoe regression (red), versus $\hat{\alpha}d$, where $\hat{\alpha}$ is the OLS estimate of the orthogonalized regression coefficient, and d is the singular value, for $n = 100$ and $p = 500$. Dashed horizontal lines are at $2\sigma^2 = 2$ and $2\sigma^2/3 = 0.67$.

81 components, and therefore SURE for the first 81 components equal to $2\sigma^2 = 2$ and the SURE is equal to $\hat{\alpha}_i^2 d_i^2$ for $i = 82, \ldots, 100$. Component-wise SURE for ridge regression are large on the signal components, and is decreasing as the singular values d decrease on the other components. But due to the large global shrinkage parameter τ ridge must select in presence of both large signals and noise terms, the magnitude of improvement over the OLS risk $2\sigma^2$ is small for the noise terms. On the other hand, the horseshoe estimator does not shrink the components with large $\hat{\alpha}_i d_i$ heavily and therefore the horseshoe SURE on the signal components are almost equal to $2\sigma^2$ (according to Theorem 4.2). SURE for the horseshoe is also much smaller than $2\sigma^2$ on many of the noise components. Lasso also appears to be quite effective for the noise terms, but its performance for the signal components is generally not as effective as the horseshoe.

Figure 2 takes a fresh look at the same results and shows component-wise SURE plotted against $\hat{\alpha}_i d_i$. The signal components as well as the first component in Table 1 have $\hat{\alpha}_i d_i > 10$. Horseshoe SURE converges to $2\sigma^2$ for large $\hat{\alpha}_i d_i$, as expected from Theorem 4.2. For these components, the SURE for both ridge and lasso are larger than $2\sigma^2$, due to the bias introduced in estimating large signals by these methods (see also Theorem 1 of Carvalho et al., 2010). When ${\hat{\alpha}_i}^2 d_i^2 \approx 0$, risks for lasso and horseshoe are comparable, with lasso being slightly better. This is because an estimate can be exactly zero for the lasso, but not for the horseshoe, which is a shrinkage method (as opposed to a selection method). Nevertheless, the upper bound on SURE for the horseshoe regression at $2\sigma^2/3$ when ${\hat{\alpha}_i}^2 d_i^2 \approx 0$ and provided τ is chosen to be small enough so that $\tau^2 \leq d_i^{-2}$, as established by Theorem 4.4, can be verified from Figure 2.

Additional simulation results are presented in Supplementary Section S.1, where we (i) treat a higher dimensional case ($p = 1000$), (i) perform comparisons with non-convex MCP (Zhang, 2010) and SCAD (Fan and Li, 2001) regressions, (iii) explore different choices of X and (iv) explore the effect of the choice of α. The main finding is that the horseshoe regression is often the best performer when α has a sparse-robust structure as in Table 1, that is most elements are very small while a few are large so that $|\alpha|^2$ is large. This is consistent with the theoretical results of Sections 5 and 6.

8. Assessing out of sample prediction in a pharmacogenomics data set

We compare the out of sample prediction error of the horseshoe regression with ridge regression, PCR, the lasso, the adaptive lasso, MCP and SCAD on a pharmacogenomics data set. The data were originally described by Szakács et al. (2004), in which the authors studied 60 cancer cell lines in the publicly available NCI-60 database (https://dtp.cancer.gov/discovery_development/nci-2011), the normal-exponential-gamma (Griffin and Brown, 2010), the generalized double 60/). The goal here is to predict the expression of the human ABC transporter genes (responses) using some compounds or drugs (predictors) at which 50% inhibition of cellular growth for the cell lines are induced. The NCI-60 database includes the concentration level of 1429 such compounds, out of which we use 853, which did not have any missing values, as predictors. We investigate the expression levels of transporter genes A1 to A12 (except for A11, which we omit due to missing values), and B1. Thus, in our study X is a $n \times p$ matrix of predictors with $n = 60, p = 853$ and Y is a n-dimensional response vector for each of the 12 candidate transporter genes under consideration.

To test the performance of the methods, we split each data set into training and testing sets, with 75% (45 out of 60) of the observations in the training sets. We standardize each response by subtracting the mean and dividing by the standard deviation. We fit the model on the training data, and then calculate mean squared prediction error (prediction MSE) on the testing data. This is repeated for 20 random splits of the data into training and testing sets. The tuning parameters in ridge regression, the lasso, the adaptive lasso, SCAD and MCP are chosen by five-fold cross validation on the training data. Similarly, the number of components in PCR and the global shrinkage parameter τ for horseshoe regression are chosen by cross validation as well. It is possible to use SURE to select the tuning parameters or the number of components, but one needs an estimate of the standard deviation of the errors in high-dimensional regressions. This is a problem of recent interest, as the OLS estimate of σ^2 is not well-defined in the $p > n$ case. Unfortunately, some of the existing methods we tried, such as the method of moments estimator of Dicker (2014), often resulted in unreasonable estimates for σ^2, such as negative numbers. Thus, we stick to cross validation here, as it is not necessary to estimate the residual standard deviation in that case.

The average prediction MSE over 20 random training-testing splits for the competing methods is reported in Table 3. Average prediction MSE for responses A1, A8 and A10 are around or larger than 1 for all of the methods. Since the responses are standardized before analysis, we might conclude that none of the methods performed well for these cases. Among the remaining nine cases, the horseshoe regression substantially outperforms the other methods for A3, A4, A9, A12 and B1. It is comparable to PCR for A5 and A7, and is comparable to the adaptive lasso for A6, which are the best performers in the respective cases. Overall, the horseshoe regression performed the best in 5 among the total 12 cases we considered.

9. Concluding remarks

We outlined some situations where the horseshoe regression is expected to perform better compared to some other commonly used "global" shrinkage or selection alternatives for high-dimensional regression. Specifically, we demonstrated that the global term helps in mitigating the prediction risk arising from the noise terms, and an appropriate choice for the tails of the local terms is crucial for controlling the risk due to the signal terms. For this article we have used the horseshoe prior as our choice for the global-local prior. However, in recent years, several other priors have been developed that fall in this class. This includes the horseshoe+ (Bhadra et al., 2017, 2016), the three-parameter beta (Armagan et al., Pareto (Armagan et al., 2013), the generalized shrinkage prior (Denison and George, 2012) and the Dirichlet–Laplace prior (Bhattacharya et al., 2015). Empirical Bayes approaches have also appeared (Martin and Walker, 2014) and the spike and slab priors have made a resurgence due to recently developed efficient computational approaches (Ročková and George, 2014; Ročková and George, 2016). Especially in the light of Theorem 4.3, we expect the results developed in this article for the horseshoe to foreshadow similar results when many of these alternatives are deployed. A particular advantage of using the horseshoe prior seems to be the tractable expression for SURE, as developed in Theorem 4.1.

Table 3: Average out of sample mean squared prediction error computed on 20 random training-testing splits (number of splits out of 20 with lowest prediction MSE), for each of the 12 human ABC transporter genes (A1–A10, A12, B1) in the pharmacogenomics example. Methods under consideration are ridge regression (RR), principal components regression (PCR) , the lasso, the adaptive lasso (A_LASSO), the minimax concave penalty (MCP), the smoothly clipped absolute deviation (SCAD) penalty, and the horseshoe regression (HS). Lowest prediction MSE and largest number of splits with the lowest prediction MSE for each response in bold.

Whether this advantage translates to some of the other global-local priors mentioned above is an open question. Following the approach of Stein (1981), our risk results are developed in a non-asymptotic setting (finite n, finite $p > n$). In the normal means model, finite sample risk properties in estimation under heavy-tailed priors have been considered by Polson and Scott (2012b). However, their work does not consider (a) predictive risk or (b) a linear regression model. Global-local priors such as the horseshoe and horseshoe+ are known to be minimax in estimation in the Gaussian sequence model (van der Pas et al., 2014, 2016). For linear regression, frequentist minimax risk results are discussed by Raskutti et al. (2011); and Castillo et al. (2015) have shown that spike and slab priors achieve minimax prediction

risk in regression. Whether the prediction risk for the horseshoe regression is optimal in an asymptotic sense is an important question to investigate and recent asymptotic prediction risk results for ridge regression (Dobriban and Wager, 2017) should prove helpful for comparing with global shrinkage methods. Another possible direction for future investigation might be to explore the implications of our findings on the predictive density in terms of an appropriate metric, say the Kullback-Leibler loss, following the results of George et al. (2006).

Appendix A. Proofs

A.1. Proof of Theorem 4.1

Part A follows from Equation (7) with standard algebraic manipulations. To prove part B, define $Z_i = 1/(1+\tau^2\lambda_i^2 d_i^2)$. Then, from Equation (13)

$$\begin{aligned} m(\hat{\alpha}) &= (2\pi\sigma^2)^{-n/2}\prod_{i=1}^{n}\int_0^1 \exp(-z_i\hat{\alpha}_i^2 d_i^2/2\sigma^2) d_i z_i^{1/2}\left(\frac{z_i\tau^2 d_i^2}{1-z_i+z_i\tau^2 d_i^2}\right)\frac{1}{\tau d_i}(1-z_i)^{-1/2}z_i^{-3/2}dz_i \\ &= (2\pi\sigma^2)^{-n/2}\prod_{i=1}^{n}\int_0^1 \exp(-z_i\hat{\alpha}_i^2 d_i^2/2\sigma^2)(1-z_i)^{-1/2}\left\{\frac{1}{\tau^2 d_i^2}+\left(1-\frac{1}{\tau^2 d_i^2}\right)z_i\right\}^{-1}dz_i. \end{aligned}$$

From the definition of the compound confluent hypergeometric (CCH) density in Gordy (1998), the result of the integral is proportional to the normalizing constant of the CCH density and we have from Proposition 4.1 that,

$$m(\hat{\alpha}) \propto (2\pi\sigma^2)^{-n/2}\prod_{i=1}^{n} H\left(1,\frac{1}{2},1,\frac{\hat{\alpha}_i^2 d_i^2}{2\sigma^2},1,\frac{1}{\tau^2 d_i^2}\right).$$

In addition, the random variable $(Z_i \mid \hat{\alpha}_i,\sigma,\tau)$ follows a $\text{CCH}(1,1/2,1,\hat{\alpha}_i^2 d_i^2/2\sigma^2,1,1/\tau^2 d_i^2)$ distribution. Lemma 3 of Gordy (1998) gives,

$$\frac{d}{ds}H(p,q,r,s,\nu,\theta) = -\frac{p}{p+q}H(p+1,q,r,s,\nu,\theta).$$

This yields after some algebra that,

$$\begin{aligned} \frac{m'(\hat{\alpha}_i)}{m(\hat{\alpha}_i)} &= -\frac{2}{3}\frac{H\left(2,\frac{1}{2},1,\frac{\hat{\alpha}_i^2 d_i^2}{2\sigma^2},1,\frac{1}{\tau^2 d_i^2}\right)}{H\left(1,\frac{1}{2},1,\frac{\hat{\alpha}_i^2 d_i^2}{2\sigma^2},1,\frac{1}{\tau^2 d_i^2}\right)}\frac{\hat{\alpha}_i d_i^2}{\sigma^2}, \\ \frac{m''(\hat{\alpha}_i)}{m(\hat{\alpha}_i)} &= \frac{-\frac{2}{3}H\left(2,\frac{1}{2},1,\frac{\hat{\alpha}_i^2 d_i^2}{2\sigma^2},1,\frac{1}{\tau^2 d_i^2}\right)\frac{d_i^2}{\sigma^2}+\frac{8}{15}H\left(3,\frac{1}{2},1,\frac{\hat{\alpha}_i^2 d_i^2}{2\sigma^2},1,\frac{1}{\tau^2 d_i^2}\right)\frac{\hat{\alpha}_i^2 d_i^4}{\sigma^4}}{H\left(1,\frac{1}{2},1,\frac{\hat{\alpha}_i^2 d_i^2}{2\sigma^2},1,\frac{1}{\tau^2 d_i^2}\right)}. \end{aligned}$$

The correctness of the assertion

$$\frac{m'(\hat{\alpha}_i)}{m(\hat{\alpha}_i)} = -\frac{\hat{\alpha}_i d_i^2}{\sigma^2}\mathbb{E}(Z_i), \quad \text{and} \quad \frac{m''(\hat{\alpha}_i)}{m(\hat{\alpha}_i)} = -\frac{d_i^2}{\sigma^2}\mathbb{E}(Z_i) + \frac{\hat{\alpha}_i^2 d_i^4}{\sigma^4}\mathbb{E}(Z_i^2),$$

can then be verified using Equation (16), completing the proof.

A.2. Proof of Theorem 4.2

Define $s_i = \hat{\alpha}_i^2 d_i^2/2\sigma^2$ and $\theta_i = (\tau^2 d_i^2)^{-1}$, with$\theta_i \geq 1, s_i \geq 1$. From Theorem 4.1, the component-wise SURE is

$$\begin{aligned} SURE_i =& 2\sigma^2 - 2\sigma^2\mathbb{E}(Z_i) - \hat{\alpha}_i^2 d_i^2\{\mathbb{E}(Z_i)\}^2 + 2\hat{\alpha_i}^2 d_i^2\mathbb{E}(Z_i^2) \\ =& 2\sigma^2[1 - \mathbb{E}(Z_i) + 2s_i\mathbb{E}(Z_i^2) - s_i\{\mathbb{E}(Z_i)\}^2], \end{aligned} \tag{A.1}$$

Thus,

$$2\sigma^2[1 - \mathbb{E}(Z_i) - s_i\{\mathbb{E}(Z_i)\}^2] \leq SURE_i \leq 2\sigma^2[1 + 2s_i\mathbb{E}(Z_i^2)].$$

To find bounds on SURE, we need upper bounds on $\mathbb{E}(Z_i^2)$ and $\mathbb{E}(Z_i)$. Clearly, $\theta_i^{-1} \leq \{\theta_i + (1-\theta_i)z_i\}^{-1} \leq 1$, when $\theta_i \geq 1$. Let $a_i = \log(s_i^{5/2})/s_i$. Then $a_i \in [0, 5/(2e))$ when $s_i \geq 1$. Now,

$$\mathbb{E}(Z_i^2) = \frac{\int_0^1 z_i^2(1-z_i)^{-\frac{1}{2}}\{\theta_i + (1-\theta_i)z_i\}^{-1}\exp(-s_i z_i)dz_i}{\int_0^1 (1-z_i)^{-\frac{1}{2}}\{\theta_i + (1-\theta_i)z_i\}^{-1}\exp(-s_i z_i)dz_i},$$

An upper bound to the numerator of $\mathbb{E}(Z_i^2)$ can be found as follows.

$$\begin{aligned} &\int_0^1 z_i^2(1-z_i)^{-\frac{1}{2}}\{\theta_i + (1-\theta_i)z_i\}^{-1}\exp(-s_i z_i)dz_i \\ &\leq \int_0^1 z_i^2(1-z_i)^{-\frac{1}{2}}\exp(-s_i z_i)dz_i \\ &= \int_0^{a_i} z_i^2(1-z_i)^{-\frac{1}{2}}\exp(-s_i z_i)dz_i + \int_{a_i}^1 z_i^2(1-z_i)^{-\frac{1}{2}}\exp(-s_i z_i)dz_i \\ &\leq (1-a_i)^{-\frac{1}{2}}\int_0^{a_i} z_i^2\exp(-s_i z_i)dz_i + \exp(-a_i s_i)\int_{a_i}^1 z_i^2(1-z_i)^{-\frac{1}{2}}dz_i \\ &= (1-a_i)^{-\frac{1}{2}}\frac{2}{s_i^3}\left\{1 - \left(1 + a_i s_i + \frac{a_i^2 s_i^2}{2}\right)\exp(-a_i s_i)\right\} + \exp(-a_i s_i)\int_{a_i}^1 z_i^2(1-z_i)^{-\frac{1}{2}}dz_i \\ &\leq \{1 - 5/(2e)\}^{-\frac{1}{2}}\frac{2}{s_i^3} + \frac{1}{s_i^{5/2}}\int_0^1 z_i^2(1-z_i)^{-\frac{1}{2}}dz_i \\ &= \frac{C_1}{s_i^3} + \frac{C_2}{s_i^{5/2}}, \end{aligned}$$

where $C_1 = \{1 - 5/(2e)\}^{-\frac{1}{2}} \approx 3.53$ and $C_2 = \int_0^1 z_i^2(1-z_i)^{-\frac{1}{2}}dz_i = \Gamma(1/2)\Gamma(3)/\Gamma(3.5) = 16/15$. Similarly, a lower bound on the denominator of $\mathbb{E}(Z_i^2)$ is

$$\begin{aligned} &\int_0^1 (1-z_i)^{-\frac{1}{2}}\{\theta_i + (1-\theta_i)z_i\}^{-1}\exp(-s_i z_i)dz_i \\ &\geq \theta_i^{-1}\int_0^1 \exp(-s_i z_i)dz_i \\ &= \theta_i^{-1}\left\{\frac{1-\exp(-s_i)}{s_i}\right\} \geq \frac{1}{\theta_i(1+s_i)}, \end{aligned}$$

Thus, combining the upper bound on the numerator and the lower bound on the denominator

$$\mathbb{E}(Z_i^2) \leq \theta_i(1+s_i)\left(\frac{C_1}{s_i^3} + \frac{C_2}{s_i^{5/2}}\right).$$

Thus,

$$\begin{aligned} SURE_i &\leq 2\sigma^2[1 + 2s_i\mathbb{E}(Z_i^2)] \\ &\leq 2\sigma^2\left\{1 + 2\theta_i(1+s_i)\left(\frac{C_1}{s_i^2} + \frac{C_2}{s_i^{3/2}}\right)\right\}. \end{aligned} \tag{A.2}$$

An upper bound to the numerator of $\mathbb{E}(Z_i)$ can be found as follows. Let $\tilde{a}_i = \log(s_i^2)/s_i$. Then, $\tilde{a}_i \in [0, 2/e)$ for $s_i \geq 1$.

$$\begin{aligned} &\int_0^1 z_i(1-z_i)^{-\frac{1}{2}}\{\theta_i + (1-\theta_i)z_i\}^{-1}\exp(-s_i z_i)dz_i \\ &\leq \int_0^1 z_i(1-z_i)^{-\frac{1}{2}}\exp(-s_i z_i)dz_i \\ &= \int_0^{\tilde{a}_i} z_i(1-z_i)^{-\frac{1}{2}}\exp(-s_i z_i)dz_i + \int_{\tilde{a}_i}^1 z_i(1-z_i)^{-\frac{1}{2}}\exp(-s_i z_i)dz_i \\ &\leq (1-\tilde{a}_i)^{-\frac{1}{2}}\int_0^{\tilde{a}_i} z_i\exp(-s_i z_i)dz_i + \exp(-\tilde{a}_i s_i)\int_{a_i}^1 z_i(1-z_i)^{-\frac{1}{2}}dz_i \\ &= (1-\tilde{a}_i)^{-\frac{1}{2}}\frac{1}{s_i^2}\left\{1 - (1 + \tilde{a}_i s_i)\exp(-\tilde{a}_i s_i)\right\} + \exp(-\tilde{a}_i s_i)\int_{\tilde{a}_i}^1 z_i(1-z_i)^{-\frac{1}{2}}dz_i \\ &\leq (1-2/e)^{-\frac{1}{2}}\frac{1}{s_i^2} + \frac{1}{s_i^2}\int_0^1 z_i(1-z_i)^{-\frac{1}{2}}dz_i \\ &= \frac{\tilde{C}_1}{s_i^2} + \frac{\tilde{C}_2}{s_i^2}, \end{aligned}$$

where $\tilde{C}_1 = (1-2/e)^{-1/2} \approx 1.95$ and $\tilde{C}_2 = \int_0^1 z_i(1-z_i)^{-\frac{1}{2}}dz_i = \Gamma(1/2)\Gamma(2)/\Gamma(2.5) = 4/3$. The lower bound on the denominator is the same as before. Thus,

$$\mathbb{E}(Z_i) \leq \frac{\theta_i(1+s_i)}{s_i^2}\left(\tilde{C}_1 + \tilde{C}_2\right).$$

Thus,

$$\begin{aligned} SURE_i &\geq 2\sigma^2[1-\mathbb{E}(Z_i)-s_i\{\mathbb{E}(Z_i)\}^2] \\ &\geq 2\sigma^2\left\{1-\theta_i(\tilde{C}_1+\tilde{C}_2)\frac{(1+s_i)}{s_i^2}-\theta_i^2(\tilde{C}_1+\tilde{C}_2)^2\frac{(1+s_i)^2}{s_i^3}\right\}. \end{aligned} \tag{A.3}$$

Thus, combining Equations (A.2) and (A.3) we get

$$\left\{1-\theta_i(\tilde{C}_1+\tilde{C}_2)\frac{(1+s_i)}{s_i^2}-\theta_i^2(\tilde{C}_1+\tilde{C}_2)^2\frac{(1+s_i)^2}{s_i^3}\right\} \leq \frac{SURE_i}{2\sigma^2} \leq \left\{1+2\theta_i(1+s_i)\left(\frac{C_1}{s_i^2}+\frac{C_2}{s_i^{3/2}}\right)\right\},$$

for $s_i \geq 1, \theta_i \geq 1$.

A.3. Proof of Theorem 4.3

Our proof is similar to the proof of Theorem 1 of Polson and Scott (2011). Note from Equations (10–11) that integrating out α_i we have

$$\hat{\alpha}_i \mid \lambda_i^2, \sigma^2, \tau^2 \overset{ind}{\sim} \mathcal{N}(0, \sigma^2(d_i^{-2}+\tau^2\lambda_i^2)).$$

Let $p(\lambda_i^2) \sim (\lambda_i^2)^{a-1}L(\lambda_i^2)$, as $\lambda_i^2 \to \infty$ where $a \leq 0$. Define $u_i = \sigma^2(d_i^{-2}+\tau^2\lambda_i^2)$. Then, as in Theorem 1 of Polson and Scott (2011), we have

$$p(u_i) \sim u_i^{a-1}L(u_i), \text{ as } u_i \to \infty.$$

The marginal of $\hat{\alpha}_i$ is then given by

$$m(\hat{\alpha}_i) = \int \frac{1}{\sqrt{2\pi u_i}} \exp\{-\hat{\alpha}_i^2/(2u_i)\}p(u_i)du_i.$$

An application of Theorem 6.1 of Barndorff-Nielsen et al. (1982) shows that

$$m(\hat{\alpha}_i) \sim |\hat{\alpha}_i|^{2a-1}L(|\hat{\alpha}_i|) \text{ as } |\hat{\alpha}_i| \to \infty.$$

Thus, for large $|\hat{\alpha}_i|$

$$\frac{\partial \log m(\hat{\alpha}_i)}{\partial \hat{\alpha}_i} = \frac{(2a-1)}{|\hat{\alpha}_i|} + \frac{\partial \log L(|\hat{\alpha}_i|)}{\partial \hat{\alpha}_i}. \tag{A.4}$$

Clearly, the first term in Equation (A.4) goes to zero as $|\hat{\alpha}_i| \to \infty$. For the second term, we need to invoke the celebrated representation theorem by Karamata. A proof can be found in Bingham et al. (1989).

Result A.1 *(Karamata's representation theorem). A function L is slowly varying if and only if there exists $B > 0$ such that for all $x \geq B$ the function can be written in the form*

$$L(x) = \exp\left(\eta(x) + \int_B^x \frac{\varepsilon(t)}{t}\,dt\right),$$

where $\eta(x)$ is a bounded measurable function of a real variable converging to a finite number as x goes to infinity $\varepsilon(x)$ is a bounded measurable function of a real variable converging to zero as x goes to infinity.

Thus, using the properties of $\eta(x)$ and $\varepsilon(x)$ from the result above

$$\frac{d\log(L(x))}{dx} = \eta'(x) + \frac{\varepsilon(x)}{x} \to 0 \quad \text{as} \quad x \to \infty.$$

Using this in Equation (A.4) shows $\partial \log m(\hat{\alpha}_i)/\partial\hat{\alpha}_i \to 0$ as $|\hat{\alpha}_i| \to \infty$. By similar calculations, $\partial^2 \log m(\hat{\alpha}_i)/\partial^2\hat{\alpha}_i \to 0$ as $|\hat{\alpha}_i| \to \infty$. From Equation (7)

$$SURE_i = \sigma^4 d_i^{-2}\left\{\frac{\partial}{\partial\hat{\alpha}_i}\log m(\hat{\alpha}_i)\right\}^2 + 2\sigma^2\left\{1+\sigma^2 d_i^{-2}\frac{\partial^2}{\partial\hat{\alpha}_i^2}\log m(\hat{\alpha}_i)\right\}.$$

Thus, $SURE_i \to 2\sigma^2$, almost surely, as $|\hat{\alpha}_i| \to \infty$.

A.4. Proof of Theorem 4.4

The proof of Theorem 4.4 makes use of technical lemmas in Appendix A.6.

Recall from Appendix A.1 that if we define $Z_i = 1/(1+\tau^2\lambda_i^2 d_i^2)$ then the density of Z_i is given by

$$(Z_i \mid \hat{\alpha}_i, d_i, \tau, \sigma^2) \sim \text{CCH}\left(Z_i \mid 1, \frac{1}{2}, 1, \frac{\hat{\alpha}_i^2 d_i^2}{2\sigma^2}, 1, \frac{1}{\tau^2 d_i^2}\right). \tag{A.5}$$

Then SURE is given by $SURE = \sum_{i=1}^n SURE_i$ with

$$\begin{aligned} SURE_i &= 2\sigma^2[1-\mathbb{E}(Z_i)+2s_i\mathbb{E}(Z_i^2)-s_i\{\mathbb{E}(Z_i)\}^2] \\ &= 2\sigma^2[1-\mathbb{E}(Z_i)+s_i\mathbb{E}(Z_i^2)+s_i\text{Var}(Z_i)], \end{aligned} \tag{A.6}$$

where $s_i = \hat{\alpha}_i^2 d_i^2/2\sigma^2$. Thus,

$$\begin{aligned} \frac{\partial\{SURE_i\}}{\partial s_i} &= -2\sigma^2\frac{\partial\mathbb{E}(Z_i)}{\partial s_i} + 2\sigma^2\frac{\partial}{\partial s_i}\{s_i\mathbb{E}(Z_i^2)\} + 2\sigma^2\frac{\partial}{\partial s_i}\{s_i\text{Var}(Z_i)\} \\ &:= \text{I} + \text{II} + \text{III}. \end{aligned} \tag{A.7}$$

Now, as a corollary to Lemma A.1, $(\partial/\partial s_i)\mathbb{E}(Z_i) = \{\mathbb{E}(Z_i)\}^2 - \mathbb{E}(Z_i^2) = -\text{Var}(Z_i) < 0$, giving $\text{I} > 0$. The strict inequality follows from the fact that Z_i is not almost surely a constant for any $s_i \in \mathbb{R}$ and $(\partial/\partial s_i)\mathbb{E}(Z_i)$ is continuous at $s_i = 0$. Next, consider II. Define $\theta_i = (\tau^2 d_i^2)^{-1}$ and let $0 \leq s_i \leq 1$. Then,

$$\begin{aligned} \frac{\partial}{\partial s_i}\{s_i\mathbb{E}(Z_i^2)\} &= \mathbb{E}(Z_i^2) + s_i\frac{\partial}{\partial s_i}\mathbb{E}(Z_i^2) \\ &= \mathbb{E}(Z_i^2) + s_i\{\mathbb{E}(Z_i)\mathbb{E}(Z_i^2) - \mathbb{E}(Z_i^3)\} \qquad \text{(by Lemma A.1)} \\ &= s_i\mathbb{E}(Z_i)\mathbb{E}(Z_i^2) + \{\mathbb{E}(Z_i^2) - s_i\mathbb{E}(Z_i^3)\}. \end{aligned}$$

Now, clearly, the first term, $s_i\mathbb{E}(Z_i)\mathbb{E}(Z_i^2) \geq 0$. We also have $Z_i^2 - s_i Z_i^3 = Z_i^2(1-s_i Z_i) \geq 0$ a.s. when $0 \leq Z_i \leq 1$ a.s. and $0 \leq s_i \leq 1$. Thus, the second term $\mathbb{E}(Z_i^2) - s_i\mathbb{E}(Z_i^3) \geq 0$. Putting the terms together gives $\text{II} \geq 0$. Finally, consider III. Denote $\mathbb{E}(Z_i) = \mu_i$. Then,

$$\begin{aligned} \frac{\partial}{\partial s_i}\{s_i\text{Var}(Z_i)\} &= \text{Var}(Z_i) + s_i\frac{\partial}{\partial s_i}\{\text{Var}(Z_i)\} \\ &= \text{Var}(Z_i) - s_i\frac{\partial^2\mathbb{E}(Z_i)}{\partial s_i^2} \\ &= \mathbb{E}\{(Z_i-\mu_i)^2\} - s_i\mathbb{E}\{(Z_i-\mu_i)^3\} \qquad \text{(by Lemma A.2)} \\ &= \mathbb{E}[(Z_i-\mu_i)^2\{1-s_i(Z_i-\mu_i)\}]. \end{aligned}$$

Now, $(Z_i-\mu_i)^2\{1-s_i(Z_i-\mu_i)\}\geq 0$ a.s. when $0\leq Z_i\leq 1$ a.s. and $0\leq s_i\leq 1$ and thus, III ≥ 0. Using I, II and III in Equation (A.7) yields $SURE_i$ is an increasing function of s_i when $0\leq s_i\leq 1$, completing the proof of Part A.

To prove Part B, we need to derive an upper bound on SURE when $s_i=0$. First, consider $s_i=0$ and $0<\theta_i\leq 1$. we have from Equation (A.6) that $SURE_i=2\sigma^2(1-\mathbb{E}Z_i)$. By Lemma A.3, $(\partial/\partial\theta_i)\mathbb{E}(Z_i)>0$ and $SURE_i$ is a monotone decreasing function of θ_i, where $\theta_i=(\tau^2d_i^2)^{-1}$. Next consider the case where $s_i=0$ and $\theta_i\in(1,\infty)$. Define $\tilde{Z}_i=1-Z_i\in(0,1)$ when $Z_i\in(0,1)$. Then, by Equation (A.11) and a formula on Page 9 of Gordy (1998), we have that $\tilde{Z}_i$ also follows a CCH distribution. Specifically,

$$(\tilde{Z}_i\mid\hat{\alpha}_i,d_i,\tau,\sigma^2)\sim\text{CCH}\left(\tilde{Z}_i\mid\frac{1}{2},1,1,-\frac{\hat{\alpha}_i^2d_i^2}{2\sigma^2},1,\tau^2d_i^2\right),$$

and we have $SURE_i=2\sigma^2\mathbb{E}(\tilde{Z}_i)$. Define $\tilde{\theta}_i=\theta_i^{-1}=\tau^2d_i^2$. Then by Lemma A.3, $(\partial/\partial\tilde{\theta}_i)\mathbb{E}(\tilde{Z}_i)=-\text{Cov}(\tilde{Z}_i,\tilde{W}_i)>0$ on $0<\tilde{\theta}_i<1$. Therefore, $SURE_i$ is a monotone increasing function of $\tilde{\theta}_i$ on $0<\tilde{\theta}_i<1$, or equivalently a monotone decreasing function of θ_i on $\theta_i\in(1,\infty)$.

Thus, combining the two cases above, we get that SURE at $s_i=0$ is a monotone decreasing function of θ_i for any $\theta_i\in(0,\infty)$, or equivalently, an increasing function of $\tau^2d_i^2$. Since $0\leq\tilde{Z}_i\leq 1$ almost surely, a natural upper bound on $SURE_i$ is $2\sigma^2$. However, it is possible to do better provided τ is chosen sufficiently small. Assume that $\tau^2\leq d_i^{-2}$. Then, since $SURE_i$ is monotone increasing in θ_i, the upper bound on SURE is achieved when $\theta_i=(\tau^2d_i^2)^{-1}=1$. In this case, $\mathbb{E}(Z_i)$ has a particularly simple expression, given by

$$\begin{aligned}\mathbb{E}(Z_i)=&\frac{\int_0^1 z_i(1-z_i)^{-\frac{1}{2}}\{\theta_i+(1-\theta_i)z_i\}^{-1}dz_i}{\int_0^1(1-z_i)^{-\frac{1}{2}}\{\theta_i+(1-\theta_i)z_i\}^{-1}dz_i}\\ =&\frac{\int_0^1 z_i(1-z_i)^{-\frac{1}{2}}dz_i}{\int_0^1(1-z_i)^{-\frac{1}{2}}dz_i}=\frac{2}{3}.\end{aligned}\tag{A.8}$$

Thus, $\sup SURE_i=2\sigma^2(1-\mathbb{E}Z_i)=2\sigma^2/3$, completing the proof of Part B.

To prove Part C, we first note that when $s_i=1$ we have

$$SURE_i=2\sigma^2[1-\mathbb{E}(Z_i)|_{s_i=1}+2\mathbb{E}(Z_i^2)|_{s_i=1}-\{\mathbb{E}(Z_i)|_{s_i=1}\}^2]$$

where $E(Z_i)$ and $E(Z_i^2)$ are evaluated at $s_i=1$. Recall that when $\theta_i\geq 1$ and $z_i\in(0,1)$ we have $\theta_i^{-1}\leq\{\theta_i+(1-\theta_i)z_i\}^{-1}\leq 1$. Thus,

$$\begin{aligned}\mathbb{E}(Z_i^2)|_{s_i=1}=&\frac{\int_0^1 z_i^2(1-z_i)^{-\frac{1}{2}}\{\theta_i+(1-\theta_i)z_i\}^{-1}\exp(-z_i)dz_i}{\int_0^1(1-z_i)^{-\frac{1}{2}}\{\theta_i+(1-\theta_i)z_i\}^{-1}\exp(-z_i)dz_i}\\ \leq&\frac{\int_0^1 z_i^2(1-z_i)^{-\frac{1}{2}}\exp(-z_i)dz_i}{\theta_i^{-1}\int_0^1(1-z_i)^{-\frac{1}{2}}\exp(-z_i)dz_i}\approx\theta_i\frac{0.459}{1.076}=0.43\theta_i,\end{aligned}\tag{A.9}$$

and

$$\begin{aligned}\mathbb{E}(Z_i)|_{s_i=1}=&\frac{\int_0^1 z_i(1-z_i)^{-\frac{1}{2}}\{\theta_i+(1-\theta_i)z_i\}^{-1}\exp(-z_i)dz_i}{\int_0^1(1-z_i)^{-\frac{1}{2}}\{\theta_i+(1-\theta_i)z_i\}^{-1}\exp(-z_i)dz_i},\\ \geq&\frac{\theta_i^{-1}\int_0^1 z_i(1-z_i)^{-\frac{1}{2}}\exp(-z_i)dz_i}{\int_0^1(1-z_i)^{-\frac{1}{2}}\exp(-z_i)dz_i}\approx\theta_i^{-1}\frac{0.614}{1.076}=0.57\theta_i^{-1}.\end{aligned}\tag{A.10}$$

Thus,

$$SURE_i\leq 2\sigma^2\left[1-\frac{0.57}{\theta_i}+0.86\theta_i-\left(\frac{0.57}{\theta_i}\right)^2\right].$$

When $\theta_i=1$, it can be seen that $SURE_i\leq 1.93\sigma^2$.

A.5. Proof of Theorem 5.1

The proof of Theorem 5.1 makes use of technical lemmas in Appendix A.6.

Recall from Appendix A.1 that if we define $Z_i=1/(1+\tau^2\lambda_i^2d_i^2)$ then the density of Z_i is given by

$$(Z_i\mid\hat{\alpha}_i,d_i,\tau,\sigma^2)\sim\text{CCH}\left(Z_i\mid 1,1/2,1,s_i,1,\theta_i\right).\tag{A.11}$$

where $s_i=\hat{\alpha}_i^2d_i^2/2\sigma^2$ and $\theta_i=(\tau^2d_i^2)^{-1}$. Consider the case where $d_i=1$ for all i and $\tau^2=1$, i.e., $\theta_i=1$ for all i. From Equation (A.6), the risk estimate is $SURE=\sum_{i=1}^n SURE_i$ with

$$\begin{aligned}SURE_i&=2\sigma^2[1-\mathbb{E}(Z_i)+s_i\mathbb{E}(Z_i^2)+s_i\text{Var}(Z_i)],\\ &\leq 2\sigma^2[1-\mathbb{E}(Z_i)+s_i+s_i\text{Var}(Z_i)]=\check{R}_i.\end{aligned}$$

We begin by showing that the upper bound $\check{R}_i=2\sigma^2[1-\mathbb{E}(Z_i)+s_i+s_i\text{Var}(Z_i)]$ is convex in s_i when $s_i\in(0,1)$. It suffices to show $-\mathbb{E}(Z_i)$ and $s_i\text{Var}(Z_i)$ are separately convex. First, $(\partial^2/\partial^2 s_i)\mathbb{E}(Z_i)=\mathbb{E}\{(Z_i-\mu_i)^3\}\leq 0$, by Lemmas A.2 and A.4, proving $-\mathbb{E}(Z_i)$ is convex. Next,

$$\begin{aligned}\frac{\partial^2}{\partial s_i^2}\{s_i\text{Var}(Z_i)\}&=\frac{\partial}{\partial s_i}\left[\text{Var}(Z_i)+s_i\frac{\partial}{\partial s_i}\{\text{Var}(Z_i)\}\right]\\ &=2\frac{\partial}{\partial s_i}\{\text{Var}(Z_i)\}+s_i\frac{\partial^2}{\partial s_i^2}\{\text{Var}(Z_i)\}\\ &=-2\mathbb{E}(Z_i-\mu_i)^3-s_i\frac{\partial}{\partial s_i}\mathbb{E}(Z_i-\mu_i)^3\quad\text{(by Lemma A.2)}\\ &=-2\mathbb{E}(Z_i-\mu_i)^3+s_i\mathbb{E}(Z_i-\mu_i)^4,\quad\text{(by Lemma A.5)}\\ &\geq 0,\end{aligned}$$

where the last inequality follows by Lemma A.4. Thus, since $\check{R}_i$ is convex, it lies entirely below the straight line joining the two end points for $s_i\in(0,1)$. But $\check{R}_i|_{s_i=0}\leq 2\sigma^2/3=0.67\sigma^2$ (by Equation (A.8)) and

$$\check{R}_i|_{s_i=1}\leq 2\sigma^2\left[1-0.57+1+0.43-(0.57)^2\right]=3.07\sigma^2,$$

by Equations (A.9) and (A.10).Thus, by convexity

$$SURE_i \leq \check{R}_i \leq 0.67\sigma^2 + s_i(3.07 - 0.67)\sigma^2 = (0.67 + 2.4s_i)\sigma^2 \text{ for } s_i \in (0,1) \tag{A.12}$$

We remark here that our simulations suggest $SURE_i$ itself is convex, not just the upper bound $\check{R}_i$, although a proof seems elusive. Nevertheless, as we shall see below, the convexity of $\check{R}_i$ is sufficient for our purposes.

Next, consider the interval $s_i \in (1,3)$. Noting that both $\mathbb{E}(Z_i)$ and $\mathbb{E}(Z_i^2)$ are monotone decreasing functions of s_i we have

$$SURE_i \leq 2\sigma^2[1 - \mathbb{E}(Z_i)|_{s_i=3} + 2s_i\{\mathbb{E}(Z_i^2)|_{s_i=1}\} - s_i\{\mathbb{E}(Z_i)|_{s_i=3}\}^2]$$

But,

$$\mathbb{E}(Z_i)|_{s_i=3,\theta_i=1} = \frac{\int_0^1 z_i(1-z_i)^{-\frac{1}{2}}\exp(-3z_i)dz_i}{\int_0^1 (1-z_i)^{-\frac{1}{2}}\exp(-3z_i)dz_i} = 0.35.$$

$\mathbb{E}(Z_i^2)|_{s_i=1} < 0.43$ from Equation (A.9). Thus,

$$SURE_i \leq 2\sigma^2[1 - 0.35 + 0.86s_i - s_i(0.35)^2\}^2] = 2\sigma^2(0.65 + 0.74s_i) \text{ for } s_i \in (1,3). \tag{A.13}$$

Using the upper bound from Theorem 4.2,

$$SURE_i \leq 11.55\sigma^2 \text{ for } s_i \geq 3. \tag{A.14}$$

When $\alpha_i = 0$, we have that $\hat{\alpha}_i \sim \mathcal{N}(0, \sigma^2 d_i^{-2})$. Thus, $\hat{\alpha}_i^2 d_i^2/\sigma^2 \sim \chi^2(1)$. Since $s_i = \hat{\alpha}_i^2 d_i^2/2\sigma^2$ we have that $p(s_i) = (\pi)^{-1/2} s_i^{-1/2}\exp(-s_i)$ for $s_i \in (0,\infty)$. Combining Equations (A.12), (A.13) and (A.14) we have

$$\begin{aligned}
\text{Risk}_i = \mathbb{E}(SURE_i) \leq & \int_0^1 \sigma^2(0.67 + 2.4s_i)\pi^{-1/2}s_i^{-1/2}\exp(-s_i)ds_i \\
& + \int_1^3 2\sigma^2(0.65 + 0.74s_i)\pi^{-1/2}s_i^{-1/2}\exp(-s_i)ds_i \\
& + \int_3^\infty 11.55\sigma^2\pi^{-1/2}s_i^{-1/2}\exp(-s_i)ds_i \\
& = 1.75\sigma^2.
\end{aligned}$$

A.6. Technical lemmas

Lemma A.1 *If $Z \sim \text{CCH}(p,q,r,s,\nu,\theta)$, then $(\partial/\partial s)\mathbb{E}(Z^k) = \mathbb{E}(Z)\mathbb{E}(Z^k) - \mathbb{E}(Z^{k+1})$.*

Lemma A.2 *If $Z \sim \text{CCH}(p,q,r,s,\nu,\theta)$, then $(\partial^2/\partial^2 s)\mathbb{E}(Z) = -(\partial/\partial s)\text{Var}(Z) = \mathbb{E}\{(Z-\mu)^3\}$, where $\mu = \mathbb{E}(Z)$.*

Lemma A.3 *If $Z \sim \text{CCH}(p,q,r,s,\nu,\theta)$, then $(\partial/\partial\theta)\mathbb{E}(Z) = -\text{Cov}(Z,W)$, for $W = (1-\nu Z)\{\theta + (1-\theta)\nu Z\}^{-1}$. If $0 < \theta \leq 1$ then $(\partial/\partial\theta)\mathbb{E}(Z) > 0$.*

Lemma A.4 *If $Z \sim \text{CCH}(p,q,r,s,1,1)$ with $q > p$, then $\mathbb{E}(Z-\mu)^3 \leq 0$, where $\mu = \mathbb{E}(Z)$.*

Lemma A.5 *If $Z \sim \text{CCH}(p,q,r,s,\nu,\theta)$, then $(\partial/\partial s)\mathbb{E}(Z-\mu)^3 = -\mathbb{E}\{(Z-\mu)^4\}$, where $\mu = \mathbb{E}(Z)$.*

A.6.1. Proof of Lemma A.1

Let, $Z \sim \text{CCH}(p,q,r,s,\nu,\theta)$. Then for any integer k

$$\mathbb{E}(Z^k) = \frac{\int_0^{1/\nu} z^{k+p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}.$$

Thus,

$$\begin{aligned}
\frac{\partial}{\partial s}\mathbb{E}(Z^k) = & \frac{\int_0^{1/\nu} -z^{k+p}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz} \\
& - \left[\frac{\int_0^{1/\nu} z^{k+p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right. \\
& \left. \times \frac{\int_0^{1/\nu} -z^{p}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right] \\
= & -\mathbb{E}(Z^{k+1}) + \mathbb{E}(Z)\mathbb{E}(Z^k).
\end{aligned}$$

For an alternative proof directly using the $H(\cdot)$ functions, see Appendix D of Gordy (1998).

A.6.2. Proof of Lemma A.2

Let, $Z \sim \text{CCH}(p,q,r,s,\nu,\theta)$. From Lemma A.1, $(\partial/\partial s)\mathbb{E}(Z) = -\mathbb{E}(Z^2) + \{\mathbb{E}(Z)\}^2 = -\text{Var}(Z)$. Let $\mu = \mathbb{E}(Z)$. Then,

$$\begin{aligned}
\frac{\partial^2}{\partial s^2}\mathbb{E}(Z) = & -\frac{\partial}{\partial s}\text{Var}(Z) \\
= & -\frac{\partial}{\partial s}\left[\frac{\int_0^{1/\nu}(z-\mu)^2 z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right] \\
= & \frac{\int_0^{1/\nu}(z-\mu)^2 z^{p}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz} \\
& - \left[\frac{\int_0^{1/\nu}(z-\mu)^2 z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right. \\
& \left. \times \frac{\int_0^{1/\nu} z^{p}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta + (1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right] \\
= & \text{Cov}(Z,(Z-\mu)^2) \\
= & \mathbb{E}[(Z-\mu)\{(Z-\mu)^2 - \mathbb{E}(Z-\mu)^2\}] \\
= & \mathbb{E}\{(Z-\mu)^3\} - \text{Var}(Z)\mathbb{E}(Z-\mu) = \mathbb{E}\{(Z-\mu)^3\}.
\end{aligned}$$

A.6.3. Proof of Lemma A.3

Let $Z \sim \text{CCH}(p, q, r, s, \nu, \theta)$ and $W = (1 - \nu Z)\{\theta + (1 - \theta)\nu Z\}^{-1}$. Then,

$$\begin{aligned}\frac{\partial}{\partial\theta}\mathbb{E}(Z) =& -\frac{\int_0^{1/\nu} z^p(1-\nu z)^q\{\theta+(1-\theta)\nu z\}^{-(r+1)}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}\\ &+\left[\frac{\int_0^{1/\nu} z^p(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right.\\ &\left.\times\frac{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q}\{\theta+(1-\theta)\nu z\}^{-(r+1)}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right]\\ =& -\mathbb{E}(ZW)+\mathbb{E}(Z)\mathbb{E}(W) = -\text{Cov}(Z, W).\end{aligned}$$

When $0 < \theta \leq 1$, it is obvious that Z and W are negatively correlated, and thus $-\text{Cov}(Z, W) > 0$.

A.6.4. Proof of Lemma A.4

Let $Z \sim \text{CCH}(p, q, r, s, 1, 1)$. Then,

$$\mathbb{E}(Z-\mu)^3 = \frac{\int_0^1 (z-\mu)^3 z^{p-1}(1-z)^{q-1}\exp(-sz)dz}{\int_0^1 z^{p-1}(1-z)^{q-1}\exp(-sz)dz},$$

which can be seen to have the same sign as the third central moment, or skewness of a $\text{Beta}(p, q)$ random variable, which is negative when $q > p$.

A.6.5. Proof of Lemma A.5

Let, $Z \sim \text{CCH}(p, q, r, s, \nu, \theta)$. Let $\mu = \mathbb{E}(Z)$. Then,

$$\begin{aligned}\frac{\partial}{\partial s}\mathbb{E}(Z-\mu)^3 =& -\frac{\int_0^{1/\nu}(z-\mu)^3 z^p(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}\\ &+\left[\frac{\int_0^{1/\nu}(z-\mu)^3 z^{p-1}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right.\\ &\left.\times\frac{\int_0^{1/\nu} z^{p}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}{\int_0^{1/\nu} z^{p-1}(1-\nu z)^{q-1}\{\theta+(1-\theta)\nu z\}^{-r}\exp(-sz)dz}\right]\\ =& -\text{Cov}(Z, (Z-\mu)^3)\\ =& -\mathbb{E}[(Z-\mu)\{(Z-\mu)^3 - \mathbb{E}(Z-\mu)^3\}]\\ =& -\mathbb{E}\{(Z-\mu)^4\} + \mathbb{E}(Z-\mu)^3\mathbb{E}(Z-\mu) = -\mathbb{E}\{(Z-\mu)^4\}.\end{aligned}$$

S.1. Additional simulations

We provide additional simulation results, complementing the results in Table 2. For each simulation setting, we report SURE when a formula is available. We also report the average out of sample prediction SSE (standard deviation of SSE) computed based on one training set and 200 testing sets. For each setting, $n = 100$. The methods under consideration are ridge regression (RR), principal components regression (PCR), the lasso, the adaptive lasso (A_LASSO), the minimax concave penalty (MCP), the smoothly clipped absolute deviation (SCAD) penalty and the proposed horseshoe regression (HS). The method with the **lowest SSE** is in bold and that with *lowest SURE* is in italics for each setting. The features of these additional simulations include the following.

1. We explore a higher dimensional case ($p = 1000$) for each setting.
2. We incorporate two non-convex regression methods for comparisons. These are SCAD (Fan and Li, 2001) and MCP (Zhang, 2010).
3. We explore different choices of the design matrix X. These include three cases: (i) X is generated from a factor model, where it is relatively ill-conditioned (as in Table 2), (ii) X is generated from a standard normal, where it is well-conditioned and (iii) X is exactly orthogonal, with all singular values equal to 1. These are reported in corresponding table captions.
4. We explore different choices of true α. These include three cases: (i) Sparse-robust α, where most elements of α are close to zero and a few are large, (ii) null α, where all elements of α are zero and (iii) dense α, where all elements are non-zero. Exact settings and the value of $||\alpha||^2$ are reported in the table captions.

The major finding is that the horseshoe regression outperforms the other global shrinkage methods (ridge and PCR) when α is sparse-robust, which is consistent with the theoretical observation in Section 5. It also outperforms the other selection-based methods in this case. On the other hand, the dense α case is most often favorable to ridge regression, while the null α case is favorable to selection-based methods such as the lasso, adaptive lasso, MCP or SCAD, due to the ability of these methods to produce exact zero estimates. However, the selection-based methods perform considerably worse compared to both global and global-local shrinkage methods in the dense α case.

Table S.1: Sparse-robust α (five large coefficients equal to 10 and other coefficients equal to 0.5 or -0.5 randomly, giving $\sum_{i=1}^{n} \alpha_i^2 = 523.75$); X generated by a factor model with 4 factors, each factor follows a standard normal distribution; d_1/d_n is the ratio of largest and smallest singular values of X.

Abstract

The quantification problem consists of determining the prevalence of a given label in a target population. However, one often has access to the labels in a sample from the training population but not in the target population. A common assumption in this situation is that of prior probability shift, that is, once the labels are known, the distribution of the features is the same in the training and target populations. In this paper, we derive a new lower bound for the risk of the quantification problem under the prior shift assumption. Complementing this lower bound, we present a new approximately minimax class of estimators, ratio estimators, which generalize several previous proposals in the literature. Using a weaker version of the prior shift assumption, which can be tested, we show that ratio estimators can be used to build confidence intervals for the quantification problem. We also extend the ratio estimator so that it can: (i) incorporate labels from the target population, when they are available and (ii) estimate how the prevalence of positive labels varies according to a function of certain covariates.

Keywords: quantification, prior probability shift, data set shift, domain shift, semi-supervised learning

1. Introduction

In several applications of binary classifiers, predicting the labels of individual observations *per se* is less important than evaluating the proportion of each label on an unlabeled target data set. The latter task is called quantification (Forman, 2008). For example, a company may be interested in evaluating the proportion of users who like each of their products, without access to labeled reviews of these products.

A common approach to such a problem is to (i) train a classifier for the user's evaluation based on labeled reviews of other products, and (ii) apply this classifier to the unlabeled target set and use the proportion of users who are classified as liking the product as an estimator. However, it is known that this two-step approach, known as "classify and count", fails because of domain shift (Forman, 2006; Tasche, 2016). In order to deal with this problem, several improvements have been proposed under an assumption named prior shift (Saerens et al., 2002; Forman, 2008; Bella et al., 2010; Barranquero et al., 2015). A particular estimator that successfully performs quantification is the adjusted count (AC) estimator (Gart and Buck, 1966; Saerens et al., 2002; Forman, 2008). Part of the success of the AC estimator is explained in Tasche (2017) by showing that it is Fisher consistent. However, there are more properties one might desire of an estimator.

In order to investigate these properties, Vaz et al. (2017) introduces the ratio estimator, which is a generalization of the AC estimator. Vaz et al. (2017) derives the asymptotic mean squared error of the ratio estimator. Here, we show that the ratio estimator is approximately minimax and consistent under the prior probability shift assumption. In order to derive this result, we prove a new lower bound for the risk of the quantification problem under the prior shift assumption. This lower bound is general and applies to every method under the prior probability shift assumption. We also derive a central limit theorem for the ratio estimator which helps to explain its good performance and leads to a method for building confidence intervals for the quantification problem. This result also allows us to propose a new type of ratio estimator based on Reproducing Kernel Hilbert spaces. Since the AC estimator and the method in Bella et al. (2010) are special cases of the ratio estimator, they benefit from all of the results above.

It is important to evaluate whether the prior probability shift assumption indeed holds, otherwise the AC method can perform poorly (Tasche, 2017). We show that the ratio estimator works under an assumption that is less stringent than the prior shift assumption. Moreover, we show how this assumption can be tested. We are not aware of other methods to test the prior shift and related assumptions.

We also generalize the ratio estimator to two extensions of the quantification problem. In the first scenario, some labels are available in the target population. The combined estimator extends the ratio estimator in order to incorporate these labels and obtain a larger effective sample size. The second scenario considers that the prevalence of each label varies according to additional covariates. This generalization allows one to use unlabeled data to identify e.g. how the approval of a product varies with age. In this scenario, we introduce the regression ratio estimator, which offers improvements over the standard methods that are used in sentiment analyses (Wang et al., 2012).

Section 2 discusses the standard quantification problem under the prior probability shift assumption. Subsection 2.1 provides new lower bounds for the risk in this scenario. Subsection 2.2 introduces the ratio estimator, uses the result from the previous subsection to show that it is approximately minimax and also derives its convergence rate and a central limit theorem. Subsection 2.3 uses the asymptotic behavior of the ratio estimator to propose a new type of ratio estimator based on Reproducing Kernel Hilbert spaces. Finally, the ratio estimator requires a weaker version of prior probability shift to obtain consistency. Subsection 2.4 discusses a new algorithm for testing this assumption.

Section 3 proposes extensions of the ratio estimator to scenarios which are more general than the standard quantification problem. Subsection 3.1 proposes the combined estimator, for cases in which some labels are available in the population of interest. Subsection 3.2 proposes the ratio regression estimator, for the situation in which the prevalence of a given label varies according to a covariate. All proofs are presented in the appendix; code and data used for the experiments is available at `https://github.com/afonsofvaz/ratio_estimator`.

2. Quantification under prior probability shift

In order to formally approach the quantification problem, we use the same notation as in Wasserman (2006). If $\mathbf{Z}_1 \in \mathbb{R}^{d_1}$ and $\mathbf{Z}_2 \in \mathbb{R}^{d_2}$ are random vectors and $R \subset \mathbb{R}^{d_1}$, then $\mathbb{P}(\mathbf{Z}_1 \in R|\mathbf{Z}_2)$ is the conditional probability that $\mathbf{Z}_1$ is in R given $\mathbf{Z}_2$. Using $\mathbb{P}$, one can obtain $F_{\mathbf{Z}_1|\mathbf{Z}_2}$, $f_{\mathbf{Z}_1|\mathbf{Z}_2}$, $\mathbb{E}[\mathbf{Z}_1|\mathbf{Z}_2]$, and $\mathbb{V}[\mathbf{Z}_1|\mathbf{Z}_2]$ which are, respectively, the conditional distribution, density, expected value and variance of $\mathbf{Z}_1$ given $\mathbf{Z}_2$. Marginal properties of $\mathbf{Z}_1$ are indicated by omitting the conditioning random variable. Also, if $(\mathbf{Z}_n)_{n\in\mathbb{N}}$ is a sequence of random vectors, then $\mathbf{Z}_n \xrightarrow{a.s.} \mathbf{Z}$, $\mathbf{Z}_n \xrightarrow{\mathbb{P}} \mathbf{Z}$, and $\mathbf{Z}_n \rightsquigarrow \mathbf{Z}$ indicate respectively, that $\mathbf{Z}_n$ converges almost surely, in probability, and in distribution to $\mathbf{Z}$. In order to express the rate at which convergence occurs, it is useful to use $\mathcal{O}$ and Ω notation. If $(a_n)_{n\in\mathbb{N}}$ is a sequence in $\mathbb{R}$, then $a_n = \mathcal{O}(g(n))$ if there exists c such that, for every n, $a_n \leq c \cdot g(n)$ and $a_n = \Omega(g(n))$ if there exists c such that, for every n, $a_n \geq c \cdot g(n)$. Finally, $\mathbb{I}$ is the indicator function. An expression such as $\mathbb{I}(g(\mathbf{X}) \in A)$ is equal to 1 when $g(\mathbf{X}) \in A$ and to 0 when $g(\mathbf{X}) \notin A$.

In the quantification problem, for each sample instance $i \in \{1, \ldots, n\}$, $(\mathbf{X}_i, Y_i, S_i)$ is a vector of random variables such that $\mathbf{X}_i \in \mathbb{R}^d$ are features, $Y_i \in \{0, 1\}$ is a label of interest and $S_i \in \{0, 1\}$ is the indicator that this instance has been labeled. That is, whenever $S_i = 0$, then Y_i is not observed. Note that S_i can be random.

In the above framework, some subsets of the instances are frequently used. The sets $A_k := \{i \in \{1, \ldots, n\} : S_i = k\}$ represent the labeled ($k = 1$) and unlabeled ($k = 0$) instances. Similarly, $A_{k,j} := \{i \in \{1, \ldots, n\} : S_i = k \text{ and } Y_i = j\}$ represent the instances that are labeled ($k = 1$) or unlabeled ($k = 0$) and have a positive ($j = 1$) or a zero ($j = 0$) label. Also the number of instances that are unlabeled, labeled or that have label j are denoted, respectively, by $n_U := |A_0|$, $n_L := |A_1|$ and $n_j := |A_{1,j}|$.

In a quantification problem, one wishes to estimate $\theta := \mathbb{P}(Y = 1|S = 0)$, that is, the prevalence of positive labels among unlabeled samples. This prevalence is not assumed to be the same as the one over labeled sets, $\mathbb{P}(Y = 1|S = 1)$. The estimator for θ can depend only on the available data, that is, the features of all instances and the labels that were obtained. Formally, letting Z_i^j denote $(Z_i, \ldots, Z_j)$, a valid estimator is a function of $\mathbf{X}_1^n$, S_1^n and $(Y_i)_{i\in A_1}$. The set of all such valid estimators is denoted by $\mathcal{S}$.

In the standard formulation of the prior probability shift problem, $\{(\mathbf{X}_i, Y_i)\}_{i\in A_0}$ is called the *target population* (since the labels are unavailable), and $\{(\mathbf{X}_i, Y_i)\}_{i\in A_1}$ is called the training population (Tasche, 2017). It is common for both populations to be i.i.d.,

Assumption 1

- $(S_1, \mathbf{X}_1, Y_1), \ldots, (S_n, \mathbf{X}_n, Y_n)$ *are independent.*
- *For every* $s \in \{0, 1\}$, $(\mathbf{X}_1, Y_1)|S_1 = s, \ldots, (\mathbf{X}_n, Y_n)|S_n = s$ *are identically distributed.*

Unless additional assumptions are made, it is not possible to learn about θ using solely the observed data. One assumption that allows learning about θ is the prior probability shift, which states that "the class-conditional feature distributions of the training and test sets are the same" (Fawcett and Flach, 2005). Prior shift is formalized in Assumption 2.

Assumption 2 ***[Prior probability shift]*** *For every* $(y_1, \ldots, y_n) \in \{0, 1\}^n$, $(\mathbf{X}_1, \ldots, \mathbf{X}_n)$ *is stochastically independent of* $(S_1, \ldots, S_n)$ *conditionally on* $(Y_1, \ldots, Y_n) = (y_1, \ldots, y_n)$.

Although Assumption 2 is written in a different way than in papers such as Moreno-Torres et al. (2012), the content is similar. While Moreno-Torres et al. (2012) uses a subscript on the probability function to determine which is the reference population, we perform this task using the random variable, S. For instance, the probability that an instance from the target population has the label "1" is referred in previous notation and in this paper, respectively, as $\mathbb{P}_{tg}(Y_i = 1)$ and $\mathbb{P}(Y_i = 1|S_i = 0)$. Using this translation, Assumption 2 is the same as the prior probability shift in Moreno-Torres et al. (2012). Assumption 2 holds if and only if $f_{\mathbf{X}|Y,S=0} \equiv f_{\mathbf{X}|Y,S=1}$, that is, $\mathbb{P}_{tg}(\mathbf{x}|y) \equiv \mathbb{P}_{tr}(\mathbf{x}|y)$.

2.1. Lower bound on the risk for quantification under prior probability shift

Under Assumptions 1 and 2 it is possible to learn about θ from the features and labels that are available in the quantification problem. For example, one can use the features and labels in the training population to learn about $f_{\mathbf{X}|Y=0}$ and $f_{\mathbf{X}|Y=1}$. Also, if these densities are sufficiently different, then one can combine the information about them to the features in the target population to learn about the unknown labels in this population and, therefore, about θ. Definition 1 formally presents two classes in which the possible values of $f_{\mathbf{X}|Y=0}$ and $f_{\mathbf{X}|Y=1}$ are separable.

Definition 1 *Let* $f_i(\mathbf{x}) = f_{\mathbf{X}|Y=i}(\mathbf{x})$, $\epsilon, K > 0$ *and* $g : \mathbb{R}^d \to \mathbb{R}$ *be a non-constant function.*

$$\begin{cases} \mathcal{F}_{\mathcal{L}_1,\epsilon} := \{(f_0, f_1) : \|f_0 - f_1\|_1 \geq \epsilon\} \\ \mathcal{F}_{g,K,\epsilon} := \left\{(f_0, f_1) : \mathbb{E}_{f_i}[g(\mathbf{X})^2|Y = i] \leq K, \text{ and } |\mathbb{E}_{f_1}[g(\mathbf{X})|Y = 1] - \mathbb{E}_{f_0}[g(\mathbf{X})|Y = 0]| \geq \epsilon\right\} \end{cases}$$

Under the classes in Definition 1 it is possible to learn about θ and the learning rate depends on both the number of labeled and unlabeled instances. A lower bound for how these sample sizes affect the rate at which one learns about θ is presented in Theorem 3.

Definition 2 *Let* $\mathcal{F}$ *be a collection of* (f_0, f_1). *The minimax rate,* $M(\mathcal{F})$, *for estimating* θ *under the squared loss,* $\mathcal{F}$, *and Assumptions 1 and 2 is*

$$M(\mathcal{F}) = \inf_{\widehat{\theta}\in\mathcal{S}} \sup_{(f_0,f_1)\in\mathcal{F};\theta\in[0,1]} \mathbb{E}_{f_0,f_1,\theta}\left[(\widehat{\theta} - \theta)^2 \middle| S_1^n\right]$$

Theorem 3 $M(\mathcal{F}_{\mathcal{L}_1,\epsilon}) \geq \Omega(\max(n_L^{-1}, n_U^{-1}))$ *and* $M(\mathcal{F}_{g,K,\epsilon}) \geq \Omega(\max(n_L^{-1}, n_U^{-1}))$.

Theorem 3 shows that it is not possible to obtain an estimator for θ which has convergence rate faster than $\Omega(\max(n_L^{-1}, n_U^{-1}))$. In particular, it is not possible to learn θ by observing solely a limited amount of labels. The following subsection introduces the ratio estimator for θ, which achieves the lower bound in Theorem 3 under $\mathcal{F}_{g,K,\epsilon}$.

2.2. The ratio estimator and its theoretical properties

Definition 4 (Ratio estimator) *Let* $g : \mathbb{R}^d \longrightarrow \mathbb{R}$. *The untrimmed ratio estimator for* θ *based on* g, $\widehat{\theta}_{UR}$, *is*

$$\widehat{\theta}_{UR} := \frac{\frac{\sum_{i\in A_0} g(\mathbf{X}_i)}{n_U} - \frac{\sum_{i\in A_{1,0}} g(\mathbf{X}_i)}{n_0}}{\frac{\sum_{i\in A_{1,1}} g(\mathbf{X}_i)}{n_1} - \frac{\sum_{i\in A_{1,0}} g(\mathbf{X}_i)}{n_0}}$$

Since $\theta \in [0,1]$, the ratio estimator, $\widehat{\theta}_R$, is

$$\widehat{\theta}_R = \max(0, \min(1, \widehat{\theta}_R))$$

The ratio estimator generalizes estimators which were previously proposed in the literature. This fact follows from observing that the terms in the untrimmed ratio estimator are sample averages of $g(\mathbf{X})$ among three groups of instances: unlabeled instances, instances labeled as 0, and instances labeled as 1. For instance, the adjusted count (AC) estimator (Gart and Buck, 1966; Saerens et al., 2002; Forman, 2008; Tasche, 2017) is the a ratio estimator when $g(\mathbf{x}) \in \{0,1\}$, that is, $g(\mathbf{x})$ is the output of a classifier for Y. Also, the estimator in Bella et al. (2010) is a ratio estimator when $g(\mathbf{x}) = \widehat{\mathbb{P}}(Y=1|\mathbf{x})$, that is, $g(\mathbf{x})$ is a soft classifier for Y.

Remark 5 *The ratio estimator can be generalized to the case in which $Y_i \in \{0,1,\ldots,k\}$. In this case, let $g : \mathbb{R}^d \to \mathbb{R}^k$ be a fixed function. By defining G as a $k \times (k+1)$ matrix such that $G_{i,j} = \mathbb{E}[g_i(\mathbf{X})|Y = j-1, S = 1]$, $p \in \mathbb{R}^{k+1}$ such that $p_i = \mathbb{P}(Y = j-1|S=0)$, and $g \in \mathbb{R}^k$ such that $g_i = \mathbb{E}[g_i(\mathbf{X})|S=0]$, $\widehat{\theta}_{UR}$ is obtained by solving the linear system*

$$\begin{cases} \widehat{g} &= \widehat{G} \cdot \widehat{\theta}_{UR} \\ 1 &= \mathbf{1}^t \cdot \widehat{\theta}_{UR} \end{cases}, \text{ where } \widehat{g}_i = \frac{\sum_{k \in A_0} g_i(\mathbf{X}_k)}{n_U} \text{ and } \widehat{G}_{i,j} = \frac{\sum_{k \in A_{1,j}} g_i(\mathbf{X}_k)}{n_j}$$

Since $\widehat{\theta}_{UR}$ might have negative components, it is generally inadmissible according to the squared error (de Finetti, 2017)[p.90-91] that is, there exist estimators which have a squared error strictly smaller than $\widehat{\theta}_{UR}$. The ratio estimator, $\widehat{\theta}_R$ satisfies this property and is the projection of $\widehat{\theta}_{UR}$ onto the simplex (Michelot, 1986): $\widehat{\theta}_R = \arg\min_{\hat{p}:\hat{p}\geq 0, \sum_i \hat{p}_i = 1} \|\widehat{\theta}_{UR} - \hat{p}\|_2^2$.

Similarly to the AC estimator (Tasche, 2017), the ratio estimator is Fisher consistent under weak assumptions.[1]. They are described in Assumptions 3 and 4.

Assumption 3 (Weak prior shift) *The function, g, is such that $g(\mathbf{X})_1^n$ is stochastically independent of $\mathbf{S}_1^n$ conditionally on $\mathbf{Y}_1^n = y_1^n$.*

Assumption 4 (Separability) *The function, g, is such that*

1. *$\mathbb{E}[g(\mathbf{X}_i)|Y_i = j, S_i = 1]$ are defined, for $j \in \{0,1\}$.*
2. *$\mathbb{E}[g(\mathbf{X}_i)|Y_i = 1, S_i = 1] - \mathbb{E}[g(\mathbf{X}_i)|Y_i = 0, S_i = 1] \neq 0$*

The condition in Assumption 3 is a relaxed type of prior probability shift that is strictly weaker than Assumption 2. Assumption 4 requires two more conditions of $g(\mathbf{x})$. According to condition 1, the population versions of the expectations in Definition 4 are defined. Condition 2 states that the ratio estimator calculated on these population parameters is defined, that is, there is no division by 0.

Theorem 6 *Under Assumptions 1, 3 and 4, $\widehat{\theta}_{UR}$ and $\widehat{\theta}_R$ are Fisher consistent for θ.*

1. Although Fisher consistency is typically not equivalent to consistency in probability (Gerow, 1989; Kass and Vos, 2011), in the sequence we show that the ratio estimator is consistent in both senses.

It is also possible to guarantee a finite population bound on the mean squared error of $\widehat{\theta}_R$. This result is obtained in Theorem 7, which substitutes Assumption 4 by the stronger condition that $(f_0, f_1) \in \mathcal{F}_{g,K,\epsilon}$.

Theorem 7 *Under Assumptions 1 and 3,*

$$\sup_{(f_0,f_1)\in\mathcal{F}_{g,K,\epsilon}} \mathbb{E}_{f_0,f_1}\left[\left(\widehat{\theta}_R - \theta\right)^2 \middle| S_1^n\right] \leq \mathcal{O}(\max(n_L^{-1}, n_U^{-1}))$$

Under the assumptions of Theorem 7, if $n_U \gg n_L$, then the convergence of the mean squared error of the ratio estimator is the same as the one that would have been obtained if one observed solely n_L labels from the target population and used the sample's label proportions to estimate θ. The same type of result cannot generally be obtained for the untrimmed ratio estimator, since the trimming is necessary to guarantee that the ratio of random variables does not have infinite variance. While these conclusions are similar to the ones obtained from Theorem 3 in Lipton et al. (2018), there exist two main differences. First, while the former assumes that there are 2 labels only, the latter applies to an arbitrary number of labels. Second, Theorem 7 upper bounds the squared error by $\mathcal{O}(\max(n_L^{-1}, n_U^{-1}))$, which is slightly tighter than the bound of $\mathcal{O}\left(\max\left(\frac{\log n_L}{n_L}, \frac{\log n_U}{n_U}\right)\right)$ in Lipton et al. (2018).

It follows from Theorem 3 and Theorem 7 that the ratio estimator satisfies several desirable properties. These properties are presented in Definition 8 and Corollary 9.

Definition 8 *Let $\mathcal{S}$ and $\mathcal{F}$ be, respectively, the classes of estimators and distributions over the data under consideration. An estimator $\widehat{\theta}^* \in \mathcal{S}$ is approximately minimax for estimating θ under the squared error loss if*

$$\mathcal{O}\left(\sup_{(f_0,f_1)\in\mathcal{F}_{g,K,\epsilon}} \mathbb{E}_{f_0,f_1}\left[\left(\widehat{\theta}^* - \theta\right)^2 \middle| S_1^n\right]\right) = \Omega\left(\inf_{\widehat{\theta}\in\mathcal{S}} \sup_{(f_0,f_1)\in\mathcal{F};\theta\in[0,1]} \mathbb{E}_{f_0,f_1,\theta}\left[(\widehat{\theta} - \theta)^2 \middle| S_1^n\right]\right)$$

That is, the squared error of $\widehat{\theta}^*$ attains the optimal rate of convergence.

Corollary 9 *Under Assumptions 1 and 3, if there exists $\epsilon, K > 0$ such that $(f_0, f_1) \in \mathcal{F}_{g,K,\epsilon}$, then $\widehat{\theta}_R$ is consistent for θ in probability and in $\mathcal{L}_2$ as $n_U \xrightarrow{\mathbb{P}} \infty$ and $n_L \xrightarrow{\mathbb{P}} \infty$. Also, under Assumptions 1, 3, and $\mathcal{F}_{g,K,\epsilon}$, $\widehat{\theta}_R$ is approximately minimax.*

Corollary 9 shows that the ratio estimator converges to θ under a weaker version of the prior probability shift assumption and that the rate of this convergence is minimax (i.e., it is the same rate as that of the minimax estimator). Since the estimators from Gart and Buck (1966); Saerens et al. (2002); Forman (2008); Bella et al. (2010) are particular cases of the untrimmed ratio estimator, their trimmed versions also converge to θ under the weak prior shift.

The ratio estimator also satisfies a central limit theorem. In order to obtain this result, besides requiring Assumptions 1, 3 and 4, it is also necessary to require that conditionally on Y, $g(\mathbf{X})$ has bounded variance and that the number of labeled samples goes to infinity. These conditions are described in Assumption 5. The central limit theorem is presented in Theorem 10.

Assumption 5

1. $\mathbb{V}[g(\mathbf{X}_i)|Y_i = j] < \infty$, *for every* $j \in \{0, 1\}$.

2. *There exists* $h(n) \geq 0$ *such that* $\lim_{n\to\infty} \frac{h(n)}{n} < 1$, $\lim_{n\to\infty} h(n) = \infty$, *and* $\frac{n_L}{h(n)} \xrightarrow{\mathbb{P}} 1$.

Theorem 10 *Define* $\mu_j := \mathbb{E}[g(\mathbf{X}_1)|Y_1 = j]$, $\sigma_j^2 := \mathbb{V}[g(\mathbf{X}_1)|Y_1 = j]$, $p_L := \lim_{n\to\infty} \frac{h(n)}{n}$, *and* $p_{j|L} := \mathbb{P}(Y = j|S = 1)$. *Under Assumptions 1, 3, 4 and 5,*

1. *If* $p_L \neq 0$, *then*

$$\sqrt{n}(\widehat{\theta}_R - \theta) \rightsquigarrow N\left(0, \frac{\frac{(1-\theta)\sigma_0^2 + \theta\sigma_1^2 + (\mu_1-\mu_0)^2\theta(1-\theta)}{1-p_L} + \frac{(1-\theta)^2\sigma_0^2}{p_L p_{0|L}} + \frac{\theta^2\sigma_1^2}{p_L p_{1|L}}}{(\mu_1 - \mu_0)^2}\right)$$

2. *If* $p_L = 0$, *then*

$$\sqrt{h(n)}(\widehat{\theta}_R - \theta) \rightsquigarrow N\left(0, \frac{\frac{(1-\theta)^2\sigma_0^2}{p_{0|L}} + \frac{\theta^2\sigma_1^2}{p_{1|L}}}{(\mu_1 - \mu_0)^2}\right)$$

It is possible to use Theorem 10 to obtain an approximate confidence interval for θ. This interval is obtained by inverting the convergence results in Theorem 10, and substituting θ for $\widehat{\theta}_R$ and the population parameters, μ_0, μ_1, σ_0^2, σ_1^2, p_L, $p_{0|L}$ and $p_{1|L}$, by their respective empirical averages. This confidence interval may also be used to test hypothesis such as $H_0 : \theta \in \Theta_0$.

Theorem 10 also provides an approximation for the mean squared error of $\widehat{\theta}_R$. This approximation for the common case in which $n_U \gg n_L$ is presented in the following corollary.

Corollary 11 *Under Assumptions 1, 3, 4 and 5, if* $p_L = 0$ ($n_U \gg n_L$), *then*

$$MSE(\widehat{\theta}_R) \approx \frac{1}{n_L(\mu_1 - \mu_0)^2}\left(\frac{\sigma_0^2(1-\theta)^2}{p_{0|L}} + \frac{\sigma_1^2\theta^2}{p_{1|L}}\right) \tag{1}$$

Corollary 11 brings some insights on how g should be chosen in order for $\widehat{\theta}_R$ to be an accurate estimator of θ. For instance, it shows that one should choose g such that $|\mu_1 - \mu_0|$ is large and both σ_0^2 and σ_1^2 are small. This implies that the distributions of $g(\mathbf{X})|Y = 1$ and $g(\mathbf{X})|Y = 0$ should place most of their masses in regions that are far apart. This conclusion explains the success of the methods in Forman (2008), in which $g(\mathbf{x})$ is a classifier, and Bella et al. (2010), in which $g(\mathbf{x})$ is an estimate of $\mathbb{P}(Y = 1|\mathbf{x})$.

One of the main deficiencies of the standard AC estimator is that its denominator can be very close to zero, which makes it very unstable (due to a large variance). In order to handle this, we can explicitly use the approximation of the MSE (Corollary 11) to choose better functions g. This procedure is discussed in the following subsection.

2.3. Choosing g via approximate MSE minimization

One possible criterion for the choice of g is the minimization of $MSE(\widehat{\theta}_R)$, defined in Corollary 11. However, the latter depends on unobservable quantities. An alternative is to minimize an estimate of $MSE(\widehat{\theta}_R)$. This estimate is presented in Definition 12.

Definition 12 *Let* $\hat{\theta}$ *be an estimator of* θ *and, for each* $i \in \{0, 1\}$, *let*

$$\widehat{\mu}_i = n_i^{-1}\sum_{A_{1,i}} g(\mathbf{X}_i) \qquad \widehat{\sigma}_i^2 = n_i^{-1}\sum_{A_{1,i}} (g(\mathbf{X}_i) - \widehat{\mu}_i)^2 \qquad \widehat{p}_{i|L} = \frac{n_i}{n_0 + n_1}$$

The empirical MSE of the ratio estimator induced by g, $\widehat{MSE}(g)$, *is*

$$\widehat{MSE}(g) \approx \frac{1}{n_L(\widehat{\mu}_1 - \widehat{\mu}_0)^2}\left(\frac{\widehat{\sigma}_0^2(1-\widehat{\theta})^2}{\widehat{p}_{0|L}} + \frac{\widehat{\sigma}_1^2\widehat{\theta}^2}{\widehat{p}_{1|L}}\right)$$

In order to avoid overfitting, we perform the minimization of $\widehat{MSE}(g)$ on a Reproducing Kernel Hilbert Space (RKHS; Wahba (1990)). More precisely, if K is a Mercer kernel and $\mathcal{H}_K$ is the RKHS associated to K, then we choose g^* as

$$g^* := \arg\min_{g\in\mathcal{H}_K} \widehat{\text{MSE}}(g) \tag{2}$$

In the following, Theorem 13 presents a characterization of g^* in eq. 2.

Theorem 13 *Let* K *be a Mercer kernel and* $\mathcal{H}_K$ *the corresponding RKHS. Also,*

- $\mathbb{K}$*: the Gram matrix defined for* $(i, j) \in A_1^2$ *and such that* $(\mathbb{K})_{i,j} = K(\mathbf{x}_i, \mathbf{x}_j)$.
- m_i*: A vector of size* $|A_1|$ *and such that, for each* $k \in A_1$, $m_{i,k} = \frac{\sum_{j\in A_{1,i}} K(\mathbf{x}_j, \mathbf{x}_k)}{n_i}$.
- $M = (m_1 - m_0)(m_1 - m_0)^t$.
- $\widehat{\Sigma}_i$*: a* $|A_1|\times|A_1|$ *matrix such that* $(\widehat{\Sigma}_i)_{k,l}$ *is the sample covariance between* $(K(\mathbf{x}_j, \mathbf{x}_k))_{j\in A_{1,i}}$ *and* $(K(\mathbf{x}_j, \mathbf{x}_l))_{j\in A_{1,i}}$.
- N*: a* $|A_1| \times |A_1|$ *matrix such that* $N = \frac{\widehat{\theta}^2}{\widehat{p}_{1|L}}\widehat{\Sigma}_1 + \frac{(1-\widehat{\theta})^2}{\widehat{p}_{0|L}}\widehat{\Sigma}_0$.
- $\mathbf{w}^* = \arg\min_{w\in\mathbb{R}^{n_L}} \frac{\mathbf{w}^t N\mathbf{w}}{\mathbf{w}^t M\mathbf{w}}$

The function g^* *in eq. 2 satisfies* $g^*(\mathbf{x}) = \sum_{i\in A_1} w_i^* K(\mathbf{x}, \mathbf{x}_i)$.

The vector, $\mathbf{w}^*$ in Theorem 13 is the eigenvector associated to the largest eigenvalue in absolute value, λ^*, of the generalized eigenvalue problem, $M\mathbf{w}^* = \lambda^* N\mathbf{w}^*$. If N is invertible, $\mathbf{w}^*$ is the eigenvector associated to the largest eigenvalue in absolute value of $N^{-1}M$. Alternatively, if N is not invertible one can substitute N in Theorem 12 by $(N + \gamma\mathbb{1})^{-1}$, where $\mathbb{1}$ is the identity matrix and γ is a small number that makes $N+\gamma\mathbb{1}$ invertible. Adding γ to the diagonal also also adds regularization and can therefore lead to an improved solution. In practice we choose γ via data-splitting.

The results in this and in the previous section rely on the weak prior shift assumption. As shown in the next subsection, one of the advantages of this assumption to the regular prior shift is that it is easier to test.

2.4. Testing the weak prior shift assumption

The following proposition is useful for testing the weak prior shift assumption:

Proposition 14 *Under Assumption 3, there exists* $0 \leq p \leq 1$ *such that*

$$pF_{g(\mathbf{X})|S=1,Y=1} + (1-p)F_{g(\mathbf{X})|S=1,Y=0} = F_{g(\mathbf{X})|S=0}.$$

It follows from Proposition 14 that Assumption 3 entails the hypothesis:

$$H_0 : \exists 0 \leq p \leq 1 \text{ such that } pF_{g(\mathbf{X})|S=1,Y=1} + (1-p)F_{g(\mathbf{X})|S=1,Y=0} = F_{g(\mathbf{X})|S=0}$$

In the following, we show how to construct an hypothesis test for H_0 when $g(\mathbf{x})$ is continuous. Since the weak prior shift entails H_0, if this test is used to test the weak prior shift, it will have the correct type I error. However, H_0 may hold when Assumption 3 is false. A specific example in which H_0 is satisfied but Assumption 3 is not satisfied is given in the following example.

Example 1 *If* $F_{g(\mathbf{X})|S=0,Y=1} = F_{g(\mathbf{X})|S=0,Y=0}$ *and* $F_{g(\mathbf{X})|S=0,Y=1} = F_{g(\mathbf{X})|S=1,Y=1}$*, then there exists* p *such that* $pF_{g(\mathbf{X})|S=1,Y=1} + (1-p)F_{g(\mathbf{X})|S=1,Y=0} = F_{g(\mathbf{X})|S=0}$ *(namely,* $p = 1$*) even if* $F_{g(\mathbf{X})|S=1,Y=0} \neq F_{g(\mathbf{X})|S=0,Y=0}$*. In this case, Assumption 3 does not hold and* H_0 *is satisfied.*

The following statistic, T, measures disagreement with H_0:

$$T = \inf_{0 \leq p \leq 1} d\left(p\widehat{F}_{g(\mathbf{X})|S=1,Y=1} + (1-p)\widehat{F}_{g(\mathbf{X})|S=1,Y=0}, \widehat{F}_{g(\mathbf{X})|S=0}\right),$$

where d is a distance between cumulative distributions, such as the Kolmogorov distance, and $\widehat{F}$ are the empirical cumulative distributions (Wasserman, 2013):

$$\widehat{F}_{g(\mathbf{X})|S=1,Y=i}(w) = \frac{1}{|A_{1,i}|}\sum_{i \in A_{1,i}} \mathbb{I}(g(\mathbf{X}_i) \leq w), \quad \widehat{F}_{g(\mathbf{X})|S=0}(w) = \frac{1}{|A_0|}\sum_{i \in A_0} \mathbb{I}(g(\mathbf{X}_i) \leq w).$$

Algorithm 1, which is presented below, obtains a p-value for H_0 based on T. The algorithm uses kernel smoothers (Wasserman, 2013) to estimate the conditional densities of $g(\mathbf{X})$ given Y, $f(g(\mathbf{x})|Y=0)$ and $f(g(\mathbf{x})|Y=1)$, by $\widehat{f}(g(\mathbf{x})|Y=0)$ and $\widehat{f}(g(\mathbf{x})|Y=1)$.

Note that our test is different from those proposed by Saerens et al. (2002) and Lipton et al. (2018). While our test evaluates whether the prior shift assumption is reasonable for the observed data, the above tests *assume prior shift* and evaluate whether the prevalence of positive labels in the unlabeled sample is the same as that in the labeled sample, that is, $\mathbb{P}(Y=1|S=0) = \mathbb{P}(Y=1|S=1)$.

The following subsection performs several experiments to test the performance of Algorithm 1 and of the ratio estimators which were discussed in previous subsections.

Algorithm 1 p-value for testing the weak prior shift assumption

Input: Labeled and unlabeled sample, number of Monte Carlo simulations, B **Output:** p-value

1: Compute T_{obs}, the test statistic for the observed data
2: Compute $\widehat{\theta}$, an estimate of θ
3: Compute $\widehat{f}(g(\mathbf{x})|Y=1)$ and $\widehat{f}(g(\mathbf{x})|Y=0)$.
4: **for all** $i \in \{1, \ldots, B\}$ **do**
5: Sample $W_1^{(0)}, \ldots, W_{n_0}^{(0)} \sim \widehat{f}(g(\mathbf{x})|Y=0)$ and $W_1^{(1)}, \ldots, W_{n_1}^{(1)} \sim \widehat{f}(g(\mathbf{x})|Y=1)$
6: Sample $W_1^{(U)}, \ldots, W_{n_U}^{(U)} \sim \widehat{\theta}\widehat{f}(g(\mathbf{x})|Y=1) + (1-\widehat{\theta})\widehat{f}(g(\mathbf{x})|Y=0)$
7: Compute T_i, the test statistic based on the labeled and unlabeled samples:

$$\{(W_i^{(0)}, Y_i = 0)\}_{i=1}^{n_0} \cup \{(W_i^{(1)}, Y_i = 1)\}_{i=1}^{n_1}; \qquad \{W_1^{(U)}, \ldots, W_{n_u}^{(U)}\}$$

8: **end for**
9: **return** $\frac{1}{B}\sum_{i=1}^{B} \mathbb{I}\left(T_{\text{obs}} \geq T_i\right)$

Estimator class	Specific method	Criteria for choosing $g(x)$
Classify and count		Logistic regression (LR), k-NN, random forest (RF).
Ratio	Forman (2006)	Logistic regression (LR), k-NN, random forest (RF).
	Bella et al. (2010)	Logistic regression (LR), k-NN, random forest (RF).
	RKHS	Linear kernel (Linear), Gaussian kernel (Gauss).
	EM (Saerens et al., 2002)	Logistic regression (LR), k-NN, random forest (RF).

Table 1: Methods compared in the experiments.

2.5. Experiments

Next, we compare the errors of the ratio estimator and of the classify and count estimator based on the estimator g when using various methods for obtaining g. We also include comparisons with the EM methods by Saerens et al. (2002). Table 1 summarizes all the variants that were tested.

We compare the above methods in five data sets: Candles (Freeman et al., 2013; Izbicki and Stern, 2013), Bank Marketing (Moro et al., 2011), SPAM e-mail (Blake, 1998), Wisconsin Breast Cancer (Mangasarian, 1990) and Blocks Classification (Malerba et al., 1996). Each database was transformed into a prior shift problem by choosing at random n_1 (n_0) instances among the ones labeled as 1 (0) to be marked as labeled instances and by choosing n_U instances to be marked as unlabeled. Each unlabeled unit is taken with probability θ randomly among the instances labeled as 1 in the original data set and with probability $1-\theta$ among those labeled as 0. The quantification sample sizes used in each of these data sets are described in Table 2. For all data sets we let θ vary in $\{0.1; 0.2; 0.3; 0.4; 0.5\}$ and repeated the generation and testing 100 times for each of the 11 methods in Table 1.

Figure 1 represents the average of the mean squared error (MSE; red point) and a confidence interval for the MSE (vertical blue bar) for each setting and method[2]. Figure 2 shows the number of experiments in which each method had the best average MSE,

2. For the sake of visualization, we omit all estimators based on K-NN on this plot. Figure 9 in Appendix B contains all methods.

	data set	n_U	n_L	n_1	n_0
1	cancer	100	300	150	150
2	candles	300	300	150	150
3	block	800	300	150	150
4	spam	2000	300	150	150
5	bank	10000	300	150	150

Table 2: Sample sizes for each data set.

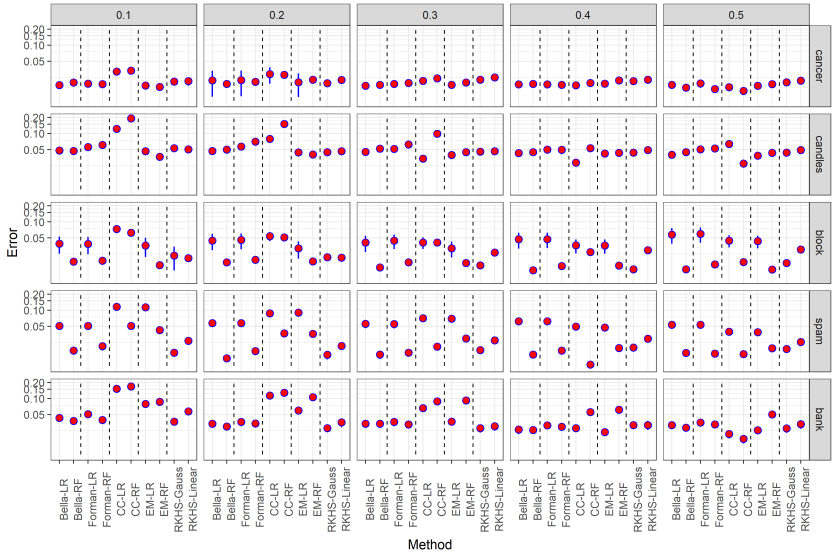

Figure 1: Root mean square deviation of each method by setting in logarithmic scale.

considering all data sets and θ values. These plots indicate that the ratio estimator generally performs better than the classify and count estimator for all choices of g. The main exception to this rule occurs when $\theta \approx 0.5$ and hence there is no prior shift. Also, the method in Bella et al. (2010) performs better than the one in Forman (2006) in essentially all scenarios. This suggests that soft classifiers might lead to better ratio estimators than hard classifiers. Moreover, the best performance is usually achieve when g is based on Random Forest, which corroborates that choosing a good classifier is key to having a good estimate of θ. The EM method was found to be very competitive in general, although the ratio estimators had better performance in some cases (e.g., for the bank data set). Finally, the RKHS approach is a competitive method, especially when using the Gaussian kernel. For additional figures related to this experiment see Appendix B.

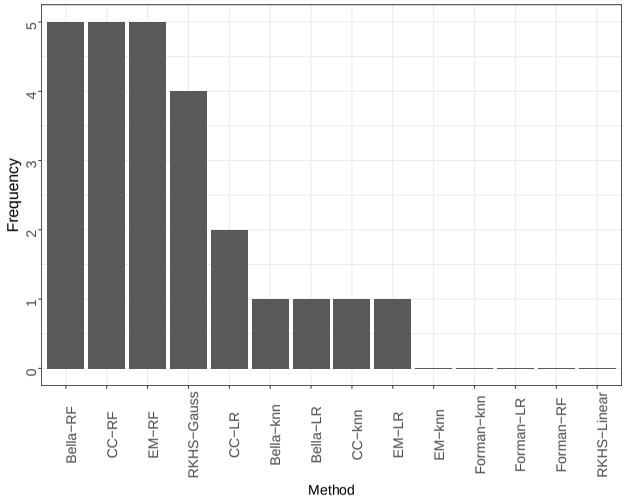

Figure 2: Number of times in which each method presented best MSE.

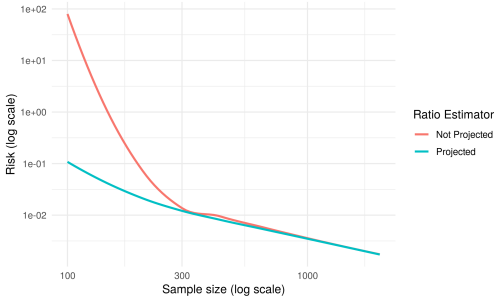

Figure 3: Mean squared error of the ratio estimator for the multiclass problem.

For all of ratio estimators, data sets and values for θ above, we construct confidence intervals for θ based on Theorem 10. We find that in all but one scenario the empirical coverage was at least as high as the specified value of 95%. The empirical coverage in the exception was 94%. The intervals constructed using Theorem 10 seem to be conservative.

Next, we simulate data using the following multiclass setting: $\mathbf{X}|Y = y \sim N(\mu_y, \Sigma)$ with $\Sigma = I_{10}$, $\mu_1 = (0, \ldots, 0)$, $\mu_2 = (0.75, \ldots, 0.75)$, $\mu_3 = (1.25, \ldots, 1.25)$, $\mathbb{P}(Y = 1|S = 1) = 0.2$,

Gaussian	**Exponential**
$g(\mathbf{x})\|S=1,Y=0 \sim \mathrm{N}(0,1)$,	$g(\mathbf{x})\|S=1,Y=0 \sim \mathrm{Exp}(1)$,
$g(\mathbf{x})\|S=1,Y=1 \sim \mathrm{N}(2,1)$,	$g(\mathbf{x})\|S=1,Y=1 \sim \mathrm{Exp}(5)$,
$g(\mathbf{x})\|S=0,Y=0 \sim \mathrm{N}(\gamma,1)$	$g(\mathbf{x})\|S=0,Y=0 \sim \mathrm{Exp}(\gamma)$
$g(\mathbf{x})\|S=0,Y=1 \sim \mathrm{N}(2,1)$,	$g(\mathbf{x})\|S=0,Y=1 \sim \mathrm{Exp}(5)$,
$\mathbb{P}(Y=1\|S=0)=0.6$,	$\mathbb{P}(Y=1\|S=0)=0.6$,
$\mathbb{P}(Y=1\|S=1)=0.2$	$\mathbb{P}(Y=1\|S=1)=0.2$
Gaussian-Exponential	**Beta**
$g(\mathbf{x})\|S=1,Y=0 \sim \mathrm{N}(1,1)$,	$g(\mathbf{x})\|S=1,Y=0 \sim \mathrm{Beta}(1,1)$,
$g(\mathbf{x})\|S=1,Y=1 \sim \mathrm{Exp}(1)$,	$g(\mathbf{x})\|S=1,Y=1 \sim \mathrm{Beta}(1,10)$,
$g(\mathbf{x})\|S=0,Y=0 \sim \mathrm{N}(\gamma,1)$	$g(\mathbf{x})\|S=0,Y=0 \sim \mathrm{Beta}(\gamma,1)$
$g(\mathbf{x})\|S=0,Y=1 \sim \mathrm{Exp}(1)$,	$g(\mathbf{x})\|S=0,Y=1 \sim \mathrm{Beta}(1,10)$,
$\mathbb{P}(Y=1\|S=0)=0.6$,	$\mathbb{P}(Y=1\|S=0)=0.6$,
$\mathbb{P}(Y=1\|S=1)=0.2$	$\mathbb{P}(Y=1\|S=1)=0.2$

Table 3: Scenarios used for testing the weak prior shift assumption.

$\mathbb{P}(Y=2|S=1)=0.3$ $\mathbb{P}(Y=1|S=0)=0.25$, and $\mathbb{P}(Y=2|S=0)=0.10$. We use a multivariate logistic regression to compute $g_1(\mathbf{x})=\widehat{P}(Y=1|\mathbf{x},S=1)$ and $g_2(\mathbf{x})=\widehat{P}(Y=2|\mathbf{x},S=1)$. Figure 3 indicates that the mean squared error of the multiclass ratio estimator goes to zero as the sample size increases. Moreover, it shows that projecting the raw estimator to the simplex improves the convergence, especially for small sample sizes.

We also evaluate the power of the weak prior shift test in Section 2.4. In order to test the weak prior shift, we generate data according to 4 scenarios, which are presented in table 2.5. In all of these scenarios, the weak prior shift assumption holds for a single value of γ. Figure 4 presents the power of the weak prior shift test in each scenario using a level of significance of $\alpha=5\%$. Besides the test achieving the level of 5% when weak prior shift holds, it also has a high power whenever the marginal distribution of $g(\mathbf{X})$ differs over the labeled and over the unlabeled data. The reason why such test presents minima when the weak priori shift assumption does not hold is described in Example 1.

The following section discusses extensions of the ratio estimator to scenarios that are more general than the standard quantification problem.

3. Extensions of the quantification problem

3.1. Combined estimator

Sometimes, a few labels are available in the target population ($S=0$). Let $A_0^*\subset A_0$ denote the indices of these labeled sample instances. In this scenario, it is possible to obtain an estimate of θ that combines the ratio estimator with the additional labels which are available. The labeled estimator of θ is defined as:

$$\widehat{\theta}_L := \frac{1}{|A_0^*|}\sum_{i\in A_0^*} Y_i$$

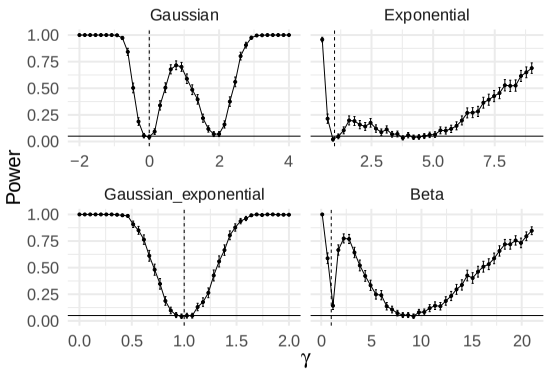

Figure 4: Power of the weak prior shift test at level $\alpha=5\%$. The dashed vertical lines indicate the value of γ for which the weak prior shift holds.

It is possible to better estimate θ by combining the labeled estimator, $\widehat{\theta}_L$, with the ratio estimator, $\widehat{\theta}_R$. We propose to combine these estimators by means of a convex combination,

$$\widehat{\theta}_C = w\widehat{\theta}_R + (1-w)\widehat{\theta}_L, \tag{3}$$

which we name the *combined* estimator. The following theorem provides an insight on how to choose w.

Theorem 15 *Under Assumptions 1, 3, 4 and 5, the value of w that minimizes the mean squared error of the combined estimator (Equation 3) is*

$$w^* = MSE[\widehat{\theta}_L] \times (MSE[\widehat{\theta}_L] + MSE[\widehat{\theta}_R])^{-1}.$$

In practice, $MSE[\widehat{\theta}_L]$ and $MSE[\widehat{\theta}_R]$ need to be estimated. Note that $MSE[\widehat{\theta}_L] = \theta(1-\theta)\times|A_0^*|^{-1}$ and $MSE[\widehat{\theta}_R]$ is given by Theorem 10. We therefore use $\widehat{w}=\widehat{MSE}[\widehat{\theta}_L]\times(\widehat{MSE}[\widehat{\theta}_L]+\widehat{MSE}[\widehat{\theta}_R])^{-1}$, where $\widehat{MSE}[\widehat{\theta}_L]$ and $\widehat{MSE}[\widehat{\theta}_R]$ are obtained by substituting the parameters in $MSE[\widehat{\theta}_L]$ and $MSE[\widehat{\theta}_R]$ by their corresponding empirical averages.

We evaluate the combined estimator under the same scenarios used for the ratio estimator in Section 2.5 and using $\theta=0.3$. For each scenario, we consider 10, 20, 30, 40 or 50 available labels from the target population. Figure 5 presents the errors for each setting scenario and number of available labels in the target population.[3] When one of $\widehat{\theta}_L$ and $\widehat{\theta}_R$ has an error which is much lower than the other, than this lowest error is comparable to that of the combined estimator. Also, when $\widehat{\theta}_L$ and $\widehat{\theta}_R$ have similar errors, then the error of the combined estimator is approximately $\sqrt{2}^{-1}$ times this common error. These results indicate that a few labels from the target population can improve the estimation of θ.

3. Similar plots (with similar conclusions) for $\theta\in\{0.1,0.2,0.4,0.5\}$ can be found in Figures 12—15 in Appendix B.

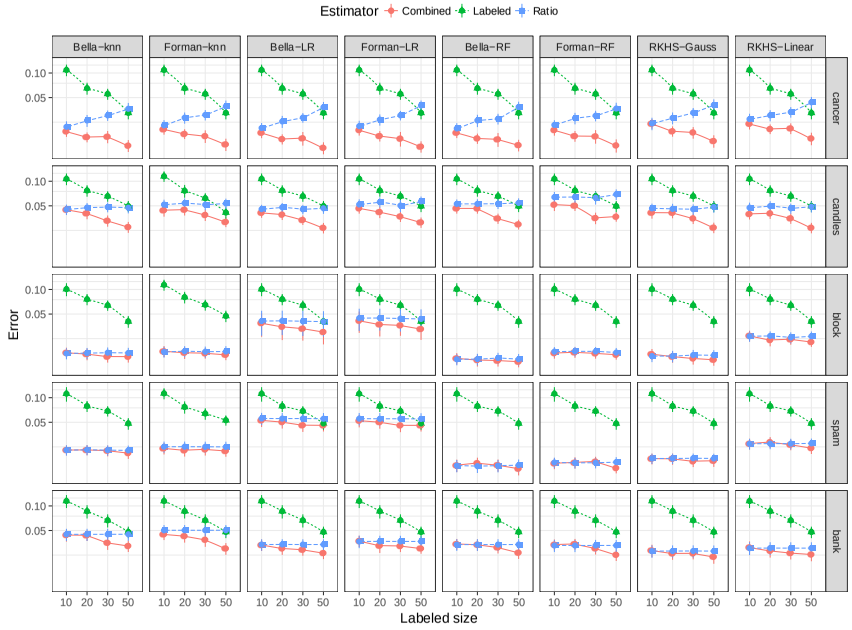

Figure 5: Root mean square deviation in logarithmic scale for each data set, method and estimator by size of the labeled sample and using $\theta = 0.3$

3.2. Regression quantification

As a generalization of the quantification problem, one might be interested on how the prevalence of Y in the target population varies according to a new set of covariates, $\mathbf{Z}$. For example, suppose that a company implements a program of continuous improvement for one of its products. In order to measure the effects of the program, it is necessary to evaluate how the proportion of positive reviews for the product varies over time. This problem fits into the generalization of the quantification problem when taking $\mathbf{Z}$ to be the date at which each review was posted. This problem is often called sentiment analysis (Wang et al., 2012) and is usually solved using a classify and count approach, which suffers from the same downsides as the ones discussed in the standard quantification problem. Other approaches can be found in Hofer and Krempl (2013).

The ratio estimator can be extended to this regression setting. Let the new sample instances be $(\mathbf{X}_1, \mathbf{Z}_1, Y_1, S_1), \ldots, (\mathbf{X}_n, \mathbf{Z}_n, Y_n, S_n)$, where $\mathbf{X}$, Y and S have the same interpretation as in the quantification problem and $\mathbf{Z}$ is the new covariate of interest. The goal

in the new setting is to estimate

$$\theta(\mathbf{z}) := \mathbb{P}(Y = 1 | S = 0, \mathbf{z}),$$

the proportion of positive labels in the target population when $\mathbf{Z} = \mathbf{z}$. In order to estimate $\theta(\mathbf{z})$, it is necessary to make additional assumptions on how $\mathbf{Z}$ relates to the other variables in the quantification problem. One such assumption is presented below.

Assumption 6 *$g(\mathbf{X})$ is stochastically independent of $\mathbf{Z}$ conditionally on Y and S.*

In the scenario in which $\mathbf{X}$ are written reviews of products and Z is time, Assumption 6 states that, if the label of a product is known, then the time at which the label was given does not affect the written review. This assumption motivates the definition of the regression ratio estimator.

Definition 16 *The untrimmed regression ratio estimator, $\widehat{\theta}_{URR}(\mathbf{z})$, is*

$$\widehat{\theta}_{URR}(\mathbf{z}) = \frac{\widehat{\mathbb{E}}[g(\mathbf{X})|S = 0, \mathbf{z}] - \widehat{\mathbb{E}}[g(\mathbf{X})|Y = 0, S = 1]}{\widehat{\mathbb{E}}[g(\mathbf{X})|Y = 1, S = 1] - \widehat{\mathbb{E}}[g(\mathbf{X})|Y = 0, S = 1]},$$

where $\widehat{\mathbb{E}}[g(\mathbf{X})|Y = 0, S = 1]$ and $\widehat{\mathbb{E}}[g(\mathbf{X})|Y = 1, S = 1]$ are the same empirical averages as in Definition 4 and $\widehat{\mathbb{E}}[g(\mathbf{X})|S = 0, \mathbf{z}]$ is an estimate of the regression function $\mathbb{E}[g(\mathbf{X})|S = 0, \mathbf{z}]$. For instance $\widehat{\mathbb{E}}[g(\mathbf{X})|S = 0, \mathbf{z}]$ could be the Nadaraya-Watson regression estimator (Nadaraya, 1964) based on the target population for $g(\mathbf{X})$ given $\mathbf{Z}$. The regression ratio estimator, $\widehat{\theta}_{RR}(\mathbf{z})$, is $\max(0, \min(1, \widehat{\theta}_{URR}(\mathbf{z})))$.

Next, we derive an upper bound on the rate of convergence of the regression ratio estimator.

Theorem 17 *Under Assumptions 1, 3 and 6,*

$$\mathbb{E}\left[\left(\widehat{\theta}_{RR}(\mathbf{Z}) - \theta(\mathbf{Z})\right)^2 \middle| S_1^n\right] \leq \mathcal{O}\left(\max\left(\mathbb{E}\left[\left(\widehat{\mathbb{E}}[g(\mathbf{X})|S = 0, \mathbf{Z}] - \mathbb{E}[g(\mathbf{X})|S = 0, \mathbf{Z}]\right)^2 | S_1^n\right], n_L^{-1}\right)\right)$$

Theorem 17 shows that the integrated mean squared error of $\widehat{\theta}_{RR}$ depends both on n_L and on the integrated mean squared error of $\widehat{\mathbb{E}}[g(\mathbf{X})|S = 0, \mathbf{Z}]$ with respect to the regression function, $\mathbb{E}[g(\mathbf{X})|S = 0, \mathbf{Z}]$. If one uses standard nonparametric methods to estimate $\mathbb{E}[g(\mathbf{X})|S = 0, \mathbf{Z}]$, then it is possible to prove the consistency of $\widehat{\theta}_{RR}$ under weak additional assumptions. For example, if in the target population the pairs $(g(\mathbf{X}_1), \mathbf{Z}_1), \ldots, (g(\mathbf{X}_{n_U}), \mathbf{Z}_{n_U})$ are i.i.d., the regression function $\mathbb{E}[g(\mathbf{X})|S = 0, \mathbf{z}]$ is sufficiently smooth over $\mathbf{z}$ and $\widehat{\mathbb{E}}[g(\mathbf{X})|S = 0, \mathbf{z}]$ is the Nadaraya-Watson kernel estimator with bandwidth $h_{n_U} = O(n_U^{-1/5})$, then it follows (Wasserman, 2006)[p.73] that

$$\mathbb{E}\left[\left(\widehat{\theta}_{RR}(\mathbf{Z}) - \theta(\mathbf{Z})\right)^2 \middle| S_1^n\right] \leq \mathcal{O}\left(\max(n_U^{-4/5}, n_L^{-1})\right)$$

In the equation above, the rate of convergence over n_U is slower than the one obtained in Theorem 7. This is expected, since the rates of convergence of nonparametric estimators are typically slower than those of sample means.

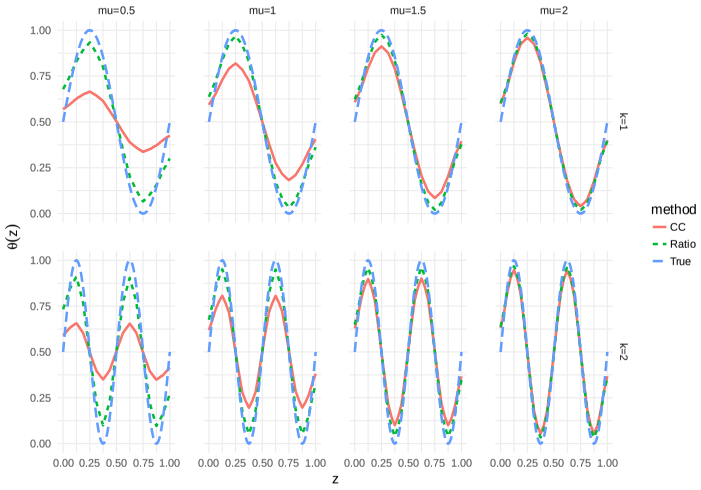

Figure 6: Average of the fitted regression in each setting.

Besides showing the consistency of the regression ratio estimator, we also show that it outperforms the classify and count method in artificial data sets. Specifically, we run the regression ratio estimator using the Nadaraya-Watson kernel estimator and generate data sets under the following specifications:

- $Z \sim U(0,1)$
- $\mathbb{P}(Y=1|S=1,Z=z)=0.5$
- $\mathbb{P}(Y=1|S=0,Z=z)=0.5(\sin(2zk\pi)+1)$, for $k \in \{1,2\}$
- $X|Y=0 \sim N(\mu,1)$ and $X|Y=1 \sim N(-\mu,1)$, for $\mu \in \{0.5,1,1.5,2\}$
- $n_L = n_U = 10^3$
- $g(X)$ is the Bayes classifier, i.e. $g(X)=\mathbb{I}(X>0)$

For each combination of k and μ, 400 independent data sets were generated. Figure 6 presents the average curve fitted for $\theta(\mathbf{z})$ using the regression ratio and classify and count estimators. One can observe that, while for small values of μ the ratio regression outperforms the classify and count estimator, for large values of μ both estimators are similar. This occurs because when μ is large, the classification problem of determining the value of Y is easier and both methods perform well. One can also observe from Figure 6 that the classify and count method performs worse than the regression ratio estimator

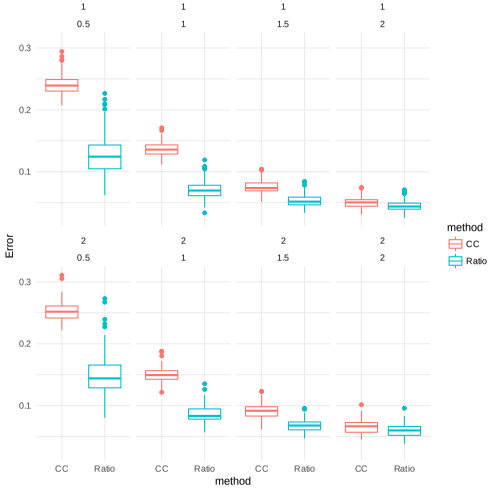

Figure 7: Boxplots of the root mean square deviation in each setting.

because its fit is generally smoother than the true regression curve. Figure 7 summarizes the mean squared error of each method in each setting. The regression ratio estimator leads to substantial improvements over the classify and count method.

4. Final remarks

We present the ratio estimator for the problem of quantification, show that it is approximately minimax under the prior probability shift assumption, and provide an hypothesis test for this assumption. Since the methods in Forman (2006) and Bella et al. (2010) are particular instances of the ratio estimator, it follows that they are also approximately minimax. The lower bound on the risk that we derive is of independent interest and can be used to investigate the optimality of other quantification methods. We also derive the limiting distribution of the ratio estimator, which allows the derivation of a ratio estimator based on Reproducing Kernel Hilbert Spaces and of confidence intervals for the quantification problem. A simulation study shows that the ratio estimator based on Reproducing Kernel Hilbert spaces is a competitive new alternative.

Besides the above results, we also generalize the ratio estimator to two other scenarios. In the first one, we consider the case in which some labels are available in the target population. The combined estimator uses these labels and the ratio estimator to obtain a larger effective sample size than the ratio estimator. In the second scenario, we consider the prevalence of positive labels varies according to a new variable, $\mathbf{Z}$. We show that, under Assumption 6, the regression ratio estimator can be made consistent for $\theta(\mathbf{Z})$. A still

unresolved issue is how much it is possible to relax Assumption 6 while still being able to learn $\theta(\mathbf{Z})$.

Appendix A. Proofs

Lemma 18 *Let $\mathbb{X}_U = (\mathbf{X}_u)_{u\in A_0}$, $\mathbf{Y}_U = (Y_u)_{u\in A_0}$, $\mathbb{X}_L = (\mathbf{X}_l)_{l\in A_1}$, and $\mathbf{Y}_L = (Y_l)_{l\in A_1}$. Under Assumptions 1 and 2, if $\theta \sim$ Uniform$(0,1)$, then $\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]] \geq \Omega(n_U^{-1})$. Under the same assumptions, if $\mathbb{P}(\theta = 0.5 - n_L^{-1}) = \mathbb{P}(\theta = 0.5 + n_L^{-1}) = 0.5$, $f_0 =$ Bernoulli(0), $\alpha \sim$ Uniform$(\epsilon^*, 1)$ $f_1|\alpha =$ Bernoulli(α), then $\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]] \geq \Omega(n_L^{-1})$.*

Proof It follows from Assumptions 1 and 2 that the dependency relations between data and parameters can be represented by figure 8.

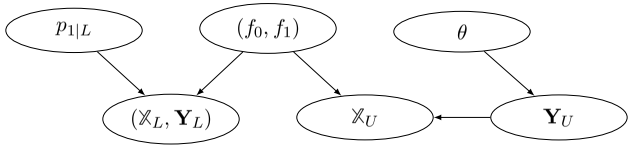

Figure 8: Dependency relations between data and parameters in the prior shift model.

If $\theta \sim U(0,1)$, then

$$\begin{aligned}\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]|S_1^n] &\geq \mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L, \mathbf{Y}_U]|S_1^n] \\ &= \mathbb{E}[\mathbb{V}[\theta|\mathbf{Y}_U]|S_1^n] && \text{fig. 8} \\ &= \Omega(n_U^{-1}) && \mathbf{Y}_U|\theta \text{ i.i.d. Bernoulli}(\theta) \end{aligned} \quad (4)$$

Next, let $\mathbb{P}(\theta = 0.5 - n_L^{-0.5}) = \mathbb{P}(\theta = 0.5 + n_L^{-0.5}) = 0.5$, $f_0 =$ Bernoulli(0) $\alpha \sim U(\epsilon, 1)$ and $f_1|\alpha =$ Bernoulli(α). Define $\mathbb{X}_{L,1} = (\mathbf{X}_l)_{l\in A_{1,1}}$ and note that

$$f(\alpha|\mathbb{X}_L, \mathbf{Y}_L) \propto \alpha^{n_{L,1}\bar{\mathbb{X}}_{L,1}}(1-\alpha)^{n_{L,1}(1-\bar{\mathbb{X}}_{L,1})}\mathbb{I}(\alpha \in (\epsilon, 1)) \quad (5)$$

Let $\lambda := \theta\alpha$ and observe that, for every $\lambda \in \left(\epsilon(0.5 + n_L^{-0.5}), 0.5 - n_L^{-0.5}\right]$,

$$\begin{aligned}\mathbb{P}(\theta = 0.5 + n_L^{-0.5}|\lambda, \mathbb{X}_L, \mathbf{Y}_L) &= \frac{f_\alpha(\lambda(0.5 + n_L^{-0.5})^{-1}|\mathbb{X}_L, \mathbf{Y}_L)}{f_\alpha(\lambda(0.5 + n_L^{-0.5})^{-1}|\mathbb{X}_L, \mathbf{Y}_L) + f_\alpha(\lambda(0.5 - n_L^{-0.5})^{-1}|\mathbb{X}_L, \mathbf{Y}_L)} \\ &= \frac{1}{1 + \frac{\left(\frac{\lambda}{0.5-n_L^{-0.5}}\right)^{n_{L,1}\bar{\mathbb{X}}_{L,1}}\left(1-\frac{\lambda}{0.5-n_L^{-0.5}}\right)^{n_{L,1}(1-\bar{\mathbb{X}}_{L,1})}}{\left(\frac{\lambda}{0.5+n_L^{-0.5}}\right)^{n_{L,1}\bar{\mathbb{X}}_{L,1}}\left(1-\frac{\lambda}{0.5+n_L^{-0.5}}\right)^{n_{L,1}(1-\bar{\mathbb{X}}_{L,1})}}} && eq.5 \\ &= \frac{1}{1 + \left(1 + \frac{4}{n_L^{0.5}-2}\right)^{n_{L,1}}\left(1 - \frac{4}{(1-2\theta\alpha)n_L^{0.5}+2}\right)^{n_{L,1}(1-\bar{\mathbb{X}}_{L,1})}} && \lambda = \theta\alpha \end{aligned} \quad (6)$$

Let $\gamma_{n_L} := \mathbb{P}(\theta = 0.5 + n_L^{-1}|\lambda, \mathbb{X}_L, \mathbf{Y}_L)$. Note that $\frac{n_{L,1}}{n_L} \xrightarrow{a.s.} p_{1|L}$ and $\bar{\mathbb{X}}_{L,1} \xrightarrow{a.s.} \alpha$. Therefore, since $|\theta - 0.5| \leq n_L^{-0.5}$, it follows from eq. 6 that γ_{n_L} converges a.s. to a quantity between $\frac{1}{1+\exp\left(\frac{-8\alpha p_{1|L}}{1-\alpha}\right)}$ and $\frac{1}{1+\exp\left(\frac{8\alpha p_{1|L}}{1-\alpha}\right)}$. That is,

$$\mathbb{E}[\gamma_{n_L}(1 - \gamma_{n_L})|S_1^n] \geq \Omega(1). \quad (7)$$

Note that $\bar{\mathbb{X}}_U$ is sufficient for (θ, α) and $\bar{\mathbb{X}}_U$ converges a.s. to λ. Therefore,

$$\begin{aligned}\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]|S_1^n] &= \mathbb{E}[\mathbb{V}[\theta|\bar{\mathbb{X}}_U, \mathbb{X}_L, \mathbf{Y}_L]|S_1^n] \\ &\geq \mathbb{E}[\mathbb{V}[\theta|\lambda, \mathbb{X}_L, \mathbf{Y}_L]|S_1^n] \\ &\geq 4n_L^{-1}\mathbb{E}\left[\gamma_{n_L}(1 - \gamma_{n,L})\mathbb{I}\left(\lambda \in \left(\epsilon(0.5 + n_L^{-1}), 0.5 - n_L^{-1}\right]\right)|S_1^n\right] \end{aligned} \quad (8)$$

Since $\mathbb{P}(\lambda \in \epsilon(0.5 + n_L^{-1}), 0.5 - n_L^{-1}) \geq 0.5$, it follows from eqs. 7 and 8 that

$$\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]|S_1^n] \geq \Omega(n_L^{-1}) \quad (9)$$

The proof follows from combining eqs. 4 and 9. ■

Proof [Theorem 3] We wish to find a lower bound for the minimax risk given a constraint, $\mathcal{F}$. In order to do so, we use the result that the minimax risk is lower bounded by the Bayes risk of any Bayes estimator associated to a prior with support in $\mathcal{F}$ (Wasserman, 2006; Esteves et al., 2017). Since we consider the squared error loss, the Bayes risk of the Bayes estimator is $\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]]$. Hence, if there exists two priors with support in $\mathcal{F}$ such that the first one satisfies $\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]] \geq \Omega(n_L^{-1})$ and the second one satisfies $\mathbb{E}[\mathbb{V}[\theta|\mathbb{X}_U, \mathbb{X}_L, \mathbf{Y}_L]] \geq \Omega(n_U^{-1})$, then we can conclude that the minimax risk is lower bounded by $\Omega(\max(n_L^{-1}, n_U^{-1}))$. Lemma 18 can be used to determine these priors for the classes $\mathcal{F}_{\mathcal{L}_1,\epsilon}$ and $\mathcal{F}_{g,k,\epsilon}$. The proof for $\mathcal{F}_{\mathcal{L}_1,\epsilon}$ follows from taking $\epsilon^* = \epsilon$ in Lemma 18. Next, if $\mathcal{F}_{g,k,\epsilon} \neq \emptyset$, then there exist a and b such that $\frac{\epsilon}{|g(a)-g(b)|} < 1$. Without loss of generality, let $a = 0$ and $b = 1$. The proof follows from taking $\epsilon^* = \frac{\epsilon}{|g(1)-g(0)|}$ in Lemma 18. ■

Lemma 19 *For every function, g, under Assumption 3,*

$$\theta := \mathbb{P}(Y=1|S=0) = \frac{\mathbb{E}[g(\mathbf{X})|S=0] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}{\mathbb{E}[g(\mathbf{X})|Y=1,S=1] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}$$

Proof Let $f(\mathbf{x})$ denote the density of $\mathbf{X}$. Note that

$$\begin{aligned}
g(\mathbf{x})f(\mathbf{x}|S=0) &= \sum_{j=0}^{1} g(\mathbf{x})f(\mathbf{x}|Y=j,S=0)\mathbb{P}(Y=j|S=0) && \text{Law of total prob.}\\
\mathbb{E}[g(\mathbf{X})|S=0] &= \sum_{j=0}^{1} \mathbb{E}[g(\mathbf{X})|Y=j,S=0]\mathbb{P}(Y=j|S=0) && \text{Integration over } \mathbf{x}\\
&= \sum_{j=0}^{1} \mathbb{E}[g(\mathbf{X})|Y=j,S=1]\mathbb{P}(Y=j|S=0) && \text{Assumption 3} \quad (10)
\end{aligned}$$

Isolating $\mathbb{P}(Y=1|S=0)$ in equation 10 yields

$$\theta := \mathbb{P}(Y=1|S=0) = \frac{\mathbb{E}[g(\mathbf{X})|S=0] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}{\mathbb{E}[g(\mathbf{X})|Y=1,S=1] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}$$

■

Proof [Theorem 6] Follows directly from the definition of $\widehat{\theta}_{UR}$ and $\widehat{\theta}_{R}$, and Lemma 19. ■

Lemma 20 *Let Z_1 and Z_2 be random variables such that $\mathbb{E}[Z_2] \neq 0$ and $\frac{\mathbb{E}[Z_1]}{\mathbb{E}[Z_2]} \in [0,1]$. Define $T = \max\left(0, \min\left(1, \frac{Z_1}{Z_2}\right)\right)$. For every random variable, S, and $\epsilon_1, \epsilon_2 \in (0,1)$.*

$$\mathbb{E}\left[\left(T - \frac{\mathbb{E}[Z_1|S]}{\mathbb{E}[Z_2|S]}\right)^2 \middle| S\right] \leq \frac{4(|\mathbb{E}[Z_1|S]| + \epsilon_1)\max\left(\mathbb{V}[Z_1|S], \mathbb{V}[Z_2|S]\right)}{\min(1, (1-\epsilon_2)^4\mathbb{E}[Z_2|S]^4)} + \epsilon_1^{-2}\mathbb{V}[Z_1|S] + (\epsilon_2\mathbb{E}[Z_2|S])^{-2}\mathbb{V}[Z_2|S]$$

Proof It follows from Taylor's expansion of $\frac{Z_1}{Z_2}$ that there exists $Z_{1,*}$ bounded between $\mathbb{E}[Z_1|S]$ and Z_1, and $Z_{2,*}$ between $\mathbb{E}[Z_2|S]$ and Z_2 such that

$$\frac{Z_1}{Z_2} = \frac{\mathbb{E}[Z_1|S]}{\mathbb{E}[Z_2|S]} + \frac{1}{Z_{2,*}}(Z_1 - \mathbb{E}[Z_1|S]) - \frac{Z_{1,*}}{Z_{2,*}^2}(Z_2 - \mathbb{E}[Z_2|S])$$

Therefore, by letting $A = \{|Z_1 - \mathbb{E}[Z_1|S]| \leq \epsilon_1, |Z_2 - \mathbb{E}[Z_2|S]| \leq \epsilon_2\mathbb{E}[Z_2|S]\}$, obtain

$$\begin{aligned}
&\mathbb{E}\left[\left(\frac{Z_1}{Z_2} - \frac{\mathbb{E}[Z_1|S]}{\mathbb{E}[Z_2|S]}\right)^2 \middle| A, S\right]\mathbb{P}(A|S)\\
=&\mathbb{E}\left[\left(\frac{1}{Z_{2,*}}(Z_1 - \mathbb{E}[Z_1|S]) - \frac{Z_{1,*}}{Z_{2,*}^2}(Z_2 - \mathbb{E}[Z_2|S])\right)^2 \middle| A, S\right]\mathbb{P}(A|S)\\
\leq& 4\max\left(\mathbb{E}\left[\frac{1}{Z_{2,*}^2}(Z_1 - \mathbb{E}[Z_1|S])^2 \middle| A, S\right], \mathbb{E}\left[\frac{Z_{1,*}^2}{Z_{2,*}^4}(Z_2 - \mathbb{E}[Z_2|S])^2 \middle| A, S\right]\right)\mathbb{P}(A|S)\\
\leq& \frac{4(|\mathbb{E}[Z_1|S]| + \epsilon_1)\max\left(E\left[(Z_1 - \mathbb{E}[Z_1|S])^2 \middle| A, S\right], E\left[(Z_2 - \mathbb{E}[Z_2|S])^2 \middle| A, S\right]\right)\mathbb{P}(A|S)}{\min(1, (1-\epsilon_2)^4\mathbb{E}[Z_2|S]^4)}\\
\leq& \frac{4(|\mathbb{E}[Z_1|S]| + \epsilon_1)\max\left(\mathbb{V}[Z_1|S], \mathbb{V}[Z_2|S]\right)}{\min(1, (1-\epsilon_2)^4\mathbb{E}[Z_2|S]^4)} \qquad (11)
\end{aligned}$$

Finally, obtain that

$$\begin{aligned}
E\left[\left(T - \frac{\mathbb{E}[Z_1|S]}{\mathbb{E}[Z_2|S]}\right)^2 \middle| S\right] &= \mathbb{E}\left[\mathbb{E}\left[\left(T - \frac{\mathbb{E}[Z_1|S]}{\mathbb{E}[Z_2|S]}\right)^2 \middle| \mathbb{I}_A, S\right] \middle| S\right]\\
&\leq \mathbb{E}\left[\left(\frac{Z_1}{Z_2} - \frac{\mathbb{E}[Z_1|S]}{\mathbb{E}[Z_2|S]}\right)^2 \middle| A, S\right]\mathbb{P}(A|S) + \mathbb{P}(A^c|S) && T, \frac{\mathbb{E}[Z_1]}{\mathbb{E}[Z_2]} \in [0,1]\\
&\leq \frac{4(|\mathbb{E}[Z_1|S]| + \epsilon_1)\max\left(\mathbb{V}[Z_1|S], \mathbb{V}[Z_2|S]\right)}{\min(1, (1-\epsilon_2)^4\mathbb{E}[Z_2|S]^4)} + \mathbb{P}(A^c|S) && \text{eq. 11}
\end{aligned}$$

The result follows from applying the union bound and Chebyshev's inequality to obtain

$$\begin{aligned}
\mathbb{P}(A^c|S) &\leq \mathbb{P}(|Z_1 - \mathbb{E}[Z_1|S]| > \epsilon_1|S) + \mathbb{P}(|Z_2 - \mathbb{E}[Z_2|S]| > \epsilon_2\mathbb{E}[Z_2|S]|S)\\
&\leq \epsilon_1^{-2}\mathbb{V}[Z_1|S] + (\epsilon_2\mathbb{E}[Z_2|S])^{-2}\mathbb{V}[Z_2|S]
\end{aligned}$$

■

Proof [Theorem 7] Define $Z_1 = \frac{\sum_{i\in A_0} g(\mathbf{X}_i)}{|A_0|} - \frac{\sum_{i\in A_{1,0}} g(\mathbf{X}_i)}{|A_{1,0}|}$ and also $Z_2 = \frac{\sum_{i\in A_{1,1}} g(\mathbf{X}_i)}{|A_{1,1}|} - \frac{\sum_{i\in A_{1,0}} g(\mathbf{X}_i)}{|A_{1,0}|}$. Note that

$$\begin{aligned}
\mathbb{E}\left[\frac{\sum_{i\in A_0} g(\mathbf{X}_i)}{|A_0|}\middle|\mathbf{S}_1^n\right] &= \mathbb{E}[g(\mathbf{X})|S=0]\\
\mathbb{E}\left[\frac{\sum_{i\in A_{1,j}} g(\mathbf{X}_i)}{|A_{1,j}|}\middle|\mathbf{S}_1^n\right] &= \mathbb{E}[g(\mathbf{X})|Y=j,S=1]
\end{aligned}$$

It follows from Lemma 19 that $\theta = \frac{\mathbb{E}[Z_1|\mathbf{S}_1^n]}{\mathbb{E}[Z_2|\mathbf{S}_1^n]}$. With $T := \widehat{\theta}_R = \max\left(0, \min\left(1, \frac{Z_1}{Z_2}\right)\right)$, obtain

$$\begin{aligned}
\mathbb{E}\left[\left(\widehat{\theta}_R - \theta\right)^2 \middle| \mathbf{S}_1^n\right] &= \mathbb{E}\left[\left(T - \frac{\mathbb{E}[Z_1|\mathbf{S}_1^n]}{\mathbb{E}[Z_2|\mathbf{S}_1^n]}\right)^2 \middle| \mathbf{S}_1^n\right] \\
&\leq \frac{4(|\mathbb{E}[Z_1|\mathbf{S}_1^n]| + \epsilon_1)\max\left(\mathbb{V}[Z_1|\mathbf{S}_1^n], \mathbb{V}[Z_2|\mathbf{S}_1^n]\right)}{\min(1, (1-\epsilon_2)^4\mathbb{E}[Z_2|\mathbf{S}_1^n]^4)} \\
&+ \epsilon_1^{-2}\mathbb{V}[Z_1|\mathbf{S}_1^n] + (\epsilon_2\mathbb{E}[Z_2|\mathbf{S}_1^n])^{-2}\mathbb{V}[Z_2|\mathbf{S}_1^n] \qquad \text{Lemma 20}
\end{aligned}$$

The result follows from observing that, under $\mathcal{F}_{g,K,\epsilon}$, $\mathbb{E}[Z_1|\mathbf{S}_1^n]$ and $\mathbb{E}[Z_2|\mathbf{S}_1^n]$ are bounded by constants, $\mathbb{V}[Z_1|\mathbf{S}_1^n] = \mathcal{O}(\max(n_L^{-1}, n_U^{-1}))$, and $\mathbb{V}[Z_2|\mathbf{S}_1^n] = \mathcal{O}(n_L^{-1})$. ■

Proof [Theorem 10] The proof strategy is divided into two parts. The first part consists of proving a joint central limit theorem for the three sample averages that appear in the untrimmed ratio estimator. The second part uses this central limit theorem and the delta method to complete the proof for each case that is considered in the theorem.

The main challenge appears when proving the central limit theorem for the sample averages that appear in the ratio estimator. This occurs since these averages are not marginally independent. However, they are independent conditional on the values of $\mathbf{Y}$ and $\mathbf{S}$. This conditional independence can be used to calculate the limiting behavior of the characteristic function of the standardized averages, which completes this part of the proof.

We tidy the proof by using the following notation: $\mu_U := \mathbb{E}[g(\mathbf{X}_i)|S_i = 0]$, $\sigma_U^2 := \mathbb{V}[g(\mathbf{X}_i)|S_i = 0]$, $Z_{U,n} := \frac{\sqrt{n_U}}{\sigma_U}\left(\frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0)}{n_U} - \mu_U\right)$, $Z_{j,n} := \frac{\sqrt{n_j}}{\sigma_j}\left(\frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0,Y_i=j)}{n_j} - \mu_j\right)$, $F_i = \mathbb{I}(S_i = 1)(Y_i + 1)$, $A_U = \{F_1 = 0\}$, $A_0 = \{F_1 = 1\}$, and $A_1 = \{F_1 = 2\}$. Note that

$$\begin{aligned}
\lim_{n\to\infty} \phi_{Z_{U,n},Z_{0,n},Z_{1,n}}(t_U, t_0, t_1) &= \lim_{n\to\infty} \mathbb{E}\left[\mathbb{E}\left[\exp\left(\sum_{j\in\{U,0,1\}} it_j Z_{j,n}\right)\middle| F_1, \ldots, F_n\right]\right] \\
&= \lim_{n\to\infty} \mathbb{E}\left[\prod_{j\in\{U,0,1\}} \mathbb{E}\left[\exp\left(it_j Z_{j,n}\right)\middle| F_1, \ldots, F_n\right]\right] \\
&= \lim_{n\to\infty} \mathbb{E}\left[\prod_{j\in\{U,0,1\}} \left(\phi_{\frac{g(\mathbf{X}_1)-\mu_j}{\sigma_j}|A_j}(t_j n_j^{-0.5})\right)^{n_j}\right] \qquad (12)
\end{aligned}$$

It follows from the Central Limit Theorem for i.i.d. random variables that, for every $j \in \{U, 0, 1\}$, $\phi^{n_j}_{\frac{g(\mathbf{X}_1)-\mu_j}{\sigma_j}|A_j}(t_j n_j^{-0.5}) \to \exp(-0.5t_j^2)$ as $n_j \to \infty$. Since $n_j \xrightarrow{a.s.} \infty$, conclude from eq. 12 and the dominated convergence theorem that

$$\lim_{n\to\infty} \phi_{Z_{U,n},Z_{0,n},Z_{1,n}}(t_U, t_0, t_1) = \prod_{j\in\{U,0,1\}} \exp(-0.5t_j^2)$$

and, using $\mathbb{1}$ as the identity matrix, obtain

$$(Z_{U,n}, Z_{0,n}, Z_{1,n}) \rightsquigarrow N(0, \mathbb{1}) \qquad (13)$$

Assume that $p_L \neq 0$. In this case, since $\frac{n_L}{n} \xrightarrow{\mathbb{P}} p_L$, it follows from eq. 13 that

$$\sqrt{n}\left(\frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0)}{n_U} - \mu_U, \frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0,Y_i=0)}{n_0} - \mu_0, \frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0,Y_i=1)}{n_1} - \mu_1\right)$$

converges in distribution to $N\left(0, diag\left(\frac{\sigma_U^2}{1-p_L}, \frac{\sigma_0^2}{p_L p_{0|L}}, \frac{\sigma_1^2}{p_L p_{1|L}}\right)\right)$. Since $\theta = \frac{\mu_U - \mu_0}{\mu_1 - \mu_0}$ (Lemma 19) and $\widehat{\theta}_{UR} = \frac{\frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0)}{n_U} - \frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0,Y_i=0)}{n_0}}{\frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0,Y_i=1)}{n_1} - \frac{\sum_{i=1}^n g(\mathbf{X}_i)\mathbb{I}(S_i=0,Y_i=0)}{n_0}}$, it follows from the delta method (Casella and Berger, 2002) that

$$\sqrt{n}(\widehat{\theta}_{UR} - \theta) \rightsquigarrow N\left(0, \frac{\sigma_U^2(1-p_L)^{-1}}{(\mu_1-\mu_0)^2} + \frac{(\mu_U-\mu_1)^2\sigma_0^2(p_L p_{0|L})^{-1}}{(\mu_1-\mu_0)^4} + \frac{(\mu_U-\mu_0)^2\sigma_1^2(p_L p_{1|L})^{-1}}{(\mu_1-\mu_0)^4}\right)$$

Since $\mu_U = (1-\theta)\mu_0 + \theta\mu_1$ and $\sigma_U^2 = (1-\theta)\sigma_0^2 + \theta\sigma_1^2 + (\mu_1-\mu_0)^2\theta(1-\theta)$ obtain that

$$\sqrt{n}(\widehat{\theta}_{UR} - \theta) \rightsquigarrow N\left(0, \frac{\frac{(1-\theta)\sigma_0^2 + \theta\sigma_1^2 + (\mu_1-\mu_0)^2\theta(1-\theta)}{1-p_L} + \frac{(1-\theta)^2\sigma_0^2}{p_L p_{0|L}} + \frac{\theta^2\sigma_1^2}{p_L p_{1|L}}}{(\mu_1-\mu_0)^2}\right)$$

Next, assume that $p_L = 0$. Obtain that $\sqrt{h(n)}(Z_{U,n} - \mu_U) \xrightarrow{\mathbb{P}} 0$ and

$$\sqrt{h(n)}\left(\frac{\sqrt{p_{0|L}}}{\sigma_0}(Z_{0,n} - \mu_0), \frac{\sqrt{p_{1|L}}}{\sigma_1}(Z_{1,n} - \mu_1)\right) \rightsquigarrow N(0, \mathbb{1})$$

It follows from the delta method and Slutsky's theorem that

$$\sqrt{h(n)}(\widehat{\theta}_{UR} - \theta) \rightsquigarrow N\left(0, \frac{\frac{(1-\theta)^2\sigma_0^2}{p_{0|L}} + \frac{\theta^2\sigma_1^2}{p_{1|L}}}{(\mu_1-\mu_0)^2}\right)$$

The same convergence results hold for $\widehat{\theta}_R$ since the derivative of the trimming function is 1 around θ. ■

Proof [Theorem 13] It follows from the Representer Theorem (Wahba, 1990) that, for every $g \in \mathcal{H}_K$, $g(\mathbf{x}) = \sum_{k\in A_1} w_k K(\mathbf{x}, \mathbf{x}_k)$. Using this fact, for every $i \in \{0, 1\}$,

$$\begin{aligned}
\widehat{\mu}_i &= \frac{\sum_{j\in A_{1,i}} g(\mathbf{x}_j)}{n_i} = \frac{\sum_{k\in A_1} w_k \sum_{j\in A_{1,i}} K(\mathbf{x}_j, \mathbf{x}_k)}{n_i} = \mathbf{w}^t m_i \\
\widehat{\sigma}_i^2 &= \frac{\sum_{j\in A_{1,i}} (g(\mathbf{x}_j) - \widehat{\mu}_i)^2}{n_i} = \mathbf{w}^t \widehat{\Sigma}_i \mathbf{w}
\end{aligned}$$

Therefore, for every $g \in \mathcal{H}_K$,

$$\widehat{\mathrm{MSE}}(g) = \frac{\mathbf{w}^t N \mathbf{w}}{\mathbf{w}^t M \mathbf{w}}.$$

Proof [Proposition 14]

$$\begin{aligned} F_{g(\mathbf{X})|S=0} &= \theta F_{g(\mathbf{X})|S=0,Y=1} + (1-\theta)F_{g(\mathbf{X})|S=0,Y=0} \\ &= \theta F_{g(\mathbf{X})|S=1,Y=1} + (1-\theta)F_{g(\mathbf{X})|S=1,Y=0} \qquad 3 \end{aligned}$$

Thus, there exists $0 \leq p \leq 1$ such that $F_{g(\mathbf{X})|S=0} = pF_{g(\mathbf{X})|S=1,Y=1} + (1-p)F_{g(\mathbf{X})|S=1,Y=0}$. ■

Proof [Theorem 15]

$$\begin{aligned} MSE[\widehat{\theta}_C] &= \mathbb{E}\left[\left((w\widehat{\theta}_R + (1-w)\widehat{\theta}_L) - \theta\right)^2\right] = \mathbb{E}\left[\left((w(\widehat{\theta}_R - \theta) + (1-w)(\widehat{\theta}_L - \theta)\right)^2\right] \\ &= w^2 MSE[\widehat{\theta}_R] + (1-w)^2 MSE[\widehat{\theta}_L] + 2w(1-w)\mathbb{E}[(\widehat{\theta}_R - \theta)(\widehat{\theta}_L - \theta)] \qquad \widehat{\theta}_R \text{ indep. } \widehat{\theta}_L, \mathbb{E}[\widehat{\theta}_L] = \theta \\ &= w^2 MSE[\widehat{\theta}_R] + (1-w)^2 MSE[\widehat{\theta}_L] \end{aligned}$$

It follows that $MSE[\widehat{\theta}_C]$ is minimized by taking $w = MSE[\widehat{\theta}_L] \times (MSE[\widehat{\theta}_L] + MSE[\widehat{\theta}_R])^{-1}$. ■

Lemma 21 *For every function, g, under Assumptions 3 and 6*

$$\theta(\mathbf{z}) = \frac{\mathbb{E}[g(\mathbf{X})|S=0,\mathbf{z}] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}{\mathbb{E}[g(\mathbf{X})|Y=1,S=1] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}$$

Proof For every $\mathbf{z} \in \mathbb{R}^{d_z}$, Let $f(\mathbf{x})$ denote the density of $\mathbf{X}$. Note that

$$\begin{aligned} g(\mathbf{x})f(\mathbf{x}|S=0,\mathbf{z}) &= \sum_{j=0}^{1} g(\mathbf{x})f(\mathbf{x}|Y=j,S=0,\mathbf{z})\mathbb{P}(Y=j|S=0,\mathbf{z}) \quad \text{Law of total prob.} \\ \mathbb{E}[g(\mathbf{X})|S=0,\mathbf{z}] &= \sum_{j=0}^{1} \mathbb{E}[g(\mathbf{X})|Y=j,S=0,\mathbf{z}]\mathbb{P}(Y=j|S=0,\mathbf{z}) \quad \text{Integration over } \mathbf{x} \\ &= \sum_{j=0}^{1} \mathbb{E}[g(\mathbf{X})|Y=j,S=0]\mathbb{P}(Y=j|S=0,\mathbf{z}) \quad \text{Assumption 6} \\ &= \sum_{j=0}^{1} \mathbb{E}[g(\mathbf{X})|Y=j,S=1]\mathbb{P}(Y=j|S=0,\mathbf{z}) \quad \text{Assumption 3} \end{aligned} \tag{14}$$

Isolating $\mathbb{P}(Y=1|S=0,\mathbf{z})$ in equation 14 yields

$$\theta(\mathbf{z}) := \mathbb{P}(Y=1|S=0,\mathbf{z}) = \frac{\mathbb{E}[g(\mathbf{X})|S=0,\mathbf{z}] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}{\mathbb{E}[g(\mathbf{X})|Y=1,S=1] - \mathbb{E}[g(\mathbf{X})|Y=0,S=1]}$$

Proof [Theorem 17] The main difference between this proof and the one of Theorem 7 is that $\widehat{\mathbb{E}}[g(\mathbf{X})|S=0,\mathbf{z}]$ is usually biased for $\mathbb{E}[g(\mathbf{X})|S=0,\mathbf{z}]$. The proof strategy consists of isolating this bias term from the squared error and then replicating steps which are similar to the ones in Theorem 7.

In order to present the proof in a compact form, some special notation is used. Specifically, $h_0(\mathbf{z}) = \mathbb{E}[g(\mathbf{X})|S=0,\mathbf{z}]$, $\hat{h}_0(\mathbf{z}) = \widehat{\mathbb{E}}[g(\mathbf{X})|S=0,\mathbf{z}]$, $h_{1,i} = \mathbb{E}[g(\mathbf{X})|S=1,Y=i]$, and $\hat{h}_{1,i} = \widehat{\mathbb{E}}[g(\mathbf{X})|S=1,Y=i]$. Using this notation and Definition 16, note that $\hat{\theta}_{RR}(\mathbf{Z}) = \max\left(0, \min\left(1, \frac{\hat{h}_0(\mathbf{z}) - \hat{h}_{1,0}}{\hat{h}_{1,1} - \hat{h}_{1,0}}\right)\right)$. Therefore,

$$\begin{aligned} &\mathbb{E}\left[\left(\widehat{\theta}_{RR}(\mathbf{Z}) - \theta(\mathbf{Z})\right)^2 \middle| S_1^n\right] \\ =&\mathbb{E}\left[\left(\widehat{\theta}_{RR}(\mathbf{Z}) - \frac{h_0(\mathbf{Z}) - h_{1,0}}{h_{1,1} - h_{1,0}}\right)^2 \middle| S_1^n\right] \quad \text{Lemma 21} \\ \leq&\mathcal{O}\left(\mathbb{E}\left[\left(\widehat{\theta}_{RR}(\mathbf{Z}) - \frac{\mathbb{E}[\hat{h}_0(\mathbf{Z})|S_1^n] - h_{1,0}}{h_{1,1} - h_{1,0}}\right)^2 + \left(\frac{\mathbb{E}[\hat{h}_0(\mathbf{Z})|S_1^n] - h_{1,0}}{h_{1,1} - h_{1,0}} - \frac{h_0(\mathbf{Z}) - h_{1,0}}{h_{1,1} - h_{1,0}}\right)^2 \middle| S_1^n\right]\right) \\ \leq&\mathcal{O}\left(\mathbb{V}[\hat{h}_{1,0}|S_1^n] + \mathbb{V}[\hat{h}_{1,1}|S_1^n] + \mathbb{V}[\hat{h}_0(\mathbf{Z})|S_1^n] + \left(\mathbb{E}[\hat{h}_0(\mathbf{Z})|S_1^n] - h_0(\mathbf{Z})\right)^2\right) \quad \text{Lemma 20} \\ =&\mathcal{O}\left(\max\left(\mathbb{V}[\hat{h}_{1,0}|S_1^n], \mathbb{V}[\hat{h}_{1,1}|S_1^n], \mathbb{E}\left[(\hat{h}_0(\mathbf{Z}) - h_0(\mathbf{z}))^2|S_1^n\right]\right)\right) \\ =&\mathcal{O}\left(\max\left(n_L^{-1}, \mathbb{E}\left[(\hat{h}_0(\mathbf{Z}) - h_0(\mathbf{z}))^2|S_1^n\right]\right)\right) \end{aligned}$$

The last equality follows from observing that $\hat{h}_{1,0}$ and $\hat{h}_{1,1}$ are sample averages. ■

Abstract

We propose a unified data-driven framework based on inverse optimal transport that can learn adaptive, nonlinear interaction cost function from noisy and incomplete empirical matching matrix and predict new matching in various matching contexts. We emphasize that the discrete optimal transport plays the role of a variational principle which gives rise to an optimization based framework for modeling the observed empirical matching data. Our formulation leads to a non-convex optimization problem which can be solved efficiently by an alternating optimization method. A key novel aspect of our formulation is the incorporation of marginal relaxation via regularized Wasserstein distance, significantly improving the robustness of the method in the face of noisy or missing empirical matching data. Our model falls into the category of prescriptive models, which not only predict potential future matching, but is also able to explain what leads to empirical matching and quantifies the impact of changes in matching factors. The proposed approach has wide applicability including predicting matching in online dating, labor market, college application and crowdsourcing. We back up our claims with numerical experiments on both synthetic data and real world data sets.

1. Introduction

Matching is a key problem at the heart of many real-world applications, including online dating (Hitsch et al., 2010), labor market (David, 2001), crowdsourcing (Yuen et al., 2011), marriage (Becker, 1973), paper-to-reviewer assignment (Charlin et al., 2011), kidney transplant donor matching (Dickerson and Sandholm, 2015) and ad allocation (Mehta et al., 2013). Owing to the wide applicability and great importance of matching, 2012 Nobel prize in economics were awarded to two economists Lloyd Shapley and Alvin Roth for their fundamental theoretic work (Gale and Shapley, 1962) and substantive empirical investigations, experiments and practical design (Roth and Sotomayor, 1989, 1992) on matching. A good matching of individuals from two sides (e.g., men vs. women, students vs. school, papers vs. reviewers) is essential to the overall health of the specific market/community. However, matching is a challenging problem due to two major complications: individuals from both sides exhibit various observable and latent features, which makes "suitability of a match" far more complex to assess; and the matching is implicitly, but significantly, influenced by the supply limitations of individuals from each side, so that the supply of an item can only satisfy a small number of users even though it is preferred by many. These two issues must be properly tackled in an optimal matching system.

In many matching problems, feature and preference data can be collected from individuals of either or both sides of the matching. Then a central planner may use such data sets to infer suitable matching or assignment. The feature and preference data collected in this way, however, can be incomplete, noisy, and biased for two reasons:

- an individual may not be aware of the competitors from her own side and/or limited quantity of her preferred match from the opposite side
- collection of a full spectrum of features is inherently difficult or even infeasible (e.g., a student's merit outside of her school curriculum in college admission, or religious belief of a person in a marriage, may not be included in the collected data)

The former factor prevents individuals from listing their orders of preferences and positioning themselves strategically in the market, and the latter results in feature data set that is incomplete and biased.

One possible approach is to use observed (and perhaps latent) features of individuals to generate rating matrix for user-item combinations as in many recomender systems (RS). However, this approach is not suitable given the bias and noise in collected feature or preference data and limited supply constraints in our matching problems. For example, in a standard movie RS problem, a movie can receive numerous high ratings and be watched by many people. In contrary, in a matching-based college admission problem, a student can enter only one college. Therefore, an optimal matching cannot be obtained solely based on personal ratings and preferences—the population of both sides also need to be taken into consideration in a matching problem. This significant difference between standard recommendation and matching demands for new theoretical and algorithmic developments.

Our approach to tackle the aforementioned challenges in matching inference is to consider a generalized framework based on inverse optimal transport, where the diversified population of each side of the matching is naturally modeled as a probability distribution,

and the bilateral preference of two individuals in a potential match is captured by a matching reward (or equivalently, negative matching cost). More specifically, we obtain kernel representation of the cost by learning the feature interaction matrix from the matching data, under which the total social surplus is supposed to be maximal in a healthy matching market as suggested by economists (Carlier and Ekeland, 2010). Moreover, we employ a robust and flexible Wasserstein metric to learn feature-enriched marginal distributions, which proves to be very effective and robust in dealing with incomplete/noisy data in the matching problem.

From a broader perspective, our approach is in the framework of optimization based on variational principles—the observed data are results of some optimization with an unknown objective function (or a known objective function with unknown parameters) that models the problem, and the goal is to learn the objective function (or its parameters) from the data. This approach is a type of prescriptive analytics: it exploits the motivation and mechanism of the subject, and produces results that are interpretable and meaningful to human. The solution process is more instructive and can make use of the observed data more effectively. In this broader sense, our proposed approach based on inverse optimal transport is in a similar spirit as inverse reinforcement learning (Ng et al., 2000). Furthermore, the learned objective can be used to understand the effect of various factors in a matching and infer optimal matching strategy given new data. For instance, in online dating, riders allocation, and many other settings, the central planners (Tinder, OkCupid, Uber, Lyft, etc.) can use such prescriptive models to improve customer experience and align social good with their own profit goal.

Our work is the first to establish a systematic framework for optimal matching learning using incomplete, noisy data under *limited-supply constraints*. In particular, we advocate a nonlinear representation of cost/reward in a matching and view the matching strategy as a solution of (regularized) optimal transport. The equilibrium of certain matching markets, such as marriage, with simplifying assumptions, coincide with optimal transport plans (Becker, 1973). Even for matching markets with complex structure and factors, whose matching mechanism is not yet completely unveiled, the proposed model serves as a powerful modeling tool to study those matchings. In terms of algorithmic development, we derive a highly efficient learning method to estimate the parameters in the cost function representation in the presence of computationally complex Wasserstein metrics. Numerical results show that our method contrasts favorably to other matching approaches in terms of robustness and efficiency, and can be used to infer optimal matching for new data sets accurately.

The rest of this paper is organized as follows: we briefly summarize related work in Section 2 and review discrete optimal transport and its regularized version as well as their close connections in Section 3. Section 4 describes the setup of proposed model and introduces our robust formulation via regularized Wasserstein distance, which tries to capture matching mechanism by leveraging regularized optimal transport. The derivation of optimization algorithm is detailed in Section 5. We evaluate our model in section 6 on both synthetic data and real-world data sets. The last section concludes the paper and points to several directions for potential future research.

2. Related Work

In this section, we briefly summarize some related work, including matching, ecological inference, recommender systems, distance metric learning and reciprocal recommendation.

2.1. Matching

Matching has been widely studied in economics community since the seminal work of Koopmans and Beckmann (1957). Gale and Shapley (1962) studied optimal matching in college admission, marriage market and proposed the famous Gale-Shapley algorithm. Becker (1973) gave a theoretic analysis in marriage market matching. Roth and Sotomayor (1992) did a thorough study and analysis in two-sided matching. Chiappori et al. (2010); Carlier and Ekeland (2010) used optimal transport theory to study the equilibrium of certain matching markets. Galichon and Salanié (2010) theoretically justified the usage of entropy-regularized optimal transport plan to model empirical matching in the presence of unobserved characteristics. Another interesting work (Charlin et al., 2011) proposed to predict optimal matching from learning suitability score in paper-to-review context where they used well-known linear regression, collaborative filtering algorithms to learn suitability scores. There are also some work studying dynamic matching theory and applications such as kidney exchange (Dickerson et al., 2012; Dickerson and Sandholm, 2015) and barter exchange (Anderson et al., 2017; Ashlagi et al., 2017).

A recent work closely related to ours is (Dupuy et al., 2016), where they worked with regularized optimal transport plan and modeled the cost by a bilinear form using an affinity matrix learned from data. By contrast, our work models the cost using a nonlinear kernel representation and incorporate regularized Wasserstein distance to tackle the challenging issues due the incomplete and noisy data in real-world matching problems.

2.2. Ecological Inference

Ecological inference infers the nature of individual level behavior using aggregate (historically called "ecological") data, and is of particular interest to political scientists, sociologists, historians and epidemiologists. Due to privacy or cost issue, individual level data are eluding from researchers, hence the inference made through aggregate data are often subject to ecological fallacy [1]. Previously, people proposed neighborhood model (Freedman et al., 1991), ecological regression (Goodman, 1953) and King's method (King, 2013). A recent progress (Flaxman et al., 2015) is made by using additional information and leverage kernel embedding of distributions, distribution regression to approach this problem.

Our work differs from classical ecological inference problem and methods in four ways. First, we assume access to empirical matching at individual-level granularity which is not available in standard ecological inference setting. Second, in our framework, we focus on learning the preference of two sides in the matching and propose a novel and efficient method to learn it, after which inference/prediction problem becomes trivial as preference is known. Third, different from previous statistical methods, we adopt a model-based approach, leverages optimal transport to model matching and draw a connection between these two fields. Lastly, thanks to the model-based approach, we are able to shed light on

1. https://en.wikipedia.org/wiki/Ecological_fallacy

what factors lead to empirical matching and quantitatively estimate the influence caused by changes of those factors, which are beyond the reach of traditional statistical approaches.

2.3. Recommender Systems

Collaborative filtering (CF) type recommender systems share many similarities with optimal matching problem as both need to learn user preference from rating/matching data and predict rating/matching in a collaborative manner. Matrix-factorization based models (Mnih and Salakhutdinov, 2008; Salakhutdinov and Mnih, 2008) enjoyed great success in Netflix Prize Competition. Rendle (2010, 2012) proposed factorization machine model with strong sparse predictive power and ability to mimic several state-of-the-art, specific factorization methods. Recently there is trend of combining collaborative filtering with deep learning (He and Chua, 2017; He et al., 2017). Most items recommended by conventional recommender systems, however, are non-exclusive and can be consumed by many customers such as movies and music. They do not take supply limit of either or both sides into consideration hence may perform poorly in matching context.

2.4. Distance Metric Learning

Our model essentially aims to learn an adaptive, nonlinear representation of the matching cost. This is closely related to, but more general than, ground metric learning. Prior research on learning different distance metrics in various contexts are fruitful, such as learning cosine similarity for face verification (Nguyen and Bai, 2010), learning Mahalanobis distance for clustering (Xing et al., 2003) and face identification (Guillaumin et al., 2009). However, distance learning for optimal transport distance is largely unexplored. Cuturi and Avis (2014) proposed to learn the ground metric by minimizing the difference of two convex polyhedral functions. Wang and Guibas (2012) formulated a SVM-like minimization problem to learn Earth Mover's distance. Both approaches work with Wasserstein distance which involves solving linear programming as subroutine hence may be computationally too expensive. This paper works with regularized optimal transport distance, involving solving a matrix scaling problem as subroutine which is much lighter than linear programming.

2.5. Reciprocal Recommendation

Another line of related research is reciprocal recommendation (Brozovsky and Petricek, 2007; Pizzato et al., 2013), which also tries to model two-side preference by computing reciprocal score via a hand-craft score function. By a sharp contrast, our model learns how two sides interact with each other from observed noisy/incomplete matching in a data-driven fashion.

3. Background and Preliminaries

In this section, we present Kantorovich's formulation of optimal transportation problem (in discretized setting) and its regularized version.

3.1. Optimal Transport

Given two probability vectors $\boldsymbol{\mu} \in \Sigma_m$ and $\boldsymbol{\nu} \in \Sigma_n$, where $\Sigma_d := \{\boldsymbol{x} \in \mathbb{R}_+^d | \mathbf{1}^T \boldsymbol{x} = 1\}$ is the standard $(d-1)$-dimensional probability simplex, denote the transport polytope of $\boldsymbol{\mu}$ and $\boldsymbol{\nu}$ by

$$U(\boldsymbol{\mu}, \boldsymbol{\nu}) := \{\pi \in \mathbb{R}_+^{m \times n} | \pi \mathbf{1} = \boldsymbol{\mu}, \pi^T \mathbf{1} = \boldsymbol{\nu}\}$$

namely the set of all $m \times n$ non-negative matrices satisfying marginal constraints specified by $\boldsymbol{\mu}, \boldsymbol{\nu}$. Note that $U(\boldsymbol{\mu}, \boldsymbol{\nu})$ is a convex, closed and bounded set containing joint probability distributions with $\boldsymbol{\mu}$ and $\boldsymbol{\nu}$ as marginals. Furthermore, if given a cost matrix $C = [C_{ij}] \in \mathbb{R}^{m \times n}$ where C_{ij} measures the cost of moving a unit mass from μ_i to ν_j, define

$$d(C, \boldsymbol{\mu}, \boldsymbol{\nu}) := \min_{\pi \in U(\boldsymbol{\mu}, \boldsymbol{\nu})} \langle \pi, C \rangle$$

where $\langle A, B \rangle = \mathrm{Tr}(A^T B)$ is the Frobenius inner product for matrices. This quantity describes how to optimally redistribute $\boldsymbol{\mu}$ to $\boldsymbol{\nu}$ so that the total cost is minimized, hence providing a means to measure the similarity between the two distributions. In particular, when $C \in \mathcal{M}^d$, that is, C is in the cone of distance matrices (Brickell et al., 2008), defined as

$$\mathcal{M}^d := \{C \in \mathbb{R}_+^{d \times d} | C_{ii} = 0, C_{ij} = C_{ji}, C_{ij} \leq C_{ik} + C_{kj}, \forall i, j, k\},$$

then it is shown that $d(C)$ is a distance (or metric) on Σ_d (Villani, 2008), named the optimal transport distance (also known as the 1-Wasserstein distance or the earth mover distance). The minimizer π is called the optimal transport plan.

In discrete case, computing OT distance amounts to solving a linear programming problem, for which there exists dedicated algorithm with time complexity $\mathcal{O}(n^3 \log n)$ (Pele and Werman, 2009). Nevertheless, this is still too computationally expensive in large scale settings. In addition, OT plan π typically admits a sparse form which is not robust in data-driven applications. We refer readers to Villani (2008); Peyré et al. (2017) for a thorough theoretical and computational treatment of optimal transport.

3.2. Regularized Optimal Transport

To address the aforementioned computational difficulty, Cuturi (2013) proposed to use a computationally-friendly approximation of OT distance by introducing entropic regularization. This also mitigates the sparsity and improve the smoothness of OT plan. Concretely, consider

$$d_\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu}) := \min_{\pi \in U(\boldsymbol{\mu}, \boldsymbol{\nu})} \{\langle \pi, C \rangle - H(\pi)/\lambda\}$$

where $H(\pi)$ is the discrete entropy defined by

$$H(\pi) = -\sum_{i,j=1}^{m,n} \pi_{ij} (\log \pi_{ij} - 1),$$

and $\lambda > 0$ is the regularization parameter controlling the trade-off between sparsity and uniformity of π. We refer the above quantity as regularized optimal transport (ROT) distance (regularized Wasserstein distance) though it is *not* an actual distance measure.

Algorithm 1 Sinkhorn-Knopp Algorithm

Input: marginal distributions $\boldsymbol{\mu}, \boldsymbol{\nu}$, cost matrix C, regularization parameter λ
$K = \exp(-\lambda C)$
$\boldsymbol{a} = \mathbf{1}$
while not converge **do**
  $\boldsymbol{b} \leftarrow \frac{\boldsymbol{\nu}}{K^T \boldsymbol{a}}$
  $\boldsymbol{a} \leftarrow \frac{\boldsymbol{\mu}}{K\boldsymbol{b}}$
end while
$\pi = \mathbf{diag}(\boldsymbol{a}) K \mathbf{diag}(\boldsymbol{b})$
return $\pi, \boldsymbol{a}, \boldsymbol{b}$

Due to the strict convexity introduced by entropy, $d_\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu})$ admits a unique minimizer with full support $\pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu})$, which we call regularized optimal transport plan in the sequel. The ROT plan π^λ has a semi-closed form solution

$$\pi^\lambda = \mathbf{diag}(\boldsymbol{a}) K \mathbf{diag}(\boldsymbol{b}) \tag{1}$$

where $\boldsymbol{a} \in \mathbb{R}^m, \boldsymbol{b} \in \mathbb{R}^n$ are positive vectors and are uniquely determined up to a multiplicative constant and $K := \exp(-\lambda C)$ is the component-wise exponential of $-\lambda C$. We can efficiently compute $\boldsymbol{a}$ and $\boldsymbol{b}$ by Sinkhorn-Knopp matrix scaling algorithm (Sinkhorn and Knopp, 1967), also known as iterative proportional fitting procedure (IPFP). The algorithm alternately scales rows and columns of K to fit the specified marginals. See Algorithm 1 for detailed description of the Sinkhorn-Knopp algorithm.

Not surprisingly, we have

$$\lim_{\lambda \to \infty} d_\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu}) = d(C, \boldsymbol{\mu}, \boldsymbol{\nu})$$

ROT distance converges to OT distance as λ tends to infinity, i.e., entropic regularization diminishes. Moreover, let

$$\Pi(C, \boldsymbol{\mu}, \boldsymbol{\nu}) = \{\pi | \langle \pi, C \rangle = \min_{\pi \in U(\boldsymbol{\mu}, \boldsymbol{\nu})} \langle \pi, C \rangle\}$$

be the set of all OT plan and

$$\pi^\star = \operatorname*{arg\,max}_{\pi \in \Pi(C, \boldsymbol{\mu}, \boldsymbol{\nu})} H(\pi)$$

be the joint distribution with highest entropy within $\Pi(C, \boldsymbol{\mu}, \boldsymbol{\nu})$, then

$$\lim_{\lambda \to \infty} \pi^\lambda = \pi^\star$$

in another word, ROT plan converges to the most uniform OT plan and the rate of convergence is exponential, as shown by Cominetti and San Martín (1994). The generalization of entropic regularization, Tsallis entropy regularized optimal transport also receives more and more attention and is studied by Muzellec et al. (2017).

ROT has more favorable computational properties than OT does, as it only involves component-wise operation and matrix-vector multiplication, all of which are of quadratic

complexity, and can be parallelized (Cuturi, 2013). This fact makes ROT popular for measuring dissimilarity between potentially unnormalized distributions in many research fields: machine learning (Geneway et al., 2017; Rolet et al., 2016; Laclau et al., 2017), computer vision (Cuturi and Doucet, 2014) and image processing (Papadakis, 2015).

Besides computation efficiency, we argue in next section why it is more appropriate to use ROT in our setting from a modeling perspective.

4. Learning to Match

For the ease of exposition, we refer two sides of the matching market as users and items. The methodology is suitable in various applications where optimal matching is considered under supply limitations, such as marriage market, cab hailing, college admission, organ allocation, paper matching ans so on. Suppose we have m user profiles $\{\boldsymbol{u}_i\}_{i \in [m]} \subset \mathbb{R}^p$, n item profiles $\{\boldsymbol{v}_j\}_{j \in [n]} \subset \mathbb{R}^q$ and N_{ij}, the count of times $(\boldsymbol{u}_i, \boldsymbol{v}_j)$ appears in matching. Let $N = \sum_{i,j=1}^{m,n} N_{ij}$ be the number of all matchings, $[\hat{\pi}_{ij}] = [N_{ij}/N]$ be the observed matching matrix and $\hat{\boldsymbol{\mu}} = \hat{\pi}\mathbf{1}, \hat{\boldsymbol{\nu}} = \hat{\pi}^T\mathbf{1}$ be the sample marginals. Suppose we are also given two cost matrices C_u and C_v, measuring user-user dissimilarity and item-item dissimilarity respectively, we can then select two appropriate constants λ_u and λ_v and use $d_{\lambda_u}(C_u, \boldsymbol{\mu}_1, \boldsymbol{\mu}_2)$ and $d_{\lambda_v}(C_v, \boldsymbol{\nu}_1, \boldsymbol{\nu}_2)$ to measure the dissimilarity of probability distributions $\boldsymbol{\mu}_1, \boldsymbol{\mu}_2$ over user profile space and that of $\boldsymbol{\nu}_1, \boldsymbol{\nu}_2$ over item profile space.

4.1. Modeling Observed Matching Matrix

Becker (1973) pointed out that equilibrium of some matching markets coincide with optimal transport plans which are often highly sparse. The implication of this theory is far from being realistic, though, as we observe heterogeneous matchings in real world. Galichon and Salanié (2015) argued that there are latent features having significant impact on matching but unfortunately unobservable to researchers. Hence they proposed to leverage a combination of pure optimal transport plan and mutual information of two sides of matching to model empirical matching data which is exactly entropy-regularized optimal transport.

Furthermore, the observed matching matrix $\hat{\pi}$ (hence the empirical marginals) often contains noisy, corrupted, and/or missing entries, consequently it is more robust to employ a regularized optimal transport plan rather than enforce an exact matching to empirical data in cost function learning.

To that end, we propose to use regularized optimal transport plan $\pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu})$ in our learning task. This also has several important benefits that take the following aspects into modeling consideration in addition to unobserved latent features:

- **Enforced Diversity.** Diversity is enforced in certain matchings as is the case when admission committee making decisions on applicants, diversity is often an important criterion and underrepresented minorities may be preferred. Entropy term captures the uncertainty introduced by diversity. The idea of connecting entropy with matching to capture/promote diversity is also adopted, for example, by Agrawal et al. (2018) and Ahmed et al. (2017).

- **Aggregated Data.** Sometimes due to privacy issues or insufficient number of matched pairs, only grouped or aggregated data, rather than individual data are available. Accordingly, the aggregated matching is usually denser than individual level matching and is less likely to exhibit sparsity.

4.2. Cost Function via Kernel Representation

The cost function $C_{ij} = c(\boldsymbol{u}_i, \boldsymbol{v}_j)$ is of critical importance as it determines utility loss of user $\boldsymbol{u}_i$ and item $\boldsymbol{v}_j$. The lower the cost is, the more likely user $\boldsymbol{u}_i$ will match item $\boldsymbol{v}_j$, subject to supply limit of items. A main contribution of this work is to learn an adaptive, nonlinear representation of the cost function from empirical matching data. To that end, we present several properties of cost function in optimal matching that support the feasibility.

First of all, we show in the following proposition that the cost function C is not unique in general but can be uniquely determined in a special and important case.

Proposition 1 *Given two marginal probability vectors $\boldsymbol{\mu} \in \Sigma_m$, $\boldsymbol{\nu} \in \Sigma_n$, define $F : \mathbb{R}^{m\times n} \to U(\boldsymbol{\mu}, \boldsymbol{\nu})$, $F(C) = \pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu})$ is the ROT plan of C. Then F is in general not injective, however, when $m = n$ and F is restricted on $\mathcal{M}^n$, $F_{|\mathcal{M}^n}(C)$ is injective.*

Proof One can easily verify that F is well-defined from the strict convexity of ROT. The optimality condition of ROT reads as

$$\pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu}) = \exp(\lambda(-C + \boldsymbol{a}\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T))$$

where $\boldsymbol{a} \in \mathbb{R}^m$ and $\boldsymbol{b} \in \mathbb{R}^n$ are Lagrangian multipliers dependent on C and λ such that $\pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu}) \in U(\boldsymbol{\mu}, \boldsymbol{\nu})$. Therefore, $\pi^\lambda(C + \epsilon\mathbf{1}\mathbf{1}^T, \boldsymbol{\mu}, \boldsymbol{\nu}) = \exp(\lambda(-C - \epsilon\mathbf{1}\mathbf{1}^T + (\boldsymbol{a} + \epsilon\mathbf{1})\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T)) = \pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu})$ for any $\epsilon > 0$. Therefore F is in general not injective.

If $m = n$ and $C_1, C_2 \in \mathcal{M}^n$, by the semi-closed form (1) of ROT plan, there exist positive vectors $\boldsymbol{a}_1, \boldsymbol{b}_1$ and $\boldsymbol{a}_2, \boldsymbol{b}_2$ such that

$$\pi^\lambda(C_1, \boldsymbol{\mu}, \boldsymbol{\nu}) = \mathbf{diag}(\boldsymbol{a}_1) \exp(-\lambda C_1) \mathbf{diag}(\boldsymbol{b}_1)$$
$$\pi^\lambda(C_2, \boldsymbol{\mu}, \boldsymbol{\nu}) = \mathbf{diag}(\boldsymbol{a}_2) \exp(-\lambda C_2) \mathbf{diag}(\boldsymbol{b}_2)$$

If $\pi^\lambda(C_1, \boldsymbol{\mu}, \boldsymbol{\nu}) = \pi^\lambda(C_2, \boldsymbol{\mu}, \boldsymbol{\nu})$, we have

$$\exp(-\lambda C_1) = \mathbf{diag}(\boldsymbol{a}) \exp(-\lambda C_2) \mathbf{diag}(\boldsymbol{b})$$

where $\exp(\cdot)$ is component-wise exponential, $\boldsymbol{a} = \log \frac{\boldsymbol{a}_2}{\boldsymbol{a}_1}$, $\boldsymbol{b} = \log \frac{\boldsymbol{b}_2}{\boldsymbol{b}_1}$.

Since C_1, C_2 are symmetric matrices, it follows that $\boldsymbol{a} = s\boldsymbol{b}$. By appropriately rescaling $\boldsymbol{a}$ and $\boldsymbol{b}$ to make them equal, we have

$$\exp(-\lambda C_1) = \mathbf{diag}(\boldsymbol{w}) \exp(-\lambda C_2) \mathbf{diag}(\boldsymbol{w})$$

where $\boldsymbol{w} = \boldsymbol{a}/\sqrt{s}$. Inspecting (i, i) entry of both sides, we immediately conclude that $\boldsymbol{w} = \mathbf{1}$ and $C_1 = C_2$. ■

Actually, the general non-uniqueness or non-identifiability of cost C is quite natural. For instance, in an online auction setting, if all bidders raise their bids by the same amount, the result of the auction will not change because the rank of bidders remain the same and the original winner still wins the auction. Therefore, by observing empirical matching alone, we can not determine cost matrix definitively without further assumption. Proposition 1 guarantees the uniqueness of learned cost if we model it as a distance matrix, e.g. Mahalanobis distance ($C_{ij} = \sqrt{(\boldsymbol{u}_i - \boldsymbol{v}_j)^T M(\boldsymbol{u}_i - \boldsymbol{v}_j)}$, where M is a positive definite matrix). However, in many cases, cost may grow nonlinearly in the difference of features. An even more serious issue is that if the number of features of two sides of matching are inconsistent or two sides do not lie in the same feature space at all, it would be infeasible to use a distance metric to capture the cost between them due to such dimension incompatibility.

Therefore, as generalized distance functions (Schölkopf, 2001), kernel representation which is able to measure matching cost even when features of two sides do not lie in the same feature space can be leveraged to model the cost function, i.e.,

$$c(\boldsymbol{u}_i, \boldsymbol{v}_j) = k(G\boldsymbol{u}_i, D\boldsymbol{v}_j)$$

where $k(\boldsymbol{x}, \boldsymbol{y})$ is a specific (possibly nonlinear) kernel, $G \in \mathbb{R}^{r\times p}$ and $D \in \mathbb{R}^{r\times q}$ are two unknown linear transformations to be learned. $G\boldsymbol{u}, D\boldsymbol{v}$ can be interpreted as the latent profile associated with users and items and are studied by Agarwal and Chen (2009).

For a wide class of commonly used kernels including linear kernel, polynomial kernel and sigmoid kernel, they depend only on the inner product of two arguments through an activation function f, i.e. $k(\boldsymbol{x}, \boldsymbol{y}) = f(\boldsymbol{x}^T\boldsymbol{y})$. For such kernels, we have

$$c(\boldsymbol{u}_i, \boldsymbol{v}_j) = f(\boldsymbol{u}_i^T G^T D \boldsymbol{v}_j)$$

and it suffices to learn $A = G^T D$. In this case, cost matrix

$$C(A) = f(U^T A V)$$

is parametrized by A and we refer A as interaction matrix. Here we apply f component-wise on $U^T AV$. For ease of presentation, we will work with kernels of this form in the sequel. With kernel function representation, it is still likely that a matching matrix corresponds to multiple cost matrices, and we will be contented with finding one of them that explains the observed empirical matching.

4.3. Kernel Inference with Wasserstein Marginal Regularization

A straight forward way to learn $C(A)$ in kernel representation is estimating parameter A through minimizing negative log likelihood

$$\min_A -\sum_{i=1}^m \sum_{j=1}^n \hat{\pi}_{ij} \log \pi_{ij} \tag{2}$$

where $\pi = \pi^\lambda(C(A), \hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\nu}})$, i.e., one enforces the optimal plan π to satisfy $\pi\mathbf{1} = \hat{\boldsymbol{\mu}}$ and $\pi^T\mathbf{1} = \hat{\boldsymbol{\nu}}$. Note that (2) is equivalent to minimizing the reverse Kullback-Leibler divergence (Bishop, 2006) of ROT plan π with respect to empirical matching $\hat{\pi}$, i.e.,

$$\min_A \mathrm{KL}(\hat{\pi} \| \pi)$$

This is the formulation proposed in Dupuy et al. (2016) which we refer as inverse optimal transport formulation (IOT) in the sequel.

In this variation principle based framework, the ROT plan π has the same marginals as the empirical matching $\hat{\pi}$ does, which is reasonable if the marginal information of empirical matching is sufficiently accurate. In practice, however, the size of samples available is hardly enough, hence the empirical marginals inferred from samples can be incomplete and noisy. To see why this is the case, suppose the ground space $\mathcal{D} = \{1, -1\}^d$, $\boldsymbol{\mu}, \boldsymbol{\nu} \in \mathbb{R}^{2^d}$ are two discrete probability distributions over $\mathcal{D}$ and $\pi^0 \in \mathbb{R}^{2^d \times 2^d}$ is the ground truth matching matrix between $\boldsymbol{\mu}, \boldsymbol{\nu}$. Let $\{X_1, X_2, \cdots, X_N\} \subset \mathbb{R}^{2^d \times 2^d}$ be i.i.d random matrices, where $X_1 = E_{ij}$ with probability π^0_{ij}. Then empirical matching matrix is given by $\hat{\pi} = \bar{X} = \frac{1}{N}\sum_{n=1}^{N} X_n$ and two empirical marginals are $\hat{\boldsymbol{\mu}} = \bar{X}\mathbf{1}, \hat{\boldsymbol{\nu}} = \bar{X}^T\mathbf{1}$. By Bretagnolle-Huber-Carol inequality (Bretagnolle and Huber, 1979; Wellner et al., 2013), for any $\epsilon > 0$, we have

$$\mathbb{P}(\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|_1 > \epsilon) < 2^{2^d} \exp(\frac{-N}{2}\epsilon^2) = \exp(2^d \ln 2 - \frac{\epsilon^2}{2}N)$$
$$\mathbb{P}(\|\hat{\boldsymbol{\nu}} - \boldsymbol{\nu}\|_1 > \epsilon) < 2^{2^d} \exp(\frac{-N}{2}\epsilon^2) = \exp(2^d \ln 2 - \frac{\epsilon^2}{2}N)$$

Hence

$$\begin{aligned}\mathbb{P}(\max\{\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|_1, \|\hat{\boldsymbol{\nu}} - \boldsymbol{\nu}\|_1\} > \epsilon) &= \mathbb{P}(\{\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|_1 > \epsilon\} \cup \{\|\hat{\boldsymbol{\nu}} - \boldsymbol{\nu}\|_1 > \epsilon\}) \\ &\leq \mathbb{P}(\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|_1 > \epsilon) + \mathbb{P}(\|\hat{\boldsymbol{\nu}} - \boldsymbol{\nu}\|_1 > \epsilon) \\ &< 2\exp(2^d \ln 2 - \frac{\epsilon^2}{2}N)\end{aligned}$$

To ensure with at least $1 - \delta$ probability, the maximum error in marginal distributions $\max\{\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|_1, \|\hat{\boldsymbol{\nu}} - \boldsymbol{\nu}\|_1\} \leq \epsilon$, we might need $N(\epsilon, \delta) = \frac{2}{\epsilon^2}(2^d \ln 2 + \ln\frac{2}{\delta})$ samples. Note that $N(\epsilon, \delta)$ is quadratic in $\frac{1}{\epsilon}$ and exponential in d, indicating that practically there are hardly enough samples for us to obtain accurate estimate of marginal distributions $\boldsymbol{\mu}, \boldsymbol{\nu}$.

If using IOT formulation with noisy estimate of marginal distributions, it causes a *systematic error* no smaller than $\max\{\|\Delta\boldsymbol{\mu}\|_1, \|\Delta\boldsymbol{\nu}\|_1\}$ as shown in proposition 2.

Proposition 2 *If empirical $\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\nu}}$ are off from true $\boldsymbol{\mu}, \boldsymbol{\nu}$ by $\Delta\boldsymbol{\mu}, \Delta\boldsymbol{\nu}$, then the matching matrix π_{IOT} recovered by solving equation (2) has error lower bounded by*

$$\|\pi_0 - \pi_{IOT}\|_1 \geq \max\{\|\Delta\boldsymbol{\mu}\|_1, \|\Delta\boldsymbol{\nu}\|_1\}$$

where $\|\pi\|_1 = \sum_{i,j=1}^{m,n} |\pi_{ij}|$, $\hat{\boldsymbol{\mu}}, \boldsymbol{\mu} \in \mathbb{R}^m$ and $\hat{\boldsymbol{\nu}}, \boldsymbol{\nu} \in \mathbb{R}^n$, π_0 is the ground truth matching matrix, $\pi_{IOT} = \pi^{\lambda}(C(A^\star), \hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\nu}})$ and $A^\star$ is the solution of equation (2).

Proof We know $\pi_0 \in U(\boldsymbol{\mu}, \boldsymbol{\nu})$ and $\pi_{\text{IOT}} \in U(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\nu}})$. By triangle inequality, we have

$$\sum_{i=1}^{m}\sum_{j=1}^{n} |(\pi_0)_{ij} - (\pi_{IOT})_{ij}| \geq \sum_{i=1}^{m} |\sum_{j=1}^{n}(\pi_0)_{ij} - (\pi_{IOT})_{ij}| = \sum_{i=1}^{m} |\boldsymbol{\mu}_i - \hat{\boldsymbol{\mu}}_i| = \|\Delta\boldsymbol{\mu}\|_1$$

Interchanging the summation and applying triangle inequality again, we obtain

$$\sum_{j=1}^{n}\sum_{i=1}^{m} |(\pi_0)_{ij} - (\pi_{IOT})_{ij}| \geq \|\Delta\boldsymbol{\nu}\|_1$$

Therefore, we conclude

$$\|\pi_0 - \pi_{\text{IOT}}\|_1 \geq \max\{\|\Delta\boldsymbol{\mu}\|_1, \|\Delta\boldsymbol{\nu}\|_1\}$$

■

We have seen that inaccurate marginal information can serious harm the recovery performance of ground truth matching matrix. Not unexpectedly, it could mislead us to learn an inaccurate cost matrix as well, as stated in proposition 4.

Lemma 3 *Suppose $M \in \mathbb{R}^{m\times n}$ and $f(\boldsymbol{a}, \boldsymbol{b}) = \|\boldsymbol{a}\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T - M\|_F^2$. Then we have*

$$f(\boldsymbol{a}, \boldsymbol{b}) \geq \|M\|_F^2 - \boldsymbol{f}^T A^+ \boldsymbol{f}$$

where $\boldsymbol{f} = [(M\mathbf{1})^T, \mathbf{1}^T M]^T$, $A = \begin{bmatrix} nI_{m\times m} & \mathbf{1}_m\mathbf{1}_n^T \\ \mathbf{1}_n\mathbf{1}_m^T & mI_{n\times n}\end{bmatrix}$, A^+ is the Moore-Penrose inverse of matrix A and $\|M\|_F = \sqrt{\sum_{i=1}^m\sum_{j=1}^n M_{ij}^2}$ is Frobenius norm. In particular, if M can not be written as $M = \boldsymbol{a}\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T$, the lower bound is strictly positive, i.e.,

$$f(\boldsymbol{a}, \boldsymbol{b}) \geq \|M\|_F^2 - \boldsymbol{f}^T A^+ \boldsymbol{f} > 0$$

Proof See Appendix A. ■

Proposition 4 *Suppose $\pi_0 \in \mathbb{R}^{m\times n}$ is the ground truth matching matrix, $\hat{\pi} \in \mathbb{R}^{m\times n}$ is an empirical matching matrix. Let C_0 be the ground truth cost matrix giving rise to π_0 and $C_{IOT} = \arg\min_{C\in\mathbb{R}^{m\times n}} KL(\hat{\pi}||C, \hat{\pi}\mathbf{1}, \hat{\pi}^T\mathbf{1})$ be the learned cost matrix via IOT formulation that gives rise to $\hat{\pi}$, i.e. $\pi_0 = \pi^{\lambda}(C_0, \pi_0\mathbf{1}, \pi_0^T\mathbf{1})$ and $\hat{\pi} = \pi^{\lambda}(C_{IOT}, \hat{\pi}\mathbf{1}, \hat{\pi}^T\mathbf{1})$. Denote $\Delta C = C_0 - C_{IOT}$ and $\Delta\log\pi = \log\pi_0 - \log\hat{\pi}$ and further assume $(\Delta\log\pi)_{ij}$ are independent (absolutely) continuous random variables (w.r.t. Lebesgue measure), we have*

$$\|\Delta C\|_F^2 \geq \frac{1}{\lambda^2}(\|\Delta\log\pi\|_F^2 - \boldsymbol{f}^T A^+ \boldsymbol{f}) > 0 \qquad a.e. \tag{3}$$

where $\boldsymbol{f} = [(\Delta\log\pi\mathbf{1})^T, \mathbf{1}^T\Delta\log\pi]^T$, $A = \begin{bmatrix} nI_{m\times m} & \mathbf{1}_m\mathbf{1}_n^T \\ \mathbf{1}_n\mathbf{1}_m^T & mI_{n\times n}\end{bmatrix}$, A^+ is the Moore-Penrose inverse of matrix A and $\|M\|_F = \sqrt{\sum_{i=1}^m\sum_{j=1}^n M_{ij}^2}$ is Frobenius norm.

Proof First we show that $\min_{C\in\mathbb{R}^{m\times n}} KL(\hat{\pi}||C, \hat{\pi}\mathbf{1}, \hat{\pi}^T\mathbf{1}) = 0$, i.e., $\hat{\pi} = \pi^{\lambda}(C_{IOT}, \hat{\pi}\mathbf{1}^T, \hat{\pi}^T\mathbf{1})$, any empirical matching can be realized as regularized optimal transport plan for some cost matrix.

Given arbitrary $\boldsymbol{\alpha} \in \mathbb{R}^m, \boldsymbol{\beta} \in \mathbb{R}^n$, let $\tilde{C} = \boldsymbol{\alpha}\mathbf{1}^\top + \mathbf{1}\boldsymbol{\beta}^\top - \frac{1}{\lambda}\log\hat{\pi}$, we see easily verify that $\hat{\pi}, \boldsymbol{\alpha}, \boldsymbol{\beta}$ solve the KKT condition of ROT

$$\min_{\pi \in U(\hat{\pi}\mathbf{1}, \hat{\pi}^T\mathbf{1})} \langle \tilde{C}, \pi \rangle - \frac{H(\pi)}{\lambda}$$

Hence $\hat{\pi} = \pi^\lambda(\tilde{C}, \hat{\pi}\mathbf{1}^T, \hat{\pi}^T\mathbf{1})$ and $\min_{C \in \mathbb{R}^{m\times n}} KL(\hat{\pi}||C, \hat{\pi}\mathbf{1}, \hat{\pi}^T\mathbf{1}) = 0$. Therefore, any minimizer C_{IOT} (need not be $\tilde{C}$) of the problem $\min_{C \in \mathbb{R}^{m\times n}} KL(\hat{\pi}||C, \hat{\pi}\mathbf{1}, \hat{\pi}^T\mathbf{1})$ must satisfy

$$\hat{\pi} = \pi^\lambda(C_{IOT}, \hat{\pi}\mathbf{1}^T, \hat{\pi}^T\mathbf{1})$$

By the optimality condition of ROT, we know that there exist $\boldsymbol{a}, \boldsymbol{b}$ such that

$$\pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu}) = \exp(\lambda(-C + \boldsymbol{a}^T\mathbf{1} + \mathbf{1}\boldsymbol{b}^T))$$

hence there exist $\boldsymbol{a}_0, \boldsymbol{b}_0, \hat{\boldsymbol{a}}, \hat{\boldsymbol{b}}$ such that

$$C_0 = \boldsymbol{a}_0\mathbf{1}^T + \mathbf{1}\boldsymbol{b}_0^T - \frac{1}{\lambda}\log\pi_0$$
$$C_{IOT} = \hat{\boldsymbol{a}}\mathbf{1}^T + \mathbf{1}\hat{\boldsymbol{b}}^T - \frac{1}{\lambda}\log\hat{\pi}$$

Take difference and denote $\boldsymbol{a}_0 - \hat{\boldsymbol{a}}, \boldsymbol{b}_0 - \hat{\boldsymbol{b}}$ by $\Delta\boldsymbol{a}, \Delta\boldsymbol{b}$ respectively, we have

$$\Delta C = \Delta\boldsymbol{a}\mathbf{1}^T + \mathbf{1}\Delta\boldsymbol{b}^T - \frac{1}{\lambda}\Delta\log\pi$$

Since singular matrices have zero Lebesgue measure and $(\Delta\log\pi)_{ij}$ are independent continuous random variables, we have

$$\mathbb{P}(\Delta\log\pi = \boldsymbol{a}\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T) \le \mathbb{P}(\det(\Delta\log\pi) = 0) = 0$$

By lemma 3, we obtain

$$\|\Delta C\|_F^2 \ge \frac{1}{\lambda^2}(\|\Delta\log\pi\|_F^2 - \boldsymbol{f}^T A^+ \boldsymbol{f}) > 0 \qquad a.e.$$

■

If we use the inaccurate cost matrix learned via IOT approach, it could negatively affect the quality of future matching prediction, as justified in proposition 5.

Proposition 5 *Let C_0 be any ground truth cost matrix, C_{IOT} be any learned cost matrix via IOT formulation and assume $C_{IOT} \notin \{C|C = C_0 + \boldsymbol{a}\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T$ for some $\boldsymbol{a}, \boldsymbol{b}\}$. Suppose the ground truth matching matrix is $\pi_0 = \pi^\lambda(C_0, \boldsymbol{\mu}, \boldsymbol{\nu})$ and the predicted matching matrix is $\pi_{predict} = \pi^\lambda(C_{IOT}, \boldsymbol{\mu}, \boldsymbol{\nu})$. Denote $\Delta C = C_0 - C_{IOT}$ and $\Delta\log\pi = \log\pi_0 - \log\pi_{predict}$, we have*

$$\|\Delta\log\pi\|_F^2 \ge \lambda^2(\|\Delta C\|_F^2 - \boldsymbol{f}^T A^+ \boldsymbol{f}) > 0 \tag{4}$$

where $\boldsymbol{f} = [(\Delta C\mathbf{1})^T, \mathbf{1}^T\Delta C]^T$, $A = \begin{bmatrix} nI_{m\times m} & \mathbf{1}_m\mathbf{1}_n^T \\ \mathbf{1}_n\mathbf{1}_m^T & mI_{n\times n} \end{bmatrix}$, A^+ is the Moore-Penrose inverse of matrix A and $\|M\|_F = \sqrt{\sum_{i=1}^m\sum_{j=1}^n M_{ij}^2}$ is Frobenius norm.

Proof The proof is almost identical to that of proposition 4 except for interchanging the role of ΔC and $\Delta\log\pi$. We hence omit the details here. ■

To address aforementioned issues, we hence propose a more robust formulation with Wasserstein marginal relaxation, dropping the hard marginal constraint. Concretely, we consider the following optimization problem.

$$\min_{A, \boldsymbol{\mu}\in\Sigma_m, \boldsymbol{\nu}\in\Sigma_n} -\sum_{i=1}^m\sum_{j=1}^n \hat{\pi}_{ij}\log\pi_{ij} + \delta\big(d_{\lambda_u}(C_u, \boldsymbol{\mu}, \hat{\boldsymbol{\mu}}) + d_{\lambda_v}(C_v, \boldsymbol{\nu}, \hat{\boldsymbol{\nu}})\big) \tag{5}$$

where $\pi = \pi^\lambda(C(A), \boldsymbol{\mu}, \boldsymbol{\nu})$ is the regularized optimal transport plan, δ is the relaxation parameter controlling the fitness of marginals, $\lambda, \lambda_u, \lambda_v$ are hyper-parameters controlling the regularity of regularized Wasserstein distance. We refer this formulation as robust inverse optimal transport (RIOT) in the sequel. Interestingly, we note that Chizat et al. (2016) proposed a similar but different formulation in solving unbalanced optimal transport problem.

The intuition of this RIOT formulation is that instead of enforcing noisy empirical marginals as hard constraints, we incorporate them as soft constraints in objective function. We use regularized Wasserstein distance as regularization because of the following reasons:

- as approximated Wasserstein distance, it drives $\boldsymbol{\mu}, \boldsymbol{\nu}$ to $\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\nu}}$, but at the same time it also allows some uncertainty hence is able to robustify the result;
- in presence of missing entries in marginals, Wassertein distance is still well defined while other measures such as KL are not;
- Wasserstein distance can be applied to continuous, discrete, or even mixed distributions;
- computation of regularized Wasserstein distance (Cuturi, 2013) is efficient and hence potentially more scalable for large scale problem (5) in practice.

To be precise, the robustness in RIOT specifically means that RIOT outperforms IOT, in terms of the quality of learned matching matrix and cost matrix, when the observed joint distributions $\hat{\pi}$ and marginal distributions $\hat{\mu}$ and $\hat{\nu}$ are inaccurate due to insufficient and noisy samples, which is generally the case in real-world applications. In this situation, enforcing hard constraints to the inaccurate distributions is shown to cause severe bias in the estimation of the ground cost C, which will further induce errors in the matching when applied to testing data. The robustness of RIOT over IOT is verified by empirical experiment results in Section 6.1.

We assume access to C_u and C_v in our model because learning user-user/item-item similarity is relatively easier than our task, there are many existing work dedicated to that end (Cheung and Tian, 2004; Agarwal and Bharadwaj, 2013) and we want to single out and highlight our main contribution—learning the cost matrix that gives rise to observed matching and leverage it to infer matching for new data sets. In fact, our framework can also be extended to learn C_u and C_v jointly if needed, the optimization algorithm of which tends to be much more complex, though. See Appendix B for the extension. We postpone the detailed algorithmic derivation of the solution to (5) to next section.

4.4. Predict New Matching

After obtaining interaction matrix A from solving RIOT, we may then leverage it to predict new matching. Concretely, for a group of new users $\{\tilde{\boldsymbol{u}}_i\}_{i\in[m]}$ and items $\{\tilde{\boldsymbol{v}}_j\}_{j\in[n]}$, two marginal distributions, i.e., users profile distribution $\tilde{\boldsymbol{\mu}}$ and item profile distribution $\tilde{\boldsymbol{\nu}}$ can be easily obtained. First compute the cost matrix $\tilde{C}_{ij} = f(\tilde{\boldsymbol{u}}_i^T A \tilde{\boldsymbol{v}}_j)$ using kernel representation and apply Sinkhorn-Knopp algorithm to computing $\tilde{\pi}^\lambda(\tilde{C}, \tilde{\boldsymbol{\mu}}, \tilde{\boldsymbol{\nu}})$, which gives us the predicted matching of the given groups of users and items.

See Figure 1 for illustration of the complete pipeline or proposed learning-to-match framework.

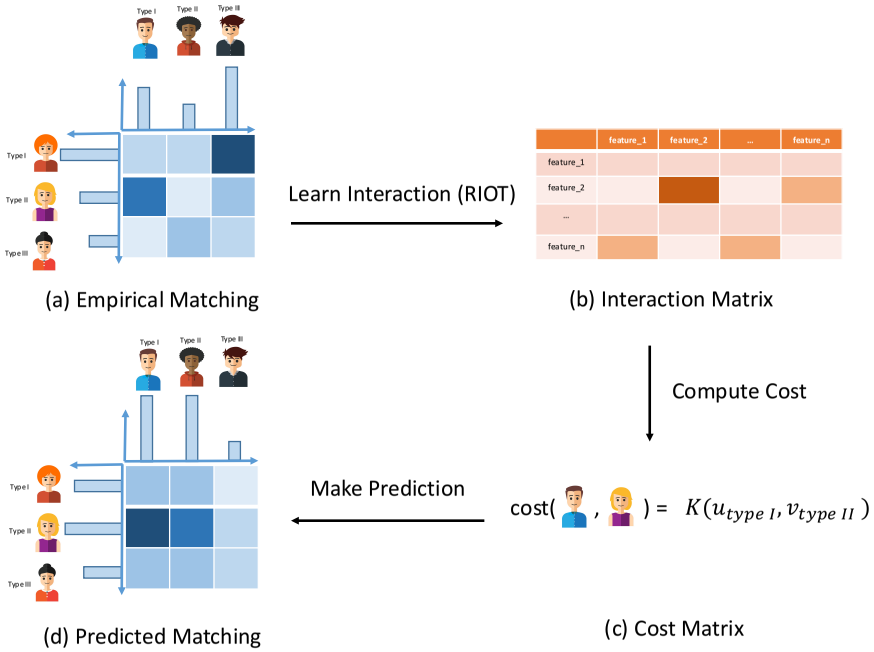

Figure 1: From noisy (a) empirical matching matrix, we learn (b) the interaction matrix via our proposed RIOT formulation. We then use kernel representation to compute (c) cost matrix and predict (d) matching matrix for new data. $\boldsymbol{u}_{type\ I}, \boldsymbol{v}_{type\ II}$ are feature vectors of type I men and type II women.

5. Derivation of Optimization Algorithm

Since the constraint set of ROT problem satisfies Slater's condition (Boyd and Vandenberghe, 2004), we have by strong duality that

$$d_\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu}) = \max_{\boldsymbol{z}} \langle \boldsymbol{z}, \boldsymbol{\mu} \rangle + \langle \boldsymbol{z}^C, \boldsymbol{\nu} \rangle - \frac{1}{\lambda}$$

where $z_j^C = \frac{1}{\lambda}\log c_j - \frac{1}{\lambda}\log(\sum_{i=1}^m e^{\lambda(z_i - C_{ij})})$. $\boldsymbol{z}, \boldsymbol{z}^C$ are essentially the Lagrangian multipliers corresponding to constraints $\pi\mathbf{1} = \boldsymbol{\mu}$ and $\pi^T\mathbf{1} = \boldsymbol{\nu}$. See also Genevay et al. (2016). Hence we have

$$d_{\lambda_u}(C_u, \boldsymbol{\mu}, \hat{\boldsymbol{\mu}}) = \max_{\boldsymbol{z}} \langle \boldsymbol{z}, \boldsymbol{\mu} \rangle + \langle \boldsymbol{z}^{C_u}, \hat{\boldsymbol{\mu}} \rangle - \frac{1}{\lambda_u}$$

$$d_{\lambda_v}(C_v, \boldsymbol{\nu}, \hat{\boldsymbol{\nu}}) = \max_{\boldsymbol{w}} \langle \boldsymbol{w}, \boldsymbol{\nu} \rangle + \langle \boldsymbol{w}^{C_v}, \hat{\boldsymbol{\nu}} \rangle - \frac{1}{\lambda_v}$$

where $z_j^{C_u} = \frac{1}{\lambda_u}\log \hat{r}_j - \frac{1}{\lambda_u}\log(\sum_{i=1}^m e^{\lambda_u(z_i - C_{uij})})$ and $w_j^{C_v} = \frac{1}{\lambda_v}\log \hat{c}_j - \frac{1}{\lambda_v}\log(\sum_{i=1}^n e^{\lambda_v(w_i - C_{vij})})$. Given sample marginals, once $\boldsymbol{z}, \boldsymbol{w}$ are fixed, $\boldsymbol{z}^{C_u}, \boldsymbol{w}^{C_v}$ are also fixed. We can then convert (5) into a min-max problem

$$\min_{A,\boldsymbol{\mu},\boldsymbol{\nu}} \max_{\boldsymbol{z},\boldsymbol{w}} -\sum_{i=1}^m \sum_{j=1}^n \hat{\pi}_{ij} \log \pi_{ij} + \delta\big(\langle \boldsymbol{z}, \boldsymbol{\mu} \rangle + \langle \boldsymbol{z}^{C_u}, \hat{\boldsymbol{\mu}} \rangle + \langle \boldsymbol{w}, \boldsymbol{\nu} \rangle + \langle \boldsymbol{w}^{C_v}, \hat{\boldsymbol{\nu}} \rangle\big) \tag{6}$$

where constants are omitted. The optimal solution is a saddle-point of the objective in (6). To solve this min-max problem, we alternately update the primal variable $(A, \boldsymbol{\mu}, \boldsymbol{\nu})$ and dual variable $(\boldsymbol{z}, \boldsymbol{w})$, each time with the other ones fixed.

5.1. Update $(A, \boldsymbol{\mu}, \boldsymbol{\nu})$ for fixed $(\boldsymbol{z}, \boldsymbol{w})$

Now $\boldsymbol{z}, \boldsymbol{w}, \boldsymbol{z}^{C_u}, \boldsymbol{w}^{C_v}$ are all fixed. Note that

$$\pi_{ij} = e^{\lambda(a_i + b_j - C_{ij})}$$

for some positive vectors $\boldsymbol{a}, \boldsymbol{b}$, such that $\pi\mathbf{1} = \boldsymbol{\mu}$, $\pi^T\mathbf{1} = \boldsymbol{\nu}$, and $\mathbf{1}^T\pi\mathbf{1} = 1$. Thus we may rewrite the minimization in this stage as

$$\begin{aligned} \min_{A,\boldsymbol{a},\boldsymbol{b}} \quad & \sum_{j=1}^n \hat{\pi}_{ij} \log \pi_{ij} + \delta(\langle z, \pi\mathbf{1} \rangle + \langle w, \pi^T\mathbf{1} \rangle) \\ \text{s.t.} \quad & \sum_{i=1}^m \sum_{j=1}^n e^{\lambda(a_i + b_j - C_{ij})} = 1 \end{aligned} \tag{7}$$

For fixed A, denote the optimum of objective function in equation (7) subject to the constraint by $E(C(A))$. Recall that the ultimate goal in this step is to find the interaction matrix A that cost C depends on, such that the minimum above can be attained. For any A, we have kernel representation $C(A)$ parameterized by interaction matrix A. Therefore the minimization above is equivalent to

$$\min_A E(C(A))$$

To minimize $E(C(A))$, the critical step is to evaluate gradient $\nabla_A E(C(A))$ and by envelope theorem (Milgrom and Segal, 2002) we have

Proposition 6 *The gradient $\nabla_A E(C(A))$ is*

$$\nabla_A E = \sum_{i=1}^{m}\sum_{j=1}^{n} \lambda[\hat{\pi}_{ij} + (\theta - \delta(z_i + w_j))\pi_{ij}]C'_{ij}(A)$$

where θ is the Lagrangian multiplier of the constrained minimization problem in equation (7).

Proof By chain rule, we have that

$$\nabla_A E = \sum_{i=1}^{m}\sum_{j=1}^{n} \frac{\partial E}{\partial C_{ij}}\frac{\partial C_{ij}}{A}$$

With the kernel representation, $C'_{ij}(A)$ is easily available. For fixed $C = C(A)$, by envelop theorem (Milgrom and Segal, 2002), we have

$$\begin{aligned}\nabla_{C_{ij}} E(C) &= \frac{\partial}{\partial C} - \sum_{i=1}^{m}\sum_{j=1}^{n}\hat{\pi}_{ij}\log\pi_{ij} + \delta\langle \boldsymbol{z}, \pi\mathbf{1}\rangle + \delta\langle \boldsymbol{w}, \pi^T\mathbf{1}\rangle - \theta(\sum_{i,j=1}^{m,n} e^{\lambda(a_i+b_j-C_{ij})}) \\ &= (-\frac{\hat{\pi}_{ij}}{\pi_{ij}} + \delta(z_i + w_j) - \theta)\frac{\partial \pi_{ij}}{\partial C_{ij}} \\ &= \lambda[\hat{\pi}_{ij} + (\theta - \delta(z_i + w_j))\pi_{ij}]\end{aligned}$$

■

Hence in each evaluation of $\nabla_C E$, we need to solve $E(C(A))$ once. If we denote $\xi_i = e^{\lambda a_i}$, $\eta_j = e^{\lambda b_j}$, $Z_{ij} = e^{-\lambda C_{ij}}$ and $M_{ij} = \delta(z_i + w_j)Z_{ij}$, then computing $E(C(A))$ is equivalent to solving

$$\begin{aligned}\min_{\boldsymbol{\xi},\boldsymbol{\eta}} \quad & -\langle\hat{\boldsymbol{\mu}}, \log\boldsymbol{\xi}\rangle - \langle\hat{\boldsymbol{\nu}}, \log\boldsymbol{\eta}\rangle + \boldsymbol{\xi}^T M\boldsymbol{\eta} \\ \text{s.t.} \quad & \boldsymbol{\xi}^T Z\boldsymbol{\eta} = 1\end{aligned} \tag{8}$$

Note that this is a non-convex optimization problem, both the objective function and constraints are non-convex which is difficult to solve in general. However, once we fix $\boldsymbol{\eta}$, the problem with respect to $\boldsymbol{\xi}$ alone is a convex problem and vice versa. We can solve this problem efficiently by alternately updating $\boldsymbol{\xi}, \boldsymbol{\eta}$.

Proposition 7 *Denote the objective in equation (8) by*

$$h(\boldsymbol{\xi}, \boldsymbol{\eta}) = -\langle\hat{\boldsymbol{\mu}}, \log\boldsymbol{\xi}\rangle - \langle\hat{\boldsymbol{\nu}}, \log\boldsymbol{\eta}\rangle + \boldsymbol{\xi}^T M\boldsymbol{\eta}$$

Initialize $\boldsymbol{\xi}^{(0)}, \boldsymbol{\eta}^{(0)}$ and alternately update $\boldsymbol{\xi}^{(k)}, \boldsymbol{\eta}^{(k)}$ in the following fashion

$$\boldsymbol{\xi}^{(k)} = \underset{\boldsymbol{\xi}^T Z\boldsymbol{\eta}^{(k-1)}=1}{\arg\min}\ h(\boldsymbol{\xi}, \boldsymbol{\eta}^{(k-1)}) \tag{9}$$

$$\boldsymbol{\eta}^{(k)} = \underset{\boldsymbol{\xi}^{(k)^T} Z\boldsymbol{\eta}=1}{\arg\min}\ h(\boldsymbol{\xi}^{(k)}, \boldsymbol{\eta}) \tag{10}$$

If $\lim_{k\to\infty}(\boldsymbol{\xi}^{(k)}, \boldsymbol{\eta}^{(k)}, \theta_1^{(k)}, \theta_2^{(k)}) = (\boldsymbol{\xi}^\star, \boldsymbol{\eta}^\star, \theta_1^\star, \theta_2^\star)$, then $\theta_1^\star = \theta_2^\star$ and $(\boldsymbol{\xi}^\star, \boldsymbol{\eta}^\star)$ is a local minimizer of h, where $\theta_1^{(k)}$ and $\theta_2^{(k)}$ are Lagrangian multipliers corresponding to problem (9) and (10) respectively.

Proof From the definition of $E(C(A))$ in equation (7) it is easily seen that $h(\boldsymbol{\xi}, \boldsymbol{\eta})$ is lower bounded. Moreover, since

$$h(\boldsymbol{\xi}^{(k)}, \boldsymbol{\eta}^{(k)}) \le h(\boldsymbol{\xi}^{(k)}, \boldsymbol{\eta}^{(k-1)}) \le h(\boldsymbol{\xi}^{(k-1)}, \boldsymbol{\eta}^{(k-1)})$$

there exists a convergent subsequence of $\{h(\boldsymbol{\xi}^{(k)}, \boldsymbol{\eta}^{(k)})\}$ and we denote the limit by $h^\star$.

The KKT condition of equation (9) and (10) are

$$-\frac{\hat{\boldsymbol{\mu}}}{\boldsymbol{\xi}^{(k)}} + M\boldsymbol{\eta}^{(k-1)} - \theta_1^{(k)} Z\boldsymbol{\eta}^{(k-1)} = 0 \tag{11}$$

$$\boldsymbol{\xi}^{(k)^T} Z\boldsymbol{\eta}^{(k-1)} = 1$$

$$-\frac{\hat{\boldsymbol{\nu}}}{\boldsymbol{\eta}^{(k)}} + M^T\boldsymbol{\xi}^{(k)} - \theta_2^{(k)} Z^T\boldsymbol{\xi}^{(k)} = 0 \tag{12}$$

$$\boldsymbol{\xi}^{(k)^T} Z\boldsymbol{\eta}^{(k)} = 1$$

Let k tend to infinity and take inner product with $\boldsymbol{\xi}^\star$ for equation (11) and take inner product with $\boldsymbol{\eta}^\star$ for equation (12), compare two equations and use the fact that both $\hat{\boldsymbol{\mu}}$ and $\hat{\boldsymbol{\nu}}$ are probability vectors, we find that $\theta_1^\star = \theta_2^\star$ and $(\boldsymbol{\xi}^\star, \boldsymbol{\eta}^\star)$ solves the KKT condition of constrained problem (9) and (10). Therefore, $(\boldsymbol{\xi}^\star, \boldsymbol{\eta}^\star)$ is a local minimizer and $h^\star = h(\boldsymbol{\xi}^\star, \boldsymbol{\eta}^\star)$ is a local minimum. ■

Once we obtain $(\boldsymbol{\xi}^\star, \boldsymbol{\eta}^\star, \theta^\star)$, we can then get $(\boldsymbol{a}, \boldsymbol{b}, \theta)$ by setting $\boldsymbol{a} = \frac{1}{\lambda}\log\boldsymbol{\xi}^\star$ and $\boldsymbol{b} = \frac{1}{\lambda}\log\boldsymbol{\eta}^\star$ and $\theta = \theta^\star$. Then plug in $(\boldsymbol{a}, \boldsymbol{b}, \theta)$ to evaluate $\nabla_C E$ for the current $C = C(A)$.

A careful analysis of the KKT condition of equations (9) and (10) shows that $\theta_1^{(k)}$ and $\theta_2^{(k)}$ are roots of

$$p(\theta) = \left\langle \frac{\hat{\boldsymbol{\mu}} \odot (Z\boldsymbol{\eta}^{(k-1)})}{(M - \theta Z)\boldsymbol{\eta}^{(k-1)}}, \mathbf{1}\right\rangle,\ \ q(\theta) = \left\langle \frac{\hat{\boldsymbol{\nu}} \odot (Z^T\boldsymbol{\xi}^{(k)})}{(M - \theta Z)^T\boldsymbol{\xi}^{(k)}}, \mathbf{1}\right\rangle$$

respectively. The univariate root finding problem can be solved efficiently by off-the-shelf package. After obtaining $\theta_1^{(k)}, \theta_2^{(k)}$, we can update

$$\boldsymbol{\xi}^{(k)} = \frac{\hat{\boldsymbol{\mu}}}{(M - \theta_1^{(k)} Z)\boldsymbol{\eta}^{(k-1)}},\ \ \boldsymbol{\eta}^{(k)} = \frac{\hat{\boldsymbol{\nu}}}{(M - \theta_2^{(k)} Z)^T\boldsymbol{\xi}^{(k)}}$$

directly. Computationally, this approach to solving problem (9) and (10) is much cheaper than gradient-type iterative methods when m and/or n are large.

5.2. Update $(\boldsymbol{z}, \boldsymbol{w})$ for fixed $(A, \boldsymbol{\mu}, \boldsymbol{\nu})$

When $(A, \boldsymbol{\mu}, \boldsymbol{\nu})$ are fixed, π is also fixed, we then only need to solve

$$\max_{\boldsymbol{z},\boldsymbol{w}} \langle \boldsymbol{z}, \pi \mathbf{1} \rangle + \langle \boldsymbol{z}^{C_u}, \hat{\boldsymbol{\mu}} \rangle + \langle \boldsymbol{w}, \pi^T \mathbf{1} \rangle + \langle \boldsymbol{w}^{C_v}, \hat{\boldsymbol{\nu}} \rangle$$

and one immediately recognizes this is equivalent to applying Sinkhorn-Knopp algorithm to compute $d_{\lambda_u}(C_u, \boldsymbol{\mu}, \hat{\boldsymbol{\mu}})$ and $d_{\lambda_v}(C_v, \boldsymbol{\nu}, \hat{\boldsymbol{\nu}})$.

To summarize, in each iteration, we perform a gradient-type update for A, followed by two calls of Sinkhorn-Knopp algorithm to compute $d_{\lambda_u}(C_u, \boldsymbol{\mu}, \hat{\boldsymbol{\mu}})$ and $d_{\lambda_v}(C_v, \boldsymbol{\nu}, \hat{\boldsymbol{\nu}})$. Algorithm 2 details the algorithm. Note that this algorithm only finds a local minimum of equation 5.

Algorithm 2 Solve RIOT

Input: observed matching matrix $\hat{\pi}$, cost matrices C_u, C_v, regularization parameter $\lambda, \lambda_u, \lambda_v$

for $l = 1, 2, \cdots, L$ **do**

$Z \leftarrow \exp(-\lambda C)$

$M \leftarrow \delta(\boldsymbol{z}\mathbf{1}^T + \mathbf{1}\boldsymbol{w}^T) \odot Z$

Initialize $\boldsymbol{\xi}^{(0)}, \boldsymbol{\eta}^{(0)}$

for $k = 1, 2, \cdots, K$ **do**

$\theta_1^{(k)} \leftarrow$ root of $p(\theta)$

$\theta_2^{(k)} \leftarrow$ root of $q(\theta)$

$\boldsymbol{\xi}^{(k)} \leftarrow \frac{\hat{\boldsymbol{\mu}}}{(M - \theta_1^{(k)} Z)\boldsymbol{\eta}^{(k-1)}}$

$\boldsymbol{\eta}^{(k)} \leftarrow \frac{\hat{\boldsymbol{\nu}}}{(M - \theta_2^{(k)} Z)^T \boldsymbol{\xi}^{(k)}}$

end for

$\boldsymbol{a} \leftarrow \frac{1}{\lambda} \log \boldsymbol{\xi}^{(k)}, \quad \boldsymbol{b} \leftarrow \frac{1}{\lambda} \boldsymbol{\eta}^{(k)}, \quad \theta = \theta_1^{(k)}$

$\pi \leftarrow \exp(\lambda(\boldsymbol{a}\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T - C))$

$\nabla_A \leftarrow \sum_{i,j=1}^{m,n} \lambda[\hat{\pi}_{ij} + (\theta - \delta(z_i + w_j))\pi_{ij}] C'_{ij}(A)$

$A \leftarrow A - s\nabla_A$

$\boldsymbol{a}_1 \leftarrow$ Sinkhorn-Knopp$(C_u, \pi\mathbf{1}, \hat{\boldsymbol{\mu}}, \lambda_u)[1]$

$\boldsymbol{a}_2 \leftarrow$ Sinkhorn-Knopp$(C_v, \pi^T\mathbf{1}, \hat{\boldsymbol{\nu}}, \lambda_v)[1]$

$\boldsymbol{z} \leftarrow \frac{1}{\lambda_u} \log \boldsymbol{a}_1, \quad \boldsymbol{w} \leftarrow \frac{1}{\lambda_v} \log \boldsymbol{a}_2$

end for

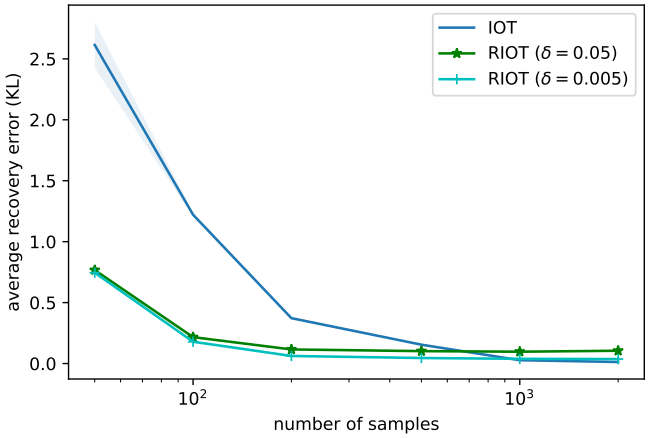
6. Experiments

In this section, we evaluate our proposed RIOT model on both synthetic data and real world data sets. For synthetic data set, we illustrate its robustness against IOT and show our model can achieve better performance in learning cost matrix C than IOT could. For election data set, we show our method can effectively learn meaningful preference of voters based on their demographics. For taxi trip data set, we demonstrate that the proposed model is able to predict matching of taxi drivers and passengers fairly accurate. For marriage

data set, we demonstrate the applicability of RIOT in predicting new matching and make recommendation accordingly by comparing it with baseline and state-of-art recommender systems.

6.1. Synthetic Data

We set $\lambda = \lambda_u = \lambda_v = 1$ and simulate $m = 10$ user profiles $\{\boldsymbol{u}_i\} \subset \mathbb{R}^{10}$, $n = 10$ item profiles $\{\boldsymbol{v}_j\} \subset \mathbb{R}^8$, two probability vectors $\boldsymbol{\mu}_0, \boldsymbol{\nu}_0 \in \mathbb{R}^{10}$, an interaction matrix A_0 of size 10×8 and pick polynomial kernel $k(\boldsymbol{x}, \boldsymbol{y}) = (\gamma \boldsymbol{x}^T \boldsymbol{y} + c_0)^d$ where $\gamma = 0.05, c_0 = 1, d = 2$, hence $C_{0ij} = (0.05\boldsymbol{u}_i^T A \boldsymbol{v}_j + 1)^2$. For C_u, C_v, we randomly generate m and n points from $\mathcal{N}(\mathbf{0}, 5I_2)$ on plane and use their Euclidean distance matrix as C_u and C_v. The ground truth entropy-regularized optimal transport plan is given by $\pi_0 = \pi^\lambda(C_0, \boldsymbol{\mu}_0, \boldsymbol{\nu}_0)$. We independently sample N samples from π_0 and then compute empirical matching matrix $\hat{\pi}$ accordingly. In algorithm 2, we set the number of iterations of inner loop $K = 20$.



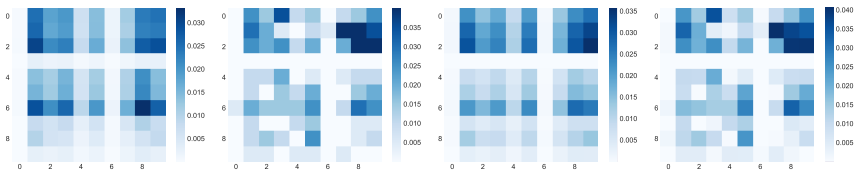


Figure 2: Comparison of recovery performance of fixed marginal approach (IOT) and marginal relaxation approach (RIOT). For sample size N, we sample from π_0, compute empiricla matching $\hat{\pi}$ and run algorithm 2 for 50 times. The shaded region is one standard deviation.

6.1.1. Improved Robustness

To produce Figure 2, we set the number of iterations in outer loop $L = 50$, learning rate $s = 10$. For each $N \in \{50, 100, 200, 500, 1000, 2000\}$ we run algorithm 2 and record Kullback-Leibler divergence between learned matching matrix π_{IOT}, π_{RIOT} and ground truth matching matrix π_0. Figure 2 shows that RIOT with different relaxation parameters

(a) π_0 (b) $\hat{\pi}$ (c) π_{RIOT} (d) π_{IOT}

Figure 3: Comparison of (a) actual matching matrix π_0 (b) noised matching matrix $\hat{\pi}$ ($\text{KL}(\pi_0\|\hat{\pi}) = 1.269$) (c) matching matrix π_{RIOT} learned by marginal relaxation approach ($\text{KL}(\pi_0\|\pi_{\text{RIOT}}) = 0.219$) (d) matching matrix π_{IOT} learned with fixed marginal approach ($\text{KL}(\pi_0\|\pi_{\text{IOT}}) = 0.464$) (sample size $N = 200$)

demonstrate improved robustness than IOT does when noise size is large. If δ is set too large (e.g. $\delta = 0.05$), however, the entropy term tends to dominate and negatively affect recovery performance when noise size is modestly small. If δ is tuned carefully (e.g. $\delta = 0.005$), RIOT can achieve comparable performance even when noise size is quite small. Moreover, we observe that curves corresponding to different δ intersect with the curve of fixed marginal at different noise size. Therefore, when prior knowledge or statistical estimate of noise size is available, we may tune δ accordingly to achieve best practical performance. In addition, we observe notable variation of KL divergence between π_0 and π_{IOT} when sample size is small (e.g., $N = 50$), in contrast, one standard deviation of $KL(\pi_0||\pi_{RIOT})$ is negligible, supporting our argument of RIOT being more robust than IOT.

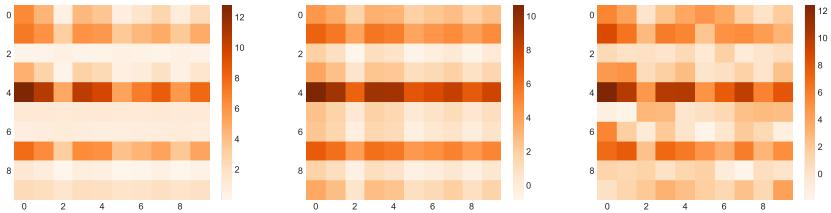
To produce Figure 3, we set sample size $N = 200$ and relaxation parameter $\delta = 0.001$ with other parameters same as those for producing Figure 2. Figure 3 visually illustrates π_0, $\hat{\pi}$, π_{RIOT} and π_{IOT} and we see that when sample size is small, sampling noise can significantly corrupts= the ground truth matching matrix. π_{RIOT} exhibits less distortion compared to π_{IOT}, which demonstrates improved robustness again. Numerical results also back up our observation.

$$\text{KL}(\pi_0\|\hat{\pi}) = 1.269,\ \text{KL}(\pi_0\|\pi_{\text{RIOT}}) = 0.219,\ \text{KL}(\pi_0\|\pi_{\text{IOT}}) = 0.464$$

Compared to IOT, marginal relaxation via regularized Wasserstein distance does help improve the robustness of solution.

6.1.2. Superior Learning Performance

To produce Figure 4, we set sample size $N = 200$, relaxation parameter $\delta = 0.001$, the number of iterations in outer loop $L = 100$ and learning rate $s = 1$, we then run algorithm 2 to compare the performance of learning cost matrix C_0. To avoid non-uniqueness/non-identifiability issue, we use



$$d(C_1, C_2) = \min_{D=\boldsymbol{a}\mathbf{1}^T+\mathbf{1}\boldsymbol{b}^T+C_1} \|D - C_2)\|_F$$

to measure the closeness of cost matrices C_1 and C_2 and denote the minimizer of $d(C, C_0)$ by $\tilde{C}$. The results are shown below,

$$d(C_{RIOT}, C_0) = 7.831, \quad d(C_{IOT}, C_0) = 12.439$$

where C_{RIOT}, C_{IOT} are cost matrices learned by RIOT formulation and IOT formulation respectively. Compared to C_{IOT}, C_{RIOT} learned via our proposed method almost halves the distance to ground truth cost matrix. Figure 4 also illustrates that our model can learn the structure of cost matrix better than IOT does. Our approach improves the learning performance and is able to reveal the structure of ground truth cost matrix.

To sum up, we show that with appropriately tuned relaxation parameter, RIOT is superior to IOT in terms of both robustness and learning performance.

(a) C_0 (b) $\tilde{C}_{\text{RIOT}}$ (c) $\tilde{C}_{\text{IOT}}$

Figure 4: Comparison of (a) ground truth cost matrix C_0 (b) $\tilde{C}_{\text{RIOT}}$, the minimizer of $d(C_{RIOT}, C_0)$ and (c) $\tilde{C}_{\text{IOT}}$, the minimizer of $d(C_{IOT}, C_0)$

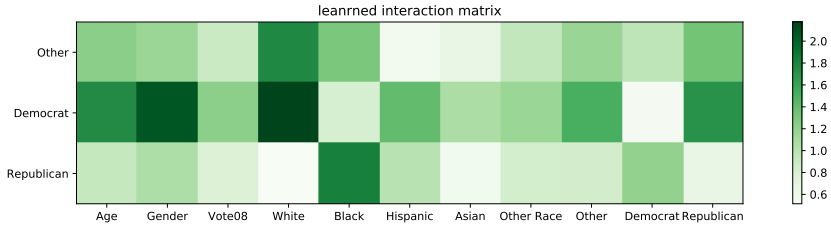


Figure 5: Interaction matrix learned by RIOT for election data set

6.2. Election data set

We show in this subsection that RIOT can effectively learn the user-item interaction by applying it to 2012 presidential election data of Florida. The experiment setup is similar to that of Muzellec et al. (2017)[2].

The data set contains more than 9.23×10^6 voters profile, each voter has features like gender, age, race, party and whether the voter voted in 2008 election. 0-1 encoding are used for gender (M:1, F:0) and voting in 2008 (Yes:1, No:0), age is linearly mapped onto $[0, 1]$ and we use one-hot encoding for both race and party. We obtain the empiricl matching data from exit poll provided by GALLUP[3]. The empirical matching matrix $\hat{\pi}$ is 3-by-5 matrix, candidates are either Democratic or Republican, or from a third party and voters are categorized into five races (White, Black, Hispanic, Asian and Other). We use mean profile as features for each race and one-hot encoding as features for candidates. We set $\lambda = \lambda_u = \lambda_v = 1, \delta = 5 \times 10^{-3}, K = 20$, for C_u, C_v, we randomly generate m and n points from $\mathcal{N}(\mathbf{0}, 5I_2)$ on plane and use their Euclidean distance matrix as C_u and C_v. Polynomial kernel $C_{ij} = (0.2\boldsymbol{u}_i^T A \boldsymbol{v}_j + 1)^2$ is used for this experiment. We run RIOT for this data set and the learned interaction matrix is shown in Figure 5.

In Figure 5, the lighter the color of a cell is, the lower the cost caused by that feature combination is. Take 'Age' column as an example, ('Democratic', 'Age') is the darkest and ('Republican', 'Age') is the lightest among the column, it means that elder voters are more likely to favor Republican candidate as it has lower cost compared to supporting Democratic candidate. Other cells can be interpreted in a similar manner.

From Figure 5, we see that most white voters tend to support Republican candidate Romney while black voters tend to support Democratic candidate Obama, Democratic and Republican voters tend to support candidate from their own party, elder voters tend to support Romney while female voters tend to support Obama. All above observations are consistent with CNN's[4] exit polls. This demonstrates that RIOT can learn meaningful interaction preference from empirical matching effectively.

6.3. New York Taxi data set

We demonstrate in this subsection that the proposed RIOT framework is able to predict fairly accurate matching on New York Taxi data set [5]. This data set contains 1458644 taxi trip records from January to June in 2016 in New York city. Each trip record is associated with one of the two data vendors (Creative Mobile Technologies, LLC and VeriFone Inc.) and contains detailed trip information such as pickup/drop-off time, longitude, latitude and so on. As no unique identifiers of taxis are provided, we can not predict new matching on individual level. Instead, we predict matching between data vendors and passengers (a passenger is matched with one of the data vendors if a taxi associated with that data vendor rides with the passenger).

2. part of the experiment in this subsection is based on the code kindly shared by Boris Muzellec(https://github.com/BorisMuzellec/TROT)
3. http://news.gallup.com/poll/160373/democrats-racially-diverse-republicans-mostly-white.aspx
4. http://www.cnn.com/election/2012/results/state/FL/president/
5. https://www.kaggle.com/c/nyc-taxi-trip-duration/data

To reflect the proximity of passengers and taxis, we cluster all trip records into 50 regions and plot them in Figure 6. If a passenger and a taxi are in the same region, it indicates they are close to each other and it is desirable to match them up. Further, since we do not have real-time location of taxis, we use the last known drop-off location as taxis' current location. This assumption is usually not true in large time scale as taxis are likely to leave the region and search for next passenger. To alleviate this issue, we only use trip records within a short time period, 6:00-6:30pm on Friday, June 3rd to predict matching of 6:00-6:30pm on Friday, June 10. Moreover, this is typically the rush hour in New York city and location of taxis are not likely to change dramatically during the period. Vendors' features are the distribution of associated taxis across 50 regions, i.e., $U \in \mathbb{R}^{50\times 2}$, passengers' features are simply the one-hot encoding of their current location, i.e, $V \in \mathbb{R}^{50\times 50}$. So the interaction matrix $A \in \mathbb{R}^{50\times 50}$. We set $\lambda = \lambda_u = \lambda_v = 1, \delta = 1\times 10^{-3}, K = 20$, for C_u, C_v, we randomly generate m and n points from $\mathcal{N}(\mathbf{0}, 5I_2)$ on plane and use their Euclidean distance matrix as C_u and C_v. Linear kernel $C_{ij} = 0.2\boldsymbol{u}_i^T A \boldsymbol{v}_j + 1$ is used for this experiment.

The comparison of the actual matching π_{new} and the predicted matching $\pi_{predicted}$ is shown in Figure 7. Visually speaking, we see that the predicted matching is able to capture the pattern of actual empirical matching and the prediction is fairly accurate. Quantitative result is also reported, measured in Kullback-Leibler divergence

$$\mathrm{KL}(\pi_{new} || \pi_{predicted}) = 0.1659.$$

6.4. Marriage data set

In this subsection, we illustrate the applicability of our model in suggesting new matching and it can make more accurate and realistic recommendations than conventional recommender systems do. Once the interaction between two sides of matching market is learned, one may use that to predict matching for new groups and make recommendations accordingly. We compare our RIOT with baseline random predictor model (Random), classical SVD model (Koren et al., 2009) and item-based collaborative filtering model (itemKNN) (Cremonesi et al., 2010), probabilistic matrix factorization model (PMF) (Mnih and Salakhutdinov, 2008) and the state-of-art factorization machine model (FM) (Rendle, 2012). To fit conventional recommender systems in our setting, one possible approach is simply treating each cell of matching matrix as rating and ignoring the underlying matching mechanism. In RIOT, we set $\lambda = \lambda_u = \lambda_v = 1$, relaxation parameter $\delta = 0.001$, inner iteration $K = 20$ and use polynomial kernel $k(\boldsymbol{x}, \boldsymbol{y}) = (0.2\boldsymbol{x}^T\boldsymbol{y} + 0.8)^2$. For C_u, C_v, we randomly generate m and n points from $\mathcal{N}(\mathbf{0}, 5I_2)$ on plane and use their Euclidean distance matrix as C_u and C_v.

We evaluate all models on Dutch Household Survey (DHS) data set [6] from 2005 to 2014 excluding 2008 (due to data field inconsistency). After data cleaning, the data set consists of 2475 pairs of couple. For each person we extract 11 features including education level, height, weight, health and 6 characteristic traits, namely irresponsible, accurate, ever-ready, disciplined, ordered, clumsy and detail-oriented. Education levels are first categorized into elementary, middle and high and then mapped linearly onto $[0, 1]$. Height and weight are normalized by dividing the largest height/weight. Health and characteristic

6. https://www.dhsdata.nl/site/users/login

Figure 6: Clusters of Taxi Trip Records

features are measured on 0-5 scale and rescaled onto $[0, 1]$. We use k-means algorithm to cluster men/women into $n_{\text{cluster}} = 50$ groups, respectively. We select each cluster center as representative. Performing clustering can better illustrate the applicability of our model in distributional setting and also helps reduce problem size. We train all models on training data set and measure error between predicted and test matching matrix by root mean

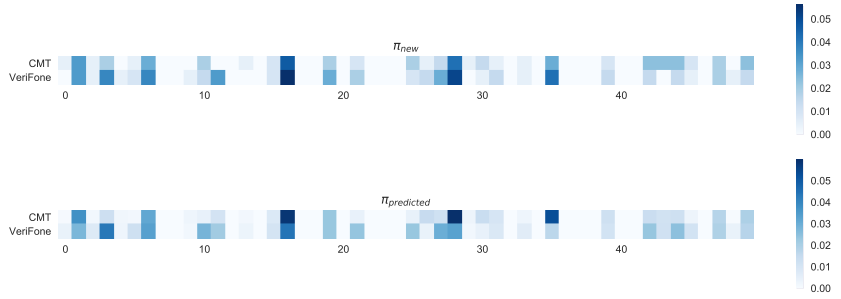

Figure 7: Comparison between actual matching π_{new} (top) and predicted matching $\pi_{predicted}$ (bottom) between 6:00-6:30pm on Friday, June 10th in New York city. Ticks of x-axis are labels of regions.

square error (RMSE) and mean absolute error (MAE) using 5-fold cross-validation. The result is shown in Table 1.

	Random	PMF	SVD	itemKNN	RIOT	FM
RMSE	54.5	8.4	29.9	2.4	**2.3**	3.6
MAE	36.6	2.0	16.8	1.6	**1.5**	2.8

Table 1: Average error of 5-fold cross-validation measured in RMSE and MAE ($\times 10^{-4}$)

In both measures, RIOT beats other conventional RS competitors. The comparison clearly shows that being able to take supply limitation into consideration and capture matching mechanism is of critical importance in suggest matching in such context and our proposed RIOT model can do a better job than conventional recommender systems do.

7. Conclusion

In this paper, we develop a novel, unified, data-driven inverse-optimal-transport-based matching framework RIOT which can learn adaptive, nonlinear interaction preference from noisy/incomplete empirical matching matrix in various matching contexts. The proposed RIOT is shown to be more robust than the state of the art IOT formulation and exhibits better performance in learning cost. Moreover, our framework can be extended to make recommendations based on predicted matching and outperforms conventional recommender systems in matching context.

In the future, our work can be continued in multiple ways. First, our model does batch prediction for a group of users and items and we would like to develop online algorithm to deal with streaming data and make matching suggestion for a previous unseen user/item in an online fashion. A recent method proposed by Perrot et al. (2016) that allows to

update the plan using out-of-sample data without recomputing might be useful. From business standpoint, we may study optimal pricing within our framework, i.e., how to set a reasonable price and adjust item distribution in a most profitable way (Azaria et al., 2013). In addition, we hope to combine impressive expressiveness of deep neural networks to further boost the performance of our proposed model.

Appendix A. Proof of Lemma 3

Proof

$$f(\boldsymbol{a},\boldsymbol{b}) = \boldsymbol{x}^T A\boldsymbol{x} - 2\boldsymbol{f}^T\boldsymbol{x} + \|M\|_F^2$$

where $\boldsymbol{x} = \begin{bmatrix}\boldsymbol{a}\\ \boldsymbol{b}\end{bmatrix}$, $\boldsymbol{f} = [(M\mathbf{1})^T, \mathbf{1}^T M]^T$ and $A = \begin{bmatrix} nI_{m\times m} & \mathbf{1}_m\mathbf{1}_n^T \\ \mathbf{1}_n\mathbf{1}_m^T & mI_{n\times n}\end{bmatrix}$. Note that A is a positive semi-definite matrix, the algebraic multiplicity of its 0 eigenvalue is 1 and $\text{null}(A) = \text{span}\{[\mathbf{1}_m^T, -\mathbf{1}_n^T]^T\}$. Moreover, $\boldsymbol{f} \perp \text{null}(A)$, hence the quadratic form $f(\boldsymbol{a},\boldsymbol{b})$ admits a minimum in $\text{null}(A)^\perp$ and it is straightforward to obtain

$$\begin{aligned}\min_{\boldsymbol{a},\boldsymbol{b}} f(\boldsymbol{a},\boldsymbol{b}) &= \min_{\boldsymbol{x}} \boldsymbol{x}^T A\boldsymbol{x} - 2\boldsymbol{f}^T\boldsymbol{x} + \|M\|_F^2 \\ &= \|M\|_F^2 - \boldsymbol{f}^T A^+ \boldsymbol{f}\end{aligned}$$

where A^+ is the Moore-Penrose inverse of matrix A. If M can not be written as $M = \boldsymbol{a}\mathbf{1}^T + \mathbf{1}\boldsymbol{b}^T$, then the minimum of $f(\boldsymbol{a},\boldsymbol{b})$ must be positive, hence

$$f(\boldsymbol{a},\boldsymbol{b}) \geq \min_{\boldsymbol{a},\boldsymbol{b}} f(\boldsymbol{a},\boldsymbol{b}) = \|M\|_F^2 - \boldsymbol{f}^T A^+ \boldsymbol{f} > 0$$

. ■

Appendix B. Extension of RIOT model to learn C_u and C_v jointly

In this section, we extend proposed RIOT model to settings where C_u and C_v are unknown and need to be learned jointly with the main cost matrix $C(A)$. Following the same derivation, we end up with an optimization problem almost identical to the one in equation (5), i.e.,

$$\min_{A,\boldsymbol{\mu}\in\Sigma_m,\boldsymbol{\nu}\in\Sigma_n,C_u,C_v} -\sum_{i=1}^{m}\sum_{j=1}^{n}\hat{\pi}_{ij}\log\pi_{ij}+\delta\big(d_{\lambda_u}(C_u,\boldsymbol{\mu},\hat{\boldsymbol{\mu}})+d_{\lambda_v}(C_v,\boldsymbol{\nu},\hat{\boldsymbol{\nu}})\big) \tag{13}$$

except for the fact that now we need to optimize two additional variables C_u and C_v. Genericly, inverse problems are usually not well-posed, in our cases, if no constraints imposed on C_u, C_v, one could trivially let, say $C_u = 0_{m\times m}, C_v = 0_{n\times n}$. To avoid such ill-posedness, we assume that $C_u \in \mathcal{M}^m \cap \Sigma^{m\times m}, C_v \in \mathcal{M}^n \cap \Sigma^{n\times n}$, where $\mathcal{M}^d$ is the cone of $d \times d$ distance matrix and Σ^d is $d-1$ simplex (see Section 3 for definition). Other regularization can also be explored.

By strong duality, we may convert equation (13) to its dual problem in a similar fashion as equation (6),

$$\min_{A,\boldsymbol{\mu},\boldsymbol{\nu},C_u,C_v}\max_{\boldsymbol{z},\boldsymbol{w}} -\sum_{i=1}^{m}\sum_{j=1}^{n}\hat{\pi}_{ij}\log\pi_{ij}+\delta\big(\langle\boldsymbol{z},\boldsymbol{\mu}\rangle+\langle\boldsymbol{z}^{C_u},\hat{\boldsymbol{\mu}}\rangle+\langle\boldsymbol{w},\boldsymbol{\nu}\rangle+\langle\boldsymbol{w}^{C_v},\hat{\boldsymbol{\nu}}\rangle\big)$$

where $z_j^{C_u}=\frac{1}{\lambda_u}\log\hat{r}_j-\frac{1}{\lambda_u}\log(\sum_{i=1}^m e^{\lambda_u(z_i-C_{uij})})$ and $w_j^{C_v}=\frac{1}{\lambda_v}\log\hat{c}_j-\frac{1}{\lambda_v}\log(\sum_{i=1}^n e^{\lambda_v(w_i-C_{vij})})$.

One way to solve equation (14), without too many changes of proposed algorithm in Section 5, is to rewrite it as

$$\min_{A,\boldsymbol{\mu},\boldsymbol{\nu}}\min_{C_u,C_v}\max_{\boldsymbol{z},\boldsymbol{w}} -\sum_{i=1}^{m}\sum_{j=1}^{n}\hat{\pi}_{ij}\log\pi_{ij}+\delta\big(\langle\boldsymbol{z},\boldsymbol{\mu}\rangle+\langle\boldsymbol{z}^{C_u},\hat{\boldsymbol{\mu}}\rangle+\langle\boldsymbol{w},\boldsymbol{\nu}\rangle+\langle\boldsymbol{w}^{C_v},\hat{\boldsymbol{\nu}}\rangle\big) \tag{14}$$

and alternatively update three groups of variables $(A,\boldsymbol{\mu},\boldsymbol{\nu})$, (C_u,C_v) and $(\boldsymbol{z},\boldsymbol{w})$.

B.1. Update $(A,\boldsymbol{\mu},\boldsymbol{\nu})$, with (C_u,C_v) and $(\boldsymbol{z},\boldsymbol{w})$ fixed

Once (C_u,C_v) and $(\boldsymbol{z},\boldsymbol{w})$ fixed, $\boldsymbol{z}^{C_u},\boldsymbol{w}^{C_v}$ are fixed as well, hence the optimization problem at this stage becomes

$$\min_{A,\boldsymbol{\mu},\boldsymbol{\nu}} -\sum_{i=1}^{m}\sum_{j=1}^{n}\hat{\pi}_{ij}\log\pi_{ij}+\delta\big(\langle\boldsymbol{z},\boldsymbol{\mu}\rangle+\langle\boldsymbol{w},\boldsymbol{\nu}\rangle\big)$$

where constants are omitted. This minimization problem is identical to that in subsection 5.1. Please see detailed update scheme for $(A,\boldsymbol{\mu},\boldsymbol{\nu})$ there.

B.2. Update (C_u,C_v), with $(A,\boldsymbol{\mu},\boldsymbol{\nu})$ and $(\boldsymbol{z},\boldsymbol{w})$ fixed

If $(A,\boldsymbol{\mu},\boldsymbol{\nu})$ and $(\boldsymbol{z},\boldsymbol{w})$ are fixed, π is also fixed as it is the regularized OT plan determined by parameters $(A,\boldsymbol{\mu},\boldsymbol{\nu})$, hence the optimization problem at this stage becomes

$$\min_{C_u\in\mathcal{M}^m\cap\Sigma^{m\times m},C_v\in\mathcal{M}^n\cap\Sigma^{n\times n}}\delta\big(\langle\boldsymbol{z}^{C_u},\hat{\boldsymbol{\mu}}\rangle+\langle\boldsymbol{w}^{C_v},\hat{\boldsymbol{\nu}}\rangle\big)$$

and can be further splitted into two independent optimization problems

$$\min_{C_u\in\mathcal{M}^m\cap\Sigma^{m\times m}}\delta\langle\boldsymbol{z}^{C_u},\hat{\boldsymbol{\mu}}\rangle,\qquad \min_{C_v\in\mathcal{M}^n\cap\Sigma^{n\times n}}\delta\langle\boldsymbol{w}^{C_v},\hat{\boldsymbol{\nu}}\rangle \tag{15}$$

which can be solved simultaneously.

Both $\mathcal{M}^d$ and $\Sigma^{d\times d}$ are convex sets, so is their intersection. Therefore we can perform projected gradient method to solve two separate minimization problems in equation (15).

B.3. Update $(\boldsymbol{z},\boldsymbol{w})$, with $(A,\boldsymbol{\mu},\boldsymbol{\nu})$ and (C_u,C_v) fixed

When $(A,\boldsymbol{\mu},\boldsymbol{\nu})$ and (C_u,C_v) are fixed, π is also fixed, we then only need to solve

$$\max_{\boldsymbol{z},\boldsymbol{w}}\langle\boldsymbol{z},\pi\mathbf{1}\rangle+\langle\boldsymbol{z}^{C_u},\hat{\boldsymbol{\mu}}\rangle+\langle\boldsymbol{w},\pi^T\mathbf{1}\rangle+\langle\boldsymbol{w}^{C_v},\hat{\boldsymbol{\nu}}\rangle$$

and one immediately recognizes this is equivalent to applying Sinkhorn-Knopp algorithm to compute $d_{\lambda_u}(C_u,\boldsymbol{\mu},\hat{\boldsymbol{\mu}})$ and $d_{\lambda_v}(C_v,\boldsymbol{\nu},\hat{\boldsymbol{\nu}})$.

To summarize, to jointly learn $C(A)$, C_u and C_v, we formulate an optimization problem similar to that in equation (5) and propose an alternating algorithm to solve it by alternately update $(A,\boldsymbol{\mu},\boldsymbol{\nu})$, (C_u,C_v) and $(\boldsymbol{z},\boldsymbol{w})$. Practically, the update of (C_u,C_v) requires expensive projection onto $\mathcal{M}^d\cap\Sigma^{d\times d}$, therefore we suggest learning C_u, C_v first and then using RIOT formulation to learn the main cost matrix $C(A)$, rather than learning three cost matrices simultaneously.

Appendix C. Hyper-parameter Tuning

There are many hyper-parameters in RIOT formulation, including regularization parameter $\lambda, \lambda_u, \lambda_v$, relaxation parameter δ, kernel function $k(\cdot,\cdot)$, cost matrix for two sides C_u, C_v and the number of iteration in inner loop K. With so many hyper-parameters, it would be very expensive to perform grid-search type tuning. Two parameters, relaxation parameter δ and kernel $k(\cdot,\cdot)$, turn out to be critical to the performance of RIOT. Therefore, we fixed other hyper-parameters (based on coarse-tuning) and (fine) tuned these two hyper-parameters.

- $\lambda, \lambda_u, \lambda_v$: as mentioned in main paper, one main motivation of introducing entropy regularization to optimal transport is computation. Too large λ usually causes numerical instability in Sinkhorn-Knopp algorithm, hence we set $\lambda = \lambda_u = \lambda_v = 1$ across all experiments.
- C_u, C_v: Randomly generate m and n points from $\mathcal{N}(\mathbf{0}, 5I_2)$ on plane and use their Euclidean distance matrix as C_u and C_v. This setting is consistent across all experiments.
- K: the number of iterations in inner loop should be large enough to ensure the iterative algorithms described in proposition 7 to converge. In all experiments, we observed the inner loop usually converges within 20 steps, hence we set $K = 20$.
- δ: Both small and large δ can regularize the problem quite well compared to IOT when sample size is small. When sample size is large, empirical matching matrix is usually accurate enough. In this case, large δ can introduce large bias whereas small δ has comparable performance of IOT. In practice, we suggest users to select small relaxation parameter. In our experiments, we found 10^{-3} is an appropriate order to work with.
- $k(\cdot,\cdot)$: we primarily work with polynomial kernels (including linear kernels) in the paper. Kernel function was chosen from $\{k(\boldsymbol{x},\boldsymbol{y}) = (\gamma \boldsymbol{x}^T\boldsymbol{y} + c_0)^d | \gamma \in \{0.05, 0.1, 0.2\}, c_0 \in \{0.5, 0.8, 1, 2\}, d \in \{1, 2, 3\}\}$

Appendix D. Table of Notations

$\boldsymbol{\mu}, \boldsymbol{\nu}$	marginal probability distributions
Σ_d	$d-1$-dimensional probability simplex
$U(\boldsymbol{\mu}, \boldsymbol{\nu})$	transport polytope
C	cost matrix
A	interaction matrix
C_{IOT}	cost matrix learned by IOT formulation
C_{RIOT}	cost matrix learned by RIOT formulation
λ	regularization parameter of entropy regularization
$d^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu})$	regularized optimal transport distance
$\pi^\lambda(C, \boldsymbol{\mu}, \boldsymbol{\nu})$	regularized optimal transport plan
$\hat{\pi}$	empirical matching matrix
$\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\nu}}$	empirical marginal distributions
δ	relaxation parameter in RIOT formulation

Abstract

The VC-dimension of a set system is a way to capture its complexity and has been a key parameter studied extensively in machine learning and geometry communities. In this paper, we resolve two longstanding open problems on bounding the VC-dimension of two fundamental set systems: k-fold unions/intersections of half-spaces and the simplices set system. Among other implications, it settles an open question in machine learning that was first studied in the foundational paper of Blumer et al. (1989) as well as by Eisenstat and Angluin (2007) and Johnson (2008).

Keywords: VC-dimension, union of concepts, intersection of concepts, combinatorial problems, PAC learning

1. Introduction

Let $(X, \mathcal{R})$ be a *set system*, where X is a set of elements and $\mathcal{R}$ is a set of subsets of X. In the theory of learning, the elements of $\mathcal{R}$ are also called *concepts*, and $\mathcal{R}$ is called a *concept class* on X. For any integer $k \geq 2$, define the *k-fold union* of $\mathcal{R}$ as the set system induced on X by the ranges

$$\mathcal{R}^{k\cup} = \{R_1 \cup \cdots \cup R_k \colon R_1, \ldots, R_k \in \mathcal{R}\}.$$

Similarly, one can define the *k-fold intersection* of $\mathcal{R}$, denoted by $\mathcal{R}^{k\cap}$, as the set system consisting of all subsets derived from the common intersection of at most k sets of $\mathcal{R}$. Note that as the subsets $R_1, \ldots, R_k$ need not necessarily be distinct, we have $\mathcal{R} \subseteq \mathcal{R}^{k\cup}$ and $\mathcal{R} \subseteq \mathcal{R}^{k\cap}$. Analogously, the *$k$-fold symmetric difference* of $\mathcal{R}$ is defined as $\mathcal{R}^{k\oplus} = \{R_1 \oplus \cdots \oplus R_k \colon R_1, \ldots, R_k \in \mathcal{R}\}$, where $R_1 \oplus \cdots \oplus R_k$ is the set of those elements that are contained in an odd number of $R_1, \ldots, R_k$.

One of the fundamental measures of complexity of a set system is its *Vapnik-Chervonenkis dimension*, or in short, *VC-dimension*. Given a set system $(X, \mathcal{R})$, for any set $Y \subseteq X$, define the *projection* of $\mathcal{R}$ onto Y as

$$\mathcal{R}|_Y = \{Y \cap R \colon R \in \mathcal{R}\}.$$

We say that $\mathcal{R}$ *shatters* Y if $|\mathcal{R}|_Y| = 2^{|Y|}$; in other words, any subset of Y can be derived as the intersection of Y with an element of $\mathcal{R}$. The *VC-dimension* of $\mathcal{R}$, denoted by VC-dim$(\mathcal{R})$, is the size of the largest subset of X that can be shattered by $\mathcal{R}$. Originally introduced in statistical learning by Vapnik and Chervonenkis (1971), it has turned out to be a key parameter in several areas, including learning theory, combinatorics, and computational geometry.

1.1. Learning Theory.

In learning theory, the VC-dimension of a concept class measures the difficulty of learning a concept of the class. The foundational paper of Blumer et al. (1989) states that "the essential condition for distribution-free learnability is finiteness of the Vapnik-Chervonenkis dimension". Among their results, they prove the following theorem.

Theorem A (Blumer et al. 1989) *Let $(X, \mathcal{R})$ be a set system and k be any positive integer. Then*

$$\text{VC-dim}\left(\mathcal{R}^{k\cup}\right) = O\Big(\text{VC-dim}\left(\mathcal{R}\right) \cdot k \log k\Big),$$

$$\text{VC-dim}\left(\mathcal{R}^{k\cap}\right) = O\Big(\text{VC-dim}\left(\mathcal{R}\right) \cdot k \log k\Big).$$

Moreover, there are set systems such that $\text{VC-dim}\left(\mathcal{R}^{k\cup}\right) = \Omega\left(\text{VC-dim}\left(\mathcal{R}\right) \cdot k\right)$ *and* $\text{VC-dim}\left(\mathcal{R}^{k\cap}\right) = \Omega\left(\text{VC-dim}\left(\mathcal{R}\right) \cdot k\right)$.

Remark. The upper bound holds in a more general setting: for any fixed set-theoretic expression $F(R_1, R_2, \ldots, R_k)$ (consisting of operations of set union, intersection, and difference) and range set $\mathcal{R}^{k*} := \{F(R_1, \ldots, R_k) : R_1, \ldots, R_k \in \mathcal{R}\}$, we have VC-dim$(\mathcal{R}^{k*}) = O($VC-dim $(\mathcal{R}) \cdot k \log k)$ (see eg. Matoušek, 2002, chap. 10). In particular, $\text{VC-dim}\left(\mathcal{R}^{k\oplus}\right) = O\left(\text{VC-dim}\left(\mathcal{R}\right) \cdot k \log k\right)$.

They also considered the question of whether the upper bounds of Theorem A are tight in the most basic geometric case when $X \subseteq \mathbb{R}^d$ is a set of points and $\mathcal{R}$ is the projection of the family of all half-spaces of $\mathbb{R}^d$ onto X. They proved that the VC-dimension of the k-fold union of half-spaces in two dimensions is exactly $2k+1$. For general dimensions $d \geq 3$, they upper-bound the VC-dimension of the k-fold union of half-spaces by $O(d \cdot k \log k)$. This follows from Theorem A together with the fact that the VC-dimension of the set system induced by half-spaces in $\mathbb{R}^d$ is $d+1$. The same upper bound holds for the VC-dimension of the k-fold intersection of half-spaces in $\mathbb{R}^d$. Later Dobkin and Gunopulos (1995) showed that the VC-dimension of the k-fold union of half-spaces in $\mathbb{R}^3$ is upper-bounded by $4k$.

Eisenstat and Angluin (2007) proved, by giving a probabilistic construction of an abstract set system, that the upper bound of Theorem A is asymptotically tight if $\text{VC-dim}\left(\mathcal{R}\right) \geq 5$ and that for $\text{VC-dim}\left(\mathcal{R}\right) = 1$, an upper bound of k holds which is tight. A few years later, Eisenstat (2009) filled the gap by showing that there exists a set system $(X, \mathcal{R})$ of VC-dimension 2 such that $\text{VC-dim}\left(\mathcal{R}^{k\cup}\right) = \Omega\left(\text{VC-dim}\left(\mathcal{R}\right) \cdot k \log k\right)$.

For $d \geq 4$, the current best upper-bound for the k-fold union and the k-fold intersection of half-spaces in $\mathbb{R}^d$ is still the one given by Theorem A almost 30 years ago, while the lower-bound has remained $\Omega\left(\text{VC-dim}(\mathcal{R}) \cdot k\right)$. We refer the reader to the PhD thesis of Johnson (2008) for a summary of the bounds on VC-dimensions of these basic combinatorial and geometric set systems.

1.2. Computational Geometry.

The following set system is fundamental in computational geometry. Given a set $\mathcal{H}$ of hyperplanes in $\mathbb{R}^d$, define

$$\Delta\left(\mathcal{H}\right) = \Big\{\mathcal{H}' \subseteq \mathcal{H} \colon \exists \text{ an open } d\text{-dimensional simplex } S \text{ in } \mathbb{R}^d \text{ such that } H \in \mathcal{H} \text{ intersects } S \text{ if and only if } H \in \mathcal{H}'\Big\}.$$

License: CC-BY 4.0, see https://creativecommons.org/licenses/by/4.0/. Attribution requirements are provided at http://jmlr.org/papers/v20/18-719.html.

Its importance derives from the fact that it is the set system underlying the construction of *cuttings* via random sampling (see Chazelle and Friedman 1990 as well as the recent survey of Mustafa and Varadarajan 2017, to appear). Cuttings are the key tool for fast point-location algorithms and were studied in detail recently by Ezra et al. (2017). They provided the best bounds so far for the VC-dimension of $\Delta(\mathcal{H})$.

Lemma B (Ezra et al. 2017) *For $d \geq 9$, we have*

$$d\,(d+1) \leq \text{VC-dim}\left(\Delta\left(\mathcal{H}\right)\right) \leq 5 \cdot d^2 \log d.$$

2. Our Results

For some time now, it has generally been expected that $\text{VC-dim}\left(\mathcal{R}^{k\cup}\right) = \text{VC-dim}\left(\mathcal{R}^{k\cap}\right) = O\left(dk\right)$ for the k-fold unions and intersections of half-spaces. This upper-bound indeed holds for a related notion: the *primal shattering dimension* of the k-fold unions and intersections of half-spaces is $O(dk)$. In fact, as it was pointed out by Bachem (2018), several papers in learning theory assume the same for VC-dimension. Likewise for computational geometry literature: for example, the coreset size bounds in the constructions of Feldman and Langberg (2011), Balcan et al. (2013), and Lucic et al. (2016) would require an additional $\log k$ factor in the coreset size—if the upper-bound of Theorem A was tight for the k-fold intersection of half-spaces.

In this paper, we resolve the question of VC-dimension for the above two set systems. Our proofs are short and we make an effort to keep them self-contained.

We show an optimal lower-bound on the VC-dimension of the k-fold union, the k-fold intersection, and the k-fold symmetric difference of half-spaces in $\mathbb{R}^d$, matching the $O(d \cdot k \log k)$ upper bound of Theorem A, and thus settling affirmatively one of the main open questions studied by Eisenstat and Angluin (2007), Johnson (2008), and Eisenstat (2009).

Theorem 1 *Let k be a given positive integer and $d \geq 4$ be an integer. Then there exists a set $\mathcal{P}$ of points in $\mathbb{R}^d$ such that the set system $\mathcal{R}$ induced on $\mathcal{P}$ by half-spaces satisfies*

$$\text{a)} \quad \text{VC-dim}\left(\mathcal{R}^{k\cup}\right) = \Omega\Big(\text{VC-dim}(\mathcal{R}) \cdot k \log k\Big) = \Omega\Big(d \cdot k \log k\Big),$$

$$\text{b)} \quad \text{VC-dim}\left(\mathcal{R}^{k\cap}\right) = \Omega\Big(\text{VC-dim}(\mathcal{R}) \cdot k \log k\Big) = \Omega\Big(d \cdot k \log k\Big),$$

$$\text{c)} \quad \text{VC-dim}\left(\mathcal{R}^{k\oplus}\right) = \Omega\Big(\text{VC-dim}(\mathcal{R}) \cdot k \log k\Big) = \Omega\Big(d \cdot k \log k\Big).$$

Remark 1. This statement also provides a non-probabilistic proof of the lower-bound of Eisenstat and Angluin (2007).

Remark 2. Note that a set of points is shattered by (the k-fold union of) closed half-spaces if and only if it is shattered by (the k-fold union of) open half-spaces. Thus Theorem 1 also holds for open half-spaces.

Remark 3. Observe that if $\overline{\mathcal{R}} := \{\mathbb{R}^d \setminus R\colon\ R \in \mathcal{R}\}$, then $\text{VC-dim}(\overline{\mathcal{R}}) = \text{VC-dim}(\mathcal{R})$ and

$$\text{VC-dim}\left(\mathcal{R}^{k\cap}\right) = \text{VC-dim}\left(\overline{\mathcal{R}^{k\cap}}\right) = \text{VC-dim}\left(\overline{\mathcal{R}}^{k\cup}\right).$$

holds by the De Morgan laws. Since for half-spaces $\overline{\mathcal{R}} = \mathcal{R}$, part a) of Theorem 1 implies part b).

Using Theorem 1, we show an asymptotically optimal bound on the VC-dimension of $\Delta(\mathcal{H})$, improving the bound of Ezra et al. (2017) and resolving a question that was studied in the computational geometry community starting in the 1980s.

Theorem 2 *Let $d \geq 4$ be a given integer. Then there exists a set $\mathcal{H}$ of $\Omega\left(d^2 \log d\right)$ hyperplanes in $\mathbb{R}^d$ such that $\Delta\left(\mathcal{H}\right) = 2^{\mathcal{H}}$, that is, we have*

$$\text{VC-dim}\left(\Delta\left(\mathcal{H}\right)\right) = \Omega\left(d^2 \log d\right).$$

Remark. In fact, we prove a more general result bounding the VC-dimension of the set system induced by intersection of hyperplanes with k-dimensional simplices in $\mathbb{R}^d$. See Section 4 for details.

Organization. Section 3 contains the proof of Theorem 1 and Section 4 contains the proof of Theorem 2.

3. Proof of Theorem 1.

We prove the theorem for d even, starting from $d = 4$. The asymptotic lower-bound for odd values of d follows from the one in $\mathbb{R}^{d-1}$. The starting point of the proof is the following lemma.

Lemma 3 (Kupavskii et al., 2016, Lemma 2) *Let $n, d' \geq 2$ be integers. Then there exists a set $\mathcal{B}_{n,d'}$ of axis-parallel boxes in $\mathbb{R}^{d'}$, with $|\mathcal{B}_{n,d'}| = (d'-1)\,(n+1)\,2^{n-2}$, such that for any subset $\mathcal{S} \subseteq \mathcal{B}_{n,d'}$, there exists a set $\mathcal{Q}$ of points in $\mathbb{R}^{d'}$ such that $|\mathcal{Q}| = 2^{n-1}$ and*

(i) $|\mathcal{Q} \cap B| = 1$ for any $B \in \mathcal{B}_{n,d'} \setminus \mathcal{S}$, and

(ii) $\mathcal{Q} \cap B = \emptyset$ for any $B \in \mathcal{S}$.

Remark. In Kupavskii et al. (2016) this lemma is stated in a weaker form, however the above stronger statement is implicit in their proof.

Let $d' = \left\lfloor \frac{d}{2} \right\rfloor$ and apply Lemma 3 with $n = \lfloor \log k \rfloor + 1$ in $\mathbb{R}^{d'}$ to get a set $\mathcal{B} = \mathcal{B}_{n,d'}$ of boxes in $\mathbb{R}^{d'}$. By translation, we can assume that all coordinates of points lying in each box in $\mathcal{B}$ are positive. Now we will construct the following mappings:

$$\begin{array}{rcl} \text{set of boxes } \mathcal{B} \text{ in } \mathbb{R}^{d/2} & \xrightarrow{\ \pi\ } & \text{points in } \mathbb{R}^d, \\ \text{points in } \mathbb{R}^{d/2} & \xrightarrow{\ \beta\ } & \text{boxes in } \mathbb{R}^d \xrightarrow{\ \gamma\ } \text{half-spaces in } \mathbb{R}^d. \end{array}$$

We will then prove the key property of these mappings, that for any $q \in \mathbb{R}^{d/2}$ and $B \in \mathcal{B}$

$$q \in B \quad \overset{(1)}{\Longleftrightarrow} \quad \pi(B) \in \beta(q) \quad \overset{(2)}{\Longleftrightarrow} \quad \pi(B) \in \gamma(\beta(q)).$$

We first define mappings π and β, with $\pi : \mathcal{B} \to \mathbb{R}^d$ and with β mapping points in $\mathbb{R}^{d'}$ to axis-parallel boxes in $\mathbb{R}^d$, such that for any $B \in \mathcal{B}$ and $q \in \mathbb{R}^{d'}$, we have

$$q \in B \iff \pi(B) \in \beta(q). \tag{1}$$

- Let $B \in \mathcal{B}$ be defined as the product of d' intervals:

  $$B = [x_1, x_1'] \times [x_2, x_2'] \times \cdots \times [x_{d'}, x_{d'}'], \quad \text{with} \quad x_i, x_i' > 0 \text{ for each } i \in [d'].$$

  Then π maps B in $\mathbb{R}^{d'}$ to the following point in $\mathbb{R}^d$ (see Pach and Tardos, 2013)

  $$\pi(B) = \left(x_1, \frac{1}{x_1'}, x_2, \frac{1}{x_2'}, \ldots, x_{d'}, \frac{1}{x_{d'}'}\right) \in \mathbb{R}^d,$$

  and we let $\pi(\mathcal{B}) := \{\pi(B)\colon B \in \mathcal{B}\}$.

- For any point $q = (q_1, q_2, \ldots, q_{d'}) \in \mathbb{R}^{d'}$, define $\beta(q)$ to be the box

$$\beta(q) = [0, q_1] \times \left[0, \frac{1}{q_1}\right] \times \cdots \times [0, q_{d'}] \times \left[0, \frac{1}{q_{d'}}\right] \subset \mathbb{R}^d.$$

Proposition 4 *The mappings π and β satisfy* (1).

Proof Let $q = (q_1, q_2, \ldots, q_{d'})$ be a point in $\mathbb{R}^{d'}$ and $B = [x_1, x_1'] \times [x_2, x_2'] \times \cdots \times [x_{d'}, x_{d'}']$ be an axis-parallel box in $\mathbb{R}^{d'}$. Then $q \in B$ if and only if $x_i \le q_i \le x_i'$ for all $i \in [d']$.

On the other hand, $\pi(B)$ lies in $\beta(q)$ if and only if $0 \le x_i \le q_i$ and $0 \le 1/x_i' \le 1/q_i$ for each $i \in [d']$—or equivalently, $0 \le x_i \le q_i$ and $q_i \le x_i'$ for each $i \in [d']$.

Note that these two conditions are exactly the same, implying (1). ∎

Recall that $\mathcal{B} = \mathcal{B}_{n,d'}$ is the set of boxes provided by Lemma 3 with parameters $d' = \lfloor \frac{d}{2} \rfloor$ and $n = \lfloor \log k \rfloor + 1$. Thus we have

$$|\mathcal{B}| = \left(\left\lfloor \frac{d}{2} \right\rfloor - 1 \right) \lfloor \log k \rfloor 2^{\lfloor \log k \rfloor - 1}.$$

Proposition 5 ("Lifted dual version" of Lemma 3) *$\pi(\mathcal{B})$ is a set of $\left(\lfloor \frac{d}{2} \rfloor - 1 \right) \lfloor \log k \rfloor 2^{\lfloor \log k \rfloor - 1}$ points in $\mathbb{R}^d$ such that for any subset $\mathcal{T} \subseteq \pi(\mathcal{B})$, there is a set $\mathcal{Q}^*$ of at most k axis-parallel boxes in $\mathbb{R}^d$ such that*

(i) each point of $\mathcal{T}$ is contained in exactly one box in $\mathcal{Q}^*$, and

(ii) no point of $\pi(\mathcal{B}) \setminus \mathcal{T}$ is contained in any box of $\mathcal{Q}^*$.

In particular, $\pi(\mathcal{B})$ is shattered by the set system induced by the k-fold union of axis-parallel boxes in $\mathbb{R}^d$ and also shattered by the set system induced by the k-fold symmetric difference of axis-parallel boxes in $\mathbb{R}^d$.

Proof Let $\mathcal{S} = \left\{ \pi^{-1}(p) \ : \ p \in \pi(\mathcal{B}) \setminus \mathcal{T} \right\}$. By Lemma 3, there is a set $\mathcal{Q}$ of at most k points in $\mathbb{R}^{d'}$ such that (i), (ii) of Lemma 3 hold for $\mathcal{S}$ and $\mathcal{Q}$. Letting $\mathcal{Q}^* = \{\beta(q) : q \in \mathcal{Q}\}$, the claim follows from (1). ∎

Next we define the function $\gamma(\cdot)$ mapping boxes in $\mathbb{R}^d$ to half-spaces in $\mathbb{R}^d$ such that for any point $p \in \pi(\mathcal{B})$ and box $B = \beta(q)$, we have

$$p \in B \iff p \in \gamma(B). \tag{2}$$

For every $i \in [d]$, let $0 < \alpha_{i,1} < \alpha_{i,2} < \ldots$ denote the sequence of distinct values of the x_i-coordinates of the elements of $\pi(\mathcal{B})$. Every such sequence has length at most $|\pi(\mathcal{B})|$. By re-scaling the coordinates, we can assume that

$$\text{for each } i \in [d] \text{ and } j \le |\pi(\mathcal{B})|, \qquad \frac{\alpha_{i,j+1}}{\alpha_{i,j}} > d. \tag{3}$$

Denote the resulting point set by $\mathcal{P}$. Note that scaling along each coordinate does not change incidences with respect to axis-parallel boxes, thus Proposition 5 still holds if we replace $\pi(\mathcal{B})$ by $\mathcal{P}$ and that $|\mathcal{P}| = |\pi(\mathcal{B})| = |\mathcal{B}|$.

We claim that $\mathcal{P}$ is shattered by the set system induced by the k-fold union of half-spaces in $\mathbb{R}^d$ and also shattered by the set system induced by the k-fold symmetric difference of half-spaces in $\mathbb{R}^d$. To see that, let $\mathcal{P}'$ be any subset of $\mathcal{P}$. Let $\mathcal{Q}^*$ be the set of axis-parallel boxes corresponding to $\mathcal{P}'$ provided by Proposition 5.

For each box $B \in \mathcal{Q}^*$, we can re-scale B if necessary, without changing its intersection with $\mathcal{P}$ so that B is of the form

$$B = [0, b_1] \times [0, b_2] \times \cdots \times [0, b_d],$$

where each b_i is equal to α_{i,j_i}, for a suitable j_i. Now for each box $B \in \mathcal{Q}^*$, we define a half-space $\gamma(B)$ as the set of points $(x_1, \ldots, x_d) \in \mathbb{R}^d$ satisfying

$$\frac{x_1}{b_1} + \frac{x_2}{b_2} + \cdots + \frac{x_d}{b_d} \le d. \tag{4}$$

Clearly for any point $(x_1, \ldots, x_d)$ contained in the box B, we have $x_i \in [0, b_i]$ and thus each term on the left-hand side of the Equation (4) is at most 1. This implies that $B \subset \gamma(B)$ and so any point in the box B lies in the half-space $\gamma(B)$.

On the other hand, for any point $(x_1, \ldots, x_d) \in \mathcal{P} \setminus B$, there exists an index $i \in [d]$ such that $x_i > b_i$. By (3), we have that $x_i/b_i > d$, and thus $(x_1, \ldots, x_d)$ cannot lie in the half-space $\gamma(B)$.

Consider the set of at most k half-spaces defined as $\mathcal{H} = \{\gamma(B) : B \in \mathcal{Q}^*\}$. Now by Proposition 5 and (2), we have

(i) each point of $\mathcal{P}'$ is contained in exactly one half-space in $\mathcal{H}$, and

(ii) no point of $\mathcal{P} \setminus \mathcal{P}'$ is contained in any half-space of $\mathcal{H}$.

In other words, the union as well as the symmetric difference of the half-spaces in $\mathcal{H}$ contains precisely the set $\mathcal{P}'$. As this is true for any $\mathcal{P}' \subseteq \mathcal{P}$, the k-fold union of half-spaces in $\mathbb{R}^d$ shatters $\mathcal{P}$ and the same holds for the k-fold symmetric difference of half-spaces in $\mathbb{R}^d$. Finally, we have

$$|\mathcal{P}| = |\mathcal{B}| = \left(\left\lfloor \frac{d}{2} \right\rfloor - 1 \right) \lfloor \log k \rfloor 2^{\lfloor \log k \rfloor - 1} = \Omega\left(d \cdot k \log k\right),$$

as desired. ∎

4. Proof of Theorem 2.

Given a set $\mathcal{H}$ of hyperplanes in $\mathbb{R}^d$, define the set system

$$\Delta_k(\mathcal{H}) = \Big\{ \mathcal{H}' \subseteq \mathcal{H} \colon \exists \text{ an open } k\text{-dimensional simplex } S \text{ in } \mathbb{R}^d \text{ such that } H \in \mathcal{H}' \text{ if and only if } H \text{ intersects } S \Big\}.$$

We prove the following more general theorem from which Theorem 2 follows immediately by setting $k = d$.

Theorem 6 *For any integer $d \ge 4$ and $k \le d$, there exists a set $\mathcal{H}$ of $\Omega(dk \log k)$ hyperplanes in $\mathbb{R}^d$ such that $|\Delta_k(\mathcal{H})| = 2^{|\mathcal{H}|}$, that is, we have*

$$\text{VC-dim}\left(\Delta_k(\mathcal{H})\right) = \Omega\left(d \cdot k \log k\right).$$

Proof Apply Theorem 1 to get a set $\mathcal{P}$ of $\Omega(dk \log k)$ points in $\mathbb{R}^d$ that is shattered by the k-fold union of open half-spaces. Using point-hyperplane duality (see eg. Matoušek, 2002), map each point $p \in \mathcal{P}$ to a hyperplane $\alpha(p)$ by

$$p = (p_1, \ldots, p_d) \quad \longmapsto \quad \alpha(p) := \left\{ (x_1, \ldots, x_d) : p_1 x_1 + p_2 x_2 + \cdots + p_{d-1} x_{d-1} - x_d = -p_d \right\}.$$

Our desired set $\mathcal{H}$ of hyperplanes will simply be

$$\mathcal{H} = \left\{ \alpha(p) \colon p \in \mathcal{P} \right\}.$$

It is easy to check that the mapping α is injective and thus $|\mathcal{H}| = |\mathcal{P}| = \Omega(dk \log k)$. We claim that $\mathcal{H}$ is shattered by the set system induced by open k-dimensional simplices; in other words, for any $\mathcal{H}' \subseteq \mathcal{H}$, there exists a k-dimensional simplex S such that the interior of S intersects each hyperplane of $\mathcal{H}'$, and no hyperplane of $\mathcal{H} \setminus \mathcal{H}'$.

Fix any $\mathcal{H}' \subseteq \mathcal{H}$ and let $\mathcal{P}' = \alpha^{-1}(\mathcal{H}')$ be the corresponding points of $\mathcal{P}$. Then there exists a set $\mathfrak{H}(\mathcal{P}')$ of k open half-spaces whose union contains all points in $\mathcal{P}'$ and no point in $\mathcal{P} \setminus \mathcal{P}'$. From Equation (4), it follows that each half-space in $\mathfrak{H}(P')$ is of the form

$$\frac{x_1}{b_1} + \frac{x_2}{b_2} + \cdots + \frac{x_d}{b_d} < d,$$

where $b_1, \ldots, b_d$ are positive reals. Map each half-space $H \in \mathfrak{H}(\mathcal{P}')$ to the point $\delta(H)$, given by

$$H = \left\{(x_1, \ldots, x_d) : \frac{x_1}{b_1} + \frac{x_2}{b_2} + \cdots + \frac{x_d}{b_d} < d\right\} \quad \longmapsto \quad \delta(H) := \left(\frac{b_d}{b_1}, \ldots, \frac{b_d}{b_{d-1}}, d \cdot b_d\right).$$

It is easy to verify that for a point $p \in \mathbb{R}^d$ and the half-space H, we have

$$\begin{aligned} p \in H &\iff \frac{p_1}{b_1} + \frac{p_2}{b_2} + \cdots + \frac{p_d}{b_d} < d \\ &\iff p_1 \cdot \frac{b_d}{b_1} + p_2 \cdot \frac{b_d}{b_2} + \cdots + p_{d-1} \cdot \frac{b_d}{b_{d-1}} + p_d < d \cdot b_d \\ &\iff \text{point } \left(\frac{b_d}{b_1}, \frac{b_d}{b_2}, \ldots, \frac{b_d}{b_{d-1}}, d \cdot b_d\right) \text{ lies strictly above the hyperplane} \\ &\qquad\qquad p_1 x_1 + p_2 x_2 + \cdots + p_{d-1} x_{d-1} - x_d = -p_d \\ &\iff \text{the point } \delta(H) \text{ lies strictly above the hyperplane } \alpha(p). \end{aligned} \tag{5}$$

Here we crucially needed the fact that all half-spaces in $\mathfrak{H}(\mathcal{P}')$ are downward facing, that is, each half-space in $\mathfrak{H}(\mathcal{P}')$ contains the origin, which lies below (with respect to the x_d-coordinate) its bounding hyperplane.

Now consider the k open half-spaces in $\mathfrak{H}(\mathcal{P}')$ and let

$$\Delta' = \{\delta(H) \colon H \in \mathfrak{H}(\mathcal{P}')\}$$

be k points in $\mathbb{R}^d$. From the relation (5), it follows that

- As each point $p \in \mathcal{P}'$ lies in *some* half-space $H \in \mathfrak{H}(\mathcal{P}')$, the point $\delta(H)$ lies strictly above the hyperplane $\alpha(p)$ in $\mathcal{H}$—or equivalently, the hyperplane $\alpha(p)$ has at least one of the k points in the set Δ' lying strictly above it.
- For each point $p \in \mathcal{P} \setminus \mathcal{P}'$, all the k points in Δ' lie on or below the hyperplane $\alpha(p) \in \mathcal{H}$.

Then, by the above discussion, $H \in \mathcal{H}'$ if and only if one of these is true:

1. H intersects the interior of $\texttt{conv}\,(\Delta')$ and so at least one vertex of Δ' lies strictly above H, or
2. H does not intersect $\texttt{conv}\,(\Delta')$, but then *all* vertices of Δ' lie strictly above H.

Finally consider the k-dimensional simplex

$$S = \texttt{conv}\left(\Delta' \bigcup (0, \ldots, 0, -\infty)\right).$$

Clearly, a hyperplane $H \in \mathcal{H}$ intersects the interior of S if and only if $H \in \mathcal{H}'$. Note that the point $(0, \ldots, 0, -\infty)$ can be any point $(0, \ldots, 0, t)$ for a small-enough value of $t \in \mathbb{R}$. This concludes the proof. ∎

Abstract

SMART is an open source web application designed to help data scientists and research teams efficiently build labeled training data sets for supervised machine learning tasks. SMART provides users with an intuitive interface for creating labeled data sets, supports active learning to help reduce the required amount of labeled data, and incorporates inter-rater reliability statistics to provide insight into label quality. SMART is designed to be platform agnostic and easily deployable to meet the needs of as many different research teams as possible. The project website[1] contains links to the code repository and extensive user documentation.

Keywords: software, supervised learning, data labeling, active learning, open source

1. Introduction

Over the past decade, supervised machine learning has made tremendous strides, achieving or surpassing human-level performance on tasks diverse as image recognition (Real et al., 2017), speech recognition (Saon et al., 2017) and language modeling (Zilly et al., 2016). While many of these achievements are at least partially due to algorithmic advances and specialized computing resources, they also all rely on large labeled data sets. However, in the research community and in industry, it is often acknowledged that the main bottleneck in machine learning adoption is no longer algorithms or hardware, but creating sufficiently large labeled data sets to address meaningful tasks.

To address this issue, we created SMART, an open source application designed to lessen manual labeling effort while maintaining data quality. SMART uses active learning (Settles, 2012) to help reduce the number of labels necessary to develop a reliable model, inter-rater reliability statistics (Cohen, 1960; Fleiss, 1971) to ensure label quality, and data visualization to help project administrators manage coding projects. SMART allows for multiple coders per project and supports on-premise installation, essential for projects where crowdsourcing is prohibited (e.g., when the data set is proprietary or sensitive in nature). While SMART was primarily designed for applied researchers and analysts needing to generate labelled training data, machine learning and human-computer interaction researchers can also use SMART to study how humans label data. This could range from running experiments on how coders interact to assessing active learning algorithms on their total labelling burden (time, costs, etc.).

SMART is part of a broad collection of commercial and open source data labeling platforms. While providing some overlap in functionality, these software products and services range widely in their intended use cases and pricing. Commercial Platform as a Service (PaaS) applications that specialize in data labelling (e.g., Figure Eight) tend to be the most full-featured and put a premium on the usability and scalability of their products. For a fee, these services provide analysts with a platform to organize, annotate, and export their labeled data. In contrast, commercial crowdsourcing platforms (e.g., Amazon Mechanical Turk) provide both annotation templates and access to an on-demand labelling workforce. While crowdsourcing may be an inexpensive and reliable way to perform many micro-tasks, it may be inappropriate for more complex tasks, those that require expert judgement, or for data that is confidential or classified. For open source projects, specialized research software applications focusing on methods like active learning (Settles, 2011) and adaptive sampling (Scott Sievert et al., 2017) are more common than platforms taking a holistic approach to the data labelling workflow. In essence, SMART is the open source alternative to commercial data labelling platforms, providing a powerful set of core features that can be modified and extended by the community to address new use cases. At the time of writing, SMART primarily supports text classification, though it can be extended to model other tasks and data types.

2. Using SMART

SMART is built using an open-source technology stack with the intention of being platform agnostic and easy to deploy. Specifically, SMART is a web application using React, Bootstrap, d3, and webpack for front-end interactions and Django, Redis, and PostgreSQL to support back-end operations. Docker and Docker-Compose[2] are used for OS-level virtualization to aid configuration management and ease deployment in new environments. Docker and Docker-Compose are also SMART's only dependencies; instructions to install SMART using these systems can be found online in the user documentation.[3]

Project Creation. Users create their own projects using a multi-step workflow. To start a project, users provide basic project information (project name and description), declare the set of classes they will annotate in the project, and upload their unlabeled data. Optionally, they can also set user permissions for multi-user projects, modify advanced project settings, and upload an instructional codebook to help define labeling tasks for users. When uploading project data, users have the option of providing a unique identifier to help link exported records and they can also provide pre-labeled data to initialize the active learning models. The advanced settings allow the user to customize the active learning

(a) Annotation Page.

(b) Administrative Dashbboard Page.

Figure 1: In this example, the SMART interface (a) prompts users to rate the sentiment of a tweet. The progress bar indicates the number of tweets labeled against the number assigned to the user in the current batch. Users with administrative privileges can access visualizations of a project's coding progress (b). The Label Distribution chart conveys the number of annotated tweets per class whereas the Time to Label chart summarizes the distribution of time spent per coder labeling tweets. Figures showcasing additional features of SMART are available in the on-line user documentation.

model, set the batch size for the number of observations to label prior to re-running computations, and to enable/disable inter-rater reliability. While sensible default settings are provided, all settings can be customized to meet the specific needs of the labeling project.

Annotating Data. SMART's annotation page allows users to perform several different tasks relating to labeling data. All project members have access to the main labeling interface (Figure 1a) as well as their personal annotation history where they can view and modify previously labeled records. For each record, users can either provide a label or skip the observation. Skipped records are forwarded to a project administrator for adjudication. To help with the labeling task, the annotation page also contains the instructional codebook and the project's labels and definitions (if included during project creation), providing easy access to important annotation resources. Privileged users can also label specific records if the label distribution is highly skewed (Attenberg and Provost, 2010), resolve skipped data elements, and remove records from the project that are completely out-of-scope or otherwise deemed unusable. If inter-rater reliability is enabled, privileged users can also adjudicate double-coded records in which there is label disagreement.

Administrative Dashboard. To help project owners manage their labeling tasks, privileged users have access to an administrator dashboard page that includes data visualizations of the labeling process, performance metrics for the active learning model, and inter-rater reliability metrics across labelers.

The main labeled data view includes two interactive visualizations and an informative data table (Figure 1b). The label distribution chart shows the count of each label per user to compare labeler progress and identify drastic differences in label distributions that might indicate a user's misunderstanding of the labeling task. The time to label chart is a box and whisker plot detailing how long each user is on the annotation page before selecting a label. This chart can help indicate if certain labelers are taking much less time than expected (indicating possible falsification) or more time than expected (indicating potential barriers to labeling).

The active learning model view provides information on the performance of a classifier trained on the labeled project data. The purpose of this view is to help provide insight on when the data labeling has hit a natural saturation point (additional labels are not improving model performance) and to add transparency to the active learning mechanism. SMART currently supports uncertainty sampling (Lewis and Gale, 1994) as the active learning algorithm using least confident, margin, and entropy as measures of uncertainty (Settles, 2012). Currently, several classifier types are supported through the Scikit-learn python library (Pedregosa et al., 2011), and text data elements are vectorized using a term frequency-inverse document frequency (tf-idf) representation (Salton and Buckley, 1988). After each batch of data is labeled, the model is retrained, and its performance is updated and displayed in an interactive data visualization.

Finally, the inter-rater reliability (IRR) view lets privileged users understand how consistently labelers agree on labels that are double-coded. This view is particularly useful early in the labeling process to discover if there is ambiguity in the class definitions or if the task is underspecified. It also provides an indication of how well humans would be expected to perform on the task, a useful benchmark to contextualize model performance. SMART uses Cohens kappa coefficient (Cohen, 1960) to measure IRR between two independent labelers and Fleiss kappa (Fleiss, 1971) for more than two labelers. Users can also view the percent overall agreement and the pairwise percent agreement for unadjusted metrics comparing consistency across labelers. As a visual summary, SMART provides a confusion matrix of labeler agreement in the form of a dynamic heat map. This visualization is valuable in diagnosing if there are particular classes in which labelers disagree, providing targeted insight into potentially ambiguous class definitions.

Exporting Data. SMART allows users to download both the labeled data and the underlying classification model used for active learning (if enabled for the project). For all projects, SMART returns a zipped file of labeled data, sorted by label. If active learning is enabled, SMART will also provide several relevant serialized Python objects using the Pickle protocol, including the preprocessed version of the input data as a tf-idf matrix, the trained classifier, and the fit vectorizer to convert text data into tf-idf vectors. Lastly, a Dockerfile and Jupyter Notebook are provided to assist users in recreating the application environment and running the sample code.

Acknowledgments

We would like to acknowledge the National Consortium for Data Science and RTI International for their generous support in funding the development of SMART. We would also like to thank Lucy Liu for creation of the SMART logo as well as valuable feedback, guidance, and user testing from Annice Kim, Maggie Cress, Jennifer Unangst, and Joey Morris.

Abstract

In this paper, we study the behavior of the Hedge algorithm in the online stochastic setting. We prove that anytime Hedge with decreasing learning rate, which is one of the simplest algorithm for the problem of prediction with expert advice, is remarkably both worst-case optimal and adaptive to the easier stochastic and adversarial with a gap problems. This shows that, in spite of its small, non-adaptive learning rate, Hedge possesses the same optimal regret guarantee in the stochastic case as recently introduced adaptive algorithms. Moreover, our analysis exhibits qualitative differences with other versions of the Hedge algorithm, such as the fixed-horizon variant (with constant learning rate) and the one based on the so-called "doubling trick", both of which fail to adapt to the easier stochastic setting. Finally, we determine the intrinsic limitations of anytime Hedge in the stochastic case, and discuss the improvements provided by more adaptive algorithms.

Keywords. Online learning; prediction with expert advice; Hedge; adaptive algorithms.

1. Introduction

The standard setting of *prediction with expert advice* (Littlestone and Warmuth, 1994; Freund and Schapire, 1997; Vovk, 1998; Cesa-Bianchi and Lugosi, 2006) aims to provide sound strategies for sequential prediction that combine the forecasts from different sources. More precisely, in the so-called *Hedge problem* (Freund and Schapire, 1997), at each round the learner has to output a probability distribution on a finite set of *experts* $\{1, \dots, M\}$; the losses of the experts are then revealed, and the learner incurs the expected loss from its chosen probability distribution. The goal is then to control the *regret*, defined as the difference between the cumulative loss of the learner and that of the best expert (with smallest loss). This online prediction problem is typically considered in the *individual sequences* framework, where the losses may be arbitrary and in fact set by an adversary that seeks to maximize the regret. This leads to regret bounds that hold under virtually no assumption (Cesa-Bianchi and Lugosi, 2006).

In this setting, arguably the simplest and most standard strategy is the *Hedge algorithm* (Freund and Schapire, 1997), also called the *exponentially weighted averaged forecaster* (Cesa-Bianchi and Lugosi, 2006). This algorithm depends on a time-varying parameter η_t called the *learning rate*, which quantifies by how much the algorithm departs from its initial probability distribution to put more weight on the currently leading experts. Given a known finite time horizon T, the standard tuning of the learning rate is fixed and given by $\eta_t = \eta \propto \sqrt{\log(M)/T}$, which guarantees an optimal worst-case regret of order $O(\sqrt{T \log M})$. Alternatively, when T is unknown, one can set $\eta_t \propto \sqrt{\log(M)/t}$ at round t, which leads to an *anytime* $O(\sqrt{T \log M})$ regret bound valid for all $T \geqslant 1$.

While worst-case regret bounds are robust and always valid, they turn out to be overly pessimistic in some situations. A recent line of research (Cesa-Bianchi et al., 2007; de Rooij et al., 2014; Gaillard et al., 2014; Koolen et al., 2014; Sani et al., 2014; Koolen and van Erven, 2015; Luo and Schapire, 2015) designs algorithms that combine $O(\sqrt{T \log M})$ worst-case regret guarantees with an improved regret on easier instances of the problem. An interesting example of such an easier instance is the stochastic problem, where it is assumed that the losses are stochastic and that at each round the expected loss of a "best" expert is smaller than those of the other experts by some gap Δ. Such algorithms rely either on a more careful, data-dependent tuning of the learning rate η_t (Cesa-Bianchi et al., 2007; de Rooij et al., 2014; Koolen et al., 2014; Gaillard et al., 2014), or on more sophisticated strategies (Koolen and van Erven, 2015; Luo and Schapire, 2015). As shown by Gaillard et al. (2014) (see also Koolen et al. 2016), one particular type of adaptive regret bounds (so-called *second-order bounds*) implies at the same time a $O(\sqrt{T \log M})$ worst-case bound and a better *constant* $O(\log(M)/\Delta)$ bound in the stochastic problem with gap Δ. Arguably starting with the early work on second-order bounds (Cesa-Bianchi et al., 2007), the design of online learning algorithms that combine robust worst-case guarantees with improved performance on easier instances has been an active research goal in recent years (de Rooij et al., 2014; Gaillard et al., 2014; Koolen et al., 2014; Sani et al., 2014). However, to the best of our knowledge, existing work on the Hedge problem has focused on developing new adaptive algorithms rather than on analyzing the behavior of "conservative" algorithms in favorable scenarios. Owing to the fact that the standard Hedge algorithm is designed for — and analyzed in — the adversarial setting (Littlestone and Warmuth, 1994; Freund and Schapire, 1997; Cesa-Bianchi and Lugosi, 2006), and that its parameters are not tuned adaptively to obtain better bounds in easier instances, it may be considered as overly conservative and not adapted to stochastic environments.

Our contribution. This paper fills a gap in the existing literature by providing an analysis of the standard Hedge algorithm in the stochastic setting. We show that the anytime Hedge algorithm with default learning rate $\eta_t \propto \sqrt{\log(M)/t}$ actually *adapts* to the stochastic setting, in which it achieves an optimal *constant* $O(\log(M)/\Delta)$ regret bound *without any dedicated tuning* for the easier instance, which might be surprising at first sight. This contrasts with previous works, which require the construction of new adaptive (and more involved) algorithms. Remarkably, this property is *not* shared by the variant of Hedge for a known fixed-horizon T with constant learning rate $\eta \propto \sqrt{\log(M)/T}$, since it suffers a $\Theta(\sqrt{T \log M})$ regret even in easier instances. This exhibits a strong difference between the performances of the anytime and the fixed-horizon variants of the Hedge algorithm.

Given the aforementioned adaptivity of Decreasing Hedge, one may wonder whether there is in fact any benefit in using more sophisticated algorithms in the stochastic regime. We answer this question affirmatively, by considering a more refined measure of complexity of a stochastic instance than the gap Δ. Specifically, we show that Decreasing Hedge does not admit improved regret under Bernstein conditions, which are standard low-noise conditions from statistical learning (Mammen and Tsybakov, 1999; Tsybakov, 2004; Bartlett and Mendelson, 2006). By contrast, it was shown by Koolen et al. (2016) that algorithms which satisfy some adaptive adversarial regret bound achieve improved regret under Bernstein conditions. Finally, we characterize the behavior of Decreasing Hedge in the stochastic regime, by showing that its eventual regret on *any* stochastic instance is governed by the gap Δ.

Related work. In the bandit setting, where the feedback only consists of the loss of the selected action, there has also been some interest in "best-of-both-worlds" algorithms that combine optimal $O(\sqrt{MT})$ worst-case regret in the adversarial regime with improved $O(M \log T)$ regret (up to logarithmic factors) in the stochastic case (Bubeck and Slivkins, 2012; Seldin and Slivkins, 2014; Auer and Chiang, 2016). In particular, Seldin and Slivkins (2014); Seldin and Lugosi (2017) showed that by augmenting the standard EXP3 algorithm for the adversarial regime (an analogue of Hedge with $\Theta(1/\sqrt{t})$ learning rate) with a special-purpose gap detection mechanism, one can achieve poly-logarithmic regret in the stochastic case. This result is strengthened in some recent follow-up work (Zimmert and Seldin, 2019; Zimmert et al., 2019), that appeared since the completion of the first version of the present paper, which obtains optimal regret in the stochastic and adversarial regimes through a variant of the Follow-The-Regularized-Leader (FTRL) algorithm with $\Theta(1/\sqrt{t})$ learning rate and a proper regularizer choice. This result can be seen as an analogue in the bandit case of our upper bound for Decreasing Hedge. Note that, in the bandit setting, the hardness of an instance is essentially characterized by the gap Δ (Bubeck and Cesa-Bianchi, 2012); in particular, the Bernstein condition, which depends on the correlations between the losses of the experts, cannot be exploited under bandit feedback, where one only observes one arm at each round. Hence, it appears that the negative part of our results (on the limitations of Hedge) does not have an analogue in the bandit case.

A similar adaptivity result for FTRL with decreasing $\Theta(1/\sqrt{t})$ learning rate has been observed in a different context by Huang et al. (2017). Specifically, it is shown that, in the case of online linear optimization on a Euclidean ball, FTRL with squared norm regularizer and learning rate $\Theta(1/\sqrt{t})$ achieves $O(\log T)$ regret when the loss vectors are i.i.d. This result is an analogue of our upper bound for Hedge, since this algorithm corresponds to FTRL on the simplex with entropic regularizer (Cesa-Bianchi and Lugosi, 2006; Hazan, 2016). On the other hand, the simplex lacks the curvature of the Euclidean ball, which is important to achieve small regret; here, the improved regret is ensured by a condition on the distribution, namely the existence of a gap Δ. Our lower bound for Hedge shows that this condition is necessary, thereby characterizing the long-term regret of FTRL on the simplex with entropic regularizer. In the case of the Euclidean ball with squared norm regularizer, the norm of the expected loss vector appears to play a similar role, as shown by the upper bound from Huang et al. (2017).

Outline. We define the setting of prediction with expert advice and the Hedge algorithm in Section 2, and we recall herein its standard worst-case regret bound. In Section 3, we consider the behavior of the Hedge algorithm on easier instances, namely the stochastic setting with a gap Δ on the best expert. Under an i.i.d assumption on the sequence of losses, we provide in Theorem 2 an upper bound on the regret of order $(\log M)/\Delta$ for Decreasing Hedge. In Proposition 4, we prove that the rate $(\log M)/\Delta$ cannot be improved in this setting. In Theorem 5 and Corollary 6, we extend the regret guarantees to the adversarial with a gap setting, where a leading expert linearly outperforms the others. These results stand for any Hedge algorithm which is worst-case optimal and with any learning rate which is larger than the one of Decreasing Hedge, namely $O(\sqrt{\log M/t})$. In Proposition 7, we prove the sub-optimality of the fixed-horizon Hedge algorithm, and of another version of Hedge based on the so-called "doubling trick". In Section 4, we discuss the advantages of adaptive Hedge algorithms, and explain what the limitations of Decreasing Hedge are compared to such versions. We include numerical illustrations of our theoretical findings in Section 5, conclude in Section 6 and provide the proofs in Section 7.

2. The expert problem and the Hedge algorithm

In the Hedge setting, also called *decision-theoretic online learning* (Freund and Schapire, 1997), the learner and its adversary (the Environment) sequentially compete on the following game: at each round $t \geqslant 1$,

1. the Learner chooses a probability vector $\boldsymbol{v}_t = (v_{i,t})_{1 \leqslant i \leqslant M}$ on the M experts $1, \dots, M$;
2. the Environment picks a bounded loss vector $\boldsymbol{\ell}_t = (\ell_{i,t})_{1 \leqslant i \leqslant M} \in [0,1]^M$, where $\ell_{i,t}$ is the loss of expert i at round t, while the Learner suffers loss $\widehat{\ell}_t = \boldsymbol{v}_t^\top \boldsymbol{\ell}_t$.

The goal of the Learner is to control its *regret*

$$R_T = \sum_{t=1}^{T} \widehat{\ell}_t - \min_{1 \leqslant i \leqslant M} \sum_{t=1}^{T} \ell_{i,t} \tag{1}$$

for every $T \geqslant 1$, irrespective of the sequence of loss vectors $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \dots$ chosen by the Environment. One of the most standard algorithms for this setting is the *Hedge* algorithm. The Hedge algorithm, also called the exponentially weighted averaged forecaster, uses the vector of probabilities $\boldsymbol{v}_t = (v_{i,t})_{1 \leqslant i \leqslant M}$ given by

$$v_{i,t} = \frac{e^{-\eta_t L_{i,t-1}}}{\sum_{j=1}^{M} e^{-\eta_t L_{j,t-1}}} \tag{2}$$

at each $t \geqslant 1$, where $L_{i,T} = \sum_{t=1}^{T} \ell_{i,t}$ denotes the cumulative loss of expert i for every $T \geqslant 1$. Let us also denote $\widehat{L}_T := \sum_{t=1}^{T} \widehat{\ell}_t$ and $R_{i,T} = \widehat{L}_T - L_{i,T}$ the regret with respect to expert i. We consider in this paper the following variants of Hedge, where $c_0 > 0$ is a constant.

Decreasing Hedge (Auer et al., 2002). This is Hedge with the sequence of learning rates $\eta_t = c_0 \sqrt{\log(M)/t}$.

Constant Hedge (Littlestone and Warmuth, 1994). Given a finite time horizon $T \geqslant 1$, this is Hedge with constant learning rate $\eta_t = c_0\sqrt{\log(M)/T}$.

Hedge with doubling trick (Cesa-Bianchi et al., 1997; Cesa-Bianchi and Lugosi, 2006). This variant of Hedge uses a constant learning rate on geometrically increasing intervals, restarting the algorithm at the beginning of each interval. Namely, it uses

$$v_{i,t} = \frac{\exp(-\eta_t \sum_{s=T_k}^{t-1} \ell_{i,s})}{\sum_{j=1}^{M} \exp(-\eta_t \sum_{s=T_k}^{t-1} \ell_{j,s})}, \tag{3}$$

with $T_l = 2^l$ for $l \geqslant 0$, $k \in \mathbf{N}$ such that $T_k \leqslant t < T_{k+1}$ and $\eta_t = c_0\sqrt{\log(M)/T_k}$.

Let us recall the following standard regret bound for the Hedge algorithm from Chernov and Zhdanov (2010).

Proposition 1 *Let $\eta_1, \eta_2, \dots$ be a decreasing sequence of learning rates. The Hedge algorithm* (2) *satisfies the following regret bound:*

$$R_T \leqslant \frac{1}{\eta_T}\log M + \frac{1}{8}\sum_{t=1}^{T}\eta_t\,. \tag{4}$$

In particular, the choice $\eta_t = 2\sqrt{\log(M)/t}$ yields a regret bound of $\sqrt{T\log M}$ for every $T \geqslant 1$.

Note that the regret bound stated in Equation (4) holds for every sequence of losses $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \dots$, which makes it valid under no assumption (aside from the boundedness of the losses). The worst-case regret bound in $O(\sqrt{T\log M})$ is achieved by Decreasing Hedge, Hedge with doubling trick and Constant Hedge (whenever T is known in advance). The $O(\sqrt{T\log M})$ rate cannot be improved either by Hedge or any other algorithm: it is known to be the minimax optimal regret (Cesa-Bianchi and Lugosi, 2006). Contrary to Constant Hedge, Decreasing Hedge is anytime, in the sense that it achieves the $O(\sqrt{T\log M})$ regret bound simultaneously for each $T \geqslant 1$. We note that this worst-case regret analysis fails to exhibit any difference between these three algorithms.

In many cases, this $\sqrt{T}$ regret bound is pessimistic, and more "aggressive" strategies (such as the follow-the-leader algorithm, which plays at each round the uniform distribution on the experts with smallest loss, Cesa-Bianchi and Lugosi, 2006) may achieve constant regret in easier instances, even though they lack regret guarantees in the adversarial regime. We show in Section 3 below that Decreasing Hedge is actually better than both Constant Hedge and Hedge with doubling trick in some easier instance of the problem (including in the stochastic setting). This entails that Decreasing Hedge is actually able to adapt, without any modification, to the easiness of the problem considered.

3. Regret of Hedge variants on easy instances

In this section, we depart from the worst-case regret analysis and study the regret of the considered variants of the Hedge algorithm on easier instances of the prediction with expert advice problem.

3.1. Optimal regret for Decreasing Hedge in the stochastic regime

We examine the behavior of Decreasing Hedge in the stochastic regime, where the losses are the realization of some (unknown) stochastic process. More precisely, we consider the standard i.i.d. case, where the loss vectors $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \dots$ are i.i.d. (independence holds over rounds, but not necessarily across experts). In this setting, the regret can be much smaller than the worst-case $\sqrt{T\log M}$ regret, since the best expert (with smallest expected loss) will dominate the rest after some time. Following Gaillard et al. (2014); Luo and Schapire (2015), the easiness parameter we consider in this case, which governs the time needed for the best expert to have the smallest cumulative loss and hence the incurred regret, is the sub-optimality gap $\Delta = \min_{i \neq i^*} \mathbb{E}[\ell_{i,t} - \ell_{i^*,t}]$, where $i^* = \operatorname{argmin}_i \mathbb{E}[\ell_{i,t}]$.

We show below that, despite the fact that Decreasing Hedge is designed for the worst-case setting described in Section 2, it is able to adapt to the easier problem considered here, Indeed, Theorem 2 shows that Decreasing Hedge achieves a *constant*, and in fact *optimal* (by Proposition 4 below) regret bound in this setting, in spite of its "conservative" learning rate.

With the exception of the high-probability bound of Corollary 6, the upper and lower bounds in the stochastic case are stated for the *pseudo-regret* $\mathcal{R}_T = \mathbb{E}[R_{i^*,T}]$ (similar bounds hold for the the expected regret $\mathbb{E}[R_T]$, since $\mathcal{R}_T \leqslant \mathbb{E}[R_T]$ and by Remark 14 in Section 7.1).

Theorem 2 *Let $M \geqslant 3$. Assume that the loss vectors $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \dots$ are i.i.d. random variables, where $\boldsymbol{\ell}_t = (\ell_{i,t})_{1 \leqslant i \leqslant M}$. Also, assume that there exists $i^* \in \{1, \dots, M\}$ and $\Delta > 0$ such that*

$$\mathbb{E}[\ell_{i,t} - \ell_{i^*,t}] \geqslant \Delta \tag{5}$$

for every $i \neq i^*$. Then, the Decreasing Hedge algorithm with learning rate $\eta_t = 2\sqrt{(\log M)/t}$ achieves the following pseudo-regret bound: for every $T \geqslant 1$,

$$\mathcal{R}_T \leqslant \frac{4\log M + 25}{\Delta}\,. \tag{6}$$

The proof of Theorem 2 is given in Section 7.1. Theorem 2 proves that, in the stochastic setting with a gap Δ, the Decreasing Hedge algorithm achieves a regret $O(\log(M)/\Delta)$, without any prior knowledge of Δ. This matches the guarantees of adaptive Hedge algorithms which are explicitly designed to adapt to easier instances (Gaillard et al., 2014; Luo and Schapire, 2015). This result may seem surprising at first: indeed, adaptive exponential weights algorithms that combine optimal regret in the adversarial setting and constant regret in easier scenarios, such as Hedge with a second-order tuning (Cesa-Bianchi et al., 2007) or AdaHedge (de Rooij et al., 2014), typically use a data-dependent learning rate η_t that adapts to the properties of the losses. While the learning rate η_t chosen by these algorithms may be as low as the worst-case tuning $\eta_t \propto \sqrt{\log(M)/t}$, in the stochastic case those algorithms will use larger, lower-bounded learning rates to ensure constant regret. As Theorem 2 above shows, it turns out that the data-independent, "safe" learning rates $\eta_t \propto \sqrt{\log(M)/t}$ used by "vanilla" Decreasing Hedge are still large enough to adapt to the stochastic case.

Idea of the proof. The idea of the proof of Theorem 2 is to divide time in two phases: a short initial phase $[\![1, t_1]\!]$, where $t_1 = O(\frac{\log M}{\Delta^2})$, and a second phase $[\![t_1, T]\!]$. The initial phase is dominated by noise, and regret during this period is bounded through the worst-case regret bound of Proposition 1, which gives a regret of $O(\sqrt{t_1 \log M}) = O(\frac{\log M}{\Delta})$. In the second phase, the best expert dominates the rest, and the weights concentrate on this best expert fast enough that the total regret incurred is small. The control of the regret in the second phase relies on the critical fact that, if η_t is at least as large as $\sqrt{(\log M)/t}$, then the following two things occur simultaneously at $t_1 \asymp \frac{\log M}{\Delta^2}$, namely at the beginning of the late phase:

1. with high probability, the best expert i^* dominates all the others linearly: for every $i \neq i^*$ and $t \geqslant t_1$, $L_{i,t} - L_{i^*,t} \geqslant \frac{\Delta t}{2}$;
2. the total weight of all suboptimal experts is controlled: $\sum_{i \neq i^*} v_{i,t_1} \leqslant \frac{1}{2}$. If $\eta_t \geqslant \sqrt{(\log M)/t}$ and the first condition holds, this amounts to $M \exp(-\frac{\Delta}{2}\sqrt{t \log M}) \leqslant \frac{1}{2}$, namely $t_1 \gtrsim \frac{\log M}{\Delta^2}$.

In other words, the learning rate $\eta_t \asymp \sqrt{(\log M)/t}$ ensures that the total weight of suboptimal experts starts vanishing at about the same time as when the best expert starts to dominate the others with a large probability (and remarkably, this property holds for every value of the sub-optimality gap Δ). Finally, the upper bound on the regret in the second phase rests on the two conditions above, together with the bound $\sum_{t \geqslant 1} e^{-c\sqrt{t}} = O(\frac{1}{c^2})$ for $c > 0$.

Remark 3 *The fact that $\sum_{t \geqslant 1} e^{-c\sqrt{t}} = O(1/c^2)$ is also used in the analysis of the EXP3++ bandit algorithm (Seldin and Slivkins, 2014, Lemma 10). In the expert setting considered here, summing the contribution of all experts (which suffices in the bandit setting to obtain the correct order of regret) would yield a significantly suboptimal $O(M/\Delta)$ regret bound, with a linear dependence on the number of experts M. In our case, the decomposition of the regret in two phases, which is explained above, removes the linear dependence on M and allows to obtain the optimal rate $(\log M)/\Delta$.*

We complement Theorem 2 by showing that the $O((\log M)/\Delta)$ regret under the gap condition cannot be improved, in the sense that its dependence on both M and Δ is optimal.

Proposition 4 *Let $\Delta \in (0, \frac{1}{4})$, $M \geqslant 4$ and $T \geqslant (\log M)/(16\Delta^2)$. Then, for any algorithm for the Hedge setting, there exists an i.i.d. distribution over the sequence of losses $(\boldsymbol{\ell}_t)_{t \geqslant 1}$ such that:*

- *there exists $i^* \in \{1, \dots, M\}$ such that, for any $i \neq i^*$, $\mathbb{E}[\ell_{i,t} - \ell_{i^*,t}] \geqslant \Delta$;*
- *the pseudo-regret of the algorithm satisfies:*

$$\mathcal{R}_T \geqslant \frac{\log M}{256\Delta}\,. \tag{7}$$

The proof of Proposition 4 is given in Section 7.2. Proposition 4 generalizes the well-known minimax lower bound of $\Theta(\sqrt{T \log M})$, which is recovered by taking $\Delta \asymp \sqrt{(\log M)/T}$.

3.2. Small regret for Decreasing Hedge in the adversarial with a gap problem

In this section, we extend the regret guarantee of Decreasing Hedge in the stochastic setting (Theorem 2), by showing that it holds for more general algorithms and under more general assumptions. Specifically, we consider an "adversarial with a gap" regime, similar to the one introduced by Seldin and Slivkins (2014) in the bandit case, where the leading expert linearly outperforms the others after some time. As Theorem 5 shows, essentially the same regret guarantee can be obtained in this case, up to an additional $\log(\Delta^{-1})/\Delta$ term. Theorem 5 also applies to any Hedge algorithm whose (possibly data-dependent) learning rate η_t is at least as large as that of Decreasing Hedge, and which satisfies a $O(\sqrt{T \log M})$ worst-case regret bound; this includes algorithms with *anytime* first and second-order tuning of the learning rate (Auer et al., 2002; Cesa-Bianchi et al., 2007; de Rooij et al., 2014). In what follows, we will assume $M \geqslant 3$ for convenience, similar results holds for $M = 2$.

Theorem 5 *Let $M \geqslant 3$. Assume that there exists $\tau_0 \geqslant 1$, $\Delta \in (0, 1)$ and $i^* \in \{1, \dots, M\}$ such that, for every $t \geqslant \tau_0$ and $i \neq i^*$, one has*

$$L_{i,t} - L_{i^*,t} \geqslant \Delta t. \tag{8}$$

Consider any Hedge algorithm with (possibly data-dependent) learning rate η_t such that

- *$\eta_t \geqslant c_0\sqrt{(\log M)/t}$ for some constant $c_0 > 0$;*
- *it admits the following worst-case regret bound: $R_T \leqslant c_1\sqrt{T \log M}$ for every $T \geqslant 1$, for some $c_1 > 0$.*

Then, for every $T \geqslant 1$, the regret of this algorithm is upper bounded as

$$R_T \leqslant c_1\sqrt{\tau_0 \log M} + \frac{c_2 \log M + c_3 \log \Delta^{-1} + c_4}{\Delta} \tag{9}$$

where $c_2 = c_1 + \frac{\sqrt{8}}{c_0}$, $c_3 = \frac{\sqrt{8}}{c_0}$ and $c_4 = \frac{16}{c_0^2}$.

The idea of the proof of Theorem 5 is the same as that of Theorem 2, the only difference being the slightly longer initial phase to account for the adversarial nature of the losses. As a consequence of the general bound of Theorem 5, we can recover the guarantee of Theorem 2 (up to an additional $\log(\Delta^{-1})/\Delta$ term), both in expectation and with high probability, under more general stochastic assumptions than i.i.d. over time. The proofs of Theorem 5 and Corollary 6 are provided in Section 7.3.

Corollary 6 *Assume that the losses $(\ell_{i,t})_{1 \leqslant i \leqslant M, t \geqslant 1}$ are random variables. Also, denoting $\mathcal{F}_t = \sigma\big((\ell_{i,s})_{1 \leqslant i \leqslant M, 1 \leqslant s \leqslant t}\big)$, assume that there exists i^* and $\Delta > 0$ such that*

$$\mathbb{E}\left[\ell_{i,t} - \ell_{i^*,t} \,|\, \mathcal{F}_{t-1}\right] \geqslant \Delta \tag{10}$$

for every $i \neq i^*$ and every $t \geqslant 1$. Then, for any Hedge algorithm satisfying the conditions of Theorem 5, and every $T \geqslant 1$:

$$\mathcal{R}_T \leqslant (5c_1 + 2c_2)\frac{\log M}{\Delta} + 2c_3\frac{\log \Delta^{-1}}{\Delta} + \frac{2c_4}{\Delta}, \tag{11}$$

with c_1, c_2, c_3, c_4 as in Theorem 5. In addition, for every $\varepsilon \in (0,1)$, we have

$$R_T \leqslant \left(c_1\sqrt{8} + 2c_2\right)\frac{\log M}{\Delta} + c_1\frac{\sqrt{8\log M \log \varepsilon^{-1}}}{\Delta} + 2c_3\frac{\log \Delta^{-1}}{\Delta} + \frac{2c_4}{\Delta} \tag{12}$$

with probability at least $1-\varepsilon$.

3.3. Constant Hedge and Hedge with the doubling trick do not adapt to the stochastic case

Now, we show that the adaptivity of Decreasing Hedge to gaps in the losses, established in Sections 3.1 and 3.2, is not shared by the two closely related Constant Hedge and Hedge with the doubling trick, despite the fact that they both achieve the minimax optimal worst-case $O(\sqrt{T\log M})$ regret. Proposition 7 below shows that both algorithms fail to achieve a constant regret, and in fact to improve over their worst-case $\Theta(\sqrt{T\log M})$ regret guarantee, even in the extreme case of experts with constant losses 0 (for the leader), and 1 for the rest (*i.e.*, $\Delta = 1$).

Proposition 7 *Let $T \geqslant 1$, $M \geqslant 2$, and consider the experts $i = 1, \dots, M$ with losses $\ell_{1,t} = 0$, $\ell_{i,t} = 1$ $(1 \leqslant t \leqslant T, 2 \leqslant i \leqslant M)$. Then, the pseudo-regret of Constant Hedge with learning rate $\eta_t = c_0\sqrt{\log(M)/T}$ (where $c_0 > 0$ is a numerical constant) is lower bounded as follows*:

$$\mathcal{R}_T \geqslant \min\left(\frac{\sqrt{T\log M}}{3c_0}, \frac{T}{3}\right). \tag{13}$$

In addition, Hedge with doubling trick (3) *also suffers a pseudo-regret satisfying*

$$\mathcal{R}_T \geqslant \min\left(\frac{\sqrt{T\log M}}{6c_0}, \frac{T}{12}\right). \tag{14}$$

The proof of Proposition 7 is given in Section 7.4. Although Hedge with a doubling trick is typically considered as overly conservative and only suitable for worst-case scenarios Cesa-Bianchi and Lugosi, 2006 (especially due to its periodic restarts, after which it discards past observations), to the best of our knowledge Proposition 7 (together with Theorem 2) is the first to formally demonstrate the advantage of Decreasing Hedge over the doubling trick version. This implies that Decreasing Hedge should not be seen as merely a substitute for Constant Hedge to achieve anytime regret bounds. Indeed, even when the horizon T is fixed, Decreasing Hedge outperforms Constant Hedge in the stochastic setting.

4. Limitations of Decreasing Hedge in the stochastic case

In this section, we explore the limitations of the simple Decreasing Hedge algorithm in the stochastic regime, and exhibit situations where it performs worse than more sophisticated algorithms. The starting observation is that the sub-optimality gap Δ is a rather brittle measure of "hardness" of a stochastic instance, which does not fully reflect the achievable rates. We therefore consider the following fast-rate condition from statistical learning, which refines the sub-optimality gap as a measure of complexity of a stochastic instance.

Definition 8 (Bernstein condition) *Assume that the losses $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \dots$ are the realization of a stochastic process. Denote $\mathcal{F}_t = \sigma(\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_t)$ the σ-algebra generated by $\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_t$. For $\beta \in [0,1]$ and $B > 0$, the losses are said to satisfy the* (β, B)-Bernstein condition *if there exists i^* such that, for every $t \geqslant 1$ and $i \neq i^*$,*

$$\mathbb{E}[(\ell_{i,t} - \ell_{i^*,t})^2 \,|\, \mathcal{F}_{t-1}] \leqslant B\mathbb{E}[\ell_{i,t} - \ell_{i^*,t} \,|\, \mathcal{F}_{t-1}]^\beta. \tag{15}$$

The Bernstein condition (Bartlett and Mendelson, 2006), a generalization of the Tsybakov margin condition (Tsybakov, 2004; Mammen and Tsybakov, 1999), is a geometric property on the losses which enables to obtain fast rates (e.g., faster than $O(1/\sqrt{n})$ for parametric classes) in statistical learning; we refer to van Erven et al. (2015) for a discussion of fast rates conditions. The Bernstein condition (15) quantifies the "easiness" of a stochastic instance, and generalizes the gap condition considered in the previous section (see Example 1 below). Roughly speaking, it states that good experts (with near-optimal expected loss) are highly correlated with the best expert. In the examples below, we assume that the loss vectors $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \dots$ are i.i.d.

Example 1 (Gap implies Bernstein) *If $\Delta_i = \mathbb{E}[\ell_{i,t} - \ell_{i^*,t}] \geqslant \Delta$ for $i \neq i^*$, then the $(1, \frac{1}{\Delta})$-Bernstein condition holds (Koolen et al., 2016, Lemma 4). Furthermore, letting $\alpha = \mathbb{E}[\ell_{i^*,t}]$ denote the expected loss of the best expert, the $(1, 1+\frac{2\alpha}{\Delta})$-Bernstein condition holds. Indeed, for any $i \neq i^*$, denoting $\mu_i := \mathbb{E}[\ell_{i,t}] = \alpha + \Delta_i$, we have (since $(u-v)^2 \leqslant \max(u^2, v^2) \leqslant u^2 + v^2 \leqslant u + v$ for $u, v \in [0,1]$):*

$$\mathbb{E}\left[(\ell_{i,t} - \ell_{i^*,t})^2\right] \leqslant \mathbb{E}\left[\ell_{i,t} + \ell_{i^*,t}\right] = \frac{\mu_i + \alpha}{\mu_i - \alpha}\mathbb{E}\left[\ell_{i,t} - \ell_{i^*,t}\right] = \left(1 + \frac{2\alpha}{\Delta_i}\right)\mathbb{E}\left[\ell_{i,t} - \ell_{i^*,t}\right],$$

which establishes the claim since $\Delta_i \geqslant \Delta$. This provides an improvement when α is small.

Example 2 (Bernstein without a gap) *Let P be a distribution on $\mathcal{X} \times \{0,1\}$, where $\mathcal{X}$ is some measurable space. Assume that $(X_1, Y_1), (X_2, Y_2) \dots$ are i.i.d. samples from P, and that the experts $i \in \{1, \dots, M\}$ correspond to classifiers $f_i : \mathcal{X} \to \{0,1\}$: $\ell_{i,t} = \mathbf{1}(f_i(X_t) \neq Y_t)$, and that expert i^* is the Bayes classifier: $f_{i^*}(X) = \mathbf{1}(\eta(X) \geqslant 1/2)$, where $\eta(X) = \mathbb{P}(Y = 1 \,|\, X)$. Tsybakov's low noise condition (Tsybakov, 2004), namely $\mathbb{P}(|2\eta(X) - 1| \leqslant t) \leqslant Ct^\kappa$ for some $C > 0$, $\kappa \geqslant 0$ and every $t > 0$, implies the $(\frac{\kappa}{\kappa+1}, B)$-Bernstein condition for some B (see, e.g., Boucheron et al., 2005). In addition, under the Massart condition (Massart and Nédélec, 2006) that $|\eta(X) - 1/2| \geqslant c > 0$, the $(1, 1/(2c))$-Bernstein condition holds. Note that these conditions may hold even with an arbitrarily small sub-optimality gap Δ, since the f_i, $i \neq i^*$, may be arbitrary.*

Theorem 9 below shows that Decreasing Hedge fails to achieve improved rates under Bernstein conditions.

Theorem 9 *For every $T \geqslant 1$, there exists a $(1,1)$-Bernstein stochastic instance on which the pseudo-regret of the Decreasing Hedge algorithm with $\eta_t = c_0\sqrt{(\log M)/t}$ satisfies $\mathcal{R}_T \geqslant \frac{1}{3}\min(\frac{1}{c_0}\sqrt{T\log M}, T)$.*

The proof of Theorem 9 is given in Section 7.6. By contrast, it was shown by Koolen et al. (2016) (and implicitly used by Gaillard et al., 2014) that some adaptive algorithms with data-dependent regret bounds enjoy improved regret under the Bernstein condition. For the sake of completeness, we state this fact in Proposition 10 below, which corresponds to Koolen et al. (2016, Theorem 2), but where the dependence on B is made explicit. We also only provide a bound in expectation, which considerably simplifies the proof. The proof of Proposition 10, which uses the same ideas as Gaillard et al. (2014, Theorem 11), is provided in Section 7.5.

Proposition 10 *Consider an algorithm for the Hedge problem which satisfies the following regret bound: for every $i \in \{1, \dots, M\}$,*

$$R_{i,T} \leqslant C_1 \sqrt{(\log M) \sum_{t=1}^{T} (\widehat{\ell}_t - \ell_{i,t})^2} + C_2 \log M \tag{16}$$

where $C_1, C_2 > 0$ are constants. Assume that the losses satisfy the (β, B)-Bernstein condition. Then, the pseudo-regret of the algorithm satisfies:

$$\mathcal{R}_T \leqslant C_3 (B \log M)^{\frac{1}{2-\beta}} T^{\frac{1-\beta}{2-\beta}} + C_4 \log M \tag{17}$$

where $C_3 = \max(1, 4C_1^2)$ and $C_4 = 2C_2$.

The data-dependent regret bound (16), a "second-order" bound, is satisfied by adaptive algorithms such as Adapt-ML-Prod (Gaillard et al., 2014) and Squint (Koolen and van Erven, 2015). A slightly different variant of second-order regret bounds, which depends on some cumulative variance of the losses across experts, has been considered by Cesa-Bianchi et al. (2007); de Rooij et al. (2014), and is achieved by Hedge algorithms with a data-dependent tuning of the learning rate. Second-order bounds refine so-called *first-order* bounds (Cesa-Bianchi et al., 1997; Auer et al., 2002; Cesa-Bianchi and Lugosi, 2006), which are adversarial regret bounds that scale as $O(\sqrt{L_T^* \log M} + \log M)$, where L_T^* denotes the cumulative loss of the best expert. While first-order bounds may still scale as the worst-case $O(\sqrt{T \log M})$ rate in a typical stochastic instance (where the best expert has a positive expected loss), second-order algorithms are known to achieve constant $O((\log M)/\Delta)$ regret in the stochastic case with gap Δ (Gaillard et al., 2014; Koolen and van Erven, 2015).

Theorem 9, in light of Proposition 10, clarifies where the advantage of second-order algorithms compared to Decreasing Hedge lies: unlike the latter, they can exploit Bernstein conditions on the losses. The contrast is most apparent for Bernstein instances with $\beta = 1$. By Example 1, the existence of a gap Δ implies that the $(1, B)$-Bernstein condition holds with $B \leqslant \frac{1}{\Delta}$. However, as shown by Example 2, B can in fact be much smaller than Δ, in which case the regret bound (17) satisfied by second-order algorithms, namely $O(B \log M)$, significantly improves over the upper bound of $O((\log M)/\Delta)$ of Decreasing Hedge from Theorem 2. Theorem 9 provides an instance where the difference does occur, in the most pronounced case where $B = 1$, so that second-order algorithms enjoy small $O(\log M)$ regret, while Decreasing Hedge suffers $\Theta(\sqrt{T \log M})$ regret.

Remark 11 *The advantage of larger learning rates on some stochastic instances may be understood intuitively as follows. Consider an instance with B small but small gap Δ. The learning rate of Decreasing Hedge is large enough so that it can rule out bad experts (with large enough gap Δ_i) at the optimal rate (i.e., at time $(\log M)/\Delta_i^2$). However, once these bad experts are ruled out, near-optimal experts (with small gap Δ_i) are ruled out late (after $(\log M)/\Delta_i^2$ rounds). On the other hand, the Bernstein assumption entails that those experts are highly correlated with the best expert, the amount of noise on the relative losses of these near-optimal experts is small, so that a larger learning rate could be safely used and would enable to dismiss near-optimal experts sooner.*

Setting the Bernstein condition aside, we conclude by investigating the intrinsic limitations of Decreasing Hedge in the stochastic setting. Indeed, it is natural to ask whether Decreasing Hedge can exploit some other regularity of a stochastic instance, apart from the gap Δ. Theorem 12 shows that this is in fact not the case.

Theorem 12 *For every i.i.d. (over time) stochastic instance with a unique best expert*

$$i^* = \operatorname*{argmin}_{1 \leqslant i \leqslant M} \mathbb{E}[\ell_{i,t}],$$

the pseudo-regret of Decreasing Hedge (with $c_0 \geqslant 1$) satisfies

$$\mathcal{R}_T \geqslant \frac{1}{450 c_0^4 (\log M)^2 \Delta}$$

for $T \geqslant \frac{1}{4\Delta^2}$, where $\Delta := \inf_{i \neq i^*} \mathbb{E}[\ell_{i,t} - \ell_{i^*,t}]$.

Theorem 12 shows (together with the upper bound of Theorem 2) that the eventual regret of Decreasing Hedge on *any* stochastic instance is determined by the sub-optimality gap Δ, and scales (up to a $\log^3 M$ factor, depending on the number of near-optimal experts) as $\Theta(\frac{1}{\Delta})$. This characterizes the behavior of Decreasing Hedge on any stochastic instance.

5. Experiments

In this section, we illustrate our theoretical results by numerical experiments that compare the behavior of various Hedge algorithms in the stochastic regime.

Algorithms. We consider the following algorithms: `hedge` is Decreasing Hedge with the default learning rates $\eta_t = 2\sqrt{\log(M)/t}$, `hedge_constant` is Constant Hedge with constant learning rate $\eta_t = \sqrt{8 \log(M)/T}$, `hedge_doubling` is Hedge with doubling trick with $c_0 = \sqrt{8}$, `adahedge` is the AdaHedge algorithm from de Rooij et al. (2014), which is a variant of the Hedge algorithm with a data-dependent tuning of the learning rate η_t (based on $\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_{t-1}$). As shown in the note Koolen (2018), AdaHedge also benefits from Bernstein conditions. A related algorithm, namely Hedge with second-order tuning of the learning rate (Cesa-Bianchi et al., 2007), performed similarly to AdaHedge on the examples considered below, and was therefore not included. `FTL` is Follow-the-Leader (Cesa-Bianchi and Lugosi, 2006) which puts all mass on the expert with the smallest loss (breaking ties randomly). While FTL serves as a benchmark in the stochastic setting, unlike the other algorithms it lacks any guarantee in the adversarial regime, where its worst-case regret is *linear* in T.

Results. We report in Figure 1 the cumulative regrets of the considered algorithms in four examples. The results for the stochastic instances (a), (b) and (c) described below are averaged over 50 trials.

(*a*) *Stochastic instance with a gap.* This is the standard instance considered in this paper. The losses are drawn independently from Bernoulli distributions (one of parameter 0.3, 2 of parameter 0.4 and 7 of parameter 0.5, so that $M = 10$ and $\Delta = 0.1$). The results of Figure 1a confirm our theoretical results: Decreasing Hedge achieves a small, constant regret which is close to that of AdaHedge and FTL, while Constant Hedge and Hedge with doubling trick suffer a larger regret of order $\sqrt{T}$ (note that, although the expected regret of Constant Hedge converges in this case, the value of this limit depends on its learning rate and hence on T).

(*b*) *"Hard" stochastic instance.* This example has a zero gap $\Delta = 0$ between the two leading experts and $M = 10$, which makes it "hard" from the standpoint of Theorem 2 (which no longer applies in this limit case). The losses are drawn from independent Bernoulli distributions, of parameters 0.5 for the 2 leading experts, and 0.7 for the 8 remaining ones. Although all algorithms suffer an unavoidable $\Theta(\sqrt{T})$ regret due to pure noise, Decreasing Hedge, AdaHedge and FTL achieve better regret than the two conservative Hedge variants (Figure 1b). This is due to the fact that for the former algorithms, the weights of suboptimal experts decrease quickly and only induce a constant regret.

(*c*) *Small loss for the best expert.* In this experiment, we illustrate one advantage of adaptive Hedge algorithms such as AdaHedge over Decreasing Hedge, namely the fact that they admit improved regret bounds when the leading expert has small loss. We considered in this experiment $M = 10$, $\Delta = 0.04$ and the leading expert is $\mathsf{Beta}(0.04, 0.96)$, then 4 $\mathsf{Beta}(0.08, 0.92)$, then 5 $\mathsf{Beta}(0.5, 0.5)$.

(*d*) *Adversarial with a gap instance.* This simple instance is not random, and satisfies the assumptions of Theorem 5. It is defined by $M = 3$, $\Delta = 0.04$, $\ell_{3,t} = \frac{3}{4}$ for $t \geqslant 1$, $(\ell_{1,t}, \ell_{2,t}) = (\frac{1}{2}, 0)$ if $t = 1$, $(0, 1)$ if $t \geqslant 80$ or if t is even, and $(1, 0)$ otherwise. FTL suffers linear regret in the first phase, while Constant Hedge and Hedge with doubling trick suffer $\Theta(\sqrt{T})$ during the second phase.

6. Conclusion

In this article, we carried the regret analysis of the standard exponential weights (Hedge) algorithm in the stochastic expert setting, closing a gap in the existing literature. Our analysis reveals that, despite being tuned for the worst-case adversarial setting and lacking any adaptive tuning of the learning rate, Decreasing Hedge achieves optimal regret in the stochastic setting. This property also enables one to distinguish it qualitatively from other variants including the one with fixed (horizon-dependent) learning rate or the one with doubling trick, which both fail to adapt to gaps in the losses. To the best of our knowledge, this is the first result that shows the superiority of the decreasing learning rate over the doubling trick. In addition, it suggests that, even for a fixed time horizon T, the decreasing learning rate tuning should be favored over the constant one.

Finally, we showed that the regret of Decreasing Hedge on any stochastic instance is essentially characterized by the sub-optimality gap Δ. This shows that adaptive algorithms,

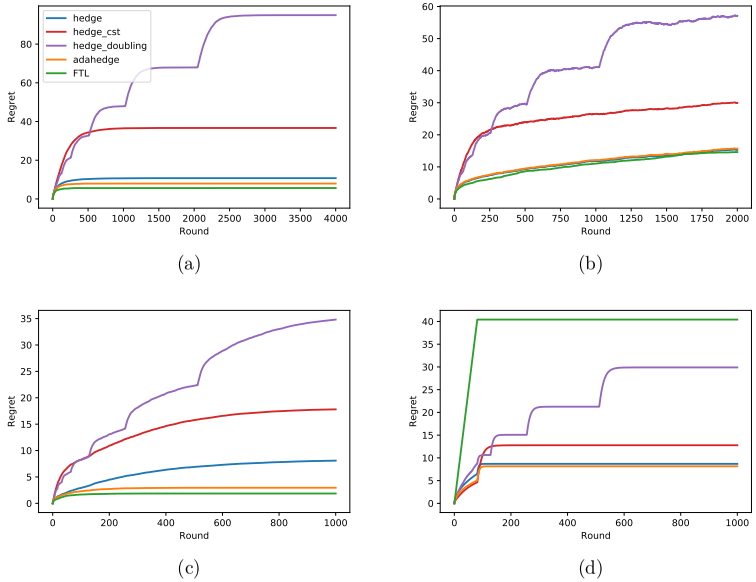

Figure 1: Cumulative regret of Hedge algorithms on four examples, see text for a precise description and discussion about the results. (a) Stochastic instance with a gap; (b) "Hard" stochastic instance; (c) Small loss for the best expert; (d) Adversarial with a gap instance.

including algorithms achieving second-order regret bounds, can actually outperform Decreasing Hedge on some stochastic instances that exhibit a more refined form of "easiness".

A link with stochastic optimization. Our results have a similar flavor to a well-known result (Moulines and Bach, 2011) about stochastic optimization: stochastic gradient descent (SGD) with learning rate $\eta_t \propto 1/\sqrt{t}$ (which is tuned for the convex case but not for the non-strongly convex case) and Polyak-Ruppert averaging achieves a fast $O(1/(\mu t))$ excess risk rate for μ-strongly convex problems, without the knowledge of μ. However, this link stops here since the two results are of a significantly different nature: the $O(1/(\mu t))$ rate is satisfied only by SGD with Polyak-Ruppert averaging, and it does not come from a regret bound; even in the μ-strongly convex case, it can be seen that SGD with step-size $\eta_t \propto 1/\sqrt{t}$ suffers a $\Theta(\sqrt{t})$ regret. In fact, the opposite phenomenon occurs: in stochastic optimization, SGD uses a *larger* $\Theta(1/\sqrt{t})$ step-size than the $\Theta(1/(\mu t))$ step size which exploits the knowledge of strong convexity, but the effect of this larger step-size is balanced by the averaging. By contrast, in the expert setting, Hedge uses a *smaller* $\Theta(\sqrt{(\log M)/t})$ learning rate than the constant, large enough learning rate which exploits the knowledge of the stochastic nature of the problem.

Acknowledgments. The authors wish to warmly thank all four Anonymous Reviewers for their helpful feedback and insights on this work. In particular, the proof of Proposition 4 was proposed by an Anonymous Referee, which allowed to shorten our initial proof.

7. Proofs

We now provide the proofs of the results from the previous Sections, by order of appearance in the text.

7.1. Proof of Theorem 2

Let $t_0 = \left\lceil \frac{8\log M}{\Delta^2} \right\rceil$, so that $\sqrt{t_0} \leqslant \sqrt{1 + \frac{8\log M}{\Delta^2}} \leqslant 1 + \frac{\sqrt{8\log M}}{\Delta}$ (since $\sqrt{a+b} \leqslant \sqrt{a} + \sqrt{b}$ for $a, b \geqslant 0$). The worst-case regret bound of Hedge (Proposition 1) shows that for $1 \leqslant T \leqslant t_0$:

$$R_{i^*,T} \leqslant \sqrt{T\log M} \leqslant \sqrt{t_0 \log M} \leqslant \sqrt{\log M} + \frac{2\sqrt{2}\log M}{\Delta} \leqslant \frac{4\log M}{\Delta} \tag{18}$$

(since $\log M \geqslant 1$ as $M \geqslant 3$, $\Delta \leqslant 1$ and $2\sqrt{2} \leqslant 3$), which establishes (6) for $T \leqslant t_0$. In order to prove (6) for $T \geqslant t_0 + 1$, we start by decomposing the regret with respect to i^* as

$$R_{i^*,T} = \widehat{L}_T - L_{i^*,T} = \widehat{L}_{t_0} - L_{i^*,t_0} + \sum_{t=t_0+1}^{T} (\widehat{\ell}_t - \ell_{i^*,t}) \,. \tag{19}$$

Since $\widehat{L}_{t_0} - L_{i^*,t_0} \leqslant R_{t_0}$ is controlled by (18), it remains to upper bound the second term in (19). First, for every $t \geqslant t_0 + 1$,

$$\widehat{\ell}_t - \ell_{i^*,t} = \sum_{i \neq i^*} v_{i,t}(\ell_{i,t} - \ell_{i^*,t}) \,. \tag{20}$$

Since $\boldsymbol{\ell}_t$ is independent of $\boldsymbol{v}_t$ (which is $\sigma(\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_{t-1})$-measurable), taking the expectation in (20) yields, denoting $\Delta_i = \mathbb{E}[\ell_{i,t} - \ell_{i^*,t}]$,

$$\mathbb{E}[\widehat{\ell}_t - \ell_{i^*,t}] = \sum_{i \neq i^*} \Delta_i \mathbb{E}[v_{i,t}] \,. \tag{21}$$

First, for every $i \neq i^*$, applying Hoeffding's inequality to the i.i.d. centered variables $Z_{i,t} := -\ell_{i,t} + \ell_{i^*,t} + \Delta_i$, which belong to $[-1 + \Delta_i, 1 + \Delta_i]$, yields

$$\begin{aligned} \mathbb{P}\left(L_{i,t-1} - L_{i^*,t-1} < \frac{\Delta_i (t-1)}{2} \right) &= \mathbb{P}\left(\sum_{s=1}^{t-1} Z_{i,s} > \frac{\Delta_i (t-1)}{2} \right) \\ &\leqslant e^{-\frac{t-1}{2}(\Delta_i/2)^2} \\ &= e^{-(t-1)\Delta_i^2/8} \,. \end{aligned} \tag{22}$$

On the other hand, if $L_{i,t-1} - L_{i^*,t-1} \geqslant \Delta_i (t-1)/2$, then

$$\begin{aligned} v_{i,t} &= \frac{e^{-\eta_t (L_{i,t-1} - L_{i^*,t-1})}}{1 + \sum_{j \neq i^*} e^{-\eta_t (L_{j,t-1} - L_{i^*,t-1})}} \\ &\leqslant e^{-2\sqrt{(\log M)/t} \times \Delta_i (t-1)/2} \\ &\leqslant e^{-\Delta_i \sqrt{(t-1)(\log M)/2}} \end{aligned} \tag{23}$$

since $t \leqslant 2(t-1)$. It follows from (23) and (22) that, for $t \geqslant t_0 + 1 \geqslant 2$,

$$\begin{aligned} \mathbb{E}[v_{i,t}] &\leqslant \mathbb{P}\left(L_{i,t-1} - L_{i^*,t-1} > \frac{\Delta_i (t-1)}{2} \right) + e^{-\Delta_i \sqrt{(t-1)(\log M)/2}} \\ &\leqslant e^{-(t-1)\Delta_i^2/8} + e^{-\Delta_i \sqrt{(t-1)(\log M)/2}} \,. \end{aligned} \tag{24}$$

Now, a simple analysis of functions shows that the functions $f_1(u) = ue^{-u}$ and $f_2(u) = ue^{-u^2/2}$ are decreasing on $[1, +\infty)$. Since $\Delta_i \geqslant \Delta$, this entails that

$$\Delta_i e^{-(t-1)\Delta_i^2/8} = \frac{2}{\sqrt{t-1}} f_2\left(\frac{\sqrt{t-1}\Delta_i}{2} \right) \leqslant \frac{2}{\sqrt{t-1}} f_2\left(\frac{\sqrt{t-1}\Delta}{2} \right) = \Delta e^{-(t-1)\Delta^2/8} \tag{25}$$

provided that $\frac{\sqrt{t-1}\Delta}{2} \geqslant 1$, *i.e.* $t \geqslant 1 + \frac{4}{\Delta^2}$, which is the case since $t \geqslant t_0 + 1 \geqslant 1 + \frac{8\log M}{\Delta^2}$. Likewise,

$$\Delta_i e^{-\Delta_i \sqrt{(t-1)(\log M)/2}} \leqslant \Delta e^{-\Delta\sqrt{(t-1)(\log M)/2}} \tag{26}$$

if $\Delta\sqrt{(t-1)(\log M)/2} \geqslant 1$, *i.e.* $t \geqslant 1 + \frac{2}{(\log M)\Delta^2}$, which is ensured by $t \geqslant t_0 + 1$. It follows from (21), (24), (25) and (26) that for every $t \geqslant t_0 + 1$:

$$\begin{aligned} \mathbb{E}[\widehat{\ell}_t - \ell_{i^*,t}] &\leqslant M\Delta e^{-(t-1)\Delta^2/8} + M\Delta e^{-\Delta\sqrt{(t-1)(\log M)/2}} \\ &= \left(Me^{-t_0\Delta^2/8}\right)\left(\Delta e^{-(t-t_0-1)\Delta^2/8}\right) + \left(Me^{-\Delta\sqrt{(t-1)(\log M)/8}}\right)\left(\Delta e^{-\Delta\sqrt{(t-1)(\log M)/8}}\right) \\ &\leqslant \Delta e^{-(t-t_0-1)\Delta^2/8} + \Delta e^{-\Delta\sqrt{(t-1)/8}} \end{aligned} \tag{27}$$

where inequality (27) comes from the bound $Me^{-t_0\Delta^2/8} \leqslant 1$ (since $t_0 \geqslant \frac{8\log M}{\Delta^2}$) and from the fact that $Me^{-\Delta\sqrt{(t-1)(\log M)/8}} \leqslant 1$ amounts to $t \geqslant 1 + \frac{8\log M}{\Delta^2}$, that is, to $t \geqslant t_0 + 1$. Summing inequality (27) yields, for every $T \geqslant t_0 + 1$,

$$\begin{aligned}
\mathbb{E}[\sum_{t=t_0+1}^{T}(\ell_t - \ell_{i^*,t})] &\leqslant \sum_{t=t_0+1}^{T}\left\{\Delta e^{-(t-t_0-1)\Delta^2/8} + \Delta e^{-\Delta\sqrt{(t-1)/8}}\right\} \\
&\leqslant \Delta\sum_{t\geqslant 0} e^{-t\Delta^2/8} + \Delta\sum_{t\geqslant 1} e^{-(\Delta/\sqrt{8})\sqrt{t}} \\
&\leqslant \Delta\left(1 + \frac{8}{\Delta^2}\right) + \Delta\times\frac{2}{(\Delta/\sqrt{8})^2} \qquad (28)\\
&\leqslant \frac{25}{\Delta} \qquad (29)
\end{aligned}$$

where inequality (28) comes from Lemma 13 below. Finally, combining inequalities (18) and (28) yields the pseudo-regret bound $\mathcal{R}_T \leqslant \frac{4\log M + 25}{\Delta}$.

Lemma 13 *For every $\alpha > 0$,*

$$\sum_{t\geqslant 1} e^{-\alpha t} \leqslant \frac{1}{\alpha} \qquad (30)$$

$$\sum_{t\geqslant 1} e^{-\alpha\sqrt{t}} \leqslant \frac{2}{\alpha^2}\,. \qquad (31)$$

Proof Since the functions $t \mapsto e^{-\alpha t}$ and $t \mapsto e^{-\alpha\sqrt{t}}$ are decreasing on $\mathbf{R}^+$, we have

$$\begin{aligned}
\sum_{t\geqslant 1} e^{-\alpha t} &\leqslant \int_0^\infty e^{-\alpha t}\mathrm{d}t = \frac{1}{\alpha} \\
\sum_{t\geqslant 1} e^{-\alpha\sqrt{t}} &\leqslant \int_0^{+\infty} e^{-\alpha\sqrt{t}}\mathrm{d}t \underset{u=\alpha\sqrt{t}}{=} \frac{2}{\alpha^2}\int_0^{+\infty} ue^{-u}\mathrm{d}u = \frac{2}{\alpha^2}.
\end{aligned}$$

■

Remark 14 *While the upper bound of Theorem 2 is stated for the pseudo-regret $\mathcal{R}_T$, a similar upper bound holds for the expected regret $\mathbb{E}[R_T]$. Indeed, under the assumptions of Theorem 2, for every $T \geqslant \frac{4\log M}{\Delta^2}$, we have $\mathbb{E}[R_T] \leqslant \mathcal{R}_T + \frac{1.1}{\Delta}$.*

Proof Note that $\mathbb{E}[R_T] - \mathcal{R}_T = \mathbb{E}[L_{i^*,T} - \min_{1\leqslant i\leqslant T} L_{i,T}]$. For every $a \geqslant 0$, Hoeffding's inequality (applied to the i.i.d. centered variables $\ell_{i^*,t} - \ell_{i,t} + \Delta_i \in [-1+\Delta_i, 1+\Delta_i]$,

$1 \leqslant t \leqslant T$) entails

$$\begin{aligned}
\mathbb{P}\left(L_{i^*,T} - \min_{1\leqslant i\leqslant T} L_{i,T} \geqslant a\right) &\leqslant \sum_{i\neq i^*}\mathbb{P}\left(L_{i^*,T} - L_{i,T} + \Delta_i T \geqslant \Delta_i T + a\right) \\
&\leqslant \sum_{i\neq i^*} e^{-(\Delta_i T + a)^2/(2T)} \qquad (32)\\
&\leqslant Me^{-T\Delta^2/2}e^{-a^2/(2T)} \\
&\leqslant e^{-T\Delta^2/4}e^{-a^2/(2T)}\,, \qquad (33)
\end{aligned}$$

where inequality (33) comes from the fact that $Me^{-T\Delta^2/4} \leqslant 1$ since $T \geqslant \frac{4\log M}{\Delta^2}$. Since the random variable $L_{i^*,T} - \min_{1\leqslant i\leqslant T} L_{i,T}$ is nonnegative, this implies that

$$\begin{aligned}
\mathbb{E}\left[L_{i^*,T} - \min_{1\leqslant i\leqslant T} L_{i,T}\right] &= \int_0^\infty \mathbb{P}\left(L_{i^*,T} - \min_{1\leqslant i\leqslant T} L_{i,T} \geqslant a\right)\mathrm{d}a \\
&\leqslant e^{-T\Delta^2/4}\int_0^\infty e^{-a^2/(2T)}\mathrm{d}a \\
&= \sqrt{\frac{\pi}{2}}\cdot\sqrt{T}e^{-T\Delta^2/4} \\
&= \frac{\sqrt{\pi}}{\Delta}\left[\Delta\sqrt{T/2}\cdot e^{-(\Delta\sqrt{T/2})^2/2}\right] \\
&\leqslant \frac{\sqrt{\pi/e}}{\Delta} \qquad (34)
\end{aligned}$$

where inequality (34) comes from the fact that the function $u \mapsto ue^{-u^2/2}$ attains its maximum on $\mathbf{R}^+$ at $u = 1$. This concludes the proof, since $\sqrt{\pi/e} \leqslant 1.1$. ■

7.2. Proof of Proposition 4

Fix M, Δ and T as in Proposition 4. For $i^* \in \{1,\dots,M\}$, denote $\mathbb{P}_{i^*}$ the following distribution on $[0,1]^{M\times T}$: if $(\ell_{i,t})_{1\leqslant i\leqslant M, 1\leqslant t\leqslant T} \sim \mathbb{P}_{i^*}$, then the variables $\ell_{i,t}$ are independent Bernoulli variables, of parameter $\frac{1}{2} - \Delta$ if $i = i^*$ and $\frac{1}{2}$ otherwise; also, denote by $\mathbb{E}_{i^*}$ the expectation with respect to $\mathbb{P}_{i^*}$. Let $\mathcal{A} = (A_t)_{1\leqslant t\leqslant T}$ be any Hedging algorithm, where $A_t : [0,1]^{M\times(t-1)} \to \mathcal{P}_M$ maps past losses $(\boldsymbol{\ell}_1,\dots,\boldsymbol{\ell}_{t-1})$ to an element of the probability simplex $\mathcal{P}_M \subset \mathbf{R}^M$ on $\{1,\dots,M\}$. For any $i^* \in \{1,\dots,M\}$, let $\mathcal{R}_T(i^*,\mathcal{A})$ denote the pseudo-regret of algorithm $\mathcal{A}$ under the distribution $\mathbb{P}_{i^*}$. Since $\boldsymbol{\ell}_t$ is independent of $\boldsymbol{v}_t$ under $\mathbb{P}_{i^*}$, we have

$$\mathcal{R}_T(i^*,\mathcal{A}) = \sum_{t=1}^{T}\sum_{i\neq i^*}\mathbb{E}_{i^*}\left[v_{i,t}(\ell_{i,t} - \ell_{i^*,t})\right] = \Delta\sum_{t=1}^{T}\sum_{i\neq i^*}\mathbb{E}_{i^*}[v_{i,t}] = \Delta\sum_{t=1}^{T}\mathbb{E}_{i^*}[1 - v_{i^*,t}] \qquad (35)$$

with $\boldsymbol{v}_t := A_t(\boldsymbol{\ell}_1,\dots,\boldsymbol{\ell}_{t-1})$. It follows from Equation (35) that, for every $\mathcal{A}$ and i^*, $\mathcal{R}_T(i^*,\mathcal{A})$ increases with T. Hence, without loss of generality we may assume that $T =$

$\lfloor (\log M)/(16\Delta^2) \rfloor$. The maximum pseudo-regret of $\mathcal{A}$ on the instances $\mathbb{P}_{i^*}$ is lower-bounded as follows:

$$\sup_{1 \leqslant i^* \leqslant M} \mathcal{R}_T(i^*, \mathcal{A}) \geqslant \frac{1}{M} \sum_{1 \leqslant i^* \leqslant M} \mathcal{R}_T(i^*, \mathcal{A}) = \frac{1}{M} \sum_{1 \leqslant i^* \leqslant M} \Delta \sum_{t=1}^{T} \mathbb{E}_{i^*}[1 - v_{i^*,t}] \,. \tag{36}$$

We now "randomize" the algorithm $\mathcal{A}$, by replacing it with a randomized algorithm which picks expert i at time t with probability $v_{i,t}$. Formally, let $\widetilde{P} = \mathcal{U}([0,1])^{\otimes T}$ be the distribution of T independent uniform random variables on $[0,1]$, and denote $\widetilde{\mathbb{P}}_{i^*} = \mathbb{P}_{i^*} \otimes \widetilde{P}$ for $i^* \in \{1, \dots, M\}$. Furthermore, for every $\boldsymbol{v} \in \mathcal{P}_M$, let $I_{\boldsymbol{v}} : [0,1] \to \{1, \dots, M\}$ be a measurable map such that $\mathbb{P}(I_{\boldsymbol{v}}(U) = i) = v_i$ for every $i \in \{1, \dots, M\}$, where $U \sim \mathcal{U}([0,1])$. For every sequence of losses $\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_T$ and random variables $U_1, \dots, U_T$ and every $1 \leqslant t \leqslant T$, let $I_t = I_{\boldsymbol{v}_t}(U_t)$, where $\boldsymbol{v}_t = A_t(\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_t)$.

Denote by $\widetilde{\mathbb{E}}_{i^*}$ the expectation with respect to $\widetilde{\mathbb{P}}_{i^*}$. By definition of $I_{\boldsymbol{v}}$, we have $\mathbb{E}_{i^*}[v_{i^*,t}] = \widetilde{\mathbb{E}}_{i^*}[\mathbf{1}(I_t = i^*)]$ so that, denoting $N_i = \sum_{i=1}^{T} \mathbf{1}(I_t = i)$ the number of times expert i is picked,

$$\sum_{t=1}^{T} \mathbb{E}_{i^*}[1 - v_{i^*,t}] = \widetilde{\mathbb{E}}_{i^*}[T - N_{i^*}] \geqslant \mathbb{P}_{i^*}(N_{i^*} \leqslant T/2) \cdot \frac{T}{2} \,.$$

Hence, letting $A_i \subseteq [0,1]^{M \times T} \times [0,1]^T$ be the event $\{N_i > T/2\}$, Equation (36) implies that

$$\sup_{1 \leqslant i^* \leqslant M} \mathcal{R}_T(i^*, \mathcal{A}) \geqslant \frac{\Delta T}{2} \times \frac{1}{M} \sum_{1 \leqslant i^* \leqslant M} \left(1 - \widetilde{\mathbb{P}}_{i^*}(A_{i^*})\right) . \tag{37}$$

It now remains to upper bound $\frac{1}{M} \sum_{i^*} \widetilde{\mathbb{P}}_{i^*}(A_{i^*})$. To do this, first note that the events A_{i^*}, $1 \leqslant i^* \leqslant M$, are pairwise disjoint. Hence, Fano's inequality (see Gerchinovitz et al., 2017, p.2) implies that, for every distribution $\widetilde{\mathbb{Q}}$ on $[0,1]^{M \times T} \times [0,1]^T$,

$$\frac{1}{M} \sum_{1 \leqslant i^* \leqslant M} \widetilde{\mathbb{P}}_{i^*}(A_{i^*}) \leqslant \frac{1}{\log M} \left\{ \frac{1}{M} \sum_{1 \leqslant i^* \leqslant M} \mathrm{KL}(\widetilde{\mathbb{P}}_{i^*}, \widetilde{\mathbb{Q}}) + \log 2 \right\} \tag{38}$$

where $\mathrm{KL}(\mathbb{P}, \mathbb{Q})$ denotes the Kullback-Leibler divergence between $\mathbb{P}$ and $\mathbb{Q}$. Here, we take $\widetilde{\mathbb{Q}} = \mathbb{Q} \otimes \widetilde{P}$, where $\mathbb{Q}$ is the product of Bernoulli distributions $\mathcal{B}(1/2)^{\otimes T}$. This choice leads to

$$\mathrm{KL}(\widetilde{\mathbb{P}}_{i^*}, \widetilde{\mathbb{Q}}) = \mathrm{KL}(\mathbb{P}_{i^*}, \mathbb{Q}) = T \cdot \mathrm{KL}(\mathcal{B}(1/2 - \Delta), \mathcal{B}(1/2)) \leqslant 4T\Delta^2 \leqslant \frac{\log M}{4} \,,$$

where the first bound is obtained by comparing KL and χ^2 divergences (Tsybakov, 2009, Lemma 2.7). Hence, inequality (38) becomes (recalling that $M \geqslant 4$)

$$\frac{1}{M} \sum_{1 \leqslant i^* \leqslant M} \widetilde{\mathbb{P}}_{i^*}(A_{i^*}) \leqslant \frac{(\log M)/4}{\log M} + \frac{\log 2}{\log M} \leqslant \frac{3}{4} \,;$$

plugging this into (37) yields, noting that $T = \lfloor (\log M)/(16\Delta^2) \rfloor \geqslant (\log M)/(32\Delta^2)$ since $(\log M)/(16\Delta^2) \geqslant 1$ (as $M \geqslant 4$ and $\Delta \leqslant \frac{1}{4}$),

$$\sup_{1 \leqslant i^* \leqslant M} \mathcal{R}_T(i^*, \mathcal{A}) \geqslant \frac{\Delta T}{2} \times \frac{1}{4} \geqslant \frac{\log M}{256\Delta} \,.$$

This concludes the proof.

7.3. Proof of Theorem 5 and Corollary 6

Let t_0 be the smallest integer $t \geqslant 1$ such that $Me^{-c_0\Delta\sqrt{t \log(M)/8}} \leqslant \Delta$, namely $t_0 = \left\lceil \frac{8}{c_0^2\Delta^2} \frac{\log^2(M/\Delta)}{\log M} \right\rceil$. Note that $\sqrt{t_0} \leqslant \sqrt{1 + \frac{8}{c_0^2\Delta^2} \frac{\log^2(M/\Delta)}{\log M}} \leqslant 1 + \frac{\sqrt{8}}{c_0\Delta} \frac{\log(M/\Delta)}{\sqrt{\log M}}$. Let $t_1 := t_0 \vee \tau_0$. For every $T \leqslant t_1$, the regret bound in the assumption of Theorem 5 implies

$$\begin{aligned} R_T &\leqslant c_1 \sqrt{T \log M} \\ &\leqslant c_1 \sqrt{\tau_0 \log M} + c_1 \sqrt{t_0 \log M} \\ &\leqslant c_1 \sqrt{\tau_0 \log M} + c_1 \sqrt{\log M} + \frac{\sqrt{8} \log(M/\Delta)}{c_0 \Delta} \end{aligned} \tag{39}$$

which implies (9) with $c_2 = c_1 + \frac{\sqrt{8}}{c_0}$ and $c_3 = \frac{\sqrt{8}}{c_0}$ (since $1 \leqslant \sqrt{\log M} \leqslant \frac{\log M}{\Delta}$). From now on, assume that $T \geqslant t_1 + 1$. Since $T \geqslant \tau_0$, we have $R_T = \widehat{L}_T - L_{i^*,T}$, so that

$$R_T = \widehat{L}_{t_1} - L_{i^*,t_1} + \sum_{t=t_1+1}^{T} \left(\widehat{\ell}_t - \ell_{i^*,t}\right) . \tag{40}$$

In addition, we have for $t \geqslant t_1 + 1$

$$\begin{aligned} \widehat{\ell}_t - \ell_{i^*,t} &= \sum_{i \neq i^*} v_{i,t}(\ell_{i,t} - \ell_{i^*,t}) \\ &\leqslant \sum_{i \neq i^*} v_{i,t} \\ &= \sum_{i \neq i^*} \frac{e^{-\eta_t(L_{i,t-1} - L_{i^*,t-1})}}{1 + \sum_{j \neq i^*} e^{-\eta_t(L_{j,t-1} - L_{i^*,t-1})}} \\ &\leqslant \sum_{i \neq i^*} e^{-c_0\sqrt{(\log M)/t} \times \Delta(t-1)} \qquad (41) \\ &\leqslant Me^{-c_0\Delta\sqrt{(t-1)(\log M)/2}} \\ &\leqslant \left(Me^{-c_0\Delta\sqrt{t_0(\log M)/8}}\right) e^{-c_0\Delta\sqrt{(t-1)/8}} \qquad (42) \\ &\leqslant \Delta e^{-c_0\Delta\sqrt{(t-1)/8}} \qquad (43) \end{aligned}$$

where (41) comes from the fact that $\eta_t \geqslant c_0\sqrt{(\log M)/t}$ and $L_{i,t-1} - L_{i^*,t-1} \geqslant \Delta(t-1)$ (since $t - 1 \geqslant t_1 \geqslant \tau_0$), (42) from the fact that $t - 1 \geqslant t_0$ and $\log M \geqslant 1$, and (43) from the

fact that $Me^{-c_0\Delta\sqrt{t_0(\log M)/8}} \leqslant \Delta$. Summing inequality (43), we obtain

$$\begin{aligned}\sum_{t=t_1+1}^{T}(\widehat{\ell}_t - \ell_{i^*,t}) &\leqslant \sum_{t=t_1+1}^{T}\Delta e^{-c_0\Delta\sqrt{(t-1)/8}}\\ &\leqslant \Delta\sum_{t\geqslant 1}e^{-c_0\Delta\sqrt{t/8}}\\ &\leqslant \Delta\times\frac{2}{(c_0\Delta/\sqrt{8})^2} \qquad (44)\\ &= \frac{16}{c_0^2\Delta} \qquad (45)\end{aligned}$$

where (44) follows from Lemma 13. Combining (40), (39) and (45) proves Theorem 5 with $c_2 = c_1 + \frac{\sqrt{8}}{c_0}$, $c_3 = \frac{\sqrt{8}}{c_0}$ and $c_4 = \frac{16}{c_0^2}$.

Proof [Proof of Corollary 6] Define $\tau = \sup\{t \geqslant 0, \exists i \neq i^*, L_{i,t} - L_{i^*,t} \leqslant \frac{\Delta t}{2}\}$. By Lemma 15 below, for every $\varepsilon > 0$ we have, with probability at least $1-\varepsilon$, $\tau \leqslant 8(\log M + \log\varepsilon^{-1})/\Delta^2$. By Theorem 5, this implies that, with probability at least $1-\varepsilon$,

$$\begin{aligned}R_T &\leqslant c_1\sqrt{\tau\log M} + \frac{c_2\log M + c_3\log\Delta^{-1} + c_4}{\Delta/2}\\ &\leqslant \Big(c_1\sqrt{8} + 2c_2\Big)\frac{\log M}{\Delta} + c_1\frac{\sqrt{8\log M\log\varepsilon^{-1}}}{\Delta} + 2c_3\frac{\log\Delta^{-1}}{\Delta} + \frac{2c_4}{\Delta}\end{aligned}$$

where c_2, c_3, c_4 are the constants of Theorem 5. The bound (11) on the pseudo-regret is obtained similarly from Theorem 5, by using the fact that $\mathcal{R}_T \leqslant \mathbb{E}[R_T]$ and

$$\mathbb{E}[\sqrt{\tau\log M}] \leqslant \sqrt{\mathbb{E}[\tau]\log M} \leqslant \sqrt{\log M}\sqrt{1 + \frac{8(\log M + 1)}{\Delta^2}} \leqslant \sqrt{\log M}\Big(1 + \frac{\sqrt{8\log M} + 1}{\Delta}\Big)$$

which is smaller than $(2+\sqrt{8})(\log M)/\Delta \leqslant 5(\log M)/\Delta$ since $M \geqslant 3$ and $\Delta \leqslant 1$. ■

Lemma 15 *Let $(\ell_{i,t})_{1\leqslant i\leqslant M, t\geqslant 1}$ be as in Theorem 2. Denote $\tau = \sup\{t \geqslant 0, \exists i \neq i^*, L_{i,t} - L_{i^*,t} \leqslant \frac{\Delta t}{2}\}$. We have*

$$\mathbb{E}[\tau] \leqslant 1 + \frac{8(\log M + 1)}{\Delta^2}\,, \qquad (46)$$

and for every $\varepsilon \in (0,1)$,

$$\mathbb{P}\Big(\tau \geqslant \frac{8(\log M + \log\varepsilon^{-1})}{\Delta^2}\Big) \leqslant \varepsilon\,. \qquad (47)$$

Proof [Proof of Lemma 15] For every $i \neq i^*$ and $t \geqslant 1$, let $\Delta_{i,t} := \mathbb{E}[\ell_{i,t} - \ell_{i^*,t} \,|\, \mathcal{F}_{t-1}]$. Using the Hoeffding-Azuma's maximal inequality to the $(\mathcal{F}_t)_{t\geqslant 1}$-martingale difference sequence $Z_{i,t} = -(L_{i,t} - L_{i^*,t}) + \Delta_{i,t}$ (such that $\Delta_{i,t} - 1 \leqslant Z_{i,t} \leqslant \Delta_{i,t} + 1$), together with the fact that $\Delta_{i,t} \geqslant \Delta$, implies that

$$\mathbb{P}\left(\exists t \geqslant t_0, L_{i,t} - L_{i^*,t} \leqslant \frac{\Delta t}{2}\right) \leqslant \mathbb{P}\left(\sup_{t\geqslant t_0}\frac{1}{t}\left(\sum_{s=1}^{t}Z_{i,s}\right) \geqslant \frac{\Delta}{2}\right) \leqslant e^{-t_0\Delta^2/8}\,. \qquad (48)$$

By a union bound, equation (48) implies that

$$\mathbb{P}\left(\tau \geqslant t_0\right) \leqslant Me^{-t_0\Delta^2/8}\,. \qquad (49)$$

Solving for the probability level in (49) yields the high probability bound (47) on τ. The bound on τ in expectation (46) ensues by integrating the high-probability bound over ε. ■

We recall Hoeffding-Azuma's maximal inequality for bounded martingale difference sequences (Hoeffding, 1963; Azuma, 1967). While it follows from a standard argument, we provide a short proof for completeness, since the inequality given in Proposition 16 below differs slightly from the one given in Hoeffding (1963).

Proposition 16 (Hoeffding-Azuma's maximal inequality) *Let $(Z_t)_{t\geqslant 1}$ be a sequence of random variables adapted to a filtration $(\mathcal{F}_t)_{t\geqslant 1}$. Assume that Z_t is a martingale difference sequence: $\mathbb{E}[Z_t \,|\, \mathcal{F}_{t-1}] = 0$ for any $t \geqslant 1$, and that $A_t - 1 \leqslant Z_t \leqslant A_t + 1$ almost surely, where A_t is $\mathcal{F}_{t-1}$-measurable. Then, denoting $S_n := \sum_{t=1}^{n} Z_t$, we have for every $n \geqslant 1$ and $a \geqslant 0$:*

$$\mathbb{P}\left(\sup_{m\geqslant n}\frac{S_m}{m} \geqslant a\right) \leqslant e^{-na^2/2}\,. \qquad (50)$$

Proof Fix $\lambda > 0$. By Hoeffding's inequality, $\mathbb{E}[e^{\lambda Z_t} \,|\, \mathcal{F}_{t-1}] \leqslant e^{\lambda^2/2}$, so that the sequence $M_t^\lambda := \exp\big(\lambda S_t - \lambda^2 t/2\big)$ is a positive supermartingale. Hence, Doob's supermartingale inequality implies that for $\varepsilon \in (0,1]$:

$$\mathbb{P}\Big(\sup_{t\geqslant 1} M_t^\lambda \geqslant \frac{1}{\varepsilon}\Big) \leqslant \frac{\mathbb{E}[M_0^\lambda]}{1/\varepsilon} = \varepsilon\,. \qquad (51)$$

Rearranging (51) and letting $\lambda = \sqrt{2\log(1/\varepsilon)/n}$ yields: with probability $1-\varepsilon$, for every $t \geqslant n$,

$$\frac{S_t}{t} \leqslant \frac{\log(1/\varepsilon)}{\lambda t} + \frac{\lambda}{2} = \sqrt{\frac{\log(1/\varepsilon)}{2}}\left(\frac{\sqrt{n}}{t} + \frac{1}{\sqrt{t}}\right) \leqslant \sqrt{\frac{2\log(1/\varepsilon)}{n}}\,. \qquad (52)$$

Setting $\varepsilon = e^{-na^2/2}$ in (52) gives the desired bound. ■

7.4. Proof of Proposition 7

Note that, since the loss vectors $\boldsymbol{\ell}_t$ are in fact deterministic, $\mathcal{R}_T = R_T$. Denoting $(v_{i,t})_{1\leqslant i\leqslant M}$ the weights selected by the Constant Hedge algorithm at time t, and letting $c = c_0\sqrt{\log M}$, we have

$$\begin{aligned}R_T &= \sum_{t=1}^{T}\sum_{i=2}^{M} v_{i,t}(\ell_{i,t} - \ell_{1,t})\\ &= \sum_{t=1}^{T}\sum_{i=2}^{M}\frac{\exp\big(-\frac{c}{\sqrt{T}}(L_{i,t-1} - L_{1,t-1})\big)}{1 + \sum_{2\leqslant i'\leqslant M}\exp\big(-\frac{c}{\sqrt{T}}(L_{i',t-1} - L_{1,t-1})\big)}\\ &= \sum_{t=1}^{T}\frac{(M-1)\exp\big(-\frac{c}{\sqrt{T}}(t-1)\big)}{1 + (M-1)\exp\big(-\frac{c}{\sqrt{T}}(t-1)\big)}\,. \qquad (53)\end{aligned}$$

Now, let $t_0 \geqslant 0$ be the largest integer such that $(M-1)\exp(-\frac{c}{\sqrt{T}}t) \geqslant 1/2$, namely

$$t_0 = \Big\lfloor \frac{\sqrt{T}}{c} \log(2(M-1)) \Big\rfloor .$$

It follows from Equation (53) that

$$R_T \geqslant \sum_{t=1}^{T\wedge(t_0+1)} \frac{(M-1)\exp\big(-\frac{c}{\sqrt{T}}(t-1)\big)}{1+(M-1)\exp\big(-\frac{c}{\sqrt{T}}(t-1)\big)} \geqslant \frac{1}{3}\min(T, t_0+1) \tag{54}$$

where the second inequality comes from the fact that $\frac{x}{1+x} \geqslant \frac{1}{3}$ for $x \geqslant \frac{1}{2}$, which we apply to $x = (M-1)\exp(-\frac{c}{\sqrt{T}}(t-1)) \geqslant \frac{1}{2}$ for $t \leqslant T \wedge (t_0+1) \leqslant t_0+1$. In order to establish inequality (13), it remains to note that

$$t_0 + 1 \geqslant \frac{\sqrt{T}}{c}\log\big(2(M-1)\big) \geqslant \frac{\sqrt{T\log M}}{c_0},$$

since $2(M-1) \geqslant M$ and $c = \sqrt{c_0 \log M}$.

Now, consider the Hedge algorithm with doubling trick. Assume that $T \geqslant 2$, and let $k \geqslant 1$ such that $T_k \leqslant T < T_{k+1}$. Since $R_T = \sum_{t=1}^{T}\sum_{2\leqslant i\leqslant M} v_{i,t}(\ell_{i,t} - \ell_{1,t})$ and each of the terms in the sum is nonnegative, R_T is lower bounded by the cumulative regret on the period $[\![T_{k-1}, T_k - 1]\!]$. During this period of length T_{k-1}, the algorithm reduces to the Hedge algorithm with constant learning rate $c_0\sqrt{\log(M)/T_{k-1}}$, so that the above bound (13) applies; further bounding $T_{k-1} \geqslant \frac{T}{4}$ establishes (14).

7.5. Proof of Proposition 10

By convexity of $x \mapsto x^2$ and concavity of $x \mapsto x^\beta$, we have:

$$\begin{aligned}
\mathbb{E}[(\widehat{\ell}_t - \ell_{i^*,t})^2] &\leqslant \mathbb{E}\Big[\sum_{i=1}^{M} v_{i,t}(\ell_{i,t} - \ell_{i^*,t})^2\Big] && (55)\\
&= \mathbb{E}\Big[\sum_{i=1}^{M} v_{i,t}\mathbb{E}\left[(\ell_{i,t} - \ell_{i^*,t})^2 \,|\, \mathcal{F}_{t-1}\right]\Big] \\
&\leqslant B\mathbb{E}\Big[\sum_{i=1}^{M} v_{i,t}\mathbb{E}\left[\ell_{i,t} - \ell_{i^*,t} \,|\, \mathcal{F}_{t-1}\right]^\beta\Big] && (56)\\
&\leqslant B\mathbb{E}\Big[\sum_{i=1}^{M} v_{i,t}\mathbb{E}\left[\ell_{i,t} - \ell_{i^*,t} \,|\, \mathcal{F}_{t-1}\right]\Big]^\beta && (57)\\
&= B\mathbb{E}[\widehat{\ell}_t - \ell_{i^*,t}]^\beta && (58)
\end{aligned}$$

where inequalities (55) and (57) come from Jensen's inequality, and (56) from the Bernstein condition (15). Taking the expectation of the regret bound (16), we obtain

$$\begin{aligned}
\mathbb{E}[R_{i^*,T}] &\leqslant \mathbb{E}\left[C_1\sqrt{(\log M)\sum_{t=1}^{T}(\widehat{\ell}_t - \ell_{i^*,t})^2} + C_2\log M\right] \\
&\leqslant C_1\sqrt{(\log M)\sum_{t=1}^{T}\mathbb{E}\big[(\widehat{\ell}_t - \ell_{i^*,t})^2\big]} + C_2\log M && (59)\\
&\leqslant C_1\sqrt{(\log M)B\sum_{t=1}^{T}\mathbb{E}\big[\widehat{\ell}_t - \ell_{i^*,t}\big]^\beta} + C_2\log M \\
&= C_1\sqrt{BT\log M}\left(\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}\big[\widehat{\ell}_t - \ell_{i^*,t}\big]^\beta\right)^{1/2} + C_2\log M \\
&\leqslant C_1\sqrt{BT\log M}\left(\frac{\mathbb{E}[R_{i^*,T}]}{T}\right)^{\beta/2} + C_2\log M && (60)
\end{aligned}$$

where inequalities (59) and (60) come from Jensen's inequality. Letting $r = \mathbb{E}[R_{i^*,T}]/T$ and $u = (\log M)/T$, inequality (60) writes $r \leqslant C_1\sqrt{Bu}r^{\beta/2} + C_2 u$. This implies that (depending on which of these two terms is larger) either $r \leqslant 2C_2 u$, or $r \leqslant 2C_1\sqrt{Bu}r^{\beta/2}$, and the latter condition amounts to $r \leqslant (2C_1)^{2/(2-\beta)}(Bu)^{1/(2-\beta)}$. This entails that

$$r \leqslant (2C_1)^{\frac{2}{2-\beta}}(Bu)^{\frac{1}{2-\beta}} + 2C_2 u\,,$$

which amounts to

$$\mathbb{E}[R_{i^*,T}] \leqslant C_3(B\log M)^{\frac{1}{2-\beta}}T^{\frac{1-\beta}{2-\beta}} + C_4\log M \tag{61}$$

where $C_3 = (2C_1)^{2/(2-\beta)} \leqslant \max(1, 4C_1^2)$ and $C_4 = 2C_2$.

7.6. Proof of Theorem 9

Consider the constant losses $\ell_{1,t} = 0$, $\ell_{i,t} = \Delta$ where $\Delta = 1 \wedge c_0^{-1}\sqrt{(\log M)/T}$. These losses satisfy the $(1,1)$-Bernstein condition since, for every $i > 1$, $\mathbb{E}[(\ell_{i,t} - \ell_{1,t})^2] = \Delta^2 \leqslant \Delta = \mathbb{E}[\ell_{i,t} - \ell_{1,t}]$. On the other hand, the regret of the Hedge algorithm with learning rate

$\eta_t = c_0\sqrt{(\log M)/t}$ writes

$$\begin{aligned}
\mathcal{R}_T &= \sum_{t=1}^{T}\sum_{i\neq 1}\mathbb{E}[v_{i,t}(\ell_{i,t}-\ell_{1,t})] \\
&= \Delta\sum_{t=1}^{T}\frac{(M-1)e^{-\eta_t\Delta(t-1)}}{1+(M-1)e^{-\eta_t\Delta(t-1)}} \\
&\geqslant \frac{\Delta}{3}\sum_{t=1}^{T}\mathbf{1}\Big((M-1)e^{-\eta_t\Delta(t-1)}\geqslant\frac{1}{2}\Big) \\
&\geqslant \frac{\Delta}{3}\sum_{t=1}^{T}\mathbf{1}\left(Me^{-c_0\Delta\sqrt{(t-1)\log M}}\geqslant 1\right) \qquad (62)\\
&\geqslant \frac{\Delta}{3}\times\min\left(\frac{\log M}{c_0^2\Delta^2},T\right) \\
&= \frac{1}{3}\min\left(\frac{1}{c_0}\sqrt{T\log M},T\right), \qquad (63)
\end{aligned}$$

where (62) relies on the inequalities $2(M-1)\geqslant M$ and $(t-1)/\sqrt{t}\leqslant\sqrt{t-1}$ for $M\geqslant 2, t\geqslant 1$, while (63) is obtained by noting that $(\log M)/(c_0^2\Delta^2)\geqslant T$ since $\Delta\leqslant c_0^{-1}\sqrt{(\log M)/T}$ and substituting for Δ.

7.7. Proof of Theorem 12

Assume that the loss vectors $\boldsymbol{\ell}_1,\boldsymbol{\ell}_2,\ldots$ are i.i.d., and denote $i^*=\operatorname{argmin}_{1\leqslant i\leqslant M}\mathbb{E}[\ell_{i,t}]$ (which is assumed to be unique), $\Delta=\min_{i\neq i^*}\Delta_i>0$ where $\Delta_i=\mathbb{E}[\ell_{i,t}-\ell_{i^*,t}]$ and $j\in\{1,\ldots,M\}$ such that $\Delta_j=\Delta$. The Decreasing Hedge algorithm with learning rate $\eta_t=c_0\sqrt{(\log M)/t}$ satisfies

$$\begin{aligned}
\mathcal{R}_T &= \sum_{t=1}^{T}\sum_{i\neq i^*}\mathbb{E}[v_{i,t}]\Delta_i \\
&\geqslant \Delta\sum_{t=1}^{T}\mathbb{E}\left[\frac{\sum_{i\neq i^*}e^{-\eta_t(L_{i,t-1}-L_{i^*,t-1})}}{1+\sum_{i\neq i^*}e^{-\eta_t(L_{i,t-1}-L_{i^*,t-1})}}\right] \\
&\geqslant \Delta\sum_{t=1}^{T}\mathbb{E}\left[\frac{e^{-\eta_t(L_{j,t-1}-L_{i^*,t-1})}}{1+e^{-\eta_t(L_{j,t-1}-L_{i^*,t-1})}}\right] \qquad (64)\\
&\geqslant \frac{\Delta}{3}\sum_{t=1}^{T}\mathbb{E}\left[\mathbf{1}\left(e^{-\eta_t(L_{j,t-1}-L_{i^*,t-1})}\geqslant\frac{1}{2}\right)\right] \\
&= \frac{\Delta}{3}\sum_{t=1}^{T}\mathbb{P}\left(\eta_t(L_{j,t-1}-L_{i^*,t-1})\leqslant\log 2\right) \qquad (65)
\end{aligned}$$

where (64) relies on the fact that the function $x\mapsto\frac{x}{1+x}$ is increasing on $\mathbf{R}^+$. Denoting $a=(\log 2)/(c_0\sqrt{\log M})$, we have for every $1\leqslant t\leqslant 1+\frac{a^2}{4\Delta^2}$:

$$\begin{aligned}
\mathbb{P}\left(\eta_t(L_{j,t-1}-L_{i^*,t-1})>\log 2\right) &= \mathbb{P}\left(L_{j,t-1}-L_{i^*,t-1}-\Delta(t-1)>a\sqrt{t}-\Delta(t-1)\right) \\
&\leqslant \mathbb{P}\left(L_{j,t-1}-L_{i^*,t-1}-\Delta(t-1)>\frac{a\sqrt{t-1}}{2}\right) \qquad (66)\\
&\leqslant e^{-a^2/8} \qquad (67)
\end{aligned}$$

where inequality (66) stems from the fact that $\Delta(t-1)\leqslant\frac{a\sqrt{t-1}}{2}$ (since $t\leqslant 1+\frac{a^2}{4\Delta^2}$), while (67) is a consequence of Hoeffding's bound applied to the i.i.d. $[-1-\Delta,1-\Delta]$-valued random variables $\ell_{j,s}-\ell_{i^*,s}-\Delta$, $1\leqslant s\leqslant t-1$. Assuming that $c_0\geqslant 1$, we have $a\leqslant\sqrt{\log 2}\leqslant 1$, so that by concavity of the function $x\mapsto 1-e^{-x/8}$, $1-e^{-a^2/8}\geqslant(1-e^{-1/8})a^2$. Combining this with inequalities (65) and (67) and using the fact that $\left\lfloor 1+\frac{a^2}{4\Delta^2}\right\rfloor\geqslant\frac{a^2}{4\Delta^2}$, we obtain for $T\geqslant\frac{1}{4\Delta^2}\geqslant\frac{a^2}{4\Delta^2}$:

$$\mathbb{E}\left[R_T\right]\geqslant\frac{\Delta}{3}\min\left(\frac{a^2}{4\Delta^2},T\right)(1-e^{-1/8})a^2=\frac{(1-e^{-1/8})a^4}{12\Delta}\geqslant\frac{1}{450c_0^4(\log M)^2\Delta}, \qquad (68)$$

where the last inequality comes from the fact that $(\log 2)^4(1-e^{-1/8})/12\geqslant\frac{1}{450}$.

Abstract

Deep learning is built on the foundational guarantee that gradient descent on an objective function converges to local minima. Unfortunately, this guarantee fails in settings, such as generative adversarial nets, that exhibit multiple interacting losses. The behavior of gradient-based methods in games is not well understood – and is becoming increasingly important as adversarial and multi-objective architectures proliferate. In this paper, we develop new tools to understand and control the dynamics in n-player differentiable games.

The key result is to decompose the game Jacobian into two components. The first, symmetric component, is related to potential games, which reduce to gradient descent on an implicit function. The second, antisymmetric component, relates to *Hamiltonian games*, a new class of games that obey a conservation law akin to conservation laws in classical mechanical systems. The decomposition motivates *Symplectic Gradient Adjustment* (SGA), a new algorithm for finding stable fixed points in differentiable games. Basic experiments show SGA is competitive with recently proposed algorithms for finding stable fixed points in GANs – while at the same time being applicable to, and having guarantees in, much more general cases.

Keywords: game theory, generative adversarial networks, deep learning, classical mechanics, hamiltonian mechanics, gradient descent, dynamical systems

1. Introduction

A significant fraction of recent progress in machine learning has been based on applying gradient descent to optimize the parameters of neural networks with respect to an objective function. The objective functions are carefully designed to encode particular tasks such as supervised learning. A basic result is that gradient descent converges to a local minimum of the objective function under a broad range of conditions (Lee et al., 2017). However, there is a growing set of algorithms that do not optimize a single objective function, including: generative adversarial networks (Goodfellow et al., 2014; Zhu et al., 2017), proximal gradient TD learning (Liu et al., 2016), multi-level optimization (Pfau and Vinyals, 2016), synthetic gradients (Jaderberg et al., 2017), hierarchical reinforcement learning (Wayne and Abbott, 2014; Vezhnevets et al., 2017), intrinsic curiosity (Pathak et al., 2017; Burda et al., 2019), and imaginative agents (Racanière et al., 2017). In effect, the models are trained via games played by cooperating and competing modules.

The time-average of iterates of gradient descent, and other more general no-regret algorithms, are guaranteed to converge to coarse correlated equilibria in games (Stoltz and Lugosi, 2007). However, the dynamics do not converge to Nash equilibria – and do not even stabilize in general (Mertikopoulos et al., 2018; Papadimitriou and Piliouras, 2018). Concretely, cyclic behaviors emerge even in simple cases, see example 1.

This paper presents an analysis of the second-order structure of game dynamics that allows to identify two classes of games, potential and Hamiltonian, that are easy to solve separately. We then derive *symplectic gradient adjustment*[1] (SGA), a method for finding stable fixed points in games. SGA's performance is evaluated in basic experiments.

1.1. Background and Problem Description

Tractable algorithms that converge to Nash equilibria have been found for restricted classes of games: potential games, two-player zero-sum games, and a few others (Hart and Mas-Colell, 2013). Finding Nash equilibria can be reformulated as a nonlinear complementarity problem, but these are 'hopelessly impractical to solve' in general (Shoham and Leyton-Brown, 2008) because the problem is PPAD hard (Daskalakis et al., 2009).

Players are primarily neural nets in our setting. For computational reasons we restrict to gradient-based methods, even though game-theorists have considered a much broader range of techniques. Losses are not necessarily convex in *any* of their parameters, so Nash equilibria are not guaranteed to exist. Even leaving existence aside, finding Nash equilibria in nonconvex games is analogous to, but much harder than, finding global minima in neural nets – which is not realistic with gradient-based methods.

There are at least three problems with gradient-based methods in games. Firstly, the potential existence of cycles (recurrent dynamics) implies there are no convergence guarantees, see example 1 below and Mertikopoulos et al. (2018). Secondly, even when gradient descent converges, the rate of convergence may be too slow in practice because 'rotational forces' necessitate extremely small learning rates, see Figure 4. Finally, since there is no single objective, there is no way to measure progress. Concretely, the losses obtained by the generator and the discriminator in GANs are not useful guides to the quality of the images generated. Application-specific proxies have been proposed, for example the inception score for GANs (Salimans et al., 2016), but these are of little help during training. The inception score is domain specific and is no substitute for looking at samples. This paper tackles the first two problems.

1.2. Outline and Summary of Main Contributions

1.2.1. The Infinitesimal Structure of Games

We start with the basic case of a zero-sum bimatrix game: example 1. It turns out that the dynamics under simultaneous gradient descent can be reformulated in terms of Hamilton's equations. The cyclic behavior arises because the dynamics live on the level sets of the Hamiltonian. More directly useful, gradient descent on the Hamiltonian converges to a Nash equilibrium.

Lemma 1 shows that the Jacobian of any game decomposes into symmetric and antisymmetric components. There are thus two 'pure' cases corresponding to when the Jacobian is symmetric and anti-symmetric. The first case, known as potential games (Monderer and Shapley, 1996), have been intensively studied in the game-theory literature because they are exactly the games where gradient descent *does* converge.

The second case, Hamiltonian[2] games, were not studied previously, probably because they coincide with zero-sum games in the bimatrix case (or constant-sum, depending on the constraints). Zero-sum and Hamiltonian games differ when the losses are not bilinear or when there are more than two players. Hamiltonian games are important because (i) they are easy to solve and (ii) general games combine potential-like and Hamiltonian-like dynamics. Unfortunately, the concept of a zero-sum game is too loose to be useful when there are many players: any n-player game can be reformulated as a zero-sum $(n+1)$-player game where $\ell_{n+1} = -\sum_{i=1}^{n} \ell_i$. In this respect, zero-sum games are as complicated as general-sum games. In contrast, Hamiltonian games are much simpler than general-sum games. Theorem 4 shows that Hamiltonian games obey a conservation law – which also provides the key to solving them, by gradient descent on the conserved quantity.

1.2.2. Algorithms

The general case, neither potential nor Hamiltonian, is more difficult and is therefore the focus of the remainder of the paper. Section 3 proposes *symplectic gradient adjustment (SGA)*, a gradient-based method for finding stable fixed points in general games. Appendix A contains TensorFlow code to compute the adjustment. The algorithm computes two Jacobian-vector products, at a cost of two iterations of backprop. SGA satisfies a few natural desiderata explained in Section 3.1: ($D1$) it is compatible with the original dynamics; and it is guaranteed to find stable equilibria in ($D2$) potential and ($D3$) Hamiltonian games.

For general games, correctly picking the *sign* of the adjustment (whether to add or subtract) is critical since it determines the behavior near stable and unstable equilibria. Section 2.4 defines stable equilibria and contrasts them with local Nash equilibria. Theorem 10 proves that SGA converges locally to stable fixed points for sufficiently small parameters (which we quantify via the notion of an additive condition number). While strong, this may be impractical or slow down convergence significantly. Accordingly, Lemma 11 shows how to set the sign so as to be attracted towards stable equilibria and repelled from unstable ones. Correctly aligning SGA allows higher learning rates and faster, more robust convergence, see Theorem 15. Finally, Theorem 17 tackles the remaining class of saddle fixed points by proving that SGA locally avoids strict saddles for appropriate parameters.

2. Lu (1992) defined an unrelated notion of Hamiltonian game.

1.2.3. Experiments

We investigate the empirical performance of SGA in four basic experiments. The first experiment shows how increasing alignment allows higher learning rates and faster convergence, Figure 4. The second set of experiments compares SGA with optimistic mirror descent on two-player and four-player games. We find that SGA converges over a much wider range of learning rates.

The last two sets of experiments investigate mode collapse, mode hopping and the related, less well-known problem of boundary distortion identified in Santurkar et al. (2018). Mode collapse and mode hopping are investigated in a setup involving a two-dimensional mixture of 16 Gaussians that is somewhat more challenging than the original problem introduced in Metz et al. (2017). Whereas simultaneous gradient descent completely fails, our symplectic adjustment leads to rapid convergence – slightly improved by correctly choosing the sign of the adjustment.

Finally, boundary distortion is studied using a 75-dimensional spherical Gaussian. Mode collapse is not an issue since there the data distribution is unimodal. However, as shown in Figure 10, a vanilla GAN with RMSProp learns only one of the eigenvalues in the spectrum of the covariance matrix, whereas SGA approximately learns all of them.

The appendix provides some background information on differential and symplectic geometry, which motivated the developments in the paper. The appendix also explores what happens when the analogy with classical mechanics is pushed further than perhaps seems reasonable. We experiment with assigning units (in the sense of masses and velocities) to quantities in games, and find that type-consistency yields unexpected benefits.

1.3. Related Work

Nash (1950) was only concerned with existence of equilibria. Convergence in two-player games was studied in Singh et al. (2000). WoLF (Win or Learn Fast) converges to Nash equilibria in two-player two-action games (Bowling and Veloso, 2002). Extensions include weighted policy learning (Abdallah and Lesser, 2008) and GIGA-WoLF (Bowling, 2004). Infinitesimal Gradient Ascent (IGA) is a gradient-based approach that is shown to converge to pure Nash equilibria in two-player two-action games. Cyclic behaviour may occur in case of mixed equilibria. Zinkevich (2003) generalised the algorithm to n-action games called GIGA. Optimistic mirror descent approximately converges in two-player bilinear zero-sum games (Daskalakis et al., 2018), a special case of Hamiltonian games. In more general settings it converges to coarse correlated equilibria.

Convergence has also been studied in various n-player settings, see Rosen (1965); Scutari et al. (2010); Facchinei and Kanzow (2010); Mertikopoulos and Zhou (2016). However, the recent success of GANs, where the players are neural networks, has focused attention on a much larger class of *nonconvex* games where comparatively little is known, especially in the n-player case. Heusel et al. (2017) propose a two-time scale methods to find Nash equilibria. However, it likely scales badly with the number of players. Nagarajan and Kolter (2017) prove convergence for some algorithms, but under very strong assumptions (Mescheder et al., 2018). Consensus optimization (Mescheder et al., 2017) is closely related to our proposad algorithm, and is extensively discussed in Section 3. A variety of game-theoretically or

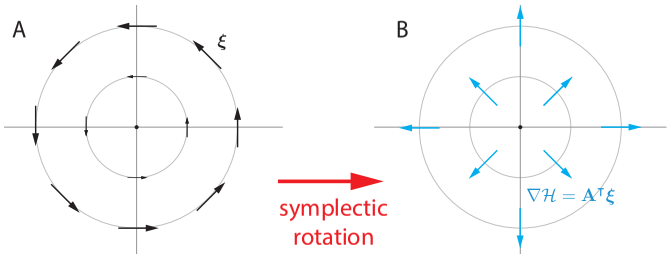

Figure 1: *A minimal example of Hamiltonian mechanics.* Consider a game where $\ell_1(x, y) = xy$, $\ell_2(x, y) = -xy$, and the dynamics are given by $\boldsymbol{\xi}(x, y) = (y, -x)$. The game is a special case of example 1. **(A)** The dynamics $\boldsymbol{\xi}$ cycle around the origin since they live on the level sets of the Hamiltonian $\mathcal{H}(x, y) = \frac{1}{2}(x^2 + y^2)$. **(B)** Gradient descent on the Hamiltonian $\mathcal{H}$ converges to the Nash equilibrium of the game, at the origin $(0, 0)$. Note that $\mathbf{A}^\intercal\boldsymbol{\xi} = (x, y) = \nabla\mathcal{H}$.

minimax motivated modifications to vanilla gradient descent have been investigated in the context of GANs, see Mertikopoulos et al. (2019); Gidel et al. (2018).

Learning with opponent-learning awareness (LOLA) infinitesimally modifies the objectives of players to take into account their opponents' goals (Foerster et al., 2018). However, Letcher et al. (2019) recently showed that LOLA modifies fixed points and thus fails to find stable equilibria in general games.

Symplectic gradient adjustment was independently discovered by Gemp and Mahadevan (2018), who refer to it as "crossing-the-curl". Their analysis draws on powerful techniques from variational inequalities and monotone optimization that are complementary to those developed here—see for example Gemp and Mahadevan (2016, 2017); Gidel et al. (2019). Using techniques from monotone optimization, Gemp and Mahadevan (2018) obtained more detailed and stronger results than ours, in the more particular case of Wasserstein LQ-GANs, where the generator is linear and the discriminator is quadratic (Feizi et al., 2017; Nagarajan and Kolter, 2017).

Network zero-sum games are shown to be Hamiltonian systems in Bailey and Piliouras (2019). The implications of the existence of invariant functions for games is just beginning to be understood and explored.

1.3.1. Notation

Dot products are written as $\mathbf{v}^\intercal\mathbf{w}$ or $\langle \mathbf{v}, \mathbf{w}\rangle$. The angle between two vectors is $\theta(\mathbf{v}, \mathbf{w})$. Positive definiteness is denoted $\mathbf{S} \succ 0$.

2. The Infinitesimal Structure of Games

In contrast to the classical formulation of games, we do not constrain the parameter sets to the probability simplex or require losses to be convex in the corresponding players' parameters. Our motivation is that we are primarily interested in use cases where players are interacting neural nets such as GANs (Goodfellow et al., 2014), a situation in which results from classical game theory do not straightforwardly apply.

Definition 1 (differentiable game)
A differentiable game consists in a set of players $[n] = \{1, \ldots, n\}$ *and corresponding twice continuously differentiable losses* $\{\ell_i : \mathbb{R}^d \to \mathbb{R}\}_{i=1}^n$. *Parameters are* $\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_n) \in \mathbb{R}^d$ *where* $\sum_{i=1}^n d_i = d$. *Player* i *controls* $\mathbf{w}_i \in \mathbb{R}^{d_i}$, *and aims to minimize its loss.*

It is sometimes convenient to write $\mathbf{w} = (\mathbf{w}_i, \mathbf{w}_{-i})$ where $\mathbf{w}_{-i}$ concatenates the parameters of all the players other than the i^{th}, which is placed out of order by abuse of notation.

The *simultaneous gradient* is the gradient of the losses with respect to the parameters of the respective players:

$$\boldsymbol{\xi}(\mathbf{w}) = (\nabla_{\mathbf{w}_1}\ell_1, \ldots, \nabla_{\mathbf{w}_n}\ell_n) \in \mathbb{R}^d.$$

By the **dynamics** of the game, we mean following the *negative* of the vector field, $-\boldsymbol{\xi}$, with infinitesimal steps. There is no reason to expect $\boldsymbol{\xi}$ to be the gradient of a *single* function in general, and therefore no reason to expect the dynamics to converge to a fixed point.

2.1. Hamiltonian Mechanics

Hamiltonian mechanics is a formalism for describing the dynamics in classical physical systems, see Arnold (1989); Guillemin and Sternberg (1990). The system is described via canonical coordinates $(\mathbf{q}, \mathbf{p})$. For example, $\mathbf{q}$ often refers to position and $\mathbf{p}$ to momentum of a particle or particles.

The Hamiltonian of the system $\mathcal{H}(\mathbf{q}, \mathbf{p})$ is a function that specifies the total energy as a function of the generalized coordinates. For example, in a closed system the Hamiltonian is given by the sum of the potential and kinetic energies of the particles. The time evolution of the system is given by Hamilton's equations:

$$\frac{d\mathbf{q}}{dt} = \frac{\partial\mathcal{H}}{\partial\mathbf{p}} \quad \text{and} \quad \frac{d\mathbf{p}}{dt} = -\frac{\partial\mathcal{H}}{\partial\mathbf{q}}.$$

An importance consequence of the Hamiltonian formalism is that the dynamics of the physical system—that is, the trajectories followed by the particles in phase space—live on the level sets of the Hamiltonian. In other words, the total energy is conserved.

2.2. Hamiltonian Mechanics in Games

The next example illustrates the essential problem with gradients in games and the key insight motivating our approach.

Example 1 (Conservation of energy in a zero-sum unconstrained bimatrix game)
Zero-sum games, where $\sum_{i=1}^n \ell_i \equiv 0$, *are well-studied. The zero-sum game*

$$\ell_1(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\intercal\mathbf{A}\mathbf{y} \quad \textit{and} \quad \ell_2(\mathbf{x}, \mathbf{y}) = -\mathbf{x}^\intercal\mathbf{A}\mathbf{y}$$

has a Nash equilibrium at $(\mathbf{x}, \mathbf{y}) = (\mathbf{0}, \mathbf{0})$. *The simultaneous gradient* $\boldsymbol{\xi}(\mathbf{x}, \mathbf{y}) = (\mathbf{A}\mathbf{y}, -\mathbf{A}^\intercal\mathbf{x})$ *rotates around the Nash, see Figure 1.*

The matrix $\mathbf{A}$ *admits singular value decomposition (SVD)* $\mathbf{A} = \mathbf{U}^\intercal\mathbf{D}\mathbf{V}$. *Changing to coordinates* $\mathbf{u} = \mathbf{D}^{\frac{1}{2}}\mathbf{U}\mathbf{x}$ *and* $\mathbf{v} = \mathbf{D}^{\frac{1}{2}}\mathbf{V}\mathbf{y}$ *gives* $\ell_1(\mathbf{u},\mathbf{v}) = \mathbf{u}^\intercal\mathbf{v}$ *and* $\ell_2(\mathbf{u},\mathbf{v}) = -\mathbf{u}^\intercal\mathbf{v}$. *Introduce the* Hamiltonian

$$\mathcal{H}(\mathbf{u},\mathbf{v}) = \frac{1}{2}\left(\|\mathbf{u}\|_2^2 + \|\mathbf{v}\|_2^2\right) = \frac{1}{2}\left(\mathbf{x}^\intercal\mathbf{U}^\intercal\mathbf{D}\mathbf{U}\mathbf{x} + \mathbf{y}^\intercal\mathbf{V}^\intercal\mathbf{D}\mathbf{V}\mathbf{y}\right).$$

Remarkably, the dynamics can be reformulated via Hamilton's equations in the coordinates given by the SVD of $\mathbf{A}$*:*

$$\boldsymbol{\xi}(\mathbf{u},\mathbf{v}) = \left(\frac{\partial\mathcal{H}}{\partial\mathbf{v}}, -\frac{\partial\mathcal{H}}{\partial\mathbf{u}}\right).$$

The vector field $\boldsymbol{\xi}$ *cycles around the equilibrium because* $\boldsymbol{\xi}$ *conserves the Hamiltonian's level sets (i.e.* $\langle\boldsymbol{\xi}, \nabla\mathcal{H}\rangle = 0$*). However,* **gradient descent on the Hamiltonian converges to the Nash equilibrium.** *The remainder of the paper explores the implications and limitations of this insight.*

Papadimitriou and Piliouras (2016) recently analyzed the dynamics of Matching Pennies (essentially, the above example) and showed that the cyclic behavior covers the entire parameter space. The Hamiltonian reformulation directly explains the cyclic behavior via a conservation law.

2.3. The Generalized Helmholtz Decomposition

The **Jacobian** of a game with dynamics $\boldsymbol{\xi}$ is the $(d \times d)$-matrix of second-derivatives $\mathbf{J}(\mathbf{w}) := \nabla_{\mathbf{w}} \cdot \boldsymbol{\xi}(\mathbf{w})^\intercal = \left(\frac{\partial\xi_\alpha(\mathbf{w})}{\partial w_\beta}\right)_{\alpha,\beta=1}^{d}$, where $\boldsymbol{\xi}_\alpha(\mathbf{w})$ is the α^{th} entry of the d-dimensional vector $\boldsymbol{\xi}(\mathbf{w})$. Concretely, the Jacobian can be written as

$$\mathbf{J}(\mathbf{w}) = \begin{pmatrix} \nabla^2_{\mathbf{w}_1}\ell_1 & \nabla^2_{\mathbf{w}_1,\mathbf{w}_2}\ell_1 & \cdots & \nabla^2_{\mathbf{w}_1,\mathbf{w}_n}\ell_1 \\ \nabla^2_{\mathbf{w}_2,\mathbf{w}_1}\ell_2 & \nabla^2_{\mathbf{w}_2}\ell_2 & \cdots & \nabla^2_{\mathbf{w}_2,\mathbf{w}_n}\ell_2 \\ \vdots & & & \vdots \\ \nabla^2_{\mathbf{w}_n,\mathbf{w}_1}\ell_n & \nabla^2_{\mathbf{w}_n,\mathbf{w}_2}\ell_n & \cdots & \nabla^2_{\mathbf{w}_n}\ell_n \end{pmatrix}$$

where $\nabla^2_{\mathbf{w}_i,\mathbf{w}_j}\ell_k$ is the $(d_i \times d_j)$-block of 2^{nd}-order derivatives. The Jacobian of a game is a square matrix, but not necessarily symmetric. Note: Greek indices α, β run over d parameter dimensions whereas Roman indices i, j run over n players.

Lemma 1 (generalized Helmholtz decomposition)
The Jacobian of any vector field decomposes uniquely into two components $\mathbf{J}(\mathbf{w}) = \mathbf{S}(\mathbf{w}) + \mathbf{A}(\mathbf{w})$ *where* $\mathbf{S} \equiv \mathbf{S}^\intercal$ *is symmetric and* $\mathbf{A} + \mathbf{A}^\intercal \equiv 0$ *is antisymmetric.*

Proof Any matrix decomposes uniquely as $\mathbf{M} = \mathbf{S} + \mathbf{A}$ where $\mathbf{S} = \frac{1}{2}(\mathbf{M} + \mathbf{M}^\intercal)$ and $\mathbf{A} = \frac{1}{2}(\mathbf{M} - \mathbf{M}^\intercal)$ are symmetric and antisymmetric. The decomposition is preserved by orthogonal change-of-coordinates: given orthogonal matrix $\mathbf{P}$, we have $\mathbf{P}^\intercal\mathbf{M}\mathbf{P} = \mathbf{P}^\intercal\mathbf{S}\mathbf{P} + \mathbf{P}^\intercal\mathbf{A}\mathbf{P}$ since the terms remain symmetric and antisymmetric. Applying the decomposition to the Jacobian yields the result. ■

The connection to the classical Helmholtz decomposition in calculus is sketched in appendix B. Two natural classes of games arise from the decomposition:

Definition 2 *A game is a* ***potential game*** *if the Jacobian is symmetric, i.e. if* $\mathbf{A}(\mathbf{w}) \equiv 0$. *It is a* ***Hamiltonian game*** *if the Jacobian is antisymmetric, i.e. if* $\mathbf{S}(\mathbf{w}) \equiv 0$.

Potential games are well-studied and easy to solve. Hamiltonian games are a new class of games that are also easy to solve. The general case is more difficult, see Section 3.

2.4. Stable Fixed Points (SFPs) vs Local Nash Equilibria (LNEs)

There are (at least) two possible solution concepts in general differentiable games: stable fixed points and local Nash equilibria.

Definition 3 *A point* $\mathbf{w}$ *is a* ***local Nash equilibrium*** *if, for all* i*, there exists a neighborhood* U_i *of* $\mathbf{w}_i$ *such that* $\ell_i(\mathbf{w}_i', \mathbf{w}_{-i}) \geq \ell_i(\mathbf{w}_i, \mathbf{w}_{-i})$ *for* $\mathbf{w}_i' \in U_i$.

We introduce *local* Nash equilibria because finding *global* Nash equilibria is unrealistic in games involving neural nets. Gradient-based methods can reliably find local—but not global—optima of nonconvex objective functions (Lee et al., 2016, 2017). Similarly, gradient-based methods cannot be expected to find global Nash equilibria in nonconvex games.

Definition 4 *A fixed point* $\mathbf{w}^*$ *with* $\boldsymbol{\xi}(\mathbf{w}^*) = 0$ *is* **stable** *if* $\mathbf{J}(\mathbf{w}^*) \succeq 0$ *and* $\mathbf{J}(\mathbf{w}^*)$ *is invertible,* **unstable** *if* $\mathbf{J}(\mathbf{w}^*) \prec 0$ *and a* **strict saddle** *if* $\mathbf{J}(\mathbf{w}^*)$ *has an eigenvalue with negative real part. Strict saddles are a subset of unstable fixed points.*

The definition is adapted from Letcher et al. (2019), where conditions on the Jacobian hold *at* the fixed point; in contrast, Balduzzi et al. (2018a) imposed conditions on the Jacobian in a *neighborhood* of the fixed point. We motivate this concept as follows.

Positive semidefiniteness, $\mathbf{J}(\mathbf{w}^*) \succeq 0$, is a minimal condition for any reasonable notion of stable fixed point. In the case of a single loss ℓ, the Jacobian of $\boldsymbol{\xi} = \nabla\ell$ is the Hessian of ℓ, i.e. $\mathbf{J} = \nabla^2\ell$. Local convergence of gradient descent on single functions cannot be guaranteed if $\mathbf{J}(\mathbf{w}^*) \not\succeq 0$, since such points are strict saddles. These are almost always avoided by Lee et al. (2017), so this semidefinite condition must hold.

Another viewpoint is that invertibility and positive semidefiniteness of the Hessian together imply *positive definiteness*, and the notion of stable fixed point specializes, in a one-player game, to local minima that are detected by the second partial derivative test. These minima are precisely those which gradient-like methods provably converge to. Stable fixed points are defined by analogy, though note that invertibility and semidefiniteness do *not* imply positive definiteness in n-player games since $\mathbf{J}$ may not be symmetric.

Finally, it is important to impose only positive *semi*-definiteness to keep the class as large as possible. Imposing strict positivity would imply that the origin is not an SFP in the cyclic game $\ell_1 = xy = -\ell_2$ from Example 1, while clearly deserving of being so.

Remark 1 *The conditions* $\mathbf{J}(\mathbf{w}^*) \succeq 0$ *and* $\mathbf{J}(\mathbf{w}^*) \prec 0$ *are equivalent to the conditions on the symmetric component* $\mathbf{S}(\mathbf{w}^*) \succeq 0$ *and* $\mathbf{S}(\mathbf{w}^*) \prec 0$ *respectively, since*

$$\mathbf{u}^\intercal\mathbf{J}\mathbf{u} = \mathbf{u}^\intercal\mathbf{S}\mathbf{u} + \mathbf{u}^\intercal\mathbf{A}\mathbf{u} = \mathbf{u}^\intercal\mathbf{S}\mathbf{u}$$

for all $\mathbf{u}$*, by antisymmetry of* $\mathbf{A}$. *This equivalence will be used throughout.*

Stable fixed points and local Nash equilibria are both appealing solution concepts, one from the viewpoint of optimisation by analogy with single objectives, and the other from game theory. Unfortunately, neither is a subset of the other:

Example 2 (stable $\not\Longrightarrow$ local Nash)
Let $\ell_1(x,y) = x^3 + xy$ *and* $\ell_2(x,y) = -xy$. *Then*

$$\boldsymbol{\xi}(x,y) = \begin{pmatrix} 3x^2 + y \\ -x \end{pmatrix} \quad \textit{and} \quad \mathbf{J}(x,y) = \begin{pmatrix} 6x & 1 \\ -1 & 0 \end{pmatrix}.$$

There is a stable fixed point with invertible Hessian at $(x,y) = (0,0)$, *since* $\boldsymbol{\xi}(0,0) = 0$ *and* $\mathbf{J}(0,0) \succeq 0$ *invertible. However any neighbourhood of* $x = 0$ *contains some small* $\epsilon > 0$ *for which* $\ell_1(-\epsilon, 0) = -\epsilon^3 < 0 = \ell_1(0,0)$, *so the origin is not a local Nash equilibrium.*

Example 3 (local Nash $\not\Longrightarrow$ stable)
Let $\ell_1(x,y) = \ell_2(x,y) = xy$. *Then*

$$\boldsymbol{\xi}(x,y) = \begin{pmatrix} y \\ x \end{pmatrix} \quad \textit{and} \quad \mathbf{J}(x,y) = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

There is a fixed point at $(x,y) = (0,0)$ *which is a local (in fact, global) Nash equilibrium since* $\ell_1(0,y) = 0 \geq \ell_1(0,0)$ *and* $\ell_2(x,0) = 0 \geq \ell_2(0,0)$ *for all* $x, y \in \mathbb{R}$. *However* $\mathbf{J} = \mathbf{S}$ *has eigenvalues* $\lambda_1 = 1$ *and* $\lambda_2 = -1 < 0$, *so* $(0,0)$ *is not a stable fixed point.*

In Example 3, the Nash equilibrium is a *saddle point* of the common loss $\ell = xy$. Any algorithm that converges to Nash equilibria will thus converge to an undesirable saddle point. This rules out local Nash equilibrium as a solution concept for our purposes. Conversely, Example 2 emphasises the better notion of stability whereby player 1 may have a local incentive to deviate from the origin *immediately*, but would later be punished for doing so since the game is locally dominated by the $\pm xy$ terms, whose only 'resolution' or 'stable minimum' is the origin (see Example 1).

2.5. Potential Games

Potential games were introduced by Monderer and Shapley (1996). It turns out that our definition of potential game above coincides with a special case of the potential games of Monderer and Shapley (1996), which they refer to as exact potential games.

Definition 5 (classical definition of potential game)
A game is a potential game if there is a single potential function $\phi : \mathbb{R}^d \to \mathbb{R}$ *and positive numbers* $\{\alpha_i > 0\}_{i=1}^n$ *such that*

$$\phi(\mathbf{w}_i', \mathbf{w}_{-i}) - \phi(\mathbf{w}_i'', \mathbf{w}_{-i}) = \alpha_i \Big(\ell_i(\mathbf{w}_i', \mathbf{w}_{-i}) - \ell_i(\mathbf{w}_i'', \mathbf{w}_{-i}) \Big)$$

for all i *and all* $\mathbf{w}_i', \mathbf{w}_i'', \mathbf{w}_{-i}$, *see Monderer and Shapley (1996).*

Lemma 2 *A game is a potential game iff* $\alpha_i \nabla_{\mathbf{w}_i} \ell_i = \nabla_{\mathbf{w}_i} \phi$ *for all* i, *which is equivalent to*

$$\alpha_i \nabla^2_{\mathbf{w}_i \mathbf{w}_j} \ell_i = \alpha_j \nabla^2_{\mathbf{w}_i \mathbf{w}_j} \ell_j = \alpha_j \left(\nabla^2_{\mathbf{w}_j \mathbf{w}_i} \ell_j \right)^\intercal \quad \forall i, j. \tag{1}$$

Proof See Monderer and Shapley (1996). ■

Corollary 3 *If* $\alpha_i = 1$ *for all* i *then Equation* (1) *is equivalent to requiring that the Jacobian of the game is symmetric.*

Proof In an exact potential game, the Jacobian coincides with the Hessian of the potential function ϕ, which is necessarily symmetric. ■

Monderer and Shapley (1996) refer to the special case where $\alpha_i = 1$ for all i as an ***exact potential game***. We use the shorthand 'potential game' to refer to exact potential games in what follows.

Potential games have been extensively studied since they are one of the few classes of games for which Nash equilibria can be computed (Rosenthal, 1973). For our purposes, they are games where simultaneous gradient descent on the losses corresponds to gradient descent on a single function. It follows that descent on $\boldsymbol{\xi}$ converges to a fixed point that is a local minimum of ϕ or a saddle.

2.6. Hamiltonian Games

Hamiltonian games, where the Jacobian is antisymmetric, are a new class games. They are related to the harmonic games introduced in Candogan et al. (2011), see Section B.4. An example from Balduzzi et al. (2018b) may help develop intuition for antisymmetric matrices:

Example 4 (antisymmetric structure of tournaments)
Suppose n *competitors play one-on-one and that the probability of player* i *beating player* j *is* p_{ij}. *Then, assuming there are no draws, the probabilities satisfy* $p_{ij} + p_{ji} = 1$ *and* $p_{ii} = \frac{1}{2}$. *The matrix* $\mathbf{A} = \left(\log \frac{p_{ij}}{1 - p_{ij}} \right)_{i,j=1}^n$ *of logits is then antisymmetric. Intuitively, antisymmetry reflects a* hyperadversarial *setting where all pairwise interactions between players are zero-sum.*

Hamiltonian games are closely related to zero-sum games.

Example 5 (an unconstrained bimatrix game is zero-sum iff it is Hamiltonian)
Consider bimatrix game with $\ell_1(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\intercal \mathbf{P} \mathbf{y}$ *and* $\ell_2(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\intercal \mathbf{Q} \mathbf{y}$, *but where the parameters are* not *constrained to the probability simplex. Then* $\boldsymbol{\xi} = (\mathbf{P}\mathbf{y}, \mathbf{Q}^\intercal \mathbf{x})$ *and the Jacobian components have block structure*

$$\mathbf{A} = \frac{1}{2} \begin{pmatrix} 0 & \mathbf{P} - \mathbf{Q} \\ (\mathbf{Q} - \mathbf{P})^\intercal & 0 \end{pmatrix} \quad \textit{and} \quad \mathbf{S} = \frac{1}{2} \begin{pmatrix} 0 & \mathbf{P} + \mathbf{Q} \\ (\mathbf{P} + \mathbf{Q})^\intercal & 0 \end{pmatrix}$$

The game is Hamiltonian iff $\mathbf{S} = 0$ *iff* $\mathbf{P} + \mathbf{Q} = 0$ *iff* $\ell_1 + \ell_2 = 0$.

However, in general there are Hamiltonian games that are *not* zero-sum and vice versa.

Example 6 (Hamiltonian game that is not zero-sum)
Fix constants a and b and suppose players 1 and 2 minimize losses

$$\ell_1(x, y) = x(y - b) \;\; \textit{and} \;\; \ell_2(x, y) = -(x - a)y$$

with respect to x and y respectively.

Example 7 (zero-sum game that is not Hamiltonian)
Players 1 and 2 minimize

$$\ell_1(x, y) = x^2 + y^2 \qquad \ell_2(x, y) = -(x^2 + y^2).$$

The game actually has potential function $\phi(x, y) = x^2 - y^2$.

Hamiltonian games are quite different from potential games. In a Hamiltonian game there is a Hamiltonian function $\mathcal{H}$ that specifies a conserved quantity. In potential games the dynamics *equal* $\nabla\phi$; in Hamiltonian games the dynamics are *orthogonal* to $\nabla\mathcal{H}$. The orthogonality implies the conservation law that underlies the cyclic behavior in example 1.

Theorem 4 (conservation law for Hamiltonian games)
Let $\mathcal{H}(\mathbf{w}) := \frac{1}{2}\|\boldsymbol{\xi}(\mathbf{w})\|_2^2$. If the game is Hamiltonian then

i) $\nabla\mathcal{H} = \mathbf{A}^\intercal\boldsymbol{\xi}$ and

*ii) $\boldsymbol{\xi}$ **preserves the level sets of** $\mathcal{H}$ since $\langle\boldsymbol{\xi}, \nabla\mathcal{H}\rangle = 0$.*

iii) If the Jacobian is invertible and $\lim_{\|\mathbf{w}\|\to\infty}\mathcal{H}(\mathbf{w}) = \infty$ then gradient descent on $\mathcal{H}$ converges to a stable fixed point.

Proof Direct computation shows $\nabla\mathcal{H} = \mathbf{J}^\intercal\boldsymbol{\xi}$ for any game. The first statement follows since $\mathbf{J} = \mathbf{A}$ in Hamiltonian games.

For the second statement, the directional derivative is $D_{\boldsymbol{\xi}}\mathcal{H} = \langle\boldsymbol{\xi}, \nabla\mathcal{H}\rangle = \boldsymbol{\xi}^\intercal\mathbf{A}^\intercal\boldsymbol{\xi}$ where $\boldsymbol{\xi}^\intercal\mathbf{A}^\intercal\boldsymbol{\xi} = (\boldsymbol{\xi}^\intercal\mathbf{A}^\intercal\boldsymbol{\xi})^\intercal = \boldsymbol{\xi}^\intercal\mathbf{A}\boldsymbol{\xi} = -(\boldsymbol{\xi}^\intercal\mathbf{A}^\intercal\boldsymbol{\xi})$ since $\mathbf{A} = -\mathbf{A}^\intercal$ by anti-symmetry. It follows that $\boldsymbol{\xi}^\intercal\mathbf{A}^\intercal\boldsymbol{\xi} = 0$.

For the third statement, gradient descent on $\mathcal{H}$ will converge to a point where $\nabla\mathcal{H} = \mathbf{J}^\intercal\boldsymbol{\xi}(\mathbf{w}) = 0$. If the Jacobian is invertible then clearly $\boldsymbol{\xi}(\mathbf{w}) = 0$. The fixed-point is stable since $0 \equiv \mathbf{S} \succeq 0$ in a Hamiltonian game, recall remark 1. ■

In fact, $\mathcal{H}$ is a Hamiltonian function for the game dynamics, see appendix B for a concise explanation. We use the notation $\mathcal{H}(\mathbf{w}) = \frac{1}{2}\|\boldsymbol{\xi}(\mathbf{w})\|^2$ throughout the paper. However, $\mathcal{H}$ can only be interpreted as a Hamiltonian function for $\boldsymbol{\xi}$ when the game is Hamiltonian.

There is a precise mapping from Hamiltonian games to symplectic geometry, see appendix B. Symplectic geometry is the modern formulation of classical mechanics (Arnold, 1989; Guillemin and Sternberg, 1990). Recall that periodic behaviors (e.g. orbits) often arise in classical mechanics. The orbits lie on the level sets of the Hamiltonian, which expresses the total energy of the system.

3. Algorithms

We have seen that fixed points of potential and Hamiltonian games can be found by descent on $\boldsymbol{\xi}$ and $\nabla\mathcal{H}$ respectively. This Section tackles finding stable fixed points in general games.

3.1. Finding Stable Fixed Points

There are two classes of games where we know how to find stable fixed points: potential games where $\boldsymbol{\xi}$ converges to a local minimum and Hamiltonian games where $\nabla\mathcal{H}$, which is orthogonal to $\boldsymbol{\xi}$, finds stable fixed points.

In the general case, the following desiderata provide a set of reasonable properties for an adjustment $\boldsymbol{\xi}_\lambda$ of the game dynamics. Recall that $\theta(\mathbf{u}, \mathbf{v})$ is the angle between the vectors $\mathbf{u}$ and $\mathbf{v}$.

3.1.1. Desiderata

To find stable fixed points, an adjustment $\boldsymbol{\xi}_\lambda$ to the game dynamics should satisfy

D1. *compatible*[3] *with game dynamics:* $\langle\boldsymbol{\xi}_\lambda, \boldsymbol{\xi}\rangle = \alpha_1 \cdot \|\boldsymbol{\xi}\|^2$;

D2. *compatible with potential dynamics:*
if the game is a potential game then $\langle\boldsymbol{\xi}_\lambda, \nabla\phi\rangle = \alpha_2 \cdot \|\nabla\phi\|^2$;

D3. *compatible with Hamiltonian dynamics:*
If the game is Hamiltonian then $\langle\boldsymbol{\xi}_\lambda, \nabla\mathcal{H}\rangle = \alpha_3 \cdot \|\nabla\mathcal{H}\|^2$;

D4. *attracted to stable equilibria:*
in neighborhoods where $\mathbf{S} \succ 0$, require $\theta(\boldsymbol{\xi}_\lambda, \nabla\mathcal{H}) \leq \theta(\boldsymbol{\xi}, \nabla\mathcal{H})$;

D5. *repelled by unstable equilibria:*
in neighborhoods where $\mathbf{S} \prec 0$, require $\theta(\boldsymbol{\xi}_\lambda, \nabla\mathcal{H}) \geq \theta(\boldsymbol{\xi}, \nabla\mathcal{H})$.

for some $\alpha_1, \alpha_2, \alpha_3 > 0$.

Desideratum $D1$ does not guarantee that players act in their own self-interest—this requires a stronger positivity condition on dot-products with subvectors of $\boldsymbol{\xi}$, see Balduzzi (2017). Desiderata $D2$ and $D3$ imply that the adjustment behaves correctly in potential and Hamiltonian games respectively.

To understand desiderata $D4$ and $D5$, observe that gradient descent on $\mathcal{H} = \frac{1}{2}\|\boldsymbol{\xi}\|^2$ will find local minima that are fixed points of the dynamics. However, we specifically wish to converge to stable fixed points. Desideratum $D4$ and $D5$ require that the adjustment improves the rate of convergence to stable fixed points (by finding a steeper angle of descent), and avoids unstable fixed points.

More concretely, desiderata $D4$ can be interpreted as follows. If $\boldsymbol{\xi}$ points at a stable equilibrium then we require that $\boldsymbol{\xi}_\lambda$ points *more* towards the equilibrium (i.e. has smaller angle). Conversely, desiderata $D5$ requires that if $\boldsymbol{\xi}$ points away then the adjustment should point *further* away.

The unadjusted dynamics $\boldsymbol{\xi}$ satisfies all the desiderata except $D3$.

3. Two nonzero vectors are compatible if they have positive inner product.

3.2. Consensus Optimization

Since gradient descent on the function $\mathcal{H}(\mathbf{w}) = \frac{1}{2}\|\boldsymbol{\xi}\|^2$ finds stable fixed points in Hamiltonian games, it is natural to ask how it performs in general games. If the Jacobian $\mathbf{J}(\mathbf{w})$ is invertible, then $\nabla\mathcal{H} = \mathbf{J}^\intercal\boldsymbol{\xi} = 0$ iff $\boldsymbol{\xi} = 0$. Thus, gradient descent on $\mathcal{H}$ converges to fixed points of $\boldsymbol{\xi}$.

However, there is no guarantee that descent on $\mathcal{H}$ will find a *stable* fixed point. Mescheder et al. (2017) propose *consensus optimization*, a gradient adjustment of the form

$$\boldsymbol{\xi} + \lambda \cdot \mathbf{J}^\intercal\boldsymbol{\xi} = \boldsymbol{\xi} + \lambda \cdot \nabla\mathcal{H}.$$

Unfortunately, consensus optimization can converge to unstable fixed points even in simple cases where the 'game' is to minimize a single function:

Example 8 (consensus optimization can converge to a global maximum) *Consider a potential game with losses $\ell_1(x, y) = \ell_2(x, y) = -\frac{\kappa}{2}(x^2 + y^2)$ with $\kappa \gg 0$. Then*

$$\boldsymbol{\xi} = -\kappa \cdot \begin{pmatrix} x \\ y \end{pmatrix} \quad \textit{and} \quad \mathbf{J} = -\begin{pmatrix} \kappa & 0 \\ 0 & \kappa \end{pmatrix}$$

Note that $\|\boldsymbol{\xi}\|^2 = \kappa^2(x^2 + y^2)$ and

$$\boldsymbol{\xi} + \lambda \cdot \mathbf{J}^\intercal\boldsymbol{\xi} = \kappa(\lambda\kappa - 1) \cdot \begin{pmatrix} x \\ y \end{pmatrix}.$$

Descent on $\boldsymbol{\xi} + \lambda \cdot \mathbf{J}^\intercal\boldsymbol{\xi}$ converges to the global maximum $(x, y) = (0, 0)$ unless $\lambda < \frac{1}{\kappa}$.

Although consensus optimization works well in two-player zero-sum, it cannot be considered a candidate algorithm for finding stable fixed points in general games since it fails in the basic case of potential games. Consensus optimization only satisfies desiderata $D3$ and $D4$.

3.3. Symplectic Gradient Adjustment

The problem with consensus optimization is that it can perform worse than gradient descent on potential games. Intuitively, it makes bad use of the symmetric component of the Jacobian. Motivated by the analysis in Section 2, we propose symplectic gradient adjustment, which takes care to only use the antisymmetric component of the Jacobian when adjusting the dynamics.

Proposition 5 *The **symplectic gradient adjustment (SGA)***

$$\boldsymbol{\xi}_\lambda := \boldsymbol{\xi} + \lambda \cdot \mathbf{A}^\intercal\boldsymbol{\xi}.$$

satisfies $D1$—$D3$ for $\lambda > 0$, with $\alpha_1 = 1 = \alpha_2$ and $\alpha_3 = \lambda$.

Proof First claim: $\lambda \cdot \boldsymbol{\xi}^\intercal\mathbf{A}^\intercal\boldsymbol{\xi} = 0$ by anti-symmetry of $\mathbf{A}$. Second claim: $\mathbf{A} \equiv 0$ in a potential game, so $\boldsymbol{\xi}_\lambda = \boldsymbol{\xi} = \nabla\phi$. Third claim: $\langle\boldsymbol{\xi}_\lambda, \nabla\mathcal{H}\rangle = \langle\boldsymbol{\xi}_\lambda, \mathbf{J}^\intercal\boldsymbol{\xi}\rangle = \langle\boldsymbol{\xi}_\lambda, \mathbf{A}^\intercal\boldsymbol{\xi}\rangle = \lambda \cdot \boldsymbol{\xi}^\intercal\mathbf{A}\mathbf{A}^\intercal\boldsymbol{\xi} = \lambda \cdot \|\nabla\mathcal{H}\|^2$ since $\mathbf{J} = \mathbf{A}$ by assumption. ■

Note that desiderata $D1$ and $D2$ are true even when $\lambda < 0$. This will prove useful, since example 9 shows that it may be necessary to pick negative λ near $\mathbf{S} \prec 0$. Section 3.5 shows how to also satisfy desiderata $D4$ and $D5$.

3.4. Convergence

We begin by analysing convergence of SGA near stable equilibria. The following lemma highlights that the interaction between the symmetric and antisymmetric components is important for convergence. Recall that two matrices $\mathbf{A}$ and $\mathbf{S}$ *commute* iff $[\mathbf{A}, \mathbf{S}] := \mathbf{AS} - \mathbf{SA} = \mathbf{0}$. That is, $\mathbf{A}$ and $\mathbf{S}$ commute iff $\mathbf{AS} = \mathbf{SA}$. Intuitively, two matrices commute if they have the same preferred coordinate system.

Lemma 6 *If $\mathbf{S} \succeq 0$ is symmetric positive semidefinite and $\mathbf{S}$ commutes with $\mathbf{A}$ then $\boldsymbol{\xi}_\lambda$ points towards stable fixed points for non-negative λ:*

$$\langle\boldsymbol{\xi}_\lambda, \nabla\mathcal{H}\rangle \geq 0 \textit{ for all } \lambda \geq 0.$$

Proof First observe that $\boldsymbol{\xi}^\intercal\mathbf{AS}\boldsymbol{\xi} = \boldsymbol{\xi}^\intercal\mathbf{S}^\intercal\mathbf{A}^\intercal\boldsymbol{\xi} = -\boldsymbol{\xi}^\intercal\mathbf{SA}\boldsymbol{\xi}$, where the first equality holds since the expression is a scalar, and the second holds since $\mathbf{S} = \mathbf{S}^\intercal$ and $\mathbf{A} = -\mathbf{A}^\intercal$. It follows that $\boldsymbol{\xi}^\intercal\mathbf{AS}\boldsymbol{\xi} = 0$ if $\mathbf{SA} = \mathbf{AS}$. Finally rewrite the inequality as

$$\langle\boldsymbol{\xi}_\lambda, \nabla\mathcal{H}\rangle = \langle\boldsymbol{\xi} + \lambda \cdot \mathbf{A}^\intercal\boldsymbol{\xi}, \mathbf{S}\boldsymbol{\xi} + \mathbf{A}^\intercal\boldsymbol{\xi}\rangle = \boldsymbol{\xi}^\intercal\mathbf{S}\boldsymbol{\xi} + \lambda\boldsymbol{\xi}^\intercal\mathbf{A}\mathbf{A}^\intercal\boldsymbol{\xi} \geq 0$$

since $\boldsymbol{\xi}^\intercal\mathbf{AS}\boldsymbol{\xi} = 0$ and by positivity of $\mathbf{S}$, λ and $\mathbf{AA}^\intercal$. ■

The lemma suggests that in general the *failure* of $\mathbf{A}$ and $\mathbf{S}$ to commute should be important for understanding the dynamics of $\boldsymbol{\xi}_\lambda$. We therefore introduce the **additive condition number** κ to upper-bound the worst-case noncommutativity of $\mathbf{S}$, which allows to quantify the relationship between $\boldsymbol{\xi}_\lambda$ and $\nabla\mathcal{H}$. If $\kappa = 0$, then $\mathbf{S} = \sigma \cdot \mathbf{I}$ commutes with *all* matrices. The larger the additive condition number κ, the larger the *potential* failure of $\mathbf{S}$ to commute with other matrices.

Theorem 7 *Let $\mathbf{S}$ be a symmetric matrix with eigenvalues $\sigma_{max} \geq \cdots \geq \sigma_{min}$. The **additive condition number**[4] of $\mathbf{S}$ is $\kappa := \sigma_{max} - \sigma_{min}$. If $\mathbf{S} \succeq 0$ is positive semidefinite with additive condition number κ then $\lambda \in (0, \frac{4}{\kappa})$ implies*

$$\langle\boldsymbol{\xi}_\lambda, \nabla\mathcal{H}\rangle \geq 0.$$

If $\mathbf{S}$ is negative semidefinite, then $\lambda \in (0, \frac{4}{\kappa})$ implies

$$\langle\boldsymbol{\xi}_{-\lambda}, \nabla\mathcal{H}\rangle \leq 0.$$

The inequalities are strict if $\mathbf{J}$ is invertible.

Proof We prove the case $\mathbf{S} \succeq 0$; the case $\mathbf{S} \preceq 0$ is similar. Rewrite the inequality as

$$\begin{aligned}\langle\boldsymbol{\xi} + \lambda \cdot \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H}\rangle &= (\boldsymbol{\xi} + \lambda \cdot \mathbf{A}^\intercal\boldsymbol{\xi})^\intercal \cdot (\mathbf{S} + \mathbf{A}^\intercal)\boldsymbol{\xi} \\ &= \boldsymbol{\xi}^\intercal\mathbf{S}\boldsymbol{\xi} + \lambda\boldsymbol{\xi}^\intercal\mathbf{AS}\boldsymbol{\xi} + \lambda\boldsymbol{\xi}^\intercal\mathbf{A}\mathbf{A}^\intercal\boldsymbol{\xi}\end{aligned}$$

4. The condition number of a positive definite matrix is $\frac{\sigma_{\max}}{\sigma_{\min}}$.

Let $\beta = \|A^\intercal \boldsymbol{\xi}\|$ and $\tilde{\mathbf{S}} = \mathbf{S} - \sigma_{\min} \cdot \mathbf{I}$, where $\mathbf{I}$ is the identity matrix. Then

$$\boldsymbol{\xi}^\intercal \mathbf{S}\boldsymbol{\xi} + \lambda \boldsymbol{\xi}^\intercal \mathbf{A}\mathbf{S}\boldsymbol{\xi} + \lambda \cdot \beta^2 \geq \boldsymbol{\xi}^\intercal \tilde{\mathbf{S}}\boldsymbol{\xi} + \lambda \boldsymbol{\xi}^\intercal \mathbf{A}\tilde{\mathbf{S}}\boldsymbol{\xi} + \lambda \cdot \beta^2$$

since $\boldsymbol{\xi}^\intercal \mathbf{S}\boldsymbol{\xi} \geq \boldsymbol{\xi}^\intercal \tilde{\mathbf{S}}\boldsymbol{\xi}$ by construction and $\boldsymbol{\xi}^\intercal \mathbf{A}\tilde{\mathbf{S}}\boldsymbol{\xi} = \boldsymbol{\xi}^\intercal \mathbf{A}\mathbf{S}\boldsymbol{\xi} - \sigma_{\min}\boldsymbol{\xi}^\intercal \mathbf{A}\boldsymbol{\xi} = \boldsymbol{\xi}^\intercal \mathbf{A}\mathbf{S}\boldsymbol{\xi}$ because $\boldsymbol{\xi}^\intercal \mathbf{A}\boldsymbol{\xi} = 0$ by the anti-symmetry of $\mathbf{A}$. It therefore suffices to show that the inequality holds when $\sigma_{\min} = 0$ and $\kappa = \sigma_{\max}$.

Since $\mathbf{S}$ is positive semidefinite, there exists an upper-triangular square-root matrix T such that $\mathbf{T}^\intercal \mathbf{T} = \mathbf{S}$ and so $\boldsymbol{\xi}^\intercal \mathbf{S}\boldsymbol{\xi} = \|\mathbf{T}\boldsymbol{\xi}\|^2$. Further,

$$|\boldsymbol{\xi}^\intercal \mathbf{A}\mathbf{S}\boldsymbol{\xi}| \leq \|\mathbf{A}^\intercal \boldsymbol{\xi}\| \cdot \|\mathbf{T}^\intercal \mathbf{T}\boldsymbol{\xi}\| \leq \sqrt{\sigma_{\max}} \cdot \|\mathbf{A}^\intercal \boldsymbol{\xi}\| \cdot \|\mathbf{T}\boldsymbol{\xi}\|.$$

since $\|\mathbf{T}\|_2 = \sqrt{\sigma_{\max}}$. Putting the observations together obtains

$$\begin{aligned}
\|\mathbf{T}\boldsymbol{\xi}\|^2 + \lambda(\|\mathbf{A}\boldsymbol{\xi}\|^2 - \langle \mathbf{A}\boldsymbol{\xi}, \mathbf{S}\boldsymbol{\xi}\rangle) &\geq \|\mathbf{T}\boldsymbol{\xi}\|^2 + \lambda(\|\mathbf{A}\boldsymbol{\xi}\|^2 - \|\mathbf{A}\boldsymbol{\xi}\| \, \|\mathbf{S}\boldsymbol{\xi}\| \\
&\geq \|\mathbf{T}\boldsymbol{\xi}\|^2 + \lambda\|\mathbf{A}\boldsymbol{\xi}\|(\|\mathbf{A}\boldsymbol{\xi}\| - \|\mathbf{S}\boldsymbol{\xi}\|) \\
&\geq \|\mathbf{T}\boldsymbol{\xi}\|^2 + \lambda\|\mathbf{A}\boldsymbol{\xi}\|(\|\mathbf{A}\boldsymbol{\xi}\| - \sqrt{\sigma_{max}}\|\mathbf{T}\boldsymbol{\xi}\|)
\end{aligned}$$

Set $\alpha = \sqrt{\lambda}$ and $\eta = \sqrt{\sigma_{max}}$. We can continue the above computation

$$\begin{aligned}
\|\mathbf{T}\boldsymbol{\xi}\|^2 + \lambda(\|\mathbf{A}\boldsymbol{\xi}\|^2 - \langle \mathbf{A}\boldsymbol{\xi}, \mathbf{S}\boldsymbol{\xi}\rangle) &\geq \|\mathbf{T}\boldsymbol{\xi}\|^2 + \alpha^2\|\mathbf{A}\boldsymbol{\xi}\|(\|\mathbf{A}\boldsymbol{\xi}\| - \eta\|\mathbf{T}\boldsymbol{\xi}\|) \\
&= \|\mathbf{T}\boldsymbol{\xi}\|^2 + \alpha^2\|\mathbf{A}\boldsymbol{\xi}\|^2 - \alpha^2\|\mathbf{A}\boldsymbol{\xi}\|\eta\|\mathbf{T}\boldsymbol{\xi}\| \\
&= (\|\mathbf{T}\boldsymbol{\xi}\| - \alpha\|\mathbf{A}\boldsymbol{\xi}\|)^2 + 2\alpha\|\mathbf{A}\boldsymbol{\xi}\| \, \|\mathbf{T}\boldsymbol{\xi}\| - \alpha^2\eta\|A\boldsymbol{\xi}\| \, \|\mathbf{T}\boldsymbol{\xi}\| \\
&= (\|\mathbf{T}\boldsymbol{\xi}\| - \alpha\|\mathbf{A}\boldsymbol{\xi}\|)^2 + \|\mathbf{A}\boldsymbol{\xi}\| \, \|\mathbf{T}\boldsymbol{\xi}\|(2\alpha - \alpha^2\eta)
\end{aligned}$$

Finally, $2\alpha - \alpha^2\eta > 0$ for any α in the range $(0, \frac{2}{\eta})$, which is to say, for any $0 < \lambda < \frac{4}{\sigma_{max}}$. The kernel of $\mathbf{S}$ and the kernel of $\mathbf{T}$ coincide. If $\boldsymbol{\xi}$ is in the kernel of $\mathbf{A}$, resp. $\mathbf{T}$, it cannot be in the kernel of $\mathbf{T}$, resp. $\mathbf{A}$ and the term $(\|\mathbf{T}\boldsymbol{\xi}\| - \alpha\|\mathbf{A}\boldsymbol{\xi}\|)^2$ is positive. Otherwise, the term $\|\mathbf{A}\boldsymbol{\xi}\|\|\mathbf{T}\boldsymbol{\xi}\|$ is positive. ■

The theorem above guarantees that SGA always points in the direction of stable fixed points for λ sufficiently small. This does not technically guarantee convergence; we use Ostrowski's theorem to strengthen this formally. Applying Ostrowski's theorem will require taking a more abstract perspective by encoding the adjusted dynamics into a differentiable map $F : \Omega \to \mathbb{R}^d$ of the form $F(\mathbf{w}) = \mathbf{w} - \alpha\boldsymbol{\xi}_\lambda(\mathbf{w})$.

Theorem 8 (Ostrowski) *Let $F : \Omega \to \mathbb{R}^d$ be a continuously differentiable map on an open subset $\Omega \subseteq \mathbb{R}^d$, and assume $\mathbf{w}^* \in \Omega$ is a fixed point. If all eigenvalues of $\nabla F(\mathbf{w}^*)$ are strictly in the unit circle of $\mathbb{C}$, then there is an open neighbourhood U of $\mathbf{w}^*$ such that for all $\mathbf{w}_0 \in U$, the sequence $F^k(\mathbf{w}_0)$ of iterates of F converges to $\mathbf{w}^*$. Moreover, the rate of convergence is at least linear in k.*

Proof This is a standard result on fixed-point iterations, adapted from Ortega and Rheinboldt (2000, 10.1.3). ■

Corollary 9 *A matrix $\mathbf{M}$ is called positive stable if all its eigenvalues have positive real part. Assume $\mathbf{w}^*$ is a fixed point of a differentiable game such that $(\mathbf{I} + \lambda\mathbf{A}^\intercal)\mathbf{J}(\mathbf{w}^*)$ is positive stable for λ in some set Λ. Then SGA converges locally to $\mathbf{w}^*$ for $\lambda \in \Lambda$ and $\alpha > 0$ sufficiently small.*

Proof Let $X = (\mathbf{I} + \lambda\mathbf{A}^\intercal)$. By definition of fixed points, $\boldsymbol{\xi}(\mathbf{w}^*) = 0$ and so

$$\nabla[X\boldsymbol{\xi}](\mathbf{w}^*) = \nabla X(\mathbf{w}^*)\boldsymbol{\xi}(\mathbf{w}^*) + X(\mathbf{w}^*)\nabla\boldsymbol{\xi}(\mathbf{w}^*) = X\mathbf{J}(\mathbf{w}^*)$$

is positive stable by assumption, namely has eigenvalues $a_k + ib_k$ with $a_k > 0$. Writing $F(\mathbf{w}) = \mathbf{w} - \alpha X\boldsymbol{\xi}(\mathbf{w})$ for the iterative procedure given by SGA, it follows that

$$\nabla F(\mathbf{w}^*) = \mathbf{I} - \alpha\nabla[X\boldsymbol{\xi}](\mathbf{w}^*)$$

has eigenvalues $1 - \alpha a_k - i\alpha b_k$, which are in the unit circle for small α. More precisely,

$$\begin{aligned}
|1 - \alpha a_k - i\alpha b_k|^2 < 1 \quad &\iff \quad 1 - 2\alpha a_k + \alpha^2 a_k^2 + \alpha^2 b_k^2 < 1 \\
&\iff \quad 0 < \alpha < \frac{2a_k}{a_k^2 + b_k^2}
\end{aligned}$$

which is always possible for $a_k > 0$. Hence $\nabla F(\mathbf{w}^*)$ has eigenvalues in the unit circle for $0 < \alpha < \min_k 2a_k/(a_k^2 + b_k^2)$, and we are done by Ostrowski's Theorem since $\mathbf{w}^*$ is a fixed point of F. ■

Theorem 10 *Let $\mathbf{w}^*$ be a stable fixed point and κ the additive condition number of $\mathbf{S}(\mathbf{w}^*)$. Then SGA converges locally to $\mathbf{w}^*$ for all $\lambda \in (0, \frac{4}{\kappa})$ and $\alpha > 0$ sufficiently small.*

Proof By Theorem 5 and the assumption that $\mathbf{w}^*$ is a stable fixed point with invertible Jacobian, we know that

$$\langle \boldsymbol{\xi}_\lambda, \nabla\mathcal{H}\rangle = \langle (\mathbf{I} + \lambda\mathbf{A}^\intercal)\boldsymbol{\xi}, \mathbf{J}^\intercal\boldsymbol{\xi}\rangle > 0$$

for $\lambda \in (0, \frac{4}{\kappa})$. The proof does not rely on any particular property of $\boldsymbol{\xi}$, and can trivially be extended to the claim that

$$\langle (\mathbf{I} + \lambda\mathbf{A}^\intercal)\mathbf{u}, \mathbf{J}^\intercal\mathbf{u}\rangle > 0$$

for all non-zero vectors $\mathbf{u}$. In particular this can be rewritten as

$$\mathbf{u}^\intercal\mathbf{J}(\mathbf{I} + \lambda\mathbf{A}^\intercal)\mathbf{u}\rangle > 0\,,$$

which implies positive definiteness of $\mathbf{J}(\mathbf{I} + \lambda\mathbf{A}^\intercal)$. A positive definite matrix is positive stable, and any matrices AB and BA have identical spectrum. This implies also that $(\mathbf{I} + \lambda\mathbf{A}^\intercal)\mathbf{J}$ is positive stable, and we are done by the corollary above. ■

We conclude that SGA converges to an SFP if λ is small enough, where 'small enough' depends on the additive condition number.

3.5. Picking $\text{sign}(\lambda)$

This section explains desiderata $D4$—$D5$ and shows how to pick $\text{sign}(\lambda)$ to speed up convergence towards stable and away from unstable fixed points. In the example below, almost any choice of positive λ results in convergence to an unstable equilibrium. The problem arises from the combination of a weak repellor with a strong rotational force.

Example 9 (failure case for $\lambda > 0$)
Suppose $\epsilon > 0$ is small and

$$\ell_1(x, y) = -\frac{\epsilon}{2}x^2 - xy \;\; \textit{and} \;\; \ell_2(x, y) = -\frac{\epsilon}{2}y^2 + xy$$

with an unstable equilibrium at $(0, 0)$. The dynamics are

$$\boldsymbol{\xi} = \epsilon \cdot \begin{pmatrix} -x \\ -y \end{pmatrix} + \begin{pmatrix} -y \\ x \end{pmatrix} \quad \textit{with} \quad \mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

and

$$\mathbf{A}^\intercal \boldsymbol{\xi} = \begin{pmatrix} x \\ y \end{pmatrix} + \epsilon \begin{pmatrix} -y \\ x \end{pmatrix}$$

Finally observe that

$$\boldsymbol{\xi} + \lambda \cdot \mathbf{A}^\intercal \boldsymbol{\xi} = (\lambda - \epsilon) \cdot \begin{pmatrix} x \\ y \end{pmatrix} + (1 + \epsilon\lambda) \cdot \begin{pmatrix} -y \\ x \end{pmatrix}$$

which converges to the unstable equilibrium if $\lambda > \epsilon$.

We now show how to pick the sign of λ to avoid unstable equilibria. First, observe that $\langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle = \boldsymbol{\xi}^\intercal(\mathbf{S} + \mathbf{A})^\intercal \boldsymbol{\xi} = \boldsymbol{\xi}^\intercal \mathbf{S} \boldsymbol{\xi}$. It follows that for $\boldsymbol{\xi} \neq 0$:

$$\begin{cases} \text{if} \quad \mathbf{S} \succeq 0 \quad \text{then } \langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle \geq 0; \\ \text{if} \quad \mathbf{S} \prec 0 \quad \text{then } \langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle < 0. \end{cases} \tag{2}$$

A criterion to probe the positive/negative definiteness of $\mathbf{S}$ is thus to check the sign of $\langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle$. The dot product can take any value if $\mathbf{S}$ is neither positive nor negative (semi-)definite. The behavior near saddle points will be explored in Section 3.7.

Recall that desiderata $D4$ requires that, if $\boldsymbol{\xi}$ points at a stable equilibrium then we require that $\boldsymbol{\xi}_\lambda$ points *more* towards the equilibrium (i.e. has smaller angle). Conversely, desiderata $D5$ requires that, if $\boldsymbol{\xi}$ points away then the adjustment should point *further* away. More formally,

Definition 6 *Let $\mathbf{u}$ and $\mathbf{v}$ be two vectors. The **infinitesimal alignment** of $\boldsymbol{\xi}_\lambda := \mathbf{u} + \lambda \cdot \mathbf{v}$ with a third vector $\mathbf{w}$ is*

$$\text{align}(\boldsymbol{\xi}_\lambda, \mathbf{w}) := \frac{d}{d\lambda} \left\{ \cos^2 \theta_\lambda \right\}_{|\lambda=0} \;\; \textit{for} \;\; \theta_\lambda := \theta(\boldsymbol{\xi}_\lambda, \mathbf{w}).$$

If $\mathbf{u}$ and $\mathbf{w}$ point the same way, $\mathbf{u}^\intercal \mathbf{w} > 0$, then align > 0 when $\mathbf{v}$ bends $\mathbf{u}$ further toward $\mathbf{w}$, see Figure 2A. Otherwise align > 0 when $\mathbf{v}$ bends $\mathbf{u}$ away from $\mathbf{w}$, see Figure 2B.

The following lemma allows us to rewrite the infinitesimal alignment in terms of known (computable) quantities, from which we can deduce the correct choice of λ.

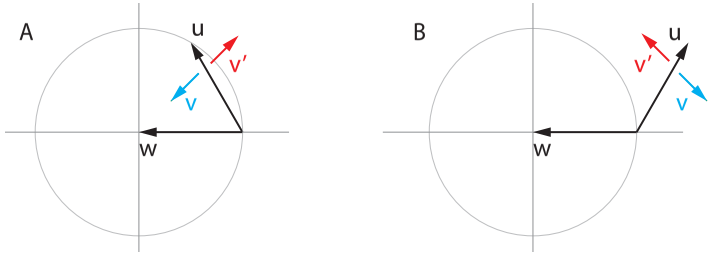

Figure 2: *Infinitesimal alignment* between $\mathbf{u} + \lambda\mathbf{v}$ and $\mathbf{w}$ is positive (cyan) when small positive λ either: **(A)** pulls $\mathbf{u}$ toward $\mathbf{w}$, if $\mathbf{w}$ and $\mathbf{u}$ have angle $< 90°$; or **(B)** pushes $\mathbf{u}$ away from $\mathbf{w}$ if their angle is $> 90°$. Conversely, the infinitesimal alignment is negative (red) when small positive λ either: **(A)** pushes $\mathbf{u}$ away from $\mathbf{w}$ when their angle is acute or **(B)** pulls $\mathbf{u}$ toward $\mathbf{w}$ when their angle is obtuse.

Algorithm 1 Symplectic Gradient Adjustment

Input: losses $\mathcal{L} = \{\ell_i\}_{i=1}^n$, weights $\mathcal{W} = \{\mathbf{w}_i\}_{i=1}^n$
$\boldsymbol{\xi} \leftarrow \left[\texttt{gradient}(\ell_i, \mathbf{w}_i) \;\; \texttt{for} \;\; (\ell_i, \mathbf{w}_i) \in (\mathcal{L}, \mathcal{W})\right]$
$\mathbf{A}^\intercal\boldsymbol{\xi} \leftarrow \texttt{get_sym_adj}(\mathcal{L}, \mathcal{W})$ // appendix A
if `align` **then**
  $\nabla\mathcal{H} \leftarrow \left[\texttt{gradient}(\frac{1}{2}\|\boldsymbol{\xi}\|^2, \mathbf{w}) \;\; \texttt{for} \;\; \mathbf{w} \in \mathcal{W})\right]$
  $\lambda \leftarrow \texttt{sign}\Big(\frac{1}{d}\langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle \langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H} \rangle + \epsilon\Big)$ // $\epsilon = \frac{1}{10}$
else
  $\lambda \leftarrow 1$
end if
Output: $\boldsymbol{\xi} + \lambda \cdot \mathbf{A}^\intercal\boldsymbol{\xi}$ // plug into any optimizer

Lemma 11 *When $\boldsymbol{\xi}_\lambda$ is the symplectic gradient adjustment,*

$$\text{sign}\left(\text{align}(\boldsymbol{\xi}_\lambda, \nabla\mathcal{H})\right) = \text{sign}\left(\langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle \cdot \langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H} \rangle\right).$$

Proof Observe that

$$\cos^2\theta_\lambda = \left(\frac{\langle \boldsymbol{\xi}_\lambda, \nabla\mathcal{H} \rangle}{\|\boldsymbol{\xi}_\lambda\| \cdot \|\nabla\mathcal{H}\|}\right)^2 = \frac{\langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle + 2\lambda \langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle \langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H} \rangle + O(\lambda^2)}{\left(\|\boldsymbol{\xi}\|^2 + O(\lambda^2)\right) \cdot \|\nabla\mathcal{H}\|^2}$$

where the denominator has no linear term in λ because $\boldsymbol{\xi} \perp \mathbf{A}^\intercal\boldsymbol{\xi}$. It follows that the sign of the infinitesimal alignment is

$$\text{sign}\left\{\frac{d}{d\lambda}\cos^2\theta_\lambda\right\} = \text{sign}\left\{\langle \boldsymbol{\xi}, \nabla\mathcal{H} \rangle \langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H} \rangle\right\}$$

as required. ■

Intuitively, computing the sign of $\langle \boldsymbol{\xi}, \nabla\mathcal{H}\rangle$ provides a check for stable and unstable fixed points. Computing the sign of $\langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H}\rangle$ checks whether the adjustment term points towards or away from the nearby fixed point. Putting the two checks together yields a prescription for the sign of λ, as follows.

Proposition 12 *Desiderata D4—D5 are satisfied for λ such that $\lambda \cdot \langle \boldsymbol{\xi}, \nabla\mathcal{H}\rangle \cdot \langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H}\rangle \geq 0$.*

Proof If we are in a neighborhood of a stable fixed point then $\langle \boldsymbol{\xi}, \nabla\mathcal{H}\rangle \geq 0$. It follows by Lemma 11 that $\text{sign}\left(\text{align}(\boldsymbol{\xi}_\lambda), \nabla\mathcal{H}\right) = \text{sign}\left(\langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H}\rangle\right)$ and so choosing $\text{sign}(\lambda) = \text{sign}\left(\langle \mathbf{A}^\intercal\boldsymbol{\xi}, \nabla\mathcal{H}\rangle\right)$ leads to the angle between $\boldsymbol{\xi}_\lambda$ and $\nabla\mathcal{H}$ being smaller than the angle between $\boldsymbol{\xi}$ and $\nabla\mathcal{H}$, satisfying desideratum $D4$. The proof for the unstable case is similar. ■

3.5.1. Alignment and Convergence Rates

Gradient descent is also known as the method of steepest descent. In general games, however, $\boldsymbol{\xi}$ does not follow the steepest path to fixed points due to the 'rotational force', which forces lower learning rates and slows down convergence.

The following lemma provides some intuition about alignment. The idea is that, the smaller the cosine between the 'correct direction' $\mathbf{w}$ and the 'update direction' $\boldsymbol{\xi}$, the smaller the learning rate needs to be for the update to stay in a unit ball, see Figure 3.

Lemma 13 (Alignment Lemma)
If $\mathbf{w}$ and $\boldsymbol{\xi}$ are unit vectors with $0 < \mathbf{w}^\intercal\boldsymbol{\xi}$ then $\|\mathbf{w} - \eta\cdot\boldsymbol{\xi}\| \leq 1$ for $0 \leq \eta \leq 2\mathbf{w}^\intercal\boldsymbol{\xi} = 2\cos\theta(\mathbf{w}, \boldsymbol{\xi})$. In other words, ensuring that $\mathbf{w} - \eta\boldsymbol{\xi}$ is closer to the origin than $\mathbf{w}$ requires smaller learning rates η as the angle between $\mathbf{w}$ and $\boldsymbol{\xi}$ gets larger.

Proof Check $\|\mathbf{w} - \eta\cdot\boldsymbol{\xi}\|^2 = 1 + \eta^2 - 2\eta\cdot\mathbf{w}^\intercal\boldsymbol{\xi} \leq 1$ iff $\eta^2 \leq 2\eta\cdot\mathbf{w}^\intercal\boldsymbol{\xi}$. The result follows. ■

The next lemma is a standard technical result from the convex optimization literature.

Lemma 14 *Let $f : \mathbb{R}^d \to \mathbb{R}$ be a convex Lipschitz smooth function satisfying $\|\nabla f(\mathbf{y}) - \nabla f(\mathbf{x})\| \leq L\cdot\|\mathbf{y} - \mathbf{x}\|$ for all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$. Then*

$$|f(\mathbf{y}) - f(\mathbf{x}) - \langle \nabla f(\mathbf{x}), \mathbf{y} - \mathbf{x}\rangle| \leq \frac{L}{2}\cdot\|\mathbf{y} - \mathbf{x}\|^2$$

for all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$.

Proof See Nesterov (2004). ■

Finally, we show that increasing alignment helps speed convergence:

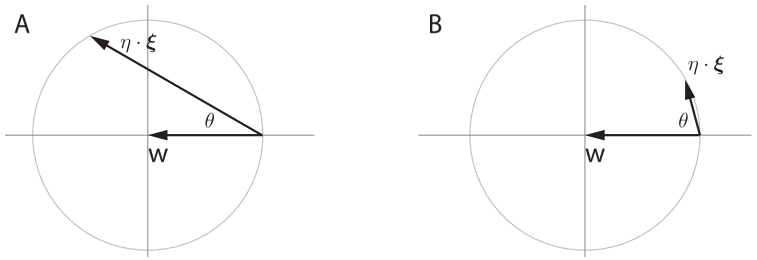

Figure 3: *Alignment and learning rates.* The larger $\cos\theta$, the larger the learning rate η that can be applied to unit vector $\boldsymbol{\xi}$ without $\mathbf{w} + \eta\cdot\boldsymbol{\xi}$ leaving the unit circle.

Theorem 15 *Suppose f is convex and Lipschitz smooth with $\|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\| \leq L\cdot\|\mathbf{x} - \mathbf{y}\|$. Let $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta\cdot\mathbf{v}$ where $\|\mathbf{v}\| = \|\nabla f(\mathbf{w}_t)\|$. Then the optimal step size is $\eta^* = \frac{\cos\theta}{L}$ where $\theta := \theta(\nabla f(\mathbf{w}_t), \mathbf{v})$, with*

$$f(\mathbf{w}_{t+1}) \leq f(\mathbf{w}_t) - \frac{\cos^2\theta}{2L}\cdot\|\nabla f(\mathbf{w}_t)\|^2.$$

The proof of Theorem 15 adapts Lemma 14 to handle the angle arising from the 'rotational force'.

Proof By the Lemma 14,

$$\begin{aligned} f(\mathbf{y}) &\leq f(\mathbf{x}) + \langle \nabla f(\mathbf{x}), \mathbf{y} - \mathbf{x}\rangle + \frac{L}{2}\|\mathbf{y} - \mathbf{x}\|^2 \\ &= f(\mathbf{x}) - \eta\cdot\langle \nabla f, \boldsymbol{\xi}\rangle + \eta^2\frac{L}{2}\cdot\|\boldsymbol{\xi}\|^2 \\ &= f(\mathbf{x}) - \eta\cdot\langle \nabla f, \boldsymbol{\xi}\rangle + \eta^2\frac{L}{2}\cdot\|\nabla f\|^2 \\ &= f(\mathbf{x}) - \eta(\alpha - \frac{\eta}{2}L)\cdot\|\nabla f\|^2 \end{aligned}$$

where $\alpha := \cos\theta$. Solve

$$\min_\eta \Delta(\eta) = \min_\eta \left\{-\eta(\alpha - \frac{\eta}{2}L)\right\}$$

to obtain $\eta^* = \frac{\alpha}{L}$ and $\Delta(\eta^*) = -\frac{\alpha^2}{2}L$ as required. ■

Increasing the cosine with the steepest direction improves convergence. The alignment computation in algorithm 1 chooses λ to be positive or negative such that $\boldsymbol{\xi}_\lambda$ is bent towards stable (increasing the cosine) and away from unstable fixed points. Adding a small $\epsilon > 0$ to the computation introduces a weak bias towards stable fixed points.

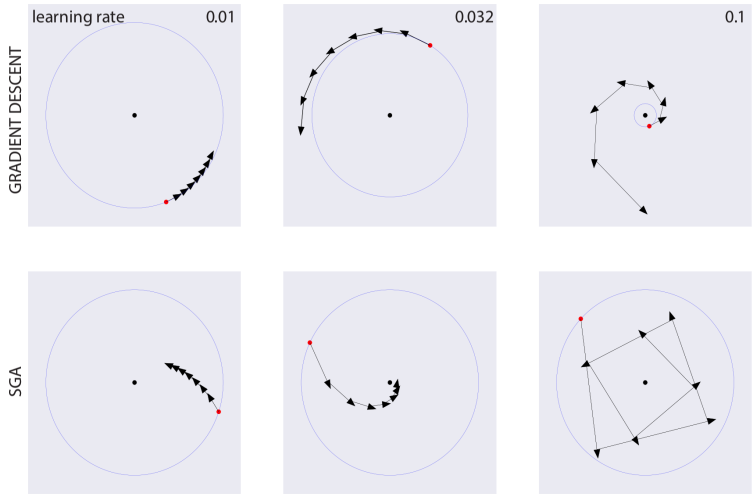

Figure 4: SGA allows faster and more robust convergence to stable fixed points than vanilla gradient descent in the presence of 'rotational forces', by bending the direction of descent towards the fixed point. Note the gradient descent diverges extremely rapidly in the top-right panel, which has a different scale from the other panels.

3.6. Aligned Consensus Optimization

The stability criterion in Equation (2) also provides a simple way to prevent consensus optimization from converging to unstable equilibria. **Aligned consensus optimization** is

$$\boldsymbol{\xi} + |\lambda| \cdot \operatorname{sign}\left(\langle \boldsymbol{\xi}, \nabla \mathcal{H} \rangle\right) \cdot \mathbf{J}^\intercal \boldsymbol{\xi}, \tag{3}$$

where in practice we set $\lambda = 1$. Aligned consensus optimization satisfies desiderata *D3*—*D5*. However, it behaves strangely in potential games. Multiplying by the Jacobian is the 'inverse' of Newton's method since for potential games the Jacobian of $\boldsymbol{\xi}$ is the Hessian of the potential function. Multiplying by the Hessian increases the gap between small and large eigenvalues, increasing the (usual, multiplicative) condition number and slows down convergence. Nevertheless, consensus optimization works well in GANs (Mescheder et al., 2017), and aligned consensus may improve performance, see experiments below.

Dropping the first term $\boldsymbol{\xi}$ from Equation (3) yields a simpler update that also satisfies *D3*—*D5*. However, the resulting algorithm performs poorly in experiments (not shown), perhaps because it is attracted to saddles.

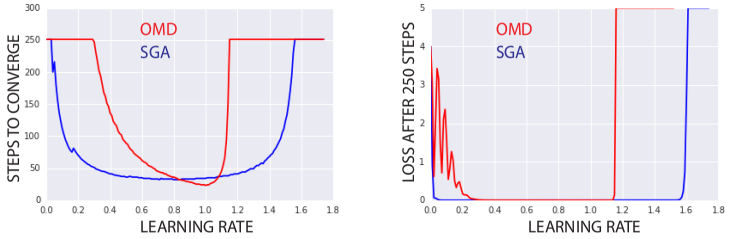

Figure 5: Comparison of SGA with optimistic mirror descent. The plots sweep over learning rates in range $[0.01, 1.75]$, with $\lambda = 1$ throughout for SGA. **(Left):** iterations to convergence, with maximum value of 250 after which the run was interrupted. **(Right):** average absolute value of losses over the last 10 iterations, 240-250, with a cutoff at 5.

3.7. Avoiding Strict Saddles

How does SGA behave near saddles? We show that Symplectic Gradient Adjustment locally avoids strict saddles, provided that λ and α are small and parameters are initialized with (arbitrarily small) noise. More precisely, let $\mathbf{F}(\mathbf{w}) = \mathbf{w} - \alpha \boldsymbol{\xi}_\lambda(\mathbf{w})$ be the iterative optimization procedure given by SGA. Then every strict saddle $\mathbf{w}^*$ has a neighbourhood U such that $\{\mathbf{w} \in U \mid \mathbf{F}^n(\mathbf{w}) \to \mathbf{w}^* \text{ as } n \to \infty\}$ has measure zero for small $\alpha > 0$ and λ.

Intuitively, the Taylor expansion around a strict saddle $\mathbf{w}^*$ is locally dominated by the Jacobian at $\mathbf{w}^*$, which has a negative eigenvalue. This prevents convergence to $\mathbf{w}^*$ for random initializations of $\mathbf{w}$ near $\mathbf{w}^*$. The argument is made rigorous using the Stable Manifold Theorem following Lee et al. (2017).

Theorem 16 (Stable Manifold Theorem)
Let $\mathbf{w}^*$ be a fixed point for the C^1 local diffeomorphism $F : U \to \mathbb{R}^d$, where U is a neighbourhood of $\mathbf{w}^*$ in $\mathbb{R}^d$. Let $E^s \oplus E^u$ be the generalized eigenspaces of $\nabla F(\mathbf{w}^*)$ corresponding to eigenvalues with $|\sigma| \leq 1$ and $|\sigma| > 1$ respectively. Then there exists a local stable center manifold W with tangent space E^s at $\mathbf{w}^*$ and a neighbourhood B of $\mathbf{w}^*$ such that $F(W) \cap B \subset W$ and $\cap_{n=0}^{\infty} F^{-n}(B) \subset W$.

Proof See Shub (2000). ■

It follows that if $\nabla F(\mathbf{w}^*)$ has at least one eigenvalue $|\sigma| > 1$ then E^u has dimension at least 1. Since W has tangent space E^s at $\mathbf{w}^*$ with codimension at least one, we conclude that W has measure zero. This is central to proving that the set of nearby initial points which converge to a given strict saddle $\mathbf{w}^*$ has measure zero. Since $\mathbf{w}$ is initialized randomly, the following theorem is obtained.

Theorem 17 *SGA locally avoids strict saddles almost surely, for $\alpha > 0$ and λ small.*

Proof Let $\mathbf{w}^*$ a strict saddle and recall that SGA is given by

$$F(\mathbf{w}) = \mathbf{w} - \alpha(\mathbf{I} - \alpha\mathbf{J})\boldsymbol{\xi}(\mathbf{w})\,.$$

All terms involved are continuously differentiable and we have

$$\nabla F(\mathbf{w}^*) = \mathbf{I} - \alpha(\mathbf{I} - \alpha\mathbf{J})\mathbf{J}(\mathbf{w}^*)$$

by assumption that $\boldsymbol{\xi}(\mathbf{w}^*) = 0$. Since all terms except $\mathbf{I}$ are of order at least α, $\nabla F(\mathbf{w}^*)$ is invertible for all α sufficiently small. By the inverse function theorem, there exists a neighbourhood U of $\mathbf{w}^*$ such that F is has a continuously differentiable inverse on U. Hence F restricted to U is a C^1 diffeomorphism with fixed point $\mathbf{w}^*$.

By definition of strict saddles, $\mathbf{J}(\mathbf{w}^*)$ has an eigenvalue with negative real part. It follows by continuity that $(\mathbf{I} - \alpha\mathbf{J})\mathbf{J}(\mathbf{w}^*)$ also has an eigenvalue $a + ib$ with $a < 0$ for α sufficiently small. Finally,

$$\nabla F(\mathbf{w}^*) = \mathbf{I} - \alpha(\mathbf{I} - \alpha\mathbf{J})\mathbf{J}(\mathbf{w}^*)$$

has an eigenvalue $\sigma = 1 - \alpha a - i\alpha b$ with

$$|\sigma| = 1 - 2\alpha a + \alpha^2(a^2 + b^2) \geq 1 - 2\alpha a > 1\,.$$

It follows that E^s has codimension at least one, implying in turn that the local stable set W has measure zero. We can now prove that

$$Z = \{\mathbf{w} \in U \mid \lim_{n\to\infty} F^n(\mathbf{w}) = \mathbf{w}^*\}$$

has measure zero, or in other words, that local convergence to $\mathbf{w}^*$ occurs with zero probability. Let B the neighbourhood guaranteed by the Stable Manifold Theorem, and take any $\mathbf{w} \in Z$. By definition of convergence there exists $N \in \mathbb{N}$ such that $F^{N+n}(\mathbf{w}) \in B$ for all $n \in \mathbb{N}$, so that

$$F^N(\mathbf{w}) \in \cap_{n\in\mathbb{N}}^{\infty} F^{-n}(B) \subset W$$

by the Stable Manifold Theorem. This implies that $\mathbf{w} \in F^{-N}(W)$, and by extension $\mathbf{w} \in \cup_{n\in\mathbb{N}} F^{-n}(W)$. Since $\mathbf{w}$ was arbitrary, we obtain the inclusion

$$Z \subseteq \cup_{n\in\mathbb{N}} F^{-n}(W)\,.$$

Now F^{-1} is C^1, hence locally Lipschitz and thus preserves sets of measure zero, so that $F^{-n}(W)$ has measure zero for each n. Countable unions of measure zero sets are still measure zero, so we conclude that Z also has measure zero. In other words, SGA converges to $\mathbf{w}^*$ with zero probability upon random initialization of $\mathbf{w}$ in U. ■

Unlike stable and unstable fixed points, it is unclear how to avoid strict saddles using only alignment, that is, independently from the size of λ.

4. Experiments

We compare SGA with simultaneous gradient descent, optimistic mirror descent (Daskalakis et al., 2018) and consensus optimization (Mescheder et al., 2017) in basic settings.

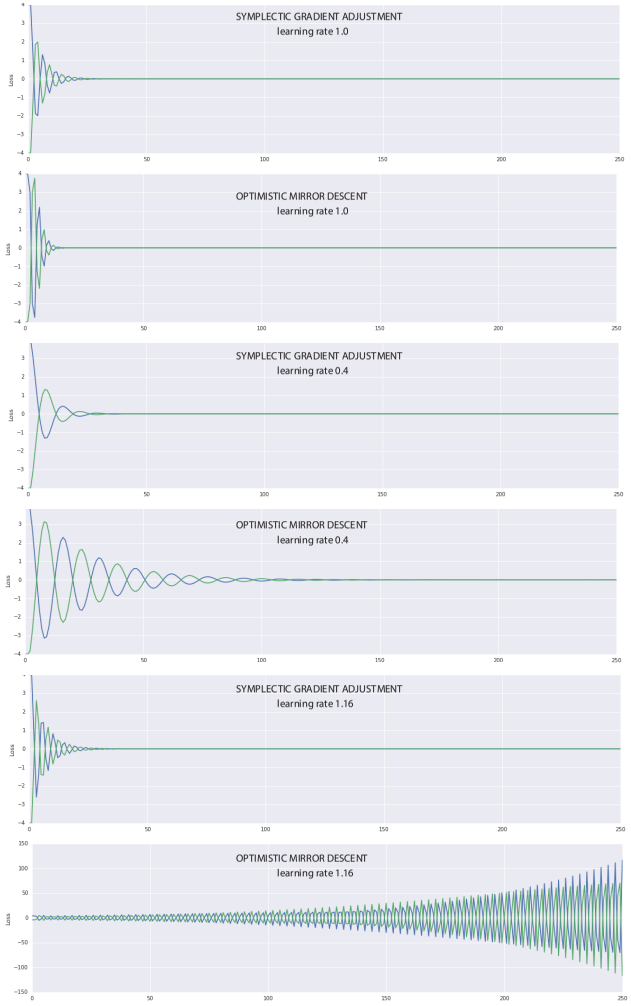

Figure 6: Individual runs on zero-sum bimatrix game in Section 4.2.

4.1. Learning rates and alignment

We investigate the effect of SGA when a weak attractor is coupled to a strong rotational force:

$$\ell_1(x,y) = \frac{1}{2}x^2 + 10xy \quad \text{and} \quad \ell_2(x,y) = \frac{1}{2}y^2 - 10xy$$

Gradient descent is extremely sensitive to the choice of learning rate η, top row of Figure 4. As η increases through $\{0.01, 0.032, 0.1\}$ gradient descent goes from converging extremely slowly, to diverging slowly, to diverging rapidly. SGA yields faster, more robust convergence. SGA converges faster with learning rates $\eta = 0.01$ and $\eta = 0.032$, and only starts overshooting the fixed point for $\eta = 0.1$.

4.2. Basic adversarial games

Optimistic mirror descent is a family of algorithms that has nice convergence properties in games (Rakhlin and Sridharan, 2013; Syrgkanis et al., 2015). In the special case of optimistic *gradient* descent the updates are

$$\mathbf{w}_{t+1} \leftarrow \mathbf{w}_t - \eta \cdot \boldsymbol{\xi}_t - \eta \cdot (\boldsymbol{\xi}_t - \boldsymbol{\xi}_{t-1}).$$

Figure 5 compares SGA with optimistic gradient descent (OMD) on a zero-sum bimatrix game with $\ell_{1/2}(\mathbf{w}_1, \mathbf{w}_2) = \pm \mathbf{w}_1^\intercal \mathbf{w}_2$. The example is modified from Daskalakis et al. (2018) who also consider a linear offset that makes no difference. A run is taken to have converged if the average absolute value of losses on the last 10 iterations is < 0.01; we end each experiment after 250 steps.

The left panel shows the number of steps to convergence (when convergence occurs) over a range of learning rates. OMD's peak performance is better than SGA, where the red curve dips below the blue. Howwever, we find that SGA converges—and does so faster—for a much wider range of learning rates. OMD diverges for learning rates not in the range [0.3, 1.2]. Simultaneous gradient descent oscillates without converging (not shown). The right panel shows the average performance of OMD and SGA on the last 10 steps. Once again, here SGA consistently performs better over a wider range of learning rates. Individual runs are shown in Figure 6.

4.2.1. OMD and SGA on a Four-Player Game

Figure 7 shows time to convergence (using the same convergence criterion as above) for optimistic mirror descent and SGA. The games are constructed with four players, each of which controls one parameter. The losses are

$$\ell_1(w,x,y,z) = \frac{\epsilon}{2}w^2 + wx + wy + wz$$
$$\ell_2(w,x,y,z) = -wx + \frac{\epsilon}{2}x^2 + xy + xz$$

$$\ell_3(w,x,y,z) = -wy - xy + \frac{\epsilon}{2}y^2 + yz$$
$$\ell_4(w,x,y,z) = -wz - xz - yz + \frac{\epsilon}{2}z^2,$$

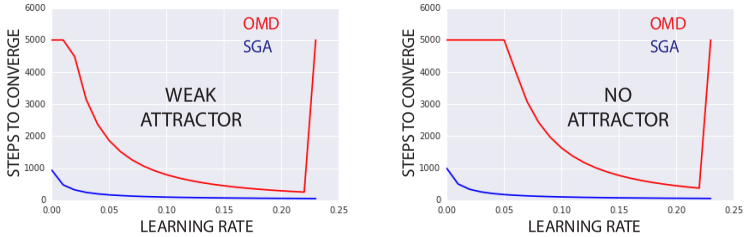

Figure 7: Time to convergence of OMD and SGA on two 4-player games. Times are cutoff after 5000 iterations. **Left panel:** Weakly positive definite $\mathbf{S}$ with $\epsilon = \frac{1}{100}$. **Right panel:** Symmetric component is identically zero.

where $\epsilon = \frac{1}{100}$ in the left panel and $\epsilon = 0$ in the right panel. The antisymmetric component of the game Jacobian is

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 & 1 \\ -1 & 0 & 1 & 1 \\ -1 & -1 & 0 & 1 \\ -1 & -1 & -1 & 0 \end{pmatrix}$$

and the symmetric component is

$$\mathbf{S} = \epsilon \cdot \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

OMD converges considerably slower than SGA across the full range of learning rates. It also diverges for learning rates > 0.22. In contrast, SGA converges more quickly and robustly.

4.3. Learning a two-dimensional mixture of Gaussians

We apply SGA to a basic Generative Adversarial Network setup adapted from Metz et al. (2017). Data is sampled from a highly multimodal distribution designed to probe the tendency of GANs to collapse onto a subset of modes during training. The distribution is a mixture of 16 Gaussians arranged in a 4×4 grid. Figure 8 shows the probability distribution that is sampled to train the generator and discriminator. The generator and discriminator networks both have 6 ReLU layers of 384 neurons. The generator has two output neurons; the discriminator has one.

Figure 9 shows results after $\{2000, 4000, 6000, 8000\}$ iterations. The networks are trained under RMSProp. Learning rates were chosen by visual inspection of grid search results at iteration 8000. More precisely, grid search was over learning rates {1e-5, 2e-5,5e-5, 8e-5, 1e-4, 2e-4, 5e-4} and then a more refined linear search over [8e-5, 2e-4]. Simultaneous gradient descent and SGA are shown in the figure.

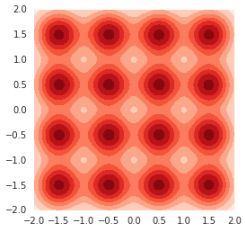

Figure 8: Ground truth for GAN experiments on a two-dimensional mixture of 16 Gaussians.

The last two rows of Figure 9 show the performance of consensus optimization without and with alignment. Introducing alignment slightly improves speed of convergence (second column) and final result (fourth column), although intermediate results in third column are ambiguous.

Simultaneous gradient descent exhibits mode collapse followed by mode hopping in later iterations (not shown). Mode hopping is analogous to the cycles in example 1. Unaligned SGA converges to the correct distribution; alignment speeds up convergence slightly. Consensus optimization performs similarly in this GAN example. However, consensus optimization can converge to local maxima even in potential games, recall example 8.

4.4. Learning a high-dimensional unimodal Gaussian

Mode collapse is a well-known phenomenon in GANs. A more subtle phenomenon, termed boundary distortion, was identified in Santurkar et al. (2018). Boundary distortion is a form of covariate shift where the generator fails to model the true data distribution.

Santurkar *et al* demonstrate boundary distortion using data sampled from a 75-dimensional unimodal Gaussian with spherical covariate matrix. Mode collapse is not a problem in this setting because the data distribution is unimodal. Nevertheless, they show that vanilla GANs fail to learn most of the spectrum of the covariate matrix.

Figure 10 reproduces their result. Panel A shows the ground truth: all 75 eigenvalues are equal to 1.0. Panel B shows the spectrum of the covariance matrix of the data generated by a GAN trained with RMSProp. The GAN concentrates on a single eigenvalue and essentially ignores the remaining 74 eigenvalues. This is similar to, but more extreme than, the empirical results obtained in Santurkar et al. (2018). We emphasize that the problem is not mode collapse, since the data is unimodal (although, it's worth noting that most of the mass of a high-dimensional Gaussian lies on the "shell").

Finally, panel C shows the spectrum of the covariance matrix of the data sampled from a GAN trained via SGA. The GAN approximately learns all the eigenvalues, with values ranging between 0.6 and 1.5.

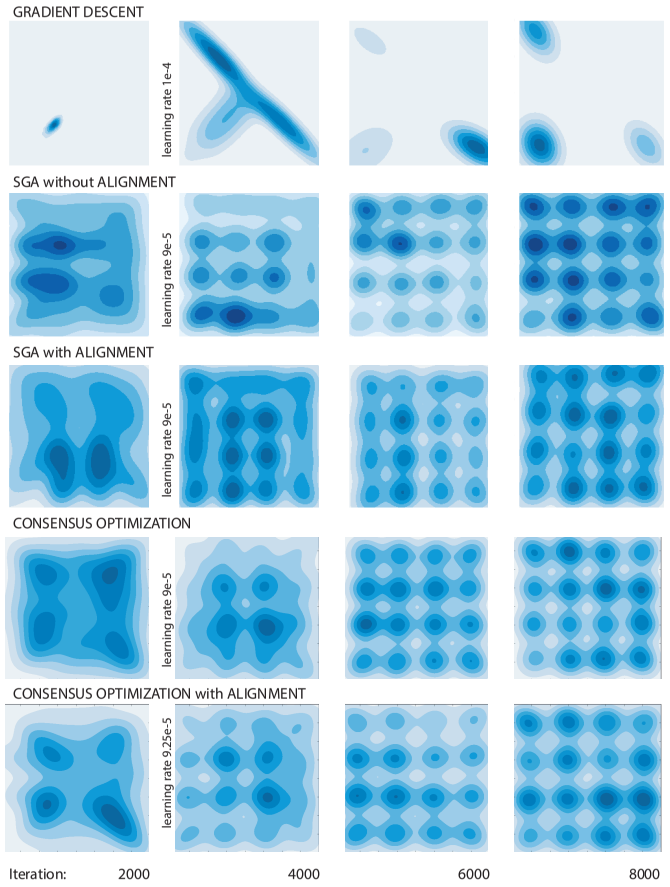

Figure 9: **First row:** Simultaneous gradient descent suffers from mode collapse and in later iterations (not shown) mode hopping. **Second and third rows:** vanilla SGA converges smoothly to the ground truth (Figure 8). SGA with alignment converges slightly faster. **Fourth and fifth rows:** Consensus optimization without and with alignment.

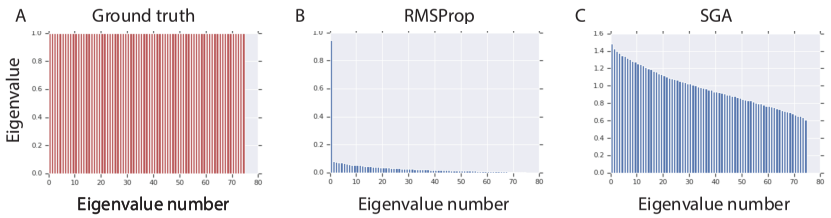

Figure 10: **Panel A:** The ground truth is a 75 dimensional spherical Gaussian whose covariance matrix has all eigenvalues equal to 1.0. **Panel B:** A vanilla GAN trained with RMSProp approximately learns the first eigenvalue, but essentially ignores all the rest. **Panel C:** Applying SGA results in the GAN approximately learning all 75 eigenvalues, although the range varies from 0.6 to 1.5.

5. Discussion

Modern deep learning treats differentiable modules like plug-and-play lego blocks. For this to work, at the very least, we need to know that gradient descent will find local minima. Unfortunately, gradient descent does *not* necessarily find local minima when optimizing multiple interacting objectives. With the recent proliferation of algorithms that optimize more than one loss, it is becoming increasingly urgent to understand and control the dynamics of interacting losses. Although there is interesting recent work on two-player adversarial games such as GANs, there is essentially no work on finding stable fixed points in more general games played by interacting neural nets.

The generalized Helmholtz decomposition provides a powerful new perspective on game dynamics. A key feature is that the analysis is indifferent to the number of players. Instead, it is the interplay between the simultaneous gradient $\boldsymbol{\xi}$ on the losses and the symmetric and antisymmetric matrices of second-order terms that guides algorithm design and governs the dynamics under gradient adjustments.

Symplectic gradient adjustment is a straightforward application of the generalized Helmholtz decomposition. It is unlikely that SGA is the best approach to finding stable fixed points. A deeper understanding of the interaction between the potential and Hamiltonian components will lead to more effective algorithms. Reinforcement learning algorithms that optimize multiple objectives are increasingly common, and second-order terms are difficult to estimate in practice. Thus, first-order methods that do not use Jacobian-vector products are of particular interest.

5.0.1. Gamification

Finally, it is worth raising a philosophical point. In this paper we are concerned with finding stable fixed points (because, for example, they yield pleasing samples in GANs). We are not concerned with the losses of the players *per se*. The gradient adjustments may lead to a

player acting against its own self-interest by increasing its loss. We consider this acceptable insofar as it encourages convergence to a stable fixed point. The players are but a means to an end.

We have argued that stable fixed points are a more useful solution concept than local Nash equilibria for our purposes. However, neither is entirely satisfactory, and the question "What is the right solution concept for neural games?" remains open. In fact, it likely has many answers. The intrinsic curiosity module introduced by Pathak et al. (2017) plays two objectives against one another to drive agents to search for novel experiences. In this case, converging to a fixed point is precisely what is to be avoided.

It is remarkable—to give a few examples sampled from many—that curiosity, generating photorealistic images, and image-to-image translation (Zhu et al., 2017) can be formulated as games. What else can games do?

Acknowledgments

Appendix A. TensorFlow Code to Compute SGA

Source code is available at `https://github.com/deepmind/symplectic-gradient-adjustment`. Since computing the symplectic adjustment is quite simple, we include an explicit description here for completeness.

The code requires a list of n losses, `Ls`, and a list of variables for the n players, `xs`. The function `fwd_gradients` which implements forward mode auto-differentiation is in the module `tf.contrib.kfac.utils`.

```
% compute Jacobian-vector product Jv
def jac_vec(ys, xs, vs):
    return fwd_gradients(ys, xs, grad_xs = vs, stop_gradients = xs)

% compute Jacobian^T-vector product J^T v
def jac_tran_vec(ys, xs, vs):
  dydxs = tf.gradients(ys, xs, grad_ys = vs, stop_gradients = xs)
  return [tf.zeros_like(x) if dydx is None
          else dydx for (x, dydx) in zip(xs, dydxs)]

% compute Symplectic Gradient Adjustment A^T ξ
def get_sym_adj(Ls, xs):
  % compute game dynamics ξ
  xi = [tf.gradients(ℓ, x)[0] for (ℓ, x) in zip(Ls, xs)]
  J_xi = jac_vec(xi, xs, xi)
  Jt_xi = jac_tran_vec(xi, xs, xi)
  % compute A^T ξ = 1/2 (J^T ξ − J ξ)
```

```
At_xi = [(jt-j)/2 for (j, jt) in zip(J_xi, Jt_xi)]
return At_xi
```

Appendix B. Helmholtz, Hamilton, Hodge, and Harmonic Games

This section explains the mathematical connections with the Helmholtz decomposition, symplectic geometry and the Hodge decomposition. The discussion is *not* necessary to understand the main text. It is also not self-contained. The details can be found in textbooks covering differential and symplectic geometry (Arnold, 1989; Guillemin and Sternberg, 1990; Bott and Tu, 1995).

B.1. The Helmholtz Decomposition

The classical Helmholtz decomposition states that any vector field $\boldsymbol{\xi}$ in 3-dimensions is the sum of curl-free (gradient) and divergence-free (infinitesimal rotation) components:

$$\boldsymbol{\xi} = \underbrace{\nabla\phi}_{\text{gradient component}} + \underbrace{\text{curl}(\mathbf{B})}_{\text{rotational component}} \qquad \Big[\ \text{curl}(\bullet) := \nabla \times (\bullet)\Big]$$

We explain the link between curl and the antisymmetric component of the game Jacobian. Recall that gradients of functions are actually differential 1-forms, not vector fields. Differential 1-forms and vector fields on a manifold are canonically isomorphic once a Riemannian metric has been chosen. In our case, we are implicitly using the Euclidean metric. The antisymmetric matrix $\mathbf{A}$ is the differential 2-form obtained by applying the exterior derivative d to the 1-form $\boldsymbol{\xi}$.

In 3-dimensions, the Hodge star operator is an isormorphism from differential 2-forms to vector fields, and the curl can be reformulated as $\text{curl}(\bullet) = *d(\bullet)$. In claiming $\mathbf{A}$ is analogous to curl, we are simply dropping the Hodge-star operator.

Finally, recall that the Lie algebra of infinitesimal rotations in d-dimensions is given by antisymmetric matrices. When $d = 3$, the Lie algebra can be represented as vectors (three numbers specify a 3×3 antisymmetric matrix) with the $\times$-product as Lie bracket. In general, the antisymmetric matrix $\mathbf{A}$ captures the infinitesimal tendency of $\boldsymbol{\xi}$ to rotate at each point in the parameter space.

B.2. Hamiltonian Mechanics

A symplectic form ω is a closed nondegenerate differential 2-form. Given a manifold with a symplectic form, a vector field $\boldsymbol{\xi}$ is **Hamiltonian vector field** if there exists a function $\mathcal{H} : M \to \mathbb{R}$ satisfying

$$\omega(\boldsymbol{\xi}, \bullet) = d\mathcal{H}(\bullet) = \langle \nabla\mathcal{H}, \bullet \rangle. \tag{4}$$

The function is then referred to as the Hamiltonian function of the vector field. In our case, the antisymmetric matrix $\mathbf{A}$ is a closed 2-form because $\mathbf{A} = d\boldsymbol{\xi}$ and $d \circ d = 0$. It may however be degenerate. It is therefore a presymplectic form (Bottacin, 2005).

Setting $\omega = \mathbf{A}$, Equation (4) can be rewritten in our notation as

$$\underbrace{\omega(\boldsymbol{\xi}, \bullet)}_{\mathbf{A}^\intercal\boldsymbol{\xi}} = \underbrace{d\mathcal{H}(\bullet)}_{\nabla\mathcal{H}},$$

justifying the terminology 'Hamiltonian'.

B.3. The Hodge Decomposition

The exterior derivative $d_k : \Omega^k(M) \to \Omega^{k+1}(M)$ is a linear operator that takes differential k-forms on a manifold M, $\Omega^k(M)$, to differential $k+1$-forms, $\Omega^{k+1}(M)$. In the case $k = 0$, the exterior derivative is the gradient, which takes 0-forms (that is, functions) to 1-forms. Given a Riemannian metric, the adjoint of the exterior derivative δ goes in the opposite direction. Hodge's Theorem states that k-forms on a compact manifold decompose into a direct sum over three types:

$$\Omega^k(M) = d\Omega^{k-1}(M) \oplus \text{Harmonic}^k(M) \oplus \delta\Omega^{k+1}(M).$$

Setting $k = 1$, we recover a decomposition that closely resembles the generalized Helmholtz decomposition:

$$\underbrace{\Omega^1(M)}_{\text{1-forms}} = \underbrace{d\Omega^0(M)}_{\text{gradients of functions}} \oplus \text{Harm}^k(M) \oplus \underbrace{\delta\Omega^2(M)}_{\text{antisymmetric component}}$$

The harmonic component is isomorphic to the de Rham cohomology of the manifold—which is zero when $k = 1$ and $M = \mathbb{R}^n$.

Unfortunately, the Hodge decomposition does not straightforwardly apply to the case when $M = \mathbb{R}^n$, since $\mathbb{R}^n$ is not compact. It is thus unclear how to relate the generalized Helmholtz decomposition to the Hodge decomposition.

B.4. Harmonic and Potential Games

Candogan et al. (2011) derive a Hodge decomposition for games that is closely related in spirit to our generalized Helmholtz decomposition—although the details are quite different. Candogan et al. (2011) work with classical games (probability distributions on finite strategy sets). Their losses are multilinear, which is easier than our setting, but they have constrained solution sets, which is harder in many ways. Their approach is based on combinatorial Hodge theory (Jiang et al., 2011) rather than differential and symplectic geometry. Finding a best-of-both-worlds approach that encompasses both settings is an open problem.

Appendix C. Type Consistency

The next two sections carefully work through the units in classical mechanics and two-player games respectively. The third section briefly describes a use-case for type consistency.

C.1. Units in Classical Mechanics

Consider the well-known Hamiltonian

$$\mathcal{H}(p, q) = \frac{1}{2}\left(\kappa \cdot q^2 + \frac{1}{\mu} \cdot p^2\right)$$

where q is position, $p = \mu \cdot \dot{q}$ is momentum, μ is mass, κ is surface tension and $\mathcal{H}$ measures energy. The units (denoted by τ) are

$$\tau(q) = m \qquad \tau(p) = \tfrac{kg \cdot m}{s}$$

$$\tau(\kappa) = \tfrac{kg}{s^2} \qquad \tau(\mu) = kg$$

where m is meters, kg is kilograms and s is seconds. Energy is measured in joules, and indeed it is easy to check that $\tau(\mathcal{H}) = \frac{kg \cdot m^2}{s^2}$.

Note that the units for differentation by x are $\tau(\frac{\partial}{\partial x}) = \frac{1}{\tau(x)}$. For example, differentiating by time has units $\frac{1}{s}$. Hamilton's equations state that $\dot{q} = \frac{\partial H}{\partial p} = \frac{1}{\mu} \cdot p$ and $\dot{p} = -\frac{\partial \mathcal{H}}{\partial q} = -\kappa \cdot q$ where

$$\tau(\dot{q}) = \tfrac{m}{s} \qquad \tau(\dot{p}) = \tfrac{kg \cdot m}{s^2}$$

$$\tau\left(\tfrac{\partial}{\partial q}\right) = \tfrac{1}{m} \qquad \tau\left(\tfrac{\partial}{\partial p}\right) = \tfrac{s}{kg \cdot m}$$

The resulting flow describing the dynamics of the system is

$$\boldsymbol{\xi} = \dot{q} \cdot \frac{\partial}{\partial q} + \dot{p} \cdot \frac{\partial}{\partial p} = \frac{1}{\mu} p \cdot \frac{\partial}{\partial q} - \kappa q \cdot \frac{\partial}{\partial p}$$

with units $\tau(\boldsymbol{\xi}) = \frac{1}{s}$. Hamilton's equations can be reformulated more abstractly via symplectic geometry. Introduce the symplectic form

$$\omega = dq \wedge dp \quad \text{with units} \quad \tau(\omega) = \frac{kg \cdot m^2}{s}.$$

Observe that contracting the flow with the Hamiltonian obtains

$$\iota_{\boldsymbol{\xi}} \omega = \omega(\boldsymbol{\xi}, \bullet) = dH = \frac{\partial \mathcal{H}}{\partial q} \cdot dq + \frac{\partial \mathcal{H}}{\partial p} \cdot dp$$

with units $\tau(d\mathcal{H}) = \tau(\mathcal{H}) = \frac{kg \cdot m^2}{s^2}$.

C.1.1. Losses in Classical Mechanics

Although there is no notion of "loss" in classical mechanics, it is useful (for the next section) to keep pushing the formal analogy. Define the "losses"

$$\ell_1(q,p) = \frac{1}{\mu} \cdot qp \quad \text{and} \quad \ell_2(q,p) = -\kappa \cdot qp \tag{5}$$

with units $\tau(\ell_1) = \frac{m^2}{s}$ and $\tau(\ell_2) = \frac{kg^2 \cdot m^2}{s^3}$. The Hamiltonian dynamics can then be recovered game-theoretically by differentiating ℓ_1 and ℓ_2 with respect to q and p respectively. It is easy to check that

$$\boldsymbol{\xi} = \frac{\partial \mathcal{H}}{\partial p}\frac{\partial}{\partial q} - \frac{\partial \mathcal{H}}{\partial q}\frac{\partial}{\partial p} = \frac{\partial \ell_1}{\partial q}\frac{\partial}{\partial q} + \frac{\partial \ell_2}{\partial p}\frac{\partial}{\partial p}.$$

C.1.2. The Duality between Vector Fields and Differential Forms

Finally recall that the symplectic form in games was not "pulled out of thin air" as $\omega = dq \wedge dp$, but rather derived as $\omega = d\boldsymbol{\xi}^\flat$, where $\boldsymbol{\xi}^\flat$ is the differential form corresponding to the vector field $\boldsymbol{\xi}$ under the musical isomorphism $\flat : TM \to T^*M$.

It is instructive to compute $\boldsymbol{\xi}^\flat$ in the case of a classical mechanical system and see what happens. Naively, we would guess that the musical isomorphism is $\left(\frac{\partial}{\partial q}\right)^\flat = dq$ and $\left(\frac{\partial}{\partial p}\right)^\flat = dp$. However, applying the naive musical isomorphism to $\boldsymbol{\xi}$ to get

$$\boldsymbol{\xi}^\flat = \frac{\partial \ell_1}{\partial q} \cdot dq + \frac{\partial \ell_2}{\partial p} \cdot dp$$

results in a *type violation* because

$$\tau\left(\frac{\partial \ell_1}{\partial q} \cdot dq\right) = \tau(\ell_1) = \frac{m^2}{s}$$

whereas

$$\tau\left(\frac{\partial \ell_2}{\partial p} \cdot dp\right) = \tau(\ell_2) = \frac{kg^2 \cdot m^2}{s^3}$$

and we cannot add objects with different types.

To correct the type inconsistency, define the musical isomorphism as

$$\left(\frac{\partial}{\partial q}\right)^\flat = \frac{\mu}{2} \cdot dq \quad \text{and} \quad \left(\frac{\partial}{\partial p}\right)^\flat = \frac{1}{2\kappa} \cdot dp$$

with inverse

$$(dq)^\sharp = \frac{2}{\mu} \cdot \frac{\partial}{\partial q} \quad \text{and} \quad (dp)^\sharp = 2\kappa \cdot \frac{\partial}{\partial p}.$$

The correction terms in the direction $\flat : TM \to T^*M$ invert the coupling terms κ and $\frac{1}{\mu}$ that were originally introduced into the Hamiltonian for physical reasons. Applying the corrected musical isomorphism to $\boldsymbol{\xi}$ yields

$$\boldsymbol{\xi}^\flat = \frac{\mu}{2} \cdot \frac{\partial f}{\partial q} \cdot dq + \frac{1}{2\kappa} \cdot \frac{\partial g}{\partial p} \cdot dp = \frac{1}{2}\left(p \cdot dq - q \cdot dp\right).$$

The two terms of $\boldsymbol{\xi}^\flat$ then have coherent types

$$\tau\left(\tfrac{\partial \ell_1}{\partial q} \cdot \mu \cdot dq\right) = \tfrac{m}{s} \cdot kg \cdot m = \tfrac{kg \cdot m^2}{s}$$
$$\tau\left(\tfrac{\partial \ell_2}{\partial p} \cdot \tfrac{1}{\kappa} \cdot dp\right) = \tfrac{kg \cdot m}{s^2} \cdot \tfrac{s^2}{kg} \cdot \tfrac{kg \cdot m}{s} = \tfrac{kg \cdot m^2}{s}$$

as required. The associated two form is

$$\omega := d\boldsymbol{\xi}^\flat = -\left(\mu \cdot \frac{\partial^2 f}{\partial q \partial p} - \frac{1}{\kappa} \cdot \frac{\partial^2 g}{\partial q \partial p}\right) dq \wedge dp = -dq \wedge dp$$

which recovers the symplectic form (up to sign) with units $\tau(\omega) = \frac{kg \cdot m^2}{s}$ as required. Finally, observe that

$$\begin{aligned}\langle \boldsymbol{\xi}, \boldsymbol{\xi}^\flat \rangle &= \frac{1}{2}\left\langle \frac{p}{\mu}\cdot\frac{\partial}{\partial q} - \kappa q \cdot \frac{\partial}{\partial p}, p\cdot dq - q \cdot dp \right\rangle \\ &= \frac{1}{2}\left(\kappa \cdot q^2 + \frac{1}{\mu}\cdot p^2\right) = \mathcal{H}(p,q)\end{aligned}$$

recovering the Hamiltonian.

C.2. Units in Two-Player Games

Without loss of generality let $\mathbf{w} = (\mathbf{x};\mathbf{y})$ where we refer to $\mathbf{x}$ as position and $\mathbf{y}$ as momentum so that $\tau(\mathbf{x}) = m$ and $\tau(\mathbf{y}) = \frac{kg\cdot m}{s}$. The aim of this section is to check type-consistency under these, rather arbitrarily assigned, units. Since we are considering a game, we do not require that $\mathbf{x}$ and $\mathbf{y}$ have the same dimension—even though this would necessarily be the case for a physical system. The goal is to verify that units can be consistently assigned to games.

Consider a quadratic two player game of the form

$$\ell_1(\mathbf{w}) = \frac{1}{2}\begin{pmatrix}\mathbf{x}^\intercal & \mathbf{y}^\intercal\end{pmatrix}\begin{pmatrix}\mathbf{A}_{11} & \mathbf{A}_{12}\\ \mathbf{A}_{21} & \mathbf{A}_{22}\end{pmatrix}\begin{pmatrix}\mathbf{x}\\ \mathbf{y}\end{pmatrix} + \begin{pmatrix}\mathbf{x}^\intercal & \mathbf{y}^\intercal\end{pmatrix}\begin{pmatrix}\mathbf{b}_1\\ \mathbf{b}_2\end{pmatrix}$$

and

$$\ell_2(\mathbf{w}) = \frac{1}{2}\begin{pmatrix}\mathbf{x}^\intercal & \mathbf{y}^\intercal\end{pmatrix}\begin{pmatrix}\mathbf{C}_{11} & \mathbf{C}_{12}\\ \mathbf{C}_{21} & \mathbf{C}_{22}\end{pmatrix}\begin{pmatrix}\mathbf{x}\\ \mathbf{y}\end{pmatrix} + \begin{pmatrix}\mathbf{x}^\intercal & \mathbf{y}^\intercal\end{pmatrix}\begin{pmatrix}\mathbf{d}_1\\ \mathbf{d}_2\end{pmatrix}$$

We restrict to quadratic games since our methods only involve first and second derivatives. We assume the matrices $\mathbf{A}$ and $\mathbf{C}$ are symmetric without loss of generality so that, for example, $\mathbf{A}_{12} = \mathbf{A}_{21}^\intercal$. Adding constant terms to ℓ_1 and ℓ_2 makes no difference to the analysis so they are omitted.

By Equation (5), the units for ℓ_1 and ℓ_2 should be $\frac{m^2}{s}$ and $\frac{kg\cdot m^2}{s^3}$ respectively. We can therefore derive the correct units for each of the components of the quadratic losses as

$$\underbrace{\begin{pmatrix}m & \frac{kg\cdot m}{s}\end{pmatrix}\begin{pmatrix}\frac{1}{s} & \frac{1}{kg}\\ \frac{1}{kg} & \frac{s}{kg^2}\end{pmatrix}\begin{pmatrix}m\\ \frac{kg\cdot m}{s}\end{pmatrix}}_{\mathbf{w}^\intercal\mathbf{A}\mathbf{w}} + \underbrace{\begin{pmatrix}m & \frac{kg\cdot m}{s}\end{pmatrix}\begin{pmatrix}\frac{m}{s}\\ \frac{m}{kg}\end{pmatrix}}_{\mathbf{w}^\intercal\mathbf{b}}$$

for ℓ_1 and

$$\underbrace{\begin{pmatrix}m & \frac{kg\cdot m}{s}\end{pmatrix}\begin{pmatrix}\frac{kg^2}{s^3} & \frac{kg}{s^2}\\ \frac{kg}{s^2} & \frac{1}{s}\end{pmatrix}\begin{pmatrix}m\\ \frac{kg\cdot m}{s}\end{pmatrix}}_{\mathbf{w}^\intercal\mathbf{C}\mathbf{w}} + \underbrace{\begin{pmatrix}m & \frac{kg\cdot m}{s}\end{pmatrix}\begin{pmatrix}\frac{kg^2\cdot m}{s^3}\\ \frac{kg\cdot m}{s^2}\end{pmatrix}}_{\mathbf{w}^\intercal\mathbf{d}}$$

for ℓ_2. It follows from a straightforward computation that the vector field $\boldsymbol{\xi} = \frac{\partial \ell_1}{\partial \mathbf{x}}\frac{\partial}{\partial \mathbf{x}} + \frac{\partial \ell_2}{\partial \mathbf{y}}\frac{\partial}{\partial \mathbf{y}}$ has type $\tau(\boldsymbol{\xi}) = \frac{1}{s}$ as required.

The presymplectic form $\omega = d\boldsymbol{\xi}^\flat$ makes use of the musical isomorphism $\flat : T^M \to T^*M$. As in Section C.1, if we naively define $(\frac{\partial}{\partial \mathbf{x}})^\flat = d\mathbf{x}$ and $(\frac{\partial}{\partial \mathbf{y}})^\flat = d\mathbf{y}$ then

$$\boldsymbol{\xi}^\flat = \frac{\partial \ell_1}{\partial \mathbf{x}}\cdot d\mathbf{x} + \frac{\partial \ell_2}{\partial \mathbf{y}}\cdot d\mathbf{y}$$

which is type inconsistent because $\tau(\frac{\partial \ell_1}{\partial \mathbf{x}}\cdot d\mathbf{x}) = \frac{m^2}{s}$ and $\tau(\frac{\partial \ell_2}{\partial \mathbf{y}}\cdot d\mathbf{y}) = \frac{kg^2\cdot m^2}{s^3}$.

C.2.1. Type-Consistency via SVD

It is necessary, as in Section C.1, to correct the naive musical isomorphism by taking into account the coupling constants for the mixed position-momentum terms. In the classical setup the coupling constants were the scalars $\frac{1}{\mu}$ and κ, whereas in a game they are the off-diagonal blocks $\mathbf{A}_{12}$ and $\mathbf{C}_{12}$.

Apply singular value decomposition to factorize

$$\mathbf{A}_{12} = \mathbf{U}_\mathbf{A}^\intercal \mathbf{D}_\mathbf{A}\mathbf{V}_\mathbf{A} \quad \text{and} \quad \mathbf{C}_{12} = \mathbf{U}_\mathbf{C}^\intercal \mathbf{D}_\mathbf{C}\mathbf{V}_\mathbf{C}$$

where the entries of the diagonal matrices have types $\tau(\mathbf{D}_\mathbf{A}) = \frac{1}{kg}$ and $\tau(\mathbf{D}_\mathbf{C}) = \frac{kg}{s^2}$, and *the types of the orthogonal matrices* $\mathbf{U}$ *and* $\mathbf{V}$ *are pure scalars.* The diagonal matrices $\mathbf{D}_\mathbf{A}$ and $\mathbf{D}_\mathbf{C}$ have the same types as $\frac{1}{\mu}$ and κ in the classical system since they play the same coupling role.

Extending the procedure adopted in the Section C.1, fix the type-inconsistency by defining the musical isomorphisms as

$$\left(\frac{\partial}{\partial \mathbf{x}}\right)^\flat = \mathbf{U}_\mathbf{A}^\intercal \mathbf{D}_\mathbf{A}^{-1}\mathbf{U}_\mathbf{A}\cdot d\mathbf{x}$$

and

$$\left(\frac{\partial}{\partial \mathbf{y}}\right)^\flat = \mathbf{V}_\mathbf{C}^\intercal \mathbf{D}_\mathbf{C}^{-1}\mathbf{V}_\mathbf{C}\cdot d\mathbf{y}.$$

Alternatively, the isomorphisms can be computed by noting that $\mathbf{U}_\mathbf{A}^\intercal \mathbf{D}_\mathbf{A}^{-1}\mathbf{U}_\mathbf{A} = (\sqrt{\mathbf{A}_{12}\mathbf{A}_{21}})^{-1}$ and $\mathbf{V}_\mathbf{C}^\intercal \mathbf{D}_\mathbf{C}^{-1}\mathbf{V}_\mathbf{C} = (\sqrt{\mathbf{C}_{21}\mathbf{C}_{12}})^{-1}$.

The dual isomorphism $\sharp : T^*M \to TM$ is then

$$(d\mathbf{x})^\sharp = \mathbf{U}_\mathbf{A}^\intercal \mathbf{D}_\mathbf{A}\mathbf{U}_\mathbf{A}\cdot\frac{\partial}{\partial \mathbf{x}} \quad \text{and} \quad (d\mathbf{y})^\sharp = \mathbf{V}_\mathbf{C}^\intercal \mathbf{D}_\mathbf{C}\mathbf{V}_\mathbf{C}\cdot\frac{\partial}{\partial \mathbf{y}}$$

If

$$\boldsymbol{\xi} = \begin{pmatrix}\mathbf{A}_{12}\mathbf{y} + \mathbf{b}_1\\ \mathbf{C}_{21}\mathbf{x} + \mathbf{d}_2\end{pmatrix}$$

then it follows that

$$\boldsymbol{\xi}^\flat = \begin{pmatrix}\mathbf{U}_\mathbf{A}^\intercal \mathbf{D}_\mathbf{A}^{-1}\mathbf{U}_\mathbf{A}\mathbf{b}_1 + \mathbf{U}_\mathbf{A}^\intercal \mathbf{U}_\mathbf{A}\mathbf{y}\\ \mathbf{V}_\mathbf{C}^\intercal \mathbf{D}_\mathbf{C}^{-1}\mathbf{V}_\mathbf{C}\mathbf{d}_2 + \mathbf{V}_\mathbf{C}^\intercal \mathbf{V}_\mathbf{C}\mathbf{x}\end{pmatrix}$$

with associated closed two form

$$\omega_\tau = d\boldsymbol{\xi}^\flat = -\left(\mathbf{U}_\mathbf{A}^\intercal \mathbf{V}_\mathbf{A} - \mathbf{U}_\mathbf{C}^\intercal \mathbf{V}_\mathbf{C}\right) d\mathbf{x}\wedge d\mathbf{y}.$$

where the notation ω_τ emphasizes that the two-form is type-consistent.

C.3. What Does Type-Consistency Buy?

Example 10 *Consider the loss functions*

$$f(x, y) = xy \quad \textit{and} \quad g(x, y) = 2xy,$$

with $\boldsymbol{\xi} = (y, 2x)$*. There is no function* $\phi : \mathbb{R}^2 \to \mathbb{R}$ *such that* $\nabla\phi = \boldsymbol{\xi}$*. However, there is a family of functions* $\phi_\alpha(x, y) = \alpha \cdot xy$ *which satisfies*

$$\langle \boldsymbol{\xi}, \nabla\phi_\alpha \rangle = \alpha \cdot (x^2 + 2y^2) \geq 0 \quad \textit{for all } \alpha > 0.$$

Although $\boldsymbol{\xi}$ is not a potential field, there is a family of functions on which $\boldsymbol{\xi}$ performs gradient descent—albeit with coordinate-wise learning rates that may not be optimal. The vector field $\boldsymbol{\xi}$ arguably does not require adjustment. This kind of situation often arises when the learning rates of different parameters are set adaptively during training of neural nets, by rescaling them by positive numbers.

The vanilla and type-consistent 1-forms corresponding to $\boldsymbol{\xi}$ are, respectively,

$$\boldsymbol{\xi}^\flat = y \cdot dx + 2x \cdot dy \quad \text{and} \quad \boldsymbol{\xi}^\flat_\tau = y \cdot dx + x \cdot dy$$

with

$$\omega = d\boldsymbol{\xi}^\flat_{\text{non}} = dx \wedge dy \quad \text{and} \quad \omega_\tau = d\boldsymbol{\xi}^\flat_\tau = 0.$$

It follows that the *type-consistent* symplectic gradient adjustment is zero. Type-consistency 'detects' that no gradient adjustment is needed in example 10.

Abstract

A typical problem in spatial data analysis is regionalization or spatially constrained clustering, which consists of aggregating small geographical areas into larger regions. A major challenge when partitioning a map is the huge number of possible partitions that compose the search space. This is compounded if we are partitioning spatio-temporal data rather than purely spatial data. We introduce a spatio-temporal product partition model that deals with the regionalization problem in a probabilistic way. Random spanning trees are used as a tool to tackle the problem of searching the space of possible partitions making feasible this exploration. Based on this framework, we propose an efficient Gibbs sampler algorithm to sample from the posterior distribution of the parameters, specially the random partition. The proposed Gibbs sampler scheme carries out a random walk on the space of the spanning trees and the partitions induced by deleting tree edges. In the purely spatial situation, we compare our proposed model with other state-of-art regionalization techniques to partition maps using simulated and real social and health data. To illustrate how the temporal component is handled by the algorithm and to show how the spatial clusters vary along the time we presented an application using human development index data. The analysis shows that our proposed model is better than state-of-art alternatives. Another appealing feature of the method is that the prior distribution for the partition is interpretable with a trivial coin flipping mechanism allowing its easy elicitation.

Keywords: Spatial Clustering, Product Partition Models, Random Spanning Trees, Bayesian Clustering

1. Introduction

Traditional cluster analysis aims at partitioning a set of n objects into k clusters such that the clusters are composed by objects with similar valued attributes while objects from different clusters tend to be dissimilar. When the objects are spatially located, inducing a neighborhood structure, the clustering can be constrained by their spatial contiguity. For instance, in mapping problems, it is common to aggregate neighboring small areas to partition the map into larger regions, named *spatial clusters*. The small areas within a given spatial cluster are relatively homogeneous with respect to attributes such as, for example, ecological characteristics (Sayre et al., 2014) or crime rates (Mennis and Harris, 2013). This spatial clustering problem is called *regionalization* or *spatially constrained clustering*.

Regionalization serves to a range of purposes, such as to facilitate the visualization and understanding of the geographical information, to reduce the noise introduced by outliers and inaccurate data, to make data analysis tractable, or to provide a better statistical handling of the data by reducing the effect of different populations (Wise et al., 1997). It has been used in widely different applied problems such as ecoregion delimitation (Sayre et al., 2014; McKenney et al., 2007), climate zoning (Zhang et al., 2016), environmental planning (Bernetti et al., 2011), image segmentation (Ribeiro et al., 2013), communication protocols in geo-sensor networks (Reis et al., 2007), map generalization (Ruas, 2008), zone design for health studies (Cockings and Martin, 2005; Ricketts, 1997), and enhanced sampling procedures (Martin, 1998).

There are two possible ways to carry out this aggregation. One way is through an artificial clustering, where the constructed regions are predetermined using official or normative designations (such as states, districts and counties). That is, the regionalization of small units of interest, such as counties, are arbitrarily specified as larger units such as states, defined for administrative or political reasons. This kind of aggregation is usually the expression of political will and may not take into account the information specific to the domain being studied. Another way is to perform the aggregation based on the analysis of data characteristics related to the phenomena under study. An outcome of a regionalization method can be found in the left hand side of Figure 1, which shows the three spatial clusters based on the values of lung cancer mortality rates in municipalities in the South of Brazil for the period 2008-2012.

Many different methods have been proposed to deal with the problem of spatial regionalization as a non-stochastic optimization problem. These previous works are presented in Section 1.1. Most of these regionalization techniques consider data as fixed, static values and prefix the number of clusters *a priori*. Frequently, these assumptions are inappropriate, as they do not allow for measurement error or uncertainty on the areas' measures nor the evaluation of the uncertainty of the obtained clusters. For example, consider the bladder cancer mortality rate of a small town in a given year. This value should not be considered as the most representative value for the true mortality rate since it can be severely impacted by small differences from one year to another, particularly if the area has a small population. The measured value can show a natural variability, expressed in this widely different bladder cancer mortality rate variation in two successive years in small population areas. Traditional regionalization techniques that emphasizes the similarity between the observations will be sensitive to this variability and may output an regionalization that discloses an undesirably high number of clusters. To illustrate this problem, the right hand side map in Figure 1 shows an outcome of the *Automatic Zoning Procedure* (AZP) regionalization technique proposed by Openshaw (1977) considering the bladder cancer mortality rate in municipalities in the South of Brazil for the period 2008-2012. This type of cancer is rare, generating small

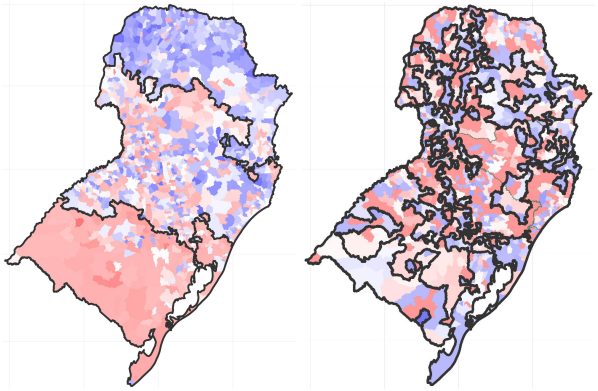

Figure 1: Example of a good (left) and a bad (right) regionalization using data from lung (left) and bladder (right) cancer mortality rates in South Brazilian municipalities for the period 2008-2012.

death counts in low population areas and thus extreme rates (high or low) in sharp contrast with their neighbors.

It is necessary to use an explicit stochastic framework to perform the regionalization if we want to take into account this natural variability in the data. An appropriate modeling approach should also allow us to quantify the uncertainty about the geographic partition. A stochastic framework accounting for such characteristics defines a random partition model. Consequently, our inference becomes more complex as there is a huge number of possible partitions that compose the parametric space.

Some attempts to achieve this goal in the spatial context have been already considered in the literature and they are reviewed in Section 1.1. In Teixeira et al. (2015), we introduce a random partition model that deals with purely spatial regionalization problems in a probabilistic way. In this article, in addition to presenting the model, we discuss in detail the elicitation of prior distributions for the partition and for the number of clusters. Such model is an alternative to the spatial product partition model (PPM) introduced by Hegarty and Barry (2008) and by Page and Quintana (2016). We also extend these models to space-time data by also accounting for spatio-temporal regionalization and provide extensive simulation results and new examples. We run a simulation study comparing the proposed model with well-known stochastic and non-stochastic regionalization techniques including Bayesian modeling alternatives. To illustrate the purely spatial case, we partition the Brazilian map based on the Human Development Index (HDI) and the Brazilian South region based on bladder and lung cancer mortality rates. The space-time case is illustrated with HDI in three decades.

The spatial and the spatio-temporal structure are both represented by a graph. The partition of graphs is not a new subject (Green and Thomas, 2013; Bornn and Caron, 2011).

Our contribution is the introduction of random spanning trees into the random partition model as a tool to handle the problem of searching in the space of possible partitions. We propose an efficient Gibbs sampler algorithm to sample from the posterior probability distribution, specially that for the partition. Conditionally on the spanning tree, the random partition has a product distribution thus defining a spatio-temporal/spatial product partition model. This strategy also greatly facilitates the scheme for sampling from the posterior distributions. By conditioning on the partitions resulting from spanning trees pruning, we substantially reduce the space of partitions or clusters to be explored. It is important to emphasize that the partition space is the set of all possible spatio-temporal/spatial partitions. The way we search this space is by selecting a new random spanning tree from the set of all possible spanning trees at each Gibbs step and then proceed with its partitioning. This guarantees that there is a positive probability that any partition will be reached in a finite time starting from any other partition in our MCMC sampling scheme.

In Section 2, we briefly review some basic concepts of graph theory we need in the construction of the proposed model. In Section 3 we introduce our proposed model and describe how we incorporate the spanning trees as a tool to drive through the partition space. In Section 4 we propose an efficient algorithm to sample from the posterior distribution. Section 5 presents a simulation study comparing the proposed model with some other well-known methods for regionalization in the spatial context. The analysis of some real data from Brazil is carried out in Section 6. Section 7 closes the paper with some final comments and the main conclusions.

1.1. Related Work

Openshaw (Openshaw, 1977) was a pioneer when he proposed *Automatic Zoning Procedure* (AZP), a heuristic method to aggregate areas that swapped regions locally improving an initial rough partitioning. Later, AZP variants were introduced using simulated annealing and tabu search (Openshaw and Rao, 1995). A modification of AZP named *Automatic Regionalization with Initial Seed Location* (ARiSeL) was presented by Duque and Church (2004). In ARiSeL, the construction of an initial feasible solution is repeated several times before running a tabu search which, according to the author, is less expensive than performing a local search. The *Self Organizing Maps* (SOM) algorithm, proposed by Kohonen (1990), is an unsupervised neural network which adjusts its weights to represent a data set distribution on a regular lattice. Although used to perform regionalization, the spatial contiguity desirable in a regionalization is not guaranteed. SOM variants have been proposed by Bação et al. (2004) and Bação et al. (2005) considering different procedures to explore the neighborhood structure. The heuristic devised by Aldstadt and Getis (2006), called AMOEBA (*A Multidirectional Optimum Ecotope-Based Algorithm*), starts with an initial area and grows it by adding neighboring areas until a local spatial autocorrelation statistic stops increasing. This process is repeated to all areas and a final step resolves overlaps. The *Max-p-regions* technique (Duque et al., 2012) does not require the previous setting of the number of spatial clusters and enforces the contiguity constraint. Clusters are formed in a such way that a regional attribute is always above certain threshold such as a minimum population or cluster area size.

The *Spatial 'K'luster Analysis by Tree Edge Removal* (SKATER) proposed by Assunção et al. (2006) is a graph based method that uses a minimal spanning tree to reduce the search space. The regions are then defined by the removal of edges from the minimal spanning tree. The removed edges are chosen to minimize a dissimilarity measure. Inspired by SKATER, Guo (2008) proposed REDCAP (*Regionalization with Dynamically Constrained Agglomerative clustering and Partitioning*) which considers six other methods to explore different connection strategies using the underlying graph structure. The model introduced in the present manuscript is also inspired by SKATER by using spanning trees as a tool to summarize the spatial connection and the variability of the data. It adopts a Bayesian approach putting prior distributions on all unknown aspects of the regionalization, including the partition itself. As a consequence, we are able to make inference on unknown parameters and, most importantly, to infer about the partition in a probabilistic way. Our method outputs a posterior distribution over all possible partitions and we can infer which ones are the most probable.

Knorr-Held and Raßer (2000) presented a Bayesian approach, named *Bayesian Detection of Clusters and Discontinuities* (BDCD), to aggregate small contiguous areas into larger regions to form spatial clusters. Focusing on the random partition, they assume a prior distribution $p(c)$ for the number c of spatial clusters. Conditioned on c, cluster centers are uniformly selected among the n available centroids. Each area is assigned to that cluster whose center is the nearest according to the number of boundaries that need to be crossed. In the Bayesian partition model (BPM) introduced by Denison and Holmes (2001), the prior distribution $p(c)$ is an uniform distribution and they use a Voronoi tessellation to determine the spatial clusters. One of the main differences between the two of them is the computational strategy to sample from the posterior distribution. While Knorr-Held and Raßer (2000) use an explicit reversible jump Markov chain Monte Carlo (MCMC) procedure (Green, 1995; Richardson and Green, 1997), Denison and Holmes (2001) proceed using a standard MCMC after integrating out some parameters.

Gangnon and Clayton (2000) proposed a different Bayesian approach for this problem by assuming a prior distribution for the number of clusters that depends on the geometry of the clusters. Such prior distribution gives more flexibility for spatial cluster analysis since, depending on our prior knowledge, it can be elicited penalizing some particular cluster aspects such as large cluster sizes or odd-shaped clusters. The algorithm proposed to approximate the posterior distribution has two components. The first is a window of plausibility, an adaptation of the Occam's window approach to model selection (Madigan and Raftery, 1994). In the second, given a window of plausibility, they use a randomized search algorithm similar to the backward elimination method used for variable selection in regression problems.

Lu and Carlin (2005) and Banerjee and Gelfand (2006) worked on a dual problem proposing a method known as boundary (or wobbling) analysis. Rather than aggregating similar areas into homogeneous regions, their method aims at identifying sharp boundaries between pairs of areas in such a way that homogeneous regions can be obtained as a byproduct. Wakefield and Kim (2013) proposed a Bayesian method for the detection of a small number of high risk zones, rather than providing a map partition. It requires the pre-specification of the maximum number of clusters, the clusters found tend to have a circular shape.

Anderson et al. (2014) proposed a two-step regionalization method. First, a hierarchical clustering method is used to define a set of possible partitions. In the second step, the

models defined by each partition are compared using a model selection tool and the best partition is thus selected.

The product partition model (PPM) introduced by Hartigan (1990) has been used for different purposes due to its flexibility in modeling heterogeneous data. However, only recently it has been considered to analyze spatial data. PPMs assume that the partition $\boldsymbol{\pi} = \{\mathcal{G}_1, \ldots, \mathcal{G}_c\}$ of a set of data is a random quantity and its main feature is to assume that the $\boldsymbol{\pi}$ distribution is a product of subjective non-negative functions $\kappa(\mathcal{G}_k)$ called prior cohesions, for $k = 1, \ldots, c$. The cohesion functions measure how likely elements in $\mathcal{G}_k$ are clustered *a priori*. The structure adopted to such cohesions defines the type of PPM we have in mind. Hegarty and Barry (2008) were the first to propose a spatial approach to PPM. They assumed that the prior cohesions of a component $\mathcal{G}_i$ of $\boldsymbol{\pi}$ is a function of the summation (over all areas in $\mathcal{G}_i$) of the number of neighboring areas not in $\mathcal{G}_i$. This cohesion may encourage maps with few contiguous clusters and discourage maps with large number of disconnected ones, which is desirable in regionalization problems. In the spatial PPM introduced by Page and Quintana (2016) the spatial dependence among the neighboring areas is incorporated into the model through both the likelihood and the prior for $\boldsymbol{\pi}$. Four prior cohesions are introduced. Differently from what was considered by Hegarty and Barry (2008), all of them are location dependent and usually dependent on the distance between areas.

2. Preliminary Concepts

Consider n contiguous geographical regions such as those in Figure 2. The map is identified with an undirected graph $\mathcal{G} = (V, E)$, where V is the set of vertices or nodes representing the areas and E is the set of edges connecting pairs of vertices and representing the adjacency relationship among regions (see Figure 2, map on the top left). If there is an edge between vertices i and j we say that the corresponding areas are neighboring areas. A *path* from node v_1 to node v_m is a sequence of nodes $v_1, v_2, \ldots, v_m$ which are connected by edges $(v_1, v_2), \ldots, (v_{m-1}, v_m)$ and with $v_i \neq v_{i+1}$ for $i = 1, \ldots, n$. All vertices are distinct except, possibly, the initial and final vertices v_1 and v_m. This exceptional case, a path with $v_1 = v_m$, is a *circuit*. A graph is said to be *connected* if, for any pair of nodes v_i and v_j, there is at least one path connecting them.

A *spatial cluster* is defined as any subset of nodes forming a connected subgraph. The graph $\mathcal{G}$ is partitioned into c spatial clusters $\mathcal{G}_1, \ldots, \mathcal{G}_c$ if the clusters are disjoint and $\mathcal{G} = \bigcup_i \mathcal{G}_i$, where $1 \leq c \leq n$. A spatial partition $\pi = \{\mathcal{G}_1, \ldots, \mathcal{G}_c\}$ can be viewed as a function from the set $\{1, \ldots, n\}$ that labels the areas into the set $\{1, \ldots, c\}$ of spatial cluster labels.

A *spanning tree* $\mathcal{T}$ of a graph $\mathcal{G}$ is a fundamental concept in our work. It is a connected subgraph with no circuits containing all nodes of $\mathcal{G}$. The second and third maps on the top row in Figure 2 show two spanning trees associated with the first graph. In a spanning tree, any two nodes of $\mathcal{G}$ are connected by a unique path and the number of edges in $\mathcal{T}$ is $n - 1$. This implies that the removal of any $c - 1$ edges from $\mathcal{T}$ partitions the graph $\mathcal{G}$ into c spatial clusters. The last property makes the spanning tree a useful tool for spatial clustering problems. This can be seen in the bottom row where three different partitions are shown. The last two are based on the removal of only four edges from the corresponding spanning trees in the top row.

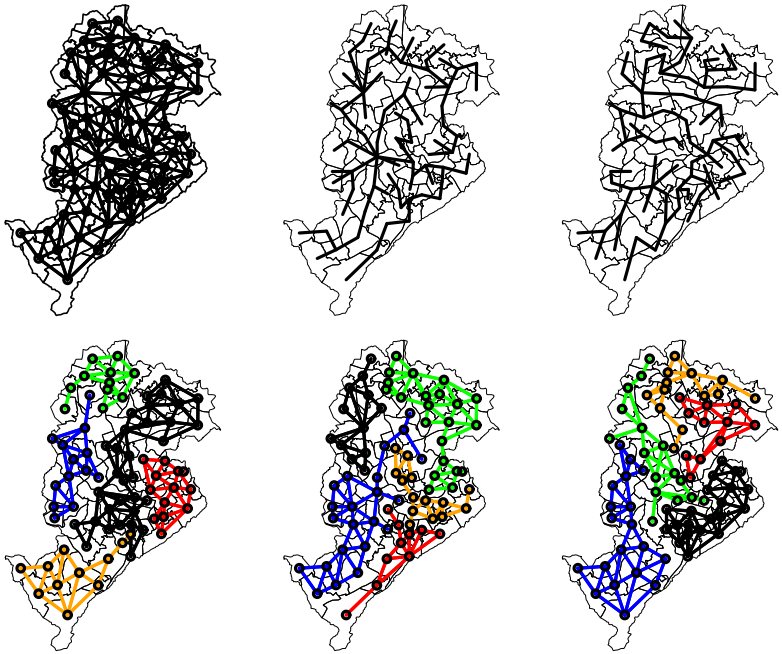

Figure 2: Map of Belo Horizonte city partitioned into 81 administrative planning units superimposed by the adjacency neighborhood graph (first map in the top row) and two spanning trees (other two maps in the top row). The bottom row shows three partitions into five spatial clusters.

Usually, there are many possible spanning trees associated with a given graph. A special kind of spanning tree can be obtained when we associate a cost or weight to each edge. The *cost of a graph* is the sum of its weights. A *minimum spanning tree* is a spanning tree with minimum cost. The minimum spanning tree is not necessarily unique. A sufficient condition for uniqueness is that the pairwise costs are distinct numbers.

Consider a spanning tree $\mathcal{T}$ and a partition π of $\mathcal{G}$ into c disjoint spatial clusters $\mathcal{G}_1, \ldots, \mathcal{G}_c$. We say that π is *compatible* with $\mathcal{T}$ if π can be obtained by pruning $c-1$ edges from $\mathcal{T}$, and we denote this by $\pi \prec \mathcal{T}$. Otherwise, they are incompatible and we write $\pi \not\prec \mathcal{T}$. The extremely large number of possible partitions of a graph is reduced tremendously by considering only those compatible with a given spanning tree. For example, there

are only $n-1$ possible partitions of a particular spanning tree into two spatial clusters while in the original graph this number is of order $O(2^n)$.

These purely spatial graph concepts can be easily extended to the space-time situation. We assume that the same map is observed for T time periods, that is, areas are not created or deleted during the observation period. Hence, we can stack the sequence of maps creating a three-dimensional lattice with nodes indexed by (t, i) where i denotes the geographical unit and t, the time. Edges between nodes (t, i) and (t, j) at the same time t are specified based only on the adjacency between the areas, as described before. Additionally, each node (t, i) is connected to itself and to all its adjacent neighboring regions at time $t+1$. Since the remaining concepts of spanning trees, paths and others are defined for general graphs, they are also valid for this extended three-dimensional graph $\mathcal{G} = (V, E)$.

3. Spatio-Temporal PPM Driven by Spanning Trees

Let $\boldsymbol{Y} = (\boldsymbol{Y}_1, \ldots, \boldsymbol{Y}_T)$ and $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_T)$ where $\boldsymbol{Y}_t = (Y_{t1}, \ldots, Y_{tn})$ and $\boldsymbol{\theta}_t = (\boldsymbol{\theta}_{t1}, \ldots, \boldsymbol{\theta}_{tn})$, respectively, denote the observable variables and the vector of parameters for the n regions of a map, at time t, $t = 1, \ldots, T$. We associate $(Y_{tr}, \boldsymbol{\theta}_{tr})$ with the node (t, r) in the graph. If the interest lies only on a purely spatial regionalization we take $T = 1$. Assume that $Y_{tj} \mid \boldsymbol{\theta}_{tj} \overset{ind}{\sim} f(Y_{tj} \mid \boldsymbol{\theta}_{tj})$, $j = 1, \ldots, n$ and $t = 1, \ldots, T$. Let $I = \{1, \ldots, nT\}$ be the set of labels for the nodes.

A major problem when partitioning a data set or a graph is the huge number of possible partitions that compose the search space. To introduce the cluster structure tackling this problem and making feasible the exploration of this space of possible partitions, let us assume a random spanning tree $\mathcal{T}$ selected from the set of all possible spanning trees associated with the graph. Denote by $\boldsymbol{\pi}$ a partition of I compatible with the selected $\mathcal{T}$ and assume that, given $\mathcal{T}$ and the partition $\boldsymbol{\pi} = \{\mathcal{G}_1, \ldots, \mathcal{G}_c\}$, there are common parameters $\boldsymbol{\theta}_{\mathcal{G}_k}$, $k = 1, \ldots, c$, such that, for all nodes with labels belonging to $\mathcal{G}_k$, we have that $\boldsymbol{\theta}_i = \boldsymbol{\theta}_{\mathcal{G}_k}, \quad i \in \mathcal{G}_k$. To establish notation, denote by $\boldsymbol{Y}_{\mathcal{G}_k}$ the set of observations associated with the nodes in $\mathcal{G}_k$. A spatio-temporal PPM induced by random spanning trees is the joint distribution of $(\boldsymbol{Y}, \boldsymbol{\theta}, \boldsymbol{\pi}, \mathcal{T})$, with $\boldsymbol{\pi} \prec \mathcal{T}$, and denoted by $(\boldsymbol{Y}, \boldsymbol{\theta}, \boldsymbol{\pi}, \mathcal{T}) \sim \text{SPPM}$, satisfying the following conditions:

(i) Given $\mathcal{T}$, $\boldsymbol{\pi} = \{\mathcal{G}_1, \ldots, \mathcal{G}_c\} \prec \mathcal{T}$ and $\boldsymbol{\theta}_{\mathcal{G}_1}, \ldots, \boldsymbol{\theta}_{\mathcal{G}_c}$, the observations $\boldsymbol{Y}_{\mathcal{G}_1}, \ldots, \boldsymbol{Y}_{\mathcal{G}_c}$ are independent and such that

$$Y_i \mid \boldsymbol{\theta}_{\mathcal{G}_k} \overset{iid}{\sim} f(Y_i \mid \boldsymbol{\theta}_{\mathcal{G}_k}),\ \forall\, i \in \mathcal{G}_k\,;$$

(ii) Given $\mathcal{T}$ and $\boldsymbol{\pi} = \{\mathcal{G}_1, \ldots, \mathcal{G}_c\} \prec \mathcal{T}$, the common parameters $\boldsymbol{\theta}_{\mathcal{G}_1}, \ldots, \boldsymbol{\theta}_{\mathcal{G}_c}$ are independent with joint distribution given by

$$\boldsymbol{\theta}_{\mathcal{G}_1}, \ldots, \boldsymbol{\theta}_{\mathcal{G}_c} \mid \boldsymbol{\pi}, \mathcal{T} \sim \prod_{k=1}^{c} f(\boldsymbol{\theta}_{\mathcal{G}_k})\,;$$

(iii) Given $\mathcal{T}$, the prior distribution of $\boldsymbol{\pi} \prec \mathcal{T}$ is a product distribution such that, for each partition $\{\mathcal{G}_1, \ldots, \mathcal{G}_c\}$ for $c \in \{1, \ldots, nT\}$, **we have**

$$\mathbb{P}(\boldsymbol{\pi} = \{\mathcal{G}_1, \ldots, \mathcal{G}_c\} \mid \mathcal{T}) = \frac{\prod_{k=1}^{c} \kappa(\mathcal{G}_k)}{\sum_{\mathcal{G}'_k \in \mathcal{C}(\mathcal{T})} \prod_{k=1}^{c} \kappa(\mathcal{G}'_k)}\,, \tag{1}$$

where $\kappa(\mathcal{G}_k) \geq 0$ denotes the prior cohesion associated to the subgraph $\mathcal{G}_k$ and represents how likely elements in $\mathcal{G}_k$ are clustered a priori. The summation in the denominator is over all the elements in the set $\mathcal{C}(\mathcal{T})$ which represents all the $2^{nT-1}-1$ partitions compatible with the specific spanning tree $\mathcal{T}$ in which we are conditioning.

(iv) The prior distribution of the spanning tree $\mathcal{T}$ is $\mathbb{P}(\mathcal{T})$ with the support on the set of all possible spanning trees of $\mathcal{G}$.

Usually, there is very little prior information to guide our choice of this last distribution. Hence, we assume that $\mathcal{T}$ is uniformly distributed over the space of spanning trees of the original graph.

The partition of a graph consists simply of the removal of a set of edges resulting in disjoint connected subgraphs. By conditioning on a spanning tree, this task is substantially simplified. We have only $nT-1$ edges and the removal of any $c-1$ of them immediately partition the original graph into c space-times clusters. We want to emphasize that we do not prune a single and fixed spanning tree. Rather, we randomly walk on the space of all spanning trees and, at each step, we generate a new partition. The final inference about the partition is obtained by integrating out over the spanning tree space.

With this motivation, we specify the prior cohesions as functions of ρ_e, the probability of removing a given edge e. For instance, if all edges have a common probability ρ, the prior cohesion related to group $\mathcal{G}_k$ becomes

$$\kappa(\mathcal{G}_k) = \begin{cases} (1-\rho)^{n_{\mathcal{G}_k}-1}\rho, & \text{if } k < c \\ (1-\rho)^{n_{\mathcal{G}_k}-1}, & \text{if } k = c, \end{cases} \tag{2}$$

where $n_{\mathcal{G}_k}$ is the number of remaining edges in $\mathcal{G}_k$. This prior cohesion is similar to that one considered by Barry and Hartigan (1993) to analyze problems involving the identification of contiguous clusters, such as in change point analysis in time series. In that context, this structure is a consequence of the Markovian behavior usually assumed for the change points.

Considering the prior cohesions in (2), given $\mathcal{T}$ and ρ, the prior probability of $\boldsymbol{\pi} = \{\mathcal{G}_1, \ldots, \mathcal{G}_c\}$ is given by

$$\mathbb{P}(\boldsymbol{\pi} \mid \mathcal{T},\ \rho) = \begin{cases} \rho^{(c-1)}(1-\rho)^{(nT-c)}, & \text{if } \boldsymbol{\pi} \prec \mathcal{T} \\ 0, & \text{otherwise.} \end{cases}$$

It is more relevant to obtain the unconditional prior distributions for the partition $\boldsymbol{\pi}$ and for the number C of clusters. Let $N_{\mathcal{T}}$ be the total number of spanning trees associated with $\mathcal{G}$ and $N_{\mathcal{T}}(\boldsymbol{\pi})$ the total number of spanning trees compatible with a partition π. It follows that, given ρ, the prior distributions for $\boldsymbol{\pi}$ and C are given respectively by

$$\begin{aligned} \mathbb{P}(\boldsymbol{\pi} \mid \rho) &= \sum_{\mathcal{T}} \mathbb{P}(\boldsymbol{\pi} \mid \mathcal{T},\ \rho)\mathbb{P}(\mathcal{T}) \\ &= \sum_{\mathcal{T}} \rho^{(c-1)}(1-\rho)^{(nT-c)}\mathbb{P}(\mathcal{T})\ I[\boldsymbol{\pi} \prec \mathcal{T}] \\ &= \rho^{(c-1)}(1-\rho)^{(nT-c)}\frac{N_{\mathcal{T}}(\boldsymbol{\pi})}{N_{\mathcal{T}}} \end{aligned}$$

and

$$\mathbb{P}(C = c \mid \rho) = \sum_{\boldsymbol{\pi}} I[\boldsymbol{\pi}, c]\mathbb{P}(\boldsymbol{\pi} \mid \rho) = \binom{nT-1}{c-1}\rho^{(c-1)}(1-\rho)^{(nT-c)}\frac{N_{\mathcal{T}}(\boldsymbol{\pi})}{N_{\mathcal{T}}}$$

where the last sum is over all partitions $\boldsymbol{\pi}$ and $I[\boldsymbol{\pi}, c]$ is an indicator function assuming 1, if the partition $\boldsymbol{\pi}$ has c clusters, and 0, otherwise.

Assuming *a priori* that $\mathbb{P}(\rho = 1/2) = 1$, it becomes clear the dependence of the prior distribution for $\boldsymbol{\pi}$ on the graph topology since $\mathbb{P}(\pi) = 2^{-nT+1}N_{\mathcal{T}}(\boldsymbol{\pi})N_{\mathcal{T}}^{-1}$. As $N_{\mathcal{T}}(\boldsymbol{\pi})$ depends on $\boldsymbol{\pi}$, we have that $\mathbb{P}(\boldsymbol{\pi})$ is not uniform over all possible partitions. As a consequence, the prior distribution of the number of clusters C is also influenced by the graph structure. Figure 3 shows a simple graph with three different partitions. The left hand side partition is given by $\pi_1 = \{\mathcal{G}_1, \mathcal{G}_2\} = \{\{1,2,3\},\{4,5,6\}\}$ and $N_{\mathcal{T}}(\boldsymbol{\pi}_1) = 9$. The middle partition is $\pi_2 = \{\mathcal{G}_1, \mathcal{G}_2, \mathcal{G}_3\} = \{\{1,2,3\},\{4,5\},\{6\}\}$ and $N_{\mathcal{T}}(\boldsymbol{\pi}_2) = 6$. The number $N_{\mathcal{T}}(\boldsymbol{\pi})$ does not depend only on the number c of spatial clusters in $\boldsymbol{\pi}$. The right hand side partition is $\pi_3 = \{\mathcal{G}_1, \mathcal{G}_2\} = \{\{1,2,3,4,5\},\{6\}\}$, with the same number of clusters as $\boldsymbol{\pi}_1$ but with $N_{\mathcal{T}}(\boldsymbol{\pi}_3) = 6$.

It will be more common to assume a prior distribution for ρ such as Beta(r, s). Then

$$\begin{aligned} \mathbb{P}(\boldsymbol{\pi}) &= \frac{N_{\mathcal{T}}(\boldsymbol{\pi})}{N_{\mathcal{T}}}\frac{\Gamma(r+s)\Gamma(r+nT-c)\Gamma(s+c-1)}{\Gamma(r)\Gamma(s)\Gamma(nT+r+s-1)} \\ \mathbb{P}(C = c) &= \binom{nT-1}{c-1}\frac{N_{\mathcal{T}}(\boldsymbol{\pi})}{N_{\mathcal{T}}}\frac{\Gamma(r+s)\Gamma(r+nT-c)\Gamma(s+c-1)}{\Gamma(r)\Gamma(s)\Gamma(nT+r+s-1)}\,. \end{aligned}$$

Although the prior distribution for C is dependent on the graph topology, the expected number of clusters *a priori* is not. Given $\mathcal{T}$ and ρ, the number of removed edges from the

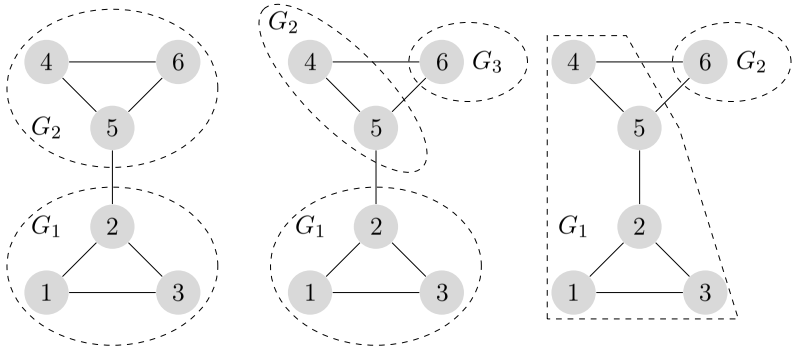

Figure 3: A graph composed by six nodes and with three different partitions $\boldsymbol{\pi}_1$ (left), $\boldsymbol{\pi}_2$ (middle), and $\boldsymbol{\pi}_3$ (right). The number of trees compatible with each partition is $N_{\mathcal{T}}(\boldsymbol{\pi}_1) = 9$, and $N_{\mathcal{T}}(\boldsymbol{\pi}_2) = N_{\mathcal{T}}(\boldsymbol{\pi}_3) = 6$.

tree compatible with the partition has a Binomial distribution with parameters $nT-1$ and ρ. Consequently, the expected number C of clusters is

$$\mathbb{E}(C) = \mathbb{E}\left(\mathbb{E}(C \mid \mathcal{T}, \rho)\right) = \mathbb{E}\left((nT-1)\rho + 1\right) = (nT-1)E(\rho) + 1\,. \tag{3}$$

As (3) reveals, the prior distribution of ρ determines how many clusters we expect *a priori*. A larger value for $\mathbb{E}(\rho)$ would indicate that we expect a high number of clusters, while a smaller value has the opposite effect. Note that the choice of a non informative uniform prior for ρ would stimulate the partition of the graph into a large number of clusters, around $\mathbb{E}(C) = (nT+1)/2$.

4. Sampling Partitions Using Spanning Trees

The great advantage of removing edges from spanning trees for regionalization is the reduction of the search space of partitions. Originally, we have to move through the huge space of all partitions of the graph avoiding those that do not respect the spatial constraint. By pruning the spanning trees, the search space of partitions is drastically reduced and all partitions generated in this way will, by definition, respect the spatial constraint. After all, the spanning tree is built from the neighborhood structure and, therefore, the clusters formed will be spatially or spatio-temporally connected.

To sample from the posterior distribution of $(\boldsymbol{\theta}, \boldsymbol{\pi}, \mathcal{T}, \rho \mid \boldsymbol{Y})$, we introduce an MCMC algorithm. The full conditional distributions of $\boldsymbol{\theta}_i$, $i = 1, \ldots, nT$, ρ are, respectively, given by:

$$\begin{aligned}
\boldsymbol{\theta}_i \mid \boldsymbol{\pi}, \mathcal{T}, \rho, \boldsymbol{Y} &\sim \mathbb{P}(\boldsymbol{\theta}_{\mathcal{G}^*} \mid \boldsymbol{Y}_{\mathcal{G}^*}), \;\; \text{if} \;\; i \in \mathcal{G}^*, \\
\rho \mid \boldsymbol{\theta}, \boldsymbol{\pi}, \mathcal{T}, \boldsymbol{Y} &\sim \text{Beta}(r + c - 1, s + nT - c)\,.
\end{aligned}$$

The full conditional distribution for $\mathcal{T}$ assuming a general prior cohesion is given by

$$\mathbb{P}(\mathcal{T} \mid \boldsymbol{\theta}, \boldsymbol{\pi}, \mathcal{T}, \boldsymbol{Y}) \propto \begin{cases} \left(\sum_{\mathcal{C}(\mathcal{T})} \prod_{k=1}^{c} \kappa(\mathcal{G}_k)\right)^{-1}, & \text{if } \boldsymbol{\pi} \prec \mathcal{T} \\ 0, & \text{otherwise.} \end{cases} \tag{4}$$

Assuming the prior cohesion specified in (2), this full conditional distribution assumes the simple uniform distribution

$$\mathbb{P}(\mathcal{T} \mid \boldsymbol{\theta}, \boldsymbol{\pi}, \mathcal{T}, \boldsymbol{Y}) \propto \begin{cases} 1, & \text{if } \boldsymbol{\pi} \prec \mathcal{T} \\ 0, & \text{otherwise.} \end{cases} \tag{5}$$

because, in this case, the denominator in (1) is constant and equal to 1 for any spanning tree $\mathcal{T}$:

$$\sum_{\mathcal{C}(\mathcal{T})} \prod_{k=1}^{c} \kappa(\mathcal{G}_k) = \sum_{c=1}^{nT} \binom{nT-1}{c-1} \rho^{(c-1)} (1-\rho)^{(nT-c)} = 1\,.$$

A more efficient algorithm that has a fast convergence is obtained when we integrate out $\boldsymbol{\theta}$ and ρ from the full conditional distribution $\mathbb{P}(\boldsymbol{\pi} \mid \boldsymbol{\theta}, \mathcal{T}, \rho, \boldsymbol{Y})$ thus obtaining

$$\mathbb{P}(\boldsymbol{\pi} \mid \boldsymbol{Y}, \mathcal{T}) = \begin{cases} f_{\mathcal{T}}(\boldsymbol{Y}) \frac{\Gamma(r+s)\Gamma(s+nT-c)\Gamma(r+c-1)}{\Gamma(r+s+nT-1)\Gamma(r)\Gamma(s)}, & \text{for } \pi \prec \mathcal{T} \\ 0, & \text{otherwise} \end{cases} \tag{6}$$

where $f_{\mathcal{T}}(\boldsymbol{Y}) = \prod_{k=1}^{c} \int_{\Theta} f(\boldsymbol{Y}_{\mathcal{G}_k} \mid \theta_{\mathcal{G}_k}) f(\theta_{\mathcal{G}_k})\, \mathrm{d}\theta_{\mathcal{G}_k}$. We reinforce that $f_{\mathcal{T}}(\boldsymbol{Y})$ is calculated only for partitions $\boldsymbol{\pi}$ compatible with a given spanning tree $\mathcal{T}$. The posterior distribution for the partition $\boldsymbol{\pi}$ should be obtained by marginalizing over all spanning trees compatible with a given partition: $\mathbb{P}(\boldsymbol{\pi} \mid \boldsymbol{Y}) = \sum_{\mathcal{T} \prec \boldsymbol{\pi}} \mathbb{P}(\boldsymbol{\pi} \mid \boldsymbol{Y}, \mathcal{T})\, \mathbb{P}(\mathcal{T} \mid \boldsymbol{Y})$. This would imply the need to additionally derive the posterior $\mathbb{P}(\mathcal{T} \mid \boldsymbol{Y})$. Rather than following this approach, we decide to adopt a different strategy, by sampling from the joint posterior of compatible pairs of $\mathcal{T}$ and $\boldsymbol{\pi}$. The challenge is to sample partitions and the spanning trees that are compatible to each other. The proposed strategy to achieve this is presented in the following.

4.1. Sampling a Partition Compatible with the Current Tree

The transformation suggested by Barry and Hartigan (1993) inspired the Gibbs sampler we describe here. A partition $\boldsymbol{\pi}$ of the graph can be transformed into a vector $\boldsymbol{U}$ of $nT-1$ dependent binary variables, given a compatible spanning tree $\mathcal{T}$. The coordinate U_i of $\boldsymbol{U}$ is 1 if the i-th edge is not removed from the tree to form $\boldsymbol{\pi}$, and 0, otherwise. With this multidimensional random variable, we can sample from the posterior of $\boldsymbol{\pi}$ using Gibbs sampler. Let $\boldsymbol{U}_{-i} = \{U_1, \cdots, U_{i-1}, U_{i+1}, \cdots, U_{nT-1}\}$. To decide if each edge in the tree should be removed or not, it is sufficient to know the ratio between the $\mathbb{P}(U_i = 1 \mid \boldsymbol{U}_{-i}, \mathcal{T}, \boldsymbol{Y})$ and $\mathbb{P}(U_i = 0 \mid \boldsymbol{U}_{-i}, \mathcal{T}, \boldsymbol{Y})$. For the model assumed here such ratio is given by

$$R_i = \frac{f_{\mathcal{T}}^{(1)}\left(\boldsymbol{Y}_{\mathcal{G}_k}\right)}{f_{\mathcal{T}}^{(0)}\left(\boldsymbol{Y}_{\mathcal{G}_k}^{(L)}\right) f_{\mathcal{T}}^{(0)}\left(\boldsymbol{Y}_{\mathcal{G}_k}^{(R)}\right)} \frac{(r+c-2)}{(s+nT-c)}\,,$$

where $f_{\mathcal{T}}^{(1)}\left(Y_{\mathcal{G}_k}\right)$ is the prior predictive of the group formed when the edge i is present, whereas $f_{\mathcal{T}}^{(0)}\left(\boldsymbol{Y}_{\mathcal{G}_k}^{(L)}\right)$ and $f_{\mathcal{T}}^{(0)}\left(\boldsymbol{Y}_{\mathcal{G}_k}^{(R)}\right)$ are the predictive distributions for the observations of the two groups formed when the edge i is removed from the tree $\mathcal{T}$ pruned by $\boldsymbol{U}_{-i}$.

Thus, we can sample from the distribution of U_i simply by sampling a uniform value $u \sim \text{Uniform}(0,1)$ and using the following accept/reject criterion:

$$U_i = \begin{cases} 1, & \text{if } R_i \geq \frac{u}{1-u} \\ 0, & \text{otherwise.} \end{cases} \tag{7}$$

4.2. Sampling a tree compatible with the current partition

We need to sample trees that are compatible with the current partition. The valid trees are uniformly distributed over the subset of trees compatible with the partition as shown in (5). The generation of uniformly distributed spanning trees **without constraints** is a subject of study since 1989 (Broder, 1989). Wilson algorithm (Wilson, 1996) is the main algorithm in the literature and it is based on a certain random walk on the adjacency graph. Under the constraint that the generated trees must be compatible with the current partition at each step of the Gibbs sampler, Wilson's algorithm could be used using a rejection sampling approach. Uniformly select a spanning tree from the adjacency graph $\mathcal{G}$ and reject it if it is not compatible with the current partition. Otherwise, accept it. This is a very expensive way to generate uniformly from the set of spanning trees compatible with $\boldsymbol{\pi}$. For example, suppose that $\mathcal{G}$ is a regular 26×26 rectangular lattice split into two spatial clusters, the

upper half and the lower half. We did not obtain a single compatible spanning tree after uniformly generating 3.8 million spanning trees. Another example is the Brazilian map partitioned into 5564 municipalities (see Figure 7a), again split only into two groups, one being the municipalities within the three most Southern states of Brazil (see Figure 13 for the states' boundaries). This partitioning of the map has 67 edges connecting municipalities of different groups. After 1.5 million simulations by Wilson's method, none was compatible with that partition.

Another possibility is to adapt Wilson's algorithm to obey the constraints imposed by the current partition. A reviewer suggested the following procedure. Suppose a clustering as in Figure 3 (middle). First sample a uniform spanning tree by Wilson's algorithm within each of $\mathcal{G}_1, \mathcal{G}_2, \mathcal{G}_3$. Next, define a collapsed graph where the nodes are the three clusters and we set an edges between $\mathcal{G}_i$ and $\mathcal{G}_j$ if there is at least one edge between the two subgraphs. Sample a uniform spanning tree on that collapsed graph. Finally, for each edge sampled in the collapsed graph, sample one of the edge uniformly in the original bipartite graph.

While this procedure may sound promising at first, it, unfortunately fails to generate trees uniformly. What is problematic in this approach is that the number of edges between clusters can be imbalanced, which could lead to trees being sampled with different probability.

Consider the graph in Figure 4. We would first sample a uniform tree inside of each of the tree groups. In this example, there are 3 independent options for each group, so in this first step a choice is made with probability $\left(\frac{1}{3}\right)^3 = \frac{1}{27}$. Now, the collapsed graph is a complete graph of size 3 (a triangle). Once again, there is a choice between three spanning trees. Assume we uniformly select a spanning tree which contains an edge between Group A and Group B and between Group B and Group C. This choice has probability $\frac{1}{3}$. Finally, we need to uniformly choose among the corresponding edges between the clusters. For the connection between Group B and Group C, there is only one option, while for Group A and Group B, there are three choices. Uniformly selecting the edges, thus, will have a probability of $\frac{1}{3} \cdot 1 = \frac{1}{3}$. The final tree, then, will have been selected with probability $\frac{1}{27}\frac{1}{3}\frac{1}{3} = \frac{1}{247}$.

Consider now another possible combination of choices. For the first step, we select the same trees inside the groups, with probability $\frac{1}{27}$. For the second step, we choose the spanning tree of the collapsed graph which contains a connection between Group A and Group C and between Group C and Group B. This step, again, has probability $\frac{1}{3}$. Finally, to select the corresponding trees in the original bipartite graph, there is only one choice corresponding to each connection, namely (B2, C3) and (A2, C1). Therefore, the choice in this final step was made with probability 1. The final tree, then, was chosen with probability $\frac{1}{27}\frac{1}{3}1 = \frac{1}{81}$. Therefore, this method will sample the trees with a probability which is not uniform.

Instead of Wilson's algorithm, we employ another procedure to sample trees using a minimum spanning tree (MST) algorithm. We sample a new tree $\mathcal{T}$ compatible with the current partition π by assigning weights to the edges in the graph respecting this current partition in the following way. The edges that connect vertices belonging to the same cluster receive a low weight, obtained from a uniform distribution which generates low values (e.g. between 0 and 1). The edges that connect vertices belonging to different clusters receive a high weight, obtained from a uniform distribution which generates higher values (e.g.

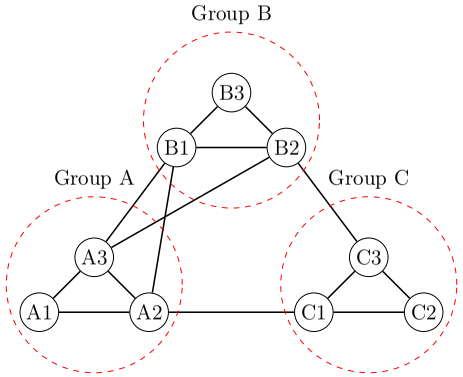

Figure 4: Counter example of graph where the approach of adapting Wilson's algorithm as a multi-step procedure to obey the constraints imposed by the partition fails to sample trees uniformly.

between 10 and 20). Once the weights are assigned, the minimum spanning tree is obtained and it is the new sampled tree, compatible with the current partition.

The reason for using these two sets of values is that the algorithm computes the spanning tree with minimum sum of weights. When we use weights in this way, we ensure that the tree will be compatible with the partition, since the edges with higher weights are added to the tree only when all possible connections through edges with a lower weight are already explored. So, it only adds a connection between clusters when all the possible connections inside a cluster have been visited.

The proposed algorithm works because the MST algorithm, either by Prim algorithm or by the Kruskal algorithm (Cormen et al., 2009), selects the edges according to their weights. Since all edges separating clusters have higher weights, they are selected only after the lower weight edges connecting vertices inside a cluster. The random attribution of weights ensures that the tree will respect the partition and, since we randomly assign weights each time we sample a tree, we get a random tree, even though the algorithm is deterministic.

This procedure does not sample exactly from a uniform distribution. To see this, consider the following example. Consider the graph in the left hand side of Figure 5 where we disregard any partition. There are 5 spanning trees that do not include the $(3-4)$ edge, each one obtained by the removal of $(3-4)$ and one of the remaining edges. There are 6 other spanning trees including the $(3-4)$ edge: we need to prune one of the three edges located at the left-hand side of $(3-4)$ and one of the two located at its right-hand side. Our method would assign independent $U(0,1)$ random variables $W_1, \ldots, W_6$ to the six edges and then select its minimum spanning tree. This is equivalent to substitute the W_i's by their rank statistics $R_1, \ldots, R_6$ where $R_i = \sum_{j=1}^{6} I[W_j \leq W_i]$ and to select the minimum spanning tree using these ranks. The total number of possible ranks assignment to the

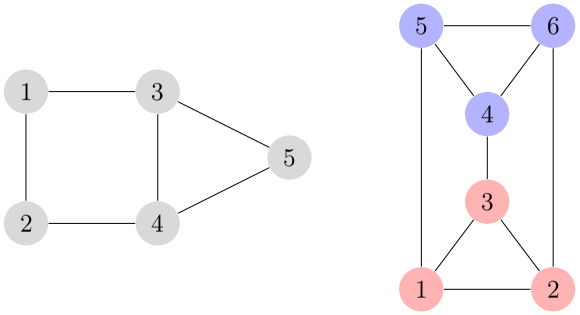

Figure 5: Two graphs to discuss different possibilities to randomly generate spanning trees.

edges is equal to the number of permutations of the six edges, that is, $6! = 720$. Each rank statistic configuration is equally likely and each one of the 11 spanning trees is associated with a subset of these 720 ranking patterns. The cardinality of these subsets should be the same if we have a uniform sampling procedure. However, 11 is not a divisor of 720 and therefore some spanning trees are selected with higher frequency than others.

However, this simple and fast procedure is a good approximation for the uniform sampling of spanning trees and we show this by means of an example. Consider the graph in the right-hand side of Figure 5 with 6 nodes divided into 2 groups (nodes 1-3 and nodes 4-6). A complete enumeration shows that there are 27 spanning trees compatible with this partition, which, if uniformly sampled, should have a selection probability equal to $1/27 \approx 0.03704$. Using Wilson's algorithm, we selected 100 thousand random spanning trees. The observed frequencies of the 27 spanning trees varied from 0.03588 to 0.03831. Using our method based on 100 thousand simulations of $U(0, 1)$ random variables for the edges within cluster and $U(10, 20)$ random variables for the edges between clusters, the observed frequencies of the spanning trees varied from 0.03588 to 0.03811. Additionally, Wilson's algorithm requires generating about 3 spanning trees before one is accepted (compatible with the partition), even in this small example, while for our approach each generated tree is guaranteed to be compatible with the partition.

5. Analysis of Simulated Data Sets

In this section, we evaluate the performance of our model for regionalization in spatial settings only. The main goal is to compare it with the following state-of-art regionalization techniques: *SKATER*, through its implementation on the `spdep` R package[1], the original Automatic Zoning Procedure (*AZP*), and its variations with Simulated Annealing (*AZP_SA*), Tabu (*AZP_TABU*), Reactive tabu (*AZP_RTABU*), the Automatic Regionalization with Initial Seed Location (*ARISEL*), the Max-p-regions Tabu model (*MAXP*) and the "A Multidirectional Optimum Ecotope-Base Algorithm" (*AMOEBA*), all implemented

1. `http://cran.r-project.org/package=spdep`

in the Python ClusterPy[2] library (Duque et al., 2011). For Poisson data sets, the proposed spatial PPM is also compared to the BDCD model, implemented in C++ code (available at `http://www.statistik.lmu.de/sfb386/software/bdcd/download.html`) and to BPM, implemented in R software by ourselves.

To define the spatial structure of the simulated data (coordinates, shapes and spatial adjacency), we consider two geographical neighborhood structures of Brazilian regions. In the Gaussian data sets, inspired by the human development index map shown in Section 6, we considered 853 Brazilian regions grouped into three clusters: two large clusters and a third small cluster, composed by 10 regions and islanded in the middle of one of the other two clusters. The small cluster mean is very different from that in surrounding regions. In Scenario 1, the observations within each cluster are *iid* generated from normal distributions. To mimic the observed data, we choose means $\mu_i = 0.73$ and precision $\tau_i = 4000$, for the small cluster, $\mu_i = 0.63$ and $\tau_i = 754.20$, for the large cluster containing the small one, and $\mu_i = 0.70$ and $\tau_i = 878.35$, for the other large cluster. In Scenario 2, the spatial structure also presents three clusters but inside each cluster, the distribution varies slightly from a region to another. The regions means within the large cluster containing the smaller one vary from 0.612 up to 0.685 and precision varies between 435 and 484. The other large cluster have $\mu_i \in (0.663, 0.726)$ and $\tau_i \in (471, 497)$. Finally, the small cluster is composed by three areas with common mean equal to 0.780 and precision 10000.

For the Poisson data sets, we were inspired by the epidemiological studies presented in Section 6. We considered smaller areas in the southern region of Brazil, the 1188 Brazilian municipalities divided into clusters. Each observation y_i simulates a cancer death count and the expected count E_i is extracted from the real data analysis and based on true population in each area. Motivated by the high mortality rates observed in the lung cancer data, we simulated Poisson data with high rates in Scenarios 3 and 4, while in Scenarios 5 and 6, we assumed low rates similar to those observed in the bladder cancer data. Rates assumed in high rate scenarios are, on average, 8 times higher than those for the low rate scenarios. Similarly to the normal case, we assume areas with the same rate (Scenarios 3 and 5) and with distinct but similar rates (Scenarios 4 and 6) within each cluster.

In Scenarios 3 and 4, the map is divided into 10 clusters with the common rates in Scenario 3 ranging from 0.45 to 1.40. The distinct rates for the 1188 regions considered in Scenario 4 range from 0.45 to 1.75. In bladder cancer inspired low rate scenarios, the map is divided into 13 clusters. The common rates in Scenario 5 has values varying from 0.24 to 1.74, while for Scenario 6, the distinct parameters for each region vary from 0.77 to 1.42.

Concerning the inference, we assume that $Y_i \mid \mu_{\mathcal{G}_k}, \tau_{\mathcal{G}_k} \overset{iid}{\sim} \text{Normal}\left(\mu_{\mathcal{G}_k}, \tau_{\mathcal{G}_k}^{-1}\right)$, for all $i \in \mathcal{G}_k$, in the normal case. We also consider the normal-gamma prior distribution with $\mu_{\mathcal{G}_k} \mid \tau_{\mathcal{G}_k} \sim \text{Normal}\left(m, [v\tau_{\mathcal{G}_k}]^{-1}\right)$ and $\tau_{\mathcal{G}_k} \sim \text{Gamma}\,(a, b)$, where $m = 0.65$, $v = 1$, $a = 400$ and $b = 1$. For the Poisson data, $Y_i \mid \phi_{\mathcal{G}_k} \overset{iid}{\sim} \text{Poisson}\,(E_i \cdot \phi_{\mathcal{G}_k})$ and $\phi_{\mathcal{G}_k} \sim \text{Gamma}(a, b)$, where $a = b = 2$. This prior distribution for $\phi_{\mathcal{G}_k}$ puts probability mass around 1, as we usually expect for the relative risk. Furthermore, 90% of its probability mass is concentrated between 0.18 and 2.37, which is a reasonable range for many human disease relative risks. As usually done in real problems, in our analysis, the expected count E_i is assumed to

2. `http://www.rise-group.org/`

be known. Besides, we assume that each edge is removed from the spanning tree with probability $\rho \sim \text{Beta}(5, 1000)$.

Our algorithm was implemented in C++ and is available upon request. For the MCMC we run a chain of 5000 iterations, skipping the first 500 samples as a *burn-in* period and, to avoid correlation, we use a thinning of 5 simulated values.

5.1. Evaluation Metrics

We consider two groups of metrics. The first group is based on the estimates of the parameters that index the data distributions. We consider the mean absolute error (MAE), the mean relative error (MRE) and the mean squared error (MSE) based on the distance between the true parameters and their estimates. Under BPM, BDCD and the proposed PPM the parameter estimates in each region are the posterior means. Under the usual regionalization methods, such estimates are obtained by averaging the observations Y_i into the cluster. For normal data, these are given by $\hat{\theta}_i = \sum_{j \in \mathcal{G}_k} Y_j / n_k \quad \forall i \in \mathcal{G}_k$ and, in the Poisson case, they are $\hat{\theta}_i = [\sum_{j \in \mathcal{G}_k} Y_j][\sum_{j \in \mathcal{G}_k} E_j]^{-1}$, $\forall i \in \mathcal{G}_k$.

The other set of metrics is based on the difference between the true clusters used to generate the data and the clusters obtained by the different methods. Each pair of areas is labeled as positive if they are in the same cluster and as negative if they are in different clusters. We looked at the number of true positives (TP) classifications, the number of pairs that are in the same cluster both, in the true partition as well as in the estimated one. False positive classifications (FP) is the number of pairs assigned to distinct clusters but that actually are in the same cluster in the true partition. True negatives (TN) classification is the number of pairs correctly assigned to distinct clusters. Finally, false negatives (FN) classification is the number of pairs incorrectly assigned to distinct clusters. In our evaluation, we consider the rand measure (RAND), the F_1 score (F1), the Jaccard index (JI) and the Fowlkes-Mallows index (FM) which are given, respectively, by

$$RAND = [TP + TN] \cdot [TP + FP + FN + TN]^{-1},$$
$$F1 = 2 \cdot P \cdot R \cdot [P + R]^{-1},$$
$$JI = TP \cdot [TP + FP + FN]^{-1},$$
$$FM = \sqrt{P \cdot R},$$

where $P = TP \cdot [TP + FP]^{-1}$ and $R = TP \cdot [TP + FN]^{-1}$.

Most of the traditional regionalization techniques considered in our analysis requires the pre-definition of the number of clusters to be generated as an input. In all cases, we use three different values: the true number c of clusters as well as 3 more and 3 less (1 less for the normal case) clusters than the true number. The max-p-regions model clusters a set of geographic areas into the maximum number of homogeneous regions such that the value of a spatially extensive regional attribute is above a predefined threshold value. In clusterPy we measure heterogeneity as the within-cluster sum of squares from each area to the attribute centroid of its cluster. The parameter values shown in the tables for this method correspond to this threshold.

To summarize the posterior information about the random partition provided by our method, we take the underlying graph of the spatial structure of the data and, for each edge

connecting neighboring areas, we compute how often they are in the same cluster based on the generated partitions. This percentage is assigned to each edge. Then, we trim the edges by removing all those which are below a certain threshold. Once the infrequent edges are removed, the remaining components of the graph define the clusters. The reasoning is that the removed edges are exactly those which are frequently crossing the borders between clusters in the sampled partitions. By removing them, the bulk of the clusters frequently present in the sampled partitions remain connected in the graph. We consider three thresholds: 70%, 80% and 90%. The same strategy is used for the BPM and BDCD methods.

5.2. Results

Tables 1 to 3 show the model fit measures for the proposed model and the competitor methods for normal and Poisson data. For each evaluation measure, the best outcome is underlined and shown in bold.

In almost all the simulated data sets, our model outperformed all the other methods. The only scenarios where our method had inferior results were in the normal data set with common parameter, where the MAE for the *SPPM* was the second best and the Poisson data set with low rate and common parameter where *SKATER* had the lowest MRE. However, in both cases, the *SPPM* had better performance according to all other metrics we consider to evaluate the models. Furthermore, in these two exceptional cases, even in those losing metrics, *SPPM* had a very close value to the better competitors.

In all data sets, particularly in the Poisson data sets, the error metrics (MAE, MSE, MRE) for our method were from 1.5 to 5 times smaller than the other methods. For *SKATER*, *ARISEL* and the *AZP*-type methods, we notice that the bias in the parameter estimates (either the normal mean or the Poisson rate) depends on the number of clusters we assume to implement the method as well as on the type of scenario. We notice, for instance, that *SKATER* produced less biased estimates for such parameters in all scenarios if the assumed number of cluster is $c - 3$ (and $c - 1$ for the normal case), the exception occurring in Scenario 1. Moreover, in Scenario 3, less biased estimates are obtained by all such methods, except *SKATER*, if the number of clusters is correctly assumed. This bias may be explained by the poor capacity of these methods to identify correctly the clusters. The non-stochastic methods were favored in the sense that they received good information about the number of clusters. We either provided the exact number or a close one. In some cases, even with the correct number of clusters, the *AZP*-type methods had a worse performance than with the wrong number of clusters.

Our method also achieved better results if compared to the Bayesian models *BPM* and *BDCD* (only implemented for Poisson models). *BPM* had a very poor performance for both, cluster identification and parameter estimation, in all four Poisson scenarios. *BDCD* and the proposed *SPPM* are comparable with respect to the parameter estimation, with proposed model usually providing only slightly better estimates. However, the proposed model has much better performance for cluster identification, except for Scenario 3 and thresholds 70% and 80%, and Scenarios 4 and 6 and thresholds 70%.

Table 1: Model fit summaries for all methods, Normal data, Scenarios 1 and 2.

Method	Parameter	MAE	MSE	MRE	RAND	F1	JI	FM
				Common parameters

6. Case Studies

The analysis described in this section illustrates the usefulness of our method in three relevant applications. The first one is a purely spatial case with Gaussian data and aims at the regionalization of the Brazilian municipalities according to their Human Development Index (HDI) in 2010. The second application is also purely spatial but assumes a Poisson distribution for death counts. It aims at the regionalization of the Southern Brazilian municipalities according to lung and bladder cancer mortality. We restrict the analysis to the Brazilian region where the mortality data is not affected by under reporting. The third application is a spatio-temporal situation with Gaussian data. We analysed the HDI as in the first application but now we describe its evolution from 1991 to 2010. In the three analysis, for the MCMC, we ran chains of size 10000, skipping the first 1000 samples as the *burn-in* period and take a lag of 10 to avoid correlation.

6.1. HDI Data: A Spatial Regionalization with Gaussian SPPM

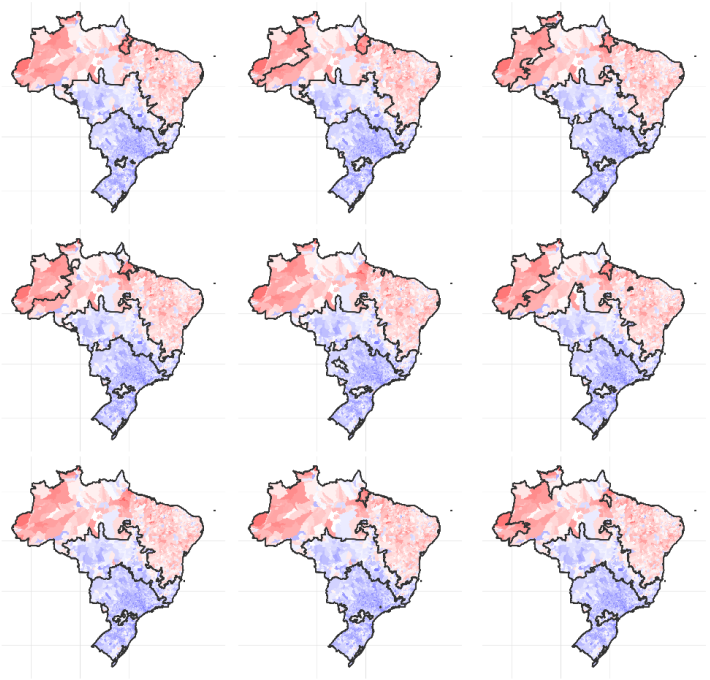
The HDI is an index combining life expectancy, education and income measures developed by the United Nations Development Programme (UNDP) and it is often used to rank countries. Together with UNDP, the *Instituto de Pesquisa Econômica e Aplicada* (IPEA) and *Fundação João Pinheiro* developed a version of the HDI incorporating additional variables extracted from the demographic census to evaluate the Brazilian municipalities.

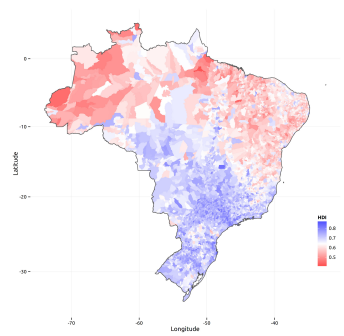
The data set is composed of the HDI of 5564 municipalities of Brazil (see Figure 7) in 2010. which is assumed to be normally distributed with mean and variance changing over the space. We consider the neighborhood structure computed through the geographic adjacency. As prior distribution for the cluster parameters we assume a conjugate Normal-Gamma distribution such that $\mu_{\mathcal{G}_k} \mid \tau_{\mathcal{G}_k} \sim N\left(0.65, (0.04\tau_{\mathcal{G}_k})^{-1}\right)$ and $\tau_{\mathcal{G}_k} \sim \text{Gamma}\,(100, 1)$. This prior distribution for the precision concentrates its probability mass around 100, which yields a standard deviation of about 0.1 for the observations of the clusters. Consequently, the cluster means are most probably around 0.65, with a deviation of 0.5. This spans most of the range the HDI can take, which is from 0.0 to 1.0. *A priori*, we assume that each edge is removed from the tree with probability $\rho \sim \text{Beta}(2, 7)$. As a result, the expected number of clusters in the map is around 1236. This is likely to be much larger than one would expect. However, we selected these values for two reasons. First, we want to allow a possible large variability in the parameters to be expressed by the prior. Second, we want to verify if the data provide enough evidence to shrink the distribution of the number of clusters.

The posterior distribution for the number c of clusters has mode equal to 12 and varies between 10 and 16, the 5% and 95% quantiles, respectively. The posterior probability of edge removal ρ has mean 0.0025 and median 0.0022.

In Figure 6 we show a random sample of partitions generated by our algorithm. The main difference between samples is on the frontier between the clusters. As expected, the boundaries are hard to be established because, for this type of data, we do not expect a clearly defined and sharp transition in the data.

To summarize the posterior partition distribution, we present Figure 7b. It is constructed by deleting the boundary between neighboring municipalities that belong to the same cluster in at least 80% of the sampled partitions. Therefore, the boundaries that remain indicates





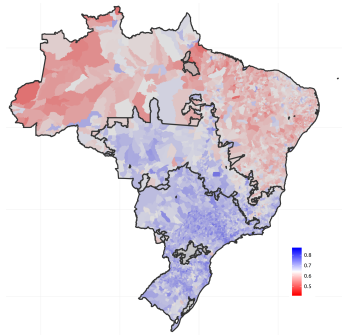


Figure 6: Some of the sampled partitions (HDI data)

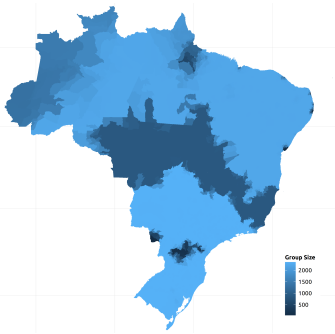
areas that cannot be sharply allocated together into a cluster with its neighbor. It does not mean that the area necessarily stays isolated from their neighbors most of the time. It means that it is often allocated to clusters with different area components. Lines clearly splitting large portions of the map indicate sharp transition zones. Another posterior partition summary is given in Figure 7c . Each area is colored according to the size of cluster to which it belongs. Darker colors indicate that the area belong to a small cluster.



These figures show the presence of three large regions in the country. Additionally, we can see a number of small groups in the frontier and some tiny clusters located on the Northeast coast, hard to visualize on the figure. We also have two small clusters isolated in the middle of the big clusters, both with average HDI. The Southern one is surrounded by better HDI areas while the Northern one is relatively better than its neighbors. Although the main groups are well defined, the separation between them is not, causing a certain level of noise. In fact, this discloses the natural characteristic of this kind of data where there is a transition between two distinct groups but frontiers are not well defined. Another result is related to the tiny clusters found on the Northeast coast. These areas are frequently assigned to small clusters, with size within 9000 squared kilometers in at least 90% of the

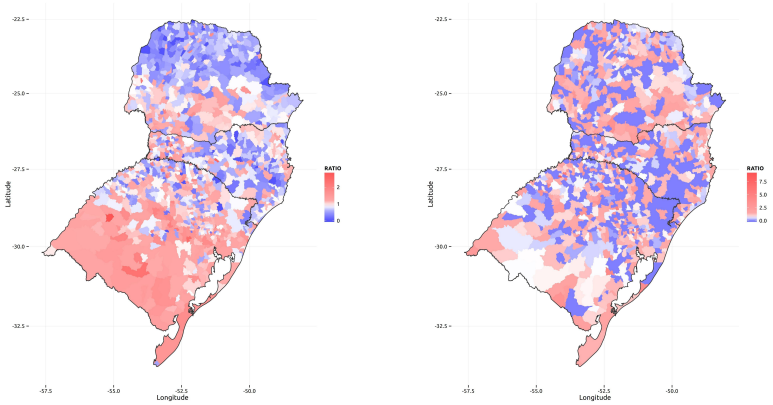
(b) Summary of the sampled partitions for Brazilian municipalities (HDI data)



(c) Average group size for each municipality in the sampled partitions

Figure 7: Posterior regionalization of Brazilian municipalities according to their HDI

sampled partitions. Such areas are the capital of states in the northeast region and their neighboring towns. The HDI in the northeast region is generally very low, as can be seen in Figure 7a, but the capital cities and their surroundings are more developed and have a stronger economy than other regions on the State.

6.2. Lung and Bladder Cancer Data: A Spatial Regionalization with Poisson SPPM

To illustrate the use of the Poisson SPPM we consider the number of deaths by bladder and lung cancer in the south region of Brazil. These two types of cancers were selected due to their different incidence rate. Bladder cancer is almost an order of magnitude rarer than lung cancer. Thus, the incidence rate for bladder cancer is more affected by small variations.

(a) Lung cancer (b) Bladder cancer

Figure 8: Ratio between the actual and expected number of deaths by lung and bladder cancer in Brazilian south region

This scenario is a good example where the benefits of using a stochastic method instead of traditional approaches may be more easily perceived.

For both data sets, we obtained the total number of deaths by age group and gender, in each municipality, in the years 2008 - 2012. Data are available in the DATASUS website (`http://datasus.saude.gov.br/`). We also obtained demographic information of the same years, for the same age groups and gender, from IBGE. We summed over the years the number of deaths in each area to obtain the total number of events in the period generating one single count Y_i for each municipality. We assume that, conditional on a parameter θ_i, the random variable Y_i follows a Poisson distribution with mean $\mu_i = E_i\theta_i$. The values of E_i represent the expected number of deaths in area i if the risk was spatially constant in each age and sex class. That is, after obtaining the age-sex-specific mortality rates for the entire map, we applied them on each municipality respecting their demographic distribution by age and sex. We end up with the expected number of events in each municipality under this spatially homogeneous hypothesis. The θ_i parameters are called relative risks and they represent multiplicative factors with respect to the baseline E_i. In Figure 8 we show the ratio between the observed and the expected number of deaths by cancer.

We assume that, a priori, the cluster mortality rate has a Gamma distribution with parameters $a = 1.1$, and $b = 1.1$. This distribution concentrates its mass around 1.1, with a variance of 0.91, so the relative risk is concentrated in values mostly between 0 and 2. This seems reasonable as we expect the incidence rate to deviate from the expected value by a factor smaller than 2. We also assume that $\rho \sim \text{Beta}(5, 1000)$ and thus the expected number of cluster *a priori* is 6.9. The proposed model is compared to ARISEL and SKATER.

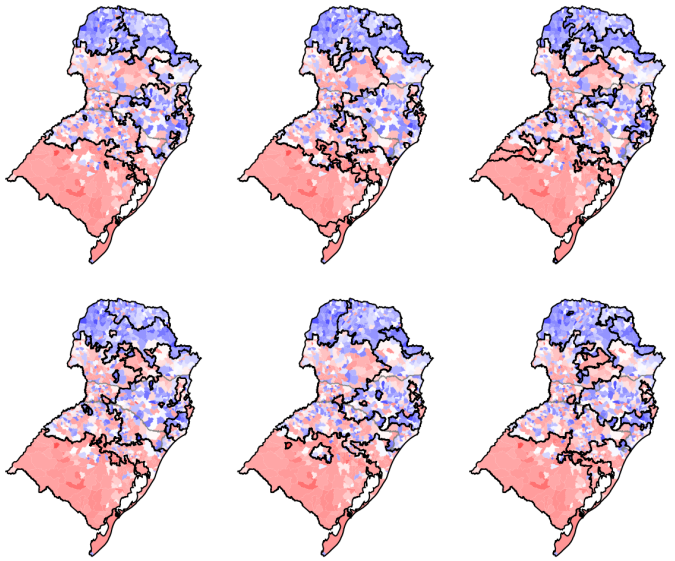


Figure 9: Some of the sampled partitions (lung cancer)

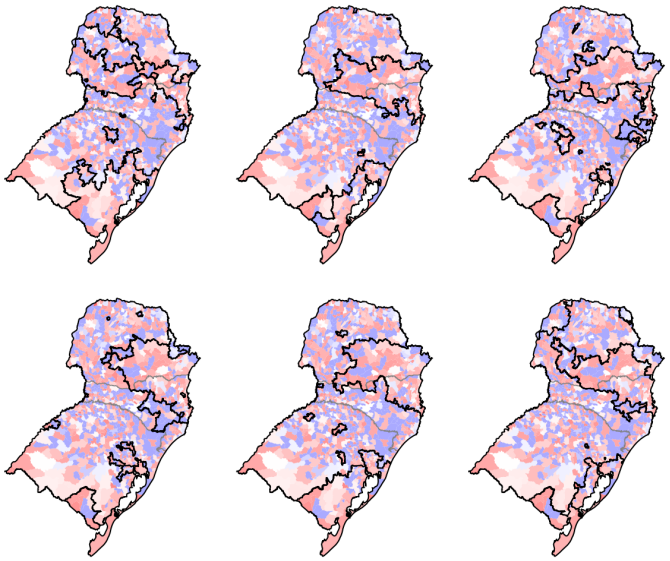
Inspired by our findings by applying the proposed model, for such approaches, we fixed the number the clusters equal to 4.

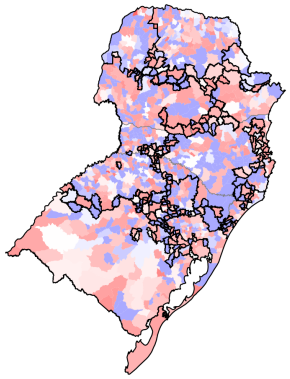
The posterior distribution for the number of clusters c has mode 29 (lung) and 13 (bladder) with 5% and 95% quantiles given by 18 and 34 (lung) and 7 and 22 (bladder). The edge removal parameter ρ has posterior mean and median around 0.013 and 0.008 for the lung and bladder examples, respectively.

In Figures 9 and 10 we show some of the partitions sampled by our algorithm for the lung and bladder cancer data sets, respectively.

As in the normal case, we summarize the posterior distribution of these partitions in Figure 11. Maps in (a) and (b) that are constructed taking into consideration the neighboring municipalities belonging to the same cluster in at least 85% of the sampled partitions. Maps in (c) and (d) represent the average size of the cluster to which each region belongs.

Our method is able to find the easily spotted clusters in the extreme North and South regions in Figure 8a for the lung cancer. However, it goes beyond that by also finding additional clusters that divide the central area into West and East. In the bladder cancer case, our model finds evidence in favor of the existence of clusters in the West and South regions. These findings are hardly identified by visual inspection of Figure 8b or by using some of the traditional approaches.





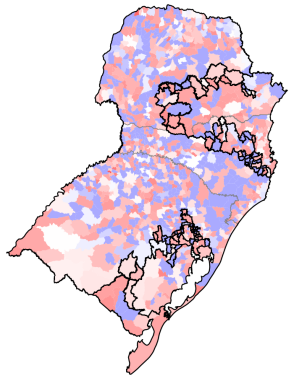


Figure 10: Some of the sampled partitions (bladder cancer)

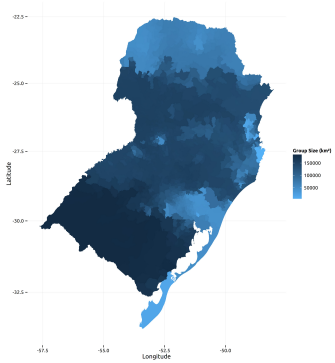
As we can see in Figure 12, the *ARiSEL* and *SKATER* techniques result in regionalizations that capture only the most obvious visual aspects of the raw data maps. These deterministic methods were run with 4 groups. The *SKATER* method was still able to separate the top from the bottom of the lung cancer map, while *ARiSEL* detected only the southern boundary and with a more jagged line. For the bladder cancer, however, neither method was able to detect the region in the northeast of the map. They seemed to be more sensitive to local variations in the rate. This is the practical exemplification of what we expected. Given that these methods do not use a statistical model, they are more susceptible to this kind of problem where the population incidence rate is small.



Lung cancer is linked to smoking and the rate increases going south, which could be related to the colder climate. This explains the clusters in the two extreme parts of the North-South gradient in Figure 11a. With the help of hindsight, we can see that the right portion of the middle region in this figure is where some of the large cities are located, and presents a lower rate than its western counterpart. The deterministic methods either separates out only the extreme south region and fail to identify the regions in the center. A more visible difference between the methods is in Figure 11b. SPPM identified a cluster in the northeast of the map, where Curitiba (capital of Paraná state) and the most populated cities of the state of Santa Catarina are located. All the other methods failed to find this

cluster and instead identified noisy small regions, which is a demonstration of how these methods are sensitive to the variations of the data.

6.3. HDI Data: A Space-Time Regionalization

In this section, we provide a short example of our space-time method using the state-level HDI for the 26 Brazilian states and the Federal district. We have data for three different time moments, the 1991, 2000, and 2010 Census years, which implies in 81 graph nodes. We used the state-level graph to simplify the analysis and the interpretation of the results. We considered the same prior choices as in Section 6.1: $\mu_{\mathcal{G}_k} \mid \tau_{\mathcal{G}_k} \sim N\left(0.65, (0.04\tau_{\mathcal{G}_k})^{-1}\right)$, $\tau_{\mathcal{G}_k} \sim \text{Gamma}\,(100, 1)$, and $\rho \sim \text{Beta}(2, 7)$.

Figure 13 shows the HDI in each year in the top row and the summary of our posterior distribution in the bottom row. We delete the boundary between neighboring states that belong to the same cluster in at least 70% of the sampled partitions. It is clear the improvement of the Brazilian socio-economic condition over the three decades. In the first decade, the small Federal District was isolated from the other regions presenting the highest HDI level. In the second decade, this cluster is enlarged including the states in southern part of the map. Such regions, in fact, presented an improvement in their socio-economic conditions if compared with the first decade under analysis, getting closer of the Federal District. Another small cluster was identified separating Amapá state, located in the North, from the other regions. After three decades, all Brazilian states are assembled in a single cluster.

7. Conclusion

In this work we dealt with the problem of regionalization, an important type of clustering problem which arises in many areas. We proposed a new product partition model that accounts for spatial and spatio-temporal clustering. The innovative aspect of this paper is the use of random spanning trees as a tool to reduce the search space of partitions. This random spanning tree trick allowed us to represent the random partitions as fixed dimensional vector with binary elements. We presented a posterior sampling algorithm for the proposed model that keeps fixed the dimension of the parametric space and resorts to a regular Gibbs sampling procedure.

We evaluated of our method using simulated and real data. In the simulated study, we compared our approach to available implementations of non-stochastic optimization methods and Bayesian proposals and showed how our results were consistently superior. This was particularly noticed in low rate Poisson generated data. We applied our technique to perform the regionalization of Brazilian municipalities based on the human development index and on bladder and lung cancer mortality data. We discussed how the results we obtained were suitable for the domain subjects and how the use of our model obtained better and more meaningful results.

The model proposed has some limitations. The temporal component is not dealt with typical time series techniques and this prevents us to make inference in a prospective way. More importantly, the prior distribution on the set of spanning trees is an artificial tool to make inference on the partitions and these spanning trees do not have an obvious interpretation making difficult a prior distribution elicitation for $\mathcal{T}$. However, the spanning tree plays

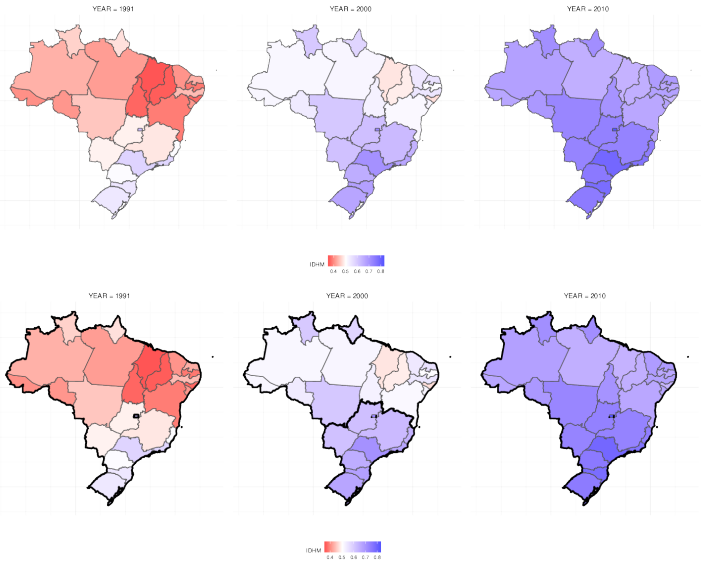

Figure 13: Map of Brazilian states and their HDI data (first row) and the evolution of the posterior summaries for cut point 0.7 (second row), over the years 1991, 2000, and 2010.

an important role in the prior elicitation for the partition. Coupled with the simplification of the computational search for a good partition by restricting this search to n edges, it allowed us to write the prior cohesion as functions of ρ, the prior probability of removing edges from the tree.

In conclusion, we proposed a stochastic model for the problem of space-time regionalization that captures much of the prior reasoning one could have for its formation. We introduced the use of spanning trees to provide an effective sampling algorithm. Our model is flexible enough to accommodate different types of data and provides good results.

Acknowledgments

The authors would like to thank CNPq, CAPES and FAPEMIG, three Brazilian funding agencies, for partial support. We also thank the comments provided by Pedro O. S. Vaz de Melo and Fábio Cozman on a first version of this paper and the comments provided by the editor and reviewers, which contributed to improve the paper. We also want to thank Vinícius Fernandes dos Santos for suggesting the counter-example illustrated in the left hand-side of Figure 4. The research for this project was conducted while the first author was a student at the Departamento de Ciência da Computação, Universidade Federal de Minas Gerais, where he obtained his Master of Science degree in Computer Science.

Abstract

Linear subspace models are pervasive in computational sciences and particularly used for large datasets which are often incomplete due to privacy issues or sampling constraints. Therefore, a critical problem is developing an efficient algorithm for detecting low-dimensional linear structure from incomplete data efficiently, in terms of both computational complexity and storage.

In this paper we propose a streaming subspace estimation algorithm called Subspace Navigation via Interpolation from Partial Entries (SNIPE) that efficiently processes blocks of incomplete data to estimate the underlying subspace model. In every iteration, SNIPE finds the subspace that best fits the new data block but remains close to the previous estimate. We show that SNIPE is a streaming solver for the underlying nonconvex matrix completion problem, that it converges globally to a stationary point of this program regardless of initialization, and that the convergence is locally linear with high probability. We also find that SNIPE shows state-of-the-art performance in our numerical simulations.

1. Introduction

Linear models are the backbone of computational science, and Principal Component Analysis (PCA) in particular is an indispensable tool for detecting linear structure in collected data (van Overschee and de Moor, 2012; Ardekani et al., 1999; Krim and Viberg, 1996; Tong and Perreau, 1998). Principal components of a dataset are used, for example, to perform linear dimensionality reduction, which is in turn at the heart of classification, regression and other learning tasks that often suffer from the "curse of dimensionality", where having a small number of training samples in relation to the number of features typically leads to overfitting (Hastie et al., 2013).

In this work, we are particularly interested in applying PCA to data that is presented sequentially to a user, with limited processing time available for each item. Moreover, due to hardware limitations, we assume the user can only store small amounts of data. Finally, we also consider the possibility that the incoming data is incomplete, either due to physical sampling constraints, or deliberately subsampled to facilitate faster processing times or to address privacy concerns.

As one example, consider monitoring network traffic over time, where acquiring complete network measurements at fine time-scales is impractical and subsampling is necessary (Lakhina et al., 2004; Gershenfeld et al., 2010). As another example, suppose we have a network of cheap, battery-powered sensors that must relay summary statistics of their measurements, say their principal components, to a central node on a daily basis. Each sensor cannot store or process all its daily measurements locally, nor does it have the power to relay all the raw data to the central node. Moreover, many measurements are not reliable and can be treated as missing. It is in this and similar contexts that we hope to develop a *streaming* algorithm for PCA from incomplete data.

More formally, we consider the following problem: Let $\mathcal{S}$ be an r-dimensional subspace with orthonormal basis $S \in \mathbb{R}^{n\times r}$. For an integer T, let the coefficient vectors $\{q_t\}_{t=1}^T \subset \mathbb{R}^r$ be independent copies of a random vector $q \in \mathbb{R}^r$ with bounded expectation, namely, $\mathbb{E}\|q\|_2 < \infty$. Consider the sequence of vectors $\{Sq_t\}_{t=1}^T \subset \mathcal{S}$ and set $s_t := Sq_t$ for short. At each time $t \in [1:T] := \{1, 2, \cdots, T\}$, we observe each entry of s_t independently with a probability of p and collect the observed entries in $y_t \in \mathbb{R}^n$. Formally, we let $\omega_t \subseteq [1:n]$ be the random index set over which s_t is observed and write this measurement process as $y_t = P_{\omega_t} \cdot s_t$, where $P_{\omega_t} \in \mathbb{R}^{n\times n}$ is the projection onto the coordinate set ω_t, namely, it equals one on its diagonal entries corresponding to the index set ω_t and is zero elsewhere.

Figure 1: The sequence of generic vectors $\{s_t\}_{t=1}^T$ drawn from an unknown r-dimensional subspace $\mathcal{S}$ in panel (a) is only partially observed on random index sets $\{\omega_t\}_{t=1}^T$. That is, we only have access to incomplete data vectors $\{y_t\}_{t=1}^T$ in panel (b), where the white entries are missing. Our objective is to estimate the subspace $\mathcal{S}$ from the incomplete data vectors, when limited storage and processing resources are available. See Section 1 for the detailed setup.

Our objective in this paper is to design a streaming algorithm to identify the subspace $\mathcal{S}$ from the incomplete data $\{y_t\}_{t=1}^T$ supported on the index sets $\{\omega_t\}_{t=1}^T$. Put differently, our objective is to design a streaming algorithm to compute leading r principal components of the full (but hidden) data matrix $[s_1\, s_2 \cdots s_T]$ from the incomplete observations $[y_1\, y_2 \cdots y_T]$, see Figure 1. By the Eckart-Young-Mirsky Theorem, this task is equivalent to computing leading r left singular vectors of the full data matrix from its partial observations (Eckart and Young, 1936; Mirsky, 1966).

Assuming that $r = \dim(\mathcal{S})$ is known *a priori* (or estimated from data by other means), we present the SNIPE algorithm for this task in Section 2. SNIPE is designed based on the *principle of least-change* and, in every iteration, finds the subspace that best fits the new data block but remains close to the previous estimate. SNIPE requires $O(n)$ bits of memory and performs $O(n)$ flops in every iteration, which is optimal in its dependence on the ambient dimension n. As discussed in Section 3, SNIPE has a natural interpretation as a streaming algorithm for low-rank matrix completion (Davenport and Romberg, 2016).

Section 4 discusses the global and local convergence of SNIPE. In particular, the local convergence rate is linear near the true subspace, namely, the estimation error of SNIPE reduces by a factor of $1-cp$ in every iteration, for a certain factor c and with high probability. This local convergence guarantee for SNIPE is a key technical contribution of this paper which is absent in its close competitors, see Section 5.

Even though we limit ourselves to the "noise-free" case of $y_t = P_{\omega_t} s_t$ in this paper, SNIPE can also be applied (after minimal changes) when $y_t = P_{\omega_t}(s_t + n_t)$, where we might think of $n_t \in \mathbb{R}^n$ as measurement noise from a signal processing viewpoint. Alternatively from a statistical viewpoint, n_t represents the tail of the covariance matrix of the generative model, from which $\{s_t\}_t$ are drawn. Moreover, SNIPE can be easily adapted to the *dynamic* case where the underlying subspace $\mathcal{S} = \mathcal{S}(t)$ changes over time. We leave the convergence analysis of SNIPE under a noisy time-variant model to a future work. Similarly, entries of incoming vectors are observed uniformly at random in our theoretical analysis but SNIPE also applies to any incomplete data.

A review of prior art is presented in Section 5, and the performance of SNIPE and rival algorithms are examined numerically in Section 6, where we find that SNIPE shows the state-of-the-art performance. Technical proofs appear in Section 7 and in the appendices, with Appendix A (Toolbox) collecting some of the frequently-used mathematical tools. Finally, Appendix L offers an alternative initialization for SNIPE.

2. SNIPE

In this section, we present Subspace Navigation via Interpolation from Partial Entries (SNIPE), a streaming algorithm for subspace identification from incomplete data, received sequentially.

Let us first introduce some additional notation. Recall that we denote the incoming sequence of incomplete vectors by $\{y_t\}_{t=1}^T \subset \mathbb{R}^n$, which are supported on index sets $\{\omega_t\}_{t=1}^T \subseteq [1:n]$. For a block size $b \geq r$, we concatenate every b consecutive vectors into a data block, thereby partitioning the incoming data into $K = T/b$ non-overlapping blocks $\{Y_k\}_{k=1}^K$, where $Y_k \in \mathbb{R}^{n\times b}$ for every k. We assume for convenience that K is an integer. We also often take $b = O(r)$ to maximize the efficiency of SNIPE, as discussed below.

At a high level, SNIPE processes the first incomplete block Y_1 to produce an estimate $\widehat{\mathcal{S}}_1$ of the true subspace $\mathcal{S}$. This estimate is then iteratively updated after receiving each of the new incomplete blocks $\{Y_k\}_{k=2}^K$, thereby producing a sequence of estimates $\{\widehat{\mathcal{S}}_k\}_{k=2}^K$, see Figure 2. Every $\widehat{\mathcal{S}}_k$ is an r-dimensional subspace of $\mathbb{R}^n$ with orthonormal basis $\widehat{S}_k \in \mathbb{R}^{n\times r}$; the particular choice of orthonormal basis is inconsequential throughout the paper.

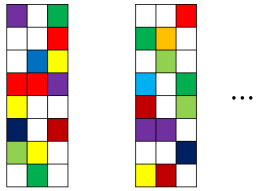

Figure 2: SNIPE concatenates every b incoming vectors into a block and iteratively updates its estimate of the true subspace $\mathcal{S}$ after receiving each new block. That is, SNIPE updates its estimate of $\mathcal{S}$, from $\widehat{\mathcal{S}}_{k-1}$ to $\widehat{\mathcal{S}}_k$, after receiving the incomplete data block $Y_k \in \mathbb{R}^{n\times b}$, see Section 2 for the details.

More concretely, SNIPE sets $\widehat{\mathcal{S}}_1$ to be the span of leading r left singular vectors of Y_1, namely, the left singular vectors corresponding to largest r singular values of Y_1, with ties broken arbitrarily. Then, at iteration $k \in [2:K]$ and given the previous estimate $\widehat{\mathcal{S}}_{k-1} = \mathrm{span}(\widehat{S}_{k-1})$, SNIPE processes the columns of the kth incomplete block Y_k one by one and forms the matrix

$$R_k = \left[\cdots \quad y_t + P_{\omega_t^C} \widehat{S}_{k-1} \left(\widehat{S}_{k-1}^* P_{\omega_t} \widehat{S}_{k-1} + \lambda I_r \right)^\dagger \widehat{S}_{k-1}^* y_t \quad \cdots \right] \in \mathbb{R}^{n\times b}, \qquad t \in [(k-1)b+1 : kb], \tag{1}$$

where $\dagger$ denotes the pseudo-inverse and $\lambda \geq 0$ is a parameter. Above, $P_{\omega_t^C} = I_n - P_{\omega_t} \in \mathbb{R}^{n\times n}$ projects a vector onto the complement of the index set ω_t. The motivation for the particular choice of R_k above will become clear in Section 3. SNIPE then updates its estimate by setting $\widehat{\mathcal{S}}_k$ to be the span of leading r left singular vectors of R_k. Algorithm 1 summarizes these steps. Note that Algorithm 1 rejects ill-conditioned updates in Step 3 for the convenience of analysis and that similar reject options have precedence in the literature (Balzano and Wright, 2015). We however found implementing this reject option to be unnecessary in numerical simulations.

Remark 1 [Computational complexity of SNIPE] We measure the *per-iteration* algorithmic complexity of SNIPE by calculating the average number of floating-point operations (flops) performed on an incoming vector. Every iteration of SNIPE involves finding leading r left singular vectors of an $n \times b$ matrix. Assuming that $b = O(r)$, this could be done with $O(nr^2)$ flops. At the kth iteration with $k \geq 2$, SNIPE also requires finding the pseudo-inverse of $P_{\omega_j} \widehat{S}_{k-1} \in \mathbb{R}^{n\times r}$ for each incoming vector which costs $O(nr^2)$ flops. Therefore the overall computational complexity of SNIPE is $O(nr^2)$ flops per vector. As further discussed in Section 5, this matches the complexity of other algorithms for streaming PCA even though here the received data is highly incomplete.

Remark 2 [Storage requirements of SNIPE] We measure the storage required by SNIPE by calculating the number of memory elements stored by SNIPE at any given instant. At the kth iteration, SNIPE must store the current estimate $\widehat{S}_{k-1} \in \mathbb{R}^{n\times r}$ (if available) and the new incomplete block $Y_k \in \mathbb{R}^{n\times b}$. Assuming that $b = O(r)$, this translates into $O(nr) + O(pnr) = O(nr)$ memory elements. SNIPE therefore requires $O(nr)$ bits of storage, which is optimal up to a constant factor.

Algorithm 1 SNIPE for streaming PCA from incomplete data

Input:

- Dimension r,
- Received data $\{y_t\}_{t=1}^T \subset \mathbb{R}^n$ supported on index sets $\{\omega_t\}_{t=1}^T \subseteq [1:n]$, presented sequentially in $K = T/b$ blocks of size $b \geq r$,
- Tuning parameter $\lambda \geq 0$,
- Reject thresholds $\sigma_{\min}, \tau \geq 0$.

Output:

- r-dimensional subspace $\widehat{\mathcal{S}}_K$.

Body:

- Form $Y_1 \in \mathbb{R}^{n\times b}$ by concatenating the first b received vectors $\{y_t\}_{t=1}^b$. Let $\widehat{\mathcal{S}}_1$, with orthonormal basis $\widehat{S}_1 \in \mathbb{R}^{n\times r}$, be the span of leading r left singular vectors of Y_1, namely, those corresponding to r largest singular values. Ties are broken arbitrarily.
- For $k \in [2:K]$, repeat:
  1. Set $R_k \leftarrow \{\}$.
  2. For $t \in [(k-1)b+1 : kb]$, repeat
     - Set
     $$R_k \leftarrow \begin{bmatrix} R_k & y_t + P_{\omega_t^C}\widehat{S}_{k-1}\left(\widehat{S}_{k-1}^* P_{\omega_t}\widehat{S}_{k-1} + \lambda I_r\right)^\dagger \widehat{S}_{k-1}^* y_t \end{bmatrix},$$
     where $P_{\omega_t} \in \mathbb{R}^{n\times n}$ equals one on its diagonal entries corresponding to the index set ω_t, and is zero elsewhere. Likewise, $P_{\omega_t^C}$ projects a vector onto the complement of the index set ω_t.
  3. If $\sigma_r(R_k) < \sigma_{\min}$ or $\sigma_r(R_k) \leq (1+\tau)\cdot\sigma_{r+1}(R_k)$, then set $\widehat{\mathcal{S}}_k \leftarrow \widehat{\mathcal{S}}_{k-1}$. Otherwise, let $\widehat{\mathcal{S}}_k$, with orthonormal basis $\widehat{S}_k \in \mathbb{R}^{n\times r}$, be the span of leading r left singular vectors of R_k. Ties are broken arbitrarily. Here, $\sigma_i(R_k)$ is the ith largest singular value of R_k.
- Return $\widehat{\mathcal{S}}_K$.

3. Interpretation of SNIPE

SNIPE has a natural interpretation as a streaming algorithm for low-rank matrix completion, which we now discuss. First let us enrich our notation. Recall the incomplete data blocks $\{Y_k\}_{k=1}^K \subset \mathbb{R}^{n\times b}$ and let the random index set $\Omega_k \subseteq [1:n]\times[1:b]$ be the support of Y_k for every k. We write that $Y_k = P_{\Omega_k}(S_k)$ for every k, where the complete (but hidden) data block $S_k \in \mathbb{R}^{n\times b}$ is formed by concatenating $\{s_t\}_{t=(k-1)b+1}^{kb}$. Here, $P_{\Omega_k}(S_k)$ retains only the entries of S_k on the index set Ω_k, setting the rest to zero. By design, $s_t = Sq_t$ for every t and we may therefore write that $S_k = S\cdot Q_k$ for the coefficient matrix $Q_k \in \mathbb{R}^{r\times b}$ formed by concatenating $\{q_t\}_{t=(k-1)b+1}^{kb}$. To summarize, $\{S_k\}_{k=1}^K$ is formed by partitioning $\{s_t\}_{t=1}^T$ into K blocks. Likewise, $\{Q_k, Y_k, \Omega_k\}_{k=1}^K$ are formed by partitioning $\{q_t, y_t, \omega_t\}_{t=1}^T$, respectively.

With this introduction, let us form $Y \in \mathbb{R}^{n\times T}$ by concatenating the incomplete blocks $\{Y_k\}_{k=1}^K \subset \mathbb{R}^{n\times b}$, supported on the index sets $\Omega \subseteq [1:n]\times[1:T]$. To find the true subspace $\mathcal{S}$, one might consider solving

$$\begin{cases} \min\limits_{X,\mathcal{U}} \ \|P_{\mathcal{U}^\perp}X\|_F^2 + \lambda\|P_{\Omega^C}(X)\|_F^2 \\ P_\Omega(X) = Y, \end{cases} \tag{2}$$

where the minimization is over a matrix $X \in \mathbb{R}^{n\times T}$ and r-dimensional subspace $\mathcal{U} \subset \mathbb{R}^n$. Above, $P_{\mathcal{U}^\perp} \in \mathbb{R}^{n\times n}$ is the orthogonal projection onto the orthogonal complement of subspace $\mathcal{U}$ and $P_\Omega(X)$ retains only the entries of X on the index set Ω, setting the rest to zero. Note that Program (2) encourages its solution(s) to be low-rank while matching the observations Y on the index set Ω. The term $\lambda\|P_{\Omega^C}(X)\|_F^2$ for $\lambda \geq 0$ is the *Tikhonov regularizer* that controls the energy of solution(s) on the complement of index set Ω.

With complete data, namely, when $\Omega = [1:n]\times[1:T]$, Program (2) reduces to PCA, as it returns $X = Y$ and searches for an r-dimensional subspace that captures most of the energy of Y. That is, Program (2) reduces to $\min_{\mathcal{U}} \|P_{\mathcal{U}^\perp}Y\|_F^2$ when $\Omega = [1:n]\times[1:T]$, solution of which is the span of leading r left singular vectors of Y in light of the Eckart-Young-Mirsky Theorem (Eckart and Young, 1936; Mirsky, 1966). In this sense then, Program (2) performs PCA from incomplete data. Note crucially that Program (2) is a nonconvex problem because the Grassmannian $\mathbb{G}(n,r)$, the set of all r-dimensional subspaces in $\mathbb{R}^n$, is a nonconvex set.[1] However, given a fixed subspace $\mathcal{U} \in \mathbb{G}(n,r)$, Program (2) reduces to the simple least-squares program

$$\begin{cases} \min\limits_{X} \ \|P_{\mathcal{U}^\perp}X\|_F^2 + \lambda\|P_{\Omega^C}(X)\|_F^2 \\ P_\Omega(X) = Y, \end{cases} \tag{3}$$

where the minimization is over $X \in \mathbb{R}^{n\times T}$. If in addition λ is positive, then Program (3) is strongly convex and has a unique minimizer. Given a fixed feasible $X \in \mathbb{R}^{n\times T}$, Program (2) has the same minimizers as

$$\min_{\mathcal{U}\in\mathbb{G}(n,r)} \|P_{\mathcal{U}^\perp}X\|_F^2. \tag{4}$$

1. The Grassmannian can be embedded in $\mathbb{R}^{n\times n}$ via the map that takes $\mathcal{U} \in \mathbb{G}(n,r)$ to the corresponding orthogonal projection $P_{\mathcal{U}} \in \mathbb{R}^{n\times n}$. The resulting submanifold of $\mathbb{R}^{n\times n}$ is a nonconvex set.

That is, for a fixed feasible X, Program (2) simply performs PCA on X. We might also view Program (2) from a matrix completion perspective. More specifically, let

$$\rho_r^2(X) = \sum_{i \geq r+1} \sigma_i^2(X), \tag{5}$$

be the *residual* of X, namely, the energy of its trailing singular values $\sigma_{r+1}(X) \geq \sigma_{r+2}(X) \geq \cdots$. Like the popular nuclear norm $\|X\|_* = \sum_{i \geq 1} \sigma_i(X)$ in (Davenport and Romberg, 2016), the residual $\rho_r(X)$ gauges the rank of X. In particular, $\rho_r(X) = 0$ if and only if $\text{rank}(X) \leq r$. Unlike the nuclear norm, however, the residual is still a nonconvex function of X. We now rewrite Program (2) as

$$\begin{aligned} \begin{cases} \min\limits_{X, \mathcal{U}} \ \|P_{\mathcal{U}^\perp} X\|_F^2 + \lambda \|P_{\Omega^C}(X)\|_F^2 \\ P_\Omega(X) = Y \end{cases} &= \begin{cases} \min\limits_{X} \ \min\limits_{\mathcal{U} \in \mathbb{G}(n,r)} \ \|P_{\mathcal{U}^\perp} X\|_F^2 + \lambda \|P_{\Omega^C}(X)\|_F^2 \\ P_\Omega(X) = Y \end{cases} \\ &= \begin{cases} \min\limits_{X} \ \rho_r^2(X) + \lambda \|P_{\Omega^C}(X)\|_F^2 \\ P_\Omega(X) = Y. \end{cases} \end{aligned} \tag{6}$$

That is, if we ignore the regularization term $\lambda \|P_{\Omega^C}(X)\|_F^2$, Program (2) searches for a matrix with the least residual, as a proxy for least rank, that matches the observations Y. In this sense then, Program (2) is a "relaxation" of the low-rank matrix completion problem. Several other formulations for the matrix completion problem are reviewed in (Davenport and Romberg, 2016; Eftekhari et al., 2018b,a). We can also rewrite Program (2) in terms of its data blocks by considering the equivalent program

$$\begin{cases} \min \ \sum_{k=1}^K \|P_{\mathcal{U}}^\perp X_k\|_F^2 + \lambda \|P_{\Omega_k^C}(X_k)\|_F^2 \\ P_{\Omega_k}(X_k) = Y_k \qquad k \in [1:K], \end{cases} \tag{7}$$

where the minimization is over matrices $\{X_k\}_{k=1}^K \subset \mathbb{R}^{n \times b}$ and subspace $\mathcal{U} \in \mathbb{G}(n,r)$. Let us additionally introduce a number of auxiliary variables into Program (7) by considering the equivalent program

$$\begin{cases} \min \ \sum_{k=1}^K \|P_{\mathcal{U}_k}^\perp X_k\|_F^2 + \lambda \|P_{\Omega_k^C}(X_k)\|_F^2 \\ P_{\Omega_k}(X_k) = Y_k \qquad k \in [1:K] \\ \mathcal{U}_1 = \mathcal{U}_2 = \cdots = \mathcal{U}_K, \end{cases} \tag{8}$$

where the minimization is over matrices $\{X_k\}_{k=1}^K \subset \mathbb{R}^{n \times b}$ and subspaces $\{\mathcal{U}_k\}_{k=1}^K \subset \mathbb{G}(n,r)$. Indeed, Programs (2,7,8) are all equivalent and all nonconvex. Now consider the following approximate solver for Program (8) that alternatively solves for matrices and subspaces:

- Setting $X_1 = Y_1$ in Program (8), we minimize $\|P_{\mathcal{U}_1}^\perp Y_1\|_F^2$ over $\mathcal{U}_1 \in \mathbb{G}(n,r)$ and, by the Eckart-Young-Mirsky Theorem, find a minimizer to be the span of leading r left singular vectors of Y_1, which coincides with $\widehat{\mathcal{S}}_1$ in SNIPE.
- For $k \in [2:K]$, repeat:
  - Setting $\mathcal{U}_k = \widehat{\mathcal{S}}_{k-1}$ in Program (8), we solve

$$\begin{cases} \min_{X_k} \ \|P_{\widehat{\mathcal{S}}_{k-1}^\perp} X_k\|_F^2 + \lambda \|P_{\Omega_k^C}(X_k)\|_F^2 \\ P_{\Omega_k}(X_k) = Y_k, \end{cases} \tag{9}$$

    over matrix $X_k \in \mathbb{R}^{n \times b}$. We verify in Appendix B that the minimizer of Program (9) coincides with R_k in SNIPE, see (1).
  - If $\sigma_r(R_k) < \sigma_{\min}$ or $\sigma_r(R_k) \leq (1+\tau)\sigma_{r+1}(R_k)$, then no update is made, namely, we set $\widehat{\mathcal{S}}_k = \widehat{\mathcal{S}}_{k-1}$. Otherwise, setting $X_k = R_k$ in Program (8), we solve $\min \|P_{\mathcal{U}_k}^\perp R_k\|_F^2$ over $\mathcal{U}_k \in \mathbb{G}(n,r)$ to find $\widehat{\mathcal{S}}_k$. That is, by the Eckart-Young-Mirsky Theorem again, $\widehat{\mathcal{S}}_k$ is the span of leading r left singular vectors of R_k. The output of this step matches $\widehat{\mathcal{S}}_k$ produced in SNIPE.

To summarize, following the above procedure produces $\{R_k\}_{k=1}^K$ and $\{\widehat{\mathcal{S}}_k\}_{k=1}^K$ in SNIPE. In other words, we might think of SNIPE as an approximate solver for Program (2), namely, SNIPE is a streaming algorithm for low-rank matrix completion. In fact, the output of SNIPE always converges to a stationary point of Program (2) in the sense described in Section 4.

Another insight about the choice of R_k in (1) is as follows. Let us set $\lambda = 0$ for simplicity. At the beginning of the kth iteration of SNIPE with $k \geq 2$, the available estimate of the true subspace is $\widehat{\mathcal{S}}_{k-1}$ with orthonormal basis $\widehat{S}_{k-1}$. Given a new incomplete vector $y \in \mathbb{R}^n$, supported on the index set $\omega \subseteq [1:n]$, $z = \widehat{S}_{k-1}(P_\omega \widehat{S}_{k-1})^\dagger y$ best approximates y in $\widehat{\mathcal{S}}_{k-1}$ in ℓ_2 sense. In order to agree with the measurements, we minimally adjust this to $y + P_{\omega^C} z$, where P_{ω^C} projects onto the complement of index set ω. This indeed matches the expression for the columns of R_k in SNIPE. We note that this type of least-change strategy has been successfully used in the development of quasi-Newton methods for optimization (Nocedal and Wright, 2006, Chapter 6).

4. Performance of SNIPE

To measure the performance of SNIPE—whose output is a subspace—we naturally use principal angles as an error metric. More specifically, recall that $\mathcal{S}$ and $\widehat{\mathcal{S}}_K$ denote the true subspace and the output of SNIPE, respectively. Then the ith largest singular value of $P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_K}$ equals $\sin(\theta_i(\mathcal{S}, \widehat{\mathcal{S}}_K))$, where

$$\theta_1(\mathcal{S}, \widehat{\mathcal{S}}_K) \geq \theta_2(\mathcal{S}, \widehat{\mathcal{S}}_K) \geq \cdots \geq \theta_r(\mathcal{S}, \widehat{\mathcal{S}}_K)$$

denote the principal angles between the two r-dimensional subspaces $\mathcal{S}, \widehat{\mathcal{S}}_K$ (Golub and Van Loan, 2013). The estimation error of SNIPE is then

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K) := \sqrt{\frac{1}{r} \sum_{i=1}^r \sin^2\left(\theta_i(\mathcal{S}, \widehat{\mathcal{S}}_K)\right)} = \frac{\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_K}\|_F}{\sqrt{r}}, \tag{10}$$

which also naturally induces a metric topology on the Grassmannian $\mathbb{G}(n,r)$.[2] Note also that we will always reserve calligraphic letters for subspaces and capital letters for their orthonormal bases, for example subspace $\mathcal{S}$ and its orthonormal basis S.

Our first result loosely speaking states that a subsequence of SNIPE converges to a stationary point of the nonconvex Program (2) as T goes to infinity, see Section 7.1 for the proof.

Theorem 3 [Global convergence] *Consider an r-dimensional subspace $\mathcal{S}$ with orthonormal basis $S \in \mathbb{R}^{n\times r}$. For an integer T, let the coefficient vectors $\{q_t\}_{t=1}^T \subset \mathbb{R}^r$ be independent copies of a random vector $q \in \mathbb{R}^r$ with bounded expectation, namely, $\mathbb{E}\|q\|_2 < \infty$. For every $t \in [1:T]$, we observe each coordinate of $s_t = Sq_t \in \mathcal{S}$ independently with a probability of p and collect the observations in $y_t \in \mathbb{R}^n$, supported on a random index set $\omega_t \subseteq [1:n]$. Fix positive λ, block size $b \geq r$, positive reject thresholds $\sigma_{\min}, \tau$, and consider the output sequence of* SNIPE *in Algorithm 1, namely, $\{(R_k, \widehat{\mathcal{S}}_k)\}_k$. Also by partitioning $\{q_t, s_t, y_t, \omega_t\}_t$, form the coefficient blocks $\{Q_k\}_k \subset \mathbb{R}^{r\times b}$, data blocks $\{S_k\}_k \subset \mathbb{R}^{n\times b}$, and incomplete data blocks $\{Y_k\}_k \subset \mathbb{R}^{n\times b}$ supported on index sets $\{\Omega_k\}_k \subseteq [1:n]\times[1:b]$, as described in Section 3.*

For every integer l, there exists an integer k_l, for which the following asymptotic statement is almost surely true as $T \to \infty$. Consider the restriction of Program (2) to iteration k_l, namely,

$$\begin{cases} \min_{X,\mathcal{U}} \ \|P_{\mathcal{U}^\perp} X\|_F^2 + \lambda \|P_{\Omega_{k_l}^C}(X)\|_F^2 \\ P_{\Omega_{k_l}}(X) = Y_{k_l}, \end{cases} \tag{11}$$

where the minimization is over matrix $X \in \mathbb{R}^{n\times b}$ and r-dimensional subspace $\mathcal{U}$. Then there exists $R \in \mathbb{R}^{n\times b}$ and r-dimensional subspace $\widehat{\mathcal{S}}$ such that

- *$\widehat{S}$ is the span of leading r left singular vectors of R,*
- *$(R, \widehat{\mathcal{S}})$ is a stationary pair of Program (11), namely, it satisfies the first-order optimality conditions of Program (11),*
- *$\lim_{l\to\infty} \|R_{k_l} - R\|_F = 0$,*
- *$\lim_{l\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_{k_l}, \mathcal{S}) = 0$.*

Remark 4 [Discussion of Theorem 3] Theorem 3 roughly speaking states that there is a subsequence of SNIPE that converges to a stationary point of Program (2), which was the program designed in Section 3 for PCA from incomplete data or, from a different perspective, for low-rank matrix completion. Theorem 3 is however silent about the nature of this stationary point, whether it is a local or global minimizer/maximizer, or a saddle point. To some extent, this question is addressed below in Proposition 6.

More generally, we have been able to show that this stationary point is in fact rank-r. When the block size of SNIPE is sufficiently large, namely when $b = \Omega(n)$, we can further establish that the limit point of SNIPE is indeed a global minimizer of Program (2)

2. Another possible error metric is simply the largest principal angle $\theta_1(\mathcal{S}, \widehat{\mathcal{S}}_K)$. The two metrics are very closely related: $\theta_1(\mathcal{S}, \widehat{\mathcal{S}}_K)/\sqrt{r} \leq d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K) \leq \theta_1(\mathcal{S}, \widehat{\mathcal{S}}_K)$. However, we find that $\theta_1(\mathcal{S}, \widehat{\mathcal{S}}_K)$ is not amenable for analysis of our problem, as opposed to $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K)$.

and moreover SNIPE recovers the true subspace, namely, $\lim_{l\to\infty} d(\widehat{\mathcal{S}}_{k_l}, \mathcal{S}) = 0$, with high probability and under certain standard conditions on the *coherence* of the true subspace $\mathcal{S}$ and sampling probability p. We have not included these results here because SNIPE is intended as a streaming algorithm and we are therefore more interested in the setting where $b = O(r)$, see Remarks 1 and 2 about the implementation of SNIPE. It is not currently clear to us when SNIPE converges in general but, as suggested by Proposition 6 below, if SNIPE converges, it does indeed converge to the true subspace $\mathcal{S}$.

Remark 5 [Technical point about Theorem 3] Note that Theorem 3 is proved for positive (but possibly arbitrarily small) $\sigma_{\min}$ and τ. In particular, an update $(R_k, \widehat{\mathcal{S}}_k)$ is rejected in Algorithm 1 if

$$\frac{\sigma_r(R_k)}{\sigma_{r+1}(R_k)} \leq 1 + \tau, \tag{12}$$

for an (otherwise arbitrary) positive τ and whenever the ratio is well-defined. Here, $\sigma_i(R_k)$ is the ith largest singular value of R_k. This is merely a technical nuance, limited to the rth singular value gap, that helps prevent the the output subspace $\widehat{\mathcal{S}}_k$ from oscillating in the limit. Likewise, Theorem 3 does not address the case $\lambda = 0$ in Program (11), even though λ can be made arbitrarily small in Theorem 3. This is again for technical convenience and in fact the numerical simulations in Section 6 are all conducted with $\lambda = 0$.

Our second result establishes that, if SNIPE converges, then it converges to the true subspace $\mathcal{S}$, see Section 7.2 for the proof.

Proposition 6 [Convergence] *Consider the setup in the first paragraph of Theorem 3. Suppose that r independent copies of random coefficient vector $q \in \mathbb{R}^r$ almost surely form a basis for $\mathbb{R}^r$.*[3] *Suppose also that the output of* SNIPE *converges to an r-dimensional subspace $\widehat{\mathcal{S}}$, namely,*

$$\lim_{k\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_k, \widehat{\mathcal{S}}) = 0. \tag{13}$$

Then almost surely it must hold that $\widehat{\mathcal{S}} = \mathcal{S}$.

Remark 7 [Discussion of Proposition 6] Proposition 6 does not specify the conditions under which SNIPE converges. Indeed, if the sampling probability p is too small, namely, if very few of the entries of incoming vectors are observed, then SNIPE might not converge at all as the numerical evidence suggests, see also Remark 4. However, if SNIPE converges, then it converges to the true subspace $\mathcal{S}$. The local rate of convergence is specified below.

The concept of *coherence* is critical in specifying the local convergence rate, since we consider entrywise subsampling. The coherence of an r-dimensional subspace $\mathcal{S}$ with orthonormal basis $S \in \mathbb{R}^{n\times r}$ is defined as

$$\eta(\mathcal{S}) := \frac{n}{r} \max \|S[i,:]\|_2^2, \tag{14}$$

3. For example, this requirement is met if entries of q are independent Gaussian random variables with zero-mean and unit variance.

where $S[i,:]$ is the ith row of S. It is easy to verify that $\eta(\mathcal{S})$ is independent of the choice of orthonormal basis S and that

$$1 \le \eta(\mathcal{S}) \le \frac{n}{r}. \tag{15}$$

It is also common to say that $\mathcal{S}$ is *coherent* (*incoherent*) when $\eta(\mathcal{S})$ is large (small). Loosely speaking, when $\mathcal{S}$ is coherent, its orthonormal basis S is "spiky." An example is when $\mathcal{S}$ is the span of a column-subset of the identity matrix. In contrast, when $\mathcal{S}$ is incoherent, entries of S tend to be "diffuse." Not surprisingly, identifying a coherent subspace from subsampled data may require many more samples (Balzano and Wright, 2015; Mitliagkas et al., 2014; Chen, 2015).

We will also use $\lesssim$ and $\gtrsim$ below to suppress (most of) the universal constants. Moreover, throughout C represents a universal constant, the value of which is subject to change in every appearance.

Our next results specify the local convergence rate of SNIPE. Indeed, the convergence speed near the true subspace $\mathcal{S}$ is linear as detailed in Theorems 8 and 10, and proved in Section 7.3. In particular, Theorem 8 states that, when sufficiently small, the expected estimation error of SNIPE reduces by a factor of $1 - p/32$ in every iteration.

Theorem 8 [Locally linear convergence of SNIPE **in expectation]** *Consider the setup in the first paragraph of Theorem 3. Fix a positive tuning parameter α, iteration $k \in [2:K]$, and let $\mathfrak{E}_{k-1}$ be the event where*

$$\frac{1}{\sqrt{nb}} \gtrsim p \gtrsim \log n \log^2\left(p\sqrt{r} d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1})\right) \frac{\eta(\mathcal{S}) r}{n}, \tag{16}$$

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) \log\left(\frac{16}{p\sqrt{r} d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1})}\right) \lesssim \frac{p^{\frac{3}{2}}}{\sqrt{\log n}}, \tag{17}$$

$$\|Q_k\| \le \frac{\sigma_{\min}}{\sqrt{1 - p/4}}, \tag{18}$$

where $\sigma_{\min}$ is the reject threshold in SNIPE*. Let also $\mathcal{A}_k$ be the event where the kth iteration of* SNIPE *is not rejected (see Step 3 of Algorithm 1) and let $1_{\mathcal{A}_k}$ be the indicator for this event, taking one if the event happens and zero otherwise. Then it holds that*

$$\mathbb{E}\left[1_{\mathcal{A}_k} \cdot d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}\right] \le \left(1 - \frac{p}{32}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}). \tag{19}$$

Remark 9 [Discussion of Theorem 8] When the sampling probability p is large enough and SNIPE is near the true subspace $\mathcal{S}$, Theorem 8 states that the expected estimation error of SNIPE reduces by a factor of $1 - p/32$, if the iterate of SNIPE is not rejected. Note that: ① The lower bound on the sampling probability p in (16) matches the one in the low-rank matrix completion literature up to a logarithmic factor (Davenport and Romberg, 2016). Indeed, SNIPE can be interpreted as a streaming matrix completion algorithm as discussed in Section 3. The upper bound on p in (16) is merely for technical convenience and a tidier presentation in the most interesting regime for p. Indeed, since we often take $b = O(r) \ll n$, one might loosely read (16) as

$$\frac{1}{\sqrt{nr}} \gtrsim p \gtrsim \frac{\eta(\mathcal{S}) r}{n}, \tag{20}$$

in which the upper bound hardly poses a restriction even for moderately large data dimension n, as it forces $r = O(n^{\frac{1}{3}})$. ② Ignoring the logarithmic factors for simplicity, we may read (17) as $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) \lesssim p^{3/2}$, which "activates" (19). In other words, the basin of attraction of the true subspace $\mathcal{S}$ as a (possibly local) minimizer of the (nonconvex) Program (2) has a radius of $O(p^{3/2})$. ③ The indicator $1_{\mathcal{A}_k}$ in (19) removes the rejected iterates and similar conditions implicitly exist in the analysis of other streaming PCA algorithms (Balzano and Wright, 2015).

Note that Theorem 8 *cannot* tell us what the local convergence rate of SNIPE is, even in expectation. Indeed, the expected reduction in the estimation error of SNIPE, specified in (19), is not enough to activate (17) for the next iteration (namely, with k instead of $k-1$). That is, we cannot apply Theorem 8 iteratively and find the expected convergence rate of SNIPE. A key technical contribution of this paper is specifying the local behaviour of SNIPE below. With high probability, the estimation error does not *increase* by much in every iteration near the true subspace. However, only in some of these iterations does the error reduce. Overall, on a long enough interval, the estimation error of SNIPE near the true subspace indeed reduces substantially and with high probability as detailed in Theorem 10 and proved in Section 7.3. Performance guarantees for stochastic algorithms on long intervals is not uncommon, see for example (Cartis and Scheinberg, 2017).

Theorem 10 [Locally linear convergence of SNIPE**]** *Consider the setup in the first paragraph of Theorem 3. Suppose that the output $\widehat{\mathcal{S}}_{K_0}$ of* SNIPE *at iteration $K_0 \in [2:K]$ satisfies*

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0}) \lesssim \frac{e^{-\frac{Cp^3 nb}{\widetilde{\eta}}} p^{\frac{7}{2}} nb}{\widetilde{\eta} \log b \log\left(C\widetilde{\eta} n\right) \log^2(K - K_0)}, \tag{21}$$

and that

$$K - K_0 \gtrsim \frac{\widetilde{\eta} \log b \log(K - K_0)}{p^2 nb}. \tag{22}$$

Above, C is a universal constant that might change in every appearance. Then it holds that

$$\prod_{k=K_0+1}^{K} 1_{\mathcal{A}_k} \cdot d(\mathcal{S}, \widehat{\mathcal{S}}_K) \lesssim \left(1 - \frac{Cp^3 nb}{\widetilde{\eta} \log b \log(K - K_0)}\right)^{K-K_0} d(\mathcal{S}, \widehat{\mathcal{S}}_{K_0}), \tag{23}$$

except with a probability of at most

$$b^{-C\log(K-K_0)} + \sum_{k=K_0+1}^{K} \Pr\left[\|Q_k\| > \left(1 + \frac{Cp^3 nb}{\widetilde{\eta} \log b}\right) \sigma_{\min}\right] \tag{24}$$

and provided that

$$\frac{1}{\sqrt{nb}} \gtrsim p \gtrsim \log^2 b \log n \frac{\eta(\mathcal{S}) r}{n}. \tag{25}$$

Above, $\sigma_{\min}$ is the reject threshold of SNIPE *and*

$$\widetilde{\eta} = \max_{k \in [K_0:K]} \widetilde{\eta}_k, \tag{26}$$

$$\widetilde{\eta}_k := nb \cdot \frac{\|P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} S_k\|_\infty^2}{\|P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} S_k\|_F^2}. \tag{27}$$

Remark 11 [Discussion of Theorem 10] Loosely speaking, Theorem 10 states that, with high probability, the estimation error of SNIPE over $O(\widetilde{\eta} n)$ iterations reduces linearly (i.e., exponentially fast) when SNIPE is near the true subspace and the sampling probability p is large enough. Most of the remarks about Theorem 8 are also valid here. Let us also point out that the dependence on the coefficient matrix Q_k in (24) is mild but necessary. As an example, consider the case where the coefficient vectors $\{q_t\}_t$ are standard random Gaussian vectors so that the coefficient matrices $\{Q_k\}_k$ are standard random Gaussian matrices, namely, populated with independent zero-mean Gaussian random variables with unit variance. Then by taking

$$\sigma_{\min} = C\sqrt{b} / \left(1 + \frac{Cp^3 nb}{\widetilde{\eta} \log b}\right),$$

we find that

$$\Pr\left[\|Q_k\| > \left(1 + \frac{Cp^3 nb}{\widetilde{\eta} \log b}\right) \sigma_{\min}\right] = \Pr\left[\|Q_k\| \gtrsim \sqrt{b}\right] \leq e^{-Cb} \tag{28}$$

and consequently the failure probability in (24) becomes $b^{-C\log(K-K_0)} + (K-K_0)e^{-Cb}$, which can be made arbitrarily small by modestly increasing the block size b. For the reader's convenience, Appendix K collects the relevant spectral properties of a standard random Gaussian matrix. The dependence on $\|Q_k\|$ in Theorem 8 is *not* an artifact of our proof techniques. Indeed, when $\|Q_k\| \gg 1$, it is likely that certain directions in $\mathcal{S}$ are over represented which will skew the estimate of SNIPE in their favor.

Remark 12 [Coherence factor $\widetilde{\eta}$] A key quantity in Theorem 10 is the new "coherence" factor $\widetilde{\eta}$ which is absent in the expected behavior of SNIPE in Theorem 8. Somewhat similar to the coherence $\eta(\cdot)$ in (14), $\widetilde{\eta}_k$ measures how "spiky" the matrix $P_{\mathcal{S}_{k-1}^{\perp}} S_k \in \mathbb{R}^{n\times b}$ is. In fact, one may easily verify that

$$\widetilde{\eta}_k \leq \operatorname{rank}(P_{\mathcal{S}_{k-1}^{\perp}} S_k) \cdot \nu(P_{\mathcal{S}_{k-1}^{\perp}} S_k)^2 \cdot \eta(\operatorname{span}(P_{\mathcal{S}_{k-1}^{\perp}} S_k)) \cdot \eta(\operatorname{span}(S_k^* P_{\mathcal{S}_{k-1}^{\perp}})), \tag{29}$$

where $\nu(P_{\mathcal{S}_{k-1}^{\perp}} S_k)$ is the condition number of $P_{\mathcal{S}_{k-1}^{\perp}} S_k$, namely, the ratio of largest to smallest nonzero singular values. The number of iterations needed to see a reduction in estimation error in (22) and the convergence rate of SNIPE in (23) both prefer $\widetilde{\eta}$ to be small, namely, prefer that $\{P_{\mathcal{S}_{k-1}^{\perp}} S_k\}_k$ are all incoherent as measured by $\widetilde{\eta}_k$.

When SNIPE is close enough to true subspace $\mathcal{S}$ as required in (21), one would expect that iterates of SNIPE would be nearly as coherent as $\mathcal{S}$ itself in the sense that $\eta(\widehat{\mathcal{S}}_k) \approx \eta(\mathcal{S})$. This intuition is indeed correct and also utilized in our analysis. However, even when $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1})$ is small and $\eta(\widehat{\mathcal{S}}_{k-1}), \eta(\mathcal{S})$ are both small, $\widetilde{\eta}_k$ might be very large, namely, $P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} S_k$ might be a spiky matrix. Indeed, when $b = r$, $(\widehat{\mathcal{S}}_{k-1}^{\perp})^* S_k$ is approximately the (horizontal) tangent at $\widehat{\mathcal{S}}_{k-1}$ to the geodesic on the Grassmannian $\mathbb{G}(n, r)$ that connects $\widehat{\mathcal{S}}_{k-1}$

to $\mathcal{S}$. Even though both $\widehat{\mathcal{S}}_{k-1}$ and $\mathcal{S}$ are incoherent subspaces, namely, $\eta(\widehat{\mathcal{S}}_{k-1}), \eta(\mathcal{S})$ are both small, the tangent direction connecting the two is not necessarily incoherent. Despite the dependence of our results on $\widetilde{\eta}$, it is entirely possible that SNIPE with high probability approaches the true subspace $\mathcal{S}$ from an incoherent tangent direction, of which there are many. Such a result has remained beyond our reach. In fact, similar questions arise in matrix completion. Iterative Hard Thresholding (IHT) is a powerful algorithm for matrix completion with excellent empirical performance (Tanner and Wei, 2013), the convergence rate of which has remained unknown, to the best of our knowledge. With $\{M_k\}_k$ denoting the iterates of IHT, it is not difficult to see that if the differences $\{M_k - M_{k-1}\}_k$ are incoherent matrices (i.e., not spiky), then the linear convergence rate of IHT would follow from rather standard arguments.

5. Related Work

In this paper, we presented SNIPE for streaming PCA from incomplete data and, from a different perspective, SNIPE might be considered as a streaming matrix completion algorithm, see Section 3. In other words, SNIPE is a "subspace tracking" algorithm that identifies the linear structure of data as it arrives. Note also that t in our framework need not correspond to time, see Figure 1. For example, only a small portion of a large data matrix Y can be stored in the fast access memory of the processing unit, which could instead use SNIPE to fetch and process the data in small chunks and iteratively update the principal components. Moreover, SNIPE can be easily adapted to the dynamic case where the distribution of data changes over time. In dynamic subspace tracking for example, the (hidden) data vector s_t is drawn from the subspace $\mathcal{S}(t) \in \mathbb{G}(n, r)$ that varies with time. Likewise, it is easy to slightly modify SNIPE to handle noisy observations or equivalently to the case where $\{s_t\}_t$ are generated from a distribution with possibly full-rank covariance matrix. We leave investigating both of these directions to a future work.

Among several algorithms that have been proposed for tracking low-dimensional structure in a dataset from partially observed streaming data (Mitliagkas et al., 2014; Chi et al., 2013; Mardani et al., 2015; Xie et al., 2013; Eftekhari et al., 2017), SNIPE might be most closely related to GROUSE (Balzano et al., 2010; Balzano and Wright, 2013). GROUSE performs streaming PCA from incomplete data using stochastic gradient projection on the Grassmannian, updating its estimate of the true subspace with each new incomplete vector. Both GROUSE and SNIPE were designed based on the principle of least-change, discussed in Section 3. In fact, when GROUSE is sufficiently close to the true subspace and with a specific choice of its step length, both algorithms have nearly identical updates, see (Balzano and Wright, 2015, Equation 1.9). A weaker analogue of Theorem 8 for GROUSE was recently established in (Balzano and Wright, 2015). More specifically, (Balzano and Wright, 2015) stipulates that, if the current estimate $\widehat{\mathcal{S}}_k$ is sufficiently close to the true subspace $\mathcal{S}$, then $\widehat{\mathcal{S}}_{k+1}$ will be even closer to $\mathcal{S}$ in expectation. Such a result however *cannot* tell us what the local convergence rate of SNIPE is, even in expectation, see the discussion right before Theorem 10 above. In this sense, a key technical contribution of our work is establishing the local linear convergence of SNIPE, see Theorem 10, which is missing from its close competitor GROUSE. In fact, the global convergence guarantees listed in Theorem 3

and Proposition 6 are also unique to SNIPE; such theoretical guarantees are not available for GROUSE.

It might be interesting to add that our proposed update in SNIPE was inspired by that of GROUSE when we found zero-filled updates were unreliable (Eftekhari et al., 2017). However, GROUSE was derived as a purely streaming algorithm, and it therefore is not designed to leverage common low-rank structure that may be revealed when a block of vectors is processed at once. Therefore, for each block SNIPE often achieves a more significant reduction in error than is possible with GROUSE.

Lastly, both SNIPE and GROUSE have a computational complexity of $O(nr^2)$ flops per incoming vector, see Remark 1. Also, SNIPE and GROUSE both require $O(nr)$ memory elements of storage, see Remark 2. With complete data, namely, when no entries are missing, a close relative of both SNIPE and GROUSE are incremental SVD algorithms, a class of algorithms that efficiently compute the SVD of streaming data (Bunch and Nielsen, 1978; Balsubramani et al., 2013; Oja and Karhunen, 1985; Watanabe and Pakvasa, 1973; Balsubramani et al., 2013; Brand, 2002).

A streaming PCA algorithm might also be interpreted as a stochastic algorithm for PCA (Arora et al., 2012). Stochastic projected gradient ascent in this context is closely related to the classical power method. In particular, the algorithm in (Mitliagkas et al., 2014) extends the power method to handle missing data, in part by improving the main result of (Lounici, 2014). With high probability, this algorithm converges globally and linearly to the true subspace and, most notably, succeeds for arbitrarily small sampling probability p, if the scope of the algorithm T is large enough. Additionally, this algorithm too has a computational complexity of $O(nr^2)$ operations per vector and a storage requirement of $O(nr)$ memory elements. In practice, SNIPE substantially outperforms the power method, as we will see in Section 6. A disadvantage of the power method is that it updates its estimate of the true subspace with every $O(n)$ incoming vectors; the waiting time might be prohibitively long if n is large. In contrast, SNIPE frequently updates its estimate with every $b = O(r)$ incoming vectors. As we will see in Section 6, SNIPE substantially outperforms the power method in practice. Let us add that POPCA (Gonen et al., 2016) is closely related to the power method, for which the authors provide lower bounds on the achievable sample complexity. However, POPCA has substantially greater memory demand than SNIPE, since it maintains an estimate of the possibly dense $n \times n$ sample covariance matrix of incoming data.

The PETRELS algorithm (Chi et al., 2013) operates on one column at a time (rather than blocks) and global convergence for PETRELS, namely, convergence to a stationary point of the underlying nonconvex program, is known. Designed for streaming matrix completion, the algorithm in (Mardani et al., 2015) also operates on one column at a time and asymptotic onvergence to the true subspace is established, see Propositions 2 and 3 therein. This framework is also extended to tensors. MOUSSE in (Xie et al., 2013) tracks a union of subspaces rather than just one; SNIPE would function more like an ingredient of this algorithm. Asymptotic consistency of MOUSSE is also established there. The theoretical guarantees of SNIPE are more comprehensive in the sense that we also offer local convergence rate for SNIPE, see Theorems 8 and 10. ReProcs, introduced in (Lois and Vaswani, 2015), tracks a slowly changing subspace when initialized sufficiently close.

In the next section, we compare the performance of several of these algorithms in practice and find that SNIPE competes empirically with state-of-the-art algorithms.

Even though we consider uniform random sampling of the entries of incoming vectors, SNIPE can be applied to any incomplete data. For example, instead of uniform sampling analyzed here, one can perhaps sample the entries of every incoming vector based on their estimated importance. More specifically, in iteration k, one might observe each entry of the incoming vector with a probability proportional to the *leverage score* of the corresponding row of the current estimate $\widehat{\mathcal{S}}_{k-1}$. In batch or offline matrix completion, using the idea of *leveraged sampling* (as opposed to uniform sampling) alleviates the dependence on the coherence factor $\eta(\mathcal{S})$ in (16) (Eftekhari et al., 2018a; Chen, 2015). While interesting, we have not pursued this direction in the current work.

6. Simulations

This section consists of two parts: first, we empirically study the dependence of SNIPE on various parameters, and second we compare SNIPE with existing algorithms for streaming subspace estimation with missing data. In all simulations, we consider an r-dimensional subspace $\mathcal{S} \subset \mathbb{R}^n$ and a sequence of generic vectors $\{s_t\}_{t=1}^T \subset \mathcal{S}$. Each entry of these vectors is observed with probability $p \in (0, 1]$ and collected in vectors $\{y_t\}_{t=1}^T \subset \mathbb{R}^n$. Our objective is to estimate $\mathcal{S}$ from $\{y_t\}$, as described in Section 1.

Sampling probability We first set $n = 100$, $r = 5$, and let $\mathcal{S}$ be a generic r-dimensional subspace, namely, the span of an $n \times r$ standard random Gaussian matrix. For various values of probability p, we run SNIPE with block size $b = 2r = 10$ and scope of $T = 500r = 2500$, recording the average estimation error $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K)$ over 50 trials, see (10). The average error versus probability is plotted in Figure 3a.

Subspace dimension With the same setting as the previous paragraph, we now set $p = 3r/n = 0.15$ and vary the subspace dimension r, block size $b = 2r$, and scope $T = 500r$. The average error versus subspace dimension is plotted in Figure 3b.

Ambient dimension This time, we set $r = 5$, $p = 3r/n$, $b = 2r$, $T = 500r$, and vary the ambient dimension n. In other words, we vary n while keeping the number of samples per vector fixed at about $pn = 3r$. The average error versus ambient dimension is plotted in Figure 3c. Observe that the performance of SNIPE steadily degrades as n increases. This is in agreement with Theorem 8 by substituting $p = 3r/n$ there, which states that the error reduces by a factor of $1 - Cr/n$, in expectation. A similar behavior is observed for our close competitor, namely, GROUSE (Balzano and Wright, 2015).

Block size Next we set $n = 100$, $r = 5$, $p = 3r/n$, $T = 500r$, and vary the block size b. The average error versus block size in both cases is depicted in Figure 3d. From Step 3 of Algorithm 1, a block size of $b \geq r$ is necessary for the success of SNIPE and qualitatively speaking larger values of b lead to better stability in face of missing data, which might explain the poor performance of SNIPE for very small values of b. However, as b increases, the number of blocks $K = T/b$ reduces because the scope T is held fixed. As the estimation error of SNIPE scales like $(1 - cp)^{-K}$ in Theorem 10 for a certain factor c, the performance

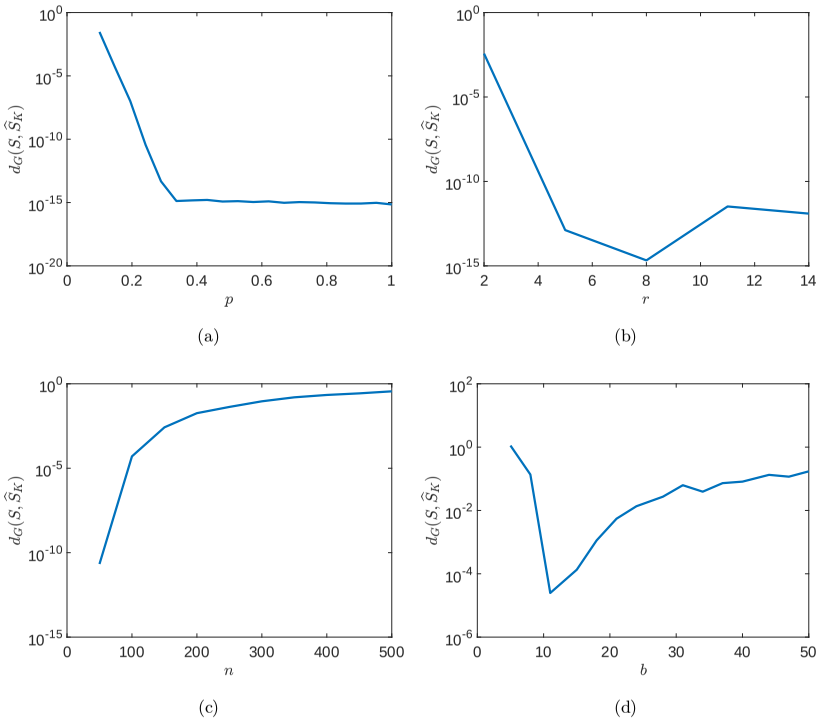

Figure 3: Performance of SNIPE as (a) sampling probability p, (b) subspace dimension r, (c) ambient dimension n, (d) block size b vary. $\widehat{\mathcal{S}}_K$ is the output of SNIPE and $d_G(\mathcal{S},\widehat{\mathcal{S}}_K)$ is its distance to the true subspace $\mathcal{S}$, which generated the input of SNIPE. See Section 6 for details and note that each panel is generated with a different and random subspace $\mathcal{S}$.

suffers in Figure 3d. It appears that the choice of $b = 2r$ in SNIPE guarantees the best empirical performance.

Coherence Lastly, we set $n = 300$, $r = 10$, $p = 3r/n$, $b = 2r$, and $T = 500r$. We then test the performance of SNIPE as the coherence of $\mathcal{S}$ varies, see (14). To that end, let $\mathcal{S} \subset \mathbb{R}^n$ be a generic subspace with orthonormal basis $S \in \mathbb{R}^{n\times r}$. In particular S is obtained by orthogonalizing the columns of a standard $n \times n$ random Gaussian matrix. Then, the average coherence of $\mathcal{S}$ over 50 trials was $3.3334 \ll n/r$ and the average estimation error of SNIPE was $2.795 \cdot 10^{-5}$. On the other hand, let $D \in \mathbb{R}^{n\times n}$ be a diagonal matrix with entries $D[i,i] = i^{-1}$ and consider $S' = DS$. Unlike $\mathcal{S}$, the new subspace $\mathcal{S}' := \text{span}(S')$ is

	$p=0.15$		$p=0.30$		$p=0.45$		$p=0.60$		$p=0.75$	
	$d_{\mathbb{G}}<10^{-3}$	$d_{\mathbb{G}}<10^{-7}$	$d_{\mathbb{G}}<10^{-3}$	$d_{\mathbb{G}}<10^{-7}$	$d_{\mathbb{G}}<10^{-3}$	$d_{\mathbb{G}}<10^{-7}$	$d_{\mathbb{G}}<10^{-3}$	$d_{\mathbb{G}}<10^{-7}$	$d_{\mathbb{G}}<10^{-3}$	$d_{\mathbb{G}}<10^{-7}$
GROUSE	**878.0** (76.1)	**1852.4** (85.2)	**294.9** (20.6)	**646.1** (26.8)	181.6 (13.8)	391.2 (18.0)	130.2 (10.3)	277.2 (12.8)	105.1 (11.7)	213.5 (12.8)
PETRELS	1689.0 (1394.1)	2853.7 (916.9)	421.8 (31.3)	1100.5 (64.2)	262.1 (25.3)	802.0 (31.1)	181.8 (20.2)	671.4 (22.8)	133.3 (21.3)	599.1 (24.0)
SNIPE	1815.7 (137.9)	3946.9 (182.4)	537.4 (39.9)	1236.4 (62.5)	282.4 (25.8)	649.6 (41.5)	171.4 (17.2)	391.4 (25.4)	105.5 (9.1)	241.6 (15.6)
SNIPE-overlap	1588.3 (183.8)	3319.5 (232.9)	318.7 (27.1)	704.6 (36.8)	**131.8** (11.6)	**296.4** (17.4)	**71.3** (5.7)	**155.6** (9.9)	**44.2** (4.2)	**91.8** (6.8)

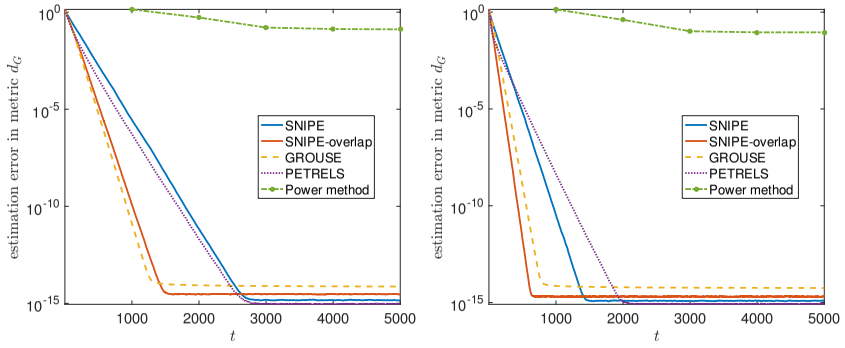

Table 1: Average number of revealed data columns needed to reach the indicated subspace recovery error for various sampling probabilities p over 100 random trials. Standard deviations are given in parenthesis.

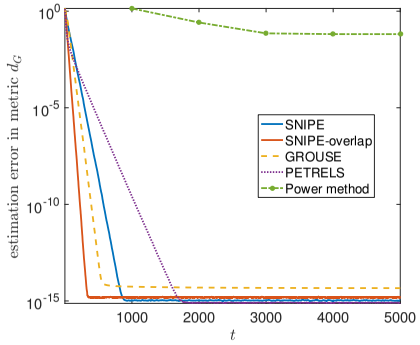
typically coherent since the energy of its orthonormal basis S' is mostly concentrated along its first few rows. This time, the average coherence of $\mathcal{S}'$ over 50 trials was $19.1773 \approx n/r$ and the average estimation error of SNIPE was substantially worse at 0.4286.



Comparisons Next we empirically compare SNIPE with GROUSE (Balzano et al., 2010; Zhang and Balzano, 2016), PETRELS (Chi et al., 2013), and the modified power method in (Mitliagkas et al., 2014). In addition to the version of SNIPE given in Algorithm 1, we also include comparisons with a simple variant of SNIPE, which we call SNIPE-overlap. Unlike SNIPE which processes disjoint blocks, SNIPE-overlap processes all overlapping blocks of data. More precisely, for a block size b, SNIPE-overlap first processes data columns $t = 1, 2, ..., b$, followed by columns $t = 2, 3, ..., b+1$, and so on, whereas regular SNIPE processes columns $t = 1, 2, ..., b$ followed by $t = b+1, b+2, ..., 2b$, etc. The theory developed in this paper does not hold for SNIPE-overlap because of lack of statistical independence between iterations, but we include the algorithm in the comparisons since it represents a minor modifications of the SNIPE-overlap framework and appears to have some empirical benefits, as detailed below.

In these experiments, we set $n = 100$, $r = 5$, $T = 5000$, and take $\mathcal{S} \subset \mathbb{R}^n$ to be a generic r-dimensional subspace and simulate noiseless data samples as before. In Figure 4 we compare the algorithms for three values of sampling probability p, which shows the average over 100 trials of the estimation error of algorithms (with respect to the metric $d_{\mathbb{G}}$) relative to the number of revealed data columns. For SNIPE, we used the block size of $b = 2r$. Having tried to get the best performance from GROUSE, we used the "greedy" step-size as proposed in (Zhang and Balzano, 2016). For (Mitliagkas et al., 2014), we set the block size as $b = 1000$ which was found empirically to yield the lowest subspace error after $T = 5000$ iterations.

In Table 1 we also compare the average number of revealed columns needed to reach a given error tolerance for each algorithm (as measured by error metric $d_{\mathbb{G}}$) for various values of the sampling probability p. We omit the modified power method from the results since it was unable to reach the given error tolerances in all cases. For the medium/high sampling rates $p = 0.45, 0.60, 0.75$, SNIPE-overlap is fastest to converge, while regular SNIPE is competitive with GROUSE and PETRELS. For the lower sampling rates $p = 0.15, 0.30$ we find GROUSE yields the fastest convergence, although SNIPE-overlap is also competitive with GROUSE for $p = 0.30$.

(a) $p = 0.30$ (b) $p = 0.45$

(c) $p = 0.60$

Figure 4: Average subspace estimation error versus number of revealed data columns at the specified sampling probability p, see Section 6 for details.

7. Theory

In this section, we prove the technical results presented in Section 4. A short word on notation is in order first. We will frequently use MATLAB's matrix notation so that, for example, $A[i,j]$ is the $[i,j]$th entry of A, and the row-vector $A[i,:]$ corresponds to the ith row of A. By $\{\epsilon_i\}_i \overset{\text{ind.}}{\sim} \text{Bernoulli}(p)$, we mean that $\{\epsilon_i\}_i$ are independent Bernoulli random variables taking one with probability of p and zero otherwise. Throughout, $E_{i,j}$ stands for the $[i,j]$th canonical matrix so that $E_{i,j}[i,j] = 1$ is its only nonzero entry. The size of $E_{i,j}$ may be inferred from the context. As usual, $\|\cdot\|$ and $\|\cdot\|_F$ stand for the spectral and Frobenius norms. In addition, $\|A\|_\infty$ and $\|A\|_{2\to\infty}$ return the largest entry of a matrix A (in magnitude) and the largest ℓ_2 norm of the rows of A, respectively. Singular values of

a matrix A are denoted by $\sigma_1(A) \geq \sigma_2(A) \geq \cdots$. For purely aesthetic reasons, we will occasionally use the notation $a \vee b = \max(a,b)$ and $a \wedge b = \min(a,b)$.

7.1. Convergence of SNIPE to a Stationary Point (Proof of Theorem 3)

Consider Program (2), namely,

$$\begin{cases} \min \;\; f_\Omega(X,\mathcal{U}) := \|P_{\mathcal{U}}^\perp X\|_F^2 + \lambda \|P_{\Omega^C}(X)\|_F^2, \\ P_\Omega(X) = Y, \end{cases} \tag{30}$$

where the minimization is over matrix $X \in \mathbb{R}^{n\times T}$ and subspace $\mathcal{U} \in \mathbb{G}(n,r)$. Before proceeding with the rest of the proof, let us for future reference record the partial derivatives of f_Ω below. Consider a small perturbation to X in the form of $X + \Delta$, where $\Delta \in \mathbb{R}^{n\times T}$. Let $U \in \mathbb{R}^{n\times r}$ and $U^\perp$ be orthonormal bases for $\mathcal{U}$ and its orthogonal complement $\mathcal{U}^\perp$, respectively. Consider also a small perturbation to U in the form of $U + U^\perp \Delta' \in \mathbb{R}^{n\times r}$, where $\Delta' \in \mathbb{R}^{(n-r)\times r}$. The perturbation to $f_\Omega(X,\mathcal{U}) = f_\Omega(X,U)$ can be written as

$$\begin{aligned} f_\Omega\left(X+\Delta, U+U^\perp\Delta'\right) &= f_\Omega(X,\mathcal{U}) + \langle \Delta, \partial_X f_\Omega(X,\mathcal{U})\rangle \\ &\quad + \left\langle \Delta', \partial_{\mathcal{U}} f_\Omega(X,\mathcal{U})\right\rangle + o(\|\Delta\|_F) + o(\|\Delta'\|_F), \end{aligned} \tag{31}$$

where $o(\cdot)$ is the standard little-o notation. The partial derivatives of f_Ω are listed below and derived in Appendix D.

Lemma 13 *For f_Ω in Program (30), the first-order partial derivatives at $(X,\mathcal{U}) \in \mathbb{R}^{n\times T} \times \mathbb{G}(n,r)$ are*

$$\begin{aligned} \partial_X f_\Omega(X,\mathcal{U}) &= 2P_{\mathcal{U}^\perp} X + 2\lambda P_{\Omega^C}(X) \in \mathbb{R}^{n\times T}, \\ \partial_{\mathcal{U}} f_\Omega(X,\mathcal{U}) &= -2(U^\perp)^* X X^* U \in \mathbb{R}^{(n-r)\times r}, \end{aligned} \tag{32}$$

where $U \in \mathbb{R}^{n\times r}$ and $U^\perp \in \mathbb{R}^{n\times(n-r)}$ are orthonormal bases for $\mathcal{U}$ and its orthogonal complement, respectively.

Recall that $Q_k \in \mathbb{R}^{r\times b}$ is a random matrix with bounded expectation, namely, $\mathbb{E}\|Q_k\|_F < \infty$. As $K \to \infty$, $\{Q_k\}_{k=1}^K$ therefore has a bounded subsequence. To keep the notation simple and without any loss of generality, we assume that in fact the sequence $\{Q_k\}_k$ is itself bounded. As $K \to \infty$ and for an integer l, we can always find an interval of length l over which the same index set and nearly the same coefficient matrix repeats. More specifically, consider an index set $\widehat{\Omega} \subseteq [1:n] \times [1:b]$ and a matrix $\widehat{Q} \in \mathbb{R}^{r\times b}$ in the support of the distributions from which $\{\Omega_k\}_{k=1}^K$ and $\{Q_k\}_{k=1}^K$ are drawn. For every integer l, as a result of the second Borel-Cantelli lemma (Durrett, 2010, pg. 64), almost surely there exists a contiguous interval

$$\kappa_l := [k_l - l + 1 : k_l], \tag{33}$$

such that

$$\Omega_k = \widehat{\Omega}, \qquad k \in \kappa_l, \tag{34}$$

$$\max_{k\in\kappa_l} \|Q_k - \widehat{Q}\|_F \leq \frac{1}{l}. \tag{35}$$

As $l \to \infty$, the measurements corresponding to the interval κ_l converge. To be specific, let $\widehat{Y} := P_{\widehat{\Omega}}(S\widehat{Q})$ and note that

$$\begin{aligned}\lim_{l\to\infty} \max_{k\in\kappa_l} \ \|Y_k - \widehat{Y}\|_F &= \lim_{l\to\infty} \max_{k\in\kappa_l} \ \|P_{\Omega_k}(SQ_k) - \widehat{Y}\|_F \\ &= \lim_{l\to\infty} \max_{k\in\kappa_l} \ \|P_{\widehat{\Omega}}(SQ_k) - \widehat{Y}\|_F \\ &= \lim_{l\to\infty} \max_{k\in\kappa_l} \ \|P_{\widehat{\Omega}}(S(Q_k - \widehat{Q}))\|_F \\ &\le \lim_{l\to\infty} \max_{k\in\kappa_l} \ \|Q_k - \widehat{Q}\|_F \\ &= 0. \end{aligned} \tag{36}$$

The above observation encourages us to exchange (Ω_k, Y_k) with $(\widehat{\Omega}, \widehat{Y})$ on the interval κ_l. Let us therefore study the program

$$\begin{cases} \min \ \ f_{\widehat{\Omega}}(X, \mathcal{U}), \\ P_{\widehat{\Omega}}(X) = \widehat{Y}, \end{cases} \tag{37}$$

where the minimization is over all matrices $X \in \mathbb{R}^{n\times b}$ and subspaces $\mathcal{U} \in \mathbb{G}(n, r)$. From a technical viewpoint, it is in fact more convenient to relax the equality constraint above as

$$\begin{cases} \min \ \ f_{\widehat{\Omega}}(X, \mathcal{U}), \\ \|P_{\widehat{\Omega}}(X) - \widehat{Y}\|_F \le \epsilon, \end{cases} \tag{38}$$

for $\epsilon > 0$. We fix ϵ for now. Let us next use alternative minimization to solve Program (38). More specifically, recall (33) and consider the initialization $\widehat{\mathcal{S}}_{k_l-l,\epsilon} := \widehat{\mathcal{S}}_{k_l-l}$, where $\widehat{\mathcal{S}}_{k_l-l}$ is the output of SNIPE at iteration $k_l - l$, see Algorithm 1. For every $k \in \kappa_l$, consider the program

$$\begin{cases} \min \ \ f_{\widehat{\Omega}}(X, \widehat{\mathcal{S}}_{k-1,\epsilon}), \\ \|P_{\widehat{\Omega}}(X) - \widehat{Y}\|_F \le \epsilon, \end{cases} \tag{39}$$

and let $R_{k,\epsilon}$ be a minimizer of Program (39). We then update the subspace by solving

$$\min_{\mathcal{U}\in\mathbb{G}(n,r)} \ f_{\widehat{\Omega}}(R_{k,\epsilon}, \mathcal{U}), \tag{40}$$

and setting $\widehat{\mathcal{S}}_{k,\epsilon}$ to be a minimizer of Program (40). Recalling the definition of $f_{\widehat{\Omega}}$ in Program (30) and in light of the Eckart-Young-Mirsky Theorem, Program (40) can be solved by computing top r left singular vectors of $R_{k,\epsilon}$ (Eckart and Young, 1936; Mirsky, 1966). For future reference, note that the optimality and hence stationarity of $\widehat{\mathcal{S}}_{k,\epsilon}$ in Program (40) dictates that

$$\partial_{\mathcal{U}} f_{\widehat{\Omega}}(R_{k,\epsilon}, \widehat{\mathcal{S}}_{k,\epsilon}) = 0, \qquad k \in \kappa_l, \tag{41}$$

where $\partial_{\mathcal{U}} f$ was specified in Lemma 13. From the above construction of the sequence $\{(R_{k,\epsilon}, \widehat{\mathcal{S}}_{k,\epsilon})\}_{k\in\kappa_l}$, we also observe that

$$0 \le f_{\widehat{\Omega}}(R_{k,\epsilon}, \widehat{\mathcal{S}}_{k,\epsilon}) \le f_{\widehat{\Omega}}(R_{k,\epsilon}, \widehat{\mathcal{S}}_{k-1,\epsilon}) \le f_{\widehat{\Omega}}(R_{k-1,\epsilon}, \widehat{\mathcal{S}}_{k-1,\epsilon}), \tag{42}$$

for every $k \in [k_l - l + 2 : k_l] \subset \kappa_l$, see (33). That is, $\{f_{\widehat{\Omega}}(R_{k,\epsilon}, \widehat{\mathcal{S}}_{k,\epsilon})\}_{k\in\kappa_l}$ is a nonincreasing and nonnegative sequence. It therefore holds that

$$\lim_{l\to\infty} \left| f_{\widehat{\Omega}}(R_{k_l-1,\epsilon}, \widehat{\mathcal{S}}_{k_l-1,\epsilon}) - f_{\widehat{\Omega}}(R_{k_l,\epsilon}, \widehat{\mathcal{S}}_{k_l-1,\epsilon}) \right| = 0. \tag{43}$$

By the feasibility of $R_{k_l-1,\epsilon}$ in Program (39) and by the continuity of $f_{\widehat{\Omega}}(X, \mathcal{U})$ in X, we conclude in light of (43) that $R_{k_l-1,\epsilon}$ too is a minimizer (and hence also a stationary point) of Program (39) and in the limit of $l \to \infty$. We therefore find by writing the stationarity conditions of Program (39) at $R_{k_l,\epsilon}$ that

$$\|P_{\widehat{\Omega}}(R_{k_l,\epsilon}) - \widehat{Y}\|_F \le \epsilon, \tag{44}$$

$$\lim_{l\to\infty} \left\| \partial_X f_{\widehat{\Omega}}(R_{k_l,\epsilon}, \widehat{\mathcal{S}}_{k_l,\epsilon}) + \lambda_{k_l,\epsilon}(P_{\widehat{\Omega}}(R_{k_l,\epsilon}) - \widehat{Y}) \right\|_F = 0. \tag{45}$$

for nonnegative $\lambda_{k_l,\epsilon}$. Recalling the definition of $f_{\widehat{\Omega}}$ and that $\lambda > 0$ by assumption, we observe that Program (39) is strongly convex in $P_{\widehat{\Omega}^C}(X)$ and consequently any pair of minimizers of Program (39) must agree on the index set $\widehat{\Omega}^C$. Optimality of $R_{k_l,\epsilon}$ and limit optimality of $R_{k_l-1,\epsilon}$ in Program (39) therefore imply that

$$\lim_{l\to\infty} \left\| P_{\widehat{\Omega}^C}(R_{k_l-1,\epsilon} - R_{k_l,\epsilon}) \right\|_F = 0. \tag{46}$$

On the index set $\widehat{\Omega}$, on the other hand, the feasibility of both $R_{k_l-1,\epsilon}$ and $R_{k_l,\epsilon}$ in Program (39) implies that

$$\begin{aligned} \|P_{\widehat{\Omega}}(R_{k_l-1,\epsilon} - R_{k_l,\epsilon})\|_F &\le \|P_{\widehat{\Omega}}(R_{k_l-1,\epsilon}) - \widehat{Y}\|_F + \|P_{\widehat{\Omega}}(R_{k_l,\epsilon}) - \widehat{Y}\|_F \qquad \text{(triangle inequality)} \\ &\le 2\epsilon. \end{aligned} \tag{47}$$

Combining (46) and (47) yields that

$$\begin{aligned} &\lim_{l\to\infty} \|R_{k_l-1,\epsilon} - R_{k_l,\epsilon}\|_F \\ &\le \lim_{l\to\infty} \|P_{\widehat{\Omega}}(R_{k_l-1,\epsilon} - R_{k_l,\epsilon})\|_F + \lim_{l\to\infty} \|P_{\widehat{\Omega}^C}(R_{k_l-1,\epsilon} - R_{k_l,\epsilon})\|_F \qquad \text{(triangle inequality)} \\ &\le 2\epsilon, \qquad \text{(see (46,47))} \end{aligned} \tag{48}$$

In light of (39), $\{R_{k_l,\epsilon}\}_l$ is bounded and consequently has a convergent subsequence. Without loss of generality and to simplify the notation, we assume that $\{R_{k_l,\epsilon}\}_l$ is itself convergent, namely, that there exists $R_\epsilon \in \mathbb{R}^{n\times b}$ for which

$$\lim_{l\to\infty} \|R_{k_l,\epsilon} - R_\epsilon\|_F \le 2\epsilon. \tag{49}$$

Let us now send ϵ to zero in (49) to obtain that

$$\lim_{\epsilon\to 0} \lim_{l\to\infty} \|R_{k_l,\epsilon} - R_\epsilon\|_F \le \lim_{\epsilon\to 0} 2\epsilon = 0. \tag{50}$$

We next show that it is possible to essentially change the order of limits above and also conclude that $(R, \widehat{\mathcal{S}})$ coincides with the output of SNIPE in limit. The following result is proved in Appendix E.

Lemma 14 *With the setup above, there exist a sequence* $\{\epsilon_i\}_i$ *with* $\lim_{i\to\infty}\epsilon_i = 0$ *and a matrix* $R \in \mathbb{R}^{n\times b}$ *such that*

$$\lim_{l,i\to\infty} \|R_{k_l,\epsilon_i} - R\|_F = \lim_{l\to\infty}\lim_{i\to\infty} \|R_{k_l,\epsilon_i} - R\|_F = \lim_{i\to\infty}\lim_{l\to\infty} \|R_{k_l,\epsilon_i} - R\|_F = 0. \tag{51}$$

Moreover, suppose that the output of SNIPE *in every iteration has a spectral gap in the sense that there exists* $\tau > 0$ *such that*

$$\frac{\sigma_r(R_k)}{\sigma_{r+1}(R_k)} \geq 1 + \tau, \tag{52}$$

for every k. *Let* $\widehat{\mathcal{S}}_{k_l,\epsilon_i}$ *and* $\widehat{\mathcal{S}}$ *be the span of top* r *left singular vectors of* R_{k_l,ϵ_i} *and* R, *respectively. Then it holds that*

$$\lim_{l,i\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_{k_l,\epsilon_i}, \mathcal{S}) = 0. \tag{53}$$

Lastly, in the limit of $l \to \infty$, SNIPE *produces* $(R, \widehat{\mathcal{S}})$ *in every iteration, namely,*

$$\lim_{l\to\infty} \|R_{k_l} - R\|_F = \lim_{l\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_{k_l}, \widehat{\mathcal{S}}) = 0, \tag{54}$$

where $(R_{k_l}, \widehat{\mathcal{S}}_{k_l})$ *is the output of* SNIPE *in iteration* k_l, *see Algorithm 1.*

In fact, the pair $(R, \widehat{S})$ from Lemma 14 is stationary in limit in the sense described next and proved in Appendix F.

Lemma 15 *The pair* $(R, \widehat{S})$ *in Lemma 14 is a stationary point of the program*

$$\begin{cases} \min \ \ f_{\Omega_{k_l}}(X,\mathcal{U}), \\ P_{\Omega_{k_l}}(X) = Y_{k_l}, \end{cases} \tag{55}$$

as $l \to \infty$. *The minimization above is over all matrices* $X \in \mathbb{R}^{n\times b}$ *and subspaces* $\mathcal{U} \in \mathbb{G}(n, r)$. *More specifically, it holds that*

$$\lim_{l\to\infty} \|\partial_{\mathcal{U}} f_{\Omega_{k_l}}(R, \widehat{\mathcal{S}})\|_F = 0, \tag{56}$$

$$\lim_{l\to\infty} \|P_{\Omega_{k_l}}(R) - Y_{k_l}\|_F = 0, \tag{57}$$

$$\lim_{l\to\infty} \|P_{\Omega^C_{k_l}}(\partial_X f_{\Omega_{k_l}}(R, \widehat{\mathcal{S}}))\|_F = 0. \tag{58}$$

In words, Lemmas 14 and 15 together imply that the output of SNIPE in limit is a stationary point of Program (55). This completes the proof of Theorem 3.

7.2. Convergence of SNIPE (Proof of Proposition 6)

In iteration k of SNIPE, we partially observe the data block $SQ_k \in \mathbb{R}^{n\times b}$ on a random index set $\Omega_k \subset [1:n] \times [1:b]$, where $Q_k \in \mathbb{R}^{r\times b}$ is a random coefficient matrix. We collect the observations in $Y_k = P_{\Omega_k}(SQ_k) \in \mathbb{R}^{n\times b}$, see Sections 2 and 3 for the detailed setup. Note that R_k in (1) can be written as

$$R_k = Y_k + P_{\Omega_k^C}(\widehat{S}_{k-1}Q'_k) = P_{\Omega_k}(SQ_k) + P_{\Omega_k^C}(\widehat{S}_{k-1}Q'_k), \tag{59}$$

where

$$Q'_k := \begin{bmatrix} \cdots & \left(\widehat{S}^*_{k-1}P_{\omega_t}\widehat{S}_{k-1} + \lambda I_r\right)^\dagger y_t & \cdots \end{bmatrix} \in \mathbb{R}^{r\times b}. \tag{60}$$

By (13), there exists $Q''_k \in \mathbb{R}^{r\times b}$ and

$$R'_k := P_{\Omega_k}(SQ_k) + P_{\Omega_k^C}(\widehat{S}Q''_k), \tag{61}$$

such that

$$\lim_{k\to\infty} \|R_k - R'_k\|_F = 0. \tag{62}$$

In (61) above, $\widehat{S} \in \mathbb{R}^{n\times r}$ is an orthonormal basis for the subspace $\widehat{\mathcal{S}}$. In Algorithm 1, the rank-r truncated SVD of R_k spans $\widehat{\mathcal{S}}_k \in \mathbb{G}(n, r)$, namely, the output of SNIPE in iteration k. Let also $\widehat{\mathcal{S}}'_k \in \mathbb{G}(n, r)$ denote the span of rank-r truncated SVD of R'_k. The existence of the reject option in Algorithm 1 with positive τ implies that R_k has a spectral gap and therefore $\widehat{\mathcal{S}}_k$ is uniquely defined. Combining this with (62), we find that $\widehat{\mathcal{S}}'_k$ too is uniquely defined in the limit of $k \to \infty$. Therefore another consequence of (62) is that

$$\lim_{k\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_k, \widehat{\mathcal{S}}'_k) = 0. \tag{63}$$

Then we have that

$$\lim_{k\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}'_k, \widehat{\mathcal{S}}) \leq \lim_{k\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}'_k, \widehat{\mathcal{S}}_k) + \lim_{k\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_k, \widehat{\mathcal{S}}) \leq 0 + 0, \qquad \text{(see (63,13))} \tag{64}$$

namely, $\widehat{\mathcal{S}}'_k$ converges to $\widehat{\mathcal{S}}$ in the limit too. Let us now rewrite R'_k as

$$R'_k = P_{\Omega_k}(SQ_k - \widehat{S}Q''_k) + \widehat{S}Q''_k, \qquad \text{(see (61))} \tag{65}$$

which, together with (64), implies that

$$\lim_{k\to\infty} \|\widehat{S}^* P_{\Omega_k}(SQ_k - \widehat{S}Q''_k)\|_F = 0. \tag{66}$$

We can rewrite the above limit in terms of the data vectors (rather than data blocks) to obtain that

$$\lim_{t\to\infty} \|\widehat{S}^* P_{\omega_t}(Sq_t - \widehat{S}q''_t)\|_F = 0, \tag{67}$$

where $\{q_t, q''_t\}_t$ form the columns of the blocks $\{Q_k, Q''_k\}_k$, and the index sets $\{\omega_t\}_t \subseteq [1:n]$ form $\{\Omega_k\}_k$. There almost surely exists a subsequence $\{t_i\}_i$ over which $\omega_{t_i} = \{1\}$, namely, there is a subsequence where we only observe the first entry of the incoming data vector. Consider a vector $q^1 \in \mathbb{R}^r$ in the support of the distribution from which $\{q_t\}_t$

are drawn. Then there also exists a subsequence of $\{t_i\}_i$, denoted by $\{t_{i_j}\}_{i_j}$, such that $\lim_{j\to\infty}\|q_{t_{i_j}} - q^1\|_2 = 0$. Restricted to the subsequence $\{t_{i_j}\}_j$, (67) reads as

$$0 = \lim_{j\to\infty}\|\widehat{S}^* P_{\omega_{t_{i_j}}}(Sq_{t_{i_j}} - \widehat{S}q''_{t_{i_j}})\|_F = \lim_{j\to\infty}\|\widehat{S}^* P_{\{1\}}(Sq_{t_{i_j}} - \widehat{S}q''_{t_{i_j}})\|_F = \|\widehat{S}^* P_{\{1\}}(Sq^1 - \widehat{S}q''^1)\|_F, \tag{68}$$

where we set $q''^1 := \lim_{j\to\infty} q''_{t_{i_j}}$; the limit exists by (60). Likewise, we can show that

$$v^l := P_{\{l\}}(Sq^l - \widehat{S}q''^l) \in \mathcal{S}^\perp, \qquad l \in [1:n], \tag{69}$$

where $\{q''^l\}_l$ are defined similarly. Because $\dim(\mathcal{S}^\perp) = n - r$, at most $n - r$ of the vectors $\{v^l\}_{l=1}^n$ are linearly independent. Because the supports of $\{v^l\}_l$ are disjoint, it follows that there are at most $n - r$ of the vectors $\{v^l\}_{l=1}^n$ are nonzero. Put differently, there exists an index set $I \subset [1:n]$ of size at least r such that

$$Sq^l = \widehat{S}q''^l, \qquad l \in I. \tag{70}$$

Almost surely, $\{q^l\}_{l\in I} \subset \mathbb{R}^r$ form a basis for $\mathbb{R}^r$, and therefore $\mathcal{S} \subseteq \widehat{\mathcal{S}}$. Because $\widehat{\mathcal{S}} \in \mathbb{G}(n,r)$ by assumption, it follows that $\widehat{\mathcal{S}} = \mathcal{S}$, which completes the proof of Proposition 6.

7.3. Locally Linear Convergence of SNIPE (Proof of Theorems 8 and 10)

At iteration $k \in [2:K]$, SNIPE uses the current estimate $\widehat{\mathcal{S}}_{k-1}$ and the new incomplete block Y_k to produce a new estimate $\widehat{\mathcal{S}}_k$ of the true subspace $\mathcal{S}$. The main challenge here is to compare the new and old principal angles with $\mathcal{S}$, namely, compare $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k)$ and $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1})$. Lemma 16 below, proved in Appendix G, loosely speaking states that $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k)$ reduces by a factor of $1 - O(p)$ in expectation in every iteration, when $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \lesssim p^{\frac{5}{2}}$ and ignoring all other parameters in this qualitative discussion. In other words, when sufficiently small, the estimation error of SNIPE reduces in every iteration, but in expectation. The actual behavior of SNIPE is more nuanced. Indeed, Lemma 16 below also adds that the estimation error $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k)$ in fact contracts in *some* iterations by a factor of $1 - Cp$, namely,

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \lesssim (1 - Cp) \cdot d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}),$$

provided that $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) \lesssim p^{\frac{5}{2}}$. That is, when sufficiently small, the estimation error of SNIPE reduces in some but not all iterations. In the rest of iterations, the error does not increase by much, namely,

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \approx d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}),$$

with high probability and provided that $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) \lesssim p^{\frac{5}{2}}$.

Lemma 16 *Fix $k \in [2:K]$, $\alpha, \nu \geq 1$, and $c > 0$. Let $\mathfrak{E}_{k-1}$ be the event where*

$$p \gtrsim \alpha^2 \log^2 b \log n \frac{\eta(\widehat{\mathcal{S}}_{k-1})r}{n}, \tag{71}$$

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) \lesssim \frac{p^{\frac{7}{2}} nb}{\alpha c \log b \sqrt{r \log n}}, \tag{72}$$

and let $\mathfrak{E}'_k$ be the event where $\|Q_k\| \leq \nu \cdot \sigma_{\min}$, where $\sigma_{\min}$ is the reject threshold in SNIPE, *see Algorithm 1. Then it holds that*

$$\mathbb{E}\left[d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k\right] \leq \nu\left(1 - \frac{p}{2} + \frac{p^3 nb}{c}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) + \frac{b^{-C\alpha}}{\sqrt{r}}. \tag{73}$$

Moreover, conditioned on $\widehat{\mathcal{S}}_{k-1}$ and the event $\mathfrak{E}_{k-1} \cap \mathfrak{E}'_k$, it holds that

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \leq \nu\left(1 + \frac{p^3 nb}{c}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}), \tag{74}$$

except with a probability of at most $b^{-C\alpha}$. Lastly, a stronger bound holds conditioned on $\widehat{\mathcal{S}}_{k-1}$ and the event $\mathfrak{E}_{k-1} \cap \mathfrak{E}'_k$, namely,

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \leq \nu\left(1 - \frac{p}{4} + \frac{p^3 nb}{c}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) \tag{75}$$

with a probability of at least

$$\phi_k(\alpha) := 1 - \exp\left(-\frac{C_1 p^2 nb}{\widetilde{\eta}_{k-1}}\right) - b^{-C\alpha}, \tag{76}$$

where

$$\widetilde{\eta}_k = \widetilde{\eta}(P_{\widehat{\mathcal{S}}_{k-1}^\perp} S_k) := nb \cdot \frac{\|P_{\widehat{\mathcal{S}}_{k-1}^\perp} S_k\|_\infty^2}{\|P_{\widehat{\mathcal{S}}_{k-1}^\perp} S_k\|_F^2}. \tag{77}$$

Let us now use Lemma 16 to complete the proofs of Theorems 8 and 10.

7.3.1. Proof of Theorem 8

With the choice of $c = 4p^2 nb$ and $\nu = 1/\sqrt{1 - p/4}$, (73) reads as

$$\begin{aligned}
\mathbb{E}\left[d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k\right] &\leq \nu\left(1 - \frac{p}{2} + \frac{p^3 nb}{c}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) + \frac{b^{-C\alpha}}{\sqrt{r}} \qquad \text{(see (73))} \\
&= \sqrt{1 - \frac{p}{4}}\, d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) + \frac{b^{-C\alpha}}{\sqrt{r}} \\
&\leq \left(1 - \frac{p}{8}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) + \frac{b^{-C\alpha}}{\sqrt{r}}.
\end{aligned} \tag{78}$$

With the choice of

$$\alpha = -\frac{C \log\left(p\sqrt{r}\, d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1})/16\right)}{\log b}, \tag{79}$$

for an appropriate constant C above, the bound in (78) simplifies to

$$\begin{aligned}
\mathbb{E}\left[d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k) \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k\right] &\leq \left(1 - \frac{p}{8}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) + \frac{b^{-C\alpha}}{\sqrt{r}} \qquad \text{(see (78))} \\
&\leq \left(1 - \frac{p}{8}\right) d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1}) + \frac{p}{16} d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{k-1})
\end{aligned}$$

$$\leq \left(1-\frac{p}{16}\right) d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{k-1}). \tag{80}$$

Lastly we remove the conditioning on $\mathfrak{E}'_k$ above. Using the law of total expectation, we write that

$$\begin{aligned}
&\mathbb{E}\left[d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\,|\,\widehat{\mathcal{S}}_{k-1},\mathfrak{E}_{k-1}\right]\\
&=\mathbb{E}\left[d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\,|\,\widehat{\mathcal{S}}_{k-1},\mathfrak{E}_{k-1},\mathfrak{E}'_k\right]\cdot\Pr[\mathfrak{E}'_k]+\mathbb{E}\left[d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\,|\,\widehat{\mathcal{S}}_{k-1},\mathfrak{E}_{k-1},\mathfrak{E}'^C_k\right]\cdot\Pr[\mathfrak{E}'^C_k]\\
&\leq\mathbb{E}\left[d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\,|\,\widehat{\mathcal{S}}_{k-1},\mathfrak{E}_{k-1},\mathfrak{E}'_k\right]+\Pr[\mathfrak{E}'^C_k]\qquad\text{(see (10))}\\
&\leq\left(1-\frac{p}{16}\right)d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{k-1})+\Pr[\mathfrak{E}'^C_k]\qquad\text{(see (80))}\\
&\leq\left(1-\frac{p}{32}\right)d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{k-1}),
\end{aligned}\tag{81}$$

where the last line holds if

$$\Pr[\mathfrak{E}'^C_k]\leq\frac{p}{32}d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{k-1}).$$

With the choice of c,ν,α above, let us also rewrite the event $\mathfrak{E}_{k-1}$ in Lemma 16. First, we rewrite (72) as

$$\begin{aligned}
d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{k-1})&\lesssim\frac{p^{\frac{7}{2}}nb}{\alpha c\log b\sqrt{r\log n}}=\frac{Cp^{\frac{3}{2}}}{\alpha\log b\sqrt{r\log n}}\\
&=-\frac{Cp^{\frac{3}{2}}}{\log\left(p\sqrt{r}d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{k-1})/16\right)\sqrt{r\log n}}.\qquad\text{(see (79))}
\end{aligned}\tag{82}$$

Second, we replace the coherence $\eta(\widehat{\mathcal{S}}_{k-1})$ in (71) with the simpler quantity $\eta(\mathcal{S})$. We can do so thanks to Lemma 20 which roughly speaking states that a pair of subspaces $\mathcal{A}$ and $\mathcal{B}$ with a small principal angle have similar coherences, namely, $\theta_1(\mathcal{A},\mathcal{B})\approx 0\Longrightarrow\eta(\mathcal{A})\approx\eta(\mathcal{B})$. More concretely, note that

$$\begin{aligned}
\sqrt{\eta(\widehat{\mathcal{S}}_{k-1})}&\leq\sqrt{\eta\left(\mathcal{S}\right)}+d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{k-1})\sqrt{n}\qquad\text{(see Lemma 20)}\\
&\leq\sqrt{\eta(\mathcal{S})}+Cp^{\frac{3}{2}}\sqrt{\frac{n}{r\log n}}\qquad\text{(see (82))}\\
&\leq\sqrt{\eta(\mathcal{S})}+1\qquad\left(\text{if }p\lesssim\frac{1}{\sqrt{nb}}\right)\\
&\leq 2\sqrt{\eta(\mathcal{S})}.\qquad\text{(see (15))}
\end{aligned}\tag{83}$$

This completes the proof of Theorem 8.

7.3.2. Proof of Theorem 10

For $K_0\in[1:K]$, we condition on $\widehat{\mathcal{S}}_{K_0}$. For positive c to be set later, suppose that

$$d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0})\lesssim\frac{e^{-\frac{Cp^3nb}{\eta}}p^{\frac{7}{2}}nb}{\alpha c\log b\sqrt{\log n}}.\tag{84}$$

In particular, (84) implies that the error at iteration K_0 is small enough to activate Lemma 16, see (72). For $\nu\geq 1$ to be set later, we condition for now on the event

$$\mathfrak{E}':=\cap_{k=K_0+1}^{K}\mathfrak{E}'_k,\tag{85}$$

where the event $\mathfrak{E}'_k$ was defined in Lemma 16. Suppose also that (71) holds for every $k\in[K_0+1:K]$, namely,

$$p\gtrsim\max_{k\in[K_0:K-1]}\eta(\widehat{\mathcal{S}}_k)\cdot\frac{r\log^2 b\log n}{n},\tag{86}$$

which will next allow us to apply Lemma 16 repeatedly to all iterations in the interval $[K_0+1:K]$. With the success probability $\phi_k(\alpha)$ defined in Lemma 16, let us also define

$$\phi(\alpha):=\min_{k\in[K_0+1:K]}\phi_k(\alpha)=1-\exp\left(-\frac{C_1p^2nb}{\widetilde{\eta}}\right)-b^{-C\alpha},\qquad\widetilde{\eta}:=\max_{k\in[K_0+1:K]}\widetilde{\eta}_k\geq 1,\tag{87}$$

where the inequality above follows because $\widetilde{\eta}_k\geq 1$ for every k, see (77). We now partition $[K_0+1:K]$ into (non-overlapping) intervals $\{I_i\}_i$, each with the length

$$l=\frac{C_2\log b\log(K-K_0)}{\phi(\alpha)},\tag{88}$$

except possibly the last interval which might be shorter. Consider one of these intervals, say I_1. Then by Lemma 16 and the union bound, (74) holds for every iteration $k\in I_1$ except with a probability of at most $l\cdot b^{-C\alpha}$ because the length of I_1 is l. That is, the estimation error does not increase by much in every iteration in the interval I_1. In some of these iterations, the error in fact reduces. More specifically, (75) holds in iteration k with a probability of at least $\phi_k(\alpha)$, see (76). While $b^{-C\alpha}$ in (76) can be made arbitrary small by increasing the tuning parameter α, this of course would not necessarily make $\phi_k(\alpha)$ arbitrary close to one. That is, there is a sizable chance that the estimation error does not contract in iteration k. However, (75) holds at least in one iteration in the interval I_1 except with a probability of at most

$$(1-\phi(\alpha))^l\leq e^{-\phi(\alpha)l}=b^{-C_2\log(K-K_0)}.\qquad(1+a\leq e^a)$$

Therefore, except with a probabilty of at most $lb^{-C\alpha}+b^{-C_2\log(K-K_0)}$, (75) holds at least once and (74) holds for all iterations in the interval I_1. It immediately follows that

$$\begin{aligned}
&\frac{d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0+l})}{d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0})}\\
&\leq\nu\left(1-\frac{p}{4}+\frac{p^3nb}{c}\right)\cdot\nu^{l-1}\left(1+\frac{p^3nb}{c}\right)^{l-1}\qquad\text{(see (74,75))}\\
&\leq\nu^l\exp\left(-\frac{p}{4}+\frac{p^3np}{c}+(l-1)\frac{p^3nb}{c}\right)\qquad(1+a\leq e^a)\\
&=\nu^l\exp\left(-\frac{p}{4}+\frac{lp^3nb}{c}\right),
\end{aligned}\tag{89}$$

except with a probability of at most

$$lb^{-C\alpha} + b^{-C_2 \log(K-K_0)}. \tag{90}$$

In particular, suppose that

$$c \geq 4lp^2nb, \tag{91}$$

so that the exponent in the last line of (89) is negative. Let

$$i_{\max} := \left\lfloor \frac{K-K_0}{l} \right\rfloor,$$

and note that

$$\frac{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K)}{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0})} = \prod_{i=1}^{i_{\max}} \frac{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0+il})}{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0+(i-1)l})} \cdot \frac{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K)}{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0+i_{\max}l})}. \tag{92}$$

By applying the bound in (89) to all intervals $\{I_i\}_i$, we then conclude that

$$\begin{aligned}
&\frac{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K)}{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0})} \\
&= \prod_{i=1}^{i_{\max}} \frac{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0+il})}{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0+(i-1)l})} \cdot \frac{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K)}{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0+i_{\max}l})} \qquad \text{(see (92))} \\
&\leq \left(\nu^l \exp\left(-\frac{p}{4} + \frac{lp^3nb}{c}\right)\right)^{\left\lfloor \frac{K-K_0}{l} \right\rfloor} \cdot \nu^l \left(1 + \frac{p^3nb}{c}\right)^l \qquad \text{(see (89,74))} \\
&\leq \left(\nu^l \exp\left(-\frac{p}{4} + \frac{lp^3nb}{c}\right)\right)^{\left\lfloor \frac{K-K_0}{l} \right\rfloor} \cdot \nu^l \exp\left(\frac{lp^3nb}{c}\right) \qquad (1+a \leq e^a) \\
&\leq \nu^{K-K_0} \exp\left(\left\lfloor \frac{K-K_0}{2l} \right\rfloor \left(-\frac{p}{4} + \frac{lp^3nb}{c}\right)\right) \cdot \exp\left(\frac{lp^3nb}{c}\right) \\
&\leq \nu^{K-K_0} \exp\left(\frac{K-K_0}{2l} \left(-\frac{p}{4} + \frac{lp^3nb}{c}\right)\right) \cdot \exp\left(\frac{lp^3nb}{c}\right) \quad \text{(if } K-K_0 \geq l \text{ and (91) holds)} \\
&\leq \nu^{K-K_0} \exp\left(\frac{K-K_0}{2l} \left(-\frac{p}{4} + \frac{3lp^3nb}{c}\right)\right), \qquad \text{(if } K-K_0 \geq l\text{)}
\end{aligned} \tag{93}$$

except with a probability of at most

$$\begin{aligned}
&\left\lceil \frac{K-K_0}{l} \right\rceil \left(lb^{-C\alpha} + b^{-C_2 \log(K-K_0)}\right) \\
&\quad \leq \frac{2(K-K_0)}{l} \left(lb^{-C\alpha} + b^{-C_2 \log(K-K_0)}\right) \qquad \text{(if } K-K_0 \geq l\text{)} \\
&\quad \leq (K-K_0)e^{-C\alpha} + b^{-CC_2 \log(K-K_0)},
\end{aligned} \tag{94}$$

which follows from an application of the union bound to the failure probability in (90). With the choice of $\alpha = \alpha' \log b \log(K-K_0)$ with sufficiently large α', the failure probability in (94) simplifies to

$$(K-K_0)e^{-C\alpha} + b^{-C\log(K-K_0)} = (K-K_0) \cdot (K-K_0)^{-C\alpha' \log b} + b^{-C\log(K-K_0)}$$

$$\begin{aligned}
&\leq (K-K_0)^{-C\alpha' \log b} + b^{-C\log(K-K_0)} \\
&= b^{-C\alpha' \log(K-K_0)} + b^{-C\log(K-K_0)} \\
&\leq b^{-C\log(K-K_0)}.
\end{aligned} \tag{95}$$

The next step involves elementary bookkeeping to upper-bound the last line of (93). Suppose that

$$\alpha \gtrsim \frac{\log\left(\frac{C\widetilde{\eta}}{p^2nb}\right)}{\log b}, \tag{96}$$

$$p \lesssim \frac{1}{\sqrt{nb}}. \tag{97}$$

Using (96) and (97) with appropriate constants replacing $\gtrsim$ and $\lesssim$ above, we may verify that

$$b^{-C\alpha} \leq \frac{C_1p^2nb}{4\widetilde{\eta}}, \qquad \text{(see (96))} \tag{98}$$

$$\frac{C_1p^2nb}{\widetilde{\eta}} \lesssim 2, \qquad \text{((97) and } \widetilde{\eta} \geq 1\text{)} \tag{99}$$

$$\begin{aligned}
\phi(\alpha) &= 1 - \exp\left(-\frac{C_1p^2nb}{\widetilde{\eta}}\right) - b^{-C\alpha} \qquad \text{(see (87))} \\
&\geq \frac{1}{2} \cdot \frac{C_1p^2nb}{\widetilde{\eta}} - b^{-C\alpha} \qquad \left(\text{(99) and } e^{-a} \leq 1 - \frac{a}{2} \text{ for } a \lesssim 2\right) \\
&\geq \frac{C_1p^2nb}{4\widetilde{\eta}}, \qquad \text{(see (98))}
\end{aligned} \tag{100}$$

$$\begin{aligned}
l &= \frac{C_2 \log b \log(K-K_0)}{\phi(\alpha)} \qquad \text{(see (88))} \\
&\leq \frac{4C_2\widetilde{\eta} \log b \log(K-K_0)}{C_1p^2nb}. \qquad \text{(see (100))}
\end{aligned} \tag{101}$$

Now with the choice of

$$c = \frac{96C_2}{C_1}\widetilde{\eta} \log b \log(K-K_0), \tag{102}$$

we may verify that

$$-\frac{p}{4} + \frac{3lp^3nb}{c} \leq -\frac{p}{8}, \qquad \text{(see (101,102))} \tag{103}$$

and, revisiting (93), we find that

$$\begin{aligned}
&\frac{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_K)}{d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_{K_0})} \\
&\leq \nu^{K-K_0} \exp\left(\frac{K-K_0}{2l} \left(-\frac{p}{4} + \frac{3lp^3nb}{c}\right)\right) \qquad \text{(see (93))}
\end{aligned}$$

$$
\begin{aligned}
&\le \nu^{K-K_0}\exp\left(-\frac{(K-K_0)p}{16l}\right) && \text{(see (103))}\\
&= \left(\nu\exp\left(-\frac{p}{16l}\right)\right)^{K-K_0}\\
&\le \left(\nu\exp\left(-\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}\right)\right)^{K-K_0} && \text{(see (101))}\\
&\le \nu^{K-K_0}\left(1-\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}\right)^{K-K_0} && \text{((97) and } \widetilde{\eta}\ge 1)\\
&\le \left(1-\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}\right)^{K-K_0}, && (104)
\end{aligned}
$$

where we set

$$\nu = 1+\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}, \tag{105}$$

for an appropriate choice of constant C. To reiterate, conditioned on the event $\mathfrak{E}'$ in (85), (104) is valid provided that (84,86,96,97) hold and except with the probability of at most $b^{-C\log(K-K_0)}$, see (95). In particular, to better interpret (86), we next replace the coherence $\eta(\widehat{\mathcal{S}}_k)$ therein with the simpler quantity $\eta(\mathcal{S})$. We can do so thanks to Lemma 20 which roughly speaking states that a pair of subspaces $\mathcal{A}$ and $\mathcal{B}$ with a small principal angle have similar coherences, namely, $\theta_1(\mathcal{A},\mathcal{B})\approx 0 \implies \eta(\mathcal{A})\approx\eta(\mathcal{B})$. More concretely, Lemma 20 implies that

$$\sqrt{\eta(\widehat{\mathcal{S}}_k)} \le \sqrt{\eta(\mathcal{S})} + d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\sqrt{n}. \tag{106}$$

for every k. To bound the distance in the last line above, we observe that (104) holds also after replacing K with any $k\in[K_0+l:K]$, implying in particular that

$$d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\le d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}),\qquad k\in[K_0+l:K]. \tag{107}$$

When $k\in[K_0+1:K_0+l-1]$ however, we cannot guarantee that the error reduces and all we can say is that that the error does not increase by much. That is, for every $k\in[K_0+1:K_0+l-1]$, we have that

$$
\begin{aligned}
d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k) &\le \nu^{k-K_0}\left(1+\frac{p^3nb}{c}\right)^{k-K_0} d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}) && \text{(see (74))}\\
&\le \nu^{l}\left(1+\frac{p^3nb}{c}\right)^{l} d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0})\\
&= \nu^{l}\left(1+\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}\right)^{l} d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0})\\
&\le \left(1+\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}\right)^{2l} d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}), && \text{(see (105))} \qquad (108)
\end{aligned}
$$

with an appropriate choice of C in (105). We continue by writing that

$$d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\le\left(1+\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}\right)^{2l} d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}) \qquad \text{(see (108))}$$

$$
\begin{aligned}
&\le \exp\left(\frac{Cp^3nb}{\widetilde{\eta}\log b\log(K-K_0)}\cdot l\right) d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}) && (1+a\le e^a)\\
&\le e^{Cp} d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}) && \text{(see (101))}\\
&\lesssim d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}). && (p\le 1) \qquad (109)
\end{aligned}
$$

Combining (107) and (109), we arrive at

$$d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\lesssim d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0}), \tag{110}$$

for every $k\in[K_0+1:K]$, provided that (84,86,96,97) hold and except with a probability of at most $b^{-C\log(K-K_0)}$, see (95). Substituting the above bound into (106) yields that

$$
\begin{aligned}
\sqrt{\eta(\widehat{\mathcal{S}}_k)} &\le \sqrt{\eta(\mathcal{S})} + d_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_k)\sqrt{n} && \text{(see (106))}\\
&\le \sqrt{\eta(\mathcal{S})} + Cd_{\mathbb{G}}(\mathcal{S},\widehat{\mathcal{S}}_{K_0})\sqrt{n} && \text{(see (110))}\\
&\le \sqrt{\eta(\mathcal{S})} + \frac{Cp^{\frac{7}{2}}n^{\frac{3}{2}}b}{\alpha c\log b\sqrt{\log n}} && \text{(see (84))}\\
&\le \sqrt{\eta(\mathcal{S})} + \frac{Cp^{\frac{7}{2}}n^{\frac{3}{2}}b}{\alpha\widetilde{\eta}\log^2 b\sqrt{\log n}\log(K-K_0)} && \text{(see (102))}\\
&\le \sqrt{\eta(\mathcal{S})} + 1. && (\text{(97) and } \widetilde{\eta}\ge 1)\\
&\le 2\sqrt{\eta(\mathcal{S})}. && (\eta(\mathcal{S})\ge 1) \qquad (111)
\end{aligned}
$$

Plugging back the bound above into (86) yields that

$$p\gtrsim \log^2 b\log n\frac{\eta(\mathcal{S})r}{n}. \tag{112}$$

To summarize, conditioned on the event $\mathfrak{E}'$, we have established that (104) is valid under (84,96,97,112) and except with a probability of at most $b^{-C\log(K-K_0)}$. The event $\mathfrak{E}'=\cap_{k=K_0+1}^{K}\mathfrak{E}'_k$ itself holds except with a probability of at most $\sum_{k=K_0+1}^{K}\Pr[\mathfrak{E}'^C_k]$ by the union bound. With an application of the law of total probability, (104) is therefore valid except with a probability of at most $b^{-C\log(K-K_0)}+\sum_{k=K_0+1}^{K}\Pr[\mathfrak{E}'^C_k]$. This completes the proof of Theorem 10.

Acknowledgments

AE would like to thank Anand Vidyashankar and Chris Williams for separately pointing out the possibility of a statistical interpretation of SNIPE, as discussed at the end of Section 3. AE is also extremely grateful to Raphael Hauser for his helpful insights. Lastly, the authors would like to acknowledge and thank Dehui Yang for his involvement in the early phases of this project. For this project, AE was supported by the Alan Turing Institute under the EPSRC grant EP/N510129/1 and partially by the Turing Seed Funding grant SF019. GO and LB were supported by ARO Grant W911NF-14-1-0634. LB was also supported by DARPA grant 16-43-D3M-FP-037. MBW was partially supported by NSF grant CCF-1409258 and NSF CAREER grant CCF-1149225.

Appendix A. Toolbox

This section collects a number of standard results for the reader's convenience. We begin with the following large-deviation bounds that are repeatedly used in the rest of the appendices (Gross, 2011; Tropp, 2012). Throughout, C is a universal constant the value of which might change in every appearance.

Lemma 17 [Hoeffding inequality] *Let $\{z_i\}_i$ be a finite sequence of zero-mean independent random variables and assume that almost surely every z_i belongs to a compact interval of length l_i on the real line. Then, for positive α and except with a probability of at most $e^{-C\alpha^2/\sum_i l_i^2}$, it holds that $\sum_i z_i \le \alpha$.*

Lemma 18 [Matrix Bernstein inequality for spectral norm] *Let $\{Z_i\}_i \subset \mathbb{R}^{n\times b}$ be a finite sequence of zero-mean independent random matrices, and set*

$$\beta := \max_i \|Z_i\|,$$

$$\sigma^2 := \left\|\sum_i \mathbb{E}\left[Z_i^* Z_i\right]\right\| \vee \left\|\sum_i \mathbb{E}\left[Z_i Z_i^*\right]\right\|.$$

Then, for $\alpha \ge 1$ and except with a probability of at most $e^{-C\alpha}$, it holds that

$$\left\|\sum_i Z_i\right\| \lesssim \alpha \cdot \max\left(\log(n\vee b)\cdot\beta, \sqrt{\log(n\vee b)}\cdot\sigma\right).$$

For two r-dimensional subspaces $\mathcal{A}$ and $\mathcal{B}$ with principal angles $\theta_1(\mathcal{A},\mathcal{B}) \ge \theta_2(\mathcal{A},\mathcal{B}) \ge \cdots \ge \theta_r(\mathcal{A},\mathcal{B})$, recall the following useful identities about the principal angles between them:

$$\sin\left(\theta_1\left(\mathcal{A},\mathcal{B}\right)\right) = \|P_{\mathcal{A}^\perp} P_{\mathcal{B}}\| = \|P_{\mathcal{A}} - P_{\mathcal{B}}\|, \tag{113}$$

$$\sqrt{\sum_{i=1}^r \sin^2\left(\theta_i\left(\mathcal{A},\mathcal{B}\right)\right)} = \|P_{\mathcal{A}^\perp} P_B\|_F = \frac{1}{\sqrt{2}}\|P_{\mathcal{A}} - P_{\mathcal{B}}\|_F. \tag{114}$$

Note also the following perturbation bound that is slightly stronger than the standard ones, but proved similarly nonetheless (Wedin, 1972).

Lemma 19 [Perturbation bound] *Fix a rank-r matrix A and let $\mathcal{A} = \mathrm{span}(A)$. For matrix B, let B_r be a rank-r truncation of B obtained via SVD and set $\mathcal{B}_r = \mathrm{span}(B_r)$. Then, it holds that*

$$\|P_{\mathcal{A}} - P_{\mathcal{B}_r}\| = \|P_{\mathcal{A}^\perp} P_{\mathcal{B}_r}\| \le \frac{\|P_{\mathcal{A}^\perp} B\|}{\sigma_r(B)} \le \frac{\|B-A\|}{\sigma_r(B)} \le \frac{\|B-A\|}{\sigma_r(A) - \|B-A\|},$$

$$\frac{1}{\sqrt{2}}\|P_{\mathcal{A}} - P_{\mathcal{B}_r}\|_F = \|P_{\mathcal{A}^\perp} P_{\mathcal{B}_r}\|_F \le \frac{\|P_{\mathcal{A}^\perp} B\|_F}{\sigma_r(B)} \le \frac{\|B-A\|_F}{\sigma_r(B)},$$

where $\sigma_r(A)$ is the r largest singular value of A.

Proof Let $B_{r^+} := B - B_r$ denote the residual and note that

$$\begin{aligned}
\|P_{\mathcal{A}^\perp} P_{\mathcal{B}_r}\| &= \left\|P_{\mathcal{A}^\perp} B_r B_r^\dagger\right\| \qquad (\mathcal{B}_r = \mathrm{span}(B_r)) \\
&= \left\|P_{\mathcal{A}^\perp}\left(B - B_{r^+}\right) B_r^\dagger\right\| \qquad (B = B_r + B_{r^+}) \\
&= \left\|P_{\mathcal{A}^\perp} B B_r^\dagger\right\| \qquad \left(\mathrm{span}\left(B_{r^+}^*\right) \perp \mathrm{span}\left(B_r^*\right) = \mathrm{span}\left(B_r^\dagger\right)\right) \\
&\le \|P_{\mathcal{A}^\perp} B\| \cdot \|B_r^\dagger\| \\
&= \frac{\|P_{\mathcal{A}^\perp} B\|}{\sigma_r(B_r)} \\
&= \frac{\|P_{\mathcal{A}^\perp}(B-A)\|}{\sigma_r(B_r)} \\
&\le \frac{\|B-A\|}{\sigma_r(B_r)} \\
&\le \frac{\|B-A\|}{\sigma_r(A) - \|B-A\|}. \qquad \text{(Weyl's inequality)}
\end{aligned}$$

The proof is identical for the claim with the Frobenius norm and is therefore omitted. ■

Lastly, let us record what happens to the coherence of a subspace under a small perturbation, see (14).

Lemma 20 [Coherence under perturbation] *Let $\mathcal{A}, \mathcal{B}$ be two r-dimensional subspaces in $\mathbb{R}^n$, and let $d_{\mathbb{G}}(\mathcal{A},\mathcal{B})$ denote their distance, see (10). Then their coherences are related as*

$$\sqrt{\eta(\mathcal{B})} \le \sqrt{\eta(\mathcal{A})} + d_{\mathbb{G}}(\mathcal{A},\mathcal{B})\sqrt{n}.$$

Proof Let $\theta_i = \theta_i(\mathcal{A},\mathcal{B})$ be the shorthand for the ith principal angle between the subspaces $\mathcal{A}$ and $\mathcal{B}$. It is well-known (Golub and Van Loan, 2013) that there exist orthonormal bases $A, B \in \mathbb{R}^{n\times r}$ for the subspaces $\mathcal{A}$ and $\mathcal{B}$, respectively, such that

$$A^* B = \mathrm{diag}\left(\begin{bmatrix}\cos\theta_1 & \cos\theta_2 & \cdots & \cos\theta_r\end{bmatrix}\right) =: \Gamma \in \mathbb{R}^{r\times r}, \tag{115}$$

where $\mathrm{diag}(a)$ is the diagonal matrix formed from vector a. There also exists $A' \in \mathbb{R}^{n\times r}$ with orthonormal columns such that

$$\left(A'\right)^* B = \mathrm{diag}\left(\begin{bmatrix}\sin\theta_1 & \sin\theta_2 & \cdots & \sin\theta_r\end{bmatrix}\right) =: \Sigma \in \mathbb{R}^{r\times r}, \qquad \left(A'\right)^* A = 0, \tag{116}$$

and, moreover,

$$\mathrm{span}\left(\begin{bmatrix} A & B\end{bmatrix}\right) = \mathrm{span}\left(\begin{bmatrix} A & A'\end{bmatrix}\right). \tag{117}$$

With $\mathcal{A}' = \mathrm{span}(A')$, it follows that

$$B = P_{\mathcal{A}} B + P_{\mathcal{A}'} B = A A^* B + A'(A')^* B = A\Gamma + A'\Sigma. \qquad \text{(see (115) and (116))} \tag{118}$$

Consequently,

$$\sqrt{\eta(\mathcal{B})} = \sqrt{\frac{n}{r}}\max_i \|B[i,:]\|_2 \qquad \text{(see (14))}$$

$$
\begin{aligned}
&\le \sqrt{\frac{n}{r}} \max_i \|A[i,:]\cdot\Gamma\|_2 + \sqrt{\frac{n}{r}} \max_i \left\|A'[i,:]\cdot\Sigma\right\|_2 \quad \text{((118) and triangle inequality)}\\
&\le \sqrt{\frac{n}{r}} \max_i \|A[i,:]\|_2 \|\Gamma\| + \sqrt{\frac{n}{r}} \max_i \left\|A'[i,:]\right\|_2 \|\Sigma\|\\
&= \sqrt{\eta(\mathcal{A})}\,\|\Gamma\| + \sqrt{\eta(\mathcal{A}')}\,\|\Sigma\| \qquad \text{(see (14))}\\
&\le \sqrt{\eta(\mathcal{A})}\,\|\Gamma\| + \sqrt{\frac{n}{r}}\,\|\Sigma\| \qquad \left(\eta(\mathcal{A}') \le \frac{n}{r}\right)\\
&\le \sqrt{\eta(\mathcal{A})} + \sqrt{\frac{n}{r}}\sin\theta_1 \qquad \text{(see (115) and (116))}\\
&= \sqrt{\eta(\mathcal{A})} + \sqrt{\frac{n}{r}}\,\|P_{\mathcal{A}^\perp} P_{\mathcal{B}}\| \qquad \text{(see (113))}\\
&\le \sqrt{\eta(\mathcal{A})} + \sqrt{\frac{n}{r}}\,\|P_{\mathcal{A}^\perp} P_{\mathcal{B}}\|_F\\
&= \sqrt{\eta(\mathcal{A})} + d_{\mathbb{G}}(\mathcal{A},\mathcal{B})\sqrt{n}, \qquad \text{(see (10))} \qquad (119)
\end{aligned}
$$

which completes the proof of Lemma 20. ■

Appendix B. Supplement to Section 3

In this section, we verify that

$$
R_k = \begin{cases} \arg\min \ \ \|P_{\widehat{\mathcal{S}}_{k-1}^\perp} X_k\|_F^2 + \lambda \|P_{\Omega_k^C}(X_k)\|_F^2 \\ P_{\Omega_k}(X_k) = Y_k, \end{cases} \qquad (120)
$$

when $k \ge 2$. The optimization above is over $X_k \in \mathbb{R}^{n\times b}$. First note that Program (120) is separable and equivalent to the following b programs:

$$
R_k[:,j] = \begin{cases} \arg\min \ \ \|P_{\widehat{\mathcal{S}}_{k-1}^\perp} x\|_2^2 + \lambda \|P_{\omega_t^C} x\|_F^2 \\ P_{\omega_t}\cdot x = y_t, \end{cases} \qquad t = (k-1)b + j, \ \ j \in [1:b]. \qquad (121)
$$

Above, $R_k[:,j] \in \mathbb{R}^n$ is the jth column of R_k in MATLAB's matrix notation and the optimization is over $x \in \mathbb{R}^n$. To solve the jth program in (121), we make the change of variables $x = y_t + W_{\omega_t^C}\cdot z$. Here, $z \in \mathbb{R}^{n-m}$ and $W_{\omega_t^C} \in \{0,1\}^{n\times(n-m)}$ is defined naturally so that $P_{\omega_t^C} = W_{\omega_t^C} W_{\omega_t^C}^*$. We now rewrite (121) as the following b unconstrained programs:

$$
\begin{aligned}
z_j &:= \arg\min \ \ \|P_{\widehat{\mathcal{S}}_{k-1}^\perp} y_t + P_{\widehat{\mathcal{S}}_{k-1}^\perp} W_{\omega_t^C} z\|_2^2 + \lambda \|P_{\omega_t^C} W_{\omega_t^C} z\|_F^2\\
&= \arg\min \ \ \|(\widehat{S}_{k-1}^\perp)^* y_t + (\widehat{S}_{k-1}^\perp)^* W_{\omega_t^C} z\|_2^2 + \lambda\|z\|_F^2, \qquad t = (k-1)b + j, \ \ j \in [1:b].
\end{aligned} \qquad (122)
$$

Above, $\widehat{S}_{k-1}^\perp \in \mathbb{R}^{n\times(n-r)}$ is an orthonormal basis for the subspace $\widehat{\mathcal{S}}_{k-1}^\perp \in \mathbb{G}(n, n-r)$ and in particular $P_{\widehat{\mathcal{S}}_{k-1}^\perp} = \widehat{S}_{k-1}^\perp (\widehat{S}_{k-1}^\perp)^*$. The optimization above is over $z \in \mathbb{R}^{n-m}$. Note that

$$
z_j = -\left(W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}^\perp} W_{\omega_t^C} + \lambda I_{n-m}\right)^{-1} W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}^\perp} y_t, \qquad j \in [1:b], \qquad (123)
$$

are solutions of the least squares programs in (122) when m is large enough. For fixed j, we simplify the expression for z_j as follows:

$$
\begin{aligned}
z_j &= -\left(\lambda I_{n-m} + W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}^\perp} W_{\omega_t^C}\right)^{-1} W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}^\perp} y_t\\
&= -\left((1+\lambda) I_{n-m} - W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}} W_{\omega_t^C}\right)^{-1} W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}^\perp} y_t \qquad \left(P_{\widehat{\mathcal{S}}_{k-1}^\perp} = I_n - P_{\widehat{\mathcal{S}}_{k-1}}\right)\\
&= \frac{-1}{1+\lambda}\left(I_{n-m} + W_{\omega_t^C}^* \widehat{S}_{k-1}\left((1+\lambda) I_r - \widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* W_{\omega_t^C}\right) W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}^\perp} y_t\\
&\qquad \text{(inversion lemma)}\\
&= \frac{-1}{1+\lambda}\left(I_{n-m} + W_{\omega_t^C}^* \widehat{S}_{k-1}\left((1+\lambda) I_r - \widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* W_{\omega_t^C}\right) W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}^\perp} P_{\omega_t} y_t\\
&\qquad (y_t = P_{\omega_t} y_t)\\
&= \frac{1}{1+\lambda}\left(I_{n-m} + W_{\omega_t^C}^* \widehat{S}_{k-1}\left((1+\lambda) I_r - \widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* W_{\omega_t^C}\right) W_{\omega_t^C}^* P_{\widehat{\mathcal{S}}_{k-1}} y_t\\
&\qquad \left(W_{\omega_t^C} P_{\omega_t} = 0\right)\\
&= \frac{W_{\omega_t^C} P_{\widehat{\mathcal{S}}_{k-1}} y_t}{1+\lambda} + \frac{W_{\omega_t^C}^* \widehat{S}_{k-1}}{1+\lambda}\left((1+\lambda) I_r - \widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* P_{\omega_t^C} P_{\widehat{\mathcal{S}}_{k-1}} y_t\\
&\qquad \left(P_{\omega_t^C} = W_{\omega_t^C} W_{\omega_t^C}^*\right)\\
&= \frac{W_{\omega_t^C} P_{\widehat{\mathcal{S}}_{k-1}} y_t}{1+\lambda}\\
&\quad + \frac{W_{\omega_t^C}^* \widehat{S}_{k-1}}{1+\lambda}\left((1+\lambda) I_r - \widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1}\right)^{-1}\left(\widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1} - (1+\lambda) I_r\right) \widehat{S}_{k-1}^* y_t\\
&\quad + W_{\omega_t^C}^* \widehat{S}_{k-1}\left((1+\lambda) I_r - \widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* y_t\\
&= W_{\omega_t^C}^* \widehat{S}_{k-1}\left((1+\lambda) I_r - \widehat{S}_{k-1}^* P_{\omega_t^C} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* y_t\\
&= W_{\omega_t^C}^* \widehat{S}_{k-1}\left(\lambda I_r + \widehat{S}_{k-1}^* P_{\omega_t} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* y_t, \qquad (124)
\end{aligned}
$$

which means that

$$
y_t + W_{\omega_t^C} z_j = y_t + P_{\omega_t^C} \widehat{S}_{k-1}\left(\lambda I_r + \widehat{S}_{k-1}^* P_{\omega_t} \widehat{S}_{k-1}\right)^{-1} \widehat{S}_{k-1}^* y_t, \qquad (125)
$$

is a solution of the jth program in (121) which indeed matches the jth column of R_k defined in (1).

Appendix C. Proof of Proposition 24

Let us form the blocks $Q_1 \in \mathbb{R}^{b_1\times r}$, $S_1 \in \mathbb{R}^{n\times b_1}$, and $\Omega_1 \subseteq [1:n]\times[1:b_1]$ as usual, see Section 3. As in that section, we also write the measurement process as $Y_1 = P_{\Omega_1}(S_1)$, where $P_{\Omega_1}(\cdot)$ projects onto the index set Ω_1. Let us fix Q_1 for now. Also let $Y_{1,r} \in \mathbb{R}^{n\times b_1}$ be a

rank-r truncation of Y_1 obtained via SVD. SNIPE then sets $\widehat{\mathcal{S}}_1 = \mathrm{span}(Y_{1,r})$. Our objective here is to control $\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_1}\|_F$. Since

$$\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_1}\|_F \le \sqrt{r}\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_1}\|, \qquad \left(\widehat{\mathcal{S}}_1 \in \mathbb{G}(n,r)\right) \tag{126}$$

it suffices to bound the spectral norm. Conditioned on Q_1, it is easy to verify that $\mathbb{E}[Y_1] = \mathbb{E}[P_{\Omega_1}(S_1)] = p \cdot S_1$, suggesting that we might consider Y_1 as a perturbed copy of $p \cdot S_1$ and perhaps consider $\widehat{\mathcal{S}}_1 = \mathrm{span}(Y_{1,r})$ as a perturbation of $\mathcal{S} = \mathrm{span}(p \cdot S_1)$. Indeed, the perturbation bound in Lemma 19 dictates that

$$\begin{aligned}
\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_1}\| &\le \frac{\|Y_1 - pS_1\|}{p \cdot \sigma_r(S_1) - \|Y_1 - pS_1\|} \\
&= \frac{\|Y_1 - pS_1\|}{p \cdot \sigma_r(Q_1) - \|Y_1 - pS_1\|} \qquad (S_1 = SQ_1,\ S^*S = I_r) \\
&\le \frac{2}{p} \cdot \frac{\|Y_1 - pS_1\|}{\sigma_r(Q_1)}. \qquad \left(\text{if } \|Y_1 - pS_{Q_1}\| \le \frac{p}{2} \cdot \sigma_r(Q_1)\right)
\end{aligned} \tag{127}$$

It remains to bound the norm in the last line above. To that end, we study the concentration of Y_1 about its expectation by writing that

$$Y_1 - pS_1 = P_{\Omega_1}(S_1) - pS_1 = \sum_{i,j} (\epsilon_{i,j} - p)\, S_1[i,j] \cdot E_{i,j} =: \sum_{i,j} Z_{i,j}, \tag{128}$$

where $\{\epsilon_{i,j}\}_{i,j} \overset{\text{ind.}}{\sim} \text{Bernoulli}(p)$ and $E_{i,j} \in \mathbb{R}^{n \times b_1}$ is the $[i,j]$th canonical matrix. Additionally, $\{Z_{i,j}\}_{i,j}$ are independent zero-mean random matrices. In order to appeal to the matrix Bernstein inequality (Lemma 18), we compute the β and σ parameters below, starting with β:

$$\begin{aligned}
\|Z_{i,j}\| &= \|(\epsilon_{i,j} - p)\, S_1[i,j] \cdot E_{i,j}\| \\
&= |(\epsilon_{i,j} - p)\, S_1[i,j]| \qquad (\|E_{i,j}\| = 1) \\
&\le |S_1[i,j]| \qquad (\epsilon_{i,j} \in \{0,1\}) \\
&\le \|S_1\|_\infty \\
&\le \|S\|_{2\to\infty} \|Q_1\|_{2\to\infty} \qquad (S_1 = SQ_1,\ \|AB^*\|_\infty \le \|A\|_{2\to\infty}\|B\|_{2\to\infty}) \\
&\le \sqrt{\frac{\eta(\mathcal{S})\, r}{n}} \cdot \sqrt{\frac{\eta(\mathcal{Q}_1)\, r}{b_1}} \cdot \|Q_1\| \qquad (\text{see (14)}) \\
&=: \beta.
\end{aligned} \tag{129}$$

Above, $\|A\|_\infty$ and $\|A\|_{2\to\infty}$ return the largest entry of A in magnitude and the largest ℓ_2 norm of the rows of matrix A, respectively. As for σ, we write that

$$\begin{aligned}
\left\|\mathbb{E}\left[\sum_{i,j} Z_{i,j} Z_{i,j}^*\right]\right\| &= \left\|\sum_{i,j} \mathbb{E}\left[(\epsilon_{i,j} - p)^2\right] S_1[i,j]^2 \cdot E_{i,i}\right\| \\
&= \left\|\sum_{i,j} p(1-p) S_1[i,j]^2 \cdot E_{i,i}\right\| \qquad (\epsilon_{i,j} \sim \text{Bernoulli}(p))
\end{aligned}$$

$$\begin{aligned}
&\le p \left\|\sum_{i,j} S_1[i,j]^2 \cdot E_{i,j}\right\| \\
&= p \left\|\sum_{i} \|S_1[i,:]\|_2^2 \cdot E_{i,i}\right\| \\
&= p \max_i \|S_1[i,:]\|_2^2 \\
&= p\, \|S_1\|_{2\to\infty}^2 \\
&\le p\, \|S\|_{2\to\infty}^2 \cdot \|Q_1\|^2 \qquad (S_1 = SQ_1,\ \|AB\|_{2\to\infty} \le \|A\|_{2\to\infty}\|B\|) \\
&= p \cdot \frac{\eta(\mathcal{S})\, r}{n} \cdot \|Q_1\|^2. \qquad (\text{see (14)})
\end{aligned} \tag{130}$$

In a similar fashion, we find that

$$\begin{aligned}
\left\|\mathbb{E}\left[\sum_{i,j} Z_{i,j}^* Z_{i,j}\right]\right\| &\le p \left\|\sum_{j} \|S_1[:,j]\|_2^2\, E_{j,j}\right\| \\
&= p\, \|S_1^*\|_{2\to\infty}^2 \\
&\le p \cdot \|S\|^2 \cdot \|Q_1\|_{2\to\infty}^2 \qquad (S_1 = SQ_1,\ \|AB\|_{2\to\infty} \le \|A\|_{2\to\infty}\|B\|) \\
&\le p \cdot \frac{\eta(\mathcal{Q}_1)\, r}{b_1} \cdot \|Q_1\|^2, \qquad (\|S\| = 1,\ \text{see (14)})
\end{aligned} \tag{131}$$

and eventually

$$\begin{aligned}
\sigma^2 &= \left\|\mathbb{E}\left[\sum_{i,j} Z_{i,j}^* Z_{i,j}\right]\right\| \vee \left\|\mathbb{E}\left[\sum_{i,j} Z_{i,j} Z_{i,j}^*\right]\right\| \\
&\le \frac{pr}{n}\left(1 \vee \frac{n}{b_1}\right)\left(\eta(\mathcal{S}) \vee \eta(\mathcal{Q}_1)\right)\|Q_1\|^2. \qquad (\text{see (130) and (131)})
\end{aligned} \tag{132}$$

Lastly,

$$\begin{aligned}
&\max\left(\log(n \vee b_1) \cdot \beta, \sqrt{\log(n \vee b_1)} \cdot \sigma\right) \\
&\lesssim \max\left(\log(n \vee b_1) \cdot \frac{r}{n}, \sqrt{\log(n \vee b_1)} \cdot \sqrt{\frac{pr}{n}}\right) \sqrt{1 \vee \frac{n}{b_1}} \cdot \sqrt{\eta(\mathcal{S}) \vee \eta(\mathcal{Q}_1)} \cdot \|Q_1\| \\
&\qquad (\text{see (129) and (132)}) \\
&\le \sqrt{\log(n \vee b_1)} \cdot \sqrt{\frac{pr}{n}} \sqrt{1 \vee \frac{n}{b_1}} \cdot \sqrt{\eta(\mathcal{S}) \vee \eta(\mathcal{Q}_1)} \cdot \|Q_1\|. \qquad \left(\text{if } p \ge \frac{\log(n \vee b_1)\, r}{n}\right)
\end{aligned} \tag{133}$$

The Bernstein inequality now dictates that

$$\|Y_1 - pS_1\| = \left\|\sum_{i,j} Z_{i,j}\right\| \qquad (\text{see (128)})$$

$$\lesssim \alpha \max\left(\log(n \vee b_1)\cdot\beta, \sqrt{\log(n\vee b_1)}\cdot\sigma\right) \qquad \text{(see Lemma 18)}$$
$$\lesssim \alpha\sqrt{\log(n\vee b_1)}\cdot\sqrt{\frac{rp}{n}}\sqrt{1\vee\frac{n}{b_1}}\cdot\sqrt{\eta(\mathcal{S})\vee\eta(\mathcal{Q}_1)}\cdot\|Q_1\|, \qquad \text{(see (133))} \tag{134}$$

except with a probability of at most $e^{-\alpha}$. In particular, suppose that

$$p \gtrsim \alpha^2\nu(Q_1)^2\left(1\vee\frac{n}{b_1}\right)\frac{(\eta(\mathcal{S})\vee\eta(\mathcal{Q}_1))\, r\log(n\vee b_1)}{n}, \qquad \left(\nu(Q_1)=\frac{\|Q_1\|}{\sigma_r(Q_1)}\right) \tag{135}$$

so that (127) holds. Then, by substituting (134) back into (127) and then applying (126), we find that

$$\begin{aligned}\frac{\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_1}\|_F}{\sqrt{r}} &\le \|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_1}\| \qquad \text{(see (126))}\\ &\le \frac{2}{p}\cdot\frac{\|Y_1-pS_1\|}{\sigma_r(Q_1)} \qquad \text{(see (127))}\\ &\lesssim \alpha\sqrt{\log(n\vee b_1)\cdot\frac{r}{pn}\left(1\vee\frac{n}{b_1}\right)(\eta(\mathcal{S})\vee\eta(\mathcal{Q}_1))}\cdot\nu(Q_1) \qquad \text{(see (134))}\\ &=: \delta_1(\nu(Q_1),\eta(Q_1)),\end{aligned} \tag{136}$$

except with a probability of at most $e^{-\alpha}$ and for fixed Q_1. In order to remove the conditioning on Q_1, fix $\nu\ge 1$, $1\le\eta_1\le\frac{b_1}{r}$, and recall the following inequality for events $\mathcal{A}$ and $\mathcal{B}$:

$$\Pr[\mathcal{A}] = \Pr[\mathcal{A}|\mathcal{B}]\cdot\Pr[\mathcal{B}] + \Pr\left[\mathcal{A}|\mathcal{B}^C\right]\cdot\Pr\left[\mathcal{B}^C\right] \le \Pr[\mathcal{A}|\mathcal{B}] + \Pr\left[\mathcal{B}^C\right]. \tag{137}$$

Set $\mathcal{Q}_1=\operatorname{span}(Q_1^*)$ and let $\mathcal{E}$ be the event where both $\nu(Q_1)\le\nu$ and $\eta(\mathcal{Q}_1)\le\eta_1$. Thanks to the inequality above, we find that

$$\begin{aligned}&\Pr\left[\frac{\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_1}\|_F}{\sqrt{r}}\gtrsim\delta_1(\nu,\eta_1)\right]\\ &\le \Pr\left[\frac{\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_1}\|_F}{\sqrt{r}}\gtrsim\delta(\nu,\eta_1)\mid\mathcal{E}\right]+\Pr\left[\mathcal{E}^C\right] \qquad \text{(see (137))}\\ &\le e^{-\alpha}+\Pr[\nu(Q_1)>\nu]+\Pr[\eta(Q_1)>\eta_1], \qquad \text{(see (136))}\end{aligned} \tag{138}$$

which completes the proof of Proposition 24.

Appendix D. Proof of Lemma 13

We conveniently define the orthonormal basis

$$B=\begin{bmatrix} U & U^\perp\end{bmatrix}\in\mathbb{R}^{n\times n}.$$

Then the perturbation from $\mathcal{U}$ can be written more compactly as

$$U+U^\perp\Delta' = B\begin{bmatrix} I_r\\ \Delta'\end{bmatrix}\in\mathbb{R}^{n\times r}.$$

In particular, orthogonal projection onto $\operatorname{span}(U+U^\perp\Delta')$ is

$$\begin{aligned}(U+U^\perp\Delta')(U+U^\perp\Delta')^\dagger &= B\begin{bmatrix} I_r\\ \Delta'\end{bmatrix}\cdot\begin{bmatrix} I_r\\ \Delta'\end{bmatrix}^\dagger B^*\\ &= B\begin{bmatrix} I_r\\ \Delta'\end{bmatrix}\left(I_r+\Delta'^*\Delta'\right)^{-1}\begin{bmatrix} I_r & \Delta'^*\end{bmatrix}O^*\\ &= B\begin{bmatrix} I_r & \Delta'^*\\ \Delta' & 0_{n-r}\end{bmatrix}B^* + o(\|\Delta'\|_F),\end{aligned} \tag{139}$$

where $0_{n-r}\in\mathbb{R}^{(n-r)\times(n-r)}$ is the matrix of zeros of size $n-r$. From (30), note also that

$$f_\Omega(X,\mathcal{U}) = \langle P_{\mathcal{U}^\perp}, XX^*\rangle + \lambda\|P_{\Omega^C}(X)\|_F^2 = \left\langle I_n - UU^\dagger, XX^*\right\rangle + \lambda\|P_{\Omega^C}(X)\|_F^2.$$

We can now write that

$$\begin{aligned}&f_\Omega\left(X+\Delta, U+U^\perp\Delta'\right)\\ &= \left\langle I_n - B\begin{bmatrix} I_r & \Delta'^*\\ \Delta' & 0_{n-r}\end{bmatrix}B^*, (X+\Delta)(X+\Delta)^*\right\rangle + 2\lambda P_{\Omega^C}(X) + o(\|\Delta\|_F) + o(\|\Delta'\|_F)\\ &\qquad \text{(see (139))}\\ &= \left\langle B\begin{bmatrix} 0_r & -\Delta'^*\\ -\Delta' & I_{n-r}\end{bmatrix}B^*, (X+\Delta)(X+\Delta)^*\right\rangle + 2\lambda P_{\Omega^C}(X) + o(\|\Delta\|_F) + o(\|\Delta'\|_F)\\ &= \left\langle \begin{bmatrix} 0_r & -\Delta'^*\\ -\Delta' & I_{n-r}\end{bmatrix}, B^*\left(XX^*+\Delta X^*+X\Delta^*\right)B\right\rangle + 2\lambda P_{\Omega^C}(X) + o(\|\Delta\|_F) + o(\|\Delta'\|_F)\\ &= \left\langle \begin{bmatrix} 0_r & 0_{r\times(n-r)}\\ 0_{(n-r)\times r} & I_{n-r}\end{bmatrix}, B^*XX^*B\right\rangle\\ &\quad + \left\langle \begin{bmatrix} 0_r & 0_{r\times(n-r)}\\ 0_{(n-r)\times r} & I_{n-r}\end{bmatrix}, B^*\Delta X^*B + B^*X\Delta^*B\right\rangle\\ &\quad - \left\langle \begin{bmatrix} 0_r & \Delta'^*\\ \Delta' & 0_{n-r}\end{bmatrix}, B^*XX^*B\right\rangle + 2\lambda P_{\Omega^C}(X) + o(\|\Delta\|_F) + o(\|\Delta'\|_F).\end{aligned} \tag{140}$$

We can further simplify the above expansion as

$$\begin{aligned}&f_\Omega\left(X+\Delta, U+U^\perp\Delta'\right)\\ &= f_\Omega(X,\mathcal{U}) + 2\langle\Delta, P_{\mathcal{U}^\perp}X\rangle - 2\left\langle\Delta', (U^\perp)^*XX^*U\right\rangle + 2\lambda P_{\Omega^C}(X) + o(\|\Delta\|_F) + o(\|\Delta'\|_F).\end{aligned} \tag{141}$$

Therefore the partial derivatives of f are

$$\begin{aligned}\partial_X f_\Omega(X,\mathcal{U}) &= 2P_{\mathcal{U}^\perp}X + 2\lambda P_{\Omega^C}(X)\in\mathbb{R}^{n\times T},\\ \partial_{\mathcal{U}} f_\Omega(X,\mathcal{U}) &= -2(U^\perp)^*XX^*U\in\mathbb{R}^{(n-r)\times r},\end{aligned} \tag{142}$$

which completes the proof of Lemma 13.

Appendix E. Proof of Lemma 14

By definition in (39), $\{R_{\epsilon'}\}_{\epsilon' \le \epsilon}$ is a bounded set, see also Program (30) for the definition of $f_{\widehat{\Omega}}$. Therefore there exist a subsequence $\{R_{\epsilon_i}\}_i$ and a matrix $R \in \mathbb{R}^{n \times b}$ such that

$$\lim_{i \to \infty} \epsilon_i = 0, \tag{143}$$

$$\lim_{i \to \infty} \|R_{\epsilon_i} - R\|_F = 0. \tag{144}$$

That is, $\{R_{\epsilon_i}\}_i$ converges to R. On the other hand, for every $\delta \ge 0$, (49) implies that there exists an integer l_δ that depneds on δ and

$$\|R_{k_l,\epsilon} - R_\epsilon\|_F \le 2\epsilon l' + \delta, \qquad l \ge l_\delta. \tag{145}$$

Restricted to the sequence $\{\epsilon_i\}_i$ above, (145) reads as

$$\|R_{k_l,\epsilon_i} - R_{\epsilon_i}\|_F \le 2\epsilon_i l' + \delta, \qquad l \ge l_\delta, \tag{146}$$

which, in the limit of $i \to \infty$, yields that

$$\lim_{i \to \infty} \|R_{k_l,\epsilon_i} - R_{\epsilon_i}\|_F \le \lim_{i \to \infty} 2\epsilon_i + \delta = \delta, \qquad l \ge l_\delta. \tag{147}$$

We used (143) to obtain the identity above. An immediate consequence of (147) is that

$$\lim_{l \to \infty} \lim_{i \to \infty} \|R_{k_l,\epsilon_i} - R_{\epsilon_i}\|_F = 0. \tag{148}$$

Invoking (144), it then follows that

$$\begin{aligned} \lim_{l \to \infty} \lim_{i \to \infty} \|R_{k_l,\epsilon_i} - R\|_F &= \lim_{l \to \infty} \lim_{i \to \infty} \|R_{k_l,\epsilon_i} - R_{\epsilon_i}\|_F \qquad \text{(see (144))} \\ &= 0. \qquad \text{(see (148))} \end{aligned} \tag{149}$$

Exchanging the order of limits above yields that

$$\begin{aligned} &\lim_{i \to \infty} \lim_{l \to \infty} \|R_{k_l,\epsilon_i} - R\|_F \\ &\le \lim_{i \to \infty} \lim_{l \to \infty} \|R_{k_l,\epsilon_i} - R_{\epsilon_i}\|_F + \lim_{i \to \infty} \|R_{\epsilon_i} - R\|_F \qquad \text{(triangle inequality)} \\ &= \lim_{i \to \infty} \lim_{l \to \infty} \|R_{k_l,\epsilon_i} - R_{\epsilon_i}\|_F \qquad \text{(see (144))} \\ &= 0. \qquad \text{(see (50))} \end{aligned} \tag{150}$$

Therefore, (149) and (150) together state that R_{k,ϵ_i} converges to R as $l, i \to \infty$, namely,

$$\lim_{l,i \to \infty} \|R_{k_l,\epsilon_i} - R\|_F = 0, \tag{151}$$

thereby proving the first claim in Lemma 14, see (51). In order to prove the claim about subspaces in Lemma 14, we proceed as follows. Recall the output of SNIPE, namely, $\{(R_k, \widehat{\mathcal{S}}_k)\}_k$ constructed in Algorithm 1. In light of Section 3, R_k is also the unique minimizer of Program

(9). Recall that $\kappa_l = [k_l - l + 1 : k_l]$ from (33). Recall also the construction of sequence $\{(R_{k,\epsilon}, \widehat{\mathcal{S}}_{k,\epsilon})\}_{k \in \kappa_l}$ in the beginning of Section 7.1 and note that both procedures are initialized identically at the beginning of interval κ_l, namely, $\widehat{\mathcal{S}}_{k_l - l,\epsilon} = \widehat{\mathcal{S}}_{k_l - 1}$. Therefore, for fixed l, observe that[4]

$$\lim_{\epsilon \to 0} \|R_{k,\epsilon} - R_k\|_F = 0, \qquad k \in \kappa_l, \tag{152}$$

which, when restricted to $\{\epsilon_i\}_i$, reads as

$$\lim_{i \to \infty} \|R_{k,\epsilon_i} - R_k\|_F = 0, \qquad k \in \kappa_l. \tag{153}$$

By design, every R_k has a spectral gap in the sense that there exists $\tau > 0$ such that

$$\frac{\sigma_r(R_k)}{\sigma_{r+1}(R_k)} \ge 1 + \tau, \tag{154}$$

for every k. Recall that $\widehat{\mathcal{S}}_k$ is the span of top r left singular vectors of R_k. An immediate consequence of (154) is that $\widehat{\mathcal{S}}_k$ is uniquely defined, namely, there are no ties in the spectrum of R_k. By (153), there are no ties in the spectrum of R_{k,ϵ_i} as well for sufficiently large i, namely,

$$\lim_{i \to \infty} \frac{\sigma_r(R_{k,\epsilon_i})}{\sigma_{r+1}(R_{k,\epsilon_i})} \ge 1 + \tau, \qquad k \in \kappa_l. \tag{155}$$

By sending l to infinity above, we find that

$$\begin{aligned} 1 + \tau &\le \lim_{l \to \infty} \lim_{i \to \infty} \frac{\sigma_r(R_{k_l,\epsilon_i})}{\sigma_{r+1}(R_{k_l,\epsilon_i})} \qquad \text{(see (155))} \\ &= \lim_{l,i \to \infty} \frac{\sigma_r(R_{k_l,\epsilon_i})}{\sigma_{r+1}(R_{k_l,\epsilon_i})} \qquad \text{(see (151))} \\ &= \frac{\sigma_r(R)}{\sigma_{r+1}(R)}. \qquad \text{(see (151))} \end{aligned} \tag{156}$$

Recall that $\widehat{\mathcal{S}}_{k,\epsilon_i}$ is by definition the span of leading r left singular vectors of R_{k,ϵ_i}. Likewise, let $\widehat{\mathcal{S}}$ be the span of leading r left singular vectors of R. An immediate consequence of the second line of (156) is that $\widehat{\mathcal{S}}_{k_l,\epsilon_i}$ is uniquely defined, namely, no ties in the spectrum of R_{k_l,ϵ_i} in the limit of $l, i \to \infty$. The third line of (156) similarly implies that $\widehat{\mathcal{S}}$ is uniquely defined. Given the uniqueness of these subspaces, another implication of (151) is that

$$\lim_{l,i \to \infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_{k_l,\epsilon_i}, \widehat{\mathcal{S}}) = 0, \tag{157}$$

where $d_{\mathbb{G}}$ is the metric on Grassmannian defined in (10). Lastly we show that SNIPE in the limit produces copies of $(R, \widehat{\mathcal{S}})$ on the interval $\kappa_{l,l'}$. This is done by simply noting that

$$\lim_{l \to \infty} \|R_{k_l} - R\|_F = \lim_{l \to \infty} \lim_{i \to \infty} \|R_{k_l,\epsilon_i} - R\|_F \qquad \text{(see (153))}$$

4. To verify (152), note that for every feasible X_ϵ in Program (38), $X = Y + P_{\widehat{\Omega}^C}(X_\epsilon)$ is feasible for Program (37). Moreover, as $\epsilon \to 0$, $\|X_\epsilon - X\|_F \to 0$ and consequently, by continuity, $|f_{\widehat{\Omega}}(X_\epsilon, \mathcal{U}) - f_{\widehat{\Omega}}(X, \mathcal{U})| \to 0$. On the other hand, by definition, R_k is the unique minimizer of Program (37), namely, $f_{\widehat{\Omega}}(R_k, \mathcal{U}) < f_{\widehat{\Omega}}(X, \mathcal{U})$ for any $X \neq R_k$ feasible for Program (37). For sufficiently small ϵ, it follows that $f_{\widehat{\Omega}}(R_k, \mathcal{U}) < f_{\widehat{\Omega}}(X_\epsilon, \mathcal{U})$ for any X_ϵ that is feasible for Program (38) and $\liminf_{\epsilon \to 0} \|X_\epsilon - R_k\| > 0$. That is, the unique minimizer of Program (38) approaches R_k in the limit, namely, $\lim_{\epsilon \to 0} \|R_{k,\epsilon} - R_k\|_F = 0$.

$$
\begin{aligned}
&= \lim_{l,i\to\infty} \|R_{k_l,\epsilon_i} - R\|_F \qquad \text{(see (151))} \\
&= 0, \qquad \text{(see (151))}
\end{aligned} \tag{158}
$$

$$
\begin{aligned}
\lim_{l\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_{k_l}, \widehat{\mathcal{S}}) &= \lim_{l\to\infty} \lim_{i\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_{k_l,\epsilon_i}, \widehat{\mathcal{S}}) \qquad \text{(see (153))} \\
&= \lim_{l,i\to\infty} \lim_{i\to\infty} d_{\mathbb{G}}(\widehat{\mathcal{S}}_{k_l,\epsilon_i}, \widehat{\mathcal{S}}) \qquad \text{(see (157))} \\
&= 0, \qquad \text{(see (157))}
\end{aligned} \tag{159}
$$

which completes the proof of Lemma 14.

Appendix F. Proof of Lemma 15

By restricting (41) to $\{\epsilon_i\}_i$, we find that

$$
\begin{aligned}
0 &= \partial_{\mathcal{U}} f_{\widehat{\Omega}}(R_{k_l,\epsilon_i}, \widehat{\mathcal{S}}_{k,\epsilon_i}) \qquad \text{(see (41))} \\
&= \partial_{\mathcal{U}} f_{\Omega_{k_l}}(R_{k_l,\epsilon_i}, \widehat{\mathcal{S}}_{k,\epsilon_i}), \qquad \text{(see (34))}
\end{aligned} \tag{160}
$$

for every l, i. By the joint continuity of $\partial_{\mathcal{U}} f_{\Omega_{k_l}}$ in Lemma 13, it follows that

$$
\begin{aligned}
0 &= \lim_{l,i\to\infty} \left\| \partial_{\mathcal{U}} f_{\Omega_{k_l}}(R_{k_l,\epsilon_i}, \widehat{\mathcal{S}}_{k_l,\epsilon_i}) \right\|_F \\
&= \lim_{l\to\infty} \left\| \partial_{\mathcal{U}} f_{\Omega_{k_l}}(R, \widehat{\mathcal{S}}) \right\|_F, \qquad \text{(see Lemma 14)}
\end{aligned} \tag{161}
$$

which establishes (56). To establish (57), we restrict (44) to $\{\epsilon_i\}_i$ and then send i, l to infinity to find that

$$
\begin{aligned}
0 &= \lim_{i\to\infty} \lim_{l\to\infty} \|P_{\widehat{\Omega}}(R_{k_l,\epsilon_i}) - \widehat{Y}\|_F \qquad \text{(see (44))} \\
&= \lim_{i\to\infty} \lim_{l\to\infty} \|P_{\Omega_k}(R_{k_l,\epsilon_i}) - Y_{k_l}\|_F \qquad \text{(see (34,36))} \\
&= \lim_{l\to\infty} \|P_{\Omega_{k_l}}(R) - Y_{k_l}\|_F. \qquad \text{(see Lemma 14)}
\end{aligned} \tag{162}
$$

To establish (58), we restrict (45) to $\{\epsilon_i\}_i$ and then send i to infinity to find that

$$
\begin{aligned}
0 &= \lim_{i\to\infty} \lim_{l\to\infty} \left\| \partial_X f_{\widehat{\Omega}}(R_{k_l,\epsilon_i}, \widehat{\mathcal{S}}_{k_l,\epsilon_i}) + \lambda_{k_l,\epsilon_i}(P_{\widehat{\Omega}}(R_{k_l,\epsilon_i}) - \widehat{Y}) \right\|_F^2 \\
&= \lim_{i\to\infty} \lim_{l\to\infty} \left\| P_{\widehat{\Omega}^C}\left(\partial_X f_{\widehat{\Omega}}(R_{k_l,\epsilon_i}, \widehat{\mathcal{S}}_{k_l,\epsilon_i}) \right) \right\|_F^2 \\
&\quad + \lim_{i\to\infty} \lim_{l\to\infty} \left\| P_{\widehat{\Omega}}\left(\partial_X f_{\widehat{\Omega}}(R_{k_l,\epsilon}, \widehat{\mathcal{S}}_{k_l,\epsilon_i}) + \lambda_{k,\epsilon_i}(R_{k_l,\epsilon_i} - \widehat{Y}) \right) \right\|_F^2 \\
&\geq \lim_{i\to\infty} \lim_{l\to\infty} \left\| P_{\widehat{\Omega}^C}\left(\partial_X f_{\widehat{\Omega}}(R_{k_l,\epsilon_i}, \widehat{\mathcal{S}}_{k_l,\epsilon_i}) \right) \right\|_F^2 \\
&= \lim_{l\to\infty} \left\| P_{\Omega_{k_l}^C}\left(\partial_X f_{\Omega_{k_l}}(R, \widehat{\mathcal{S}}) \right) \right\|_F^2. \qquad \text{(see (34) and Lemma 14)}
\end{aligned} \tag{163}
$$

This completes the proof of Lemma 15.

Appendix G. Proof of Lemma 16

Recall that by construction in Section 3, the rows of the coefficient matrix $Q_k \in \mathbb{R}^{b\times r}$ are independent copies of the random vector $q \in \mathbb{R}^r$. Setting $S_k = S \cdot Q_k^* \in \mathbb{R}^{n\times b}$, we observe in iteration k each entry of the data block S_k independently with a probability of p, collect the observed entries in $Y_k \in \mathbb{R}^{n\times b}$, supported on the index set $\Omega_k \subseteq [1:n]\times[1:b]$. We write this as $Y_k = P_{\Omega_k}(S_k)$, where the linear operator P_{Ω_k} retains the entries on the index set Ω_k and sets the rest to zero. Recall also that Q_k is obtained by concatenating the coefficient vectors $\{q_t\}_{t=(k-1)b+1}^{kb} \subset \mathbb{R}^r$. To unburden the notation, we enumerate these vectors as $\{q_j\}_{j=1}^b$. Likewise, we use the indexing $\{s_j, y_j, \omega_j\}_{j=1}^b$ for the data vectors, incomplete data vectors, and their supports, respectively.

Given the new incomplete block Y_k at iteration k, we update our estimate of the true subspace $\mathcal{S}$ from the old $\widehat{\mathcal{S}}_{k-1}$ as follows. We calculate the random matrix

$$
\mathbb{R}^{n\times b} \ni R_k := Y_k + P_{\Omega_k^C}\left(O\left(Y_k\right)\right), \tag{164}
$$

where the linear operator $P_{\Omega_k^C}$ projects onto the complement of index set Ω_k, and

$$
O(Y_k) = \left[\cdots \widehat{S}_{k-1}(P_{\omega_j}\widehat{S}_{k-1})^\dagger y_j \cdots \right] \in \mathbb{R}^{n\times b}. \tag{165}
$$

Above, $\widehat{S}_{k-1} \in \mathbb{R}^{n\times r}$ is an orthonormal basis for the r-dimensional subspace $\widehat{\mathcal{S}}_{k-1}$. If $\sigma_r(R_k) < \sigma_{\min}$, reject this iteration, see Algorithm 1. Otherwise, let $R_{k,r}$ denote a rank-r truncation of R_k obtained via SVD. Then our updated estimate is $\widehat{\mathcal{S}}_k = \text{span}(R_{k,r})$.

We condition on the subspace $\widehat{\mathcal{S}}_{k-1}$ and the coefficient matrix Q_k for now. To control the estimation error $d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_k)$, our strategy is to treat R_k as a perturbed copy of $S_k = SQ_k^*$ and in turn treat $\widehat{\mathcal{S}}_k = \text{span}(R_{k,r})$ as a perturbed copy of $\mathcal{S} = \text{span}(S_k)$. Indeed, an application of the perturbation bound in Lemma 19 yields that

$$
\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F \leq \frac{\|P_{\mathcal{S}^\perp} R_k\|_F}{\sigma_r\left(R_k\right)}. \tag{166}
$$

To control the numerator above, we begin with some preparation. First, recalling the definition of $O(Y_k)$ from (165), we observe that

$$
\begin{aligned}
O\left(Y_k\right) &= O\left(P_{\Omega_k}\left(S_k\right)\right) \qquad \left(Y_k = P_{\Omega_k}\left(S_k\right)\right) \\
&= O(P_{\Omega_k}(P_{\widehat{\mathcal{S}}_{k-1}} S_k)) + O(P_{\Omega_k}(P_{\widehat{\mathcal{S}}_{k-1}^\perp} S_k)) \qquad \text{(linearity of } O\text{)} \\
&= P_{\widehat{\mathcal{S}}_{k-1}} S_k + O(P_{\Omega_k}(P_{\widehat{\mathcal{S}}_{k-1}^\perp} S_k)). \qquad \text{(see (165))}
\end{aligned} \tag{167}
$$

The above decomposition allows us to rewrite R in (164) as

$$
\begin{aligned}
R_k &= Y_k + P_{\Omega_k^C}\left(O\left(Y_k\right)\right) \qquad \text{(see (164))} \\
&= P_{\Omega_k}(S_k) + P_{\Omega_k^C}\left(O\left(Y_k\right)\right) \qquad \left(Y_k = P_{\Omega_k}(S_k)\right) \\
&= P_{\Omega_k}\left(S_k\right) + P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}_{k-1}} S_k) + [P_{\Omega_k^C} \circ O \circ P_{\Omega_k}](P_{\widehat{\mathcal{S}}_{k-1}^\perp} S_k) \\
&\qquad \text{(see (167), } f \circ g(x) := f(g(x))\text{)}
\end{aligned}
$$

$$= S_k - P_{\Omega_k^C}(S_k) + P_{\Omega_k^C}(P_{\widehat{S}_{k-1}} S_k) + [P_{\Omega_k^C} \circ O \circ P_{\Omega_k}](P_{\widehat{S}_{k-1}^\perp} S_k)$$
$$= S_k - P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) + [P_{\Omega_k^C} \circ O \circ P_{\Omega_k}](P_{\widehat{S}_{k-1}} S_k)$$
$$= S_k - P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) - [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}} S_k\right) + [O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right). \tag{168}$$

Since $P_{\mathcal{S}^\perp} S_k = P_{\mathcal{S}^\perp} S Q_k^* = 0$, it immediately follows that

$$P_{\mathcal{S}^\perp} R_k = -P_{\mathcal{S}^\perp} \cdot P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) - P_{\mathcal{S}^\perp} \cdot [P_{\Omega_k} \circ O \circ P_{\Omega_k}](P_{\widehat{S}_{k-1}^\perp} S_k) + P_{\mathcal{S}^\perp} \cdot [O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right).$$

In particular, with an application of the triangle inequality above, we find that

$$\|P_{\mathcal{S}^\perp} R_k\|_F$$
$$\leq \left\|P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}](P_{\widehat{S}_{k-1}^\perp} S_k)\right\|_F + \left\|P_{\mathcal{S}^\perp} \cdot [O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right)\right\|_F. \tag{169}$$

We proceed by controlling each norm on the right-hand side above using the next two technical lemmas, proved in Appendices H and I, respectively.

Lemma 21 *It holds that*

$$\mathbb{E}\left[\left\|P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right)\right\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, Q_k\right]$$
$$\leq \sqrt{1-p} \cdot \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \cdot \|Q_k\|. \tag{170}$$

For fixed $\widehat{\mathcal{S}}_{k-1}$ and Q_k, we also have

$$\left\|P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right)\right\|_F \leq \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \cdot \|Q_k\|. \tag{171}$$

and the stronger bound

$$\left\|P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right)\right\|_F \leq \sqrt{1-p/2} \cdot \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \cdot \|Q_k\|, \tag{172}$$

except with a probability of at most

$$\exp\left(-\frac{C_1 p^2 nb}{\widetilde{\eta}_k}\right), \tag{173}$$

where

$$\widetilde{\eta}_k = \widetilde{\eta}(P_{\widehat{S}_{k-1}^\perp} S_k) = nb \cdot \frac{\|P_{\widehat{S}_{k-1}^\perp} S_k\|_\infty^2}{\|P_{\widehat{S}_{k-1}^\perp} S_k\|_F^2}. \tag{174}$$

Lemma 22 *For fixed $\widehat{\mathcal{S}}_{k-1}, Q_k$ and $\alpha \geq 1$, it holds that*

$$\left\|P_{\mathcal{S}^\perp} \cdot [O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right)\right\|_F \lesssim \alpha \log b \sqrt{\frac{\log n}{p}} \cdot \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\| \cdot \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \cdot \|Q_k\|, \tag{175}$$

except with a probability of at most $b^{-C\alpha}$ and provided that $p \gtrsim \alpha^2 \log^2 b \log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r/n$.

We next use Lemmas 21 and 22 to derive two bounds for the numerator of (166), the weaker bound holds with high probability but the stronger bound holds with only some probability. More specifically, substituting (171) and (175) into (169) yields that

$$\|P_{\mathcal{S}^\perp} R_k\|_F$$
$$\leq \left\|P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right)\right\|_F + \left\|P_{\mathcal{S}^\perp} \cdot [O \circ P_{\Omega_k}]\left(P_{\widehat{S}_{k-1}^\perp} S_k\right)\right\|_F$$
(see (169))
$$\leq \left(1 + C\alpha \log b \sqrt{\frac{\log n}{p}} \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|\right) \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \|Q_k\|, \tag{176}$$

except with a probability of at most $b^{-C\alpha}$ and provided that $p \gtrsim \alpha^2 \log^2 b \log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r/n$. For positive c to be set later, let us further assume that

$$\|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\| \leq \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \lesssim \frac{p^{\frac{7}{2}} nb}{c\alpha \log b \sqrt{\log n}}. \tag{177}$$

With an appropriate constant replacing $\lesssim$ above, (176) simplifies to

$$\|P_{\mathcal{S}^\perp} R_k\|_F \lesssim \left(1 + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \|Q_k\|. \tag{178}$$

A stronger bound is obtained by substituting (172, 175) into (169), namely,

$$\|P_{\mathcal{S}^\perp} R_k\|_F$$
$$\leq \left\|P_{\Omega_k^C}(P_{\widehat{S}_{k-1}^\perp} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}](P_{\widehat{S}_{k-1}^\perp} S_k)\right\|_F + \left\|P_{\mathcal{S}^\perp} \cdot [O \circ P_{\Omega_k}](P_{\widehat{S}_{k-1}^\perp} S_k)\right\|_F$$
(see (169))
$$\leq \left(\sqrt{1 - \frac{p}{2}} + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \|Q_k\| \qquad \text{(see (172,175,177))}$$
$$\leq \left(1 - \frac{p}{4} + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{S}_{k-1}}\|_F \|Q_k\|, \tag{179}$$

provided that $p \gtrsim \alpha^2 \log^2 b \log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r/n$ and except with a probability of at most

$$\exp\left(-\frac{C_1 p^2 nb}{\widetilde{\eta}_k}\right) + b^{-C\alpha}.$$

Note that (178) and (179) offer two alternative bounds for the numerator in the last line (166), which we will next use to complete the proof of Lemma 16.

Fix the subspace $\widehat{\mathcal{S}}_{k-1}$ for now. Let $\mathfrak{E}_{k-1}$ be the event where $p \gtrsim \alpha^2 \log^2 b \log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r/n$ and (177) holds. For $\nu \geq 1$ to be set later, let $\mathfrak{E}'_k$ be the event where

$$\|Q_k\| \leq \nu \cdot \sigma_{\min}. \tag{180}$$

Conditioned on the event $\mathfrak{E}_{k-1} \cap \mathfrak{E}'_k$, we write that

$$\|P_{\mathcal{S}^\perp} P_{\widehat{S}_k}\|_F \leq \frac{\|P_{\mathcal{S}^\perp} R_k\|_F}{\sigma_r(R_k)} \qquad \text{(see (166))}$$

$$\leq \frac{\|P_{\mathcal{S}^\perp} R_k\|_F}{\sigma_{\min}}$$
$$\lesssim \nu \left(1 + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F, \qquad \text{(see (178))} \tag{181}$$

except with a probability of at most $b^{-C\alpha}$. A stronger bound is obtained from (179), namely,

$$\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F \leq \frac{\|P_{\mathcal{S}^\perp} R_k\|_F}{\sigma_r(R_k)} \qquad \text{(see (166))}$$
$$\leq \nu \left(1 - \frac{p}{4} + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F, \qquad \text{(see (179))} \tag{182}$$

conditioned on the event $\mathfrak{E}_{k-1} \cap \mathfrak{E}'_k$ and except with a probability of at most

$$\exp\left(-\frac{C_1 p^2 nb}{\widetilde{\eta}_k}\right) + b^{-C\alpha}. \tag{183}$$

This completes the proof of the probabilistic claims in Lemma 16, namely, (74) and (75). To complete the proof of Lemma 16, we next derive a bound for the conditional expectation of $\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F$. Let $\mathfrak{E}''_k$ be the event where $p \gtrsim \alpha^2 \log^2 b \log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r/n$ and

$$\left\| P_{\mathcal{S}^\perp} \cdot [O \circ P_\Omega] \left(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k\right) \right\|_F \lesssim \frac{p^3 nb}{c} \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F \|Q_k\|. \tag{184}$$

In light of Lemma 22, we have that

$$\Pr[\mathfrak{E}''_k | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_k, \mathfrak{E}'_k] \geq 1 - b^{-C\alpha}. \tag{185}$$

Using the law of total expectation, we now write that

$$\begin{aligned}
&\mathbb{E}\left[\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k\right] \\
&= \mathbb{E}\left[\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k\right] \cdot \Pr[\mathfrak{E}''_k | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k] \\
&\quad + \mathbb{E}\left[\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''^C_k\right] \cdot \Pr[\mathfrak{E}''^C_k | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k] \\
&\leq \mathbb{E}\left[\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k\right] + \sqrt{r} \Pr[\mathfrak{E}''^C_k | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k] \qquad \left(\widehat{\mathcal{S}}_k \in \mathbb{G}(n,r)\right) \\
&\leq \mathbb{E}\left[\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k\right] + \sqrt{r} b^{-C\alpha} \qquad \text{(see (185))} \\
&\leq \mathbb{E}\left[\frac{\|P_{\mathcal{S}^\perp} R_k\|_F}{\sigma_r(R_k)} \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k\right] + b^{-C\alpha} \qquad \text{((166) and } b \geq r) \\
&\leq \sigma_{\min}^{-1} \mathbb{E}\left[\|P_{\mathcal{S}^\perp} R_k\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k\right] + b^{-C\alpha}.
\end{aligned} \tag{186}$$

We next bound the remaining expectation above by writing that

$$\begin{aligned}
&\mathbb{E}\left[\|P_{\mathcal{S}^\perp} R_k\|_F | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k\right] \\
&\leq \mathbb{E}\left[\left\| P_{\Omega_k^C} (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}] (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F \right. \\
&\quad \left. + \left\| P_{\mathcal{S}^\perp} \cdot [O \circ P_\Omega] (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k \right] \qquad \text{(see (169))} \\
&\leq \mathbb{E}\left[\left\| P_{\Omega_k^C} (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}] (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F \right. \\
&\quad \left. + \frac{p^3 nb}{c} \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F \|Q_k\| \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k \right] \qquad \text{(see (184))} \\
&= \mathbb{E}\left[\mathbb{E}\left[\left\| P_{\Omega_k^C} (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}] (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F | \widehat{\mathcal{S}}_{k-1}, Q_k \right] \right. \\
&\quad \left. + \frac{p^3 nb}{c} \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F \|Q_k\| | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k \right] \\
&\leq \mathbb{E}\left[\sqrt{1-p} \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F \|Q_k\| + \frac{p^3 nb}{c} \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F \|Q_k\| | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k \right] \\
&\qquad \text{(see (170))} \\
&= \mathbb{E}\left[\nu \cdot \sigma_{\min} \left(\sqrt{1-p} + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k \right] \qquad \text{(see (180))} \\
&= \nu \cdot \sigma_{\min} \left(\sqrt{1-p} + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F \\
&\leq \nu \cdot \sigma_{\min} \left(1 - \frac{p}{2} + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F.
\end{aligned} \tag{187}$$

Plugging the bound above back into (186) yields that

$$\begin{aligned}
&\mathbb{E}\left[\|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_k}\|_F | \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k\right] \\
&\leq \sigma_{\min}^{-1} \mathbb{E}\left[\|P_{\mathcal{S}^\perp} R_k\|_F \,|\, \widehat{\mathcal{S}}_{k-1}, \mathfrak{E}_{k-1}, \mathfrak{E}'_k, \mathfrak{E}''_k\right] + b^{-C\alpha} \qquad \text{(see (186))} \\
&= \nu \left(1 - \frac{p}{2} + \frac{p^3 nb}{c}\right) \|P_{\mathcal{S}^\perp} P_{\widehat{\mathcal{S}}_{k-1}}\|_F + b^{-C\alpha},
\end{aligned} \tag{188}$$

which proves (73) and completes the proof of Lemma 16.

Appendix H. Proof of Lemma 21

Throughout, $\widehat{\mathcal{S}}_{k-1}, Q_k$ is fixed. Recalling the definition of operator $O(\cdot)$ from (165), we write that

$$\begin{aligned}
&[P_{\Omega_k} \circ O \circ P_{\Omega_k}] (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \\
&= \left[\begin{array}{cccc} \cdots & \left(P_{\omega_j} \widehat{S}_{k-1}\right) \left(P_{\omega_j} \widehat{S}_{k-1}\right) \cdot P_{\omega_j} P_{\widehat{\mathcal{S}}^\perp_{k-1}} S q_j & \cdots \end{array}\right] \qquad \text{(see (165))} \\
&= \left[\begin{array}{cccc} \cdots & \left(P_{\omega_j} \widehat{S}_{k-1}\right) \left(P_{\omega_j} \widehat{S}_{k-1}\right) \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} S q_j & \cdots \end{array}\right] \\
&= \left[\begin{array}{cccc} \cdots & P_{\widehat{\mathcal{S}}_{k-1,j}} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} S q_j & \cdots \end{array}\right]. \qquad \left(\widehat{\mathcal{S}}_{k-1,j} := \text{span}(P_{\omega_j} \widehat{S}_{k-1})\right)
\end{aligned} \tag{189}$$

Let also $\widehat{\mathcal{S}}^C_{k-1,j} := \text{span}(P_{\omega_j^C} \widehat{S}_{k-1})$. Note that $\widehat{S}_{k-1} = P_{\omega_j} \widehat{S}_{k-1} + P_{\omega_j^C} \widehat{S}_{k-1}$ and that $(P_{\omega_j} \widehat{S}_{k-1})^* (P_{\omega_j^C} \widehat{S}_{k-1}) = 0$. Consequently, $\widehat{\mathcal{S}}_{k-1,j} \perp \widehat{\mathcal{S}}^C_{k-1,j}$ and then $P_{\widehat{\mathcal{S}}_{k-1}} = P_{\widehat{\mathcal{S}}_{k-1,j}} +$

$P_{\widehat{\mathcal{S}}^C_{k-1,j}}$. Put differently, $\widehat{\mathcal{S}}_{k-1} = \widehat{\mathcal{S}}_{k-1,j} \oplus \widehat{\mathcal{S}}^C_{k-1,j}$. Using this decomposition, we simplify (189) as

$$\begin{aligned}
&[P_{\Omega_k} \circ O \circ P_{\Omega_k}]\,(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \\
&= \begin{bmatrix} \cdots & P_{\widehat{\mathcal{S}}_{k-1,j}} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j & \cdots \end{bmatrix} \qquad \text{(see (189))} \\
&= \begin{bmatrix} \cdots & (P_{\widehat{\mathcal{S}}_{k-1}} - P_{\widehat{\mathcal{S}}^C_{k-1,j}}) \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j & \cdots \end{bmatrix} \qquad \left(\widehat{\mathcal{S}}_{k-1} = \widehat{\mathcal{S}}_{k-1,j} \oplus \widehat{\mathcal{S}}^C_{k-1,j}\right) \\
&= -\begin{bmatrix} \cdots & P_{\widehat{\mathcal{S}}^C_{k-1,j}} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j & \cdots \end{bmatrix}. \qquad (190)
\end{aligned}$$

It immediately follows that

$$\begin{aligned}
&P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\,(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \\
&= \begin{bmatrix} \cdots & P_{\omega_j^C} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j - P_{\widehat{\mathcal{S}}^C_{k-1,j}} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j & \cdots \end{bmatrix} \\
&= \begin{bmatrix} \cdots & P_{\omega_j^C}(I_n - P_{\widehat{\mathcal{S}}^C_{k-1,j}}) P_{\omega_j^C} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j & \cdots \end{bmatrix}, \qquad \left(\widehat{\mathcal{S}}^C_{k-1,j} = \operatorname{span}(P_{\omega_j^C} \widehat{S}_{k-1})\right) \qquad (191)
\end{aligned}$$

and consequently

$$\begin{aligned}
&\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\,(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F^2 \\
&= \sum_{j=1}^{b} \left\| P_{\omega_j^C}(I_n - P_{\widehat{\mathcal{S}}^C_{k-1,j}}) P_{\omega_j^C} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j \right\|_2^2 \qquad \text{(see (191))} \\
&\le \sum_{j=1}^{b} \left\| P_{\omega_j^C} \cdot P_{\widehat{\mathcal{S}}^\perp_{k-1}} Sq_j \right\|_2^2 \\
&= \left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} SQ_k) \right\|_F^2 \\
&= \left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F^2. \qquad (S_k = SQ_k) \qquad (192)
\end{aligned}$$

Note that

$$\begin{aligned}
&\mathbb{E}\left[\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\,(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F \mid \widehat{\mathcal{S}}_{k-1}, Q_k \right] \\
&\le \sqrt{\mathbb{E}\left[\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\,(P_{\mathcal{S}^\perp_{k-1}} S_k) \right\|_F^2 \mid \widehat{\mathcal{S}}_{k-1}, Q_k \right]} \qquad \text{(Jensen's inequality)} \\
&\le \sqrt{\mathbb{E}\left[\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F^2 \mid \widehat{\mathcal{S}}_{k-1}, Q_k \right]} \qquad \text{(see (192))} \\
&= \sqrt{\mathbb{E}\left[\sum_{i,j} (1 - \epsilon_{i,j}) \left| (P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k)[i,j] \right|^2 \mid \widehat{\mathcal{S}}_{k-1}, Q_k \right]} \\
&= \sqrt{1-p}\, \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F
\end{aligned}$$

$$\le \sqrt{1-p}\, \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S \|_F \| Q_k \| \qquad (S_k = SQ_k^*, \qquad \|AB\|_F \le \|A\|_F \cdot \|B\|) \qquad (193)$$

where $\{\epsilon_{i,j}\}_{i,j} \overset{\text{ind.}}{\sim} \text{Bernoulli}(p)$. We thus proved the first claim in Lemma 21, namely, (170). Then note that

$$\begin{aligned}
&\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\,(P_{\mathcal{S}^\perp_{k-1}} S_k) \right\|_F^2 \\
&\le \left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F^2 \qquad \text{(see (192))} \\
&\le \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F^2 \\
&\le \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S \|_F^2 \| Q_k \|^2, \qquad (S_k = SQ_k) \qquad (194)
\end{aligned}$$

which proves the second claim, namely, (171). In fact, with some probability, a stronger bound can be derived by controlling the deviation from the expectation in (193) using the Hoeffding inequality (Lemma 17). With $\alpha = \frac{p}{2} \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F^2$ in Lemma 17 and recalling that $\widehat{\mathcal{S}}_{k-1}, Q_k$ are fixed for now, we find that

$$\begin{aligned}
\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F^2 &\le \mathbb{E}\left[\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F^2 \mid \widehat{\mathcal{S}}_{k-1}, Q_k \right] + \alpha \\
&= (1 - p/2) \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F^2 \qquad \text{(see (193))} \\
&= (1 - p/2) \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} SQ_k \|_F^2 \qquad (S_k = SQ_k) \\
&\le (1 - p/2) \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S \|_F^2 \, \| Q_k \|^2, \qquad (195)
\end{aligned}$$

except with a probability of at most

$$\begin{aligned}
\exp\left(-\frac{C_1 p^2 \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F^4}{\sum_{i,j} |(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k)[i,j]|^4} \right) &\le \exp\left(-\frac{C_1 p^2 \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F^4}{\| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_\infty^2 \cdot \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F^2} \right) \\
&= \exp\left(-\frac{C_1 p^2 \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_F^2}{\| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k \|_\infty^2} \right) \\
&=: \exp\left(\frac{-C_1 p^2 nb}{\widetilde{\eta}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k)} \right), \qquad (196)
\end{aligned}$$

where $\|A\|_\infty$ returns the largest entry of A in magnitude. Substituting (195) back into (194) yields that

$$\begin{aligned}
&\left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) + [P_{\Omega_k} \circ O \circ P_{\Omega_k}]\,(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F \\
&\le \left\| P_{\Omega_k^C}(P_{\widehat{\mathcal{S}}^\perp_{k-1}} S_k) \right\|_F \qquad \text{(see (194))} \\
&\le \sqrt{1 - p/2} \cdot \| P_{\widehat{\mathcal{S}}^\perp_{k-1}} S \|_F \| Q_k \|, \qquad (197)
\end{aligned}$$

which proves the last claim in Lemma 21, namely, (172).

Appendix I. Proof of Lemma 22

We fix $\widehat{\mathcal{S}}_{k-1}, Q_k$ throughout. We begin by bounding the target quantity as

$$\begin{aligned}
&\left\|P_{\mathcal{S}^\perp}\cdot[O\circ P_{\Omega_k}]\left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k\right)\right\|_F\\
&=\left\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_{k-1}}\cdot[O\circ P_{\Omega_k}]\left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k\right)\right\|_F \qquad \text{(see (165))}\\
&\le\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_{k-1}}\|\cdot\left\|[O\circ P_{\Omega_k}]\left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k\right)\right\|_F \qquad (\|AB\|_F\le\|A\|\cdot\|B\|_F). \qquad (198)
\end{aligned}$$

We bound the random norm in the last line above in Appendix J.

Lemma 23 *For $\alpha\ge 1$ and except with a probability of at most $b^{-C\alpha}$, it holds that*

$$\left\|[O\circ P_{\Omega_k}]\left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k\right)\right\|_F\lesssim\alpha\log b\sqrt{\frac{\log n}{p}}\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_{k-1}}\|_F\cdot\|Q_k\|, \qquad (199)$$

provided that $p\gtrsim\alpha^2\log^2 b\log n\cdot\eta(\widehat{\mathcal{S}}_{k-1})r/n$.

In light of the above lemma, we conclude that

$$\begin{aligned}
&\left\|P_{\mathcal{S}^\perp}\cdot[O\circ P_{\Omega_k}]\left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k\right)\right\|_F\\
&\le\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_{k-1}}\|\cdot\left\|[O\circ P_{\Omega_k}]\left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k\right)\right\|_F \qquad \text{(see (198))}\\
&\lesssim\alpha\log b\sqrt{\frac{\log n}{p}}\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_{k-1}}\|\cdot\|P_{\mathcal{S}^\perp}P_{\widehat{\mathcal{S}}_{k-1}}\|_F\cdot\|Q_k\|, \qquad \text{(see (199))} \qquad (200)
\end{aligned}$$

except with a probability of at most $b^{-C\alpha}$ and provided that $p\gtrsim\alpha^2\log^2 b\log n\cdot\eta(\widehat{\mathcal{S}}_{k-1})r/n$. This completes the proof of Lemma 22.

Appendix J. Proof of Lemma 23

Using the definition of operator O in (165), we write that

$$\begin{aligned}
&\left\|[O\circ P_{\Omega_k}]\left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k\right)\right\|_F^2\\
&=\sum_{j=1}^b\left\|\widehat{S}_{k-1}(P_{\omega_j}\widehat{S}_{k-1})^\dagger P_{\omega_j}\cdot P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j\right\|_2^2 \qquad (\text{(165) and } S_k=SQ_k)\\
&=\sum_{j=1}^b\left\|\widehat{S}_{k-1}(P_{\omega_j}\widehat{S}_{k-1})^\dagger P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j\right\|_2^2\\
&=\sum_{j=1}^b\left\|(P_{\omega_j}\widehat{S}_{k-1})^\dagger P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j\right\|_2^2. \qquad \left(\widehat{S}_{k-1}^*\widehat{S}_{k-1}=I_r\right) \qquad (201)
\end{aligned}$$

For fixed $j\in[1:b]$, consider the summand in the last line above:

$$\begin{aligned}
\left\|(P_{\omega_j}\widehat{S}_{k-1})^\dagger P_{\widehat{\mathcal{S}}_{k-1}^\perp}S\cdot q_j\right\|_2&\le\left\|(P_{\omega_j}\widehat{S}_{k-1})^\dagger P_{\widehat{\mathcal{S}}_{k-1}^\perp}\right\|\cdot\|P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j\|_2\\
&=\left\|(P_{\omega_j}\widehat{S}_{k-1})^\dagger\widehat{S}_{k-1}^\perp\right\|\cdot\|P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j\|_2 \qquad \left(P_{\widehat{\mathcal{S}}_{k-1}^\perp}=\widehat{S}_{k-1}^\perp(\widehat{S}_{k-1}^\perp)^*\right)\\
&=:\|\widehat{Z}_j\|\cdot\|P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j\|_2. \qquad (202)
\end{aligned}$$

Above, $\widehat{S}_{k-1}^\perp$ is as usual an orthonormal basis for the subspace $\widehat{\mathcal{S}}_{k-1}^\perp$. We can now revisit (201) and write that

$$\begin{aligned}
\left\|O(P_{\widehat{\mathcal{S}}_{k-1}^\perp}S_k)\right\|_F^2&=\sum_{j=1}^b\left\|(P_{\omega_j}\widehat{S}_{k-1})^\dagger P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j)\right\|_2^2 \qquad \text{(see (201))}\\
&\le\max_j\|\widehat{Z}_j\|^2\cdot\sum_{j=1}^b\|P_{\widehat{\mathcal{S}}_{k-1}^\perp}Sq_j\|_2^2 \qquad \text{(see (202))}\\
&=\max_j\|\widehat{Z}_j\|^2\cdot\|P_{\widehat{\mathcal{S}}_{k-1}^\perp}SQ_k\|_F^2\\
&\le\max_j\|\widehat{Z}_j\|^2\cdot\|P_{\widehat{\mathcal{S}}_{k-1}^\perp}S\|_F^2\|Q_k\|^2. \qquad (\|AB\|_F\le\|A\|_F\cdot\|B\|) \qquad (203)
\end{aligned}$$

It remains to control the maximum in the last line above. We first focus on controlling $\|\widehat{Z}_j\|$ for fixed $j\in[1:b]$. Observe that $\widehat{Z}_j$ is a solution of the least-squares problem

$$\min_{Z\in\mathbb{R}^{n\times(n-r)}}\left\|\widehat{S}_{k-1}^\perp-(P_{\omega_j}\widehat{S}_{k-1})Z\right\|_F^2,$$

and therefore satisfies the *normal equation*

$$(P_{\omega_j}\widehat{S}_{k-1})^*\left((P_{\omega_j}\widehat{S}_{k-1})\widehat{Z}_j-\widehat{S}_{k-1}^\perp\right)=0,$$

which is itself equivalent to

$$(\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1})\widehat{Z}_j=\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}^\perp. \qquad \left(P_{\omega_j}^2=P_{\omega_j}\right) \qquad (204)$$

In fact, since

$$\begin{aligned}
\mathbb{E}\left[\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}^\perp\right]&=p\cdot\widehat{S}_{k-1}^*\widehat{S}_{k-1}^\perp=0,\\
\mathbb{E}\left[\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}\right]&=p\cdot I_r, \qquad \left(\widehat{S}_{k-1}^*\widehat{S}_{k-1}=I_r\right)
\end{aligned}$$

we can rewrite (204) as

$$\left(\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}-\mathbb{E}\left[\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}\right]\right)\widehat{Z}_j+p\cdot\widehat{Z}_j=\widehat{S}_{k-1}^TP_{\omega_j}\widehat{S}_{k-1}^\perp-\mathbb{E}\left[\widehat{S}_{k-1}^TP_{\omega_j}\widehat{S}_{k-1}^\perp\right].$$

An application of the triangle inequality above immediately implies that

$$p\|\widehat{Z}_j\|\le\left\|\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}-\mathbb{E}\left[\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}\right]\right\|\cdot\|\widehat{Z}_j\|+\left\|\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}^\perp-\mathbb{E}\left[\widehat{S}_{k-1}^*P_{\omega_j}\widehat{S}_{k-1}^\perp\right]\right\|. \qquad (205)$$

To control $\|\widehat{Z}_j\|$, we therefore need to derive large devation bounds for the two remaining norms on the right-hand side above. For the first spectral norm, we write that

$$\left\|\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1} - \mathbb{E}\left[\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}\right]\right\| = \left\|\sum_i (\epsilon_i - p) \cdot \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\right\| =: \left\|\sum_i A_i\right\|, \quad (206)$$

where $\{\epsilon_i\}_i \overset{\text{ind.}}{\sim} \text{Bernoulli}(p)$ and $E_{i,i} \in \mathbb{R}^{n\times n}$ is the $[i,i]$th canonical matrix. Furthermore, $\{A_i\}_i \subset \mathbb{R}^{r\times r}$ above are independent and zero-mean random matrices. To apply the Bernstein inequality (Lemma 18), we first compute the parameter β as

$$\begin{aligned}
\|A_i\| &= \left\|(\epsilon_i - p) \cdot S_{k-1}^* E_{i,i} S_{k-1}\right\| \qquad \text{(see (206))} \\
&\le \|\widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\| \qquad (\epsilon_i \in \{0,1\}) \\
&= \|\widehat{S}_{k-1}[i,:]\|_2^2 \\
&\le \frac{\eta(\widehat{\mathcal{S}}_{k-1})r}{n} =: \beta. \qquad \text{(see (14))}
\end{aligned} \quad (207)$$

To compute the weak variance σ, we write that

$$\begin{aligned}
\left\|\mathbb{E}\left[\sum_i A_i^2\right]\right\| &= \left\|\sum_i \mathbb{E}\left[(\epsilon_i - p)^2\right] (\widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1})^2\right\| \qquad \text{(see (206))} \\
&= \left\|\sum_i p(1-p)(\widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1})^2\right\| \qquad (\epsilon_i \sim \text{Bernoulli}(p)) \\
&\le p \left\|\sum_i (\widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1})^2\right\| \\
&= p \left\|\sum_i \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1} \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\right\| \\
&= p \left\|\sum_i \|\widehat{S}_{k-1}[i,:]\|_2^2 \cdot \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\right\| \\
&\le p \cdot \max_i \|\widehat{S}_{k-1}[i,:]\|_2^2 \cdot \left\|\sum_i \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\right\| \\
&= p \left\|\sum_i \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\right\| \\
&= p \cdot \frac{\eta(\widehat{\mathcal{S}}_{k-1})r}{n} \cdot \left\|\sum_i \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\right\| \qquad \text{(see (14))} \\
&= p \cdot \frac{\eta(\widehat{\mathcal{S}}_{k-1})r}{n} \qquad \left(\sum_i E_{i,i} = I_n,\ \widehat{S}_{k-1}^* \widehat{S}_{k-1} = I_r\right) \\
&=: \sigma^2.
\end{aligned} \quad (208)$$

It also follows that

$$\begin{aligned}
&\max\left(\log r \cdot \beta, \sqrt{\log r} \cdot \sigma\right) \\
&= \max\left(\frac{\log r \cdot \eta(\widehat{\mathcal{S}}_{k-1})r}{n}, \sqrt{\frac{\log r \cdot p \cdot \eta(\widehat{\mathcal{S}}_{k-1})r}{n}}\right) \qquad \text{(see (207) and (208))} \\
&\le \sqrt{\frac{\log r \cdot p \cdot \eta(\widehat{\mathcal{S}}_{k-1})r}{n}}. \qquad \left(\text{if } p \ge \frac{\log r \cdot \eta(\widehat{\mathcal{S}}_{k-1})r}{n}\right)
\end{aligned} \quad (209)$$

As a result, for $\alpha \ge 1$ and except with a probability of at most $e^{-C\alpha}$, it holds that

$$\begin{aligned}
\left\|\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1} - \mathbb{E}\left[\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}\right]\right\| &\lesssim \alpha \max\left(\log r \cdot \beta, \sqrt{\log r} \cdot \sigma\right) \qquad \text{(see Lemma 18)} \\
&\le \alpha \sqrt{\frac{\log r \cdot p \cdot \eta(\widehat{\mathcal{S}}_{k-1})r}{n}}.
\end{aligned} \quad (210)$$

On the other hand, in order to apply the Bernstein inequality to the second spectral norm in (205), we write that

$$\left\|\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}^\perp - \mathbb{E}\left[\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}^\perp\right]\right\| = \left\|\sum_i (\epsilon_i - p)\, \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}^\perp\right\| =: \left\|\sum_i A_i\right\|, \quad (211)$$

where $\{\epsilon_i\}_i \overset{\text{ind.}}{\sim} \text{Bernoulli}(p)$, $E_{i,i} \in \mathbb{R}^{n\times n}$ is the ith canonical matrix, and $\{A_i\}_i \subset \mathbb{R}^{r\times(n-r)}$ are zero-mean and independent random matrices. To compute the parameter β here, we write that

$$\begin{aligned}
\|A_i\| &= \left\|(\epsilon_i - p)\, \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}^\perp\right\| \qquad \text{(see (211))} \\
&\le \|\widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}^\perp\| \qquad (\epsilon_i \in \{0,1\}) \\
&\le \|\widehat{S}_{k-1}^* E_{i,i}\| \qquad \left((\widehat{S}_{k-1}^\perp)^* \widehat{S}_{k-1}^\perp = I_{n-r}\right) \\
&= \|\widehat{S}_{k-1}[i,:]\|_2 \\
&\le \sqrt{\frac{\eta(\widehat{\mathcal{S}}_{k-1})r}{n}} =: \beta. \qquad \text{(see (14))}
\end{aligned} \quad (212)$$

To compute the weak variance σ, we notice that

$$\begin{aligned}
\left\|\mathbb{E}\left[\sum_i A_i A_i^*\right]\right\| &= \left\|\sum_i \mathbb{E}\left[(\epsilon_i - p)^2\right] \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}^\perp (\widehat{S}_{k-1}^\perp)^* E_{i,i} \widehat{S}_{k-1}\right\| \qquad \text{(see (211))} \\
&= \left\|\sum_i p(1-p) \cdot \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}^\perp (\widehat{S}_{k-1}^\perp)^* E_{i,i} \widehat{S}_{k-1}\right\| \qquad (\epsilon_i \sim \text{Benoulli}(p)) \\
&\le p \left\|\sum_i \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}^\perp (\widehat{S}_{k-1}^\perp)^* E_{i,i} \widehat{S}_{k-1}\right\|
\end{aligned}$$

$$\begin{aligned}
&\le p\left\|\sum_i \widehat{S}_{k-1}^* E_{i,i} E_{i,i} \widehat{S}_{k-1}\right\| \qquad \left(\widehat{S}_{k-1}^{\perp}(\widehat{S}_{k-1}^{\perp})^* \preceq I_n\right)\\
&= p\left\|\sum_i \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}\right\|\\
&= p. \qquad \left(\sum_i E_{i,i} = I_n,\ \widehat{S}_{k-1}^* \widehat{S}_{k-1} = I_r\right)
\end{aligned} \tag{213}$$

In a similar fashion, we find that

$$\begin{aligned}
\left\|\mathbb{E}\left[\sum_i A_i^* A_i\right]\right\| &\le p\left\|\sum_i (\widehat{S}_{k-1}^{\perp})^* E_{i,i} \widehat{S}_{k-1} \widehat{S}_{k-1}^* E_{i,i} \widehat{S}_{k-1}^{\perp}\right\|\\
&= p\left\|\sum_i \|\widehat{S}_{k-1}[i,:]\|_2^2 \cdot (\widehat{S}_{k-1}^{\perp})^* E_{i,i} \widehat{S}_{k-1}^{\perp}\right\|\\
&\le p \cdot \max_i \|\widehat{S}_{k-1}[i,:]\|_2^2 \cdot \left\|\sum_i (\widehat{S}_{k-1}^{\perp})^* E_{i,i} \widehat{S}_{k-1}^{\perp}\right\|\\
&= p \cdot \max_i \|\widehat{S}_{k-1}[i,:]\|_2^2 \qquad \left(\sum_i E_{i,i} = I_n,\ (\widehat{S}_{k-1}^{\perp})^* \widehat{S}_{k-1}^{\perp} = I_{n-r}\right)\\
&= p \cdot \frac{\eta(\widehat{\mathcal{S}}_{k-1}) r}{n}, \qquad \text{(see (14))}
\end{aligned} \tag{214}$$

and finally

$$\begin{aligned}
\sigma &= \max\left(\left\|\mathbb{E}\sum_i A_i A_i^*\right\|, \left\|\mathbb{E}\sum_i A_i^* A_i\right\|\right)\\
&= \max\left(\sqrt{p}, \sqrt{p} \cdot \sqrt{\frac{\eta(\widehat{\mathcal{S}}_{k-1}) r}{n}}\right) \qquad \text{(see (213) and (214))}\\
&= \sqrt{p}. \qquad \left(\eta(\widehat{\mathcal{S}}_{k-1}) \le \frac{n}{r}\right)
\end{aligned} \tag{215}$$

We now compute

$$\begin{aligned}
\max\left(\log n \cdot \beta, \sqrt{\log n} \cdot \sigma\right) &= \max\left(\log n \sqrt{\frac{\eta(\widehat{\mathcal{S}}_{k-1}}{n}}, \sqrt{\log n \cdot p}\right) \qquad \text{(see (212) and (215))}\\
&= \sqrt{\log n \cdot p}. \qquad \left(\text{if } p \ge \frac{\log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r}{n}\right)
\end{aligned} \tag{216}$$

Therefore, for $\alpha \ge 1$ and except with a probability of at most $e^{-C\alpha}$, it holds that

$$\left\|\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}^{\perp} - \mathbb{E}\left[\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}^{\perp}\right]\right\| \lesssim \alpha \max\left(\log n \cdot \beta, \sqrt{\log n} \cdot \sigma\right) \qquad \text{(see Lemma 18)}$$

$$= \alpha\sqrt{\log n \cdot p}. \tag{217}$$

Overall, by substituting the large deviation bounds (210) and (217) into (205), we find that

$$\begin{aligned}
p\|\widehat{Z}_j\| &\le \left\|\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1} - \mathbb{E}\left[\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}\right]\right\| \cdot \|\widehat{Z}_j\|\\
&\quad + \left\|\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}^{\perp} - \mathbb{E}\left[\widehat{S}_{k-1}^* P_{\omega_j} \widehat{S}_{k-1}^{\perp}\right]\right\| \qquad \text{(see (205))}\\
&\lesssim \alpha\sqrt{\frac{\log r \cdot p \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r}{n}} \cdot \|\widehat{Z}_j\| + \alpha\sqrt{\log n \cdot p}, \qquad \text{(see (210) and (217))}
\end{aligned}$$

except with a probability of at most $e^{-C\alpha}$ and under (209) and (216). It immediately follows that

$$\begin{aligned}
\|\widehat{Z}_j\| &\lesssim \frac{\alpha\sqrt{\frac{\log n}{p}}}{1 - \sqrt{\frac{\alpha^2 \log r \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r}{pn}}} \qquad \text{(see the next line)}\\
&\lesssim \alpha\sqrt{\frac{\log n}{p}}, \qquad \left(\text{if } \frac{\alpha^2 \log r \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r}{pn} \lesssim 1\right)
\end{aligned} \tag{218}$$

except with a probability of at most $e^{-C\alpha}$. In light of (209) and (216), we assume that $p \gtrsim \alpha^2 \log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r/n$. Then using the union bound and with the choice of $\alpha = \alpha' \log b$, it follows that

$$\max_{j \in [1:b]} \|\widehat{Z}_j\| \lesssim \alpha' \log b \sqrt{\frac{\log n}{p}},$$

provided that $p \gtrsim \alpha'^2 \log^2 b \cdot \log n \cdot \eta(\widehat{\mathcal{S}}_{k-1}) r/n$ and except with a probability of at most $be^{-C\alpha' \log b} = b^{-C\alpha'}$. Invoking (203), we finally conclude that

$$\begin{aligned}
\left\|O(P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} S_k)\right\|_F &\le \max_j \|\widehat{Z}_j\| \cdot \|P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} P_{\mathcal{S}}\|_F \|Q_k\| \qquad \text{(see (203))}\\
&\lesssim \alpha' \log b \sqrt{\frac{\log n}{p}} \cdot \|P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} P_{\mathcal{S}}\|_F \|Q_k\|.
\end{aligned}$$

A bound in expectation also easily follows: Let δ denote the factor of δ' in last line above. Then we have that

$$\begin{aligned}
\mathbb{E}\left\|P_{\mathcal{S}^{\perp}} \cdot [O \circ P_{\Omega_k}] (P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} S_k)\right\|_F &= \delta \int_0^{\infty} \Pr\left[\left\|P_{\mathcal{S}^{\perp}} \cdot [O \circ P_{\Omega}] (P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} S_k)\right\|_F > \alpha'\delta\right] d\alpha'\\
&\le \delta\left(1 + \int_1^{\infty} \Pr\left[\left\|P_{\mathcal{S}^{\perp}} \cdot [O \circ P_{\Omega}] (P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} S_k)\right\|_F > \alpha'\delta\right] d\alpha'\right)\\
&\le \delta\left(1 + \int_1^{\infty} b^{-\alpha'} d\alpha'\right)\\
&\le 2\delta\\
&= 2\log b \sqrt{\frac{\log n}{p}} \cdot \|P_{\widehat{\mathcal{S}}_{k-1}^{\perp}} P_{\mathcal{S}}\|_F \|Q_k\|.
\end{aligned} \tag{219}$$

This completes the proof of Lemma 23.

Appendix K. Properties of a Standard Random Gaussian Matrix

As a supplement to Remark 25, we show here that a standard random Gaussian matrix $G \in \mathbb{R}^{b\times r}$ is well-conditioned and incoherent when b is sufficiently large. From (Vershynin, 2012a, Corollary 5.35) and for fixed $\alpha \geq 1$, recall that

$$\sqrt{b} - C_3\alpha\sqrt{r} \leq \sigma_r(G) \leq \sigma_1(G) \leq \sqrt{b} + C_3\alpha\sqrt{r}, \tag{220}$$

except with a probability of at most $e^{-\alpha^2 r}$. It follows that

$$\nu(G) = \frac{\sigma_1(G)}{\sigma_r(G)} \leq \frac{\sqrt{b} + C_3\alpha\sqrt{r}}{\sqrt{b} - C_3\alpha\sqrt{r}}, \tag{221}$$

which can be made close to one by choosing $b \gtrsim \alpha^2 r$.

For the coherence, note that $G(G^*G)^{-\frac{1}{2}} \in \mathbb{R}^{b\times r}$ is an orthonormal basis for $\mathrm{span}(G)$. Using the definition of coherence in (14), we then write that

$$\begin{aligned}
\eta\left(\mathrm{span}(G)\right) &= \frac{b}{r}\max_{i\in[1:b]} \left\| G[i,:]\left(G^*G\right)^{-\frac{1}{2}} \right\|_2^2 \qquad \text{(see (14))} \\
&\leq \frac{b}{r}\max_i \|G[i,:]\|_2^2 \cdot \| \left(G^*G\right)^{-\frac{1}{2}} \|^2 \\
&= \frac{b}{r}\max_i \|G[i,:]\|_2^2 \cdot \left(\sigma_r(G)\right)^{-2} \\
&\leq \frac{b}{r}\max_i \|G[i,:]\|_2^2 \cdot \left(\sqrt{b} - C_3\alpha\sqrt{r}\right)^{-2} \qquad \text{(see (220))} \\
&\leq \frac{b}{r}\max_i \|G[i,:]\|_2^2 \cdot \left(\frac{b}{2} - C_3^2\alpha^2 r\right)^{-1} \qquad \left((a-b)^2 \geq \frac{a^2}{2} - b^2\right) \\
&\lesssim \frac{b}{r}\max_i \|G[i,:]\|_2^2 \cdot \left(b - C_4\alpha^2 r\right)^{-1},
\end{aligned} \tag{222}$$

except with a probability of at most $e^{-\alpha^2 r}$. For fixed i, $\|G[i,:]\|_2^2$ is a chi-squared random variable with r degrees of freedom so that

$$\Pr\left[\|G[i,:]\|_2^2 \gtrsim \beta\cdot r\right] \leq e^{-\beta}, \tag{223}$$

for $\beta \geq 1$. An application of the union bound and the choice of $\beta = C\alpha\log b$ then leads us to

$$\Pr\left[\max_{i\in[1:b]} \|G[i,:]\|_2^2 \gtrsim \alpha\log b\cdot r\right] \leq b\cdot b^{-C\alpha} = b^{-C\alpha}. \tag{224}$$

Substituting the bound above back into (222) yields that

$$\begin{aligned}
\eta\left(\mathrm{span}(G)\right) &\lesssim \frac{b}{r}\max_i \|G[i,:]\|_2^2 \cdot (b - C_4 r)^{-1} \qquad \text{(see (222))} \\
&\lesssim \frac{b}{r}\cdot r\alpha\log b\cdot (b - C_4 r)^{-1} \qquad \text{(see (224))} \\
&\lesssim \frac{\alpha b\log b}{b - C_4\alpha^2 r},
\end{aligned} \tag{225}$$

except with a probability of at most $e^{-\alpha r} + b^{-C\alpha}$. In particular, when $b \geq 2C_4\alpha^2 r$, we find that $\eta(\mathrm{span}(G)) \lesssim \alpha\log b$ except with a probability of at most $e^{-\alpha r} + b^{-C\alpha}$.

Appendix L. Alternative Initialization

SNIPE in Algorithm 1 is initialized by truncating the SVD of the first incomplete block $Y_1 \in \mathbb{R}^{n\times b}$, where we often take $b = O(r)$ to keep the computational and storage requirements of SNIPE minimal, see Remarks 1 and 2. Put differently, with the notation of Section 3, even though our end goal is to compute rank-r truncated SVD of the full (but hidden) data block $S_1 \in \mathbb{R}^{n\times b}$, SNIPE is initialized with truncated SVD of the incomplete (but available) block $Y_1 = P_{\Omega_1}(S_1) \in \mathbb{R}^{n\times b}$, which fills in the missing entries with zeros. Indeed, when the first incomplete block Y_1 arrives, there is no prior knowledge to leverage and zero-filling the missing entries in Y_1 is a sensible strategy. In contrast, for the rest of blocks $k \geq 2$, SNIPE uses its previous estimate $\widehat{\mathcal{S}}_{k-1}$ to fill out the erased entries in Y_k before updating its estimate to $\widehat{\mathcal{S}}_k$, see Algorithm 1.

One might instead initialize SNIPE with a larger block. More specifically, suppose that we change the first block size to $b_1 \geq b$ while keeping the rest of the blocks at the same size b. Then we set $\widehat{\mathcal{S}}_1$ to be the span of leading r left singular vectors of the first incomplete block $Y_1 \in \mathbb{R}^{n\times b_1}$, while the rest of steps in Algorithm 1 do not change. As the size of the first block b_1 increases, $\widehat{\mathcal{S}}_1$ increasingly better approximates the true subspace $\mathcal{S}$. Indeed, one might consider $Y_1 = P_{\Omega_1}(S_1) = S_1 + (P_{\Omega_1}(S_1) - S_1)$ as a "noisy" copy of S_1, where the noise is due to the erasures. Roughly speaking then, as b_1 increases, the energy of the "signal" part, namely, $\|S_1\|_F$, grows faster than and eventually dominates the energy of the random noise $\|P_{\Omega_1}(S_1) - S_1\|_F$. This intuition is made precise by the following result which loosely speaking states that

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_1) \lesssim \sqrt{\frac{r}{pn}},$$

when $b_1 = \Omega(n)$. This result is proved in Appendix C with the aid of standard large deviation bounds.

Proposition 24 *Consider an r-dimensional subspace $\mathcal{S}$ with orthonormal basis $S \in \mathbb{R}^{n\times r}$. For an integer $b_1 \geq r$, let the coefficient vectors $\{q_t\}_{t=1}^{b_1} \subset \mathbb{R}^r$ be independent copies of a random vector $q \in \mathbb{R}^r$. For every $t \in [1:b_1]$, we observe each coordinate of $s_t = Sq_t \in \mathcal{S}$ independently with a probability of p and collect the observed entries in $y_t \in \mathbb{R}^n$, supported on the random index set $\omega_t \subseteq [1:n]$. We set $Q_1 = [q_1\, q_2 \cdots q_{b_1}] \in \mathbb{R}^{r\times b_1}$ and $Y_1 = [y_1\, y_2 \cdots y_{b_1}] \in \mathbb{R}^{n\times b_1}$ for short. Let also $\widehat{\mathcal{S}}_1$ be the span of leading r left singular vectors of Y_1.*

Then, for fixed $\alpha, \nu \geq 1$ and $1 \leq \eta \leq b_1/r$, it holds that

$$d_{\mathbb{G}}(\mathcal{S}, \widehat{\mathcal{S}}_1) \lesssim \alpha\cdot\nu\sqrt{\left(1 \vee \frac{n}{b_1}\right)\frac{\left(\eta \vee \eta\left(\mathcal{S}\right)\right) r\log(n \vee b_1)}{pn}}, \tag{226}$$

except with a probability of at most $e^{-\alpha} + \Pr[\nu(Q_1) > \nu] + \Pr[\eta(\mathcal{Q}_1) > \eta]$. Above, $\nu(Q_1)$ is the condition number of Q_1, $\eta(\mathcal{Q}_1)$ is the coherence of $\mathcal{Q}_1 = \mathrm{span}(Q_1^*)$ (see (14)), and $a \vee b := \max\{a, b\}$.

Remark 25 [Discussion of Proposition 24] As (226) suggests, for $\widehat{\mathcal{S}}_1$ to be close to $\mathcal{S}_1$, the first block should be a wide matrix, namely, $b_1 = O(n)$. This dependence on the block size was anticipated. Indeed, it is well-understood that one needs $O(n)$ samples in order

for the sample covariance matrix to closely approximate the covariance matrix of a random vector in $\mathbb{R}^n$ (Vershynin, 2012b). As an example, consider the case where the coefficient vectors $\{q_t\}_{t=1}^{b_1}$ are standard random Gaussian vectors and so $Q_1 \in \mathbb{R}^{n\times b_1}$ is a standard random Gaussian matrix, namely, populated with zero-mean independent Gaussian random variables with unit variance. Then both probabilities above are small when b_1 is sufficiently large. More specifically, we show in Appendix K that

$$\Pr[\nu(Q_1) > \nu] \leq \exp\left(-C\frac{\nu-1}{\nu+1}\right), \qquad \text{when } b \gtrsim r, \tag{227}$$

$$\Pr[\eta(\mathcal{Q}_1) > \eta] \leq \exp(-C\eta/\log b), \qquad \text{when } b\log^2 b \gtrsim \eta^2 r, \tag{228}$$

for a Gaussian coefficient matrix Q_1.

It is also worth noting that initializing SNIPE with a large first block can be done *without* increasing the storage requirement or computational complexity of SNIPE, namely, replacing the block size $b = O(r)$ in first step of Algorithm 1 with $b_1 = O(n)$ can be done without losing the streaming nature of SNIPE. More specifically, with the alternative initialization, naively computing the truncated SVD of the first block requires $O(b_1 n) = O(n^2)$ bits of storage and $O(rb_1 n) = O(rn^2)$ flops. These requirements can be significantly lowered by implementing a state-of-the-art streaming PCA algorithm such as the "power method" in (Mitliagkas et al., 2013). This suggests a two-phase algorithm. In the first phase, the power method is applied to the incoming data, where the missing entries are filled with zeros. This phase produces the estimate $\widehat{\mathcal{S}}_1$ in SNIPE, which serves as an initialization for the second phase in which the main loop of SNIPE is applied to the incoming blocks, producing the estimates $\{\widehat{\mathcal{S}}_k\}_{k\geq 2}$. If b_1 is sufficiently large, the first phase brings us within the basin of attraction of the true subspace $\mathcal{S}$ and activates the locally linear convergence of SNIPE to $\mathcal{S}$ in the second phase, see Theorems 8 and 10.

Abstract

We investigate and compare the fundamental performance of several distributed learning methods that have been proposed recently. We do this in the context of a distributed version of the classical signal-in-Gaussian-white-noise model, which serves as a benchmark model for studying performance in this setting. The results show how the design and tuning of a distributed method can have great impact on convergence rates and validity of uncertainty quantification. Moreover, we highlight the difficulty of designing nonparametric distributed procedures that automatically adapt to smoothness.

Keywords: distributed learning, nonparametric models, high-dimensional models, Gaussian processes, convergence rates

1. Introduction

Both in statistics and machine learning there has been substantial interest in the design and study of distributed statistical or learning methods in recent years. One driving reason is the fact that in certain applications datasets have become so large that it is often unfeasible, or computationally undesirable, to carry out the analysis on a single machine. In a distributed method the data are divided over a cluster consisting of several machines and/or cores. The machines in the cluster then process their data locally, after which the local results are somehow aggregated on a central machine to finally produce the overall outcome of the statistical analysis. Distributed methods are not only used for computational reasons, but are for instance also of interest in situations where privacy is important and it is undesirable that all data are handled at a single location. Moreover, there are applications in which data are by construction gathered at multiple locations and first processed locally, before being combined at a central location.

Over the last years a variety of distributed methods have been proposed. Recent examples include Consensus Monte Carlo (Scott et al. (2016)), WASP (Srivastava et al. (2015)), distributed GP's (Deisenroth and Ng (2015)), and methods proposed in Shang and Cheng (2015), Jordan et al. (2016), Lee et al. (2015), Volgushev et al. (2017), to mention but a few. Most papers on distributed methods do extensive experiments on simulated, benchmark and real data to numerically assess and compare the performance of the various methods. Some papers also derive a number of theoretical properties. Theoretical results on the performance of distributed methods are not yet widely available however and there is certainly no common theoretical framework in place that allows a clear theoretical comparison of methods and the development of an understanding of fundamental performance guarantees and limitations. Clearly we can not consider the complete list of all existing methods in this paper. We limit ourselves to a number of representative methods that are Bayesian in nature, allowing for a meaningful comparison.

Since a better theoretical understanding of distributed methods can help to pinpoint fundamental difficulties and opportunities, we develop a framework in this paper which allows us to study and compare the performance of various methods. We are in particular interested in high-dimensional, or nonparametric problems. It is by now well known that the performance of learning or statistical methods in such settings depends crucially on wether or not a method succeeds in realizing the correct bias-variance trade-off, or, in different terminology, succeeds in balancing under- and overfitting. For classical, non-distributed settings we have a rather well-developed understanding of how methods should be tuned to achieve a proper bias-variance trade-off. For distributed methods however, such theory is currently not yet available.

To be able to develop relevant theory we study an idealized model, which is a distributed version of the canonical "signal-in-white-noise" model that serves as an important benchmark model in mathematical statistics (see for instance Tsybakov (2009); Johnstone (2017); Giné and Nickl (2016)). The model is on the one hand rich enough to be interesting, in the sense that it is really distributed in nature and the unknown object that needs to be learned is truly infinite-dimensional. On the other hand it is tractable enough to allow detailed mathematical analysis. In the non-distributed case the signal-in-white-noise model is well known to be very closely related to other nonparametric models, such as nonparametric regression and density estimation. (This can be made very precise in the context of Le Cam's theory of limits of experiments (e.g. Le Cam (2012), Brown and Low (1996), Nussbaum (1996)).) Similarly, the distributed signal-in-white-noise model that we consider in this paper provides a unified framework to compare methods that were originally introduced in different settings. Therefore, although our theoretical results are all obtained in the context of this relatively simple "benchmark model" and we consider only a number of representative distributed methods, we believe that the conclusions that we draw are relevant more generally. We introduce the model in Section 2.

It is not difficult to see that if the number of machines m is relatively large with respect to the total sample size, or signal-to-noise-ratio n, then doing things completely naively in the distributed case leads to a sub-optimal bias-variance trade-off (see also the simulation example in Section 2). In particular, just computing the "usual" estimators on every local machine and then averaging them on the central machine typically leads to a global estimator with a bias that is too large. To achieve good performance, the trade-off has to be

adjusted somehow. This can in principle be done in various ways. For instance by locally choosing the "wrong" settings for tuning parameters on purpose, or, in a Bayesian setting, by adjusting the likelihood (e.g. raising it to some power) or by adjusting the prior. In Section 3 we study to what degree various methods that have been proposed in the literature succeed in ultimately achieving the right trade-off. We will see that some are more successful than others in this respect.

An important observation that we make is that the methods that are shown to work well in Section 3 all use information on aspects of the true signal that are in principle unknown, such as its degree of regularity. A key question is whether in distributed settings it is fundamentally possible to set tuning parameters correctly in a purely data-driven way, without using such information. In the non-distributed setting it is well known that such adaptive methods indeed exist (e.g. Tsybakov (2009) or Giné and Nickl (2016)). In the distributed case that we study here however, this is much less clear. In Section 4 we show that using a distributed version of a standard adaptation method that is known to work in the non-distributed case, such as maximum marginal likelihood empirical Bayes, can lead to sub-optimal results in the distributed setting. We will argue that this seems to be a fundamental issue and that we expect that correct automatic setting of tuning parameters in distributed methods is fundamentally more challenging than in the classical, non-distributed case. We believe this is an important issue and want to highlight it as an important and interesting topic for future research.

To further study the fundamental potential and limitations of distributed methods, one should also take into account that there are typically computational and/or communication cost restrictions in such settings. In fact, without such restrictions the matter of obtaining good strategies is essentially non-existent, since we could simply communicate all data to a central machine and then apply an existing optimal non-distributed method. The main goal of this paper, however, is to study and compare the theoretical performance of a number of *existing* distributed methods. The methods we consider are all divide-and-conquer algorithms in which computational or communication limitations are not explicitly imposed, however such restrictions do motivate the methods and all methods implicitly or explicitly consider situations in which simply aggregating and handling all data in one machine is not an option. Formally taking into account communication restrictions in the theoretical analysis is an important next step, but turns out to be rather delicate. We recently obtained some first results in the follow-up paper Szabo and van Zanten (2019), see also Zhu and Lafferty (2018) for related work.

The remainder of the paper is organized as follows. In the next section we introduce the distributed version of the signal-in-white-noise model and provide a simple simulation example to show that in a distributed setting, naively combining inferences from local machines into a global estimator may produce misleading results. In Section 3 we study the performance of a number of Bayesian procedures for signal reconstruction in the distributed signal-in-white-noise model introduced in Section 2. We include a number of methods that have recently been proposed in the literature. We show that some succeed in obtaining the appropriate bias-variance trade-off, but others do not. Moreover, the ones that do produce good results are all non-adaptive, in the sense that they use knowledge of the smoothness of the unkown signal to set their tuning parameters. In the final Section 4 we consider the more realistic setting in which this smoothness is unknown. We study a distributed method

that has been proposed for data-driven tuning of the hyperparameters and show that there exist "difficult signals", which this method can not recover in the distributed model at an optimal rate. We argue that this appears to be a fundamental issue, and that designing procedures that automatically adapt to smoothness is fundamentally more challenging in the distributed framework. Mathematical proofs are collected in appendix Sections A and B.

2. Distributed signal-in-white-noise model

Consider the problem of estimating a signal in Gaussian white noise. This is the continuous regression-type problem in which we observe a signal $X = (X_t : t \in [0,1])$ satisfying a stochastic differential equation

$$X_t = \int_0^t f(s)\,ds + \frac{\sigma}{\sqrt{n}} W_t,$$

where W is a Brownian motion, modelling the "white noise", and f is an unknown signal, modelled by a square integrable function, that needs to be recovered from the data. The natural number n is the signal-to-noise ratio. Its size affects the difficulty of the problem and n can be seen as playing the role of sample size in this problem.

By expanding the data in a fixed orthonormal basis of $L^2[0,1]$ (for instance the classical Fourier basis), it is seen that the statistical problem of recovering the signal f from the data X is equivalent to the problem of recovering the sequence of (Fourier) coefficients $\theta \in \ell^2$ from noisy observations $Y_1, Y_2, \ldots$, satisfying

$$Y_i = \theta_i + \sqrt{\frac{\sigma^2}{n}} Z_i, \qquad i = 1, 2, \ldots, \tag{2.1}$$

where the Z_i are independent standard normal variables. This is the usual setting in which there is a single observer that observes every coefficient θ_i with additive Gaussian noise with variance σ^2/n. See for instance Tsybakov (2009); Johnstone (2017); Giné and Nickl (2016) for more details on this classical model.

In the distributed version of the model we divide the "precision budget" n over m different observers, so that each one observes the signal in Gaussian noise with variance $\sigma^2 m/n$, independent of the others. In other words, observer j has data $Y_1^j, Y_2^j, \ldots$ satisfying

$$Y_i^j = \theta_i + \sqrt{\frac{\sigma^2 m}{n}} Z_i^j, \qquad i = 1, 2, \ldots, \tag{2.2}$$

where the Z_i^j are independent, standard Gaussian random variables. We call the m independent sub-problems in which the signal-to-noise ratio is $\sigma^2 m/n$ the "local" problems.

Note that the classical, non-distributed signal-in-white-noise model is obtained again from the distributed model by aggregating all the local data. Indeed, if for $j = 1, 2, \ldots$ we define $Y_i = m^{-1} \sum_{j=1}^m Y_i^j$, then (2.1) holds, with $Z_i = m^{-1/2} \sum_{j=1}^m Z_i^j$ independent standard normal variables. This model has been studied extensively in the literature, serving as a canonical model for understanding the performance of high-dimensional or nonparametric

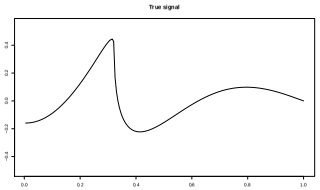

Figure 1: True signal.

statistical procedures. It is well known for instance that if the true signal θ belongs to an ellipsoid or a hyper rectangle of the form

$$\{\theta \in \ell^2 : \sum i^{2\beta}\theta_i^2 \leq M^2\} \text{ or } \{\theta \in \ell^2 : \sup_i(i^{1+2\beta}\theta_i^2) \leq M^2\}$$

for some $\beta, M > 0$, then the optimal rate of convergence of estimators (relative to the ℓ^2-norm) is of the order $n^{-\beta/(1+2\beta)}$. Moreover, there exist so-called adaptive estimators, which achieve this rate without using knowledge about the parameters β or M that describe the complexity, or regularity of the true signal. See, for instance, Tsybakov (2009) or Giné and Nickl (2016). Our central question is whether or not the same results can be obtained in the distributed setting in which each of the m different observers first separately make inference about the signal, and then the local estimates are aggregated into one joint estimator. For technical convenience we will quantify regularity using hyper rectangles in the remainder of the paper, but the analoguous results can be obtained for ellipsoids.

The specific examples of distributed procedures that we consider in this paper are about distributed Bayesian methods. These methods have in common that each local observer first chooses a prior distribution and computes the corresponding local posterior distribution using the local data (or an appropriate modification). In the next step the m local posteriors are somehow aggregated into a global posterior-type distribution, which is then used to produce an estimate of the signal and/or a quantification of the associated uncertainty. In general there is no guarantee that this "aggregated posterior" resembles the posterior distribution that would be obtained in the non-distributed setting, using all the data at once. In particular, it is not clear beforehand how a distributed Bayes method should be constructed in order to have good theoretical properties, like optimal convergence rates, reliable uncertainty quantification or adaptation properties. In this paper we investigate various distributed methods that have been proposed from this point of view.

To see that interesting things can happen it is exemplifying to compare the results of a distributed and a non-distributed (Bayesian) analysis of simulated data. Concretely, we consider a true signal θ consisting of the Fourier coefficients of the function shown in Figure 1. For this signal we simulate data according to (2.2), with $\sigma = 1$, $m = 40$ and $n = 120 \times 40 = 4800$. Then for every local observer a Bayesian procedure is carried out with a Gaussian prior on θ, postulating that the coordinates θ_i are independent and $N(0, i^{-1-2\alpha})$-distributed. The hyperparameter α, which describes the regularity of the prior,

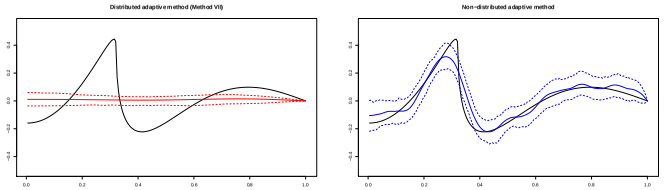

Figure 2: Signal reconstruction using the distributed method (left) and the non-distributed method (right).

is determined using a distributed version of maximum marginal likelihood, as described in Section 4. This analysis leads to $m = 40$ local posterior distributions. These are then combined to produce an overall posterior distribution for the signal. The precise procedure is described in Section 4. The resulting estimator for the signal, together with pointwise 95% credible intervals, is shown in the left plot in Figure 2. The corresponding non-distributed result is obtained by first aggregating all local data as in (2.1) and then carrying out the same Bayesian procedure on these complete data. The resulting non-distributed reconstruction of the signal is shown on the right in Figure 2.

The non-distributed version of this method was studied theoretically for instance in Knapik et al. (2016) and Szabó et al. (2015), where it was shown that the method is adaptive and rate-optimal. The simulation suggests however that an apparently reasonable distributed analogue of the method does not necessarily inherit these favourable properties. The procedure seems to be underfitting and the credible intervals appear to be too narrow. We will argue that this is in some sense a fundamental issue and in the next sections we will study various proposed distributed methods to investigate to what degree they succeed in avoiding or solving these problems.

3. Results for non-adaptive procedures

In this section we study the performance of a number of Bayesian procedures for signal reconstruction in the distributed signal-in-white-noise model introduced in Section 2. All methods involve putting a prior distribution on the unknown signal $\theta \in \ell^2$ in each local problem and then combining the resulting local posteriors into one global posterior-type distribution. To be able to compare the various methods we consider the same Gaussian process (GP) prior in every case, namely the prior

$$\Pi(\cdot|\alpha) = \bigotimes_{i=1}^{\infty} N(0, i^{-1-2\alpha}), \tag{3.1}$$

which postulates that the coefficients θ_i of the signal θ are independent and $N(0, i^{-1-2\alpha})$-distributed. The hyper parameter $\alpha > 0$ essentially controls the regularity of the prior, since

it basically controls how fast the Fourier coefficients decrease. (Some of the methods we consider use exactly this prior, others modify it in a certain way with the aim of achieving better performance.) The global posterior-type distribution depends on all the data $\mathbf{Y} = (Y_i^j : j = 1, \ldots, m; i = 1, 2, \ldots)$ and is denoted by $\Pi(\cdot \,|\, \mathbf{Y})$. It is generally some type of average of the local posteriors, but its precise construction differs between proposed methods. We will see that this can have a significant effect on the performance.

We take an asymptotic perspective and investigate in every case the rate at which the global posterior contracts around the true signal as $n \to \infty$ relative to the ℓ^2-norm, which is as usual defined by $\|\theta\|_2^2 = \sum \theta_i^2$. For a sequence of positive numbers $\varepsilon_n \to 0$ we say that the global posterior contracts at the rate ε_n around the true signal θ_0 if for all sequences $M_n \to \infty$,

$$\mathrm{E}_{\theta_0} \Pi(\theta \in \ell^2 : \|\theta - \theta_0\|_2 > M_n \varepsilon_n \,|\, \mathbf{Y}) \to 0$$

as $n \to \infty$. This means that asymptotically, all posterior mass is concentrated in balls around the true signal θ_0 with ℓ^2-radius of the order ε_n.

Additionally, we study how well the posterior quantifies the remaining uncertainty. Specifically, we consider the coverage probabilities of credible balls around the global posterior mean. These credible sets are constructed by first computing the mean $\hat{\theta}$ of the global "posterior" $\Pi(\cdot \,|\, \mathbf{Y})$. Then for a level $\gamma \in (0, 1)$, the posterior is used to determine the radius r_γ such that the ball around $\hat{\theta}$ with radius r_γ receives $1 - \gamma$ posterior mass, i.e.

$$\Pi(\theta : \|\theta - \hat{\theta}\|_2 \leq r_\gamma | \mathbf{Y}) = 1 - \gamma.$$

For $L > 0$, the credible set $\hat{C}(L)$ is subsequently defined by

$$\hat{C}(L) = \{\theta : \|\theta - \hat{\theta}_n\|_2 \leq L r_\gamma\}. \tag{3.2}$$

(The extra constant L gives some added flexibility, for $L = 1$ we obtain an exact $1 - \gamma$ credible set.) We are interested in the coverage probabilities $\mathrm{P}_{\theta_0}(\theta_0 \in \hat{C}(L))$. If this tends to 0 as $n \to \infty$, the credible sets are asymptotically not frequentist confidence sets, hence give a misleading quantification of the uncertainty. Ideally, the coverage probabilities stay bounded away from 0 as $n \to \infty$.

In the non-distributed case $m = 1$ it is well known that both the rate at which the posterior contracts around the truth and the behaviour of the coverage probabilities of credible sets depend crucially on how the hyper parameter α is tuned. The correct bias-variance trade-off is achieved if α is in accordance with the regularity of the unknown signal. To make this precise, we will consider signals belonging to hyper rectangles of the form

$$H^\beta(M) = \left\{\theta \in \ell^2 : \sup_i (i^{1+2\beta} \theta_i^2) \leq M^2\right\} \tag{3.3}$$

for some $\beta, M > 0$. It is shown for instance in Knapik et al. (2011) for the non-distributed case that if $\theta_0 \in H^\beta(M)$ and we set $\alpha = \beta$, then the posterior contracts around θ_0 at the optimal rate $n^{-\beta/(1+2\beta)}$. Moreover, for L large enough it then holds that $\mathrm{P}_{\theta_0}(\theta_0 \notin \hat{C}(L)) \leq \gamma$. Hence, in the non-distributed case it is optimal to choose the hyper parameter α in such a way that the regularity α of the prior matches the regularity β of the true signal.

In the remainder of this section we investigate distributed methods from this point of view. We will see that the different proposed methods lead to different behaviours in terms

of contraction rates and coverage. We stress that the results in this section are non-adaptive, in the sense that we allow the tuning parameter α and other aspects of the constructions to use knowledge of the regularity β of the true signal. This is of course not realistic. It is however important to first understand for every method whether ideally, if the value of β is given to us by an oracle, it is possible to tune the method optimally. Whether this is also possible adaptively, without knowing β, is then the next natural question, which we address in Section 4.

3.1. Naive averaging of local posterior draws

Recall that we have m local observers that each have a dataset $\mathbf{Y}^j = (Y_1^j, Y_2^j, \ldots)$ of noisy coefficients satisfying (2.2). The aim is to recover the true sequence of coefficients θ.

As a starting point, and to have a baseline case to compare the other methods to, we analyse the naive distributed approach in which in every local problem we simply use the prior $\Pi(\cdot \,|\, \alpha)$ defined by (3.1), with $\alpha = \beta$ equal to the regularity of the true sequence θ, in the sense of (3.3). Every local observer then computes its corresponding local posterior, $\Pi^j(\cdot \,|\, \mathbf{Y}^j)$. By Bayes' formula this is given by

$$d\Pi^j(\theta \,|\, \mathbf{Y}^j) \propto p(\mathbf{Y}^j \,|\, \theta)\, d\Pi(\theta \,|\, \beta),$$

where the likelihood for the jth local problem is given by

$$p(\mathbf{Y}^j \,|\, \theta) \propto \prod e^{-\frac{1}{2} \frac{n (Y_i^j - \theta_i)^2}{\sigma^2 m}}. \tag{3.4}$$

Finally these local posteriors are combined into a global, "average posterior" $\mathbf{\Pi}_I(\cdot \,|\, \mathbf{Y})$ by postulating that a draw from this global posterior is generated by first drawing once from each local posterior and then averaging these m independent draws. (Formally, this means that the global "posterior" $\mathbf{\Pi}_I(\cdot \,|\, \mathbf{Y})$ is the convolution of the rescaled local posteriors $\Pi^1(m \times \cdot \,|\, \mathbf{Y}^1), \ldots, \Pi^m(m \times \cdot \,|\, \mathbf{Y}^m)$).

This distributed method is conceptually very simple, but it turns out that neither from the point of view of contraction rates, nor from the point of view of uncertainty quantification it performs very well. The reason is basically that although the choice $\alpha = \beta$ of the tuning parameter of the prior correctly matches squared bias, variance and posterior spread in the local problems, the averaging procedure results in a global "posterior" for which the spread and the variance of the mean are too small relative to the squared bias. The following theorem asserts that for every smoothness level $\beta > 0$ there exist β-regular truths for which the contraction rate of the posterior deteriorates substantially and for which the uncertainty quantification by the credible sets (3.2) constructed from the global posterior $\mathbf{\Pi}_I(\cdot \,|\, \mathbf{Y})$ is useless, no matter how far they are blown up by a constant $L > 0$.

Theorem 1 (naive averaging) *For every $\beta, M > 0$ there exists a $\theta_0 \in H^\beta(M)$ such that for small enough $c > 0$,*

$$E_{\theta_0} \mathbf{\Pi}_I(\theta : \|\theta - \theta_0\|_2 \leq c m^{\frac{\beta}{1+2\beta}} n^{-\frac{\beta}{1+2\beta}} | \beta, \mathbf{Y}) \to 0$$

as $m \to \infty$ and $n/m \to \infty$. Furthermore, for all $L > 0$ it holds that

$$P_{\theta_0}\big(\theta_0 \in \hat{C}(L)\big) \to 0.$$

Proof The proof of the theorem is given in Section A.1. ■

In the literature several less naive distributed strategies have been proposed. These methods either change the local likelihoods in a certain way, and/or the priors that are locally used, and/or the way that the local posteriors are aggregated. In the next few sections we investigate whether such strategies can improve the bad asymptotic performance of the naive averaging method.

3.2. Adjusted local likelihoods and averaging

One perspective on the bad performance of the naive method is to say that since the "sample size" n/m in the local problems is too small, the influence of the data on the local posterior is too small, resulting in a variance (and spread) that is too small relative to the squared bias in the global posterior. A possible way to remedy this that has been proposed in several papers is to raise the local likelihoods to the power m, in order to mimic the situation that we have sample size n in the local problems. This generalized Bayesian approach for the local problems has for instance been considered in the distributed context by Srivastava et al. (2015). They combine it with a different aggregation method however, which we consider in Section 3.4. In this section we still consider the simple averaging scheme, in order to isolate the effect of adjusting the local likelihoods.

So in method II all local observers use the prior $\Pi(\cdot\,|\,\alpha)$ again, with $\alpha = \beta$ equal to the regularity of the truth. They now each compute a generalized local posterior $\tilde{\Pi}^j(\cdot\,|\,\mathbf{Y}^j)$, defined by

$$d\tilde{\Pi}^j(\theta\,|\,\mathbf{Y}^j) \propto \Big(p(\mathbf{Y}^j\,|\,\theta)\Big)^m d\Pi(\theta\,|\,\beta).$$

As before the global "posterior" $\mathbf{\Pi}_{II}(\cdot\,|\,\mathbf{Y})$ is defined by postulating that a draw from this global posterior is generated by first drawing once from each local generalized posterior and then averaging these m independent draws.

The following theorem states that this method indeed improves the naive approach of Section 3.1. The global posterior now contracts at the optimal rate for every β-regular truth. Unfortunately, the bad behaviour of the credible sets has not been remedied. For this approach the uncertainty quantification is in fact misleading for all β-regular truths.

Theorem 2 (adjusted likelihoods + averaging) *For all $\beta, M > 0$ and all sequences $M_n \to \infty$,*

$$\sup_{\theta_0 \in H^\beta(M)} \mathrm{E}_{\theta_0} \mathbf{\Pi}_{II}(\theta : \|\theta - \theta_0\|_2 \geq M_n n^{-\frac{\beta}{1+2\beta}} | \mathbf{Y}) \to 0$$

as $n, m \to \infty$. However, for all $\theta_0 \in H^\beta(M)$ and all $L > 0$ it holds that

$$\mathrm{P}_{\theta_0}\big(\theta_0 \in \hat{C}(L)\big) \to 0.$$

Proof The proof is given in Section A.2. ■

3.3. Adjusted priors and averaging

Adjusting the likelihood as in the preceding section resulted in a correct trade-off between the bias and the variance of the global posterior mean, yielding an optimal posterior contraction rate. The spread of the posterior remained too small in comparison however, resulting in credible sets with zero asymptotic coverage. Instead of raising the local posteriors to the power m, as considered in the preceding section, we could alternatively raise the prior density to the power $1/m$. This has for instance been proposed in the context of the "Consensus Monte Carlo" approach by Scott et al. (2016), in combination with simple averaging of the local posteriors. In this section we investigate the performance of this method in terms of posterior contraction and uncertainty quantification in our distributed signal-in-white-noise model.

The prior $\Pi(\cdot\,|\,\alpha)$ that we use in the local problems is again a product of centered Gaussians with variance $i^{-1-2\alpha}$. Raising the corresponding densities to the power $1/m$ has the effect of multiplying the ith prior variance by m. Hence, in our case raising the prior density to the power $1/m$ is the same as multiplicative rescaling, postulating that θ is a-priori distributed according to $\Pi(\cdot\,|\,\alpha, m)$, where

$$\Pi(\cdot|\alpha, \tau) = \bigotimes_{i=1}^{\infty} N(0, \tau i^{-1-2\alpha}) \tag{3.5}$$

for $\alpha, \tau > 0$. Rescaled GPs have also been considered by Shang and Cheng (2015), who have used them in the distributed setting to construct global credible sets from local ones.

Using rescaling we can actually obtain good results if the prior regularity α is not exactly equal to the true regularity β. By using a scaling different from $\tau = m$ we can somehow compensate for the mismatch between α and β, at least in the range $\beta \leq 1 + 2\alpha$. In the non-distributed setting this is a well-known phenomenon, see for instance van der Vaart and van Zanten (2007); Knapik et al. (2011); Szabó et al. (2013).

The distributed procedure that we consider in this section then takes the following form. Every local observer uses the rescaled prior $\Pi(\cdot|\alpha, \tau)$ defined by (3.5), with $\alpha > 0$ and

$$\tau = m n^{\frac{2(\alpha-\beta)}{1+2\beta}},$$

where β is the regularity of the truth. Next the (normal, unadjusted) corresponding posteriors are computed and they are averaged into a global "posterior" $\mathbf{\Pi}_{III}(\cdot\,|\,\mathbf{Y})$ as in the preceding sections. (Note that if in the local problems the prior regularity $\alpha = \beta$ is used, then $\tau = m$, so the method corresponds to raising the prior density to the power $1/m$.)

The following theorem gives the posterior contraction and coverage results for this method.

Theorem 3 (adjusted priors + averaging) *Suppose $\beta, M > 0$ and $\beta \leq 1 + 2\alpha$. Then for all sequences $M_n \to \infty$,*

$$\sup_{\theta_0 \in H^\beta(M)} \mathrm{E}_{\theta_0} \mathbf{\Pi}_{III}(\theta : \|\theta - \theta_0\|_2 > M_n n^{-\frac{\beta}{1+2\beta}} | \mathbf{Y}) \to 0$$

as $n \to \infty$. *Moreover, for all* $\gamma \in (0,1)$ *it holds that*

$$\sup_{\theta_0 \in H^\beta(M)} \mathrm{P}_{\theta_0}\Big(\theta_0 \notin \hat{C}(L)\Big) \leq \gamma$$

for large enough $L > 0$.

Proof See Section A.3. ■

So adjusting the prior in this way actually works better than adjusting the likelihood. Not only do we get optimal contraction rates, but the credible sets that this method produces have asymptotic frequentist coverage too. The proof shows that the credible sets have optimal radius of the order $n^{-\beta/(1+2\beta)}$ as well.

3.4. Adjusted local likelihoods and Wasserstein barycenters

In Section 3.2 we saw that raising the local likelihoods to the power m and then averaging the corresponding generalized posteriors yields optimal contraction rates, but can produce badly performing credible sets. In this section we study the approach considered by Minsker et al. (2014); Srivastava et al. (2015) in the context of their "WASP" method, which consists in aggregating the local posteriors not by simple averaging, but by computing their Wasserstein barycenter.

The generalized local posteriors $\tilde{\Pi}^j(\cdot \,|\, \mathbf{Y}^j)$, as defined in Section 3.2, are (Gaussian) measures on ℓ^2. The 2-Wasserstein distance $W_2(\mu,\nu)$ between two probability measures μ and ν on ℓ^2 is defined by

$$W_2^2(\mu,\nu) = \inf_\gamma \iint \|x-y\|_2^2 \, \gamma(dx,dy),$$

where the infimum is over all measures γ on $\ell^2 \times \ell^2$ with marginals μ and ν. The corresponding 2-Wasserstein barycenter of m probability measures $\mu_1, \dots, \mu_m$ on ℓ^2 is then defined by

$$\bar{\mu} = \operatorname*{argmin}_\mu \frac{1}{m} \sum_{j=1}^m W_2^2(\mu, \mu_j),$$

where the minimum is over all probability measures on ℓ^2 with finite second moments. There exist effective algorithms to compute Wasserstein barycenters in many cases, see for instance Cuturi and Doucet (2014) and the references therein.

Having this notion at our disposal the distributed method we consider in this section proceeds as follows. In every local problem the prior $\Pi(\cdot \,|\, \alpha)$ is used, with $\alpha = \beta$ equal to the regularity of the truth. Next, the corresponding generalized posteriors $\tilde{\Pi}^j(\cdot \,|\, \mathbf{Y}^j)$ are computed locally, which involves raising the likelihood to the power m as described in Section 3.2. Finally, the global "posterior" $\mathbf{\Pi}_{IV}(\cdot \,|\, \mathbf{Y})$ is constructed as the 2-Wasserstein barycenter of the local measures $\tilde{\Pi}^1(\cdot \,|\, \mathbf{Y}^1), \dots, \tilde{\Pi}^m(\cdot \,|\, \mathbf{Y}^m)$.

The following theorem asserts that this method results in optimal posterior contraction rates and correct quantification of uncertainty.

Theorem 4 (adjusted likelihoods + barycenters) *For all* $\beta, M > 0$ *and all sequences* $M_n \to \infty$,

$$\sup_{\theta_0 \in H^\beta(M)} \mathrm{E}_{\theta_0} \mathbf{\Pi}_{IV}(\theta : \|\theta - \theta_0\|_2 > M_n n^{-\frac{\beta}{1+2\beta}} \,|\, \mathbf{Y}) \to 0$$

as $n \to \infty$. *Moreover, for all* $\gamma \in (0,1)$ *it holds that*

$$\sup_{\theta_0 \in H^\beta(M)} \mathrm{P}_{\theta_0}\Big(\theta_0 \notin \hat{C}(L)\Big) \leq \gamma$$

for large enough $L > 0$.

Proof See Section A.4. ■

3.5. Product of Gaussian process experts

The proofs of the theorems presented so far show that since in our context the global "posterior" is always a Gaussian measure, the behaviour of the procedure can be understood by analyzing three central quantities: the bias of the posterior mean, the variance of the posterior mean, and the spread of the posterior. Depending on how these quantities are related we have found different behaviours: sub-optimal posterior contraction and bad coverage of credible sets (Section 3.1), optimal posterior contraction but bad coverage of credible sets (Section 3.2), and optimal posterior contraction and also good coverage of credible sets (Sections 3.3 and 3.4).

In principle it is now straightforward to analyze different methods as well, provided the three central quantities can be controlled. As an illustration we consider in this section the single-layer version of the product-of-Gaussian-process-expert (PoE) model, introduced in Ng and Deisenroth (2014) and a generalization proposed in Cao and Fleet (2014). An interesting fact is that we will encounter a combination of behaviours that we have not seen yet: sub-optimal contraction rates, but good coverage of credible sets. These methods were introduced to deal with the distributed non-parametric regression model, but for the sake of comparison we analyze them in the context of our distributed signal-in-white-noise model, which can be thought of as an idealized version of the regression model.

The idea of the basic version of the Gaussian PoE model is to employ a Gaussian prior in every local machine, compute the corresponding posterior densities and approximate the global posterior density by multiplying and normalizing these. In our infinite-dimensional setting this does not make sense strictly speaking, since we can not express priors and posteriors on ℓ^2 in terms of densities with respect to some generic dominating measure. We could remedy this by considering a truncated version of our distributed model, where we assume we only observe the first n noisy coefficients Y_i^j in every machine, say, and focus on making inference about the first n true coefficients θ_i. This would make the setting finite-dimensional, allowing us to write prior and posterior densities with respect to the Lebesgue measure. Alternatively, we can stay in the infinite-dimensional setting of the paper and just reason formally and still arrive at a well-defined global PoE "posterior". This is the approach we follow here.

Indeed, say that as before we use the prior $\Pi(\cdot \,|\, \alpha)$ given by (3.1) in every local machine, with $\alpha = \beta$ equal to the regularity of the true signal. This prior has formal "density" proportional to

$$\theta \mapsto \prod e^{-\frac{1}{2}\frac{\theta_i^2}{i^{-1-2\beta}}}.$$

By completing the square we see that the product of this expression with the local likelihood given by (3.4) is, still formally, proportional to

$$\theta \mapsto \prod e^{-\frac{1}{2}\frac{\theta_i^2}{i^{-1-2\beta}}} e^{-\frac{1}{2}\frac{n(Y_i^j-\theta_i)^2}{\sigma^2 m}} \propto \prod e^{-\frac{1}{2}\theta_i^2(i^{1+2\beta}+\frac{n}{m\sigma^2})+\theta_i\frac{nY_i^j}{m\sigma^2}}.$$

Taking the product over j we then obtain the formal density of the PoE posterior, which is proportional to

$$\theta \mapsto \prod e^{-\frac{1}{2}\theta_i^2(mi^{1+2\beta}+\frac{n}{\sigma^2})+\theta_i\frac{n\sum_{j=1}^m Y_i^j}{m\sigma^2}}.$$

Now this last expression is, up to a constant, the density of a product of Gaussians with means $\hat{\theta}_i$ and variances t_i^2 given by

$$\hat{\theta}_i = \frac{nm^{-1}\sum Y_i^j}{n+\sigma^2 mi^{1+2\beta}}, \qquad t_i^2 = \frac{\sigma^2}{n+\sigma^2 mi^{1+2\beta}}.$$

The latter is in fact a well-defined Gaussian measure on ℓ^2, so we can now simply define the global PoE "posterior" $\mathbf{\Pi}_V(\cdot \,|\, \mathbf{Y})$ as the latter measure.

We see that the expressions for the global mean and spread are in fact the same as what we found in Section A.1 for the naive averaging method. As a consequence, the negative result of Theorem 1 holds for the basic version of the Gaussian PoE model as well.

Theorem 5 (product of Gaussian experts) *For every $\beta, M > 0$ there exists a $\theta_0 \in H^\beta(M)$ such that for small enough $c > 0$,*

$$\mathrm{E}_{\theta_0}\mathbf{\Pi}_V(\theta : \|\theta-\theta_0\|_2 \leq cm^{\frac{\beta}{1+2\beta}}n^{-\frac{\beta}{1+2\beta}} \,|\, \mathbf{Y}) \to 0$$

as $m \to \infty$ and $n/m \to \infty$. Furthermore, for all $L > 0$ it holds that

$$\mathrm{P}_{\theta_0}\big(\theta_0 \in \hat{C}(L)\big) \to 0.$$

One can generalize the PoE model by raising the local posterior densities to some power before multiplying and normalizing them, as proposed in Cao and Fleet (2014). In the subsequent analysis we consider the choice $1/m$ for the power, as suggested in Deisenroth and Ng (2015). Adapting the preceding analysis for the ordinary PoE model we see that for this generalized PoE model the global "posterior" $\mathbf{\Pi}_{VI}(\cdot \,|\, \mathbf{Y})$ is in our setting again a product of Gaussians, but now with means and variances given by

$$\hat{\theta}_i = \frac{nm^{-1}\sum Y_i^j}{n+\sigma^2 mi^{1+2\beta}}, \qquad t_i^2 = \frac{\sigma^2 m}{n+\sigma^2 mi^{1+2\beta}}.$$

So the global posterior mean is unaltered compared to the basic PoE model, but the global posterior spread has been blown up by a factor m. As a result, there still exists the same

Method	Description	Optimal rate	Coverage
I	naive averaging	no	no
II	adjusted likelihoods, averaging	yes	no
III	adjusted priors, averaging	yes	yes
IV	adjusted likelihoods, barycenter	yes	yes
V	product of experts	no	no
VI	generalized product of experts	no	yes

Table 1: Performance of the various non-adaptive methods.

class of truths as in Section A.1 for which the squared bias and the variance of the posterior mean will be incorrectly balanced, resulting in a sub-optimal rate of posterior contraction. However, the larger posterior spread ensures that we do have asymptotic coverage of credible sets. It should be noted however that these sets have a diameter that is sub-optimal, i.e. they are too conservative.

Theorem 6 (generalized product of Gaussian experts) *For every $\beta, M > 0$ there exists a $\theta_0 \in H^\beta(M)$ such that for small enough $c > 0$,*

$$\mathrm{E}_{\theta_0}\mathbf{\Pi}_{VI}(\theta : \|\theta-\theta_0\|_2 \leq cm^{\frac{\beta}{1+2\beta}}n^{-\frac{\beta}{1+2\beta}} \,|\, \mathbf{Y}) \to 0$$

as $m \to \infty$ and $n/m \to \infty$. However, for all $\gamma \in (0,1)$ it holds that

$$\sup_{\theta_0 \in H^\beta(M)} \mathrm{P}_{\theta_0}\Big(\theta_0 \notin \hat{C}(L)\Big) \leq \gamma$$

for large enough $L > 0$.

Proof The proof of the theorem can be found in Section A.5. ■

3.6. Summary of results for non-adaptive methods

We have seen that the various methods for aggregation of the local posteriors can give quite different results. The methods we considered produce different global "posterior" measures. Depending on the relation between the bias and variance of the global posterior mean and the spread of this global posterior, the posterior contraction rate and coverage probabilities of credible sets can have different behaviours. We summarize our findings in Table 1. This is certainly not meant to be an exhaustive list of methods, but rather an illustration of how the design of distributed procedures can affect their fundamental performance.

Simulations further illustrate the theoretical results. We have considered a true signal θ consisting of the Fourier coefficients of the function shown in the left panel of Figure 3. This is a signal which has regularity $\beta = 1$ in the sense of (3.3). For this signal we simulated data according to (2.2), with $\sigma = 1$, $n = 4800$ and $m = 40$, i.e. we considered a distributed setting with $m = 40$ machines. For the sake of comparison, the right panel of Figure 3 shows the

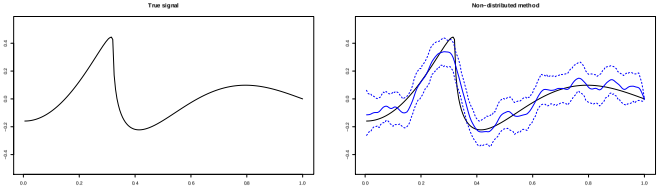

Figure 3: Left: true signal. Right: posterior mean (blue solid curve) and 95% pointwise credible bands (dashed blue curves) for the non-distributed method.

signal reconstruction and uncertainty quantification for the non-distributed method which first aggregates all data in a single machine and then computes the posterior corresponding to the prior $\Pi(\cdot\,|\,\alpha)$ defined by (3.1), with $\alpha = \beta$. This is a method which is known to have an optimal convergence rate and correct quantification of uncertainty. This classical, non-distributed result should be compared to Figure 4, which visualizes the "posteriors" generated by each of the distributed methods I–VI.

In accordance with our theoretical results, we see that the results of methods III and IV are comparable with the non-distributed method. Methods I, V and VI have worse signal reconstruction. The posterior mean of Method II is comparable to that of the optimal methods, but the uncertainty is underestimated.

An important observation to make is that the methods that achieve the same optimal performance as non-distributed methods, all use information about the regularity β of the unkown signal, mostly through the setting of tuning parameters in the priors. In that sense, they are non-adaptive. They serve as useful results that indicate what is possible in principle if we have certain oracle knowledge about the truth we are trying to learn. To understand what realistic procedures can achieve this has to be combined with insight into what can be learned about this oracle knowledge from the data. In the next section we address this issue in the context of our distributed signal-in-white-noise model.

4. Results for adaptive procedures

In the non-distributed case it is well known that there exist adaptive methods that achieve the same optimal performance as non-adaptive procedures, without using knowledge of the regularity β of the unkown signal. These methods somehow succeed in correctly trading off bias, variance (and spread in Bayesian methods) in a purely data-driven manner. For several such result in the context of the signal-in-white-noise model, see, for instance, Giné and Nickl (2016) and the references therein. For distributed methods the issue of adaptation appears to be a lot more subtle. In this paper we only have a first, negative result on adaptive properties of distributed methods.

So now we do not assume that we know the true regularity β of the unknown signal. As before we employ the prior $\Pi(\cdot\,|\,\alpha)$ in the local machines. To tune the regularity parameter α

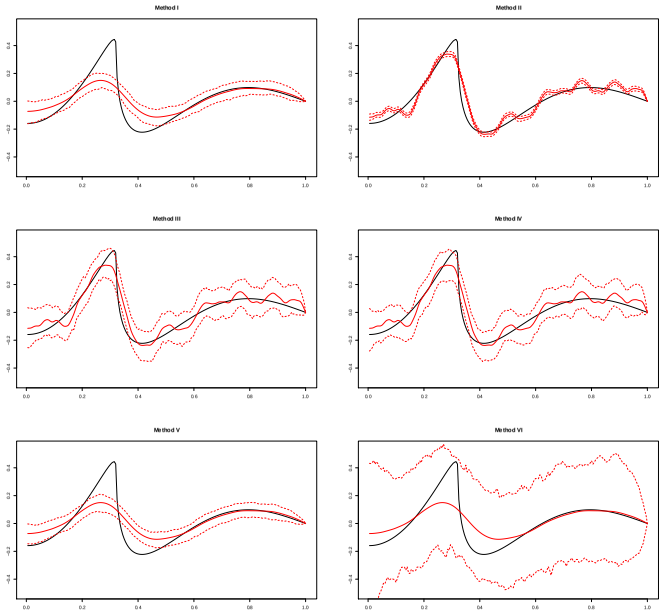

Figure 4: Global posterior mean (solid red curve) and 95% pointwise credible bands (dashed red curves) for each of the methods I–VI.

of the prior we consider a distributed version of maximum marginal likelihood estimator, as proposed by Deisenroth and Ng (2015). The usual, non-distributed version of that method would use the maximizer of the map

$$\alpha \mapsto \log \int \Big(\prod_{j=1}^{m} p(\mathbf{Y}^j \,|\, \theta) \Big) \, \Pi(d\theta \,|\, \alpha)$$

as tuning parameter. Maximizing this function however requires having all data available in a central machine. In the distributed setting, Deisenroth and Ng (2015) argue that this map is well approximated by the map

$$\alpha \mapsto \sum_{j=1}^{m} \log \Big(\int p(\mathbf{Y}^j \,|\, \theta) \, \Pi(d\theta \,|\, \alpha) \Big).$$

Now every term in the sum just depends on one of the local machines and this function can be maximized on the central machine by repeatedly asking the local machines for function evaluations and gradients of the local log-marginal likelihoods

$$\log \int p(\mathbf{Y}^j \,|\, \theta) \, \Pi(d\theta \,|\, \alpha).$$

The resulting estimator is denoted by $\hat{\alpha}$, i.e.

$$\hat{\alpha} = \operatorname*{argmax}_{\alpha \in [0, \log n]} \sum_{j=1}^{m} \log \Big(\int p(\mathbf{Y}^j \,|\, \theta) \, \Pi(d\theta \,|\, \alpha) \Big).$$

(We maximize over a compact interval to ensure that the maximizer exists.)

It turns out that in the distributed setting, the local machines are in general not able to learn enough about the true signal regularity β. The following lemma asserts that there exist "difficult" signals for which the estimator $\hat{\alpha}$ overestimates the regularity.

Lemma 7 *For $\beta, M > 0$, consider a signal $\theta_0 \in \ell^2$ such that*

$$\theta_{0,i}^2 = \begin{cases} M^2 i^{-1-2\beta} & \text{if } i \geq (n/(\sigma^2 \sqrt{m}))^{1/(1+2\beta)}, \\ 0 & \text{else.} \end{cases} \tag{4.1}$$

Then $\theta_0 \in H^\beta(M)$ and if M is small enough, then

$$\mathrm{P}_{\theta_0}(\hat{\alpha} \geq \beta + 1/2) \to 1 \tag{4.2}$$

if $n/m \to \infty$ and $m \to \infty$.

Proof The proof is given in Section B.1. ∎

In view of Lemma 7 it is perhaps not surprising that if the approximated maximum marginal likelihood estimator $\hat{\alpha}$ is used to tune the local prior that is used in every machine, sub-optimal performance is obtained for certain truths. Intuitively this is because due to the smaller signal-to-noise ratio, or "sample size" in the local machines, certain truths may appear more regular than they really are. It turns out that using the estimator $\hat{\alpha}$ in combination with any of the methods considered in the preceding section indeed leads to sub-optimal rates and bad coverage probabilities for certain truths. As an illustration we present a rigorous statement for the method of Section 3.4, but similar results can be derived for the others methods as well.

So suppose that in every local problem the prior $\Pi(\cdot \,|\, \alpha)$ is used, the corresponding generalized posterior $\tilde{\Pi}^j(\cdot \,|\, \mathbf{Y}^j)$ is computed locally (which involves raising the local likelihood to the power m), and then the tuning parameter α is substituted by the estimator $\hat{\alpha}$ defined above. In the central machine, the global "posterior" $\mathbf{\Pi}_{VII}(\cdot \,|\, \mathbf{Y})$ is constructed as the 2-Wasserstein barycenter of the local "posterior" measures $\tilde{\Pi}^1(\cdot \,|\, \hat{\alpha}, \mathbf{Y}^1), \ldots, \tilde{\Pi}^m(\cdot \,|\, \hat{\alpha}, \mathbf{Y}^m)$.

Theorem 8 *For $\beta, M > 0$ and θ_0 as in Lemma 7 we have, for some $c > 0$,*

$$\mathrm{E}_{\theta_0} \mathbf{\Pi}_{VII}(\theta : \, \|\theta - \theta_0\|_2 \leq c(n/\sqrt{m})^{-\frac{\beta}{1+2\beta}} | \mathbf{Y}) \to 0$$

as $m \to \infty$ and $n/m \to \infty$. Furthermore, for all $L > 0$ it holds that

$$\mathrm{P}_{\theta_0}\big(\theta_0 \in \hat{C}(L)\big) \to 0.$$

Proof See Section B.2. ∎

A simulation illustrating the theoretical result of the theorem is given in Figure 2. The left panel visualizes the "posterior" generated by method VII, in the same distributed setting, and using the same simulated data as considered in Section 3.6.

So when combined with a data-driven tuning method like the distributed version of maximum marginal likelihood considered here, even the distributed methods that perform well in the non-adaptive setting loose their favourable properties. None of the methods yields a procedure that automatically adapts to regularity and achieves the optimal non-distributed rate. This does not imply of course that such an adaptive method does not exist. We expect however that the matter is delicate and that fundamental limitations exist.

The issue appears to be similar to that of the existence of adaptive confidence sets. To achieve adaptation in our distributed setting the local machines must be able to learn the "global" regularity of the signal from the limited local data that they have available. Analogous to the adaptive confidence problem we expect that this is in general only possible under additional assumptions on the true signal, like the self-similarity or polished tail conditions proposed for instance in Giné and Nickl (2010), Bull (2012), Szabó et al. (2015), Nickl and Szabó (2016), Belitser et al. (2017). Making these admittedly somewhat loose claims mathematically precise takes considerably more effort. Recent work shows that in a distributed setting with communication restrictions, some degree of adaptation to smoothness is in principle possible, but requires different kinds of algorithms (see Szabo and van Zanten (2019)). Many open questions remain at the moment however. It is for instance unclear how the possibility of adaptation, or purely data-driven tuning, is related the degree of communication or the amount of central computation allowed. It would in particular be interesting to better understand the theoretical performance of distributed methods which allow multiple rounds of communication (e.g. Shamir et al. (2014), Heinze et al. (2016), Wang et al. (2017a,b), Lu et al. (2016)).

Appendix A. Proofs for Section 3

A.1. Proof of Theorem 1

By completing the square we see that under the local posterior $\Pi^j(\cdot\,|\,\mathbf{Y}^j)$ the coefficients θ_i are independent and Gaussian, with mean $\hat\theta_i^j$ and variance s_i^2 given by

$$\hat\theta_i^j = \frac{n}{n+\sigma^2 m i^{1+2\beta}} Y_i^j, \qquad s_i^2 = \frac{\sigma^2 m}{n+\sigma^2 m i^{1+2\beta}}.$$

Hence the global "posterior" $\mathbf{\Pi}_I(\cdot\,|\,\mathbf{Y})$ is Gaussian as well, and under that measure the coefficients θ_i are independent and have mean $\hat\theta_i$ and variance t_i^2 given by

$$\hat\theta_i = \frac{1}{m}\sum_{j=1}^m \hat\theta_i^j, \qquad t_i^2 = \frac{s_i^2}{m}.$$

For the global posterior mean we have, for every $\theta_0 \in \ell^2$,

$$\mathrm{E}_{\theta_0}\hat\theta_i - \theta_{0,i} = \frac{-\sigma^2 m i^{1+2\beta}}{n+\sigma^2 m i^{1+2\beta}}\theta_{0,i}, \qquad \mathrm{Var}_{\theta_0}\hat\theta_i = \frac{\sigma^2 n}{(n+\sigma^2 m i^{1+2\beta})^2},$$

and hence,

$$\mathrm{E}_{\theta_0}\|\hat\theta-\theta_0\|_2^2 = \sum \frac{\sigma^4 m^2 i^{2+4\beta}}{(n+\sigma^2 m i^{1+2\beta})^2}\theta_{0,i}^2 + \sum \frac{\sigma^2 n}{(n+\sigma^2 m i^{1+2\beta})^2}.$$

By Lemma 9 the second, variance term is of the order

$$m^{-1/(1+2\beta))} n^{-2\beta/(1+2\beta)},$$

as $n/m \to \infty$. For $\theta_{0,i}^2 = M i^{-1-2\beta}$, by the same lemma, the first, squared bias term is proportional to $(n/m)^{-2\beta/(1+2\beta)}$. For the global spread, again in view of Lemma 9, we have

$$\sum t_i^2 = \sum \frac{\sigma^2}{n+\sigma^2 m i^{1+2\beta}} \asymp m^{-1/(1+2\beta))} n^{-2\beta/(1+2\beta)}. \tag{A.1}$$

By the triangle inequality we have

$$\begin{aligned}&\mathbf{\Pi}_I(\|\theta-\theta_0\|_2 \le c m^{\frac{\beta}{1+2\beta}} n^{-\frac{\beta}{1+2\beta}}\,|\mathbf{Y})\\ &\le \mathbf{\Pi}_I(\theta:\ \|\mathrm{E}_{\theta_0}\hat\theta-\theta_0\|_2 - c m^{\frac{\beta}{1+2\beta}} n^{-\frac{\beta}{1+2\beta}} - \|\hat\theta-\mathrm{E}_{\theta_0}\hat\theta\|_2 \le \|\theta-\hat\theta\|_2|\mathbf{Y}).\end{aligned}$$

It follows from the bounds on the variance and squared bias of the posterior mean that for θ_0 as chosen above, the quantity

$$\|\mathrm{E}_{\theta_0}\hat\theta-\theta_0\|_2 - c m^{\frac{\beta}{1+2\beta}} n^{-\frac{\beta}{1+2\beta}} - \|\hat\theta-\mathrm{E}_{\theta_0}\hat\theta\|_2$$

appearing in the posterior probability is with P_{θ_0}-probability tending to one bounded from below by $c m^{\frac{\beta}{1+2\beta}} n^{-\frac{\beta}{1+2\beta}}$ for $c>0$ small enough. Then by the upper bound for the posterior spread and Chebyshev's inequality we obtain the first statement of the theorem.

For the coverage we note that the radius r_γ of the credible set is a multiple of $m^{-1/(2+4\beta)} n^{-\beta/(1+2\beta)}$, which follows from the Gaussianity of the posterior and (A.1). Then by similar computations as above we get that for the same truth θ_0,

$$\begin{aligned}\mathrm{P}_{\theta_0}(\theta_0 \in \hat C(L)) &= \mathrm{P}_{\theta_0}(\|\hat\theta-\theta_0\|_2 \le L r_\gamma)\\ &\le \mathrm{P}_{\theta_0}\big(\|\hat\theta-\mathrm{E}_{\theta_0}\hat\theta\|_2 \ge \|\mathrm{E}_{\theta_0}\hat\theta-\theta_0\|_2 - L r_\gamma\big)\\ &\le \mathrm{P}_{\theta_0}\big(\|\hat\theta-\mathrm{E}_{\theta_0}\hat\theta\|_2 \ge c m^{\frac{\beta}{1+2\beta}} n^{-\frac{\beta}{1+2\beta}}\big)\\ &\lesssim m^{\frac{-2\beta}{1+2\beta}} n^{\frac{2\beta}{1+2\beta}} \mathrm{E}_{\theta_0}\|\hat\theta-\mathrm{E}_{\theta_0}\hat\theta\|_2^2 \lesssim m^{-1} \to 0.\end{aligned}$$

This completes the proof of the theorem.

A.2. Proof of Theorem 2

Raising the local likelihood (3.4) to the power m makes it proportional to

$$\prod e^{-\frac{1}{2}\frac{n(Y_i^j-\theta_i)^2}{\sigma^2}},$$

which is the likelihood for the case $m=1$. It follows that under the generalized local posterior $\tilde\Pi^j(\cdot\,|\,\mathbf{Y}^j)$ the coefficients θ_i are independent and Gaussian, with mean $\hat\theta_i^j$ and variance s_i^2 given by

$$\hat\theta_i^j = \frac{n}{n+\sigma^2 i^{1+2\beta}} Y_i^j, \qquad s_i^2 = \frac{\sigma^2}{n+\sigma^2 i^{1+2\beta}}.$$

Hence the global "posterior" $\mathbf{\Pi}_{II}(\cdot\,|\,\mathbf{Y})$ is again Gaussian, and under this global measure the coefficients θ_i are independent and have mean $\hat\theta_i$ and variance t_i^2 given by

$$\hat\theta_i = \frac{1}{m}\sum_{j=1}^m \hat\theta_i^j, \qquad t_i^2 = \frac{s_i^2}{m}.$$

For the global posterior mean we have in this case, for every $\theta_0 \in \ell^2$,

$$\mathrm{E}_{\theta_0}\hat\theta_i - \theta_{0,i} = \frac{-\sigma^2 i^{1+2\beta}}{n+\sigma^2 i^{1+2\beta}}\theta_{0,i}, \qquad \mathrm{Var}_{\theta_0}\hat\theta_i = \frac{\sigma^2 n}{(n+\sigma^2 i^{1+2\beta})^2},$$

and hence,

$$\mathrm{E}_{\theta_0}\|\hat\theta-\theta_0\|_2^2 = \sum \frac{\sigma^4 i^{2+4\beta}}{(n+\sigma^2 i^{1+2\beta})^2}\theta_{0,i}^2 + \sum \frac{\sigma^2 n}{(n+\sigma^2 i^{1+2\beta})^2}.$$

For all $\theta_0 \in H^\beta(M)$, in view of Lemma 9, the squared bias term is bounded by

$$M^2 \sum \frac{\sigma^4 i^{1+2\beta}}{(n+\sigma^2 i^{1+2\beta})^2} \lesssim M^2 n^{-2\beta/(1+2\beta)}$$

for large n, and the variance term behaves like a constant times $n^{-2\beta/(1+2\beta)}$ as well. The global spread $\sum t_i^2$ is of the order $m^{-1} n^{-2\beta/(1+2\beta)}$ for large n, again following from Lemma 9.

For $M_n \to \infty$ and $\theta_0 \in H^\beta(M)$ we now have, by the triangle inequality,

$$\begin{aligned}&\mathbf{\Pi}_{II}(\theta:\ \|\theta-\theta_0\|_2 \geq M_n n^{-\beta/(1+2\beta)} \,|\, \mathbf{Y})\\ &\leq \mathbf{\Pi}_{II}(\theta:\ \|\theta-\hat\theta\|_2 \geq M_n n^{-\beta/(1+2\beta)} - \|\hat\theta - \mathrm{E}_{\theta_0}\hat\theta\|_2 - \|\theta_0 - \mathrm{E}_{\theta_0}\hat\theta\|_2 \,|\, \mathbf{Y}).\end{aligned}$$

By the bounds on the bias and the variance of the posterior mean derived above the quantity on the right of the inequality in the last posterior probability is bounded from below by $(M_n/2)n^{-\beta/(1+2\beta)}$ with P_{θ_0}-probability tending to one as $n, m \to \infty$, uniformly in $\theta_0 \in H^\beta(M)$. By Chebychev's inequality, and the bound on the posterior spread, we conclude that the first statement of the theorem holds.

For the second statement we first note that by Chebychev's inequality and by the upper bound on the posterior spread the radius r_γ of the credible set is for large n bounded by $Cm^{-1/2}n^{-\beta/(1+2\beta)}$ for some $C > 0$. Hence, since the posterior mean is Gaussian and the Gaussian measure of a ball of a fixed size is maximal if the ball is centered at the mean (a consequence of Anderson's inequality, e.g. Lifshits (1995), Section 11), we have

$$\begin{aligned}\mathrm{P}_{\theta_0}\big(\theta_0 \in \hat C(L)\big) &\leq \mathrm{P}_{\theta_0}\big(\|\hat\theta - \theta_0\|_2 \leq CLm^{-1/2}n^{-\beta/(1+2\beta)}\big)\\ &\leq \mathrm{P}_{\theta_0}\big(\|\hat\theta - \mathrm{E}_{\theta_0}\hat\theta\|_2 \leq CLm^{-1/2}n^{-\beta/(1+2\beta)}\big).\end{aligned}$$

By Chebychev's inequality,

$$\mathrm{P}_{\theta_0}\big(\|\hat\theta - \mathrm{E}_{\theta_0}\hat\theta\|_2^2 \leq \sum \sigma_i^2 - a\sqrt{2\sum \sigma_i^4}\big) \leq \frac{1}{a^2}$$

for all $a > 0$, where $\sigma_i^2 = \mathrm{Var}_{\theta_0}\hat\theta_i$. Above we saw that $\sum \sigma_i^2 \asymp n^{-2\beta/(1+2\beta)}$. Similarly, it is easily seen that $\sum \sigma_i^4 \asymp n^{(-1-4\beta)/(1+2\beta)}$. Hence by taking $a = n^{(1/4)/(1+2\beta)}$, for instance, we see that for $c > 0$ small enough,

$$\mathrm{P}_{\theta_0}\big(\|\hat\theta - \mathrm{E}_{\theta_0}\hat\theta\|_2 \leq cn^{-\beta/(1+2\beta)}\big) \to 0$$

as $n \to \infty$. But then also

$$\mathrm{P}_{\theta_0}\big(\|\hat\theta - \mathrm{E}_{\theta_0}\hat\theta\|_2 \leq CLm^{-1/2}n^{-\beta/(1+2\beta)}\big) \to 0$$

as $m, n \to \infty$.

A.3. Proof of Theorem 3

In this case the jth local posterior is a product of Gaussians with means and variances given by

$$\hat\theta_i^j = \frac{n}{n + \sigma^2 m\tau^{-1}i^{1+2\alpha}}Y_i^j, \qquad s_i^2 = \frac{\sigma^2 m}{n + \sigma^2 m\tau^{-1}i^{1+2\alpha}}.$$

As before the global "posterior" is Gaussian as well, and under that measure the coefficients θ_i are independent and have mean $\hat\theta_i$ and variance t_i^2 given by

$$\hat\theta_i = \frac{1}{m}\sum_{j=1}^m \hat\theta_i^j, \qquad t_i^2 = \frac{s_i^2}{m}.$$

For the global posterior mean we have, for every $\theta_0 \in \ell^2$,

$$\mathrm{E}_{\theta_0}\hat\theta_i - \theta_{0,i} = \frac{-\sigma^2 m\tau^{-1}i^{1+2\alpha}}{n + \sigma^2 m\tau^{-1}i^{1+2\alpha}}\theta_{0,i}, \qquad \mathrm{Var}_{\theta_0}\hat\theta_i = \frac{\sigma^2 n}{(n + \sigma^2 m\tau^{-1}i^{1+2\alpha})^2},$$

and hence

$$\mathrm{E}_{\theta_0}\|\hat\theta - \theta_0\|_2^2 = \sum \frac{\sigma^4 m^2\tau^{-2}i^{2+4\alpha}}{(n + \sigma^2 m\tau^{-1}i^{1+2\alpha})^2}\theta_{0,i}^2 + \sum \frac{\sigma^2 n}{(n + \sigma^2 m\tau^{-1}i^{1+2\alpha})^2}.$$

Then in view of Lemma 9, we see that for $\beta < 1 + 2\alpha$ and uniformly for $\theta_0 \in H^\beta(M)$, the squared bias term is bounded by a constant times

$$M^2(\tau n/m)^{-2\beta/(1+2\alpha)}.$$

Similarly, the variance term and the posterior spread $\sum t_i^2$ both behave like a constant times

$$(\tau/m)^{1/(1+2\alpha)}n^{-2\alpha/(1+2\alpha)}$$

as $n \to \infty$. The choice $\tau = mn^{2(\alpha-\beta)/(1+2\beta)}$ balances these quantities, so that all three are of the order $n^{-2\beta/(1+2\beta)}$.

By exactly the same reasoning as in Section A.2, the fact that the squared bias bound and the variance and spread are of the same order implies the first statement of the theorem. For the coverage statement we first note that the squared credible set radius r_γ^2 is the $1-\gamma$ quantile of the distribution of $\sum t_i^2 Z_i^2$, with t_i^2 as above and Z_i independent standard normals. This distribution has mean $\sum t_i^2 \asymp n^{-2\beta/(1+2\beta)}$ and variance

$$2\sum t_i^4 \asymp \frac{1}{n}n^{-2\beta/(1+2\beta)},$$

following from Lemma 9. As the standard deviation is of smaller order than the mean, it follows from Chebychev's inequality that $r_\gamma \geq cn^{-\beta/(1+2\beta)}$ for some $c > 0$. For the coverage probability we then have

$$\mathrm{P}_{\theta_0}\Big(\theta_0 \notin \hat C(L)\Big) \leq \mathrm{P}_{\theta_0}\Big(\|\hat\theta - \theta_0\|_2 \geq cLn^{-\beta/(1+2\beta)}\Big) \leq \frac{n^{2\beta/(1+2\beta)}}{c^2L^2}\mathrm{E}_{\theta_0}\|\hat\theta - \theta_0\|_2^2.$$

By the bounds on the bias and variance of the posterior mean the right-hand side is smaller than γ for L large enough, uniformly for $\theta_0 \in H^\beta(L)$.

A.4. Proof of Theorem 4

As we saw in Section A.2, the jth local generalized posterior is a product of Gaussians with means $\hat\theta_i^j$ and variances s_i^2 given by

$$\hat\theta_i^j = \frac{n}{n + \sigma^2 i^{1+2\beta}}Y_i^j, \qquad s_i^2 = \frac{\sigma^2}{n + \sigma^2 i^{1+2\beta}}.$$

In other words, the jth local measure is a Gaussian measure on ℓ^2 with mean $\hat\theta^j = (\hat\theta_i^j)_i$ and (diagonal) covariance operator $R : \ell^2 \to \ell^2$ given by $(Rx)_i = s_i^2 x_i$, which is the same for

every local machine. The Wasserstein barycenter of a finite collection of Gaussian measures is a Gaussian measure again (e.g. Agueh and Carlier (2011)). By Theorem 3.5 of Gelbrich (1990) the squared 2-Wasserstein distance between the jth local measure and a Gaussian measure on ℓ^2 with mean μ and covariance operator K is given by

$$\|\hat\theta^j-\mu\|_2^2+\mathrm{tr}(R)+\mathrm{tr}(K)-2\mathrm{tr}\sqrt{R^{1/2}KR^{1/2}}.$$

It follows that the barycenter $\mathbf{\Pi}_{IV}(\cdot\,|\,\mathbf{Y})$ of the local generalized posteriors is the Gaussian measure on ℓ^2 with mean $\hat\theta$ equal to the average of the local means $\hat\theta^j$ and covariance operator equal to R. In other words, the global "posterior" is a product of Gaussians with means and variances given by

$$\hat\theta_i=\frac{1}{m}\sum_{j=1}^m\hat\theta_i^j,\qquad t_i^2=s_i^2.$$

So the global posterior mean is the same as in Section A.2 and the posterior spread $\sum t_i^2$ is a factor m larger. It then follows from the considerations in Section A.2 that the squared bias of the global posterior mean is bounded by a constant times $M^2n^{-2\beta/(1+2\beta)}$, uniformly for $\theta_0\in H^\beta(M)$. Moreover, the variance term $\sum s_i^2$ and the posterior spread $\sum t_i^2$ behave like a multiple of $n^{-2\beta/(1+2\beta)}$ as well. As was explained in Section A.3, this leads to the statement of the theorem.

A.5. Proof of Theorem 6

The proof of the first statement is the same as in Section A.1, since the mean of the global "posterior" is the same as for the naive averaging method.

For the second statement, we observe that for $\theta_0\in H^\beta(M)$, the squared bias term for the posterior mean satisfies

$$\sum\frac{\sigma^4m^2i^{2+4\beta}}{(n+\sigma^2mi^{1+2\beta})^2}\theta_{0,i}^2\le M^2\sum\frac{\sigma^4m^2i^{1+2\beta}}{(n+\sigma^2mi^{1+2\beta})^2}\lesssim M^2(n/m)^{-2\beta/(1+2\beta)}.$$

for $n/m\to\infty$. As was shown in Section A.1 the variance of the posterior mean behaves as $m^{-1/(1+2\beta)}n^{-2\beta/(1+2\beta)}$. Since the spread $\sum t_i^2$ of the posterior is a factor m larger than in Section A.1, it is of the same order $(n/m)^{-2\beta/(1+2\beta)}$ as the squared bias term. Since squared bias and spread are of the same order, the variance is of smaller order, and

$$\sqrt{\sum t_i^4}\asymp\Big(\frac{n}{m}\Big)^{\frac{-1/2}{1+2\beta}}\sum t_i^2$$

is of lower order than $\sum t_i^2$, the coverage statement can be proved as in Section A.3.

A.6. Technical Lemma

Lemma 9 *For $s,t>0$ with $st>1$ and $r<st-1$ consider the function $f(x)=x^r(x^s+1)^{-t}$ and set $f_\nu=\sum_{k=1}^\infty\nu^{-1}f(k/\nu)$. Then as $\nu\to\infty$,*

(i) If $r>-1$, then $f_\nu\asymp\int_0^\infty f(x)dx$.

(ii) If $r=-1$, then $f_\nu\asymp\log\nu$.

(iii) If $r<-1$, then $f_\nu\asymp\nu^{r-1}\sum_{k=1}^\infty k^{-r}$.

Proof Assertions (ii) and (iii), along with (i) for $-1<r\le0$ are proved in Lemma A.1 of Szabó et al. (2013), hence it remains to verify assertion (i) for $0<r<st-1$. Note that

$$\sum_{k=1}^{N\nu}\nu^{-1}f(k/\nu)<f_\nu<\sum_{k=1}^{N\nu}\nu^{-1}f(k/\nu)+\sum_{k=N\nu+1}^{\infty}\nu^{-1}f(k/\nu).\tag{A.2}$$

Since the function $f(x)$ is continuous on $[0,N]$ it is Riemann integrable (see for instance Theorem 6.8 of Rudin (1976)), hence the right Riemann sum converges to the integral, i.e. $\sum_{k=1}^{N\nu}\nu^{-1}f(k/\nu)\to\int_0^Nf(x)dx$ as $\nu\to\infty$ (for simplicity assume that $\nu\in\mathbb{N}$). Furthermore, for every $\nu>0$,

$$\sum_{k=N\nu+1}^{\infty}\nu^{-1}f(k/\nu)\le\nu^{st-r-1}\sum_{k=N\nu+1}^{\infty}k^{r-st}\le\nu^{st-r-1}\int_{N\nu}^\infty x^{r-st}dx\le\frac{1}{st-r-1}N^{r+1-st}$$

and $\int_{N+1}^\infty f(x)dx\le\int_{N+1}^\infty x^{r-st}dx\le N^{-st+r+1}/(st-r-1)$. Therefore by choosing N sufficiently large, both sides of (A.2) gets arbitrarily close to $\int_0^\infty f(x)dx$ as $\nu\to\infty$, concluding the proof of the statement. ∎

Appendix B. Proofs for Section 4

B.1. Proof of Lemma 7

The estimator $\hat\alpha$ is the maximizer of the random map $\alpha\mapsto\sum_j\ell_j(\alpha)$, where

$$\ell_j(\alpha)=\log\int p(\mathbf{Y}^j\,|\,\theta)\,\Pi(d\theta\,|\,\alpha).$$

The asymptotic behaviour of the local log-marginal likelihood ℓ_j has been studied in Knapik et al. (2016). Denote the derivative of ℓ_j with respect to α by $\dot\ell_j$ and let $k=n/(\sigma^2m)$ be the local "sample size". Moreover, for $l>0$, define

$$\underline\alpha=\inf\{\alpha>0:h_k(\alpha)>l\}\wedge\sqrt{\log k},$$

where

$$h_k(\alpha)=\frac{1+2\alpha}{k^{1/(1+2\alpha)}\log k}\sum_i\frac{k^2i^{1+2\alpha}\theta_{0,i}^2\log i}{(k+i^{1+2\alpha})^2}.$$

Note that the expectation $\mathrm{E}_{\theta_0}\dot\ell_j(\alpha)$ does not depend on j. It is proved in Section 5.3 of Knapik et al. (2016) that if l is smaller than some universal threshold, then for every j

$$\liminf_{k\to\infty}\inf_{\alpha\le\underline\alpha}\frac{1+2\alpha}{k^{1/(1+2\alpha)}\log k}\mathrm{E}_{\theta_0}\dot\ell_j(\alpha)=\delta>0,$$

$$\mathrm{E}_{\theta_0} \sup_{\alpha \le \underline{\alpha}} \frac{1+2\alpha}{k^{1/(1+2\alpha)} \log k} |\dot{\ell}_j(\alpha) - \mathrm{E}_{\theta_0} \dot{\ell}_j(\alpha)| \lesssim e^{-C\sqrt{\log k}}$$

for constants $\delta, C > 0$. But then we also have

$$\liminf_{k\to\infty} \inf_{\alpha \le \underline{\alpha}} \frac{1+2\alpha}{k^{1/(1+2\alpha)} \log k} \mathrm{E}_{\theta_0} \sum_j \dot{\ell}_j(\alpha) > m\delta$$

and

$$\mathrm{E}_{\theta_0} \sup_{\alpha \le \underline{\alpha}} \frac{1+2\alpha}{k^{1/(1+2\alpha)} \log k} \Big| \sum_j \dot{\ell}_j(\alpha) - \mathrm{E}_{\theta_0} \sum_j \dot{\ell}_j(\alpha) \Big| \lesssim m e^{-C\sqrt{\log k}}.$$

By Markov's inequality, it follows that with probability at least $1 - C_1 \exp(-C_2\sqrt{\log k})$ the map $\alpha \mapsto \sum_j \ell_j(\alpha)$ is strictly increasing on the interval $[0, \underline{\alpha}]$. Hence, on that event we have $\hat{\alpha} \ge \underline{\alpha}$.

It remains to show that $\underline{\alpha} \ge \beta + 1/2$. To that end it suffices to prove that $h_k(\alpha) \le l$ for all $\alpha \le \beta + 1/2$. To see this, suppose first that $\alpha < \beta$. Define $N_\beta = (n/(\sigma^2\sqrt{m}))^{1/(1+2\beta)}$ and $M_\alpha = k^{1/(1+2\alpha)}$. By definition of θ_0 we then have

$$\begin{aligned}
h_k(\alpha) &= \frac{M^2}{M_\alpha \log M_\alpha} \sum_{i=N_\beta}^{\infty} \frac{k^2 i^{2\alpha-2\beta} \log i}{(i^{1+2\alpha}+k)^2} \\
&\le \frac{M^2}{M_\alpha \log M_\alpha} \sum_{i=N_\beta}^{M_\alpha} i^{2\alpha-2\beta} \log i + \frac{M^2 k^2}{M_\alpha \log M_\alpha} \sum_{i=M_\alpha}^{\infty} i^{-2-2\alpha-2\beta} \log i \\
&\le M^2 \frac{M_\alpha N_\beta^{2\alpha-2\beta} \log M_\alpha}{M_\alpha \log M_\alpha} + M^2 \frac{k^2 M_\alpha^{-1-2\alpha-2\beta} \log M_\alpha}{M_\alpha \log M_\alpha} \\
&\lesssim M^2
\end{aligned}$$

for n, m large enough. Hence, if M is small enough, then $h_k \le l$ for $\alpha < \beta$. For $\beta \le \alpha \le \beta + 1/2$ we have

$$\begin{aligned}
h_k(\alpha) &\le \frac{M^2 k^2}{M_\alpha \log M_\alpha} \sum_{i=N_\beta}^{\infty} i^{-2-2\alpha-2\beta} \log i \\
&\le \frac{M^2 k^2 N_\beta^{-1-2\alpha-2\beta} \log N_\beta}{M_\alpha \log M_\alpha} \\
&= M^2 (n/\sigma^2)^{\frac{2\alpha}{1+2\alpha} - \frac{2\alpha}{1+2\beta}} m^{-2+\frac{1}{1+2\alpha}+\frac{1+2\alpha+2\beta}{2(1+2\beta)}} \frac{\log N_\beta}{\log M_\alpha} \lesssim m^{-\frac{2\alpha}{1+2\alpha}} \log m
\end{aligned}$$

for n/m large enough. Together, this shows that if both n/m and m are large enough, then indeed $h_k(\alpha) \le l$ for all $\alpha \le \beta + 1/2$.

B.2. Proof of Theorem 8

In view of the proof of Theorem 4 the jth local generalized posterior is a product of Gaussians with means $\hat{\theta}_i^j$ and variances s_i^2 given by

$$\hat{\theta}_i^j = \frac{n}{n + \sigma^2 i^{1+2\hat{\alpha}}} Y_i^j, \qquad s_i^2 = \frac{\sigma^2}{n + \sigma^2 i^{1+2\hat{\alpha}}}.$$

Using again that the Wasserstein barycenter of a finite collection of Gaussian measures is a Gaussian measure in combination with the explicit expression for the 2-Wasserstein distance between Gaussians (see Section A.4) we see that the global "posterior" is a product of Gaussians with means $\hat{\theta}_i$ and variances t_i^2 given by

$$\hat{\theta}_i = \frac{1}{m} \sum_{j=1}^m \hat{\theta}_i^j, \qquad t_i^2 = s_i^2.$$

The posterior mean can be written as $\hat{\theta} = \hat{\theta}(\hat{\alpha})$, where $\hat{\theta}(\alpha)$ is the estimator with a fixed choice α for the hyperparameter, i.e.

$$\hat{\theta}_i(\alpha) = \frac{1}{m} \sum_{j=1}^m \frac{n}{n + \sigma^2 i^{1+2\alpha}} Y_i^j.$$

For fixed α we also define the corresponding expectation $E(\alpha) = \mathrm{E}_{\theta_0} \hat{\theta}(\alpha)$. Then by the triangle inequality,

$$\|\hat{\theta} - \theta_0\|_2 \ge \|E(\hat{\alpha}) - \theta_0\|_2 - \|E(\hat{\alpha}) - \hat{\theta}(\hat{\alpha})\|_2.$$

We have the explicit expressions

$$\|E(\alpha) - \theta_0\|_2^2 = \sum_i \frac{\sigma^4 i^{2+4\alpha} \theta_{0,i}^2}{(n + \sigma^2 i^{1+2\alpha})^2}$$

and

$$\|E(\alpha) - \hat{\theta}(\alpha)\|_2^2 = \sum_i \frac{\sigma^2 n}{(n + \sigma^2 i^{1+2\alpha})^2} \Big(\frac{1}{\sqrt{m}} \sum_{j=1}^m Z_i^j \Big)^2.$$

Since the first expression is increasing in α and the second one is decreasing, we see that on the event $A = \{\hat{\alpha} \ge \beta + 1/2\}$ it holds that

$$\|\hat{\theta} - \theta_0\|_2 \ge \sqrt{\sum_i \frac{\sigma^4 \theta_{0,i}^2 i^{4+4\beta}}{(n + \sigma^2 i^{2+2\beta})^2}} - \sqrt{\sum_i \frac{\sigma^2 n}{(n + \sigma^2 i^{2+2\beta})^2} \Big(\frac{1}{\sqrt{m}} \sum_{j=1}^m Z_i^j \Big)^2}.$$

By definition of θ_0, the square of the first term on the right is bounded from below by

$$M^2 \sum_{i \ge \left((n/(\sigma^2\sqrt{m}))\right)^{1/(1+2\beta)}} \frac{\sigma^4 i^{3+2\beta}}{(n + \sigma^2 i^{2+2\beta})^2}.$$

In view of Lemma 9 we see that it is of the order $M^2 (n/\sqrt{m})^{-2\beta/(1+2\beta)}$. The square of the second term can be written as

$$\sum_i \frac{\sigma^2 n}{(n + \sigma^2 i^{2+2\beta})^2} U_i^2,$$

with the U_i independent and standard normal under P_{θ_0}. Again in view of Lemma 9 it is easily seen that the mean and variance of this sum behave as $n^{-(1+2\beta)/(2+2\beta)}$ and $n^{-(3+4\beta)/(2+2\beta)}$, respectively. Hence the standard deviation is of smaller order than the mean for large n, so that by Chebychev's inequality the square of the second term is of stochastic order $n^{-(1+2\beta)/(2+2\beta)}$. Since this is of smaller order than $(n/\sqrt{m})^{-2\beta/(1+2\beta)}$, we conclude that for the global "posterior" mean we have, for some constant $c > 0$,

$$\mathrm{P}_{\theta_0}(\|\hat{\theta} - \theta_0\|_2 \geq c(n/\sqrt{m})^{-\beta/(1+2\beta)}) \to 1$$

as $n/m \to \infty$ and $m \to \infty$. The spread $\sum t_i^2$ of the global posterior is on the event A bounded by

$$\sum_i \frac{1}{n + i^{2+2\beta}},$$

which is of the order $n^{-(1+2\beta)/(2+2\beta)} \ll (n/\sqrt{m})^{-2\beta/(1+2\beta)}$ as well, see Lemma 9. The conclusions of the theorem now follow.

Abstract

We derive an objective function that can be optimized to give an estimator for the Vapnik-Chervonenkis dimension for use in model selection in regression problems. We verify our estimator is consistent. Then, we verify it performs well compared to seven other model selection techniques. We do this for a variety of types of data sets.

Keywords: Vapnik-Chervonenkis dimension, model selection, Bayesian information criterion, sparsity methods, empirical risk minimization, multi-type data.

1. Complexity and Model Selection

Model selection is often the first problem that must be addressed when analyzing data. In M-closed problems, see Bernardo and Smith (2000), the analyst posits a list of models and assumes one of them is true. In such cases, model selection is any procedure that uses data to identify one of the models on the model list. There is a vast literature on model selection in this context including information based methods such as the Aikaikie Information Criterion (AIC), the Bayes information criterion (BIC), residual based methods such as Mallows C_p or branch and bound, and code length methods such as the two-stage coding proposed by Barron and Cover (1991). We also have computational search methods such as simulated annealing and genetic algorithms. In addition, cross-validation (CV) is often used with non-parametric methods such as recursive partitioning, neural networks (aka deep learning) and kernel methods. A less well developed approach to model selection is via complexity as assessed by the Vapnik-Chervonenkis (VC) dimension, here denoted by d_{VC}. Its earliest usage seems to be in Vapnik and Chervonenkis (1968). A translation into English was published as Vapnik and Chervonenkis (1971).

Although, the VC dimension goes back to 1968, it wasn't until Vapnik et al. (1994) that a method for estimating d_{VC} was proposed in the classification context. Specifically, given a collection $\mathbb{C}$ of classifiers, Vapnik et al. (1994) tried to estimate the VC dimension of $\mathbb{C}$ by deriving an objective function based on the expected value of the maximum difference between two empirical evaluations of a single loss function, here denoted by Δ. The two empirical values come from dividing a given data set into a first and second part. The objective function proposed by Vapnik et al. (1994) depends on d_{VC}, the sample size n, and several constants that had to be determined. Using their objective function, they derived an estimator $\hat{d}_{VC}$ for d_{VC} given a class $\mathbb{C}$ of classifiers. This algorithm treated possible sample sizes as design points $n_1, n_2, \cdots, n_L$ and requires one level of bootstrapping. Despite the remarkable contribution of Vapnik et al. (1994), the objective function was over-complex and the algorithm did not give a tight enough bound on Δ. Later, Vapnik and his collaborators suggested a fix to tighten the bound on Δ. We do not use this here; it is unclear if this 'fix' will work in classification, let alone regression.

Choosing the design points is a nontrivial source of variability in the estimate of d_{VC}. So, Shao et al. (2000) proposed an algorithm, based on extensive simulations, to generate optimal values of $n_1, n_2, \cdots, n_L$, given L. They argued that non-uniform values of the n_l's gave better results than the uniform n_l's used in Vapnik et al. (1994).

More recently, in a pioneering paper that deserves more recognition that it has received, McDonald et al. (2011) established the consistency of the Vapnik (1998) estimator $\hat{d}_{VC}$ for d_{VC} in the classification context.

The main reason the estimator for d_{VC} of Vapnik et al. (1994) did not become more widely used, despite the result in McDonald et al. (2011), is, we suggest, that it was too unstable because the objective function did not bound Δ tightly enough in terms of d_{VC}. In addition, the form of the objective function in Vapnik et al. (1994) is more complicated and less well-motivated than our result Theorem 2. The reason is that the derivation in Vapnik et al. (1994) uses conditional probabilities, one of which goes to zero quite quickly (with n). So, it contributes negligibly to the upper bound. Our derivation ignores the conditioning and bounds a CV form of Δ that is typically larger than that used in Vapnik et al. (1994).

Our consistency proof is a simplification of the proof of the main result McDonald et al. (2011). Accordingly, we obtain a slower rate of consistency, but the probability of correct model selection still goes to one.

Our overall strategy is to derive an objective function for estimating d_{VC} in the regression setting that provides, we think, a tighter bound on a modified form of Δ. To convert from classification to regression, we discretize the loss used for regression into m intervals (the case $m = 1$ would then apply to classification). To get a tighter bound, we change the form of Δ from what Vapnik et al. (1994) used and we optimize over the leading factor in our upper bound. To use our estimator, we use an extra layer of bootstrapping so the quantity we empirically optimize represents the quantity we derive theoretically more accurately. The extra layer of bootstrapping stabilizes our estimator of d_{VC} and appears to reduce its dependency on the n_l's. If the models are nested in order of increasing VC dimension, it is straightforward to choose the model with VC dimension closest to our estimate $\hat{d}_{VC}$. Otherwise, we can convert a non-nested problem to the nested case by ordering the inclusion of the covariates using a shrinkage method such as the 'smoothly clipped absolute deviation' (SCAD, Fan and Li (2001)), or correlation (see Fan and Lv (2008)), and use our $\hat{d}_{VC}$ as before. Even when we force a model list to be nested, our model selection method performs well compared to a range of competitors including Vapnik et al. (1994)'s original method, two forms of penalized empirical risk minimization (denoted $\widehat{PERM}_1$ and $\widehat{PERM}_2$), AIC, BIC, CV (10-fold), SCAD, and adaptive LASSO (ALASSO, Zou (2006)). Our general findings indicate that in realistic settings, model selection via estimated VC dimension,

when properly done, is fully competitive with existing methods and, unlike them, rarely gives abberant results.

This manuscript is structured as follows. In Sec. 2 we present the main theory justifying our estimator. In Subsec. 2.1 we discretize bounded loss functions so that upper bounds for the distinct regions involved in the definition of Δ can be derived and in Subsec. 2.2 we define our estimator of the VC dimension and give an algorithm for how to compute it. In Sec. 3 we use McDonald et al. (2011)'s consistency theorem to motivate our consistency theorem for $\hat{d}_{VC}$. In Sec. 4 we present our studies using simulated, benchmark, and real data. We compare our method for model selection to AIC, BIC, CV, $\widehat{PERM}_1$, and $\widehat{PERM}_2$. In this context, we suggest criteria to guide the selection of design points. Our comparisons also include simplifying non-nested model lists by using correlation, SCAD, and ALASSO. In Sec. 5 we discuss our overall findings.

2. Deriving an optimality criterion for estimating VC dimension

This section concerns Δ, the expected supremal difference between two evaluations of a bounded loss function, formally defined in (18) and (19). These bounds will enable us to derive an estimator for the VC dimension. In Sec. 2.1, we present our alternative version of the Vapnik et al. (1994) bounds and in Sec. 2.2, we present our estimator of d_{VC}.

2.1. Extension of the Vapnik et al. (1994) bounds to regression

Let $Z = (X, Y)$ be a random variable with outcomes $z = (x, y)$ assuming values on $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$. The first entry, $X = x$, is regarded as an explanatory variable leading to $Y = y$. Let $P \in \mathcal{M}(\mathcal{Z})$ be the distribution of Z, where $\mathcal{M}(\mathcal{Z})$ is the collection of probability measures on $\mathcal{Z}$, and let $Z_{1:2n} = (Z_1, \ldots, Z_n, Z_{n+1}, \ldots, \ldots, Z_{2n})$ be a data set of size $2m$ of independently and identically distributed (IID) copies of Z. Write $D^1 = \{Z_1, \ldots, Z_n\}$ for the first half and $D^2 = \{Z_{n+1}, \ldots, Z_{2n}\}$ for the second half. Writing $Z_i = (X_i, Y_i)$ for $i = 1 \ldots 2n$, let

$$Q(Z_i, \alpha) = L(Y_i, f(X_i, \alpha)),$$

for a bounded real valued loss function L and $\alpha \in \Lambda$. We assume that Λ is a compact set in a finite dimensional real space, that the interior of Λ, $\mathrm{Int}(\Lambda)$, is non-void and convex, and that $\Lambda = \overline{\mathrm{Int}(\Lambda)}$. Also, we assume the continuous functions $f(\cdot \mid \alpha)$ are parametrized by α continuously and one-to-one. Thus, in our examples, Λ will be the parameter space for a class of regression functions $f(\cdot \mid \alpha)$. For ease of exposition we assume L, and hence Q, are also continuous.

For a fixed $\alpha \in \Lambda$, discretize $Q(z, \alpha)$ using m disjoint intervals (with union $[0, B)$):

$$Q^m(z, \alpha) = \sum_{j=0}^{m-1} \frac{(2j+1)B}{2m} \mathbb{I}\left[Q(Z, \alpha) \in I_j^m\right]. \tag{1}$$

The discretization is based on the uniform left-closed, right-open partition of $[0, B)$ into m subintervals, here denoted I_j^m and the numbers $((2j+1)B)/(2m)$ are the midpoints. In (1), $\mathbb{I}[\cdot]$ is an indicator function taking value 1 when its argument is true and value 0 when it is false. We use losses of the form (1) to define a cross-validation form for Δ.

Start by letting $\alpha_1, \alpha_2 \in \Lambda$, with $\alpha_1 \neq \alpha_2$, and let

$$\nu(D^2, \alpha_1) = \frac{1}{n} \sum_{i=1}^{n} Q(Z_{n+i}, \alpha_1) \quad \text{and} \quad \nu(D^1, \alpha_2) = \frac{1}{n} \sum_{i=1}^{n} Q(Z_i, \alpha_2). \tag{2}$$

These are the empirical risks of model α_1 on the second half of the data and of model α_2 on the first half of the sample, respectively. Observe that the empirical counts of the data points whose losses land in I_j^m are

$$N_j^m(D^2, \alpha_1) = \sum_{i=1}^{n} \mathbb{I}\left[Q(Z_{n+i}, \alpha_1) \in I_j^m\right] \quad \text{and} \quad N_j^m(D^1, \alpha_2) = \sum_{i=1}^{n} \mathbb{I}\left[Q(Z_i, \alpha_2) \in I_j^m\right]. \tag{3}$$

This means we are counting the errors of the α_1 model on the second half of the data and the erors of the α_2 model on the first half of the data. This begins the set up of the cross-validation form of the error that we use and leads to the following expressions for the empirical losses of the discretized loss functions:

$$\nu^m\left(D^2, \alpha_1\right) = \frac{1}{n} \sum_{j=0}^{m-1} N_j^m(D^2, \alpha_1) \frac{(2j+1)B}{2m}$$

$$\text{and} \quad \nu^m\left(D^1, \alpha_2\right) = \frac{1}{n} \sum_{j=0}^{m-1} N_j^m(D^1, \alpha_2) \frac{(2j+1)B}{2m}. \tag{4}$$

It is seen that the expressions in (4) are formed from the counts within each of the intervals. Let these be denoted by

$$\nu_j^m(D^2, \alpha_1) = \frac{1}{n} N_j^m(D^2, \alpha_1) \frac{(2j+1)B}{2m} \quad \text{and} \quad \nu_j^m(D^1, \alpha_2) = \frac{1}{n} N_j^m(D^1, \alpha_2) \frac{(2j+1)B}{2m}. \tag{5}$$

The first step in bounding Δ is to bound the probability of the 'bad set' where $\nu^m(D^2, \alpha_1)$ and $\nu^m(D^1, \alpha_2)$ are not close. Let $\epsilon > 0$ and, using the discretization into m intervals, define the set A_ϵ by the union:

$$A_\epsilon = \bigcup_{m=0}^{m-1} A_{\epsilon,m}, \tag{6}$$

where

$$A_{\epsilon,m} = \left\{ Z_{1:2n} \middle| \sup_{\alpha_1, \alpha_2 \in \Lambda} \left[\nu^m(Z_{n+1:2n}, \alpha_1) - \nu^m(Z_{1:n}, \alpha_2)\right] \geq \epsilon \right\}. \tag{7}$$

The only way a $Z_{1:2n} = z_{1:2n}$ can be in $A_{\epsilon,m}$ is that at least one value of j satisfies

$$\sup_{\alpha_1,\ \alpha_2 \in\ \Lambda} \left(\nu_j^m(z_{n+1:2n}, \alpha_1) - \nu_j^m(z_{1:n}, \alpha_2)\right) \geq \frac{\epsilon}{m}.$$

Since A_ϵ is defined on the entire range of our loss function, and we want to partition the range into m disjoint intervals, write

$$A_{\epsilon,m} \subseteq \{ Z_{1:2n} \mid \exists\ j \sup_{\alpha_1,\ \alpha_2 \in \Lambda} \left(\nu_j^m(Z_{n+1:2n}, \alpha_1) - \nu_j^m(Z_{1:n}, \alpha_2)\right) \geq \frac{\epsilon}{m} \} \subseteq \bigcup_{j=0}^{m-1} A_{\epsilon,m,j},$$

where $A_{\epsilon,m,j} = \{Z_{1:2n} \Big| \sup_{\alpha_1,\ \alpha_2 \in \Lambda} (\nu_j^m(Z_{n+1:2n}, \alpha_1) - \nu_j^m(Z_{1:n}, \alpha_2)) \geq \frac{\epsilon}{m}\}$.

Next, fix any value $j \in \{0, 1, \ldots, m-1\}$. For any fixed $z_{1:2n}$, and any given $\alpha_1, \alpha_2 \in \Lambda$, define the vector of length $2n$

$$(Q_j^m(z_{n+1}, \alpha_1), \ldots, Q_j^m(z_{2n}, \alpha_1), Q_j^m(z_1, \alpha_2), \ldots, Q_j^m(z_n, \alpha_2)), \tag{8}$$

where $Q_j^m(z, \alpha) = \mathbb{I}(Q(z, \alpha) \in I_j^m)$. Now define $(\alpha_1, \alpha_2) \sim (\alpha_1', \alpha_2')$ when the corresponding $2n$-tuples are equal (for the given $z_{1:2n}$). It is seen that $\sim$ is an equivalence relation on $\Lambda \times \Lambda$ and therefore partitions $\Lambda \times \Lambda$ into disjoint equivalence classes. Let $K_j = K_j(z_{1:2n})$ be the number of equivalence classes for given j and $z_{1:2n}$ and for given $(\alpha_1, \alpha_2) \in \Lambda \times \Lambda$, write $[(\alpha_1, \alpha_2)]$ for the equivalence class that contains it. Now, for $k = 1 \ldots, K_j$ let

$$\left(\alpha_{1jk}^*, \alpha_{2jk}^*\right) = \arg \sup_{\alpha_1, \alpha_2 \in (\Lambda \times \Lambda)_k} \left(\nu_j^m\left(z_{n+1:2n}, \alpha_1\right) - \nu_j^m\left(z_{1:n}, \alpha_2\right)\right), \tag{9}$$

where $(\Lambda \times \Lambda)_k$ is the k-th equivalence class. Now, $\bigcup_{k=1}^{K_j} \left[(\alpha_{1jk}^*, \alpha_{2jk}^*)\right] = \Lambda \times \Lambda$ and $\left[(\alpha_{1jk}^*, \alpha_{2jk}^*)\right] \cap \left[(\alpha_{1jk}^*, \alpha_{2jk'}^*)\right] = \phi$ unless $k = k'$.

Any permutation π of $\{1, \ldots, 2n\}$ induces a permutation map $T_\pi : \mathcal{Z}^{2n} \to \mathcal{Z}^{2n}$ which acts by shuffling coordinates according to the indices permuted by π. There are $(2n)!$ such maps that can be denoted T_i for $i = 1, \ldots, 2n$. The IID assumption implies that the distribution of any $T_i(Z_{1:2n})$ is the same as the distribution of $Z_{1:2n}$. So, if any function $f : \mathcal{Z}^{2n} \to \mathbb{R}$ satisfies the symmetry condition $f(T_i(z_{1:2n})) = f(z_{1:2n})$ and is integrable, its integral satisfies

$$\int_{\mathcal{Z}^{2n}} f\left(Z_{1:2n}\right) \mathrm{d}P^{2n}\left(z_{1:2n}\right) = \int_{\mathcal{Z}^{2n}} f\left(T_i Z_{1:2n}\right) \mathrm{d}P^{2n}\left(z_{1:2n}\right), \tag{10}$$

in which $\mathrm{d}P^{2n}(z_{1:2n}) = \mathrm{d}P(z_1) \cdots \mathrm{d}P(z_{2n})$ and $P \in \mathcal{M}(\mathcal{Z})$.

One of the quantities that will be essential to getting a tight enough bound on $P^{2n}(A_\epsilon)$ is the annealed entropy $H_{ann}^{\Lambda}(2n)$. Given a sample, say $z_{1:2n}$, let $N^{\Lambda}(z_{1:2n})$ be the number of different separations of $z_{1:2n}$ by a given set of functions. In the proof we will choose all the functions in (8) for a given j. Since $N^{\Lambda}(z_{1:2n}) \leq 2^{2n}$ and the $N^{\Lambda}(z_{1:2n})$'s are measurable, $\mathbb{E}N^{\Lambda}(Z_{1:2n})$ exists. The annealed entropy is the natural logarithm (base e) of this, $H_{ann}^{\Lambda}(2n) = \log \mathbb{E}N^{\Lambda}(Z_{1:2n})$. As is customary, $\mathbb{E}$ means expectation in the true distribution, $P \in \mathcal{M}(\mathcal{Z})$.

Our first main result is similar to the corrresponding result in Vapnik et al. (1994). However, there are numerous differences are in the details. For instance, our equivalence class is defined on $\Lambda \times \Lambda$, we use a cross-validation form of the error, we discretized the loss function, and our result leads to Theorem 2 that only has one term, whereas the corresponding result in Vapnik et al. (1994) has three terms.

Theorem 1 : *Let $\epsilon \geq 0$ and $m \in \mathbb{N}$. If $d_{VC} = VC\left(\{Q\left(\cdot, \alpha\right) : \alpha \in \Lambda\}\right)$ is finite, then*

$$P^{2n}\left(A_\epsilon\right) \leq 2m \left(\frac{2ne}{d_{VC}}\right)^{d_{VC}} \exp\left\{-\frac{n\epsilon^2}{m^2}\right\}. \tag{11}$$

Remark: The technique used to prove (11) is similar to the proof of Theorem 4.1 in Vapnik (1998) giving bounds for the uniform convergence of the empirical risk. The hypotheses of Theorem 4.1 in Vapnik (1998) require only the existence of the key quantities e.g the annealed entropy, and the growth function. Our only extra condition is that d_{VC} be finite.

Proof : Let $m \in \mathbb{N}$ and $j \in \{0, 1, \ldots, m-1\}$. For any given $z_{1:2n}$, α_1, and α_2 write $\Delta_j^m\left(z_{1:2n}, \alpha_1, \alpha_2\right) = \nu_j^m\left(z_{n+1:2n}, \alpha_1\right) - \nu_j^m\left(z_{1:n}, \alpha_2\right)$. Also, denote

$$\begin{aligned} \left(\alpha_{1j}^*, \alpha_{2j}^*\right) &= \arg \sup_{(\alpha_1, \alpha_2) \in \Lambda \times \Lambda} \Delta_j^m\left(z_{1:2n}, \alpha_1, \alpha_2\right) \\ &= \arg \sup_{(\alpha_1, \alpha_2) \in \Lambda \times \Lambda} \left[\nu_j^m(z_{n+1:2n}, \alpha_1) - \nu_j^m(z_{1:n}, \alpha_2)\right] \end{aligned} \tag{12}$$

It is seen that $(\alpha_{1j}^*, \alpha_{2j}^*)$ are estimated using D^2 and D^1 respectively; this reversal of the estimators with respect to the data is the essence of the cross-validation form of the error that we use. Using some manipulations, we have by dropping the superscript $2n$ on P:

$$\begin{aligned} P\left(A_\epsilon\right) &\leq P\left(\bigcup_{j=0}^{m-1} A_{\epsilon,m,j}\right) \leq \sum_{j=0}^{m-1} P\left(A_{\epsilon,m,j}\right) \\ &= \sum_{j=0}^{m-1} P\left(\left\{z_{1:2n} : \sup_{\alpha_1,\ \alpha_2 \in \Lambda} \left(\nu_j^m(z_{n+1:2n}, \alpha_1) - \nu_j^m(z_{1:n}, \alpha_2)\right) \geq \frac{\epsilon}{m}\right\}\right). \\ &= \sum_{j=0}^{m-1} P\left(\left\{z_{1:2n} : \sup_{\alpha_1,\ \alpha_2 \in \Lambda} \Delta_j^m(z_{1:2n}, \alpha_1, \alpha_2) \geq \frac{\epsilon}{m}\right\}\right) \\ &= \sum_{j=0}^{m-1} P\left(\left\{z_{1:2n} : \Delta_j^m(z_{1:2n}, \alpha_{1j}^*, \alpha_{2j}^*) \geq \frac{\epsilon}{m}\right\}\right). \end{aligned}$$

Now, for each T_i write $T_i(z_{1:2n})$ for the permuted sample and correspondingly write $D^1_{T_i(z_{1:2n})}$ and $D^2_{T_i(z_{1:2n})}$ for the first and second halves of the permuted sample. This implies

$$\Delta_j^m(T_i(z_{1:2n}), \alpha_1, \alpha_2) = \nu_j^m(D^2_{T_i(z_{1:2n})}, \alpha_1) - \nu_j^m(D^1_{T_i(z_{1:2n})}, \alpha_2).$$

By symmetry of this function and (10) we can write

$$P\left(\left\{z_{1:2n} : \Delta_j^m(z_{1:2n}, \alpha_{1j}^*, \alpha_{2j}^*) \geq \frac{\epsilon}{m}\right\}\right) = \frac{1}{(2n)!} \sum_{i=1}^{(2n)!} P\left(\left\{z_{1:2n} : \Delta_j^m(T_i(z_{1:2n}), \alpha_{1j}^*, \alpha_{2j}^*) \geq \frac{\epsilon}{m}\right\}\right)$$

and therefore $P(A_\epsilon)$ is bounded from above by

$$\frac{1}{(2n)!} \sum_{j=0}^{m-1} \sum_{i=1}^{(2n)!} P\left(\left\{z_{1:2n} : \Delta_j^m(T_i(z_{1:2n}), \alpha_{1j}^*, \alpha_{2j}^*) \geq \frac{\epsilon}{m}\right\}\right). \tag{13}$$

Using the properties of the equivalence relation $\sim$ and letting Z' denote a dummy variable with the same distribution as Z, we have that for each fixed i, j and $z_{1:2n}$

$$\begin{aligned} I_{\left\{Z'_{1:2n}:\Delta_j^m\left(T_iZ'_{1:2n},\alpha^*_{1j},\alpha^*_{2j}\right)\geq\frac{\epsilon}{m}\right\}}(\cdot) &\leq I_{\left\{Z'_{1:2n}:\Delta_j^m\left(T_iZ'_{1:2n},\alpha^*_{1j1},\alpha^*_{2j1}\right)\geq\frac{\epsilon}{m}\right\}}(\cdot) \\ &+ \cdots + I_{\left\{Z'_{2n}:\Delta_j^m\left(T_iZ'_{1:2n},\alpha^*_{1jK_j(z_{1:2n})}\alpha^*_{2jK_j(z_{1:2n})}\right)\geq\frac{\epsilon}{m}\right\}}(\cdot) \\ &= \sum_{k=1}^{K_j(z_{1:2n})} I_{\left\{Z'_{1:2n}:\Delta_j^m\left(T_iZ'_{1:2n},\alpha^*_{1jk}\alpha^*_{2jk}\right)\geq\frac{\epsilon}{m}\right\}}(\cdot)\,. \end{aligned} \tag{14}$$

The inequality in (14) follows because each $z'_{1:2n}$ making the indicator function on the left side 1, must make at least one of the indicators on the right 1. This follows from the fact that $(\alpha^*_{1j},\alpha^*_{2j})$ is a global maximum and each $(\alpha^*_{1jk},\alpha^*_{2jk})$ is a local maximum for n equivalence class, see (12) and (9). Note that in (14) a T_i appears. Formally, this necessitates choosing $(\alpha^*_{1j},\alpha^*_{2j})$ and each $(\alpha^*_{1jk},\alpha^*_{2jk})$ for given k to be dependent on the i in T_i also; this extra step is suppressed in the notation since i has been dropped for ease of exposition.

Now, using (14), (13) is bounded by

$$\begin{aligned} P\left(A_\epsilon\right) &\leq \frac{1}{(2n)!}\sum_{j=0}^{m-1}\sum_{i=1}^{(2n)!}\int\sum_{k=1}^{K_j(z_{1:2n})} I_{\left\{Z'_{1:2n}:\Delta_j^m(T_iZ'_{1:2n},\alpha^*_{1jk}\alpha^*_{2jk})\geq\frac{\epsilon}{m}\right\}}(z_{1:2n})\,\mathrm{d}P\left(z_{1:2n}\right) \\ &= \int\sum_{j=0}^{m-1}\sum_{k=1}^{K_j(z_{1:2n})}\left[\frac{1}{(2n)!}\sum_{i=1}^{(2n)!} I_{\left\{Z'_{1:2n}:\Delta_j^m(T_iZ'_{1:2n},\alpha^*_{1jk},\alpha^*_{2jk})\geq\frac{\epsilon}{m}\right\}}(z_{1:2n})\right]\mathrm{d}P\left(z_{1:2n}\right). \end{aligned}$$

To bound the summation in square brackets, we follow Vapnik (1998), Chap. 4. Let

$$A_{\epsilon,m,j,k} = \left\{Z_{1:2n} : \Delta_j^m\left(T_iZ_{1:2n},\alpha^*_{1jk}\alpha^*_{2jk}\right)\geq\frac{\epsilon}{m}\right\}$$

for fixed j and each k, where $\left[(\alpha^*_{1jk},\alpha^*_{2jk})\right] = (\Lambda\times\Lambda)_k$. Now, the summation in square brackets is the fraction of the number of the $(2n)!$ permutations T_i of $Z_{1:2n}$ for which $A_{\epsilon,m,j,k}$ is closed under T_i for any fixed equivalence class $(\Lambda\times\Lambda)_k$. As proved in Vapnik (1998) Sec. 4.13, it equals

$$\Gamma_k = \sum_\ell \frac{\binom{b}{\ell}\binom{2n-b}{n-\ell}}{\binom{2n}{n}}$$

where $b = b(z_{1:2n})$ is the number of z_i's in $z_{1:2n}$ that satisfy $Q(z_i,\alpha^*_{1jk}) = 1$ (for $i = 1,\ldots,n$) or $Q(z_i,\alpha^*_{2jk}) = 1$ (for $i = n+1,\ldots,2n$), see Vapnik (1998), p. 136 or 143. The summation is over ℓ's in the set

$$\left\{\ell : \left|\frac{\ell}{n} - \frac{b-\ell}{n}\right| \geq \frac{\epsilon}{m}\right\}.$$

From Sec. 4.13 in Vapnik (1998), we have $\Gamma_k \leq 2\exp\left(-\frac{n\epsilon^2}{m^2}\right)$ uniformly in k.

So, using this in the last bound on $P(A_\epsilon)$ gives that $P\left(A_{\epsilon,m}\right)$ is bounded from above by

$$\begin{aligned} &\int\sum_{j=0}^{m-1}\sum_{k=1}^{K_j(z_{1:2n})} 2\exp\left(-\frac{n\epsilon^2}{m^2}\right)dP(z_{1:2n}) = 2\exp\left(-\frac{n\epsilon^2}{m^2}\right)\int\sum_{j=0}^{m-1}\sum_{k=1}^{K_j(z_{1:2n})} dP(z_{1:2n}) \\ &= 2\exp\left(-\frac{n\epsilon^2}{m^2}\right)\sum_{j=0}^{m-1}\int\sum_{k=1}^{K_j(z_{1:2n})} dP(z_{1:2n}) = 2\exp\left(-\frac{n\epsilon^2}{m^2}\right)\sum_{j=0}^{m-1}\int K_j(z_{1:2n})dP(z_{1:2n}) \\ &= 2\exp\left(-\frac{n\epsilon^2}{m^2}\right)\sum_{j=0}^{m-1} E\left(K_j(Z_{1:2n})\right). \end{aligned} \tag{15}$$

Since $K_j(z_{1:2n})$ is the number of equivalence classes given α_1, α_2, j, and $z_{1:2n}$ and N^Λ is the number of separations of $z_{1:2n}$ given by the functions in (8) i.e., over all $\alpha_1,\alpha_2\in\Lambda$, we have that

$$K_j(z_{1:2n}) \leq N^\Lambda(z_{1:2n}).$$

The reasoning is as follows and simply makes the reasoning behind the statement at the top of p. 136 in Vapnik (1998) explicit. Recall $K_j(z_{1:2n})$ is the number of equivalence classes in $\Lambda\times\Lambda$ for fixed j and $z_{1:2n}$. If (α_1,α_2) and (α'_1,α'_2) are in different equivalence classes then

$$\exists u \quad Q_j^m(z_u,\alpha_1)\neq Q_j^m(z_u,\alpha'_1) \quad \text{or} \quad Q_j^m(z_u,\alpha_2)\neq Q_j^m(z_u,\alpha'_2).$$

Without loss of generality, suppose the first inequality holds for some u. Then the two functions $Q_j^m(z_u,\alpha_1), Q_j^m(z_u,\alpha'_1)$ must assume values $(0,1)$ or $(1,0)$. Again, without loss of generality suppose the first holds. Then, these two functions can separate $z_{1:2n}$ into two disjoint subsets $\{z_v\big|Q_j^m(z_v,\alpha_1)=0\}$ and $\{z_v\big|Q_j^m(z_v,\alpha_1)=0\}$ and this is one of the separations counted by $N^\Lambda(z_{1:2n})$. Taking into account all such separations we have

$$\mathbb{E}K_j(z_{1:2n}) \leq \mathbb{E}N^\Lambda(z_{1:2n}). \tag{16}$$

The growth function is defined to be

$$G^\Lambda(2n) = \log\sup_{z_1,z_2,\ldots,z_{2n}} N^\Lambda\left(z_1,\ldots,z_{2n}\right) \geq \mathbb{E}N^\Lambda(Z_{1:2n}) = H_{ann}(2n).$$

So it is easy to see that $H^\Lambda_{ann}(2n)\leq G^\Lambda(2n)$. Now, Theorem 4.3 from Vapnik (1998) p.145 gives that

$$G(2n)\leq d_{VC}\log\left(\frac{2ne}{d_{VC}}\right)\Rightarrow \mathbb{E}\left(N^\Lambda(z_{1:2n})\right)\leq\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}. \tag{17}$$

Using (17) and (16) m times in (15) gives the theorem. ■

Next, we use use Theorem 1 to identify an objective function that can be minimized to give an estimator for d_{VC}. Formally, let

$$\Delta_m = \mathbb{E}\left(\sup_{\alpha_1,\alpha_2\in\Lambda}\left|\nu^m(D^2,\alpha_1)-\nu^m(D^1,\alpha_2)\right|\right) \tag{18}$$

and

$$\Delta = \mathbb{E}\left(\sup_{\alpha_1,\alpha_2\in\Lambda}\left|\nu\left(D^2,\alpha_1\right)-\nu\left(D^1,\alpha_2\right)\right|\right). \tag{19}$$

Obviously, $\Delta_m \approx \Delta$ provided that m, n, and $d_{VC} \to \infty$ at appropriate rates and the argument of Δ_m satisfies appropriate uniform integrability conditions. In fact, we do not use $\Delta_m \to \Delta$. For our purpose, the following bounds are sufficient. They are important to our methodology because they bound the expected maximum difference between two values of the empirical losses by an expression that can be used to estimate the VC dimension.

Theorem 2 :

1. *If $d_{VC} < \infty$, we have*

$$\Delta_m \leq m\sqrt{\frac{1}{n}\log\left(2m^3\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}\right)} + \frac{1}{m\sqrt{n\log\left(2m^3\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}\right)}} \tag{20}$$

2. *If $d_{VC} < \infty$, and*

$$D_p(\alpha) = \int_0^\infty \sqrt[p]{P\left\{Q\left(z,\alpha\right)\geq c\right\}}dc \leq \infty$$

where $1 < p \leq 2$ is some fixed parameter, we have

$$\Delta \leq \frac{D_p(\alpha^*)2^{2.5+\frac{1}{p}}\sqrt{d_{VC}\log\left(\frac{ne}{d_{VC}}\right)}}{n^{1-\frac{1}{p}}} + \frac{16D_p(\alpha^*)2^{2.5+\frac{1}{p}}}{n^{1-\frac{1}{p}}\sqrt{d_{VC}\log\left(\frac{ne}{d_{VC}}\right)}}. \tag{21}$$

3. *Assume that $d_{VC} \to \infty$, $\frac{n}{d_{VC}} \to \infty$, $m \to \infty$, $\log(m) = o(n)$, and*

$$D_p(\alpha) = \int_0^\infty \sqrt[p]{P\left\{Q(z,\alpha)\geq c\right\}}dc \leq \infty$$

where $p = 2$. Then we have that

$$\Delta \leq \min\left(1, 8D_p(\alpha^*)\right)\sqrt{\frac{d_{VC}}{n}\log\left(\frac{2ne}{d_{VC}}\right)}. \tag{22}$$

Proof : Proofs of the three clause of Theorem 2 can be found in Mpoudeu (2017) in Appendices A1–A3. They rest on using the integral of probabilities identity and then bounding the probabilities as in Theorem 1. ■

We can also use Theorem 1 to obtain an upper bound on the unknown true risk via the following propositions. Let $Q(\alpha_k)$ be the true unknown risk at α_k and $Q_{emp}(\alpha_k)$ be the empirical risk at α_k. Assume that K values of α_k have been fixed. These correspond to a set of points in the parameter space; in our examples below we use estimates. In effect, we are assuming that given an estimate, there is an α_k so close to it that the approximation error is negligible.

Proposition 3 : *For any $\eta \in (0,1)$, with probability at least $1-\eta$, the inequality*

$$Q(\alpha_k) \leq Q_{emp}(\alpha_k) + m\sqrt{\frac{1}{n}\log\left(\left(\frac{2m}{\eta}\right)\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}\right)} \tag{23}$$

holds simultaneously for all functions $Q(z,\alpha_k)$, $k = 1, 2, \cdots, K$.

Remark: This inequality follows from the additive Chernoff bounds (see, e.g., Vapnik (1998), formulae (4.4) and (4.5)) and suggests that the best model will be the one that minimizes the RHS of (23). The use of (23) in model selection as a form of risk minimization because as d_{VC} increases the second term on the right increases. This limits the size of d_{VC}; we denoted this technique by $PERM_1$ since a penalized empirical risk is being minimized.

Proof : To obtain inequality (23), we equate the RHS of Theorem 1 to a positive number $0 \leq \eta \leq 1$. Thus:

$$\eta = 2m\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}\exp\left(-\frac{n\epsilon^2}{m^2}\right).$$

Solving for ϵ gives

$$\epsilon \;=\; m\sqrt{\frac{1}{n}\log\left(\left(\frac{2m}{\eta}\right)\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}\right)}. \tag{24}$$

Proposition 3 can be obtained from the additive Chernoff bounds, expression 4.4 in Vapnik (1998) as follows

$$Q(\alpha_k) \;\leq\; Q_{emp}(\alpha_k) + \epsilon. \tag{25}$$

Using (24) in inequality (25), completes the proof. ■

Parallel to Prop. 3, we have the following for the multiplicative case.

Proposition 4 : *For any $\eta \in (0,1)$, with probability $1-\eta$, the inequality*

$$Q(\alpha_k) \leq Q_{emp}(\alpha_k) + \frac{m^2}{2n}\log\left(\frac{2m}{\eta}\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}\right)\left(1+\sqrt{1+\frac{4nQ_{emp}(\alpha_k)}{m^2\log\left(\frac{2m}{\eta}\left(\frac{2ne}{d_{VC}}\right)^{d_{VC}}\right)}}\right) \tag{26}$$

holds simultaneously for all K functions in the set $Q(z,\alpha_k)$, $k = 1, 2, \ldots, K$.

Remark: This follows from the multiplicative Chernoff bounds (see e.g., Vapnik (1998) formulae (4.17) and (4.18)) and suggests that the best model will be the one that minimizes the right hand side (RHS) of (26). Analogous to (23) we refer to the use of (26) in model selection as $PERM_2$.

Proof : Let $\epsilon, \eta > 0$. Then, inequality (4.18) in Vapnik (1998) gives, with probability at least $1-\eta$, that

$$\frac{Q(\alpha_k) - Q_{emp}(\alpha_k)}{\sqrt{Q(\alpha_k)}} \leq \epsilon.$$

Routine algebraic manipulations and completing the square give

$$\left(Q(\alpha_k) - 0.5\left(\epsilon^2 + 2Q_{emp}(\alpha_k)\right)\right)^2 - 0.25\left(\epsilon^2 + 2Q_{emp}(\alpha_k)\right)^2 \leq -Q^2_{emp}(\alpha_k).$$

Taking the square root on both sides and re-arranging gives

$$Q(\alpha_k) \leq Q_{emp}(\alpha_k) + 0.5\epsilon^2\left(1 + \sqrt{1 + \frac{4Q_{emp}(\alpha_k)}{\epsilon^2}}\right)$$

Using (24) in the last inequality completes the proof of the Proposition. ■

More details on the use of Propositions 3 and 4 can be found in Vapnik (1998) and Mpoudeu (2017).

2.2. An Estimator of the VC Dimension

The upper bound from Theorem 2 can be written as

$$\Phi_{d_{VC}}(n) = \min(1, 8D_p(\alpha^*))\sqrt{\frac{d_{VC}}{n}\log\left(\frac{2ne}{d_{VC}}\right)}. \tag{27}$$

This expression is meaningfully different from the form derived in Vapnik et al. (1994) and studied in McDonald et al. (2011). Moreover, although $\min(1, 8D_p(\alpha^*))$ does not affect the optimization, it might not be the best constant for the inequality in (22). So, we replace it with an arbitrary constant c over which we optimize to make our upper bound as tight as possible. In our computations, we let c vary from 0.01 to 100 in steps of size 0.01. However, we have observed in practice that the best value of $\hat{c}$ is usually between 1 and 8. The technique that we use to estimate $\hat{d}_{VC}$ is also different from that in Vapnik et al. (1994). Indeed, our Algorithm #1 below accurately encapsulates the way the LHS of (22) is formed unlike the algorithm in Vapnik et al. (1994).

In particular, we use two bootstrapping procedures, one as a proxy for calculating expectations and the second as a proxy for calculating a maximum. Moreover, we split the data set into two subsets. Using the first data set, we fit model I and using the second we fit model II. To explain how we find our estimate of the RHS of (22) from Theorem 2, we start by replacing the sample size n in (27) with a specified value of design point, so that the only unknown is d_{VC}. Thus, formally, we replace (27) by

$$\Phi^*_{d_{VC}}(n_l) = \widehat{c}\sqrt{\frac{d_{VC}}{n_l}\log\left(\frac{2n_le}{d_{VC}}\right)},$$

where $\hat{c}$ is the optimal data driven constant. If we knew the left hand side (LHS) of (22), even computationally, we could use it to estimate d_{VC}. However, in general we don't know the LHS of (22). Instead, we generate one observation of the form

$$\xi(n_l) = \Phi^*_{d_{VC}}(n_l) + \epsilon(n_l) \tag{28}$$

for each design point n_l by bootstrapping and denoted the realized values by $\hat{\xi}(n_l)$. In (28), we assume $\epsilon(n_l)$ has a mean zero, but an otherwise unknown, distribution. We can therefore obtain a list of values of $\widehat{\xi}(n_l)$ for the elements of N_L. In effect, we are assuming that $\Phi^*_{d_{VC}}(n_l)$ provides a tight bound on Δ, and hence Δ_m as suggested by Theorem 2. Our algorithm is as follows.

Algorithm #1

Inputs:

- A collection of regression models $\mathcal{G} = \{g_\beta\}$,
- A data set,
- Two integers b_1 and b_2 for the number of bootstrap samples,
- An integer m for the number of subintervals to discretize the losses,
- A set of design points $N_L = \{n_1, n_2, \ldots, n_L\}$.

For each $l = 1, 2, \ldots, L$ do:

1. Take a bootstrap sample of size $2n_l$ (with replacement) form the data set;
2. Randomly subdivide the bootstrap data into two groups G^1 and G^2 of size n_l each;
3. Fit two models, one for G^1 and one for G^2;
4. Compute the squared error for each model on the covariates and responses that the other model was trained on. Thus:

$$SE_1 = (\text{predict}(Model_1, x_2) - y_2)^2 \quad \text{and} \quad SE_2 = (\text{predict}(Model_2, x_1) - y_1)^2$$

   where (x_1, y_1) ranges over G^1 and (x_2, y_2) ranges over G^2. So, there are n_l values of SE_1 and n_l values of SE_2.
5. Discretize the loss function, i.e. put each SE_1 and SE_2 in one of the m disjoint intervals;
6. Estimate $\nu^m_j(G^2, \alpha_1)$ and $\nu^m_j(G^1, \alpha_2)$ using the SE_1's and SE_2's respectively in the intervals I^m_j for $j = 0, 1, \ldots, m-1$;
7. Compute the differences $|\nu^m_j(G^2, \alpha_1) - \nu^m_j(G^1, \alpha_2)|$ for $j = 0, 1, \ldots, m-1$;
8. Repeat Steps 1-7 b_1 times, take the mean interval-wise and sum it across all intervals, so we have:

$$r_{b_1}(n_l) = \sum_{j=0}^{m-1} \text{mean}\,|\nu^m_j(G^2, \alpha_1) - \nu^m_j(G^1, \alpha_2)|\,;$$

9. Repeat Steps 1-8 b_2 times to get $r_{b_1,i}$ for $i = 1, 2, \ldots, b_2$ and form

$$\hat{\xi}(n_l) = \frac{1}{b_2} \sum_{i=1}^{b_2} r_{b_1,i}(n_l) \,.$$

It is seen that Step 9 uses a mean even though the definition of Δ_m and Δ (see (18) and (19)) has a supremum inside the expectation. This is intentional because using a supremum within each interval gave a worse estimator. We suggest that summing the mean over the intervals performs well because it is not too far from the supermum and is more stable.

Note that this algorithm is parallelizable because different n_l can be sent to different nodes to speed the process of estimating $\hat{\xi}(\cdot)$ for all n_l. After obtaining $\hat{\xi}(n_l)$ for each value of n_l, we estimate d_{VC} by minimizing the squared distance between $\hat{\xi}(n_l)$ and $\Phi^*_{d_{VC}}(n_l)$. Our objective function is

$$f_{n_l}(d_{VC}) = \sum_{l=1}^{L} \left(\hat{\xi}(n_l) - \hat{c} \sqrt{\frac{d_{VC}}{n_l} \log\left(\frac{2n_l e}{d_{VC}}\right)} \right)^2 , \tag{29}$$

where L is the number of design points. Optimizing (29) usually only leads to numerical solutions and in our work below, we set $b_1 = b_2 = W$ for convenience.

3. Proof of Consistency

In this section, we provide a proof of consistency for the estimator $\hat{d}_{VC}$ for d_{VC} that we presented in Subsec. 2.2. In many respects, the structure of this proof should be credited to McDonald et al. (2011). Our contribution is to adapt McDonald et al. (2011) to our stable estimator for the regression context. We begin with some notation and definitions.

Let $\Phi = \{\phi_{d_{VC},c}\}$ be a collection of real valued functions parametrized by $d_{VC} \in \mathbb{H} = [1, M]$ and $c \in I = [a, b] \subset \mathbb{R}$ with $M \in \mathbb{N}$ large enough and $0 < a < b < \infty$ so that $b - a > 0$ is also large enough. Elements of this collection are of the form

$$\phi_{d_{VC},c}(n_l) = c \sqrt{\frac{d_{VC}}{n_l} \log\left(\frac{2n_l e}{d_{VC}}\right)} \tag{30}$$

as derived in Subsec. 2.2 (see expression (27)). In expression (30), we assume L values $n_1, \ldots, n_L$ have been pre-specified. Fix a value of c and let $\Phi_c \subset \Phi$ be the section of elements corresponding to the fixed c. The proof holds for each fixed c and if we optimize over c to obtain $\hat{c}$ as explained in Subsec. 2.2, the convergence of $\hat{d}_{VC}$ to the true value d_{VC} will only be faster.

The collection of functions Φ is the continuous image of a compact set and hence is compact. Now, without loss of generality, we can choose $R > \sup_{d_{VC}} \|\phi_{d_{VC}}\|_L$ where the norm $\|\cdot\|_L$ is derived from the inner product

$$\langle f, g \rangle_L = \frac{1}{L} \sum_{l=1}^{L} f(n_l)\, g(n_l)$$

for real valued functions of a real variable. Thus $\phi_{d_{VC}} = (\phi_{d_{VC}}(n_1), \ldots, \phi_{d_{VC}}(n_L))$ (where the subscript c on the $\phi_{d_{VC},c}(n_L)$'s in expression (30) have been dropped for ease of notation). Fix a value of c and consider the compact subclass of Φ given by

$$\Phi_c(R) = \left\{ \phi \in \Phi_c : \|\phi - \phi_{d_{VC}}\|_L < R \right\}, \tag{31}$$

where $\phi_{d_{VC}}$ is the element of Φ_c corresponding to the correct value of d_{VC}. For a given n_l, we have

$$\hat{\xi}(n_l) = \frac{1}{b_2} \sum_{i=1}^{b_2} r_{b_1,i}(n_l) \tag{32}$$

where $r_{b_1,i}(n_l)$ is the i bootstrapped value of the integrand of Δ_m for each n_l, $i = 1, \ldots, W$ and $l = 1, \ldots, L$. In vector form, write $\hat{\xi} = \left(\hat{\xi}(n_1), \ldots, \hat{\xi}(n_L)\right)$. Using (28), each $\hat{\xi}(n_l)$ can be represented as

$$\hat{\xi}(n_l) = \phi_{d_{VC}}(n_l) + \epsilon(n_l) \,. \tag{33}$$

We have the following result.

Theorem 5 : *Suppose the true $d_{VC} \in [1, M]$ and that $\forall i = 1, \ldots, W$, $\forall l = 1, \ldots, L$, $r_{b_1,i}(n_l) \sim N\left(\phi_{d_{VC}}(n_l), \sigma^2\right)$ and independent, $\mathbb{E}(\epsilon(n_l)) = 0$, $Var(\epsilon(n_l)) = \sigma^2$. Then, on $\Phi_c(R)$, as $n \to \infty$, $m \to \infty$ and $W = W(n) \to \infty$ at suitable rates we have that*

$$P\left(\left\| \phi_{\hat{d}_{VC}} - \phi_{d_{VC}} \right\|_L \geq \delta \right) = \mathcal{O}\left(\frac{1}{W}\right). \tag{34}$$

Remark: In fact, the $r_{b_1,i}(n_l)$'s are only approximately independent $N\left(\phi_{d_{VC}}(n_l), \sigma^2\right)$. However, as n increases they become closer and closer to being independent $N\left(\phi_{d_{VC}}(n_l), \sigma^2\right)$, assuming $\phi_{d_{VC}}(n_l)$ is a tight enough upper bound, as $n, m \to \infty$ at appropriate rates. Also, it is seen that if $L = L(n)$ is increasing then $\|\cdot\|_L$ averages the evaluations of more and more components of, say, $\phi_{\hat{d}_{VC}}$. In the limit, this can be exihibited as an integral, i.e. as a quadratic norm. So, $\|\cdot\|_L$ can be regarded as an approximation of a L^2-space norm that strengthens as a norm (or inner product) as $n \to \infty$. In Theorem 5, if we controlled the distance between $\|\cdot\|_L$ and its limit, we could get a stronger mode of consistency.

Proof : By definition of $\phi_{d_{VC}}$, we have

$$\sum_{l=1}^{L} \left(\hat{\xi}(n_l) - c \sqrt{\frac{\hat{d}_{VC}}{n_l} \log\left(\frac{2n_l e}{\hat{d}_{VC}}\right)} \right)^2 \leq \sum_{l=1}^{L} \left(\hat{\xi}(n_l) - c \sqrt{\frac{d_{VC}}{n_l} \log\left(\frac{2n_l e}{d_{VC}}\right)} \right)^2 \tag{35}$$

or more compactly $\left\| \hat{\xi} - \phi_{\hat{d}_{VC}} \right\|_L^2 \leq \left\| \hat{\xi} - \phi_{d_{VC}} \right\|_L^2$. Expanding both sides of (35) gives

$$\sum_{l=1}^{L} \left(\phi^2_{\hat{d}_{VC}}(n_l) - \phi^2_{d_{VC}}(n_l) \right) \leq 2 \sum_{l=1}^{L} \hat{\xi}(n_l) \left(\phi_{\hat{d}_{VC}} - \phi_{d_{VC}}(n_l) \right)$$

and hence

$$\begin{aligned}\left\|\phi_{\hat{d}_{VC}}\right\|_L^2 - \|\phi_{d_{VC}}\|_L^2 &\leq \frac{2}{L}\sum_{l=1}^{L}\left(\phi_{d_{VC}}(n_l)+\epsilon(n_l)\right)\left(\phi_{\hat{d}_{VC}}(n_l)-\phi_{d_{VC}}(n_l)\right)\\ &= \frac{2}{L}\sum_{l=1}^{L}\Big(\phi_{d_{VC}}(n_l)\,\phi_{\hat{d}_{VC}}(n_l)-\phi_{d_{VC}}^2(n_l)\\ &\qquad +\epsilon(n_l)\left(\phi_{\hat{d}_{VC}}(n_l)-\phi_{d_{VC}}(n_l)\right)\Big).\end{aligned}$$

Rearranging gives

$$\left\|\phi_{\hat{d}_{VC}}\right\|_L^2 - 2\langle\epsilon,\phi_{\hat{d}_{VC}}\rangle + \|\phi_{d_{VC}}\|_L^2 \leq 2\langle\epsilon,\phi_{d_{VC}}-\phi_{\hat{d}_{VC}}\rangle_L,$$

where $\epsilon=(\epsilon(n_1),\ldots,\epsilon(n_L))$, i.e.

$$\left\|\phi_{\hat{d}_{VC}}-\phi_{d_{VC}}\right\|_L^2 \leq 2\langle\epsilon,\phi_{\hat{d}_{VC}}-\phi_{d_{VC}}\rangle_L. \tag{36}$$

It is seen that the LHS is the main quantity we want to control. We have

$$\begin{aligned}P\left(\left\|\phi_{\hat{d}_{VC}}-\phi_{d_{VC}}\right\|_L>\delta\right) &\leq P\left(\langle\epsilon,\phi_{d_{VC}}-\phi_{\hat{d}_{VC}}\rangle\geq\frac{\delta^2}{2}\right)\\ &\leq P\left(\|\epsilon\|_L\left\|\phi_{d_{VC}}-\phi_{\hat{d}_{VC}}\right\|_L>\frac{\delta^2}{2}\right)\\ &\leq \frac{2R^2}{\delta^2}\mathbb{E}\|\epsilon\|_L^2,\end{aligned} \tag{37}$$

using the Cauchy-Schwarz inequality, the bound in (31), and Markov's inequality.

By construction, we have that

$$\begin{aligned}\mathbb{E}\|\epsilon\|_L^2 &= \frac{1}{L}\sum_{l=1}^{L}\mathbb{E}\left(\epsilon^2(n_l)\right)\\ &= \frac{1}{L}\sum_{l=1}^{L}\mathbb{E}\left[\left(\frac{1}{W}\sum_{i=1}^{W}r_{b_1,i}(n_l)\right)-\phi(n_l)\right]^2\\ &= \frac{1}{L}\sum_{l=1}^{L}\mathbb{E}\left[\frac{1}{W}\sum_{i=1}^{W}\left(r_{b_1,i}(n_l)-\phi(n_l)\right)\right]^2\\ &= \frac{1}{LW^2}\sum_{l=1}^{L}\sum_{i=1}^{W}\mathbb{E}\left(r_{b_1,1}(n_l)-\phi(n_l)\right)^2\\ &= \frac{1}{LW^2}\sum_{l=1}^{L}\sum_{i=1}^{W}Var\left(r_{b_1,1}(n_l)\right)=\frac{\sigma^2}{W}.\end{aligned} \tag{38}$$

Using (38) in (37) gives

$$P\left(\left\|\phi_{\hat{d}_{VC}}-\phi_{d_{VC}}\right\|_L\geq\delta\right)\leq\frac{2R^2\sigma^2}{\delta^2W} \tag{39}$$

in which the upper bound decreases as n increases because $W(n)$ is increasing, thereby giving (34). ■

A notable difference between (34) and the corresponding theorem in McDonald et al. (2011) is that our simplified result effectively only gives

$$P\left(\left\|\phi_{\hat{d}_{VC}}-\phi_{d_{VC}}\right\|_L\geq\delta\right)=\mathcal{O}\left(\frac{1}{W}\right) \tag{40}$$

rather than $\mathcal{O}\left(e^{-\gamma W}\right)$ for some $\gamma>0$, a much faster rate. We conjecture that the more sophisticated techniques used in McDonald et al. (2011) could be adapted to our setting and thereby give an exponentially fast rate of convergence of $\hat{d}_{VC}$ to d_{VC} in probability. However, as yet, we have not been able to show this. Also, although it is suppressed in the notation, our result implicitly requires $m\to\infty$ to justify the use of $\phi_{d_{VC}}$.

Using Theorem 5, we can show that our $\hat{d_{VC}}$ is consistent. Suppose that $\phi_{d_{VC}}(\cdot)$ is κ-expansive, or simply expansive when κ is understood, i.e. $\forall n_l, \exists\kappa=\kappa(n_l)$ so that $\kappa(n_l)\left|d_{VC}-d_{VC}^{'}\right|\leq\left|\phi_{d_{VC}}(n_l)-\phi_{d_{VC}^{'}}(n_l)\right|$, where $\kappa(n)$, the expansion factor, is bounded on compact sets. Since the form of $\phi_{d_{VC}}(n_l)$ is known from (27), it is clear that the uniform expansivity condition we have assumed below actually holds, at least for appropriately chosen compact sets. We also observe that for $c\in I$ there exists a neighborhood $B(c,\epsilon_l),\eta>0$, on which (34) is true. Cover $I\times\mathbb{H}$ by sets of the form $B(c,\eta)\times\{d_{VC}\}$; finitely many will be enough since $I\times\mathbb{H}$ is compact.

Theorem 6 : *Given that the assumptions of Theorem 5 hold and that $\phi_{d_{VC}}(\cdot)$ is expansive, we have, as $n\to\infty$, that*

$$P\left(\left|\hat{d_{VC}}-d_{VC}\right|\geq\delta\right)\leq\frac{2R^2\sigma^2}{\delta^2\kappa W}=\mathcal{O}\left(\frac{1}{W}\right),\ \textit{as } W_n\to\infty, \tag{41}$$

where $\kappa=\sqrt{\frac{1}{L}\sum_{l=1}^{L}\kappa(n_l)}$ is the overall expansion factor.

Proof : Since all L of the $\phi_{d_{VC}}(n_l)$'s are at least locally expansive, their local expansivity inequalities can be summarized by an inequality of the form

$$\begin{aligned}\left|d_{VC}-d_{VC}^{'}\right|\sqrt{\frac{1}{L}\sum_{l=1}^{L}\kappa(n_l)} &\leq \sqrt{\frac{1}{L}\sum_{l=1}^{L}\left(\phi_{d_{VC}}(n_l)-\phi_{d_{VC}^{'}}(n_l)\right)^2}\\ &= \|\phi_{d_{VC}}(n_l)-\phi_{d_{VC}^{'}}(n_l)\|_L,\end{aligned} \tag{42}$$

where d_{VC} is the true value and $d_{VC}^{'}$ is any other value in $\mathbb{H}$, and any extra constant from the local expansion factors are assumed to have been absorbed into the $\kappa(n_l)$'s as needed. Let $\kappa=\sqrt{\frac{1}{L}\sum_{l=1}^{L}\kappa(n_l)}$. Using Theorem 5, and (42) we have

$$\begin{aligned}P\left(\left|\hat{d}_{VC}-d_{VC}\right|\geq\delta\right) &\leq P\left[\|\phi_{\hat{d}_{VC}}(n_l)-\phi_{d_{VC}}(n_l)\|_L\geq\delta\kappa\right]\\ &\leq\frac{2R^2\sigma^2}{\kappa\delta^2W},\end{aligned} \tag{43}$$

where the last upper bound decreases as $W = W_n \to \infty$ as $n \to \infty$, giving (41). ■

4. Numerical Comparisons

For any model, we can estimate the LHS of (22) from Theorem 2 by Algorithm #1 in Sec. 2.2. Then, we can use nonlinear regression in (29) to find $\hat{d}_{VC}$. So, it is seen that $\hat{d}_{VC}$ is a function of the conjectured model. In principle, for any given model class, the VC dimension can be found, so our method can be applied.

Since our goal is to estimate the true VC dimension, when a conjectured model $P(\cdot \mid \beta)$ is linear and correct, we expect $VC(P(\cdot \mid \beta)) \cong \hat{d}_{VC}$. By the same logic, if $P(\cdot \mid \beta)$ is far from the true model, we expect $VC(P(\cdot \mid \beta)) \gg \hat{d}_{VC}$ or $VC(P(\cdot \mid \beta)) \ll \hat{d}_{VC}$. This suggests we estimate d_{VC} by seeking

$$\hat{d}_{VC} = \arg\min_k \left| VC\left(P_k(\cdot \mid \beta)\right) - \hat{d}_{VC,k} \right|, \tag{44}$$

where $\{P_k(\cdot \mid \beta) \,|k = 1, 2, \cdots, K\}$ is some set of models and $\hat{d}_{VC,k}$ is calculated using model k, t is a positive and usually small number that such that $t \leq 2$. In the case of linear models, with $q = 1, 2, \cdots, Q$ explanatory variables, we get

$$\hat{d}_{VC} = \arg\min_q \left| q - \hat{d}_{VC,q} \right|, \tag{45}$$

where $\hat{d}_{VC,q}$ is the estimated VC dimension for model of size q. Note that (44) can identify a good model even when consistency fails. The reason is that (44) only requires a minimum at the VC dimension not convergence to the true VC dimension which may be any model under consideration. Here, to achieve uniqueness we use (45) and choose the smalest q achieving the smallest value of $|q - \hat{d}_{VC,q}|$, provided this makes sense in context.

Our numerical work uses linear models, since for these we know the VC dimension equals the number of explanatory variables, see Anthony and Bartlett (2009). To establish notation, we write the regression function as a linear combination of the fixed effect covariates x_j, $j = 0, 1, \cdots, p$,

$$y = f(x, \beta) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p = \sum_{j=0}^{p} \beta_j x_j.$$

Given a data set, $\{(x_i, y_i),\ i = 1, 2, \ldots, n\}$, the matrix representation is $Y = X\beta + \epsilon$ where Y is the $n \times 1$ vector of response values, X is the $n \times (1 + p)$ matrix with rows $(1, x_{1,1}, x_{1,2}, \ldots, x_{1,p})$, $\beta = (\beta_0, \beta_1, \ldots, \beta_p)^T$ is the vector of model parameters, and $\epsilon = (\epsilon_1, \epsilon_2, \ldots, \epsilon_n)^T$ is a $n \times 1$ mean zero Gaussian random vector. The least squares estimator $\widehat{\beta}$, assuming it exists, is given by $\widehat{\beta} = \left(X'X\right)^{-1} X'Y$.

4.1. Simulated data

We simulate data from

$$Y = \beta_0 x_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p + \epsilon,$$

where $\epsilon \sim N(0, \sigma_\epsilon = 0.4)$ and

$$x_0 = 1,\ \beta_j \sim N(\mu = 5, \sigma_\beta = 3), x_j \sim N(\mu = 5, \sigma_x = 2),\ \text{for } j = 1, 2, \cdots p,$$

in which all the β's, x's and ϵ's are independently generated. We center and scale all our variables, including the response. For convenience, we use a nested sequence of model lists. If our covariates were highly correlated, before applying our method we could de-correlate them by sphering, i.e. transforming the covariates using their covariance matrix so they become approximately uncorrelated with variance one, see Murphy (2012) p. 144.

In Subsec. 4.1.1, we present a typical simulation result to verify our estimator for VC dimension is consistent for the VC dimension of the true model. In Subsec. 4.1.2, we discuss simulations we have done where results do not initially appear to be consistent with the theory. First, large values of n are needed to get good performance with large values of p. Second as p increases, we must choose n_l's that are properly spread out over $[0, n]$.

4.1.1. A first example

We implemented simulations for a range of model sizes $p = 15, 30, 40, 50, 60$ and 70 and applied six model selection techniques AIC, BIC, CV, $\widehat{PERM}_1$, $\widehat{PERM}_2$, and VC dimension (VCD), see Mpoudeu and Clarke (2018) for details. We tended to use larger sample sizes with larger values of p and spaced the design points uniformly over $[0, n]$, even though this may be suboptimal. We arbitrarily set $m = 10$ and $W = 50$. Our models were nested, including models that were too small and some that were too large, so that the estimate of d_{VC} would uniquely specify a model.

As a typical example, Fig. 1 shows the results for $n = 700$ and $p = 70$ with $L = 7$. When the size of the conjectured model is strictly less than the size of the true model, $\hat{d}_{VC}$ is equal to the smallest design point. However, when the conjectured model exactly matches the true model, $\hat{d}_{VC} \approx 61$, underestimating d_{VC}. Interestingly, if we simply look at the minimal VCD value it occurs at the conjectured model of size 70, the true values of p. When the conjectured model is more complex than the true model, the VCD value is visibly higher than the VCD value for the true model. Thus, using VCD favors parsimony more than the other methods do. In results not shown here, we increased n to 2000 and used good design points (as discussed in Subsec. 4.1.2) and found $\hat{d}_{VC} \approx 70$. Our observation for the other five model selection methods is that they are less affected by the small sample size, but decrease and 'flatline' in the sense that the AIC, BIC and CV values decrease very slowly (making it unclear which model to choose) while $\widehat{PERM}_1$ and $\widehat{PERM}_2$ routinely give models that are too small if one follows the usual rule of choosing the smallest local minimum. Overall, using VCD penalizes models that are too large more than other methods do, thereby giving a clearer statement about which model is true, at least in the limit with intelligently chosen design points. Other choices of n, p, the design points, and other inputs, gave results compatible with this interpretation.

Although the diagrams are not shown here (but see Mpoudeu and Clarke (2018), Sec. 4) the smallest discrepancy between the size d_{VC} of the model and $\hat{d}_{VC}$ usually occurs at the true model. This indicates that $\hat{d}_{VC}$ is consistent. In addition, even though the VCD values generally increase as the size of the conjectured model exceeds the size of the true model, in some cases, past a certain value d_{VC}, the VCD value may flatline as well. The

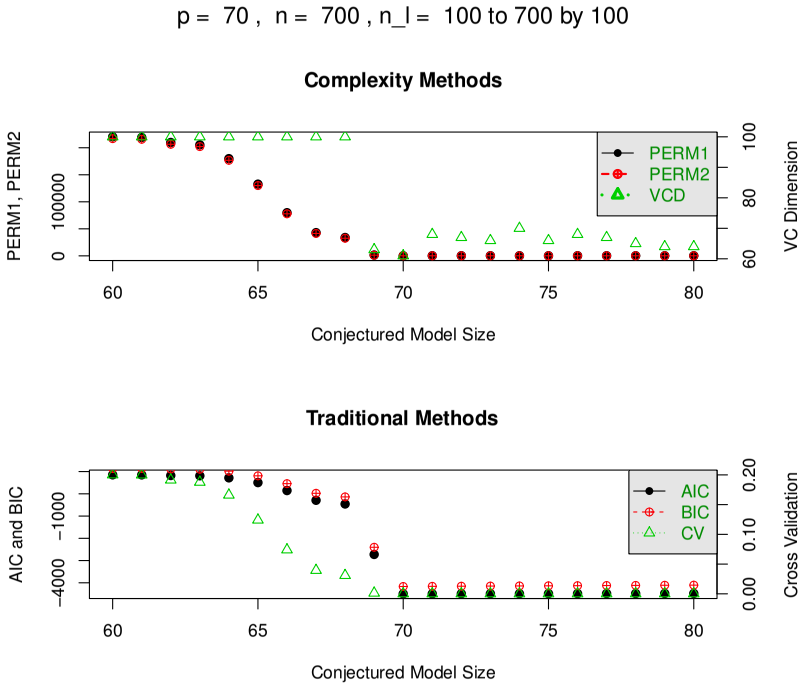

Figure 1: Upper: Values of $\widehat{PERM}_1$, $\widehat{PERM}_2$, and VC dimension. Lower: Values of AIC, BIC and CV for $p = 70$, $\sigma_\epsilon = 0.4$, $\sigma_\beta = 3$, $\sigma_x = 2$.

problem with $\hat{d}_{VC}$ flatlining (or decreasing) past a certain value of d_{VC} occurs mostly due to instability, e.g., when n is not large enough relative to p.

We argue that estimating VC dimension directly is better than using $\widehat{PERM}_1$ or $\widehat{PERM}_2$. There are several reasons. First, the computation of $\widehat{PERM}_1$ and $\widehat{PERM}_2$ requires $\hat{d}_{VC}$. It also requires a threshold η be chosen (see Propositions 3 and 4) and is more dependent on m than $\hat{d}_{VC}$ is. Being more complicated than $\hat{d}_{VC}$, $\widehat{PERM}_1$, $\widehat{PERM}_2$ will break down faster than $\hat{d}_{VC}$. This is seen, for instance in tables of Mpoudeu (2017) Chap. 3 and the discussion there. More generally, we argue that $\widehat{PERM}_1$, and $\widehat{PERM}_2$ break down faster than $\hat{d}_{VC}$ with increasing p, if the sample size is held constant. That is, $\widehat{PERM}_1$ and $\widehat{PERM}_2$ are less efficient than $\hat{d}_{VC}$.

Finally for this subsection, we reiterate our observation that in practice, when our VC dimension technique is used properly i.e., n is large enough relative to p, the σ used in Theorem 6 and the design points are adequately chosen, $\left|\hat{d}_VC - d_{VC}\right|$ has a well defined minimum at the true value of d_{VC}. Also, in contrast with other methods (including using shrinkage methods to nest models) our technique is generally more sensitive to over fit, thereby giving better parsimony.

4.1.2. Dependence of $\hat{d}_{CV}$ on n and N_L

It is no surprise that the higher n/p is the better the discrimination of $\hat{d}_{VC}$ over models is. However, our findings are more complicated because of the design points. The informal rule is that one wants $n \approx 10p$ for good parametric inference. However, this does not take into account model selection that often requires $n > 10p$. Indeed, for good model selection with d_{VC}, we find that $n \geq 15$ is usually sufficient, provided the design points are not badly chosen. In our examples choosing the n_l's uniformly over $[0, n]$ generally gives decent but not optimal performance and for typical ranges of model sizes $L \geq 5$ will suffice even though larger values of L are usually better, say $7 \leq L \leq 10$. Although we are unable at this point to chracterize the tradeoff between design points and sample size, we have noted that in some cases, good choice of design points can compensate for insufficient sample size. Indeed, relatively small changes in the n_l's can have a large numerical effect when n is small; possible due to instability in the nonlinear regression step, (29).

We leave the question of optimally choosing L and the n_l's as future work even though we make the following recommendations: 1) Good choices of n_l's are spread over $[0, n]$. 2. More n_l's should be in $[n/2, n]$ than in $[0, \frac{n}{2}]$, but neither should be empty. 3. Good choices for n_l's tend to remain good while poor choices of n_l's may not be as damaging to inference, as $n \to \infty$. 4. It is better to use fewer design points over a larger range than more design points over a smaller range. 5. As n increases the n_l's should shift upward, i.e., more in $[n/2, n]$. 6. If enough n_l's are large relative to p, $\hat{d}_{VC}$ may be accurate for smaller n, perhaps $n \geq 12p$ will suffice.

4.2. Analysis of a Benchmark Data Set

The goal of this section is to evaluate our method on a 'benchmark' data set Tour obtained from the Tour de France[1]. We start by giving some information about Tour, then in Sec.

1. Tour de France Data was compiled by B. Clarke. More information can be found at http://www.letour.fr/.

4.2.1 we analyze it using a model list based on two of the explanatory variables. The list is a sequence of models nested by SCAD. We evaluate our method by comparing $\hat{d}_{VC}$ to AIC, BIC, CV, $\widehat{PERM}_1$, and $\widehat{PERM}_2$. In Subsec. 4.2.2, we look at the effect of outliers in the estimates $\hat{d}_{VC}$, $\widehat{PERM}_1$, and $\widehat{PERM}_2$.

The full data set Tour has $n = 103$ data points. The data points are dependent (associated) because many cyclists competed in the Tour de France for more than one year. Here we ignore the dependence structure because the dependencies are small enough that the complication of accounting for them is not worthwhile. Each data point has a value of the response variable (Speed), the average speed in kilometers per hour (km/h) of the winner of the Tour. The explanatory variables are the Year (Y) of the Tour and its distance (D) in kilometers. Our data is from 1903 to 2016. However, during World Wars 1 and 2 there was no Tour, so we do not have data points for those years. The effect of World War I on the speed of the winner of the tour can be seen in a scatterplot of Speed vs. Y – the lowest winning speeds were in the years just after World War I, probably due to casualties. After World War II, there was also a decrease in average winning speed, but the decrease was less than after World War I. There is a curvilinear relationship between Speed and Year and a roughly linear relationship between Speed and D; the variability of Speed increases with D.

4.2.1. Analysis of Tour Using a Nested Collection of Models

We identify a nested model list using Y, D, Y^2, D^2 and the interaction between Year and Distance denoted $Y : D$ as covariates. Because the size of the data set is not large, we can only use a small model list.

We order the variables using SCAD because as a shrinkage method it perturbs parameter estimates the least and satisfies an oracle property. Under SCAD, the order of inclusion of variables is Y, D, D^2, Y^2, and $Y : D$. We therefore fit five different models. We use the six model selection techniques from Sec. 4.1 and include $\hat{d}_{VC}$ the original estimator in Vapnik et al. (1994) for the sake of comparison. It is seen that Vapnik et al. (1994)'s original

Model	$\hat{d}_V$	$\hat{d}_{VC}$	$\widehat{PERM}_1$	$\widehat{PERM}_2$	AIC	BIC	CV
Y	20	4	16.42	44.95	84	79.67	0.1294
$Y,\ D$	20	4	15.10	42.83	77	71.66	0.1209
$Y,\ D,\ D^2$	20	4	11.21	36.37	24	**26.21**	0.0727
$Y, D,\ D^2,\ Y^2$	20	4	11.09	36.16	**17**	28.77	**0.0681**
$Y, D,\ D^2,\ Y^2,\ Y : D$	20	4	**11.06**	**36.11**	19	32.96	0.0691

Table 1: Model selection for the Tour de France data using seven methods. The design points for $\hat{d}_V$ and $\hat{d}_{VC}$ are 20, 30, 40, 50, 60, 70, 80, 90, and 100 and $W = 50$. So $\hat{d}_V$ equals the smallest design point in all cases. This problem frequently occurs for $\hat{d}_V$.

method is helpful only if it is reasonable to surmise that there are 15 missing variables whereas our method uniquely identifies one of the models on the list. Even though there is likely no model for Tour de France data set that is accurate to infinite precision, our method is giving a useful result. Indeed, our method is choosing the fourth model list the same as

indicated by AIC and CV. The BIC drops the Y^2 term which is not unreasonable because the curvilinearity is less than quadratic. $\widehat{PERM}_1$ and $\widehat{PERM}_2$ include the interaction term (which can be seen to be zero by a simple t-test). It may also be the case that the derivation of the BIC rests heavily on the independent of data which is not the case here.

4.2.2. Analysis of The Tour de France data set with outliers removed

The observations just after World War I may be outliers. So, we consider the data set formed by deleting the points from 1919 to 1926. Let us see how the six model selection techniques now behave.

The process of analyzing this reduced data set is the same: We identify the nested model lists by SCAD and then find the models corresponding to $\hat{d}_{VC}$, AIC, BIC, CV, $\widehat{PERM}_1$, and $\widehat{PERM}_2$. The results are given in Table 2.

Model Size	$\hat{d}_{VC}$	$\widehat{PERM}_1$	$\widehat{PERM}_2$	AIC	BIC	CV
Y	4	12.87	40.72	67	75	0.1181
$Y,\ D^2$	4	12.01	39.26	69	79	0.1336
$Y,\ D^2,\ D$	4	11.66	38.36	46	59	0.0919
$Y,\ D^2,\ D,\ Y^2$	**4**	11.48	38.34	**28**	**43**	0.0742
$Y,\ D^2,\ D,\ Y^2,\ Y : D$	4	**11.35**	**38.13**	29	46	**0.0735**

Table 2: Model selection for the Tour de France data set with outliers removed.

Under SCAD, the order of inclusion of our covariates is: Y, D^2, D, Y^2 and $Y : D$. This order is different from when we used all data points. The outliers suggest $Y : D$ was more important than it probably is. Note also that when we used all the data points, D was included before D^2 and D^2 was included after Y^2. Again, we fit 5 nested models.

From Table 2, if we choose a model using $\hat{d}_{VC}$, we get the same answer as in Sec. 4.2.1, the model with four variables: Y, D^2, D, Y^2. AIC and BIC choose the same model probably because $(Y : D)$ has low correlation with Speed (-0.08). $\widehat{PERM}_1$, $\widehat{PERM}_2$ and CV choose the model of size 5, which we discount as before because $Y : D$ is only slightly correlated with Speed. That is, the reasoning in Subsec. 4.2.1 for why we think that the model chosen by $\hat{d}_{VC}$ is best continues to hold.

4.3. Application to a Real Data Set

To demonstrate the use of our technique, we re-analyze the Wheat data set presented and studied in Campbell et al. (2003), Dilbirligi et al. (2006), and Dhungana et al. (2007) from a non-complexity based standpoint. The Wheat data set has 2912 observations. More information concerning the data set and the design structure can be found in Campbell et al. (2003). The response variable is YIELD (MG/ha), the covariates that we used are 1000 kernel weight (TKWT), kernels per spike (KPS), Spikes per square meter (SPSM), height of the plant (HT), test weight (TSTWT(KG/hl)), and kernels per square meter (KPSM). Often, in agronomic data sets, there are several classes of explanatory variables, here we have phenotypic, single nucleotide polymorphisms (SNP's) and the variables defining the design. We compare VC dimension based model selection to the methods used in the last subsection and verify our method gives good results.

Our collection of explanatory variables can be grouped into three categories: phenotype, SNP, and design variables. For brevity, we fit only the phenotype variables in Subsec. 4.3.1 and phenotype plus design variables in Subsec. 4.3.2. Comparing these will show that the model selection is unaffected by the design. Also, for brevity, our only analysis is 'multilocation' because we pooleded the data over location-year pairs. A full analysis is in Mpoudeu and Clarke (2018).

4.3.1. Estimation of VC Dimension Using Phenotypic Covariates Only

Intuition suggests

$$YIELD = \beta_0 + \beta_1 \cdot TKWT \cdot KPSM + \epsilon \tag{46}$$

will be a good model because YIELD is essentially the product of the number of kernels and their average weight. Likewise,

$$YIELD = \beta_0 + \beta_1 \cdot TKWT \cdot KPS \cdot SPSM + \epsilon \tag{47}$$

should also be a good model. So, using only phenotpic variables does not lead to a *unique* good model. Both are over simplifications and we can be confident that other influences on YIELD must be considered. Indeed, a 3-dimensional plot of the vectors (YIELD, TKWT, KPSM) looks like a triangle that is bowed out to one side. The bowing means that (46) is only an approximation; other terms are required to explain YIELD. Henceforth, we focus on (46) rather than (47) because we have limited ourselves to second order models.

To implement our multilocation analysis, we first find the order of inclusion of the phenotypic variables in the model, using correlation with YIELD. Then, we find values for $\hat{d}_{VC}$, AIC, BIC, CV, $\widehat{PERM}_1$, $\widehat{PERM}_2$, and the models given by SCAD and ALASSO. Under absolute value of correlation with YIELD, the order of inclusion of the explanatory variables is: TKWT · KPSM, TSTWT · KPSM, KPSM, SPSM · KPS, KPSM^2, KPSM · HT, TKWT · SPSM, TSTWT^2, TSTWT, SPSM · KPSM, KPS · KPSM, TSTWT · SPSM, SPSM SPSM · HT, SPSM^2, TKWT · TSTWT, TKWT, TSTWT · HT, TKWT^2 TKWT · KPS, TSTWT · KPS, TKWT · HT, KPS · HT, HT, HT^2 KPS, KPS^2. So, we consider 27 nested models. This leads to Table 3.

First, we note there is no variability in $\widehat{PERM}_1$ and $\widehat{PERM}_2$ so following standard usage, they select a model with TKWT · KPSM as the only explanatory variable. Likewise, AIC, BIC, and CV suggest the one term model. However, $\hat{d}_{VC} = 14$ means the VC dimension chooses the model with the first 14 terms from the ordered list. SCAD and ALASSO both give the one term model

$$\widehat{YIELD} = 3.43 + 1.12 \cdot TKWT \cdot KPSM, \tag{48}$$

the same as $\widehat{PERM}_1$, $\widehat{PERM}_2$, AIC, BIC and CV. Thus the only reasonable model is the one chosen by $\hat{d}_{VC}$.

4.3.2. Analysis of Wheat Using Phenotypic Data and the Design Structure

Our objective in this subsection is to take the design structure into account and see its impact on the values of the VC dimension and hence on the chosen model. As before, we implement a multilocation analysis. Including design variables forces us to use a more

Size	$\hat{d}_{VC}$	$\widehat{PERM}_1$	$\widehat{PERM}_2$	AIC	BIC	CV

Table 3: The column labeled size gives the number of coefficients for each linear model. The 2^{nd} through 7^{th} columns give the corresponding estimates for $\hat{d}_{VC}$, $\widehat{ERM}_1$, $\widehat{ERM}_2$, AIC, BIC, and CV for Wheat.

complicated bootstrap procedure that would otherwise be sufficient. Thus, to implement our method here, we perform a *restricted* bootstrap. Specifically, we bootstrap in each level of the design variable (incomplete block) so that each half data set has all levels of the design structure. We do this to maintain the design structure and its effects. To include phenotypic variables in the models, we use the same order of inclusion as in Subsec. 4.3.1.

The natural comparison is between Tables 3 and 4. Apart from random variation, they are identical. Moreover, the sparsity methods give exactly the same results in both settings. Thus the conclusions here are the same as in Subsec. 4.3.1: The design variables have no impact on model selection and $\hat{d}_{VC}$ gives the only plausible model.

5. Conclusions

A concise summary of the contributions in this paper is as follows. Sec. 2.1 presents the derivation of the objective function we used to estimate the VC dimension. It is essentially an upper bound on the expected difference between two losses that we have defined as Δ_m or Δ, where the m indicates the discretization of the loss function for a regression problem. In Subsec. 2.2 we give an estimator for d_{VC} that uses our upper bound, nonlinear regression treating sample sizes as design points, a data driven estimator of Δ_m, and an optimization over an arbitrary constant. While this sounds complex, in practice the computations can usually be done in minutes on a regular laptop. Even though we only have an upper bound on Δ_m, in Sec. 3 we are able to give conditions under which our estimator is consistent. This is circumstantial evidence that our upper bound is tight.

Size	$\hat{d}_{VC}$	$\widehat{PERM}_1$	$\widehat{PERM}_2$	AIC	BIC	CV

Table 4: The column labeled size gives the number of coefficients for each linear model. The 2^{nd} through 7^{th} columns give the corresponding estimates for $\hat{d}_{VC}$, $\widehat{PERM}_1$, $\widehat{PERM}_2$, AIC, BIC, and CV for multi-location analysis with design structure.

We have done an extensive comparison of our estimator of VC dimension as a model selection method with seven established model selection methods, namely two forms of empirical risk minimization, AIC, BIC, CV, and two sparsity criteria. Other examples can be found in Mpoudeu and Clarke (2018). We did this for the special case of linear models but the same reasoning can be used for any class of nonlinear models e.g., trees, for which the VC dimension can be identified. We also gave one example of how our estimator for VC dimension performs better than the original estimator in Vapnik et al. (1994). As a generality, our method equals or outperforms these other methods.

Abstract

In many problem settings, parameter vectors are not merely sparse but dependent in such a way that non-zero coefficients tend to cluster together. We refer to this form of dependency as "region sparsity." Classical sparse regression methods, such as the lasso and automatic relevance determination (ARD), which model parameters as independent *a priori*, and therefore do not exploit such dependencies. Here we introduce a hierarchical model for smooth, region-sparse weight vectors and tensors in a linear regression setting. Our approach represents a hierarchical extension of the relevance determination framework, where we add a transformed Gaussian process to model the dependencies between the prior variances of regression weights. We combine this with a structured model of the prior variances of Fourier coefficients, which eliminates unnecessary high frequencies. The resulting prior encourages weights to be region-sparse in two different bases simultaneously. We develop Laplace approximation and Monte Carlo Markov Chain (MCMC) sampling to provide efficient inference for the posterior. Furthermore, a two-stage convex relaxation of the Laplace approximation approach is also provided to relax the inevitable non-convexity during the optimization. We finally show substantial improvements over comparable methods for both simulated and real datasets from brain imaging.

1. Introduction

Recent work in statistics has focused on high-dimensional inference problems in which the number of parameters equals or exceeds the number of samples. We focus specifically on the linear regression setting: consider a scalar response $y_i \in \mathbb{R}$ generated from an input vector $\mathbf{x}_i \in \mathbb{R}^p$ via the linear model:

$$y_i = \mathbf{x}_i{}^\top \mathbf{w} + \epsilon_i, \quad \text{for} \quad i = 1, 2, \cdots, n, \tag{1}$$

with observation noise $\epsilon_i \sim \mathcal{N}(0, \sigma^2)$. The regression (linear weight) vector $\mathbf{w} \in \mathbb{R}^p$ is the quantity of interest. This general problem is ill-posed when $n \leq p$. However, it is surprisingly tractable when $\mathbf{w}$ has special structure, such as sparsity in an appropriate basis. A large literature has provided theoretical guarantees about the solvability of such problems, as well as a suite of practical methods for solving them.

Methods based on simple sparsity such as the lasso (Tibshirani, 1996) typically treat regression weights as independent *a priori*. This neglects a statistical feature of many real-world problems, which is that non-zero weights tend to arise in local groups or clusters. In many problem settings, weights have an explicit geometric relationship, such as indexing in time (e.g., time series regression) or space (e.g., brain imaging data). If a single regression weight is non-zero, nearby weights in time or space are also likely to be non-zero. Conversely, in a region where most weights are zero, any particular coefficient is also likely to be zero. Thus, nearby weights exhibit dependencies that are not captured by independent priors. We refer to this form of dependency as *region sparsity*.

A variety of methods have been developed to incorporate local dependencies between regression weights, such as the group lasso (Yuan and Lin, 2006). However, these methods typically require the user to pre-specify the group size or to partition the weights into groups *a priori*. Such information is unavailable in many applications of interest, and hard partitioning into groups breaks dependencies between nearby coefficients that are assigned to different groups.

In this paper, we take a Bayesian approach to inferring regression weights with region-sparse structure. We introduce a hierarchical prior over $\mathbf{w}$ of the form:

$$\mathbf{u} \sim \mathcal{GP} \tag{2}$$

$$\mathbf{w}|\mathbf{u} \sim \mathcal{N}(0, C(\mathbf{u})), \tag{3}$$

where $\mathbf{u}$ is a latent vector that captures dependencies in the sparsity pattern of $\mathbf{w}$, and $\mathbf{w}|\mathbf{u}$ has a zero-mean Gaussian distribution with a diagonal covariance matrix $C(\mathbf{u})$, given by a deterministic function of $\mathbf{u}$. We use a Gaussian process (GP) prior over $\mathbf{u}$ to encode structural assumptions about region sparsity (e.g., the typical size of clusters of non-zero weights and the spacing between them). This model can be seen as an extension of automatic relevance determination (ARD), in which the elements of $\mathbf{u}$ are *a priori* independent (MacKay, 1992; Neal, 1995). We therefore refer to it as *dependent relevance determination* (DRD).

Note that region-sparsity refers only to the sparsity pattern of regression weights, i.e., the locations where they are non-zero, not to the particular values of the weights themselves.

This is reflected in the fact that we define the DRD prior covariance matrix $C(\mathbf{u})$ to be diagonal, making the weights conditionally independent given the pattern defined by $\mathbf{u}$. In many cases, however, we expect weights to be smooth as well as sparse due to the continuity of the input regressors in space or time. Most of the real datasets do exhibit spatial and temporal correlations. Coefficients usually possess contiguous regions and smoothness. Hence, we are aiming at developing a universal approach easily integrating both structured sparsity and smoothness concurrently. To incorporate smoothness, we combine the standard DRD prior with a squared exponential covariance function. The resulting prior has a non-diagonal covariance matrix that encourages smoothness as well as sparsity. We refer to this extension as *smooth dependent relevance determination* (smooth-DRD). Samples from the smooth-DRD prior have local islands of smooth and non-zero weights, surrounded by large regions of zeros. We will show that combining region-sparsity and smoothness together will significantly enhance the performance in a non-trivial way.

Unfortunately, exact inference under DRD and smooth-DRD priors is analytically intractable. We therefore introduce an approximate inference method based on a Laplace approximation to the posterior over $\mathbf{u}$, and a sampling-based inference method using Monte Carlo Markov Chain (MCMC) sampling. We also derive a two-stage convex relaxation of the Laplace approximation approach in order to overcome the effects of bad local optima.

We show experimental evaluations on 1D simulated datasets comparing the performance among different methods. In addition, the phase transition curve analyses are carried out against lasso to show the superiority of DRD and smooth-DRD in support recovery for group structure sparsity with or without smoothness. Furthermore, the DRD based priors are exploited for three brain imaging datasets. Domain expertise and current evidence in brain imaging suggest that discrimination performance is primarily driven by spatially smooth activation within spatially sparse regions, and several estimation algorithms have been proposed that exploit this structure (Grosenick et al., 2011; Michel et al., 2011; Baldassarre et al., 2012; Gramfort et al., 2013). We provide experimental comparisons to these methods, showing the superiority of DRD in practice. In particular, DRD provides spatial decoding weights for brain imaging data that are both more interpretable and achieve higher decoding performance.

Here we highlight our key contributions as follows:

- We introduce a new hierarchical model for smooth, region-sparse weight tensors. The model uses a Gaussian process to introduce dependencies between prior variances of regression weights governing localized sparsity in weights and simultaneously imposes smoothness by integrating a smoothness-inducing covariance function into the prior distribution of weights.

- We describe two methods for inferring the model parameters: one based on the Laplace approximation and a second based on MCMC. We propose a fast approximate inference method based on the Laplace approximation involving a novel two-stage convex relaxation of the log posterior in order to overcome the effects of bad local optima.

- We show phase transition curves governing the transition from imperfect to near-perfect recovery for lasso and DRD estimators, revealing that group structure and smoothness can have a major impact on the recoverability of sparse signals.

This paper is organized as follows. In Sec. 2, we review the related structured sparsity literature. In Sec. 3, we introduce our new region-sparsity and smoothness inducing priors. In Sec. 4, we propose two approaches to Bayesian inference for parameter estimation, the evidence optimization via Laplace approximation and the MCMC sampling. A two-stage convex relaxation of the Laplace approximation approach is also introduced to alleviate the non-convexity with a more robust two-stage convexity. Sec. 5 introduces a detailed analysis of the structured sparsity and smoothness properties of the DRD based priors and the other methods that can be used for this purpose. Sec. 6 presents the phase transition analysis for lasso and DRD estimators. Sec. 7 shows some experiments on three real brain imaging datasets, comparing different methods that can be used for structured sparsity. Finally, Sec. 8 presents the conclusion and discussion of this work.

2. Related work

The classic method for sparse variable selection is the lasso, introduced by Tibshirani (1996), which places an l_1 penalty on the regression weights. This method can be interpreted as a *maximum a posteriori* (MAP) estimate under a Laplace (or double-exponential) prior. A fully Bayesian treatment of this model was later developed by Park and Casella (2008). A variety of Bayesian methods based on other sparsity-inducing prior distributions have been developed, including the horseshoe prior (Carvalho et al., 2009), which uses a continuous density with an infinitely tall spike at the origin and heavy tails, and the spike-and-slab prior (Mitchell and Beauchamp, 1988) which consists of a weighted mixture of a delta function (the spike) and a broad Gaussian (the slab), both centered at the origin.

Another approach to sparse variable selection comes from empirical Bayes (also known as evidence optimization or "type-II" marginal likelihood). These methods rely on a two-step inference procedure: (1) optimize hyperparameters governing the sparsity pattern via ascent of the marginal likelihood; and then (2) compute MAP estimates of the parameters given the hyperparameters. The most popular such estimator is automatic relevance determination (ARD), which prunes unnecessary coefficients by optimizing the precision of each regression coefficient under a Gaussian model (MacKay, 1992; Neal, 1995). The relevance vector machine (RVM) was later formulated as a general Bayesian framework for obtaining sparse solutions to regression and classification tasks (Tipping, 2001). The RVM has an identical functional form to the support vector machine, but provides probabilistic analysis. Tipping and Faul (2003) then was proposed for RVM to scale up its training procedure.

All these methods can be interpreted as imposing a sparse and independent prior on the regression weights. The resulting posterior over weights has high concentration near the axes, so that many weights end up at zero unless forced away strongly by the likelihood.

In the field of structured sparsity learning, group lasso is the most straightforward extension of lasso to capture sparsity existing across collections of variables (Yuan and Lin, 2006).

They achieved the group sparse structure by introducing an l_1 penalty on the l_2 norms of each group. Moreover, Huang et al. (2011) generalized the group sparsity idea by using coding complexity regularization methods associated with the structure. A variety of other papers have proposed alternative approaches to correlated or structured regularization (Jacob et al., 2009; Liu et al., 2009; Kim and Xing, 2009; Friedman et al., 2010; Jenatton et al., 2011; Kowalski et al., 2013).

Previous literature has also explored Bayesian methods for structured sparse inference. A common strategy is to introduce a latent multivariate Gaussian that controls the correlation structure governing conditionally independent densities over coefficients. Gerven et al. (2009) extended the univariate Laplace prior to a novel multivariate Laplace distribution represented as a scale mixture that induces coupling. Hernández-Lobato and Hernández-Lobato (2013) described a similar approach that results in a marginally horseshoe prior. Several other papers have proposed dependent generalizations of the spike-and-slab prior. Hernández-Lobato et al. (2013) described a group spike-and-slab distribution using a multivariate Bernoulli distribution over the indicators of the spikes associated with a group specification. Subsequently, Andersen et al. (2014, 2015) relaxed the hard-coded group specification by encoding the structure with a generic covariance function. Meanwhile, Engelhardt and Adams (2014) introduced a Bayesian model for structured sparsity that uses a Gaussian process (GP) to control the mixing weights of the spike and slab prior in proportion to feature similarity. Apart from imposing the correlation structure on the independent spike and slab elements, Yu et al. (2012) put forward a hierarchical Bayesian framework with the mixing weights of the cluster patterns generated from Beta distributions. Our work is most similar to Engelhardt and Adams (2014) and Andersen et al. (2015), except that we use an ARD-like approach with a conditionally Gaussian density over coefficients instead of a spike and slab prior. Our work is also the first that we are aware of that simultaneously captures sparsity and smoothness.

3. Dependent relevance determination (DRD) priors

In this section, we introduce the DRD prior and the smooth-DRD prior, an extension to incorporate smoothness of regression weights. We focus on the linear regression setting with conditional responses distributed as:

$$\mathbf{y}|X, \mathbf{w}, \sigma^2 \sim \mathcal{N}(\mathbf{y}|X\mathbf{w}, \sigma^2 I), \tag{4}$$

where $X = [\mathbf{x}_1, \ldots, \mathbf{x}_n]^\top \in \mathbb{R}^{n\times p}$ denotes the design matrix, $\mathbf{y} = [y_1, \cdots, y_n]^\top \in \mathbb{R}^n$ is the observation vector, and σ^2 is the observation noise variance, where p is the dimension of the input vectors and n is the number of samples.

3.1. Automatic relevance determination

The relevance determination framework includes a family of estimators that rely on a zero-mean multivariate normal prior:

$$\mathbf{w}|\boldsymbol{\theta} \sim \mathcal{N}(0, C(\boldsymbol{\theta})), \tag{5}$$

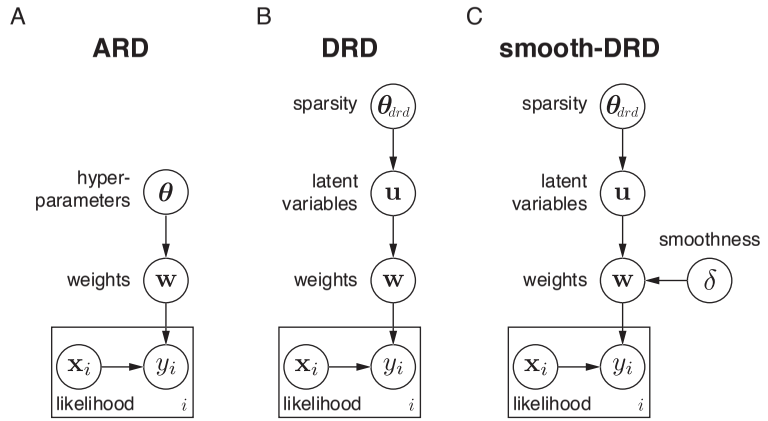

Figure 1: Graphical models for ARD, DRD and smooth-DRD.

where the prior covariance matrix $C(\boldsymbol{\theta})$ is a function of some hyperparameters $\boldsymbol{\theta}$. The form of the dependence of C on θ leads to different forms of assumed structure, including sparsity (Tipping, 2001; Faul and Tipping, 2002; Wipf and Nagarajan, 2008), smoothness (Sahani and Linden, 2003; Schmolck, 2008), or locality (Park and Pillow, 2011).

Automatic relevance determination (ARD) defines the prior covariance to be diagonal, $C_{ii} = \theta_i^{-1}$, where a distinct hyperparameter θ_i specifies the prior precision for the i'th regression coefficient. ARD places an independent improper gamma prior on each hyperparameter, $\theta_i \sim \text{gamma}(0, 0)$, and performs inference for $\{\theta_i\}$ by maximizing the marginal likelihood. This sends many θ_i to infinity, pruning the corresponding coefficients out of the model. A typical graphical model for ARD is presented in Fig. 1A. The independence assumption in the prior over hyperparameters means that there is no tendency for nearby coefficients to remain in or be pruned from the model. This is the primary shortcoming that our method seeks to overcome.

3.2. DRD: A hierarchical extension of ARD

We extend the standard ARD model by adding a level of hierarchy. Instead of directly optimizing hyperparameters that control sparsity of each weight, as in ARD, we introduce a latent vector governed by a GP prior to capture dependencies in the sparsity pattern over weights (see Fig. 1B). Let $\mathbf{u} \in \mathbb{R}^p$ denote a latent vector distributed according to a GP prior

$$\mathbf{u} \sim \mathcal{GP}(b\mathbf{1}, K), \tag{6}$$

where $b \in \mathbb{R}$ is the scalar mean, $\mathbf{1}$ is a length-p vector of ones, and covariance matrix K is determined by a squared exponential kernel. The i,j'th entry of K is given by

$$K_{ij} = \rho \exp\left(-\frac{||\chi_i - \chi_j||^2}{2l^2}\right), \tag{7}$$

where χ_i and χ_j are the spatial locations of weights w_i and w_j, respectively, and kernel hyperparameters are the marginal variance $\rho > 0$ and length scale $l > 0$. Samples from this GP on a grid of locations $\{\chi_i\}$ are smooth on the scale of l, and have mean b and marginal variance ρ.

To obtain a prior over region-sparse weight vectors, we transform $\mathbf{u}$ to the positive values via a nonlinear function f, and the transformed latent vector $\mathbf{g} = f(\mathbf{u})$ forms the diagonal of a diagonal covariance matrix for a zero-mean Gaussian prior over the weights:

$$C_{drd} = \text{diag}\Big[f(\mathbf{u})\Big], \tag{8}$$

where f is a monotonically increasing function that squashes negative values of $\mathbf{u}$ to near zero. Here we will mainly consider the exponential function $f(u) = \exp(u)$, but we will also consider "soft-rectification" function $f(u) = \log(1+\exp(u))$ in the experiment for numerical stability. When the GP mean b is very negative relative to the prior standard deviation $\sqrt{\rho}$, most elements of $\mathbf{g}$ will be close to zero, resulting in weights $\mathbf{w}$ with a high degree of sparsity (i.e., few weights far from zero). The length scale l determines the smoothness of samples $\mathbf{u}$ and thereby determines the typical width of bumps in the prior variance $\mathbf{g}$. We denote the set of hyperparameters governing the GP prior on $\mathbf{u}$ by $\boldsymbol{\theta}_{drd} = \{b, \rho, l\}$. Fig. 2A shows a depiction of sampling from the DRD generative model.

3.3. Smooth-DRD

The standard DRD model imposes smooth dependencies in the prior variances of the regression weights, but the weights themselves remain uncorrelated (as reflected by the fact that the covariance C_{drd} is diagonal). In many settings, however, we expect weights to exhibit smoothness in addition to region sparsity. To capture this property, we can augment DRD with a second Gaussian process, denoted as smooth-DRD, that induces smoothness, contributing off-diagonal structure to the prior covariance matrix while preserving the marginal variance pattern imposed by DRD (see Fig. 1C).

Let Σ denote a covariance matrix governed by a standard squared-exponential GP kernel:

$$\Sigma_{ij} = \exp\left(-\frac{||\chi_i - \chi_j||^2}{2\delta^2}\right), \tag{9}$$

with length scale δ and marginal variance set to 1. Then we define the *smooth-DRD* covariance as the "sandwich" matrix given by:

$$C_{smooth-DRD} = C_{drd}^{\frac{1}{2}} \, \Sigma \, C_{drd}^{\frac{1}{2}}, \tag{10}$$

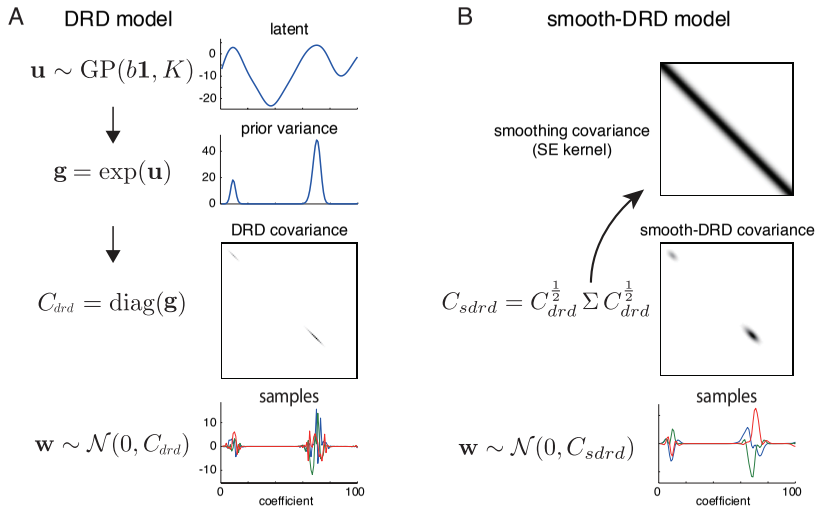

Figure 2: The sampling procedures for the generative models of DRD and smooth-DRD.

where $C_{drd}^{\frac{1}{2}}$ is simply the matrix square root of the diagonal covariance matrix C_{drd}. The resulting matrix has the same diagonal entries as C_{drd}, but has off-diagonal structure governed by Σ that induces smoothness. This matrix is positive semi-definite because, for all $\mathbf{x} \in \mathbb{R}^p$, $\mathbf{x}^\top C_{smooth-DRD}\mathbf{x} = (C_{drd}^{\frac{1}{2}}\mathbf{x})^\top \Sigma (C_{drd}^{\frac{1}{2}}\mathbf{x}) \geq 0$, due to the positive semi-definiteness of Σ. It is therefore a valid covariance matrix. Fig. 2B shows a depiction of sampling from the smooth-DRD generative model. In the following, we will let $\boldsymbol{\theta}$ denote the entire hyperparameter set for the smooth-DRD prior and the noise variance, where $\boldsymbol{\theta} = \{\boldsymbol{\theta}_{drd}, \delta, \sigma^2\}$.

4. Parameter estimation

In this section, we describe two methods for inference under the DRD and smooth-DRD priors: (1) empirical Bayesian inference via evidence optimization using the Laplace approximation; and (2) fully Bayesian inference via MCMC sampling. The first seeks to find the MAP estimate of the latent vector $\mathbf{u}$ governing region sparsity via optimization of the log marginal likelihood, and then provides a conditional MAP estimate of the weights $\mathbf{w}$. The second uses MCMC sampling to integrate over $\mathbf{u}$ and provides the posterior mean of $\mathbf{w}$ given the data via an average over samples.

4.1. Empirical Bayes inference with Laplace approximation

The likelihood $p(\mathbf{y}|X, \mathbf{w}, \sigma^2)$ (eq. 4) and the prior $p(\mathbf{w}|\mathbf{u}, \boldsymbol{\theta}_{drd}, \delta)$ (eq. 5) are both Gaussian given the latent variables $\mathbf{u}$ and hyperparameters $\boldsymbol{\theta}$, giving a conditionally Gaussian posterior over the regression weights:

$$p(\mathbf{w}|X, \mathbf{y}, \mathbf{u}, \boldsymbol{\theta}) = \mathcal{N}(\boldsymbol{\mu}_{\mathbf{w}}, \Lambda_{\mathbf{w}}), \tag{11}$$

with covariance and mean given by

$$\Lambda_{\mathbf{w}} = (\tfrac{1}{\sigma^2} X^\top X + C^{-1})^{-1}, \quad \boldsymbol{\mu}_{\mathbf{w}} = \tfrac{1}{\sigma^2} \Lambda_{\mathbf{w}} X^\top \mathbf{y}, \tag{12}$$

where prior covariance matrix C is a function of $\mathbf{u}$ and $\boldsymbol{\theta}$. The posterior mean $\boldsymbol{\mu}_{\mathbf{w}}$ is also the MAP estimate of $\mathbf{w}$ given latent vector $\mathbf{u}$ and hyperparameters $\boldsymbol{\theta}$.

Empirical Bayes inference involves setting the hyperparameters by maximizing the marginal likelihood or evidence, given by

$$p(\mathbf{y}|X, \boldsymbol{\theta}) = \iint p(\mathbf{y}|X, \mathbf{w}, \sigma^2) p(\mathbf{w}|\mathbf{u}, \delta) p(\mathbf{u}|\boldsymbol{\theta}_{drd})\, d\mathbf{w}\, d\mathbf{u}. \tag{13}$$

We can take the integral over $\mathbf{w}$ analytically due to the conditionally Gaussian prior and the likelihood, giving the simplified expression

$$p(\mathbf{y}|X, \boldsymbol{\theta}) = \int p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta)\, p(\mathbf{u}|\boldsymbol{\theta}_{drd})\, d\mathbf{u}, \tag{14}$$

where the conditional evidence given $\mathbf{u}$ is a normal density evaluated at $\mathbf{y}$,

$$p(\mathbf{y}|X, \mathbf{u}, \boldsymbol{\theta}) = \mathcal{N}(\mathbf{y}|\mathbf{0}, XCX^\top + \sigma^2 I). \tag{15}$$

However, the integral over $\mathbf{u}$ has no analytic form. We therefore resort to the Laplace's method to approximate this integral.

4.1.1. Laplace approximation

Laplace's method provides a technique for approximating intractable integrals using a second-order Taylor expansion in $\mathbf{u}$ of the log of the integrand in (eq. 14). This method is equivalent to approximating the posterior over $\mathbf{u}$ given $\boldsymbol{\theta}$ by a Gaussian centered on its mode (MacKay (2003), chap. 27). The exact posterior is given by Bayes' rule:

$$p(\mathbf{u}|X, \mathbf{y}, \boldsymbol{\theta}) = \frac{1}{Z}\, p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta) p(\mathbf{u}|\boldsymbol{\theta}_{drd}), \tag{16}$$

where the normalizing constant, $Z = p(\mathbf{y}|X, \boldsymbol{\theta})$, is the marginal likelihood we wish to compute. The Gaussian approximation to the posterior is

$$p(\mathbf{u}|X, \mathbf{y}, \boldsymbol{\theta}) \approx \mathcal{N}(\mathbf{m}_{\mathbf{u}}, \Lambda_{\mathbf{u}}), \tag{17}$$

where $\mathbf{m}_{\mathbf{u}}$ is the posterior mode and $\Lambda_{\mathbf{u}}$ is a local approximation to the posterior covariance. Substituting this approximation into (eq. 16), we can directly solve for Z:

$$Z \approx \frac{p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta) p(\mathbf{u}|\boldsymbol{\theta}_{drd})}{\mathcal{N}(\mathbf{m}_{\mathbf{u}}, \Lambda_{\mathbf{u}})}. \tag{18}$$

The right-hand-side of this expression can be evaluated at any $\mathbf{u}$, but it is conventional to use the mode, $\mathbf{u} = \mathbf{m}_{\mathbf{u}}$, given that this is where the approximation is most accurate.

To compute the Laplace approximation, we first numerically optimize the log of the posterior (eq. 16) to find its mode:

$$\mathbf{m}_{\mathbf{u}} = \arg\max_{\mathbf{u}} \Big[\log p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta) + \log p(\mathbf{u}|\boldsymbol{\theta}_{drd}) \Big], \tag{19}$$

where the first term is the log of the conditional evidence given $\mathbf{u}$ (eq. 15),

$$\log p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta) = -\frac{1}{2} \log |XCX^\top + \sigma^2 I| - \frac{1}{2} \mathbf{y}^\top (XCX^\top + \sigma^2 I)^{-1} \mathbf{y} + const, \tag{20}$$

and the second is the log of the GP prior for $\mathbf{u}$,

$$\log p(\mathbf{u}|\boldsymbol{\theta}_{drd}) = -\frac{1}{2} (\mathbf{u} - b\mathbf{1})^\top K^{-1} (\mathbf{u} - b\mathbf{1}) - \frac{1}{2} \log |K| + const. \tag{21}$$

We use quasi-Newton methods to optimize this objective function because the fixed point methods developed for ARD (e.g., MacKay (1992); Tipping and Faul (2003)), which operate on one element of the prior precision vector at a time, are inefficient due to the strong dependencies induced by the GP prior. However, because this high-dimensional optimization problem is non-convex, we also formulate a novel approach for optimizing $\mathbf{u}$ using a two-stage convex relaxation inspired by Wipf and Nagarajan (2008). We will present the method in Sec. 4.1.2.

Given the mode of the log-posterior $\mathbf{m}_{\mathbf{u}}$, the second step to computing the Laplace-based approximation to the marginal likelihood is to compute the Hessian (2nd derivative matrix) of the log-posterior at $\mathbf{m}_{\mathbf{u}}$. The negative inverse of the Hessian gives us the posterior covariance for the Laplace approximation (eq. 17):

$$\Lambda_{\mathbf{u}} = \left(-\frac{\partial^2}{\partial \mathbf{u} \partial \mathbf{u}^\top} \Big[\log p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta) + \log p(\mathbf{u}|\boldsymbol{\theta}_{drd}) \Big] \right)^{-1}. \tag{22}$$

See Appendix A for the explicit derivation of Hessian for the DRD model.

Given these ingredients, we can now write down the approximation to the log marginal likelihood (eq. 18):

$$\log p(\mathbf{y}|X, \boldsymbol{\theta}) \approx \log p(\mathbf{y}|X, \mathbf{m}_{\mathbf{u}}, \sigma^2, \delta) + \log p(\mathbf{m}_{\mathbf{u}}|\boldsymbol{\theta}_{drd}) + \tfrac{1}{2} \log |\Lambda_{\mathbf{u}}| + const, \tag{23}$$

where the first term is simply the log conditional evidence (eq. 20) with prior covariance C evaluated at $\mathbf{m}_{\mathbf{u}}$.

It is this log-marginal likelihood that we seek to optimize in order to learn hyperparameters $\boldsymbol{\theta}$. The key difficulty is that the Laplace approximation parameters $\mathbf{m}_{\mathbf{u}}$ and $\Lambda_{\mathbf{u}}$ depend

implicitly on $\boldsymbol{\theta}$ (since $\mathbf{m_u}$ is determined by numerical optimization at a fixed value of $\boldsymbol{\theta}$), making it impractical to evaluate their derivatives with respect to $\boldsymbol{\theta}$. To address this problem, we introduce a method for partially decoupling the Laplace approximation from the hyperparameters (Sec. 4.1.3).

4.1.2. A two-stage convex relaxation to Laplace Approximation

The optimization for $\mathbf{m_u}$ (eq. 19), the mode of the posterior over the latent vector $\mathbf{u}$, is a critical step for computing the Laplace approximation. However, the negative log-posterior is a non-convex function in $\mathbf{u}$, meaning that there is no guarantee of obtaining the global minimum. In this section, DRD resembles the original ARD model. Neither of the two most popular optimization methods for ARD, MacKay's fixed-point method (MacKay, 1992) and Tipping and Faul's fast-ARD (Tipping and Faul, 2003), are guaranteed to converge to a local minimum or even a fixed point of the log-posterior.

In this section, we introduce an alternative formulation of the cost function in (eq. 19) using an auxiliary function: this provides a tight convex upper bound that can be optimized more easily. The technique is similar to the iterative re-weighted l_1 formulation of ARD in Wipf and Nagarajan (2008).

Let $\mathcal{L}(\mathbf{u})$ denote the sum of terms in the negative log-posterior (eq. 19) that involve $\mathbf{u}$,

$$\mathcal{L}(\mathbf{u}) = \frac{1}{2}\log|XCX^\top + \sigma^2 I| + \frac{1}{2}\mathbf{y}^\top(XCX^\top + \sigma^2 I)^{-1}\mathbf{y} + \frac{1}{2}(\mathbf{u} - b\mathbf{1})^\top K^{-1}(\mathbf{u} - b\mathbf{1}), \quad (24)$$

where $C = \mathrm{diag}(e^{\mathbf{u}})$. We denote the three terms it contains as:

$$\mathcal{L}_1(\mathbf{u}) = \frac{1}{2}\log|X\mathrm{diag}(e^{\mathbf{u}})X^\top + \sigma^2 I| \quad (25)$$

$$\mathcal{L}_2(\mathbf{u}) = \frac{1}{2}\mathbf{y}^\top(X\mathrm{diag}(e^{\mathbf{u}})X^\top + \sigma^2 I)^{-1}\mathbf{y} \quad (26)$$

$$\mathcal{L}_3(\mathbf{u}) = \frac{1}{2}(\mathbf{u} - b\mathbf{1})^\top K^{-1}(\mathbf{u} - b\mathbf{1}). \quad (27)$$

Here $\mathcal{L}_1(\mathbf{u})$ and $\mathcal{L}_3(\mathbf{u})$ are both convex in $\mathbf{u}$ (see proof in Appendix B). We can derive a tight convex upper bound for $\mathcal{L}_2(\mathbf{u})$, thus providing a tight convex upper bound for $\mathcal{L}(\mathbf{u})$.

We know that $\mathcal{L}_2(\mathbf{u})$ is non-convex, but we are interested in rewriting it using concave duality. Let $\mathbf{h}(\mathbf{u}) : \mathbb{R}^p \to \Omega \subset \mathbb{R}^p$ be a mapping with range Ω, which may or may not be a one-to-one map. We assume that there exists a concave function $\Phi(\boldsymbol{\eta}) : \Omega \to \mathbb{R}, \forall \boldsymbol{\eta} \in \Omega$, such that $\mathcal{L}_2(\mathbf{u}) = \Phi(\mathbf{h}(\mathbf{u}))$ holds. To exploit this technique, we first rewrite $\mathcal{L}_2$ using the matrix inverse lemma (Higham, 2002) as:

$$\mathcal{L}_2(\mathbf{u}) = \frac{1}{2\sigma^2}\mathbf{y}^\top\mathbf{y} - \frac{1}{2\sigma^4}\mathbf{y}^\top X\left(\frac{1}{\sigma^2}X^\top X + \mathrm{diag}(e^{-\mathbf{u}})\right)^{-1}X^\top\mathbf{y}. \quad (28)$$

Then, setting $\mathbf{h}(\mathbf{u}) = e^{-\mathbf{u}}$, which is convex in $\mathbf{u}$, we have

$$\mathcal{L}_2(\mathbf{u}) = \Phi(\mathbf{h}(\mathbf{u})) = \frac{1}{2\sigma^2}\mathbf{y}^\top\mathbf{y} - \frac{1}{2\sigma^4}\mathbf{y}^\top X\left(\frac{1}{\sigma^2}X^\top X + \mathrm{diag}(\mathbf{h}(\mathbf{u}))\right)^{-1}X^\top\mathbf{y}. \quad (29)$$

Algorithm 1 A two-stage convex relaxation method for DRD Laplace approximation

Input: $X, \mathbf{y}, \boldsymbol{\theta} = \{\sigma^2, \delta, b, \rho, l\}$
Output: $\hat{\mathbf{u}}$
initialize dual variable $\hat{\mathbf{z}}_i = 1$, $\forall i = 1, 2, ..., p$
Repeat the following two steps until convergence:
1. Fix $\hat{\mathbf{z}}$, let $\hat{\mathbf{u}} = \mathrm{argmin}_{\mathbf{u}\in\mathbb{R}^p}\left[\mathbf{z}^\top\mathbf{h}(\mathbf{u}) + \mathcal{L}_1(\mathbf{u}) + \mathcal{L}_3(\mathbf{u})\right]$ in (eq. 33)
2. Fix $\hat{\mathbf{u}}$, let $\hat{\mathbf{z}} = \nabla_{\boldsymbol{\eta}}\Phi(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\mathbf{h}(\hat{\mathbf{u}})}$ in (eq. 34)

This expression is concave in $\mathbf{h}(\mathbf{u})$ (inverse of a matrix is convex), and thus can be expressed as a minimum over upper-bounding hyperplanes via

$$\mathcal{L}_2(\mathbf{u}) = \Phi(\mathbf{h}(\mathbf{u})) = \inf_{\mathbf{z}\in\mathbb{R}^p}\left[\mathbf{z}^\top\mathbf{h}(\mathbf{u}) - \mathcal{L}^*_{\mathbf{h}}(\mathbf{z})\right], \quad (30)$$

where $\mathcal{L}^*_{\mathbf{h}}(\mathbf{z})$ is the concave conjugate of $\Phi(\boldsymbol{\eta})$ that is defined by the duality relationship

$$\mathcal{L}^*_{\mathbf{h}}(\mathbf{z}) = \inf_{\boldsymbol{\eta}\in\mathbb{R}^p}\left[\mathbf{z}^\top\boldsymbol{\eta} - \Phi(\boldsymbol{\eta})\right], \quad (31)$$

and $\mathbf{z}$ is the dual variable. Note, however, that for our purpose it is not necessary to ever explicitly compute $\mathcal{L}^*_{\mathbf{h}}(\mathbf{z})$. This leads to the following upper-bounding auxiliary cost function

$$\Phi(\mathbf{h}(\mathbf{u}), \mathbf{z}) = \mathbf{z}^\top\mathbf{h}(\mathbf{u}) - \mathcal{L}^*_{\mathbf{h}}(\mathbf{z}) \geq \Phi(\mathbf{h}(\mathbf{u})). \quad (32)$$

Thus, it naturally admits the tight convex upper bound for $\mathcal{L}(\mathbf{u})$,

$$\mathcal{L}(\mathbf{u}, \mathbf{z}) \triangleq \mathbf{z}^\top\mathbf{h}(\mathbf{u}) - \mathcal{L}^*_{\mathbf{h}}(\mathbf{z}) + \mathcal{L}_1(\mathbf{u}) + \mathcal{L}_3(\mathbf{u}) \geq \mathcal{L}(\mathbf{u}). \quad (33)$$

Moreover, for any fixed $\boldsymbol{\eta} = \mathbf{h}(\mathbf{u})$, it's well-known that the minimum of the right hand side of (eq. 31) is achieved at

$$\hat{\mathbf{z}} = \nabla_{\boldsymbol{\eta}}\Phi(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\mathbf{h}(\mathbf{u})}. \quad (34)$$

This leads to the general optimization procedure presented in Algorithm 1. By repeatedly refining the dual parameter $\mathbf{z}$, we can obtain a repeatedly improved convex relaxation, leading to a solution superior to that of the initial convex relaxation.

Now we show the analysis of global convergence. According to the Zangwill's *Global Convergence Theorem* (Zangwill, 1969), let $\mathcal{A}(\cdot) : \mathcal{U} \to \mathcal{P}(\mathcal{U})$ be a point-to-set mapping to handle the multi-global minima case, which satisfies Steps 1 and 2 of the proposed algorithm, then

Theorem 1 *From any initialization point $\mathbf{u}^0 \in \mathbb{R}^p$, the sequence of parameter estimates $\{\mathbf{u}^k\}$ generated via $\mathbf{u}^{k+1} \in \mathcal{A}(\mathbf{u}^k)$ is guaranteed to converge monotonically to a local minimum (or saddle point) of $\mathcal{L}(\mathbf{u})$.*

Proof Let $\Gamma \in \mathcal{U}$ be a solution set. In order to use the global convergence theorem, we need to show that

1) all points $\{\mathbf{u}^k\}$ are contained in a compact set $S \in \mathcal{U}$, where $\mathcal{U}$ is $\mathbb{R}^p$ in our problem;
2) there is a continuous function Z on $\mathcal{U}$ such that
(a) if $x \notin \Gamma$, then $Z(y) < Z(x)$ for all $y \in \mathcal{A}(x)$;
(b) if $x \in \Gamma$, then $Z(y) \leq Z(x)$ for all $y \in \mathcal{A}(x)$;
3) the mapping $\mathcal{A}$ is closed at points outside Γ.

First, let's define the mapping $\mathcal{A}$ to be achieved by

$$\mathbf{u}^{k+1} \in \mathcal{A}(\mathbf{u}^k) = \text{argmin}_{\mathbf{u}\in\mathbb{R}^p}\, \mathcal{F}(\mathbf{u}, \mathbf{u}^k) = \text{argmin}_{\mathbf{u}\in\mathbb{R}^p}\, \mathbf{z}^{k\top}\mathbf{h}(\mathbf{u}) - \mathcal{L}^*_{\mathbf{h}}(\mathbf{z}) + \mathcal{L}_1(\mathbf{u}) + \mathcal{L}_3(\mathbf{u}), \quad (35)$$

where $\mathbf{z}^k = \nabla_{\boldsymbol{\eta}}\Phi(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\mathbf{h}(\mathbf{u}^k)}$. We can prove that $\mathcal{F}$ is coercive, i.e., when $||\mathbf{u}|| \to \infty$, we have $\mathcal{F}(\mathbf{u}) \to \infty$ (proof in Appendix C). Therefore, the solution set of $\mathcal{F}(\mathbf{u})$ is bounded and nonempty. Accordingly, $\mathcal{A}(\mathbf{u})$ is nonempty. Using Proposition 7 in (Gunawardana and Byrne, 2005), we can further show that the point-to-set mapping $\mathcal{A}$ is closed at $\mathbf{u} \in \mathcal{U}$. Condition 3 is satisfied.

For each $\mathbf{u}^k$, $\mathbf{u}^{k+1}$ is the solution of $\mathcal{F}(\mathbf{u})$, and $\mathcal{A}(\mathbf{u})$ is a closed mapping; therefore each $\mathbf{u}^{k+1}$ belongs to a compact set. We know that the union of two compact sets is compact. Therefore, all points $\{\mathbf{u}^k\}$ are contained in a compact set $S \in \mathcal{U}$. Condition 1 is satisfied.

To prove condition 2, we must show that for any $\mathbf{u}^k$, $\mathcal{L}(\mathbf{u}^{k+1}) < \mathcal{L}(\mathbf{u}^k)$ for all $\mathbf{u}^{k+1} \in \mathcal{A}(\mathbf{u}^k)$ if $\mathbf{u}^k \notin \Gamma$; $\mathcal{L}(\mathbf{u}^{k+1}) \leq \mathcal{L}(\mathbf{u}^k)$ for all $\mathbf{u}^{k+1} \in \mathcal{A}(\mathbf{u}^k)$ if $\mathbf{u}^k \in \Gamma$. At any $\mathbf{u}^k$, the auxiliary cost function $\mathcal{F}(\mathbf{u})$ (eq. 35) is strictly tangent to $\mathcal{L}(\mathbf{u})$ at $\mathbf{u}^k$. Therefore, if $\mathbf{u}^k \notin \Gamma$, $\mathcal{L}(\mathbf{u}^k) = \mathcal{F}(\mathbf{u}^k) > \mathcal{F}(\mathbf{u}^{k+1}) \geq \mathcal{L}(\mathbf{u}^{k+1})$, thus $\mathcal{L}(\mathbf{u}^k) > \mathcal{L}(\mathbf{u}^{k+1})$; if $\mathbf{u}^k \in \Gamma$, $\mathcal{L}(\mathbf{u}^k) = \mathcal{F}(\mathbf{u}^k) = \mathcal{F}(\mathbf{u}^{k+1}) \geq \mathcal{L}(\mathbf{u}^{k+1})$, thus $\mathcal{L}(\mathbf{u}^k) \geq \mathcal{L}(\mathbf{u}^{k+1})$. Condition 2 is satisfied. ■

The algorithm could theoretically converge to a saddle point, but any minimal perturbation would easily lead to escape.

4.1.3. Decoupled Laplace approximation

To optimize the marginal likelihood for the DRD hyperparameters (eq. 23), we should ideally replace $\mathbf{m}_\mathbf{u}$ and $\Lambda_\mathbf{u}$ with explicit expressions in $\boldsymbol{\theta}$ in order to accurately compute derivatives with respect to $\boldsymbol{\theta}$. However, the deterministic formulation of such functions is intractable. We can nevertheless partially overcome this dependence by introducing a "decoupled" Laplace approximation that takes into account the dependence of $\Lambda_\mathbf{u}$ on the hyperparameters $\boldsymbol{\theta}_{drd}$. Wu et al. (2017) also proposed a conceptually similar decoupled Laplace approximation.

Specifically, we rewrite the inverse Laplace posterior covariance (eq. 22):

$$\Lambda_\mathbf{u} = (\Gamma + \Psi(\boldsymbol{\theta}_{drd}))^{-1} \quad (36)$$

where Γ is the negative Hessian of the log-likelihood (which is independent of $\boldsymbol{\theta}_{drd}$),

$$\Gamma = -\frac{\partial^2}{\partial\mathbf{u}\partial\mathbf{u}^\top}\log p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta), \quad (37)$$

and $\Psi(\boldsymbol{\theta}_{drd})$ is the precision matrix of the prior distribution for $\mathbf{u}$,

$$\Psi(\boldsymbol{\theta}_{drd}) = -\frac{\partial^2}{\partial\mathbf{u}\partial\mathbf{u}^\top}\log p(\mathbf{u}|\boldsymbol{\theta}_{drd}) = K^{-1}, \quad (38)$$

Algorithm 2 Evidence optimization using decoupled Laplace approximation

Input: $X, \mathbf{y}$
Output: latents $\hat{\mathbf{u}}$, hyperparameters $\hat{\boldsymbol{\theta}} = \{\hat{\sigma^2}, \hat{\delta}, \hat{b}, \hat{\rho}, \hat{l}\}$.
At iteration t:
1. Numerically optimize log-posterior for latents $\mathbf{m}^t_\mathbf{u}$ using (eq. 19) or Algorithm 1.
2. Compute Γ^t using negative Hessian of the log conditional evidence (eq. 37).
3. Numerically optimize $p(\mathbf{y}|X, \boldsymbol{\theta}, \mathbf{m}^t_\mathbf{u}, \Gamma^t)$ (eq. 39) for $\boldsymbol{\theta}^t$.
Repeat step 1, 2 and 3 until $\{\mathbf{m}_\mathbf{u}, \Gamma\}$ and $\boldsymbol{\theta}$ converge.

which is the inverse of the GP prior covariance governing $\mathbf{u}$ (eq. 7). Substituting for $\Lambda_\mathbf{u}$ in (eq. 23), this gives:

$$\log p(\mathbf{y}|X, \boldsymbol{\theta}) \approx \log p(\mathbf{y}|X, \mathbf{m}_\mathbf{u}, \sigma^2, \delta) + \log p(\mathbf{m}_\mathbf{u}|\boldsymbol{\theta}_{drd}) - \tfrac{1}{2}\log|\Gamma + K^{-1}| + const. \quad (39)$$

This form decomposes the curvature at the posterior mode into the likelihood curvature and the prior curvature. In this way, the posterior curvature tracks the influence of the change in the prior curvature as we optimize the hyperparameters $\boldsymbol{\theta}$, while keeping the influence of the likelihood curvature fixed. This decoupling allows us to update the posterior without recomputing the Hessian. It will be accurate so long as the Hessian of the likelihood changes slowly over local regions in parameter space.

To optimize hyperparameters under the decoupled Laplace approximation, we fix $\mathbf{m}_\mathbf{u}$ and Γ using the current mode of the posterior, and optimize (eq. 39) directly for $\boldsymbol{\theta}$, incorporating the dependence of K on $\boldsymbol{\theta}_{drd}$. With this approach, the first term, $\log p(\mathbf{y}|X, \mathbf{m}_\mathbf{u}, \sigma^2, \delta)$, captures the dependence on σ^2 and δ; the second term, $\log p(\mathbf{m}_\mathbf{u}|\boldsymbol{\theta}_{drd})$, restricts $\boldsymbol{\theta}_{drd}$ around the current mode; and the third term $-\frac{1}{2}\log|\Gamma + K^{-1}|$ pushes $\boldsymbol{\theta}_{drd}$ along the second order curvature given the GP kernel. This decoupling weakens the strong dependency between $\boldsymbol{\theta}_{drd}$ and $\mathbf{m}_\mathbf{u}$, maintaining the accuracy of the Laplace approximation as we adjust $\boldsymbol{\theta}_{drd}$.

To ensure the accuracy of the Laplace approximation, in each iteration t, we optimize eq. (39) over a restricted region of the hyperparameter space around the previous hyperparameter setting θ^{t-1}, which allows varying within 20% of its current value on each iteration in our experiments. This prevents $\boldsymbol{\theta}$ from moving too far from the region where the current Laplace approximation ($\mathbf{m}_\mathbf{u}$ and Γ) is accurate. Then, based on a new hyperparameter setting $\boldsymbol{\theta}^t$, we update the Laplace approximation parameters $\mathbf{m}_\mathbf{u}$ and Γ. This procedure is summarized in Algorithm 2. The algorithm stops when $\{\mathbf{m}_\mathbf{u}, \Gamma\}$ and $\boldsymbol{\theta}$ converge. The empirical Bayes estimate is then given by the MAP estimate of the weights $\mathbf{w}_{map} = \boldsymbol{\mu}_\mathbf{w}$ (eq. 12) conditioned on the optimal latents $\hat{\mathbf{u}} = \mathbf{m}_\mathbf{u}$ and hyperparameters $\hat{\boldsymbol{\theta}}$.

4.2. Fully Bayesian inference with MCMC

An alternate approach to the empirical Bayesian inference procedure described above is to perform fully Bayesian inference using Markov Chain Monte Carlo (MCMC). Using sampling, we can compute the integrals over $\mathbf{u}$ and $\boldsymbol{\theta}$ in order to compute the posterior mean (Bayes' least squares estimates) for $\mathbf{w}$. The full posterior distribution over $\mathbf{w}$ can be

written as

$$p(\mathbf{w}|X,\mathbf{y}) = \iint p(\mathbf{w}|X,\mathbf{y},\mathbf{u},\boldsymbol{\theta})p(\mathbf{u},\boldsymbol{\theta}|X,\mathbf{y})\,d\mathbf{u}\,d\boldsymbol{\theta} \quad (40)$$

$$= \iint \mathcal{N}(\mathbf{w}|\boldsymbol{\mu}_{\mathbf{w}},\Lambda_{\mathbf{w}})p(\mathbf{u},\boldsymbol{\theta}|X,\mathbf{y})\,d\mathbf{u}\,d\boldsymbol{\theta}, \quad (41)$$

where mean $\boldsymbol{\mu}_{\mathbf{w}}$ and covariance $\Lambda_{\mathbf{w}}$ are functions of $\mathbf{u}$ and $\boldsymbol{\theta}$ (eq. 12). This suggests a Monte Carlo representation of the posterior as

$$p(\mathbf{w}|X,\mathbf{y}) = \frac{1}{N}\sum_{i=1}^{N}\mathcal{N}\left(\mathbf{w}\;\middle|\;\boldsymbol{\mu}_{\mathbf{w}}(\mathbf{u}^{(i)},\boldsymbol{\theta}^{(i)}),\Lambda_{\mathbf{w}}(\mathbf{u}^{(i)},\boldsymbol{\theta}^{(i)})\right) \quad (42)$$

$$\mathbf{u}^{(i)},\boldsymbol{\theta}^{(i)} \sim p(\mathbf{u},\boldsymbol{\theta}|X,\mathbf{y}), \quad (43)$$

where i is the index of the samples and N is the total number of samples. We can use Gibbs sampling to alternately sample $\mathbf{u}$ and $\boldsymbol{\theta}$ from their conditional distributions given the other. The joint posterior distribution of $\mathbf{u}$ and $\boldsymbol{\theta}$ has the following proportional relationship,

$$p(\mathbf{u},\boldsymbol{\theta}|X,\mathbf{y}) \propto p(\mathbf{y}|X,\mathbf{u},\sigma^2,\delta)p(\mathbf{u}|\boldsymbol{\theta}_{drd})\text{Prior}(\boldsymbol{\theta}), \quad (44)$$

where $p(\mathbf{y}|X,\mathbf{u},\sigma^2,\delta)$ and $p(\mathbf{u}|\boldsymbol{\theta}_{drd})$ have the likelihoods given in (eq. 20) and (eq. 21), and $\text{Prior}(\boldsymbol{\theta})$ is the prior distribution for $\boldsymbol{\theta}$.

Sampling latents $\mathbf{u}|\boldsymbol{\theta}$
The first phase of Gibbs sampling is to sample $\mathbf{u}$ from the conditional distribution of $\mathbf{u}$ given $\boldsymbol{\theta}$,

$$\mathbf{u}|\boldsymbol{\theta} \sim p(\mathbf{y}|X,\mathbf{u},\sigma^2,\delta)p(\mathbf{u}|\boldsymbol{\theta}_{drd}). \quad (45)$$

This is the product of a Gaussian process prior $p(\mathbf{u}|\boldsymbol{\theta}_{drd})$ and a likelihood function $p(\mathbf{y}|X,\mathbf{u},\boldsymbol{\theta})$ that ties the latent variables $\mathbf{u}$ to the observed data. This setting meets the requirements of elliptical slice sampling (ESS), a rejection-free MCMC (Murray et al., 2009). ESS generates random elliptical loci using the Gaussian prior and then searches along these loci to find acceptable points by evaluating the data likelihood. This method takes into account strong dependencies imposed by GP covariance on the elements of the vector $\mathbf{u}$ to facilitates faster mixing. It also requires no tuning parameters, unlike alternative samplers such as Metropolis-Hastings or Hamiltonian Monte Carlo, but performs similarly to the best possible performance of a related M-H scheme. To overcome slow mixing that can result when the prior covariance is highly elongated, we apply ESS to a whitened variable using a reparametrization trick, discussed in more details in Sec. 4.3.

Sampling hyperparameters $\boldsymbol{\theta}|\mathbf{u}$
The conditional distribution for sampling $\boldsymbol{\theta}$ given $\mathbf{u}$ is

$$\boldsymbol{\theta}|\mathbf{u} \sim p(\mathbf{y}|X,\mathbf{u},\sigma^2,\delta)p(\mathbf{u}|\boldsymbol{\theta}_{drd})\text{Prior}(\boldsymbol{\theta}), \quad (46)$$

where $\boldsymbol{\theta} = \{\sigma^2, b, \rho, l, \delta\}$ contains five individual hyperparmaters. We therefore perform slice sampling for each variable conditioned on the others. We use prior distributions of the form:

$$\log(\sigma^2) \sim \mathcal{N}(m_n,\sigma_n^2), \quad b \sim \mathcal{N}(m_b,\sigma_b^2), \quad \rho \sim \Gamma(a_\rho,b_\rho), \quad l \sim \Gamma(a_l,b_l), \quad \delta \sim \Gamma(a_\delta,b_\delta). \quad (47)$$

We put a Gaussian prior on the log of σ^2 instead of σ^2. We will provide the values for these priors in Sec. 5 on synthetic experiments. To control the number of samples, we inspect burn-in of MCMC, e.g., the training error and the change of coefficient given the averaged coefficient samples.

4.3. Whitening the GP prior using reparametrization

In both Laplace approximation and MCMC frameworks, the latent vector $\mathbf{u}$ depends on the product of the conditional evidence $p(\mathbf{y}|X,\mathbf{u},\sigma^2,\delta)$ and the GP prior $p(\mathbf{u}|\boldsymbol{\theta}_{drd})$. The GP prior (which is the primary difference between our model and standard ARD) introduces strong dependencies between $\mathbf{u}$ and GP hyperparameters, resulting in a highly elliptical joint distribution. Such distributions are often problematic for both optimization and sampling. For example, if we are trying to perform Gibbs sampling on $\mathbf{u}$ and the GP length scale hyperparameter l, and the prior is strong relative to the evidence term, the samples $\mathbf{u}|l^{(i)}$ will have smoothness strongly determined by $l^{(i)}$, and the samples $l|\mathbf{u}^{(i)}$ will in turn be strongly determined by the smoothness of the current sample $\mathbf{u}^{(i)}$. In this case, mixing will be slow, and Gibbs sampling will take a long time to explore the full posterior over different values of l.

We can overcome this difficulty with a technique known as the "reparametrization trick," which involves reparameterizing the model so that the unknown variables are independent under the prior (Murray and Adams, 2010). If we have prior $P(\mathbf{u}) = \mathcal{N}(b\mathbf{1},K)$, then $\mathbf{u}$ can be described equivalently by a deterministic transformation of a standard normal random variable $\mathbf{v}$:

$$\mathbf{v} \sim \mathcal{N}(0,I), \quad \mathbf{u} = L\mathbf{v} + b\mathbf{1}, \quad (48)$$

where $K = LL^\top$ is the Cholesky factorization of prior covariance K.

This reparametrization simplifies Laplace-approximation-based inference by allowing a change of variables in (eq. 19) so that we directly maximize $p(\mathbf{y}|X,\mathbf{v},\boldsymbol{\theta})\mathcal{N}(\mathbf{v}|0,I)$ for $\mathbf{v}$. This optimization problem has better conditioning, and eliminates the computational problem of computing $\mathbf{u}^\top K^{-1}\mathbf{u}$ in the log prior, which is replaced by a simple ridge penalty of the form $\mathbf{v}^\top\mathbf{v}$.

For sampling-based inference, the reparametrization allows us to improve mixing performance because the conditionals $\mathbf{v}|\boldsymbol{\theta}$ and $\boldsymbol{\theta}|\mathbf{v}$ exhibit much weaker dependencies than $\mathbf{u}|\boldsymbol{\theta}$ and $\boldsymbol{\theta}|\mathbf{u}$. Moreover, elliptical slice sampling for $\mathbf{v}|\boldsymbol{\theta}$ is more efficient because it involves loci on a sphere instead of a highly elongated ellipsoid.

4.4. Fourier dual form

A second trick for improving the computational performance of DRD is to perform optimization of the latent variable $\mathbf{u}$ (or $\mathbf{v}$) in the Fourier domain. When the GP prior induces a high degree of smoothness in $\mathbf{u}$, the prior covariance K becomes approximately low rank, meaning that it has a small number of non-negligible eigenvalues. Because the covariance function (eq. 7) is shift-invariant, the eigenspectrum of K has a diagonal representation

in the Fourier domain, a consequence of Bochner's theorem (Stein, 1999; Lázaro-Gredilla et al., 2010). We can exploit this representation to optimize $\tilde{\mathbf{u}}$ (the discrete Fourier transform of $\mathbf{u}$) while ignoring Fourier components above a certain high-frequency cutoff, where this cutoff depends on the length scale l. This results in a lower-dimensional optimization problem. Fourier-domain representation of the latent vector $\mathbf{u}$ also simplifies the application of the reparametrization trick described above because the Cholesky factor L is now a diagonal matrix that can be computed analytically from the spectral density of the squared-exponential prior.

To summarize the joint application of the reparametrization and Fourier dual tricks in our model, they can be understood as allowing us to draw samples $\mathbf{u} \sim \mathcal{N}(b\mathbf{1}, K)$ via the series of transformations:

$$\tilde{\mathbf{v}} \sim \mathcal{N}(0, I), \qquad \textit{whitened Fourier domain sample} \tag{49}$$

$$\tilde{\mathbf{u}} = L\tilde{\mathbf{v}} + \tilde{\mathbf{b}}, \qquad \textit{transformed Fourier domain sample} \tag{50}$$

$$\mathbf{u} = B\tilde{\mathbf{u}}, \qquad \textit{inverse Fourier transform} \tag{51}$$

where $\tilde{\mathbf{b}}$ is the discrete Fourier transform of $b\mathbf{1}$, a vector of zeros except for a single non-zero element carrying the DC component, and B is the truncated (tall skinny) discrete inverse Fourier transform matrix mapping the low-frequency Fourier components represented in $\tilde{\mathbf{u}}$ to the space domain.

Note that the smoothness on $\mathbf{u}$, which controls the spatial scale of dependent sparsity, is different from the smoothing prior used in smooth-DRD to induce smoothness in the coefficients $\mathbf{w}$, although both can benefit from sparse Fourier-domain representation in cases where the relevant length scale is large.

5. Synthetic experiments

5.1. Simulated example with smooth and sparse weights

To illustrate and give intuition for the performance of the DRD estimator, we performed simulated experiments with a vector of regression weights in a one-dimensional space. We sampled a $p = 4000$ dimensional weight vector $\mathbf{w}$ from the smooth-DRD prior (see Fig. 1), with hyperparameters GP mean $b = -8$, GP length scale $l = 100$, GP marginal variance $\rho = 36$, smoothness length scale $\delta = 50$, measurement noise variance $\sigma^2 = 5$. We then sampled $n = 500$ responses $\mathbf{y} = X\mathbf{w} + \epsilon$, where X is an $n \times p$ design matrix with entries drawn i.i.d. from a standard normal distribution, and noise $\epsilon \sim \mathcal{N}(0, 5I)$.

Fig. 3 shows an example weight vector drawn from this prior, along with estimates obtained from a variety of different estimators:

- lasso (Tibshirani, 1996), using Least Angle Regression (LARS) implemented by glmnet[1];

1. https://web.stanford.edu/~hastie/glmnet/glmnet_alpha.html

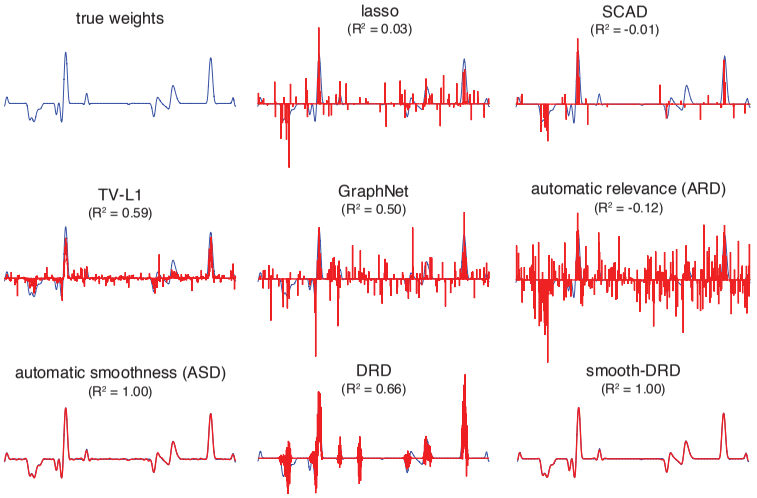

Figure 3: Example 4000-element weight vector $\mathbf{w}$ sampled from the smooth-DRD prior (upper left), and estimates obtained from different methods on a simulated dataset with $n = 500$ samples. The R^2 performance of each estimate in recovering $\mathbf{w}$ is indicated above each plot. The bottom row shows our estimators: DRD-Laplace (bottom center) and smooth-DRD-Laplace (bottom right); the other DRD and smooth-DRD estimators (not shown) achieved similar performance.

- Automatic Relevance Determination (ARD) (Neal, 1995; MacKay, 1992), implemented with the classic fixed point algorithm.
- Automatic Smoothness Determination (ASD) (Sahani and Linden, 2003), which uses numerical optimization of marginal likelihood to learn the hyperparameters of a squared exponential kernel governing $\mathbf{w}$.
- Total Variation l_1 (TV-L1) (Michel et al., 2011; Baldassarre et al., 2012; Gramfort et al., 2013), combining total variation penalty (also known as fused lasso), which imposes an l_1 penalty on the first-order differences of $\mathbf{w}$, with a standard lasso penalty.
- GraphNet (Grosenick et al., 2011), a graph-constrained elastic net, developed for spatial and temporally correlated data that yields interpretable model parameters by incorporating sparse graph priors based on model smoothness or connectivity, as well as a global sparsity inducing a prior that automatically selects important variables.
- Smoothly Clipped Absolute Deviation (SCAD) (Fan and Li, 2001), an estimator with non-convex sparsity penalty.

We computed total variation l_1 (TV-L1) and graph net (GraphNet) estimates using the Nilearn[2] package (Abraham et al., 2014). SCAD was implemented by SparseReg[3] (Zhou and Gaines, 2017). For lasso, GraphNet, TV-L1 and SCAD, we used cross-validation to set hyperparameters, whereas ARD and ASD used evidence optimization to automatically set hyperparameters. For the DRD estimators, we used evidence optimization to set hyperparameters for Laplace-approximation based estimates and used sampling to integrate over hyperparameters for MCMC-based estimates.

For the basic DRD model, which incorporates structured sparsity but not smoothness, we compared three different inference methods: (1) Laplace approximation based inference ("DRD-Laplace"); (2) Markov Chain Monte Carlo ("DRD-MCMC"); and (3) Convex relaxation based optimization ("DRD-Convex"). Lastly, for the smooth-DRD model, we used two inference methods: (4) Laplace approximation ("smooth-DRD-Laplace"); and (5) MCMC ("smooth-DRD-MCMC"). For the non-MCMC estimators, we initialized the vector of Fourier domain coefficients $\tilde{\mathbf{v}}$ (eq. 49) to values of 10^{-3} in the first iteration when learning $\mathbf{u}$. The hyper-hyperparameters in the MCMC methods (eq. 47) were set to: $m_n = -2, \sigma_n^2 = 5, m_b = -10, \sigma_b^2 = 8, a_\rho = 4, b_\rho = 5, a_l = 4, b_l = 25, a_\delta = 4, b_\delta = 25$.

Fig. 3 shows the reconstruction performance (R^2) of the true regression weight $\mathbf{w}$ for different estimators. The reconstruction performance metric for an estimate $\hat{\mathbf{w}}$ is given by $R^2 = 1 - \frac{||\mathbf{w}-\hat{\mathbf{w}}||_2^2}{||\mathbf{w}-\bar{\mathbf{w}}||_2^2}$, where $||\cdot||_2$ denotes the l_2-norm and $\bar{\mathbf{w}} = \frac{1}{p}\sum_{i=1}^{p} \mathbf{w}_i$ is the mean of vector $\mathbf{w}$. The true weight vector was sampled from the smooth DRD model. The smooth-DRD estimate achieved the best performance in terms of R^2. The ASD estimate also performed well, although the estimate was not sparse, exhibiting small wiggles where the coefficients should be zero. The standard DRD estimate recovered the support of $\mathbf{w}$ with high accuracy, but had larger error than smooth-DRD estimates due to the smoothness of the true $\mathbf{w}$. The other methods (lasso, ARD, TV-L1, GraphNet and SCAD) all had lower accuracy in recovering both the support and values of the regression weights.

To provide insight into the performance of ARD, DRD, and smooth-DRD, we plotted the inferred prior covariance of each model (Fig. 4). The DRD and smooth-DRD models were both similar to ARD in that they achieved sparsity by shrinking the prior variance of unnecessary coefficients to zero. However, unlike ARD, their inferred prior covariances both exhibited clusters of non-zero coefficients, reflecting the dependencies introduced by the latent Gaussian process. Note also that ARD and DRD covariances were both diagonal, making the weights independent given the prior variances, whereas the smooth-DRD covariance had off-diagonal structure that induced smoothness.

To quantitatively validate that our estimators succeed at identifying structured sparse and smooth structure, we performed simulated experiments using data drawn from the DRD generative model. For each experiment, we generated simulated data with $n = 500$ samples from a p-element weight vector, and varied p from 500 to 4000. We used hyperparameters GP mean $b = -8$, GP length scale $l = p/40$, GP marginal variance $\rho = 36$, smoothness length scale $\delta = p/20$, and varied measurement noise variance σ^2 between 1 and 50. The sparsity ratio for the sampled weights $\mathbf{w}$ was approximately 0.20, where we considered

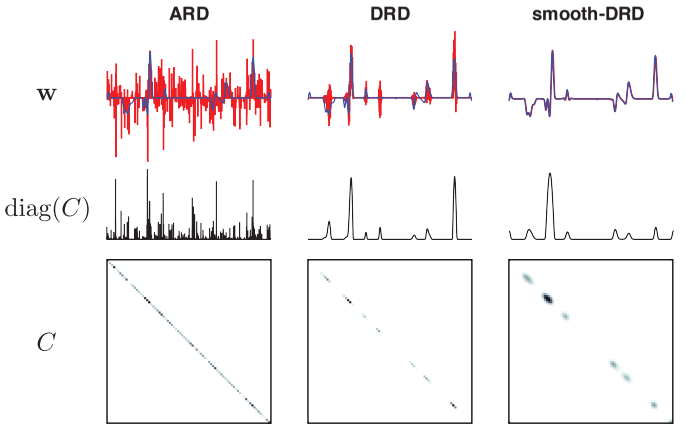

Figure 4: Estimated filter weights and prior covariances. The upper row shows the true filter (blue) and estimated ones (red); the middle row displays the diagonal of each estimated covariance matrix; and the bottom row shows the entire estimated covariance matrix for each prior.

weights with $|w_i| > 0.005$ to be non-zero. We varied training set size from $n = 100$ to 400 and kept a fixed test size of 100 samples. (We noted that even with $n = 400$ samples, the problem resides in the $n < p$ small-sample regime). We repeated each experiment 5 times.

We compared performance of DRD estimators to the above-mentioned estimators. Fig. 5 shows the reconstruction performance (R^2) of the true regression weights $\mathbf{w}$ for different estimators as a function of noise variance, training set size and dimension.

We found that Laplace and MCMC estimates for the smooth-DRD model outperformed other estimators and were approximately equally accurate, indicating that use of Laplace approximation did not noticeably harm performance relative to the fully Bayesian estimate. ASD had a good performance indicating that for these extremely smooth weights, smoothness was a more useful form of regularization than structured sparsity conferred by DRD. DRD models came next. DRD-MCMC was slightly better due to the robustness of the fully Bayesian inference. DRD-Laplace-exp and DRD-Convex employed the exponential nonlinearity when transforming $\mathbf{u}$ to the diagonal of the covariance matrix. DRD-Laplace-rec used a soft-rectifier nonlinearity which was more numerically stable. They had similar R^2 values with TV-L1 when recovering $\mathbf{w}$, but were better than all the other methods. We can also investigate the influence of each variable, i.e. noise variance, training size or dimension. When increasing the noise variance, all the R^2 values dropped; smooth-DRD-MCMC outperformed others with $\sigma^2 = 50$ indicating the power of the fully Bayesian estimate and the nontrivial effect of simultaneously imposing local sparsity and smoothness. When increasing the training size, DRD-Laplace models and DRD-Convex outperformed TV-L1

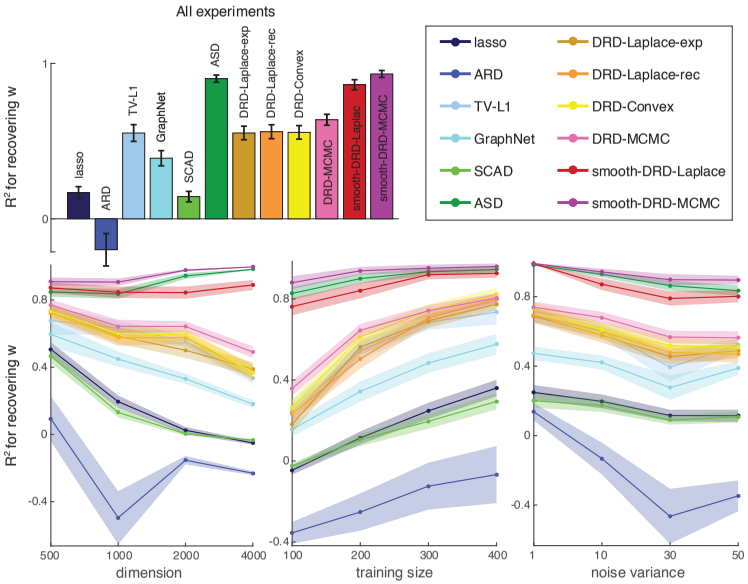

Figure 5: Comparison of performance recovering true regression weights $\mathbf{w}$ in simulated experiments as a function of dimensions p (lower left), number of samples n (lower middle), and noise variance σ^2 (lower right). Experiments were repeated five times for each of 64 combinatorial settings of four values for p, n, and σ^2. Traces show average R^2 (± 1 standard error of the mean (SEM)) as a function of each variable, and the bar plot (top row) shows average R^2 (± 1 SEM) over all $5 \times 64 = 320$ experiments.

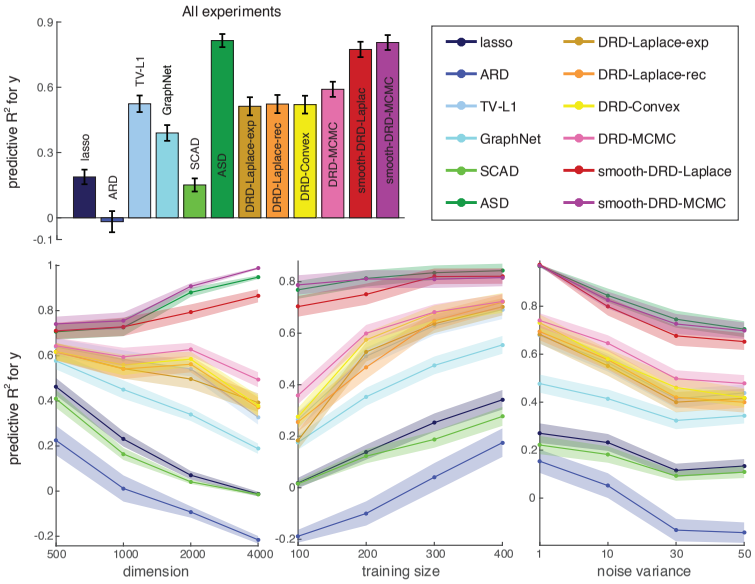

Figure 6: Comparison of performance predicting held-out responses $\mathbf{y}_{test}$ in simulated experiments as a function of dimensions p (lower left), number of samples n (lower middle), and noise variance σ^2 (lower right). Traces show average R^2 (± 1 SEM), and the bar plot (top row) shows average R^2 (± 1 SEM) over all experiments. Simulation experiments were the same as in Fig. 5.

and were comparable with DRD-MCMC, which was due to the decreasing optimizing complexity. Also surprisingly, smooth-DRD estimators achieved nearly perfect reconstruction performance over all the training sizes and all the dimensions.

Fig. 6 shows the R^2 performance for regression prediction on the test set for different estimators as a function of noise variance, training set size and dimension. The reconstruction performance for recovering the true $\mathbf{y}_{test}$ is given by $R^2 = 1 - \frac{||\mathbf{y}_{test} - \hat{\mathbf{y}}_{test}||_2^2}{||\mathbf{y}_{test} - \bar{\mathbf{y}}_{test}||_2^2}$, where $\bar{\mathbf{y}}_{test} = \frac{1}{n_{test}} \sum_{i=1}^{n_{test}} \mathbf{y}_{test,i}$ is the mean of vector $\mathbf{y}_{test}$. The top-left subfigure presents the averaged R^2 values and the confidence intervals for $\hat{\mathbf{y}}_{test}$ over all runs. Similar to R^2 for $\mathbf{w}$, ASD estimate, Laplace and MCMC estimates for the smooth-DRD model outperformed other estimators.

Fig. 7 shows the AUC (Area Under the receiver operator characteristic Curve) values for different estimators as a function of noise variance, training set size and dimension. The AUC metric quantifies accuracy in recovering the binary support for $\mathbf{w}$, which is useful for assessing the effects of structured sparsity. For this metric, the smooth DRD estimators outperformed other methods, and the ASD estimator performed much worse due to its lack of sparsity. The Laplace approximation based DRD models performed slightly better than DRD-MCMC because the sparsity of MCMC estimates was diluted by averaging across multiple samples.

Overall, smooth-DRD outperformed all other methods using all metrics. This shows that combining sparsity and smoothness can provide major advantages over methods that impose only one or the other. This flexible framework for integrating structured sparsity and smoothness is one of the primary contributions of our work, in contrast to previous methods

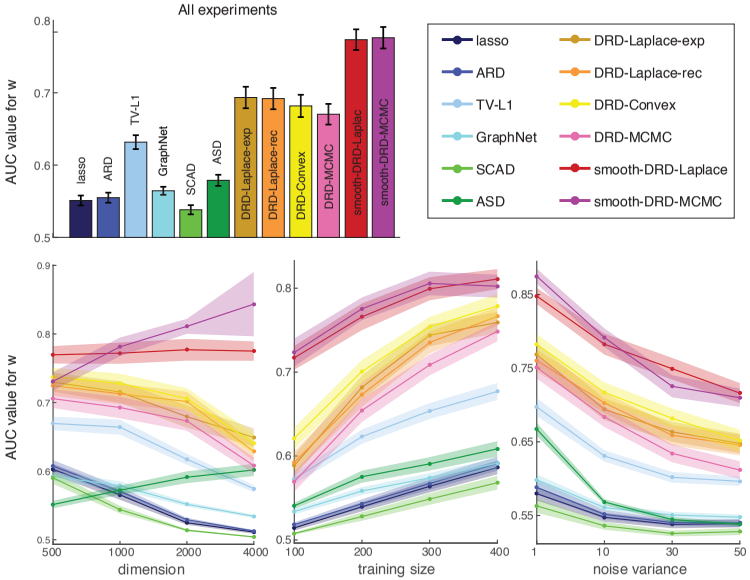

Figure 7: Comparison of performance at recovering support of regression weights in simulated experiments, quantified with area under the ROC curve (AUC), as a function of dimensions p (lower left), number of samples n (lower middle), and noise variance σ^2 (lower right). Traces show average AUC (± 1 SEM), and the bar plot (top row) shows average AUC (± 1 SEM) over all experiments. Simulation experiments were the same as in Fig. 5. Support recovery was quantified by taking all coefficients $|\mathbf{w}_i| > 0.005$ as non-zero.

in the structured sparsity literature which consider only sparsity. The code and simulated results are available online[4].

5.2. Computational complexity and optimization

We have described two basic approaches to inference for DRD: evidence optimization using the Laplace approximation and MCMC sampling-based inference. The main computational difficulty associated with Laplace-based methods is the Hessian matrix, which provides the precision matrix for the approximate Gaussian posterior distribution. This matrix costs $O(p^2)$ to store and contributes $O(p^3)$ time complexity for computation of the log-determinant. We can reduce these costs to $O(p_f^2)$ storage and $O(p_f^3)$ time, where $p_f < p$

4. https://github.com/waq1129/DRD.git

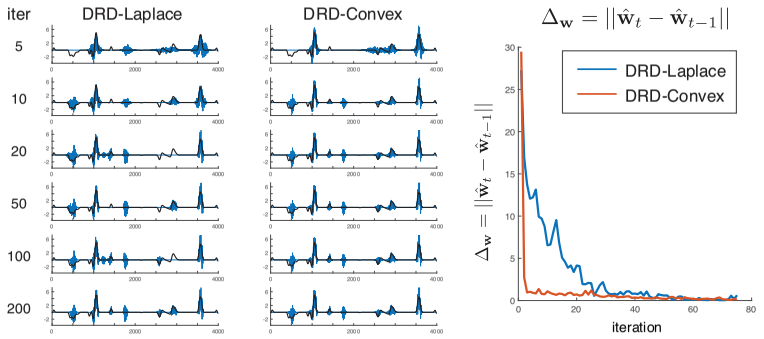

Figure 8: Comparison of the optimization of weights $\hat{\mathbf{w}}$ between DRD-Laplace and DRD-Convex. The first two columns show the weights obtained after 5, 10, 20, 50, 100, and 200 iterations with the same initialization under the two estimators, with true weights indicated in black. The third column shows the change in weights after each iteration of the standard and convex optimization algorithms over the first 80 iterations, showing that the convex algorithm made much smaller adjustments to the weights after the first few iterations and thus converged more rapidly.

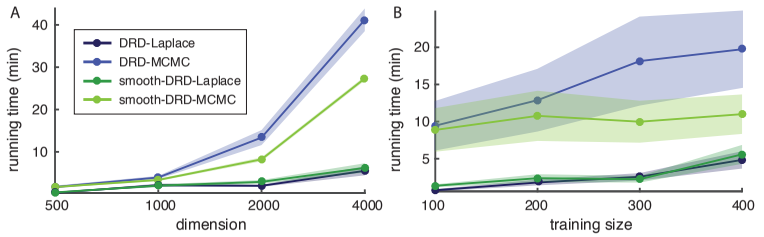

Figure 9: Running times for DRD estimators as a function of dimensions p (left) and number of samples n (right). Each point is an average across 20 simulated experiments, and the shaded area represents ± 1 SEM. For MCMC, running time was determined by the time to collect 100 posterior samples after burn-in.

is the number of non-zero Fourier coefficients in the spectral domain representation of the latent Gaussian process. This savings can be significant in problems with strong region sparsity, that is, when the zero coefficients arise in large contiguous blocks. However, in very high dimensions, the Laplace based methods may be practically infeasible due to the impossibility of storing the Hessian.

We also described a two-step convex relaxation of the Laplace method (DRD-Convex), which takes more time per iteration than the standard Laplace method (DRD-Laplace) due to the need for a two-step optimization procedure. However, we find that the DRD-Convex takes fewer iterations to converge (see Fig. 8), and in some cases proves more successful at avoiding sub-optimal local optima.

The MCMC-based inference has a time complexity of only $O(n^2 p_f)$ per sample, due to the fact that there is no need to compute the Hessian. However, MCMC-based inference is typically slower due to the need for a burn-in period and the generation of many samples from the posterior. Fig. 9 shows a comparison of running time for the two inference methods for both DRD and smooth-DRD models. For the Laplace method, we used a stopping criterion that the change in $\mathbf{w}$ was less than 0.0001. For the MCMC method, we assessed burn-in using a criterion on the relative change in $\mathbf{w}$, and then collected 100 posterior samples. Inference for the smooth-DRD model was faster than for standard DRD due to the fact that the smoothing prior effectively prunes high frequencies, reducing the dimensionality of the search space for $\mathbf{w}$. In these experiments, increasing dimension p elicited larger increases in computation time than increasing training set size n.

6. Phase transition in sparse signal recovery

Compressive sensing focuses on the recovery of sparse high-dimensional signals in settings where the number of signal coefficients p exceeds the number of measurements n. Recent work has shown that the recovery of sparse signals exhibits a phase transition between perfect and imperfect recovery as a function of the number of measurements (Ganguli and Sompolinsky, 2010; Amelunxen et al., 2014). Namely, when the measurement fraction $\gamma = n/p$ exceeds some critical value that depends on signal sparsity, the signal can be recovered perfectly with probability approaching 1, whereas for γ below this value, estimates contain errors with probability approaching 1. However, these results were derived for the case where non-zero coefficients are randomly located within the signal vector. Here we show that DRD can obtain dramatic improvements over the phase transition curve for *iid* sparse signals when the non-zero coefficients arise in clusters.

We performed simulated experiments to examine the effects of group structure on the empirical phase transition between perfect and imperfect recovery of sparse signals. The measurement equation is given by the noiseless version of the linear system we have considered so far: $\mathbf{y} = X\mathbf{w}$, where $\mathbf{w} \in \mathbb{R}^p$ is the sparse signal, $\mathbf{y} \in \mathbb{R}^n$ is the (dense) measurement vector, and here $X \in \mathbb{R}^{n \times p}$ is a (short, fat) random measurement matrix with entries drawn *iid* from a standard normal distribution. We define the sparsity of the signal as $\alpha = k/p$, where k is the number of non-zero signal coefficients in $\mathbf{w}$.

To explore the effects of group structure, we considered the signal coefficients in $\mathbf{w}$ to have 1D spatial structure and introduced a parameter g specifying the number of spatial groups or clusters into which the non-zero coefficients were divided. When $g = 1$, the non-zero coefficients formed a single contiguous block of length k, with location uniformly distributed within $\mathbf{w}$. When $g > 2$, the non-zero coefficients were divided into g blocks of size k/g, and the locations of these blocks were uniformly distributed within $\mathbf{w}$ subject to

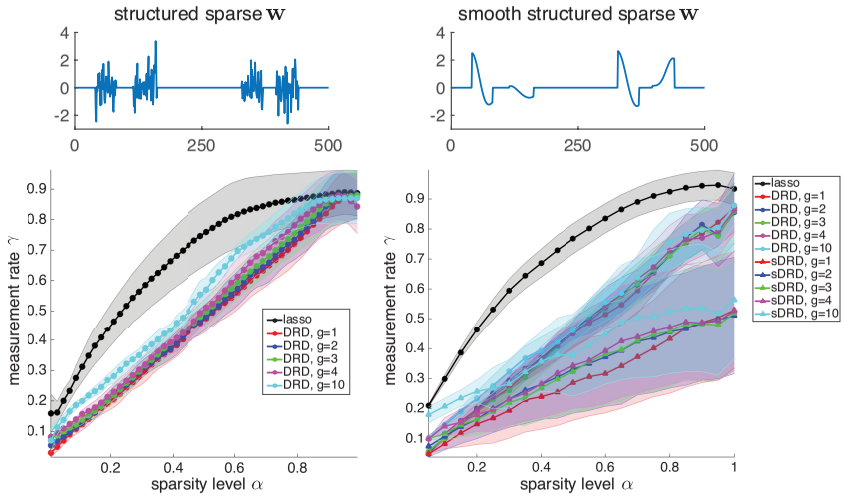

Figure 10: **Phase transitions for DRD and smooth-DRD (sDRD) estimators on signals with structured sparsity.** Top row shows example signals $\mathbf{w}$ of dimensions $p = 500$, which contain randomly positioned blocks of non-zero coefficients. Non-zero coefficients were clustered into varying numbers of groups g, and drawn either iid from a standard normal distribution (left column) or from a Gaussian with a smoothing kernel (length scale was 20) (right column), to illustrate the effects of smoothness. To compute phase transition curves, we analyzed the recovery behavior of each estimator at every point in a 2D grid of sparsity levels α and measurement rates γ. At each point, we generated 10 random signals $\mathbf{w}$, projected them noiselessly onto a random Gaussian measurement matrix X, and computed lasso and DRD estimates $\hat{\mathbf{w}}$. We then calculated the R^2 value of the estimates for each trial at every grid point (α, γ). An estimator was considered to achieve perfect recovery if all 10 trials resulted in $R^2 > 0.95$, and perfect failure if all 10 trials resulted in $R^2 \leq 0.95$; remaining points were considered to fall in the phase transition region. For each estimator, the shaded region indicates the phase transition region, and solid line indicates its center of mass along the y-axis.

the constraint that blocks remained disjoint. Once the sparsity pattern was determined, we sampled the non-zero coefficients from a standard normal distribution.

Fig. 10 shows the empirical phase transition curves for lasso and DRD estimators for sparse signals with non-zero coefficients clustered into varying numbers of groups g. These curves

show the boundary between perfect and imperfect signal recovery for different estimators in the 2D space of signal sparsity level α and measurement fraction γ. The left bottom plot shows that DRD estimators achieved perfect signal recovery for much lower measurement rates, even when non-zero coefficients were clustered into as many as 10 groups. Here DRD achieved transition to perfect recovery along the main diagonal, whereas lasso exhibited an arc-shape transition curve described previously (Ganguli and Sompolinsky, 2010; Amelunxen et al., 2014), indicating that more measurements were required to recovery signals of equal sparsity. In the right bottom plot, we generated the non-zero coefficients from a Gaussian distribution with a smoothing kernel whose length scale equaled to 20, so that non-zero coefficients were smooth as well as sparse. In these plots, we compared lasso estimates (which do not benefit from group or smooth structure) to standard DRD and smooth-DRD estimates. This reveals that smoothness allows for further reductions in measurement rates, with perfect signal recovery achievable well below that of the non-smooth DRD estimates.

7. Applications to brain imaging data

Functional magnetic resonance imaging (fMRI) measures blood oxygenation levels, which provide a proxy for neural activity in different parts of the brain. Although these measurements are noisy and indirect, fMRI is one of the primary non-invasive methods for measuring activity in human brains, and it has provided insight into the neural basis for a wide variety of cognitive abilities and functional pathologies.

A primary problem of interest in the fMRI literature is "decoding", which involves the use of linear classification and regression methods to identify the stimulus or behavior associated with measured brain activity. Decoding is a challenging statistical problem because the number of volumetric pixels or "voxels" measured with fMRI is typically far greater than the number of trials in an experiment; a full brain volume typically contains 50K voxels whereas most experiments produce only a few hundred observations.

Standard approaches to decoding have therefore tended to exploit sparsity, corresponding to the assumption that only a small set of brain voxels are relevant for decoding a particular set of stimuli (Carroll et al., 2009). However, the set of voxels useful for a specific decoding task are not randomly distributed throughout the brain, but tend to arise in clusters; if one voxel carries information useful for decoding, it is *a priori* likely that nearby voxels do too, given that voxels represent an arbitrary discretization of continuous underlying brain structures. We therefore explored brain decoding as an ideal application for evaluating the performance of our estimators.

7.1. Gambling task

We first considered the regression problem of decoding gains and losses from fMRI measurements recorded in a gambling task (Tom et al., 2007, 2011). In this experiment, event-related fMRI was administered while healthy human participants performed a decision-making task. In each trial, a gamble with a potential gain and loss (each with 50% probability) was pre-

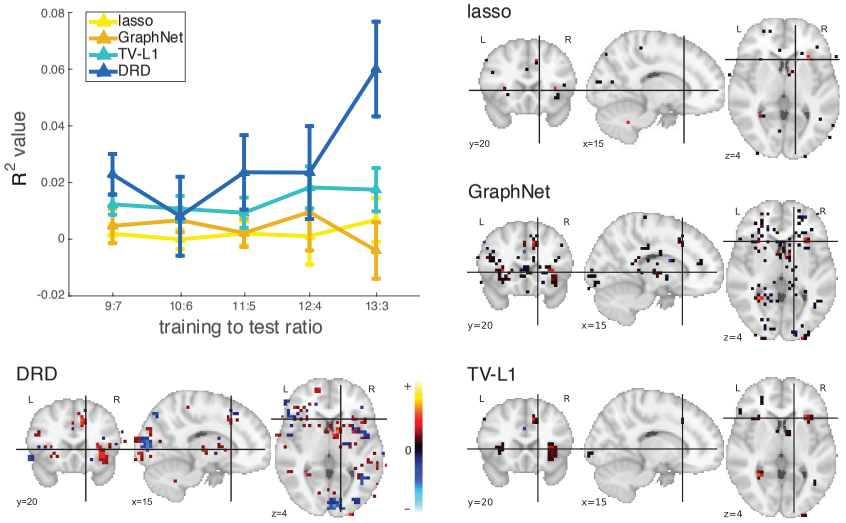

Figure 11: Top left panel shows average test R^2 values on the gambling dataset as a function of the train-test ratio for lasso, GraphNet, TV-L1 and DRD. The x-axis is the train-test split ratio and the y-axis is the R^2 criterion. The remaining panels show the estimated fMRI weight maps, overlaid on a structural fMRI image. Colors indicate the sign and magnitude of the weights (see color bar, red for positive, blue for negative, black for small). The DRD figure was obtained by cutting off small weight coefficients with a small threshold value at 0.004 (about 12% of the maximal absolute coefficient value).

sented for 3s, and the participants were instructed to decide whether to accept or reject the gamble. Experimenters varied amount of the potential gain and loss across trials. The regression task is to predict the gain of the gamble from the fMRI images recorded during the decision-making task.

After standard preprocessing, the regression dataset consisted of 16 subjects with 48 fMRI measurements per subject (resulting from 6 repeated presentations of 8 different gambles). fMRI measurements were obtained from a 3D brain volume of $40 \times 48 \times 34$ voxels, each of size $4 \times 4 \times 4$ mm, from which a subset of 33,177 valid brain voxels were used for analysis. The full dataset of 16 subjects therefore contained $n = 768$ samples in a $p = 33,177$ dimensional space.

We evaluated inter-subject prediction performance by estimating regression weights with data from a subset of the 16 subjects, and computing prediction accuracy for data from

held-out subjects. To assess the performance, we varied the train-test ratio in number of subjects from 9:7 to 13:3. We performed 10 different random train-test splits for each ratio. We used 5-fold cross-validation to set hyperparameters for all models, including DRD. For DRD models, the Laplace approximation was intractable due to the high dimensionality of the weight vector ($p = 33,177$). We therefore computed MAP estimates of the latent vector $\mathbf{u}$ conditioned on the hyperparameters, and set hyperparameters using cross-validation.

The curves in the top left panel of Fig. 11 show the performance of lasso, GraphNet, TV-L1 and DRD estimators. We found that DRD outperformed other estimators at nearly all train-test ratios, with a noticeable advantage at the largest training set size. However, we noted that the SNR of this dataset was low, making inter-subject prediction difficult and resulting in low accuracy for all methods. A non-trivial preprocessing stage, such as hyper-alignment (Chen et al., 2015), could be used to map different subjects into a shared subspace, which reduces the low SNR induced by inter-subject variability and could possibly improve performance.

Fig. 11 also shows the inferred regression weights for each estimator. The GraphNet and lasso weights had high sparsity, presumably due to the low SNR of the dataset, while TV-L1 weights exhibited small blocks of non-zero coefficients with constant value within each block, consistent with the structure expected for the TV-L1 penalty. The DRD weights were not sparse in a strict L0 sense, due to the fact that sparsity arises from soft-rectification of negative latents governing the prior variance. We therefore thresholded DRD weights for plotting purposes, revealing that the weights contributing most to prediction performance tended to cluster, as expected, although weights within each cluster were not constant. One noteworthy observation is that DRD estimate had positive (red) as well as negative weights (blue), while other estimates were largely devoid of regions with negative weights. Note that voxels in black indicate weights close to zero, which therefore contributed relatively little to readout.

7.2. Age prediction task

Next we considered the problem of predicting a subject's age from a measured map of gray-matter concentration, using data from the Open Access Series of Imaging Studies (OASIS) (Marcus et al., 2007). The OASIS dataset consisted of T1-weighted MRI scans data from 403 subjects aged 18 to 96, with 3 or 4 scans per subject. One hundred of these subjects were over 60 years of age and had been clinically diagnosed with Alzheimer's. The repeated scans provided high signal-to-noise ratio, making the dataset feasible for inter-subject analyses.

A natural regression problem for this dataset is to predict the age of subject from their anatomical MRI data. The full dataset consisted of 403 samples with a $91 \times 109 \times 91$ 3D volume and 129,081 valid voxels. To assess the performance, we varied the training ratio from 0.4 to 0.8 out of the 403 subjects, and averaged over 5 random splits for each ratio.

The curves in the top left panel of Fig. 12 show mean absolute errors between the true age and the predicted age for each estimator, evaluated on test data. The DRD and smooth-DRD estimators, which performed similarly well, achieved lower error than lasso, GraphNet, and TV-L1 estimators. The inferred regression weights (Fig. 12) reveal that the most

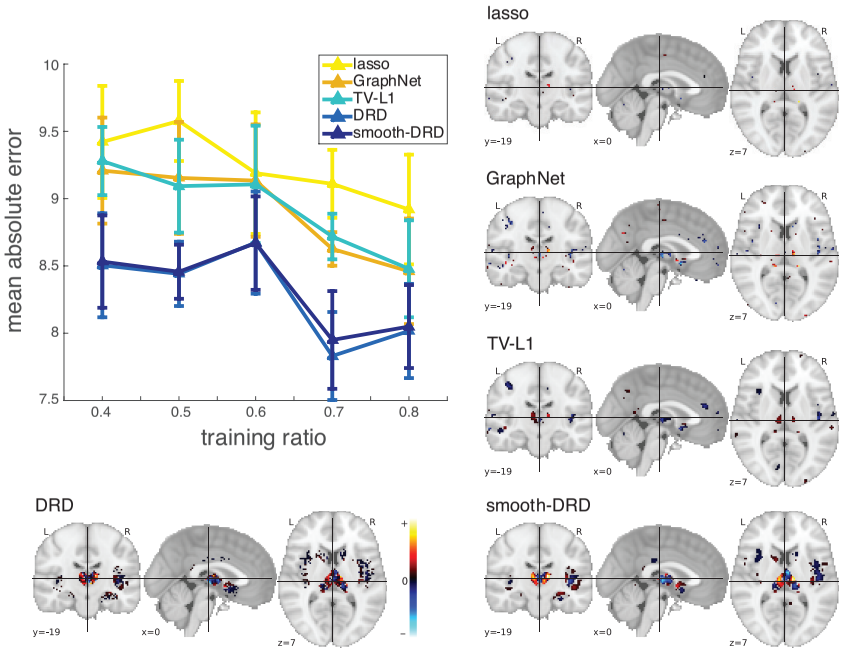

Figure 12: Top left panel shows average test mean absolute error values on the age regression dataset as a function of the training ratio for lasso, GraphNet, TV-L1, DRD and smooth-DRD. The x-axis is the ratio of the training data over the entire dataset and the y-axis is the mean absolute error criterion. The remaining panels show the estimated MRI weight maps, overlaid on a structural MRI image. Colors indicate the sign and magnitude of the weights (see color bar).

informative voxels for predicting age lie in thalamus and the basal ganglia; this is consistent with previous findings about the relationship between Alzheimer's disease progression and anatomical changes in gray matter (de Jong et al., 2008; Cho et al., 2014). Thalamus and basal ganglia were more clearly highlighted in the inferred DRD and smooth-DRD regression weights, which contained larger and more concentrated regions around these two structures. The smooth-DRD weights exhibited stronger spatial clustering than DRD weights, although regression performance was not noticeably different between the two estimators.

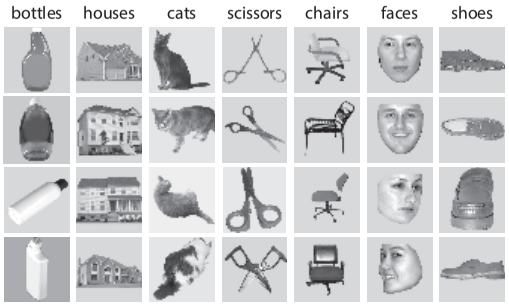

Figure 13: Examples of the stimuli for 7 categories (except for scrambled control images).

7.3. Visual recognition task

In a third application, we examined the problem of decoding faces and objects from fMRI measurements during a visual recognition task. We used a popular fMRI dataset from a study on face and object representation in human ventral temporal cortex (Haxby et al., 2001). In this experiment, 6 subjects were asked to recognize 8 different types of objects (bottles, houses, cats, scissors, chairs, faces, shoes and scrambled control images, examples in Fig. 13). Each subject participated 12 sessions of experiment. In each session, the subjects viewed images of eight object categories, with 9 full-brain measurements per category.

We assessed performance by training linear classifiers to discriminate between pairs of objects, e.g., face vs. bottle, for each of the 28 possible binary classifications among 8 objects. We trained the weights $\mathbf{w}$ for each model to linearly map fMRI measurements $\mathbf{x}$ to binary labels $y \in \{-1, +1\}$ by minimizing squared error. Note that a Bernoulli log-likelihood or logistic loss would be more appropriate for this binary classification task, but we used squared error loss because it allows for analytic marginalization over weights. We assessed decoding accuracy on test data using predicted labels $\hat{y} = \text{sign}(\mathbf{w}^\top \mathbf{x})$. We divided 12 sessions of data per subject into train-test splits of 5:7, 6:6 and 7:5. When training with data from N sessions, the training dataset consisted of 18N full-brain measurements (9 measurements per category $\times$ 2 categories). Each measurement contained 24,083 valid voxels from a $40 \times 64 \times 64$ 3D volume.

Fig. 14 shows the classification performance of lasso, GraphNet, TV-L1, DRD, and smooth-DRD estimators, averaged over 6 subjects and across the three train-test splits. The smooth-DRD estimate achieved the highest accuracy for most of the binary classifications, while the DRD estimate achieved second highest accuracy. The left column in Fig. 15 shows the regression weights estimated for the house vs. bottle classification task. The DRD and smooth-DRD weights both had significant positive regions in the parahippocampal place area (PPA), an area known to respond to images of places (Epstein et al., 1999) and negative regions in the lateral occipital complex (LOC), an area known to respond to objects (Eger

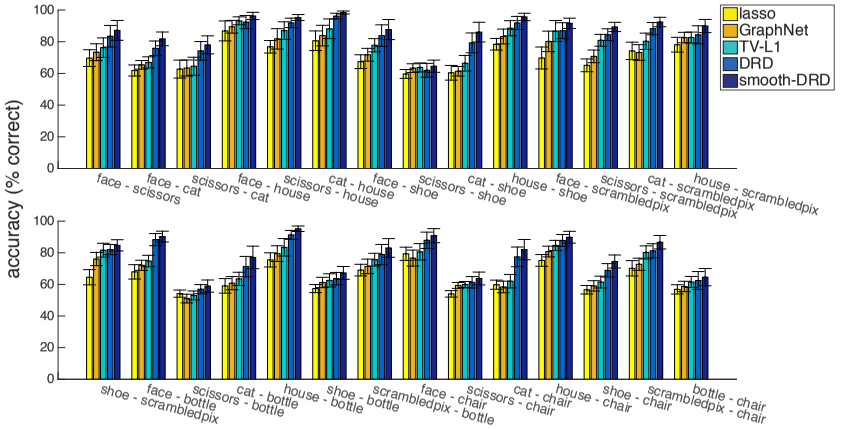

Figure 14: Classification accuracy performance for lasso, GraphNet, TV-L1, DRD and smooth-DRD, averaged across 6 subjects and three different train-test splits (5:7, 6:6 and 7:5). Error bars indicate ± 1 SEM, averaged over train-test splits. The x-axis labels indicate pairs of object categories considered for binary classification.

et al., 2008). By comparison, TV-L1 and GraphNet weights in LOC were neither strong nor clustered. The right column in Fig. 15 shows regression weights for the face vs. scrambled-pixels classification task. All methods managed to discover active responses around LOC and fusiform face area (FFA) (specialized for facial recognition) (Kanwisher et al., 1997), though DRD and smooth-DRD weights exhibited fewer isolated non-zero weights in areas far from the temporal and occipital lobes.

8. Discussion

In this paper, we introduced dependent relevance determination (DRD), a hierarchical Bayesian model for sparse, localized, and smooth regression weights. This model is appropriate for regression settings in which the regressors can be arranged geometrically as a vector, matrix, or tensor, and exhibit local dependencies within this structure (e.g., tensors of 3D brain measurements).

The DRD model takes its inspiration from the automatic relevance determination (ARD) model (Tipping, 2001), but adds a Gaussian process to introduce dependencies between prior variances of regression weights as a function of distance between their regressors. Samples from the DRD prior therefore exhibit clustering of non-zero weights. However, weights

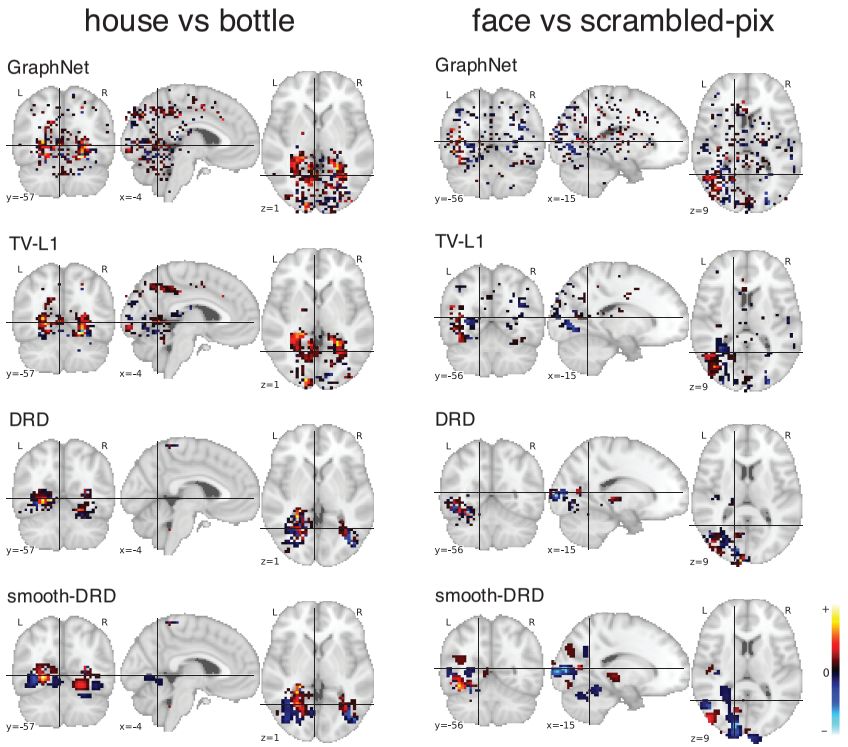

Figure 15: **Left column**: weight maps for the house vs bottle pair. **Right column**: weight maps for the face vs scrambled-pix pair. The methods shown are GraphNet, TV-L1, DRD and smooth-DRD.

sampled from the standard DRD prior are uncorrelated, meaning there is no tendency for such weight tensors to be smooth. For this reason, we introduced the smooth-DRD model, which composes the standard DRD prior with a smoothness-inducing covariance function (Sahani and Linden, 2003; Park and Pillow, 2011). Weights sampled from the resulting model tend to be sparse as well as smooth, with islands of smooth, non-zero weight features surrounded by oceans of zeros.

We described two methods for inferring the model parameters: one based on the Laplace approximation and a second based on MCMC. We proposed a novel variant of the Laplace based approach involving a two-stage convex relaxation of the log posterior.

Lastly, we carried out simulated and real application experiments to compare DRD with a variety of other methods, including lasso, SCAD, GraphNet, TV-L1, and etc. For an L_2 loss, a convex L_1 penalty leads to strong amplitude bias for lasso, while a non-convex penalty, e.g., SCAD, can overcome the strong bias. Lasso could underfit in order to get a tight support due to incorrect amplitudes of the coefficients when doing cross-validation using a L_2-based criterion. Therefore, we included SCAD apart from lasso and employed AUC as the metric for support identification. The synthetic experiments generated true weight vectors from the proposed generative model, thus aiming at validating the proposed model. We also examined phase transitions between perfect and imperfect recovery using data from a generating model different from DRD, showing that the DRD and smooth-DRD model could achieve perfect recovery with far fewer measurements when the non-zero weights in a signal were clustered. We further applied our models to three real-world brain imaging datasets. We found that DRD and smooth DRD achieved better prediction performance than previous methods, while also achieving high interpretability with regression/classification weights defined by smooth, clustered sets of voxels. Note that for the final fMRI decoding application task, a Bernoulli noise model (corresponding to a logistic loss function) would have been more appropriate than the Gaussian noise model we assumed, due to the binary nature of the outputs. Gaussian noise is a useful modeling assumption for the DRD model because it yields an analytical expression for the conditional evidence (eq. 14), which can be directly optimized for the latent process governing region sparsity. An important direction for future research will therefore be to extend DRD to incorporate Bernoulli and other likelihoods. Such extensions will need to use approximate inference methods or sampling to compute the integral over regression weights (eq. 13), but there is no conceptual barrier to incorporating region sparsity into models with binary and other non-Gaussian outputs.

The DRD and smooth-DRD models offer a powerful statistical framework for attacking problems in which sparsity is overlaid with local dependencies, a scenario that arises commonly in (for example) spatial and temporal regression problems. Recent work has shown successful application of a closely related model for capturing dependencies between sparse variables in genomic data (Engelhardt and Adams, 2014). In future work, we expect the DRD framework to find applications beyond the regression/classification setting, including structured latent factor models (Chen et al., 2015) and false discovery rate estimation (Tansey et al., 2017).

Appendix A. The Hessian of the negative log-posterior in Laplace approximation for smooth-DRD

Now we derive the Hessian matrix inside of the inverse of (eq. 22).

$$H = -\frac{\partial^2}{\partial \mathbf{u} \partial \mathbf{u}^\top}\Big[\log p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta) + \log p(\mathbf{u}|\boldsymbol{\theta}_{drd})\Big]. \tag{52}$$

The first term to take the partial derivatives of is (eq. 20):

$$\log p(\mathbf{y}|X, \mathbf{u}, \sigma^2, \delta) = -\frac{1}{2}\log|XCX^\top + \sigma^2 I| - \frac{1}{2}\mathbf{y}^\top (XCX^\top + \sigma^2 I)^{-1}\mathbf{y} + const, \tag{53}$$

and the second is (eq. 21):

$$\log p(\mathbf{u}|\boldsymbol{\theta}_{drd}) = -\frac{1}{2}(\mathbf{u} - b\mathbf{1})^\top K^{-1}(\mathbf{u} - b\mathbf{1}) - \frac{1}{2}\log|K| + const. \tag{54}$$

Define $S = XCX^\top + \sigma^2 I$, where $C = C_{drd}^{\frac{1}{2}} \Sigma C_{drd}^{\frac{1}{2}}$. Let $Z = XC_{drd}^{\frac{1}{2}}\Sigma^{\frac{1}{2}}$, then,

$$\begin{aligned} S &= XC_{drd}^{\frac{1}{2}}\Sigma C_{drd}^{\frac{1}{2}}X^\top + \sigma^2 I = ZZ^\top + \sigma^2 I, & (55)\\ \log p(\mathbf{u}|\mathbf{y}, X, \boldsymbol{\theta}) &= -\frac{1}{2}\mathbf{y}^\top S^{-1}\mathbf{y} - \frac{1}{2}\log|S| - \frac{1}{2}(\mathbf{u} - b\mathbf{1})^\top K^{-1}(\mathbf{u} - b\mathbf{1}) + const. & (56)\end{aligned}$$

The first derivative with respect to $\mathbf{u}_i$ is given by:

$$\begin{aligned} \frac{\partial}{\partial \mathbf{u}_i}\log p(\mathbf{u}|\mathbf{y}, X, \boldsymbol{\theta}) &= \frac{1}{2}\frac{\partial}{\partial \mathbf{u}_i}\left(-\mathbf{y}^\top S^{-1}\mathbf{y} - \log|S| - (\mathbf{u} - b\mathbf{1})^\top K^{-1}(\mathbf{u} - b\mathbf{1})\right) & (57)\\ &= \mathrm{Tr}\left[Z^\top S^{-1}\mathbf{y}\mathbf{y}^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_i}Z\right) - Z^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_i}Z\right)\right] & (58)\\ &\quad - \left[K^{-1}(\mathbf{u} - b\mathbf{1})\right]_i, & (59)\end{aligned}$$

where

$$\frac{\partial}{\partial \mathbf{u}_i}Z = X\left(\frac{\partial}{\partial \mathbf{u}_i}C_{drd}^{\frac{1}{2}}\right)\Sigma^{\frac{1}{2}}. \tag{60}$$

The second derivative with respect to $\mathbf{u}_j$ is given by:

$$\frac{\partial^2}{\partial \mathbf{u}_i \partial \mathbf{u}_j}\log p(\mathbf{u}|\mathbf{y}, X, \boldsymbol{\theta}) = H_1 + H_2 + H_3 - K_{ij}^{-1} = -H_{ij}, \tag{61}$$

$$H_1 = \mathrm{Tr}\left[Z^\top S^{-1}\mathbf{y}\mathbf{y}^\top S^{-1}\left(\frac{\partial^2}{\partial \mathbf{u}_i \partial \mathbf{u}_j}Z\right) - Z^\top S^{-1}\left(\frac{\partial^2}{\partial \mathbf{u}_i \partial \mathbf{u}_j}Z\right)\right], \tag{62}$$

$$H_2 = \mathrm{Tr}\left[\left(\frac{\partial}{\partial \mathbf{u}_j}Z\right)^\top S^{-1}\mathbf{y}\mathbf{y}^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_i}Z\right) - \left(\frac{\partial}{\partial \mathbf{u}_j}Z\right)^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_i}Z\right)\right], \tag{63}$$

$$H_3 = 2\mathrm{Tr}\left[-Z^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_j}Z\right)Z^\top S^{-1}\mathbf{y}\mathbf{y}^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_i}Z\right)\right. \quad (64)$$

$$-Z^\top S^{-1}\mathbf{y}\mathbf{y}^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_j}Z\right)Z^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_i}Z\right) \quad (65)$$

$$\left.+Z^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_j}Z\right)Z^\top S^{-1}\left(\frac{\partial}{\partial \mathbf{u}_i}Z\right)\right], \quad (66)$$

where

$$\frac{\partial^2}{\partial \mathbf{u}_i \partial \mathbf{u}_j}Z = X\left(\frac{\partial^2}{\partial \mathbf{u}_i \partial \mathbf{u}_j}C_{drd}^{\frac{1}{2}}\right)\Sigma^{\frac{1}{2}}. \quad (67)$$

For DRD only, we can just derive the Hessian by replacing $C_{drd}^{\frac{1}{2}}\Sigma^{\frac{1}{2}}$ with $C_{drd}^{\frac{1}{2}}$.

Appendix B. Proof of convexity of $\mathcal{L}_1(\mathbf{u})$

We ignore the scaling $\frac{1}{2}$ here for simplicity, and write,

$$\mathcal{L}_1(\mathbf{u}) = \log|X\mathrm{diag}(e^{\mathbf{u}})X^\top + \sigma^2 I| \quad (68)$$

$$= \log|\mathrm{diag}(e^{\mathbf{u}})\frac{X^\top X}{\sigma^2} + I| + const \quad (69)$$

$$= \log|\frac{X^\top X}{\sigma^2} + \mathrm{diag}(e^{-\mathbf{u}})| + \log|\mathrm{diag}(e^{\mathbf{u}})| + const. \quad (70)$$

Let $V = \frac{X^\top X}{\sigma^2}$, which is p.s.d., then

$$\begin{aligned}\frac{\partial}{\partial \mathbf{u}}\log|V + \mathrm{diag}(e^{-\mathbf{u}})| &= -\mathrm{diag}\left((\mathrm{diag}(e^{-\mathbf{u}}) + V)^{-1} \odot \mathrm{diag}(e^{-\mathbf{u}})\right)\\ \frac{\partial^2}{\partial^2 \mathbf{u}}\log|V + \mathrm{diag}(e^{-\mathbf{u}})| &= \left(V(\mathrm{diag}(e^{\mathbf{u}})V + I)^{-1}\right) \odot \left(\mathrm{diag}(e^{-\mathbf{u}}) + V\right)^{-1},\end{aligned} \quad (71)$$

where $\odot$ is the Hadamard product. Moreover, we know that

$$\begin{aligned}V(\mathrm{diag}(e^{\mathbf{u}})V + I)^{-1} &= \frac{X^\top X}{\sigma^2}(\mathrm{diag}(e^{\mathbf{u}})\frac{X^\top X}{\sigma^2} + I)^{-1}\\ &= X^\top(X\mathrm{diag}(e^{\mathbf{u}})X^\top + \sigma^2 I)^{-1}X \succeq 0.\end{aligned} \quad (72)$$

Thanks to the Schur product theorem stating that the Hadamard product of two positive semi-definite matrices is also a positive semi-definite matrix, we have $\frac{\partial^2}{\partial^2 \mathbf{u}}\log|V + \mathrm{diag}(e^{-\mathbf{u}})| \succeq 0$, thus $\log|\frac{X^\top X}{\sigma^2} + \mathrm{diag}(e^{-\mathbf{u}})|$ is convex in $\mathbf{u}$. In addition, $\log|\mathrm{diag}(e^{\mathbf{u}})|$ is also convex in $\mathbf{u}$. Therefore, $\mathcal{L}_1(\mathbf{u})$ is convex in $\mathbf{u}$.

Appendix C. Proof of boundedness and non-emptiness of $\mathcal{F}(\mathbf{u})$

We want to prove that for (eq. 35), when $||\mathbf{u}|| \to \infty$, we have $\mathcal{F}(\mathbf{u}) \to \infty$. Rewrite $\mathcal{F}$ here,

$$\mathcal{F}(\mathbf{u}) = \mathbf{z}^{k\top}\mathbf{h}(\mathbf{u}) - \mathcal{L}_{\mathbf{h}}^*(\mathbf{z}) + \mathcal{L}_1(\mathbf{u}) + \mathcal{L}_3(\mathbf{u}), \quad (73)$$

where $\mathbf{h}(\mathbf{u}) = e^{-\mathbf{u}}$, $\mathcal{L}_1(\mathbf{u}) = \frac{1}{2}\log|X\mathrm{diag}(e^{\mathbf{u}})X^\top + \sigma^2 I|$ and $\mathcal{L}_3(\mathbf{u}) = \frac{1}{2}(\mathbf{u} - b\mathbf{1})^\top K^{-1}(\mathbf{u} - b\mathbf{1})$.

1) Each element in $\mathbf{h}(\mathbf{u})$ is bounded by 0 and 1. Thus when $||\mathbf{u}|| \to \infty$, $\mathbf{z}^{k\top}\mathbf{h}(\mathbf{u})$ will be bounded.
2) K^{-1} is a positive semi-definite (p.s.d.) matrix. Thus $\mathcal{L}_3(\mathbf{u})$ is lower-bounded by 0. When $||\mathbf{u}|| \to \infty$, $\mathcal{L}_3(\mathbf{u}) \geq 0$. The upper bound is unclear.
3) Denote $\Gamma = \mathrm{diag}(e^{\mathbf{u}})$ whose diagonal values are all nonnegative. Now we want to prove when $||\mathbf{u}|| \to \infty$, we have $\mathcal{L}_1(\mathbf{u}) = \frac{1}{2}\log|X\Gamma X^\top + \sigma^2 I| \to \infty$.

First, we note that $\mathcal{L}_1(\mathbf{u})$ has a lower bound. It can be easily shown that the eigenvalues of $X\Gamma X^\top + \sigma^2 I$ should be greater than or equal to σ^2, given $X\Gamma X^\top$ is a p.s.d. matrix.

If $||\mathbf{u}|| \to \infty$, we can assume $u_1 \to \infty, ..., u_s \to \infty$ where $\mathbf{u} \in \mathbb{R}^p$ and $s \leq p$, then $e^{u_i} \to \infty$, for all $i \in \{1, ..., s\}$. For $\{u_i\}_{i=s+1}^p$, if u_i is finite, e^{u_i} will be finite; else if $u_i \to -\infty$, $e^{u_i} = 0$. Thus e^{u_i} is a finite value for all $i \in \{s+1, ..., p\}$. We can write Γ as an addition of two matrices A and B, i.e. $\Gamma = A + B$.

$$A = \begin{bmatrix} e^{u_1} & & & & & & \\ & e^{u_2} & & & & 0 & \\ & & \ddots & & & & \\ & & & e^{u_s} & & & \\ & & & & 0 & & \\ & & & & & \ddots & \\ & 0 & & & & & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & & & & & & \\ & 0 & & & & 0 & \\ & & \ddots & & & & \\ & & & 0 & & & \\ & & & & e^{u_{s+1}} & & \\ & & & & & \ddots & \\ & 0 & & & & & e^{u_p} \end{bmatrix} \quad (74)$$

The nonzero elements in A are infinite values. The nonzero elements in B are finite nonnegative values. Let $M = XBX^\top + \sigma^2 I \in \mathbb{R}^{n\times n}$. $XBX^\top$ is a p.s.d. matrix. The smallest eigenvalue of $XBX^\top$ should be nonnegative. Therefore the smallest eigenvalue of M is greater than or equal to σ^2. This implies the invertibility of M. Since M^{-1} is also positive definite, we can factorize M^{-1} into $S \in \mathbb{R}^{n\times n}$ and $S^\top$, i.e. $M^{-1} = SS^\top$. Thus, we can write

$$\mathcal{L}_1(\mathbf{u}) = \frac{1}{2}\log|XAX^\top + XBX^\top + \sigma^2 I| \quad (75)$$

$$= \frac{1}{2}\log|XAX^\top + M| \quad (76)$$

$$= \frac{1}{2}\log|XAX^\top M^{-1} + I| + \frac{1}{2}\log|M| \quad (77)$$

$$= \frac{1}{2}\log|XAX^\top SS^\top + I| + \frac{1}{2}\log|M| \quad (78)$$

$$= \frac{1}{2}\log|S^\top XAX^\top S + I| + \frac{1}{2}\log|M| \quad (79)$$

Combining $X^\top S$ to be one matrix $Z \in \mathbb{R}^{p\times n}$, we can investigate the elements in $Z^\top AZ$. $Z^\top AZ$ should be equal to $\infty * \widetilde{Z}^\top\widetilde{Z}$ where $\widetilde{Z} \in \mathbb{R}^{s\times n}$ is a trimmed Z by throwing away the rows with indices from $s+1$ to p. Therefore, nonzero eigenvalues of $\widetilde{Z}^\top\widetilde{Z}$ will turn into ∞ in $Z^\top AZ$. Zero eigenvalues will remain zero.

Let $\lambda_i \geq 0$ denote the ith eigenvalue of $Z^\top AZ$, then

$$\mathcal{L}_1(\mathbf{u}) \quad = \quad \frac{1}{2}\sum_{i=1}^{p}\log(\lambda_i + 1) + \frac{1}{2}\log|M| \tag{80}$$

Since there exists at least one eigenvalue λ_i in $Z^\top AZ$ approaching ∞, we can conclude that $\mathcal{L}_1(\mathbf{u})$ also approaches ∞ in such a case.

Accordingly, if $||\mathbf{u}|| \to \infty$, we have $\mathcal{F}(\mathbf{u}) \to \infty$, then there must exist a solution set for minimizing $\mathcal{F}(\mathbf{u})$. This validates the nonemptiness of the solution set. Furthermore, the solution set must be bounded. If it's not bounded, there must be a solution at ∞ with the minimal $\mathcal{F}(\mathbf{u})$, but this contradicts the assumption that $\mathcal{F}(\mathbf{u}) \to \infty$ when $||\mathbf{u}|| \to \infty$. Therefore, we can claim that the solution set of $\mathcal{F}(\mathbf{u})$ is bounded and nonempty.

Abstract

Bayesian Non-negative Matrix Factorization (BNMF) is a promising approach for understanding uncertainty and structure in matrix data. However, a large volume of applied work optimizes traditional non-Bayesian NMF objectives that fail to provide a principled understanding of the non-identifiability inherent in NMF—an issue ideally addressed by a Bayesian approach. Despite their suitability, current BNMF approaches have failed to gain popularity in an applied setting; they sacrifice flexibility in modeling for tractable computation, tend to get stuck in local modes, and can require many thousands of samples for meaningful uncertainty estimates. We address these issues through a particle-based variational approach to BNMF that only requires the joint likelihood to be differentiable for computational tractability, uses a novel transfer-based initialization technique to identify multiple modes in the posterior, and thus allows domain experts to inspect a small set of factorizations that faithfully represent the posterior. On several real datasets, we obtain better particle approximations to the BNMF posterior in less time than baselines and demonstrate the significant role that multimodality plays in NMF-related tasks.

Keywords: Bayesian, Non-negative Matrix Factorization, Stein discrepancy, Non-identifiability, Transfer Learning

1. Introduction

The goal of non-negative matrix factorization (NMF) is to find a rank-R_{NMF} factorization for a non-negative data matrix X (D dimensions by N observations) into two non-negative factor matrices A and W. Typically, the rank R_{NMF} is much smaller than the dimensions and observations ($R_{\text{NMF}} \ll D, N$).

$$X \approx AW \quad | \quad X \in \mathbb{R}_+^{D\times N}, \quad A \in \mathbb{R}_+^{D\times R_{\text{NMF}}}, \quad W \in \mathbb{R}_+^{R_{\text{NMF}}\times N}$$

The linear, additive structure of these non-negative factor matrices makes NMF a popular unsupervised learning framework for discovering and interpreting latent structure in data. Each observation in the data X is approximated by an additive combination of the R_{NMF} columns of A with the combination weights given by the column of W corresponding to that observation. In this way, the basis matrix A provides a part-based representation of the data and the weights matrix W provides an R_{NMF}-dimensional latent representation of the data under this part-based representation.

The ability to easily interpret NMF solutions in this way has made them appealing in many applied areas. A few applications of NMF include understanding protein-protein interactions (Greene et al., 2008), topic modeling (Roberts et al., 2016), hyperspectral unmixing (Bioucas-Dias et al., 2012), polyphonic music transcription (Smaragdis and Brown, 2003), discovering molecular pathways from genomic samples (Brunet et al., 2004), and summarizing activations of a neural network for greater interpretability (Olah et al., 2018).

However, the analysis and interpretation of latent structure in a dataset via NMF is affected by the possibility that several non-trivially different pairs of A, W may reconstruct the data X equally well. This non-identifiability of the NMF solution space has been studied in detail in the theoretical literature (Pan and Doshi-Velez, 2016; Donoho and Stodden, 2003; Arora et al., 2012; Ge and Zou, 2015b; Bhattacharyya et al., 2016), and domain experts using NMF as a tool have noticed this issue as well. Greene et al. (2008) use ensembles of NMF solutions to model chemical interactions, while Roberts et al. (2016) conduct a detailed empirical study of multiple optima in the context of extracting topics from large corpora.

Bayesian approaches to NMF promise to characterize this parameter uncertainty in a principled manner by solving for the posterior $p(A, W|X)$ given prior $p(A, W)$ and likelihood $p(X|A, W)$ e.g. Schmidt et al. (2009); Moussaoui et al. (2006). Having a representation of uncertainty in the parameters of the factorizations can assist with the proper interpretation of the factors, allowing us to place low or high confidence on parameters of the factorization. However, computational tractability of inference limits the application of the Bayesian approach. Uncertainty estimates obtained from current Bayesian methods are often of limited use: variational approaches (e.g. Paisley et al. (2015); Hoffman and Blei (2015)) typically underestimate uncertainty and fit to a single mode; sampling-based approaches (e.g. Schmidt et al. (2009); Moussaoui et al. (2006)) also rarely switch between multiple modes and often require many thousands of samples for meaningful uncertainty estimates.

As a result of the limitations of current Bayesian approaches, domain experts tend to rely on non-Bayesian approaches to characterize uncertainty in NMF parameters. For example, Greene et al. (2008); Roberts et al. (2016); Brunet et al. (2004) all use random restarts to find multiple solutions.[1] Random restarts have no Bayesian interpretation (as they depend on the basins of attraction of each mode), but they do often find multiple optima in the objective that can be used to understand and interpret the data.

Contributions In this work, we present a transfer-learning approach that remains faithful to a principled Bayesian framework and can efficiently identify multiple, disconnected modes for any differentiable prior and likelihood model. Our transfer-learning based approach provides high-quality and diverse NMF initializations to seed a particle-based approximation to the Bayesian NMF (BNMF) posterior. We demonstrate our inference approach on two different BNMF models: first, the common exponential-Gaussian model; second, a novel

1. Random restarts involve repeating an optimization procedure with different starting points that are independently sampled.

model that corresponds more closely with the desires of domain experts. Through our experiments, we demonstrate that:

- On a large number of real-world datasets, our particle-based posterior approximations consistently outperform baselines in terms of both posterior quality and computational running time.
- Our approach allows us to produce relatively small (less than 100 NMFs) sets of particles that belong to multiple modes of the posterior landscape, have distinct interpretations, and exhibit variability in performance on downstream tasks—all of which may be essential for a domain expert to inspect and understand the full solution space.
- Our novel practitioner-friendly BNMF model involves a new scale-fixing prior that removes many uninteresting multiple optima and captures the kinds of loss-insensitive regions that are important in many applications. Inference in this non-conjugate model is significantly more challenging than with more standard BNMF models, but our approach handles this case with ease.

2. Inference Setting

The general process of Bayesian modeling consists of three main parts. First, we must select a model (a likelihood and prior). Next, we perform inference on the model given data (under some objective). Finally, we evaluate the quality of the inference. The main innovation in this work is a novel transfer-based approach to the inference phase (Section 4). Along the way, we also introduce a novel model for BNMF that is more closely aligned to what domain experts desire from NMFs (Section 5.2).

When performing inference, we must choose how we will approximate the true posterior $p(A, W|X)$. For notational simplicity, let θ represent NMF parameters (A, W). We approximate the full BNMF posterior $p(\theta|X)$ with a discrete variational distribution $q(\theta|\theta_{1:M}, w_{1:M})$ that has M different point-masses θ_m. Each θ_m represents a different NMF solution's full set of parameters: $\theta_m = \text{vec}[A_m^T, W_m]$, and is assigned probability mass w_m. The functional form of the variational distribution is given by:

$$p(\theta|X) \approx q(\theta|\theta_{1:M}, w_{1:M}) = \sum_{m=1}^{M} w_m \delta(\theta - \theta_m) \quad \text{s.t } w_{1:M} \in \Delta^{M-1}, \quad \text{where} \quad \theta_m = \text{vec}[A_m^T, W_m] \tag{1}$$

where δ is the Dirac delta distribution and Δ^{M-1} is the probability simplex in $\mathbb{R}^M$. Particle-based approximations are attractive to domain experts because each sample represents something that they can inspect and understand.

While there exist many methods for particle-based approximations (Monte Carlo, Sequential Monte Carlo, Markov Chain Monte Carlo), these techniques often only enjoy theoretical guarantees in the limit of infinite or very large samples. Recent work in Stein discrepancy evaluation (Liu and Feng (2016); Chwialkowski et al. (2016); Gretton et al. (2006); Liu et al. (2016); Gorham and Mackey (2015); Ranganath et al. (2016); details in

Section 3) now enables us to measure the quality of an *arbitrary* finite collection as a posterior approximation.[2] As such, it opens the door to entirely new classes of particle-generation techniques, where traditional conditions, such as detailed balance, are now replaced with minimizing the Stein discrepancy $\mathbb{S}_p(q)$[3] between the true BNMF posterior $p(\theta|X)$ and the discrete approximation $q(\theta|\theta_{1:M}, w_{1:M})$:

$$q^*(\theta|\theta_{1:M}, w_{1:M}) = \text{argmin}_{q(\theta|\theta_{1:M}, w_{1:M})} \mathbb{S}_{p(\theta|X)}(q(\theta|\theta_{1:M}, w_{1:M})) \text{ s.t. } w_{1:M} \in \Delta^{M-1} \tag{2}$$

As with all variational inference problems, the problem of posterior inference is now reduced to the problem of optimizing the objective above; we are free to explore any method for producing settings $\{\theta_{1:M}, w_{1:M}\}$ to minimize the Stein discrepancy to the true posterior.

In the following, we observe that the task of minimizing this Stein discrepancy often depends on producing high-quality, diverse factorization collections $\theta_{1:M}$ and determining their associated weights $w_{1:M}$. In Section 4, we introduce a transfer-learning based approach to efficiently suggest a diverse collection of particles and optimize their associated weights. We describe traditional BNMF as well as a novel threshold-based NMF model, and discuss their merits in the context of our approach in Section 5. Experimental details including parameter choices for our approach as well as description of baselines and evaluation metrics is provided in Section 6. In Section 7, we compare our approach to more traditional particle-based approaches (MCMC), more naive ways of generating candidate particle collections, as well as directly attempting to optimize the Stein objective above. We evaluate the quality of different posterior approximations both based on their Stein discrepancies, likelihoods and reconstruction on held-out data.

3. Background

Bayesian Non-negative Matrix Factorization In BNMF, we define a prior $p(A, W)$ and a likelihood $p(X|A, W)$ and seek to characterize the posterior $p(A, W|X)$. These are related by Bayes' rule:

$$p(A, W|X) = \frac{p(X|A, W)p(A, W)}{p(X)}$$

There exist many options for the choice of prior and likelihood (e.g., exponential-Gaussian, (Paisley et al., 2015; Schmidt et al., 2009), Gamma Markov chain priors (Dikmen and Cemgil, 2009) and volume-based priors (Arngren et al., 2011)). The likelihood and prior choices are often chosen to have good computational properties (e.g. the resulting partial conjugacy of the exponential-Gaussian model). One advantage of our work is that we do not require the computationally convenient priors for inference.

Transfer learning The field of transfer learning aims to leverage models and inference applied to one problem to assist in solving related problems. It is of practical value because

2. While the popular Kullback-Leibler divergence requires comparing the ratio of probability densities or probability masses, the Stein discrepancy can be used to compare a particle-based collection defined by probability masses with a continuous target distribution.
3. This notation refers to the Stein discrepancy (a variational objective) between two distributions p and q. For a precise definition, see Section 3

there may be an abundance of data and computational resources for one problem but not another (see Pan and Yang (2010) for a survey). In this work, we shall use the solutions to BNMF from small, synthetic problems to help solve much larger NMF problems.

Stein discrepancy The Stein discrepancy $\mathbb{S}_p(q)$ is a divergence from distributions $q(\theta)$ to $p(\theta)$ that only requires sampling from the variational distribution $q(\theta)$ and evaluating the score function of the target distribution $p(\theta)$. The Stein discrepancy is computed over some class of test functions $f \in \mathcal{F}$ and satisfies the closeness property for operator variational inference (Ranganath et al., 2016): it is non-negative in general and zero only for some equivalence class of distributions $q \in \mathcal{Q}_0$. For a rich enough function class, the only distribution for which the Stein discrepancy is zero is the distribution p itself. For discrete distributions like our $q(\theta|\theta_{1:M}, w_{1:M})$ from Section 2, the approximation quality to the posterior distribution $p(\theta|X)$ of interest can be analytically computed using recent advances in Stein discrepancy evaluation with kernels (Liu and Feng, 2016; Chwialkowski et al., 2016; Gretton et al., 2006; Liu et al., 2016; Gorham and Mackey, 2015). The Stein discrepancy is related to the maximum mean discrepancy (MMD): a discrepancy that measures the worst-case deviation between expectations of functions $h \in \mathcal{H}$ under p and q (Gretton et al., 2006).

$$\text{MMD}(\mathcal{H}, q, p) := \sup_{h \in \mathcal{H}} \mathbb{E}_{\theta \sim q}[h(\theta)] - \mathbb{E}_{\theta' \sim p}[h(\theta')]$$

The Stein operator $\mathcal{T}_p$ corresponding to the distribution p is given by

$$(\mathcal{T}_p h)(x) := \frac{1}{p(x)} \langle \nabla, p(x) h(x) \rangle$$

and under its application, the function space $\mathcal{H}$ is transformed into another function space $\mathcal{T}_p(\mathcal{H}) = \mathcal{F}$. The advantage of applying this operator to the MMD equation is that expectations under p of any $f \in \mathcal{F}$ are zero, i.e. $\mathbb{E}_{\theta' \sim p} f(\theta')) = 0$ (Barbour and Brown, 1992). The Stein discrepancy is given by:

$$\mathbb{S}_p(\mathcal{H}, q) := \sup_{f \in \mathcal{T}_p(\mathcal{H})} (\mathbb{E}_{\theta \sim q} f(\theta))^2$$

Computing the Stein discrepancy is of particular interest when the distribution p is intractable. Evaluating the Stein discrepancy does not require expectations over p and the Stein operator $\mathcal{T}_p$ only depends on the unnormalized distribution via the score function $\nabla_\theta \log p(\theta)$.

In this work, we use a kernelized form of the Stein discrepancy. For every positive definite kernel $k(\theta, \theta')$, a unique Reproducing Kernel Hilbert Space (RKHS) $\mathcal{H}$ is defined. Chwialkowski et al. (2016) showed that the Stein operator applied to an RKHS defines a modified positive definite kernel $\mathcal{K}_p$ given by:

$$\begin{aligned} \mathcal{K}_p(\theta, \theta') = &\nabla_\theta \log p(\theta)^T \nabla_{\theta'} \log p(\theta') k(\theta, \theta') \\ &+ \nabla_{\theta'} \log p(\theta')^T \nabla_\theta k(\theta, \theta') \\ &+ \nabla_\theta \log p(\theta)^T \nabla_{\theta'} k(\theta, \theta') \\ &+ \sum_{i=1}^{d} \frac{\partial^2 k(\theta, \theta')}{\partial \theta_i \partial \theta_i'} \end{aligned} \tag{3}$$

Finally, the Stein discrepancy is simply the expectation of the modified kernel $\mathcal{K}_p$ under the joint distribution of two independent variables θ, $\theta' \sim q$.

$$\mathbb{S}_p(q) = \mathbb{E}_{\theta, \theta' \sim q}[\mathcal{K}_p(\theta, \theta')]$$

For a discrete distribution over $\theta_{1:M}$ with probability masses $w_{1:M}$ (of the form in equation 1), this can be evaluated exactly (Liu and Lee, 2016) as:

$$\begin{aligned} \mathbb{S}_p(q) &= \sum_{i,j=1}^{M} w_i w_j \mathcal{K}_p(\theta_i, \theta_j) \\ &= \mathbf{w}^T \mathbf{K} \mathbf{w} \end{aligned} \tag{4}$$

The (pure) quadratic form $\mathbf{w}^T \mathbf{K} \mathbf{w}$ is a reformulation where $\mathbf{K} \in \mathbb{R}^{M \times M}$ is the (positive definite) pairwise kernel matrix with entries $\mathbf{K}_{ij} = \mathcal{K}_p(\theta_i, \theta_j)$ and the probability masses $w_{1:M}$ are embedded into a vector $\mathbf{w} \in \mathbb{R}^{M \times 1}$. Our particle-based variational objective (equation 2) simplifies to the form in equation 4. In Section 4, we will provide a method for estimating $\theta_{1:M}$ and $w_{1:M}$ for the BNMF problem.

4. Approach

In this Section, we describe our transfer-based inference. As noted in Section 2, creating a particle-based posterior involves two distinct parts: creating a collection of candidate NMFs $\theta_{1:M}$, and then optimizing their weights $w_{1:M}$. We introduce a novel transfer-based approach that uses state-of-the-art (non-Bayesian) algorithms to efficiently generate the candidate NMFs $\theta_{1:M}$ (Section 4.1). Given $\theta_{1:M}$, we optimize the weights $w_{1:M}$ via standard convex optimization tools to minimize Stein discrepancy. (See Algorithm 1 for the full algorithm.) In Section 7, we compare our approach for generating candidate NMFs and weights to other baselines, including those that use traditional methods for particle generation (MCMC), other ways of creating candidate NMFs (and then again using a convex optimization on the weights), and gradient-based optimization of the objective.

4.1. Learning factorization parameters $\theta_{1:M}$ via Transfer Learning

A natural approach to finding the factorization parameters $\theta_{1:M}$ is to optimize for them directly via the variational objective (equation 2), however, as we shall see in Section 7, the direct approach tends to get stuck in poor local optima and is computationally expensive. Since the quality of the variational approximation is determined solely by the value of the variational objective under a given set of parameters $\theta_{1:M}$, $w_{1:M}$, we are free to employ any technique that produces a suitable collection $\theta_{1:M}$.

We observe that to minimize the Stein discrepancy, we will need solutions that are both high-quality and diverse. Random restarts have been previously used to find multiple solutions in general (Gendreau and Potvin, 2010) and for NMF in particular (Greene et al., 2008; Roberts et al., 2016; Brunet et al., 2004). These restarts can take advantage of specialized (non-Bayesian) optimization algorithms for NMF (Lee and Seung, 2001; Lin, 2007; Hsieh and Dhillon, 2011) that are widely used in applied settings to produce single factorization parameters θ_m from some initialization; there also exist algorithms to speed up

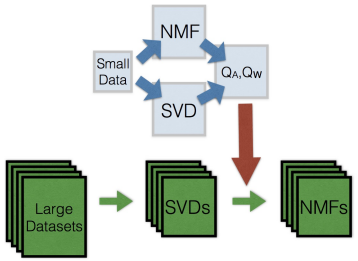

Figure 1: A schematic of the transfer learning procedure for NMF: A small dataset is used to learn transformation matrices Q_A, Q_W. We then apply these transformation matrices to multiple larger datasets (with any number of dimensions or observations) using its SVD to obtain a transfer-based initialization.

convergence of these methods (Salakhutdinov et al., 2002; Wild et al., 2004; Xue et al., 2008; Boutsidis and Gallopoulos, 2008). However, these random restarts do not take advantage of any structure of NMF; for each new NMF instance they propose random initializations from scratch. As such, many initializations may converge to the same mode—a waste of computational effort—while missing other modes (especially when the number of restarts is small).

In this Section, we introduce a transfer-based technique (which we will call Q-Transform) to speed-up, as compared to random restarts, the process of finding a diverse set of factorizations from high-density regions of the posterior. Our initializations are determined by identifying the low-rank subspace of the data (via singular value decomposition (SVD)) and then transforming it in specific ways. Figure 1 shows a schematic illustrating the idea: we generate subspace transformation matrices Q_A, Q_W from a number of small, synthetic datasets and then apply those transformations to the dataset of interest. These transformations serve as more intelligent initializations—compared to random restarts—from which to apply NMF algorithms to obtain a more diverse collection of high-quality NMFs. Because our initializations are almost always already decent NMFs, convergence is also computationally faster. To explain our Q-Transform procedure, we first define the subspace transformation matrices, then describe the method for generating transformation matrices Q_A, Q_W using synthetic data, and finally discuss how to apply them to real data sets (transfer learning).

Subspace transformations Q_A, Q_W relating SVD and NMF A low dimensional approximation for the data X can be obtained via the top R_{SVD} vectors of the SVD $A_{\text{SVD}}, W_{\text{SVD}}$. An NMF A, W of rank R_T (which may be different from R_{SVD}) also leads to an approximation of the data. The NMF factors are interpretable due to the non-negativity constraint whereas the SVD factors typically violate non-negativity. However, both approaches describe low dimensional subspaces that can be used to understand and approximate the data. These subspaces are the same when $R_{\text{SVD}} = R_T$ and the NMF is exact (i.e. $X = AW$; corresponds to Type I non-identifiability in Pan and Doshi-Velez (2016). Under

Algorithm 1 Particle-based Variational Inference for BNMF using Q-Transform

Input: Data $\{X\}$, Rank $\{R_{\text{NMF}}\}$, # Factorizations M
Step 1: Perform M repetitions of Algorithm 2 to get matrices $\{Q_A^m, Q_W^m\}_{m=1}^M$ or re-use them if previously constructed
Step 2: Apply Q-Transform (Algorithm 3) to get Initializations $\{A_0^m, W_0^m\}_{m=1}^M$
Step 3: Apply NMF algorithm to get Factorizations $\{A^m, W^m\}_{m=1}^M$
Step 4: Apply Algorithm 5 using a given BNMF model to get weights $\{w^m\}_{m=1}^M$ for approximate posterior
Output: Discrete NMF Posterior $\{w^m, A^m, W^m\}_{m=1}^M$

these conditions, there exist transformation matrices Q_A, Q_W to obtain the non-negative basis and weights exactly in terms of the singular value decomposition matrices:

$$\text{If} \quad X = A_{\text{SVD}} W_{\text{SVD}} = AW \quad \text{then}$$
$$A = A_{\text{SVD}} Q_A \quad W = Q_W W_{\text{SVD}}$$

When the data X is not an exact NMF but rather a perturbation of it (i.e. $X = AW + \epsilon$), the singular subspace of the matrix is bounded by Wedin's theorem (Wedin, 1972). We therefore still expect that there exist transformation matrices $Q_A \in \mathbb{R}^{R_{\text{SVD}} \times R_T}, Q_W \in \mathbb{R}^{R_T \times R_{\text{SVD}}}$ to yield approximations of the NMF factorizations that can be expressed in terms of the singular value decomposition matrices.

$$A_Q = A_{\text{SVD}} Q_A \approx A \quad W_Q = Q_W W_{\text{SVD}} \approx W$$

Our transfer-based strategy will involve identifying candidate matrices $A_Q \in \mathbb{R}^{D \times R_T}, W_Q \in \mathbb{R}^{R_T \times N}$ such that $A_{\text{SVD}} Q_A$ and $Q_W W_{\text{SVD}}$ are likely to be good initializations for an NMF of the data X. (Note that we assume that computing the SVD to obtain A_{SVD} and W_{SVD} from the data X is straight-forward.) We will describe the details for using these initializations below, but first we describe how we might create a collection of candidate transformation matrices Q_A, Q_W.

Generating transformations Q_A, Q_W for NMF initialization. To generate candidate transformations, we note that if we have already computed an NMF A, W for a dataset X, the appropriate transforms Q_A, Q_W can be computed by relating the SVD factors $A_{\text{SVD}}, W_{\text{SVD}}$ to A, W (e.g. via linear least squares). We propose to generate candidate transforms by using random restarts on small, synthetic datasets X_s that follow some generative model for NMF, where we can run (non-Bayesian) NMF algorithms quickly and solve for Q_A, Q_W (Algorithm 2). Multiple pairs of transformation matrices can be obtained by repeating Algorithm 2 with different random initializations to compute NMF of the synthetic data X_s, as well as by generating multiple synthetic datasets (see Section 8.1 for experiments and discussion of alternate generation procedures). Since the transformations Q_A, Q_W act on the inner dimensions (columns of A_{SVD} and rows of W_{SVD}), we emphasize that they can be applied to new datasets with any number of dimensions D and number of observations N.

Algorithm 2 Generate Q-Transform Matrices

Input: Synthetic Data $\{X_s\}$, SVD Dimension $\{R_{\text{SVD}}\}$, Transfer Dimension $\{R_T\}$
$A_{\text{SVD}}, W_{\text{SVD}} \leftarrow$ Compute top R_{SVD} SVD of X_s
$A_{\text{NMF}}, W_{\text{NMF}} \leftarrow$ Compute rank-R_T NMF of X_s using random initialization
$Q_A = \arg\min_Q \|A_{\text{NMF}} - A_{\text{SVD}}Q\|_F$ via linear least squares
$Q_W = \arg\min_Q \|W_{\text{NMF}} - QW_{\text{SVD}}\|_F$ via linear least squares
Output: Q_A, Q_W

Algorithm 3 Apply Q-Transform

Input: Real Data $\{X\}$, SVD Rank $\{R_{\text{SVD}}\}$, NMF Rank $\{R_{\text{NMF}}\}$, Transformation Matrices $\{Q_A, Q_W\}$
$A_{\text{SVD}}, W_{\text{SVD}} \leftarrow$ Compute top R_{SVD} SVD of X
$\tilde{A}_0 = A_{\text{SVD}}Q_A, \quad \tilde{W}_0 = Q_W W_{\text{SVD}}$
$A_0, W_0 \leftarrow$ Apply non-negativity and fix dimensions: Algorithm 4 $(\tilde{A}_0, \tilde{W}_0, R_{\text{NMF}})$
Output: A_0, W_0

Creating initializations for a new dataset. Given the top SVD factors of a new dataset $A_{\text{SVD}}, W_{\text{SVD}}$, we apply the Q-Transform (Algorithm 3) which multiplies SVD factors by the Q_A, Q_W matrices and adjusts entries of $A_{\text{SVD}}Q_A$ and $Q_W W_{\text{SVD}}$ to ensure non-negativity and correct dimensions using Algorithm 4 to obtain initializations A_0, W_0 that can be used as input for any standard (non-Bayesian) NMF algorithm (e.g. Cichocki and Phan (2009), Févotte and Idier (2011)). Algorithm 4 ensures that all values in the initialization A_0, W_0 are non-negative as well as provides a way to pad the initialization if the size R_T of the transforms Q_A, Q_W are smaller than the desired NMF rank R_{NMF}. The latter is an important point: in Section 8.3 we find that it is often the first few dimensions of the transformation that contain transferable information, and the rest provide little benefit. This observation also allows us to use transforms of some rank R_T on problems with a range of desired NMF ranks R_{NMF}. Finally, running the algorithm gives us a set of factorization parameters $\theta_m = \text{vec}[A_m^T, W_m]$ that we may (or may not) ultimately decide to keep in our approximation of the true posterior.

In the experiments in Section 7, we find that knowledge from these transformations Q_A, Q_W can be transferred to real datasets by re-using them to relate the top SVD factors of other datasets to high quality, approximately non-negative factorizations.[4]

4.2. Learning weights $w_{1:M}$ given parameters $\theta_{1:M}$

To infer the weights corresponding to a given factorization collection $\theta_{1:M}$, we minimize the Stein discrepancy (Algorithm 5) subject to the simplex constraint on the weights. This process involves first computing the pairwise kernel matrix[5] $\mathbf{K}$ using the kernel $\mathcal{K}_p$ in equation 3. The objective function is convex and can be solved using standard convex optimization solvers. Given point-masses $\theta_{1:M}$, this framework can be employed to infer weights

4. Code and demonstrations at https://github.com/dtak/Q-Transfer-Demo-public-/
5. As the kernel $\mathcal{K}_p$ is positive definite, $\mathbf{K}$ is also positive definite.

Algorithm 4 Initialization Adjustment

Input: Approximation matrices $\{A_Q, W_Q\}$, NMF Rank $\{R_{\text{NMF}}\}$
$\tilde{A}_0 \leftarrow$ Absolute Value(A_Q)
$\tilde{W}_0 \leftarrow$ Absolute Value(W_Q)
Transfer Rank R_T = # Columns of A_Q
if NMF Rank R_{NMF} > Transfer Rank R_T **then**
  $r = R_{\text{NMF}} - R_T$
  Pad $\tilde{A}_0, \tilde{W}_0$ with matrices $M_{D\times r}$ and $M_{N\times r}$ having small random entries so that initializations are the correct dimensions and matrices $M_{D\times r}, M_{N\times r}$ have little effect of the product $\tilde{A}_0\tilde{W}_0$.
  $A_0 \leftarrow [\tilde{A}_0, M_{D\times k}]$
  $W_0 \leftarrow [\tilde{W}_0^T, M_{N\times k}]^T$
else if NMF Rank R_{NMF} < Transfer Rank R_T **then**
  Pick the top R_{NMF} columns of $\tilde{A}_0$ and rows of $\tilde{W}_0$
  $A_0 \leftarrow \tilde{A}_0[:, 0 : R_{\text{NMF}}]$
  $W_0 \leftarrow \tilde{W}_0[0 : R_{\text{NMF}}, :]$
end if

Algorithm 5 Kernelized Stein inference for discrete approximations to posterior

Input: Particles $\theta_{1:M}$, Score $\nabla_\theta \log p(\theta)$, RKHS $\mathcal{H}$ defined by kernel k
Step 1: Compute pairwise kernel matrix $\mathbf{K_{i,j}} = \mathcal{K}_p(\theta_i, \theta_j)$ (from equation 3)
Step 2: Find probability masses that minimize the Stein discrepancy for the given point-masses: $\mathbf{w}^* = \arg\min_{\mathbf{w}} \mathbf{w}^T\mathbf{K}\mathbf{w} \quad \text{s.t.} \quad \mathbf{w} \in \Delta^{M-1}$ via standard convex optimization.
Output: Probability masses $\mathbf{w}^*$

for discrete approximations to any posterior for which the score function $\nabla_\theta \log p(\theta)$ can be computed.

5. BNMF Models

Section 4 outlined a general procedure for producing a particle-based approximation to the BNMF posterior using transfer learning. In Section 7, we compare our approach to other particle-based approaches for BNMF. However, before going to the results, we first describe the two BNMF models (below) as well as our experimental procedure (Section 6).

The first model we shall use in our experiments is the commonly-used exponential-Gaussian model. This model is computationally convenient to use (e.g. Schmidt et al. (2009) derive a Gibbs sampler for this model) but the scale-flexible prior allows for multiple optima that are essentially the same factorization, and the Gaussian likelihood severely penalizes solutions of differing quality even when all solutions may be far from perfect reconstructions. These properties make this popular model less desirable from the perspective of a domain expert seeking to understand their data. The second model is a novel threshold-based model with a scale-fixing prior that at once removes scale ambiguities and allows for the kinds of likelihood ambiguities that practitioners expect—in particular, when the NMF is already an approximation of the data, solutions with different absolute likelihoods but whose relative

differences are small compared to the magnitude of the likelihood may be considered similar by a practitioner (Roberts et al., 2016). Our threshold-based likelihood model allows the practitioner to choose what levels of error are effectively the same for their purposes.

Before continuing, we emphasize again that our transfer-based inference approach can be applied to *any* BNMF model; in this paper we demonstrate our approach on the following two models because together they include a standard model often-used in the machine learning community and a novel model of interest to the practitioner community. Importantly, because our inference approach decouples the process of model choice, particle generation, and particle weighting, we use the same particle generation process (non-Bayesian optimization algorithms using the Frobenius objective) for both models. In Section 7, we demonstrate empirically that this particle generation process is robust enough; that is, we do not require processes tuned to each model.

5.1. Exponential-Gaussian Model for BNMF

The commonly used exponential-Gaussian BNMF model uses a Gaussian likelihood and exponential priors for the basis and weights matrices:

$$p_{\mathcal{N}}(X|A,W) = \prod_{d,n} \mathcal{N}(X_{d,n}, (AW)_{d,n}, \sigma_X^2)$$

$$p(A) = \prod_{d=1}^{D}\prod_{r=1}^{R} p(A_{d,r}), \quad A_{d,r} \sim \text{Exp}(\lambda_{d,r})$$

$$p(W) = \prod_{n=1}^{N}\prod_{r=1}^{R} p(W_{r,n}), \quad W_{r,n} \sim \text{Exp}(\lambda_{r,n})$$

As derived in Schmidt et al. (2009), the combination of exponential priors and Gaussian likelihoods results in element-wise conjugate parameter updates; in general, this model enjoys relatively straightforward inference approaches.

That said, as noted above, the exponential-Gaussian has several drawbacks from the perspective of a domain expert seeking to interpret their data via NMF. First, especially in settings where the model is misspecified (which will almost always be the case), the reconstruction error of even the best factorization may be relatively large. Even so, the Gaussian likelihood will tend to make the posterior highly peaked around the MAP solution—and exclude factorizations of only slightly worse (relative approximation) quality with respect to the overall error. However, domain experts may have found those factorizations interesting, as they have about the same relative error. Second, the exponential prior allows for some amount of uncertainty simply due to scale, which is typically uninteresting for domain experts. In the following, we introduce a model that addresses both of these shortcomings; because our transfer-based inference approach does not require conjugacy, we will be able to efficiently compute approximate posteriors for such more complex models.

5.2. Threshold-based, Scale-Fixing Model for BNMF

The procedure described in Algorithm 1 for finding a discrete approximation to the BNMF posterior does not depend on any special properties (such as conjugacy) and only requires

the joint density $p(X, W, A)$ to be differentiable in order to make inference tractable. Such flexibility is important as different applied domains use different notions of factorization quality: squared Euclidean distance is commonly used in hyperspectral unmixing (Bioucas-Dias et al., 2012), Kullback-Leibler divergence in image analysis (Lee and Seung, 2001) and Itakura-Saito divergence in music analysis (Févotte et al., 2009).

A common theme in many applied domains is that small differences in factorization quality may not be important if all factorizations have some large level of approximation error. In such cases, domain experts may be interested in all of these solutions (Roberts et al., 2016). At the same time, solutions that are different only in scale are likely uninteresting. Below, we present a novel prior and likelihood that reflect these application-specific preferences of practitioners in a Bayesian framework. In particular, our model class allows domain experts to take any application-specific notion of a high-quality factorization—conjugate or not—and put it into a Bayesian context.

Likelihood: Soft Insensitive Loss Function (SILF) over NMF objectives We define a likelihood that is maximum (and flat) in the region of high quality factorizations and decays as factorization quality decreases. To do so, we use the soft insensitive loss function (SILF) (Chu et al., 2004): a loss function defined over the real numbers $\mathbb{R}$, where the loss is negligible in some region around zero defined by the insensitivity threshold ϵ, and grows linearly outside that region (see figure 2). A quadratic term depending on the smoothness parameter β, makes the transition between the two main regions smooth. This transition region has length 2β, making smaller values of β correspond to sharper transitions between the flat and linear loss regions. We adapt the SILF from (Chu et al., 2004) to only be defined over the non-negative numbers $\mathbb{R}_+$ (as is typical with NMF objectives) and define it as:

$$\text{SILF}_{\epsilon,\beta}(y) = \begin{cases} 0 & 0 \leq y \leq (1-\beta)\epsilon \\ \frac{(y-(1-\beta))^2}{4\beta\epsilon} & (1-\beta)\epsilon \leq y \leq (1+\beta)\epsilon \\ y-\epsilon & y \geq (1+\beta)\epsilon \end{cases}$$

To form the likelihood, we apply the SILF loss to an NMF objective $f_X(A, W)$ to give:

$$P(X|W,A) = \frac{1}{Z} e^{(-C \times \text{SILF}_{\epsilon,\beta}(f_X(A,W)))} \tag{5}$$

We emphasize that the SILF-based likelihood allows the domain expert to use an NMF objective $f_X(A, W)$ that is best suited to their task and can specify a threshold under that objective for identifying high-quality factorizations. Once an NMF objective is chosen, the domain expert can easily choose appropriate parameters for the SILF-based likelihood since the parameters (insensitivity factor ϵ and smooth transition factor β) are interpretable and the likelihood can be visually inspected (as a one-dimensional function of a chosen NMF objective) to validate parameter choices.

Prior: uniform over basis and unambiguous in factorization scaling Often, domain experts do not have specific notions of what the prior over factorizations should be. However, prior distributions can have a large effect. These effects are undesirable if the prior was chosen for computational convenience rather than based on some true knowledge about the problem. Another concern is that NMF has a scaling and permutation ambiguity

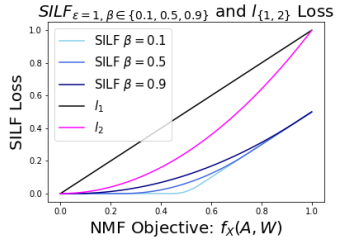

Figure 2: A comparison of SILF loss and commonly used l_1, l_2 loss functions. The SILF insensitivity parameter ϵ is set to 0.5, and the smooth transition factor β is varied. Small values of β lead to sharp transition in the SILF loss profile whereas the transition is less abrupt for large values of β. In contrast, other popular loss functions such as l_1 or l_2 do not have insensitive regions, and in the case of NMF, treat the objective function as the sole guide for factorization quality.

that is uninteresting in practice:

$$AW = \underbrace{ASP}_{\widetilde{A}}\underbrace{(SP)^{-1}W}_{\widetilde{W}} \quad \text{where S is a positive diagonal matrix, P is a permutation matrix} \tag{6}$$

Depending on the priors chosen, this ambiguity can add redundancy to the posterior distribution.

To facilitate exploration of the space of distinct high-quality factorizations, we propose an NMF prior that eliminates redundancy due to scale and is also uniform over the space of factorizations. Specifically, we let each column of the basis matrix A_r be generated by a symmetric Dirichlet distribution with parameter $\alpha = 1$. This prior determines a unique scale of the factorization and is uniform over the basis matrix A for that scaling. For W, we use a prior where each entry $W_{r,n}$ is i.i.d from an exponential distribution with parameter $\lambda_{r,n}$. The exponential distribution has support over all $\mathbb{R}_+$ ensuring that any weights matrix W corresponding to a column-stochastic basis matrix A is a valid parameter setting under our model, and that the posterior is proper.

$$p(A) = \prod_{r=1}^{R} p(A_r), \quad A_r \sim \text{Dir}(\mathbf{1}_D)$$

$$p(W) = \prod_{n=1}^{N}\prod_{r=1}^{R} p(W_{r,n}), \quad W_{r,n} \sim \text{Exp}(\lambda_{r,n})$$

6. Experimental Setup

In this Section, we provide details of our experimental settings and parameter choices, and describe our baseline algorithms and datasets. Our experiments are performed on a wide

array of benchmark NMF datasets as well as on Electronic Health Records (EHR) data of patients with Autism Spectrum Disorder (ASD) that is of interest to the medical community (see quantitative and qualitative results in Section 7).

6.1. Model, Evaluation, and Inference Settings

Model: exponential-Gaussian model parameters: We set the standard deviation σ_X to be equal to the empirical standard deviation of a reference NMF. The exponential parameter was set to one for each entry in the basis and weights matrices ($\lambda_{d,r} = \lambda_{r,n} = 1$).

Model: SILF model parameters: While any objective can be put into the SILF likelihood, in the following, we used the squared Frobenius objective $f_X(A, W) = \|X - AW\|_F^2$. To set the threshold parameter ϵ for each dataset, we use an empirical approach where we find a collection of 50 high-quality factorizations under default settings of scikit-learn (Pedregosa et al., 2011). The objective function is evaluated for each of them $\{f_i\}_{i=1}^{50}$ and $\epsilon = 1.2 \max_i f_i$. We set the remaining SILF likelihood sensitivity parameters $\beta = 0.1$, $C = 2$. For the prior, we identically set the exponential parameter for each entry: $\lambda_{r,n} = 1$.

Inference: Generating Q-transform matrices for transfer: For the Q-Transform initializations, we set the transfer rank and SVD rank $R_T = R_{\text{SVD}} = 3$. We generated twenty sets of synthetic data $X_s \in \mathbb{R}_+^{12\times 12}$ using non-negative matrices of rank R_T with truncated Gaussian noise. For each synthetic dataset, we find five pairs of transformation matrices through random restarts. In *all* our experiments, the *same* set of $M_{\max} = 100$ pairs of transformation matrices $\{Q_A^m, Q_W^m\}_{m=1}^{100}$ are applied to each of the real datasets.

Inference: Solver for inferring weights $w_{1:M}$: The optimization for the weights $w_{1:M}$ (Step 2 in Algorithm 5) is carried out using the Splitting Conic Solver (SCS) in the convex optimization package CVXPY (Diamond and Boyd, 2016).

Inference and evaluation: Stein discrepancy base RKHS and parameters: The Stein discrepancy for our variational objective requires a function space to optimize over. This optimization over the function space has an analytical solution when a Reproducing Kernel Hilbert Space (RKHS) is used. Gorham and Mackey (2017) show that the Inverse Multiquadric (IMQ) kernel is a suitable kernel choice for Stein discrepancy calculations as it detects non-convergence to posterior[6] for $c > 0$ and $b \in (-1, 0)$.

$$k_{\text{IMQ}}(\theta_i, \theta_j) = (\|\theta_i - \theta_j\|^2 + c^2)^b$$

Since the length scales of the basis and weights matrix differ, we define a kernel via a linear combination of two IMQ kernels defined separately over the basis A and weights W.

$$k([A_1, W_1], [A_2, W_2]) = \frac{1}{2\gamma_A}(\|A_1 - A_2\|^2 + c_A^2)^{b_A} + \frac{1}{2\gamma_W}(\|W_1 - W_2\|^2 + c_W^2)^{b_W} \tag{7}$$

Here $\gamma_A = (c_A^2)^{b_A}$ and similarly $\gamma_W = (c_W^2)^{b_W}$ are scaling factors that ensure the kernel takes values between 0 and 1. In general, across our datasets, the Dirichlet prior on the

6. Gorham and Mackey (2017) also prove that popular Gaussian and Matern kernels fail to detect non-convergence when the dimensionality of its inputs is greater than 3.

basis matrix induces a small length scale for A and a larger length scale for the weights W. We uniformly set $c_A = 1 \times 10^{-2}$, $c_W = 1 \times 10^3$ and $b_A = b_W = -0.5$ across all our datasets.

We note that choosing sensible values for these parameters—and validating them—is important. Kernel parameters that induce length scales that are too small or too large give rise to a similarity measure that either considers all factorizations completely dissimilar or completely similar respectively. In our experiments, our kernel choice gives rise to a similarity measure that distinguishes across collections of factorizations obtained from different algorithms. Our kernel similarity analysis shows agreement with difference between factorizations as measured by the Frobenius distances between basis and weights matrices (see figures 24, 25, 26 in Appendix). The range in kernel similarity values and its agreement with alternative measures indicates that our parameter choices for the kernel are reasonable and fairly robust.[7]

Evaluation: Measuring computational time In experiments, we keep track of the time taken (initialization and optimization) to produce each of the $M_{\max} = 100$ factorizations. We sample collections of size $M = \{5, 25, 50\}$ from these factorizations and report the total time taken to produce the factorizations in the collection alongside reporting the Stein Discrepancies for the approximate BNMF posteriors.

For the baselines below, the reported runtimes correspond to time taken to generate NMFs $\{\theta_m\}_{m=1}^M$ in the approximate posterior. For initialization approaches this corresponds to the time taken to generate the initialization and subsequent optimization time. To allow for a transparent comparison of the performance of these initialization approaches with MCMC and gradient-based algorithms, we report runtimes at various points in the duration of the MCMC chain and for the gradient-based algorithms. For more details on measuring computational time, see Appendix E in supplementary materials.

6.2. Baselines

In the previous Section, we described the implementation details for our transfer-based inference approach. In this Section, we describe implementation details for three classes of baselines for our experiments: MCMC, which represents standard practice for generating particle-based posteriors; gradient-based approaches which directly minimize the Stein variational objective, which represent our main competitors; and alternate initialization approaches, which represent simpler ablations on our approach.

Markov Chain Monte Carlo baselines MCMC approaches involve sampling from a Markov Chain whose stationary distribution is the posterior of interest, and are often considered the gold-standard for approximating posterior distributions (as opposed to variational methods). That said, for a finite sample size, MCMC will still be approximate—and thus we must still evaluate its quality with respect to the Stein objective. In this work, we consider two different MCMC baselines:

- **Hamiltonian Monte Carlo (HMC)** Our HMC was initialized with an NMF obtained using the default settings of scikit-learn (Pedregosa et al., 2011) (warm start), and adaptively selects the step-size using the procedure outlined in Neal et al. (2011).

7. Factorizations across our different datasets have different scales but the kernel parameters were fixed across all datasets.

We run the chain for a total of 10000 samples and at various intermediate points thin it to $M = \{5, 25, 50\}$ factorizations and compute the Stein discrepancy using Algorithm 5. We repeat this experiment three times to capture variability in the performance of the HMC.

For our scale-fixing prior in Section 5.2, we needed to simulate Hamiltonian dynamics as defined on the manifold of the simplex. To do this, we incorporate a reparametrization trick (Betancourt, 2012; Altmann et al., 2014) to sample under the column-stochastic (simplex) constraints of the basis matrix A, and a mirroring trick (Patterson and Teh, 2013) for sampling from the positive orthant for the weights matrix W.

- **Gibbs Sampling**. Only the exponential-Gaussian model admits a conjugate form for straight-forward Gibbs sampling. For experiments using the exponential-Gaussian, we use the same number of samples and thinning factor as with HMC for a Gibbs sampler. Similarly to the HMC baseline, the Gibbs sampler was also initialized with an NMF obtained using the default settings of scikit-learn (Pedregosa et al., 2011) (warm start).

Gradient-based baselines Gradient-based baselines optimize the collection of factorizations directly via gradient descent on the Stein variational objective. They represent the class of inference approaches most similar to ours. Gradient-based approaches typically require fixing the size of the collection. In our experiments, we set the size of this collection to be equal to $M = 5$. Due to the large memory requirement of running this algorithm with automatic differentiation using autograd (Maclaurin et al., 2015), we were unable to run these algorithms for larger M. We impose scaling and non-negativity constraints after every gradient step (for a total of 2000 steps) and keep track of the Stein discrepancy in relation to the algorithm's runtime. The experiment is repeated three times to capture variability in its performance over multiple iterations. We use the following three algorithms:

- **SVGD**: Stein Variational Gradient Descent is a functional gradient descent algorithm (Liu and Wang, 2016) that optimizes a collection of particles (factorizations) to approximate the posterior. We replace the RBF kernel from the original work with the more principled IMQ-based kernel defined in equation 7.
- **SVGD-Q** is a variant were we initialize SVGD with the Q-Transform.
- **DSGD**: Direct Stein Gradient Descent is a variant where we replace the functional gradient descent of SVGD with the gradient of the Stein discrepancy (using automatic differentiation (Baydin et al., 2015; Maclaurin et al., 2015)).

Initialization-based baselines Our Q-transform approach can be thought of as an initialization approach: we provide a way of creating a collection of particles that we believe are likely to be representative of the posterior. Our main algorithm can be run with any process for creating the collection (step 2 of Algorithm 1). Our final set of baselines considers other alternatives to creating the collection.

- **Random restarts** Our random restart initializations for NMF in scikit-learn (Pedregosa et al., 2011) set each entry of the factors A, W as independent, coming

from a truncated standard normal distribution. These entries are all scaled by $\eta = \sqrt{\frac{1}{R_{\text{NMF}}} \sum_{D,N} X_{d,n}}$ and are given by: $A^0_{d,k}, W^0_{k,n} \sim \eta|\mathcal{N}(0,1)|$.

- **NNDSVDar** NNDSVDar is a variant of a popular initialization technique called Nonnegative Double Singular Value Decomposition (NNDSVD) which was introduced by Boutsidis and Gallopoulos (2008). It is based on approximating the SVD expansion with non-negative matrices. Since the NNDSVD algorithm is deterministic, this only gives a single initialization. The NNDSVDar variant of this initialization replaces the zeros in the NNDSVD initialization with small random values. We use the scikit-learn initialization for NNDSVDar which uses a randomized SVD algorithm (Halko et al., 2011), and note that it introduces some additional variability in the initializations.

6.3. Datasets

Our datasets cover a range of different types and can be divided into three main categories (count data, grayscale face images and hyperspectral images). The ranks for hyperspectral data are chosen according to ground truth values. In the 20-Newsgroups data, we select articles from 16 newsgroups (hence the rank 16) and for other datasets we pick a rank that corresponds to explaining at least 70 percent of the variance in the data (as measured by the SVD). Table 1 provides a description of each dataset as well as the rank used and a citation. The Autism dataset is of interest to the medical community for understanding disease subtypes in the Autism spectrum and is not publicly available. The remaining datasets are public and are considered standard benchmark datasets for NMF. In our experiments, we hold out ten percent of the observations and report performance on both provided and held-out observations.

Table 1: Datasets for NMF

Dataset	Dimension	Observations	Rank	Description
20-Newsgroups	1000	8926	16	Newspaper articles (20NG, 2013)
Autism	2862	5848	20	Patient visits (Doshi-Velez et al., 2014)
LFW	1850	1288	10	Grayscale Faces Images (LFW, 2017)
Olivetti Faces	4096	400	10	Grayscale Faces Images (Samaria, 1994)
Faces CBCL	361	2429	10	Grayscale Faces Images (CBCL, 2000)
Faces BIO	6816	1514	10	Grayscale Faces Images (Jesorsky et al., 2001)
Hubble	100	2046	8	Hyperspectral Image (Nicolas Gillis, 1987)
Salinas A	204	7138	6	Hyperspectral Image (SalinasA, 2015)
Urban	162	10404	6	Hyperspectral Image (Zhu et al., 2014)

7. Results

In this Section, we compare computational time and Stein discrepancy values for variational posteriors obtained through different algorithms. For the exponential-Gaussian model, our approach using Q-Transform is either the most-competitive or second in performance to the Gibbs sampler for this model. Under the SILF model, we find that our approach for BNMF posterior approximation using transfer learning (Q-Transform) consistently produces the highest quality posterior approximations in the shortest amount of time (see Section 6.1 for details on runtime calculation). Inspection of factorization parameters from Q-Transform reveals that the parameter uncertainty captured by the BNMF posterior approximation has meaningful consequences for interpreting and utilizing these factorizations.

In the supplement, we provide an in-depth look at our results. We report on quality metrics for both the training data (figures 18, 19, 15 and 16) as well as held-out data (figures 20 and 17); we report on multiple metrics for measuring diversity of factorizations obtained from different algorithms (figures 24, 25, 26, 21, 22 and 23). Overall, these results support the notion that the Stein discrepancy is lowest for algorithms with the most diverse collection of high-quality factorizations.

7.1. Exponential-Gaussian Model Results

In figure 3, we show the performance of our algorithm and other competing baselines across our various datasets. Overall, we note that the best approximate posteriors are produced in the shortest time either by our Q-Transform algorithm or the Gibbs sampler for this model. Using random restarts for initialization yields approximate posteriors with similar Stein discrepancies to our approach but typically takes more time. The gradient-based approaches (even Q-SVGD which is initialized with Q-Transform) rarely do well, often plateauing at much higher discrepancies.

While the likelihood term in this model is invariant to (redundant) scalings[8], a limitation is that the prior (chosen for computational convenience) is dependent on the scaling. We find that this is an undesirable feature because the posterior landscape includes infinite redundant scalings and therefore requires greater effort from the inference procedure to find appropriate scalings of factorizations. Another concern is that the likelihood model is not directly expressible in terms of whatever properties might be of interest to a practitioner. To address our concerns regarding the exponential-Gaussian model, we focus for the remainder of this work on the threshold-based model with scale-fixing prior.

7.2. SILF-based Model Results

In figure 4, we show the performance of our algorithm and other competing baselines across our various datasets. Recall that the Stein discrepancy variational objective involves terms that consider both the quality of the factorizations (as given by the score function $\nabla_\theta \log p(\theta)$) and their similarity (as given by the base RKHS kernel $k(\theta_i, \theta_j)$). The NNDSVDar initializations and thinned HMC samples lead to factorizations that are high-quality but often not diverse (see diversity analysis in supplementary material: figures 24, 25, 26). The SVGD and the DSGD are generally the worst performing algorithms. These methods are often unable to find factorization parameters that meet the quality criteria of the SILF likelihood (see quality analysis in supplementary material: figures 18 and 19). This is understandable because even using simple gradient-based approaches to find a single high-quality NMF turns out to be difficult, hence the existence of a literature on specialized algorithms for performing NMF. Our Q-transform algorithm and random restarts are able to find sam-

8. Basis and weights matrices can be multiplied by any positive diagonal matrix and its inverse (respectively) to yield 'new' factors that identically reconstruct the data but differ in scale

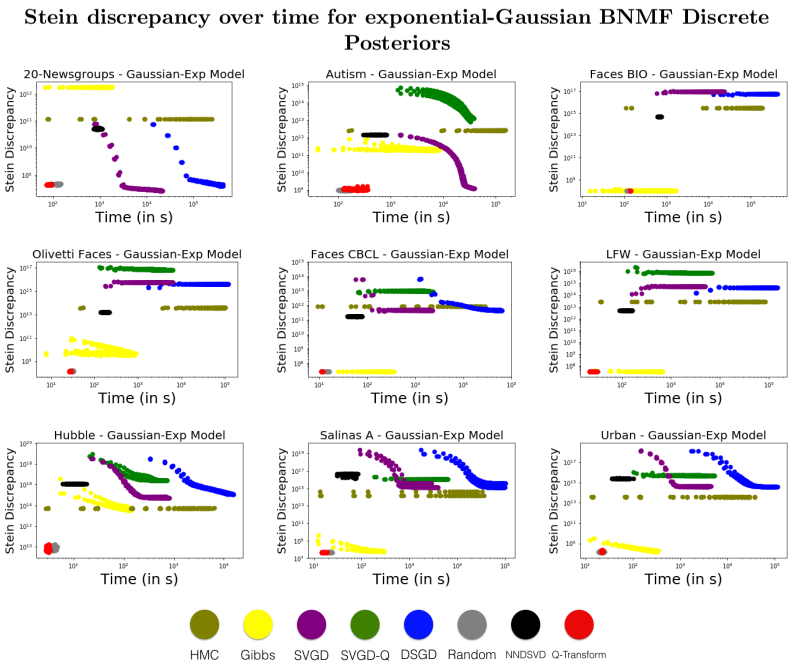

Figure 3: For each dataset we show the quality of the BNMF approximate posterior ($M = 5$) and the corresponding runtime of Q-Transform and the other baselines. Across multiple datasets, we see that the best discrete posteriors to the exponential-Gaussian BNMF (lowest Stein discrepancy) are produced either using the Q-Transform initializations (in red) for the Gibbs sampler (in yellow).

ples that are both high-quality and diverse, thus achieving the lowest Stein discrepancies; however, our Q-transform algorithm does so in the shortest time.

Figures 31 and 32 in the Appendix show results for $M = \{25, 50\}$ where Q-Transform continues to have a runtime advantage over other baselines. Additionally, for some datasets (Olivetti Faces, LFW and Faces BIO) Q-Transform also produces higher quality of the posterior approximations. Variational posteriors constructed using thinned samples from HMC significantly lack diversity as the Stein discrepancies for collections of size 5, 25 and 50 are comparable. This indicates that the HMC chain only explores a small region of the posterior distribution and can be confirmed through the diversity analysis in the Appendix (figures 24, 25, 26). Sminchisescu et al. (2007) notes that in high dimensional spaces, we expect there to be many ridges of probability as there are likely to be some directions in which the posterior density decays sharply. Alternatively, there may be several isolated modes with no connecting regions of high probability making it particularly challenging for the HMC chain to avoid getting stuck in a local mode of the BNMF posterior.

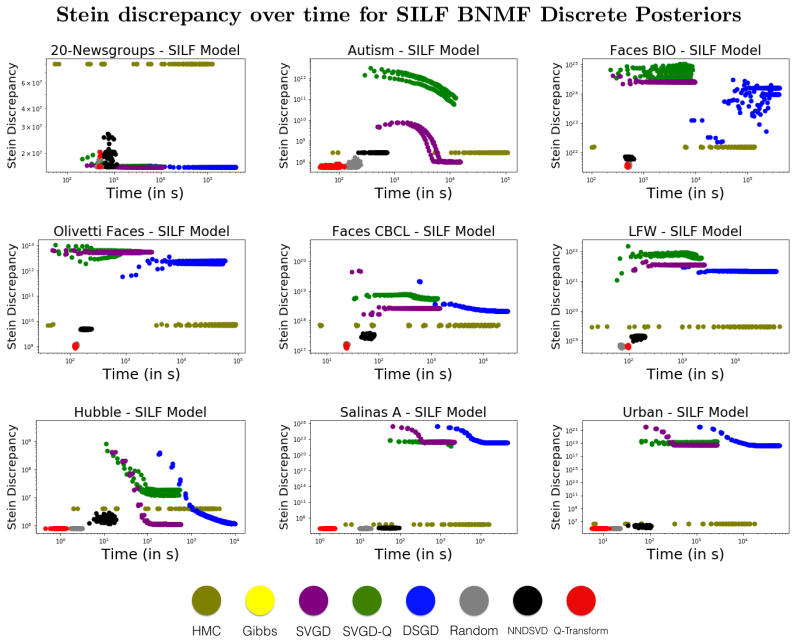

Figure 4: For each dataset we show the quality of the BNMF approximate posterior ($M = 5$) and the corresponding runtime of Q-Transform and the other baselines. Across multiple datasets, we see that the best discrete posteriors to BNMF (lowest Stein discrepancy) are produced in the least time using the Q-Transform initializations (in red).

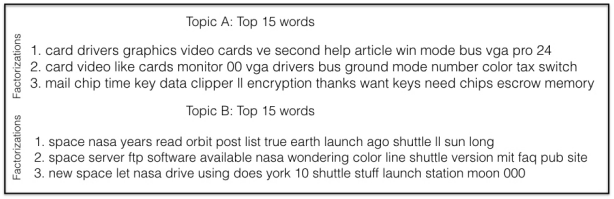

Figure 5: The top 15 words for topic A (computers/electronics) and topic B (space) shows that different factorizations provide an emphasis on different terms. In topic A, the top word from factorization 1 and 2 is 'card', but it does not appear in the top 15 words of factorizations 3. Instead a similar term 'chip' is emphasized in Factorization 3. In topic B, the terms 'space' and 'nasa' appear in all three factorizations but factorization 2 is the only one with digital terms like 'ftp', 'server','site' and 'faq'. In contrast factorization 1 and 3 both contain more physical terms like 'sun', 'moon','launch'.

7.2.1. Interpretation and Utilization of Posterior Estimates

BNMF posteriors can provide insight into the non-identifiability present within a particular dataset. Different factorizations may explain the data as a whole equally well, but do it through dictionary elements that have different interpretations, or can be used to understand specific parts of the data better than other factorizations. We show visual examples of diversity in the top words of the 20 Newsgroups BNMF posteriors and examples of how performance in downstream tasks for the 20 Newsgroups and Autism dataset is dependent on the posterior samples. Our analysis yields meaningful insights that could not be gained through a single factorization.

20-Newsgroups Our BNMF of 20-Newsgroups was a rank 16 decomposition of posts from 4 categories. In figure 6, we show the held-out AUC of a classifier trained to predict those categories based on the weights matrix W from each factorization in our variational posterior. Even though all of these factorizations have essentially equivalent reconstruction (see figure 19 in supplementary material), there exists a significant variation in the performance of these NMFs on the prediction tasks. The best performing NMF for one category is generally not the best (or even one of the top performing) NMFs for other categories. This observation may be valuable to a practitioner intending to use the NMF for some downstream task: different samples explain different patterns in the data. In figure 5, we see that this is indeed true: even after alignment,[9] distinct NMF factorizations have top words that indicate different emphasis across topics.

Autism Spectrum Disorder (ASD) In addition to core autism symptoms, Doshi-Velez et al. (2014) describe three major subtypes in autism spectrum disorder: those with higher rates of neurological disorder, those with higher rates of autoimmune disorders, and those with higher rates of psychiatric disorders. In figure 7, we show the number of topics that

9. We compare topics after finding the permutation of columns that best aligns them by solving the bipartite graph matching problem. We minimize the cost given by the angle between topics.

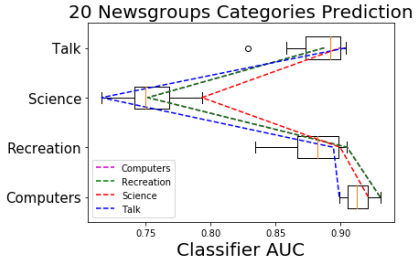

Figure 6: Classifiers trained on feature vectors from different factorizations yield variability in prediction performance (as measured by AUC). The dotted lines show the factorization that produces the best performing classifier for each category. The factorization (blue dotted line) that predicts the 'Talk' category best is actually one of the worst performing factorizations for the 'Science' category. This variability in performance demonstrates that no single factorization gives the best latent representation for the overall prediction task.

contain key terms corresponding to these areas (expressive language disorder, epilepsy, asthma, and attention deficit disorder) across different factorizations in the variational posterior obtained via Q-Transform. The large variation suggests that different factorizations in the particle-based posterior are spending different amount of modeling effort across these known factors; knowing that such uncertainty exists is essential for clinicians who may be trying to interpret topics to understand patterns in autism spectrum disorder.

On the same set of patients, we can also ask whether we can predict the onset of certain medical issues in the subsequent patient trajectory. We train a classifier on the weights of the NMFs to predict the onset of these medical issues. Similar to the category prediction results in 20-Newsgroups, figure 8 shows that there is a large variability (around 0.1 in AUC) in the performance of classifiers trained on the weights matrices of different factorizations on the prediction task. No single factorization has the best performance across the different prediction tasks.

7.3. Extension: BNMF in the presence of missing data

In the presence of missing data, there is perhaps an even greater need to understand the uncertainty in factorization parameters for NMF. The factorization space of a fully observed dataset forms a subset of the factorization space in the presence of missing data. Our particle-based approach to BNMF posterior approximation can be applied to the missing data setting by making some minor adjustments to the experimental settings.

The multiplicative update algorithm for NMF (Lee and Seung, 2001) can be adjusted so that the update equations for factorization parameters only consider the observed data. We use an implementation of this modification to the multiplicative update algorithm[10] to find a completion of the data X, compute the SVD subspace and then apply our Q-Transform initializations. Figure 9 demonstrates that our approach to BNMF can be extended to the

10. https://github.com/scikit-learn/scikit-learn/pull/8474/commits/a838f94c8c832aaf57140f23bd8c8a14daec2626

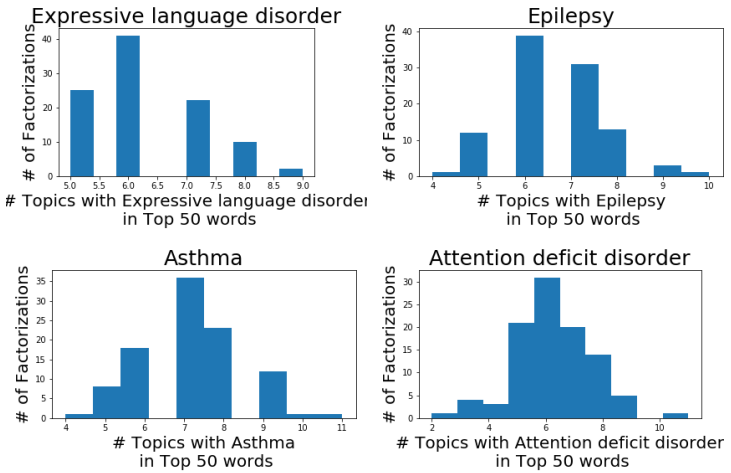

Figure 7: We explore top words in the topics relating to key terms of interest to clinicians and discover that different NMFs place varying amount of emphasis on different terms. Such variability is of interest to clinicians who may be trying to interpret topics to understand patterns in ASD.

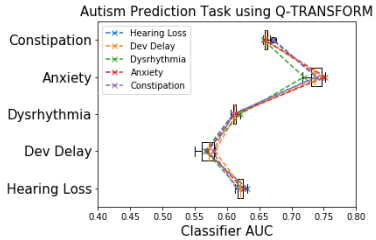

Figure 8: Classifiers trained on weights matrix of $M_{\max} = 100$ different factorizations to predict the presence of certain medical codes in a patient's trajectory exhibit significant variability in prediction on a test set (as measured by AUC). Different factorizations lead to top predictors for the onset of different medical issues.

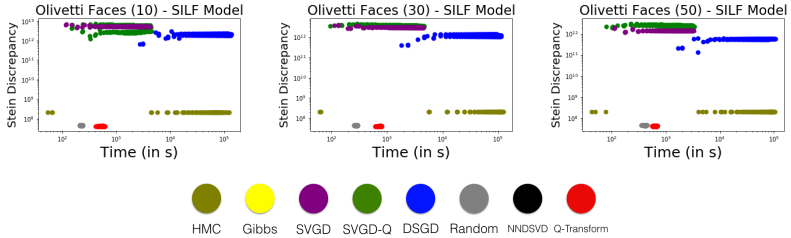

Figure 9: Under different percentages of missingness in the Olivetti Faces dataset (10%, 30%, 50%), the quality of the BNMF approximate posterior and the corresponding runtime of Q-Transform and the other baselines is shown. The best discrete posterior approximations to BNMF are produced using the Q-Transform initializations (in red).

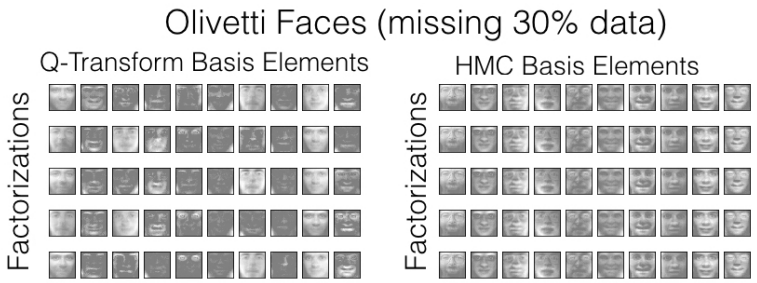

Figure 10: Sample factorizations from the variational posterior using Q-Transforms show that a diverse range of basis elements can be use to approximate the data. However, HMC samples seem to be identical indicating that HMC was only exploring a very small region of the posterior space.

case where the data matrix X is partially observed. For the Olivetti Faces dataset with varying degrees of missingness, the Q-Transform approach to BNMF consistently finds posterior approximations that are significantly better (as measured by Stein discrepancy) than other baselines whereas for a given M, the runtime is second-lowest.

Figure 10 shows sample factorizations from the variational posterior using Q-Transform and HMC samples. To allow for comparison, we have aligned the positions of the basis (dictionary) elements to a reference factorization using the bipartite matching algorithm. It is clear from looking at the Q-Transform factorizations that a diverse range of dictionaries can be used to approximate the data well whereas the HMC chain only explores one set of dictionary elements. Interestingly, the diversity of solutions obtained using Q-Transform have visually interpretable differences, i.e. these are not simply perturbations of some ground truth basis elements. Some of the basis elements look like faces and some of them look like different shadow or lighting configurations. In contrast, the factorization samples

from HMC have basis elements that look identical. This indicates that the HMC has explored a limited region of the posterior space.

8. Discussion: When is Q-Transform successful?

Our ability to extract *transferable* low-rank transformation matrices from an SVD and an instance of NMF indicates that there exist similarities across different NMF problems. In this Section we seek to develop a better intuition behind the success of the Q-Transform initializations at exploiting these similarities. In this Section, we provide discussion and smaller-scale experiments to shed light on when, why, and how our Q-transform approach is successful.

8.1. Q-Transform Generating Process

In our approach, we generated candidate Q-Transform matrices (Algorithm 2) by applying random restarts to small, synthetic data sets. We focused on this approach because small datasets are much faster to train, and with synthetic data sets, we can know at least one ground truth NMF and level of noise. However, there are obviously a large number of choices for the data used to generate candidate Q-Transform matrices.

In figure 11, we present results with a variety of different methods for generating candidates. In all cases, the source data was of small dimension ($X_S \in \mathbb{R}^{15\times 15}$), and the target data was larger ($X_T \in \mathbb{R}^{500\times 500}$). The target data had a true non-negative rank of 10 and factors were generated with i.i.d. entries from a standard normal. In all these experiments we set the transfer rank to be $R_T = R_{\text{SVD}} = 3$. We explored six ways of generating candidates from the source data:

- Uniform data: Generating a dataset X_S where each entry is i.i.d. with a uniform distribution in [0,1]; then apply random restarts to find candidate transforms.
- Simple sub-sample data: Generating dataset X_S by uniformly selecting 15 rows and columns of the target data X_T; then apply random restarts to find candidate transforms
- Column-projection data: Generating dataset X_S by sub-sampling 15 columns of X_T and applying a random projection into $\mathbb{R}^{15}$ for each each column; then apply random restarts to find candidate transforms.
- Dirichlet factors: Generating factors A, W with each column of A, W from a Dirichlet distribution (with concentration parameter α set to 1); let $X_S = AW$+Gaussian Noise; then apply random restarts to find candidate transforms.
- Uniform factors: Generating factors A, W with each entry i.i.d. from a uniform distribution in [0,1]; let $X_S = AW$ + Gaussian Noise; then apply random restarts to find candidate transforms.
- Gaussian factors: Generating factors A, W with each entry i.i.d. from a standard normal distribution; let $X_S = AW$ + Gaussian Noise; then apply random restarts to find candidate transforms.

The methods that produced the source data from some true NMF factors produced candidate transformations that resulted in the highest quality initializations on the target data (figure 11). In settings where a practitioner deals with a collection of similar NMF datasets (e.g. music analysis, hyper spectral images), there may be more clever ways in which the NMF solution spaces corresponding to a real dataset may yield more appropriate Q-Transforms specific to that type of data. Finally, we find in figure 12 that the performance of Gaussian factors method does not vary with the rank of the synthetic data (the transfer rank is still held fixed).

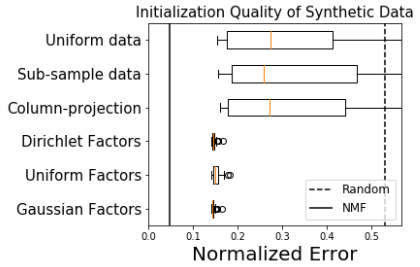

Figure 11: For different synthetic data X_S generating procedures, we show the initialization quality obtained via the Q-Transform matrices on a target data X_T. Dirichlet, Uniform, Gaussian have significantly superior performance compared to Sub-sample, Column-projection and Uniform data. For comparison, we show the quality of NMF solutions (solid line) and random initializations (dashed line).

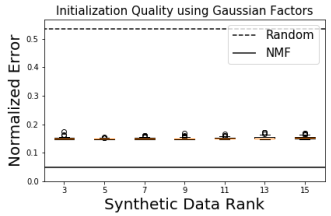

Figure 12: Using Gaussian factors for the synthetic data generation process with different ranks does not appear to change the quality of the Q-Transform initialization quality on the target data X_T. This indicates that this generating procedure is not sensitive to the rank in order to produce high quality (close to true NMF solution) initializations using Q-Transform. For comparison, we show the quality of NMF solutions (solid line) and random initializations (dashed line).

8.2. The Q-Transform Initialization versus Noise

In Section 4, we sought high-quality initializations because they generally require less time to converge. On synthetic target data $X_T = AW + \epsilon N_o$ (D = N = 500, R = 20) we explore the effect of increasing noise (ϵ) on the quality of our transfer-based NMF initializations and the time taken to converge. Specifically: are there noise regimes in which the Q-transform method works better, and noise regimes in which it does not?

We normalize the norm of the noise matrix to be equal to the norm of the data $\|N_o\| = \|AW\|$ so that the contribution of signal AW and noise ϵN_o to the data is equal when $\epsilon = 1$. We continue to use the same 100 pairs of Q_A, Q_W matrices. We compare the performance of Q-Transform over random restarts in terms of initialization quality (ratio of the reconstruction error from Q-Transform to the reconstruction error from random restart)

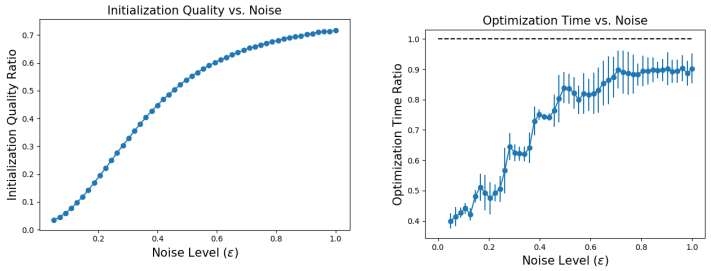

Figure 13: In the low-noise regime, the reconstruction error of Q-Transform initializations is significantly less than random restart initializations. This relative advantage gets smaller as the noise level increases. Similarly, the time taken to converge is significantly shorter than the random restart approach under the low noise scenario and continues to increase with noise. As expected, at high noise levels there exists no additional advantage to the Q-Transform approach (the optimization time ratio approaches 1).

and time to convergence (ratio of time taken using Q-Transform initialization to time taken using random restart). In both metrics, the Q-Transform has an advantage over random restarts for values of the noise ϵ smaller than 1, and the advantage is greatest for smallest noise. Figure 13 shows that the advantage of Q-Transform initializations is highest in a low noise regime and decreases as the noise increases. This behavior makes sense because as noise increases, the data is no longer truly low rank.

8.3. Selecting ranks

We emphasize that there are two distinct ranks that need to be chosen when applying our technique. The first is the rank of the factorization R_{NMF}. There exist multiple approaches for choosing this rank, e.g. Tan and Févotte (2009); Alquier and Guedj (2017), and they can be applied to our approach (as well as any other NMF algorithm).

The second is choosing the transfer rank R_T. The transformation dimensions R_T and R_{SVD} determine the dimensions of transformation matrices Q_A, Q_W which map basis vectors defining the top SVD subspace of dimension R_{SVD} to a set of R_T non-negative basis vectors that approximate the same subspace. The full initialization for NMF is obtained by either padding the initialization with small entries ($R_T < R_{\text{NMF}}$) or removing extra columns and rows of the factor matrices ($R_T > R_{\text{NMF}}$). (For simplicity, we consider the case where the transfer rank and SVD rank are equal $R_T = R_{\text{SVD}}$ and the resulting transformation matrices Q_A, Q_W are square.)

The choice of the transfer rank R_T is specific to our algorithm, and in figure 14 we investigate how well our transfer learning performs for different choices of transfer rank R_T. In the experiment, we extract a set of 100 transformation matrices Q_A, Q_W for transfer dimensions $R_T = R_{\text{SVD}} = \{1, 2, \ldots, 10\}$ using synthetic source data ($D = N = 15$). Once constructed, we applied the transformation matrices to a 500×500 target dataset X_T of rank $R = 10$. We find that even though the dataset X_T has rank 10, the rank 10 transformation

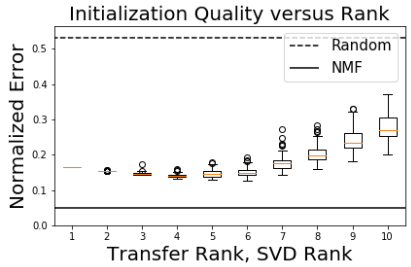

Figure 14: On a synthetic target dataset ($D = N = 500, K_{\text{NMF}} = 10$), we apply Q-Transform initializations using varying transfer ranks and SVD ranks $R_T = R_{\text{SVD}} = \{1, 2, \ldots, 10\}$. We see that for a range of low rank values, the Q-Transform initializations are high quality, but at larger values the quality of initializations gets worse. The dotted line shows the quality of random initializations and the solid line shows the quality NMF solutions. The reconstruction errors are normalized by the norm of the data.

matrices found using the 15×15 synthetic source dataset are unable to successfully transfer to this new dataset. We see that the error initially decreases, but then increases as the transfer rank increases. This result suggests that the top directions of variation hold the most transferable information across NMF problems.

8.4. Sign Convention for SVD

In considering when Q-Transform is successful, we note that there exists an intrinsic ambiguity in the sign of the singular vectors of X: changing the sign of any column of A_{SVD} and corresponding row of W_{SVD} gives a valid SVD. For Q-Transform to work, we must apply a consistent resolution of the sign ambiguity (e.g. from Bro et al. (2008)). This ensures that learned transformations Q_A, Q_W map in a consistent way to SVD decompositions of new datasets.

9. Related Work

There is a large body of work on inference for BNMF. Sampling-based approaches include Gibbs sampling (Schmidt et al., 2009), Hamiltonian Monte Carlo (Schmidt and Mohamed, 2009), and reversible jump variants (Schmidt and Mørup, 2010). All of these have trouble escaping local modes (Masood et al., 2016), and are often constrained to a limited class of tractable distributions. Variational approaches to BNMF have successfully yielded interpretable factorizations (Bertin et al., 2009; Cemgil, 2009; Paisley et al., 2014; Hinrich and Mørup, 2018) but also typically only capture one mode and rely on mean-field or other modeling assumptions to make inference tractable. We note that in many cases, priors of convenience—for example, exponential distributions—can induce a single dominant mode, even when that was not the intent of the practitioner.

Closer to the goals of our work, Gershman et al. (2012) develop a non-parametric approach to variational inference that provides flexibility in modeling the number of Gaussian components required to approximate a posterior. However, the isotropic covariance in the model makes it unsuitable for applying it to BNMF. With regard to the inference process, our Q-Transform approach to finding multiple optima is most similar to Ročková and George (2016) and Paatero and Tapper (1994), who use rotations to find solutions to a single matrix factorization problem that are sparse and non-negative respectively. In contrast, we use rotations to find multiple non-negative solutions, and also demonstrate how these rotations can be *re-used* for transfer learning.

More broadly, recent work on NMF has involved theoretical work on non-identifiability with new algorithms that can provably recover the NMF under certain assumptions (Li and Liang, 2017; Bhattacharya et al., 2016; Ge and Zou, 2015a). However, these assumptions are often difficult to check and may indeed be violated in practice; Bayesian methods typically provide more flexibility in modeling and assumptions.

All of the works above typically assume some desired factorization rank. There also exists work on models that automatically detect the rank—through automatic relevance determination for NMF (Tan and Févotte, 2009) or more recently, via a rank-adaptive prior Alquier and Guedj (2017). These works are complementary to ours, in that those techniques could be combined with our transfer-based approach of generating candidates of whatever rank those algorithms determine is appropriate.

The ability of Stein discrepancies to assess the quality of any collection of particles (Gorham and Mackey, 2015) has resulted in large recent interest in other ways to create collections of samples (Oates et al., 2017; Liu and Wang, 2016). Liu et al. (2016) and Chwialkowski et al. (2016) showed that kernelized Stein discrepancy could be computed analytically in Reproducing Kernel Hilbert Spaces (RKHS); Pu et al. (2017) and Feng et al. (2017) use neural networks instead. Ranganath et al. (2016) establish the Stein discrepancy as a valid variational objective. To our knowledge, Stein discrepancy-based posterior approximation has not been applied to NMF, and yet, we see that it allows us to leverage existing non-Bayesian approaches to characterize these multi-modal posteriors. In our work, the Dirichlet prior on the columns of the basis matrix A is important to ensure that we avoid a known saddle point of the zero factorization (from likelihood term) that yields a corresponding zero for the score function.

10. Conclusion

In this work, we presented a novel transfer learning-based approach to posterior estimation in BNMF. Simply creating collections of factorizations via random restarts on our Q-Transform initializations, and then weighing them, produces diverse collections that approximate the posterior well (the NNDSVDar-based methods fail to produce diverse collections for posterior estimation). In contrast, the functional gradient descent of SVGD and direct gradients of Stein discrepancy (DSGD) perform worse to the collection-based approaches, requiring more time and also limiting the user to specify in advance the number of factorizations. Hamiltonian Monte Carlo also suffers from difficulties in exploring the posterior space, something random initializations are well suited to. Our transfer learning approach consistently produces the highest quality posterior approximations.

Through Q-Transform, we introduce a way to speed-up the process of finding multiple diverse NMFs. The discovery that Q-Transform matrices can transfer from synthetic to multiple real datasets is exciting and also suggests interesting questions for further research. For example, what is the theoretical nature of the similarities between principal eigenspaces of different non-negative matrices and the relation between their SVD and NMF bases? And, how does the synthetic data generation process used to obtain Q-Transform matrices impact the initializations and the effectiveness of the Q-Transform algorithm in general?

More broadly, our qualitative results demonstrate that even relatively simple models, such as NMF, can have multiple optima that are comparable under the objective function but have large variation in how well they explain different portions of the data—or how they perform on different downstream tasks. Thus, it is important to be able to compute these posteriors efficiently.

Acknowledgments

Appendix A: Quality of factorizations

We measure the quality of factorizations in terms of the log of the joint likelihood (figures 18 and 15) as well the Frobenius NMF objective (figures 19 and 16). We see that both quality measures are in agreement with each other. We also assess the quality of factorizations via the reconstruction error of heldout data (figures 20 and 17).

Overall, Q-Transform, Random, NNDSVDar, HMC and (for the exponential-Gaussian model) Gibbs produce high quality factorizations. The initialization-based approaches all work well as they use specialized NMF algorithms that are designed to find high quality factorizations. HMC was given a warm start with a high likelihood initialization and the chain continues to stay in high likelihood regions. The remaining gradient-based approaches for optimizing a collection of particles (SVGD and DSGD) fail to produce high quality factorizations. This is indicative of the need for specialized NMF algorithms designed to work with the constraints and structure of the NMF problem and highlight how difficult it is to apply a naive gradient descent approach for finding NMFs.

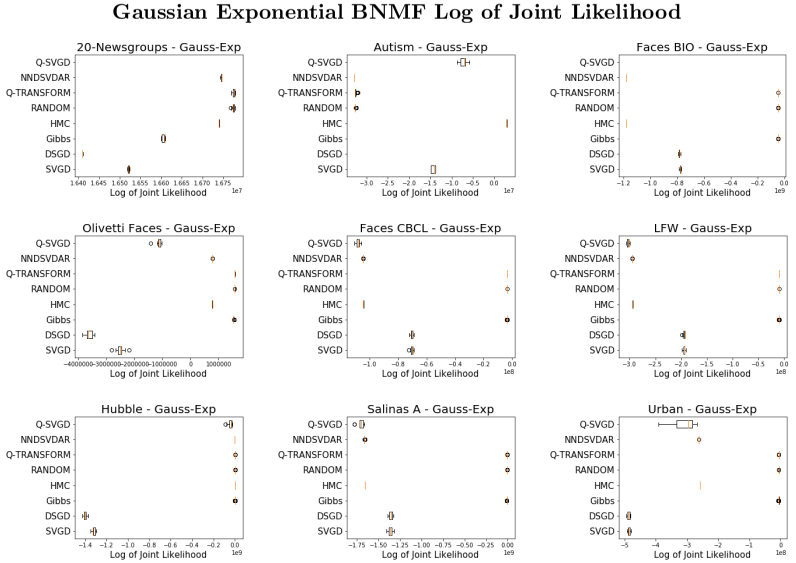

Figure 15: The joint likelihood of factorizations shows that SVGD and DSGD generally produce the worst quality factorizations. The remaining algorithms produce higher quality factorizations.

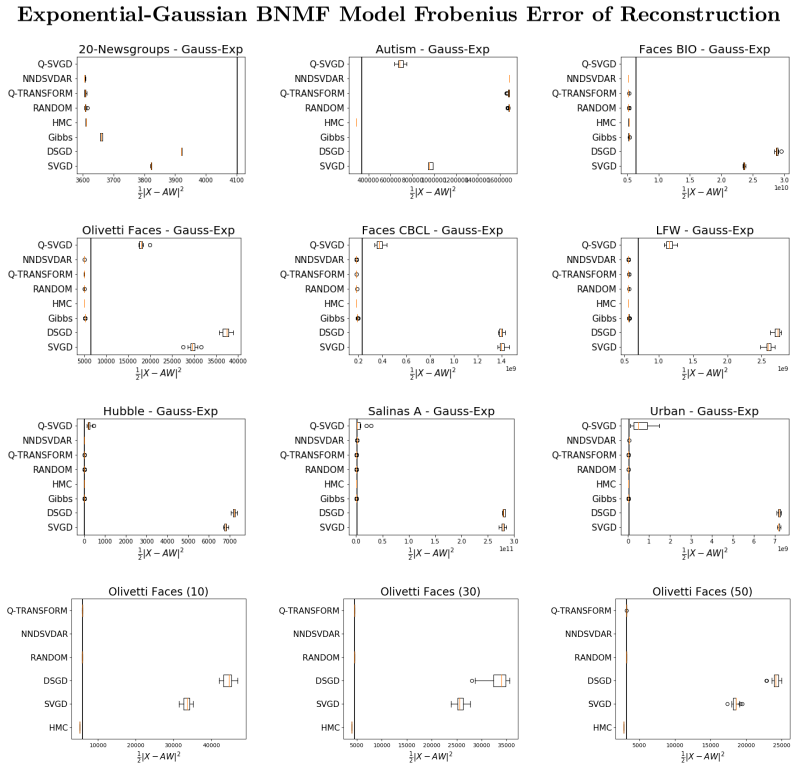

Figure 16: The reconstruction error of the factorizations shows that SVGD and DSGD are typically unable to find factorization parameters that meet the threshold quality (black line) for useful factorizations. The other approaches consistently produce factorizations that meet this minimum quality requirement.

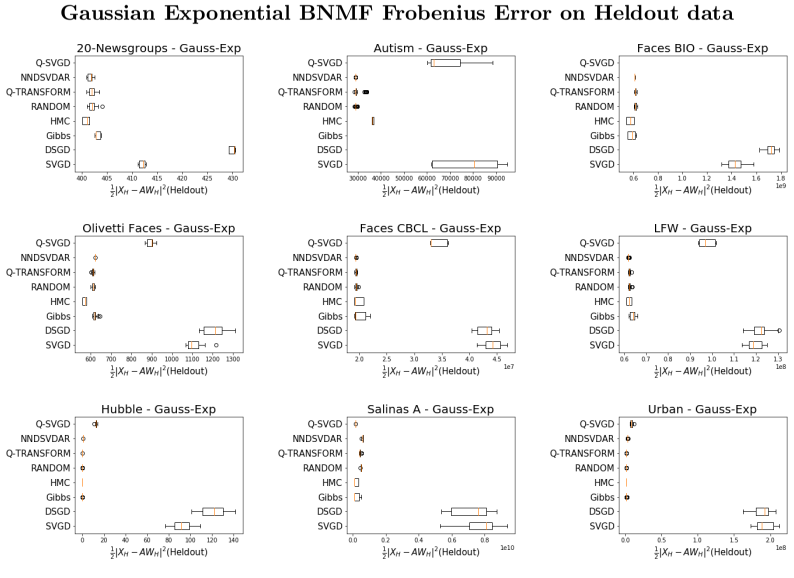

Figure 17: The reconstruction error of the factorizations shows that SVGD and DSGD are typically unable to find factorization parameters that result in low error on heldout data. The other approaches consistently produce factorizations which generalize better and give low error on heldout data.

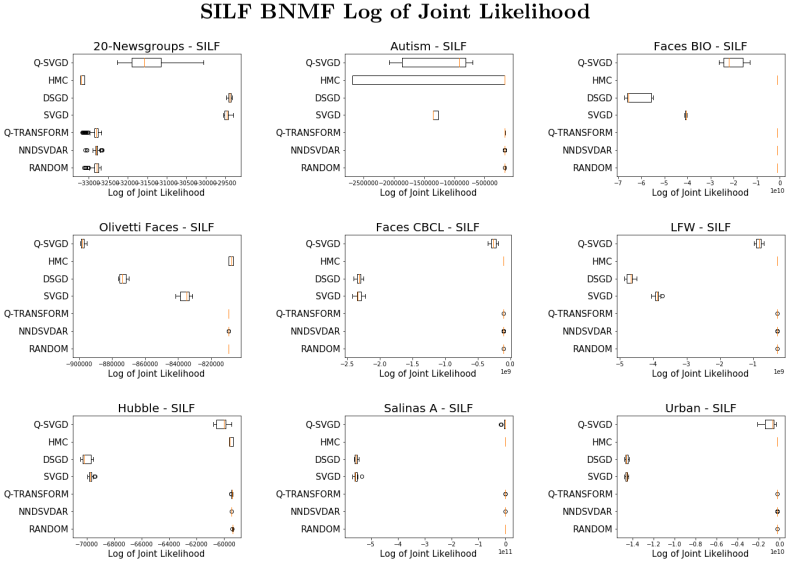

Figure 18: The joint likelihood of factorizations shows that SVGD and DSGD generally produce the worst quality factorizations. HMC, NNDSVDar, Random and Q-Transform produce high quality factorizations.

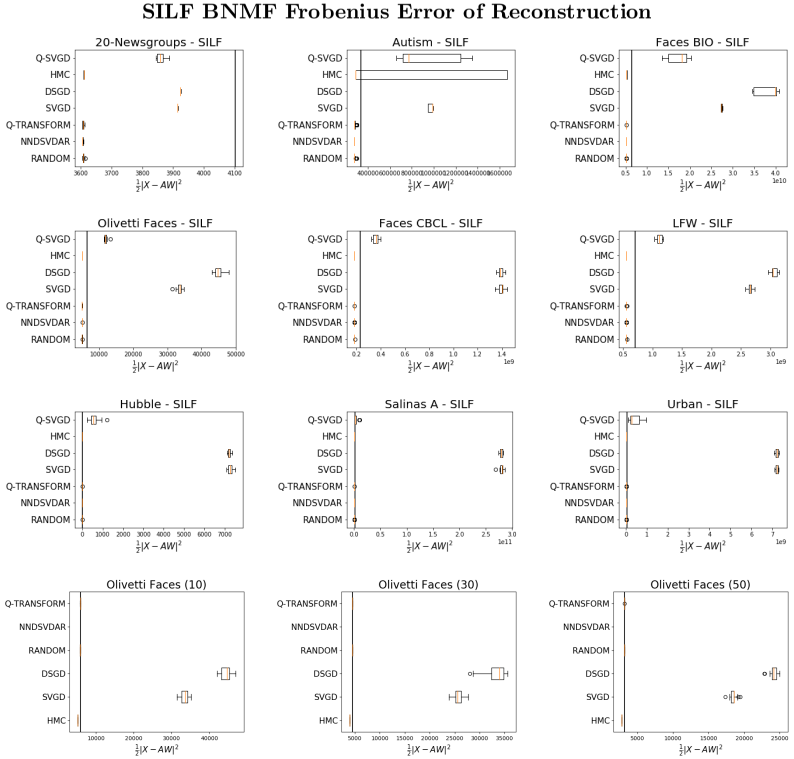

Figure 19: The reconstruction error of the factorizations shows that SVGD and DSGD are typically unable to find factorization parameters that meet the threshold quality (black line) for useful factorizations. The other approaches consistently produce factorizations that meet this minimum quality requirement.

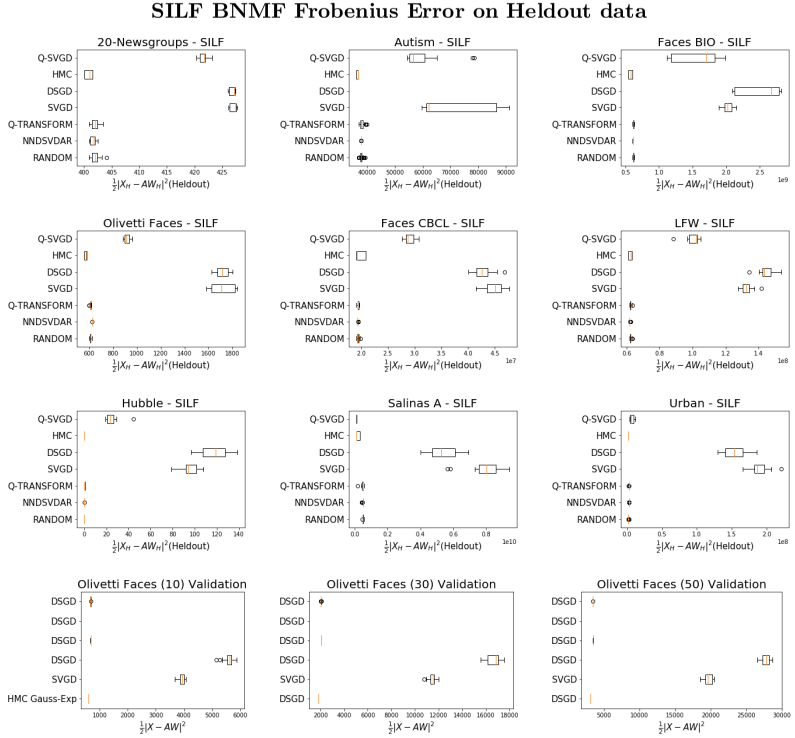

Figure 20: The reconstruction error of the factorizations shows that SVGD and DSGD are typically unable to find factorization parameters that result in low error on heldout data. The other approaches consistently produce factorizations which generalize better and give low error on heldout data. The matrix completion error on the missing data variant of the Olivetti faces dataset also gives similar results.

Appendix B: Diversity of factorizations

Similarity of factorizations is measured by the kernel (equation 7) for the base RKHS (figures 24 and 21) used in evaluating the Stein discrepancy and by pairwise distances between basis matrices (figures 25 and 22) and weights matrices (figures 26 and 23)[11]. Generally, the HMC chain exhibits the least exploration of the factorization space. Remaining algorithms, particularly Q-Transform exhibits higher amounts of diversity in the factorization space. The diversity metrics indicate that SVGD and DSGD give diverse factorizations but the quality metrics indicate that these factorizations are poor quality (do not correspond to high likelihood regions of the posterior) therefore such diversity is of little interest.

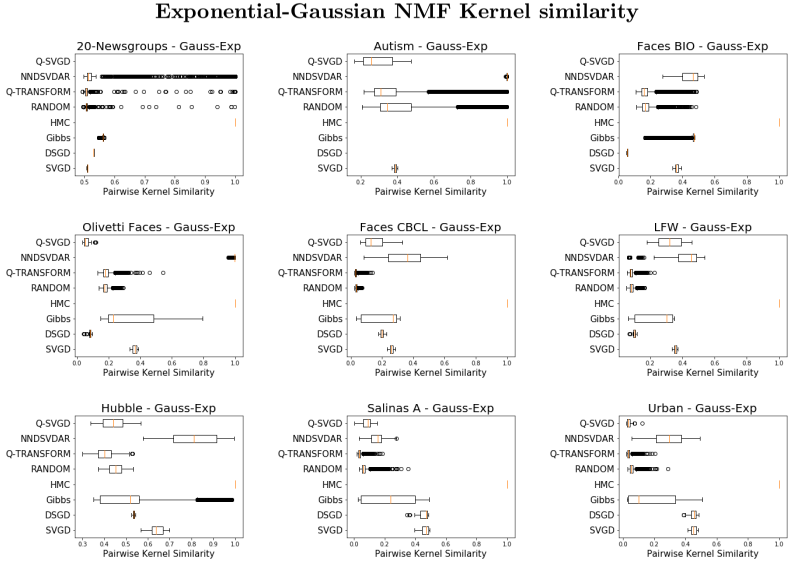

Figure 21: The kernel similarity indicates that factorization collections obtained by HMC are most similar indicating that the HMC chain is only exploring a small region of the posterior. In many cases NNDSVDar factorizations are also very similar. Q-Transform and Random are the only algorithms that produce factorizations of high quality that are not similar.

11. In the exponential-Gaussian model, we adjust the scalings of the factorizations so that we can meaningfully compare pairwise distances between basis and weights matrices.

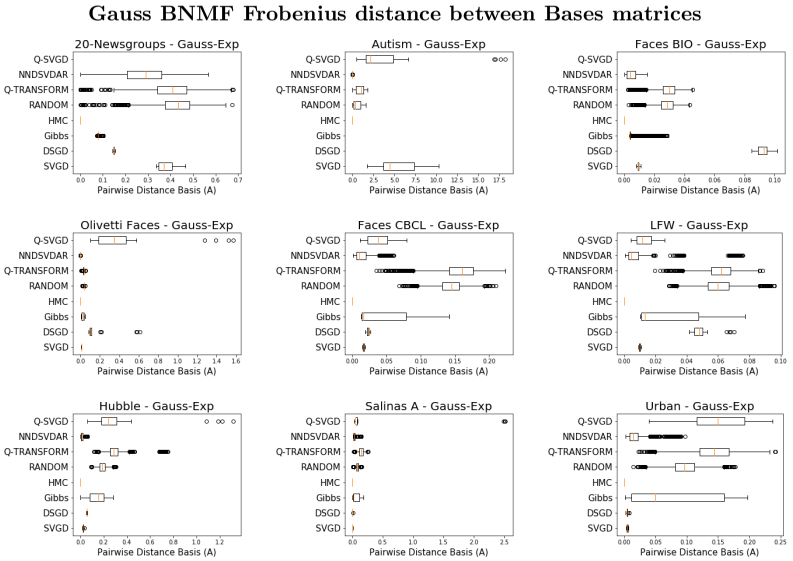

Figure 22: The pairwise distance between basis matrices shows that factorization collections obtained by HMC are most similar indicating that the HMC chain is only exploring a small region of the posterior. In many cases NNDSVDar, Q-SVGD, DSGD and SVGD factorizations are also very similar. Q-Transform and Random produce basis matrices that are more distinct than the Gibbs sampler.

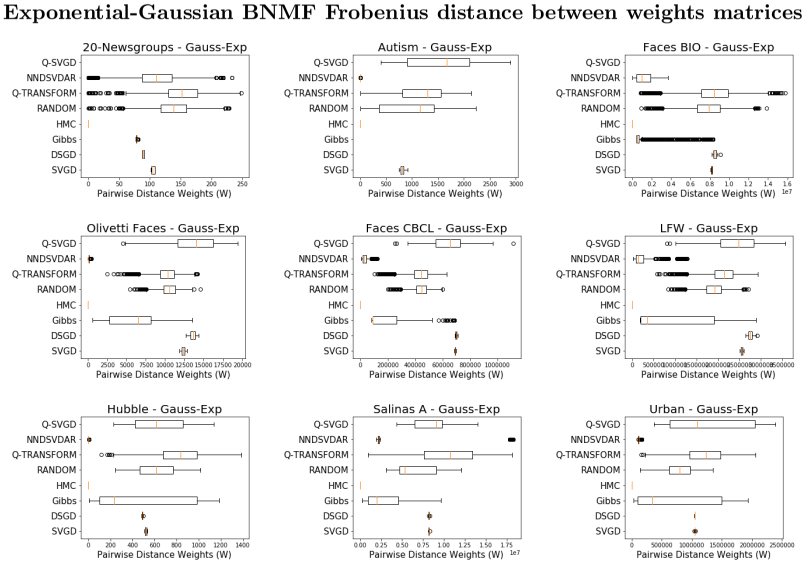

Figure 23: The pairwise distance between weights matrices shows that factorization collections obtained by DSGD, SVGD and Q-SVGD lead to diverse weights matrices. The remaining methods lead to similar levels of diversity within the factorization collections.

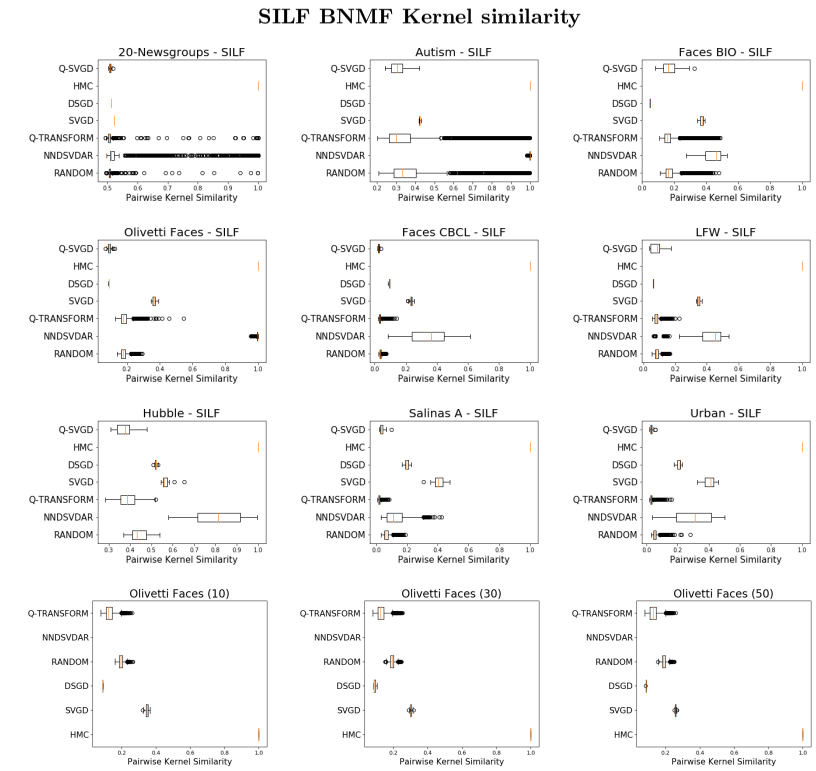

Figure 24: The kernel similarity indicates that factorization collections obtained by HMC are most similar indicating that the HMC chain is only exploring a small region of the posterior. In many cases NNDSVDar factorizations are also very similar.

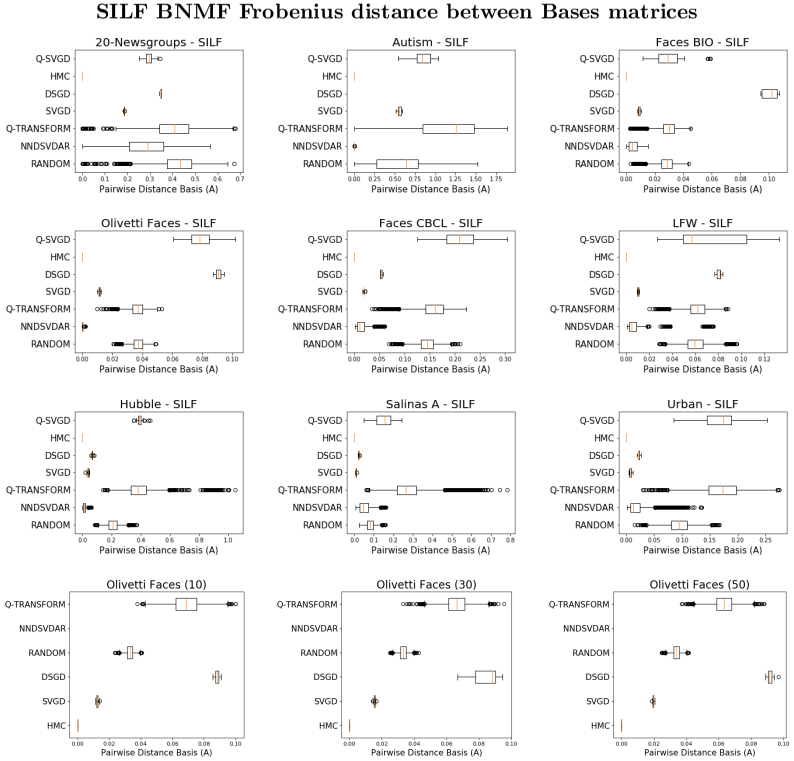

Figure 25: The pairwise distance between basis matrices shows that factorization collections obtained by HMC are most similar indicating that the HMC chain is only exploring a small region of the posterior. In many cases NNDSVDar factorizations are also very similar. *Q*-Transform and Random are the only algorithms that produce factorizations of high quality that are different.

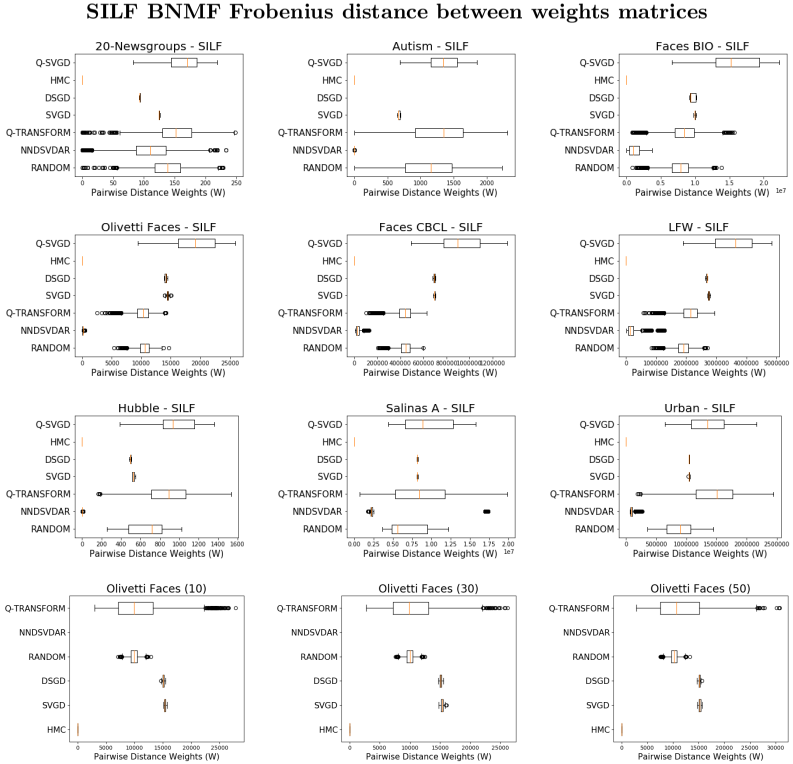

Figure 26: The pairwise distance between weights matrices shows that factorization collections obtained by HMC are most similar indicating that the HMC chain is only exploring a small region of the posterior. In many cases NNDSVDar factorizations are also very similar. *Q*-Transform and Random are the only algorithms that produce factorizations of high quality that are different.

Appendix C: Baseline Performance on Prediction Tasks

We show the performance of other baseline algorithms on the prediction tasks for the 20-Newsgroups and Autism datasets (see figures 6 and 8 in main text for reference)

Autism Prediction Task: Performance of baseline algorithms

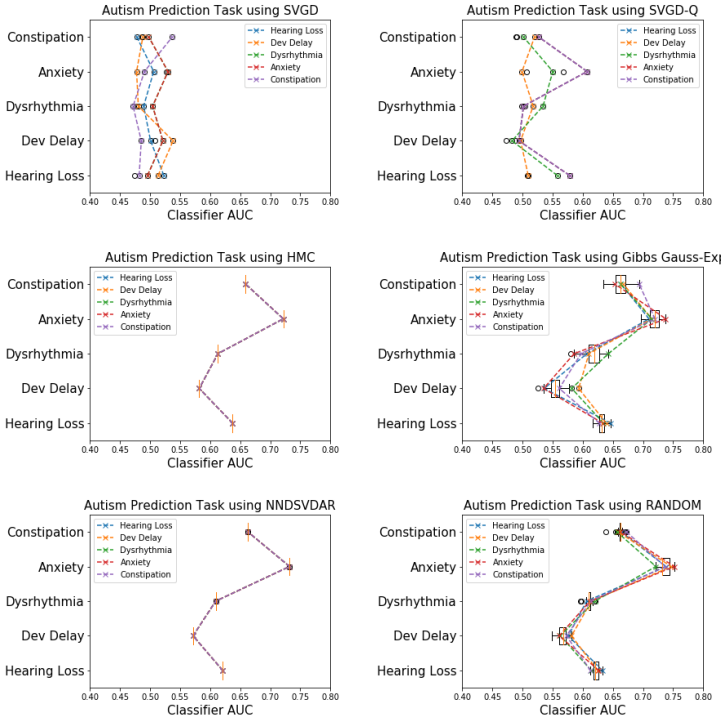

Figure 27: Variability in the prediction task on the Autism dataset shows that SVGD factorizations yield poor prediction (that are slightly improved upon by Q-SVGD), HMC and NNDSVDar factorizations predictions are high but not diverse, and Gibbs and random restarts yields performance similar to Q-Transform

20 Newsgroups Prediction Task: Performance of baseline algorithms

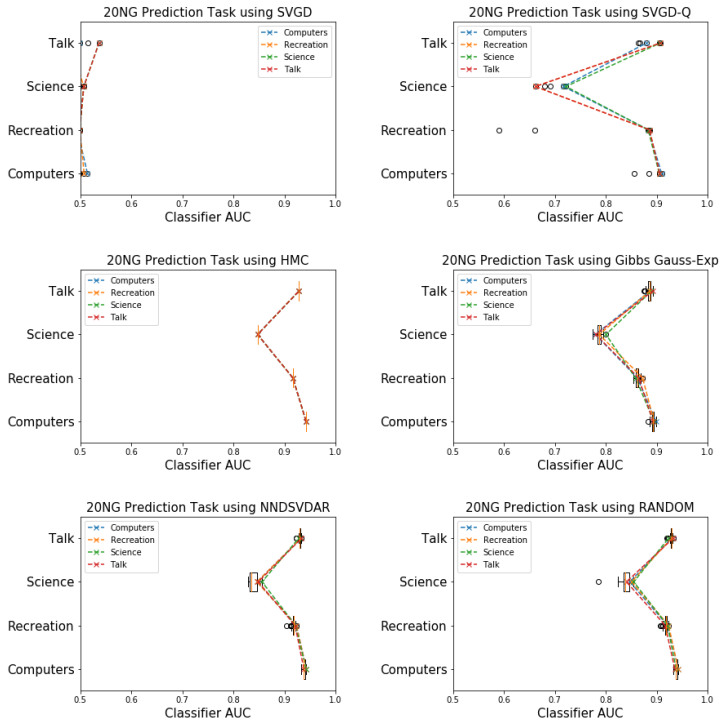

Figure 28: Variability in the prediction task on the 20 Newsgroups dataset shows that SVGD factorizations yield poor prediction (that is drastically improved upon by Q-SVGD), HMC factorizations are not diverse, NNDSVDar, Gibbs and random restarts yields some variability in prediction that is similar to Q-Transform

Appendix D: Discrete posteriors for $M = \{25, 50\}$

We provide results on the quality of discrete BNMF posteriors for the SILF and exponential-Gaussian models for $M = 25$ and $M = 50$.

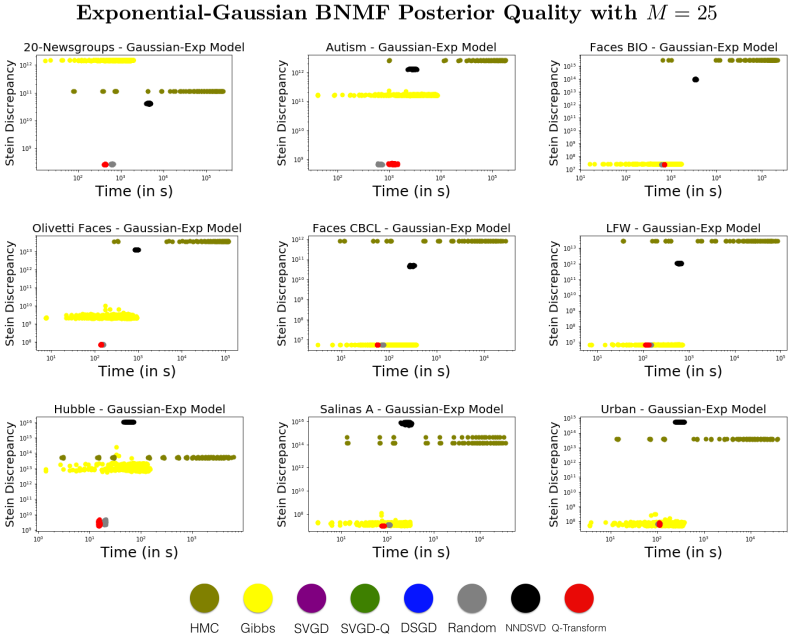

Figure 29: For each dataset we show the quality of the BNMF approximate posterior ($M = 25$) and the corresponding runtime of Q-Transform and the other baselines. Across multiple datasets, we see that the best discrete posteriors to BNMF (lowest Stein discrepancy) are produced in the least time using the Q-Transform initializations (in red).

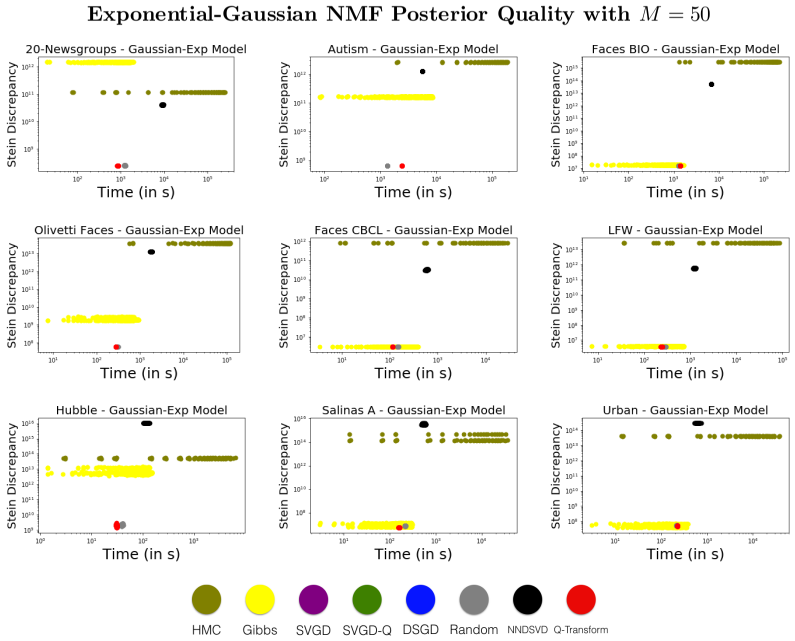

Figure 30: For each dataset we show the quality of the BNMF approximate posterior ($M = 50$) and the corresponding runtime of Q-Transform and the other baselines. Across multiple datasets, we see that the best discrete posteriors to BNMF (lowest Stein discrepancy) are produced in the least time using the Q-Transform initializations (in red).

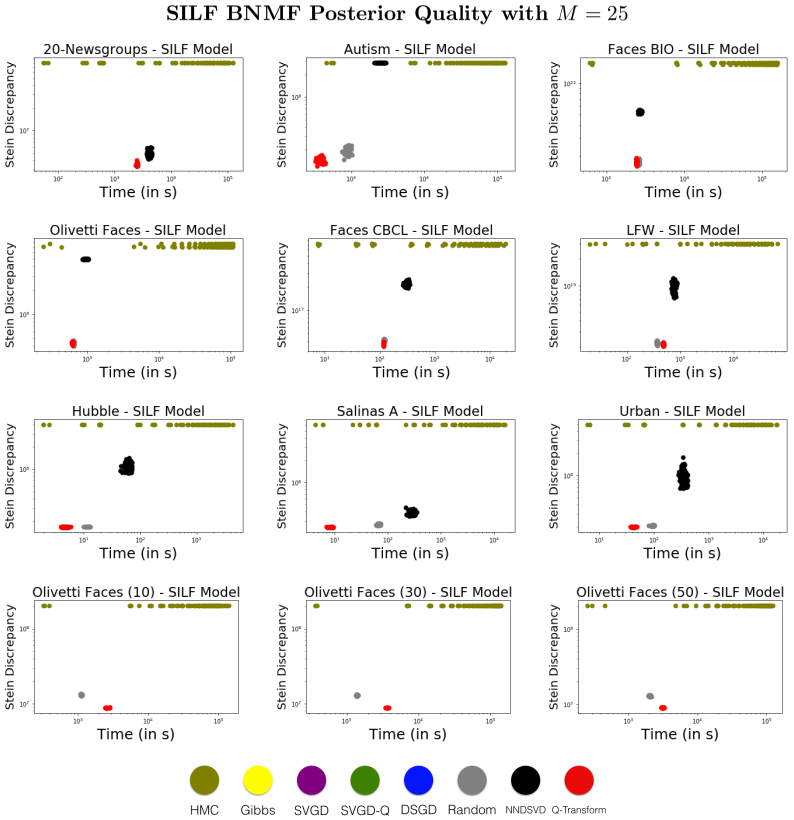

Figure 31: For each dataset we show the quality of the BNMF approximate posterior ($M = 25$) and the corresponding runtime of Q-Transform and the other baselines. Across multiple datasets, we see that the best discrete posteriors to BNMF (lowest Stein discrepancy) are produced in the least time using the Q-Transform initializations (in red).

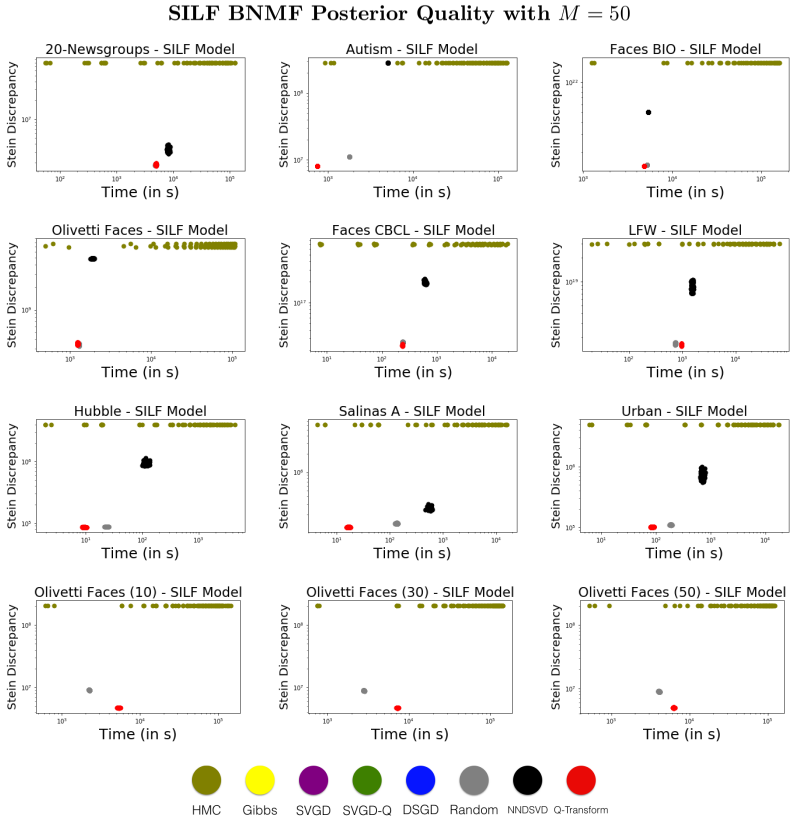

Figure 32: For each dataset we show the quality of the BNMF approximate posterior ($M = 50$) and the corresponding runtime of Q-Transform and the other baselines. Across multiple datasets, we see that the best discrete posteriors to BNMF (lowest Stein discrepancy) are produced in the least time using the Q-Transform initializations (in red).

Appendix E: Runtime Calculation

Here we provide full details on how our runtimes were calculated. Recall that both our transfer-based algorithm and the baselines all can be considered as having two phases: (1) Producing candidate particles $\{\theta_m\}_{m=1}^M$, and (2) Calculating the optimal weights $\{w_m\}_{m=1}^M$ to minimize the Stein discrepancy. Importantly, to give all the methods their best performance, we calculate optimal weights for *all* the methods, including those such as MCMC that produce unweighted collections.

Runtime for generating candidate particles Thus, all the methods only differ in how the candidate particles $\{\theta_m\}_{m=1}^M$ are found. To focus on the parts that differ, in our figures, we only report on the computational time required to produce these candidate particles. Below we describe the computations for obtaining the candidate particles:

- MCMC Methods: We keep track of the time from the initialization of the chain through each element added to the chain. At various points, we thin the current chain to the desired number of particles and record the time elapsed since initialization.
- Gradient-based Optimization: We keep track of the time taken from initialization through all gradient updates. At various points, we output the current particles and record the time elapsed since initialization.
- Initialization Approaches: For each factorization θ_m, we keep track of the time taken from initialization through optimization using NMF solvers. In the case of Q-Transform, we also include the time taken to find the transferable Q matrices (less than 0.5 seconds for all 100 pairs of Q-Transform matrices!), even though that cost is shared by all the datasets because we re-use the same matrices. The reported runtime is the sum of the time taken for the initialization procedure and for running the NMF solver.

Runtime for optimizing weights We do not report the time required to weight the particles because it is the same for all methods. In figure 33 we see the time to optimize the weights depends only on the number of particles and not their parameter values or quality.

Runtime for calculating weights: NMF with different parameters

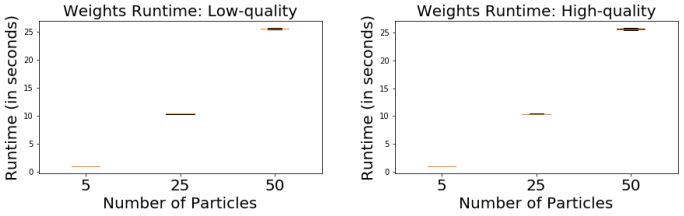

Figure 33: The runtime for calculating optimal weights (left: low-quality random parameters, right: "good" parameters obtained from NMF solvers) does not depend on the parameters; both have the same runtime costs and depend only on collection size.

Note for efficient batch weight optimization To produce the confidence intervals in our experiments, we had to run our approaches many times. To speed up these repetitions, we observed that the weight optimization step first requires computing the pairwise kernel matrix $\mathbf{K}_{ij} = \mathcal{K}_p(\theta_i, \theta_j)$ (from equation 3) and given $\mathbf{K}$, running a solver to find the weights $\{w_m\}_{m=1}^M$. When computing the weights for many subsets of a collection of factorizations (as is the case with the initialization based approaches), we can avoid recomputing terms in the kernel matrix multiple times by calculating the pairwise kernel matrix $\mathbf{K}_{\max}$ for a large collection of $M_{\max}$ factorizations. Subsequently, the matrix $\mathbf{K}_M$ for a given subset of size M (from this large collection) can be determined by simply choosing the relevant columns and rows of $\mathbf{K}_{\max}$. We use this approach to compute quickly compute weights for any M-sized collection sampled from a larger set of $M_{\max}$ factorizations. Note that this efficiency in experimental design trick does not affect our reported numbers, which include only the time to generate the candidate particles, but may help others achieve faster computational times if they are replicating our results.

Abstract

This paper studies active learning in the context of robust statistics. Specifically, we propose a variant of the Best Arm Identification problem for *contaminated bandits*, where each arm pull has probability ε of generating a sample from an arbitrary contamination distribution instead of the true underlying distribution. The goal is to identify the best (or approximately best) true distribution with high probability, with a secondary goal of providing guarantees on the quality of this distribution. The primary challenge of the contaminated bandit setting is that the true distributions are only partially identifiable, even with infinite samples. To address this, we develop tight, non-asymptotic sample complexity bounds for high-probability estimation of the first two robust moments (median and median absolute deviation) from contaminated samples. These concentration inequalities are the main technical contributions of the paper and may be of independent interest. Using these results, we adapt several classical Best Arm Identification algorithms to the contaminated bandit setting and derive sample complexity upper bounds for our problem. Finally, we provide matching information-theoretic lower bounds on the sample complexity (up to a small logarithmic factor).

Keywords: multi-armed bandits, best arm identification, robust statistics, contamination model, partial identifiability

1. Introduction

Consider Pat, an aspiring machine learning researcher deciding between working in a statistics, mathematics, or computer science department. Pat's sole criterion is salary, so Pat surveys current academics with the goal of finding the department with highest median income. However, some subset of the data will be inaccurate: some respondents obscure their salaries for privacy, some convert currency incorrectly, and some do not read the question and report yearly instead of monthly salary, etc. How should Pat target his or her surveys, in an adaptive (online) fashion, to find the highest paying department with high probability in the presence of contaminated data?

In this paper, we study the Best Arm Identification (BAI) problem for multi-armed bandits where observed rewards are not completely trustworthy. The multi-armed bandit problem has received extensive study in the last three decades (Lai and Robbins, 1985; Bubeck and Cesa-Bianchi, 2012). We study the *fixed confidence*, or (α, δ)-PAC, BAI problem, in which the learner must identify an α-suboptimal arm with probability at least $1 - \delta$, using as few samples as possible. Most BAI algorithms for the fixed-confidence setting assume i.i.d. rewards from distributions with relatively strict control on the tails, such as boundedness or more generally sub-Gaussianity (Jamieson et al., 2014). However, for Pat, the data are neither i.i.d. nor from a distribution with controllable tails. How can we model this data, and how can we optimally explore these arms?

To answer the first question, we turn to robust statistics, which has studied such questions for over fifty years. In a seminal paper, Huber (1964) introduced the contamination model, which we adapt to the multi-armed bandit model by proposing the *Contaminated Best Arm Identification problem* (CBAI). This is formally defined in Section 2, but is informally described as follows. There are $k \geq 2$ arms, each endowed with a fixed base distribution F_i and arbitrary contamination distributions $G_{i,t}$ for $t \geq 1$. We place absolutely no assumptions on $G_{i,t}$. When arm i is pulled in round t, the learner receives a sample that with probability $1 - \varepsilon$ is drawn from the arm's true distribution F_i, and with the remaining probability ε is drawn from an arbitrary contamination distribution $G_{i,t}$. The goal is to identify the arm whose true distribution has the highest (or approximately highest) median. The median is the goal rather than the mean since the distributions are not assumed to have finite first moments; and even if they do, the true distributions' means are impossible to estimate from contaminated samples since the contaminations may be arbitrary. A key point is that suboptimality of the arms is based on the quality of the underlying true distributions F_i, not the contaminated distributions $\tilde{F}_{i,t}$ of the observed samples. Note that existing BAI algorithms, fed with samples from $\tilde{F}_{i,t}$, will not necessarily work.

This contamination model nicely fits Pat's problem: samples are usually trustworthy, but sometimes they are completely off and cannot be modeled by a distribution with controlled tails. Additionally, the nature of contamination changes with the respondent, and hence $G_{i,t}$ should be considered as time varying, which completely breaks the usual i.i.d. data assumption. Finally, Pat wants to determine the department with highest *true* median salary, not highest *contaminated* median (or mean) salary.

The contaminated bandit setup also naturally models many other situations that the classical bandit setup cannot, such as any bandit problem where data may be subject to measurement or recording error with some probability. For example, consider the canonical problem of optimal experiment design where we are measuring drug responses, but in a setting where samples can be corrupted or where test results can be incorrectly measured or recorded. Another example is testing new software features, where yet-unfixed bugs may distort responses but will be fixed before release. More scenarios are discussed in Subsection 1.2 when comparing to other models in previous works, and in Subsection 2.1 after the formal definition of the CBAI problem.

Importantly, the CBAI problem is nontrivially harder than the BAI problem since there are no consistent estimators for statistics (including the mean or median) of F_i if the contaminations are allowed to be arbitrary. Under some mild technical assumptions on F_i, the contamination can cause the median of $\tilde{F}_{i,t}$ to be anywhere in an $\Theta(\varepsilon)$-neighborhood of the median of F_i, and hence we can only determine the median of F_i up to some unavoidable estimation bias, U_i, of order ε (see Section 2 for details). This leads us to generalize our study to the more abstract *Partially Identifiable Best Arm Identification* (PIBAI) problem (defined formally in Section 3), which includes CBAI as a special case.

This PIBAI problem can be seen as an active-learning version of the classical problem of estimation under partial identifiability, which has been studied for most of the last century in the econometrics literature (Marschak and Andrews, 1944; Manski, 2009). A canonical problem in this field is trying to learn the age distribution of a population by only asking in which decade each subject was born; clearly the median age can only be learned up to certain unidentifiability regions.

1.1. Our Contributions

To the best of our knowledge, this is the first paper to consider the Best Arm Identification problem with arbitrary contaminations. This contaminated bandit setup models many practical problems that the classical bandit setup cannot. However, developing algorithms for this setup requires overcoming the challenge of partial identifiability of the arms' true distributions. Indeed, it is not hard to show that the adversary's ability to inject arbitrary contaminations can render "similar" underlying distributions indistinguishable, even with access to infinite samples.

We analyze this CBAI problem under three models of the adversary's power: the *oblivious* adversary chooses all contamination distributions a priori; the *prescient* adversary may choose the contamination distributions as a function of all realizations (past and future) of the true rewards and knowledge of when the learner will observe contaminated samples; and the *malicious* adversary may, in addition, correlate when the learner observes contaminated samples with the true rewards. Subsection 2.1 gives formal definitions of these adversarial settings, as well as motivating examples and applications for each.

Our technical contributions can be divided into three parts:

(i) we prove tight, non-asymptotic sample complexity bounds for estimation of the first two robust moments (median and median absolute deviation) from contaminated samples,

(ii) we use the statistical results in (i) to develop efficient algorithms for the CBAI problem and provide sample complexity upper bounds for the fixed-confidence setting, and

(iii) we prove matching information-theoretic lower bounds showing that our algorithms have optimal sample complexity (up to small logarithmic factors).

We elaborate on each of these below.

Contribution (i). These concentration inequalities are the main technical contributions of the paper and may be of independent interest to the robust statistics community. We consider estimating statistics of a single arm from contaminated samples and show that although estimation of standard moments (mean, variance) is impossible, estimation of robust moments (median, median absolute deviation) is possible. Specifically, for each of the three adversarial models, we show that with probability at least $1-\delta$, the empirical median of the contaminated samples lies in a region around the true median of width $U_i + E_{n,\delta}$, where U_i is some unavoidable bias that depends on quantiles of F_i and the power of the adversary, n is the number of samples, and $E_{n,\delta}$ is a confidence-interval term that decreases at the optimal $\sqrt{\frac{\log 1/\delta}{n}}$ rate. Our results neatly capture the effect of the adversary's power by deriving different U_i for each scenario, thereby precisely quantifying the hardness of

the three different adversarial settings. We also present non-asymptotic sample complexity guarantees for estimation of the second robust moment, often called the Median Absolute Deviation (MAD), under all three adversarial settings. The MAD is a robust measure of the spread of F_i and controls the width U_i of the median's unidentifiability region.

Contribution (ii). We show that, surprisingly, several classical BAI algorithms are readily adaptable to the PIBAI problem. This suggests a certain inherent robustness of these classical bandit algorithms. We first present these algorithms for an abstract version of the PIBAI problem so that our algorithmic results may be easily transferrable to other application domains with different statistics of interest or different contamination models. We then combine these general results with our statistical results from (i) to obtain PAC algorithms for CBAI, the problem this paper focuses on. We give fixed-confidence sample complexity guarantees that mirror the sample complexity guarantees for BAI in the classical stochastic multi-armed bandit setup. The main difference is that BAI sample complexities depend on the suboptimality "gaps" $\Delta_i := p_{i^*} - p_i$ between the statistics of the optimal arm i^* and each suboptimal arm i, whereas our CBAI sample complexities depend on the suboptimality "*effective gaps*" $\tilde{\Delta}_i := (p_{i^*} - U_{i^*}) - (p_i + U_i) = \Delta_i - (U_{i^*} + U_i)$, which account for the unavoidable estimation uncertainties in the most pessimistic way. We also show how to apply the MAD estimations results from (i) to obtain guarantees on the quality of the underlying distribution of the selected arm.

Contribution (iii). We prove matching information-theoretic lower bounds (up to a small logarithmic factor) on the sample complexity of CBAI via a reduction to classical lower bounds for the stochastic multi-armed bandit problem. We argue that for CBAI the effective gap $\tilde{\Delta}_i$ is the right analog of the traditional gap since it appears in matching ways in both our upper and lower bounds.

1.2. Previous Work

The Best Arm Identification problem in the fixed-confidence setting has a long history, starting from work by Bechhofer et al. (1968) and Lai and Robbins (1985). Recent interest from the learning theory community was sparked by the seminal paper by Even-Dar et al. (2002), which proposed several algorithms obtaining instance-adaptive sample complexity bounds. Since then, there has been significant work on the algorithmic side (see work by Kalyanakrishnan et al., 2012; Gabillon et al., 2012; Karnin et al., 2013; Jamieson et al., 2013, 2014). Concurrently, a parallel line of work has focused on improving lower bounds, starting with the 2-armed setting (Chernoff, 1972; Anthony and Bartlett, 2009), extending to the multi-armed setting (Mannor and Tsitsiklis, 2004), and, more recently, continuing with more finely tuned lower bounds that include properties of the arm distributions aside from the gaps (Chen and Li, 2015; Kaufmann et al., 2016; Garivier and Kaufmann, 2016).

In the cumulative regret setting, the online learning literature has considered both stochastic bandits with mild tail assumptions (for example, Bubeck et al. (2013) only assumed the existence of a $(1+\varepsilon)$ moment) and algorithms that obtain near-optimal regret guarantees if the environment is stochastic or adversarial (Bubeck and Cesa-Bianchi, 2012). The partial monitoring problem, where the learner only knows the loss up to some subset (Bartók et al., 2014), is also loosely similar to the CBAI problem in the sense that both problems feature partial identification. We note, however, that minimizing cumulative

regret is not a reasonable goal in our contamination setup since the contaminations can be arbitrary and even unbounded. (Furthermore, even when boundedness is assumed, minimizing cumulative regret can still be a poor criteria; see below for concrete examples.)

The existing literature closest to our work studies the BAI problem in settings more general than i.i.d. arms, for example stochastic but non-stationary distributions (Allesiardo et al., 2017; Allesiardo and Féraud, 2017) or arbitrary rewards where each arm converges to a limit (Jamieson and Talwalkar, 2016; Li et al., 2016). However, neither setting fits the contamination model or allows for arbitrary perturbations.

A related contamination model is studied by Seldin and Slivkins (2014); however, they make a boundedness assumption which makes their setup drastically different from ours.[1] Specifically, they consider cumulative regret minimization in a setting where rewards are bounded in $[0, 1]$ and contaminations can be arbitrary. Because of this $[0, 1]$ boundedness, contamination can move the means by at most ε, which is why it is reasonable that they base their algorithms on the contaminated means. However, the best contaminated mean is *not* a reasonable proxy for the best mean without the $[0, 1]$ boundedness assumption. First off, the contaminated distributions may not even have finite first moments. Moreover, when rewards are bounded but only within a large range, the contaminated mean can deviate from the true mean by ε times the size of that range. This can lead to an error bound that is extremely loose—sometimes to the point of being useless for prediction or estimation—compared to the tight bound given by quantiles (see Lemma 1) which our algorithms achieve (see Subsection 4.2).

For instance, consider the adaptive survey example mentioned earlier. There might be a wide range of (true) academic salaries, say between zero and a million dollars. As such, contaminating an ε fraction of the data could move the mean by roughly $10^6 \cdot \varepsilon$; even for a reasonable value of $\varepsilon = 0.1$, this error bound of roughly 10^5 is so large that it may drown out the actual information that the survey was trying to investigate. On the other hand, the median may be moved a significantly smaller amount since the (true) distribution of academic salaries might have reasonably narrow quantiles around the median (for example, being somewhat bell-shaped is sufficient). This performance improvement is intuitively explained by the fact that most academic salaries are not at the extremes of 0 or a million dollars, but rather are fairly regular around the median. An identical phenomenon occurs in the canonical problem of optimal experiment design where we are measuring drug responses but samples can be corrupted or where test results can be incorrectly measured or recorded. Indeed, if the measurements of interests are, say, blood pressure or weight, the values might only be bounded within a large range, but the true distribution might have reasonably narrow quantiles around the median.

We note that the need for robust bandit algorithms is further motivated by the recent work of Jun et al. (2018), which shows that in a similar model, an adversary can make certain classical bandit algorithms perform very poorly by injecting only a small amount of contamination into the observed samples.

This paper also makes connections between several long bodies of work. The contamination model (Huber, 1964) has a long history of more than fifty years in robust statistics; for examples, see work by Hampel (1974); Maronna and Yohai (1976); Rousseeuw and Leroy (2005); Hampel et al. (2011). Contamination models and malicious errors also have a long history in computer science, including the classical work of Valiant (1985); Kearns and Li (1993) and a recent burst of results on algorithms that handle estimation of means and variances (Lai et al., 2016), efficient estimation in high dimensions (Diakonikolas et al., 2018), PCA (Cherapanamjeri et al., 2017), and general learning (Charikar et al., 2017) in the presence of outliers or corrupted data. Finally, the partial identification literature from econometrics also has a rich history (Marschak and Andrews, 1944; Horowitz and Manski, 1995; Manski, 2009; Romano and Shaikh, 2010; Bontemps et al., 2012).

1. Another difference is that our setup and results also work for more powerful types of contaminating adversaries.

1.3. Notation

We denote the Dirac measure at a point $x \in \mathbb{R}$ by δ_x, the Bernoulli distribution with parameter $p \in [0, 1]$ by $\mathrm{Ber}(p)$, and the uniform distribution over an interval $[a, b]$ by $\mathrm{Unif}([a, b])$. The interval $[a - b, a + b]$ is denoted by $[a \pm b]$, the set of non-negative real numbers by $\mathbb{R}_{\geq 0}$, the set of positive integers by $\mathbb{N}$, and the set $\{1, \dots, n\}$ by $[n]$ for $n \in \mathbb{N}$. We abbreviate "with high probability" by "w.h.p." and "cumulative distribution function" by "cdf".

Let F be a cdf. We denote its left and right quantiles, respectively, by $Q_{L,F}(p) := \inf\{x \in \mathbb{R} : F(x) \geq p\}$ and $Q_{R,F}(p) := \inf\{x \in \mathbb{R} : F(x) > p\}$; the need for this technical distinction arises when F is not strictly increasing. We denote the set of medians of F by $m_1(F) := [Q_{L,F}(\frac{1}{2}), Q_{R,F}(\frac{1}{2})]$. When F has a unique median, we overload $m_1(F)$ to be this point rather than a singleton set containing it. For shorthand, we often write $m_1(X)$ for a random variable X to denote $m_1(F)$, where F is the law of X. When F has a unique median, we denote the median absolute deviation (MAD) of F by $m_2(F) := m_1(|X - m_1(F)|)$ where $X \sim F$. When $m_2(F)$ is unique, we define $m_4(F) := m_1(||X - m_1(F)| - m_2(F)|)$. Note that $m_1(F)$, $m_2(F)$, and $m_4(F)$ are robust analogues of centered first (mean), second (variance), and fourth (kurtosis) moments, respectively.

The empirical median of a (possibly random) sequence $x_1, \dots, x_n \in \mathbb{R}$ is denoted by $\hat{m}_1(x_1, \dots, x_n)$: if n is odd, this is the middle value; and if n is even, it is the average of the middle two values. The empirical MAD $\hat{m}_2(x_1, \dots, x_n)$ is then defined as $\hat{m}_1(|x_1 - \hat{m}_1(x_1, \dots, x_n)|, \dots, |x_n - \hat{m}_1(x_1, \dots, x_n)|)$.

1.4. Outline

Section 2 formally defines the CBAI problem and the power of the adversary, describes several motivating applications and examples, and discusses the primary challenge of the problem: partial identifiability. Section 3 presents our algorithmic results for the abstract setting of best arm identification under partial identifiability (the PIBAI problem). We state these algorithms in this general setting so that they may be easily transferrable later to other application domains with different statistics of interest or different contamination models. Section 4 then specializes to the CBAI problem. In order to implement the aforementioned general-purpose PIBAI algorithms for CBAI, concentration results are needed for estimation of medians given contaminated samples. These statistical results are developed in Subsection 4.1, and then used to derive upper bounds on the sample complexity of our CBAI algorithms in Subsection 4.2. Subsection 4.3 gives matching information-theoretic lower bounds on the sample complexity, showing that our algorithms are optimal

(up to small logarithmic factors). This answers the primary question the paper sets out to solve: understanding the complexity of identifying the arm with best median given contaminated samples. Section 5 then turns to our secondary goal: providing guarantees on the distribution of the selected arm. This goal requires additionally estimating the second robust moment. Subsection 5.1 develops the necessary statistical results, which are then used in Subsection 5.2 provide our algorithmic results. Section 6 concludes and discusses several open problems.

2. Formal Setup

Here we formally define the *Contaminated Best Arm Identification problem (CBAI)*. Let $k \geq 2$ be the number of arms, $\varepsilon \in (0, \frac{1}{2})$ be the contamination level, $\{F_i\}_{i\in[k]}$ be the true but unknown distributions, and $\{G_{i,t}\}_{i\in[k],t\in\mathbb{N}}$ be arbitrary contamination distributions. This induces contaminated distributions $\tilde{F}_{i,t}$, samples from which are equal in distribution to $(1 - D_{i,t})Y_{i,t} + D_{i,t}Z_{i,t}$, where $D_{i,t} \sim \text{Ber}(\varepsilon)$, $Y_{i,t} \sim F_i$, and $Z_{i,t} \sim G_{i,t}$. Note that if all of these random variables are independent, then each $\tilde{F}_{i,t}$ is simply equal to the contaminated mixture model $(1-\varepsilon)F_i + \varepsilon G_{i,t}$. However, we generalize by also considering the setting when the $Y_{i,t}, D_{i,t}, Z_{i,t}$ are not all independent, which allows an adversary to further obfuscate samples by adapting the distributions of the $D_{i,t}$ and $Z_{i,t}$ based on the realizations of the $Y_{i,t}$ (that is, by coupling these random variables); see below for details.

At each iteration t, a CBAI algorithm chooses an arm $I_t \in [k]$ to pull and receives a sample $X_{I_t,t}$ distributed according to the corresponding contaminated distribution $\tilde{F}_{I_t,t}$. After T iterations (a possibly random stopping time that the algorithm may choose), the algorithm outputs an arm $\hat{I} \in [k]$. For $\alpha \geq 0$ and $\delta \in (0, 1)$, the algorithm is said to be (α, δ)-*PAC* if, with probability at least $1 - \delta$, $\hat{I}$ has median within $\alpha + U$ of the optimal; that is,

$$\mathbb{P}\left(m_1(F_{\hat{I}}) \geq \max_{i\in[k]} m_1(F_i) - (\alpha + U)\right) \geq 1 - \delta, \tag{1}$$

where U is the unavoidable uncertainty term in median estimation that is induced by partial identifiability (see Subsection 2.2 for a discussion of U, and see Subsection 4.1 for an explicit computation of this quantity). Thus, the goal is to find an algorithm achieving the PAC guarantee in (1) with small expected sample complexity T.

2.1. Power of the Adversary

As is typical in online learning problems, it is important to define the power of the adversary since this affects the complexity of the resulting problem. Interestingly, CBAI is still possible even when we grant the adversary significant power. We consider three settings, presented in increasing order of adversarial power. The key differences between these different types of adversaries are twofold: (1) whether they can choose the contaminated distributions "presciently" based on all other realizations $\{Y_{i,t}, D_{i,t}\}_{i\in[k],t\geq 1}$ both past and future; and (2) whether they can "maliciously" couple the distributions of each $D_{i,t}$ with the corresponding $Y_{i,t}$, subject only to the constraint that the marginals $D_{i,t} \sim \text{Ber}(\varepsilon)$ and $Y_{i,t} \sim F_i$ stay correct.

- **Oblivious adversary.** For all $i \in [k]$, the triples $\{(Y_{i,t}, D_{i,t}, Z_{i,t})\}_{t\geq 1}$ are independent, and for all $t \geq 1$, $Y_{i,t} \sim F_i$, $D_{i,t} \sim \text{Ber}(\varepsilon)$, and $Y_{i,t}$ and $D_{i,t}$ are independent.
- **Prescient adversary.** Same as the oblivious adversary except that the contaminations $Z_{i,t}$ may depend on everything else (i.e. $\{Y_{j,s}, D_{j,s}, Z_{j,s}\}_{j\in[k],s\geq 1}$). Formally, for all $i \in [k]$, the pairs $\{(Y_{i,t}, D_{i,t})\}_{t\geq 1}$ are independent, and for all $t \geq 1$, $Y_{i,t} \sim F_i$, $D_{i,t} \sim \text{Ber}(\varepsilon)$, $Y_{i,t}$ and $D_{i,t}$ are independent, and $Z_{i,t}$ may depend on all $\{Y_{j,s}, D_{j,s}, Z_{j,s}\}_{j\in[k],s\geq 1}$.
- **Malicious adversary.** Same as the prescient adversary except that $Y_{i,t}$ and $D_{i,t}$ do not need to be independent. Formally, for all $i \in [k]$, the pairs $\{(Y_{i,t}, D_{i,t})\}_{t\geq 1}$ are independent, and for all $t \geq 1$, $Y_{i,t} \sim F_i$, $D_{i,t} \sim \text{Ber}(\varepsilon)$, and $Z_{i,t}$ may depend on all $\{Y_{j,s}, D_{j,s}, Z_{j,s}\}_{j\in[k],s\geq 1}$.

We note that for all three of these adversarial settings, we do not require independence between the outputs $(Y_{i,t}, D_{i,t}, Z_{i,t})$ across the arms for each fixed t.

The oblivious adversary is well-motivated, as many real-world problems where contaminations may occur fit naturally into this model. Indeed, this setting encompasses any bandit problem where data may be subject to measurement or recording error with some probability, such as measuring drug responses for clinical trials (Lai and Robbins, 1985), conducting surveys (Martin and Miron, 1992), or testing new software features with yet-unfixed bugs as mentioned in the introduction. The theory we develop extends naturally and with little modification for the prescient and malicious adversaries. Moreover, these different settings allow for the modeling of many other real-world scenarios in which the contamination models are not as simple. For instance, all data may already exist but not yet be released to the learning algorithm. If adversaries have access to all the data from the beginning, they may be able to contaminate samples depending on all the data—this is captured by the prescient setting. The malicious setting includes, for example, scenarios in which adversaries (for example, hackers) can successfully contaminate a given sample depending on the amount of effort they put into it, and the adversaries can try harder to contaminate certain samples depending on their values.

Perhaps surprisingly, we will show that the sample complexity is the same for both oblivious and prescient adversaries. Indeed for these two settings, we will prove our upper bounds for the more powerful setting of prescient adversaries, and our lower bounds for the less powerful setting of oblivious adversaries. We also note that the rate for malicious adversaries is only worse by at most a "factor of 2"; see Section 4 for a precise statement.

2.2. The Challenge of Partial Identifiability of the Median

In the introduction, we emphasized the point that a contaminating adversary can render different underlying distributions of an arm statistically indistinguishable. That is, even with infinite samples, it is impossible to estimate statistics of an arm's true distribution exactly. Consider, for example, the problem of estimating the median of a single arm with true distribution F against an oblivious adversary, which is the weakest of our three adversarial settings. Define S to be the set of all distributions F' for which there exists adversarially chosen distributions G and G' such that $(1 - \varepsilon)F + \varepsilon G = (1 - \varepsilon)F' + \varepsilon G'$. How large is this set S, and in particular, how far can the medians of distributions in S be from the median of F?

The following simple example shows that S is non-trivial (and thus in particular contains more than just F). Let F be the uniform distribution on the interval $[-1,1]$, and let G be the uniform distribution on $[-1-c,-1]\cup[1,1+c]$, where $c=\varepsilon(1-\varepsilon)^{-1}$. The contaminated distribution $\tilde{F}:=(1-\varepsilon)F+\varepsilon G$ is the uniform distribution on $[-1-c,1+c]$. However, for any $p\in[-c,c]$, $\tilde{F}$ is also equal to $(1-\varepsilon)F(\cdot-p)+\varepsilon G_p$, where G_p is the uniform distribution over $[-1-c,1+c]\setminus[-1+p,1+p]$. We conclude that F is statistically indistinguishable from any of the translations $\{F(\cdot-p)\}_{p\in[-c,c]}$. Hence, S is non-trivial and contains distributions with medians at least $\Omega(c)$ away from $m_1(F)$. Even in this simple setting, infinite samples only allow us to identify the median of F at most up to the unidentifiability region $[-c,c]$.

In fact, this toy example captures the correct dependence on ε of how far the median of the contaminated distribution can be shifted, as formalized by the following simple lemma.

Lemma 1 *For any $\varepsilon\in(0,\frac{1}{2})$, any distribution F, and any median $m\in m_1(F)$,*

$$\sup_{\substack{\text{distribution } G,\\ \tilde{m}\in m_1((1-\varepsilon)F+\varepsilon G)}} |\tilde{m}-m| = \max\left\{Q_{R,F}\left(\frac{1}{2(1-\varepsilon)}\right)-m, m-Q_{L,F}\left(\frac{1-2\varepsilon}{2(1-\varepsilon)}\right)\right\}.$$

Proof The fact that the left hand side is no smaller than the right hand side is straightforward: to shift the median to the right (resp. left), let $\{G_n\}_{n\in\mathbb{N}}$ be a sequence of distributions which are Dirac measures at n (resp. $-n$).

We now prove the reverse direction, the "$\leq$" inequality for any fixed distribution G. For shorthand, denote the contaminated distribution by $\tilde{F}:=(1-\varepsilon)F+\varepsilon G$, and denote its left and right medians by $\tilde{m}_L:=Q_{L,\tilde{F}}(\frac{1}{2})$ and $\tilde{m}_R:=Q_{R,\tilde{F}}(\frac{1}{2})$, respectively. Since every median of $\tilde{F}$ lies within $[\tilde{m}_L,\tilde{m}_R]$, it suffices to show that $\tilde{m}_L\geq Q_{L,F}(\frac{1-2\varepsilon}{2(1-\varepsilon)})$ and $\tilde{m}_R\leq Q_{R,F}(\frac{1}{2(1-\varepsilon)})$. We bound $\tilde{m}_L$ presently, as bounding $\tilde{m}_R$ follows by a similar argument or by simply applying the $\tilde{m}_L$ bound to $F(-\cdot)$. By definition of $\tilde{m}_L$, for all $t>0$, $\frac{1}{2}\leq\tilde{F}(\tilde{m}_L+t)=(1-\varepsilon)F(\tilde{m}_L+t)+\varepsilon G(\tilde{m}_L+t)\leq(1-\varepsilon)F(\tilde{m}_L+t)+\varepsilon$, where the last step is because $G(\tilde{m}_L+t)\leq 1$ since G is a distribution. Rearranging yields $F(\tilde{m}_L+t)\geq\frac{1-2\varepsilon}{2(1-\varepsilon)}$, which implies that $\tilde{m}_L\geq Q_{L,F}(\frac{1-2\varepsilon}{2(1-\varepsilon)})$. ■

Finally, we note that for some simple contamination models, partial identifiability in CBAI is not a problem for identifying the arm with the best median. For example, if all arms are contaminated with a common distribution, then although the true medians are only partially identifiable, the contaminated medians are ordered in the same way as the true medians, albeit perhaps not strictly. However, for general (arbitrary) contaminations, such an ordering invariance is clearly not guaranteed.

3. Algorithms for Best Arm Identification Under Partial Identifiability

Our algorithms for CBAI actually work for the more general problem of best arm identification in *partially identified* settings. Specifically, consider any setting where the statistic (for example, the median or mean) which measures the goodness of an arm can be estimated only up to some unavoidable error term due to lack of identifiability. The main result of this section is informally that certain BAI algorithms for the classical stochastic multi-armed

bandit setting can be adapted with little modification to such partially identified settings. Perhaps surprisingly, this suggests a certain innate robustness of these existing classical BAI algorithms.

We present our algorithms in this section for this slightly more abstract problem of *Partially Identifiable Best-Arm-Identification* problem (PIBAI), which we define formally below. This abstraction allows our algorithmic results to later be transferred easily to other variants of the Best Arm Identification problem with different contamination models or different statistics of interest. We will show in Section 4 how to adapt this to the CBAI problem, the main focus of the paper, after first developing the necessary statistical results.

We now formally define the setup of PIBAI. Let $k\geq 2$ be the number of arms. For each arm $i\in[k]$, consider a family of distributions $\mathcal{D}_i=\{D_i(p_i,G)\}_{G\in\mathcal{G}}$ where p_i is a real-valued measure of the quality of arm i and G is a nuisance parameter in some abstract space $\mathcal{G}$. We let $i^*:=\arg\max_{i\in[k]}p_i$ be the best arm. We assume the existence of non-negative unavoidable biases $\{U_i\}_{i\in[k]}$ satisfying

(i) even from infinitely many independent samples $X_t, t=1,2,\ldots$ with $X_t\sim D_i(p_i,G_t)$ for some unknown, possibly varying $G_t\in\mathcal{G}$ $(t\geq 1)$, it is impossible to estimate p_i more precisely than the region $[p_i\pm U_i]$, and

(ii) there exists some estimator that, for any $\alpha>0$ and $\delta\in(0,1)$, uses $n_{\alpha,\delta}=O(\alpha^{-2}\log\frac{1}{\delta})$ i.i.d. samples[2] from D_i to output an estimate $\hat{p}_i$ satisfying

$$\mathbb{P}\Big(\hat{p}_i\in[p_i\pm(U_i+\alpha)]\Big)\geq 1-\delta. \tag{2}$$

The PIBAI problem is then precisely the standard fixed-confidence stochastic bandit problem using these distributions where in each iteration t, the algorithm chooses an arm $I_t\in[k]$ and receives a sample from $D_{I_t}(p_{I_t},G_t)$ for some unknown $G_t\in\mathcal{G}$.

By the partial identifiability property (i), it is clear that even given infinite samples, it is impossible to distinguish between the optimal arm i^* and any suboptimal arm $i\neq i^*$ satisfying $p_i+U_i\geq p_{i^*}-U_{i^*}$. Therefore, we assume henceforth the statistically possible setting in which the *effective gaps* $\tilde{\Delta}_i:=(p_{i^*}-U_{i^*})-(p_i+U_i)$ are strictly positive for each suboptimal arm $i\neq i^*$.

For any $\alpha\geq 0$, arm i is said to be *α-suboptimal* if $\tilde{\Delta}_i\leq\alpha$. Moreover, for any $\alpha\geq 0$ and $\delta\in(0,1)$, a PIBAI algorithm is said to be *(α,δ)-PAC* if it outputs an arm $\hat{I}$ that is α-suboptimal with probability at least $1-\delta$. That is,

$$\mathbb{P}\big(\tilde{\Delta}_{\hat{I}}\leq\alpha\big)\geq 1-\delta,$$

where the above probability is taken over the possible randomness of the samples, the estimator from (ii), and the PIBAI algorithm.

2. Using the same techniques as presented in this paper, one can also consider PIBAI for general $n_{\alpha,\delta}\neq O(\alpha^{-2}\log\frac{1}{\delta})$ and compute the resulting sample complexities. However, for simplicity of presentation, we assume that $n_{\alpha,\delta}=O(\alpha^{-2}\log\frac{1}{\delta})$ since anyways this is the natural (and optimal) quantity for many estimation problems such as estimating a median from contaminated samples (see Corollaries 14 and 15), or using Chernoff bounds to estimate the mean of a $[0,1]$-supported distribution for classical stochastic MAB, etc.

for $i \in [k]$ **do**
  Sample arm i for $n_{\alpha/2,\delta/k}$ times and produce estimate $\hat{p}_i$
end
Output $\hat{I} := \max_{i\in[k]} \hat{p}_i$.

Algorithm 1: Simple uniform exploration algorithm for PIBAI.

We now present algorithms for the PIBAI problem. First, in Subsection 3.1, we present a simple algorithm that performs uniform exploration among all arms. Next, in Subsection 3.2, we obtain more refined, instance-adaptive sample complexity bounds by adapting the Successive Elimination algorithm of (Even-Dar et al., 2006). All algorithms use as a blackbox an estimator satisfying the above property (ii) of the PIBAI problem.

3.1. Simple Algorithm

A simple (α, δ)-PAC PIBAI algorithm is the following: pull each of the k arms $n_{\alpha/2,\delta/k}$ times to create estimates $\hat{p}_i$ and output the arm $\hat{I} := \max_{i\in[k]} \hat{p}_i$ with the highest estimate. Pseudocode is given in Algorithm 1.

Theorem 2 *For any $\alpha > 0$ and $\delta \in (0,1)$, Algorithm 1 is an (α,δ)-PAC* PIBAI *algorithm with sample complexity $O(kn_{\alpha/2,\delta/k}) = O\left(\frac{k}{\alpha^2}\log\frac{k}{\delta}\right)$.*

Proof By (2) and a union bound, we have that with probability at least $1-\delta$, all estimates $\hat{p}_i \in [p_i \pm (U_i + \frac{\alpha}{2})]$. Whenever this occurs,

$$\tilde{\Delta}_{\hat{I}} = (p_{i^*} - U_{i^*}) - (p_{\hat{I}} + U_{\hat{I}}) \le (\hat{p}_{i^*} + \tfrac{\alpha}{2}) - (\hat{p}_{\hat{I}} - \tfrac{\alpha}{2}) \le \alpha,$$

implying that $\hat{I}$ is α-suboptimal. The sample complexity bound is clear. ■

3.2. Instance-adaptive Algorithms

The sample complexity of the simple Algorithm 1 is not adaptive to the difficulty of the actual instance: an arm is sampled $n_{\alpha/2,\delta/k}$ times even if it is far from α-suboptimal (meaning that $\tilde{\Delta}_i \gg \alpha$) and could potentially be eliminated much more quickly. In this subsection, we obtain such an instance-adaptive sample complexity by modifying the Successive Elimination algorithm of (Even-Dar et al., 2006), which was originally designed for the classical multi-armed bandit problem.

Pseudocode is given in Algorithm 2. At each round r, Algorithm 2 gets a single new sample from each remaining arm in order to update its estimate $\hat{p}_{i,r}$. Then, for the next round $r+1$, it only keeps the arms i whose estimates $\hat{p}_{i,r}$ are α-close to the best estimate, where the threshold α is updated at each round. The algorithm and analysis are almost identical to the original. As such, proof details are deferred to Appendix C. The main difference is that in the proof of correctness, we show the event $\{|\hat{p}_{i,r} - p_i| \le U_i + \alpha_{r,6\delta/(\pi^2 k r^2)},\ \forall r \in [R],\ \forall i \in S_r\}$ occurs with probability at least $1-\delta$. This ensures that in each round r, each estimate $\hat{p}_{i,r}$ is accurate enough to use for the elimination step.

$S \leftarrow [k]$, $r \leftarrow 1$
while $|S| > 1$ **do**
  Sample each arm $i \in S$ once and produce $\hat{p}_{i,r}$ from all r past samples of it
  $S \leftarrow \{i \in S : \hat{p}_{i,r} \ge \max_{j\in S} \hat{p}_{j,r} - 2\alpha_{r,6\delta/(\pi^2 k r^2)}\}$
  $r \leftarrow r+1$
end
Output the only arm left in S

Algorithm 2: Adaptation of Successive Elimination algorithm for PIBAI. Here, $\alpha_{r,\delta} := \sqrt{\frac{c\log\frac{1}{\delta}}{r}}$, where c is a universal constant satisfying $n_{\alpha,\delta} \le c\alpha^{-2}\log\frac{1}{\delta}$ (see Equation 2).

Note that Algorithm 2 returns the optimal arm w.h.p. (without knowing the smallest effective gap), unlike Algorithm 1 above which only returns a near-optimal arm w.h.p.

Theorem 3 *Let $\delta \in (0,1)$. With probability at least $1-\delta$, Algorithm 2 outputs the optimal arm after using at most $O\left(\sum_{i\neq i^*} \frac{1}{\tilde{\Delta}_i^2}\log\left(\frac{k}{\delta\tilde{\Delta}_i}\right)\right)$ samples.*

Moreover, as noted in Remark 9 of (Even-Dar et al., 2006), Algorithm 2 is easily modified (by simply terminating early) to be an (α,δ)-PAC algorithm with sample complexity

$$O\left(\frac{N_\alpha}{\alpha^2}\log\left(\frac{N_\alpha}{\delta}\right) + \sum_{i\in[k]:\,\tilde{\Delta}_i>\alpha} \frac{1}{\tilde{\Delta}_i^2}\log\left(\frac{k}{\delta\tilde{\Delta}_i}\right)\right),$$

where N_α is the number of α-suboptimal arms with $\tilde{\Delta}_i \le \alpha$.

Remark 4 *In the multi-armed bandit literature, the sample complexity of the Successive Elimination algorithm (tight up to a logarithmic factor) was improved upon by (Karnin et al., 2013)'s Exponential-Gap Elimination (EGE) algorithm (tight up to a doubly logarithmic factor). A natural idea is to analogously improve upon the* PIBAI *guarantee in Theorem 3 by adapting the EGE algorithm. However, this approach does not work. The same holds for adapting the Median Elimination algorithm of (Even-Dar et al., 2006) and the PRISM algorithm of (Jamieson et al., 2013). The reason for the inadaptability of these algorithms—in contrast to the easy adaptability of the Successive Elimination algorithm above—is that these algorithms heavily rely on the "additive property of suboptimality" for* BAI*:*

> *"If arm i has Δ_i suboptimality gap w.r.t. the optimal arm i^*, and if arm j has $\Delta_j^{(i)}$ suboptimality gap w.r.t. arm i, then arm j has suboptimality gap $\Delta_j = \Delta_i + \Delta_j^{(i)}$ w.r.t. the optimal arm i^*."*

The critical point is that PIBAI *does not have this property since errors propagate from adding the uncertainties U_i in the suboptimality gaps: that is, $(p_{i^*} - U_{i^*}) - (p_j + U_j) \neq [(p_{i^*} - U_{i^*}) - (p_i + U_i)] + [(p_i - U_i) - (p_j + U_j)]$. Because of this, in order to return an α-suboptimal arm for* PIBAI*, we must ensure that all arms that are more than α-suboptimal*

are eliminated before the optimal arm is eliminated (if it ever is). This is in contrast to BAI *in the classical multi-armed bandit setup: there, it is not problematic if the best (or even currently best) arm is eliminated at round r, so long as the best arm in consecutive rounds r and $r+1$ changes at most by a small amount.*[3] *We stress that this nuance is not merely a technicality but actually fundamental to the correctness proofs for* PIBAI.

4. Finding the Best Median

The previous section provided algorithms for the general PIBAI problem; in this section, these algorithms are adapted to the special case of the CBAI problem, which is the focus of the paper. This requires an estimator of the median from contaminated samples that concentrates at an exponential rate[4]. Subsection 4.1 develops these statistical results, which are of potential independent interest to the robust statistics community. Subsection 4.2 then combines these results with the results of the previous section to conclude algorithms for CBAI, and gives upper bounds on their sample complexity. Finally, Subsection 4.3 gives information-theoretic lower bounds showing that the sample complexities of these algorithms are optimal (up to a small logarithmic factor).

4.1. Estimation of Median from Contaminated Samples

In this subsection, we develop the statistical results needed to obtain algorithms for the CBAI problem. Specifically, we obtain tight, non-asymptotic sample-complexity bounds for median estimation from contaminated samples. We do this for all three adversarial models for the contamination (oblivious, prescient, and malicious). These results may be of independent interest to the robust statistics community.

The subsection is organized as follows. First, Subsection 4.1.1 studies the concentration of the empirical median under the most general distributional assumptions and provides, for all three adversarial settings, tight upper and lower bounds on the sample complexity of median estimation from contaminated samples. Next, in Subsection 4.1.2 we obtain more algorithmically useful guarantees by specializing these results to a family of distributions where the cdfs increase at least linearly in a neighborhood of the median, a very common assumption in the robust estimation literature. For this family of distributions, we explicitly compute for all three adversarial settings the unavoidable bias terms mentioned in Section 2 for median estimation from contaminated samples. It is worth emphasizing that these results precisely quantify the effect of the three different adversarial strengths on the complexity of the problem of median estimation in the contamination model.

Throughout this subsection, we will only consider a single arm, and its true distribution will be denoted by F. For brevity of the main text, all proofs are deferred to Appendix B.

3. In particular, at most $2^{-r}\alpha$ for most of these aforementioned algorithms, since this implies that the final arm $\hat{I}$ is at most $\sum_{r=1}^{\infty} 2^{-r}\alpha = \alpha$-suboptimal.
4. For the formal statement, see (ii) in the definition of PIBAI in Section 3.

4.1.1. General Concentration Results for Median Estimation

Lemma 1 implies that some control of the quantiles of F is necessary to obtain guarantees for estimation of $m_1(F)$ from contaminated samples. We begin by considering F in the following family of distributions, which we stress makes the most general such assumption.

Definition 5 *For any $\bar{t} \in (0, \frac{1}{2})$ and any non-decreasing function $R : [0, \bar{t}] \to \mathbb{R}_{\geq 0}$, define $\mathcal{H}_{\bar{t},R}$ to be the family of all distributions F satisfying*

$$R(t) \geq \max\left\{ Q_{R,F}\left(\frac{1}{2}+t\right) - m, m - Q_{L,F}\left(\frac{1}{2}-t\right)\right\} \tag{3}$$

for any $t \in [0, \bar{t}]$ and any median $m \in m_1(F)$.

In words, the function R dictates the the maximal deviation from the median that a cdf F can have for all quantiles in a small neighborhood $[\frac{1}{2} - \bar{t}, \frac{1}{2} + \bar{t}]$ around the median. Since R is an arbitrary non-decreasing function, Definition 5 gives the most general possible bound on these quantiles.

Note that if $\varepsilon > \bar{\varepsilon}(\bar{t}) := \frac{2\bar{t}}{1+2\bar{t}}$, it is impossible to control the deviation of the contaminated median from the true median for $F \in \mathcal{H}_{\bar{t},R}$. Indeed, the requirement $\varepsilon \leq \bar{\varepsilon}(\bar{t}) := \frac{2\bar{t}}{1+2\bar{t}}$ is equivalent to $\bar{t} \geq \frac{\varepsilon}{2(1-\varepsilon)}$, which, by Lemma 1, is the largest possible deviation from the $\frac{1}{2}$-quantile.

Combining Lemma 1 with the definition of R in Definition 5 immediately yields the following tight bound on how far the contaminated median can be moved from the true median for any $F \in \mathcal{H}_{\bar{t},R}$.

Corollary 6 *For any $\bar{t} \in (0, \frac{1}{2})$, any $\varepsilon \in (0, \bar{\varepsilon}(\bar{t}))$, and any non-decreasing function $R : [0, \bar{t}] \to \mathbb{R}_{\geq 0}$,*

$$\sup_{\substack{F \in \mathcal{H}_{\bar{t},R},\, m \in m_1(F),\\ \text{distribution } G,\, \tilde{m} \in m_1((1-\varepsilon)F + \varepsilon G)}} |\tilde{m} - m| = R\left(\frac{\varepsilon}{2(1-\varepsilon)}\right)$$

We now turn to estimation results. At this point it is necessary to distinguish between the three adversarial settings for the contamination. We begin with guarantees for the oblivious and prescient adversarial settings, which—somewhat surprisingly—turn out to have the same rates. In particular, we show that with probability at least $1-\delta$, the estimation error is bounded above by $R(\frac{\varepsilon}{2(1-\varepsilon)} + O(\sqrt{\frac{\log 1/\delta}{n}}))$. Note that if R is Lipschitz, then this quantity is bounded above by the unavoidable uncertainty term $R\left(\frac{\varepsilon}{2(1-\varepsilon)}\right)$ (see Corollary 6) plus an error term that decays quickly with $n^{-1/2}$ rate and has sub-Gaussian tails in δ. This confidence-interval term is of optimal order since it is tight even for estimating the mean (and thus median) of a Gaussian random variable with known unit variance from *uncontaminated* samples.

Lemma 7 *Let $\bar{t} \in (0, \frac{1}{2})$, $\varepsilon \in (0, \bar{\varepsilon}(\bar{t}))$, and $F \in \mathcal{H}_{\bar{t},R}$. Let $Y_i \sim F$ and $D_i \sim Ber(\varepsilon)$, for $i \in [n]$, all be drawn independently. Let $\{Z_i\}_{i\in[n]}$ be arbitrary random variables possibly*

depending on $\{Y_i, D_i\}_{i\in[n]}$*, and define* $X_i = (1-D_i)Y_i + D_iZ_i$*. Then, for any confidence level* $\delta \in (0,1)$ *and number of samples* $n \geq 2\left(\bar{t} - \frac{\varepsilon}{2(1-\varepsilon)}\right)^{-2}\log\frac{2}{\delta}$ *, we have*

$$\mathbb{P}\left(\sup_{m\in m_1(F)} |\hat{m}_1(X_1,\dots,X_n) - m| \leq R\left(\frac{\varepsilon}{2(1-\varepsilon)} + \sqrt{\frac{2\log(2/\delta)}{n}}\right)\right) \geq 1-\delta.$$

Note that because the class $\mathcal{H}_{\bar{t},R}$ only assumes control on the $[\frac{1}{2}\pm\bar{t}]$ quantiles, the minimum sample complexity n must grow as $\bar{t}$ approaches $\frac{\varepsilon}{2(1-\varepsilon)}$, since by Lemma 1 this is the largest quantile deviation that the contaminated median can be moved from the true median.

We now turn to malicious adversaries and derive analogous tight, non-asymptotic sample complexity bounds for median estimation from contaminated samples. We show that it possible to obtain estimation accuracy of $R(\varepsilon)$ in this malicious adversarial setting (Lemma 8). Note that this is weaker than the the accuracy of $R(\frac{\varepsilon}{2(1-\varepsilon)})$ obtained above against oblivious and prescient adversaries. However, we also show that this dependency is tight and unavoidable (Lemma 9). Moreover, the $O(\sqrt{\frac{\log 1/\delta}{n}})$ error term in Lemma 8 is tight for the same reason as it was in Lemma 7; see the discussion there. Finally, we remark that the upper bound on ε and the lower bound on the sample complexity n in Lemma 8 are exactly the analogues of the corresponding bounds in Lemma 7; the only difference is that malicious adversaries can force the contaminated distributions to have medians at roughly $F^{-1}(\frac{1}{2}\pm\varepsilon)$, resulting in our need for control of these further quantiles.

Lemma 8 *Let* $\bar{t} \in (0,\frac{1}{2})$*,* $\varepsilon \in (0,\bar{t})$*, and* $F \in \mathcal{H}_{\bar{t},R}$*. Let* (Y_i, D_i)*, for* $i \in [n]$*, be drawn independently with marginals* $Y_i \sim F$ *and* $D_i \sim Ber(\varepsilon)$*. Let* $\{Z_i\}_{i\in[n]}$ *be arbitrary random variables possibly depending on* $\{Y_i, D_i\}_{i\in[n]}$*, and define* $X_i = (1-D_i)Y_i + D_iZ_i$*. Then for any confidence level* $\delta \in (0,1)$ *and number of samples* $n \geq 2(\bar{t}-\varepsilon)^{-2}\log\frac{3}{\delta}$*,*

$$\mathbb{P}\left(\sup_{m\in m_1(F)} |\hat{m}_1(X_1,\dots,X_n) - m| \leq R\left(\varepsilon + \sqrt{\frac{2\log(3/\delta)}{n}}\right)\right) \geq 1-\delta.$$

Lemma 9 *Let* $\bar{t} \in (0,\frac{1}{2})$*,* $\varepsilon \in (0,\bar{t})$*,* $\delta \in (0,1)$*,* $n \geq \frac{1}{2}\varepsilon^{-2}\log\frac{1}{\delta}$*, and* $R : [0,\bar{t}] \to \mathbb{R}_{\geq 0}$ *be any strictly increasing function. Then there exists a distribution* $F \in \mathcal{H}_{\bar{t},R}$ *and a joint distribution on* (D,Y,Z) *with marginals* $D \sim Ber(\varepsilon)$ *and* $Y \sim F$*, such that* F *has unique median and*

$$\mathbb{P}\left(|\hat{m}_1(X_1,\dots,X_n) - m_1(F)| \geq R\left(\varepsilon - \sqrt{\frac{\log(1/\delta)}{2n}}\right)\right) \geq 1-\delta,$$

where each $\{(D_i,Y_i,Z_i)\}_{i\in[n]}$ *is drawn independently from the joint distribution, and* $X_i := (1-D_i)Y_i + D_iZ_i$*.*

4.1.2. Improved Concentration under Quantile Control

Note that if a cdf F changes little around its median, then the neighboring quantiles are harder to distinguish from each other, and thus it is more difficult to estimate the median. In order to obtain more algorithmically useful rates for median estimation from contaminated samples, we now introduce a more specific class of cdfs F that increase at least linearly in a

neighborhood around the median. This ensures that F is not "too flat" in this neighborhood, which we stress is a very standard assumption for median estimation.

Definition 10 *For any* $\bar{t} \in (0,\frac{1}{2})$ *and* $B > 0$*, let* $\mathcal{F}_{\bar{t},B}$ *be the family of distributions* F *that have a unique median and satisfy*

$$|F(x_1) - F(x_2)| \geq \frac{1}{Bm_2(F)}|x_1 - x_2| \tag{4}$$

for all $x_1, x_2 \in \left[Q_{L,F}(\frac{1}{2}-\bar{t}), Q_{R,F}(\frac{1}{2}+\bar{t})\right]$*.*

We make a few remarks about the definition. i) Requiring the right-hand side of Equation 4 to scale inversely in the median absolute deviation (MAD) $m_2(F)$ ensures closure of $\mathcal{F}_{\bar{t},B}$ under scaling; see below. We also mention that $m_2(F)$ is a robust measure of the spread of F (it is the "median moment" analogue of variance), and controls the width of the median's unidentifiability region. ii) If $F \in \mathcal{F}_{\bar{t},B}$, then $F \in \mathcal{H}_{\bar{t},R}$ for $R(t) = Bm_2(F)t$. iii) Distributions in $\mathcal{F}_{\bar{t},B}$ are not required to have densities, nor even be continuous. iv) The family $\mathcal{F}_{\bar{t},B}$ has many natural and expected properties, such as closure under scaling and translation. These properties are gathered in Lemma 26, which is deferred to Appendix A for brevity of the main text.

Remark 11 (Examples) *Most common distributions belong to* $\mathcal{F}_{\bar{t},B}$ *for some values of the parameters* $\bar{t}$ *and* B*. Moreover, by Lemma 26, if a distribution is in* $\mathcal{F}_{\bar{t},B}$*, then all scaled and translated versions are as well. A short list includes: i) the Gaussian distribution, for any* $\bar{t} \in (0,\frac{1}{2})$ *and any* $B \geq \frac{q_{3/4}}{\phi(q_{1/2+\bar{t}})}$*, where* ϕ *is the standard Gaussian density and* q_α *is the corresponding* α*-quantile; ii) the uniform distribution on any interval, for any* $\bar{t} \in (0,\frac{1}{2})$ *and any* $B \geq 4$*; and iii) any distribution* F *with positive density* F'*, for any* $\bar{t} \in (0,\frac{1}{2})$ *and any* $B \geq \left(m_2(F)\min_{x\in[Q_{L,F}(\frac{1}{2}-\bar{t}),Q_{R,F}(\frac{1}{2}+\bar{t})]} F'(x)\right)^{-1}$*.*

We now apply the estimation results for $\mathcal{H}_{\bar{t},R}$ to estimation for $\mathcal{F}_{\bar{t},B}$. By Lemma 26, whenever $F \in \mathcal{F}_{\bar{t},B}$, then $F \in \mathcal{H}_{\bar{t},R}$ for $R(t) = tBm_2(F)$. Corollary 6 immediately yields a bound on the size of the contamination region in terms of the quantity

$$U_{\varepsilon,B,m_2} := Bm_2\frac{\varepsilon}{2(1-\varepsilon)}.$$

Corollary 12 *For any* $\bar{t} \in (0,\frac{1}{2})$*, any* $\varepsilon \in (0,\bar{\varepsilon}(\bar{t}))$*, and any* $F \in \mathcal{F}_{\bar{t},B}$*,*

$$\sup_{\substack{\text{distribution } G,\\ \tilde{m}\in m_1((1-\varepsilon)F+\varepsilon G)}} |\tilde{m} - m_1(F)| \leq U_{\varepsilon,B,m_2(F)}.$$

Remark 13 (Tightness of Corollary 12) *For any* $a > 0$*, let* F *be the uniform distribution over* $[0,a]$*. Then* $m_1(F) = \frac{a}{2}$ *and* $m_2(F) = \frac{a}{4}$*, and thus* $F \in \mathcal{F}_{\bar{t},B}$ *for any* $\bar{t} \in (0,\frac{1}{2})$ *and* $B = 4$*. Now for any* $\varepsilon \in (0,\bar{\varepsilon}(\bar{t})) \subset (0,\frac{1}{2})$*, let* G *be the uniform distribution over*

$[a, \frac{a}{1-\varepsilon}]$. *Then* $\tilde{F} = (1-\varepsilon)F + \varepsilon G$ *is the uniform distribution over* $[0, \frac{a}{1-\varepsilon}]$ *and has median* $m_1(\tilde{F}) = \frac{a}{2} + \frac{\varepsilon}{2(1-\varepsilon)}a = m_1(F) + U_{\varepsilon,B,m_2(F)}$. *An identical argument on* $F(-\cdot)$ *and* $G(-\cdot)$ *yields an example where the median decreases by* $-U_{\varepsilon,B,m_2(F)}$, *so the bound in Corollary 12 is tight.*

Now we turn to median estimation bounds for $\mathcal{F}_{\bar{t},B}$. Since $R(t) = tBm_2(F)$ is clearly Lipschitz, the discussion preceding Lemmas 7 and 8 about the optimality of the following error bounds applies. That is, the error decomposes into the sum of the unavoidable uncertainty term $U_{\varepsilon,B,m_2(F)}$ plus a confidence-interval term decaying at a $n^{-1/2}$ rate and with sub-Gaussian tails in δ, both of which are optimal. The $\bar{t}$ terms in the sample complexity bounds appear for the analogous reasons as in Lemma 7; see the discussion there. For brevity, we omit the proofs of the following corollaries since they follow immediately from Lemmas 7, 8, and 26.

Corollary 14 *Consider the same setup as in Lemma 7, except with the added restriction that* $F \in \mathcal{F}_{\bar{t},B}$. *Then, for any confidence level* $\delta \in (0,1)$, *error level* $E > 0$, *and number of samples* $n \geq 2\max\left(\frac{B^2 m_2^2(F)}{E^2}, \left(\bar{t} - \frac{\varepsilon}{2(1-\varepsilon)}\right)^{-2}\right)\log\frac{2}{\delta}$, *we have*

$$\mathbb{P}\left(|\hat{m}_1(X_1,\dots,X_n) - m_1(F)| \leq U_{\varepsilon,B,m_2(F)} + E\right) \geq 1-\delta.$$

Corollary 15 *Consider the same setup as in Lemma 8, except with the added restriction that* $F \in \mathcal{F}_{\bar{t},B}$. *Then for any confidence level* $\delta \in (0,1)$, *error level* $E > 0$, *and number of samples* $n \geq 2\max\left(\frac{B^2 m_2^2(F)}{E^2}, (\bar{t}-\varepsilon)^{-2}\right)\log\frac{3}{\delta}$,

$$\mathbb{P}\left(|\hat{m}_1(X_1,\dots,X_n) - m_1(F)| \leq U^{(\text{MALICIOUS})}_{\varepsilon,B,m_2(F)} + E\right) \geq 1-\delta.$$

In Corollary 15 above, we have defined

$$U^{(\text{MALICIOUS})}_{\varepsilon,B,m_2} := Bm_2\varepsilon,$$

which is a tight bound on the uncertainty in median estimation that a malicious adversary can induce (see Lemma 9).

4.2. Algorithms

In this subsection, we apply the algorithms developed in Section 3 for the general problem of PIBAI to the special case of CBAI. In order to implement the estimator required by part (ii) of the definition of PIBAI (see Section 3), we make use of the guarantees proved in Subsection 4.1 for median estimation from contaminated samples. Nearly matching information-theoretic lower bounds are provided in the following subsection and show that the algorithms below have optimal sample complexity (up to a small logarithmic factor).

We will only assume that the arms' distributions are in $\mathcal{F}_{\bar{t},B}$ and have robust second moments uniformly bounded[5] by some $\bar{m}_2$; this will allow us to perform median estimation

5. It is typically necessary to have bounds on higher order moments in order to control the error of estimating lower order moments, see e.g. (Bubeck et al., 2013).

from contaminated samples. For simplicity, the parameters of this family are assumed to be known to the algorithm beforehand[6]. Note, however, that it is not necessary to know ε, but only an upper bound ε_0 on ε; indeed ε can be replaced with ε_0 in all our algorithms. It is very standard in the robust statistics literature to assume knowledge of such an upper bound ε_0 on the amount of contamination. The parameter $\bar{t}$ can then be arbitrarily chosen by the algorithms, so long as it is bigger than $\varepsilon_0/(2(1-\varepsilon_0))$ (or ε_0 in the malicious case) and smaller than $1/2$.

The sample complexities we prove below are in terms of the *effective gaps* $\tilde{\Delta}_i := (m_1(F_{i^*}) - U_{i^*}) - (m_1(F_i) + U_i)$ of the suboptimal arms $i \neq i^*$, where $i^* := \arg\max_{i\in[k]} m_1(F_i)$ is the arm with the highest median. Here U_i is the unavoidable uncertainty term for median estimation from contaminated samples under the given adversarial setting. In Subsection 4.1, we explicitly computed $U_i = U_{\varepsilon,B,m_2(F_i)}$ for oblivious and prescient adversaries (Corollary 14) and $U_i = U^{(\text{MALICIOUS})}_{\varepsilon,B,m_2(F_i)}$ for malicious adversaries (Corollary 15). We emphasize that the strength of the adversarial setting is encapsulated in the corresponding U_i.

First, we discuss how the simple Algorithm 1 yields an (α,δ)-PAC algorithm for CBAI without modification. In this setting, $\hat{p}_i$ is the empirical median of the payoffs of arm i. The quantity $n_{\alpha,\delta}$ is equal to $2\max(\frac{B^2\bar{m}_2^2}{\alpha^2}, (\bar{t} - \frac{\varepsilon}{2(1-\varepsilon)})^{-2})\log\frac{2}{\delta}$ against oblivious and prescient adversaries (Corollary 14) and is equal to $2\max(\frac{B^2\bar{m}_2^2}{\alpha^2}, (\bar{t}-\varepsilon)^{-2})\log\frac{3}{\delta}$ against malicious adversaries (Corollary 15). Theorem 2 along with the observation that the constant term in the sample complexity $n_{\alpha,\delta}$ only introduces a term that is negligible in the overall sample complexity of Algorithm 1, immediately yields the following result.

Theorem 16 *Let* $F_i \in \mathcal{F}_{\bar{t},B}$ *with* $m_2(F) \leq \bar{m}_2$ *for each arm* $i \in [k]$, *and let the adversary be oblivious, prescient, or malicious. For any* $\alpha > 0$ *and* $\delta \in (0,1)$, *Algorithm 1 is an* (α,δ)*-PAC* CBAI *algorithm with sample complexity* $O(kn_{\alpha/2,\delta/k}) = O\left(\frac{k}{\alpha^2}\log\frac{k}{\delta}\right)$.

Algorithm 1 does not adapt to the difficulty of the problem instance. A natural approach is to try to apply the Successive Elimination Algorithm to BAI directly. Unfortunately, this algorithm needs concentration inequalities even for small sample sizes, whereas our guarantees are only valid when the sample size is greater than a certain threshold. Hence, we slightly modify the Successive Elimination Algorithm to obtain additional samples in an initial exploration phase; the number of samples required in this initial exploration phase is dictated by our median estimation results form Subsection 4.1. We similarly modify later rounds to take additional samples in order to produce updated median estimates at the desired certainty levels. Pseudocode is given in Algorithm 3.

6. The classes of distributions that we define have two parameters that would be hard or even impossible to estimate in practice, namely B and $\bar{m}_2$. In classical setups in which algorithms need to learn means instead of medians, it is common to assume that there is a second moment σ^2 which is known, or at least bounded by a known constant. This is because in practice σ^2 is hard to estimate from the data. Note that if the distributions F_i are known to have bounded support, $\bar{m}_2$ can be chosen as the size of the domain. It seems that knowing B is the price to pay to go from the classical to the robust setup. Indeed, even in the non-contaminated case, it is well known that the median of a distribution can be estimated at a parametric rate only when the distribution is not too flat around its median. In that case, the estimation rate depends on how "*non-flat*" the distribution is, which is exactly $Bm_2(F)$ in the present setup. In a parametric setup, i.e., when the distributions of the arms $F_i, i = 1,\dots,K$ are known up to some location and/or scale parameters, B would be known since it is translation and scale invariant (see Lemma 26).

$S \leftarrow [k]$, $r \leftarrow 1$
Sample each arm $\lceil N \log(\frac{\pi^2 k}{2\delta}) \rceil$ times
while $|S| > 1$ **do**
  Sample each arm $i \in S$ for $1 + \lceil 2N \log(\frac{r+1}{r}) \rceil$ times and produce $\hat{p}_{i,r}$ from all past samples
  $S \leftarrow \{i \in S : \hat{p}_{i,r} \geq \max_{j \in S} \hat{p}_{j,r} - 2\alpha_{r,6\delta/(\pi^2 k r^2)}\}$
  $r \leftarrow r + 1$
end
Output the only arm left in S

Algorithm 3: Adaptation of successive elimination algorithm (see Algorithm 2) for CBAI. For oblivious and prescient adversaries, $N := 2(\bar{t} - \frac{\varepsilon}{2(1-\varepsilon)})^{-2}$; and for malicious adversaries $N := 2(\bar{t} - \varepsilon)^{-2}$. In all settings, $\alpha_{r,\delta} := \sqrt{\frac{2B\bar{m}_2^2 \log \frac{3}{\delta}}{r}}$.

Theorem 17 *Let $\delta \in (0,1)$, let $F_i \in \mathcal{F}_{\bar{t},B}$ with $m_2(F) \leq \bar{m}_2$ for each arm $i \in [k]$, and let the adversary be either oblivious, prescient, or malicious. With probability at least $1-\delta$, Algorithm 3 outputs the optimal arm after using at most $\tilde{O}\left(\sum_{i \neq i^*} \left(\frac{1}{\tilde{\Delta}_i^2} + N\right) \log\left(\frac{k}{\delta \tilde{\Delta}_i}\right)\right)$ samples.*

The proof follows from Theorem 3 and is deferred to Appendix C. Like Algorithm 2, Algorithm 3 can be stopped earlier in order to obtain an (α, δ)-PAC guarantee.

4.3. Lower Bounds

Here we provide information-theoretic lower bounds on the sample complexity of the CBAI problem that match, up to small logarithmic factors, the algorithmic upper bounds proved above in Subsection 4.2 for each of the three adversarial settings. The main insight is that we can reduce hard instances of the BAI problem to hard instances of the CBAI problem. In this way, we can leverage the sophisticated lower bounds already developed in the classical multi-armed bandit literature.

Let $i^* := \arg\max_{i \in [k]} m_1(F_i)$ denote the optimal arm. As in Section 3, $\tilde{\Delta}_i := (m_1(F_{i^*}) - U_{i^*}) - (m_1(F_i) + U_i)$ denotes the effective gap for suboptimal arms $i \neq i^*$, and U_i denotes the unavoidable uncertainty term for median estimation. We emphasize that since the power of the adversary is encapsulated in the U_i, and therefore also the effective gaps $\tilde{\Delta}_i$, we can address all three adversarial settings simultaneously by proving a lower bound in terms of the effective gaps.

In Section 3, we argued that the PIBAI problem is impossible when there exists suboptimal arms with non-positive effective gaps; the CBAI problem also has this property. Indeed, if $i \neq i^*$ satisfies $\tilde{\Delta}_i \leq 0$, then there exist distributions G_{i^*} and G_i such that the resulting contaminated distributions $\tilde{F}_i := (1-\varepsilon)F_i + \varepsilon G_i$ and $\tilde{F}_{i^*} := (1-\varepsilon)F_{i^*} + \varepsilon G_{i^*}$ have equal medians. Moreover, since the distributions F are arbitrary (CBAI makes no parameteric assumptions), it is impossible to determine whether arm i or i^* has a higher true median. Thus, any CBAI algorithm, even with infinite samples, cannot succeed with probability more than $\frac{1}{2}$. Therefore, we only consider the setting where all effective gaps $\tilde{\Delta}_i$ are strictly positive.

The results in this section lower bound the sample complexity of any CBAI algorithm in terms of the effective gaps. We will focus on lower bounds for the function class $\mathcal{F}_{\bar{t},B}$ and provide lower bounds matching the upper bounds for CBAI in Section 4.2.

Theorem 18 *Consider* CBAI *against an oblivious, prescient, or malicious adversary. There exists a positive constant B such that for any number of arms $k \geq 2$, any confidence level $\delta \in (0, \frac{3}{20})$, any suboptimality level $\alpha \in (0, \frac{1}{6})$, any contamination level $\varepsilon \in (0, \frac{1}{15})$, any regularity level $\bar{t} \in (0, \frac{1}{10})$, and any effective gaps $\{\tilde{\Delta}_i\}_{i \in [k] \setminus i^*} \subset (0, \frac{1}{3})$, there exists a* CBAI *instance with $F_1, \ldots, F_k \in \mathcal{F}_{\bar{t},B}$ for which any (α, δ)-PAC algorithm has expected sample complexity*

$$\mathbb{E}[T] = \Omega\left(\sum_{i \in [k] \setminus \{i^*\}} \frac{1}{\max(\tilde{\Delta}_i, \alpha)^2} \log \tfrac{1}{\delta}\right),$$

where $i^* = \arg\max_{i \in [k]} m_1(F_i)$ is the optimal arm.

Taking the limit as $\alpha \to 0$ in Theorem 18 immediately yields the following lower bound on $(0,\delta)$-PAC algorithms.

Corollary 19 *Consider the same setup as in Theorem 18. There exists a* CBAI *instance $F_1, \ldots, F_k \in \mathcal{F}_{\bar{t},B}$ for which any $(0,\delta)$-PAC algorithm has expected sample complexity*

$$\mathbb{E}[T] = \Omega\left(\sum_{i \in [k] \setminus \{i^*\}} \frac{1}{\tilde{\Delta}_i^2} \log \tfrac{1}{\delta}\right).$$

Proof Sketches. We now sketch the proofs of Theorem 18 and Corollary 19. Full details are deferred to Appendix D.remove for brevity of the main text.

The key idea in the proof is to "lift" hard BAI instances to hard CBAI problem instances. Specifically, let $\{P_i\}_{i \in [k]}$ be distributions for arms in a BAI problem, let $\{U_i\}_{i \in [k]}$ be the corresponding unavoidable uncertainties for median estimation of P_i in CBAI , and let i^* denote the best arm. We say $\{P_i\}_{i \in [k]}$ admits an "$(\varepsilon, \mathcal{F}_{\bar{t},B})$ *CBAI-lifting*" to $\{F_i\}_{i \in [k]}$ if (i) $F_i \in \mathcal{F}_{\bar{t},B}$ for each i, (ii) there exists some adversarial distributions $\{G_i\}_{i \in [k]}$ such that each $P_i = (1-\varepsilon)F_i + \varepsilon G_i$; and (iii) the effective gaps $\tilde{\Delta}_i$ for the $\{F_i\}_{i \in [k]}$ are equal to the gaps Δ_i in the original BAI problem. Intuitively, such a lifting can be thought of as choosing F_{i^*} to have the smallest possible median and the other F_i to have the largest possible median, which still being consistent with P_i and remaining in the uncertainty region corresponding to the U_i.

Armed with this informal definition, we now outline the central idea behind the reduction. Let $\{P_i\}_{i \in [k]}$ be a "hard" BAI instance with best arm i^*, and assume it admits an $(\varepsilon, \mathcal{F}_{\bar{t},B})$-CBAI-lifting to $\{F_i\}_{i \in [k]}$. Consider running a CBAI algorithm $\mathcal{A}$ on the samples obtained from $\{P_i\}$; we claim that if $\mathcal{A}$ is (α, δ)-PAC, then it must output an α-suboptimal arm for the original BAI problem. Indeed, by (ii), the samples from the BAI instance have the same law as the samples that would be obtained from the CBAI problem with $\{F_i\}$, and by (iii), the effective gaps in the CBAI problem are equal to the gaps in the original problem. Therefore, $\mathcal{A}$ must have sample complexity for this problem that is no smaller than the sample complexity of the best BAI algorithm.

Note that the $\{F_i\}$ in the above lifting need only *exist*, as we do not explicitly use these distributions but instead simply run $\mathcal{A}$ on samples from the original bandit instance. Ensuring the existence of such a lifting is the main obstacle, due the following technical yet important nuance: most BAI lower bounds are constructed from Bernoulli or Gaussian distributions, neither of which is compatible with the reduction described above. The problem with Bernoulli arms is that they do not have liftings to $\mathcal{F}_{\bar{t},B}$: any resulting F_i would not satisfy Equation 4 and thus cannot be in $\mathcal{F}_{\bar{t},B}$. Gaussian arms run into a different problem: it is not clear how to shift Gaussian arms up or down far enough to change the median by exactly the maximum uncertainty amount U_i. We overcome this nuance by considering arms with *smoothed Bernoulli distribution* $\mathrm{SBer}(p)$, which we define to be the uniform mixture between a Bernoulli distribution with parameter p and a uniform distribution over $[0,1]$. Indeed, this distribution is $(\varepsilon, \mathcal{F}_{\bar{t},B})$-CBAI-liftable: unlike the Bernoulli distribution, it is smooth enough to have liftings in $\mathcal{F}_{\bar{t},B}$; and unlike the Gaussian distribution, the median of the appropriate lifting of $\mathrm{SBer}(p)$ is exactly U_i away from the median of $\mathrm{SBer}(p)$. Both of these facts are simple calculations; see Appendix D for details.

The only ingredient remaining in the proof is to prove that there are hard instances for BAI with SBer-distributed arms, which follows easily from Lemma 1 and Remark 5 in Kaufmann et al. (2016).

5. Quality Guarantees for the Selected Arm

In the previous Section 4, we developed algorithms for CBAI and proved that they select the best (or an approximately best) arm with high probability. However, in many applications, it is desirable to also provide guarantees on the quality of the selected arm such as "with probability at least 80%, a new random variable $Y \sim F_{\hat{I}}$ is at least 10."

Such a quality guarantee could be accomplished directly using the machinery developed earlier in Subsection 4.1 by, for example, estimating the 0.2 quantile in addition to the median (the 0.5 quantile). However, this approach has two problems. First, if we would like to obtain such a guarantee for multiple probability levels (such as $55\%, 60\%, \ldots$, etc.) we would have to perform a separate estimation for each of the corresponding quantiles. Second, and more importantly, estimation of a quantile q from contaminated samples requires control of quantiles in a $\frac{\varepsilon}{2(1-\varepsilon)}$ neighborhood of q (this follows by an identical argument as in Lemma 1), which can severely restrict the range of quantiles that are possible to estimate.

We circument both of these problems by estimating the *median absolute deviation* (MAD) in addition to the median. The MAD describes the scale of the tails of a distribution away from the median and is the appropriate analogue to variance (which may not exist for F and, we stress, is not estimable from contaminated samples) for this contamination model setting.

This section is organized as follows. Subsection 5.1 develops these statistical results for estimation of the MAD from contaminated samples. Subsection 5.2 then uses these results to prove that the CBAI algorithms presented earlier in Subsection 4.2—with no additional modifications—can also provide quality guarantees for the selected arm. That is, we show that in addition to outputting the best (or an approximately best) arm, these algorithms also provide quality guarantees to a certain precision "for free" without needing extra samples.

5.1. Estimation of Second Robust Moment from Contaminated Samples

In this subsection, we develop the statistical results needed to obtain quality guarantees for the selected arm in the CBAI problem. Specifically, we consider only a single arm and obtain non-asymptotic sample-complexity bounds for estimation of the second robust moment (the MAD) from contaminated samples. We do this for all three adversarial models for the contamination (oblivious, prescient, and malicious). These results may be of independent interest to the robust statistics community.

The subsection is organized as follows. First, Subsection 5.1.1 introduces a class of distributions for which the MAD is estimable from contaminated samples. The few assumptions we make are common in the statistics literature, and we give multiple examples showing that many common distributions are included in this class. Subsection 5.1.2 then proves finite-sample guarantees for MAD estimation from contaminated samples for this class of distributions and for all three adversarial contamination settings.

5.1.1. A Class of Distributions with Estimable Second Robust Moment

Like the median, the MAD is not fully identifiable from contaminated samples (see the discussion in Section 2.2). However, we can estimate the MAD up to a reasonable region of uncertainty with only a few additional assumptions.

Definition 20 *For any $\bar{t} \in (0, \frac{1}{2})$, $B > 0$, $\bar{m}_2 > 0$, and $\kappa \geq 0$, let $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ be the family of distributions F with unique robust moments $m_1(F)$, $m_2(F)$, and $m_4(F)$ satisfying:*

(i) (4) *holds for all $x_1, x_2 \in \left[Q_{L,F}(\frac{1}{2}-\bar{t}), Q_{R,F}(\frac{1}{2}+\bar{t})\right] \cup [m_1(F) \pm 2m_2(F)]$.*

(ii) $m_2(F) \leq \bar{m}_2$.

(iii) $m_2(F) \leq \kappa m_4(F)$.

Let us make a few remarks on this definition. i) We emphasize that our CBAI algorithms already have optimality guarantees when the arm distributions are in $\mathcal{F}_{\bar{t},B}$ (see Section 4.2); the additional assumption that the arm distributions are in $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ allows us to also obtain quantile guarantees on the arm returned by the algorithm (see Section 5.2). ii) Property (iii) of the definition requires a bound on the fourth robust moment, the strength of which is dictated by the parameter κ. Informally, higher robust moments are necessary to control the error of estimation of lower robust moments, analogous to how bounds on variance (resp. kurtosis) are typically necessary for estimation of a distribution's mean (resp. variance). iii) Note that distributions in $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ are not required to have densities, nor even be continuous. iv) The family $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ satisfies some natural and expected properties, such as closure under translation. These properties are gathered and proved in Lemma 26, which is deferred to Appendix A for brevity of the main text.

Remark 21 (Examples) *Many common distributions (e.g. the normal distribution, the uniform distribution, the Cauchy distribution, etc.) belong to $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ for some values of the parameters $\bar{t}, B, \bar{m}_2$, and κ. For instance, the uniform distribution on the interval $[a,b]$ is in $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ for any $\bar{t} \in (0, \frac{1}{2})$, any $B \geq 4$, any $\kappa \geq 2$, and any $\bar{m}_2 \geq \frac{b-a}{4}$. Another example is that the Cauchy distribution with scale parameter a belongs to $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ for any $\bar{t} \in (0, \frac{1}{2})$,*

any $B \geq \pi(1+\max(1,\tan(\pi\bar{t})^2))$*, and* $\kappa \geq \sqrt{3}-1$*, and any* $\bar{m}_2 \geq a$*. We recall that a Cauchy distribution with scale parameter* $a>0$ *has density* $\frac{1}{\pi a}\frac{1}{1+\left(\frac{x-x_0}{a}\right)^2}, x\in\mathbb{R}$*, where* $x_0 \in \mathbb{R}$ *is a location parameter. For such a distribution, it is easy to check that* $m_1(F)=x_0$*,* $m_2(F)=a$ *and* $m_4(F)=a(\sqrt{3}-1)$*. Note that neither the mean nor the variance exists for the Cauchy distribution.*

5.1.2. Concentration Results for Estimation of Second Robust Moment

We are now ready to present finite-sample guarantees on the speed of convergence of the empirical MAD $\hat{m}_2$ to the underlying distribution's MAD m_2 when given contaminated samples. For brevity, proofs are deferred to Appendix B.3.

We first present results for the oblivious and prescient adversarial settings. As before, the estimation error decomposes into the sum of two terms: a bias term reflecting the uncertainty the adversary can inject given her contamination level, and a confidence-interval term that shrinks with an optimal $n^{-1/2}$ rate and has sub-Gaussian tails in δ.

Lemma 22 *Let* $\bar{t}\in(0,\frac{1}{2})$*,* $\varepsilon\in(0,\min(\bar{\varepsilon}(\bar{t}),\frac{1}{B}))$*, and* $F\in\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$*. Let* $Y_i\sim F$ *and* $D_i\sim Ber(\varepsilon)$*, for* $i\in[n]$*, all be drawn independently. Let* $\{Z_i\}_{i\in[n]}$ *be arbitrary random variables possibly depending on* $\{Y_i,D_i\}_{i\in[n]}$*, and define* $X_i=(1-D_i)Y_i+D_iZ_i$*. Then, for any confidence level* $\delta>0$*, error level* $E>0$*, and number of samples* $n\geq 2\max\left(\frac{16\kappa^2B^2\bar{m}_2^2}{E^2},\left(\min(\bar{t},\frac{1}{B})-\frac{\varepsilon}{2(1-\varepsilon)}\right)^{-2}\right)\log\frac{4}{\delta}$*,*

$$\mathbb{P}\left(|\hat{m}_2(X_1,\dots,X_n)-m_2(F)|\leq(1+2\kappa)U_{\varepsilon,B,m_2(F)}+E\right)\geq 1-\delta.$$

Similar to median estimation above, it is possible to estimate the MAD even in the malicious adversarial setting.

Lemma 23 *Let* $\bar{t}\in(0,\frac{1}{2})$*,* $\varepsilon\in(0,\min(\bar{t},\frac{1}{B}))$*, and* $F\in\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$*. Let* (Y_i,D_i)*, for* $i\in[n]$*, be drawn independently with marginals* $Y_i\sim F$ *and* $D_i\sim Ber(\varepsilon)$*. Let* $\{Z_i\}_{i\in[n]}$ *be arbitrary random variables possibly depending on* $\{Y_i,D_i\}_{i\in[n]}$*, and define* $X_i=(1-D_i)Y_i+D_iZ_i$*. Then, for any confidence level* $\delta>0$*, error level* $E>0$*, and number of samples* $n\geq 2\max\left(\frac{16\kappa^2B^2\bar{m}_2^2}{E^2},\left(\min(\bar{t},\frac{1}{B})-\varepsilon\right)^{-2}\right)\log\frac{6}{\delta}$*,*

$$\mathbb{P}\left(|\hat{m}_2(X_1,\dots,X_n)-m_2(F)|\leq(1+2\kappa)U^{(\text{MALICIOUS})}_{\varepsilon,B,m_2(F)}+E\right)\geq 1-\delta.$$

5.2. Algorithmic Guarantees

We now apply these statistical results for MAD estimation to show that the CBAI algorithms presented earlier in Subsection 4.2—with no additional modifications—can also provide quality guarantees for the arm they select. That is, we show that in addition to outputting the best (or an approximately best) arm, these algorithms also provide quality guarantees to a certain precision "for free" without needing extra samples.

For simplicity, we will focus on error guarantees for Algorithm 1. A nearly identical (yet technically hairier) argument yields a similar guarantee for our adaptation of the Successive Elimination algorithm for CBAI (Algorithm 3).

We will make the assumption that the arms distributions are in $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ so that the MAD estimation results proved above will apply. The parameters of this family are assumed to be known to the algorithm beforehand. Distributions in $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ have the following property that their lower tails are controlled by their median and MAD.

Lemma 24 *Let* $F\in\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ *and* $Y\sim F$*. Then simultaneously for all* $t\in[0,\bar{t}]$*,*

$$\mathbb{P}\Big(Y\geq m_1(F)-tBm_2(F)\Big)\geq\tfrac{1}{2}+t.$$

Proof By item (6) of Lemma 26, we have that for all $t\in[0,\bar{t}]$, $t=\frac{1}{2}-(\frac{1}{2}-t)\geq\frac{1}{Bm_2(F)}(F^{-1}(\frac{1}{2})-F^{-1}(\frac{1}{2}-t))$. Rearranging yields $F^{-1}(\frac{1}{2}-t)\geq m_1(F)-Bm_2(F)t$ and completes the proof. ■

With this lemma in hand, we turn to guarantees for the arm returned by Algorithm 1. The following guarantees hold for all adversarial settings since the adversarial strength is encapsulated in the definition of the unavoidable uncertainty terms $U_{\hat{i}}$.

Theorem 25 *Let* $F_1,\dots,F_k\in\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$*. Let* $\varepsilon\in(0,\min(\frac{2\bar{t}}{1+2\bar{t}},\frac{1}{B}))$ *and* $\bar{U}:=U_{\varepsilon,B,\bar{m}_2}$ *if the adversary is oblivious or prescient, or let* $\varepsilon\in(0,\min(\bar{t},\frac{1}{B}))$ *and* $\bar{U}:=U^{(\text{MALICIOUS})}_{\varepsilon,B,\bar{m}_2}$ *if the adversary is malicious. Consider using Algorithm 1 for* CBAI *exactly as in Theorem 2. Let* $\hat{I}$ *denote the arm it outputs, let* Y *be a random variable whose conditional distribution on* $\hat{I}$ *is* $F_{\hat{I}}$*, and let* $\hat{m}_1$ *and* $\hat{m}_2$ *denote the empirical median and MAD, respectively, from the samples it has seen from* $F_{\hat{I}}$*. Then, simultaneously for all* $t\in[0,\bar{t}]$*,*

$$\mathbb{P}\Big(Y\geq(\hat{m}_1-tB\hat{m}_2)-\big((\tfrac{1}{2}+2\kappa tB)\alpha+(1+(1+2\kappa)Bt)\bar{U}\big)\Big)\geq\tfrac{1}{2}+t-\tfrac{3\delta}{k}.$$

Proof By definition of Algorithm 1, $\hat{I}$ is sampled $n_{\alpha/2,\delta/k}=2\max(\frac{4B^2\bar{m}_2^2}{\alpha^2},(\bar{t}-\frac{\varepsilon}{2(1-\varepsilon)})^{-2})\log\frac{2k}{\delta}$ times against oblivious and prescient adversaries, and $n_{\alpha/2,\delta/k}=2\max\left(\frac{4B^2\bar{m}_2^2}{\alpha^2},(\bar{t}-\varepsilon)^{-2}\right)\log\frac{3k}{\delta}$ times against malicious adversaries. Therefore—by Corollary 14 and Lemma 22 for oblivious and prescient adversaries, or similarly by Corollary 15 and Lemma 23 for malicious adversaries—we have by a union bound that with probability at least $1-\frac{3\delta}{k}$, both of the following inequalities hold:

$$\begin{aligned}&m_1(F_{\hat{I}})\geq\hat{m}_1-\bar{U}-\tfrac{\alpha}{2},\ \text{ and}\\&m_2(F_{\hat{I}})\leq\hat{m}_2+(1+2\kappa)\bar{U}+2\kappa\alpha.\end{aligned}$$

Whenever this event occurs, we have

$$m_1(F_{\hat{I}})-tBm_2(F_{\hat{I}})\geq(\hat{m}_1-tB\hat{m}_2)-\big((\tfrac{1}{2}+2\kappa tB)\alpha+(1+(1+2\kappa)Bt)\bar{U}\big).$$

Applying Lemma 24 and taking a union bound completes the proof. ■

Note that the bound inside the probability term in Theorem 25 can be far less conservative than the crude bound $\hat{m}_1-tB\bar{m}_2$ if ε and α are small.

6. Conclusion

In this paper, we proposed the Best Arm Identification problem for contaminated bandits (CBAI). This setup can model many practical applications that cannot be modeled by the classical bandit setup. On the way to efficient algorithms for CBAI, we developed tight, non-asymptotic sample-complexity bounds for estimation of the first two robust moments (median and median absolute deviation) from contaminated samples. These results may be of independent interest, perhaps as ingredients for adapting other online learning techniques to similar contaminated settings.

We formalized the contaminated bandit setup as a special case of the more general partially identifiable bandit problem (PIBAI), and presented ways to adapt celebrated Best Arm Identification algorithms for the classical bandit setting to this PIBAI problem. The sample complexity is essentially changed only by replacing the suboptimality "gaps" with suboptimality "effective gaps" to adjust for the challenge of partial identifiability. We then showed how these algorithms apply to the special case of CBAI by making use of the aforementioned guarantees for estimating the median from contaminated samples. We complemented these results with nearly matching information-theoretic lower bounds on the sample complexity of CBAI, showing that (up to a small logarithmic factor) our algorithms are optimal. This answers the question this paper set out to solve: determining the complexity of finding the arm with highest median given contaminated samples. Finally, we used our statistical results on estimation of the second robust moment from contaminated samples to show that without additional samples, our algorithms can also output quality guarantees on the selected arm.

Our paper suggests several potential directions for future work.

- Our upper and lower bounds on the sample complexity of CBAI are off by a logarithmic factor in the number of arms. It is an interesting open question to close this gap, especially since many of the tricks for doing this in the classical BAI setup do not seem to extend to this partially identifiable setting (see Remark 4). One concrete possibility is to obtain a tighter upper bound by adapting the algorithm of (Jamieson et al., 2014) to the CBAI problem. This would require proving a non-asymptotic version of the Law of the Iterated Logarithm for empirical medians, which would be of independent interest.

- We have developed algorithms for online learning in the presence of partial identifiability. How far does this toolkit extend? In particular, do our results apply to more complicated or more general feedback structures such as partial monitoring (see e.g. (Bartók et al., 2014)) or graph feedback (see e.g. (Alon et al., 2017))?

- The contaminated bandit setup models many real-world problems that cannot be modeled by the classical bandit setup. Is it applicable and approachable to formulate other classical online-learning problems in similar contamination setups?

- More abstractly, we think that problems at the intersection of online learning and robust statistics are not only mathematically rich, but also are increasingly relevant, given the recent influx of active learning tasks with data that are not completely trustworthy. It may be valuable to use techniques from one of the fields to approach problems in the other, as we did here.

Appendix A. Properties of $\mathcal{F}_{\bar{t},B}$ and $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$

The following lemma lists some simple properties of $\mathcal{F}_{\bar{t},B}$ (defined in Definition 10) and $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$ (defined in Definition 20), which we use often throughout the paper.

For shorthand, we denote $I_{F,\bar{t}} := \left[Q_{L,F}(\frac{1}{2}-\bar{t}), Q_{R,F}(\frac{1}{2}+\bar{t})\right]$ for a distribution F and a real number $\bar{t} \in (0, \frac{1}{2})$.

Lemma 26 *If $F \in \mathcal{F}_{\bar{t},B}$, then:*

1. *For any $a \neq 0$ and $b \in \mathbb{R}$, the distribution $F(a \cdot + b)$ is also in $\mathcal{F}_{B,\bar{t}}$.*
2. *F is strictly monotonically increasing in $I_{F,\bar{t}}$.*
3. *$Q_{L,F}(t) = Q_{R,F}(t)$, for all $t \in F(I_{F,\bar{t}}) = [\frac{1}{2} \pm \bar{t}]$.*
4. *$Q_{L,F}(F(x)) = x$ for all $x \in I_{F,\bar{t}}$ and we write F^{-1} for $Q_{L,F} = Q_{R,F}$.*
5. *The left and right quantiles of F are equal in the interval $F(I_{F,\bar{t}}) = [\frac{1}{2}-\bar{t}, \frac{1}{2}+\bar{t}]$.*
6. *For any $u_1, u_2 \in F(I_{F,\bar{t}}) = [\frac{1}{2}-\bar{t}, \frac{1}{2}+\bar{t}]$,*

$$|u_1 - u_2| \geq \frac{1}{Bm_2(F)} |F^{-1}(u_1) - F^{-1}(u_2)|.$$

Moreover if we also have $F \in \mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$, then:

7. *For any $a \neq 0$ and $b \in \mathbb{R}$, the distribution $F(a \cdot + b)$ is in $\mathcal{F}_{B,\bar{t},a\bar{m}_2,\kappa}$.*
8. *Let H be the distribution of $|Y - m|$, where $Y \sim F$. Then $H \in \mathcal{F}_{\bar{t}_H,B_H}$, where $B_H := \kappa B$ and $\bar{t}_H := \min(\frac{1}{2}, \frac{2}{B})$.*

Proof When proved in order, all of these statements follow easily from the definition of the function class and the earlier statements. The only part requiring effort is item 8, which we

now verify. Fix any $r_1, r_2 \in I_{H,\bar{t}_H}$, where without loss of generality $r_1 \geq r_2 \geq 0$. Then

$$\begin{aligned}
H(r_1) - H(r_2) &= \mathbb{P}(|Y - m_1(F)| \leq r_1) - \mathbb{P}(|Y - m_1(F)| \leq r_2) \\
&= [\mathbb{P}(Y \leq m_1(F) + r_1) - \mathbb{P}(Y \leq m_1(F) + r_2)] \\
&\quad + [\mathbb{P}(Y < m_1(F) - r_2) - \mathbb{P}(Y < m_1(F) - r_1)] \\
&\geq F(m_1(F) + r_1) - F(m_1(F) + r_2) \\
&\geq \frac{|r_1 - r_2|}{Bm_2(F)} \qquad (5) \\
&\geq \frac{|r_1 - r_2|}{\kappa B m_4(F)} \\
&= \frac{|r_1 - r_2|}{B_H m_2(H)}.
\end{aligned}$$

The only step requiring justification is the inequality in (5): this is evident by (4) if $r_1, r_2 \in [m_1(F) \pm 2m_2(F)]$, but this condition must be checked. Once we show this condition is met, we are immediately done.

Therefore, it is now sufficient to prove that $r_1, r_2 \in [m_1(F) \pm 2m_2(F)]$. Since $r_1, r_2 \geq 0$, it suffices to show that the largest value in $I_{H,\bar{t}_H}$, namely $Q_{R,H}(\frac{1}{2} + \bar{t}_H)$, is at most $2m_2(F)$. And to show this, it suffices to show $\frac{1}{2} + \bar{t}_H < H(2m_2(F))$. We show this last inequality presently: by an similar argument as in the first few lines of the above display,

$$\begin{aligned}
H(2m_2(F)) - \tfrac{1}{2} &= H(2m_2(F)) - H(m_2(F)) \\
&= [\mathbb{P}(Y \leq m_1(F) + 2m_2(F)) - \mathbb{P}(Y \leq m_1(F) + m_2(F))] \\
&\quad + \mathbb{P}(Y \in [m_1(F) - 2m_2(F), m_1(F) - m_2(F))) \\
&> F(m_1(F) + 2m_2(F)) - F(m_1(F) + m_2(F)) \qquad (6) \\
&\geq \frac{1}{B} \qquad (7) \\
&\geq \bar{t}_H,
\end{aligned}$$

where (6) is because F is monotonically increasing in $[m_1(F) - 2m_2(F), m_1(F) + 2m_2(F)]$ by property (i) in the definition of $\mathcal{F}_{\bar{t},B,\bar{m}_2,\kappa}$, and (7) is due to (4). This completes the proof. ■

Appendix B. Proofs for Estimation from Contaminated Samples

Throughout, we denote the indicator random variable for an event $\mathcal{E}$ by $\mathbb{1}\{\mathcal{E}\}$.

B.1. Estimation of Median for Oblivious and Prescient Adversaries

Proof of Lemma 7 For shorthand, let $\hat{m} := \hat{m}_1(X_1, \ldots, X_n)$ and let $m \in m_1(F)$ be any median of F. For each $i \in [n]$, define the indicator random variable

$$L_i := \mathbb{1}\left\{(D_i = 1) \text{ or } \left(D_i = 0 \text{ and } Y_i \geq Q_{R,F}\left(\tfrac{1}{2(1-\varepsilon)} + a\right)\right)\right\},$$

where $a := \frac{\sqrt{\log(2/\delta)}}{(1-\varepsilon)\sqrt{2n}} < \sqrt{\frac{2\log(2/\delta)}{n}}$. By independence of D_i and Y_i, L_i has mean

$$\mathbb{E}[L_i] = \varepsilon + (1-\varepsilon)\left(1 - \left(\tfrac{1}{2(1-\varepsilon)} + a\right)\right) = \tfrac{1}{2} - (1-\varepsilon)a.$$

Moreover, the $\{L_i\}_{i\in[n]}$ are independent, and thus by Hoeffding's inequality,

$$\mathbb{P}\left(\hat{m} \geq Q_{R,F}\left(\frac{1}{2(1-\varepsilon)} + a\right)\right) \leq \mathbb{P}\left(\sum_{i=1}^n L_i \geq \frac{n}{2}\right) \leq \exp\left(-2n(1-\varepsilon)^2 a^2\right) = \frac{\delta}{2}.$$

Therefore, with probability at least $1 - \frac{\delta}{2}$,

$$\hat{m} - m < Q_{R,F}\left(\frac{1}{2(1-\varepsilon)} + a\right) - Q_{R,F}\left(\frac{1}{2}\right) \leq R\left(\frac{\varepsilon}{2(1-\varepsilon)} + a\right),$$

where the final inequality is due to (3), which we may invoke since $\frac{1}{2} + \frac{\varepsilon}{2(1-\varepsilon)} + a \leq \frac{1}{2} + \bar{t}$ by our choice of n. An identical argument (or by symmetry with $-F$) yields the analogous result for the lower tail of $\hat{m}$, namely that $m - \hat{m} < R(\frac{\varepsilon}{2(1-\varepsilon)} + a)$ with probability at least $1 - \frac{\delta}{2}$. The lemma statement follows by a union bound. ■

B.2. Estimation of Median for Malicious Adversaries

We now turn to providing the proofs of Lemma 8 and 9. Below, it will be convenient to denote by $y_{(k)}$ the k-th order statistic of a (possibly random) sequence $y_1, \ldots, y_n \in \mathbb{R}$.

Informally, the proof of Lemma 8 proceeds by (i) showing that $\hat{m}_1(X_1, \ldots, X_n)$ is deterministically bounded within the order statistics $Y_{(\lfloor \frac{n}{2} \rfloor \pm \sum_{i=1}^n D_i)}$ (Lemma 27), (ii) applying Hoeffding's inequality to argue that w.h.p., at most $\sum_{i=1}^n D_i \approx \varepsilon n$ samples are contaminated, and (iii) reusing the techniques of Lemma 7 to argue that w.h.p., the order statistics of $Y_{(\lfloor \frac{n}{2} \rfloor \pm \varepsilon n)}$ are within the desired error range from $m_1(F)$. Since each of these steps is tight up to a small amount of slack, the proof of the converse Lemma 9 proceeds essentially by just showing that each of these steps occurs also in the opposite direction w.h.p.

The following lemma will be helpful for step (i). Its proof is straightforward by induction on s and is thus omitted.

Lemma 27 *Let $x_i := d_i y_i + (1 - d_i) z_i$, where $y_1 \leq \cdots \leq y_n$ and $z_1, \ldots, z_n$ are arbitrary real-valued sequences, and $d_1, \ldots, d_n$ is an arbitrary binary-valued sequence satisfying $s := \sum_{i=1}^n d_i < \frac{n}{2}$. Then*

$$y_{(\lfloor \frac{n}{2} \rfloor - s)} \leq \hat{m}_1(x_1, \ldots, x_n) \leq y_{(\lceil \frac{n}{2} \rceil + s)}.$$

Proof of Lemma 8 Define for shorthand $a := \sqrt{\frac{\log(3/\delta)}{2n}}$. By Hoeffding's inequality, the event $E := \{\sum_{i=1}^n D_i \leq (\varepsilon + a)n\}$ occurs with probability at least $\mathbb{P}(E) \geq 1 - \frac{\delta}{3}$. Since $\varepsilon + a \leq \bar{t} < \frac{1}{2}$ by our choice of n, Lemma 27 implies that, whenever E occurs,

$$Y_{(\lfloor \frac{n}{2} \rfloor - \lfloor (\varepsilon+a)n \rfloor)} \leq \hat{m}_1(X_1, \ldots, X_n) \leq Y_{(\lceil \frac{n}{2} \rceil + \lfloor (\varepsilon+a)n \rfloor)}$$

also occurs. Now, define for each $i \in [n]$ the indicator random variable $L_i := \mathbb{1}\left\{Y_i > Q_{R,F}(\frac{1}{2}+\varepsilon+2a)\right\}$. Then $\mathbb{E}[L_i] \le \frac{1}{2}-\varepsilon-2a$, so by Hoeffding's inequality,

$$\mathbb{P}\left(Y_{\left(\lceil \frac{n}{2}\rceil + \lfloor(\varepsilon+a)n\rfloor\right)} > Q_{R,F}(\tfrac{1}{2}+\varepsilon+2a)\right) \le \mathbb{P}\left(\sum_{i=1}^n L_i \ge (\tfrac{1}{2}-\varepsilon-a)n\right) \le \exp(-2na^2) = \frac{\delta}{3}.$$

An identical argument (or simply by symmetry on $F(-\cdot)$) also yields that $Y_{\left(\lfloor \frac{n}{2}\rfloor - \lfloor(\varepsilon+a)n\rfloor\right)} < Q_{L,F}(\frac{1}{2}-\varepsilon-2a)$ with probability at most $\frac{\delta}{3}$. We conclude by a union bound that with probability at least $1-\delta$,

$$Q_{L,F}\left(\tfrac{1}{2}-(\varepsilon+2a)\right) \le \hat{m}_1(X_1,\dots,X_n) \le Q_{R,F}\left(\tfrac{1}{2}+(\varepsilon+2a)\right).$$

Whenever this occurs, we have by virtue of (3) that $\sup_{m\in m_1(F)} |\hat{m}_1(X_1,\dots,X_n) - m| \le R(\varepsilon+2a)$, since both $\frac{1}{2}\pm(\varepsilon+2a) \in [\frac{1}{2}\pm\bar{t}]$ by our choice of n. ■

Proof of Lemma 9 Consider any distribution F with unique median 0 satisfying $R(t) = Q_{R,F}(\frac{1}{2}+t) = -Q_{L,F}(\frac{1}{2}-t)$ for each $t \in \bar{t}$. Such an F can be constructed by starting with a Dirac measure δ_0 at zero and then pushing mass to the tails as far as Equation 3 allows. Next, consider the joint distribution on (D,Y,Z) where $Y \sim F$, the conditional distribution of D given Y is $\mathrm{Ber}(2\varepsilon \cdot \mathbb{1}\{Y \le 0\})$ and $Z \sim \delta_{Q_{R,F}(\frac{1}{2}+\varepsilon)}$. The marginal of D is easily seen to be correct, since

$$\mathbb{P}(D=1) = \mathbb{P}(D=1|Y\le 0)\cdot\mathbb{P}(Y\le 0) + \mathbb{P}(D=1|Y>0)\cdot\mathbb{P}(Y>0) = 2\varepsilon\cdot\tfrac{1}{2} = \varepsilon.$$

Let $a := \sqrt{\frac{\log(1/\delta)}{2n}}$, and note that $a < \varepsilon$ by our choice of n. For each $i \in [n]$, define the indicator random variable

$$L_i := \mathbb{1}\left\{(Y_i > R(\varepsilon-a)) \text{ or } (Y_i \le 0 \text{ and } D_i = 1)\right\}.$$

Each of these has mean

$$\mathbb{E}[L_i] \le 1 - (\tfrac{1}{2}+(\varepsilon-a)) + \tfrac{1}{2}(2\varepsilon) = \tfrac{1}{2}+a.$$

Therefore, by Hoeffding's inequality, we conclude that

$$\begin{aligned}\mathbb{P}\Big(|\hat{m}_1(X_1,\dots,X_n) - m_1(F)| < R(\varepsilon-a)\Big) &\le \mathbb{P}\Big(\hat{m}_1(X_1,\dots,X_n) < m_1(F) + R(\varepsilon-a)\Big)\\ &\le \mathbb{P}\left(\sum_{i=1}^n L_i \ge \frac{n}{2}\right) \le \exp\left(-2a^2n\right) = \delta.\end{aligned}$$

■

B.3. Estimation of Second Robust Moment

Here, we prove Lemma 22. This is done by decomposing the MAD estimation error into two terms, each of which resembles the error between a true median (of a distribution related to F) and an empirical median of contaminated samples, and then applying the median estimation guarantees from the previous section. We begin by proving several helpful lemmas.

Lemma 28 *For any (possibly random) sequence $x_1,\dots,x_n \in \mathbb{R}$ and any $c \in \mathbb{R}$,*

$$\left|\hat{m}_1(|x_1+c|,\dots,|x_n+c|) - \hat{m}_1(|x_1|,\dots,|x_n|)\right| \le |c|$$

holds almost surely, over the possible randomness of the sequence.

Proof For any fixed vector $x \in \mathbb{R}^n$, the function $c \mapsto \hat{m}_1(|x_1+c|,\dots,|x_n+c|)$ is 1-Lipschitz since it is the composition of the following 1-Lipschitz functions with respect to the L_∞ norm: adding $c\vec{1}$, taking entrywise absolute values, and taking an order statistic. ■

We also give the following distributional version of Lemma 28.

Lemma 29 *Consider any real-valued random variable X and any $c \in \mathbb{R}$. Assume that $m_1(|X|)$ and $m_1(|X+c|)$ are unique. Then*

$$\left|m_1(|X+c|) - m_1(|X|)\right| \le |c|.$$

Proof Assume without loss of generality that $c \ge 0$; the case $c < 0$ follows by an identical argument or by symmetry. For shorthand, let $m := m_1(|X|)$ and let $\tilde{m} := m_1(|X+c|)$. First, we show that $\tilde{m} \le m+c$, i.e., we show that $\mathbb{P}(|X+c| \le m+c) \ge \frac{1}{2}$. This is straightforward: $\mathbb{P}(|X+c| \le m+c) = \mathbb{P}(-m-2c \le X \le m) \ge \mathbb{P}(-m \le X \le m) = \mathbb{P}(|X| \le m) \ge \frac{1}{2}$, where we the first step is by non-negativity of m and the last step is by definition of m. A nearly identical argument shows $m \le \tilde{m}+c$, namely $\mathbb{P}(|X| \le \tilde{m}+c) = \mathbb{P}(-\tilde{m}-c \le X \le \tilde{m}+c) = \mathbb{P}(-\tilde{m} \le X \le \tilde{m}+2c) \ge \mathbb{P}(-\tilde{m} \le X \le \tilde{m}) = \mathbb{P}(|X| \le \tilde{m}) \ge \frac{1}{2}$. We therefore conclude that $|\tilde{m}-m| \le c$. ■

Lemma 30 *For any distribution F with unique $m_2(F)$ and $m_4(F)$,*

$$m_4(F) \le 2m_2(F).$$

Proof Let $Y \sim F$. By Lemma 29,

$$m_4(F) = m_1\left(\big||Y-m_1(F)| - m_2(F)\big|\right) \le m_1\left(|Y-m_1(F)|\right) + m_2(F) = 2m_2(F).$$

■

We are now ready to prove Lemma 22.

Proof of Lemma 22 For shorthand, denote $\hat{m} := \hat{m}_1(X_1, \ldots, X_n)$, and let H denote the distribution of $|Y - m_1(F)|$ where $Y \sim F$. Combining the fact that $m_2(F) = m_1(H)$ with Lemma 28 and the triangle inequality, the MAD estimation error is bounded above by

$$\begin{aligned}
&\left|\hat{m}_2(X_1, \ldots, X_n) - m_2(F)\right| \\
&= \left|\hat{m}_1\left(|X_1 - \hat{m}|, \ldots, |X_n - \hat{m}|\right) - m_1(H)\right| \\
&\leq \left|\hat{m}_1\left(|X_1 - m_1(F)|, \ldots, |X_n - m_1(F)|\right) - m_1(H)\right| + \left|\hat{m} - m_1(F)\right|. \qquad (8)
\end{aligned}$$

By Corollary 14 and our choice of n, the second error term in (8) is bounded above by $U_{\varepsilon,B,m_2(F)} + \frac{E}{2}$ with probability at least $1 - \frac{\delta}{2}$. To control the first error term in (8), we apply Corollary 14 with the distribution H in lieu of F and the contaminations $\tilde{Z}_i := |Z_i - m_1(F)|$ in lieu of Z_i. Thus, by combining item 8 in Lemma 26 with Corollary 14, this first error term is bounded above by $U_{\varepsilon,\kappa B,m_2(H)} + \frac{E}{2}$ with probability at least $1 - \frac{\delta}{2}$ whenever we have at least $2\max\left(4B^2\kappa^2 m_2^2(H)E^{-2}, (\min(\frac{1}{2}, \frac{1}{B}) - \frac{\varepsilon}{2(1-\varepsilon)})^{-2}\right)\log\frac{4}{\delta}$ samples, which is satisfied because of our choice of n and the inequality $m_2(H) = m_4(F) \leq 2m_2(F)$ from Lemma 30. Therefore, a union bound implies that, with probability at least $1 - \delta$, the MAD estimation error is at most $U_{\varepsilon,B,m_2(F)} + U_{\varepsilon,\kappa B,m_2(H)} + E$. By another application of the inequality $m_2(H) \leq 2m_2(F)$, this is bounded above by $(1 + 2\kappa)U_{\varepsilon,B,m_2(F)} + E$, as desired. ■

The proof of Lemma 23—the analogous result to Lemma 22 but for the *malicious* adversarial setting—is omitted since it is identical to the proof of Lemma 22 with the uses of Corollary 14 replaced by uses of Corollary 15.

Appendix C. Proofs for Adaptation of the Successive Elimination Algorithm

We first define some notation. Let c be a constant such that $n_{\alpha,\delta} \leq \frac{c}{\alpha^2}\log\frac{1}{\delta}$ for all $\alpha > 0$ and $\delta \in (0,1)$; such a constant clearly exists by definition of PIBAI (see Equation 2). Let R denote the number of total rounds in Algorithm 2 before termination, and for each round $r \in [R]$, let S_r denote the set of all arms still in S when entering round r. For succintness, we also denote $\delta_r := \frac{6\delta}{\pi^2 k r^2}$.

Proof of Theorem 3 Without loss of generality, assume that the best arm is $i^* = 1$. Define the event $E := \{|\hat{p}_{i,r} - p_i| \leq U_i + \alpha_{r,\delta_r}, \forall r \geq 1, \forall i \in S_r\}$. Recall that $\hat{p}_{i,r}$ is the estimate of the measure of quality for arm i after r samples, and that arm i will stop being pulled once $i \notin S_r$. For analysis purposes, consider consider virtual estimates $\hat{p}_{i,r}$ that would be obtained if we continued to pull the eliminated arms indefinitely, so that $\hat{p}_{i,r}$ is defined for all $i \in [k]$ and $r \in \mathbb{N}$. By a union bound,

$$\mathbb{P}\left(E^C\right) \leq \sum_{i=1}^{k}\sum_{r=1}^{\infty}\mathbb{P}\left(|\hat{p}_{i,r} - p_i| > U_i + \alpha_{r,\delta_r}\right) \leq \sum_{i=1}^{k}\sum_{r=1}^{\infty}\delta_r = \sum_{i=1}^{k}\sum_{r=1}^{\infty}\frac{6\delta}{\pi^2 k r^2} = \delta,$$

where above we have used (2) and the famous Basel identity.

We conclude from the above that E occurs with probability at least $1 - \delta$. Henceforth let us assume that E occurs. A simple induction argument shows that $1 \in S_r$ for each round $r \in [R]$, which implies that Algorithm 2 returns the optimal arm. Indeed, at each round r for which $1 \in S_r$, E guarantees that for all $j \in S_r$,

$$\hat{p}_{1,r} \geq p_1 - U_1 - \alpha_{r,\delta_r} = \tilde{\Delta}_j + p_j + U_j - \alpha_{r,\delta_r} > p_j + U_j - \alpha_{r,\delta_r} \geq \hat{p}_{j,r} - 2\alpha_{r,\delta_r}.$$

and so by definition of Algorithm 2, the optimal arm 1 is not eliminated at round r.

Now, still assuming that E occurs, let us bound the sample complexity T. For each $i \in [k]$, denote by T_i the number of times that arm i is pulled. Clearly, $T = \sum_{i=1}^{k} T_i$. Moreover, since arm 1 is never eliminated so long as E occurs, $T \leq 2\sum_{i=2}^{k} T_i$. For each $i \geq 2$, arm i is eliminated no later than the first round r in which $\hat{p}_{i,r} < \hat{p}_{1,r} - 2\alpha_{r,\delta_r}$ which, by E, is satisfied as soon as $p_i + U_i + \alpha_{r,\delta_r} < p_1 - U_1 - 3\alpha_{r,\delta_r}$, or equivalently $\tilde{\Delta}_i > 4\alpha_{r,\delta_r}$. We conclude that arm i is eliminated in the first round r where

$$\tilde{\Delta}_i > 4\alpha_{r,\delta_r} = 4\sqrt{\frac{c\log(\frac{\pi^2 k r^2}{6\delta})}{r}},$$

which occurs for $r \leq C\frac{1}{\tilde{\Delta}_i^2}\log\left(\frac{k}{\delta\tilde{\Delta}_i}\right)$ for some universal constant $C > 0$. Hence,

$$T \leq \sum_{j=2}^{k} T_j = O\left(\sum_{j=2}^{k}\frac{1}{\tilde{\Delta}_i^2}\log\left(\frac{k}{\delta\tilde{\Delta}_i}\right)\right).$$

■

Proof of Theorem 17 The proof is nearly identical to that of Theorem 3. The main difference in the proof of correctness is that at each round $r \geq 0$, if any arm is still in S_r, it has been pulled at least

$$\begin{aligned}
N\log\left(\frac{\pi^2 k}{2\delta}\right) + 2N\sum_{t=1}^{r}\log\left(\frac{t+1}{t}\right) + r &= N\log\left(\frac{\pi^2 k(r+1)^2}{2\delta}\right) + r \\
&\geq \left(\frac{2B^2\bar{m}_2^2}{\alpha_{r,\delta_r}^2} + N\right)\log\frac{3}{\delta_r} \\
&\geq \max\left(\frac{2B^2\bar{m}_2^2}{\alpha_{r,\delta_r}^2}, N\right)\log\frac{3}{\delta_r}
\end{aligned}$$

times. Thus, we may apply Corollary 14 (for oblivious or prescient adversaries) or Corollary 15 (for malicious adversaries) to obtain the identical guarantees as needed in the proof of Theorem 3 for estimating the median up to accuracy α_{r,δ_r} with probability at least $1 - \delta_r$. Hence, the $(0,\delta)$-PAC guarantee follows easily by identical reasoning. The only difference in the sample complexity proof is that it we must keep track of the additional draws

$$\sum_{i=1}^{k}\left[\left\lceil N\log\left(\frac{\pi^2 k}{2\delta}\right)\right\rceil + \sum_{t=1}^{T_i}\left\lceil 2N\log\left(\frac{t+1}{t}\right)\right\rceil\right] \leq \sum_{i=1}^{k}\left[(T_i+1) + N\log\left(\frac{\pi^2 k(T_i+1)^2}{2\delta}\right)\right],$$

where T_i is the number of times that arms i is pulled. By what was shown in Theorem 3, the first term $\sum_{i=1}^{k}(T_i+1) = O(\sum_{i\neq i^*}\frac{1}{\Delta_i^2}\log(\frac{k}{\delta\Delta_i}))$, and the second term $\sum_{i=1}^{k} N\log(\frac{\pi^2 k(T_i+1)^2}{2\delta}) = O(N\sum_{i\neq i^*}\log(\frac{k}{\delta\Delta_i}\log(\frac{k}{\delta\Delta_i}))) = O(N\sum_{i\neq i^*}\log(\frac{k}{\delta\Delta_i}))$. ■

Appendix D. Proofs for Lower Bounds

In this section, we make the proof sketch in Subsection 4.3 formal. The proof is broken into two parts. First, we exhibit hard instances for BAI in which the arms all have smoothed Bernoulli distributions. Second, we reduce this instance into a lower bound instance for CBAI.

Throughout, we adopt the standard assumption in the multi-armed bandit literature (Mannor and Tsitsiklis, 2004) that all algorithms we consider have a stopping time T which is almost surely finite.

D.1. BAI Lower Bound

Here, we prove a gap-dependent lower bound for the BAI problem that we will make use of in the following subsection. Mannor and Tsitsiklis (2004) gave the first such lower bound by exhibiting hard instances for BAI using Bernoulli-distributed arms. However, our CBAI reduction will not work with Bernoulli distributions (see the proof sketch in Subsection 4.3), and so here we exhibit hard instances for BAI using instead a distribution that will work for our CBAI reduction, namely the smoothed Bernoulli distribution.

Recall that we define the smoothed Bernoulli distribution with parameter $p \in (0,1)$, denoted by $\mathrm{SBer}(p)$, to be the uniform mixture of the Bernoulli distribution with parameter p and the uniform distribution on $[0,1]$ with weights $\frac{1}{2}$ and $\frac{1}{2}$. It is easy to see that for $p, q \in (0,1)$, the Kullback-Leibler divergence between $\mathrm{SBer}(p)$ and $\mathrm{SBer}(q)$ is given by

$$\begin{aligned}\mathsf{KL}(\mathrm{SBer}(p), \mathrm{SBer}(q)) &= \frac{1}{2}\mathsf{KL}(\mathrm{Ber}(p), \mathrm{Ber}(q)) \\ &= \frac{1}{2}\left(p\log\left(\frac{p}{q}\right) + (1-p)\log\left(\frac{1-p}{1-q}\right)\right).\end{aligned}$$

In particular, a second-order Taylor expansion yields that, for all $\eta \in (0, \frac{1}{2})$, there exists some positive constant C_η such that the inequality

$$\mathsf{KL}(\mathrm{SBer}(p), \mathrm{SBer}(q)) \leq C_\eta (p-q)^2 \tag{9}$$

holds for all $p, q \in [\eta, 1-\eta]$.

With Equation 9 in hand, the following lemma becomes a direct consequence of Lemma 1 and Remark 5 from Kaufmann et al. (2016).

Lemma 31 *Let $k \geq 2$, $\eta \in (0, \frac{1}{2})$, and $p_1, \ldots, p_k \in [\eta, 1-\eta]$. Consider the instance of* BAI *where arm $i \in [k]$ has distribution $SBer(p_i)$. Then, for any $\alpha > 0$ and any $\delta \in (0, \frac{3}{20})$, any (α, δ)-PAC* BAI *algorithm must use at least the following number of samples in expectation:*

$$\mathbb{E}[T] \geq \frac{C_\eta}{4}\left(\sum_{i\in[k]\setminus\{i*\}} \frac{1}{\max(\Delta_i, \alpha)^2}\log\left(\frac{1}{2.4\delta}\right)\right),$$

where $i^* := \arg\max_{i\in[k]} p_i$, and $\Delta_i := p_{i^*} - p_i$ for each $i \in [k]\setminus\{i^*\}$.

D.2. CBAI Lower Bound

In this subsection, we show how to prove the lower bounds for CBAI using the technique sketched in Subsection 4.3. In particular, we will show how to prove Theorem 18 by "CBAI-lifting" the MAB instances we proved were hard in Lemma 31. The proof of Corollary 19 then follows immediately by letting $\alpha \to 0$; since an algorithm that returns the *best* arm with probability at least $1-\delta$, is by definition a $(0,\delta)$-PAC algorithm.

Proof of Theorem 18 Fix any $k \geq 2$, $\delta \in (0, \frac{3}{20})$, $\alpha \in (0, \frac{1}{6})$, $\varepsilon \in (0, \frac{1}{15})$, and $\bar{t} \in (0, \frac{1}{10})$. With $\eta = \frac{1}{3}$, Lemma 31 proves that for any $p_1, \ldots, p_k \in [\frac{1}{3}, \frac{2}{3}]$, the BAI instance with $\tilde{F}_i := \mathrm{SBer}(p_i)$ distributed-arms has the property that any (α, δ)-PAC BAI algorithm must use at least

$$\Omega\left(\sum_{i\in[k]\setminus\{i^*\}} \frac{1}{\max(\Delta_i, \alpha)^2}\log\frac{1}{\delta}\right) \tag{10}$$

samples in expectation, where $i^* := \arg\max_{i\in[k]} p_i$ and $\{\Delta_i\}_{i\in[k]\setminus\{i^*\}}$ are the gaps w.r.t. the arm distributions $\{\mathrm{SBer}(p_i)\}_{i\in[k]}$. Without loss of generality, let us assume $1 = \arg\max_{i\in[k]} p_i$ (arm 1 is the best). At this point we now treat the different adversarial settings separately, since the lower bounds and thus also the liftings differ.

D.2.1. Lifting for Oblivious and Prescient Adversaries

Define the following distributions:

$$\begin{aligned}F_1 :&= \frac{1-2\varepsilon}{2(1-\varepsilon)}\mathrm{Ber}(r) + \frac{1}{2(1-\varepsilon)}\mathrm{Unif}([0,1]), \quad \text{and} \\ F_i :&= \frac{1-2\varepsilon}{2(1-\varepsilon)}\mathrm{Ber}(q_i) + \frac{1}{2(1-\varepsilon)}\mathrm{Unif}([0,1]) \quad \forall i \in \{2,\ldots,k\},\end{aligned}$$

where $r := \frac{p_1}{1-2\varepsilon}$ and $q_i := \frac{p_i - 2\varepsilon}{1-2\varepsilon}$. It is not hard to see that

$$\begin{aligned}\tilde{F}_1 &:= \mathrm{SBer}(p_1) = (1-\varepsilon)F_1 + \varepsilon\delta_0, \quad \text{and} \\ \tilde{F}_i &:= \mathrm{SBer}(p_i) = (1-\varepsilon)F_i + \varepsilon\delta_1 \quad \forall i \in \{2,\ldots,k\}.\end{aligned}$$

In other words, *samples generated from $SBer(p_i)$ are equal in distribution to samples generated from the above contaminated mixture model* of $(1-\varepsilon)F_i$ and ε times a Dirac measure.

Next, a simple calculation shows that $m_1(\tilde{F}_1) = p_1$, $m_1(F_1) = p_1 + \varepsilon$, and $m_2(F_1) = \frac{1-\varepsilon}{2}$. Similarly, for any $i \in \{2,\ldots,k\}$, we have $m_1(\tilde{F}_i) = p_i$, $m_1(F_i) = p_i - \varepsilon$, and $m_2(F_i) = \frac{1-\varepsilon}{2}$. Moreover, for all $i \in [k]$, we have that $F_i \in \mathcal{F}_{B,\bar{t}}$ for $B = 4$ and any $\bar{t} < \frac{1}{2(1-\varepsilon)}\min(p_i + \varepsilon, 1-$

$(p_i+\varepsilon)) \le \frac{1}{2}\cdot\frac{15}{14}\cdot\min(\frac{1}{3}, 1-(\frac{2}{3}+\frac{1}{15})) = \frac{1}{7}$. We conclude that for each $i\in[k]$, the change in median between the distribution F_i and the contaminated distribution $\tilde{F}_i$ is equal to

$$|m_1(\tilde{F}_i) - m_1(F_i)| = \varepsilon = Bm_2(F_i)\frac{\varepsilon}{2(1-\varepsilon)} = U_{\varepsilon,B,m_2(F_i)}.$$

Therefore, we conclude that running any (α,δ)-approximate CBAI algorithm $\mathcal{A}$ on the samples obtained from the above BAI instance will result in $\mathcal{A}$ returning arm $\hat{I}$ satisfying $m_1(F_i) \ge m_1(F_1) - (2U_{\varepsilon,B,\frac{1-\varepsilon}{2}} + \alpha)$ with probability at least $1-\delta$. Whenever this event occurs, we have by the above calculations that $p_{\hat{i}} \ge p_1 - \alpha$. Therefore, $\mathcal{A}$ returned an α approximate arm with probability at least $1-\delta$ for this hard BAI instance. We conclude from the lower bound in (10) that $\mathcal{A}$ must use at least $\Omega\left(\sum_{i\in[k]\setminus\{i^*\}}\frac{1}{\max(\tilde{\Delta}_i,\alpha)^2}\log\frac{1}{\delta}\right)$ samples in expectation, where $\{\tilde{\Delta}_i\}_{i\in[k]\setminus\{i^*\}}$ are the effective gaps w.r.t. the arm distributions $\{F_i\}_{i\in[k]}$.

D.2.2. Lifting for Malicious Adversaries

The idea is similar to the oblivious and prescient case done above. The difference is that malicious adversaries can shift quantiles further (see Corollary 15) and so we must exhibit a lifting that exactly matches this larger shift. Consider the distributions over the CBAI arms

$$\begin{aligned} F_1 &:= \tfrac{1}{2}\mathrm{Ber}(p_1+2\varepsilon) + \tfrac{1}{2}\mathrm{Unif}([0,1]), \quad \text{and} \\ F_i &:= \tfrac{1}{2}\mathrm{Ber}(p_i-2\varepsilon) + \tfrac{1}{2}\mathrm{Unif}([0,1]) \quad \forall i\in\{2,\dots,k\}. \end{aligned}$$

We now present the malicious CBAI adversarial strategy. For the optimal arm 1, define the joint distribution J_1 over (Y_1,Z_1,D_1) where $Y_1\sim F_1$, $Z_1\sim\delta_0$, and the conditional distribution of D_1 given Y_1 is $\mathrm{Ber}(\varepsilon(\frac{p_1}{2}+\varepsilon)^{-1}\mathbb{1}\{Y_1=1\})$. Similarly, for each suboptimal arm $i\in\{2,\dots,k\}$, define the joint distribution J_i over (Y_i,Z_i,D_i) to be $Y_i\sim F_i$ and $Z_i\sim\delta_1$, and the conditional distribution of D_i given Y_i is $\mathrm{Ber}(\varepsilon(\frac{1-p_1}{2}+\varepsilon)^{-1}\mathbb{1}\{Y_i=0\})$. It is simple to see that for each arm $i\in[k]$, the marginals are correct under each J_i. Indeed, a simple conditioning calculation yields

$$\begin{aligned} \mathbb{P}(D_1=1) &= \mathbb{P}(D_1=1|Y_1=1)\mathbb{P}(Y_1=1) + \mathbb{P}(D_1=1|Y_1\neq 1)\mathbb{P}(Y_1\neq 1) \\ &= \varepsilon(\tfrac{p_1}{2}+\varepsilon)^{-1}\cdot\tfrac{1}{2}(p_1+2\varepsilon) + 0 \\ &= \varepsilon. \end{aligned}$$

An identical argument shows that the marginal distribution of D_i is also equal to $\mathrm{Ber}(\varepsilon)$ for each suboptimal arm $i\in\{2,\dots,k\}$. Now, for each arm $i\in[k]$, denote by C_i the corresponding contaminated distributions induced by $(1-D_i)Y_i+D_iZ_i$ where $(Y_i,Z_i,D_i)\sim J_i$. It is not hard to see that

$$\begin{aligned} \tilde{F}_1 &:= \mathrm{SBer}(p_1) = C_1, \quad \text{and} \\ \tilde{F}_i &:= \mathrm{SBer}(p_i) = C_i, \quad \forall i\in\{2,\dots,k\} \end{aligned}$$

In other words, *samples generated from SBer(p_i) are equal in distribution to the samples generated by the malicious* CBAI *adversary's distribution C_i.*

A simple calculation shows that for the optimal arm, $(F_1)^{-1}(\frac{1}{2}) = p_1+2\varepsilon$ and $(\tilde{F}_1)^{-1}(\frac{1}{2}) = (F_1)^{-1}(\frac{1}{2}-\varepsilon) = p_1$. Note further that F_1 has cdf satisfying $F_1(s) = \frac{1}{2}(1-p_1-2\varepsilon)+\frac{1}{2}s$ for

all $s\in[0,1)$, and that $F_1(1)=1$. Thus, for any $x_1,x_2\in[Q_{L,F_1}(\frac{1}{2}-\bar{t}), Q_{R,F_1}(\frac{1}{2}+\bar{t})]$, we have that $|F(x_1)-F(x_2)| = \frac{1}{2}|x_1-x_2|$ since $[\frac{1}{2}\pm\bar{t}] \subseteq [0.4, 0.6]$ is contained within the interval $[\frac{1}{2}(p_1+2\varepsilon), 1-\frac{1}{2}(p_1+2\varepsilon)] \supseteq [\frac{1}{2}(\frac{2}{3}+2\cdot\frac{1}{15}), 1-\frac{1}{2}(\frac{2}{3}+2\cdot\frac{1}{15})] = [0.4,0.6]$. By definition, this implies that $F_1\in\mathcal{F}_{\bar{t},B_1}$ with $B_1m_2(F_1)=2$. (Note that B_1 is a finite constant since $p_1\in(\frac{1}{3},\frac{2}{3})\subset(0,1)$ implies $m_2(F_i)>0$.) A completely identical calculation shows that each suboptimal arm $i\in\{2,\dots,k\}$ satisfies $(F_i)^{-1}(\frac{1}{2}) = p_i-2\varepsilon$, $(\tilde{F}_i)^{-1}(\frac{1}{2}) = (F_i)^{-1}(\frac{1}{2}+\varepsilon) = p_i$, and $F_i\in\mathcal{F}_{\bar{t},B_i}$ with $B_im_2(F_i)=2$. Therefore, we conclude that for each $i\inf[k]$, the difference in medians between the distributions F_i and $\tilde{F}_i$ is equal to

$$|m_1(F_i) - m_1(\tilde{F}_i)| = 2\varepsilon = B_im_2(F_i)\varepsilon = U^{(\text{MALICIOUS})}_{\varepsilon,B_i,m_2(F_i)},$$

which is exactly equal to the largest possible uncertainty.An identical reduction argument as in the oblivious and prescient adversary finishes the proof.

Abstract

AffectiveTweets is a set of programs for analyzing emotion and sentiment of social media messages such as tweets. It is implemented as a package for the Weka machine learning workbench and provides methods for calculating state-of-the-art affect analysis features from tweets that can be fed into machine learning algorithms implemented in Weka. It also implements methods for building affective lexicons and distant supervision methods for training affective models from unlabeled tweets. The package was used by several teams in the shared tasks: EmoInt 2017 and Affect in Tweets SemEval 2018 Task 1.

Keywords: Twitter, Sentiment Analysis, Emotion Analysis, Affective Computing, Lexicon Induction, Distant Supervison

1. Introduction

Social media platforms such as Twitter are widely used to express affective states, often in relation to particular entities, topics or events. We use the term "affect" to encompass sentiment, emotion, mood, and other related mental states.

The automatic detection of affect from tweets[1] has become a popular task due to its importance in commerce, politics, and sports (Liu, 2012). Most successful solutions to this problem, including its many variations, are based on supervised machine learning models trained on manually annotated examples (Mohammad et al., 2018).

The process of building an affect detection system for tweets comprises three main components: 1) the training dataset on which the system is trained, 2) the function used for mapping tweets, provided as strings, into fixed size vectors of feature-value pairs, and 3) the machine learning algorithm used for training the model for detecting affect.

Replicating an affect detection system reported in a scientific publication can be a challenging endeavor. These systems usually include complex hand-engineered features and specific parameter setups for the learning algorithm (Mohammad et al., 2018). Unfortunately, these aspects are not always described in sufficient detail.

1. We use the terms "social media post" and "tweet" interchangeably.

We present AffectiveTweets, a software for easily prototyping affect analysis systems for social media posts using Weka (Hall et al., 2009), a widely-used open source machine learning workbench implemented in Java.

2. The AffectiveTweets Package

The software is implemented as a Weka[2] package that can be installed with the Weka package manager. It can be accessed through Weka's GUIs or the command line interface. It is licensed under the GNU General Public License, Version 3 and hosted on Github.[3] Instructions for installing, using, testing, and contributing to the software are given on the project's website.[4]

The main functionalities of the package are implemented as Weka filters: tools enabling data transformations for the underlying machine learning task. AffectiveTweets provides three types of filters: 1) tweet-level filters, 2) word-level filters, and 3) distant supervision filters.

Other resources provided by the package are: training datasets, affective lexicons (lists of words annotated by affect), pre-trained word embeddings, and wrappers to the Twitter-specific tokenizer and POS tagger implemented in the *TweetNLP* library (Gimpel et al., 2011).

The package was made available as the official baseline system for the WASSA-2017 Shared Task on Emotion Intensity (EmoInt) (Mohammad and Bravo-Marquez, 2017) and for SemEval 2018 task 1 (Affect in Tweets) (Mohammad et al., 2018). It was used by 5 teams in the former task and by 15 teams in the latter.

2.1. Tweet-level Filters

Tweet-level filters in the package act on string attributes containing the text of tweets and calculate features suitable for further processing with the learning algorithms implemented in Weka. Many of these features have been used by state-of-the-art systems (Kiritchenko et al., 2014; Mohammad et al., 2018). The filters are described in the following.

The *TweetToSparseFeatureVector* filter calculates several sparse features for every tweet: word n-grams (adding a NEG prefix to words occurring in negated contexts), character n-grams, POS tags, and Brown word clusters. The scope of a negation is determined by a simple heuristic: from the occurrence of a negator word up until a punctuation mark or the end of the sentence. A list of negator words such as *no, not, won't* and *never* is provided with the package.

The *TweetToLexiconFeatureVector* filter calculates features by aggregating word-level affect scores taken from a fixed list of well-known affect lexicons. This list includes AFINN (Årup Nielsen, 2011), the Sentiment140 lexicon (Kiritchenko et al., 2014), and others. Users are encouraged to cite the publications describing any of the lexicons or resources used with the package.[5]

3. https://github.com/felipebravom/AffectiveTweets
4. https://affectivetweets.cms.waikato.ac.nz/
5. The BibTex entries of these publications are given at the package's website.

The *TweetToInputLexiconFeatureVector* filter allows users to calculate features from a tweet using their own affective lexicons in ARFF format.[6] The features are calculated by adding or counting the affect associations of the words matching the given lexicons. All numeric and nominal attributes from each lexicon are considered. Numeric scores are added and nominal labels are counted.

The *TweetToSentiStrengthFeatureVector* filter calculates positive and negative sentiment intensities for a tweet using the *SentiStrength* lexicon-based method (Thelwall et al., 2012).

The *TweetToEmbeddingsFeatureVector* filter calculates a tweet-level feature representation using pre-trained word embeddings (word vectors) by applying one of the following aggregation schemes: average of word embeddings; addition of word embeddings; or concatenation of the first k word embeddings in the tweet. The concatenation scheme is suitable for training deep neural networks with the *WekaDeeplearning4j* package (Lang et al., 2019).

2.2. Word-level Filters

The word-level filters allow users to build their own affective lexicons, which can later be used to calculate tweet-level features via the *TweetToInputLexiconFeatureVector* filter.

The *PMILexiconExpander* filter calculates the Pointwise Mutual Information (PMI) semantic orientation score for each word in a corpus of tweets annotated by sentiment (Turney, 2002). The score is calculated by subtracting the PMI of the target word with a negative sentiment from the PMI of the target word with a positive sentiment.

The *TweetCentroid* filter calculates word distributional vectors from a corpus of unlabeled tweets by treating words as the centroid of the tweet vectors in which they appear (Bravo-Marquez et al., 2015). The resulting word vectors can be labeled with an affective lexicon in ARFF format using the *LabelWordVectors* filter, making it possible to train a word-level affective classifier on these words. This classifier can be used to expand the original affective lexicon to the words from the provided corpus that are not covered by the lexicon. Word embeddings trained with neural networks can also be used in a similar way using filters provided by the *WekaDeepLearning4j* package.

2.3. Distant Supervision Filters

Distant supervision models are heuristic labeling functions used for automatically creating training data from unlabeled corpora. These models have been widely adopted for training affective models for tweets because large amounts of unlabeled tweets can easily be obtained through the use of the Twitter API. The filters described below take a collection of unlabeled tweets and a polarity lexicon of positive and negative words in ARFF format as input.

The *LexiconDistantSupervision* filter implements the most popular distant supervision approach for Twitter affective analysis: If a word from the lexicon is found, the tweet is labeled with the word's polarity. Tweets with both positive and negative words are discarded. The filter allows the removal of the lexicon word from the tweet's content. A list of positive and negative emoticons is used as the default lexicon (Read, 2005).

Two additional distant supervision methods that generate positive and negative instances by averaging tweet vectors annotated according to a given polarity lexicon are

6. `https://waikato.github.io/weka-wiki/arff_stable/`

also provided. These methods have shown to be superior to the emoticon-based approach (Bravo-Marquez et al., 2016a),(Bravo-Marquez et al., 2016b).

The *ASA* filter implements the Annotate-Sample-Average (ASA) (Bravo-Marquez et al., 2016a) distant supervision method. It generates synthetic labeled instances by sampling a number of tweets containing at least one word from the lexicon with the desired polarity, and averaging the feature vectors of the sampled tweets.

The *PTCM* filter implements the Partitioned Tweet Centroid Model (PTCM) (Bravo-Marquez et al., 2016b). This method uses the tweet centroid model for calculating word vectors and a polarity lexicon for training a word-level classifier. The classifier is deployed on tweets represented by the original tweet-level representation used to calculate the word vectors. The model increases the number of labeled instances by partitioning the tweets associated with each word into smaller, disjoint subsets and calculating one centroid per partition, which is labeled according to the lexicon.

3. Related Tools and Benchmark

There is no existing tool for building affective models for tweets implementing all the functionalities provided by AffectiveTweets, but some related tools exist. The Stanford *CoreNLP* software allows training recursive deep models on a sentiment treebank (Socher et al., 2013). *SentiStrength* (Thelwall et al., 2012) and *Vader* (Hutto and Gilbert, 2014) are both lexicon-based systems that calculate sentiment intensity scores for social media messages. The *R* package *TM* (Meyer et al., 2008) for text mining has a plugin for sentiment classification based on an affective lexicon. *The Natural Language Toolkit* (NLTK) (Bird and Loper, 2004) provides a sentiment analysis module implementing the Vader method and the Bing Liu's lexicon.[7]

For demonstration, we benchmark *AffectiveTweets* against similar and equivalent models built using the NLTK sentiment analysis module and *Scikit-learn* (Pedregosa et al., 2011) on the dataset from the "SemEval 2013 Sentiment Analysis in Twitter Message Polarity Classification" task (Nakov et al., 2013). Classification results on the testing partition and execution times are shown in Table 1. Instructions for reproducing these experiments are given on the project's website.

Features	Implementation	Kappa	F_1	Time (seconds)
Word n-grams	Scikitlearn + NLTK	0.42	0.64	30.7
Word n-grams	AffectiveTweets	0.45	0.66	13.0
Word n-grams + Liu Lexicon	Scikitlearn + NLTK	0.48	0.68	13.4
Word n-grams + Liu Lexicon	AffectiveTweets	0.48	0.68	27.4
Liu Lexicon + Vader	Scikitlearn + NLTK	0.41	0.63	8.9
Liu Lexicon + SentiStrength	AffectiveTweets	0.40	0.63	31.9
Word n-grams + Liu Lexicon + Vader	Scikitlearn + NLTK	0.51	0.70	16
Word n-grams + Liu Lexicon + SentiStrength	AffectiveTweets	0.49	0.69	68.5
Word n-grams + All lexicons + SentiStrength	AffectiveTweets	0.52	0.71	74.6

Table 1: Benchmark results. The word n-grams include features for $n = 1, 2, 3$ and 4. Each model consists of a logistic regression trained on the corresponding features. Execution time is averaged over 10 repetitions.
